## FOREWORD

The 19th International Conference on Coastal Engineering was the first to be held in the Continental United States since 1970. This exemplifies the truly international scope and character of this conference series. The 19th ICCE, like the ones before it, was well organized with the primary objective being to share information and provide a forum for interaction with other engineers and scientists working on similar problems. The time and efforts contributed to that objective was extensive and the results have proven that the planning is a very vital part of each conference. All who attended the 19th ICCE will agree that it was a success in many ways.

At the beginning of the Conference a message was received from the President of the United States welcoming the attendees. His message is reproduced below:

TWX WHITEHOUSE WSH DLY PD  
260 GOVT DLY WHITE HOUSE DC AUG 31  
PMS MR. JOHN C. FREEMAN, //DLR DONT DWE//  
President, Institute For Storm Research  
University Of St. Thomas  
3600 Mt. Vernon  
Houston TX 77006

I am pleased to greet all participants in the Nineteenth International Conference on Coastal Engineering and to extend a special welcome to those from other countries.

Solving engineering problems associated with coastal and offshore areas is one of the most important environmental challenges we face. The many natural resources in these regions require careful management based on sound scientific and technical information. For example, our Commerce Departments National Ocean and Atmospheric Administration has storm surge problems underway that can serve as models for developing comprehensive hurricane preparedness plans.

I am confident that your conference will make an important contribution to the wise management of coastal resources and to the protection of the people who live, work and play in these areas.

You have my best wishes for every success in these deliberations.

RONALD REAGAN

92331

The papers in this Proceedings have been prepared by the authors who made presentations at the 19th International Conference on Coastal Engineering. The authors were asked to make their presentations and submit final papers based on review of the abstracts which were submitted well in advance of the conference. These abstracts were reviewed by a committee of four professionals including representation from the local organizing committee. All papers are eligible for discussion in the *Journal of Waterway, Port, Coastal and Ocean Engineering* and all papers are eligible for ASCE awards.

Venues for the 20th and 21st conferences are Taipei, Taiwan and Spain, respectively. Countries desiring to host a future conference should contact the Secretary of the Coastal Engineering Research Council to receive information on submitting a proposal.

Billy L. Edge, Secretary  
Coastal Engineering Research Council  
American Society of Civil Engineers

## **ACKNOWLEDGEMENTS**

### **ORGANIZING COMMITTEE**

Dr. John C. Freeman, Co-chairman  
Institute for Storm Research

Dr. Wayne Ingram, Co-chairman  
Sea Floor Engineering

Professor Robert Reid  
Texas A & M University

Mrs. Jill F. Hasling  
Institute for Storm Research

The Honorable Marla Forristall  
City of West University

Mr. David P. Hasling  
Institute for Storm Research

Mrs. Marjorie Freeman  
Houston, Texas

Dr. John B. Herbich  
Texas A & M University

Dr. William J. Graff  
University of Houston

Mr. Robert E. Haring  
Exxon Production Research Company

Dr. Herbert Beckman  
Rice University

### **SPONSORSHIP**

American Society of Civil Engineers  
Institute For Storm Research  
Marine Technology Society  
University Of Houston  
Texas A & M  
International Association For Hydraulic Research

# CONTENTS

Keynote Address . . . . .	1
<i>Morrough P. O'Brien</i>	

## PART I

### THEORETICAL AND OBSERVED WAVE CHARACTERISTICS

Chapter 1 THE EXPERIMENTAL VERIFICATION OF NUMERICAL MODELS OF PLUNGING BREAKERS . . . . .	15
<i>S.P. Kjeldsen</i>	
Chapter 2 BREAKING WAVE DESIGN CRITERIA . . . . .	31
<i>E.B. Thornton, C.S. Wu, and R.T. Guza</i>	
Chapter 3 REYNOLDS STRESS IN SURF ZONE . . . . .	42
<i>T. Sakai, I. Sandanbata, and M. Uchida</i>	
Chapter 4 WAVE ATTENUATION AND SET-UP ON A BEACH . . . . .	54
<i>I.A. Svendsen</i>	
Chapter 5 WAVE KINEMATICS AND DIRECTIONALITY IN THE SURF ZONE . . . . .	70
<i>J. van Heteren and M.J.F. Stive</i>	
Chapter 6 A MODEL FOR BREAKER DECAY ON BEACHES . . . . .	82
<i>W.R. Dally, R.G. Dean, and R.A. Dalrymple</i>	
Chapter 7 MODELING TURBULENT BORE PROPAGATION IN THE SURF ZONE . . . . .	99
<i>D.R. Basco and I.A. Svendsen</i>	
Chapter 8 EXTREMAL STATISTICS OF STORM SURGES BY TYPHOON .	115
<i>Y. Tsuchiya and Y. Kawata</i>	
Chapter 9 BAYWATER RESPONSE TO TSUNAMIS . . . . .	132
<i>T. Abe</i>	
Chapter 10 A RANKIN VORTEX NUMBER AS A GUIDE TO THE SELECTION OF A MODEL HURRICANE . . . . .	147
<i>C.L. Bretschneider and J.M. Lo</i>	

Chapter 11	
ESTIMATING ERROR OF COASTAL STAGE FREQUENCY CURVES.....	162
<i>M.D. Prater, T.A. Hardy, H.L. Butler, and L.E. Borgman</i>	
Chapter 12	
NUMERICAL SIMULATION OF STORM SURGES BY THE MULTI-LEVEL MODELS .....	174
<i>T. Yamashita and Y. Tsuchiya</i>	
Chapter 13	
NUMERICAL SIMULATION OF STORM SURGES INDUCED BY TROPICAL STORMS IMPINGING ON THE BANGLADESH COAST .....	190
<i>S.K. Dube, P.C. Sinha, and G.D. Roy</i>	
Chapter 14	
FREQUENCY OF OCCURRENCE OF STORM SURGES IN AN ESTUARY: A STOCHASTIC APPROACH.....	199
<i>M. Sas</i>	
Chapter 15	
UPDATE: THE NATIONAL FLOOD INSURANCE PROGRAM AND THE COAST.....	217
<i>W.G. Fry and P.A. Rhodes</i>	
Chapter 16	
SIMULATION OF TIDES AND STORM SURGES IN THE GREAT BARRIER REEF REGION.....	226
<i>K.P. Stark, L. Bode, and L.B. Mason</i>	
Chapter 17	
HURRICANE SURGE PROTOTYPE DATA COLLECTION .....	243
<i>T.H. Flor and S.C. Scott</i>	
Chapter 18	
HURRICANE ALICIA—STORM SURGES AND SHORE PROCESSES .....	257
<i>R.P. Savage</i>	
Chapter 19	
MEASUREMENT OF SURFACE WAVES FROM SUBSURFACE GAGE.....	271
<i>D.Y. Lee and H. Wang</i>	
Chapter 20	
A SHALLOW WATER DIRECTIONAL WATER RECORDER ...	287
<i>S.J. Buchan, R.K. Steedman, S.A. Stroud, and D.G. Provis</i>	
Chapter 21	
US ARMY CORPS OF ENGINEERS FIELD WAVE GAGING PROGRAM .....	304
<i>J.M. Hemsley</i>	

Chapter 22		
IRREGULAR WAVE OVERTOPPING RATES.....	316	
		<i>S.L. Douglass</i>
Chapter 23		
RUN-UP OF PERIODIC WAVES ON BEACHES OF NON-UNIFORM SLOPE .....	328	
		<i>Y. Ogawa and N. Shuto</i>
Chapter 24		
EFFECTS OF MEASUREMENT ERROR ON LONG-TERM WAVE STATISTICS .....	345	
		<i>B. Le Mehaute and S. Wang</i>
Chapter 25		
ON A DESIGN WAVE SPECTRUM .....	362	
		<i>P.C. Liu</i>
Chapter 26		
SHALLOW WATER WAVES: A SPECTRAL APPROACH.....	370	
		<i>C.L. Vincent</i>
Chapter 27		
WAVE COHERENCE IN COASTAL WATERS .....	383	
		<i>S.A. Hughes</i>
Chapter 28		
FIELD STUDIES OF RUN-UP ON DISSIPATIVE BEACHES ....	399	
		<i>C.T. Carlson</i>
Chapter 29		
A NONLINEAR MODEL OF IRREGULAR WAVE RUN-UP HEIGHT AND PERIOD DISTRIBUTIONS ON GENTLE SLOPES .....	415	
		<i>T. Sawaragi and K. Iwata</i>
Chapter 30		
A DYNAMICAL EXPRESSION OF WAVES IN SHALLOW WATER .....	435	
		<i>Y. Tsuchiya and T. Yasuda</i>
Chapter 31		
PREDICTION METHOD FOR THE WAVE HEIGHT DISTRIBUTION OFF THE WESTERN COAST OF TAIWAN ....	452	
		<i>F.L.W. Tang and J.T. Juang</i>
Chapter 32		
METHOD FOR ESTIMATING DIRECTIONAL WAVE SPECTRUM IN INCIDENT AND REFLECTED WAVE FIELD ..	467	
		<i>M. Isobe and K. Kondo</i>
Chapter 33		
CALCULATION OF DIRECTIONAL WAVE SPECTRA BY THE MAXIMUM ENTROPY METHOD OF SPECTRAL ANALYSIS ..	484	
		<i>M.J. Briggs</i>

Chapter 34		
NATURAL SEA STATES: THE COASTAL ENGINEER'S REQUIREMENTS TO THE REPRODUCTION IN MODELS.....	501	
		<i>H. Lundgren and Elias Davidsen</i>
Chapter 35		
NON-GAUSSIAN CHARACTERISTICS OF COASTAL WAVES..	516	
		<i>M.K. Ochi and W.C. Wang</i>
Chapter 36		
STATISTICAL PROPERTIES OF SHORT-TERM OVERTOPPING.....	532	
		<i>A. Kimura and A. Seyama</i>
Chapter 37		
SHALLOW-WATER SPECTRAL WAVE MODELING .....	547	
		<i>R.E. Jensen</i>
Chapter 38		
A TYPHOON WAVE HINDCASTING TECHNIQUE.....	561	
		<i>N.K. Liang and C.C. Chien</i>
Chapter 39		
INFLUENCE OF EL NINOS ON CALIFORNIA'S WAVE CLIMATE .....	577	
		<i>R.J. Seymour, R.R. Strange III, D.R. Cayan, and R.A. Nathan</i>
Chapter 40		
RUN-UP OF RANDOM WAVES ON GENTLE SLOPES.....	593	
		<i>H. Mase and Y. Iwagaki</i>
Chapter 41		
ON THE SEQUENTIAL BEHAVIOUR OF SEA-STATES .....	610	
		<i>A.S. Arcilla</i>
Chapter 42		
LOW FREQUENCY OSCILLATIONS ON THE DUTCH COAST .	625	
		<i>F. Gerritsen and J. van Heteren</i>
Chapter 43		
VERIFICATION OF KIMURA'S THEORY FOR WAVE GROUP STATISTICS .....	642	
		<i>J.A. Battjes and G.Ph. van Vledder</i>
Chapter 44		
CALIBRATION AND VERIFICATION OF A DISSIPATION MODEL FOR RANDOM BREAKING WAVES.....	649	
		<i>J.A. Battjes and M.J.F. Stive</i>
Chapter 45		
WAVE GROUP ANATOMY OF OCEAN WAVE SPECTRA.....	661	
		<i>W.C. Thompson, A.R. Nelson and D.G. Sedivy</i>

Chapter 46		
SWASH ON A NATURAL BEACH.....	678	
		<i>M. Mizuguchi</i>
Chapter 47		
WAVE GROUPS IN THE FREQUENCY AND TIME DOMAINS .	695	
		<i>R.J. Sobey and W.W. Read</i>
Chapter 48		
SWASH ON STEEP AND SHALLOW BEACHES.....	708	
		<i>R.T. Guza, E.B. Thornton, and R.A. Holman</i>
Chapter 49		
MEASUREMENTS OF SURF BEAT AND SET-DOWN		
BENEATH WAVE GROUPS.....	724	
		<i>J.K. Kostense</i>
Chapter 50		
THE PROBABILITY CHARACTERISTICS OF WAVE AND		
WAVE PRESSURES AT A VERTICAL BREAKWATER .....	741	
		<i>H. Peiji and Z. Binglai</i>
Chapter 51		
WAVE MEASUREMENT WITH DIFFERENTIAL PRESSURE		
GAUGES .....	755	
		<i>K.R. Bodge and R.G. Dean</i>
Chapter 52		
PREDICTION OF WAVE GROUP STATISTICS .....	770	
		<i>S. Elgar, R.T. Guza, and R.J. Seymour</i>
Chapter 53		
ESTIMATES OF LONG WAVES IN THE WESER ESTUARY....	782	
		<i>V. Barthel and E.R. Funke</i>
Chapter 54		
SHOALING PROPERTIES OF BOUNDED LONG WAVES .....	798	
		<i>E.P.D. Mansard and V. Barthel</i>
Chapter 55		
NUMERICAL SIMULATIONS OF THE 1964 ALASKAN		
TSUNAMI .....	815	
		<i>J.R. Houston and H.L. Butler</i>
Chapter 56		
A THREE-DIMENSIONAL MODEL OF THE BEAUFORT SEA .	831	
		<i>S.K. Liu and J.J. Leendertse</i>
Chapter 57		
MODEL HARBOUR SEICHING COMPARED TO PROTOTYPE		
DATA .....	846	
		<i>W.A.M. Botes, K.S. Russell, and P. Huizinga</i>

Chapter 58	
BOUNDARY CONDITION FOR LIMITED AREA MODELING ..	858
<i>H.L. Butler and Y.P. Sheng</i>	
Chapter 59	
IS SURF BEAT FORCED OR FREE? .....	871
<i>D.A. Huntley and C.S. Kim</i>	
Chapter 60	
EXTREME SEA LEVELS ON THE COAST OF CALIFORNIA...	886
<i>R.E. Flick and D.R. Cayan</i>	
Chapter 61	
NEW ASPECTS CONCERNING THE INCREASE OF SEA LEVEL ON THE GERMAN NORTH SEA COAST .....	899
<i>H. Rohde</i>	
Chapter 62	
SHORT-CRESTED BREAKING WAVES .....	912
<i>P.C. Machen</i>	
Chapter 63	
WAVE-INDUCED OSCILLATIONS IN HARBORS WITH WAVE-ABSORBING QUAY .....	929
<i>A. Yoshida, T. Ijima, and H. Okuzono</i>	
Chapter 64	
THE PHYSICAL BASIS OF THE MILD-SLOPE WAVE EQUATION .....	941
<i>L. Behrendt and I.G. Jonsson</i>	
Chapter 65	
STEEP UNSTEADY WATER WAVES: AN EFFICIENT COMPUTATIONAL SCHEME .....	955
<i>J.W. Dold and D.H. Peregrine</i>	
Chapter 66	
EXPLICIT SOLUTIONS TO PRACTICAL WAVE PROBLEMS ..	968
<i>P. Nielsen</i>	
Chapter 67	
THE INTERACTION OF SMALL AND FINITE AMPLITUDE LONG WAVES AND CURRENTS .....	983
<i>F. Raichlen and J.J. Lee</i>	
Chapter 68	
COMBINED REFRACTION-DIFFRACTION OF NONLINEAR WAVES IN SHALLOW WATER .....	999
<i>J.T. Kirby, P.L.F. Liu, S.B. Yoon, and R.A. Dalrymple</i>	
Chapter 69	
PROFILE ASYMMETRY OF SHOALING WAVES ON A MILD SLOPE .....	1016
<i>P.A. Hwang</i>	

Chapter 70	
THE EXACT SOLUTION OF THE HIGHEST WAVE DERIVED FROM A UNIVERSAL WAVE MODEL.....	1028
<i>Y. Y. Chen and F.L.W. Tang</i>	
Chapter 71	
COMBINED REFRACTION-DIFFRACTION CALCULATIONS WITH DIRECTIONAL WAVE SPECTRA.....	1040
<i>P. Gaillard</i>	
Chapter 72	
A NUMERICAL SOLUTION OF BOUSSINESQ TYPE WAVE EQUATIONS.....	1057
<i>H. Schaper and W. Zielke</i>	
Chapter 73	
INTERACTION OF NON-UNIFORM CURRENTS AND SURFACE WAVES .....	1073
<i>N.M. Ismail</i>	
Chapter 74	
A FINITE ELEMENT MODEL FOR WIND WAVE DIFFRACTION .....	1090
<i>O. Skovgaard, L. Behrendt, and I.G. Jonsson</i>	
Chapter 75	
CURRENT DEPTH REFRACTION OF REGULAR WAVES .....	1103
<i>I.G. Jonsson and J.B. Christoffersen</i>	
Chapter 76	
A NUMERICAL MODEL FOR REFRACTION OF LINEAR AND CNOIDAL WAVES.....	1118
<i>J.R. Headland and H.L. Chu</i>	
Chapter 77	
EFFECTS OF OPPOSING CURRENT ON WAVE TRANSFORMATION ON SLOPING SEA BED.....	1132

## COASTAL ENGINEERING

Morrrough P. O'Brien\*

These international conferences were at first organized by the Council on Wave Research of the Engineering Foundation, an organization sponsored by the engineering societies of the United States for the purpose of supporting research. Following the first conference, held in 1950 at Long Beach, California, it became clear that, in coastal engineering, the need was more for a forum at which to report and discuss results than for direct sponsorship of research. However, the charter of the Engineering Foundation did not quite encompass a council devoted solely to conferences, and the sponsorship was shifted to the American Society of Civil Engineers and the name became the Coastal Engineering Research Council.

I mention this bit of history to high-light the appropriateness of the original title -- the Council on Wave Research. The dominant agent active in the coastal zone is wave action -- wind-generated, ocean surface waves -- and it is this phenomenon which makes coastal engineering a distinct branch of the profession. In this respect, the outer coast and offshore areas, exposed to ocean waves, differ fundamentally from other shorelines -- estuaries, rivers, lagoons and small lakes. Familiarity with the theory and practice of wave phenomena is the hallmark of coastal engineering and of the coastal engineer.

Wave action has been studied intensely, theoretically and experimentally, in laboratory and field, but there remains much to be explored as the program of this conference amply illustrates.

My comments here deal with sandy beaches on the outer coast and with some problems of the interaction of ocean waves with the unconsolidated materials of the shore and bottom.

### PHYSICAL MODELS

Hydraulic models would be powerful tools for the investigation of phenomena of the outer coast -- provided that there were accurate methods for transferring model quantities to full scale. Unfortunately, there remains uncertainty regarding these "model laws," especially as applied to models with movable beds. The advantages of firmly establishing the model laws would be not only that specific locations could be studied with confidence but also that basic coastal processes could be reproduced under controlled conditions.

---

\* Dean and Professor of Engineering, College of Engineering, University of California, Berkeley.

Coastal models require relatively large surface areas, and large horizontal scale ratios, if the boundary conditions imposed by the wave climate are to be reproduced to scale: to obtain dynamically similar model waves, the depth should be as large as possible and the vertical scale ratio correspondingly small. In other words, practical considerations suggest distortion of hydraulic model of the outer coast. Unfortunately, the nature of surface waves is such that such distortion is questionable. In addition to the scale ratios, there are other limitations of applicability which need to be established such as the absolute size of the smallest dynamically similar waves and the smallest material size which avoids the effects of molecular forces. Establishing these restraints on design as well as the scaling laws is necessary for proportioning experimental basins suitable for basic studies.

#### **NUMERICAL MODELS**

The numerical model is a powerful tool -- if the validity of the underlying assumptions can be demonstrated. I am reminded of an old gag which seems pertinent here: "If you grant a mathematician his assumptions he's got you." For models of the outer coast, few field data are available for checking the validity of models: Do numerical model results stand as valid for the lack of comparative field data?

A problem of considerable importance in analyzing the material balance of a shore is the interaction of waves and currents with sediment at a tidal entrance. How, and in what quantity, does the littoral transport along the adjacent beaches cross the area seaward of the throat? Is the entrance a source or sink for sediment? What is the pattern of movement at jettied entrance? These and many other questions need to be answered. Wave action, including extreme conditions, as well as the tidal currents, must be represented in such a model, whether numerical or hydraulic.

A generally applicable numerical model representing the area seaward of tidal entrances would be a valuable tool -- but validation with field data alone seems almost an impossibility -- both because of the difficulty of field measurement and the elapsed time necessary to cover a representative range of wave conditions. I think of hydraulic models as an intermediate step between numerical models and full scale -- provided, of course, that the scaling laws are firmly established.

#### **MONITORING COMPLETED PROJECTS**

There are few complete records of the design, construction, maintenance, and demise of protective coastal structures. Failure of such works may occur (a) by physical impairment or destruction, (b) by not producing the predicted effect or (c) by either the initial or maintenance costs exceeding estimates, or by the effective life being very short. Such information on completed work is needed for the planning and design of future works. Little is available and for understandable reasons. On completion of construction, the engineers usually go on to other assignment. Seldom does the construction contract include provision for monitoring.

Monitoring structures of different types exposed to different wave climates, ranges of tide, and sand characteristics would, I believe, yield valuable data - not only for the continuing treatment of particular locations but also for basic studies. Shoreline changes develop slowly; apparently successful soon after construction, structures may show adverse effects years later.

It will be, I believe, possible to improve greatly the quantitative predictability of the effects of protective structures if a program of selective monitoring could be carried out on a national scale.

There are other studies which I would like to discuss here but my time is limited and I will devote the remainder of my talk to comments on a few completed projects. My prejudice in these matters is that beaches are primarily for use by people. Regulations, policies and laws, in many jurisdictions, represent a very different priority. An extreme view is that beaches should be allowed to go "back to nature" and that a "no structures" policy should be followed. I am convinced that the responsible public officials have been misinformed, sometimes deliberately, by enthusiasts who ignore the fact that the shorelines are the most popular areas for recreation and living.

#### ANNUAL CYCLE OF BEACH CHANGES

The annual cycle of changes which a sandy beach exhibits is a phenomenon of great importance to the planning of beach development. Figure 1 shows the surveyed profiles of East Hampton Beach at different times of the year (1). The beach is wide in summer and fall and narrow in winter, due to seasonal variations in the wave climate. The average

**Figure 1.** Selected profiles at one station showing the magnitude of the seasonal changes (Reference 1)

change in width during the year at this beach is about 150 feet. Figure 2 (Bolinas Bay, California) shows the surveyed width of a beach at high-water at different seasons (2). The year of survey is shown. The average change in width is 200 feet.

**Figure 2.** Seasonal variation of the position of the mean high-tide line, Stinson Beach spit, 1948-1970, compiled from data supplied by the California State Lands Commission (Reference 2).

Beaches everywhere show similar wave effects but the amplitude of the annual change and the times of year for maximum and minimum width differs from beach to beach because of differences in sand size and wave climate.

A number of inferences may be drawn from Figures 1 and 2 and similar data, namely

- Two profiles taken at random times of the year may show either erosion or accretion, e.g., first survey in August, second in February, erosion.
- Underlying the annual cycle there may be long-term erosion or accretion. It is difficult to identify this trend if it is only a few feet per year.
- Erosion during storms is rapid and subsequently recovery is slow. Recovery after extremely severe storms may require several years.

Ignorance or disregard of this phenomenon has generated much misinformation regarding the erosional status of beaches and, frequently, to unwise decisions on public policy.

**SOME BEACH PROJECTS**

Ocean Beach, San Francisco, is the site of two interesting structures, a seawall near the south end and the O'Shaughnessy seawall at the North end.

The steel sheet-pile seawall (Fig. 3) protects a pedestrian underpass which was threatened by erosion during a storm more than 40 years ago. Accretion followed construction and the bulkhead remained buried in sand for so many years that its existence was forgotten until uncovered recently. It appears to be in perfect condition.

**Figure 3.** Taraval seawall at the South end of Ocean Beach, San Francisco.

The 2200-foot long seawall shown in Figure 4 was built in 1915 to the design of M.M. O'Shaughnessy, City Engineer, S.F. Today it shows no sign of settlement or deterioration.

I have visited this beach many times since 1930 and I believe that the configuration of the beach around the structures cited indicates that there has not been progressive erosion over the past 50 years.

In Figure 4, note the shallow landward indentation about midway between the seawall and the underpass. Photographs taken over the past 50 years all show this configuration. When the highway was built years ago, the desired alignment cut across this indentation and the bank was reveted to hold the shore seaward of its stable position.

**Figure 4.** O'Shaughnessy seawall at Ocean Beach Esplanade, San Francisco, California.

The recent history of this area is interesting. The shore seaward of the highway has been made a Seashore under the jurisdiction of the National Parks Service. Application of their "no structures" policy has brought some controversial proposals.

The groins at Westhampton Beach, Long Island, were the subject of a study by J.M. Heikoff (3) in which he traced the political maneuvers by which an apparently sound project became completely fouled up. Reading this small volume is recommended.

The shore of Westhampton Beach is within a project authorized by Congress for beach restoration and hurricane protection from Fire Island Inlet to Montauk Point. When the Westhampton Beach section was funded, the design recommended was to replenish the beach and dunes without groins and to monitor this work. Groins were to be added if the rate of loss of sand justified their cost. Execution of the project followed a diametrically opposed plan; groins were built in 1961 with no sand fill and in an unfavorable sequence. The net annual littoral transport here is from East to West, with seasonal reversal. The unfilled groins began trapping sand at the East end and, at first, erosion was general in the groin field and westward. Later, some sand was pumped to eroded areas and this volume plus the accumulated littoral transport has stabilized the shore within the groin field and eastward.

The original design of the groin field included groins, equally spaced, from the Moriches Inlet jetties updrift (eastward). However, local opposition caused groins to be omitted from 13,000 feet of beach just eastward of Moriches Inlet (Fig. 5). The breakthrough shown occurred during a storm on January 15, 1980. Erosion by currents had occurred on the bay side but the ocean beach has not been stabilized.

Omission of groins in the 13,000 foot reach was due, I understand, to a policy of "no structures" on the part of a park district, located in this reach. Closure of the gap cost approximately \$11,000,000.

In a groin field, the spacing between groins is short and, following a change in wave direction, re-orientation of the shoreline occurs between groins, with accretion at the down drift groin and erosion at the updrift groin. The extent of the shoreline movement at the groins is roughly proportional to the spacing. The 13,000 foot gap at Westhampton Beach permitted wide swings in waterline position. All of the reported destruction of housing at Westhampton Beach occurred in this section.

In 1957-58, Madeira Beach, Florida built a groin field along 2 miles of shore just north of Johns Pass. It has firmly stabilized the high-water line well seaward of the position reached during the storm which caused the groins to be built. Hurricane Agnes in 1972 reduced the general level of the beach about 1.5 feet; the beach built back rapidly after the storm. This groin field is an excellent example of what may be accomplished with designs suited to the local wave environment.

The remarkable fact about these groins is that, despite their obvious effectiveness, the State of Florida apparently would not permit their construction today.

Lorain, Ohio on the south shore of Lake Erie is situated many miles from a good bathing beach. With help from the Corps of Engineers, an artificial beach was built in the protection of a segmented offshore breakwater (Figure 6). A similar but larger structure, built at Winthrop, Mass, by the Works Progress Administration in the 30's has stabilized the protected beach. It has required substantially no maintenance over the intervening years.

Figure 5. Moriches Inlet jetties

**Figure 6.** Photograph of Lakeview Park, Lorain, Ohio, shows what can be done with offshore breakwaters and sand fill to form the only good bathing beach for many miles on the Lake Erie shoreline. The cliffs and streams in this vicinity supply very little beach material, and the natural beaches are narrow and not adequate for recreation (Corps of Engineers photograph).

There is a place for such structures in the plans for shoreline development, with due attention, of course, to their effect on adjacent shores.

Beaches for day-time visits, such as Jones Beach (Figure 7), represent the most generally desired and the least expensive type of facility for public recreation. Studies of the utilization of publicly supported recreational facilities have shown that the annual number of daily visits to public beaches almost equals the total number of visits to all other types of public recreational facilities combined -- and at a very low public cost per visit. Permanent facilities are required to handle such crowds; once these facilities are in place, the beach area seaward must be held to maintain capacity.

Miami Beach (Figure 8) serves a different clientele than Jones Beach. Overnight accommodations of all kinds -- hotels, motels, condominiums, single family dwellings and the related support and services are necessary. There are now hundreds of miles of the mainland shores

Figure 7. Jones Beach, New York

of the U.S. which are intensively developed -- much of it close to the present high-water line. This huge investment must be protected, if possible, against damage by the sea.

**Figure 8.** Beach fill at Bakers Haulover Inlet.

At Miami Beach, the 10.5 mile reach between Bakers Haulover Inlet and Government Cut, has been restored and expanded by placement of sand dredged from offshore. The minimum width of beach anywhere is 250 feet in May. The littoral transport along this shore is small; the net annual movement is southward. If erosion occurs, it should become apparent first at the North end. Figure 8 shows no evidence of erosion there.

This inadequate and random discussion of coastal projects could be greatly extended to demonstrate the effectiveness of modern coastal engineering practice. However, the policy of "no structures" and "let the beaches go back to nature" has gained acceptance. That such a negative attitude could be diffused widely among public officials and the public generally is difficult to understand when so many other examples of success are reported in the proceedings of the nineteen conferences in this series and in many similar publications. True it is that there have been ineffective, unduly expensive and even damaging projects in the past -- and some will occur in the future -- but I believe an objec-

tive review of coastal projects built in accordance with modern concepts of shore processes would arrive at strongly positive conclusions regarding the effectiveness of coastal structures, including beach replenishment. Monitoring would supply the facts. A means of getting these facts through to the public and their elected officials must be found.

## CHAPTER ONE

### THE EXPERIMENTAL VERIFICATION OF NUMERICAL MODELS OF PLUNGING BREAKERS

by

SØREN PETER KJELDSEN  
Senior Research Engineer

#### 1. ABSTRACT

Results of a WAVE-FOLLOWER EXPERIMENT are presented, in which a moving current meter entrained in the crest of a steep Stokes wave and a moving high-speed film camera follows the wave with its non-linear phase velocity. Measurements of wave particle velocities are then obtained both in non-breaking steep wave crests, and in breaking waves. The breaking waves in deep water conditions are obtained by the application of a non-linear sweep frequency modulation technique, and the Stokes wave becomes unstable due to interaction of 43 wave components focused into one single point in space and time, KJELDSEN 1982.

The result of this interaction is a large freak wave, breaking as a plunging breaker in deep water. Measured crest particle velocities obtained with the current meter exceeded the phase velocity of this wave with 36 %. Digitalisation of the high-speed film showed that particle velocities at the very tip of the plunging jet obtained the value 2.65 times the linear phase velocity. These results are then compared with predictions obtained from numerical simulations by LONGUET-HIGGINS & COKELET 1976 and VINJE & BREVIG 1980.

#### 2. INTRODUCTION

We still have a quite high frequency of damages to structures designed by engineers, and this implies both coastal structures and floating marine structures in deep waters such as semisubmersible platforms and smaller vessels. The Court of Inquiry has now released the report on the "Ocean Ranger" accident, where a semisubmersible platform capsized in severe sea conditions east of St. John's, Newfoundland, and more than 80 crew members lost their lives. The court of Inquiry's report says that a port hole was broken, and the rig gradually lost water tight integrity, partly due to wrong actions from the crew. (Some general information about this particular accident is found in NATIONAL TRANSPORTATION SAFETY BOARD, report 1983). - In Norway on the average 3 vessels are lost each winter in severe seas and over

- 1) NORWEGIAN HYDRODYNAMIC LABORATORIES  
Division: Ship and Ocean Laboratory  
P.O. Box 4118 - Valentinlyst  
N-7001 Trondheim, NORWAY

the 9 last years not less than 26 vessels and 72 people has been lost. In 13 cases surviving members of the crews has confirmed to Courts of Inquiry that the vessels actually capsized in severe seas, and in some cases it was confirmed that these severe seas actually were breaking waves. This is a most unsatisfying situation, and even more because most of the lost vessels fulfill the requirements given by the Norwegian Maritime Directorate to their stability. And the lost vessels are not really smaller vessels, it is trawlers and freighters with total lengths 50, 60 and even 70 meters. (See KJELDSSEN, LYSTAD, MYRHAUG 1981 and KJELDSSEN 1983). Also with regard to coastal structures and in particular with regard to new breakwaters, there is an extensive literature available with cases that documents large unwanted damages to new structures and severe economic losses. Sines harbour on the west coast of Portugal is the best known example, but far from the only one. (See BAIRD et al 1980, YAMAMOTO et al 1981 and BRUUN 1979).

This most unsatisfying situation, has been the severe background for the author, to initiate the present research involving severe efforts into the performance of detailed measurements of the kinematics in the very crests of breaking waves occurring in deep waters. - AND THE RESULTS SHOWED, THAT WAVES IN DEEP WATERS WITH PERIODS AS LONG AS 19 SECONDS COULD BREAK AS PLUNGING BREAKERS WITH CREST PARTICLE VELOCITIES EXCEEDING THE PHASE VELOCITY OF SUCH WAVES WITH 36%.

### 3. EXPERIMENTAL ARRANGEMENTS

The english LORD RAYLEIGH followed the waves in a canal and studied them, riding on a horseback with "phase velocity".

For the present experimental programme a unique WAVE - FOLLOWER EXPERIMENT was designed. The experimental programme was performed in a 260 m long, 10 m deep and 10 m wide wave flume equipped with a large double-flap hydraulic wave generator hinged 1.05 m and 2.62 m below mean water level respectively. Steep regular wave trains generated with this wave generator are Stokes waves with phase locked superharmonics, as shown by KJELDSSEN 1984a. Measurements of wave kinematics were performed in such wave trains. However in order to obtain control of violent plunging breakers at a fixed time and position in deep waters, a deterministic non-linear sweep-frequency modulation technique was applied, see KJELDSSEN 1982. This particular technique takes into account the non-linear dispersion properties of Stokes wave packets. A wave train consisting of 43 transient wave phases with frequencies in the range  $0.203 \text{ Hz} < \Delta f < 1.43 \text{ Hz}$  and all with the same steepness 0.10 were generated followed by a train of Stokes waves with constant frequency. A special WAVE-FOLLOWER-SYSTEM was designed, consisting of a carriage that was perfectly synchronized with the dispersion of one particular wave phase and kept a selected current meter submerged in the wave crest while the wave dispersed over a distance of 15 - 20 meters and developed asymmetry and finally broke as a violent plunging breaker in deep waters. The maintenance of the exact position of the current meter in the wave crest during the dispersion was monitored and controlled by a moving high-speed film camera also installed on the carriage. In advance of these experiments an in-depth dynamic calibration of 4 different types of current meters operating on 4 physically different principles were performed. 2 commercial available current meters were tested and 2 current meters under development at Norwegian Hydrodynamic Laboratories were also tested. Only one of these four types of current meters fulfilled the strict requirements to a satisfying dynamic response, and only these one was used in the WAVE-FOLLOWER EXPERI-

MENTS. Fig. 1. shows the princip for the WAVE-FOLLOWER-SYSTEM. The plunging breaker in deep water was obtained experimentally taking advantage of the fact that group velocity of wave components is a function of wave steepness. 43 non-linear wave components were then phase locked i a deterministic way at one preselected point in space and time, leading to a steep elevated deep water freak wave, that broke as a plunging breaker. In Fig. 1. the full lines are energy lines. In addition phase lines and the path line for the WAVE-FOLLOWER carriage are shown.

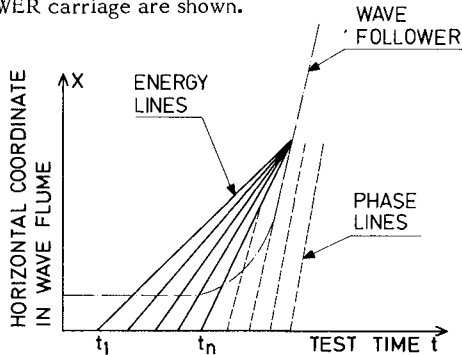

Fig. 1 Non-linear wave dispersion leading to freak waves breaking as plunging breakers in deep waters. Solid lines are energy lines. Further phase lines and the track of the WAVE-FOLLOWER carriage are shown.

Four different types of current meters based on 4 different physical principles, were selected for this particular investigation. The 4 types of instruments were the following:

- 1) Acoustic transit time current meter.
- 2) Acoustic doppler type current meter operated in backscatter mode. (Developed at NHL.)
- 3) Electromagnetic current meter based on Farady's principle.
- 4) Modified pitot tube developed at NHL.

All four types of current meters were then examined in depth during an extensive calibration programme. The evaluation of each current meter were then based on the following properties:

- a) Dynamic calibration.  
Attenuation of amplitude and phase delay in oscillatory flow mapped as a function of frequency.
- b) Surface penetration properties.
- c) Performance in a fluid containing air bubbles.

Only one of the four different types of current meters under evaluation, fullfilled the strict requirements to a satisfying dynamic response, a satisfying response in a fluid containing air bubbles, and a satisfying response when a liquid surface was penetracted by a current meter moving relatively to that surface. Thus the only current meter that passed the calibration tests and was selected for these WAVE-FOLLOWER-EXPERIMENT was an ultrasonic

transit time current meter with a working frequency of 4 Megahertz. This particular instrument measures the velocity of sound in the fluid and compensates automatically for any possible change of this velocity. It is well known, that it is impossible to use a low-frequency instrument because the velocity of sound drops significantly when air is entrained into the fluid. However, what is much less well known, is that at very high frequencies this effect disappears. Fig. 2 shows experimental results by FOX, CURLEY & LARSON 1968 and shows that in water containing air bubbles the velocity of sound stabilizes at very high frequencies close to the value for an air-free-fluid. In the present investigation a carrier frequency of 4 Megahertz was used, and this is well beyond and outside the critical limit shown in Fig. 2.

Fig.2 Velocity of sound as function of carrier frequency in a fluid containing air bubbles. (From FOX, CURLEY & LARSON 1968).

A special designed rig was used for dynamic calibration of the current meters, see Fig. 3. In this rig the current meters were oscillated at different frequencies, and amplitude attenuation as well as phase distortion were mapped. This calibration was first made with the current meter submerged at all times, and later it was performed with the current meter penetrating the free surface as shown in Fig. 3. A position galvanometer attached to the roof measured the exact position of the current meter at all times.

Fig. 4 shows an example of the obtained results from such a dynamic calibration. Above is the position of the moving current meter and below is the measured particle velocity.

Fig. 5 shows a comparison between the surface penetration properties of two different kinds of current meters. Above is shown the ideal curve for a surface penetrating instrument. The output shall be zero, and a moment later, it shall be 100 % of the true fluid velocity at that particular position. Further the intergrated velocity should be equal to the cross-hatched area. Below are shown the curves for the ultrasonic transit time current meter, and for the electromagnetic current meter. We observe that a time  $t$  elapses, that is 5 times the instrument time constant  $\tau$ , before the amplitude of the received signal has reached 95 % of the true value. As the time constant is as small as  $\tau = 0.01$  sec for the ultrasonic current meter it is nearly perfect for this kind of surface penetration experiments, while the electromagnetic current meter (Design Marsh McBirney) is much too slow and cannot be used for this kind of measurements in wave crests.

In order to further map the performance of the selected instrument in an air/fluid mixture, the current meters were installed in an oscillating water tunnel as shown in Fig. 6. From the bottom air bubbles were then released in a

controlled manner, the bubbles passed the current meter, and the response of the current meter to the passing of these free bubbles was then monitored.

Fig. 3 Rig applied for dynamic calibration of current meters.

Fig. 4 Example of results from a dynamic calibration test. Above the position of the moving current meter, below the measured particle velocity.

A more comprehensive and complete description of the experimental arrangement and the development of the instruments are given by KJELDSEN 1984.

4. RESULTS - NON-BREAKING WAVES

Phase locked superharmonics contained in the generated Stokes waves are analysed by KJELDSEN 1984a. In order to further control the quality of the generated waves a non-dimensional plot of synoptic wave shape is prepared in which experimentally obtained values of wave shape are compared with calculations for high order Stokes waves made by COKELET 1977 using Padé approximations to an order of 110 with  $\epsilon$  as the expansion parameter. This plot is shown in Fig. 7. A strong coherence is observed between experimental values and calculations made with  $\epsilon^2 = 0.70$ . Steep wave crests and flat troughs are pronounced. Use of Stokes wave theory to represent the single experimentally obtained waves, then seems to be a very good approximation, until the Stokes wave finally becomes unstable and breaks due to the deterministic non-linear focusing and wave-wave interaction.

Fig. 7. Non-dimensional synoptic comparison between experimentally obtained Stokes wave and calculations made by COKELET 1977 using  $\epsilon^2 = 0.70$  as the expansion parameter. (Conversion from time domain to synoptic domain is made by application of equations given by COKELET 1977, page 210).

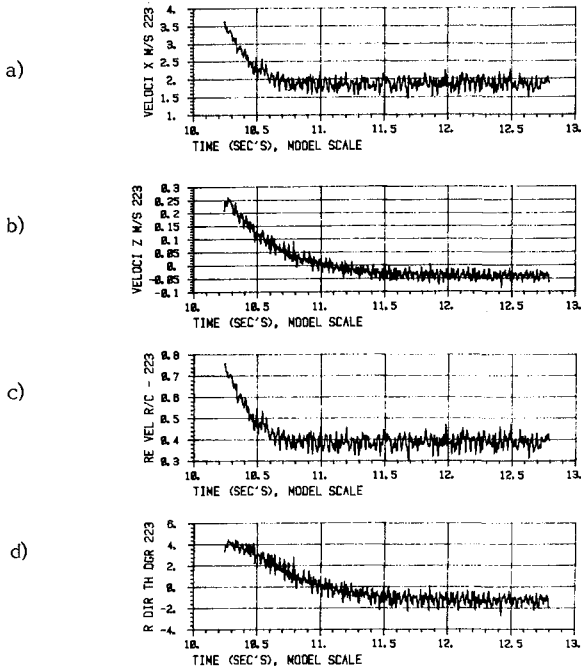

Fig. 8. Measurements of particle velocities with a moving current meter in steep Stokes waves 120 mm above mean water level.

Fig. 8 shows an example of the obtained results for steep Stokes waves. Fig. 8a is the horizontal particle velocity positive in the direction of wave dispersion. After entrainment of the current meter into the wave crest the horizontal particle velocity stabilizes at a value near 1.8 m/sec which shows, that a steady state condition is present in the interior of the wave crest, as it was expected. Fig. 8b shows the vertical particle velocity positive upwards. (In this case a slight negative vertical velocity  $-0.03$  m/sec is measured, which indicates that the position of the current meter has been slightly in the rear part of the wave. The expected value for the vertical particle velocity is 0, when the current meter is maintained directly below the wave crest. However this inaccuracy in alignment is very small as the ratio  $Z/X$  is less than 2 %). More important is it to observe that also the vertical particle velocity stabilizes at a fixed value, which proves that the current meter moves exactly with the phase velocity of the gravity wave. During these measurements the gravity wave dispersed over a distance of 16 m in the laboratory. A strong coherence is seen between the horizontal and the vertical particle velocities when the current meter is entrained. Fig. 8c then shows the resulting velocity vector normalized with respect to the phase velocity of the wave, and Fig. 8d finally shows the tilt of the velocity vector which in this case becomes  $-1.5$  degrees directed downwards from the horizontal.

Fig. 9 Resulting velocity vector normalized with respect to phase velocity measured at 4 different vertical levels. a) 420 mm, b) 320 mm, c) 220 mm and d) 120 mm above mean water level. The crest height of the wave is 440 mm.

Fig. 9 then shows the resulting velocity vector obtained in 4 different vertical levels, namely 420 mm, 320 mm and 120 mm above mean water level. In the case where the current meter is moving in the level at 420 mm, it is entrained only 10 - 20 mm below the crest. It is then most remarkable to observe that the resulting velocity vector drops significantly when the current meter is lowered only 100 mm from the top position.

These experiments indicate that a velocity distribution above mean water level, as shown in Fig. 10 could be applied for design purposes. The very large particle velocities are confined to a very local region close to the upper part of the wave crest. In this local region the obtained recording of horizontal particle velocity in a coordinate grid moving with phase velocity is very close to zero in the entire recording period. It is therefore concluded that the Stokes 120 degrees corner flow is a good approximation to the interior flow field for such a local upper region in very steep Stokes waves.

Fig. 10 Non-dimensional distribution of particle velocities above mean water level for non-breaking waves.

### 5. RESULTS - PLUNGING BREAKERS

Let us next consider the results obtained in breaking waves. The current meter then moved with phase velocity inside a steep Stokes wave over a distance as long as 16 meters until this particular wave phase due to the non-linear focusing suddenly becomes unstable and breaks as a plunging breaker, see Fig. 11.

Fig. 11 Moving current meter entrained in the very crest of a deep water plunging breaker at a level of 420 mm above mean water level.

This travel inside the wave takes less than 4 seconds, which means that the synchronisation has to be perfect. The position inside the wave crest was monitored with a moving high-speed film camera. This camera was operated with a speed of 200 frames/sec, and the camera was synchronized with a clock signal, that was recorded together with the measured particle velocities. Not less than 225 single experiments of this kind, with the current meter moving at different elevations above mean water level were performed. Fig. 12 shows the obtained horizontal and vertical particle velocities in one of these experiments. The current meter operated at a level of 420 mm above mean water level is entrained in the very crest of the wave at a time 5.1 seconds. The horizontal particle velocity then obtains the phase velocity of this particular wave which is 4 m/sec in the laboratory scale. It keeps this velocity for quite a

long time because the wave now appears as a steady wave. However suddenly the wave becomes unstable and the measured velocity increases in a burst with a value that reaches 5.42 m/sec in the laboratory scale! (Scaling of results to representative prototype values is treated in section 7). The corresponding vertical particle velocity is also displayed in Fig. 12. It has a more modest pattern and increases from 0 to 0.42 m/sec. It is directed vertically upwards.

Fig. 12

Horizontal and vertical particle velocities measured 420 mm above mean water level in the plunging breaker shown in Fig. 11. The horizontal particle velocity is steady with a value near 4.00 m/sec until the wave breaks in a violent burst at a time  $t = 8$  seconds.

a) and b) horizontal particle velocity,  
 c) and d) vertical particle velocity.

Fig. 13 Magnitude and tilt of resulting particle velocity vectors in the crest of a plunging breaker normalized with respect to the phase velocity.

The tilt and the total magnitude of the resulting particle velocity vector inside the breaking wave are shown in Fig.13 for 4 measured levels. The results are here normalized with respect to a linear phase velocity which is here taken as the velocity of the moving carriage. The measured tilt of the velocity vector at the very top of the wave crest is near 0. When the burst comes it obtains a small deflection 5.5 degrees upwards.

## 6. COMPARISON WITH MEASUREMENTS ON FILM

The experiments with non-linear focusing of wave components leading to violent plunging break waves in deep waters were repeated in a smaller wave flume with glass windows that permitted high-speed filming from the side. In order to obtain quantitative measurements from this film related to the tip of the plunging jet in the front of the wave, the velocity with which the film camera was operated was increased to 300 frames/sec. Fig. 14 shows above a typical stage in the development of the plunging jet and below the position of the tip of the jet measured on the frames of the film and plotted in a  $KX - KZ$  coordinate grid. It is then possible to obtain one of the two components of the particle velocity on the boundary, namely the one that is normal to the boundary. The time lapse between each frame is 3.33 milliseconds. At position 2, 3 locations of the tip of the jet is identified. The normal velocity is then measured and becomes 2.67 m/sec. 20 frames later at position 3, 3 new locations of the tip of the jet is identified. The normal velocity derived from these is 4.07 m/sec. Again 20 frames later at position 4, 3 locations are identified and the normal velocity becomes 4.07 m/sec. These values have then to be compared with a representative phase velocity for this particular plunging wave. This phase velocity is here defined as the linear phase velocity ( $C_0 = 1.54$  m/sec), that can be derived from the zero-downcross wave period  $T_{zd} = 0.984$  sec measured with a stationary instrument at the position of breaking. The rod visible in Fig. 14 is a stationary current meter, but also a wave gauge giving surface elevation might have been used for that purpose. The width of the wave flume is 1.00 m and the current meter is installed 0.5 m behind the tip of the jet viewed at the window. We then obtain the following non-dimensional results:

POSITION	$V_n$ (m/sec)	$\frac{V_n}{C_0}$
2	2.67	1.73
3	4.07	2.65
4	4.07	2.65

These results have then to be compared with available numerical simulations of plunging breakers in deep waters. LONGUET-HIGGINS & COKELET 1976 developed a model that in some cases achieved values as high as 2.8 times the linear phase velocity. This very high value occurred also in the numerical simulation at the very tip of the jet. The present experimental results thus confirms the physical existence of such very high values. VINJE & BREVIG 1980 developed a model that achieved values 1.8 times the linear phase velocity. This figure seems to be too low, and there is a discrepancy between the two numerical simulations, when the objective is evaluation of kinematics.

Fig. 14

Above tip of plunging jet obtained from the frames of a high-speed film. Below positions of the tip of the plunging jet viewed in a KX - KZ coordinate grid.

## 7. A NEW CRITERIA FOR INCEPTION OF BREAKING

The very high velocities in the crests of the waves of the kind reported here, have to be squared when drag forces on structures exposed to such waves are calculated. A study containing an attempt to evaluate the probabilities for encounter of such waves is available. This study is based on statistics of steepnesses of 25,000 waves observed during 22 gales on the Norwegian Continental shelf, see KJELDSEN 1981. Another most important aspect for design of structures is the crest length of breaking waves in a 3-dimensional sea, and such results are also available KJELDSEN 1984b.

The last and most important topic to consider is then the position of the violent plunging breaker relative to the envelope of the non-linear wave group in which it occurs. Fig. 15 shows the measured surface fluctuation of a focused freak wave converted to prototype values. It appears as a plunging breaker as shown on Fig. 11. However, it appears with a wave period  $T_{zd} = 19$  sec and a zero-upcross wave height  $H_{zu} = 30$  m. It thus breaks violently with a much lower steepness than the limiting steepness for monochromatic waves, and it contains very high particle velocities as measured with the current meter and plotted at the appropriate elevation. The present experiments confirm that violent breaking waves always appear in the front of the wave groups. Both the inception of wave breaking and the strength of the breaking of a particular wave phase is thus governed by a transition and a sudden jump in wave number, combined with a high wave energy flux. The breaking criteria valid for a sea containing wave groups can therefore be expressed as the joint probability of a certain wave number jump and the associated wave energy flux both exceeds certain critical thresholds (see KJELDSEN 1984 c.)

Fig. 15 The plunging breaker scaled to prototype values. The resulting particle velocity vectors obtained with the current meter are plotted at appropriate vertical elevations.

## 8. CONCLUSIONS

1) A moving current meter entrained in the very crests of focused plunging breakers showed that the ratio between the measured particle velocity vector and the phase velocity increased to a value 1.36 in a position a few millimeters below the crests in the centre of the waves.

2) Frame-to-frame analysis of a high-speed film showed that the particle velocity component normal to the boundary of the wave increased to a value that was 2.65 times the phase velocity valid for a position at the very tip of the plunging jet. This confirms the high values obtained at this particular position by LONGUET-HIGGINS & COKELET 1976 in their numerical simulation.

3) The violent breaking waves in deep waters always appeared in the front of the non-linear wave groups. Both the inception of wave breaking and the strength of the breaking of a particular wave phase within a wave group is thus governed by a transition and a sudden jump in wave number, combined with a high wave energy flux.

#### 9. ACKNOWLEDGEMENTS

Acknowledgements are given to a skilled highly professional staff at Norwegian Hydrodynamic Laboratories, that assisted during the performance of these demanding experiments. Further Norwegian Hydrodynamic Laboratories gratefully acknowledge a grant from the Continental Shelf Committee of the Royal Norwegian Council for Scientific and Industrial Research (NTNF), on the project "EXTREME RESPONSES FROM BREAKING WAVES IN DEEP WATERS".

## CHAPTER TWO

### BREAKING WAVE DESIGN CRITERIA

E.B. Thornton (M. ASCE)<sup>1</sup>, C.S. Wu (M. ASCE)<sup>1</sup>, R.T. Guza<sup>2</sup>

#### ABSTRACT

Breaking wave heights measured in both field and random wave laboratory experiments are examined. The dependence of breaker height and breaker depth on beach slope and deep water steepness is presented. The results are compared with the design curves of the Shore Protection Manual (SPM) and the predictions of the random wave model by Goda (1975). The comparisons indicate that the significant breaker height, based on Goda's model, is slightly conservative for the experimental cases; but the maximum breaker heights are reasonably predicted by the model. The design procedures in the SPM are based on a monochromatic wave breaking, and appear overly conservative, particularly for low wave steepness (less than 0.01) which occur frequently on the West Coast of the United States. The use of the Rayleigh distribution to predict wave height statistics is tested with random wave data for both deep and shallow water regions.

#### INTRODUCTION

The selection of breaking design waves is essential for the design of a coastal structure or for the coastal sediment problem. The present design practice is to specify maximum breaking waves based on empirical curves derived primarily from laboratory experiments of monochromatic waves (constant period and wave height). Several concerns arise from using monochromatic laboratory wave data as a basis for prototype design. Uncertainties exist in the scaling of laboratory waves to the prototype. More importantly, waves in nature are not monochromatic but random, having variable period, height and direction. The observed mean breaker height for random waves is generally 30-40% below the breaker inception height for periodic waves. Hence, uncertainty exists when applying criterion based on monochromatic waves to actual conditions in nature.

The objectives of this paper are to synthesize available random wave experiments, both in the field and laboratory, and to compare the

<sup>1</sup>Department of Oceanography, Naval Postgraduate School, Monterey, CA 93943

<sup>2</sup>Shore Processes Laboratory, Scripps Institution of Oceanography-A009, University of California, La Jolla, California 92093

results with the random wave model of Goda (1975) and the breaking wave design curves in the Shore Protection Manual (US Army Corps of Engineers, 1977).

#### RANDOM WAVE DATA

During the past decade, there has been a growing recognition that significant differences exist between the results of monochromatic and random wave experiments. At the same time, primarily due to better instrumentation, a large number of comprehensive nearshore field experiments have been conducted. A difficulty in synthesizing various experiments, particularly the field data, is that the data were collected in different manners. The requirements for inclusion in the data base here are: 1) the waves are random, either measured in the field or simulated in the laboratory; 2) the data are for dissipative, progressive waves on relatively plane sloping, unbarred beaches; 3) the wave measurement locations be close enough to accurately define the position of the mean breaking wave height; 4) the data be given in terms of either significant height,  $H_{1/3}$ , or maximum height,  $H_{max}$ . Based on the above requirements, two sets of field data collected under the Nearshore Sediment Transport Studies (NSTS) and two sets of laboratory experiments on wave shoaling are included in the present paper.

Torrey Pines Beach, San Diego, California. The beach and nearshore at Torrey Pines Beach is gently sloping with nearly parallel and plane contours. During the experiments, significant offshore wave heights varied between 60 and 160 cm. The average peak frequency of the incident wave spectra varied little during the experiments and was about 0.07 Hz. Shadowing by offshore islands and offshore refraction limit the angles of wave incidence in 10-m depth to less than 15°. It was shown by Guza and Thornton (1980) that because of the small incident angles, refractive effects can be neglected in calculating shoaling processes. The condition of nearly normally incident spilling (or mixed plunging-spilling) waves, breaking in a continuous way across the surf zone, prevailed during most of the experiments. Winds during the experiments were generally light and variable in direction. Surface elevation and horizontal, orthogonal velocity components were measured by using a closely spaced array of up to 17 instruments in a shore-normal transect from offshore at the 10-m depth contour to across the surf zone (see Figure 2 in Thornton and Guza [1983]).

Leadbetter Beach, Santa Barbara, California. The mean nearshore slope at Leadbetter Beach varied between 0.017 and 0.05 during the experiment, depending on the wave climate. No offshore bar was apparent. The shoreline has the unusual east-west orientation along a predominantly north-south coast. The open ocean waves are limited to a narrow window of approach (+9° centered on 270°) because of the protection from Point Conception to the north and the Channel Islands to the south. The generally highly filtered ocean swell type waves from almost due west must make a right angle turn to approach the beach normally. As a result, waves approach at large oblique angles to the bottom contours in the surf zone and drive a strong longshore current.

Because of the relatively large incident wave angles, refractive effects must be accounted for in the shoaling calculations. A similar array to that at Torrey Pines was used to measure the wave height transformation from 9-m depth to the shoreline (See Thornton and Guza, 1984).

Laboratory Experiments by Goda (1975) and CERC. Goda (1975) conducted a series of experiments in a 30 m long laboratory wave flume using random waves. Two beach slopes of 0.02 and 0.1 were used. Different wave spectra were employed simulating single peaked wind waves, double peaked sea and swell superposed, narrow swell waves, and relatively broad banded waves. Wave heights were calculated at six locations spanning the surf zone. Random wave laboratory experiments were also performed at CERC and have been variously described by Seelig et al (1983), Thompson and Vincent (1984), and Vincent (1984). The plane bottom slope was 1:30 in a 45.7 m long tank. Measurements were made at nine locations. Various theoretical wave spectra were simulated, including the Pierson-Moskowitz, JONSWAP and Ochi-Hubble Spectra.

The wave height statistics of  $H_{rms}$ ,  $H_{1/3}$  or  $H_{max}$  were calculated using the zero-up-cross technique. The surface elevations for the field data were first band-pass filtered ( $0.05-0.5 H_z$ ). Goda (1975) uses  $H_{1/260}$  for  $H_{max}$ , which is essentially the same statistic. All statistics are compared (nondimensionalized) using the deep water significant wave height  $H_0$  and deep water wave length defined as  $L_0 = (g/2\pi)T_p^2$ , where  $T_p$  corresponds to the wave period at the peak of the spectrum. Deep water wave heights were calculated by translating the measured nearshore wave heights to offshore accounting for shoaling and refraction using linear wave theory. For the data considered, refractive effects are needed to be accounted for only in the Santa Barbara data.

Monochromatic waves break on a plane beach at essentially a single location with a constant breaker height. Hence, a breaker height and depth are unambiguously defined. In contrast to monochromatic waves, there is no well-defined breakpoint for random waves; the largest waves tend to break farthest offshore and the smaller waves closer to shore. The result is a spatial distribution of breaking and unbroken waves. However, it is found that the use of a simple terminology for describing breaking wave parameters is informative and simplifies the analysis. For this reason, we introduce a mean breaker line for random waves. A "mean breaker line" is defined as the mean location where the averaged wave height reaches its maximum as the waves shoal from deep water and then dissipate due to breaking. As an example, the rms wave heights measured at Torrey Pines are shown in Figure 1. The mean rms breaker height  $H_B$  and surf zone width  $X_B$  are defined where  $H_{rms}$  reaches a maximum. Similar statistics are defined for  $H_{1/3}$  and  $H_{max}$ , and an example is shown in Figure 2. This definition of mean breaker height means that the  $H_{rms}$  and  $H_{1/3}$  statistic are made up of broken and unbroken waves. The  $H_{max}$  statistic

Figure 1. Definition of mean breaking wave height  $H_B$ , and corresponding surf zone width  $X_B$ .

Figure 2. Wave height statistics  $H_{max}$ ,  $H_{1/3}$ , and  $H_{rms}$  normalized by deep water significant wave height  $H_0$ , as functions of distance offshore.

corresponds to the single largest wave measured during the experimental interval and presumably corresponds to a breaking, or incipient breaking wave.

The difficulty of using this definition for mean breaker height is that measurement locations need to be closely spaced to accurately locate the point of the maximum wave height. Also, in some of the data there appeared to be no maximum; this result occurred for both the field and laboratory data (where the obvious blame on refractive effects are not present).

## RESULTS

The breaking wave height data are compared with breaking wave design curves calculated by Seelig (1979), who employs the random wave height transformation theory by Goda (1975). Goda's theory describes the wave heights using a modified Rayleigh distribution in which the tail of the distribution is shortened, supposedly to represent the decrease in wave height due to breaking. Wave transformation is described using the nonlinear theory by Shuto (1974). Breaker height is expressed by

$$\frac{H_b}{H_0} = A \frac{L}{H_0} \left[ 1 - \exp\left(-1.5 \frac{h}{L_0} [1 + K \tan^s \beta]\right) \right] \quad (1)$$

where  $H_b$  is the breaking wave height,  $h$  is the local depth and  $\tan \beta$  is the beach slope. The breaking wave heights are described as varying linearly over a range of values from most frequent breaker height to maximum breaker height dependent on the coefficient  $A = (0.12, 0.18)$ , and other coefficients  $K = 15$  and  $s = 4/3$ . The coefficient values were suggested by Goda (1975). Goda's theory predicts the shoreward transformation of the distribution (non-Rayleigh) of wave heights, including both broken and unbroken waves, accounting for wave growth due to shoaling and attenuation due to breaking.

Seelig (1979) used Goda's theory to calculate the "mean breaker height" and breaker depth at that location. Seelig defined the mean random breaking wave height in the same manner as used to define the breaker line for the data, i.e. the location of the maximum wave height in the shoaling transformation of the waves from offshore to the beach. Seelig calculated a series of random wave breaking design curves for various beach slopes and initial deep water wave steepnesses.

The significant breaking wave heights,  $H_{1/3}$ , are compared for various beach slopes in Figure 3. Laboratory data are indicated by open symbols and field data by closed symbols. The field data have lower wave steepness due to the predominantly low frequency Pacific swell (0.07 Hz) that prevailed during the field experiments.

The curves by Seelig, corresponding to beach slopes 0.1, 0.05 and 0.01, are shown as solid lines. The SPM breaking wave design curve based on monochromatic wave data for beach slope 0.02 is presented for

Figure 3. Significant breaking wave height,  $H_{1/3}$ , as a function of deep water wave steepness and beach slope. Shown are Seelig (1980) design curves for beach slopes 0.1, 0.05, and 0.01 based on Goda (1975) theory (solid lines) and SPM curve for beach slope 0.02 (dashed line).

Figure 4. Maximum breaking wave height,  $H_{max}$ , as a function of deep water steepness and beach slope.

comparison (dashed line). The SPM curve is flatter, but generally falls within the range of the Seelig curves for random waves.

The Seelig curves reasonably predict the steeper wave slope laboratory data. This is expected since the coefficients used in (1) specifying Goda's theory are based on the same laboratory data collected by Goda. But the curves overpredict the significant breaker heights for initially low slope waves. Therefore, the Seelig curves appear to reasonably predict significant breaker heights for initially steeper waves ( $H_0/L_0 > 0.7 \times 10^{-3}$ ), but appear overly conservative for predicting significant breaker heights for initially low steepness waves.

The maximum breaking wave heights are compared with the Seelig design curves in Figure 4. The curves give reasonable predictions of maximum breaking waves, although the data do not align well with the beach slope dependence of the curves. It is pointed out that for the low wave steepness data, the maximum wave heights compare well with that by Goda's model, whereas the significant wave heights are over-predicted. This is fortuitous. The reason is that the actual wave heights conform more closely to a Rayleigh distribution than a Rayleigh distribution with a shortened tail. The Goda model, employing a modified Rayleigh distribution with a shortened tail, predicts a smaller increase in wave height from  $H_{1/3}$  to  $H_{max}$  than the data, so that the  $H_{max}$  curves do not overpredict the measured values as much.

Thornton and Guza (1983) showed that for the Torrey Pines data the Rayleigh distribution could be used to calculate the  $H_{max}$  with an average error of -7% (under-prediction). Comparisons of the Santa Barbara data with the Rayleigh distribution are shown for  $H_{1/3}$  in Figure 5 and for  $H_{max}$  in Figure 6. The Rayleigh distribution predicts

$$H_{1/3} = 1.41 H_{rms} \quad (2)$$

Figure 5 shows that most of the  $H_{1/3}$  wave heights plotted as a function of depth fall within +5% (dashed line) of (2). The wave heights in deeper water (depth  $> 4$  m) appear to agree better with the Rayleigh distribution than wave height in shallower water within the surf zone. The  $H_{max}$  data and values predicted from the Rayleigh distribution are compared in Figure 6. The average error of the regression curve (dashed line) from the 45° line is -9%, i.e., the Rayleigh distribution under-predicts the data by 9% on the average, although the scatter is considerably greater. This implies that the use of a modified Rayleigh distribution with a shortened tail as described by Goda (1975) to predict breaking wave height design conditions is nonconservative; it is found from field measurements that the use of Rayleigh distribution is also nonconservative.

The depth at the significant breaking wave height,  $d_b$ , is plotted as a function of wave steepness and beach slope in Figure 7. A beach slope dependence is evident. The data are reasonably represented by the Seelig curves and are only underestimated at the very lowest wave steepnesses.

Figure 5. Significant wave heights,  $H_{1/3}$ , measured at Santa Barbara, California compared with wave height predicted by Rayleigh distribution (solid line) as a function of depth. Dashed lines indicate  $\pm 5\%$  error.

Figure 6. Maximum wave heights,  $H_{max}$ , measured at Santa Barbara, California compared with wave height predicted by Rayleigh distribution. Mean regression line is indicated by dashed line.

Figure 7. Depth at significant breaking wave height,  $d_b$ , as a function of wave steepness and beach slope.

## SUMMARY AND CONCLUSIONS

Breaking wave heights measured in the field and in random wave experiments in the laboratory are compared with the random wave model of Goda (1975) as calculated by Seelig (1980) and with the Shore Protection Manual (1977). The random wave model suggests that wave breaking is dependent on beach slope and wave steepness. The data spans a range of beach slopes (0.02, 0.033, 0.05 and 0.10) and deep water wave steepness. The dependence on beach slope is, however, not obvious from the data. The laboratory data are of higher wave steepness ( $H_0/L_0 > 0.7 \times 10^{-3}$ ). The field data corresponds to low wave steepness as the result of low frequency (0.07 Hz) Pacific Ocean swell waves.

The Goda's model reasonably predicts  $H_{1/3}$  and  $H_{max}$  for the higher wave steepness laboratory data; a reason being that much of the laboratory data is taken from Goda (1975), which is the same data used to calibrate the random wave model in the first place. For initially low steepness waves, the Goda model overpredicts  $H_{1/3}$ , but more reasonably predicts  $H_{max}$ . The  $H_{max}$  predictions are based on using a modified, shortened tail, Rayleigh distribution for which the  $H_{max}$  statistics are compensated for by the overprediction of  $H_{1/3}$ . Actual shallow water wave height data compare better, or are even underestimated in the tail, with a Rayleigh distribution as is demonstrated with the field data. Breaking wave heights do not exhibit a shortened or truncated, tail in their distributions.

The depth at breaking corresponding to the breaking wave height compared favorably with the Goda model for all wave steepness values. Depth at breaking exhibited a definite dependence on beach slope as suggested by the Goda model and the data.

## CHAPTER THREE

### REYNOLDS STRESS IN SURF ZONE

by  
T. Sakai<sup>1)</sup>, I. Sandanbata<sup>2)</sup> and M. Uchida<sup>3)</sup>

#### ABSTRACT

The on-offshore and the vertical components  $u, w$  of the velocity in a surf zone on a uniformly sloping beach in a wave tank were measured simultaneously with a laser-doppler velocimeter under two conditions. The time variation of the Reynolds stress  $-u'w'$  during one wave period is discussed. The Reynolds stress behaves as that in the oscillatory pipe flow does. The magnitude of the terms including the Reynolds stress terms in the on-offshore momentum equation is estimated. The Reynolds stress terms does not play any important role in the on-offshore momentum transfer during one wave period in the surf zone.

#### 1. INTRODUCTION

In the 18th Conference on Coastal Engineering, Cape Town, 1982, an experimental result on the turbulence generated by wave breaking on beaches in wave tanks was presented (Sakai et al. (1982), (6)). The vertical distribution of the turbulent intensity inside the surf zone was shown. The effects of the breaker type on this distribution was discussed. The variation of the vertical distribution of the turbulent intensity during one wave period was also shown. It was explained by extending the turbulent wake theory.

Similar works can be found in Stive (1980) (7), Flick et al. (1981) (2) and Nadaoka et al. (1982) (5). The turbulent intensity is discussed there. In oscillatory pipe flow, the turbulence generated by the shear on the boundary plays an important role in the momentum transfer (3, 4).

The Reynolds stress term is balanced with the local acceleration term and the pressure gradient term.

In the surf zone, it is believed that the turbulence generated by the wave breaking plays a role in the transfer of heat and material such as the sediment and the waste. Whether the turbulence generated by the wave breaking plays a role in the on-offshore momentum transfer during one wave period or not? Aono et al. (1981) (1) estimated the Reynolds stress in a surf zone on a horizontal bed in a wave tank. The data, however, are not sufficient to discuss this problem.

2) Engineer, Technical Inst., Hazama-Gumi Ltd., 338 Yono, Japan

3) Engineer, Tokyo Civil Branch, Hazama-Gumi Ltd., 107 Tokyo, Japan

To answer this question, an experiment under two conditions was done in a wave tank. The on-offshore and the vertical components  $u$ ,  $w$  of the velocity inside a surf zone on a beach were measured simultaneously with a laser-doppler velocimeter. The turbulence  $u'$ ,  $w'$  generated by wave breaking was defined. The Reynolds stress  $-u'w'$  was estimated. Its time variation during one wave period and its role in the on-offshore momentum transfer during one wave period are discussed.

## 2. EXPERIMENTS

### 2.1 Experimental Arrangements

The experiment was done in a wave tank in Department of Civil Engineering, Kyoto University. The length of the tank is 30m, the width is 50cm, and the height is 70cm. This wave tank has glass walls on both sides in the central part. At the opposite end of the tank to a wave generator, a beach was installed.

A two-component laser-doppler velocimeter(abbreviated as LDV hereafter) was used to measure the water particle velocity field in the surf zone on the beach. The LDV used was a Spectra Physics Stabilite 15mW He-Ne laser, with a KANOMAX optical system 8143S and two data processors 8015( of the tracker type). This system utilizes the polarization of a laser beam in order to measure simultaneously two components of the velocity.

Since both sides of the wave tank has glass walls, the photo-detector and the other optical system used were set separately on both sides of the tank. The system was operated in fringe mode with forward scatter. Due to limited space beneath the tank, the total optical system was installed on a frame hanging over the tank. This frame could move in both a vertical and a longitudinal direction.

The length of the laser tube was 1.0m, and the the length of the optical system was 60cm. It made the frame unstable if both the laser tube and the optical system were set horizontally in one line normal to the tank. The laser tube was, therefore, set vertically, and the laser beam was reflected horizontally using a mirror.

Two wave gauges were used to measure the water level variation in the surf zone.

### 2.2 Experimental Conditions

The experiment was done under 2 conditions. The experimental conditions of 2 cases are listed in Table 1.  $i$  is the beach slope,  $h_1$  is the still water depth in the uniform depth region in front of the beach,  $T$  is the wave period,  $h_b$  is the still water depth at the wave breaking point,  $H_b$  is the breaking wave height,  $w$  is the surf zone width. In both cases, the waves broke on the beach.  $H_0/L_0$  is the deepwater wave steepness. The breaker types were a spilling breaker in case 1 and a plunging breaker in case 2. Fig.1 shows a comparison

of the size of the surf zone of two cases.

### 2.3 Experimental Procedures

The measurement of the velocity in case 1 was done in 6 positions. The deepest position was located 0.5m shoreward from the breaking point. The distance between the neighbouring positions was 0.5m. The thin vertical lines in Fig.1 show these positions. In case 2, the measurement of the velocity was done in 5 positions. The deepest position was located 45cm shoreward from the breaking point. The distance between the neighbouring positions was 5cm. The measurement in case 2 was done in a rather limited region. In each positions, the velocity was measured at about 7 levels from 1cm above the bottom to near the wave trough level.

Table 1 Experimental Conditions

case	i	$h_1$ (cm)	T (sec)	$h_b$ (cm)	$H_b$ (cm)
1	1/31	35.0	1.17	18.0	12.8

1	530	0.063	spilling	LDV
2	275	0.019	plunging	LDV

Fig.1 Surf Zone of 2 Cases

### 3. DATA ANALYSIS

The outputs from the wave gauges and the LDV were digitized every 0.01sec. The digitized data of the water level at the velocity measuring point, the on-offshore velocity, the vertical velocity and two dropout signals for two velocity components were plotted graphically. The time length of the plotted data was 48sec in case 1 and 70sec in case 2.

The time intervals in which the signal from the processor of the LDV did not drop out were determined. In these non-dropout intervals, the data of the two components of the velocity were moving averaged. The time width of this moving averaging was 0.1sec in case 1 and 0.2sec in case 2 (Fig.2). The turbulence ( $u'$  and  $w'$ ) was defined as the deviation of the original velocity from this moving averaged velocity (Fig.2).

At every 0.01sec, a cross product of  $u'$  and  $w'$  can be calculated. This quantity with a minus sign may be called "an instantaneous Reynolds stress". In oscillatory pipe flow, the Reynolds stress is usually defined as an ensemble average of this instantaneous Reynolds stress at a fixed phase for many waves (3, 4). The Reynolds stress is, however, originally defined as a time average of the instantaneous Reynolds stress. The Reynolds stress was therefore defined here as a moving average of the instantaneous Reynolds stress. The time width of this moving averaging was 0.1sec in case 1 and 0.2sec in case 2. As mentioned in the Introduction, here we are interested in the role of the turbulence during one wave period. The choice of this time width depends on this interest.

The Reynolds stress defined in this way was obtained every 0.01 sec in the non-dropout intervals for all waves. Now one wave period was divided into 12 sections of 0.1sec interval in case 1 and 18 sections in case 2 (In Fig.2, which is only a sketch, one wave period is divided into 10 sections.). To see an average trend of the time variation of the Reynolds stress, an average value of the Reynolds stress values for all waves in each section was calculated.

### 4. TIME VARIATION OF REYNOLDS STRESS DURING ONE WAVE PERIOD

Fig.3 shows an example of the time variation of the Reynolds stress during one wave period at several levels in the position 2.0m shoreward from the breaking point in case 1. The top figure is an averaged wave profile during one wave period. One clear trend is seen at the upper two levels. At  $z = -1.7\text{cm}$ , the Reynolds stress changes from negative to positive after the crest phase. At  $z = -3.2\text{cm}$ , a similar change occurs before the crest phase.

Fig.4 is a different expression of Fig.3, the time variation of the vertical distribution of the Reynolds stress. Above mentioned trend is seen in the upper region near the crest phase. Aono et al. (1981)(1) reported a similar time variation of the Reynolds stress defined in a different way in a surf zone on a horizontal bed in a wave tank.

In oscillatory pipe flow, it was found that the Reynolds stress takes a maximum when the mean flow velocity decreases (Hayashi et al. (1980) (3) and Hino et al. (1980) (4)). It seems that the Reynolds stress generated by the wave breaking in surf zone behaves as that in the oscillatory pipe flow does. Fig. 5 shows an example of the time variation of the Reynolds stress in the position 55cm shoreward from the breaking point in case 2. The trend seen in Fig. 3 is more evident.

The turbulence in the oscillatory pipe flow is a wall turbulence generated by the shear on the boundary. The turbulence in the surf zone is rather a free turbulence generated by the instability of the water surface. Considering this fact, there is no positive reason why the Reynolds stress in the surf zone behaves as that in the oscillatory pipe flow does.

## 5. REYNOLDS STRESS TERM IN ON-OFFSHORE MOMENTUM EQUATION

### 5.1 Estimation of Magnitude of Terms

The on-offshore momentum equation is given as follows :

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} = \frac{1}{\rho} \frac{\partial}{\partial x} (-p - \rho \overline{u'^2}) + \frac{1}{\rho} \frac{\partial}{\partial z} (-\rho \overline{u'w'}) \quad (1)$$

, where  $t$  is the time,  $x$  and  $z$  are two horizontal coordinates,  $u$  and  $w$  are two velocity components in  $x$  and  $z$  directions,  $\rho$  is the density of the fluid,  $p$  is the pressure, and  $-\rho \overline{u'^2}$  and  $-\rho \overline{u'w'}$  are two Reynolds stresses.

The magnitude of each term in Eq.(1) at one measuring point in case 2 is estimated by using the data obtained in the experiment. This point is located 5.5cm below the still water level and 60cm shoreward from the breaking point. As explained in 3., the Reynolds stress  $-\overline{u'w'}$  is obtained every 0.1sec during one wave period. To compare the magnitude of each term in Eq.(1) every 0.1sec during one wave period, the values of  $u$ ,  $w$  and  $\overline{u'^2}$  are estimated every 0.1sec as follows : The values of  $u$  and  $w$  in each section of 0.1sec for all waves were averaged, and these averaged values in each section were used as  $u$  and  $w$  in Eq.(1). A root-mean-square value of  $u'$  value in each section for all waves was calculated. This r.m.s. value was used as  $\overline{u'^2}$  in Eq.(1).

The value of the local acceleration term was estimated from a difference between the values of  $u$  in the neighbouring two sections. The value of the gradient in  $x$  direction was estimated from a difference between the values at this point and at the nearest point in the neighbouring offshore position. The phase difference between the values at two points was taken into account. The value of the gradient in  $z$  direction was estimated from a difference between the values at this point and at the point 1.0cm below in the same position. The value of the pressure gradient term was not able to estimate due to a trouble of the wave gauges.

### 5.2 Comparison of Magnitude of Terms

Table 2 shows the result of the calculation. The time origin is at the crest phase. It is clear that the local acceleration term is large. It is supposed that the local acceleration term is balanced with the pressure gradient term which was not able to estimate. In the time interval  $t > 0.65$ sec (the wave trough phase), however, the local acceleration term becomes as small as the other terms. Fig.6 shows the time variation of two convection terms and two Reynolds stress terms. It is found that two Reynolds terms are smaller than two convection terms. Only in  $0.5$ sec  $< t < 1.0$ sec, two Reynolds stress terms are as large as two convection terms.

For case 1, a simpler comparison of the magnitude of the convection term  $u \partial u / \partial x$  and the Reynolds stress term  $\partial \overline{u'w'} / \partial z$  was done. The selected measuring point is located 4.2cm below the still water level and 1.5m shoreward from the breaking point. The comparison was

made at an intermediate phase between the zero-up crossing phase and the creast phase. At this phase,  $u \approx 20\text{cm/sec}$ .

The distance between this point and the neighbouring point is too long to estimate the  $x$  gradient. So the value of  $\partial u/\partial x$  was estimated by using the small amplitude wave theory with the values of the wave period of 1.2sec, the still water depth of 15cm and the velocity amplitude of 30cm/sec. The estimated value of the convection term  $u\partial u/\partial x$  is 14cm/sec. The Reynolds stress term  $\partial u'w'/\partial z$  is estimated 4cm/sec, from the difference between the values at this point and at the neighbouring point in the same position. The Reynolds stress term is small again compared with the convection term.

Table 2 Comparison of Magnitude of Terms in On-Offshore Momentum Equation during One Wave Period in Surf Zone (Case 2, 5.5cm below still water level and 60cm shoreward from breaking point)

$t$ (sec)	$\frac{\partial u}{\partial t}$	$u \frac{\partial u}{\partial x}$	$w \frac{\partial u}{\partial z}$	$\frac{\partial u'^2}{\partial x}$	$\frac{\partial u'w'}{\partial z}$

Fig. 6 Time Variation of Convection Terms and Reynolds Stress Terms in On-Offshore Momentum Equation during One Wave Period (Case 2, 5.5cm below still water level and 60cm shoreward from breaking point)

## 6. CONCLUSIONS

The on-offshore and the vertical components  $u$ ,  $w$  of the velocity in a surf zone on a beach were measured simultaneously with a laser-doppler velocimeter in a wave tank under two conditions. The time variation of the Reynolds stress  $-\overline{u'w'}$  during one wave period and its relative importance in the on-offshore momentum equation are discussed. The following conclusions are obtained :

- (1) The Reynolds stress  $-\overline{u'w'}$  changes from negative to positive near the crest phase. This is similar to the change of the Reynolds stress in the oscillatory pipe flow.
- (2) Since the turbulence in the surf zone is a free turbulence generated by the instability of the water surface, there is no positive reason why the Reynolds stress in the surf zone behaves as that in the oscillatory pipe flow.
- (3) The magnitude of the Reynolds stress terms in the on-offshore momentum equation during one wave period are small compared with the local acceleration term and the convection terms.
- (4) The turbulence generated by wave breaking has no significant role in the on-offshore momentum transfer during one wave period in the surf zone.

## CHAPTER FOUR

### WAVE ATTENUATION AND SET-UP ON A BEACH

by

I. A. Svendsen <sup>\*</sup>)

#### ABSTRACT

A theoretical two-dimensional model for wave heights and set-up in a surf zone is described and compared to measurements. The integral wave properties energy flux  $E_f$ , and radiation stress  $S_{xx}$  are determined from crude approximations of the actual flow in surf zone waves. Some physical aspects of the outer region are discussed and found to agree with our knowledge of the waves seawards and shorewards of this region.

#### 1. INTRODUCTION

This paper examines waves in the surf zone on a beach with no long-shore bars. We also restrict the considerations to regular waves with constant period  $T$ . The theoretical results are compared with measurements on a plane beach but in general the results should be applicable to any bottom topography provided the waves continue to break shoreward of the breaking point.

We only consider integral properties of the waves and conservation equations time averaged over a wave period. Hence the only information that can be obtained from the model is the variation of wave height, the associated energy dissipation and the set-up. In this respect the model to be described follows a long tradition of earlier investigations, although some of those only consider the wave height variation, not the set-up. The model deviates, however, from earlier contributions in the way the basic properties of the broken waves are determined.

The time averaged properties we need for the broken waves are energy flux,  $E_f$ , radiation stress,  $S_{xx}$ , and energy dissipation  $D$ . In previous models various non breaking wave theories have been used to determine  $E_f$  and  $S_{xx}$  in combination with either elaborate turbulent mixing models (Horikawa & Kuo, 1966) or energy dissipation equal to or related to the dissipation in a bore of the same height. References are Le Mehauté (1962), Divoky et al. (1968), James (1974). A somewhat different approach has been used by Dally (1980) who assumes the energy dissipation is proportional to  $E_f - E_{f,0}$  where  $E_{f,0}$  represents the energy flux in the smallest possible breaking wave which is empirically determined to be about  $H = 0.4 h$ . Sine wave theory is used for the wave integral properties.

The model presented here follows the numerical part of the solution described by Svendsen (1984) who also showed, however, that an analytical solution is possible under certain conditions. The following presentation also includes a discussion of the conditions at the shoreline.

2. THE BASIC EQUATIONS

We consider the two-dimensional problem sketched in Fig. 1 which also shows the definition of variables.

The three basic equations to be satisfied represent the conservation of mass, momentum and energy, integrated over depth and averaged over a wave period  $T$ .

The conservation of mass will not be invoked explicitly but used in the way the particle velocities in the wave are determined.

We consider regular progressive waves only and hence the momentum equation simply reads:

$$\frac{\partial S_{xx}}{\partial x} = -\rho g (h_0 + b) \frac{\partial b}{\partial x} \tag{2.1}$$

where  $S_{xx}$  is the radiation stress defined (exactly) by:

$$S_{xx} = F_m + F_p$$

$$F_m = \int_{-h_0}^{\eta+b} \rho u^2 dz ; F_p = \int_{-h_0}^{\eta+b} \rho p dz - \frac{1}{2} \rho g \overline{\eta^2} \tag{2.2}$$

Fig. 1. Definition sketch.

with  $\overline{\quad}$  denoting average over a wave period, and the dynamic pressure  $p_D$  given by:

$$p_D = \rho g (z-b) + p \tag{2.3}$$

i.e.  $p_D$  is defined on the basis of the local mean water depth. Notice that  $\eta$  is measured from the level  $z = b$  so that  $\overline{\eta} = 0$ . In (2.1) we have also neglected the mean bed shear stress.

Using  $E_f$  for mean energy flux and  $D$  for the gain in energy (i.e.  $D < 0$  for dissipation), the energy equation (also averaged over a wave period) becomes:

$$\frac{\partial E_f}{\partial x} = D \tag{2.4}$$

The definition of  $E_f$  is

$$E_f = \int_{-h_0}^{\eta+b} \left[ p_D + \frac{1}{2} \rho (u^2 + v^2 + w^2) \right] u \, dz \quad (2.5)$$

(which with  $p_D$  from (2.3) presumes no net current)

In both eqs. (2.2) and (2.5) velocities and pressures are the instantaneous values, so that these definitions also cover the turbulent flow situations in a surf zone.

In equation (2.4) we may choose at will the division between which type of energy belongs to  $E_f$ , and which is already considered lost (and hence belongs to  $D$ ). Since energy once turned into turbulence will be dissipated to heat mostly with one wave period we choose to consider turbulent energy as energy already dissipated.

This highly simplifies the computations since it implies that we do not have to keep trace of the amount of turbulent energy present at the different phases of the breaking process.

The drawback of this is of course that we cannot evaluate the contribution to the momentum balance from the turbulent velocity fluctuations ( $u', v', w'$ ). These contributions, however, are proportional to  $\tilde{u}'^2 - \tilde{w}'^2$  where  $\tilde{\phantom{x}}$  represents ensemble averaging. And the measurements of Stive & Wind (1982) shows that these contributions only increase the radiation stress by a few per cent, mainly because  $u'$  and  $w'$  are not very different.

The conclusion of this is that  $E_f$  in (2.4) is taken as the ordered wave energy defined as

$$E_f = E_{f,w} = \int_{-h_0}^{\eta+b} \left( \tilde{p}_D + \frac{1}{2} \rho (\tilde{u}^2 + \tilde{w}^2) \right) \tilde{u} \, dz \quad (2.6)$$

and  $D$  represents minus the production of turbulent energy.

To facilitate the analysis we introduce non-dimensional measures of both  $E_{f,w}$ ,  $S_{xx}$  and  $D$  using the definitions

$$B = E_{f,w} / (\rho g c H^2) \quad (2.7)$$

$$P = S_{xx} / \rho g H^2 \quad (2.8)$$

$$D = D / (4hT / \rho g H^3) \quad (2.9)$$

where  $T$  is the wave period and  $c$  the speed of propagation for the wave.

These definitions are inspired by our knowledge from, say, linear wave theory which for  $B$  would yield the result  $c(1+G)/8$  where  $(G = 2kh/\sinh 2kh)$  and for  $P$  similarly  $P = (1+2G)/16$ . The form chosen for the definition of  $D$  is related to the energy dissipation in a bore or hydraulic jump.

Thus the idea behind the dimensionless quantities  $B$ ,  $P$ , and  $D$  is that the major part of the variation of  $E_{f,w}$ ,  $S_{xx}$  and  $D$  has been factored out so that  $B$ ,  $P$ , and  $D$  may be expected to vary only slightly.

Substituting into (2.1) and (2.4) we therefore find the equations

$$\frac{d}{dx} (H^2 P) = - (h_0 + b) \frac{db}{dx} \quad \text{and} \quad (2.10)$$

$$\frac{d}{dx} (c H^2 B) = \frac{H^3}{4hT} D \quad (2.11)$$

Thus, provided we can describe B, P, D and c in terms of  $h_0$ , b, T and H then (2.10) and (2.11) represent two simultaneous equations from which  $E(x)$  and  $b(x)$  may be determined.

3. THE INTEGRAL PROPERTIES OF SURF ZONE WAVES

The ideas used in the determination of the three quantities B, P, and D are associated with the observation (see e.g. Svendsen et al., 1978) that from a point somewhat after breaking the waves become bore-like irrespective of the initial type of breaking.

B & D are determined from the definitions of  $E_{F,W}$  and  $S_{XX}$ , i.e. (2.6) and (2.2), respectively. In essence this means that we need relevant approximations for  $\tilde{u}$ ,  $\tilde{w}$  and  $\mathcal{D}_D$  in these expressions.

The important feature dominating the bore-like wave motion is the surface roller, which in essence is a volume of water carried shorewards with the breaker: Figure 2a shows a typical situation, and also indicates a typical velocity distribution along a vertical at the front of the wave.

The roller is defined as the recirculating part of the flow above the dividing streamline (in a coordinate system following the wave). Since it is resting on the front of the wave, the absolute mean velocity in the roller equals the propagation speed c for the wave, and in the following we use this value for the velocity in the roller, neglecting the z-variation.

In the present two-dimensional study we assume a zero net mass flux which of course implies that there is a return flow compensating for the surface drift.

From observations we know that in the inner region the change in wave shape is slow so the instantaneous volume flux:

$$Q = \int_{-h_0}^{\eta+b} u(x,z,t) dz \tag{3.1}$$

may for  $\bar{Q} = 0$  be determined as:

$$Q = c\eta = Ud \tag{3.2a,b}$$

where the surface profile is specified so that  $\bar{\eta} = 0$ . U is the wave particle velocity averaged over depth.

Thus assuming the particle velocity distribution shown in Fig. 2b we are able from (3.2) at any phase of the wave to express the velocity  $u_0$  below the roller in terms of  $\eta$  and  $e$  ( $e = e(x,t)$  being the vertical thickness of the roller). The resulting full expression is

$$u_0 = c \frac{\eta - e}{d - e} \tag{3.3}$$

where  $e = 0$  away from the wave front. We also assume that  $w^2 \ll u^2$  can be neglected.

The pressure is assumed to be hydrostatic. This is of course not quite correct, but in combination with the rather crude assumptions for u and in view of the very small deviations from hydrostatic pressure actually measured by Stive (1980) this is the most relevant approximation. Thus we have

$$P_D = \rho g \eta \tag{3.4}$$

Fig. 2a. Velocity distribution under the front of a breaking wave.

Fig. 2b. Approximations for the horizontal velocities in the surf zone waves.

When these approximations are substituted into (2.6) we find after some manipulations and further omission of small terms, that the leading approximation for B may be written

$$B = B_0 + \frac{1}{2} \frac{A}{H^2} \frac{h}{L} \quad (3.5)$$

where

$$B_0 \equiv \overline{(\eta/H)^2} \quad (3.6)$$

and A is the vertical cross sectional area of the roller (see Fig. 2a). The mentioned omission of small terms are based on the following approximations

$$\overline{(\eta/H)^3}, \overline{(\eta/H)^4} \ll \overline{(\eta/H)^2}$$

$$\text{and } \overline{\eta^3 e/h^4} \ll \overline{(\eta/H)^2}$$

The "wave length" L in (3.5) is defined as  $L(x) = c(x) T$ . Hence L is not the distance between two consecutive wave crests.

We have also assumed that  $c \sim \sqrt{gh}$  based on the measurements by Svendsen et al (1978) who found  $c \sim 1.05 - 1.10 \sqrt{gh}$ .

A similar procedure yields P by substitution of the assumptions for u and  $p_D$  into (2.2). The result may be written

$$P = \frac{3}{2} B_0 + \frac{A}{H^2} \quad (3.7)$$

Here the small terms omitted are of the type  $\overline{(e/H)^2}$ ,  $\overline{ne/\eta^2}$ .

Experimental information on the roller area A is only available for waves breaking behind a hydrofoil (Duncan, 1981). Fig 3 shows a plot of Duncan's data for A which suggests that we can use the approximation

$$A = 0.9 H^2 \quad (3.8)$$

by which B and P reduce to

$$B = B_0 + 0.45 h/L \quad (3.9)$$

$$P = \frac{3}{2} B_0 + 0.9 h/L \quad (3.10)$$

Fig. 3. The cross sectional area for A for the roller. Measurements by Duncan 1981.

Fig. 4. Measured values of  $B_0$  defined by (3.6.). Hansen (1982).

The energy dissipation  $D$  was analysed theoretically by Svendsen et al (1978) and more explicitly by Svendsen & Madsen (1981). The conclusion which can be derived from the expression they find for  $D$  is that the energy dissipation will normally be almost equal to that in a hydraulic jump of the same height. Deviations (in particular in the upward direction) depend on the detailed velocity and pressure distributions in the wave - particularly in the wave trough, but normally they do not seem to exceed 20%.

For the present rather crude model it is natural simply to use  $D$  equal to the value in a hydraulic jump of the same height, and this yields

$$D = \frac{-h^2}{d_c d_t} \quad (3.11)$$

where  $d_c$  and  $d_t$  are the water depths under wave crest and wave trough, respectively.

It is convenient to express  $d_c$  and  $d_t$  in terms of the crest elevation  $\eta_c$  and the wave height  $H$ . With

$$d_c = h + \eta_c, \quad d_t = h + \eta_c - H$$

(3.11) may be written:

$$D = - \left[ \left( 1 + \frac{\eta_c}{H} \frac{H}{h} \right) \left( 1 + \frac{H}{h} \left( \frac{\eta_c}{H} - 1 \right) \right) \right]^{-1} \quad (3.12)$$

which shows that for fixed  $(\eta_c/H)$ ,  $D$  depends slightly on  $H/h$ . Figure 5 shows the variation and Fig 6 gives values of  $\eta_c$  from the experiments by Hansen quoted above. As was the case for  $B_0$  the results for  $\eta_c/H$  show significant scattering but in the inner region of the surf zone the value is mostly 0.6-0.7 which from Fig. 5 is seen to represent a  $D$  nearly independent of  $H/h$ .

Figure 5 also shows that  $D$  only varies slightly with  $\eta_c/H$ . In other words the primary variation of the energy dissipation is represented by the  $H^3/h$  dependence already accounted for in the definition (2.9).

Fig. 5. The variation of  $D$  with  $H/h$  and  $\eta_c/H$  according to (3.12).

Fig. 6. Measurements of  $\eta_c/H$  in the surf zone. Hansen (1982).

4. COMPARISON WITH MEASUREMENTS

The outer and the inner region

The original concept of an outer (transition) region and an inner (bore) region was primarily based on the visual observations of wave behaviour after breaking (see Svendsen et al., 1978). The impression is one of a gradual change towards the bore shape found in the inner region. Consequently, no attempt was made to define a proper limit between the two regions, and wave height measurements truly do not suggest a natural definition.

The situation is quite different, when the variations in mean water level are considered. Figure 7 shows some examples from Hansen and Svendsen (1979) covering a wide range of deep water steepnesses. Most of them exhibit a marked change in the slope of the mean water level at some distance shoreward from the breaking point. A similar variation can also be seen in other investigations such as Bowen et al. (1968) and Stive and Wind (1982). The mean water level is horizontal or weakly sloping after the start of breaking over a distance of 5-8 times the breaker depth and then a rather sharp increase in slope occurs. The distance of nearly horizontal mean water level is comparable to the distance of the most obvious transformations of the wave shape following after the initiation of breaking, and so it will be coherent with the original concept to *define* the limit between the outer and the inner region as the point where the slope of the mean water level changes. In the following this is termed the *transition point*.

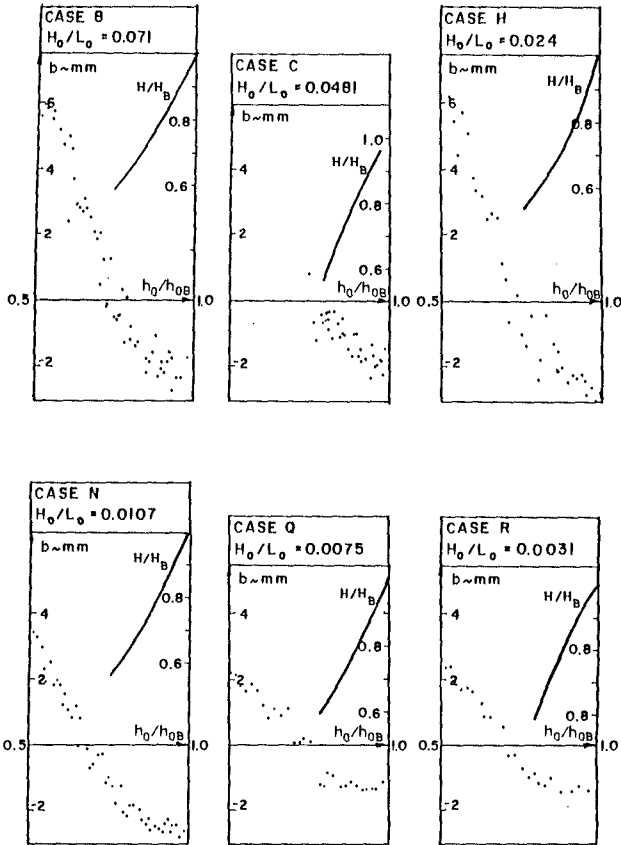

Fig. 7. Measurements of the mean water level shoreward of the breaking point. The figure also shows the simultaneous change in wave height relative to the value  $H_B$  at the breaking point (Measurements from Hansen & Svendsen, 1979).

Wave conditions in the inner region

Physical explanations for these changes are sought in section 5. First, however, we notice that since the results derived above for the parameters B, P and D are based on the wave properties in the inner zone, comparisons with experimental data should start at the transition point.

Numerical solution of equations (2.10) and (2.11) using (3.9), (3.10) and (3.12) then yields results for  $H$  and  $b$  in the inner surf zone. In the computations we have neglected the variation of  $B_0$  and  $\eta_c/H$  using the constant values  $B_0 = 0.075$  and  $\eta_c/H = 0.6$ . This, however, may not always be sufficient for obtaining reliable results but a more systematic investigation of the variation of  $B_0$  and  $\eta_c/H$  with wave parameters and bottom topography is required. For  $h/L$  is used  $T\sqrt{g/h}$  corresponding to  $c = \sqrt{gh}$ , with  $h = h_0 + b$ .

*Discussion of results*

Figures 8, 9, and 10 show a comparison with results for three rather different wave steepnesses, all on a plane slope 1/34.3. In general the agreement is quite good, particularly for the set-up. The latter is of particular interest because the calculations show that  $b$  is much more sensitive to the assumptions made than is the wave height variation. As can be expected from what was said above about  $D$ , the  $H$  variation turns out to be virtually independent of the choice of  $\eta_c/H$ .

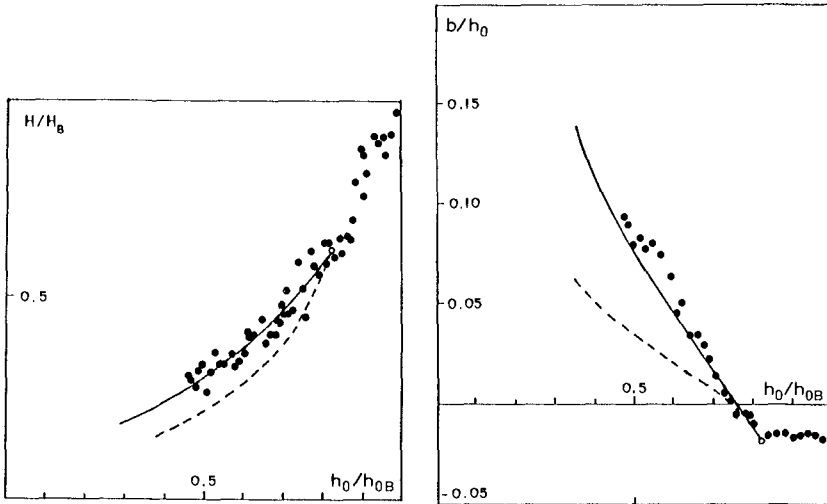

Fig. 8. Wave heights and set-up for a wave with deep water steepness  $H_0/L_0 = 0.071$  - theory using eqs. (3.9) and (3.10) - - theory without a surface roller;  $\cdot$  measurements by Hansen and Svendsen (1979), Case B.

It is noticed that in some of the cases the  $H$ -variation is slightly less curved than corresponding to the best fit of measurements, and the values of  $H$  become a little too large. This can be adjusted by using a value of  $D$  perhaps 20-30% larger than given by eq. (3.12), which is quite consistent with the results reported earlier (see Svendsen et al., 1978; Svendsen and Madsen, 1981) that the actual energy dissipation in a surf zone wave is generally larger than in a hydraulic jump of the same height.

Fig. 9. Wave heights and set-up for a wave with deep water steepness  $H_0/L_0 = 0.024$ . - theory using eqs. (2.10) and (2.11) --- theory without a surface roller; • Measurements by Hansen & Svendsen (1979) Case H.+ Measurements by Hansen (1982).

In Fig. 8-10 are also included results obtained by omitting the surface roller (dotted curve corresponding to  $B = B_0$  and  $P = 3/2 B_0$ ). The effect is quite appreciable. On the other hand, considering that the presence of the surface roller significantly increases the energy flux and radiation stress, the difference between the full and the dotted lines in these figures indicates that the effect of also including turbulence, deviation from static pressure, etc. would hardly be discernible.

Fig. 10. Wave heights and set-up for a wave with deep water steepness  $H_0/L_0 = 0.010$ . — theory using eqs. (2.10) and (2.11); - - theory without a surface roller; • measurements by Hansen and Svendsen (1979), Case N.

*The situation at the shoreline*

Svendsen (1984) found that for  $D$  and  $B$  constant an analytical solution can be obtained to the energy equation. This solution is given by

$$\frac{H}{h} = \frac{H_r}{h_r} \frac{1}{h' \frac{5}{4} [1 + KD(h'^{-3/4} - 1)]} \quad \text{with } h' = \frac{h_0 + b}{h_r} \quad (4.1)$$

where  $H_r/h_r$  corresponds to values at a reference point (boundary condition) and  $K$  is a constant also depending on the wave properties at that boundary point.

This solution predicts a (very flat) minimum for  $H/h$  at some point and shoreward from that point  $H/h$  increases with  $H/h \rightarrow \infty$  as  $h \rightarrow 0$ .

Clearly this is not in accordance with reality and turns out to be associated with the assumption that  $D$  is constant. As  $h \rightarrow 0$ ,  $D$  will

increase similarly and prevent the singularity. This can be seen by considering the energy equation in the form

$$\left(\frac{H}{h}\right)_x = - \left( \frac{h_x}{h} + \frac{c_x}{2c} + \frac{B_x}{2B} \right) \frac{H}{h} + \frac{D}{8cTB} \left(\frac{H}{h}\right)^2 \quad (4.2)$$

(For derivation see Svendsen et al., 1978). As  $h \rightarrow 0$  we assume the wave has deformed to a perfect sawtooth so that  $\eta_c = -\eta_t = \frac{1}{2}H$ . Thus we get from (3.12)

$$D = \frac{-1}{1 - \frac{1}{4}(H/h)^2} \quad ; \quad B_x = 0 \quad (4.3)$$

With  $c \sim \sqrt{gh}$  we also have  $c_x/c \sim h_x/4h$ . Substitution of (4.3) into (4.2) yields the relation

$$\left(\frac{H}{h}\right)_x = - \frac{5h_x}{4h} \frac{H}{h} - \frac{1}{1 - \frac{1}{4}(H/h)^2} \frac{1}{8T\sqrt{gh}B} \left(\frac{H}{h}\right)^2 \quad (4.4)$$

$h \rightarrow 0$  yields  $H/h$  increasing. But as  $H/h \rightarrow 2^-$  the dissipation grows. Hence

$$\frac{H}{h} \rightarrow 2 \quad \text{as } h \rightarrow 0 \quad \text{i.e. } d_t \rightarrow 0 \quad (4.5)$$

Thus the model described above has the limiting value of  $H/h = 2$  at the shoreline, not  $\infty$ .

Even this limit is considerably higher than the observed values. As  $h \rightarrow 0$ , however, we also get  $L/h \rightarrow \infty$  which implies that the parameter  $h_x L/h$  is no longer small. That is the bottom slope is not negligible and the assumption of locally horizontal bottom does not hold.

## 5. THE WAVE MOTION IMMEDIATELY AFTER BREAKING

It is tempting and illustrative to try if the solution presented in the previous chapters also applies to the region of rapid transition right after the initiation of breaking.

Figure 11a shows a computation of the wave height variation, starting at the breaking point. The agreement is surprisingly good. This, however, does not apply to Fig. 11b which gives a similar comparison for the set-up  $b/h_0$ . The two figures together show the paradoxical fact already hinted at earlier that the radiation stress in the transition region stays nearly constant even with a 30-40% decrease in wave height. Recalling eq. (2.8) this can only be true if  $P$  is increasing, roughly as  $H^{-2}$ .

By considering what happens when the breaking starts, it becomes clear that the overturning of the wave cannot immediately be matched by dissipation of a similar amount of energy. In the first transformation a large amount of the lost potential energy is converted into forward momentum flux which eventually is concentrated mainly in the roller, and this must be the reason for the simultaneous increase in  $P$ .

This is also consistent with the fact that  $P$  for very high waves is rather small. There are no results available for the skew waves at the breaking point, but the high order results for Stokes waves presented

by Cokelet (1977) can be used to determine  $P$  for very high, symmetrical waves. Values found are typically around  $P = 0.07$ , i.e. less than half the value of  $3/16$  for linear long waves and considerably less than for cnoidal waves of the same height.

Fig. 11a and b. Wave height and set-up using the theoretical results for  $B$ ,  $P$  and  $D$  from the breaking point.  
 • Measurements by Hansen & Svendsen (1979), Case H,  
 + measurements by Hansen (1982).

The increase in P, however, is inevitably associated with a similar increase in B, the energy flux for a wave of unit height and propagation speed. The mechanism is the same as for P: very steep waves with peaky crests represent a very small energy flux relative to their height and the collapse of the crest in the initial stage of breaking leads to a significant increase in B.

It may be shown that these shifts in P and B are also consistent with the result found in section 3, that waves in the inner region represent rather high values of radiation stress and energy flux relative to their height and speed.

But even with no energy dissipation an increase in B will in itself require a decreasing wave height. Hence the question arises: how much of the wave height decrease in the outer transition region is actually due to redistribution of momentum and energy (represented by the changes in P and B) and how much is real energy dissipation?

This problem and the change in B and P can be analysed by considering the conservation of momentum and energy over the transition region as a whole in analogy to the jump conditions which apply to bores and hydraulic jumps in open channel flow and to shocks in compressible flows.

Svendsen (1984) found for a specific example that the wave height in the outer region with  $S_{xx} = \text{constant}$  decreased to  $0.65 H_B$  at the transition point that,  $H^2 = 0.423 H_B^2$  corresponding to an apparent energy reduction (had B been constant) of 57.7% of the energy at the breaking. Due to the simultaneous increase in B, however, the actual energy dissipation is only about 20%, or 1/3 of the 57.7%.

## 6. ACKNOWLEDGEMENT

The author wishes to thank J. Buhr Hansen for the access to unpublished data referred to as Hansen (1982).

## CHAPTER FIVE

### WAVE KINEMATICS AND DIRECTIONALITY IN THE SURF ZONE

J. van Heteren\*, Staff member Hydraulic Division, Rijkswaterstaat.  
M.J.F. Stive \*\*, Research Engineer, Delft Hydraulics Laboratory.

#### ABSTRACT

Measurements of surface elevations and internal velocities have been conducted in a natural surf zone. The results were used to investigate the quantitative performance of linear theory in predicting the wave kinematics from the surface elevations. It appears that linear theory systematically overpredicts the horizontal velocities by 20 % in the frequency range around the peak, where the coherence with the surface motion is high, by 15 % at 2 times the peak frequency, changing in an underprediction of 15 % at higher frequencies. In these higher frequency ranges the rate of turbulent energy induced by breaking, contributes to the variance, so that the ratio of measured to theoretical r.m.s. fluctuation shows a trend of 25 % theoretical overprediction at negligible turbulent energy rates to 5 % underprediction at high turbulent energy rates. Furthermore the results were used to investigate the linear prediction of radiation stress and the effect of directionality on the radiation stress. Prediction of the radiation stress by unidirectional, linear theory gives an overestimation of 50 % at negligible turbulent energy rates to 35 % at high energy rates, which percentages reduce to 45 % and 25 % when the effect of shortcrestedness is taken into account.

#### 1. Introduction

The T.O.W. programme for Coastal Sediment Transport in the Netherlands consists of theoretical studies, laboratory investigations and investigations in the field and is carried out by 8 task groups. Within the framework of this study programme field campaigns were held in 1981 and 1982/83 covering simultaneous measurements of currents, surface elevations, wave kinematics and sediment concentrations in the surf zone on the Dutch coast near Egmond (Derks and Stive, 1984). The data are used to investigate several aspects of coastal processes. In the task group "Velocity Field in Waves" specific attention is given to the investigation of the relation between surface elevation and wave kinematics. This paper presents an analysis of the 1981 field measurements as carried out by this task group.

The quantitative performance of linear theory in predicting the wave kinematics from the surface elevation is investigated on basis of the squared coherence-, gain- and phase spectra between surface elevation and both horizontal and vertical velocity. In addition the measured

\*\* Delft Hydraulics Laboratory, p.o. box 177, 2600 MH DELFT, The Netherlands.

and theoretical r.m.s. values are compared. Relevant earlier studies on this topic are e.g. those of Mitsuguchi et al. (1980) and of Guza and Thornton (1980). Their findings are that linear theory generally overestimates wave induced horizontal velocities by 10 % to 30 %. Mitsuguchi et al. merely state their conclusion without analysing apparent trends in their data with e.g. increasing frequency. They only consider a limited set of horizontal velocity data. Guza and Thornton obtain their overall conclusion merely on basis of the r.m.s. fluctuation of the horizontal velocity as measured and as predicted with linear theory. The present study confirms the conclusions of the above investigation by and large, but extends the analysis in depth by investigating the relation with the rate of turbulent kinetic energy generated by breaking.

A second topic of attention is the directional spreading of the wave motion in the surf zone, which aspect has received very little attention sofar. The directional spreading is used to investigate the effects of non-linearity and directionality on the prediction of the principal radiation stress component. Knowledge of the radiation stress is important for the study of phenomena as set-up and long-shore currents.

In this paper only a limited number of results is presented. A more extended publication will appear elsewhere.

## 2. Measurements

### 2.1 Introduction

The field experiments were conducted on the Dutch coast near Egmond in May/June 1981. The Dutch coast is part of a concave sandy beach with coastal dunes extending from Cape of Gris Nez to the island of Texel, see fig. 1. The exposed sandy beach is typically gently sloped and barred with fairly parallel bottom contours.

fig. 1 : Situation.

The measurements were made at three locations 20 m apart in the surf zone along a line normal to the shore. In addition measurements were made at two stations outside the surfzone as reference. The stations were numbered 1 to 5 from shore to sea. The local mean tidal range is approximately 2 m. This implies that at low tide station 1 was situated on the dry beach and nearly all wave energy was dissipated on the first breaker bar, see fig. 2. Therefore, all measurements were made around high tide.

During the 5 week campaign actual measurements were made at five different days, each with a duration of about 4 hours. Offshore significant wave heights were varying from 0.50 m - 1.80 m.

fig. 2: Location stations

## 2.2 Measuring stations

The stations in the surfzone consisted of a platform resting on transparent space trusses, a sensor pile and, with exception of station 1, a wave gauge. The sensor pile and wave gauge were spaced 2 m apart along a line nearly parallel to the shore. The sensor pile was placed 1 m seaward from the platform and was equipped with a measuring car in order to change the elevation of the sensors. On both sides of the socket longitudinal pipes were welded in a direct line parallel to the coast in order to intercompare different types of velocity meters at the same depth. Nearly all measurements were made at an elevation of about 1 m above the bottom. Some measurements were made at 0.20 m above the bottom.

## 2.3 Instruments

Velocities were measured at each of the three locations, both with conventional current meters and a newly developed current meter, viz. a so called vector-akwa, a three-dimensional meter based on the principle of travel time of acoustic pulses. Temperature and salinity variations are automatically corrected for. A meter of this type designed for use in physical models has been described by Botma (1978), who also designed the vector-akwa. The sensor is highly transparent and has four 0.23 m long survey lines (see fig. 3). The advantage of the fourth survey line is, that for the calculation of the three mutually orthogonal velocity components the survey line most influenced by the sensor itself can be eliminated. From calibration tests it was found that the inaccuracy of this instrument is  $\pm 5\%$ .

fig. 3: Vector-akwa velocity meter.

Surface elevations were measured using resistance wave gauges. These gauges consisted of resistance wires mounted inside a protection tube provided with slits. The tube caused a wave height reduction as well as a phase shift. To investigate the influence of this tube experiments were carried out in a large scale laboratory flume. This experiment showed a maximal reduction of 6% depending on the steepness of the waves. Since in the laboratory flume the conditions of Egmond were not reproduced exactly, the maximal reduction is estimated to be 10%.

The phase shift due to the tube appeared to be not considerable, but difficult to determine, since it is neither linear nor constant. This phase shift was modelled mathematically. It appeared to depend on a large number of parameters. Since several of these parameters, such as the shape of the wave, are difficult to determine, the phase shift can only be estimated with a limited accuracy. The maximal phase shift due to the tube appeared to be  $13^\circ/\text{Hz}$ .

For data storage during the experiment a pulse code modulator system (P.C.M.) was used. With this system 112 channels can be sampled and recorded simultaneously. The data were recorded with a 14 track tape recorder. The sample frequency of the system at the lowest record speed ( $1\frac{7}{8}$  i.p.s.) is 133 samples per second per channel.

### 3. Data analysis procedure

Standard procedures as described by Bendat and Piersol (1971) and Jenkins and Watts (1968) have been used to calculate mean values, variances, auto- and cross spectra, which yield coherence, gain- and phase spectra. The main procedure of the computer program is Singleton's F.F.T. procedure (Singleton, 1969) using subrecords. The length of the analysed records has been taken 1800 s. For the calculation of the spectra the records are divided in 30 subrecords. Because no data window has been

used the number of degrees of freedom is 60 and the resolution is 1/60 Hz.

Mean values, variances and auto spectra were calculated of the surface elevation ( $\zeta$ ) and the three orthogonal velocity components ( $u, v, w$ ).

To intercompare the velocity meters cross spectral calculations were carried out between the onshore wave velocity components ( $v$ ) of the two velocity meters fixed at the same sensor pile. For the same reason cross spectral calculations were used between these components and the surface elevation. These calculations have also been used to calculate the coherence-, gain- and phase spectra. However, this method cannot be used for the calculation of the coherence-, gain- and phase spectra of the surface elevation and the resultant velocity component in the horizontal plane ( $\hat{u}$ ) because of the shortcrestedness of the waves. Therefore, the gain spectrum of  $\zeta$  and  $\hat{u}$  has been calculated from:

$$H_{\zeta\hat{u}}^{\sim} = \{ (S_{uu} + S_{vv}) / S_{\zeta\zeta} \}^{1/2}$$

in which  $S_{uu}$ ,  $S_{vv}$  and  $S_{\zeta\zeta}$  are the auto spectra of the two horizontal velocity components,  $u$ ,  $v$ , and the surface elevation  $\zeta$ . This procedure does not permit the estimation of confidence intervals. For the coherence- and phase spectra the spectra of  $\zeta$  and  $v$  are used, since  $v$  contains the major part of the wave energy in the horizontal plane.

Assuming the water motion and the measurements to be linear and noise-free, the calculated auto- and cross spectra of ( $u, v, w$ ) can be used to estimate the directional properties of the waves by standard procedures (see Borgman, 1979). Using the auto- and cross spectra the truncated Fourier series and the parameters of the  $\cos^2$  ( $\theta/2$ )-model of the directional spectrum have been calculated for different frequencies (Longuet-Higgins et al., 1963 and Mitsuyasu et al., 1975). The spreading parameter of this model can easily be expressed in degrees.

#### 4. Intercomparison of velocity meters

One of the objectives of the field campaign was to investigate the performance of several types of current meters in a natural surf zone by intercomparison. To this end the velocity meters were closely placed at the same height above the bottom. The meters have been compared on basis of the r.m.s. values of  $\hat{u}$  and of the squared coherence and gain of the two onshore wave components at the peak frequency,  $f_p$ . Due to the lack of an absolute measurement result and of insight into the spatial variability of the velocity field these comparisons give no definite answer to the question which meter is the better one. The only quality assessment of the meters may be based on the squared coherence between  $\zeta$  and  $v$ . The results of the 1981 campaign indicate that the hydrodynamically well-designed vector-akwa shows in general a higher coherence (0.80 - 0.95) with the surface elevation than the signals of the other types of current meters. This intercomparison is based on a limited set of data obtained in the lower half of the water column. An extension of the intercomparison was realized in the 1982/83 field campaign of which the results are summarized in Derks and Stive (1984).

#### 5. Wave kinematics results

##### 5.1 Introduction

A comparison of measurement results with linear theory has been made in two ways. Firstly, the gain- and phase spectra are considered and compared with those according to linear theory. Secondly, the r.m.s.

values of the horizontal and vertical velocity components are compared with the estimated variances derived from the surface elevation spectra with linear theory.

This paper presents one typical example of squared coherence-, gain- and phase spectra of surface elevation and horizontal velocity component of one of the stations in the surf zone and the r.m.s. values of all horizontal velocity results.

## 5.2 The spectra

The surface elevation spectrum,  $\hat{S}_{\zeta\zeta}$ , and the corresponding 90% confidence interval is shown in fig. 4. The peak frequency appears at 1/6 Hz and, since we are dealing with breaking waves, second harmonics appear around twice the peak frequency. The local significant wave height in this example was about 1 m, the elevation of the velocity meter above the bottom was 0.80 m and the mean water depth was 2.30 m.

The squared coherence spectrum between surface elevation and on-shore velocity component,  $\hat{\gamma}_{\zeta v}^2$ , is shown in fig. 5. The dashed lines indicate the 90% confidence interval. In the frequency range where the bulk of the energy is concentrated the coherence is quite high. This implies a nearly linear relationship between  $\zeta$  and  $v$  and a relatively small contribution to the variance of the turbulent motion.

Fig. 6 exemplifies the gain spectra of surface elevation and horizontal velocity component in the propagation direction  $\hat{H}_{\zeta v}^{\gamma}$ . This example shows a typical overestimation of the horizontal velocity component by linear theory for the frequency range of 0.1 to 0.4 Hz of about 10 %, which changes in an underprediction of 20 % at higher frequencies. This can be seen more clearly in figure 7, where the ratio between the measured and the theoretical gain according to linear theory has been plotted versus frequency. It must be noted that this result is not corrected for the reduction caused by the tube of the wave gauge, which was estimated to be maximally 10 %. The phase spectrum of  $\zeta$  and  $v$ ,  $\hat{\phi}_{\zeta v}$ , is shown in fig. 8. This phase spectrum has been corrected for time delays due to: the tube of the wave gauge, the electronics of the wave gauge and the distance between wave gauge and velocity meter. The magnitude of these delays could only be estimated. The inaccuracy of the estimated phase corrections for this example is  $-28^\circ/\text{Hz}$  to  $+33^\circ/\text{Hz}$ . This phase spectrum shows a slight trend with frequency which, however, may be explained by the inaccuracies of the applied corrections, indicated by the thick broken line. Another reason may be that for the correction due to the spacing the main wave direction was used. Neglect of the wave spreading results in an overestimation of the time delay. Summarizing, it can be concluded that the phase spectrum of  $\zeta$  and  $v$  is consistent with linear theory within the accuracy margin.

In view of the above results concerning the phase spectrum of the horizontal onshore velocity component and the vertical velocity component,  $\hat{\phi}_{wv}$ , are of particular interest since this spectrum is neither influenced by a lag between two instruments nor by a spacing. This spectrum is shown in fig. 9. The theoretically expected value between these components is within the 90 % confidence interval of the estimate, confirming the theoretically predicted quadrature relation between these velocity components.

fig. 4 : surface elevation spectrum.

fig. 5 : squared coherence spectrum of surface elevation and onshore velocity component.

fig. 6 : gain spectrum of surface elevation and horizontal velocity component in the propagation direction.

fig. 7 : ratio measured to the theoretical gain spectrum of surface elevation and horizontal velocity component in the propagation direction.

fig. 8 : phase spectrum of surface elevation and horizontal onshore velocity component.

fig. 9 : phase spectrum of vertical and horizontal onshore velocity component.

5.3 The r.m.s. values

A correlation between the measured and theoretical r.m.s. values of the horizontal velocity component in the propagation direction is shown in fig. 10. No discrimination has been made between the r.m.s. values calculated from the measurements made at different elevations, because of the depth-uniformity of the horizontal velocity field in the lower water column. For the low r.m.s. values the deviations are generally outside the  $\pm 10\%$  interval, for the higher values they are generally within this interval. Again : these values are not corrected for the reduction due to the tube of the gauge (which would increase the theoretical estimate by 10 % maximally).

To investigate whether a systematic relationship between the discrepancy with linear theory and the relative turbulent energy level exists, a dimensionless parameter for this energy level has been used, defined as  $\hat{q}^2$ :

$$\hat{q}^2 = \rho h q^2 / E_{kin, inc}$$

in which  $\rho$  = water density [ kg/m<sup>3</sup> ],  $h$  = local water depth [ m ],  $q^2$  = turbulent kinetic energy [ m/s ],  $E_{kin, inc}$  = incident kinetic energy =  $\frac{1}{16} \rho g H_{rms}^2$  [ J/m<sup>2</sup> ],  $g$  = gravity acceleration [ m/s<sup>2</sup> ].

The turbulent kinetic energy is derived from :  $q^2 \approx (D/\rho)^{2/3}$  Battjes (1975). Here  $D$  is the energy dissipation due to breaking which is approximated by :  $D = \frac{1}{4} \rho g f_p Q_b H_m^2$ , according to Battjes and Janssen (1978),  $H_m$  being the maximum wave-height and  $Q_b$  the fraction of breaking waves.

The relation between this parameter and the ratio of the measured r.m.s. value of the horizontal velocity component to the theoretical one is shown in fig. 11. The results indicate that the discrepancy with linear theory is correlated with the rate of turbulent energy.

fig. 10 : Correlation measured and theoretical r.m.s. values of the horizontal velocity component in the propagation direction.

fig. 11 : ratio measured r.m.s. values of the horizontal velocity component in the propagation direction to the theoretical ones as a function of the relative turbulent energy level.

6. Wave directionality and radiation stress

An example of the wave direction results is shown in fig. 12. The upper diagram gives the main wave direction,  $\theta_0$ , as a function of frequency for the three stations in the surfzone. The lower diagram in this figure gives the spreading of the waves as a function of frequency. This spreading has been defined more or less analogously to the standard deviation of the Gaussian distribution and is expressed in degrees, see Van der Vlugt et al. (1981). Between this parameter and the spreading parameter of the  $\cos^2 s(\theta/2)$  model the following relation exists (Kuik et al., 1984):

$$\sigma = \sqrt{\frac{2}{s+1}} \cdot \frac{360^\circ}{2\pi}$$

The upper diagram shows that two different wave fields were present, one coming from the sea with a frequency of 0.10 Hz - 0.30 Hz and another caused by local winds at higher frequencies with the same direction as the wind direction,  $\theta_w$ . The wave directions of both wave fields clearly show refraction effects (station 3 is the most seaward station).

The spreading of the waves has a minimum at the peak frequency, which was also noticed from measurements made in deeper water, see Mitsuyasu et al. (1975). Another phenomenon which is clearly shown in this example is the decrease in spreading as the waves travel towards the shore. This can also be ascribed to refraction.

One of the effects of shortcrestedness is a decrease of the radiation stress. In a statistically homogeneous and stationary wave field the principal radiation stress component in the main wave direction is

fig. 12 : Main wave direction (upper diagram) and wave spreading (lower diagram) as a function of frequency for the three stations located in the surf zone.

given, correct to second order in wave elevation (Battjes 1972), by :

$$S_{11, meas} = \frac{1}{2} \rho g \zeta^2 + \rho \int_0^{\infty} (\overline{v_*^2} - \overline{w^2}) dz$$

where  $\overline{v_*^2}$  is the variance of the horizontal orbital velocity in the main wave direction, which term can be derived from the measured variances  $\overline{u^2}$ ,  $\overline{v^2}$  and the cross variance  $\overline{u.v}$  (Battjes and Van Heteren, 1980). Assuming a linear longcrested wave field, the above expression reduces to an expression in which the main principal radiation stress component is :

$$S_{11, theor} = \int_0^{\infty} S_{\zeta\zeta}(f) \cdot \{2kh/\sinh(2kh) + \frac{1}{2}\} df$$

where k is the linear wave number. Battjes (1972) shows how the reducing effect of shortcrestedness on  $S_{11,theor}$  may be incorporated. For the simplified case of shallow water the reduction factor is given by  $(1-2/3.\epsilon)$  where  $\epsilon = (2s_0 + 1) \cdot (s_0 + 1)^{-1} \cdot (s_0 + 2)^{-1}$  in which  $s_0$  is the spreading parameter of the  $\cos^2 s(\theta/2)$  model. The radiation stress has been calculated for  $S_{11,meas}$  and for  $S_{11,theor}$  and for  $S_{11,theor}$  corrected for shortcrestedness. The results are shown in fig. 13. The results show that the reducing effect of shortcrestedness is 10% typically.

The correlation between the ratio of measured to theoretical estimates of the principal radiation stress component and the relative turbulent energy level is presented in fig. 14. This result clearly shows a trend with the rate of turbulent energy. The unidirectional linear theory overestimates the radiation stress by 40 % at negligible turbulent energy rates and by 25 % at higher rates. Corrected for shortcrestedness these percentages decrease to 35 % and 15 % respectively (these percentages are not corrected for the reduction caused by the tube of the gauge).

fig. 13: correlation measured and theoretical values of principal radiation stress component.

fig. 14: ratio measured values of principal radiation stress component to theoretical ones as a function of the relative turbulent energy level.

### 9. Conclusions

The following conclusions have not only been based on the examples presented in this paper, but more generally on the results of all measurements made in the surf zone of the beach near Egmond during the 1981 T.O.W. measuring campaign. All given values in this paragraph have been corrected for the reduction of surface elevation caused by the tube of the wave gauge which was estimated to be maximally 10 %. For this correction the mean value was used (5 %) accepting a random error of  $\pm 5\%$ . Furthermore, the inaccuracy of the velocity meter must be taken into account, which was found to be also  $\pm 5\%$ .

(1) In the surf zone linear theory systematically overpredicts the horizontal velocity component in the frequency range of high coherence with surface elevation. Average values of 21 % at the peak frequency and 17 % at two times the frequency have been found. This overprediction changes in an underprediction (in some cases as high as 15 %) at higher frequencies which is due to the presence of turbulent energy. Resultingly, the ratio of measured to theoretical r.m.s. fluctuations of the horizontal velocity shows a trend correlated with the turbulent energy rate from 25 % theoretical overprediction at negligible turbulent energy rates to 5 % underprediction at high turbulent energy rates.

(2) The estimated phases of the horizontal velocity component and surface elevation are generally consistent with linear theory within the margin of the sampling variability and the accuracy of the corrections applied. Corrections were needed due to the time delays caused by the sensor systems as well as by the distance between wave gauges and velocity meters.

(3) The wave direction results clearly show refraction effects. The spreading of the waves has a minimum at the peak frequency and decreases in onshore direction. Shortcrestedness decreases the magnitude of the radiation stress. Prediction of the radiation stress by unidirectional linear theory leads to an overestimation of 45 % at negligible turbulent energy rates and of 30 % at higher rates. These percentages reduce to 40 % and 20 % after correction for the effects of shortcrestedness.

## CHAPTER SIX

### A Model for Breaker Decay on Beaches

William R. Dally<sup>1</sup>, Robert G. Dean<sup>1</sup>, and Robert A. Dalrymple<sup>2</sup>

#### ABSTRACT

Based on the observation that a shallow water breaking wave propagating over a region of uniform depth will reform and stabilize after some distance, an intuitive expression for the rate of energy dissipation is developed. Using linear wave theory and the energy balance equation, analytical solutions for monochromatic waves breaking on a flat shelf, plane slope, and "equilibrium" beach profile are presented and compared to laboratory data from Horikawa and Kuo (1966) with favorable results. Set-down/up in the mean water level, bottom friction losses, and bottom profiles of arbitrary shape are then introduced and the equations solved numerically. The model is calibrated and verified to laboratory data with very good results for wave decay for a wide range of beach slopes and incident conditions, but not so favorable for set-up. A test run on a prototype scale profile containing two bar and trough systems demonstrates the model's ability to describe the shoaling, breaking, and wave reformation process commonly observed in nature. Bottom friction is found to play a negligible role in wave decay in the surf zone when compared to shoaling and breaking.

#### INTRODUCTION

A major problem encountered in modeling nearshore wave-induced phenomena is the description of wave parameters subsequent to the initiation of wave breaking. Specifically, wave height and its spatial gradients generate or have direct impact on sediment mobilization and suspension, littoral currents in both the alongshore and on/offshore directions, wave induced set-down/up in the mean water level, and forces on coastal structures. While the "0.78" criterion (ratio of breaker height to water depth = 0.78) appears to provide a reasonable prediction of incipient breaking on mildly sloping beaches, data show that this criterion does not hold farther into the surf zone (Horikawa and Kuo (1966), Nakamura, Shiraishi, and Sasaki (1966), Divoky, LeMéhauté and Lin (1970)). In fact, this data shows that such a similarity model is especially inappropriate on mild slopes - just where many coastal scientists assume it is most valid. Another shortcoming of this and most other representations developed to date is that they are not applicable on non-monotonic beach profiles such as those containing bar/trough formations. Such a model, capable of describing wave

- 1) Department of Coastal and Oceanographic Engineering, 336 Weil Hall, University of Florida, Gainesville, Florida 32611 (U.S.A.)
- 2) Department of Civil Engineering, 355 DuPont Hall, University of Delaware, Newark, Delaware 19711 (U.S.A.)

transformation across beaches of irregular profile shape, is essential to an adequate understanding of nearshore hydrodynamics and sediment transport.

#### BACKGROUND AND LITERATURE REVIEW

Aside from the similarity model which assumes that breaker height is strictly controlled by and directly proportional to water depth, investigations carried out over the past two decades have been based on the steady state equation governing energy balance for waves advancing directly toward shore:

$$\frac{\partial EC_g}{\partial x} = - \delta(x) \quad (1)$$

in which E is the wave energy per unit surface area,  $C_g$  is the group velocity, and  $\delta$  is the energy dissipation rate per unit surface area due to boundary shear, turbulence due to breaking, etc. The main thrust in previous studies has been the development of a rational and universally valid formulation for  $\delta$ . The most physically appealing approach, first advanced by LeMéhauté (1962), has been the approximation of a breaking wave as a propagating bore (hydraulic jump). The energy dissipation appears to be proportional to wave height cubed in this model. However, the adaptation of  $\delta$  from a jump to a breaking wave is not as straightforward as one might expect, and order of magnitude arguments by Battjes and Janssen (1978) produced a bore model in which  $\delta$  was proportional to wave height squared, with good results.

Horikawa and Kuo (1966) represent the internal energy dissipation in terms of turbulent velocity fluctuations which are assumed to decay exponentially with distance from the wave break point, while Mizuguchi (1981) applies the analytical solution for internal energy dissipation due to viscosity (Lamb, 1932) with the molecular kinematic viscosity replaced by the eddy viscosity. In these last two models the energy dissipation goes like wave height squared as well. All the dissipation models have coefficients which must be fitted empirically. It appears that until a precise model for breaking waves is developed, the existing ones must be judged by their abilities to predict accurately over the ranges of beach slope/shape, wave height, and wave period found in nature without changing these coefficients, or at least changing them in a systematic and easily applied manner. A summary of the studies which dealt with regular waves is presented in Table 1, including the dissipation model used in each.

Table 1 - Previous Investigations of Regular Breaking Waves

<u>Author(s)</u>	<u>Dissipation Model Used</u>
LeMéhauté (1962)	propagating bore
Horikawa & Kuo (1966)	turb. vel. fluc.
Divoky, LeMéhauté, & Lin (1970)	propagating bore
Hwang and Divoky (1970)	propagating bore
Svendsen, Madsen, & Hansen (1978)	propagating bore
Peregrine & Svendsen (1978)	propagating bore
Mizuguchi (1981)	internal energy

One of the features of breaking waves that is not represented in most of these models is that of the wave height stabilizing at some value in a uniform depth following the initiation of wave breaking. The laboratory data of Horikawa and Kuo (1966), general observations, and intuition support such a phenomenon, yet none of the dissipation models based on the moving hydraulic jump predict this effect. Although the model by Mizuguchi (1981) includes this stabilization, it is only included when waves are breaking in a surf zone of constant depth and does not play a role in governing the wave decay on a uniformly sloping beach - no matter how mild the slope. In fact, on a plane beach this model reverts to the similarity model, which as previously stated (and subsequently shown) does not compare well to the data collected on laboratory beaches of realistic slope.

In the present paper we concentrate on the development and evaluation of a somewhat intuitive model for monochromatic waves originally proposed in Dally (1980) which includes the wave height "stabilization". The model is calibrated using laboratory data, verified both qualitatively and quantitatively, and tested at prototype scale. Although one could question the significance of comparison against laboratory data when some field data are available, the field data are much more limited. Also, while the dependence of breaker decay on beach slope and wave steepness appear only as vague trends in the random wave data, it is clearly discernible and tractable in the monochromatic data. So it appears that the evaluation of a model by laboratory data would provide a useful step toward an understanding of the problem of greater interest in nature.

#### MODEL DEVELOPMENT

Consider a beach profile that rises from deep water in a gently sloping manner and at some point in shallow water becomes horizontal (see Figure 1). Consider further, a wave propagating onto this profile with characteristics such that breaking starts at the point where the bottom becomes horizontal. The wave will not instantaneously stop breaking because the bottom becomes horizontal (as dictated by the similarity model), but breaking would continue until some stable wave height is attained. Breaking would be most intense just shoreward of line AA and would decrease until the approximate stable wave height is reached at line BB. The rate of energy dissipation per unit plan area,

Figure 1 - Shelf beach presentation of the surf zone.

$\delta(x)$ , used in (1) is assumed to be proportional to the difference between the local energy flux and the stable energy flux, i.e.

$$\frac{\partial ECg}{\partial x} = \frac{-K}{h'} [ECg - ECg_s] \tag{2}$$

$ECg$  is now taken to be the depth-integrated time-averaged energy flux as given by shallow water linear wave theory,  $K$  is a dimensionless decay coefficient,  $h'$  is the still water depth, and  $ECg_s$  is the energy flux associated with the stable wave that the breaking wave is striving to attain. Horikawa and Kuo (1966) conducted laboratory tests with a bottom configuration identical to the one described. As shown in Figure 2, their data indicate a stable wave criterion given by

$$H_s = \Gamma h' \tag{3}$$

where  $H_s$  is the stable wave height, and  $\Gamma$  is a dimensionless coefficient whose value appears to lie somewhere between 0.35 and 0.40. Examination of another figure in their paper, where wave height was plotted versus still water depth for a uniform beach slope of 1/65, revealed that the breaking waves tended to approach asymptotically the line  $H = 0.5h'$ . In any event (3) appears to be a reasonable supposition and (2) can then be written:

$$\frac{\partial (H^2 \sqrt{h'})}{\partial x} = \frac{-K}{h'} [H^2 \sqrt{h'} - \Gamma^2 (h')^{5/2}] \tag{4}$$

where  $Cg$  is taken as  $\sqrt{gh'}$ . It should be noted that (2), (3), and (4) can be applied to a bottom of varying depth and slope until the stable wave criterion is reached because shoaling is included implicitly (if  $K = 0$ , the model satisfies conservation of energy, i.e. Green's Law).

ANALYTICAL SOLUTIONS

The problem to ultimately be addressed includes set-up, bottom friction, and beach profiles of irregular shape and consequently must be solved numerically. However, closed form solutions which exist for the

Figure 2 - The stable wave criterion, and comparison of analytical solution (7) with experimental results of Horikawa and Kuo (1966) for waves breaking on a shelf as shown in Figure 1.

simpler case of breaking on beaches of more idealized shapes, without including set-up, are both enlightening and potentially valuable for future analytical work with wave-induced currents and sediment transport. For brevity, the final results of the analytical solutions will just be stated here, but their full derivation can be found in Dally, Dean, and Dalrymple (1984).

Shelf Beach - For the idealized beach with a horizontal bottom described in the previous section given by,

$$h'(x) = \text{constant} = h' \quad (5)$$

and applying the boundary condition

$$G = G_b = H_b^2 \sqrt{h'} \quad , \quad x = 0 \quad (6)$$

the decay in wave height on a shelf beach in dimensionless form is

$$\frac{H}{h'} = \left( \left[ \left( \frac{H}{h'} \right)_b^2 - \Gamma^2 \right] \exp\left(-K \frac{x}{h'}\right) + \Gamma^2 \right)^{1/2} \quad (7)$$

where the subscript b denotes conditions at incipient breaking and x has its origin at the breaker line and is directed onshore. This expression dictates that the energy flux decays exponentially across the surf zone, never quite reaching the stable wave state known to exist. However, (7) may still be valid because internal and bottom friction losses could be accountable for the last bit of energy dissipation required to reach the stable condition. Note that if  $K = 0$  (no breaking), the wave height remains constant as would be expected. Equation (7) is plotted in Figure 2 with  $K = 0.2$ ,  $\Gamma = 0.35$ , and  $(H/h')_b = 0.8$ .

Plane Beach - The same general solution and boundary condition is applied to determine the analytical solution for the breaker model on a plane beach given by

$$h'(x) = h'_b - mx \quad (8)$$

where m is the beach slope. The result in dimensionless form is

$$\frac{H}{H_b} = \left[ \left( \frac{h'}{h'_b} \right)^{K/m - 1/2} \left( 1 + \alpha \right) - \alpha \left( \frac{h'}{h'_b} \right)^2 \right]^{1/2} \quad (9)$$

$$\text{where} \quad \alpha = \frac{K \Gamma^2}{m(5/2 - K/m)} \left( \frac{h'_b}{H_b} \right)^2 \quad (10)$$

Note that the solution is invalid if  $K/m = 5/2$ . For this special case the solution is

$$\frac{H}{H_b} = \left( \frac{h'}{h'_b} \right) \left[ 1 - \beta \ln \left( \frac{h'}{h'_b} \right) \right]^{1/2} \quad (11)$$

$$\text{where} \quad \beta = \frac{5}{2} \Gamma^2 \left( \frac{h'_b}{H_b} \right)^2 \quad (12)$$

Also note that if  $K$  is set equal to zero, (9) becomes Green's Law. If  $\alpha = -1.0$ , (9) reverts to the common similarity model  $H \sim h'$ . Equations (9) and (11) are plotted in Figure 3a for several values of  $K/m$  and  $(h'_b/H_b)$ . Figure 4 compares (9) to the data presented in Horikawa and Kuo (1966). Here  $K = 0.17$  and  $\Gamma = 0.5$  which are the recommended values for use with the "still water" model on a plane beach of slope less than approximately  $1/20$ .

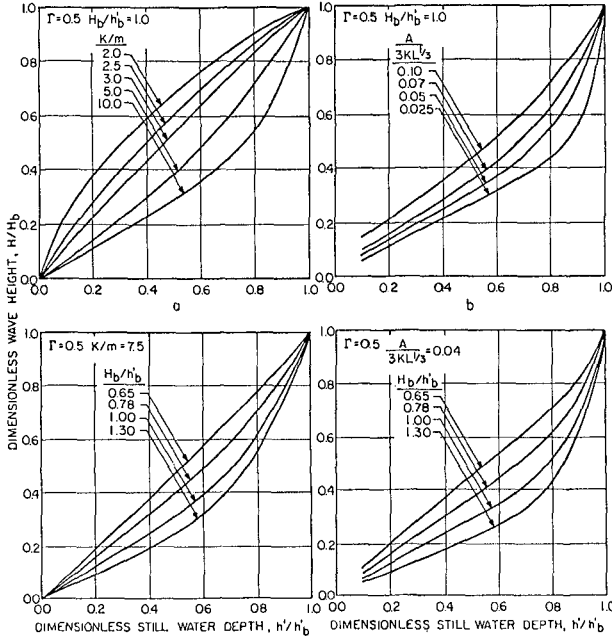

Figure 3a,b - Dependence of analytical solutions for plane beach (9) and equilibrium beach (14) on incipient conditions, and  $K/m$  and  $\phi$  respectively.

"Equilibrium" Beach Profile - The final closed form solution to be presented is for the profile shape which seems to best represent "equilibrium" beach profiles as determined by Dean (1977), and is expressed by

$$h'(x) = A(L - x)^{2/3} \tag{13}$$

where  $A$  is a parameter dependent on fluid and sediment characteristics,  $L$  is the distance from the still water line to the breaker line, and the origin of  $x$  remains at the breaker line directed onshore. Again with the same boundary condition as the two previous cases, the breaker decay on an equilibrium beach profile in dimensionless form is

$$\frac{H}{H_b} = \left( \left\{ -\Gamma^2 \left( \frac{H_b}{h'_b} \right)^{-2} \sum_{n=0}^5 \left[ x - \left( \frac{h'}{h'_b} \right)^{\frac{4-n}{2}} \right] \frac{\phi^n}{(5-n)!} \right\} + x \right)^{1/2} \tag{14}$$

where

$$x = \left( \frac{h'}{h'_b} \right)^{-1/2} \exp \left\{ \frac{1}{\phi} \left[ \left( \frac{h'}{h'_b} \right)^{1/2} - 1 \right] \right\} \tag{15}$$

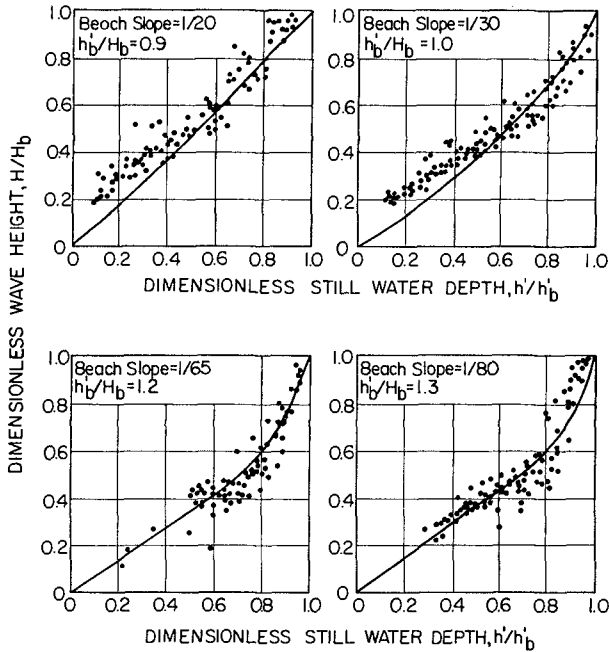

Figure 4 - Comparison of analytical solution (9) to wave decay data on a plane beach as presented in Horikawa and Kuo (1966) for various beach slopes ( $K = 0.17$ ,  $\Gamma = 0.5$ ).

and  $\phi$  is a similarity parameter given by

$$\phi = \frac{A}{3K L^{1/3}} \quad (16)$$

The effects of the incipient conditions and the parameter  $\phi$  on breaker decay on an equilibrium beach profile given by (14) are shown in Figure 3b. Note that the curves do not extend to the shoreline. This is because as the beach slope approaches infinity, shoaling causes the solution to become unbounded.

#### SET-UP AND BOTTOM FRICTION

During initial examination of the complete raw data set collected by Horikawa and Kuo, it was noticed that in all cases where measurements were taken in the inner portion of the surf zone, as the still water depth approached zero the wave height did not. This may also be apparent to the reader in Figure 4. To better model this phenomenon, including wave-induced set-up/down of the mean water level is necessary - the same conclusion reached originally by Hwang and Divoky (1970). From Longuet-Higgins and Stewart (1963), the slope of the mean water level,  $\bar{\eta}$ , is given by

$$\frac{\partial \bar{\eta}}{\partial x} = \frac{-3}{16} \frac{1}{(h' + \bar{\eta})} \frac{\partial H^2}{\partial x} \quad (17)$$

and can be used in conjunction with a slightly different form of (4) in which  $h'$ , the still water depth, is replaced by the mean water depth,  $h$ , given by  $h = h' + \bar{\eta}$ .

Although energy dissipation due to bottom friction will be negligible when compared to breaking in the cases to be examined, it will be incorporated in an elementary form for completeness. The average rate of energy dissipation per plan area due to bottom friction for shallow water (see Putnam and Johnson (1949)) is expressed by

$$\delta_{BF} = \rho \frac{f H^3}{12\pi h} \quad (18)$$

where  $f$  is a drag coefficient dependent on flow and bottom/sediment characteristics, and shallow water linear wave theory has been applied. (The bottom shear stress is defined as  $\tau = \rho \frac{f}{2} u|u|$ ).

#### NUMERICAL SOLUTION

Closed form solutions for the breaker model with the inclusion of set-up, beach profiles of more realistic shape, or bottom friction have not yet been discovered. A numerical scheme was therefore developed, which is capable of describing the one-dimensional transformation of wave height over bottoms of arbitrary shape due to shoaling, breaking, reformation, and bottom friction, including the effects of set-up in mean water level. Briefly outlining this scheme, (4) (with  $h$  replacing  $h'$ ) and (17) are explicitly finite differenced using a central average for each of the quantities on their right-hand sides. Before the wave height at the next spatial step can be calculated, the mean water level is required, but not known a priori. Using the mean water level at the present location as an initial guess, the program iterates between the wave height and set-up equations until the updated value for the mean water depth is close to the previous value. In the calibration runs, it usually required only one or two iterations for the difference in estimates to become less than a millimeter.

Early on in this investigation the decay in wave energy due to bottom friction was included in the model in an uncoupled fashion. That is, after utilizing the scheme described above at an individual cell, additional energy was then extracted using a finite-differenced form of (18) and energy flux considerations. As will be shown subsequently, for realistic values of the drag coefficient the energy dissipation due to bottom friction was found to be negligible for all cases examined, and this mechanism was therefore dropped from the model.

To apply the model in a given situation, the following information is required: 1) the wave height and still water depth at a known near-shore location, 2) the wave height to water depth ratio at incipient breaking, 3) the bottom friction coefficient, and 4) the bottom profile. The breaking height to depth ratio is not easily predicted and was not treated in an extensive manner in this study. Assuming the starting point is in shallow water and outside the surf zone, the set-down in mean water level as given by Longuet-Higgins and Stewart (1963) is

$$\bar{\eta}_1 = -H_1^2 / 16 h_1 \quad (25)$$

From these initial conditions and using the method described, the wave height will increase (with some losses due to bottom friction) as the wave moves shoreward until the incipient breaking criterion is reached. The wave then breaks to a location where local stability, as defined by (3), is achieved (if at all). On barred profiles, the combination of the wave decay and the increasing water depth as the wave passes over the trough enable the wave to reach stability, where the breaking aspect of the model is shut off. The "reformed" wave then shoals again until the breaking criterion is reached, and the process repeats until the mean water depth reaches an arbitrarily chosen small value (0.25 meters is a reasonable choice at prototype scale).

#### CALIBRATION

The model is calibrated by determining the best values for the stable wave factor ( $\Gamma$ ) and the wave decay factor ( $K$ ) using a least squares procedure. The original raw laboratory data of waves breaking on plane slopes obtained by Horikawa and Kuo and used in their paper (1966) were examined. Starting at incipient breaking, they measured wave heights at known distances across the surf zone under monochromatic wave conditions for plane smooth rubber and concrete slopes of 1/20, 1/30, 1/65, and 1/80. The wave period varied from 1.2 to 2.3 seconds and the incipient breaker height from 7 to 27 cm. Although not specifically stated, the breakers must have spanned both the plunging and spilling types because the ratio of wave height to water depth at incipient breaking ranged from 0.63 to 1.67. Over 85 waves from the 1/30, 1/65, and 1/80 slopes containing more than 750 data points were analyzed. Data from the 1/20 slope were not included in the calibration because the measurements were taken too far apart for the model to remain numerically stable. The error function to be minimized is defined by

$$\epsilon(\Gamma, K) = \left( \sum_{j=1}^N [H_{p_j}(\Gamma, K) - H_{m_j}]^2 / \sum_{j=1}^N H_{m_j}^2 \right)^{1/2} \quad (26)$$

where  $H_{m_j}$  is the measured wave height,  $H_{p_j}$  is the wave height at that location as predicted by the numerical scheme for given incipient conditions and values of  $\Gamma$  and  $K$ , and  $N$  is the number of data points analyzed. Attempts to best fit  $\Gamma$  and  $K$  using a non-linear least squares iterative procedure were unsuccessful, apparently because the error surface is too highly non-linear. However, by calculating the error at regular intervals of  $K$  and  $\Gamma$ , a discretized error surface can be generated whose low point occurs near the best-fit values for the factors. The surfaces for all three slopes were found to have recurved shapes, with the 1/65 and 1/80 surfaces also containing saddle points. The best fit values for  $\Gamma$  and  $K$  for the three slopes analyzed are presented in Table 2.

The best fit values for the two factors do vary with beach slope, especially as the beach gets very steep. However, it would be preferable to choose single values for  $\Gamma$  and  $K$  which give satisfactory results for all beach slopes, allowing the model to be used on beach

Table 2 - Best Fit Values for  $\Gamma$  and K

Slope	$\Gamma$	K	Minimum Error
1/80	0.350	0.100	0.1298
1/65	0.355	0.115	0.1054
1/30	0.475	0.275	0.1165

profiles of more realistic shape. Fortunately, the error surfaces for the three slopes tested are relatively broad and flat in the vicinity of their minimums (probably due to the reasonable scatter in the data), so the factors can be changed somewhat without excessively increasing the combined error. The procedure followed was to superimpose the contour plots for each of the three slopes and find the location where the sum of the three error values is minimized. This point occurs where:  $\Gamma = 0.40$ ,  $K = 0.15$ , and the mean error was 0.1423. It is recommended that these values be used in situations where the bottom slope varies over a wide range. If the beach is nearly planar, the values from Table 2 may be used accordingly.

#### RESULTS AND DISCUSSION - LABORATORY CONDITIONS

Wave Height - Figures 5, and 6 display a representative sample of model-predicted breaker decay as compared to the aforementioned laboratory data for plane beaches of 1/20, 1/30, 1/65 and 1/80 slopes. They are dimensional plots of wave height versus still water depth. In all cases, the wave decay factor K was set equal to 0.15 and the stable wave factor  $\Gamma$  was taken to be 0.40. Bottom friction was considered negligible. Each curve was generated by inputting the wave height and still water depth at incipient breaking as given in the data, and calculating stepwise ( $\Delta x = 1/\text{beach slope (cm)}$ ) the set-up and decay profiles.

Examination of these results shows that the model developed in this study appears to provide a good representation of breaking wave decay on plane beaches of laboratory scale. It is important to note that the model is in good quantitative agreement over the wide range of slopes tested (including the 1/20 slope not involved in the calibration), even with the two factors held constant at values that are not necessarily the best fit values for each particular slope. Coupled with the fact that the error surfaces are broad and flat in the vicinity of their minimums, this indicates the proposed governing equation (2) has the correct form, and that varying the empirical factors does not significantly affect the accuracy when considering the reasonable scatter already present in the data.

The line  $H = 0.78 h'$  is plotted in each of the figures, and appears to be an acceptable description of breaker decay only for the 1/30 slope (Figure 5). In fact, the similarity model ( $H \sim h'$ ) so prevalent in the coastal literature seems to be approximately valid only for beaches of much greater slope than those commonly found in nature. The dependence of breaker decay on beach slope is clearly observed in this monochromatic data, with the decay approaching an increasingly steeper asymptote as the beach slope increases. The model displays the exact same behavior, which is also explicitly derived in the closed form solution (9) as was shown in Figure 3a. Those collecting random wave

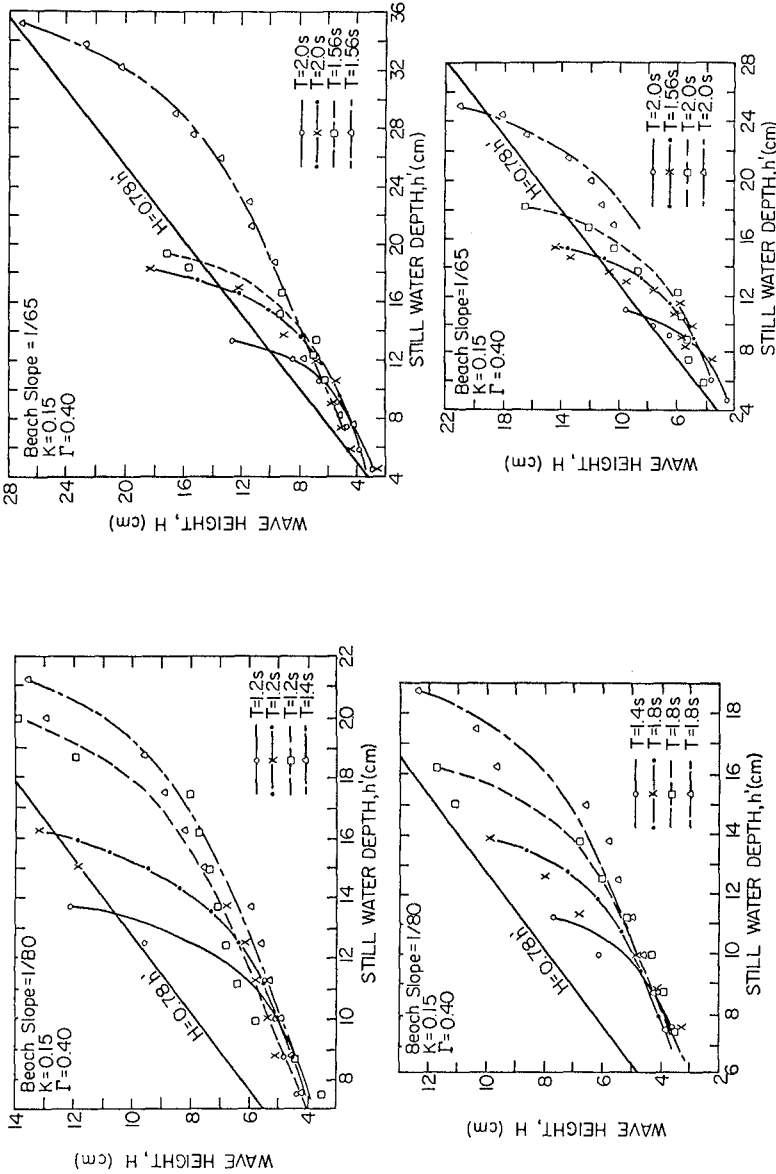

Figure 5 - Model comparison to laboratory data of Horikawa and Kuo (1966) for 1/80 and 1/65 beach slopes.

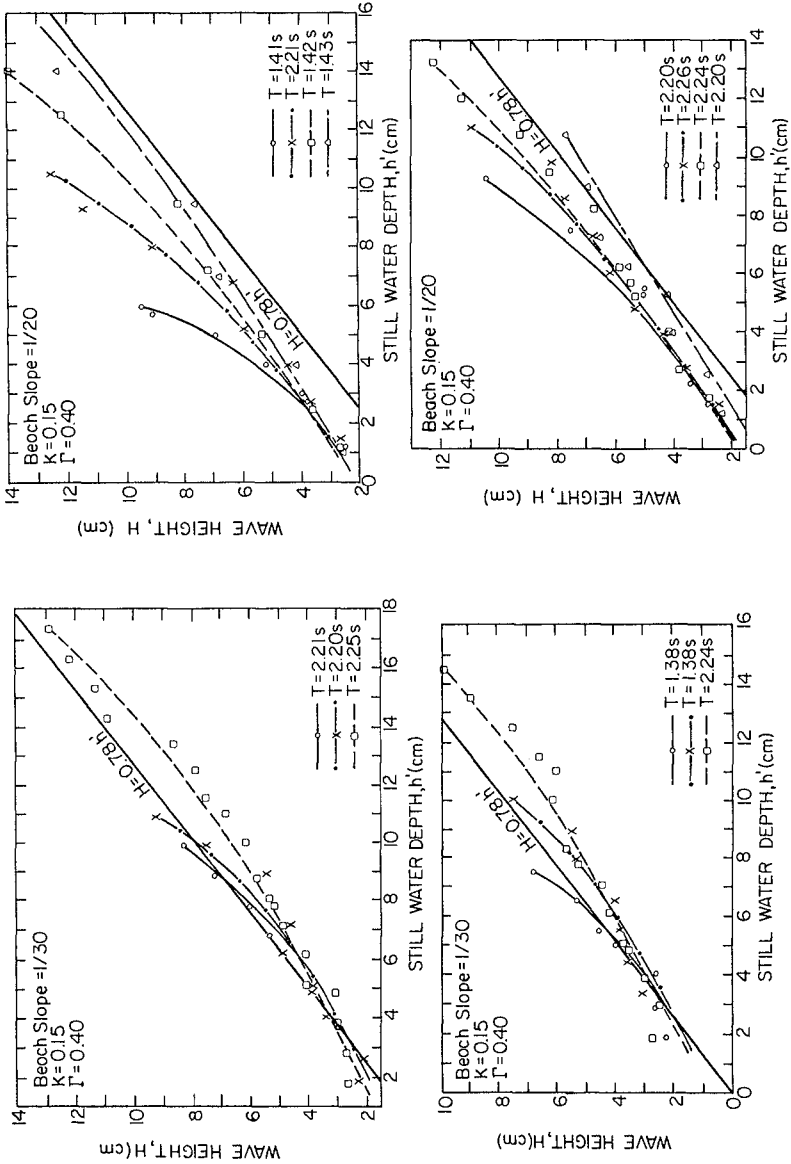

Figure 6 - Model comparison to laboratory data of Horikawa and Kuo (1966) for 1/30 and 1/20 beach slopes.

data in the laboratory and the field are also beginning to acknowledge this behavior, which is understandably less tractable when both breaking and non-breaking waves are present.

Although the range in wave period in the data is limited (1.2 - 2.26 s), it appears that wave period is not a primary factor in the decay of wave height after breaking is initiated. Wave period does affect the wave height to water depth ratio at incipient breaking (along with beach shape/slope and deepwater wave height) and therefore affects the shape of the decay profile through the initial condition.

Figure 7 demonstrates the negligible effect bottom friction losses have on the wave decay profile when compared to breaking. The upper curve is a test case of the model without bottom friction. The lower curve was generated with the same conditions, except greatly exaggerated bottom friction losses were included using the uncoupled scheme. The bottom drag coefficient,  $f$ , was set equal to a value (0.1) about two orders of magnitude greater than is realistic for the smooth rubber and concrete slopes used by Horikawa and Kuo in order for the two curves to be distinguishable from each other.

Set-down/up. - The Horikawa and Kuo data set does not include measurements of setdown/up in mean water level, and so data presented in Bowen, Inman, and Simmons (1968) was examined. Wave height and mean water level measurements were made on a relatively steep plane beach of 1/12 slope and the results of one test are presented in Figure 8, along with decay and set-down/up as predicted by the model. It was required to set  $K = 0.25$  and  $\Gamma = 0.35$  due to the unrealistically steep beach slope. With these values, the breaker decay now compares well, and the maximum set-up values are reasonable if the

Figure 7 - Comparison of model-predicted wave decay with and without bottom friction losses.

Figure 8 - Model-predicted wave decay and set-down/up as compared to laboratory data from Bowen, et. al. (1968).

swash zone is neglected; however, the predicted set-down/up curves do not follow the data. Apparently, linear wave theory does not provide a good representation of the onshore excess momentum flux for near breaking and breaking conditions, as might be expected. Higher order wave theories yield significantly less momentum flux for a given wave height than linear theory (see Stive and Wind (1982)), and this difference is the most likely explanation for the discrepancy between the measured and predicted set-down/up profiles.

#### RESULTS AND DISCUSSION - LARGE SCALE CONDITIONS

In order to demonstrate use of the model for waves breaking on beach profiles containing bars, and to lend some validity to the model for prototype situations, computations for large scale conditions were carried out. Prototype scale beach profiles measured by Saville (1957) in the Beach Erosion Board large wave tank were utilized and one is displayed in Figure 9. The profile is characterized by two offshore bar/trough systems, along with a monotonic section in the nearshore region. Test conditions, although not completely documented, were taken from the lab notes to be:

Wave period,  $T = 3.75$  s

Wave height at incipient breaking,  $H_b = 1.83$  to  $1.98$  m

Location of primary breaker line =  $75.6$  to  $78.0$  m from datum

Location of secondary breaker line =  $39.6$  m from datum

Mean sediment diameter,  $D = 0.2$  mm

In applying the model,  $\Gamma$  was set equal to  $0.4$ , but with  $K = 0.15$  conditions would not permit the broken wave to reform and break again as stated in the lab notes. It was necessary to increase  $K$  to a value of  $0.2$ , due to the extremely steep seaward faces of the bars - much steeper than those found in nature. Following the procedure described by Kamphuis (1975) and assuming the bottom was not rippled, the bottom friction factor,  $f$ , was found to be approximately  $0.005$ . Initial runs showed that bottom friction caused decay only on the order of millimeters, and friction was again left out of the model for this test. The distribution of model predicted set-down/up and wave height are shown in Figures 9a and b respectively. Note that the wave reaches the stable criterion in the deepest portion of the outermost trough as might be expected, shoals on the inner bar until the incipient condition is again attained (at a location close to that quoted in the lab notes), and then breaks continuously until the shoreline is reached.

The results of the application of the model under large scale conditions seem reasonably valid, at least in a qualitative sense. The example has demonstrated the ability of the model to describe wave breaking and reformation - a commonly observed process on natural beaches. The predicted wave decay and set-down/up profiles are continuous and well-behaved until the mean water depth becomes quite small ( $h < 0.25$  meters), where a swash zone model would be more appropriate.

#### SUMMARY AND CONCLUSIONS

Based on laboratory data collected by Horikawa and Kuo (1966) for regular wave conditions, the parameters found to most affect the decay in wave height due to breaking in the surf zone are the ratio of wave height to water depth at incipient breaking, and the beach slope.

**Figure 9** - Test of wave transformation model at prototype scale on large wave tank profile from Saville (1957).

Wave-induced set-down/up in mean water level plays a smaller but by no means trivial role in governing the shape of the wave decay profile, especially in the inner region of the surf zone. The similarity model,  $H \sim h'$ , commonly used by the coastal profession appears to be reasonable only on steep beaches ( $1/20$  to  $1/30$  at laboratory scale), and the "0.78" criterion predicts with marginal accuracy only for a  $1/30$  slope.

The model developed herein appears to qualitatively and quantitatively describe wave transformation in the surf zone due to shoaling, breaking, and reformation over a wide range of beach slopes ( $1/80$  to  $1/12$ ) and incipient conditions ( $0.63 \leq (H/h)_b \leq 1.67$ ). Closed form solutions neglecting set-up and bottom friction for the idealized profile shapes of a flat shelf, plane slope, and "equilibrium" beach

profile provide valuable insight because the apparently correct dependence on beach slope and incipient conditions appears explicitly. The best-fit values of the two assignable parameters in the model,  $\Gamma$  and  $K$ , were found to be relatively constant for beaches encompassing natural slope ranges (1/80 to 1/20). The greatest assets of the model are its simplicity and ease of application. Although it is most successful on profiles of monotonic shape, it is also employable when multiple bar/trough systems are present.

The model predicts maximum set-up values with reasonable accuracy for test cases presented by Bowen, et al. (1968); however, it does not describe the distribution of set-down/up across the surf zone satisfactorily.

From calculations based on the work by Kamphuis (1975), it can be concluded that bottom friction plays a negligible role in wave decay in the surf zone for most naturally occurring conditions when compared to the effects of breaking and shoaling. Bottom friction could be significant in nearshore regions that have very mild slopes or rough bottoms. This same conclusion was reached by Thornton and Guza (1983).

With the knowledge gained from this regular wave model, the irregular wave problem found in nature can now be investigated with greater insight and confidence.

#### ACKNOWLEDGEMENTS

The authors would like to thank Professor Kiyoshi Horikawa of the University of Tokyo for graciously providing the laboratory data used in this work. They would also like to express their appreciation to Mr. Philip Vitale for his assistance in generating the contour plots of error.

## CHAPTER SEVEN

### Modeling Turbulent Bore Propagation in the Surf Zone

David R. Basco<sup>1</sup> and Ib A. Svendsen<sup>2</sup>

#### Abstract

Initial efforts to numerically simulate surf zone waves by using a modified form of the nonlinear shallow water equations are described. Turbulence generated at the front of the moving bore-like wave spreads vertically downward to significantly alter the velocity profile and hence the horizontal momentum flux. This influence of turbulence is incorporated into the momentum balance equation through a momentum correction coefficient,  $\alpha$  which is prescribed based in part upon the theoretical  $\alpha(x)$  distribution beneath stationary hydraulic jumps. The numerical results show that with a suitably chosen  $\alpha(x)$  distribution, the equations not only dissipate energy as the waves propagate, but also that the wave shape stabilizes as a realistic profile rather than progressively steepening as when the nonlinear shallow water equations are employed. Further research is needed to theoretically determine the appropriate  $\alpha(x,t)$  distribution.

#### 1. Introduction

The transformation of breaking and broken waves in the surf zone is the dominant factor in the hydrodynamics of nearshore circulation, runup and sediment transport. Development of rational theories to describe breaking waves is just beginning.

After the moment the plunging jet strikes the onrushing trough, the wave undergoes a rapid transition in the region termed the outer surf zone (Fig. 1). Soon a bore-like shape appears which is maintained onto the beach or onto a bar profile as long as the depth decreases. This inner surf zone region involves the propagation of unsteady bores of non-constant form as they shoal, dissipate energy and create a mean water level setup on the beach.

This paper describes initial efforts to numerically model surf zone waves by using a modified form of the nonlinear shallow water equations (SWE) with additional momentum flux induced by the mean velocity profile through the bore. Numerical integration is by the finite-difference method and emphasis is on the many factors influencing the numerical results when compared with laboratory data.

Fig. 1 Wave characteristics in the surf zone. (from Svendsen, et al., 1978)

Fig. 2 Moving bores and jumps - relative coordinate system.

Fig. 3 Nonconstant form bores - fixed coordinate system.

An early approach to this problem idealized the moving bore front as a sharp discontinuity in the flow and used a "shock-fitting" procedure from classic hydraulic jump theory across the front (Meyer and Taylor, 1972, give a review). Others (Lax and Wendroff, 1960; Hibberd and Peregrine, 1979) rely on numerical viscosity induced by the coarse grid resolution at the front to produce a dissipative effect. Both methods do not permit details of the front wave shape nor internal dynamics to be resolved and consequently the wave propagation celerity is questionable.

As physically demonstrated by Peregrine and Svendsen (1978), turbulence is generated at the "toe" or front of the moving bore and spreads vertically to significantly influence the velocity profile in this high shear flow region. Madsen and Svendsen (1983) quantify this concept to develop an analytical model for steady flow, classic hydraulic jumps or moving bores on constant water depth. Turbulence closure is by a one-equation ( $k-\epsilon$ ) theory for transport of turbulent kinetic energy. The mixing-length is related to the turbulent wedge (Fig. 2) spreading from the surface at the toe and adjusting the similarity velocity profile in the downstream direction. Four dependent variables result that require solution of the depth-integrated continuity, total momentum, energy, and potential core-region momentum (Bernoulli) equations.

These ideas and methods were generalized and extended to unsteady, non-permanent form, propagating bores by Svendsen and Madsen (1984, in review). In a fixed frame of reference, a hyperbolic system of four simultaneous partial differential equations result. Additional turbulence closure relations are also required. Specification of the boundary conditions becomes difficult for the numerical solution of the four equation system. Without turbulence, the four equations reduce to the SWE.

In the present paper we only consider the depth-integrated equations of continuity and total momentum and include the influence of turbulence on the momentum flux through a momentum correction coefficient,  $\alpha$  which is prescribed. The purpose is to show that with a suitably chosen  $\alpha(x)$  - distribution, the equations will not only dissipate energy as the waves propagate, but the wave shape will stabilize as a realistic profile instead of progressively steepening as when the ordinary SWE are employed.

The basic equations of the four equation system are summarized in Section 2, where the theory for the two equation method is also presented. Section 3 summarizes the theoretical  $\alpha(x)$  - distribution in steady jumps and what has been postulated for a non-constant form, periodic bore wave including the model used in this paper. The numerical model is discussed in Section 4. Section 5 gives the results of some laboratory measurements of inner surface zone waves used as input boundary conditions and to check the numerical experiments as discussed in Section 6.

## 2. Theory - Basic Equations

For non-permanent form propagating bores in a fixed reference frame, the four equation system employed by Svendsen and Madsen (1984) is (see Fig. 3) in conservation form:

conservation of mass,

$$\eta_t + Q_x = 0 \quad (2.1)$$

conservation of total momentum,

$$Q_t + \left( \int_{-h}^{\eta} u^2 dz + \frac{1}{2} g d^2 \right)_x = g d h_x \quad (2.2)$$

conservation of mean energy,

$$E_t + (E_f)_x = D \quad (2.3)$$

and the

momentum conservation in core region,

$$(u_o)_t + u_o (u_o)_x + g \eta_x = 0 \quad (2.4)$$

where:

volumetric flowrate per unit width,

$$Q(x,t) = \int_{-h}^{\eta} u dz \quad (2.5)$$

total water depth,

$$d(x,t) = h(x) + \eta(x,t) \quad (2.6)$$

energy density per unit surface area,

$$E(x,t) = \int_{-h}^{\eta} \frac{1}{2} u^2 dz + \frac{1}{2} g \eta^2 \quad (2.7)$$

flux of energy through a vertical slice,

$$E_f(x,t) = \int_{-h}^{\eta} \frac{1}{2} u^3 dz + g \eta Q \quad (2.8)$$

loss of mean energy to turbulence,

$$D(x,t) = \int_{-h}^{\eta} \overline{u'w'} \frac{\partial u}{\partial z} dz \quad (2.9)$$

with  $u_o(x,t)$  the velocity in the lower constant-velocity, core region beneath the turbulent wedge with  $\overline{u'w'}$  the Reynolds shear stresses resulting from the turbulence and correlated by ensemble averaging. The subscripts  $x$  or  $t$  means partial differentiation with respect to  $x$  or  $t$ .

The primary assumption is that the horizontal length scale of the motion is much larger than the vertical scale so that the vertical

momentum balance is omitted and consequently a hydrostatic pressure distribution is taken. Normal turbulent stresses in (2.2) and bottom generated turbulence and shear stress are also neglected.

To solve the four equation system (2.1-2.4) requires relating the turbulent shear stress,  $\overline{u'w'}$  to the mean flow properties. The turbulence closure methods employed permit local nonequilibrium between turbulence advection and dissipation, but further details are beyond the scope of this paper.

This system (2.1-2.4) with closure represents one possible extension of the nonlinear shallow water equations (SWE) that includes the effects of turbulence.

Another approach as followed in this paper is to only invoke the following two, depth-integrated conservation laws:

conservation of mass,

$$\eta_t + Q_x = 0 \quad (2.10)$$

and

conservation of total momentum,

$$Q_t + \left( I + \frac{1}{2} g d^2 \right)_x = g d h_x \quad (2.11)$$

where:

momentum flux density,

$$I(x,t) \equiv \int_{-h}^{\eta} u^2 dz \quad (2.12)$$

and the effects of turbulence are now singularly brought in through  $I(x,t)$  which itself only depends on the mean velocity profile  $u(x,z,t)$ . All the assumptions in the four equation system are retained. The problem reduces to finding  $I(x,t)$ .

One possibility is to introduce a momentum flux correction coefficient,  $\alpha(x,t)$  so that

$$I(x,t) \equiv \frac{\alpha Q^2}{d} \quad (2.13)$$

where

$$\alpha(x,t) \equiv \frac{d}{Q^2} \int_{-h}^{\eta} u^2 dz \quad (2.14)$$

Now the problem is to find  $\alpha(x,t)$  for non-permanent form, surf zone waves. When  $\alpha(x,t) = 1.0$ , the SWE are recovered and the front face continuously steepens with no turbulence effects since the velocity profile remains uniform. In real propagating bores, water spills down the front face generating turbulence at the toe and creating a strongly non-uniform velocity profile, so that behind the toe  $\alpha(x,t) > 1.0$ .

### 3. Velocity and $\alpha$ -Distribution Models

It is instructive to review some typical  $u(z)$  profiles and resulting  $\alpha$  values as shown in Fig. 4. A log profile in uniform, open channel flow (Fig. 4b) gives  $\alpha = 1.05$  (Chow, 1955). The roller of a hydraulic jump causes a flow reversal (Fig. 2 and Fig. 4c) and significantly enhances the total momentum flux. The extreme case is a complete flow reversal (Fig. 4d) which essentially doubles the momentum flux created by each half.

The velocity distribution  $u(z)$  employed for this paper is the similarity profile used by Madsen and Svendsen (1983) for steady jumps:

$$f(\sigma) = \frac{u - u_0}{u_s - u_0} \quad 0 \leq \sigma \leq 1 \quad (3.1)$$

where

$$\sigma = \frac{z-d}{b} \quad b = d-a \quad (3.2)$$

with  $u_s(x,t)$  at the free surface, and  $b(x,t)$  the width of the turbulent wedge. The choice of  $f(\sigma)$  depended somewhat on the turbulent closure and a third order polynomial of the form

$$f(\sigma) = -A\sigma^3 + (1+A)\sigma^2 \quad (3.3)$$

with  $A = 1.4$  was found to give a good fit to measured mean velocity profiles for a wide range of inlet Froude numbers,  $F_1^2 = u_1^2/gd_1$ , with  $u_1, d_1$  the entrance jump conditions.

The  $\alpha$ -distribution that results from the Madsen and Svendsen (1983) theory is found by putting (3.1-3.3) into (2.14) to give

$$\alpha_r(x) = \xi \left[ 1 + \frac{1}{F_1^2} (1 - \xi^2) \right] \quad \xi = \frac{d(x)}{d_1} \quad (3.4)$$

with  $d(x)$  part of the solution for the jump profile. Here  $\alpha_r(x)$  is the distribution for a steady hydraulic jump or a moving bore on a horizontal bottom in a relative coordinate system moving with the bore celerity (Fig. 2). Some typical distributions of  $\alpha_r(x)$  for  $F_1^2 = 3.0, 3.95$  and  $8.0$  are shown by the solid line in Fig. 6.

For a fixed coordinate system (Fig. 3) and the  $\alpha(x)$  required by (2.11) and (2.13) it can be shown that

$$\alpha(x) = \left(\frac{h}{\eta}\right)^2 (\alpha_r - 1) + 1 \quad (3.5)$$

For example, when  $F_1^2 = 3$  (a weak jump) and at  $\eta/h = 0.3$ , then  $\alpha_r = 1.2$  and  $\alpha = 3.2$ . The turbulence significantly alters the velocity profile and enhances the momentum flux.

For constant form steady jumps and propagating bores, the water depth gradually increases so that  $\alpha_r$  gradually rises above 1.0 to a peak value  $\alpha_p$  within the jump at some distance  $x_p$  from the toe then gradually decreases back to 1.0 downstream. This is shown

Fig. 4 Some velocity profiles and resulting momentum coefficients.

Fig. 5 Schematic variation of momentum coefficient  $\alpha$  with downstream water surface elevation  $\eta$ . (after Madsen, 1981)

Fig. 6 Typical momentum coefficient distributions. The solid line is for the hydraulic jump. The dashed line (Model No. 1) is for a propagating wave-like bore of nonuniform shape. Model No. 2 is a variation not tested.

schematically in Fig. 5 (from Madsen, 1981) and for typical values in Fig. 6. The theory was exercised for a large range of  $F_1^2$  values and least squares curve fitting employed to find that for constant form jumps

$$\alpha_p(F_1^2) = 0.098F_1^2 + 0.902$$

and

$$X_p(F_1^2) = \begin{cases} 0.3F_1^2 + 0.05 & F_1^2 \leq 4 \\ 0.0833F_1^2 + 0.92 & F_1^2 > 4 \end{cases} \quad (3.6)$$

$$(3.7)$$

But what is the  $\alpha_r(x)$  distribution beneath non-permanent form, surf zone waves? Experimental evidence (Svendsen, et al., 1978) suggests that surf zone waves have similar-shaped fronts but changing backs as the broken wave shoals and dissipates energy up a slope. Fig. 5 schematically illustrates that non-constant form waves have an  $\alpha_r(x)$  distribution that must return to 1.0 as  $\eta(x)$  also decreases. This suggests an  $\alpha_r$ -distribution similar to the steady, constant form jumps up to  $\alpha_p$  on the front side (from trough to near the crest) but then rapidly decreasing again on the back side.

The initial, empirical  $\alpha_r$ -distribution chosen for this study was a parabolic shape as shown by the dashed line in Fig. 6 and labeled Model No. 1. The vertex ( $\alpha_p, x_p$ ) was found from (3.6) and (3.7) as key variables in the parabolic distribution with one limb passing through the toe ( $x=0, \alpha=1.0$ ). A procedure to theoretically calculate the  $I(x,t)$  distribution can be developed from the four equation system of Svendsen and Madsen (1984). Model No. 2 (Fig. 6, dotted) was never tested.

#### 4. Numerical Model

An explicit, finite-difference code based on the Lax-Wendroff, 2-Step algorithm (LW2S) has been developed for numerical solution of (2.10) and (2.11) using (2.13) and the parabolic model for the  $\alpha(x)$  distribution. The code uses the method of characteristics and interpolation subroutines to provide the needed additional boundary data. For example, when  $\eta(t)$  is specified on the incoming boundary, the code calculates  $Q(t)$  values at upper level time steps on the boundary as required by the LW2S algorithm. At the opposite, outgoing boundary a radiation boundary condition together with excessive numerical dissipation is introduced over a short reach to prevent wave energy reflections.

A large number of initial and boundary conditions with  $\alpha(x,t) = 1.0$  giving known analytical solutions for simple cases were employed during development and testing to insure the validity of the code and given confidence in the results.

The toe location was a key variable in the model since the parabolic  $\alpha$ -distribution began from this point. For a steady jump or constant form bore the toe is well defined since fixed in space. For the non-permanent form bore on a sloping bed, Svendsen and Madsen (1984) used as initial conditions a permanent bore starting seaward of the

slope with well defined toe. They then propagated the toe point itself at a celerity calculated by

$$C = \frac{Q_x}{\eta_x} \approx \frac{Q_j - Q_{j-1}}{\eta_j - \eta_{j-1}} \quad (4.1)$$

as a first order, upwind difference with  $j$  as the first grid point behind the toe.

For surf zone waves the toe position is ill defined since the approaching trough is a continuously varying curve. The toe position for these initial tests was heuristically taken midway between the trough (maximum negative  $\eta$ ) and the maximum front face slope. This was from observations in the laboratory that showed the toe point slightly up the curved trough. The toe position was then reestablished by this procedure each time step rather than propagating the initial toe position. This method proved to be expensive on the computer and caused problems as discussed in Section 7.

To numerically calculate  $F_1^2$  and hence  $\alpha_p$  and  $x_p$  to derive the  $\alpha$ -distribution, (4.1) was employed to calculate  $C$ , but with  $j$  at the point of maximum slope. The relative volumetric flowrate,  $Q_m$  was found from

$$Q_m = cd - Q \quad (4.2)$$

and finally

$$F_1^2 = \frac{Q_m^2}{gd^3} \quad (4.3)$$

with  $d$  and  $Q$  taken at the trough position to give an overall, representative value of  $F_1^2$ .

## 5. ISVA Experiments

Results of laboratory experiments at the Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Denmark as performed by Hansen (1980,1982) were adapted for numerical testing. The experiments were made in a 60 cm wide, 32 m long and 36 cm deep (SWL) wave basin with a 1:34 plane sloping beach. Twelve wave gages spaced throughout the inner surf zone monitored the change in wave height and shape. Of the twenty test runs available, one test with wave period,  $T = 2.22$  sec and initial, "deepwater" wave height,  $H_0 = 10$  cm was selected for numerical simulation. Within the surf zone, surface wave measurements averaged over 20 waves at the first gage (CHANNEL 00,  $H_i = 5.48$  cm) became the boundary data as input into the numerical model.

The experimentally measured results of this particular test (Run No. 201) are summarized in Fig. 7 for relative variation of wave height,  $H/H_i$  versus distance up the slope and in Fig. 8 for the wave shape at four selected locations. The last gage (CHANNEL 11) was located 2.8 m from the first gage (CHANNEL 00). Fig. 8 shows rapidly changing back side slopes of these waves whereas the front slopes are relatively unchanged. The wave is clearly of non-constant form.

Fig. 7 Relative wave height versus position up the beach for run no. 201. (courtesy J.B. Hansen, 1982)

Fig. 8 Variation of wave shape at four locations for run no. 201. (courtesy J.B. Hansen, 1982)

Further details regarding the facilities, instrumentation and data analysis procedures employed can be found in Hansen and Svendsen (1979).

## 6. Numerical Experiments

The numerical experiments investigated the initial shape and wave height changes and celerity of the broken wave (labelled CHAN 00 in Fig. 8) as it shoaled and dissipated energy further up the beach. The detailed wave profile used as input boundary conditions is shown in Fig. 9. An arbitrary, smaller wave was placed in the "numerical" wave basin as initial conditions to avoid a completely "cold start" condition. Mean water depth (MWS) from the laboratory experiments which included wave induced setup was used as datum.

For an incoming wave length of about 2.5 m, the use of  $\Delta x = 0.025$  m gave roughly 50 grid intervals per wave for the staggered computational mesh of the LW2S scheme. This resulted in very low numerical dissipation. The  $\Delta t = 0.014$  sec was determined by using the maximum expected wave celerity together with the Courant number,  $Cr < 1.0$  restriction inherent in all explicit numerical schemes. As a result, for a wave period,  $T = 2.22$  sec,  $N = 80$  time steps correspond to about one-half a wave cycle. The shoreline ( $d = 0$ ) is about 3.3 m from the input boundary or at a grid index  $j = 133$ .

Fig. 10 is a baseline test result. It shows a wave propagating from left to right up the beach for the case when  $\alpha(x,t) = 1.0$  for all time and space and represents a solution to the SWE. The wave shoals and a secondary wave forms behind as the front face steepens. No mechanism exists in the numerical model to dissipate energy. The reason for the formation of the secondary wave is unclear but may be due to the original input wave shape (Fig. 9); the nonlinear advection term in the SWE creating harmonic components or, there being no real mechanism in the model to dissipate higher wave number energy. Running longer caused the scheme to go unstable. Fig. 11 demonstrates the use of a numerical smoothing filter on these results where

$$\eta_j^n = \gamma \eta_{j+1}^n + (1-2\gamma)\eta_j^n + \gamma \eta_{j-1}^n \quad (6.1)$$

with  $\gamma = 0.125$ , and using the filter every other time step ( $NR=2$ ) or every ten time steps ( $NR=10$ ). The use of this filter smoothed out the smaller oscillations and permitted the scheme to run beyond a full wave cycle. The crest elevation at  $N=80$  is 0.063 m and 0.046 after filtering. This filter behaves as an energy dissipative mechanism to remove higher wave energy (like turbulence) and changes the front face slope but not the phase speed of the wave.

Figures 12 and 13 show analogous plots but now with Model No. 1 used for the parabolic  $\alpha$ -distribution beneath the wave crest so that  $\alpha(x,t)$  varies in space and time. The effect of broken wave generated turbulence alters the velocity profile to enhance the momentum flux beneath the wave crest and behind the toe of the bore. Fig. 12 includes the numerical filter ( $NR=10$ ) to give a smoothed, clearer picture of the wave shape changes. The wave is seen to initially shoal

Fig. 9 Initial conditions and input wave boundary conditions for numerical simulation.

Fig. 10 Baseline numerical test results with no turbulence ( $\alpha=1.0$ ) for the five time steps.  $N=80$  equivalent to one-half wave period. A 2.22 sec wave with initial height of 0.055 m moves up a 1:34 slope.

Fig. 11 Same as Fig. 10 at  $N=80$  except includes use of numerical filter every other ( $NR=2$ ) and every ten ( $NR=10$ ) time steps.

Fig. 12 Numerical test results with parabolic  $\alpha$ -distribution (Model No. 1) for 10 different time steps.

Fig. 13 Same as Fig. 12 at  $N=80$  including raw results and the effect of numerical filters.

Fig. 14 The effect of different widths of the parabolic,  $\alpha$ -distribution model on the wave shape at  $N=80$ . Double width ( $XWF=2$ ) and trebled width ( $XWF=3$ ) shapes are shown below. Also shown is the laboratory measured wave shape as thick solid line.

in crest elevation (while dissipation takes place) and the trough elevation also rises. This is felt to be due to the initial conditions in the numerical basin. Beyond  $N=70$ , the numerical wave has established some type of equilibrium within the basin and dissipation dominates. Fig. 13 shows the wave shape after  $N=80$  time steps (one-half period) and demonstrates that high wave number oscillations (solid line) are still present when no numerical filtering is employed. Clearly, Fig. 13 reveals that the  $\alpha$ -distribution model must be responsible for the wave crest elevation reduction for now  $\eta_{\max} = 0.045$  m as compared to  $\eta_{\max} = 0.063$  m for the SWE ( $\alpha=1.0$ ) and the unfiltered results. It is also evident in Fig. 13 that additional numerical smoothing actually increases the front face steepness while smoothing out the higher wave number oscillations. Thus although both the  $\alpha$ -distribution mechanism and the numerical smoothing effectively result in energy dissipation, the general wave shape changes are primarily controlled by the  $\alpha(x,t)$  model.

This is demonstrated further in Fig. 14 for three different widths of the  $\alpha$ -distribution model. The results again show the wave shape at  $N=80$  with numerical filtering included. The width of the parabolic  $\alpha$ -distribution is arbitrarily doubled ( $XWF=2$ ) and trebled ( $XWF=3$ ) and this results in a significant change in both the crest elevation and slope of the front face. The  $\alpha$ -distributions are also shown below the wave with the toe located as discussed in Section 4. Widening the  $\alpha$ -distribution is seen to flatten the front shape. Entirely different results would be expected if the initial toe position were itself propagated as part of the solution procedure.

The thick solid line in Fig. 14 is from the measured laboratory results at a comparable position in space. The wave profile in time was converted to a space profile using the celerity of a local measured bore wave as reference. This wave was taken from the CHANNEL 05 position (see Fig. 7) so that the comparison is not exact. The measured shape in Fig. 14 is only included to give some rough idea of how the numerically calculated wave compares with that reported from the laboratory measurements.

## 7. Summary

This paper summarizes initial efforts to model surf zone wave shoaling and energy dissipation through the use of a semi-empirical, momentum correction coefficient distribution,  $\alpha(x,t)$  in the nonlinear SWE. The qualitative trends are correct in that energy is lost and the wave shape stabilizes rather than steepening. The numerical model can be improved by independently propagating the initial toe position as part of the solution procedure and by the development of a more rational theory for the  $\alpha(x)$ -distribution beneath the wave. In addition, many more waves need to be propagated through the numerical basin to reach an equilibrium state as found in the laboratory basin in order to make a proper comparison. Some additional energy loss occurs in boundary layer shear that should also be accounted for in the numerical model.

Further research is needed to theoretically determine the appropriate  $\alpha(x,t)$ -distribution.

## CHAPTER EIGHT

### EXTREMAL STATISTICS OF STORM SURGES BY TYPHOON

Yoshito TSUCHIYA, M. ASCE<sup>\*</sup> and Yoshiaki KAWATA, M. ASCE<sup>\*\*</sup>

#### ABSTRACT

The objective of this paper is to propose a new approach based on the direction of the typhoon track for determining the probability of occurrence of extremal tides due to storm surges, as well as their return period. The study includes the effects of periods in tidal data and of tidal variation stemming from extensive reclamation along coasts on the fitness of the extremal data to probability density functions. The method is justified by application to an analysis of the probability of occurrence of storm surges in Osaka bay.

#### INTRODUCTION

Storm surges generated by typhoons have caused extensive damage at estuaries facing the Pacific Ocean in Japan. Historically, we know that there have been many storm surge disasters. There are records of 188 such disasters in certain zones between 701 and 1865, and 100 more have been recorded since 1865. It is, thus, clear that there is a high probability of occurrence of large storm surges in Japan during the typhoon season.

Unfortunately, methods available for the estimation of the return period of an abnormal tide have not as yet been completely established. This is due to not only the limited availability of long-term tidal data (usually more than 100 years are needed for reliable design predictions), but also the inaccuracy of absolute ground elevation measurements coupled with land subsidence in coastal industrial regions. Moreover, the hydrodynamic behavior of storm surges in the estuaries may have changed due to large-scale reclamation along the coast during the last two decades. To overcome these limitations and inaccuracies in the data, much effort has been expended. Generally, the extreme tidal data do not conform to any probability density function. Therefore, the main objective of these investigations is to discover why systematic divergence from the theoretical probability distribution curves appears at extreme tidal values. Führböter(1978) tried to

---

\* Professor, Disaster Prevention Research Institute, Kyoto University, Kyoto, Japan

\*\* Associate Professor, Disaster Prevention Research Institute, Kyoto University, Kyoto, Japan

explain this discrepancy as the nature of time-dependent tidal data and proposed a hypothetical model for practical use. Graff et al.(1978), Pugh et al.(1978), DeYong et al.(1975) and Tayfun (1979) discussed the joint probability of astronomical tides and storm surges after excluding their trend effects, even those for annual maximum anomaly which is a highly random occurrence relative to the astronomical tide. However, no one has successfully shown significant agreement between the data and any probability density function.

#### REARRANGEMENT OF DATA AND TRADITIONAL ANALYSIS

##### [a] Outline of the data

In Osaka and Kobe, tidal observations have been made since 1900 and 1927 respectively. During the Showa Era (since 1925), there have been three large storm surge disasters, in 1934, 1950 and 1961. A map of the region is shown in Fig. 1. Firstly, the characteristics of extreme tidal data in Osaka and Kobe such as the highest tidal level, the maximum anomaly and the lowest tidal level (not very widely used) need to be discussed in detail.

1] Highest tidal level: Fig. 2 shows the annual variation in the highest tidal levels in kobe and Osaka, including those in Tannowa and Kushimoto. The data for Osaka covers the longest period, but the data before 1946 is questionable for two reasons. One is the correction of ground level due to land subsidence. Local benchmarks, which in most cases corresponded to the original Osaka Pile, cannot be completely corrected from records of land subsidence. For Kobe, however, the correction of ground levels was made by the Kobe Marine Observatory. The other reason is the malfunction of an old tidal gage. A few slip between the pulley and the measuring rope connected to the float are needed to be justified, but attempts have as yet been unsuccessful.

Fig. 1 Location map of study area

Fig. 2 reveals that the highest tidal level has exceeded 2 m T.P. [Tokyo Pile] four times since 1925. The highest tidal levels in Osaka and Kobe were recorded in 1934 (Muroto typhoon) and the second highest, in 1961 (Daini-Muroto typhoon). Third and fourth highest were recorded in 1950 (Jane typhoon) and for Typhoon 6420. There seems to be a periodic variation of three to five years and to be characterized by the group occurrence of storm surges between the end of World War II and 1970. This period will be studied by time series analysis in a later section. The data from Tannowa show the locality of storm surge generation and the influence of the typhoon path as in 1964 the rise of the sea level due to the typhoon was not marked in comparison with those in Osaka and Kobe. In Kushimoto, meteorological tides due to storm surges on the open coast affected the records. Therefore, it is valuable to have a boundary condition when the numerical simulation of a storm surge is attempted.

2] Maximum anomaly: Data for the annual maximum anomaly generated by typhoons and cyclones (low pressure) have been recorded since 1928 in Osaka and since 1931 in Kobe. Both have a few gaps, but from the historical reports of storm surges during these gaps, it has been determined that no large storm surges could have hit the area then. An annual maximum anomaly of over 2m was recorded four times in Osaka due to the large typhoons mentioned, but in Kobe there was only one recorded incidence, in 1934. This is proof that the probability of a storm surge disaster occurring in Osaka is much higher than in Kobe.

3] Lowest tidal level: The period covered by the time series data for the lowest tidal level is the same as for the highest tidal level. There are no extreme peak values, as for the highest tidal level and

Fig. 2 Annual variation in the highest tidal levels in Kobe and Osaka

maximum anomaly. The occurrence of extremely low tides depends on the northwesterly monsoons in December or January. The low tidal levels due to the resurgence of a storm surge are not significant in comparison with those in monsoon season.

[b] Extremal statistics by traditional methods

To obtain the return period of occurrence of a storm surge, traditional methods of extremal statistics are usually applied to data such as the highest tidal level and the maximum anomaly. Originally, these methods were applied for the analysis of the statistical characteristics of other hydrological events, such as precipitation and river discharge. It has always been held that the fitness of data to any probability density function depends chiefly on the sampling size. For the application of extremal statistics, the period of the tidal records must usually be much shorter than the return periods. For practical use, however, the design tidal level or the maximum anomaly has to be determined in order to take countermeasures against storm surges. In any analysis, some risks are inevitable, so that slight overestimates are preferable for engineering application.

A statistical analysis of storm surges in Osaka has already been carried out by Nachi (1972). Now, about ten years of new data can be added to the old ones and improvement in the fitness due to this increment in the amount of data is studied in this section. A Gumbel distribution and a log-normal distribution have already been found to give a relatively reasonable description of the tendencies of the data. They are used here for the analysis of the new data set with a  $\chi$ -square test of fitness.

1] Highest tidal level: Figs.3(a) and(b) show the occurrence of highest tidal level in Osaka and Kobe on the probability papers of a Gumbel distribution and a log-normal distribution with Thomas plot. No distribution could follow the tendency of the data exactly because, especially for very large tidal levels, the discrepancy is remarkable. The statistical characteristics of the data from Osaka are very similar to those from Kobe. Comparison of these results with Nachi's fails to show any improvement in the degree of fitness. It is, therefore, concluded that the degree of fitness of the data to a probability density function does not necessarily depend only on the period of the data recorded.

For further improvement, Führböter proposed a new method of treatment for tidal data which had been recorded for over 120 years in West Germany. In the method, he has not described any physical background for selecting the annual highest tidal levels every two or three years. It was, however, shown that the estimated tidal levels corresponding to the 100 year return period approach a constant value with the increment in sampling years. Fig. 4 shows the results in Kobe by applying this method. The same characteristics are recognizable in Osaka. The method includes the smoothing of annual variations in the highest tidal level, so that the clearly small sample size leads to a rough prediction of the return period of storm surges.

2] Lowest tidal level: Fig. 5 shows the probability distribution for

the occurrence of lowest tidal levels in Osaka and Kobe. The data fit well into a Gumbel distribution. This agreement has never been found in any other extremal statistics for tidal data except for the lowest tidal level. Annually, the lowest tidal levels occur in January or in December. During these months, the northwesterly monsoon blows continuously for one or two days after reaching a stable distribution of atmospheric pressure (in this situation, an anticyclone stagnates in western Siberia and a developing cyclone slowly moves eastward in the central part of the Japan Sea ) causing extraordinarily low tide. Under these circumstances, the lowest tidal level can be treated as statistically independent variables. This will be discussed later with the time series for the lowest tidal level. The effect of sampling interval on the return period is not evident as has already been shown in Fig. 4.

(a) Log-normal distribution

(b) Gumbel distribution

Fig. 3 Probability of occurrence of the highest tidal level by traditional methods

3) Maximum anomaly: Fig. 6 shows the probability distribution for the occurrence of the maximum anomaly. The discrepancies between the data and theoretical curves are marked, as for as the highest tidal level. The scattering of the data in Osaka resembles that in Kobe, so that on the basis of the physical background of storm surges, the occurrence of the maximum anomaly may be analyzed.

[c] Effect of tidal observation period on degree of fitness

The tides have been recorded for more than ten years since the last study done by Nachi(1972). However, in spite of this increase in the available sample size, the degree of fitness of the data to the probability distribution did not improve as was hoped. Thus, the sample size is not the dominant factor determining the degree of fitness. Even if the maximum anomaly can be regarded as a statistically independent variable, the "accidental" data do not agree with the theoretical curves. From Figs. 3 and 6, it is evident that the fitness of the maximum anomaly to a Gumbel distribution is worse than in the case of the highest tidal level. The influence of the period of the data is, of

Fig. 4 Changes in estimated tidal values in Kobe with sampling years corresponding to 100 year return period analyzed by Führbötter's method

Fig. 5 Gumbel distribution for the lowest tidal level

course, part of this difference in fitness.

One of the probable explanations for this discrepancy is the effect of marked reclamation along the coast in Osaka Bay. Reclamation was rapid in the 1960's and since Osaka is located at the northeast end of the bay, as shown in Fig. 1, the effect is easily amplified. If the characteristics of the data have statistically changed due to this reclamation, it is necessary to divide them into two groups, for example, into the annual extremal values before and after reclamation. At the same time, the statistical independency of the data has to be justified. For example, if periodicity is to be found in the number of typhoons and cyclones which hit or move alongshore, the tide will consequently include their influences to some degree and careful editing should show the periodicity.

Attention must also be paid to changes in tidal characteristics due to differences in the wind fields along the tracks of typhoons. When a typhoon passes the west side of the bay, it results in a large storm surge by strong winds blowing over the sea counterclockwise. Therefore, the effect of wind drift on sea water accumulating in the semicircle is more remarkable than that in a western one. In this process, the influences of solid boundaries, such as the geographic shape of reclaimed areas and the general direction of coastlines, are also significant.

INFLUENCE OF RECLAMATION ON TIDE AND ITS TREND

[a] Influence of reclamation

Fig. 7 shows the cumulative curve for reclamation on Osaka Bay.

Fig. 6 Gumbel distribution for maximum anomaly

Fig. 7 Cumulative curve of reclamation area around Osaka Bay

The survey covers the coast between Akashi and Tannowa, a distance of about 90km. The acceleration in reclamation in the 1960's was a result of the rapid economic growth in Japan. According to an environmental white paper, natural beach, such as Nishikinohama and Suma beaches, occupies less than two percent of the length of the coastline. In general, the coast can be divided into rectangular areas of reclamation having sides less than several hundred meters in length continuously located along the coast. In small strips, behavior of storm surges may be amplified. In Kobe, man-made Port Island and Rokko Island are relatively large in comparison with the reclaimed areas in Osaka, so that the former unevenness in shape is not remarkable enough to make small rectangular strips of reclaimed areas.

It is very difficult to estimate quantitatively the effects of the reclamation on the tide because changes in astronomical tides are a slowly varying phenomenon. However, every tidal observations are carried out close to coast, and so the geographical boundary conditions must surely affect the tidal measurements. For this reason, changes in tidal constituents are first discussed on the basis of a comparison of predicted and observed tides, and secondly, the annual variation in high water level in the spring tide during typhoon season (July to September) is studied.

Fig. 8 shows the annual changes in the amplitude and phase angle of the tidal constituent M2 in tidal predictions. In Kobe, the changes are trivial, but in Osaka, an annual increase in the amplitude and a decrease in the phase angle can be seen. Other tidal constituents such as S2, K1 and O1 have also been found to have similar clear trends in Osaka. In order to confirm this phenomenon, further investigation is required, but at present, it can be surmised that the cumulative influences due to wide reclamation near Osaka have changed the behavior of the tide.

Fig. 9 shows the annual variation in the high water level of the spring tide during the typhoon season since 1950. A period of three to four years is evident in Osaka and Kobe with no phase lag between the two places. This phenomenon has also been detected at other tidal observation points around Osaka Bay, but the variations in amplitude are smaller than those in Osaka and Kobe. Probable factors which generate these variations, that is, the influence of typhoons and the meandering of the Kuroshio along the southwest coast of Japan have been investigated with field data; however, it appears that they do not contribute to this periodic variation in the high water level.

Fig. 8 Annual changes in amplitude and phase angle of tidal constituent  $M_2$

Fig. 9 Annual changes in high water level of spring tide in typhoon season

Next, hourly changes of the tide are studied to see if the reclamation could be causing the unusually high water levels. Fig. 10 shows the hourly changes in the tide in Osaka for four days around the spring tide of August 14 and 27, 1965. The discrepancies between the predicted and observed tides are clearly greater just before and after the spring tide. Such systematic discrepancies are usually observed during the rising stage of a tide. Moreover, flattening of the high tidal level peaks in the spring tide has been pointed out by the Kobe Marine Observatory since 1970, which almost coincides with the construction of Port Island in Kobe. Therefore, the tide may be under the influence of the reclamation

The above investigation gives the quantitative effects of the reclamation on the tide and shows that the tidal level tends to be amplified by a rapid increment in reclaimed areas.

[b] Time series of tide and its trend

Trends may be included in the time series for extremal values, such as the highest tidal level and the maximum anomaly. Such trends are due to long-term natural changes or to artificial impacts, such as rise of sea level or reclamation along the coast, land subsidence, etc.

The trend index is given with the rank correlation by

$$IT = \sqrt{18} \left( \sum_{i=1}^{N-1} n_i - N(N-1)/2 \right) / \sqrt{N(N-1)(2N+5)} \quad (1)$$

in which  $N$  is the number of samples,  $n_i$  the number of events larger than  $x_i$  after the occurrence of  $x_i$ . If  $IT > 1$ , the time series includes an increasing trend. On the contrary, if  $IT < -1$ , there is a decreasing trend. In the case of the highest tidal level,  $IT$  is 2.08 in Osaka and -0.78 in Kobe. The same tendency can be detected in the lowest tidal level, but there is no trend in the maximum anomaly for either place.

Fig. 10 Hourly changes in tide in Osaka

When the trend is detected, it is usual to eliminate it from the data by applying a polynomial expression. However, it is also evident that in the future, the situations affecting the tidal level will inevitably change. Reclamation, as mentioned affects the characteristics of the tide, but the trend that results will change again with more reclamation. Moreover, the rising trend of the highest tidal level in Osaka is due to a group occurrence of storm surges after World War II. In this paper, therefore, the trend due to natural factors are also included in the analysis.

Fig. 11 shows the auto- and serial-correlation coefficients of time series of the extreme tidal data in Kobe. From this figure, it is recognized that the maximum anomaly changes in periods of four, twelve and fourteen years. This situation is almost the same in Osaka. The reason this clear periodicity exists is mainly due to the characteristics of typhoons as the external force causing storm surges. Fig. 12 shows the auto-correlation coefficients of the number of typhoons generated and the number of typhoons which struck. The observation period of the data is the same as in Fig. 11. A periodicity of four, twelve and sixteen years can be found in the number of typhoons which struck. This result has also been confirmed by analysis with a periodogram. It is clear that the occurrence of the maximum anomaly strongly depends on characteristics of typhoons approaching Japan.

Another problem is revealed by this analysis. When the maximum anomaly is not made up of statistically independent variables, as shown in Fig. 12, it is, in a strict sense, impossible to apply the theory of extremal statistics, but as Gumbel (1957) said, it is reasonable that the probabilistic distribution of statistically dependent variables has some of asymptotic characteristics found in independent variables. Therefore, practically speaking, extremal statistics is also applicable to the maximum anomaly.

#### EXTREMAL STATISTICS OF STORM SURGES

##### {a} Changes of tide with typhoon track

As already pointed out, acceptable fitness of the highest tidal level and the maximum anomaly to a Gumbel distribution is not obtainable by traditional methods. The investigation shows that the shortness of the observation period is not always the main reason for the discrepancy between the observed data and theoretical distribution curves. On the contrary, for the lowest tidal level, the fitness of the data to a Gumbel distribution or a log-normal distribution is good.

For improvement in the degree of fitness, the process of the occurrence of an extremal tide should be studied. Most extremal data, except those in recent years, are due to typhoons. In the east area of the typhoon track, in which the moving speed of a typhoon is superposed on the gradient wind, strong wind are blown. Therefore, storm surges in the east semicircle are generally larger than those in the west one. Thus, the extremal data can be divided into two groups according to the directional characteristics of the typhoon tracks. Weather charts can

be used to clarify the position of typhoons.

Fig. 13 shows the auto correlation coefficients of the highest tidal level in Kobe when the typhoon tracks are considered. The characteristics of variation of the auto-correlation coefficients differ from those shown in Fig. 12 where the directional characteristics of the typhoons are not considered. This situation is the same in Osaka. Furthermore, comparison of the auto-correlation coefficients for west-

Fig. 11 Auto- and serial-correlation coefficients of time series for extreme tidal values in Kobe

Fig. 12 Auto-correlation coefficients of numbers of typhoons generated and of typhoons striking Japan

Fig. 13 Auto-correlation coefficients of the highest tidal level in Kobe, considering direction of typhoon track

FIG. 14 Auto- and serial-correlation coefficients of maximum anomaly in the case of westbound typhoons

bound and eastbound typhoons shows that their phases are different. At the same time, the auto-correlation coefficients of the highest tide due to a cyclone are quite different from those due to typhoons. Therefore, the typhoon tracks and the source of generation of the highest tidal level govern the characteristics of the time series. In other words, the highest tidal level data are usually composed of three different ensembles, so that it is difficult to make a single law of extremal statistics.

From a practical point of view, the data associated with a westbound typhoon is the most important among them because it corresponds to the generation of big storm surges. In the case of eastbound typhoons, however, there seems to have upper

(a) Log-normal distribution

(b) Gumbel distribution

Fig. 15 Probability of occurrence of maximum anomaly generated by typhoons passing through area west of Osaka and Kobe

limit of wind speed in their west side, a scale of storm surges may be under certain level.

Fig. 14 shows the auto and serial correlation coefficients of the maximum anomaly for westbound typhoons. In comparison with Fig. 13, the overall characteristics of the maximum anomaly in Osaka are governed by the typhoons which pass through its western side. In the figure, the data are divided into two groups, just before and after 1950. In both groups, an eleven-year period can be seen. This periodicity coincides with that of the typhoons striking Japan.

[b] Extremal statistics of storm surges

Fig. 15 shows the probability of occurrence for the maximum anomaly generated by typhoons passing through the western side of the bay. From this figure, it is clear that the fitness of the data to a Gumbel distribution or a log-normal distribution improves in comparison with Fig. 3. In Fig. 16, data smaller than 50cm are included in order to obtain a larger sampling period. Every newspapers, weather charts and meteorological reports show that there was no storm surges at those years. The fitness of the data in Fig. 16 also improves over that in Fig. 15. From these figures, it is clear that Osaka is more susceptible to storm surges than Kobe. In this analysis the distance between the eye of a typhoon and the tidal measuring points has not been included. Its consideration would further improve this method.

Fig. 16 Gumbel distribution of maximum anomaly in which data less than 50cm are newly added to those in Fig. 15

The frequency distributions for the highest tidal level in Osaka analyzed by the method proposed here are shown in Fig. 17. It is found that the fitness of the data to a Gumbel distribution is fairly good in comparison with Fig. 3. In particular, the scattering of the data is much improved for portion of relatively large tidal levels generated by typhoons passing through the western side of the bay. For eastbound typhoons, a certain upper limitation for the highest tidal level can be observed. Therefore, this classification of typhoon by track contributes much to the improvement of fitness.

#### CONCLUSIONS

We have developed a method for estimating the occurrence probability of abnormal tides by considering the characteristics of typhoon tracks. It is clear that the fitness of the data to any probability density function cannot be improved by lengthening the period of tidal data or by taking into consideration the effects of extensive reclamation on characteristics of tides. It is concluded that this method has high applicability for determination of the return periods of abnormal tides due to storm surges.

The study reported here was supported by Grant-in-Aids for Scientific Research from the Ministry of Education, Science and Culture of Japan, under Grant No. 302027.

## CHAPTER NINE

### BAYWATER RESPONSE TO TSUNAMIS

Tetsuo Abe\*

#### ABSTRACT

To investigate the transient characteristics of the tsunami-induced oscillations, records of tsunami caused by the Off-Miyagi earthquake in June, 1978 were analysed on the basis of theories on stationary and non-stationary stochastic processes. The stationary spectra show the average feature of the phenomenon. Discrepancies, however, are recognized between the first half oscillations and the second half oscillations during the tsunamis. Besides, the energy densities of non-stationary spectra do not always indicate stationary value at the periods which correspond to the predominant ones of the stationary spectra. These suggest that tsunami-induced oscillations are translative.

#### 1.0 INTRODUCTION

Tsunami waves are basically generated by dislocation of sea-bottom in earthquakes of magnitudes of over 6.5. Waves which attack the coast give greater height as the magnitude of an earthquake increases. Such waves are still in the dispersive process even at the coastline, because the source regions of tsunamis which attack the Japan Island are usually at the western slope of the Japan Submarine Trench and the distance to the coast is nearly the same order of the breadth of the source. Moreover, these waves are transformed by reflection and refraction superimposed by shelf resonance and the edge waves to give complicated dynamic phenomena near-coast offshore region( Iwasaki(4) ).

Dynamic phenomena such as baywater oscillations have been of considerable interest to coastal engineers in relation to engineering evaluation of structures against tsunami disaster. Many researchers have treated them so far, both theoretically and experimentally. Consequently, the understanding of the response of water bodies to external disturbance has progressed greatly. However, less attention has been paid on the investigations based on the actual tide gauge records, because of the limited amount of the tide gauge stations and tide gauge records available in ordinary bays. So that the detailed behaviours of actual bay oscillations were not so well investigated and the verification of experimental or numerical results by observed data is often hindered.

Then, the transient process of baywater response to tsunamis should be investigated based on the observation data, which is the object of this study.

#### 2.0 OUTLINE OF THE OFF-MIYAGI TSUNAMI IN JUNE, 1978

The Sanriku Coast is the name of the coast which is situated in the northeastern part of the mainland of Japan facing the Pacific Ocean and stretching from 38°N to 41.5°N in latitude. Although this coast is famous

\* Professor of Tohoku Institute of Technology, 35/1 Yagiyama-Kasumicho Sendai 982, JAPAN.

by the inundation of tsunamis and a lot of tsunamis attacked there in the past, there were only three cases for which scientific records were obtained among those which originated off this coast and severe damage. They were the Sanriku Tsunami in 1896, the Sanriku Tsunami in 1933 and the Tokachi-oki Tsunami in 1968. Thus, data acquisition of tsunami waves is not easy, because earthquakes of magnitude of over 7.0 are very much seldom.

In 1978, small tsunamis were caused by an earthquake of the magnitude of 7.4 which originated off the coast of the Miyagi Prefecture, the southernmost part of the Sanriku Coast, at 17:14 on June 12. Its source was reported to be at  $142^{\circ}14'E$  longitude,  $38^{\circ}10'N$  latitude and about 25 km deep. According to records of the present tsunamis, the initial motion of tsunamis was in the upward direction at the whole stations in the Sanriku Coast, suggesting the uplift of the sea-bottom in the tsunami source area. The tsunami source area which was estimated by using the adverse refraction diagram was reported by Iwasaki and Mano(5) as shown in Fig. 1, of which the longer axis of 65 km lies in the E-W direction and the shorter one of 50 km lies in the N-S direction, roughly along a bathymetric line of 600 m deep.

As to the Miyagi district, Hatori(3) reported two historical tsunamis as shown in Fig.1. These tsunamis caused by the earthquakes of magnitude of 7.5 and 7.4, respectively, whose seismic intensities were inferred from old documents. The present area of aftershocks coincided with the wave source area of the historical tsunami caused by the earthquake on October 21, 1861. This historical tsunami caused waves of 3 to 4 m high at Ryori near Ofunato Bay. However, wave heights of the present tsunamis were small in compare with those in 1861. The maximum height was only about 1.22 m at Onagawa Bay and about 1.18 m at Kesennuma Bay in the north of the Miyagi Prefecture. Generally speaking, historical tsunamis were generated at the similar locations to the source regions of recent tsunamis. Then, the area in the sea near the Miyagi district may still be considered a region of relatively high tsunami risk, because no conspicuous tsunami has been generated in this region since 1861, as pointed out by Hatori(3).

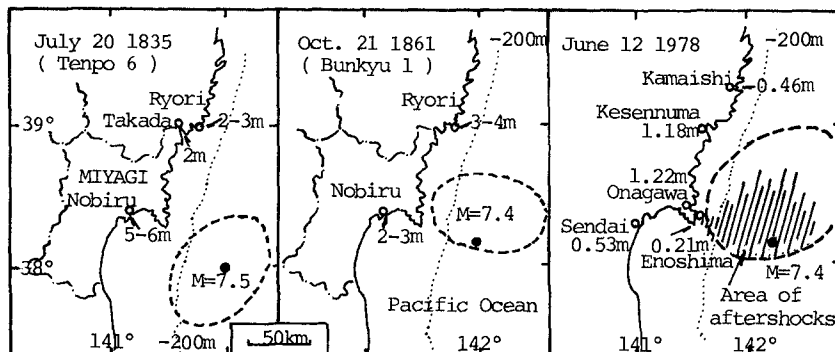

Fig. 1 Tsunami heights and tsunami source areas of the 1835 Tenpo and the 1861 Bunkyo earthquakes inferred from old documents by Hatori ( 3 ), and the tsunami source area caused by the Off-Miyagi Earthquake in 1978 as defined by Iwasaki and Mano( 4 ).

3.0 STATIONARY CHARACTERISTICS OF THE BAYWATER RESPONSE TO TSUNAMIS

3.1 Stationary Spectrum of Oscillation by Tsunamis

Onagawa Bay and Kesennuma Bay were selected for the analysis of gauge records, because the tsunami heights at two bays were relatively high in compare with those of other stations in the Sanriku Coast. Besides, Onagawa Bay was just located near the present tsunami source area and Kesennuma Bay was just opened to that. In Onagawa Bay, there are a tidal gauge station at the head and a tsunami observatory of the Earthquake Research Institute, University of Tokyo, at Enoshima Island offshore of the bay. In particular, Enoshima data may be used to estimate the spectral characteristics of wave offshore. In Kesennuma Bay, there is a big island inside the bay, so that the bay is almost like a long and narrow bay.

Table 1 shows the general discription of wave data and Fig. 2 shows the time sequence records of water level, namly tsunami waves, which were deduced from gauge records by subtracting meteorological tides estimated by the moving average method. Wave data at Onagawa and at Kesennuma were divided into two parts, "before the tsunamis" and "after the tsunamis". Furthermore, data after the tsunamis were divided into "first half" and "second half" for the spectral analysis on the basis of stationary stochastic process.

Spectrum is a widely used idea for presenting the constitution of a given time series. Wave oscillations originated in the open sea or induced within the bay are, in fact, typical time series in nature. There are several methods which can be used to estimate the spectrum of the stationary band-limited time series. The " Maximum Entropy Method " as introduced by Burg(2) is used here. This method is very convenient for the analysis of tsunani waves, because it can produce a highly resoluted spectrum with accurate frequencies and power estimates, even for the observed time series with very few samples.

For a given stationary time series, the maximum entropy power spectrum is defined by the following power spectrum, S(f), which maximizes the entropy of the given time series:

$$S(f) = \frac{\Delta t \sigma_{M+1}^2}{\left| \sum_{m=0}^M \gamma_{m+1, K+1} \exp(i2\pi f m t) \right|^2} \quad (1)$$

Hereafter, S(f) is called MEM-spectrum, where  $\sigma_{M+1}^2$  and  $\gamma_{m+1, K+1}$  are the variance of prediction errors and the prediction error filter for the filter number K+1, respectively. M is the number of the maximum correlation lag, and f is the frequency. The actual time step,  $\Delta t$ , was determined by the chart speed of tide gauge. Since  $\Delta t$  was selected as 5 min, the maximum frequency available is 1/15(HZ), that is, the minimum period available is 15 minutes here. The frequency range was, then,

Fig. 2 Time sequence records of water level deduced from tide and tsunami gauge records.

divided into 100 unites, which enabled the calculation of MEM-spectrum. The number of filter terms was tentatively selected by the "Final Prediction Errors Standard", and the optimal one was decided so that the spectrum would include the first mode which had been estimated by a preliminary test with fewer filter terms.

Fig. 3 shows the MEM-spectra of Onagawa Bay, where the broken line was derived from the first half data after the tsunamis at Enoshima near the bay mouth and chain line is the one at Onagawa in the bay head. In this spectra, ordinate of  $S(f)$  is normalized such that 100 and 1 are the reference maximum and minimum values of spectra. According to the results of Onagawa, there are four predominant oscillation modes during the tsunamis. Their periods are 41, 32, 18 and 13 minutes. The oscillation of 41 min is the basic mode along the bay axis, whose node exists near bay mouth. The oscillation with the period of 18 min is corresponding to the first longitudinal mode, whose node exists near the branched bay at the bay head as reported by Aida(1). The oscillation with the period of 13 min may be corresponding to the second lateral mode between two branched bays. Spectra of Enoshima show four peaks at the period of 43, 26, 18 and 12 minutes. The predominant oscillation period 43 min shows that the water oscillation at Enoshima, although the tide gauge station is considered to be located at the open sea, is affected by the existence of Onagawa Bay. The oscillation of rather longer period is evidently reflecting the effect of the continental shelf off Onagawa Bay. Enoshima is located at the mouth of Onagawa Bay and was just on the edge of the present tsunami source area. So, the spectra at Enoshima may provide information on the waves in the tsunami source area. The oscillation of the period of 26 min seems to be related to the waves in the present tsunami source area. However, further data and considerations are needed to specify it. The oscillation energy is developed mainly with respect to the basic mode. Their magnitudes at the bay head are much higher than those at the bay mouth.

Fig. 3 MEM spectrum of Onagawa Bay, where the broken line is derived from the first half data after the tsunami at Enoshima, and the chain line at Onagawa.

Fig.4 shows the MEM-spectra at Onagawa and Kesennuma. The spectra at Onagawa show the several predominant oscillation periods of 38, 27, 18 and 15 minutes for the wave data before the tsunamis invade; for the first half data after the tsunamis, those of 41, 32, 18 and 13 minutes; and for the second half data after the tsunamis, those of 37, 30, 16 and 12 minutes, respectively. The oscillation of 38 min is the basic mode along the bay axis and the oscillation period of 18 min is corresponding to the first longitudinal mode. The oscillation with the period of 15 min is corresponding to the first lateral mode. It represents the interaction of oscillations in two branched bays, named Onagawa Harbour and Gobaura Bay, and may be considered a lateral oscillation between these two bays. By the intrusion of tsunamis, the basic mode with the period of 38 min in ordinary times before the tsunamis is slightly shifted to the longer period range, 41 min, in the first half of the tsunamis; and to shorter period range, 37 min, in the second half of the tsunamis, suggesting that the position of node moves toward the open sea; and moves back into the bay during the tsunamis. The oscillation energy is especially amplified in the basic mode in the first half of tsunamis. One of another typical facts is that rather remarkable rise in the spectrum is recognized at around 71 minutes in the final stage, evidently reflecting the effect of the continental shelf off Onagawa Bay.

As to Kesennuma Bay, three remarkable peaks were noticed at 52, 33 and 19 minutes in the spectra derived from data before the tsunamis; Two remarkable peaks were noticed at 50 and 32 min in the first half data after the tsunamis; and at 59 and 30 minutes in the second half data after the tsunamis. The largest period is corresponding to the basic oscillation mode of the bay whose node exists near the bay mouth, and the others are related to the oscillations near the bay head. However, the response features are different from the ones of Onagawa Bay. In the first stage of tsunami times, the mode at the period of 19 min disappears and the others are slightly shifted to shorter periods of 50 and 32 min. The energy of the basic oscillation is especially developed in this stage. It can be said that the location of the node of the basic mode moves into the bay and moves toward the open sea by the intrusion of the tsunamis.

### 3.2 Numerical Analysis

In contrast to the spectral analysis of the observed wave data, a theoretical investigation on the resonant oscillation in Onagawa Bay would be done in this study. Through this investigation, a discrete set of natural oscillation modes of Onagawa Bay and the corresponding relative wave heights at every point inside the bay are estimated, from which the system function of the baywater oscillation system can then easily be found. Furthermore, on the basis of the power spectrum of the waves observed at Enoshima near the bay mouth, the response power spectrum at various sites inside the bay can also be estimated.

Records of wave gauge set in bays show very much different behaviour in each locality where the gauges are set. It is the influence of the local features, the transient nature of the incident waves and the bay dynamics. From the foregoing statement, a simple concept is realized that the occurrence of the baywater oscillations, at least, is concerned with two parameters; one is the natural periods of the bay, the other is the period range of the incident waves. For the case of a long and narrow bay, only longitudinal oscillations are importance. Then, the natural period of the first mode of free oscillation on continental shelves or bays is

Fig. 4 MEM spectra at Onagawa and at Kesennuma, where the solid line is derived from data before the tsunami; the chain line is derived from first half data; and the broken line from second-half data after the tsunami.

calculated by  $T=4\ell / 60\sqrt{gh}$  (min.), where  $h$  and  $\ell$  are the average depth and length. However, tsunami-induced oscillations in bays are different from the free oscillations. They should be considered as forced oscillations. In this study, the basic equation used to analyse numerically this problem is the Helmholtz equation, which describes the spatial variation of the linear oscillation in a bay; that is,

the long wave equation for periodic waves is

$$\frac{\partial}{\partial x} \left( h \frac{\partial \zeta}{\partial x} \right) + \frac{\partial}{\partial y} \left( h \frac{\partial \zeta}{\partial y} \right) - \frac{1}{g} \frac{\partial^2 \zeta}{\partial t^2} = 0 \quad ( 2 )$$

where  $\zeta$  is the surface elevation,  $g$  is the acceleration of gravity. To obtain a solution of the steady oscillations for the bay, we assume that the induced wave oscillation is a simple harmonic; that is,

$$\zeta(x,y,t)=A(x,y)\exp(i\sigma t) \quad ( 3 )$$

where  $\sigma$  is the angular frequency. Then, the long wave equation is converted to the well-known Helmholtz equation;

$$\frac{\partial}{\partial x} \left( h \frac{\partial A}{\partial x} \right) + \frac{\partial}{\partial y} \left( h \frac{\partial A}{\partial y} \right) + \frac{\sigma^2}{g} A = 0 \quad ( 4 )$$

To solve this equation is then equivalent to finding out the unknown function  $A(x,y)$ . In this study, one of the numerical methods, that is, " Finite Element Method " is used to solve that equation. Then, the solution of the Helmholtz equation is finally converted to the problem of solving an eigen-value system given by

$$[ K ] \{ A \} - \lambda [ M ] \{ A \} = 0 \quad ( 5 )$$

with the boundary conditions of  $A=A_0$  at the entrance of the bay and  $\frac{\partial A}{\partial n} = 0$  at the rigid boundary, where  $\lambda=\sigma^2$ ,  $\{ A \}$ : unknown node value vector,  $[ K ] = \sum_{k=1}^m [ K ]_k$  : the stiffness matrix,  $[ M ] = \sum_{k=1}^m [ M ]_k$  : the mass matrix.

The solution domain defined in this study covers not only the confined water area, but also some area of open sea. In fact, the seaward boundary of the domain is just located at the edge of the bay mouth and the width of the extended part is almost the same as that of the confined part. The domain was divided into 98 triangular elements with 71 nodes. According to the above definition of the solution domain, the seaward boundary is assumed to be the entrance and all the others are taken as rigid boundary.

Next, from the Fourier analysis, we know that

$$S_y(f) = |H(f)|^2 S_x(f) \quad ( 6 )$$

where  $H(f)$  is the Fourier transform of the impulse response function of a given system;  $S_x(f)$  and  $S_y(f)$  are the power spectrum functions of the input  $x(t)$  and the output  $y(t)$ , respectively. Then, the output power spectrum can easily be computed if the input power spectrum and the system function are given. An example of the system functions of Onagawa Bay referred to Enoshima has been computed and the power spectrum of the waves observed at Enoshima has also been estimated as shown before.

Fig. 5 shows examples of the system function and the power spectrum estimated in this way. From this figure, it can be seen that the oscillations of natural mode theoretically obtained for Onagawa Bay are those with the periods of 38.5, 14.8, 9.0 and 7.9 minutes. Among them, the oscillations with the periods of 38.5 and 14.8 min are almost the same as the predominant oscillations of the first half after the tsunami records of Onagawa. The system functions say that oscillations on the bay and harbour cause greatly the amplification of oscillation energy at the bay head. Table 2 is the summary of the results of spectral analyses and numerical analyses on the stationary characteristics of the tsunami-induced oscillations, including the results reported by Aida(1).

Fig. 5 System functions and computed power spectra at Onagawa in Onagawa Bay.

Table 2 Periods of oscillations in Onagawa and Kesennuma bays

Bay	Tide gauge station		Period (minutes)								
			Oscillation on continental shelves				Oscillation in bay				
			NR	ENR	E	ESE	SE	F	L <sub>1</sub>	T <sub>1</sub>	L <sub>2</sub>

3.3 Amplification Factor

Fig. 6 shows the amplification factors at various sites within Onagawa Bay relative to Enoshima, which are directly estimated through the computation by using the numerical model based on finite element method as a set of natural oscillation modes and corresponding relative wave height vectors. The amplification factor at the period of 38.5 min is corresponding to the basic mode of the bay and the part at the period of 7.9 min is respect to the harbour resonance. However, values of the amplification factors seem to be large.

Then, the amplification factor at Onagawa relative to Enoshima (i.e. bay head vs. bay mouth) was computed from the MEM-spectrum at Enoshima,  $S_E(f)$ , and at Onagawa,  $S_O(f)$ , with the assumption of no reflection at the bay mouth; that is,

$$R(f) = \sqrt{\frac{(1 + \mu) S_O(f)}{S_E(f)}} \quad (7)$$

where  $\mu=0$  (without reflection). The results are shown in Fig.7 and Table3, from which the amplification factors estimated from the MEM-spectrum in this way seem to be explained, to a reasonable degree, by the relative tsunami heights obtained from the tsunami records which are shown in Table 4. They are very much dependent on the oscillatory periods.

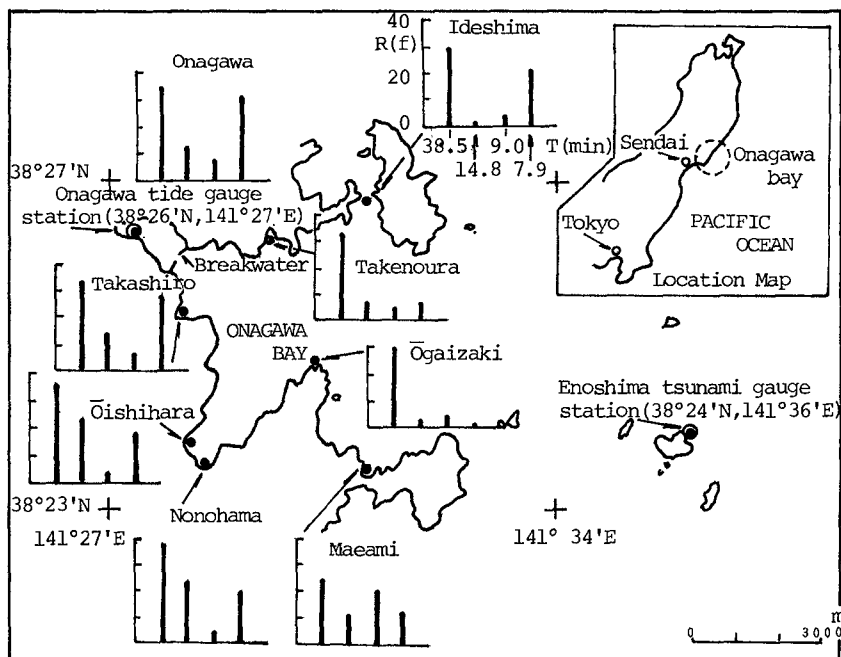

Fig. 6 Amplification factor at various sites within Onagawa Bay relative to Enoshima.

Fig. 7 Amplification factor at Onagawa (bay head) vs. Enoshima (bay mouth), which is derived from the MEM-spectra for the first half data after the tsunamis.

6th wave	8.2	12.0	9.3	25	40	
7th wave	14.5	2.8	6.1	55	40	
8th wave	4.0	3.5	3.7	45	50	
9th wave	5.7	6.0	5.8	30	40	
10th wave	-	8.5	13.0	20	30	

Water bodies on the continental shelf and in a bay usually oscillate by themselves. Such water oscillations are excited more by tsunami. The mechanisms of the wave amplification have been mainly considered to be energy concentration and resonance. The former has been discussed by Green's law and as to the latter, there are many solutions of the steady state oscillations for bays with various topography. However, as I was saying just now, the results are still unreliable enough to apply to the tsunami-induced oscillations, because of their transient characteristics as pointed out by Mano(7).

#### 4.0 NON-STATIONARY CHARACTERISTICS OF THE BAYWATER RESPONSE TO TSUNAMI

Through the results of stationary spectrum, discrepancies were recognized between the first half oscillations and the second half oscillations. It will suggest that the further advanced considerations on the characteristics of the baywater oscillations due to tsunamis will be needed. Then, in order to investigate a non-stationary stochastic time series, a so called "instantaneous Fourier spectrum" was used, which represents the constitutions of the given time series at each time steps. The definition and the estimation scheme of the instantaneous Fourier spectrum which adopted in this study are as follows:

Let  $x(t)$  be a given non-stationary time series, and let  $y_n(t)$  be outputs through a series of system functions  $H_n(f)$ . In linear systems, the following relationship is well known( Papoulis(8) ).

$$Y_n(f) = H_n(f) X(f) \quad ( 8 )$$

where  $X(f)$  and  $Y_n(f)$  are the Fourier transform of the input  $x(t)$  and the outputs  $y_n(t)$  of the system, respectively. Taking inverse transforms of these separated transform functions,  $Y_n(f)$ , respectively, the outputs are then derived as

$$y_n(t) = \int_{-\infty}^{\infty} X(f) H_n(f) \exp(i2\pi ft) df \quad ( 9 )$$

This set of time functions referred to different frequency indicates the components of the given time series at every time step. The envelope of these time functions is, then, defined as the instantaneous Fourier spectrum,  $F(f,t)$ , in this study( Kamiyama(6) ).

To estimate this instantaneous Fourier spectrum, the system function with the Gaussian type is assumed here, i.e.,

$$H_n(f) = \exp\left(-\alpha \frac{f-f_n}{f_n}\right)^2 \quad ( 10 )$$

Because the parameter  $\alpha$  and the band width of the frequency  $\Delta f_n$  can not be determined uniquely, values of  $\alpha$  and  $\Delta f_n$  were chosen as  $50 f_n$  and  $0.15$ , respectively, after the several trial tests. Furthermore, the numerical Fourier integration were carried out based on the well known "fast Fourier transform method".

Fig. 8 shows the instantaneous Fourier spectra at Enoshima in Onagawa Bay. According to the results, oscillation in the period range between 43 and 49 min, in which the basic oscillation mode of the bay is included, are at first excited remarkably. As time was elapsed, the energy was slightly transferred to shorter spectrum bands. Spectra in the period bands between 25 and 35 min are also developed, which corresponds to the waves in the present tsunami source area. The energy densities depend on the oscillatory periods. However, they do not always keep the constant.

Fig. 9 shows the instantaneous spectra at Onagawa. It is quite natural that the energy density before the tsunamis invade is very small. However, the oscillation energies are excited remarkably by the intrusion of the tsunamis. In the first half after the tsunamis, two remarkable oscillations around 39 to 43 minutes and 33 minutes are noticed in which the natural period of the bay is included. After that, at the 3rd wave, the above two remarkable oscillation modes become much more clear with the center periods at 31 and 41 minutes, respectively. And at the 4th wave, the oscillation becomes simple with the center period of 41 min. The oscillation energies in the range between 31 and 41 minutes occupy the major portion of baywater oscillations, and the period of these oscillation modes changes slightly with the lapse of time, which suggests the energy transfers among these modes. And the results agree with the ones of the stationary spectra.

Fig.10 shows the instantaneous Fourier spectra at Kesennuma. Although the spectral energies in the period range 45 and 51 min are excited by the intrusion of tsunamis, the oscillatory mode is relatively simple. The predominant oscillation with the center period at 53 minutes is noticed, which is corresponding to the basic mode of the bay. However, as time elapsed, the energy is gradually transferred to shorter spectrum band and the oscillations are superimposed to give complicated spectra.

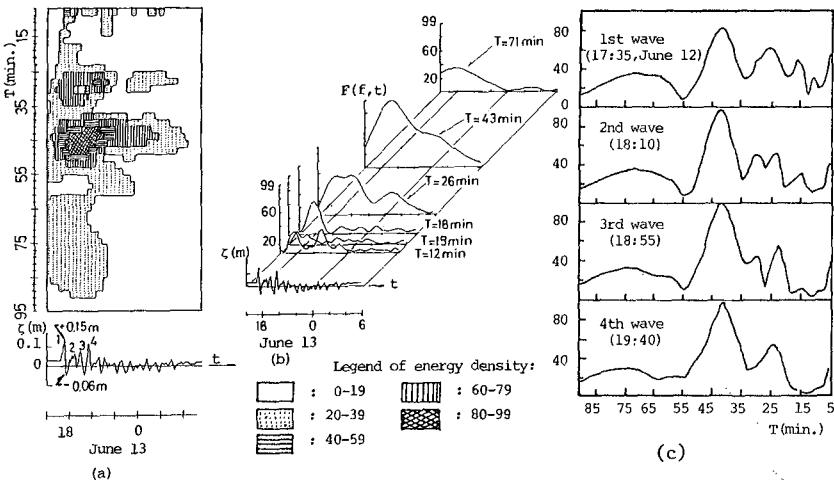

Fig. 8 (a) is energy densities in contour plotted by elapsed time  $t$  and periods  $T$ (min.). Values of energy density function  $F(f, t)$  were normalized 0 (minimum) to 99 (maximum). (b) is the time history of instantaneous Fourier spectra plotted for the predominant periods of oscillation in the stationary spectra. And (c) is the instantaneous spectra at 4 instants selected from the time sequence records of water level, which correspond to from the 1st wave to the 4th wave.

## 5.0 CONCLUSIONS

Stationary and non-stationary characteristics of tsunami-induced oscillations in bays were mainly investigated on the basis of records of tsunami caused by the Off-Miyagi earthquake in June, 1978. The estimated stationary spectra show that the main part of the oscillation energy is included in the basic mode and the secondary mode of oscillations based on the locality of bays, including the effect of continental shelf. The predominant period of these modes shifts to longer and/or shorter period ranges with the lapse of time, suggesting that the position of node moves toward the open sea and moves back into the bay during the tsunamis. The energies of non-stationary spectra do not always indicate stationary value at the periods which correspond to the predominant ones of stationary spectra, because of the transient characteristics of tsunami waves. Then, the results of the steady state oscillations are still not reliable enough to apply directly to the tsunami-induced oscillations.

## ACKNOWLEDGEMENTS

The author is most indebted to Professor Toshio Iwasaki, Ashikaga Institute of Technology, for his helpful criticisms and suggestions.

#### 1. INTRODUCTION

A model hurricane is defined by a model pressure profile, which is the same in all radial directions from the center of the hurricane. The model describes concentric circles of constant pressure known as isobars. The slope of the pressure profile gives the pressure gradient used in the gradient wind equation, together with other considerations determines the time history moving hurricane wind and pressure fields. The appropriate model hurricane can then be coupled with various other models for the determination of design criteria such as wind, waves, currents, wave forces, storm surge, wave run-up, coastal flooding and inundation limits. Because of the many requirements for accurate output data, there have always been concerns of the proper use of and selection of the appropriate hurricane model for a particular task and location.

The primary purpose of the paper is to begin to build a guide for determining the appropriate model to be used for a particular situation and criteria. When the data pressure profile is available, there is no need for a model since the slope of the data pressure profile gives the pressure gradient, which can be used directly in the gradient wind equation. The data pressure profile can also be fitted to the most appropriate model by various techniques of correlation.

After a sufficient number of data pressure profiles have been determined and correlated with various models, to determine the most appropriate model, then one should be able to extend the guide for better selection of model. One can then make better use of the standard project, maximum probable and actual tabulated hurricane data ( $R_G$ ,  $P_0$ ,  $P_W$ ,  $\phi$ ,  $V_F$ , etc.) given in the NOAA Report by Schwerdt, Ho and Watkins (1979).

The present guide for selection of a particular model has to do with the hurricane parameters  $R_G$ ,  $P_0$ ,  $P_N$ , and  $\phi$  as related to the cyclostrophic and gradient wind equations. For the convenience, in this paper  $R$  is the radius of maximum cyclostrophic wind as distinguished from  $R_G$ , the radius of maximum wind in the report by Schwerdt, et al. (1979). The

parameters determined by data pressure profile analysis are:

1.  $R$  = radius of maximum cyclostrophic wind,
2.  $P_R$  = pressure from the data pressure profile at  $R$ , and
3.  $\text{MAX} [rdP/dr]$  = related to the maximum cyclostrophic wind and determine the location of  $R$ .

## 2. DATA PRESSURE PROFILE

The data pressure profile is determined from the cyclone weather chart, and is an average of eight traverses from the center of the cyclone crossing identical isobars to the last closed or nearly closed isobar. The average distance  $r$  is plotted versus the corresponding isobar pressure. This method of analysis eliminates or at least minimizes the distortions in the isobar pattern due to personal judgement in construction of the isobars, possible effects due to forward motion to the cyclone and blocking effects due to adjacent pressure systems or land effects. The net result is a cyclone having concentric circular isobars, the definition of a model cyclone.

The step-by-step procedure is simple and straightforward in this method of analysis. A smooth S-curve is constructed through the data points, defining the data pressure profile. It is not necessary to have a complete data pressure profile, including  $P_0$  and  $P_N$ , which can be calculated by theory depending on choice of the model. The pressure gradient is a smooth profile through points calculated from the slope of the data pressure profile. The cyclostrophic profile is calculated from the smooth pressure gradient profile by multiplying corresponding points of the slope of the pressure profile by the radial distance  $r$ . Some fine tuning may be required to increase the accuracy in the range of radius of maximum wind, which can easily be estimated at a distance equal to about twice that of the maximum or peak of the pressure gradient profile, which occurs at the inflection point of the data pressure profile. Three important parameters are then determined as follows:

1.  $R$  = radius of maximum cyclostrophic wind at  $\text{max} [r dp/dr]$ ,
2.  $\text{max} [r dp/dr]$  at  $R$ , and
3.  $P_R$  the pressure from that data pressure profile at  $R$ .

It then follows by theory that  $P_0$  and  $P_N$  can be calculated from the following relations:

$$\Delta P_0 = P_N - P_0 = 1/C_1 \text{max} [r dp/dr] \quad (1)$$

$$P_0 = P_R - C_2 \Delta P_0, \text{ and} \quad (2)$$

$$P_N = P_0 + \Delta P_0 \quad (3)$$

where  $C_1$  and  $C_2$  are theoretical constants depending on the choice of the model.

The theoretical maximum cyclostrophic wind speed can be determined from:

$$V_C = \sqrt{1/\rho_a \text{MAX} [rdP/dr]} = K \sqrt{\text{MAX} rdp/dr} \quad (4)$$

where  $\rho_a$  = air density of  $P_R$  at  $r = R$ , radius of maximum wind.

Eq. 4 is independent of choice of model, and  $K = 18.7$  to  $19.3$  for all pressure profiles.

All theoretical pressure profiles will be in agreement with the data pressure profile at  $P_R$ ,  $R$ , and  $\max [r dp/dr]$  by the very nature of the analysis of the cyclone weather charts. Furthermore all model pressure profiles will be in very close agreement with the data pressure profile over the range of  $0.5 R < R < 1.5 R$  approximately, but there will be deviations outside this range. A high correlation will always be achieved between data pressure profile and model pressure profile because of the above range in agreement, but the choice of the model will be that model which has the overall best correlation with the data pressure profile, excluding  $P_0$  and  $P_N$ , except when available by measurements. Spot check data points such as  $P_0$ ,  $P_N$ ,  $V_{max}$ , etc. if available by measurements should also be considered.

Six Indian Seas cyclones have been analyzed by the above method. Regression analysis between the original data of the data pressure profile and the corresponding theoretical pressure points for BRET MODEL-X was made, and the following regression coefficients were obtained:  $\rho = 0.9890$ ,  $0.9995$ ,  $0.9993$ ,  $0.9824$  and  $0.9996$ . Figure 1 presents the example theoretical hurricane relations for BRET MODEL-X, and Figures 2 to 7 are the Indian Seas cyclones data pressure profile analysis. Because of the very nature of the method of determination of  $R$ ,  $P_R$  and  $\max [r dp/dr]$ , high regression correlations are expected, and therefore one might reject those cyclones for which  $\rho < 0.98$  or  $0.99$ .

FIG. 1 EXAMPLE THEORETICAL HURRICANE RELATIONS FOR BRET MODEL - X

The choice of the model can also be based in part on previous investigations reported in the literature. By theory the maximum cyclostrophic wind speed for model hurricanes is given by:

$$V_c = K_1 \sqrt{P_N - P_0} \quad (5)$$

where

$$K_1 = (C_1 / \rho_a)^{1/2} \quad (6)$$

where  $\rho_a$  is the air density and generally increases slightly with latitude.  $C_1$  is a theoretical constant, depending on choice of model.

Obviously the choice of model depends on  $V_c$  of Eq. 5 is equal to  $V_c$  of Eq. 4.

It would seem prudent to analyze cyclones, hurricanes and typhoons by the simple straightforward method introduced in this paper, and determine a large number of values for  $R$ ,  $P_R$  and  $\max [r dp/dr]$ .  $P_0$  and  $P_N$

can then be determined for choice of model for correlation purposes.

In summary the uniqueness of this paper is the method of analyzing cyclone weather charts to determine the three parameters  $R$ ,  $P_R$  and  $\max [r dp/dr]$ , the determination of  $P_0$  and  $P_\infty$  by theory depending on choice of model, and the correlation between the data pressure profile and the theoretical pressure profile over the range of isobaric pressure data.

3. MODEL PRESSURE PROFILES

Besides, the Hydromet model pressure profile, there are a number of other available model pressure profiles found in the literature. A modification of the Hydromet model was made by Holland (1980) giving a family of pressure profiles, of which one of the pressure profiles reduces to the Rankin Vortex model. This family of pressure profiles has been in use with some success by Rosendal (1982).

A number of other pressure profile models from various sources are given in the NOAA Report by Schwerdt, Ho and Watkins (1979). Fujita (1962) proposed a different model, which Uji (1975) fitted quite well to Typhoon Vera, 22-27 September 1959, a very large western north pacific typhoon. Bretschneider (1982) proposed a new general form of hurricane models, of which Fujita (1962) model is a special case. Jelenianski (1966) used a non-dimensional surface profile corresponding to the BRET MODEL-X non-dimensional cyclostrophic wind profile.

In summary there are two general types of hurricane models: (1) the modified Rankin Vortex model by Holland (1980), of which the Hydromet model is a special case; and, (2) the BRET-General model of which the BRET MODEL-X, the Fujita model and Jelenianski model are all special cases. The mathematical form of the pressure profiles for the two families of models are:

$$\frac{P_r - P_0}{P_\infty - P_0} = A e^{-B [R/r]} \tag{7}$$

and

$$\frac{P_r - P_0}{P_\infty - P_0} = 1 - \left[ 1 + a \left( \frac{r}{R} \right)^2 \right]^{-b} \tag{8}$$

where

- $P_0$  = central pressure of hurricanes
- $P_r$  = pressure at radial distance  $r$
- $P_\infty$  = pressure at infinite distance  $r$
- $R$  = radius of maximum cyclostrophic wind

The constants  $A = B^{-1}$  and  $a = b^{-1}$  must always hold true to satisfy the mathematics of the cyclostrophic wind equation.

Eq. 7, proposed by Holland (1980), and when  $A = B = 1$ , becomes the original Rankin Vortex model after Schloemer (1954) or before. Eq. 8 was proposed by Bretschneider (1981) after pressure profile data analysis.

When  $a = b - 1$ , Eq. 8 is called BRET MODEL-X. When  $a = b^{-1} = 2$ , Eq. 8 becomes the same as Fujita model (1962).

Eqs. 7 and 8 above represent families of models that overlap. The deviations between models have to do with (1) the size of the hurricane as governed by the radius of maximum cyclostrophic wind, (2) the wind intensity of the hurricane as governed by the central pressure reduction, and (3) an assumption that there is a latitude affect as governed by the Coriolis parameter. The above assumptions lead to the introduction of a non-dimensional Coriolis or Rankin Vortex number for hurricane classification. Table 1 presents the theoretical constants  $K_1$  for four hurricane models -- Hydromet Model, NOAA Model-I, Fujita Model-J, and BRET MODEL-X. Table 2 presents the parameters for the six Indian Seas cyclones data pressure profile analysis.

Table 1: THEORETICAL CONSTANTS FOR FOUR HURRICANE MODELS				
	HYDROMET MODEL-HM	NOAA MODEL-I	FUJITA MODEL-J	BRET MODEL-X
$K_1 = \left(\frac{C_1}{\rho a}\right)^{1/2}$	$\left(\frac{1}{e\rho a}\right)^{1/2}$	$\left(\frac{1}{\pi\rho a}\right)^{1/2}$	$\left(\frac{2}{3\sqrt{3}\rho a}\right)^{1/2}$	$\left(\frac{1}{2\rho a}\right)^{1/2}$
FOR V = KNOTS and P = INCHES Hg				
$K_1$	66.0 68.0	61.39 63.25	67.51 69.56	76.74 79.28
FOR V = KNOTS and P = millibars				
$K_1$	11.34 11.68	10.55 10.87	11.60 11.95	13.22 13.62

#### 4. THE GRADIENT WIND EQUATION

The radius of maximum gradient wind and the maximum gradient wind, respectively are not identical to the corresponding radius of maximum cyclostrophic wind and the gradient wind at the radius of maximum cyclostrophic wind. The above was shown to be the case by Bretschneider (1959), using the Hydromet-Rankin Vortex model after Schloemer (1954) and Myers (1954). This will be true for any wind field developed from the pressure gradient by the very nature of the gradient wind equation.

The gradient wind equation for a stationary cyclone can be given as follows:

$$V_g^2 + frV_g = \frac{r}{\rho a} \frac{dp}{dr} \quad (9)$$

where

- V<sub>g</sub> = gradient wind speed at radial distance r from the center of the cyclone
- f = Coriolis parameter
- $\rho$  = air density
- dp/dr = pressure gradient

In the absence of the Coriolis term fr Eq. 9 becomes the cyclostrophic wind equation as follows:

$$V_r^2 = \frac{r}{\rho_a} \frac{dp}{dr} \quad (10)$$

where  $V_r$  is the cyclostrophic wind speed, resulting from the balance between the centripetal force directed toward the center of the cyclone and the force due to the pressure gradient.

Thus Eq. 9 can be written as follows:

$$V_g^2 + frV_g = V_r^2 \quad (11)$$

The maximum cyclostrophic wind velocity can be obtained from

$$V_c^2 = \frac{1}{\rho_a} \text{MAX} \left[ \frac{r dp}{dr} \right] \quad (12)$$

where  $V_c$  occurs at  $R$  radius of maximum cyclostrophic wind.  $R_g$  is the radius of maximum gradient wind, and is somewhat smaller than  $R$ , depending on the value of  $fr/V_c$  or  $frR/V_c$ .

The most accurate evaluation of Eq. 12 would be by use of an accurately determined pressure profile from data, but this is seldom possible because of lack of sufficient data. The procedure is to best fit a pressure profile to the data pressure. Then, an analytical pressure profile or model pressure profile can be selected which best fits all the data including the central pressure, if available. Ideally, it would be excellent to have available the pressure at the radius of maximum cyclostrophic wind.

Once the maximum cyclostrophic wind  $V_c$  is obtained, then one can obtain the gradient wind at  $R$  as follows:

$$V_{gR}^2 + fr V_{gR} = V_c^2 \quad (13)$$

or

$$V_{gR} = \frac{1}{2} - fr + \sqrt{(1/2 - fr)^2 + V_c^2} \quad (14)$$

As can be seen from the works of Bretschneider (1959) Eq. 13 or Eq. 14 does not give the maximum gradient wind  $V_g$  and consequently the maximum 10-meter level wind speed  $V_s$  at the radius of maximum wind. The radius of maximum gradient wind,  $R_g$  for  $V_g$  is not the same as the radius of maximum cyclostrophic wind  $R = R_c$  for  $V_c$ .

Actually  $R_g = R_c$  and  $V_g = V_c$  for the Rankin Vortex model only, which implies that  $R_c = R_g$  as  $R \rightarrow 0$ ,  $V_g = V_c$  as  $V \rightarrow \infty$ . Otherwise everything can only be approximate, the approximation depends upon the Rankin or the Coriolis non-dimensional number, which can be defined as follows:

$$N_c = fr/V_c \quad (15)$$

where

$f$  = the well known Coriolis parameter  
 $R$  = radius of maximum cyclostrophic wind  
 $V_C$  = maximum cyclostrophic wind

When  $N_C$  is very small (0.01 to 0.05) the Rankin Vortex model applies. When  $N_C > 0.1$  the Rankin vortex cannot apply. The problem is when does some other model or modification of the Rankin Vortex model become important?

What is required is to establish certain relationships between cyclostrophic wind, gradient wind, and surface wind, usually defined as the 1-minute or the 10-minute average at the 10-meter standard anemometer level.

In sequence of maximum cyclostrophic wind  $V_C$ , maximum gradient wind  $V_G$  and maximum surface wind  $V_S$  we have

$$V_G > V_C \quad \text{and} \quad V_S R_G = C_f V_G \quad (16)$$

where  $C_f$  is the friction reduction factor.

What has not been recognized for hurricane is that the radii of maximum of the above types of winds are not the same. It is very easy to state that:

$$R_S = R_G < R_C \quad (17)$$

In fact one can prove always for a stationary model hurricane that:

$$R_G < R_C \quad (18)$$

However it is not apparent that  $R_G$  is not the same as  $R_S$  because of different relationships for reduction friction factors. Unlike  $R_C$  and  $R_G$  which are quite apparent, it is quite probable that  $R_G = R_S$ .

## 5. AN INVESTIGATION OF MODEL HURRICANE

To begin with, all model hurricane pressure and wind fields are assumed to be stationary models, after which forward speed of translations are applied to change only the winds but not the pressures.

What is required here is to establish relationships for the stationary hurricane between  $R_G$ , radius of maximum gradient wind,  $V_{GR}$  and  $R$ , the radius of maximum cyclostrophic wind,  $V_C$ .

It is important to note here that  $R_G$  and not  $R$ , the appropriate parameters to establish the radial distance at which  $V_G$  applies.

Three cases will be worked out here: (1) the Hydromet-Rankin Vortex model, (2) the BRET MODEL-X and (3) the Fujita model. Similar approaches can be worked out for the other models.

HYDROMET-RANKIN VORTEX MODEL, A=B=1

The pressure profile is given by:

$$\frac{P_r - P_0}{P_N - P_0} = e^{-R/r} \quad (19)$$

The pressure gradient is obtained as follows:

$$\frac{dp}{dr} = \frac{P_N - P_0}{R} \left(\frac{R}{r}\right)^2 e^{-(R/r)} \quad (20)$$

and the cyclostrophic wind equation by:

$$V_r^2 = \frac{1}{\rho_a} \frac{rdp}{dr} = \frac{1}{\rho_a} (P_N - P_0) \left(\frac{R}{r}\right) e^{-R/r} \quad (21)$$

The maximum cyclostrophic wind velocity occurs at  $r = R$ . Whence

$$V_c^2 = \frac{1}{\rho_a} \text{MAX} \left(\frac{rdp}{dr}\right) = \frac{1}{\rho_a} (P_N - P_0) e^{-1} \quad (22)$$

Dividing Eq. 21 by 22 we obtain

$$V_r^2 = V_c^2 \left(\frac{R}{r}\right) e^{(1 - R/r)} \quad (23)$$

Substituting Eq. 23 into Eq. 11 we obtain

$$V_g^2 + fr V_g = V_c^2 \frac{R}{r} e^{(1 - R/r)} \quad (24)$$

To find the maximum gradient wind  $V_G$  at radius of maximum wind  $R_G$ , we differentiate Eq. 24 and set the results equal to zero and let  $r = R_G$ .

$$\frac{V_G}{fR_G} = \left(\frac{V_c}{fR}\right)^2 \left(\frac{R}{R_G}\right)^3 \left(\frac{R}{R_G} - 1\right) e^{(1 - R/R_G)} \quad (25)$$

For any particular set of conditions

$$\frac{fR}{V_c} = \text{const} = \text{cyclostrophic Coriolis number}$$

$$\text{when } \frac{R}{R_G} = 1$$

$$fR_G = fR = 0$$

$$\frac{V_G}{V_c} = 1$$

The simultaneous solution of Eq. 25 and Eq. 14 will give the proper relationships between  $R/R$  and  $V_G/V_c$  as functions of the Coriolis number  $N_c = fR/V_c$ .

FUJITA MODEL,  $a=b^{-1}=2$

The cyclostrophic wind relationship for the Fujita model is given by

$$V_r^2 = V_c^2 \frac{3\sqrt{3} \left(\frac{r}{R}\right)^2}{\left[1 + 2 \left(\frac{r}{R}\right)^2\right]^{3/2}} \quad (26)$$

Substituting Eq. 26 into Eq. 11, the gradient wind equation becomes

$$V_g^2 + frV_g = V_c^2 \frac{3\sqrt{3} \left(\frac{r}{R}\right)^2}{\left[1 + 2 \left(\frac{r}{R}\right)^2\right]^{3/2}} \quad (27)$$

In a similar manner as was done for the Hydromet Rankin Vortex model, differentiate Eq. 27 and set  $dV_g/dr = 0$  to find the radius,  $R_G$  of maximum gradient wind  $V_G$

$$\frac{V_G}{fR_G} = 6\sqrt{3} \left(\frac{V_c}{fr}\right)^2 \frac{1 - \left(\frac{R_G}{R}\right)^2}{\left[1 + 2 \left(\frac{R_G}{R}\right)^2\right]^{5/2}} \quad (28)$$

and from Eq. 27, let  $r = R_G$  it becomes

$$V_G^2 + fR_G V_G = \frac{3\sqrt{3} V_c^2 \left(\frac{R_G}{R}\right)^2}{\left[1 + 2 \left(\frac{R_G}{R}\right)^2\right]^{3/2}} \quad (29)$$

The simultaneous solution of Eqs. 28 and 29 gives relationships between  $fR/V_c$  and  $R_G/R$ .

BRET MODEL-X,  $a=b=1$

The cyclostrophic wind relationship for the BRET MODEL-X is given by:

$$V_r^2 = V_c^2 \frac{4(r/R)^2}{(R^2 + r^2)^2} \quad (30)$$

and the gradient wind equation becomes

$$V_g^2 + frV_g = \frac{4(r/R)^2}{(R^2 + r^2)^2} V_c^2 \quad (31)$$

In a similar manner as was done for the Hydromet Rankin Vortex model differentiate Eq. 31 and set  $dV_g/dr = 0$  to find the radius,  $R_G$  of maximum gradient wind  $V_G$ .

$$\frac{V_G}{fR_G} = 8 \left( \frac{V_C}{fR} \right)^2 \left( \frac{R}{R_G} \right)^4 \frac{\left( \frac{R}{R_G} \right)^2 - 1}{\left[ \left( \frac{R}{R_G} \right)^2 + 1 \right]^3} \quad (32)$$

and from Eq. 31 let  $r = R_G$ , we have

$$V_G + fR_G V_G = \frac{4V_C^2 \left( \frac{R}{R_G} \right)^2}{\left[ 1 + \left( \frac{R}{R_G} \right)^2 \right]^2} \quad (33)$$

The simultaneous solution of Eqs. 32 and 33 gives relationships between  $fR/V_C$  and  $R_G/R_C$ .

Table 3 presents the relationships between the ratio of radius of maximum gradient wind versus radius of maximum cyclostrophic wind and the Rankin Vortex number for Hydromet Rankin Vortex model, Fujita model, and BRET-X model. Table 3 can be used in two ways.

1. Where  $R_G$  is given such as for the conditions of previous studies for the Gulf of Mexico, one can calculate the approximate  $R$  for the maximum cyclostrophic wind,  $V_C$ .
2. Where  $R$  is obtained by analysis by pressure profiles, then  $R_G$  can be used for the maximum gradient wind  $V_G$ .

## 6. NON-DIMENSIONAL RANKIN VORTEX NUMBER

The non-dimensional Rankin Vortex number,  $N_C$  has been defined in Eq. 15. It presents the ratio between the Coriolis velocity (a fictitious velocity) and the cyclostrophic wind velocity (a theoretical velocity) at the radius of the maximum cyclostrophic wind velocity. When  $\Delta P_0 = P_N - P_0$  (Eq. 1) is given in millibar,  $R$  in nautical miles, and  $V_C$  in knots, Eq. 15 becomes

$$N_C = \frac{0.522 R \sin \phi}{K \sqrt{\Delta P_0}} \quad (34)$$

where  $\phi$  is the latitude,  $K = 11.3$  to  $11.7$  depending on the air density at  $P_R$ .

Tabulated data from Schwerdt, et al. (1979) for 51 U.S. East Coast and 71 Gulf of Mexico hurricanes were used to calculate values of  $N_{CR}$  from Eq. 34 using  $K = 11.7$ . There was found a wide scatter of the data with respect to latitude. The average values of  $N_{CR}$  increased from 0.05 at  $\text{lat } \phi = 24^\circ$ , to 0.07 at  $30^\circ$  to 0.165 at  $41^\circ$ , where existing models probably do not apply any way. Two lowest values for  $N_{CR}$  were 0.01 for Key West (1909) and 0.018 for Camille (1969), both of which can be

considered as classical examples of the Rankin Vortex model. Maximum values for the Gulf were between 0.12 and 0.15, and for the East Coast 0.15 to 0.30.  $N_{CR} = 0.15$  for Western Pacific Typhoon Vera (1959), and for Hawaii Hurricane Iwa,  $N_{CR} = 0.15$  to 0.22.  $N_{CR} = 0.052$  to 0.22 for the Indian Seas cyclones. Data pressure profiles for Vera (1959), Iwa (1982) and Indian Seas cyclones, and also mean, minimum and maximum values of  $N_{CR}$  for the U.S. East and Gulf Coast hurricanes were used to suggest a guide for selection of model pressure profiles, given in Table 4.

Table 4: A SUGGESTED GUIDE FOR SELECTION OF MODEL

HYDROMET RANKIN VORTEX MODEL (Eq. 7)

A=B=1  $0.0 < N_{CR} < 0.05$   
 A=B=5/4 (approx. est.)  $0.03 < N_{CR} < 0.08$

BRET MODELS (Eq. 8)

Fujita (b = 1/2)  $0.03 < N_{CR} < 0.08$   
 BRET-X (b = 1)  $0.06 < N_{CR} < 0.15$

NOTE: The above table is only suggested. Revisions will be in order after sufficient hurricane analyses.

## 7. SUMMARY

The radius of maximum gradient wind and the maximum gradient wind to the corresponding radius of maximum cyclostrophic wind and the maximum cyclostrophic wind have been carefully studied with various theoretical hurricane models. The accuracy of the predicted hurricane wind field heavily depends on the choice of the hurricane model. In the current study, it found that the selection of the hurricane model are determined by the range of the non-dimensional Rankin Vortex number. This number presents the ratio between the Coriolis velocity and the cyclostrophic wind velocity at the radius of the maximum cyclostrophic wind velocity. Table 4 gives a suggested guidance for the selection of the hurricane model. But it is only a general guide. Additional data pressure profiles need to be analyzed for various  $P_R$ , hurricane intensive  $V_{CR}$ , and for different latitude  $\phi$ , as well as regional locations.

#### LIST OF SYMBOLS

- $R = R_C$  = Radius of maximum cyclostrophic wind  
 $R_G$  = Radius of maximum gradient wind (corresponding to radius of maximum wind of published data on  $R = R_G$ )  
 $r$  = Distance from center of hurricane  
 $V_C$  = Maximum cyclostrophic wind at  $R$   
 $V_r$  = Cyclostrophic wind at radial distance  $r$   
 $V_G$  = Maximum gradient wind at  $R_G$   
 $V_g$  = Gradient wind at radial distance  $r$   
 $P_R$  = Atmospheric pressure at radius of maximum cyclostrophic wind  
 $P_r$  = Atmospheric pressure at radial distance  $r$

#### 9. ACKNOWLEDGEMENTS

The original work on the data pressure profiles Figures 2 through 6 was done by various members of Engineers India Limited under the support of UNIDO (United Nations Industrial Organization) and Figure 7 at the Coastal Engineering Research Center-Poona under the support of UNDP (United Nations Development Program). The drafting of the figures was done by HIG (Hawaii Institute of Geophysics) and typing of the final manuscript by the Department of Ocean Engineering.

## CHAPTER ELEVEN

### Estimating Error of Coastal Stage Frequency Curves

Mark D. Prater<sup>1</sup>, A.M. ASCE, Thomas A. Hardy<sup>1</sup>,  
H. Lee Butler<sup>2</sup> M. ASCE, and Leon E. Borgman<sup>3</sup> M. ASCE

#### Abstract

A computer intensive statistical procedure known as the bootstrap has been used to estimate the error in coastal stage-frequency relationships due to uncertainties in hurricane meteorological distributions. These stage-frequency relationships are developed through the use of a joint probability method, so that the probability of a storm event is the product of the probabilities of the individual independent components which comprise that storm event. The bootstrap technique provides an estimate of the error of the stage-frequency by determining the variation possible in each component's probability distribution. This variability is due to the construction of the distribution from a finite set of historical events. An example of the bootstrap is given and stage-frequency results and error estimates typical of a coastal region are shown.

#### Introduction

Efficiency in design of coastal protection is becoming more and more important. Development of coastal regions, costs of damages from storm induced water levels, and costs of protection from these waters are all increasing. Adequate protection for coastal regions is desired; however, due to monetary constraints what amount of water level protection that can be considered adequate becomes a question for which there is no easy answer. Therefore, inherent in any coastal protection project, there is a need to develop the best possible estimate of the stage-frequency relationship for the project area, as well as an estimate of the error in this relationship.

The tool in most widespread use for the development of coastal flood frequency, especially from hurricane induced water levels, is the joint probability method (4). However, a generally accepted method to judge the correctness of the produced flood frequency, or to estimate

the error of these frequencies, is not available. This paper introduces a method which can be used to develop error estimates from meteorological uncertainty for stage-frequency relationships derived through the joint probability method.

This paper will first outline the joint probability method as it is used to develop stage frequency relationships for regions whose extreme water levels are dominated by hurricane surges. Secondly, a computer intensive statistical tool known as the "bootstrap" (1,2) will be introduced and a procedure will be described which uses the bootstrap to obtain error estimates from meteorological uncertainties. Finally, an example will be given showing the use of the bootstrap technique for developing confidence intervals for a coastal stage-frequency curve.

#### Joint Probability Method

When developing a hurricane stage-frequency relationships, it is not necessary, or even possible, to model all hurricane windfield configurations that are possible in the region of interest. It is assumed that a storm's configuration can be completely and uniquely described by a set of parameters. Therefore, all possible hurricanes are represented by a large number of synthetic storms, each with its own specified configuration, defined by the values of its parameters.

Commonly, five parameters are used to describe the configuration of a hurricane windfield (Figure 1). The central pressure deficit is the difference between the ambient atmospheric pressure and the extreme low pressure in the center of the hurricane, and is directly related to the intensity and magnitude of the storm. The radius of maximum winds is the distance from the center of the storm to the region of the strongest winds, and is a measure of the size of the hurricane. The forward speed is the storm's rate of translation. The direction of storm motion and location of landfall determine the track of the storm.

General relationships can be expressed which relate the movement and distribution of wind magnitudes and directions with specific values of the above parameters (6). If these parameters can be shown to act independently of one another, the probability of a hypothetical storm occurring is the product of the probabilities of the component parameter values. If independence of parameters cannot be justified, the joint probability method and the bootstrap can still be used, but procedures become more complex. For simplicity, independence will be assumed in the following discussion.

Probability distributions for hurricane parameters are derived by ranking historical values observed for each parameter. A plotting position method such as the Weibull formula (3) is then used to relate rank of parameter value to a probability of exceedance for that value (Figure 2).

Specific values of each parameter are then chosen to represent the entire range of parameter values obtainable in the area of interest. These representative values are chosen through a series of sensitivity tests by simulating the storm surge at a specified location with the

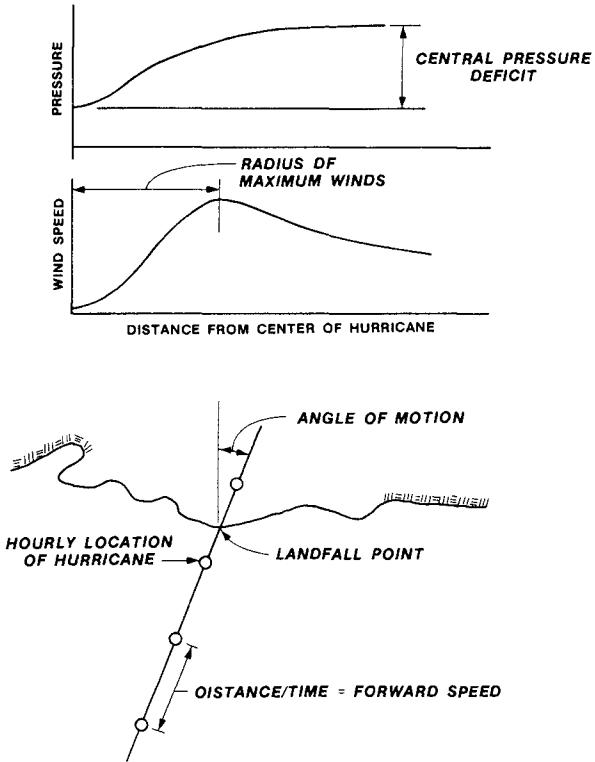

Figure 1. Schematic of Hurricane Parameters

WEIBULL FORMULA

$$\text{PROBABILITY OF EXCEEDANCE} = \frac{m}{N+1}$$

WHERE  $m$  IS THE RANK OF THE VALUE  
 $N$  IS THE NUMBER OF VALUES  
 (IN THIS EXAMPLE,  $N = 8$ )

 $P_i$  = ASSIGNED PROBABILITY

Figure 3. Parameter Value Probability Assignment

use of a parameterized model which produces a windfield from the hurricane parameter values, and a numerical hydrodynamic model. The purpose of these tests is to determine the variability of the surge level purely due to the variation in the value of a specific parameter. Often, all of the other parameters are assigned mean values while the remaining parameter is varied through the range of possible values. If the resulting surge levels vary greatly, more parameter values may be needed to represent the parameter probability distribution. Fewer values are needed for representation if little variation in surge is observed or if the variation in surge can be defined mathematically, i.e., by a linear function. The amount of probability which a parameter value receives is proportional to the amount of the probability distribution that the value is to represent (Figure 3).

The total number of storms simulated is the product of the number of representative values chosen for each parameter. If three values are chosen for each parameter, then  $(3)(3)(3)(3)(3)=243$  different synthetic hurricanes will be modeled, with each simulation resulting in a surge time history. The total number of storms will vary greatly with the number of values chosen to represent each parameter. Often, the outcome of a hurricane simulation is not reported as a surge time history, but as the maximum surge height obtained. The effect of the hurricane, in this case the maximum surge height, is assumed to have the same probability as the hurricane itself. However, this refers to the probability of the maximum surge height from an individual event occurring, not the probability of the same maximum surge height occurring from any other event. For example, a hurricane is given a probability  $P_1$ ; therefore, its maximum surge height of  $H$  is given probability  $P_1$ . Another storm can occur with probability  $P_2$  which also produces a surge height of  $H$ . The probability of the  $H$ -level surge height, however, is neither  $P_1$  or  $P_2$ , but the accumulative probability of all events causing a surge height of  $H$ .

To include the effect of tidal action on the total water level experienced at the coast, all of the computed surge records are convolved with a tidal record which is representative of the tides that the hurricane might encounter at the study site. This is possible if the water depth and other physical features allow the linear addition of surge and tide level to obtain a total water level. The hurricane surge and the tide both behave as shallow water waves, and thus their behavior depends on the water depth. In shallow areas the height of the surge or tide is a significant portion of the total water depth. In deep water, the surge and tide heights are a small fraction of the water depth, so that the behavior of the surge would be the same whether the tide is present or not. In most cases this linearity condition is met. The length of record used for the convolution process can vary from a minimum of a lunar month as long as 18.6 years, which is the cycle length for tidal activity. The length of tidal record is a decision which must be made on a case-by-case basis. For the following example, one lunar month was used.

The process of convolution involves creating all possible combinations of the surge and the tide records. This is achieved by adding the surge height time history produced through simulation to a

continuous tidal record of equal length to form a total water level record. In most cases, convolution is done by sampling the tidal and surge records at small time intervals, in this case one hour. The tidal record is then shifted one hour and the process is repeated (Figure 4). A lunar month is roughly 672 hours, so a convolution of a single synthetic storm surge record produces 672 different surge-tide combinations. Since the occurrence of a storm and a tide in nature is a random event, a storm can occur at any time of the month. Thus the probability of any hourly tidal height occurring is uniform and equal to  $1/672$ . When all of the storm surge records have been treated in the above manner, using the previous example,  $(243)(672)=163,296$  different surge-tide combinations will have been produced. The maximum water level is then found for each combination, and the water level's probability is the product of the probabilities of the producing storm and tide.

The final stage of this process is the construction of a water level vs. return period relationship, usually expressed as a curve. An array of intervals is created, each labeled with a unique water level value and spaced by a specified increment, for example 0.1 ft (0.03 m). The large number of maximum water levels are sorted and their probabilities are added to the appropriate interval. This process generates a water level probability distribution (Figure 5). The cumulative summation of the probabilities at each height produces an exceedance distribution, thereby providing the probability of a specified water level being equaled or exceeded.

A major factor not yet mentioned is the average recurrence interval for hurricanes. This value is found by dividing the number of recorded hurricanes into the record length. If the occurrence of hurricanes can be taken to be a Poisson process, then the average return interval, or return period between occurrences of a specified water level or greater, is the average recurrence interval divided by the exceedance probability. This produces a water level vs. return period relationship which is often the end result of the stage-frequency study (Figure 6).

The magnitude of error needs to be addressed before the above relationships should be used. The stage-frequency curve would give an exact reproduction of the behavior of the water level if absolutely no errors or uncertainties were introduced. This unfortunately is not possible. The parameterization of the hurricanes by only five parameters may not completely describe the windfield. The windfield and storm surge model may be either biased or inaccurate. These are factors which should be considered but are not the focus of this paper. A remaining problem is in the selection and assignment of parameter value probabilities. In the northern latitudes of the Atlantic Ocean for example, adequately monitored hurricane occurrences are scarce, and developing accurate parameter distributions with limited data becomes difficult. It is through the uncertainty of these parameter distributions that the error estimates on the stage-frequency curve are derived.

#### Bootstrap Method

The bootstrap (1,2) is a recently developed statistical tool which utilizes the computational speed of modern computers. This technique

Figure 4. Tide Plus Surge Convolution Process

Figure 5. Probability Distribution for Total Water Level

Figure 6. Stage-Frequency Curve From Joint Probability Method

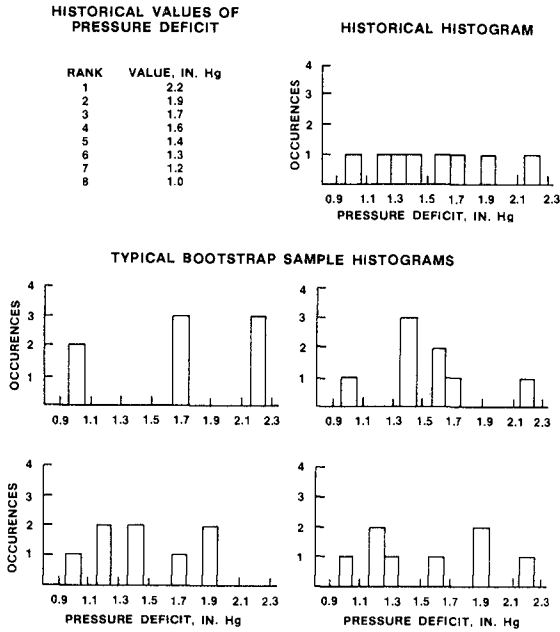

Figure 7. Variability of Synthetic Samples

is used here to develop stage-frequency relationships while accounting for the uncertainties of the parameter distributions due to a finite record length of hurricane occurrences. This section of the paper will give some insight on how the method works.

In the northeast coast of the United States, for example, only eight values of hurricane central pressure deficit have been recorded. The central pressure deficit is the most influential of the five hurricane parameters, and is directly responsible for the intensity, and therefore the surge height produced by the hurricane simulation. A stage-frequency curve developed on only eight values may be unreliable; therefore, the uncertainty inherent in such a small sample must be accounted for. These eight central pressure values can be thought of as being a random sample from a population whose distribution is unknown. It is desirable to estimate the unknown distribution as best possible, as well as calculate the possible difference, or error, between the true and estimated distributions. It is also advantageous if this can be done without the constraint of using a theoretical distribution.

The bootstrap method approximates the unknown population distribution with the historical sample distribution. This is what is done in most joint probability studies. However, instead of having only one historical sample from which to develop distributions, the bootstrap technique proposes to sample from the assumed population many thousands of synthetic "historical" sets. Each synthetic set generated by the bootstrap mimics how the parameter values might have occurred historically, since the synthetic bootstrapped set and the historical set are assumed to have been sampled from the same population. In this manner, the variation of the synthetic distributions about the assumed population can be quantified. The underlying assumption of the bootstrap is that all relationships between the assumed population and the synthetic samples also apply to the actual unknown population and the historical sample.

The bootstrap is performed in the following manner. For our example, the eight historical values are, in effect, placed in a box. A value is then randomly selected from the box, recorded, and replaced. This process continues until eight values, the size of the original set, have been chosen (Figure 7). This set of values constitutes a synthesized sample, from which a probability distribution of the sample can be formed. This new distribution is as likely to exist as the original historical distribution, since they both were assumed to have been sampled from the same population. The above process is repeated over and over, on the order of several thousand times, thus creating a large number of equally likely distributions. The variation among the synthesized distributions is caused by creating distributions from small samples, even though the population distribution is assumed to be known. This variability is not observed with historical sets since only one set of each parameter exists. This variability, estimated through the bootstrap process, indicates that the single historical parameter set should not be taken as an exact representation of the population distribution, but does not show the variability of the sample distributions.

The bootstrap is then applied to the remaining four parameters, creating several thousand synthesized probability distributions for each parameter. The stage-frequency curve discussed earlier was developed from the distributions of the five historical parameter sets. Other stage-frequency curves could just as well be generated from the synthetic parameter distributions. No additional hydrodynamic simulations need to be made in order to create these new curves. The change of a probability distribution for a parameter only changes the probability assigned to the parameter values, not the values themselves.

A new bootstrapped stage-frequency curve is generated by choosing one synthesized probability distribution at random for each parameter. A new probability assignment is made for each parameter value, and a new probability is calculated for each hurricane previously simulated. The tidal convolution process can be by-passed since only the probabilities of the water levels change, not the heights. Finally, a stage-frequency curve is created which can be considered as likely a representation of the true, unknown stage-frequency curve as was the stage-frequency curve generated from historical sample sets. If this process is repeated 1000 times, a family of 1000 such stage-frequency curves will be generated.

It is common for water levels to be determined at return periods of 10, 25, 50, 100, 200, 500 and 1000 years. After the bootstrapping process, 1000 possible values of water level, one from each of the bootstrapped stage-frequency curves, is obtained at each return period. If the 1000 values found at each return period are ranked in decreasing order, the 500th value will be by definition the 50th percentile, or median, value. This value will be the best estimate of the water level for the given recurrence interval. Estimates of confidence intervals can be obtained from other percentile levels. The 90th percent confidence interval can be estimated as the interval between the 95th percentile value (rank 950) and the fifth percentile value (rank 50). When the above process is done at each return period, an estimate of the uncertainty of a stage-frequency curve is obtained (Figure 8). This uncertainty is purely due to the small sample size of the hurricane parameters.

The bootstrap was used to estimate the error in stage-frequency curves during a project performed at the U. S. Army Engineer Waterways Experiment Station by the Coastal Engineering Research Center (CERC) for the U. S. Army Engineer District, New York. The details of the study are found elsewhere (5) and will not be discussed here.

For the study performed at CERC, it was found that 4000 synthetic parameter distributions and 1000 synthetic stage-frequency curves gave very stable results, stability defined as little change in final result with increased number of bootstrapped samples. The stability also increased as the historical sample size increased. The bootstrap procedure is fairly simple to program and implement, and when performed on a CRAY-1 computer, cost less than a single hurricane simulation.

Figure 8. Bootstrapped Stage-Frequency Confidence Intervals

### Summary and Conclusion

A bootstrap procedure has been introduced which estimates the error due to meteorological uncertainty in coastal stage-frequency curves produced by the joint probability method. The procedure consists of assuming that the unknown population distribution for each hurricane parameter is the same as the parameter distribution obtained from historical data. Synthetic parameter distributions are created by repeated sampling from this assumed population. The variation of the synthetic parameter distributions is due to the small sample sizes. Synthetic stage-frequency curves are then generated by randomly selecting a synthetic distribution for each parameter. A large number of these stage-frequency curves are then used to estimate confidence intervals. The bootstrap method is flexible, simple to program, and inexpensive to implement.

### Acknowledgments

The methods developed in this paper were part of a numerical investigation of extreme water levels along the southern coast of Long Island funded by the U. S. Army Engineer District, New York. Permission was granted by the Chief of Engineers to publish this information.

## CHAPTER TWELVE

### Numerical Simulation of Storm Surges by Multi-Level Models

by

Takao Yamashita<sup>1</sup> and Yoshito Tsuchiya<sup>2</sup>, M. ASCE

**Abstract** The numerical simulation of storm surges in shallow bays is investigated by multi-level models such as the 2-level and FE-FD models which are used to consider the velocity profiles in wind-induced currents. These models were applied to hindcast the storm surge caused by Typhoon 7916 in Osaka Bay with the result that the water surface elevations and currents induced by the storm surge were successfully simulated.

#### 1. Introduction

In the recent years, rapid advancement in both the physical sciences for marine modeling and in the numerical calculation techniques for the governing differential equations have made new developments in fields such as storm surges, tides, mixing in the upper ocean and the air-sea interactions possible. We investigate here numerical simulation models of the storm surge which is one of the most complex, large scale and disastrous natural air-sea interaction phenomena in the ocean and coastal zones.

Such numerical calculation techniques have advanced greatly, particularly in the fields of computer-aided engineering and mathematics. Until now, the FEM(Finite Element Method), BEM (Boundary Element Method) as well as the classical FDM(Finite Difference Method) have prevailed as the techniques most used to solve differential equations in fluid dynamics. However, a number of types of numerical schemes have been proposed to carry out such calculations more accurately and stably, particularly in the case of the application of the FDM to a time-evolutional equation.

The physical modeling for storm surges is generally constructed by combining the wind and pressure fields of an atmospheric low pressure area with its accompanying tides and progressive waves of long periods. Assuming incompressive, viscous fluid, the basic equations for storm surges can be described by the Navier-Stokes equations. The most typical modeling is the so-called 1-level model based on depth-integrated equations in which velocity profiles are uniform.

2 Professor, Disaster Prevention Research Institute, Kyoto University, Kyoto 611, JAPAN.

Considering, however, the dynamics of storm surges in partially enclosed shallow water, the flow structure and patterns of induced currents should be three dimensional because of the co-existence of wind driven currents and their return flows. In such regions, not only the nonlinearity of governing equations and complex geometrical features of coastlines but the three dimensionality of flow structures must be taken into consideration, so many types of models have been proposed.

Previous studies of the numerical simulation of storm surges have been made in three directions. The first direction has been to search for optimal schemes for time discretization in the FDM, which has resulted in schemes such as the leap-frog scheme (explicit) and the ADI (Alternating Direction Implicit) scheme. These are usually adopted for their time-efficiency scheme. In the second direction, researchers have made efforts to reproduce coastlines in calculations by using triangular grid systems. Thacker(1979) proposed the irregular-grid, finite-difference techniques for curving coastlines by approximating partial derivatives using the slopes of planar surfaces associated with the triangular components of the grid. This offers the advantages of greater flexibility than the coordinate transformation method (Wanstrath et al(1976)); and greater economy than the finite-element method (Pinder and Gray(1977), Tanaka(1978)), which have been used to include curving coastlines in calculations. The third direction has been to study mathematical modeling in order to introduce the three-dimensionalities of flow features into calculations of storm surges in shallow bays and estuaries. Koutitas and O'Connor(1980), examined the computer modeling of three-dimensional coastal currents induced by winds by the application of a composite finite-element/finite-difference procedure (referred to here as it the FE-FD model). The authors(1982) have modified the FE-FD model into a 3-level model which is more economical and more applicable generally than the previous multi-level models.

In this paper, we discuss the applicabilities and present limitations of the multi-level models by comparison of the theoretical results generated and the actual currents and tides observed at the storm surge caused by Typhoon 7916 in Osaka Bay, Japan.

## 2. Multi-Level Models

### 2.1 The 2-level model

The vertical distribution of the horizontal velocity component of wind-induced current in partially enclosed shallow water have been investigated theoretically and experimentally. It has been shown that there is a conversion point of mean velocity in the range from 0.2 to 0.4 in nondimensional depth (Baines and Knapp(1965)). This suggests that bottom stresses evaluated in the 1-level model are questionable in their magnitude and direction. To overcome these inconsistencies, the authors (8) have proposed the 2-level model, in which the upper level represents the wind-driven current and the lower, the return flow.

Using the definition sketch and notations for the 2-level model shown in Figure 1, the model equations for both the upper and lower levels, and for the continuity equation are written as

Figure 1. Definition sketch and notations for the 2-level model.

a) for the upper level

$$\frac{\partial M_u}{\partial t} + (NL)_{ux} + (uw)_i = fN_u - gH_u \frac{\partial \zeta}{\partial x} - \frac{1}{\rho_w} \frac{\partial p}{\partial x} + \frac{\tau_{sx}}{\rho_w} - \frac{\tau_{ix}}{\rho_w} + (HM)_u \quad (1)$$

$$\frac{\partial N_u}{\partial t} + (NL)_{uy} + (vw)_i = -fM_u - gH_u \frac{\partial \zeta}{\partial y} - \frac{1}{\rho_w} \frac{\partial p}{\partial y} + \frac{\tau_{sy}}{\rho_w} - \frac{\tau_{iy}}{\rho_w} + (HM)_u \quad (2)$$

b) for the lower level

$$\frac{\partial M_l}{\partial t} + (NL)_{lx} - (uw)_i = fN_l - gH_l \frac{\partial \zeta}{\partial x} - \frac{1}{\rho_w} \frac{\partial p}{\partial x} + \frac{\tau_{ix}}{\rho_w} - \frac{\tau_{bx}}{\rho_w} + (HM)_{lx} \quad (3)$$

$$\frac{\partial N_l}{\partial t} + (NL)_{ly} - (vw)_i = -fM_l - gH_l \frac{\partial \zeta}{\partial y} - \frac{1}{\rho_w} \frac{\partial p}{\partial y} + \frac{\tau_{iy}}{\rho_w} - \frac{\tau_{by}}{\rho_w} + (HM)_{ly} \quad (4)$$

where the discharges per unit width are defined by

$$M_u = \int_{-h_i}^{\zeta} u dz, \quad N_u = \int_{-h_i}^{\zeta} v dz, \quad M_l = \int_{h_i}^h u dz, \quad N_l = \int_{h_i}^h v dz$$

and  $H_u = \zeta + h_i$ ,  $H_l = h - h_i$ ,  $(NL)$  and  $(HM)$  indicate the nonlinear and horizontal mixing terms respectively,  $(uw)_i$  and  $(vw)_i$  are the mass fluxes at the interface, and  $f$  is the Coriolis parameter. The shearing stresses at the sea surface and the sea bottom are expressed in quadratic form, using the drag coefficients  $C_D$  and  $C_f$ , as

$$\left. \begin{aligned} \tau_{sx} &= \rho_w C_D W_x \sqrt{W_x^2 + W_y^2}, & \tau_{sy} &= \rho_w C_D W_y \sqrt{W_x^2 + W_y^2}, \\ \tau_{bx} &= \rho_w C_f U_l \sqrt{U_l^2 + V_l^2}, & \tau_{by} &= \rho_w C_f V_l \sqrt{U_l^2 + V_l^2} \end{aligned} \right\} \quad (5)$$

The shearing stress at the interface is given in the linear form.

$$\tau_{ix} = -2C_i \rho_w \nu_i (U_u - U_l)/h, \quad \tau_{iy} = -2C_i \rho_w \nu_i (V_u - V_l)/h \quad (6)$$

where,  $\nu_i$  is the eddy viscosity. The coefficient  $C_i$  of Eq.(6) has been determined as 3/2, assuming a steady, uniform current in the enclosed domain with uniform water depth.

The continuity equation is given by

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x}(M_u + M_l) + \frac{\partial}{\partial y}(N_u + N_l) = 0 \tag{7}$$

The model equations mentioned can be integrated numerically by the finite-difference technique.

2.2 The FE-FD model

Using the Navier-Stokes equation for fluid elements and the continuity equations for a water column, neglecting the horizontal diffusion of momentum and using the notations shown in Figure 2, where  $H$  is the total water depth,  $h$  the water depth in the M.W.L. and  $\zeta$  the water elevation induced by the storm surge, the fundamental equations can be described as

Figure 2. Definition sketch and notations for the FE-FD model.

$$L_u(x, y) = \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} - fv + g \frac{\partial \zeta}{\partial x} - \nu_i \frac{\partial^2 u}{\partial z^2} = 0 \tag{8}$$

$$L_v(x, y) = \frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + fv + g \frac{\partial \zeta}{\partial y} - \nu_i \frac{\partial^2 v}{\partial z^2} = 0 \tag{9}$$

The continuity equation is written as

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} \left( \int_{-h}^{\zeta} u dz \right) + \frac{\partial}{\partial y} \left( \int_{-h}^{\zeta} v dz \right) = 0 \tag{10}$$

As to the three-dimensional problem, the coastal area is first covered by a regular-grid network in the x-y plane, and the water depth is divided into the same number of elements in the vertical water column. Next, the finite-element method is applied to Eqs.(8) and (9) and the finite difference method of fractional step is applied to Eq.(10) to obtain the components of currents  $(u_k(x, y), v_k(x, y))$  at the

nodal point  $k$  and water surface  $\zeta(x,y)$ . In the case of the three-level model, the equations of motion are, consequently, written in matrix form, by

$$\{A_x\} \cdot \{u\} = \{B_x\} \text{ FINAL-BRACKET, } \quad \{A_y\} \cdot \{v\} = \{B_y\} \quad (11)$$

in which, for example, the matrices and vectors of the x-components are respectively expressed as

$$\{A_x\} = \begin{bmatrix} l_{x,1ij}/3\Delta t & l_{x,1ij}/6\Delta t & 0 \\ l_{x,1ij}/6\Delta t & (l_{x,1ij}+l_{x,2ij})/3\Delta t & l_{x,2ij}/6\Delta t \\ 0 & l_{x,2ij}/6\Delta t & l_{x,2ij}/3\Delta t \end{bmatrix} \quad (12)$$

$$\{u\} = \begin{bmatrix} u_{1j}^{n+1} \\ u_{2j}^{n+1} \\ u_{3j}^{n+1} \end{bmatrix} \quad \{B_x\} = \begin{bmatrix} B_{1x} \\ B_{2x} \\ B_{3x} \end{bmatrix} \quad (13)$$

where  $B_i$  is the vector of known variables calculated at the time step of  $n-1/2$  in the fractional method, whose components include the atmospheric pressure gradients, and the shearing stresses at the water surface, interfaces and bottom.

### 3. Hindcast of Storm Surge Caused by Typhoon

#### 3.1 The calculation conditions

Using the 2-level and FE-FD models, the storm surges caused by Typhoon 7916 are hindcasted in the region shown in Figure 3. This typhoon which passed through Osaka Bay on November 30, 1979 caused peculiar tidal changes in the inner part of the bay. The tidal records measured at 9 points along the bay are shown in Figure 4. Resurgences are remarkable immediately after the peak of storm surge.

The computation was made by the leap-frog staggered system, in which the horizontal grid spaces were chosen as  $\Delta s=1.5$  km in order to approximately cover the two channels in computation, and time space  $\Delta t=20$  sec. And the depths at two channels were adjusted to cover the same area of the cross section. Considering that the mean water depth of the bay is 28m, the upper level depth in the 2-level model is determined as  $h_i = 8$  m. The open boundary conditions are given by the surface elevations which were estimated by interpolation of the observed anomaly of meteorological tides at the points Nushima, Kainan, Akashi and Higashi-Futami, and the so-called fixed boundary conditions are used along the coastlines.

It is important in numerical modeling for storm surges to determine the unknown physical parameters such as the drag-coefficients at the water surface  $C_b$ , the at the bottom  $C_f$ , the friction coefficient  $C_f$ , and the eddy viscosity  $\nu_i$ , which are expressed practically as,

Figure 3. The computation region.

Figure 4. Observed tidal records showing anomalies in meteorological tides caused by Typhoon 7916 in Osaka Bay.

$$(C_{x0}, C_{y0}) = 1.50 \times 10^{-3} (w_x^{0.19}, w_y^{0.19}) \quad \text{for } w_x, w_y \leq 8 \text{ (m/sec)} \quad (14)$$

$$(C_{x0}, C_{y0}) = 2.04 \times 10^{-4} (w_x^{0.74}, w_y^{0.74}) \quad \text{for } w_x, w_y > 8 \text{ (m/sec)} \quad (15)$$

respectively and

$$C_f = 0.0026 \quad , \quad \nu_i = 0.01 \text{ (m}^2\text{/sec)} \quad (16)$$

where Eqs. (14) and (15) for the drag coefficient at the surface are those proposed by Mitsuyasu (1981).

### 3.2 Computation of tides

The dominant tides in the Seto Inland Sea including Osaka Bay are the  $M_2$  semi-diurnal lunar tide which is a semi-diurnal lunar tide coming in through the Kitan Channel in the south of the bay which flows out through the Akashi Channel in the west. The duration of the tide is about 2 hours and its amplitude reduces to 1/3 in the bay. The  $S_2$  tide is also similar to the  $M_2$  in these tendencies. We here consider only the semi-diurnal tides ( $M_2$ ,  $S_2$ ) whose amplitudes and phases are listed in Table 1.

Table 1 Amplitudes and phases of tides

Points	Amplitudes ( $M_2 + S_2$ )	Phases (deg.)
Nushima	0.629 m	179.8°
Kainan	0.661 m	188.2°
Higashi-Futami	0.285 m	294.6°
Ei	0.334 m	327.7°

The computation of tides was carried out by the 1-level model for four periods to obtain the initial flow conditions prior to the computation for storm surges.

### 3.3 Typhoon model

The wind and pressure gradients of a typhoon are expressed practically by Fujita model as

$$\left. \begin{aligned} \frac{\partial P}{\partial x} &= -\frac{P_0 r_0 x}{(r^2 + r_0^2)^{3/2}}, & \frac{\partial P}{\partial y} &= -\frac{P_0 r_0 y}{(r^2 + r_0^2)^{3/2}} \\ W_x &= C_1 F_x - C_2 G_x, & W_y &= C_1 F_y + C_2 G_y \end{aligned} \right\} \quad (17)$$

In this case, the wind field associated with the moving speed of a typhoon  $(V_x, V_y)$  (m/sec) and the baroclinic wind field are expressed, respectively as

$$\left. \begin{aligned} F_x &= V_x \exp\left(\frac{-r\pi}{5 \times 10^5}\right), & F_y &= V_y \exp\left(\frac{-r\pi}{5 \times 10^5}\right) \\ G_x &= \left(\sqrt{3y/2+x/2}\right) \left\{ \sqrt{f^2/4 + (\rho_w/\rho_a)gP_0 r_0 / (r_0^2 + r^2)^{3/2}} - f/2 \right\}, \\ G_y &= \left(\sqrt{3x/2-y/2}\right) \left\{ \sqrt{f^2/4 + (\rho_w/\rho_a)gP_0 r_0 / (r_0^2 + r^2)^{3/2}} - f/2 \right\} \end{aligned} \right\} \quad (18)$$

where  $r = \sqrt{x^2 + y^2}$  is the distance from the center of typhoon,  $P_0$  (m) the pressure head corresponding to the atmospheric pressure drop, and  $r_0$ ,  $C_1$ ,  $C_2$  are the typhoon parameters for which values for Typhoon 7916 were 60(km), 0.6 and 0.6, respectively.

### 3.4 Computations for the storm surge

#### a) The 2-level model

Using the finite-difference method, the computation of storm surge was performed by the 1- and 2-level models. The calculated anomalies in meteorological tides at points, Kobe, Osaka and Sumoto are shown in Figure 5 with the astronomical tides. Figure 6 shows the flow patterns calculated by the 2-level model. We conclude that the results obtained by the 2-level model agree well with the observed tides around the peak of storm surge, including its forerunners. Disagreement at the resurgences appearing immediately after the peak can be seen in the results of both models, which may be caused by the rapid changes in its pressure fields. This fact has already been suspected by the authors(1981).

The current measurements have been carried out at point A shown in Figure 3, using magnetic current meters at three points of which the depths are 3, 9 and 16m. Comparison between the calculated and observed west-east components of currents at the point 3m deep is shown in Figure 7. In contrast to the agreement for surface elevation, both currents calculated by the 1- and 2-level models do not agree well with the observations at point A. The effects of the 2-level modeling are, however, remarkable in this figure in that changes in current velocities with time calculated by the 2-level model approach those observed.

(b) At 0:00 Oct. 1

Figure 6. Flow patterns computed by the 2-level model.

Figure 7. Comparison of calculated and observed east-west velocity components at point A.

b) The FE-FD model

Koutitas and O'Connor have made reference to the importance of an accurate estimate of the value for the vertical eddy viscosity  $\nu_i$  when applying the FE-FD model to a wind-induced flow. It is important, of course, to make clear its value physically and empirically. In this paper, the FE-FD modeling procedure is employed as a tool of new approach to establish a 3-level model which has simplicity and generality, so that the same values for  $\nu_i$  used in the 2-level model can be used, without further discussion. The ratios of thickness of the upper, middle and lower layers to the water depth at each level (element) are set respectively as 3:6:1, and the shearing stresses at the surface are determined as

$$\left. \begin{aligned} S_x &= \rho_a C_D W_x \sqrt{W_x^2 + W_y^2} = \rho_a \nu_i \left. \frac{\partial u}{\partial z} \right|_{\text{surface}}, \\ S_y &= \rho_a C_D W_y \sqrt{W_x^2 + W_y^2} = \rho_a \nu_i \left. \frac{\partial v}{\partial z} \right|_{\text{surface}} \end{aligned} \right\} \quad (19)$$

In addition the non-slip condition can be used at the bottom because the bottom shearing stresses can be automatically determined from the velocity gradient. This simplicity is one of remarkable features of the model.

The computational results for water surface elevations and currents in the vertical direction (east-west and north-south components) at point A are shown in Figures 8 and 9, respectively. Comparison with the results of the 1- and 2-level models shows that the water surface elevations are over-estimated at the inner part of the bay. In Figure 9, the solid lines show the velocity profiles of the currents due to the anomalies in the meteorological tides and the dotted lines, those caused by the storm surge. The flow patterns in the upper and lower levels at 13hr (actually 22:00 Sept. 30) and 15hr (actually 0:00 Oct. 1) are shown

Figure 8. Surface disturbances computed by the FE-FD model at point A.

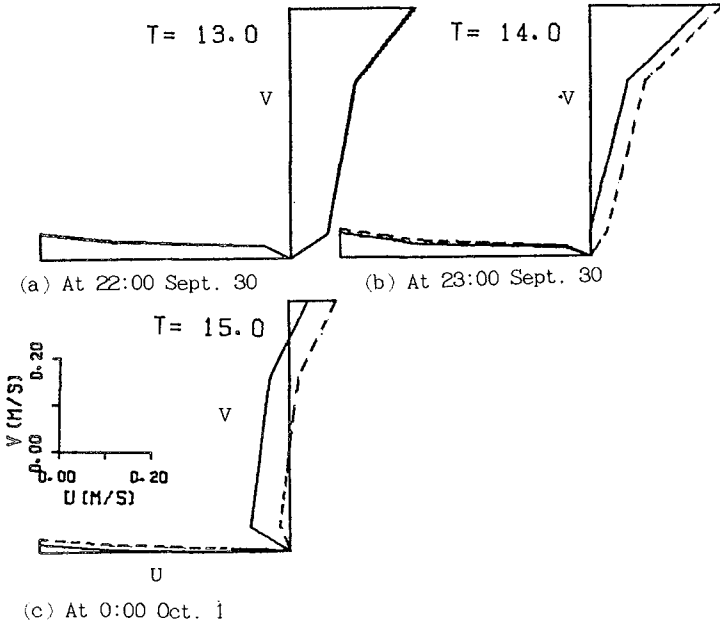

Figure 9. Velocity distributions calculated by the FE-FD model at point A.

in Figure 10, in which opposite currents in the upper and lower levels are recognized clearly, but no opposite ones exist in the results from the 2-level model as shown in Figure 6. Comparison of the calculated and observed current vectors is shown in Figure 11, in which the solid lines are the observed current vectors, the dotted lines calculated ones by the FE-FD model. 1-L and 2-L express the vector obtained by the 1- and 2-level models, respectively. The current vectors calculated by the FE-FD model are in better agreement with the observed ones than those calculated by the 1- or 2-level models, however the strong current to the southeast observed at 15hr (actually at 0:00 Oct. 1) is still not completely simulated.

#### 4. Discussions and Conclusions

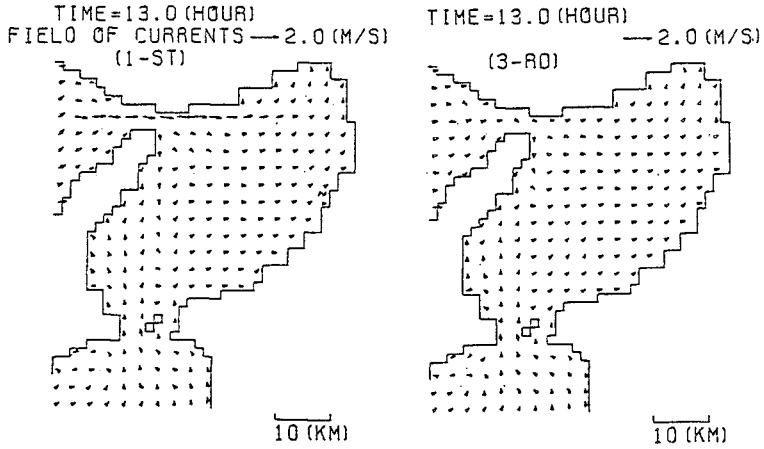

Thus far, we have presented the multi-level model numerical calculation methods and the results of storm surge hindcasting, with considerations. The multi-level models used in this paper are fundamentally based on the concept of introducing the effects of three-dimensionality of currents into the calculations for the storm surge.

Using the 2-level model, which is a modification of the 1-level model, water surface elevations and currents caused by storm surges in shallow bays can be simulated by estimating the shearing stresses at the interface between the upper and lower levels more reasonably. As the above formulation, of course, depends on the accuracy of the eddy viscosity estimate, the optimal coefficients in the model should be found practically by applying the model proposed to many cases of storm surges.

The FD-FE model proposed here deals with the modified 3-level model which has more simplicity and flexibility than previous multi-level models. This model is so economical in calculation time that the actual prediction of storm surges including their induced-currents as well as their associated tides even without using a so-called "super computer" may be feasible in the near future. But this model as yet requires practical improvement to determine reasonable formulas for shearing stresses at the bottom and the water surface.

It is concluded that the multi-level models are applicable to the numerical prediction of storm surges in shallow bays. As to further developments in the multi-level models, we think that it is possible and useful to introduce the BEM (Boundary Element Method) into this model instead of the finite-element technique to calculate the equations of motion and the irregular-grid finite-difference method for solving the continuity equation.

We are grateful to Messrs. T. Oka and T. Hiraishi, former graduate students for their kindest assistance in the numerical computations. This study was supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan, under Grant No.302027.

## CHAPTER THIRTEEN

### NUMERICAL SIMULATION OF STORM SURGES INDUCED BY TROPICAL STORMS IMPINGING ON THE BANGLADESH COAST

S.K. Dube<sup>1</sup>, P.C. Sinha<sup>2</sup>, and G.D. Roy<sup>3</sup>

**ABSTRACT:** In the present paper a vertically integrated coastal zone numerical model has been described for the simulation of the surges generated by the tropical storms striking the Bangladesh coast. The model is fully nonlinear and uses a conditionally stable explicit finite-difference scheme for solving the relevant equations of motion. In this model the analysis area extends from 87°E to 93°E along the south coast of Bangladesh and there are three open-sea boundaries situated along 87°E, 93°E and 19°N. The model utilises a curvilinear boundary treatment to represent the coastline and uses a non-uniform off-shore grid spacing adjacent to the coastal boundary. This allows an increased resolution near the Bangladesh coast.

Using a forcing wind-stress distribution representative of the 1970 Chittagong cyclone, we compare the model predicted surges with the observed sea-surface elevations along the Bangladesh coast. The predicted peak surge elevation above mean sea level compares well with the observed values at Chittagong port. A comparison of the results has also been made with those obtained from the corresponding model having uniform off-shore grid spacing.

#### INTRODUCTION

The tropical storms and the associated surges are very common occurrences along the coastal regions of Bangladesh. These systems directly affect the life and property of the habitants which is a heavy burden on the country's exchequer. About 500,000 lives were lost in one of the most severe cyclones that hit Bangladesh (then East Pakistan) in November, 1970. There can be little doubt that the number of casualties would have been considerably lower if the storm surges could have been predicted well in advance to allow effective warnings in the threatened areas.

In an earlier paper, Dube et al.(4) have developed a vertically integrated coastal zone numerical model for the simulation of storm

surges along the Bangladesh coast. This model uses a staggered finite-difference grid on which the sea-surface elevation and components of velocity are computed at different computational points. The sea-surface elevations are not directly carried out at points along the coastline. Thus, the coastal surge elevations are derived by extrapolating from the computed elevations of those adjacent off-shore grid points at which they are carried. In this model the grid spacing across the coastal zone is uniform and relatively coarse. Consequently, the extrapolated coastal surge elevations may not be very realistic as these are dependent on the elevations computed directly at those off-shore points which are far away from the coast. This deficiency may be overcome by overall increasing the off-shore resolution in the model which would lead to a substantial increase in the computational overheads and is, in any case, unnecessary far away from the coastline.

Accordingly, in the present paper, the model described by Dube et al.(4) has been extended to allow for an increased resolution near the Bangladesh coast. The noteworthy difference in our method from those earlier used by Jelesnianski (5), Das et al. (1) and Johns and Ali (6) is that it does not depend on the patching together of computational regions having different uniform grid spacings. Our approach is analogous to that used by Johns et al.(8) for the simulation of surges along the east coast of India. The model uses a continuously contracting non-uniform off-shore grid spacing adjacent to the coastal boundary which permits an increased resolution near the Bangladesh coast.

The model covers an analysis area lying between 87°E and 93°E, and between 19°N and the south coast of Bangladesh. There are three open-sea boundaries situated along 87°E, 93°E and 19°N. Numerical experiments performed with this model for simulating the surge generated by the November 1970 Chittagong cyclone lead to a surge response along the Bangladesh coast which is in good agreement with the observed values.

FORMULATION OF THE MODEL

The sphericity of the earth's surface is neglected and we use a system of rectangular Cartesian coordinates in which the origin, *o*, is in the equilibrium level of the sea-surface. *ox* points towards the south, *oy* points towards the east and *oz* is directed vertically upwards. The displaced position of the sea-surface is given by  $z = \zeta(x, y, t)$  and the position of the sea-floor by  $z = -h(x, y)$ . A northern coastal boundary (the south coast of Bangladesh) is situated at  $x = b_1(y)$  and the southern open-sea boundary is at  $x = b_2(y)$ . The western and the eastern open-sea boundaries are at  $y = 0$  and  $y = L$  respectively. This configuration is shown in Fig.1.

The basic equations of continuity and momentum in the vertically integrated form may then be given by

$$H_t + (Hu)_x + (Hv)_y = 0 \tag{1}$$

$$u_t + uu_x + vv_y - fv = -g \zeta_x + \frac{1}{H\rho} \{ \tau_x^\zeta - c_f \rho u(u^2 + v^2)^{\frac{1}{2}} \} \tag{2}$$

$$v_t + uv_x + vv_y + fu = -g \zeta_y + \frac{1}{H\rho} \{ \tau_y^\zeta - c_f \rho v(u^2 + v^2)^{\frac{1}{2}} \} \tag{3}$$

Fig.1 The analysis area and idealised track,  
 -.-.- open-sea boundaries  
 o 5 hourly positions of the centre of the cyclone (on the track)

where  $f$  denotes the Coriolis parameter, the pressure is taken as hydrostatic and  $H$  is the total depth  $\zeta + h$ . ( $\tau_x^\zeta, \tau_y^\zeta$ ) denotes the applied surface wind-stress and the bottom stress is parameterised in terms of a quadratic law.  $\rho$  denotes the water density and the friction coefficient,  $c_f$ , is taken as  $2.6 \times 10^{-3}$ .

Following Dube et al.(4), the appropriate boundary conditions are given by

$$u - v (b_1)_y = 0 \quad \text{at } x = b_1(y) \quad (4)$$

$$u - v (b_2)_y - (g/h)^{1/2} \zeta = 0 \quad \text{at } x = b_2(y) \quad (5)$$

$$v + (g/h)^{1/2} \zeta = 0 \quad \text{at } y = 0 \quad (6)$$

$$v - (g/h)^{1/2} \zeta = 0 \quad \text{at } y = L \quad (7)$$

COORDINATE TRANSFORMATION

In order to facilitate the numerical treatment of an irregular boundary configuration and to incorporate increased resolution adjacent to the coastline, we introduce the following coordinate transformations (Das et al.(3)).

$$\xi = \{ x - b_1(y) \} / b(y) \tag{8}$$

$$\eta = \xi + \epsilon \ln(1 + \xi / \xi_0) \tag{9}$$

where  $b(y) = b_2(y) - b_1(y)$  is the breadth of the basin and,  $\epsilon$  and  $\xi_0$  are disposable parameters.

Taking  $\eta$ ,  $y$  and  $t$  as new independent coordinates, Eqs.(1)-(3) may be transformed to

$$(b \xi)_t + F(\eta) (bU)_\eta + \tilde{v}_y = 0 \tag{10}$$

$$\begin{aligned} \tilde{u}_t + F(\eta) (U\tilde{u})_\eta + (v\tilde{u})_y - f\tilde{v} = & -gHF(\eta) \zeta_\eta + b \tau_x^\zeta / \rho \\ & - c_f \tilde{u} (u^2 + v^2)^{1/2} / H \end{aligned} \tag{11}$$

$$\begin{aligned} \tilde{v}_t + F(\eta) (U\tilde{v})_\eta + (v\tilde{v})_y + f\tilde{u} = & -gH \{ b \zeta_y - (b_{1y} + \xi b_y) \\ & F(\eta) \zeta_\eta \} + b \tau_y^\zeta / \rho - c_f \tilde{v} (u^2 + v^2)^{1/2} / H \end{aligned} \tag{12}$$

where,

$$bU = u - (b_{1y} + \xi b_y)v \tag{13}$$

$$(\tilde{u}, \tilde{v}) = bH (u, v) \tag{14}$$

$$F(\eta) = 1/\xi_\eta = 1 + \epsilon / (\xi + \xi_0) \tag{15}$$

The boundary conditions (4) and (5) become

$$U = 0 \quad \text{at } \eta = 0 \tag{16}$$

$$bU - (g/h)^{1/2} \zeta = 0 \quad \text{at } \eta = \eta_m \tag{17}$$

where  $\eta_m = 1 + \epsilon \ln(1 + 1/\xi_0)$ .

Eqs. (10)-(12) form the basic set for the numerical solution process.

NUMERICAL PROCEDURE

For the solution of the Eqs. (10)-(12) subject to the relevant boundary conditions, a conditionally stable explicit finite-difference scheme with a staggered grid is used. The details of the discretization procedure and the finite-difference grid selection are completely analogous to those reported in Das et al.(3).

The stability characteristics of this computational scheme have

been discussed in detail by Johns et al.(7). In fact, stability is only conditional upon the time step being limited by the space increment and the gravity wave speed.

#### NUMERICAL EXPERIMENTS

Numerical experiments are performed by using the analysis area which extends from 87°E to 93°E along the south coast of Bangladesh and there are three open sea boundaries situated along 87°E, 93°E and 19°N (Fig.1). Thus, on an average, the width of the coastal zone is about 168 miles (270 km) while the east-west extent,  $L$ , of the analysis area is about 375 miles (600 km). An idealised cyclone moves along the indicated straight-line track with uniform speed of translation for about 21 hours before landfall near Chittagong port (Fig.1). The five hourly positions of the centre of the cyclone is also indicated in the figure.

The wind field associated with this cyclone is simulated by applying the following empirically based formula suggested by Jelesnianski (5)

$$V = \begin{cases} V_0 (r/R)^{3/2} & \text{for } r \leq R \\ V_0 (R/r)^{1/2} & \text{for } r > R \end{cases}$$

where  $V_0$  is the maximum sustained wind,  $R$  the radius of maximum wind and  $r$  is the distance from the centre of the cyclone. Following Das et al.(1), we take

$$V_0 = 164 \text{ ft s}^{-1} (50 \text{ ms}^{-1}) \text{ and } R = 25 \text{ miles (40 km)}.$$

The optimum grid resolution in the computational plane is chosen with  $m = 10$ ,  $n = 21$ ,  $\epsilon = 0.04$  and  $\xi_0 = 0.001$ . Thus,  $\eta_m \approx 1.27$  and  $\Delta\eta \approx 0.14$ . This is obtained as a result of several experiments performed with the 1970 Chittagone cyclone for testing the adequacy of the resolution. It may be seen that with the above selection of parameters, the first off-shore grid point at which the elevation is computed is, on an average, about 3 miles (5 km) from the coastline and  $\Delta y \approx 18.5$  miles (30 km).

In our numerical experiments we prescribed an initial state of rest and integrated the governing equations ahead in time for a period of 50 hours. A time-step of 3 min. was found to be consistent with the computational stability. We also considered the sea-surface response during several hours after landfall when the system starts to enter the resurgence phase.

#### RESULTS AND DISCUSSIONS

The surges associated with the 1970 Chittagong cyclone have been computed by using a number of off-shore grid resolutions. However, the results are presented only for two resolutions corresponding to  $m = 10$ ,  $n = 21$  and  $m = 20$ ,  $n = 21$  for comparison and for an optimal selection of the grid size.

In Fig.2 we give the distribution of the predicted maximum sea-surface elevation (peak surge envelope), its time of occurrence and the

Fig.2 Maximum predicted surge and its time of occurrence  
 Place of landfall ● Time of landfall (on time axis)  
 — Peak surge envelop ( $m=10$ ) --- Time of occurrence ( $m=10$ )  
 —●— Peak surge envelop ( $m=20$ ) —●— Time of occurrence ( $m=20$ )  
 —○— Peak surge envelop ( $m=20$ , obtained in (4))  
 —○— Time of occurrence ( $m=20$ , obtained in (4))

observed surge along the Bangladesh coast. It may be seen from the figure that by increasing the number of off-shore grid points from 10 to 20 the maximum change in the peak surge values at various coastal stations is within two percent. Further, the time of occurrence of the peak surge in the two cases is almost same. A further increase in the number of off-shore grid points also show similar results.

The adequacy of the alongshore resolution has also been tested by increasing the value of  $n$ , which has not resulted in any significant change in the elevations and their time of occurrence along the coastal stations.

These tests on the selection of optimum resolution indicate that there is insignificant quantitative change in the results for the two resolutions (10X21 and 20X21). However, the computer overheads in the later case are much higher. Keeping these facts in view, it is appropriate to use a 10X21 grid for the present numerical experimentation.

The Fig.2 provides an idea of the coastal stretch upto which the significant surge may be expected. It may be seen from the figure that the maximum surge height of 21.6 ft (6.6m) is predicted at Maijdi which is about 25 miles (40 km) to the left of the landfall. A maximum surge of about 18.0 ft (5.5m) is predicted at Chittagong port (about 17.5 miles (28 km) to the right of the landfall point) at 0540 hrs BST on 13 November, 1970. A peak elevation of 19.7 - 29.5 ft (6-9 m) was reported at this tidal station on the morning of 13 November while according to the Tide-Table the predicted astronomical tide was 5.9 ft (1.8m) at about the same time. Thus, if we assume that the total sea-surface elevation is the result of purely linear superposition of surge and tide, it may be noted that the observed sea-surface elevation at Chittagong was in excess of 13.8 - 23.6 ft (4.2 - 7.2m) over the usual high-tide (Das et al.(2)). Hence, it may be seen that our predicted surge of 18.0 ft (5.5m) is in good agreement with the observed range of maximum surge of 13.8 - 23.6 ft (4.2 - 7.2 m) at Chittagong.

Further, it is worthwhile to compare the results of the present study with those obtained by Dube et al.(4) who have used a uniform off-shore grid spacing for the simulation of surges along the Bangladesh coast. It may be seen from Fig.2 that there is significant improvement in the computed surge heights by using a non-uniform off-shore grid spacing which allows an increased resolution adjacent to the coast.

Fig.3 depicts the time variation of the storm surge at four stations along the Bangladesh coast. All the three stages of the surge-forerunner, the main surge, and the resurgence phase may clearly be seen from the temporal variation of the coastal sea-surface elevations. The maximum surge height of 21.6 ft (6.6m) is predicted at Maijdi. The peak occurred at 0240 hrs BST on the morning of 13 November. This main surge remains for a very short period (about 30 min.) and is followed by the resurgence phase. During resurgence phase the sea-surface elevation falls rapidly from its maximum value and becomes negative after about the next 6 hours period and a sea-surface depression of 10.2 ft (3.1m) is predicted at 1700 hrs BST on 13 November.

The predicted surge height at Chittagong is about 18.0 ft (5.5m) which occurs in the morning of 13 November at about 0540 hrs BST. It may be seen that the time of occurrence of the peak surge is in exce-

llent agreement with the time of landfall. This main surge persists for about half an hour before falling rapidly and becoming negative at 1430 hrs BST. At Chittagong, a maximum sea-surface depression at 7.2ft (550mm) is predicted at about 1800 hrs BST on 13 November with a subsequent increase in the water height leading to a depression of about 15 cm in the early morning of 14 November.

Fig. 3. Time variation of the predicted sea-surface elevation at four coastal stations.

● Time of landfall

At Bhola Island which is about 68 miles (110 km) to the west of landfall, the sea-surface elevation rises gradually to attain its peak value of about 18.0 ft (5.5m) at 0000 hrs BST on 13 November. Here again the main surge is short-lived (about 40 min.) and the surge becomes negative within 6 hours of the occurrence of its peak value. A sea-surface depression of about 10.8 ft (3.3m) is predicted at 1230 hrs BST on 13 November.

The predicted time history of the surge at Cox's Bazar which is about 87 miles (140 km) to the SE of landfall, indicate a maximum sea-surface elevation of 10.5 ft (3.2m) in the morning of 13 November at about 0500 hrs BST. This main surge is again very short-lived and it falls gradually to become negative in the afternoon of 13 November.

#### Abstract

This paper presents the results of a study on the frequency of occurrence of storm surge levels in the river Scheldt at Antwerp, related to the design of a storm surge barrier and the evaluation of the dike safety in the Scheldt basin.

The basic principles of the extreme value distribution methods, the joint probability methods and simulation models are examined.

A new technique, based upon the simulation of storms by variables characterizing the resulting surge is proposed.

Results are compared with those of other methods.

#### 1. Introduction

This study concerns a statistical evaluation of extreme waterlevels on the river Scheldt near Antwerp, for which the highest registered level is NKD+8m with an "estimated frequency of 1/100 years, based upon extrapolation of data along the Dutch North Sea coast.

Due to hydrodynamic and hydraulic actions in the estuary, the accuracy of such frequencies is poor, and since enough observations are available for Antwerp (1902 - present), the frequency of occurrence of storm levels was investigated for this city itself.

At this moment all levels exceeding NKD+6.5m are called "storm surges" (till 1954 that datum was NKD+6.0m).

This study doesn't analyse tidal characteristics either in a statistical way, nor in a fundamental, physical and hydrodynamic way.

#### 2. Analysis of storm surge levels

The different components of a surge level on the river Scheldt are represented in Fig. 1.

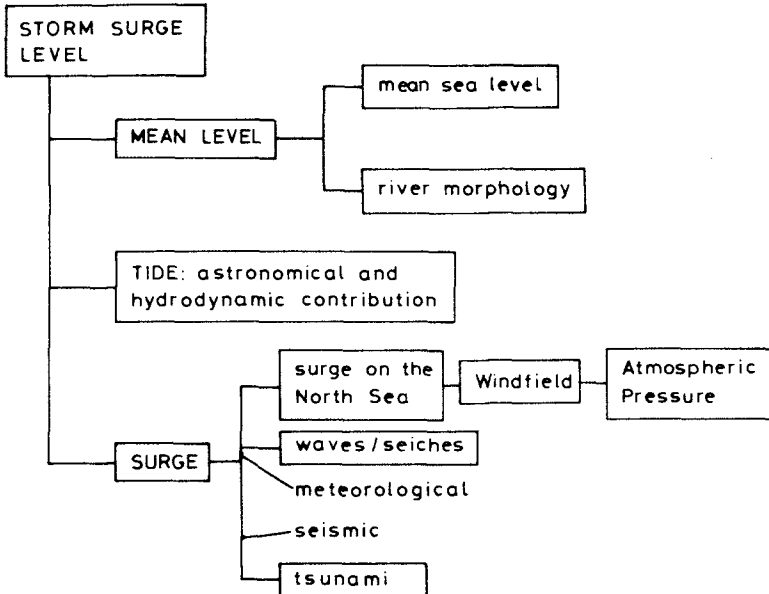

Fig.1: Components of storm surge level

### 2.1. Mean level

The variation of mean level, dealt with in this paragraph consists of periodic and secular changes, in which periodic means 'with a period of at least one year', thus excluding diurnal and shorter-period oscillations, classified as tidal effects. The variation in mean level, often substituted for by 'mean tidal level', is caused by mean sea level variations and by morphological changes of the river, due to the dynamic physical processes in the river and due to human interventions (35, 40). The most important causes of mean sea level variation are: changes in the total water balance, movements in the land reference level (bench mark), time variations in the atmospheric forces (wind stress and air pressure), time variations in the oceanographic forces (temperature, salinity, currents) and finally long period astronomical tides. For a description of these phenomena reference is made to specific geophysical literature (24, 35, 37, 39). With a view to obtain an homogeneous set of water level data along an estuary, one has to investigate not only mean sea level variations, but (depending upon the calculation procedure to determine frequencies of occurrence) also trends in annual maxima and in tidal amplitude must be considered (see § 3.1.).

## 2.2. Tidal movements

In the river Scheldt tidal activity is a cooscillating tide in an estuary, propagated in the basin and caused by tidal movements on the North Sea. The principal constituents are the M2 lunar semidiurnal tide, with a period of 12.42 hours and the S2 solar semidiurnal tide (period = 12h). Furthermore it must be mentioned that both observed and predicted tidal levels consist of pure "astronomical tides" and hydrodynamic influences.

## 2.3. Surge elevation

Surges on the river Scheldt are mainly caused by meteorological activities, acting on the water mass in the North Sea. For a description of the sources, physical phenomena and mathematical calculation schemes we refer to literature (32, 42). Waves and oscillations have neglectable influence on resulting water levels, while seismic surges didn't occur till now.

## 2.4. Interaction of surge and tide

The interaction effects between surge and tide are caused by frictional resistance and variations in the celerity of waves (due to differences in waterdepth), modifying surges in tidal regions (2, 15, 21, 28, 36, 38, 48).

The main conclusions of several investigators are :

Keers deduced that the interaction increases linearly with the surge height and that the degree of interaction is quite correlated with the tidal amplitude and with the ratio of the amplitude and mean waterdepth (21). Banks stated that the most important interaction is between the M2 semidiurnal tide and the surge (2). Although Pugh and Vassie (30) concluded that any interactions were of second order, so that surge and tide can be treated statistically independent, it seems important to mention the qualitative investigations of the dutch 'Deltacommissie' (33) : the increasing levels due to surge cause an advancement with regard to the predicted tide (in absence of surge), they cause a enfeeblement of the tide since low levels remain higher and finally they cause a deformation because geometrical elements, such as the topography of banks and gullies) which are boundaries for the tidal movement are oriented in a different way. Walden, Prescott and Webber (48) compared two methods to determine the degree of interaction, based upon hourly surge residuals : a first approach is to examine the distribution of these residuals at various phases of the tidal cycle (see also (28)), whilst the second method determines the distribution of residuals at different tidal levels (see also (29)). They concluded that the more a port is remote from the open sea, the more the interaction is prominent. This implies that the use of the joint probability method (see § 3.2.) is justified if the degree of interaction is negligible.

## 3. Methods to determine the frequency of occurrence of high surge levels

Depending upon the set of available tidal records, two principal methods can be used to determine the frequency of occurrence of high

water levels : extreme value distributions and methods based upon the joint surge-tide probability.

### 3.1. Extreme value distributions

For a series of M annual maximum water levels an extreme value distribution is assumed, characterized by a set of parameters, which are estimated in procedures such as the method of moments, maximum likelihood, etc. (4). Some of these distributions, such as Fisher-Tippet-distribution (10), Barricelli (3), Gumbel (14) and Jenkinson (19, 20), have been applied to estimate the frequency of occurrence of extreme sea-levels. Suthons (44) and Lennon (22) published studies with respect to the south-east and the west coast of England. Akers e.a. (1), Webber e.a. (9, 50), Blackman e.a. (6, 12) reviewed these reports to add more recent information. For the Scheldt estuary frequencies were calculated by SVKS (43), Janssens e.a. (19), Sas e.a. (40) and Berlamont e.a. (5). The results are listed in Table 1.

As conclusion, we believe that

1. Although no exact information is available, frequencies depending upon the extreme value distributions are reliable for design periods up to 4 times the length of the series of observed data (12).
2. Using the method of extreme value distributions includes the disadvantage of neglecting important information about exceptional but not maximal events : such as the increase of the frequency of occurrence of high water levels from 1960 on (see Table 2, and (40)).
3. If a persistent trend is apparent, its effect must be estimated and data must be adjusted accordingly in order to get a homogeneous set of data (6, 44, 47), using for example Suthon's adjustment method, based upon 10-year forward or backward accumulation (13, 44) or 19-yearly mean values to eliminate nodal periodic variations of mean sea level (34, 40).
4. To achieve any reliability, the observed data must cover a period of a least 30 years (11).

### 3.2. Joint surge tide probability methods

If the set of observed tidal data is not long enough, extreme value distributions can't provide reliable information concerning the frequency of occurrence. In this case several methods based upon the principal of joint probability can be applied. A recorded level (H) can be split up into three constituents, after filtering for wave influences :

$$H(t) = Z_0(t) + G(t) + M(t) \quad [1]$$

in which  $Z_0(t)$  : mean level (i.e. mean sea level),  $G(t)$  : tidal component,  $M(t)$  : meteorological component (i.e. surge).

#### 3.2.1. The convolution method

From a series of observations H the hourly surge component M can be derived by calculating the mean level  $Z_0(t)$ , and the tidal component  $G(t)$  from its harmonic constituents. If surge and tide can be treated as statistically independent (see § 2.4.); the probability density function  $p(h)$  can be written as the convolution of the individually

estimated density functions of tide  $p_G$  and surge  $p_S$ .

$$p(h) = \int_{-\infty}^{\infty} p_G(h-y) p_S(y) dy \quad [2]$$

with  $h = H(t) - Z_0$ ,  $y = M(t)$  and  $x = h - y = G(t)$ .

Eq. [2] is valid only if  $h$ ,  $y$  and  $x$  are deduced from a stationary stochastic process, which condition is nearly never completely satisfied. The probability of exceedance of a level  $h_0$  can be evaluated from the cumulative distribution function  $P_h(h_0)$  :

$$P_h(h_0) = 1 - \int_{h_0}^{\infty} p(h) dh = \int_{-\infty}^{\infty} P_G(h_0-y) p_S(y) dy \quad [3]$$

and the return period of height  $h_0$  :

$$T(h_0) = 1 / [ (1 - P_h(h_0)) \cdot (\text{average number of hourly values in a year}) ] \quad [4]$$

Pugh e.a. (30, 31) applied this method to the English south coast port of Portsmouth over a period of 12 years. For return periods of 50, 100 and 250 yr, they estimated sea levels of 2.86, 2.91 and 2.98 whereas application of the extreme value theory using the 12 annual maxima resulted in 2.69, 2.71 and 2.74 : which is an underestimate of 6, 7 and 8 % respectively.

### 3.2.2. Duration methods

In the aforementioned methods the duration of the storm is not considered; the surge is characterized by its magnitude only. Other methods however account for the transient nature of the surge event by considering the effective duration of the process.

Tayfun (45) developed an analytical procedure to determine the probability distribution function of extreme levels, caused by coincidence of a rare event with the astronomic tide. If we consider tide and surge to be statistically independent and if we characterize a storm surge by an equivalent magnetidue  $X$  and an effective duration  $\tau$  (Fig. 2) and if

$$Z = \max_{t_0 \leq t \leq t_0 + \tau} [G(t) + M(t)]$$

in which  $M(t)$  is a positive surge, starting at any time  $t_0$  of the tidal cycle, and if we assume that the water level increase caused by  $M(t)$  is gradual enough that an approximation by a constant height surge  $X$  is allowed over the period  $(t_0, t_0 + \tau)$  then

$$Z \approx \max_{t_0 \leq t \leq t_0 + \tau} [G(t) + X]$$

in which  $\tau$  and  $X$  are random variables. Considering the conditional probability function of  $Z$  for given value of  $\tau$  :

Fig 2: Tayfun method

$$\begin{aligned}
 P_{Z/\tau}(z/\tau) &= \text{Prob} [G(t) + X < z \text{ for } t \leq t \leq t_0 + \tau/\tau] \\
 &= \int_{-\infty}^z P [X < z - g / (G = g \text{ for } t_0 \leq t \leq t_0 + \tau/\tau)] \\
 &\quad \cdot P_{G/\tau}(g/\tau) dg \qquad [5]
 \end{aligned}$$

and assuming that the non-negative X is statistically independent of  $\tau$  and G :

$$P [X < z - g / (G = g \text{ for } t_0 \leq t \leq t_0 + \tau/\tau)] = P_X(z - g) \qquad [6]$$

and

$$P_{G/\tau}(g/\tau) dg = \text{Prob} (g \leq G \leq g + dg \text{ for } t_0 \leq t \leq t_0 + \tau/\tau) \qquad [7]$$

in which tide is assumed to be a Gaussian process.

For  $\tau$  varying over all possible values :

$$P_Z(z) = \int_0^\infty \int_{-\infty}^z P_X(z - g) P_{G/\tau}(g/\tau) p_\tau(\tau) dg d\tau \qquad [8]$$

so that the return period for a water level  $z = h_0$  caused by positive surges, occurring at a mean rate of  $\sigma$  per year :

$$T(h_0) = 1 / [\sigma (1 - P_Z(h_0))] \qquad [9]$$

Walden, Prescott and Webber (49) developed an adapted Tayfun method for use in European waters since tide can not be represented by a Gaussian process because frequency distributions tend to be bimodal (30). Furthermore, surge duration is longer than one tidal cycle ( $\approx 13$  hours) and the magnitude is rather moderate compared with the tidal

amplitude. For surges with duration  $\tau$  greater than 13 hours ( $= T_0$ ), only the largest equivalent magnitude  $X$  over a 13-hour interval must be considered. This  $X$  value results from moving the  $T_0$ -interval through the  $\tau$ -interval (= surge) in steps of one hour, and at each step  $T_1$  equating the area above  $(T_1, T_1 + T_0)$  to  $T_0X$  (in general  $\tau \leq 50$  hours (18, 49)). The conditional density function  $P_{G/\tau}(g/\tau)$  can be obtained from the conditional probability distribution function

$$P_{G/\tau}(g/\tau) = \text{Prob} \{G(t) \leq g \text{ for } t_0 \leq t \leq t_0 + \tau/\tau\} \quad [10]$$

by numerical differentiation.

Such probability can be estimated for different values of  $\tau$  for a series of  $g$  values by moving the interval of duration  $\tau$  through the hourly predicted  $G(t)$  series and dividing the number of hours for which the condition of eq. 10 is satisfied by the total number of  $G(t)$  values. The conditional distribution function of the maximum sea level  $Z$  for given  $\tau$  is derived in the following way. If  $g_{\min}$  and  $g_{\max}$  are the lowest and highest hourly predicted tides and if  $Z$  is chosen as a sea level which can occur only by adding a positive surge to  $g_{\max}$ , i.e.  $z \geq g_{\max}$ , then  $\text{Prob} (X \leq z - g/\tau) = 1$  for a range of  $g$  values between  $g_{\min}$  and  $g_{\max}$ . Let us denote this boundary by  $g_b$ , hence

$$P_{Z/\tau}(z/\tau) = \int_{g_{\min}}^{g_{\max}} P(X \leq z - g/\tau) P_{A/\tau}(g/\tau) dg$$

Further derivation leads to

$$P_{Z/\tau}(z/\tau) = 1 - \int_{g_b}^{g_{\max}} [1 - P(X \leq z - g/\tau)] P_{G/\tau}(g/\tau) dg \quad [11]$$

The adapted Tayfun method is completed by using eq. [8] and [9]. For return periods of 50, 100 and 250 yr, Walden, Prescott and Webber (49) estimated water levels of 2.74, 2.78 and 2.83 differing from the "convolution estimates" by 4.3, 4.7 and 5.3 % respectively (see § 3.2.1.).

Beside these analytical methods to calculate the frequency of occurrence of high water levels, several simulation procedures were developed in which the transient event is reconstructed.

1. Myers (25) pointed out three important aspects in developing a simulation procedure
  - assess the behaviour of surges from past records, analyze all factors causing and determining the event, such as atmospheric pressure, forward speed and direction of the storm
  - develop a hydrodynamic mathematical model to simulate storms (hurricanes) from a random input of the stochastic parameters, determined in the first step, and calculate the resultant surge
  - calculate density distributions and probability functions for all parameters and deduce the frequency of occurrence of the rare event, simulated in step 2.

This method has been applied several times in the U.S.A. (ref. 16, 17, 25, 26, 27). The major disadvantage is the development of the hydrodynamic model and the required calculation time for each simulation.

2. For this reason, the author proposes a simulation technique, based upon the parameters, characterizing the resulting surge (and not

based upon the event-causing parameters), such as duration and magnitude of surge and tidal amplitude and phase angle. Application of the Tayfun method is rejected since hourly water level data had to be digitized over a period of several years. As a list of storm events, exceeding the storm level of  $NKD+6.5m$  was available from 1900 on, this information was used to determine surge characteristics.

#### 4. Determination of surge

##### 4.1. Predicted tide during storm

For all storm periods predicted levels of high and low tide were available, as well as the time of occurrence. In order to avoid harmonic calculation of tidal levels, tide is reconstructed using the typical (mean) tidal cycle of the period 1961-1970 (8). This curve is transformed both in time and height (so that in the extremes coincide with the predicted values) by linear interpolation. In this way the tidal component during the storm is reconstructed similar with the typical tidal curve.

##### 4.2. Surge

To determine the surge from the observed levels and from the tidal elevations, several methods were examined. The Dutch Deltacommission (32) suggests to subtract predicted tide from observations which leads to inadequate surge levels, since the interaction between storm and tide causes transformations in the tidal phenomenon. Theuns (46) draws a smooth curve  $S$  through the registered storm water levels  $R$ , so that the area above and below  $S$  and limited by  $R$  are equal one to the other. Subtraction of mean water level from curve  $S$  gives the surge event. This is a practical method, producing reliable information in regions where mean water level doesn't vary with time. Due to the secular and periodic variations (Fig. 3) on the river Scheldt this method was rejected. Schalkwijk (42) proposes a method based upon harmonic analysis and recalculation of tidal levels. Subtraction of these levels from the observations and application of forward and backward means over 3 hours each to eliminate the  $M_4$  lunar component, produces a reliable approximation of the surge in the "linear" parts of the tidal cycle. To improve the surge residue in the neighbourhood of the extremes a flattening procedure is developed, based upon a trial and error method to draw a smooth curve through the surge residue. This method was also rejected for it requires a harmonic tidal calculation and because of the 'trial and error'-nature of the graphical flattening procedure. Janssens & Sas (18) propose a numerical technique. Subtraction of predicted tide, calculated in the aforementioned way (§ 4.1.), from the observed levels doesn't account for tide-surge interaction. Since no quantitative data are available on this interaction mechanism, the predicted tide is moved through the observations until no periodically oscillating surge residue is obtained. In this way the tidal 'advancement' due to storm is accounted for. The flattening procedure is realized by an approximation of the surge residue by a third order polynomial (higher order approximations cause inflexions and successive maxima), determined by the least square method and applying a Lagrangian multiplier so that the area below the resultant surge equals the one below the first non-oscillating surge approximation

## ANTWERPEN - SCHELDE

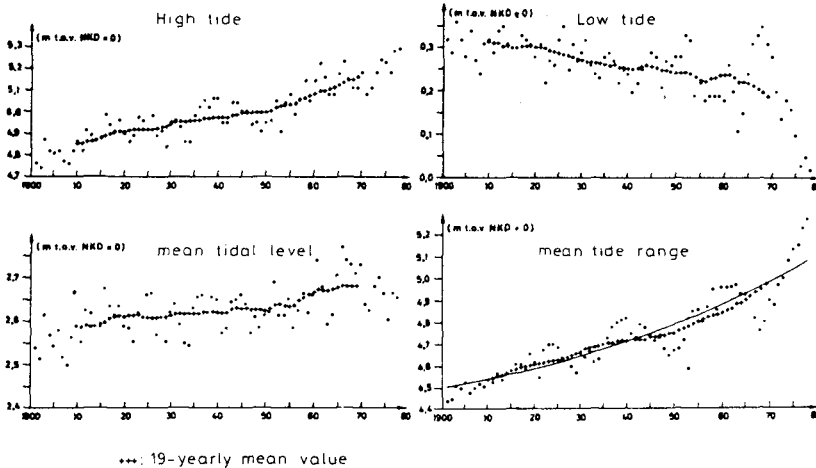

Fig. 3: Variation of tidal variables

(Fig. 4). For 33 storm periods the surge elevation was calculated in this way. It was discovered that there was no tendency at all for the maximum surge to occur at high tide, nor at any other stage of the tidal cycle, which is in strong agreement with the statements of Heaps (15) and Wemelsfelder (32). The resultant duration and magnitude for each surge was derived: 'Duration' is determined (with an accuracy of 0.5 hour) by comparing the time between the zero-points of the surge, the time between the minima of the surge and the time between the points of coincidence of predicted and observed water level. The 'magnitude' is assumed to be the maximum of the polynomial. After checking the dependency of both characteristics, it seems that there is no linear correlation (coefficient = 0.013). Hence magnitude and duration are treated as statistically independent stochastic variables. The probability distribution functions are a normal distribution ( $\mu = 42.5$  h,  $\sigma = 11.6$  h) for the duration and a Gumbel distribution

$$p(x) = \alpha \exp \{-\alpha(x - u) - \exp[-\alpha(x - u)]\}, u = 1.32, \alpha = 3.04$$

for the magnitude.

#### 4.3. Frequency of occurrence of storms

On the basis of the information concerning the penetration of storms in the Scheldt estuary (50 arrivals in 77 years) a uniform distribution of these storms was assumed. The time interval  $\Delta t$  of this Poisson process has a distribution function

$$p(\Delta t) = a \exp(-a\Delta t)$$

Fig. 4: Determination of a storm surge

with  $a = 1/E(\Delta t)$ . Since more storms occur during winter (October till March) :  $E_{winter}(\Delta t) = 10.74$  winter months and  $E_{summer}(\Delta t) = 66$  summer months (or 1 storm occurs in summer during 11 years).

4.4. Simulation of surge

From the set of surges, determined as explained in § 4.2., the most suitable shape was found to be a polynomial of order 3. For a surge of duration  $D$  and magnitude  $M_{max}$ , the component reads (Fig. 5)

$$M(t) = 6.75 M_{max} \left[ \left(\frac{ts}{D}\right)^3 - \left(\frac{ts}{D}\right)^2 \right] + M_{max}$$

Fig. 5: Surge

5. Determination of tidal variables

As described in § 3.1. and illustrated in Fig. 3 tidal variables vary with time. Since the simulated tide is characterized by mean water level and tidal amplitude, the appropriate values of those variables must be determined. To eliminate secular, i.e. nodal, variations 19-yearly (forward and backward) mean values are calculated and are used to estimate actual values of both mean tidal level (= NKD+2.70m) and tidal amplitude (= 2.54 m). To account for variations of amplitude between neap and spring tide (= luni-solar fortnightly  $M_{sf}$  constituent) with a period of 14.76 days, the tidal amplitude is assumed to vary in a sinusoidal way with amplitude = 0.42 m. Variations in tidal amplitude of periodic nature are determined from annual mean amplitudes so that relative magnitude of all effects can be analysed :

$$\text{amplitude (t)} = A \cos \left( \frac{2\pi}{T} t \right) + B \sin \left( \frac{2\pi}{T} t \right) + C + DT \quad [12]$$

(where T = period of variation, t = time in years, C + DT is the trend due to secular variation). Using the method of least squares, the most important long term period can be determined. For the river Scheldt the nodal tide (T = 18.67 years, amplitude = 0.06 m) was found to be the most important). If tide is simulated by a simple sinusoidal variation; the tidal constituent during the surge event can be represented by

$$G(t) = A(t) \sin \left( \frac{2\pi}{12.42} t_s + \varphi_0 \right) \\ = (\bar{A} + A_{nodal}^* + A_{M_{sf}}^*) \sin \left( \frac{2\pi}{12.42} t_s + \varphi_0 \right)$$

$$G(t) = [\bar{A} + A_{nodal} \sin \left( \frac{2\pi}{18.67} t \right) + A_{M_{sf}} \sin \left( \frac{2\pi}{14.76 \times 24} t_h + \varphi_{M_{sf}} \right)] \\ \cdot \left[ \sin \left( \frac{2\pi}{12.42} t_s + \varphi_0 \right) \right] \quad [13]$$

(with t = time in years since the beginning of the simulation,  $t_h$  = hours since the surge in started,  $\varphi_{M_{sf}}$  = phase angle of the  $M_{sf}$  constituent,

$\bar{A}$  = annual mean amplitude,  $A_{nodal}$  = nodal amplitude,  $A_{M_{sf}}$  = luni-solar fortnightly amplitude).

For Antwerp  $\bar{A}$  = 2.54 m,  $A_{nodal}$  = 0.06 m,  $A_{M_{sf}}$  = 0.42 m.

## 6. The simulation model

In this model tide during the surge is described as observed during recent years, including periodic variations over a nodal period. Surge and interaction are treated together and their magnitude is based upon observations of the last century. From the probability distribution functions and the frequency distribution, the model parameters to reconstruct all components are generated by random numbers. These parameters, treated as stochastic variables are :  $\Delta t$ ,  $D$ ,  $M_{\text{Max}}$  and  $\varphi_0$ . Superposition of  $Z_0$ ,  $G(t)$  and  $M(t)$  each 10 minutes (according to eq[1]) during a storm (Fig. 6) leads to a series of  $n$  maximal storm levels  $H_{\text{max}}$  over a range of  $j$  simulated years. The return period  $T$  of a level  $h_0^{\text{max}}$  is calculated as  $j/m$ , with  $m$  the number of surges exceeding level  $h_0^{\text{max}}$ :

$$T(h_0) = \frac{\text{simulated years}}{\text{number of storms with } H_{\text{max}} > h_0} \quad [14]$$

To obtain suitable results :

- the simulation model must use enough random numbers so that the results are not influenced by the initial random number
- the simulation must cover a span of years of at least 10 times the largest requested return period
- the simulation results must be compared with historical data and if possible with other calculation methods.

Furthermore it seems obvious that the model can not give more information or more accurate data than those included in the set of observations. Hence one should try to collect as much data as possible to increase the reliability of the model parameters and their probability distributions. For the river Scheldt near Antwerp 10000 years were simulated, in which 5952 storms exceeded the lower limit level of NKD+6m. The results are given in Table 1 and Fig. 7.

## 7. Comparison of results - conclusions

The results in Table 1 indicate that the simulation model gives a higher water level than the extreme value distributions, for the same return period. Since the frequency of occurrence of high levels increases with time (Table 2), one should account for trends in determining the frequency of occurrence of extreme water levels. Classical extreme value distributions assume the series of annual maximal water levels as homogeneous, and thus underestimate the frequencies. To avoid inhomogeneity, trends must be corrected for, but one must be aware of the different possible estimates of these trends (Table 3) and the influence on the water levels corresponding to several return periods. The proposed simulation technique avoids these difficulties by using tidal variables based upon recent years observations and by simulating surge events as they happened over the last century. Examination of Table 1 shows that the extreme value distributions give estimates of water levels which become higher the more recent years are considered or the more a homogeneous set of annual maxima is used, whilst the estimates derived from the simulation model are greater than the pure annual maxima results but smaller than the estimates obtained after correction for trends.

Fig. 6: Simulated storm

Fig. 7: Frequency of occurrence =  $1/T$  ( $T$ : return period in year)

The simulation technique overcomes the difficulties of applying extreme value distributions. Compared with the joint probability methods it avoids the problem of correlated residuals of the convolution method by considering surge duration and magnitude. It has been illustrated that in comparison with the Tayfun method, detailed observations are required in storm periods and not hourly values over 10 or 15 years. In this way laborious work of data collection is avoided. Compared with the simulation model the proposed technique has the big advantage of not using a hydrodynamic model, since surges are simulated depending on surge-characterizing parameters and not on surge-causing parameters. Although it remains difficult to draw any firm conclusions this simulation technique seems quite promising, especially in estuaries where shallow water components influence surge propagation so that hydrodynamic models become complex, and where trends in annual maxima are apparent. The technique serves to calculate a best estimate for extreme water level frequencies, which is a problem for which no definitely correct answer exists.

## CHAPTER FIFTEEN

UPDATE: THE NATIONAL FLOOD INSURANCE PROGRAM AND THE COAST

By: William G. Fry, P.E., and Perry A. Rhodes, P.E.,  
Respectively, Principal and Civil Engineer for  
Dewberry & Davis, Fairfax, Virginia

### ABSTRACT

This report will update the coastal zone practitioner on the National Flood Insurance Program (NFIP) as it affects the implementation of manmade changes along the coastline.

It is our intent to place in proper perspective this fast-changing and often difficult to interpret national program. Readers will achieve an overall understanding of the NFIP on the coast, and will be in a position to apply the program's requirements in their efforts.

We will begin with a history of the application of the NFIP to the coastal zone. The history of the problems encountered will lead into current regulations, methodologies, and the changes the Federal Emergency Management Agency plans for the future.

### INTRODUCTION

The NFIP, operated by the Federal Emergency Management Agency (FEMA), has been in existence since 1968. This program has been a major force in directing the course of development in the U.S., not only on the coast, but throughout all the flood-prone areas of the country. However, with regard to the coastal areas, the program was slow to get and to give direction to development, and the application of the program in coastal areas was an area of major criticism during its early years.

It is only now, 1984, that we feel the NFIP has achieved a steady state in the coastal areas. It has established a sound technical backing for its requirements, gained a national understanding, and achieved a fairly strong assurance of being accepted by local governments.

The achievement of this steady state has been made only after a period of loosely defined rules and regulations for the coastal areas. This has left considerable confusion to builders and developers, engineers and architects, the insurance industry, and local governments. The purpose of this paper is to summarize the current rules, regulations, and technical bases of the NFIP in the coastal area. This paper will also present what can be expected in the foreseeable future.

Our presentation will cover the following topics:

- o History of the coastal zone and the NFIP
- o Flood insurance zones in the coastal areas
- o The flood plain management and construction regulations of the NFIP
- o Representative examples of flood insurance rates
- o A summary of the storm surge models
- o A summary of the wave height and wave runup models
- o A brief discussion of the application of the barrier island regulations
- o Current updates to the surge and wave height models now being completed and contemplated by FEMA

#### HISTORY OF THE COASTAL ZONE DESIGNATIONS

Itemized below are the key dates for the NFIP in the coastal areas.

1969 - Inundation of the 100-year flood (A zones) was identified in the coastal zone.

1972 - First V zones (coastal high hazard area<sup>1</sup>) in areas of obvious wave action were applied to the coastal area. Zones V1 through V30, when determined, utilized the popular surge models of the early 1970s.

1975 - The Galveston District Corps of Engineers established the three-foot wave as that wave which will induce significant damage above and beyond inundation to structures (Reference 1). From this, using a convention of maximum wave height equaling 78% of the depth, a four-foot stillwater storm depth was established to identify V zones. In other words, areas of stillwater inundation with depths greater than four feet which had significant exposure to waves were considered V zones.

1977 - The National Academy of Sciences (NAS) completed its wave height methodology for V zone identification (Reference 2). It was to be applied using established stillwater elevations.

1979 - A cost benefit study, undertaken by FEMA, showed a positive ratio, as high as 8:1 in some instances, for implementation of the wave height methodology.

September 1979 - Hurricane Frederick occurred, establishing itself as the most costly natural disaster in U.S. history.

April 1980 - The first wave height study became effective on the coast of Alabama. The Federal Insurance Administration (FIA) initiated a major program to study communities on the Gulf and Atlantic coasts.

---

<sup>1</sup>"Coastal high hazard area" means the area subject to high velocity waters including but not limited to hurricane wave wash or tsunamis.

1981 - A storm surge model by Tetra Tech was published by FEMA (Reference 3). The purpose was to standardize coastal storm elevation determination for flood insurance applications.

1984 - Virtually all communities requiring coastal studies have studies in progress or completed.

1984 - Refinements to the NAS wave height model and the Tetra Tech surge model have been undertaken and evaluated by FEMA.

It should be noted that the coastal studies have been a major area of criticism for the Program. With the early utilization of only storm surges to identify the coastal hazards, it was well recognized that the overall coastal hazards were vastly underrated. As a result, allegations were made that the NFIP was encouraging development along the coast by providing unrealistically low insurance rates to protect those who built. Changes in technology and insurance premiums made in the past few years have done much to nullify this argument.

#### FLOOD INSURANCE ZONES

The medium by which the flood insurance zones are identified for a community is the Flood Insurance Rate Map (FIRM). A FIRM is created for every community participating in the NFIP. The definitions below are for effective FIRMs with detailed studies.

- o Zones V1-V30 - Coastal high hazard areas inundated by the 100-year flood where a three-foot or greater wave could occur. Wave crest elevations are shown as the base flood elevation.
- o Zone V - Areas of estimated inundation by the 100-year flood with depths greater than four feet and exposed to provide wave generation. No base flood elevations shown.
- o Zones A1-A30 - Special Flood Hazard Areas (SFHAs) inundated by the 100-year flood with waves less than three feet. The wave crest elevations are shown as the base flood elevations.
- o Zone A - Areas of approximate determination of 100-year inundation. No base flood elevations shown.
- o Zone A0 - SFHAs of shallow flooding caused by sheetflow from the 100-year flood. Depths are between one and three feet and are shown.
- o Zone AH - SFHAs of shallow flooding caused by ponding. Depths are between one and three feet, with the ponding elevations shown.
- o Zone B - Areas of moderate flood hazard, usually expected to be inundated by the 500-year flood. In coastal areas, only the stillwater elevations are utilized. No base flood elevations are shown.
- o Zone C - Areas of minimal flood hazard.

## FLOOD PLAIN MANAGEMENT REGULATIONS FOR ALL FLOOD-PRONE AREAS

The next two sections summarize briefly the requirements of Part 60.3, Title 44, Code of Federal Regulations (Reference 4). These are four very readable pages of the Federal Regulations, which should be reviewed by anyone practicing engineering in the coastal zone. Communities are required to adopt and enforce these minimum standards in order to be eligible for participation in the NFIP. The regulations for all flood-prone areas are discussed below and the additional regulations applicable to the coastal high hazard areas are discussed in the following section.

## REGULATIONS FOR SPECIAL FLOOD HAZARD AREAS

1. Participating communities must require permits for all proposed construction in SFHAs.
2. Participating communities must review proposed development to assure approval of all state and Federal regulations including Section 404 of the Federal Water Pollution Control Act.
3. Participating communities must review all development to assure safety from flooding with appropriate building standards.
4. Participating communities must assure that all subdivisions are designed with flood damage mitigation standards, applying to both structures and utilities.
5. For subdivisions of 50 lots or five acres or greater, if base flood elevations have not been established by the NFIP, they must be developed. This implies that where only Zones V or A are shown on a map, it is a requirement that studies be undertaken to establish base flood elevations.
6. Communities must utilize any available base flood elevation data available to them.
7. Communities must notify all neighboring communities of watercourse alterations and they must ensure the conveyance of all existing watercourses.
8. Mobile homes in SFHAs must be elevated and anchored using specific design standards.
9. Communities must maintain evacuation plans for mobile home parks and subdivisions.
10. New construction of, or substantial improvements to, residential structures in Zones A1-A30 and AH zones (ponding) must have the lowest floor, including the basement, elevated to or above the base flood elevation. For non-residential structures, certified waterproofing may be utilized.
11. In A0 zones (sheetflow) residential structures must have their lowest floor elevated above the adjacent grade by the depth of flooding identified (1-3 feet). Again, floodproofing is permitted for non-residential structures if certified by a registered architect or engineer.
12. There must be adequate drainage paths around all structures in Zones AH (ponding) and A0 (sheetflow).

13. Floodways (that portion of a reduced flood plain which would carry the 100-year flood without greater than a one-foot surcharge to the flood elevation) must not have any construction in them which will result in any increase in flood elevations. Mobile homes are prohibited except in existing parks.

#### SUMMARY OF ADDITIONAL REGULATIONS FOR THE COASTAL HIGH HAZARD AREAS

1. All new construction and substantial improvements must be landward of mean high tide.
2. All new construction and substantial improvements must be on piles, secured with the lowest structural member above the base flood elevation.
3. All new construction and substantial improvements must be certified by a registered architect or engineer to be designed to withstand the wave and water forces of the 100-year storm.
4. For all new construction and substantial improvements, the space below the lowest floor is prohibited for use for habitation. It must be free of obstructions and may utilize only breakaway walls for enclosure.
5. No fill is allowed for structural support.
6. No new mobile homes may be placed, except in existing parks.
7. There must be no degradation of sand dunes and mangroves.

In summary, for the coastal high hazard area, there are additional locational requirements, structural certification requirements, structural design requirements, and environmental requirements. Of particular note is the unique requirement that the lowest structural member must be above the base flood elevation as opposed to simply the lowest habitable floor.

The NFIP is voluntary. If a community chooses not to participate, flood insurance is not available, and grants, loans, or guarantees made by Federal agencies such as the Small Business Administration, Federal Housing Administration, and Veterans' Administration are prohibited for acquisition or construction in identified areas. Lending institutions insured or regulated by a Federal agency may make conventional loans at their own discretion in these areas. By law, if a flood disaster situation occurs in a nonparticipating flood-prone community, no Federal assistance for acquisition or construction may be provided in flood hazard areas. Individual and Family Grant assistance for housing and personal property is also not available after a flood disaster.

#### REPRESENTATIVE INSURANCE RATES

For comparison, indicated below are the annual premiums for three different structures. The premiums are based on the maximum structure insurance of \$185,000, and the maximum contents insurance of \$60,000 (References 5 and 6).

- o For a structure in Zones A1-A30 with the lowest habitable floor at the base flood elevation, the annual premium is \$287.50.

- o For a structure in Zones V1-V30 with the lowest structural member at the base flood elevation, the annual premium is \$2,442.00.
- o For a structure in Zones V1-V30 with the lowest structural member at four feet or more above the base flood elevation, the annual premium is \$946.00.

#### STORM SURGE MODELS

In performing coastal Flood Insurance Studies (FISs), determination of the stillwater elevations is the initial step. FEMA has used many different sources for stillwater elevations. These sources include frequency analyses of tidal gage data and storm surge models. In 1981, FEMA adopted Tetra Tech's storm surge model for use on the East and Gulf coasts (Reference 3). This model incorporates two separate models: a hurricane model to generate hurricane wind and pressure fields and a finite difference hydrodynamic model to generate storm surges using the hurricane data. The hurricane model uses an array of five hurricane parameters to simulate the wind and pressure fields of selected storms. The storm model uses a variable grid mesh which incorporates water depth, bottom friction, shoreline configuration, barrier islands, and inlets. The model results in a time history of storm surges. These are combined with the predicted astronomical tide for the same time period to produce the stillwater elevation. A joint probability analysis is used to assign frequencies to the stillwater elevations. This model has been applied extensively in the Gulf and South Atlantic states.

For Virginia, Maryland, and Delaware, FEMA has used a joint probability analysis by the National Oceanic and Atmospheric Administration (NOAA), which utilizes the SPLASH model with modifications similar to those in SLOSH (Reference 7). It should be noted that FEMA is using SLOSH for hurricane evacuation studies. Because these studies do not assign a frequency to the storm being modeled, the results from the SLOSH model cannot be used in FISs.

In the New England states, an additional model is applied for consideration of the effects of northeasters. FEMA has adopted a model developed by Stone & Webster (S&W) which simulates wind and pressure fields for northeasters (Reference 8). This data is then used in the same manner as the hurricane fields to generate storm surges and stillwater elevations.

#### WAVE HEIGHT AND RUNUP MODELS

To evaluate the wave action effects, FEMA had the NAS prepare a methodology applicable to most areas along the Gulf and Atlantic coasts (Reference 2). This methodology considers the effects of wind fetches, stillwater depths and all types of stationary obstructions in determining wave heights and corresponding wave crest elevations. An incident wave height is calculated at the shoreline based on available fetch and stillwater depth. This wave height is modeled as it propagates inland. Energy losses due to vegetation, buildings, and other structures are considered, as well as wave generation over unobstructed

areas. The calculated wave heights are used to determine the wave crest elevations which become the regulatory base flood elevations. This methodology has been applied to nearly all of the Gulf and Atlantic coastal communities.

The NAS methodology does not account for wave runup on steep shorelines subject to intense long period waves. In the New England states, many structures above the stillwater elevation were damaged by runup during the 1978 northeaster. To account for this hazard, FEMA contracted S&W to develop a model to determine the height of wave runup. S&W's computer model incorporates laboratory runup data from Phillip Stoa and uses the composite beach slope method developed by Thorndike Saville (Reference 9). The height of calculated runup is a function of beach slope and roughness, deepwater wave height and wave period. The maximum runup elevation is combined with the results of the NAS methodology to produce a simple yet realistic wave profile consistent with existing state-of-the-art technology to describe wave height variation in the surf and runup zones.

#### WEST COAST FLOODING

Most of the above-mentioned models and methodologies are not applicable to the West Coast. The West Coast is subject to severe flooding from tsunamis, winter storms, tropical storms, extratropical storms and the swells from these types of storms. For a large part of the West Coast, including Hawaii, the phenomenon that was determined to result in the worst flooding was modeled and mapped. For southern California, a joint probability analysis of astronomical tides, tsunami, offshore storms and landfalling storms is being performed for the coastline between the Mexican border and Morro Bay. FEMA has also just contracted for a tsunami model of the entire coast of Alaska. These last two models will complete the study of the areas of the West Coast subject to coastal flooding.

#### COASTAL BARRIER RESOURCES ACT

Another service provided by FEMA is the placing on the FIRMS of the "undeveloped barriers" identified under the Coastal Barrier Resources Act of 1982, by the Department of the Interior. Any development after October 1, 1983, in these areas is not eligible for any Federal funds, including flood insurance and disaster assistance. The classification of areas as "undeveloped barriers" has been challenged in court many times regarding the definition of "undeveloped" and "barrier." Most cases have been unsuccessful. Although not involved in the identification of the undeveloped barriers, FEMA has mapped these areas on the FIRMS for all of the affected communities. This was completed by October 1, 1983.

#### FUTURE ACTIONS

So far, we have briefly covered the flood hazard zones and regulations for coastal communities, and the methods of determining the flood hazards. We would now like to discuss FEMA's future involvement with coastal analyses.

Due to recent technological advances in the state of the art, unique situations encountered, and experience gained from application of their models, FEMA is currently reviewing and/or updating several of their methodologies. The National Weather Service of NOAA has been contracted to develop a comprehensive and authoritative set of hurricane climatological statistics to be utilized in future FISs. This will update a 1975 hurricane climatology study, NWS-15. All previous storms influencing the Gulf and Atlantic coasts will be analyzed to provide tabulated data of hurricane frequency parameters for determination of the wind and pressure fields for storm surge calculations. This will make variations of storm parameters smooth enough so that contractors can use the information directly. Decisions on the statistical representativeness of the sample size and final analysis will be made by NOAA and not left to individual contractors. It is estimated that this will be completed within 2 years.

In addition, FEMA has contracted a review of the complete Tetra Tech model for areas that could be potentially updated due to advances in the state of the art. Upon completion of this review, necessary updates will be made.

FEMA has just completed two updates to the NAS wave height methodology. These updates are really additions to account for unique situations. The first concerns the Mississippi Delta. The Mississippi River has deposited millions of tons of fine sediments into the Gulf of Mexico to form a soft mud bottom in contrast to the typical sand bottom of most coastal areas. This plastic, viscous bottom deforms under the action of a surface wave. This wave-like reaction requires energy from the surface waves, thus reducing the surface waves. Joseph Suhayda has just completed a methodology for FEMA to account for the wave energy losses in the Mississippi Delta. Waves in the offshore area are tracked over the muddy bottom resulting in lower wave heights at the shoreline. This methodology will be applied only to the Louisiana communities affected by this phenomenon.

The other situation FEMA has investigated is the effect of marsh grass on wave dissipation. The NAS methodology models vegetation as a rigid cylinder. This does not account for the flexibility of marsh plants. A FEMA task force is in the process of completing a methodology that accounts for different types of marsh plants, flexure of the plants, and wind energy input.

e Another service provided by FEMA is their "Design and Construction Manual for Residential Buildings in Coastal High Hazard Areas." FEMA is currently negotiating a contract for an updated and more detailed version.

#### CONCLUSION

By the end of FY 85, all of the coastal communities in the United States will have detailed studies completed or in progress. This will not be the end of FEMA's involvement in the coastal areas. Refinements will continue to be made with advances in the state of the art. Although FEMA does not plan any massive restudies as a result of upgrades

to their methodologies, these advances will be incorporated in future revisions and restudies as they become necessary.

To summarize, we have seen the Coastal Flood Insurance Program go from being controversial and very subjective to a program utilizing recent technical developments with well defined criteria and regulations. FEMA has provided a reasonable representation of potential flood hazards for nearly all of the coastal communities in the U.S. Along with its regulations, the FIRM becomes a flood plain management tool available to the coastal areas. While not promoting development, FEMA has provided this tool so that future development in the coastal areas will be constructed to minimize potential flood damage. Without FEMA's involvement in the coastal areas, development could be rampant and unsafe, with yearly flood losses drastically escalating.

## CHAPTER SIXTEEN

### SIMULATION OF TIDES AND STORM SURGES IN THE GREAT BARRIER REEF REGION

K.P. Stark,<sup>1</sup> L. Bode<sup>2</sup> and L.B. Mason<sup>3</sup>

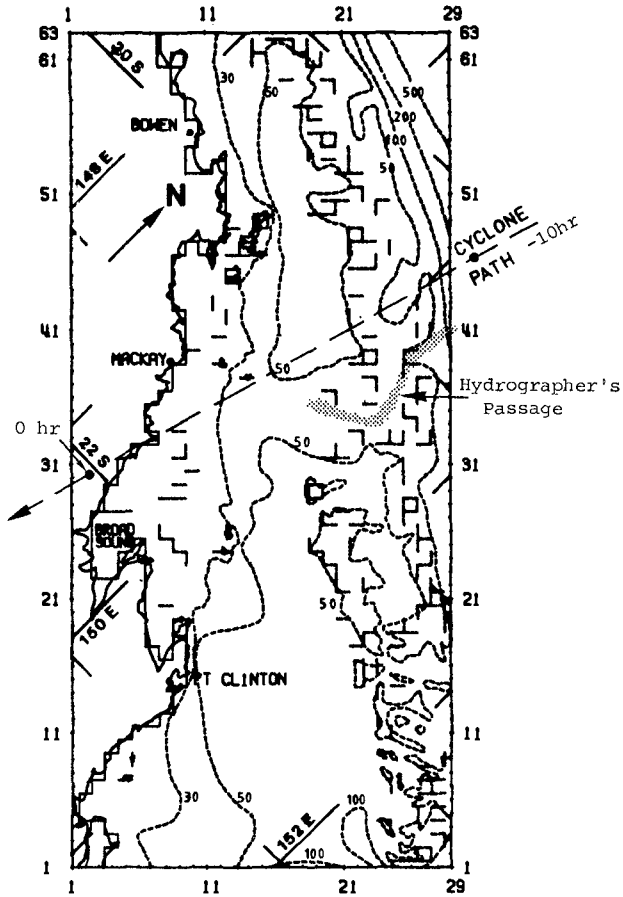

The Great Barrier Reef Region which constitutes the north-eastern continental shelf waters of Australia, is an area that is subject to both large astronomical tides and the passage of tropical cyclones (hurricanes). One section of this area, centred on Mackay, is characterised by particularly high tides, with a springs range of order 10 metres. Numerical hydrodynamic modelling is used in the present study to: (a) simulate the M<sub>2</sub> tide to investigate possible effects of the reef barrier on tidal amplification; (b) simulate the passage of a tropical cyclone across the continental shelf; (c) investigate the effect and consequences of non-linear surge/tide interactions. The recent discovery of a major shipping route through the reef in this area and the continuing development of natural resources makes a much more detailed understanding of the region's hydrodynamics essential for coastal engineering.

#### INTRODUCTION

The Great Barrier Reef (GBR) extends in an almost unbroken chain along some 1200 miles of the Queensland coast of Australia. The area between the coastline and reef (the 'lagoon') is of key importance to engineers, oceanographers, development consultants and shipping; it is of unique biological importance and supports significant fishing and tourism industries. The area of particular interest to the present study is centred on the city of Mackay, with the model's location and extent being delineated in Fig. 1. This area's hinterland is rich in natural resources and this has resulted recently in an upsurge of development, particularly in the exploitation of massive nearby coal reserves. The possibility also exists of large scale development of extensive shale-oil deposits in the longer term.

Shipping within the GBR Region is therefore very important and coastal engineering projects range from the development of port and harbour facilities, and the construction of deep-water ports to consideration of environmental problems associated with potential shipping disasters. The newly-discovered shipping channel through the main reef, Hydrographer's Passage, is also shown in Fig. 1. This provides much easier and more economical access for international shipping to Mackay.

1. Professor and Head of Dept., 2. Research Fellow, 3. Research Officer, Department of Civil and Systems Engineering, James Cook University of North Queensland, Townsville. Q. 4811. AUSTRALIA.

**Fig. 1** Model region with solid rectilinear boundaries of computational region superimposed on the actual coastline. Dashed curves depict bathymetry (m); dashed rectilinear elements represent reef and low barriers. The hatched region is Hydrographer's Passage. Also shown is the cyclone track through the region. Latitude and longitude of the region are indicated.

However, it is also clear that although the initial shipping traffic through the new passage will be relatively small, it will be necessary to evaluate the additional risks, environmental and ecological, that will be superimposed on the region. Such evaluations require a detailed understanding of the hydrodynamic interactions of the complex tidal and meteorological forcing mechanisms that apply in this area.

In this southern (Mackay) section of the GBR Region, the pattern of the astronomical tides is of considerable scientific and applied interest. Tides are much higher than, and exhibit large phase lags relative to areas to the north and south. Spring tides can have a range of up to 10 metres. Recent numerical studies by the authors have lent weight to the hypothesis [first proposed, incidentally, by the maritime explorer Matthew Flinders in 1814], that the reef chain itself plays a key role in the attainment of such large water levels (1). The area is also subjected to the influence of strong and persistent longshore winds for a large part of the year. In addition, the occasional incidence of the passage of tropical cyclones means that such extreme meteorological forcing and the associated water levels and currents, must be included in any coastal engineering assessment of the area.

#### Aims and Objectives

The work to be discussed in this paper comprises three parts. The first is an investigation of the factors which lead to the large amplification of the semi-diurnal astronomical tides. In particular the role played by the dense reef barrier in the tidal dynamics is considered by means of numerical modelling. The second part of the work considers the effect of the passage of a tropical cyclone through this area. In view of the extremely large water levels that are attainable from each of these forcing mechanisms, the ultimate effect of surge/tide interactions on the total water level and currents could well be considerable and should be incorporated in the design of important coastal engineering works in this area, since variations of fractions of a metre in levels could have significant economic implications. This aspect of the coastal hydrodynamics is often neglected and forms the third part of the study.

#### METHOD OF SOLUTION

The above cases are treated numerically by the solution of the two-dimensional (depth-integrated) long wave equations. Solution techniques for such models are by now more or less conventional and will not be referred to in any detail. Further details of the model can be found in Refs. (1,7,11,12). The equations of motion to be solved are:

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x} \left( \frac{U^2}{H} \right) + \frac{\partial}{\partial y} \left( \frac{UV}{H} \right) - fV = -H \frac{\partial}{\partial x} \left[ g \eta + \frac{p_a}{\rho} \right] + \frac{1}{\rho} (\tau_{sx} - \tau_{bx}), \quad (1)$$

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x} \left( \frac{UV}{H} \right) + \frac{\partial}{\partial y} \left( \frac{V^2}{H} \right) + fU = -H \frac{\partial}{\partial y} \left[ g \eta + \frac{p_a}{\rho} \right] + \frac{1}{\rho} (\tau_{sy} - \tau_{by}), \quad (2)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0, \quad (3)$$

The notation used is:

t	time,
x, y	local horizontal Cartesian co-ordinates,
$\eta = \eta(x, y, t)$	sea-surface elevation, referred to M.S.L. datum,
$h = h(x, y)$	undisturbed water depth,
$H = h + \eta$	total water depth,
f	Coriolis parameter, assumed constant
g	gravitational acceleration,
P	atmospheric pressure
$\rho^a$	water density, assumed constant,
$\tau_{sx}, \tau_{sy}$	components of surface stress $\tau_s$ due to wind forcing,
$\tau_{bx}, \tau_{by}$	components of bottom stress $\tau_b$ ,
U, V	components of horizontal transport per unit width of cross section, defined by
$U = \int_{-h}^{\eta} u \, dz$	where u is the average velocity and $\bar{u}$ the depth averaged mean velocity, in the x-direction.
$= \bar{H}u$	

A similar definition holds for V (and  $\bar{v}$ ). The equations are solved by an explicit finite-difference technique on a uniform grid that is staggered both spatially and temporally (a Richardson lattice).

An additional and complicating factor in this region, however, is the necessity of formulating a suitable physical model of the GBR chain that can be incorporated within the numerical model. The reef would appear to play a number of roles, acting as a possible means for both large-scale tidal amplification plus considerable smaller-scale dissipation, a generator of extreme currents locally, and as possible offshore protection from even more extreme storm surge levels. In this and the works cited above, reefs and other low barriers (such as the extensive band of sandbanks at the mouth of Broad Sound) are modelled as weirs - after the approach of Reid and Bodine (11) and Sobey *et. al.* (12,13).

The model region has been shown already in Fig. 1. Both the actual coastline and its model approximation on the square grid of spatial resolution,  $\Delta s = 5$  n miles are shown. This value allows considerable, although not complete resolution of individual reef elements. The figure also shows the region's bathymetry as well as the model's approximation of the reef structure and submerged barriers, which are represented by the dashed rectilinear elements. For the purposes of comparison of the various results that follow, particular attention will be paid to grid point (5,29) in the mouth of Broad Sound. This is the location of Flat Isles where, in fact, Flinders was moored for two weeks in 1814. This point is in the area of maximum tides as well as surge for the chosen model cyclone.

## TIDAL MODEL

In the Mackay region, tides are predominantly semi-diurnal. In particular the  $M_2$  constituent accounts for roughly 50% of the total tidal range, as seen from Table I. As a result,  $M_2$  can be taken as representative of a mean tide over the spring-neap cycle. It should be remembered, however, that total tidal water levels can be up to double these values. The tidal model is driven by imposing the  $M_2$  tide (amplitude and phase) along the three open boundaries. The tidal amplitude is increased from zero to its full value over a build-up period of 6 hours in order to reduce the unwanted effects of initial transients (1,2).

TABLE I

RANGE OF PRINCIPAL TIDAL CONSTITUENTS (METRES) AT SELECTED LOCATIONS IN THE STUDY AREA, TOGETHER WITH THEIR SUM

Location	$M_2$	$S_2$	$N_2$	$K_1$	$O_1$	$P_1$	Sum
Bowen	1.50	0.61	0.40	0.64	0.34	0.21	3.70
Hook Island	1.72	0.63	0.45	0.71	0.35	0.24	4.10
Mackay	3.36	1.20	0.80	0.76	0.40	0.23	6.75
Broad Sound (McEwin Islet)	4.84	1.42	0.43	0.92	0.42	0.25	9.28
Pt. Clinton	2.74	1.10	0.63	0.64	0.32	0.21	5.64
Bell Cay	2.26	1.20	0.42	0.46	0.32	0.21	4.87
Gladstone	2.32	0.84	0.53	0.50	0.28	0.16	4.63

[(1,1) on Fig.1]

At present, there remains some uncertainty about this specification of the open boundary conditions, particularly along the edge of the continental shelf. Obtaining data along this stretch is made difficult by the fact that, apart from Hydrographer's Passage, no approach to the shelf edge can be made from the lagoon. Outside the reef, seas are generally too large for safe and recoverable deployment of instruments. Fortunately, this situation is improving and proposed field experiments should help to remedy some of the inevitable uncertainties.

Tidal Results

Fig. 2 shows the results of a simulation of the  $M_2$  tide in this region. The notable feature is the effect of the 'reef': the relatively large gradients of surface elevation and the large phase change across the central (and densest) portion of the reef chain, indicate considerable flow retardation. The mechanism of tidal amplification can also be seen from this figure. The phases of the resultant tidal streams from the north and south are such that they tend to reinforce each other in the central part of the region. The resulting pattern is essentially a standing wave, with almost uniform phase over this large central portion. The tide subsequently progresses up Broad Sound with considerable further amplification.

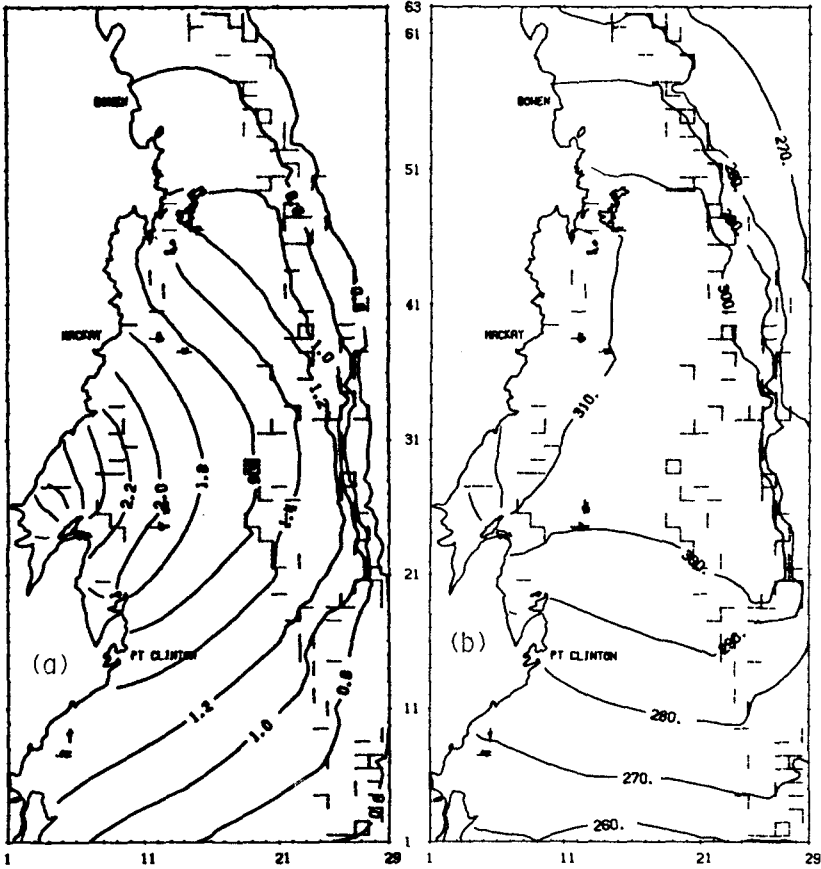

Fig. 2. Co-amplitude (m) and co-phase ( $^{\circ}$ ) contours for  $M_2$  tide. Grid size is 5 n miles; rectilinear elements depict reefs, etc.

$M_2$  tidal ellipses, shown at every grid point in each coordinate direction, are presented in Fig. 3. They show the essential pattern of the tidal streams, while the indicated phase depicts the variation from an essentially progressive wave towards a standing wave pattern. The maximum amplitude of the tidal current is  $1.8 \text{ ms}^{-1}$  (or roughly 3.5 knots) near grid point (25,32). However, personal observations indicate that for the area of the outer reef, tidal currents of order 6 knots are not uncommon between individual reefs.

**Fig. 3**  $M_2$  tidal ellipses for central 'window' of model region.

The effects of the reef on the propagation of the tides can be further demonstrated with a numerical model by the complete removal of the reef elements from the model. The results of this numerical experiment are shown in Fig. 4. The amplification of the tides is now much reduced. For example, at grid point (5,29), the  $M_2$  amplitude is reduced from 2.66 m in Fig. 2 to 2.01 m in Fig. 4. In addition, the tides are no longer so retarded at the edge of the shelf and phases and, as a result, are significantly earlier - by roughly 0.7 h - in the central coastal portion of the model region. The results of this simulation lend strong support to the original Flinders hypothesis of reef retardation leading to longshore lagoonal resonance - see also Ref. (9).

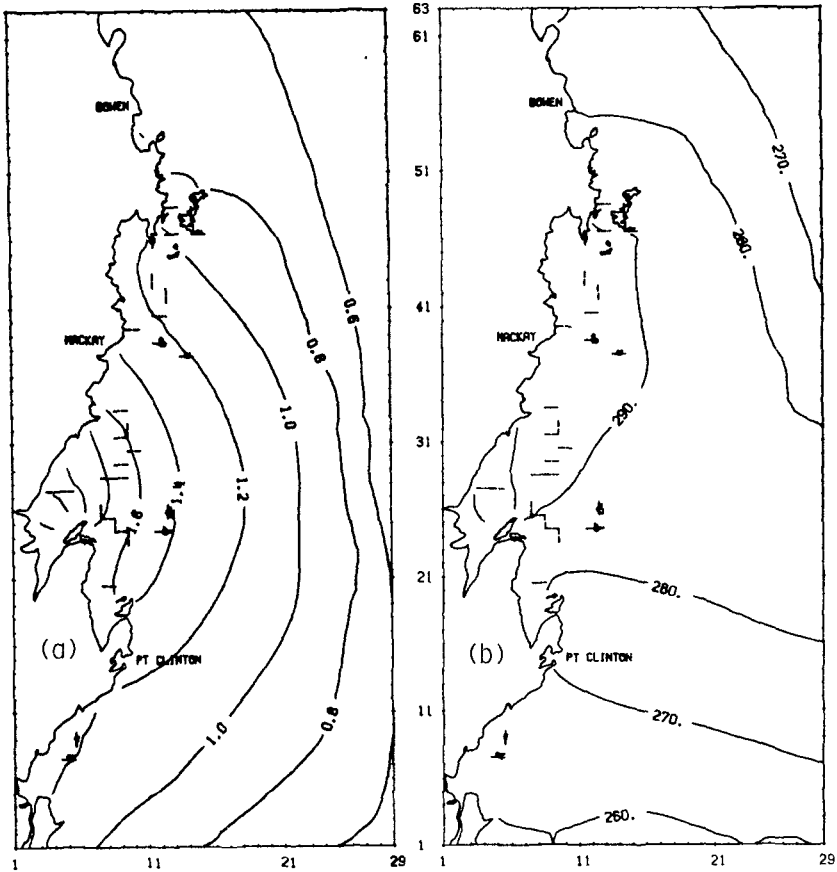

Fig. 4 As for Fig. 2 but without 'reef'.

#### STORM SURGE SIMULATION

In 1918 Mackay was hit by a tropical cyclone with an estimated central pressure of 940 mb. A significant component of the damage was due to the effects of storm surge (estimated at over 3.6 m at Mackay) and wave action, with the storm crossing the coast near the time of high tide. The combination of extreme winds and very high surge water levels devastated the town.

An engineering study of the effects of storm surges without tides at Mackay has been carried out previously - Ref. (5). In the present study, a simulated tropical cyclone of similar estimated magnitude to the 1918 storm is allowed to pass through the model region along the track indicated in Fig. 1. Altogether, a number of different simulations were effected, mainly to investigate the effect of the speed of forward movement and the phase of the storm relative to the tides, on the strength of the surge/tide interaction. The prototype storm, however, is identical to that used by Bode and Stark (3), although some recent modifications to the parameterisation of the wind stress field, suggested by Bode and Sobey (4) have been incorporated subsequently. The actual parameters governing the storm are detailed in Table II.

TABLE II  
PHYSICAL PARAMETERS GOVERNING THE SIMULATED  
TROPICAL CYCLONE OF THIS STUDY

Return Period	500 years
Central Pressure	940 mb
Ambient Pressure	1013 mb
Radius of Max. Winds	30 km
Track (Bearing)	255°
Speed of forward movement	30 kph
Simulation Time	- 10 h to + 1 h
Initial Grid Position	(30.9, 46.1)
Final Grid Position	(0.2, 28.4)
Build-Up Time	4 hours

As with the tidal modelling, the storm is built up in magnitude over a number of hours, in order to minimise the unwanted effects of initial transients. The landfall position and path (Fig. 1) have been designed deliberately to cause maximum enhancement of the storm surge in the region of maximum tides (Fig. 2). According to Sobey *et al.* (11), the maximum surge for Southern Hemisphere cyclones should be situated a distance of order  $R$ , the radius of maximum winds, to the left of the eye at landfall, looking along the track of the storm. Thus both maximum tides and surge should occur around the mouth of Broad Sound, and it is hypothesised that this should result in a very considerable surge/tide interaction, to be discussed in the following section.

Figs. 5(a) and (b) show storm surge water levels for the standard run, at times of one hour before and after landfall ( $t = -1$  and  $+1$ ) respectively. At the chosen point (5,29), the maximum surge is of order 4.3 m, although larger values are obtained farther up Broad Sound. Longshore currents are particularly intense and reach a maximum value roughly two hours prior to landfall ( $t = -2$ ), as shown in Fig. 6. Maximum currents at this time are of order  $1.7 \text{ ms}^{-1}$ , or roughly 3.3 knots.

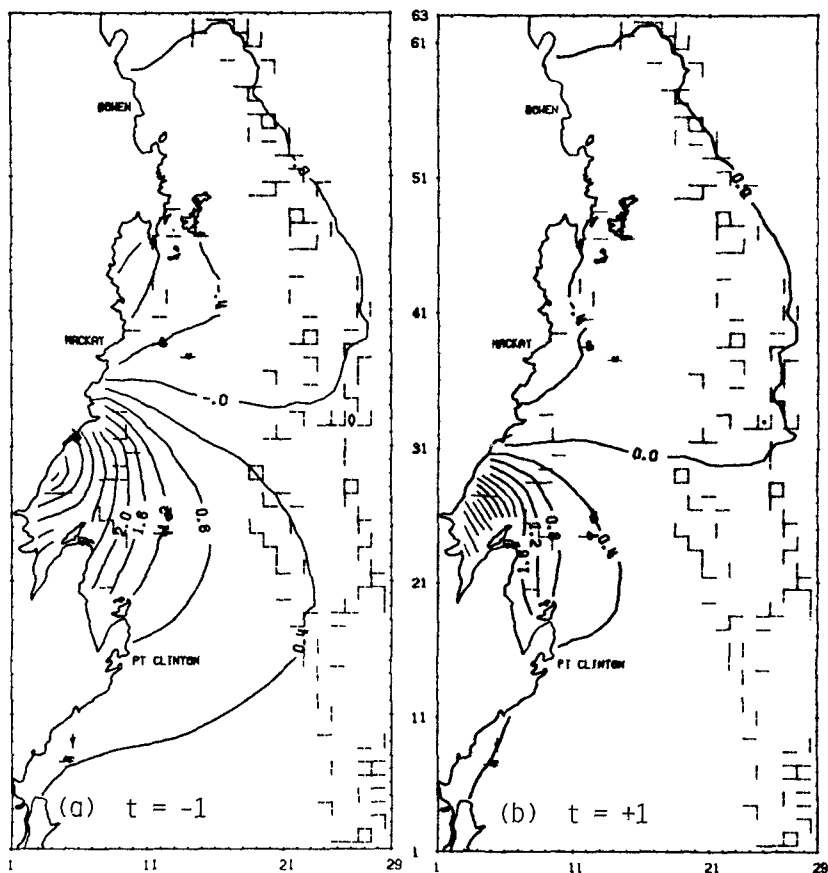

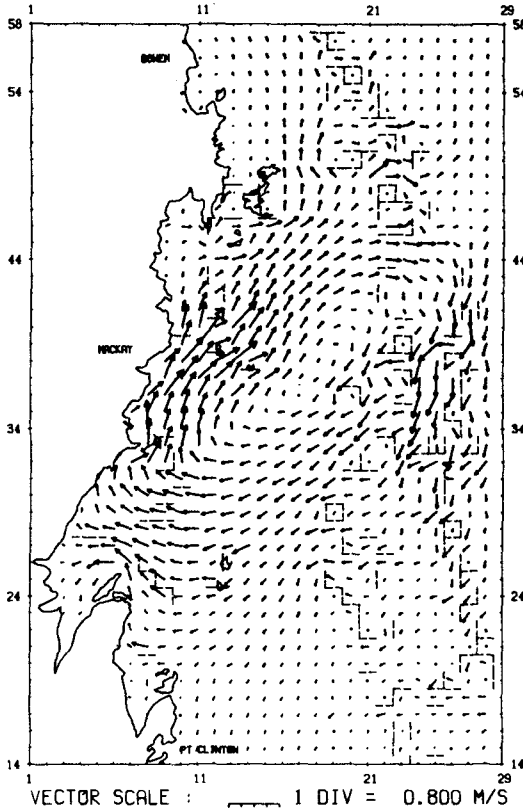

Fig. 5 Sea surface elevation (m) above MSL for surge alone at times (a)  $t = -1$  h and (b)  $+1$  h with respect to landfall.

Fig. 7 shows the results of the standard surge simulation, but without reef elements at  $t = -1$  - c.f. Fig. 4 for the corresponding tidal result. When compared with Fig. 5, it can be seen that, unlike the tides, storm surge water levels (and currents) are insensitive to the presence of even such dense reef structure as in the model region - see also Ref. (12). Apart from some minor differences, surge levels are almost unchanged by the absence of reef and peak levels are identical. Presumably, the transient nature of the rapidly moving cyclone, together with the intensely local nature of the forcing dictates such a response.

**Fig. 6** Depth-averaged currents for 'window' region at  $t = -2$ .

#### **SURGE/TIDE INTERACTION**

The calculations of the previous two sections have shown that both the storm surge and tidal phenomena have substantial magnitude, that are roughly of the same order. When this is considered along with the non-linearities of Eqs. (1)-(3), it would appear essential to consider the possible effects of surge/tide interactions. In other circumstances, this may not be necessary. For example, if the tide is the dominant effect, then it is possible to linearise the surge equation by appropriate techniques. Here, however, surge and tide are of the same order, but this presents no real difficulty with numerical modelling - boundary conditions and forcing terms from the individual simulations are added. The basic question is whether or not surge plus tide provided a sufficiently accurate estimate of the combined surge/tide simulation, and, if not, by how much does it under-estimate or possibly even over-estimate this?

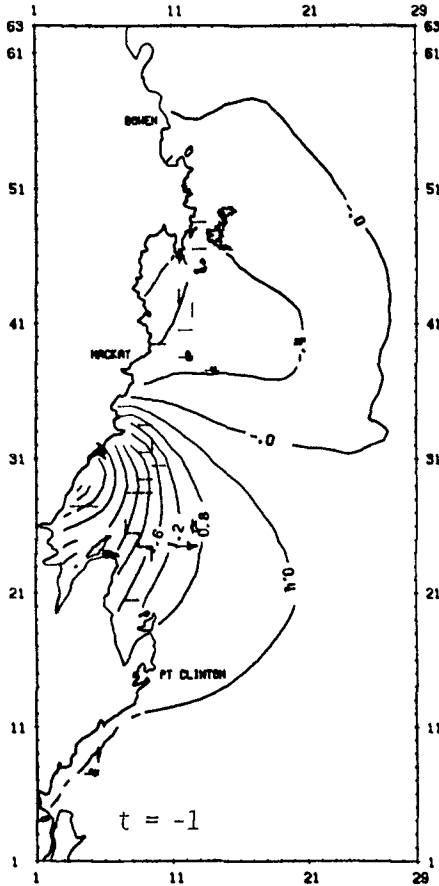

Fig. 7 As for Fig. 5(a) but without reef.

In spite of the above, there has been scant attention given to hurricane surge/astronomical tide interactions, although there are some good reasons for this omission. Hurricanes in the US impact predominantly in the Gulf of Mexico where the astronomical tide is negligible, and hence total water loads are basically provided by the storm surge alone. In the UK and Europe tides are quite significant, particularly in the North Sea region, which has been subject to a number of devastating storm surges (10). However storms are of the mid-latitude variety: they are almost always less intense and slower moving than hurricanes and

consequently differ considerably in their hydrodynamic response. The mid-latitude storm surge would appear also to be more amenable to analytical techniques. In this case, however, numerical modelling has demonstrated the importance of surge/tide interactions. Flather (5,8) has shown that surge hindcasts in the North Sea have been improved quite appreciably by joint consideration of the two effects.

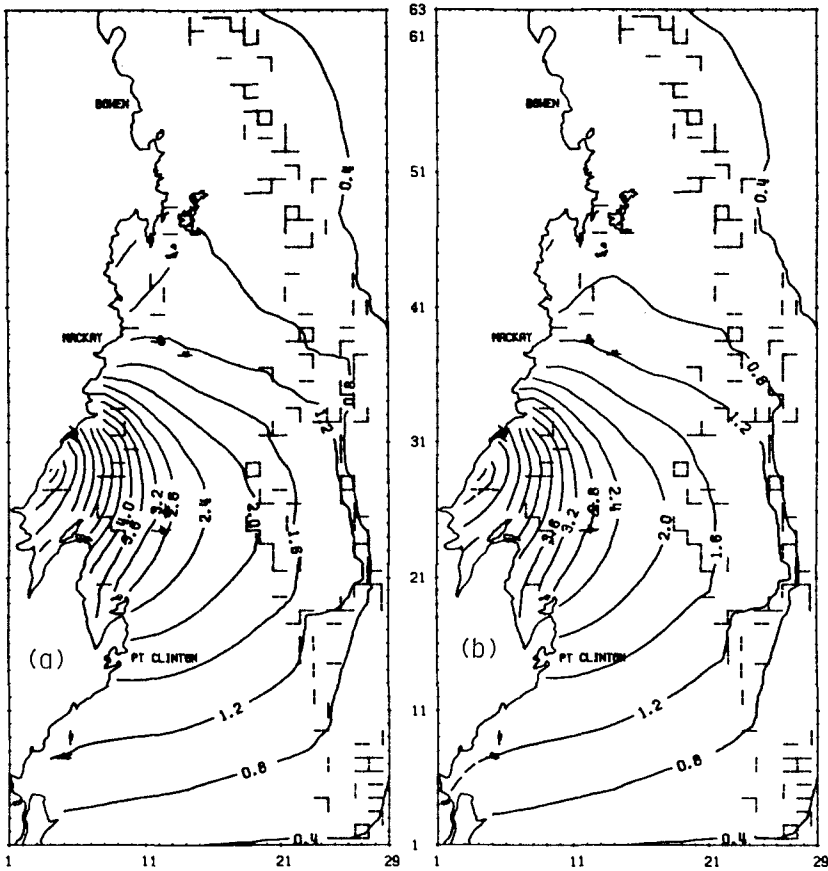

#### Theoretical Considerations

The essential non-linearity of the problem has also made it difficult to assess analytically. One approach that has managed some progress is that of Prandle and Wolf (10), through a combination of statistical, analytical and numerical techniques, that concentrated mainly on the (one-dimensional) response of the Thames Estuary to a North Sea surge. Here it has been observed that the net surge tends to peak on the rising tide but not at high tide. In addition, it appears possible in some circumstances for there to be surge *amplification* as well as a change in the phase of the surge (10).

There are two main non-linear terms in the equations of motion. In Eq. (1), these are the pressure terms  $(h+\eta)\partial\eta/\partial x$  and the quadratic bottom friction term. The first is affected by changes in the background water level and can be expected to change the propagation characteristics of a surface wave (its phase, principally), the second term is dissipative and is also affected by changes in water level - Eq. (1) - but the predominant effect is clearly due to the quadratic velocity term. Overall, the effect of a combined surge/tide might be expected to provide enhanced dissipation (by up to a factor of two!) if the surge and tide are of comparable magnitudes. An exception to this in one dimension is the case of opposing streams where the reduced dissipation may lead to possible surge amplification. An examination of the present two-dimensional case indicates that surge magnification would be most unlikely. In the case of a tropical cyclone storm surge, intense longshore currents (Fig. 6) are associated with the storm's passage across shallow continental shelf waters are . These provide a background against upon the quadratic friction term is applied, and the overwhelmingly likely result is a much higher dissipation rate with consequent damping in resultant elevation and current values. Prandle and Wolf (10) were able to show that the primary mechanism for surge dissipation was bottom friction; the pressure term had a negligible effect on surge levels, although, as noted above, the increase in background water level in the combined surge/tide case can result in higher wave celerities and consequent phase leads of peak surge levels. Both of these points are addressed below.

#### Results

Fig. 8 is a comparison of the sea surface elevations at 1 hour before landfall for the two cases: the sum of surge alone plus tide alone in (a) and the combined surge/tide simulation in (b). At the test position, grid point (5,29) the elevation at  $t = -1$ , which corresponds closely to the time of maximum surge, the elevations are 6.9 m and 6.1 m respectively. The marked reduction in total water levels for the combined simulation is apparent and is a most significant result.

**Fig. 8** Comparison of surface elevations (m) at  $t = -1$  for (a) Surge + Tide, (b) combined Surge/Tide simulations.

The net surge at  $t = -1$  is depicted in Fig. 9(a). This is obtained by subtracting the tidal elevation at  $t = -1$  from the combined surge/tide elevation at the same time. The elevation at (5,29) is 3.5 m. This result can be compared with the case of surge alone in Fig. 5(a) for which the corresponding elevation is over 4.3 m. An alternative representation is shown in Fig. 9(b) which is a 'window' view of the central portion of the model region - reefs are omitted for clarity, although they were retained in the simulation. This figure gives the

Fig. 9 (a) Net surge at  $t = -1$  for combined surge/tide; (b) Excess elevation (m) of surge plus tide over surge/tide at  $t = -1$ .

excess elevation obtained from the addition of surge plus tide at  $t = -1$  over the combined surge/tide elevations at the same time. This is obtained by subtracting the elevations of Fig. 9(a) from those of Fig. 5(a) and provides a measure of the extent to which the surge + tide result is conservative. Fig. 10 shows traces or time histories of the elevation and depth-averaged velocity components at (5,29). The chipping of the peaks is artificial and is due to the results of the numerical simulations being sampled much less frequently than the time step. Again, the reduction due to interaction, of both  $\eta$  and the velocity, particularly around the time of landfall, is clearly seen.

**Fig. 10** Traces of elevation and velocity components for surge plus tide and surge/tide simulations.

#### CONCLUSIONS

A number of important conclusions can be drawn from the present study. Firstly, the active role of the GBR chain in tidal amplification has been demonstrated. This is an unusual result, since elsewhere in the GBR Region, the reef appears to have a slightly dissipative effect on the tides, although in no way does it appear to act as a significant barrier. Here, by acting as a partial barrier to cross-shelf motion, longshore tidal streams are enhanced leading to an amplification, by the mechanism outlined. Storm surge levels, particularly for a track similar to that of the model storm of Fig. 1, would be very high in Broad Sound while longshore currents between there and Mackay would be of such magnitude as to cause significant changes to coastal morphology. The major result, however, is to show the significance of the surge/tide interaction. A reduction of total water levels of 1 metre is shown to be quite feasible and the corresponding economic and engineering implications warrant further attention in major coastal engineering studies.

#### ACKNOWLEDGEMENT

This work has been supported by a Marine Sciences and Technologies grant from the Australian Government.

## CHAPTER SEVENTEEN

### HURRICANE SURGE PROTOTYPE DATA COLLECTION

Thomas H. Flor<sup>1</sup>, and Susan C. Scott<sup>2</sup>

#### INTRODUCTION

Storm surges from hurricanes have even more devastating effects on human lives and property than the high wind velocities associated with such storms. Storm surge forecasts are necessary as a guide for emergency action to prevent disasters due to coastal flooding caused by tropical storms. The design and evaluation of coastal structures are also dependent on estimates of storm surge levels. Several numerical models have been developed that appear to reasonably predict the surge from storms of given size and intensity, but they sometimes differ significantly among themselves. A comprehensive data set is needed to quantitatively evaluate these models. These data will also provide a better understanding of coastal processes during periods of severe wave activity and high water levels, and will better define coastal and inland water elevation time histories, high water marks, and water velocity fields caused by tropical storms and hurricanes.

The U. S. Army Engineer Waterways Experiment Station (WES), Coastal Engineering Research Center (CERC), under the sponsorship of the Office Chief of Engineers (OCE), has been involved for several years in a project entitled Hurricane Surge Prototype Data Collection Work Unit, the primary objective of which is to collect such a data set. In addition to the work being performed by CERC personnel, a cooperative program has been established with the Nuclear Regulatory Commission (NRC) and the University of Florida to collect surge data along the coast of Florida. A cooperative program has also been established with the National Ocean Service (NOS) to "harden" tide stations in the Gulf of Mexico and along the Atlantic Coast of Florida to survive hurricane forces and record the full range of anticipated surge levels.

This paper describes CERC's long term, ongoing Hurricane Surge Prototype Data Collection project, as well as the data collected.

## SURGE CHARACTERISTICS

The most destructive element of a hurricane is the storm surge. Simpson and Riehl (3) define it as "a shoal water process generated by hurricanes resulting in a superelevation due to a combination of direct wind driven water and an uplift induced by the pressure drop; together they reach maximum heights as the hurricane center arrives at an ocean or bay shore". In addition to the wind and pressure induced rise in water level, astronomical, secular and seasonal tides, freshwater runoff from heavy rains, and the outfalls from rivers and streams all have a hand in the creation of a massive still water platform. This platform can reach far inland to places that ordinarily would remain quite safe and dry.

The hurricane storm surge height,  $H_s$ , is a function of three principal sources of setup (Simpson and Riehl, 3):

$$H_s = f(S_b, S_w, S_v)$$

where,

$S_b$  = setup due to the dynamic inverse-barometer effect, and is concentric to the low pressure center

$S_w$  = setup due to the stresses from the irrotational component of the wind

$S_v$  = setup due to the stresses from the rotational component of the wind

$S_w$  is the major component of the surge in more protected areas, such as basins, bays, or estuaries; whereas,  $S_v$  is the major component of storm surge along the open coast.

When a hurricane reaches landfall at an open coast, its peak surge height will be larger with lower central pressures; with an increase in the radius of maximum winds up to 30 miles (48 km); with increased speed of coastal approach; and with a decreasing slope of the bottom surface from the beach seaward for a distance equal to the diameter of the maximum winds (1,3). Storm surges in bays and estuaries may be larger than those at an open coast by 50% or more for slow moving storms.

## HURRICANE SURGE DATA COLLECTION

The approach selected to provide a high quality, comprehensive data set was to develop rapidly deployable instrument packages that could be installed at preselected sites 24 to 48 hours before predicted landfall of a hurricane or tropical storm. To provide a sufficient quantity and quality of data, site surveys were undertaken approximately every 10 miles (16 km) along the entire Gulf Coast and the Atlantic Coast of Florida to select onshore locations for instrument deployment. More closely spaced sites were selected to provide

a better picture of the time histories of hurricane induced water levels in major bays and estuaries in the project area.

Selection criteria for the onshore sites were as follows:

- a. Smooth, flat terrain where possible, to minimize small scale effects on the storm surge measurements.
- b. Absence, or a minimal number, of man made or natural structures near the site that could influence propagation of surge, but would not be represented in numerical surge models.
- c. The existence of a structure on which to mount instrument packages that had a high probability of surviving a major hurricane.

Obviously, not many sites could meet the criteria exactly. The site selection process required numerous compromises in selecting locations that would both provide quality data and withstand the rigors of a severe storm. At this time, 265 sites have been selected and catalogued in Texas, Louisiana, Mississippi, Alabama, and Florida. These locations are depicted in Figure 1.

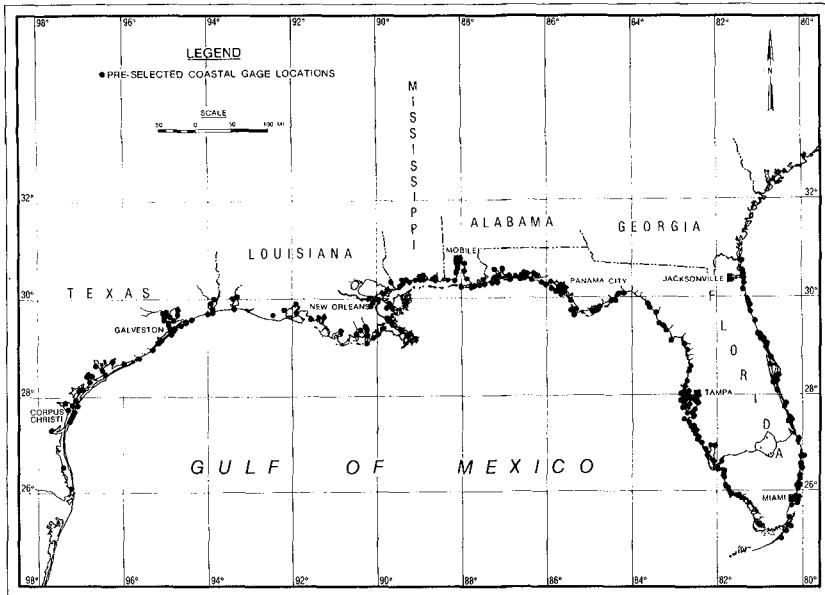

Figure 1. Preselected sites for onshore surge gages.

When a hurricane or tropical storm threatens the coast and the area most likely to be inundated is identified, water level instruments and mounting hardware necessary to occupy the preselected sites are loaded aboard a specially equipped deployment vehicle and the

field team proceeds to that area. The final decision on which preselected sites to occupy is made as more specific information on the expected point of landfall becomes available from the National Weather Service (NWS).

As soon as possible after landfall, the CERC field team recovers all instruments and surveys the area to delineate points of maximum inundation and the areal extent of hurricane induced flooding. The elevation of each instrument is marked and later tied into the National Geodetic Vertical Datum (NGVD) during post storm high water mark surveys.

In coastal areas without substantial structures on which to mount the instruments (e.g. south Louisiana), instrument packages are operated continuously throughout each hurricane season on available offshore structures. Three instruments are currently maintained on Shell Oil Company Platforms. These offshore sites are particularly useful since they provide surge data with virtually no small scale local effects from the coastal terrain, so that the data can be used in establishing boundary conditions in offshore areas. All three offshore sites are shown in Figure 2 as WES instruments.

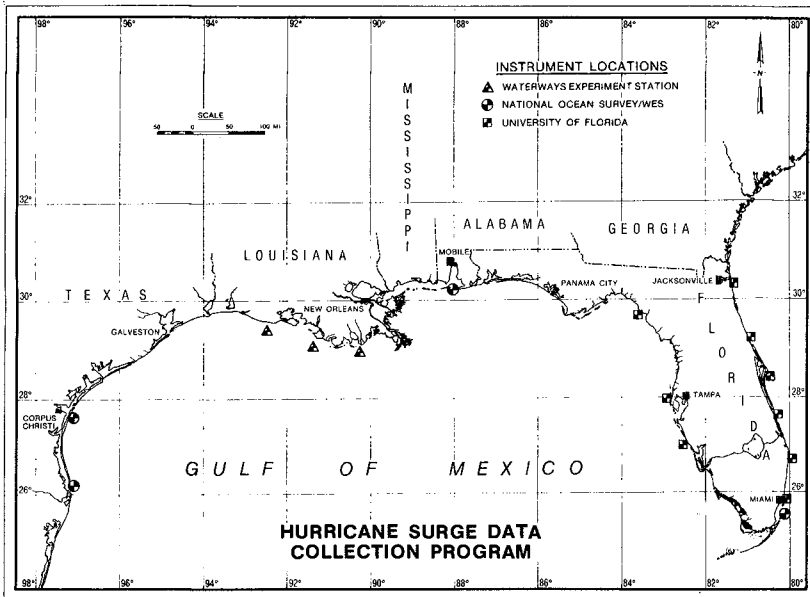

Figure 2. Permanent offshore surge gage sites.

Those instruments shown in Figure 2 as National Ocean Survey/WES sites are maintained as part of a cooperative effort with NOS. The sites in Miami, Dauphin Island, Alabama and Corpus Christi, Texas are NOS primary tide stations that have been "hardened" to survive hurricane conditions and contain a dedicated surge gage in addition to a

standard float-well type tide gage. The fourth NOS/WES instrument in Cameron County near the southern end of Padre Island was installed specifically for hurricane surge measurements. The nine University of Florida sites on the Atlantic and Gulf coasts of Florida are wave and surge gages maintained as part of a cooperative effort with the Nuclear Regulatory Commission and the University of Florida.

#### INSTRUMENTATION

In order to quickly deploy large numbers of instruments prior to landfall of a threatening hurricane, the instrument packages needed to be compact, rugged, and easily deployable by a 2-man team in a conventional size truck. Other desirable factors were: an independent power supply for continuous data collection throughout the storm, and digital recording capability to interface with existing data processing systems.

Twenty internally recording pressure sensors were acquired for this purpose. These instruments are microprocessor controlled data loggers which use a strain gage sensor to measure pressure at selectable time intervals and record data on small, continuous loop tape wafers. The submersible instruments can be quickly clamped to a bridge or pier pile.

For the sites at which a water level gage is maintained throughout each hurricane season, it was necessary to acquire instruments that could operate unattended for long periods and still collect data at short time intervals. Digitally recording wave and tide gages were selected to meet this requirement and to fulfill an additional objective, collection of wind generated wave data during a hurricane or tropical storm. These instruments sense pressure with a quartz crystal transducer and record both instantaneous wave heights and time integrated tide heights on four track data cassettes.

The hardened surge gages maintained by WES and NOS employ a gas purged pressure gage to measure surge due to tropical storms or hurricanes. Gas purged pressure gages, commonly known as bubbler gages, use a compressed dry gas, usually nitrogen, to activate a pressure sensitive diaphragm. Changes in water level are detected through an open-ended gas filled tube and recorded on a clock driven strip chart.

#### CORRECTION OF ABSOLUTE PRESSURE TIDE RECORDERS

Use of uncompensated pressure measuring sensors such as those employed at the preselected sites requires the data to be compensated for changes in atmospheric pressure during passage of the storm. A change of 1 mb in atmospheric pressure is approximately equivalent to a change of 1 cm in water level. Changes in atmospheric pressure of 50 mb are common during passage of a storm, consequently, it is essential such changes be taken into account when computing a hydrograph from uncompensated pressure data.

The simplest and most accurate means of compensating the pressure record would be to place a barograph near the tide gage; however,

this is seldom feasible both from logistic and economic standpoints. An alternative method is via an analytic model to interpolate in time and space using data observed elsewhere in the affected area. There are a number of models to choose from, some developed from theoretical considerations, others by empirical best fit to the smoothed pressure profiles of several hurricanes.

The model found to give the best fit to the observed data for previous hurricanes is:

$$\frac{P - P_0}{P_\infty - P_0} = C (\text{Arctangent } r/R)$$

where

- P - pressure to be computed
- $P_0$  - central pressure of storm
- $P_\infty$  - far field pressure
- R - radius to maximum winds
- r - distance from storm center at which pressure is to be computed
- C - constant

## RESULTS

Since the Hurricane Surge Data Collection program was initiated in 1980, Hurricane Alicia (August 1983) gave the CERC field team its first opportunity to use the technique described under actual hurricane conditions. Alicia was the first storm of the 1983 hurricane season and the first to make landfall in the continental U. S. since Allen in August 1980. Hurricane Alicia was unusual in that it developed in the central Gulf of Mexico and made landfall less than 2 days after showing signs of becoming a significant storm. Alicia was classed as a minimal category 3 at landfall on the SAFFIR/SIMPSON scale, which ranges from one to five.

Alicia was declared a hurricane at 0000 GMT 17 August 1983 with a central pressure of 991 mb and maximum sustained winds of 75 mph (120 kmph). The hurricane continued to intensify until it made landfall at the western tip of Galveston Island, Texas at approximately 0700 GMT 18 August. Its central pressure at that time was 963 mb with maximum sustained winds close to 115 mph (185 kmph).

The staff of CERC had been closely monitoring Alicia's development, when it became evident at 1700 GMT on 16 August that the storm was rapidly deepening, the field team was sent to the Houston-Galveston area, arriving at daybreak on 17 August. Galveston Island by this time was being evacuated. Since coastal water levels had already risen and the sea state was high, it was not possible to deploy onshore gages along the gulf side of Galveston Island and lower Galveston Bay. Information from the National Hurricane Center

at the time indicated the storm would make landfall between Corpus Christi and Freeport, Texas. The field team thus departed from the Houston-Galveston vicinity for the Matagorda Bay area. Enroute, the team deployed one gage package at Baytown, Texas near the head of Galveston Bay, in the event that Alicia turned northward as it later did.

In the time remaining before landfall, the field team deployed gage packages at Port Lavaca and Palacios, Texas in the Matagorda Bay area. At 0300 GMT, 18 August, approximately four hours before landfall, the field team retreated to Houston to wait out the storm.

Hurricane Alicia made landfall at the western tip of Galveston Island, traveled northward and was classified as a tropical depression after moving past Houston at 0600 GMT 19 August.

After the passage of the storm, the field team returned to the Galveston area to recover the instrument packages and begin a survey of high water marks.

The final compiled data set was obtained from a variety of sources including gage records from the Corps of Engineers, National Ocean Service, and private corporations.

The data set contains:

- a. Maximum water elevations from post-storm high water mark surveys.
- b. Histories of the time averaged water level at both coastal and inland locations.
- c. Areal extent of inundation.

Table 1 lists the gage location, responsible agency or institution for data, maximum water elevation, time and date, and reference datum. Figure 3 shows the locations of instruments that recorded water level data in the Galveston Bay area during hurricane Alicia.

Hydrographs at the Pleasure Pier and Pier 21 in Galveston (Figures 4 and 5) show the peak of the surge coincided with the predicted high tide. Assuming the tide and surge effects were linearly superimposed, the surge relative to the predicted tide was about 7.4 ft (2.25 m) at the Pleasure Pier on the ocean side and 4.9 ft (1.5 m) at Pier 21 on the bay side of Galveston Island. At Freeport, Texas, there were three peaks, two on 17 August, one day prior to landfall and one approximately coinciding with landfall. The three peaks were about 2.9 ft (0.88 m), 3.1 ft (0.94 m), and 2.5 ft (0.76 m) relative to the predicted tide. The highest surge value did not occur at landfall because Freeport was on the "backside" of the storm, i.e., the winds at Freeport were primarily offshore at the time.

As shown in Figure 3, the Pier 21 and Pleasure Pier gages are located quite close to one another and the hydrographs reflect this. The Hanna Reef gage, located on the opposite side of the bay, shows a

Figure 5. Hydrograph from NOS tide gage at Pier 21 inside the entrance to Galveston Bay.

broader peak followed by a relatively long tail. The broader peak and slower fall in water level were probably caused by waters that had been blown into the northwest reaches of the bay by the predominantly southeast winds during the storm flowing back into the Hanna Reef area after the storm had passed.

The gage at Anahuac recorded until submerged; attempts were made to determine a high water elevation nearby but the adjacent land is flat and featureless and overgrown with scrub vegetation.

The data obtained at the EXXON Corporation Baytown Refinery are a combination of readings from a strip chart recorder and digital readout. The strip chart recorder had a maximum excursion corresponding to about eight ft elevation. The water level sensor continued to function normally driving a remote readout from which surge heights were logged manually. The maximum surge recorded at the Baytown Refinery agrees very closely with nearby high water marks.

The CERC field team deployed two surge packages in Matagorda Bay, one at Port Lavaca and one at Palacios, Texas. Data from these gages showed no significant departure from the expected tide during passage of the storm. This is not unexpected as these gages were on the "backside" of the storm about 70 miles (112 km) from the point of closest approach.

The CERC gage T-14 functioned until about 0300 CDT 18 August when it failed. The cause of the failure was determined to be a defective pressure case which allowed water into the electronic circuits.

Figure 6. Hydrograph from tide gage at Hanna Reef in Galveston Bay.

#### POSTSTORM SURVEY OF HIGH WATER LEVELS

A poststorm visual survey of high water marks was made from Matagorda Bay east to High Island, Texas, including the shoreline of Galveston Bay, during the period 21-23 August 1983. The westernmost extent of surge induced flooding appeared to have been in the vicinity of Sargent, Texas at the eastern end of Matagorda Bay. Coastal flooding in this area, due to storm surge and wave setup, overtopped the low berm on the beach and built numerous washover fans on vegetated wetlands between the beach and a high man-made dune along the Intracoastal Waterway. The surge generated component of this rise in water level appeared not to exceed +3 ft (0.9 m) NGVD. Debris lines along the banks of the Intracoastal Waterway indicated a rise in water level of approximately +2 ft (0.6 m) NGVD.

At the U. S. Coast Guard Station in Freeport near the mouth of the Old Brazos River, high water overtopped a low bulkhead approximately 3 ft (0.9 m) above the normal water line but caused minimal flooding of the station itself. On Follets Island, located between Freeport and San Luis Pass, highwater overtopped highway 257 which is at an elevation of +8 ft (2.4 m) NGVD and caused numerous cuts through the dunes and sections of the roadbed. As described by Savage et. al., (2), these cuts were formed by highwater flowing from

Christmas Bay across the barrier island and out into the Gulf. The entire eastern tip of Follets Island at San Luis Pass appeared to have been inundated by the surge.

Between San Luis Pass and Jamaica Beach, 10 miles (16 km) to the east, the surge exceeded +9 ft (2.7 m) NGVD, overtopping Highway 257, the highest point on the western end of Galveston Island. Residences in this area exhibited extensive damage primarily from wind action. The total rise in water level reached approximately +11 ft (3.4 m) NGVD in Jamaica Beach and tapered to about +7 ft (2.1 m) NGVD near the western end of the Galveston seawall. Water levels rose from both the Gulf of Mexico and East Bay sides on this portion of the island but did not exceed the elevation of the coastal highway.

In the city of Galveston the storm surge did not exceed the +15 ft (4.6 m) NGVD elevation of the seawall. Storm damage was limited to wind damage, some wave overtopping of the seawall and flooding of low lying areas near the causeway on the bay side. At East Beach, seaward of the Galveston seawall, the surge reached approximately +7 ft (2.1 m) NGVD, causing extensive damage to residences and commercial buildings and leaving large debris piles at the base of the seawall. Surge levels on the Bolivar Peninsula reached +7 to +8 ft (2.1 to 2.4 m) NGVD between the western end of the peninsula and Crystal Beach, rising from both the Gulf and Bay sides of the peninsula but failing to inundate Highway 87 and many homes built on high ground along the highway. At High Island, 50 miles (80 km) east of the point of landfall, the surge reached +4 to +5 ft (1.2 to 1.5 m) NGVD flooding extensive low lying marsh areas and depositing large amounts of sand on Highway 87.

At Virginia Point, just north of Galveston Island, the surge covered the Gulf Freeway up to approximately +7 ft (2.1 m) NGVD, cutting off access to the island during the height of the storm. The Texas City Dike was overtopped along most of its length but the Texas City Levee system protected the city from surge induced flooding. The surge along this section of the bay is estimated to have been between +7 and +10 ft (2.1 and 3.0 m) NGVD. At Seabrook, 15 miles (24 km) north of Texas City, the storm surge reached approximately +9 ft (2.7 m) NGVD, the water level remained considerably higher than normal in this area for at least 3 days after landfall.

High water marks at Baytown indicated a surge at the north end of Galveston Bay of approximately +10 ft (3.0 m) NGVD. The water level in this area rose 3 to 4 ft (0.9 to 1.2 m) above normal by the morning of 17 August 1983 and remained several feet higher than normal for at least 3 days after landfall. East of Baytown, in the Houston Point area, the shoreline is backed by bluffs 15 ft to 20 ft (4.5 to 6.0 m) high which prevented significant surge damage. No distinct highwater marks were located in this area.

The maximum water level at Anahuac, in the northeast corner of the bay exceeded +8 ft (2.4 m) NGVD, flooding a Texas Water Resources Board recording tide gage. The topography in this area is flat and low lying, allowing the surge to propagate north past the Interstate 10 crossing of the Trinity River 7 miles (11 km) north of Anahuac.

Debris along the I-10 causeway indicated a surge level near +10 ft (3.0 m) NGVD. At Smith Point, 15 miles (24 km) south of Anahuac, high water marks in a county park indicated a rise in water level of approximately +5 ft (1.5 m) NGVD. Smith Point and the bay shoreline to the east are low lying wetland areas that were inundated by the surge except for high ground along Highway 562 and isolated highspots 5 to 10 ft (1.5 to 3.0 m) above NGVD.

#### FUTURE PLANS

While much of the coastline presently encompassed by the study is either accessible from inland or has some offshore structure suitable for semi-permanent instrumentation, there are some lengthy reaches where the only feasible means of data acquisition is by use of a temporarily deployed offshore device. To address this need, WES, with the assistance of the U. S. Army Research and Development Center, Natick, MA, has under development an air deployable wave/surge gage. The primary goal of this effort is the development of a launch vehicle and the methodology to successfully deploy the device from a C-130 type aircraft. Presently, the system is designed to accommodate acoustic or electromagnetic type water level and current meters.

In October, 1983, an agreement was reached with the National Hurricane Center (NHC) to provide manpower and equipment (trucks, helicopters, etc.) to deploy surge gages when a storm threatened the South Florida coastline. Since storms tend to travel parallel to the south Florida coast, a small error in predicted track can translate to a large error in point of landfall. The assistance of supplemental field teams allows coverage of a greater reach of coastline thereby increasing the probability that the storm will be intercepted.

Hopefully, more joint programs with District CE offices can be established to provide additional benefits to the surge data collection effort. Two field teams and twenty instrument packages will be maintained in a state of readiness for the next 3 to 4 hurricane seasons to collect data from any hurricane making landfall on the U. S. Gulf Coast. Individual data reports for each storm will be published by CERC.

#### ACKNOWLEDGEMENTS

This paper was prepared as part of the Hurricane Surge Prototype Data Collection Work Unit, Coastal Flooding and Storm Protection Program, Coastal Engineering Area of Civil Work R&D. The work unit is a multiyear project of the U. S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center. The authors wish to acknowledge the Office, Chief of Engineers, U. S. Army Corps of Engineers, for authorizing publication of this paper.

Additional thanks go to Mr. Andrew Garcia, principal investigator of the Hurricane Surge Prototype Data Collection Work Unit, and Ms. Joe Ann Green, Ms. Mary M. Logan and Mr. Toby Wilson for their assistance.

## CHAPTER EIGHTEEN

### Hurricane Alicia Storm Surges And Shore Processes

R. P. Savage\*

#### Abstract

Hurricane Alicia moved inland over the Texas coast during the night of August 17, 1983 creating waves and surges in the Gulf of Mexico and adjacent bays. Waves eroded beaches and dunes and surges overtopped low-lying areas of barrier islands and inland areas adjacent to the bays behind the barriers. A three-day survey of field evidence of water levels and flow directions was carried out one week after the storm. Physical evidence, such as the elevation of debris lines, water marks in buildings and debris caught on fences was used along with additional data from tide gages operating in the area to estimate the maximum flood levels and flow directions associated with the storm. Before and after aerial photography was used to obtain data on beach recession, retreat of the vegetation line behind the beach and extent of overwash deposits. The evidence gathered shows that the barrier islands were overtopped from front-to-back in some areas and from back-to-front in other areas with quite different results. There was little or no beach erosion to the left of the storm as it came ashore; however, serious beach erosion occurred for 18 miles (29.0 km) to the right of the storm and there was significant erosion for 55 miles (88.5 km) to the right of the storm. Maximum water levels in the Gulf, including the effects of normal tides and storm effects, were 9 to 11 feet (2.74 to 3.35 m) and maximum water levels along the northern portion of Galveston Bay were 11 to 14 feet (3.35 to 4.27 m).

#### Introduction

Hurricane Alicia made landfall near the western end of Galveston Island (Figure 1) during the predawn hours of Thursday, August 18, 1983. At landfall, the storm was a little above average in size and intensity with highest winds near 100 miles per hour (44.73 m/sec-ond). The area of high winds covered most of Galveston Island and extended eastward along Bolivar Peninsula. High storm water levels and waves overtopped western Galveston Island, Galveston's East Beach and the front of western Bolivar Peninsula. Surges also created high water levels in the bays behind the islands. Waves and surges modified beaches and dunes creating overwash deposits and cutting channels through dunes. This paper presents and discusses field and other evidence of the magnitude and effects of Alicia's waves and water levels.

### Data Collection

#### Storm Water Levels

Water level estimates were obtained from field evidence gathered during a field survey on 23, 24 and 25 August (Savage et al. 1984). Field observations included water marks in buildings, debris lines, beach and dune changes, overwash deposits and scour marks. Unless otherwise noted, all elevations refer to the National Geodetic Vertical Datum (NGVD).

Watermarks in closed buildings are good indicators of maximum water levels that do not include the effects of wave action. However, during the field survey, watermarks were difficult to distinguish, probably because the flood waters contained little or no sediment. No water marks were observed on the outside of buildings, and water

marks inside buildings were composed of bits of vegetation, including seeds. Debris lines, usually composed of loose vegetation, were common and were usually a clear, though not precise, indicator of maximum water level. Where their height spanned the flood level range, fences were also a good indicator of maximum water level because bits of floating vegetation were caught by the individual fence strands. Thus the line between bare and "clothsline" strands clearly indicated the maximum water level. Estimates of water levels from water marks, debris lines and fences were made by visually estimating the distance of the evidence above the ground level. The elevation of the ground level was obtained from the 7.5 minute series of topographic quadrangle sheets (quad sheets) published by the U. S. Geological Survey (USGS). Maximum water level estimates are probably accurate to plus or minus 1.5 feet (0.46 m). Water level estimates were also obtained from operating tide gages. NOAA maintains two gages in the immediate Galveston area and other gages at Freeport and Sabine Pass, however the Sabine Pass gage did not operate during Alicia's landfall. Other gages, operated by companies, The Corps of Engineers, and Civil Defense Offices were operating in the area affected by the storm (U. S. Army Corps of Engineers, Galveston District, 1984).

#### Shore Processes

Estimates of horizontal beach, dune and vegetation line changes were obtained from aerial photographs taken before and after the storm by NOAA. The "before" set (nominal scale 1 to 40,000) was taken on October 15, 1982 and November 5, 1982. The "after" set (nominal scale 1 to 30,000) was taken on August 24, 1983, seven days after storm passage. Ground measurements between points visible on the aerial photographs were made from Geological Survey (GS) quadrangle sheets and used to establish scales for individual photographs. Data was scaled from the photographs along selected lines, usually along streets perpendicular to the beach, using a scale divided into 600 parts/foot (1962 parts/m). Though individual measurements were estimated to a tenth of the smallest division, ground distance errors as large as plus or minus 30 feet (9.14 m) are possible. Measurements were made from the cross street nearest the beach to the feature of interest. Horizontal features measured were the high water line, the vegetation line just behind the beach and the scarp line where a scarp existed.

#### Storm Water Levels and Flow Patterns

Maximum water levels along the Gulf side of Galveston Island varied from 9 to possibly 11 feet (2.74 to 3.35) above NGVD. The NOAA tide gage on Pleasure Pier recorded a maximum water level of 9.0 feet (2.74 m) at 1:24 a. m. Central Standard Time (CST), August 18th (Figure 2). Since the peak of the storm surge occurred at high tide, which should have been at el. 1.7 feet (0.52 m), the storm surge portion of the high water level was about 7.3 feet (2.23 m). Observations along the front of Galveston Island during the field survey showed considerable overtopping of East Beach (a 3.5-mile (5.6 km) beach fronting the Galveston seawall just west of Galveston Inlet)

Figure 2. Tide hydrographs from gages at Baytown, Pleasure Pier, Pier 21, and Freeport during Hurricane Alicia. The reference level for the Baytown gage is mean sea level.

and the western portion of Galveston Island all the way to San Luis Pass. Maximum water levels along the back of Galveston Island varied from 6 feet (1.82 m) to as much as 9 feet (2.74 m). The NOAA tide gage on Pier 21 in Galveston Channel (behind Galveston) recorded a maximum water level of 5.8 feet (1.77m) at 2:12 a. m. CST on August 18th (Figure 2). Observations along the back of Galveston Island indicated that the maximum water level was generally not more than 1 to 2 feet (0.31 to 0.62 m) above the land level - estimated at 5 to 7 feet (1.52 to 2.13 m) from quadrangle sheets. Maximum water levels along the back of the island increased from about 6 feet (1.82 m) at the eastern end of the island to about 9 feet (2.74 m) 3 miles (4.8 km) east of San Luis Pass. To the west, water level elevations exceeded 10 feet (3.05 m) in the bays behind Follets Island.

Along the front of East Beach, the beach was overtopped by 2 to 4 feet (0.62 to 1.24 m) of water which then flowed landward toward the seawall. When the overtopping water reached the seawall, it turned eastward and ran over the shoreward part of the north jetty into Galveston Inlet. The higher dunes on the front of East Beach were not overtopped, but were partially eroded while acting as headlands that created accelerated flow and scour channels in low areas between dunes (Figure 3). Observations along the front of Galveston Island west of the seawall showed that the front of the island had been overtopped by a foot (0.31 m) or more of water along most of the island length. Two areas not overtopped, a half-mile (0.8 km)

Figure 3. View toward Gulf showing channel cut by overtopping Gulf water on East Beach. Note vegetation along back of beach, showing cut did not extend through beach, and beginning of outwash fan that forms the landward end of the cut.

section about one-half mile (0.8 km) east of Galveston Island State Park and a two and one-half mile (4.0 km) section eastward from Sea Isle (Figure 1), had dunes higher than 10 feet (3.05 m) in elevation. In other areas, debris lines on fences and against embankments and dunes along the highway indicated maximum Gulf water elevations of 8 to 11 feet (2.44 to 3.35 m), including the effects of wave action. Evidence of water flow across the body of the island from the bay toward the Gulf began about 3 miles (4.8 km) east of San Luis Pass. Otherwise, all evidence pointed to water flow from the Gulf toward the bay.

Follets Island is immediately west of Galveston Island across San Luis Pass. Only the eastern eight and one-half miles (13.7 km) of this island were covered by the ground survey. In this area, flow evidence was remarkably consistent - water flowed only from the bays toward the Gulf. Maximum water elevations in the bays were about 10 feet (3.05 m) or more. Maximum water level evidence consisted of debris lines on the bay side of the dunes at distances of 1.5, 2.0, 4.5, 7.5 and 8.5 miles (2.4, 3.2, 7.3, 12.1 and 13.7 km) from the eastern end of the island and a stranded houseboat between the highway and the dunes fronting the Gulf at the 4.5 mile (7.3 km) point. Evidence for flow direction was the location of debris lines on the bay side of the dunes, the location of the grounded houseboat and the characteristics of several cuts through the dunes and body of the island between the highway and the Gulf (Figures 4-6).

Figure 4. Aerial view of cut formed by Gulfward flowing water on Follets Island.

These cuts started at the beach and ended seaward of or at the highway; however, one cut extended completely through the highway and other cuts ended in the highway pavement (Figures 4 & 6).

Bolivar Peninsula lies eastward across Galveston Inlet from Galveston Island. Only the first 11 miles (17.7 km) of the Peninsula were surveyed during the ground survey. The 3 miles (4.8 km) of the island immediately east of Galveston Inlet is low with maximum elevations of 6 feet (1.83 m) or less. East of this point, a relic dune ridge rises near the middle (front-to-back) of the island and extends eastward to Caplen (1.5 miles (2.4 km) west of Rollover Pass - Figure 1) where the dune ridge joins the dunes behind the beach. Maximum elevations of the dune ridge vary from 9 to 11 feet (2.74 to 3.35 m). Debris lines on fences, scour adjacent to the highway and the way the grasses were bent showed that the first 5 miles (8.1 km) of the road along the Peninsula had been overtopped by water flowing from the Gulf toward the sound. Evidence of overtopping ended abruptly where the road rose from the lower elevation to cross and run behind the relic dune ridge. Thus, water levels in the Gulf along the western part of Bolivar Peninsula were higher than 6 feet (1.83 m), but lower than 10 feet (3.05 m).

Figure 5. Gulfward view of Follets Island cut showing erosion of dunes behind beach. Highway pavement is in foreground.

Figure 6. Landward end of a Follets Island cut showing undercutting of road pavement.

Study of the aerial photographs of Bolivar Peninsula taken after the storm showed that the front of the western 17 miles (27.4 km) of the Peninsula had been overtopped by the Gulf storm surge. Though water flowed across the western 3 miles (4.8 km) of the Peninsula, the relic dune ridge running from the center (front-to-back) of the Peninsula at the 3-mile (4.8 km) point to the beach at Caplen caused the overtopping water to pond between the Gulf frontal dunes and the relic dune ridge. When the water level in the Gulf dropped, the ponded water flowed back into the Gulf through a series of low points (at least 4) in the frontal dunes creating cuts across the beach and through the frontal dunes similar to those on Follets Island (Figure 4). However, the cuts were different in that they were triangular - wide at the beach and narrow inland - presumably because the cutting flow rates diminished as the level of the ponded water level dropped.

Only two mainland areas adjacent to Galveston Bay were covered by the ground survey - Seabrook and the Texas City hurricane flood protection dike, both on the western side of the Bay. The debris line on the Texas City dike was low on the front of the dike indicating maximum water levels there of about 5 feet (1.52 m). At Seabrook, along Todville Road, scour in the yards of houses and damage to structures showed water levels had been at least 3 feet (0.93 m) above the ground level. In the Baytown area, tide gage records (Figure 2) and debris line measurements showed maximum water levels of 10 to 11 feet (3.05 to 3.35 m).

#### Shore Processes

A total of about 70 miles (112.7 km) of coastline are covered by the aerial photograph measurements; about 55 miles (88.6 km) to the east (right) of the storm and about 15 miles (24.2 km) to the west (left) of the storm. No measurements were made in front of the Galveston seawall or just east of Galveston Inlet. Results of the measurements are presented in Table 1 and Figures 7-9 where the inland direction is positive. Change in the high water line and vegetation line is shown in columns 2 and 3 of Table 1 for the distances in column 1. Columns 4 and 5 contain data only where a beach or dune scarp existed after the storm. The change in high water line (column 2) is a rough measure of beach retreat during the storm. The measure is rough because the data (aerial photographs) were taken about a year apart and some of the change may have occurred before the storm. In addition, the measurement technique could result in errors of 50 feet or more in the change figures. The meaning of the change in the vegetation line (column 3) varies with conditions after the storm at the measurement point. In overwash areas the change in the vegetation line measures the magnitude of both erosion and overwash. Where there was beach and dune erosion that ended in a scarp, the change in the vegetation line is a measure of the beach and dune recession (column 4). In some areas overwash deposits extended inland from scarps. In these cases, the horizontal magnitude of both the beach and dune erosion and the overwash deposits (column 5) were defined.

A striking aspect of the high water line changes is the abrupt change where the center of the storm crossed the coast. Recession prevailed to the right of the storm and accretion to the left of the storm. The demarcation at the center of the storm is a strong indication that the large, erosive waves generated by the onshore winds to the right of the storm during the nearshore storm surge were closely confined to the area of the strong onshore winds. A second, somewhat unexpected result, is the advance of the high water line immediately to the left of the storm. Two phenomena could account for this. First, flattening of the beach profile by the storm could shift the high water shoreline seaward even though there had been volumetric erosion of the beach and dunes. Second, from Figure 4 it is apparent that considerable beach accretion (50 feet (15.24 m) or more) occurred after the storm, but before the photograph was taken. Since the Figure 4 photograph was taken on August 26 and the aerial photographs were taken on August 24, it is likely that the accretion is included in the beach change measurements. If so, similar accretion is probably included in the high water line change measurements to the right of the storm. Thus, the column 2 figures probably underestimate the beach recession by as much as 50 feet (15.24 m).

The largest recession rates occurred just to the right of the storm center and measured recession of 100 feet (30.5 m) or more extended up to 17 miles (27.4 km) to the right of the storm center where the Galveston seawall starts. There was little or no beach in front of the seawall either before or after the storm and no measurements were made there. While recession of more than 100 feet (30.48 m) was measured on Bolivar Peninsula, not many points changed that much. Recession appeared to be tapering off at High Island, 55 miles (88.6 km) to the right of the center of the storm.

Changes in the vegetation line generally followed the pattern of high water line changes. Changes in the vegetation line were larger because the vegetation line can be changed by both erosion (the vegetation is carried away) and overwash (the vegetation is buried). The largest change in the vegetation line (over 1000 feet (304.8 m)) was measured at Terramar Beach. From both the ground survey and the photographs, it was obvious that most of this change was caused by overwash which buried the vegetation under up to three feet of sand. On western Galveston Island, the vegetation line receded over 100 feet (30.48 m) at all points where measurements were made except for two adjacent points between Jamaica Beach and Sea Isle. The ground survey showed that this area was one of the limited areas not overtopped by the storm surge on western Galveston Island. Vegetation line retreat was over 200 feet (60.96 m) at three of the measurement points on Bolivar Peninsula and over 100 feet (30.48) at three others, but tapered off in the vicinity of High Island, 55 miles (88.6 km) to the right of the center of the storm.

Figures 7-9 present the Table 1 data as averages over 5-mile (8.1 km) intervals along the coast. The number of measurements used in 5-mile (8.1 km) intervals varies from none along the seawall, across Galveston Inlet and the western portion of Bolivar Peninsula to as many as 7 along part of western Galveston Island.

Figure 7. Change in high water line compared to the change in the vegetation line.

Beach and dune erosion and the width of overwash deposits could be measured separately where a scarp existed. A scarp was common along western Galveston Island, uncommon along Bolivar Peninsula and non-existent in the measurements made to the right of the storm center. Where measured separately (Figure 8), beach and dune recession on western Galveston Island averaged 90 feet (27.43 m) with a maximum of 160 feet (48.76 m). Overwash deposit widths on western Galveston Island that could be measured separately (Figure 9) averaged 87 feet (26.52 m) with a maximum of 154 feet (46.92 m).

Figure 8. Erosion of vegetation line as shown by erosion scarps compared to the total change in the vegetation line.

Figure 9. Width of overwash fans landward of erosion scarps compared to the magnitude of the change in the vegetation line.

## Conclusions

### Coastal Surges

1. Storm water levels in the Gulf of Mexico reached a maximum level of 9 to 10 feet (2.74 to 3.35 m) in the area from the west jetty of the Galveston entrance westward to and just past Bay Harbor on western Galveston Island, a distance of about 25 miles (40.3 km). Maximum water levels decreased slowly with distance both eastward and westward of this central area.

2. Maximum water levels in East and West Bays just behind Bolivar Peninsula and Galveston Island were generally 6 to 7 feet (1.83 to 2.13 m). However, in the Bays behind Follets Island, water levels increased reaching elevations of from 8 to 10 feet (2.44 to 3.05 m).

3. Maximum water levels around the west side of Galveston and Trinity Bays reached elevations ranging from around 8 feet (2.44 m) near Texas City and Baycliff to between 10 and 11 feet (3.05 to 3.35 m) in the Baytown area.

4. With the exception of the 9.5-mile (15.3 km) section protected by the Galveston seawall, almost all of Galveston Island was overtopped by a foot or more of water from the Gulf of Mexico. East Beach, in front of the Galveston Seawall, was overtopped by 3 to 6 feet (0.91 to 1.83 m) of water.

5. Follets Island was overtopped by the high water level in the bays behind the island from San Luis Pass to within 4 miles (6.4 km) of the Freeport entrance channel. This overtopping from bays-to-Gulf cut more than 30 distinctive channels starting at the beach, through the frontal dunes, toward, to, and in some cases into, the highway running behind the beach.

6. The western 3 miles (4.8 km) of Bolivar Peninsula was overtopped by water from the Gulf of Mexico. East of that point the front of the Peninsula was overtopped, with water ponding between the foredunes behind the beach and a relic dune ridge inland on the island. When the Gulf surge retreated, the ponded water ran back into the Gulf, cutting at least four large, triangular channels through the frontal dunes and beach.

### Shore Processes

1. A striking aspect of the shore processes during the storm was the strong demarcation between high-water line recession to the right of where the center of the storm crossed the coastline, and high water line advance just to the left of the storm center.

2. Retreat of the high-water line on western Galveston Island, measured from before and after aerial photographs, ranged from about

15 feet (4.57 m) near the seawall to almost 200 feet (60.96 m) near San Luis Pass. Along most of the beach from Jamaica Beach westward, retreat was more than 100 feet (30.48 m). At Terramar Beach and westward, high-water line recession was 170 feet (51.82 m) or more.

3. The vegetation line retreated more than 1,000 feet (304.8 m) at Terramar Beach, with an average retreat of 200 ft or more on western Galveston Island.

4. On Follets Island, the mean high-water line advanced an average of about 30 feet (9.14 m). Vegetation line retreat was small, usually less than 25 feet (7.62 m).

5. There was serious retreat of the high-water line (100 feet (30.48 m) or more) for the first 17 miles (27.4 km) to the right of the storm and significant retreat (20 feet (6.10 m) or more) for at least 55 miles (88.6 km).

6. Changes in the vegetation line generally followed the pattern of changes in the high-water line, but vegetation line changes were larger because they were a result of both erosion and overwash.

7. There was a marked difference in the frequency and appearance of scour cuts made in areas where water flowed from Gulf to bay as opposed to areas where water flowed from bay to Gulf. Where water flowed from Gulf to bay, there were few scour cuts and the cuts that were found were short and shallow, starting behind the beach and ending in an outwash deposition fan. Where water flowed from bay to Gulf, cuts were frequent and deep and it appears that if flow had continued long enough, scour would have cut completely through the island.

## CHAPTER NINETEEN

### MEASUREMENT OF SURFACE WAVES FROM SUBSURFACE GAGE

Dong-Young Lee and Hsiang Wang\*

#### ABSTRACT

Wave measurement using subsurface pressure gage has many advantages, especially in coastal waters. However, there are some disadvantages associated with indirect measurement of surface waves. This paper deals with the problems in the recovery of surface waves from the subsurface pressure measurement. Two problems are examined: more exact recovery of the surface waves from subsurface pressure signal and a simple real time recovery of surface waves from the pressure record.

The commonly used linear transformation from the subsurface pressure to surface elevation is evaluated and possible sources of error are examined. The effect of nonlinearity and effect of current are shown to be small in the intermediate water depth. For the case of shallow water where effects of nonlinearity and current are not negligible, a method of proper recovery of surface waves from the combination of pressure and current measurements is given.

A simple method to recover the time series surface waves from subsurface record is proposed which enables speedy near real-time recovery of surface waves from pressure measurement using a micro-processor.

#### 1. INTRODUCTION

Subsurface pressure transducer has been extensively used in measuring surface waves. It is particularly suitable for application in shallow and intermediate depth water. It does not require a supporting structure which penetrates the surface, hence is less susceptible to being damaged by ships and fishing activities and has better survivability in severe sea conditions due to storms. It is also not affected by high tidal range or storm surge which make the surface piercing gage impractical. In addition, it provides information for the mean water level variation due to tide and storm surge, that can not be obtained from moored surface gage such as pitch and roll buoy.

\* Department of Coastal and Oceanographic Engineering, University of Florida, Gainesville, Florida 32611

However, since the device measures the subsurface pressure, a proper transformation has to be carried out to obtain surface wave information. The commonly used practice is to recover the surface wave information by means of a transfer function based on the linear first order wave theory. There are several sources of error such as instrumental noise, nonlinearity, effect of current, etc. A number of these sources of error are examined here to establish the reliability and limitations of the subsurface wave measurement and a refined method of recovery is proposed.

As a second objective, a simple numerical filter is introduced here which can perform fast recovery of time series of surface wave from pressure record with minimum computation.

## 2. ANALYSIS OF SUBSURFACE PRESSURE RECORD

The record from the subsurface pressure gage contains signals of two widely separated time scales; small time scale signal due to wave induced motion and larger time scale signal due to tide, storm surge etc. The data measured from the subsurface gage is considered as a linear summation of various contributing components :

$$P(t) = P_a + \rho g[(h - H_g) + K_p \eta] \quad (1)$$

where  $P(t)$  is the measured pressure at gage and  $P_a$  is the atmospheric pressure at the surface,  $h$  and  $H_g$  denote mean water depth and gage height above bottom, respectively, and  $\eta$  is surface wave and  $K_p$  is the pressure response function, and  $\rho$  is water density and  $g$  is gravitational acceleration.

By averaging the time series with a time interval much larger than the time scale of gravity waves but smaller than the large time scale phenomena, the mean water depth ( $h$ ) is obtained as

$$h(t) = (\bar{P} - p_a) / (\rho g) + H_g \quad (2)$$

where  $\bar{P}$  denotes the time averaged mean pressure at the gage. The tide and storm surge information can be deduced from  $h(t)$  (Howell et al., 1983).

The pressure ( $p$ ) induced by surface gravity waves can be obtained from

$$p = \rho g K_p \eta = [P(t) - \bar{P}] \quad (3)$$

The pressure response function,  $K_p$ , is usually defined through linear wave theory as follows

$$K_p(\omega_n) = \{ \text{Cosh } k_n(h+z) / \text{Cosh } k_n(h) \} \quad (4)$$

such that

$$p(t) = \rho g \sum_n A_n \text{Cos}(\omega_n t - \epsilon_n) \quad (5)$$

$$\eta(t) = \sum_n \frac{A_n}{K_p(\omega)} \cos(\omega_n t - \epsilon_n) \quad (6)$$

where  $h$  is water depth and  $z$  is location of pressure gage, and  $A_n$ ,  $\omega_n$ ,  $\epsilon_n$  and  $k_n$  are wave amplitude, frequency, phase and wave number of  $n$ -th component wave, respectively. The wave number and the frequency are related by

$$\omega_n = \sqrt{gk_n \text{Tanh}(k_n h)} \quad (7)$$

The surface variance spectrum,  $E_{\eta\eta}(\omega)$ , commonly known by wave energy spectrum can be obtained from the subsurface pressure spectrum,  $E_{pp}(\omega)$ , by the following relation:

$$E_{\eta\eta}(\omega) = E_{pp}(\omega)/K_p^2 \quad (8)$$

The time series of the surface waves can be obtained by Eq. (6) where  $A_n$ ,  $\omega_n$  and  $\epsilon_n$  are obtained from the Fast Fourier Transform (FFT) of the pressure data. Another method of recovery of  $\eta(t)$  is obtained by means convolution integral,

$$\eta(t) = \int_{-\infty}^{\infty} h(\tau) p(t-\tau) d\tau \quad (9)$$

where

$$h(\tau) = \int_{-\infty}^{\infty} H(\omega) \text{Exp}(i\omega\tau) d\omega \quad (10)$$

$$H(\omega) = \frac{1}{K_p(\omega)}$$

The convolution integral method is usually more time consuming than the FFT method.

### 3. SOURCES OF ERROR AND IMPROVEMENT

#### 3.1. Noise

The signal due to high frequency wave components is small due to depth attenuation and sometimes is completely lost due to the instrument limitation. The electronic noise in the power system, pressure transducer, and the analog filter, and the numerical noise associated with analog-to-digital conversion, on the other hand, are introduced. These noise components are amplified when converting into surface waves.

The noise from many possible sources cannot be totally avoided, hence, the true surface elevation information in the high frequency range is very difficult to recover from pressure record.

In theory, the pressure signal can be corrected if the noise is a known function of frequency. Unfortunately, such is not the case. It is, thus, suggested to remove the averaged overall noise level for the higher frequency range as

$$E_{\eta\eta} = (E_{pp} - C)/K_p^2 \quad (11)$$

where C is the overall noise level in high frequency range. This seemingly trivial process is important as a slight error in the high frequency region may produce a significant error in the surface elevation through amplification. A simple way that is commonly used to resolve this problem is the application of windowed transfer function simply by cutting off the high frequency range above a certain cut-off frequency ( $\omega_a$ ) such that

$$\begin{aligned} H(\omega) &= H(\omega) & \text{for } \omega < \omega_a \\ &= 0 & \text{for } \omega > \omega_a \end{aligned} \quad (12)$$

The pressure record is usually represented as discrete and finite record. The use of finite record length, i.e. rectangular window results in an undesirable energy leakage to the neighboring frequency components. The spill over error in pressure spectrum is amplified in wave energy spectrum. A data window is to be applied to the data to reduce spectral leakage.

### 3.2 Nonlinearity of Coastal Waves

Many of the nonlinear wave theories are confined to cases of monochromatic waves, which are not practical to apply to the random waves. The higher order correction to the first order random (free) waves using perturbation method is used here to deal with the weakly nonlinear irregular waves. The surface elevation  $\eta$  is expressed up to second order as (Sharma et al., 1981),

$$\eta = \eta_1 + \eta_2 \quad (13)$$

where

$$\eta_1 = \sum_i A_i \cos(\omega_i t - \epsilon_i) \quad (14)$$

and

$$\begin{aligned} \eta_2 = \frac{1}{4} \sum_i \sum_j C_{ij}^- A_i A_j \cos[(\omega_i - \omega_j)t - (\epsilon_i - \epsilon_j)] \\ + \frac{1}{4} \sum_i \sum_j C_{ij}^+ A_i A_j \cos[(\omega_i + \omega_j)t - (\epsilon_i + \epsilon_j)] \end{aligned} \quad (15)$$

where

$$C_{ij}^- = \frac{D_{ij}^- + (\vec{k}_i \cdot \vec{k}_j + R_i R_j)}{\sqrt{R_i R_j}} + (R_i + R_j) \quad (16)$$

$$C_{ij}^+ = \frac{D_{ij}^+ - (\vec{k}_i \cdot \vec{k}_j + R_i R_j)}{\sqrt{R_i R_j}} + (R_i + R_j) \quad (17)$$

where

$$\begin{aligned}
 D_{1j}^- &= \{(\sqrt{R_1} - \sqrt{R_j}) [\sqrt{R_j} (k_1^2 - R_1^2) - \sqrt{R_1} (k_j^2 - R_j^2)] \\
 &\quad + 2(\sqrt{R_1} - \sqrt{R_j})^2 (\vec{k}_1 \cdot \vec{k}_j + R_1 R_j)\} \\
 &\div [(\sqrt{R_1} - \sqrt{R_j})^2 - k_{1j}^- \tanh k_{1j}^- h]
 \end{aligned} \tag{18}$$

$$\begin{aligned}
 D_{1j}^+ &= \{(\sqrt{R_1} + \sqrt{R_j}) [\sqrt{R_1} (k_j^2 - R_j^2) + \sqrt{R_j} (k_1^2 - R_1^2)] \\
 &\quad + 2(\sqrt{R_1} + \sqrt{R_j})^2 (\vec{k}_1 \cdot \vec{k}_j - R_1 R_j)\} \\
 &\div [(\sqrt{R_1} + \sqrt{R_j})^2 - k_{1j}^+ \tanh k_{1j}^+ h]
 \end{aligned} \tag{19}$$

and  $R_1 = k_1 \tanh k_1 h$ ,  $k_{1j}^- = |\vec{k}_1 - \vec{k}_j|$ ,  $k_{1j}^+ = |\vec{k}_1 + \vec{k}_j|$

The subsurface pressure at location  $z$  can be written as

$$p = p_1 + p_2 \tag{20}$$

where  $p_1 = \rho g \sum_1 \cosh[k(h+z)]/\cosh(kh) A_1 \cos(\omega_1 t - \epsilon_1)$  (21)

$$\begin{aligned}
 p_2 &= \frac{1}{4} \rho g \sum_1 \sum_j G_{1j}^- A_1 A_j \cos[(\omega_1 - \omega_j)t - (\epsilon_1 - \epsilon_j)] \\
 &\quad + \frac{1}{4} \rho g \sum_1 \sum_j G_{1j}^+ A_1 A_j \cos[(\omega_1 + \omega_j)t - (\epsilon_1 + \epsilon_j)]
 \end{aligned} \tag{22}$$

where  $\sqrt{R_1 R_j} G_{1j}^- = \frac{\cosh k_{1j}^- (h+z)}{\cosh k_{1j}^- h} D_{1j}^-$

$$\begin{aligned}
 &- \frac{k_1 k_j}{\cosh k_{1j}^+ h + \cosh k_{1j}^- h} \{ \cosh k_{1j}^+ (h+z) \\
 &\quad \cdot [1 + \cos(\theta_1 - \theta_j)] - \cosh k_{1j}^- (h+z) \\
 &\quad \cdot [1 - \cos(\theta_1 - \theta_j)] \}
 \end{aligned} \tag{23}$$

and  $\sqrt{R_1 R_j} G_{1j}^+ = \frac{\cosh k_{1j}^+ (h+z)}{\cosh k_{1j}^+ h} D_{1j}^+$

$$\begin{aligned}
 & - \frac{k_i k_j}{\cosh k_{ij}^P h + \cosh k_{ij}^M h} \{ \cosh k_{ij}^P (h+z) \\
 & \cdot [-1 + \cos (\theta_i - \theta_j)] + \cosh k_{ij}^M (h+z) \\
 & \cdot [1 + \cos (\theta_i - \theta_j)] \} \tag{24}
 \end{aligned}$$

where  $k_{ij}^P = |\vec{k}_i| + |\vec{k}_j|$ ,  $k_{ij}^M = |\vec{k}_i| - |\vec{k}_j|$   
 and  $\theta_i$  is wave angle.

By comparing the surface elevation and subsurface pressure, we may define two or more transfer functions as

$$K_{1i} = \cosh[k(h+z)] / \cosh(kh) \tag{25}$$

$$K_{2ij}^- = C_{ij}^- / G_{ij}^- \tag{26}$$

$$K_{2ij}^+ = C_{ij}^+ / G_{ij}^+ \tag{27}$$

The transfer function for the first order free component is shown in Figure 1.

Figure 1. Variation of Linear Pressure Transfer Function with Dimensionless Water Depth (kh) for Various Dimensionless Gage Depth (d/h).

The transfer function for second order nonlinear component depends on the combination of the first order frequency components and their directions. Figure 2 shows the ratio of transfer function for the second order component to the linear transfer function for the simple case where all wave components propagate in the same direction. We can see that the transfer functions for the second order terms are slightly smaller than the linear transfer function for the subharmonics (frequency difference components) and slightly higher for the superharmonic (frequency sum components).

For example, considering just one free waves with its harmonics, the surface elevation  $\eta$  expressed by Stoke's wave is

$$\eta(t) = \eta_1 + \eta_2 \quad (28)$$

where

$$\eta_1 = a \cos(kx - \omega t) \quad (29)$$

$$\eta_2 = 1/2 k a^2 \cosh(kh) [2 + \cosh(2kh)] / \sinh^3(kh) \cos(2kx - 2\omega t) \quad (30)$$

The pressure at elevation of  $z$  can be expressed as

$$p(t) = K_1 \eta_1 + K_2 \eta_2 \quad (31)$$

where  $K_1 = \cosh[k(h+z)] / \cosh(kh)$

$$K_2 = \frac{3/4 k a^2 \tanh(kh) / \sinh^2(kh) [\cosh[2k(h+z)] / \sinh^2 kh - 1/3]}{\cosh(kh) [2 + \cosh(2kh)] / \sinh^3(kh)} \quad (32)$$

The second harmonic which is phase locked to the fundamental wave shows different characteristics from the free waves with the same frequency or wave length. The response function of the phase locked second order components is different from that of the free linear wave with the same frequency as shown in Figure 3. The pressure correspondent to second order superharmonic decays with depth at a slower rate than those of free waves with same frequency.

The nonlinearity effect is not significant in the intermediate depth water waves since the contribution of the nonlinear components are comparatively small and the difference of the transfer functions between the linear term and nonlinear term is not significant. However, in shallow water or in surf zone, the nonlinearity correction is essential.

### 3.3 Effects of Current

Current affects waves in two respects: the kinematic effect leading to the change of wave number and the dynamic effect leading to the change of dynamic pressure. Both will affect the pressure transfer function.

Figure 2.

Example of the Pressure Transfer Function for the Second Order Component Compared to that of Linear Component for Simple Case of Unidirectional Wave When  $h=7.5$  m,  $d=1.0$  m. (2-a). Subharmonic ( $\omega_1-\omega_j$ ) component. (2-b). Superharmonic ( $\omega_1+\omega_j$ ) component.

Figure 3. Pressure Transfer Function of the Second Order Harmonic of Stoke's Wave Compared to that of First Order Linear Wave Component.

As shown in Eq. 6, the transfer function,  $K_p$ , is related to the wave number. In the presence of current, the change of wave number can be obtained by following equation

$$n = \vec{k} \cdot \vec{u} + \sqrt{gk \tanh(kh)} \tag{33}$$

where  $n$  is the intrinsic wave frequency and  $\vec{u}$  is current vectors. This effect becomes increasingly significant in higher frequency range especially for the current against the waves.

The wave induced dynamic pressure by the combined current and wave motions is

$$\begin{aligned} p &= \frac{1}{2} \rho \left\{ \left( \sum_i U_i \cos(\omega_i t - \epsilon_i) + U_c \cos \alpha \right)^2 + (U_c \sin \alpha)^2 \right\} \\ &= \frac{1}{2} \rho \sum_i \sum_j U_i U_j \cos(\omega_i t - \epsilon_i) \cos(\omega_j t - \epsilon_j) \\ &\quad + \rho U_c \cos \alpha \sum_i U_i \cos(\omega_i t - \epsilon_i) + \frac{1}{2} \rho U_c^2 \end{aligned} \tag{34}$$

where  $U_i$  is the amplitude of wave induced velocity and  $U_c$  is the current speed and  $\alpha$  denotes the angle between the wave propagation and current direction. The first term in the right hand side of Eq. 34 is the second order components with frequency components of  $(\omega_i - \omega_j)$  and

$(\omega_1 + \omega_2)$  that contribute a part of  $p_2$  in Eq. 22. Its effect has been considered from the nonlinearity point of view. The third term gives only a constant drift. The effect of the superimposed current on the recovery of pressure data comes from the second term, which is proportional to the wave induced flow and the proportionality factor  $U_c \cos \alpha$  depends on the current speed and the angle between current and wave  $\alpha$ .

The relation between the pressure fluctuation and surface wave is now

$$p(t) + p_2(t) = \rho g K_p' \eta \quad (35)$$

where  $K_p$  is corrected transfer function. It can be shown that

$$\begin{aligned} K_p' &= [1 + U_c \cos(\alpha) k_n / \omega_n] K_p \\ &= (1 + \cos(\alpha) U_c / C) K_p \end{aligned} \quad (36)$$

where  $C$  is the wave phase speed.

Figure 4 shows the effect of the current on the transfer function,  $H(\omega)$  due to current effect in the change of wave number, and in the change of dynamic pressure. These two effects are in opposition hence somewhat neutralize each other. The resultant effect is dominated by the dynamic effect in the lower frequency range whereas it is dominated by the kinematic effect in the higher frequency range.

#### 4. APPLICATION TO THE FIELD DATA

##### 4.1. Comparison of the Surface and Subsurface Measurements

To determine the validity of the linear pressure transfer function, surface data and subsurface data obtained simultaneously during ARSLOE experiment are analysed and compared. The pressure gage is located at 0.9 meter above the bottom at the water depth of about 7.5 meter. The surface gage is the Baylor type gage at water depth of about 9.0 meter. The distance between the two gage is about 40 meters. Figure 5 shows an example comparing wave spectrum obtained from surface gage to that from subsurface gage using linear transfer. The pressure response function obtained from the measured data and from the theoretical linear transfer function are also compared in Figure 5.

The linear transfer function is found to perform well in the energy containing region but underestimates energy in the lower frequency range while slightly over estimates energy in the higher frequency range. This trend is consistent with other investigators (Cavaleri et al., 1978; Forristal, 1982). This may be partially explained by the nonlinear effect discussed earlier. The transfer function of the second order term for the frequency difference components (lower frequency) is smaller than that of the linear component at the same frequency, while the opposite is true for the

Figure 4. Variation of the Correction Factor to the Transfer Function  $H(\omega)$  due to the change of wave number (4-a) and due to the Dynamic Pressure (4-b) and the Total Effect (4-c).

Figure 5. Example of the Comparison of Wave Energy Obtained from Surface Gage and that from Subsurface Pressure Gage (5-a) and Comparison of Linear Pressure Transfer Function with the Measured One (5-b).

frequency summation components (high frequency) as shown in Figures 2 and 3. However, the nonlinearity effect cannot fully account for the differences revealed by the data. Another possible contribution to this discrepancy may be due to the effect of current as shown in Figure 4. For the storm waves generated by the local wind force, the wave propagation is considered to be approximately in the same direction with the wind drift surface current. In this case the resultant effect of current on the transfer function overestimates energy in comparison to the linear transfer function in the higher frequency range, while it underestimates energy in the lower frequency range, which is consistent with the measured data.

#### 4.2 Surface Wave Recovery from the Simultaneous Subsurface Pressure and Current Measurement

When the nonlinearity and/or the current effects become significant, adequate surface wave recovery requires the information of current as well as wave direction for each frequency component. In this case, both pressure and horizontal current vector should be measured by using p-u-v gage or other means. The procedures of correctly recovering the surface waves information are outlined here.

- 1). obtain directional wave spectrum using p-u-v data and linear pressure and current transfer functions.
- 2). decompose spectral components of pressure and velocity components into linear and second order components by means of Eqs. 13 - 24 for p and similar equations for u and v using iteration method.
- 3). recompute wave directions using linear components, i.e.,  $p_1$ ,  $u_1$  and  $v_1$  only using linear transfer functions.

- 4). recompute wave number and thus transfer function including the effect of current using the mean current data.
- 5). recompute the wave energy spectrum with the inclusion of the second order correction and current interaction term.

This method has been implemented for the Coastal Data Network System at the University of Florida. The general experience is that the effect of nonlinearity and current are small in intermediate water depth such as the case of the Data Network. The details will be reported separately in the future.

Since the directional spectrum is expressed by only five Fourier coefficients, it is not possible to separate wave direction for two or more trains. One of the interesting case is where wind driven sea and swell are present at the site. The proper estimation of the swell component from the measurement is practically important. The signal in the low frequency component is contaminated by the nonlinear components of local wind waters. The wave energy of the free waves of the local wind waves may not be significant in high frequency. But in case that the second order nonlinear component is substantial, it is difficult to subtract the swell components from the measured data. By mean of the above mentioned detailed analysis, the swell components may be more reliably obtained.

#### 5. A SIMPLE FILTER TO RECOVER THE SURFACE WAVES FROM SUBSURFACE PRESSURE MEASUREMENT

The second topic of this paper is the introduction of a simple filter for the recovery of surface wave information from subsurface pressure measurement. The spectral analysis method used to compensate the depth attenuation to recover the surface elevation from subsurface pressure record requires a fast computing machine to handle FFT algorithm, which makes the pressure gage inconvenient and sometimes impractical if real-time wave information is needed.

As discussed earlier, the time series of surface elevation,  $\eta(n\Delta t)$ , can be obtained by means of inverse FFT or convolution integration. In the convolution integral method,  $N$  discrete points of pressure data sampled at  $\Delta t$ , are used to recover the surface wave time series through the following equation:

$$\eta(n \Delta t) = C_0 p(n \Delta t) + (1/2) \sum_m^{N/2} C_m [p((n+m) \Delta t) + p((n-m)\Delta t)] \quad (37)$$

where  $C_m$  is defined as

$$H(k \pi/N) = C_0 + \sum_{m=1}^{N/2} C_m \cos (mk\pi/N) \quad (38)$$

Thus, the surface elevation  $\eta(n \Delta t)$  is recovered from the  $N$  points of pressure record. A certain window function is to be applied to the transfer function to avoid problems of noise in the high frequency. Usually a simple window to cutoff the high frequency above a certain

value as in Eq. 16. In general the computation is cumbersome and takes longer than FFT method.

A very convenient windowed transfer function is proposed here which drastically reduces the computation, thus, renders the convolution integral method more effective. The proposed windowed transfer function takes a simple form:

$$H'(\omega) = A + B \cos(\omega) \tag{39}$$

here A and B are constant to fit the original transfer function,  $H(\omega)$ , for the desired frequency range for a specific water depth. Since  $H(\omega)$  is function of water depth (h) and gage-bottom distance (d), the constant A and B are also functions of h, d. Figure 6 compares the simple windowed transfer function in Eq. 39 and original transfer function for water depth of 6.0 meter where  $d=0.5$  meter.  $H'(\omega)$  fits the original transfer function for the low frequency region and smoothly reduces the value at high frequency. The simplified transfer function fit the original one well for the energy containing range and the blowing in the high frequency is reduced to avoid the serious problems of the errors in high frequency range. The transfer function is simple and defined by just two constants A and B for a given water depth.

Using the windowed transfer function,  $H'(\omega)$ , the recovery of the surface elevation can be done by means of simple three point convolution.

Figure 6. Simple Windowed Transfer Function Compared Original Linear Transfer Function. Two Parameter Filter (6-a) and One Parameter Filter (6-b).

$$\eta(n \Delta t) = A p(n \Delta t) + 1/2 B [P(n+1)\Delta t) + P(n-1)\Delta t)] \quad (40)$$

Three point convolution recovery is equivalent to that of surface waves from pressure and its local curvature. The filter is so simple that a small micro processor attached to the underwater package can easily handle the computation.

An even simpler one parameter filter of the following form also performs well:

$$H'(\omega) = (1 + A') - A' \cos(\omega) \quad (41)$$

where  $A'$  is a parameter depend on water depth (for fixed gage) obtained by curve fitting to the original  $H(\omega)$ . As shown in Figure 6, this filter has a slightly larger value than  $H(\omega)$  in the low frequency but is smaller in the high frequency range, which has the same trend as the nonlinear transfer function or measured transfer function discussed above. Therefore, it can be considered as an empirical fitting to a nonlinear transfer function.

When more accurate recovery is desired, we may increase number of convolution with more coefficients. The improvement will be largely in the high frequency range.

One of the application of the above simple filter is the real-time detection of the sea condition without using fast computing machine. A simple but reliable way of detection of sea state can be obtained by use of the significant wave height is estimated as

$$H_s = 4 H_{rms} \quad (42)$$

where  $H_{rms}$  is the root mean square height calculated from a record of recovered time series of surface elevation.

Since the values of  $A$  and  $B$  depend on water depth, for fixed gage height, the functional dependency of  $A$  and  $B$  on  $h$  can be precalculated by means of computer and stored in the microprocessor.

## 6. CONCLUSIONS

In spite of its many advantages, there is still hesitation by many to use subsurface pressure gage as a means to recover the surface wave information owing to the problems associated with signal recovery technique. The center of the problem is the dispute on the appropriateness of the linear transfer function and its limitation. A rather detailed analysis was performed to examine various sources of error involved in the conventional recovery technique.

In terms of wave energy spectrum, the linear transfer function is found to be good for intermediate-water-depth application. The bulk of the spectral components can be faithfully recovered except in the high frequency range. As water becomes shallower, nonlinearity effect and current influence may also become more prominent. In this case,

the linear transfer function should be modified to account for these effects. Methods of modification are proposed. When water becomes real shallow, the wave spectral approach may eventually become unsuitable. A transfer function should be developed to facilitate wave-by-wave recovery.

For more complete recovery of surface information, p-u-v gage should be used in shallow water. It not only provides directional information but also gives more correct estimation of wave energy.

The simple filter method proposed here has the potential of providing real-time wave information by using micro-electronic component instead high-speed computer. It will be a major asset from the operational point of view.

The subsurface pressure instrument is definitely a viable solution for surface wave measurement. The operational convenience reliability and cost of maintenance make it an attractive choice.

#### ACKNOWLEDGEMENT

This paper is prepared as part of the work for Coastal Data Network (CDN), University of Florida. The system is partially supported by Coastal Engineering Research Center, U.S. Army Corp of Engineer DACW39-80-C-0118. The authors wish to thank Jean Branson and Lillean Pieter for preparing the manuscript.

## CHAPTER TWENTY

### A SHALLOW WATER DIRECTIONAL WAVE RECORDER

S.J. Buchan, R.K. Steedman, S.A. Stroud, D.G. Provis

#### ABSTRACT

Shallow water wave theory shows that estimates of directional wave climate may be obtained from the measurement of near-bottom pressure and horizontal velocity components. Recent developments in low powered sensors and high density data loggers, incorporated into a bottom-mounted directional wave recorder, make the collection of directional shallow water wave data possible on a routine basis. The instrument is compact, robust, reliable and easily manageable from small craft, providing deployment capacities of up to four months. Analysis methods have been developed which provide for conversion of the recorded data to useful, convenient information.

#### 1. INTRODUCTION

During recent years, recognition of the importance of directional wave information in many facets of coastal and ocean engineering design has been increasing. Goda et al. (1978) have illustrated the importance of wave directionality for studies of wave diffraction and refraction in harbours; Forristall et al. (1978) have demonstrated the inadequacies of uni-directional wave theories in describing wave kinematics; and Sand et al. (1981) have discussed the applications of directional wave information to the hydrodynamics and design of offshore structures and pipelines.

Advances in remote low powered logger and sensor technology have allowed the development of reliable, compact, robust and manageable water current and pressure measuring devices. In May 1980, Sea Data Corporation were commissioned to modify their 635-11 Wave and Tide Recorder (based on bottom-mounted pressure measurements) to include synchronous horizontal velocity measurements within each "burst" of pressure data. The result was the Sea Data 635-12S Directional Wave and Tide Recorder, the use of which is the subject of this paper. Reference is made to the instrument operation and to the underlying theory on which the data analyses are based. Various analysis techniques are illustrated, and verification of instrument and analysis performance is provided.

## 2. INSTRUMENTATION

The instrument measures fluctuations in absolute pressure and horizontal current velocity, at both tide and wind wave frequencies. Instrument temperature is also logged. A complete description of the instrument is given by Aubrey and Hill (1984), and a detailed analysis of sensor specifications is given by Grosskopf et al. (1983).

In operation the 635-12S runs two separate sampling schemes in parallel. These are the mean (tide) and burst (wave) recording modes. Data from each mode are recorded in an interleaved format on a magnetic cassette tape.

In the mean mode, water pressure is integrated continuously over a specified sample interval. To conserve battery power, the mean current is computed only over every eighth mean pressure sample interval. The mean sample interval may be selected in the range 3.75 to 60 minutes. An instantaneous temperature measurement from a thermistor within the instrument housing is sampled after every 8 mean pressure samples. Data recording takes place every 8 sample intervals when an elapsed time, 8 tide measurements, a water temperature measurement and the mean current components are recorded.

In burst mode, the instrument rapidly samples the water pressure and the two current velocity components at a preset interval in the range 0.5 to 4 seconds. The number of samples in each burst may be adjusted in steps between 64 and 2048, or alternatively the instrument may be set to run continuously. The interval between bursts may be varied from 0.5 to 24 hours. The burst samples are recorded as triples of the water pressure, easterly and northerly current components.

## 3. DEPLOYMENT AND RETRIEVAL

The directional wave recorder is usually deployed in an aluminium tripod which is lowered to the sea bed by winch from a work vessel. The tripod is attached to small surface floats by a buoyant line, to facilitate recovery. Thus, deployment and retrieval operations can be carried out without diver assistance.

Within the tripod, the velocity and pressure sensors are located at 1.5 m above the base. Provided the sea bed is relatively smooth and flat (easily checked using an echo sounder), then the sensors should be located above the bottom boundary layer.

An alternative deployment arrangement is provided by fixing the directional wave recorder to an offshore pile. This arrangement allows the sensors to be located near the water surface, but can only be used when the pile wake effects are not of significance. Deployment and retrieval of the instrument using this arrangement does require diver assistance.

#### 4. UNDERLYING THEORY

To obtain a representation of the surface sea state from subsurface measurements of pressure and velocity, an appropriate theory describing the kinematics of flow beneath surface waves must be applied. An assessment of available wave theories is presented in Forristall et al. (1978).

The simplest approach is to use linear wave theory which may be extended through spectral concepts to model irregular (i.e. aperiodic) sea. The most serious deficiency of linear theory occurs due to the non-linearity of the free surface boundary condition.

Higher order regular (periodic) and irregular (aperiodic) theories provide a better match to the free surface boundary condition, but their complexity precludes their incorporation in any practical analysis of directionally spread sea states.

From analysis of measurements conducted during Tropical Storm Delia in the Gulf of Mexico, Forristall et al. (1978) demonstrated that using a linear theory which accounted for the directional nature of the measured sea state provided a better representation of wave kinematics than higher-order, uni-directional wave theories.

Linear Wave Theory : A linear representation of the surface elevation  $\eta$ , above or below the equilibrium water level, of an arbitrary cosine wave component of a random sea is given by,

$$\eta = \alpha \cos(kx \cos\theta + ky \sin\theta - 2\pi ft + \phi) \quad (1)$$

This formulation has been set in a right-hand, rectangular coordinate system (x,y,z) with z chosen as positive upward from the sea bed where

$\alpha$  is the wave amplitude;

$\theta$  is the direction of phase propagation, measured counter-clockwise from the x axis;

$\phi$  is the wave phase;

t is time;

k is the horizontal wave number;

f is the wave frequency in cycles per second.

The horizontal wave number  $k = 2\pi/\lambda$ , where  $\lambda$  is the wave length.

A freely propagating surface gravity wave described by the above formula should satisfy a dispersion relation given by,

$$(2\pi f)^2 = gk \tanh kd \quad (2)$$

where g is the acceleration due to gravity, and d is the water depth.

At any level  $z$  in the water column below such a wave, the horizontal velocity components are described by,

$$u = \alpha 2\pi f \frac{\cosh kz}{\sinh kd} \cos\theta \cos(kx \cos\theta + ky \sin\theta - 2\pi ft + \phi) \quad , \quad (3)$$

and

$$v = \alpha 2\pi f \frac{\cosh kz}{\sinh kd} \sin\theta \cos(kx \cos\theta + ky \sin\theta - 2\pi ft + \phi) \quad . \quad (4)$$

the wave-induced pressure at  $z$  is given by,

$$p = \alpha \rho g \frac{\cosh kz}{\cosh kd} \cos(kx \cos\theta + ky \sin\theta - 2\pi ft + \phi) \quad , \quad (5)$$

where  $\rho$  is the water density.

A confused sea state may be represented by a summation of linear waves, given by (1), at various frequencies, propagation directions and phases, and may be described by a "random" sum

$$\eta(x, y, t) = \sum_m \sum_n \alpha_{mn} \cos\psi_{mn} \quad , \quad (6)$$

where the indices  $m, n$  run over selected frequencies and directions respectively, and the composite phase function is given by

$$\begin{aligned} \psi_{mn} &= \psi_{mn}(x, y, t) \\ &= k_m x \cos\theta_n + k_m y \sin\theta_n - 2\pi f_m t + \phi_{mn} \end{aligned} \quad . \quad (7)$$

In the above,  $\phi_{mn}$  is the random phase for the  $(m, n)$  wavelet, assumed to be uniformly distributed over the direction interval  $(0, 2\pi)$  and independent from wavelet to wavelet.

According to linear theory, the kinematics of a confused sea state described by (6) may be obtained by superposition from equations (3) to (5) as:

$$u(x, y, z, t) = \sum_m \sum_n \alpha_{mn} 2\pi f_m \frac{\cosh k_m z}{\sinh k_m d} \cos\theta_n \cos\psi_{mn} \quad , \quad (8)$$

$$v(x, y, z, t) = \sum_m \sum_n \alpha_{mn} 2\pi f_m \frac{\cosh k_m z}{\sinh k_m d} \sin\theta_n \cos\psi_{mn} \quad , \quad (9)$$

and

$$p(x, y, z, t) = \sum_m \sum_n \alpha_{mn} \rho g \frac{\cosh k_m z}{\cosh k_m d} \cos\psi_{mn} \quad , \quad (10)$$

where  $u(x, y, z, t)$  is the  $x$  component of the water particle velocity at space location  $(x, y, z)$  at some time  $t$ . Similarly,  $v(x, y, z, t)$  is the  $y$  component velocity and  $p(x, y, z, t)$  is the pressure.

Spectral Representation of Wave Properties : In practice, p,u,v measurements are taken over time at the same horizontal location, i.e. setting (x,y) = (0,0). Further, (u,v) measurements are made at the same height z = z<sub>v</sub> above the sea bed. Pressure measurements may be made at a different height z = z<sub>p</sub>. It is important that z<sub>p</sub> and z<sub>v</sub> are chosen to be above the bottom boundary layer.

We may introduce a frequency domain description of the wave field. The spectral density, S(f<sub>m</sub>, θ<sub>n</sub>), of the surface elevation is related to the mean (or expectation) of the square of the random amplitude, E(α<sub>mn</sub><sup>2</sup>), by

$$S(f_m, \theta_n) = \frac{1}{2\Delta f_m \Delta \theta_n} E(\alpha_{mn}^2) \quad , \quad (11)$$

where Δf<sub>m</sub> and Δθ<sub>n</sub> are the increments of frequency and direction "occupied" by the (m,n) wave component.

By taking lagged products of measured quantities (p,u,v) and passing from summation to integration, cross-covariances of p,u and v may be formed (Borgman, 1979). Fourier transformation of the cross-covariances provides the following cospectral expressions which may be used to estimate the direction surface sea state:

$$c_{uu}(f) = A^2(f) \int_0^{2\pi} S(f, \theta) \cos^2 \theta \, d\theta \quad , \quad (12)$$

$$c_{uv}(f) = A^2(f) \int_0^{2\pi} S(f, \theta) \sin \theta \cos \theta \, d\theta \quad , \quad (13)$$

$$c_{vv}(f) = A^2(f) \int_0^{2\pi} S(f, \theta) \sin^2 \theta \, d\theta \quad , \quad (14)$$

$$c_{pp}(f) = B^2(f) \int_0^{2\pi} S(f, \theta) \, d\theta \quad , \quad (15)$$

$$c_{up}(f) = A(f)B(f) \int_0^{2\pi} S(f, \theta) \cos \theta \, d\theta \quad , \quad (16)$$

$$c_{vp}(f) = A(f)B(f) \int_0^{2\pi} S(f, \theta) \sin \theta \, d\theta \quad , \quad (17)$$

where

$$A(f) = 2\pi f \frac{\cosh kz_v}{\sinh kd} \quad , \quad (18)$$

and

$$B(f) = \rho g \frac{\cosh kz}{\cosh kd} \quad , \quad (19)$$

represent velocity and pressure attenuation functions, respectively.

The Directional Spreading Function : Progress in the determination of the spectral density function  $S(f, \theta)$  is made by recasting the function as

$$S(f, \theta) = E(f) H(f, \theta) \quad , \quad (20)$$

with the constraint

$$\int_0^{2\pi} H(f, \theta) d\theta = 1 \quad . \quad (21)$$

In the above, the directional energy spectrum  $S(f, \theta)$  has been separated into a non-directional energy spectrum  $E(f)$ , and a directional spreading function  $H(f, \theta)$ .  $E(f)$  represents the surface wave energy summed over all propagation directions, i.e.

$$E(f) = \int_0^{2\pi} S(f, \theta) d\theta \quad . \quad (22)$$

$H(f, \theta)$  describes the distribution of the total energy  $E(f)$  over all possible propagation directions  $\theta$ . Its estimation is the key to obtaining a directional description of a sea state.

Following Longuet-Higgins et al. (1963), a convenient approximation to the directional spreading function may be obtained by expansion of  $H(f, \theta)$  in a truncated Fourier series, such that

$$H(f, \theta) = \frac{1}{2\pi} + \sum_{m=1}^M (a_m \cos m\theta + b_m \sin m\theta) \quad . \quad (23)$$

The  $p, u, v$  measurements which form the basis of this directional wave analysis contain sufficient information for the estimation of the above Fourier series truncated at  $M = 2$ .

Parametric Description of the Directional Spreading Function :

Further improvement to the description of the directional sea state may be obtained by introducing a subjectively selected, parametric approximation to the directional spreading function,  $H(f, \theta)$ . A model which has been widely used is that of Longuet-Higgins et al. (1963),

$$\begin{aligned} H(f, \theta) &= \frac{\Gamma(s+1)}{2\sqrt{\pi} \Gamma(s+1/2)} \cos^{2s}[(\theta - \theta_0)/2] \\ &= (1/\pi) \left[ 1/2 + \sum_{n=1}^{\infty} (r_n \cos n\theta_0) \cos n\theta \right. \\ &\quad \left. + \sum_{n=1}^{\infty} (r_n \sin n\theta_0) \sin n\theta \right] \quad , \quad (24) \end{aligned}$$

where

$$r_n = \frac{\Gamma^2(s+1)}{\Gamma(s+n-1) \Gamma(s-n+1)}$$

In the above,  $s$  is referred to as the "sharpness index", and  $\theta_0$  is the predominant direction of wave propagation. The multiplying term involving the Gamma function  $\Gamma$  arises from the constraint equation (13). This model should provide a satisfactory description of a uni-modal wave field with wave directions dispersed over a narrow sector centred about  $\theta_0$ . A high value of "sharpness index" indicates that all wave directions are concentrated about  $\theta_0$ .

5. ANALYSIS TECHNIQUES

Primary Data Plots : The wave-induced velocity data returned from each "burst" of the Sea Data 635-12S are illustrated by the cross plots of the horizontal current velocity components (figure 1).

Figure 1 Example cross plots of the u-v horizontal current velocities measured near the sea bed. The elliptical scatter is caused by wave-induced currents, and displaced by tidal currents.

The velocity cross plot shows the elliptical spread of horizontal wave-induced motions. The principle direction of wave propagation is along the major axis of the ellipse. The 180° ambiguity about the direction of phase propagation is resolved by examination of the pressure time history. Horizontal wave-induced velocities under wave crests are in the same direction as the phase propagation.

Frequency Domain Estimation of Directional Parameters : The directional spectrum of a random sea state may be estimated from Fourier transformations of a set of N triplets of simultaneous u,v,p measurements, consecutively sampled at a time spacing of  $\Delta t$ .

Fourier transformations of the measured p,u,v time series provide estimates of the left-hand sides of equations (12) to (17), the p,u,v cospectra. Using the velocity and pressure attenuation functions (18) and (19) determined from linear wave theory, and the description of the spectral density function given by (20) to (22), the coefficients  $a_1, b_1, a_2$  and  $b_2$  of the truncated Fourier expansion of the spreading function (23), may be estimated from the p,u,v cospectra.

First order estimates of the directional spectral parameters of the  $\cos^{2S} [(\theta - \theta_0)/2]$  model may be obtained by comparing equation (24) with equation (23), from which

$$s = \frac{r_1}{1-r_1} \quad (25)$$

where

$$r_1^2 = a_1^2 + b_1^2 \quad , \quad (26)$$

and

$$\theta_0 = \arctan \left( \frac{b_1}{a_1} \right) \quad , \quad (27)$$

which are obtained from the pressure-velocity cospectra.

An alternative estimate of s and  $\theta_0$ , known as the second order fit, is also available, as

$$s = \frac{(1+3r_2) + (1-14r_2 + r_2^2)^{1/2}}{2(1-r_2)} \quad (28)$$

where

$$r_2^2 = a_2^2 + b_2^2 \quad , \quad (29)$$

and

$$\theta_0 = \frac{1}{2} \arctan \left( \frac{b_2}{a_2} \right) \quad . \quad (30)$$

which is obtained from velocity-velocity cospectra.

An example of the directional spectral information attainable from each "burst" of p,u,v measurements of the Sea Data 635-12S Directional Wave and Tide Recorder is presented in figure 2. First and second order estimates of wave direction agree very well. First and second order estimates of sharpness index are not theoretically equivalent, but are expected to display similar trends.

Figure 2 Example of the spectral information attainable from each "burst" of a directional wave recorder. First and second order estimates are derived from equations (25) to (27) and (28) to (30), respectively.

Following the example of Forristall et al. (1978) the gain ratio  $Q(f)$  has also been calculated. It represents the ratio of the measured pressure to velocity transfer function and that predicted by linear theory. From equations (18) and (19),  $Q(f) = A(f)/B(f)$ . If  $Q(f)$  remains near unity, linear theory is providing a satisfactory description of wave kinematics. Figure 2 shows that  $Q(f)$  departs from unity for very high frequencies where ambient turbulence contaminates the data, and for low frequencies where surface wave energy is very low.

Also presented on this plot is a dotted vertical line which marks where the spectral moment computations have been truncated (high frequency cut off), to avoid the increasing noise contamination of the wave signal.

Time Domain Estimation of Directional Parameters : The mean wave direction and sharpness index estimates may be obtained without recourse to spectral analysis, from the covariance (time domain) equivalents of equations (25), (27), (28) and (30). For each set of  $N$  triplets of  $p, u, v$  the variances and covariances  $C_{\gamma\zeta}$  of the measured quantities are computed by taking the dot products as follows:

$$C_{\gamma\zeta} = \frac{1}{N} \sum_{i=1}^N (\gamma_i - \bar{\gamma})(\zeta_i - \bar{\zeta}) \quad ,$$

where the overbars denote sample means, and the subscripts  $\gamma$  and  $\zeta$  denote  $p, u$  or  $v$ .

First order estimates of mean direction  $\bar{\theta}$  and sharpness index  $\bar{s}$  are obtained explicitly from

$$\bar{\theta} = \arctan \left\{ \frac{C_{pv}}{C_{pu}} \right\} \quad , \quad (31)$$

and

$$\bar{s} = \frac{r_1}{1-r_1} \quad , \quad (32)$$

where

$$r_1^2 = \frac{C_{pu}^2 + C_{pv}^2}{\{C_{uu} + C_{vv}\} C_{pp}} \quad . \quad (33)$$

The second order estimates are obtained from

$$\bar{\theta} = \frac{1}{2} \arctan \left\{ \frac{2C_{uv}}{C_{uu} - C_{vv}} \right\} \quad , \quad (34)$$

and

$$\bar{s} = \frac{(1+3r_2) + (1-14r_2 + r_2^2)^{1/2}}{2(1-r_2)} \quad , \quad (35)$$

where

$$r_2^2 = \frac{\{C_{uu} - C_{vv}\}^2 + 4C_{uv}^2}{C_{uu} + C_{vv}} \quad . \quad (36)$$

It should be noted that these estimates are derived from measurements of wave kinematics which have suffered frequency dependent depth attenuation. As the depth of measurements increases, these estimates become more biased towards longer period waves.

## 6. INSTRUMENT PERFORMANCE

Local deployments of the Sea Data 635-12S Directional Wave and Tide Recorder have now returned in excess of two years of data. Improvements in the design and operation of the instrument, and in the data transcription and processing techniques, now allow better than 98% data recovery.

Experience with deployments at various locations around Australia shows that minimum wave periods of 2, 5 and 8 seconds may be satisfactorily resolved in water depths of 2, 20 and 50 metres, respectively. The directionality of recorded wave fields has been evident in all deployments.

The performance of the 635-12S is illustrated by measurements conducted in 20 metres of water at a location 30 km south of Barrow Island off the north west coast of Australia, during the passage of tropical cyclone "Chloe". The measurement location and tropical cyclone track are shown in figure 3. The storm track passed about 150 km to the south east of the measurement location.

Figure 3 Location diagram showing directional wave measurement site and the track of tropical cyclone "Chloe". Arrow heads on the track correspond to 1200 hours GMT. Date and storm central pressure (mb) are shown adjacent each mark.

Figure 2 shows the directional spectral information obtained from one "burst" of the 635-12 near the time of closest approach of the storm. This includes the presentation of  $\theta(f)$  and  $s(f)$  as a function of frequency, derived from equations (25) to (30). In this figure, the distinct bimodality of the sea state is evident, with swell waves (periods longer than 8 seconds) propagating from the north west, and short period, locally generated wind waves propagating from the south.

Averages weighted by the non-directional energy spectrum were taken to produce burst mean estimates, denoted by  $\bar{\theta}$  and  $\bar{s}$ . Figure 4 shows the variation of the directional wave climate during the passage of tropical cyclone "Chloe", using burst mean parameters.

Figure 4 Description of the temporal variation of the directional climate using mean spectral parameters, for the period of the passage of tropical cyclone "Chloe".

Wind speeds and directions shown are 20 minute mean values recorded on Barrow Island, about 30 km north of the measurement location. The first order estimate of the wave direction  $\theta$ , initially shows the incidence of westerly to north westerly swell, then tracks the wind direction after the onset of the storm. The sharpness index  $s$  peak is observed to coincide with the storm peak, as also noted by Mitsuyasu et al. (1975).

Non-directional spectral parameters  $H_s$  (significant wave height) and  $T_p$  (period of the spectral peak) illustrate the incidence of low amplitude, long period swell prior to the arrival of the storm, followed by the generation of a high energy, short period sea state.

The 635-12S may also be used to establish frequency dependent variations in the wave climate. This is achieved by taking averages of  $E(f)$ ,  $s(f)$ ,  $\theta(f)$  and  $Q(f)$  for each spectral ordinate over entire deployments. Figure 5 illustrates the result of averaging the spectral parameters over a six week deployment period.

Figure 5 Spectral parameter means providing a description of the frequency dependent variation of the directional wave climate, over the period of an entire deployment.

$Q(f)$  determines the limits of applicability of the frequency dependent wave climate description, which holds only while  $Q(f)$  is near unity. Within this frequency range, the wave climate is seen to be distinctly bimodal, with swell periods in excess of 10 seconds typically incident from the north west, and shorter period wind waves (6 to 10 seconds) typically incident from the north-north-east. For this deployment, bathymetric constraints limit wave propagation from the east. The sharpness and energy density estimates also reflect the bimodality of the wave climate.

Comparison of Analysis Techniques : Figure 2 shows that first and second order estimates of  $\theta$  are very similar. Estimates of  $s$  vary, but they do display similar trends.

Estimates of  $\bar{\theta}$  and  $\bar{s}$  may be obtained without recourse to spectral analysis, using the covariance equations (31) to (36). A comparison of these estimates with their spectral equivalents,  $\hat{\theta}$  and  $\hat{s}$ , (weighted by the energy density) is presented in figure 6, again using data recorded during the passage of tropical cyclone "Chloe".

Figure 6 Comparison of mean wave directions and sharpness indices derived by time domain (covariance estimates  $\bar{\theta}$  and  $\bar{s}$ ) and frequency domain (cospectral estimates  $\hat{\theta}$  and  $\hat{s}$ ) techniques.

First and second order estimates of  $\theta$  in either the time domain (covariances) or frequency domain (cospectra), are almost indistinguishable. However, small differences are evident between time domain and frequency domain estimates, particularly during periods of rapid change in the sea state.

First and second order estimates of  $s$  show the expected similar trends, but time domain estimates are generally less than the frequency domain estimates.

Comparison with Surface Wave Measurements : A Datawell Waverider buoy was deployed concurrently with the Sea Data 635-12S, at the same location during the passage of tropical cyclone "Chloe". This allowed comparison of non-directional wave parameter estimates, which are presented in figure 7.

Figure 7 Comparison of non-directional spectral surface wave parameters derived from surface displacement measurements, and near-bottom pressure and velocity measurements.

Estimates of significant wave height derived from both near-bottom pressure and velocity measurements agree very well, except at the storm peak where dynamic pressure effects may have become important. Generally, Waverider estimates of significant wave height exceed those derived from the near-bottom measurements due to the depth attenuation of short period waves (5 seconds or less). At the storm peak, estimates from the Waverider and the near-bottom pressure measurements coincide.

Estimates of average zero upcrossing period and spectral peak period derived from both near-bottom pressure and velocity measurements also agree very well. While Waverider measurements provide good agreement for spectral peak period, average zero upcrossing periods are seen to be much lower than those derived from near-bottom measurements, because of the predominance of short period surface waves.

In accordance with Forristall et al. (1978), comparisons of measured near-bottom wave-induced velocity spectra with those derived from surface wave measurements using non-directional linear wave theory, show the theory to overpredict near-bottom velocities by about 20%.

#### 7. COMMENTS AND CONCLUSIONS

The Sea Data 635-12S Directional Wave and Tide Recorder provides a reliable means of measurement of near-bottom wave-induced kinematics and of shallow water directional wave climate.

Uni-directional linear wave theory is seen to overpredict near-bottom wave-induced velocities derived from surface wave measurements.

A variety of analysis techniques are available, several of which have been applied to the measured data. Analyses undertaken to date have not indicated a preference for first or second order estimates of directional wave parameters. Maximum likelihood techniques which combine both estimates have been successfully applied to simulated data, but small (sensor induced) phase differences between measured pressures and velocities inhibit application to field data. It is hoped to apply these types of data adaptive techniques in the future.

The Sea Data 635-12S Directional Wave and Tide Recorder can routinely provide important information for determination of wave-induced forces on coastal structures and submarine pipelines, for shallow water wave refraction and diffraction studies and for sediment transport studies.

## CHAPTER TWENTY ONE

US Army Corps of Engineers  
Field Wave Gaging Program

J. Michael Hemsley, M. ASCE\*

### Introduction

While the timely collection and reporting of climatological and environmental data have become routine in many countries, a similar capability for waves, currents, and coastal winds has not. The need for long-term, high quality wave data, in particular, has long frustrated the coastal engineer. In 1974, both Prof. Robert Wiegel and Dean Morrrough P. O'Brien commented publically on the need for information on the nearshore wave climate comparable to data routinely available on many other natural phenomena. O'Brien further expressed his concern for improving the accuracy of wave forecasting and hind-casting techniques through comparison with reliable measurements (2).

The need for characterizing the nearshore wave climate is much like the experience of conventional meteorological measurement programs. Along coastlines with high population densities, usage of the resource is intense. Ignorance of the processes at work carries a significant penalty. Past programs either have emphasized the collection of deepwater wave climatology or have been too regional or even site specific. With the Field Wave Gaging Program (FWGP), the US Army Corps of Engineers intends to collect the long-term, nearshore wave data that are necessary for planning, design, construction, operation, and maintenance of coastal projects.

### History and Objectives

In 1974, the American Society of Civil Engineers (ASCE) sponsored a Conference on Ocean Wave Measurement and Analysis. As a direct result of that conference, Scripps Institution of Oceanography installed a regional wave monitoring network for the State of California in 1975. The network began modestly, with only four stations operating by mid-1976, supported by the California Department of Boating and Waterways (Cal Boating) and the National Oceanographic and Atmospheric Administration (NOAA) Sea Grant Program. In 1978, the Corps of Engineers' South Pacific Division (SPD) became involved and provided funding to begin the expansion of this network throughout California. The Coastal Data Information Program (CDIP) became a cooperative effort between the Corps and Cal Boating, with Scripps acting as a contractor for data collection, analysis, and reporting (6).

---

\* Research Hydraulic Engineer, Coastal Engineering Research Center, USAE  
Waterways Experiment Station, PO Box 631, Vicksburg, MS 39180-0631

Almost concurrently with the formation of the CDIP, the Corps established a nationwide Coastal Field Data Collection Program (CFDCP), one element of which was the FWGP. The goals of the FWGP are to collect nearshore and relatively deepwater wave data to satisfy the immediate needs of the coastal planner, designer, and project operator; to support the Corps' effort to develop a wave hindcast/forecast model; and to provide a long-term data record for all of the nation's coastlines.

In addition to the FWGP, the CFDCP funds efforts to (1) hindcast 20 years of wave information from available wind data in the Atlantic, Gulf of Mexico, and Pacific; (2) identify, catalog, and make available beach profile data already obtained on the US coasts and obtain additional profile data in areas of particular interest; (3) identify, catalog, make available, and continue to update shoreline change maps; (4) continue Littoral Environmental Observations (LEO) in areas of interest; and (5) develop a database management system for the archiving of coastal data that have been and continue to be collected. The CFDCP also provides the mechanism through which valuable coastal data are collected, analyzed, distributed, and archived.

The existence of the CDIP has been very beneficial to the FWGP in two ways: (1) by having begun development on the automated data collection, analysis, and reporting system, and (2) by establishing a network of CDIP gages to provide a starting point from which the national wave gaging system could expand.

#### Gage Network

Eventually, the FWGP will acquire wave data along each of the nation's coasts. Primary data for the program will be collected at a number of deepwater, or index sites (Figure 1). These stations will be operated continuously in order to provide reliable long-term statistical wave data for use in planning, design, operation, and maintenance of coastal engineering projects. They are located in water sufficiently deep to minimize bathymetric effects on the measured waves, often as deep as 200 m (650 ft). An additional and unfortunately critical consideration in siting the index gages is to find a location that is not in a commercially fished area. Commercial fishermen using bottom-dragging equipment can break a deepwater mooring with their nets. This is an all too frequent occurrence in commercial fishing grounds even though instruments are reported in the US Coast Guard "Notice to Mariners."

Augmenting the index stations are nearshore gages located in areas generally representative of long stretches of coastline. These nearshore gages are, on occasion, single pressure gages, or, more often, slope arrays. Data are to be collected from these stations for five years to provide the nearshore wave information so necessary to coastal projects and to assist in verification of the numerous wave propagation models. Site selection for slope arrays requires reasonably straight, parallel offshore contours and, like the index stations, consideration of commercial fishing activity. A bottom-mounted sensor can be destroyed by the heavy nets used on large trawlers.

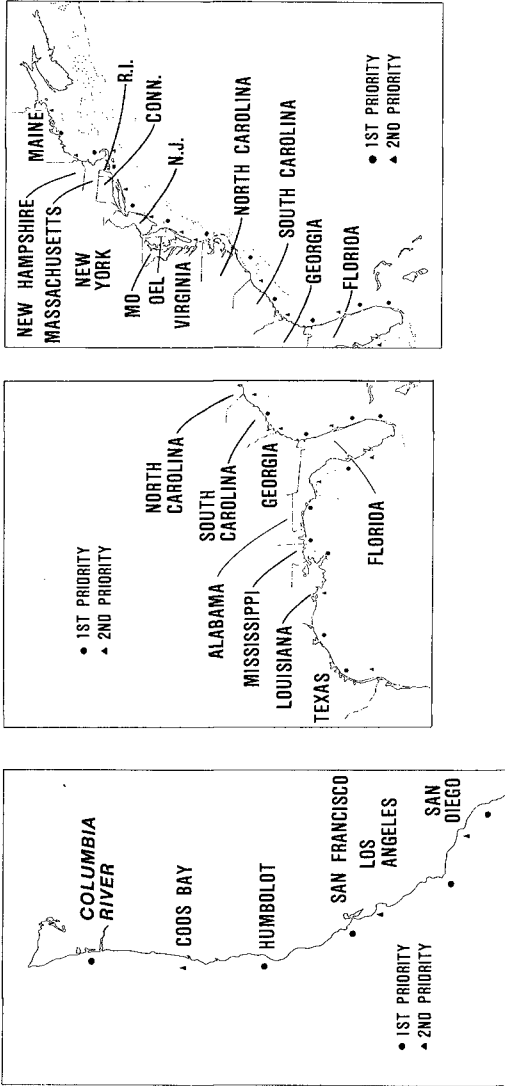

Figure 1. Proposed Index Sites

To date, Datawell Waverider buoys have been used in all of the index station installations; the depth of these installations precludes the use of bottom-mounted sensors. The Waverider buoy is a proven instrument which uses a vertically stabilized accelerometer to sense the vertical component of the buoy's motion. Heave data from the buoy are transmitted up to 50 km (31 miles) to shore.

Nearshore wave measurements, in depths of up to 15 m (50 ft), are made using a bottom-mounted Kulite semiconductor strain gage pressure transducer. The transducer and its circuitry are housed in a plastic pressure case mated to an underwater cable by a plastic underwater connector. The cable is used both to carry the signal ashore and to supply power to the sensor. Sufficient cable is stored in a service loop to allow the sensor housing to be brought to the surface for servicing, thereby increasing the system's reliability (9).

An array of four pressure sensors has been developed by Scripps to obtain directional wave data. This array is 6m (20 ft) square on a side and uses a specially designed armored underwater cable for data and power transmission. This cable has effective abrasion resistance, waterblocking integrity, tensile strength, and resistance to cutting which greatly enhance the system's reliability. Details of the array are described by Seymour and Higgins (8), and results of laboratory and field tests are discussed by Higgins, Seymour, and Pawka (3). Seymour, Domurat, and Pirie (7) describe a test at Santa Cruz, CA, where the estimates of gross and net longshore transport calculated from the array compared favorably with the actual sediment volume dredged from the harbor entrance.

Installation of the Waverider buoy and single pressure sensor is fairly straightforward, requiring only a small craft. The standard Datawell mooring has been employed successfully with few modifications. A tripod or jetted pipe is most often used for the single pressure sensor installation. Some innovation is needed when installing the array because of its size. When available, an amphibious vehicle can be effectively used to deploy the array and lay the cable from offshore across the surf zone and beach to the shore station. On two occasions when an amphibious vehicle was unavailable, an array was carried as a sling load beneath a US Army Reserve Chinook helicopter. The cable spool was carried inside its cargo area.

Figures 2 and 3 show the data collection sites currently being operated under the FWGP and provide information on gage type, percent data return, operational status, and gage ownership in programs other than this one. Operation of the system has been successful. Many of the stations that are not operational were lost or damaged during the severe storms in the early months of 1983 or as a possible result of that year's persistent "El Nino" current. Several arrays sustained cable damage as a result of beach protection or restoration efforts. An increase in buoy losses was experienced that appears attributable to the migration of commercially fished species as a result of "El Nino" and the expansion of the commercial fishing market to include species not previously considered marketable. All but one of the gages should be operational in 1984.

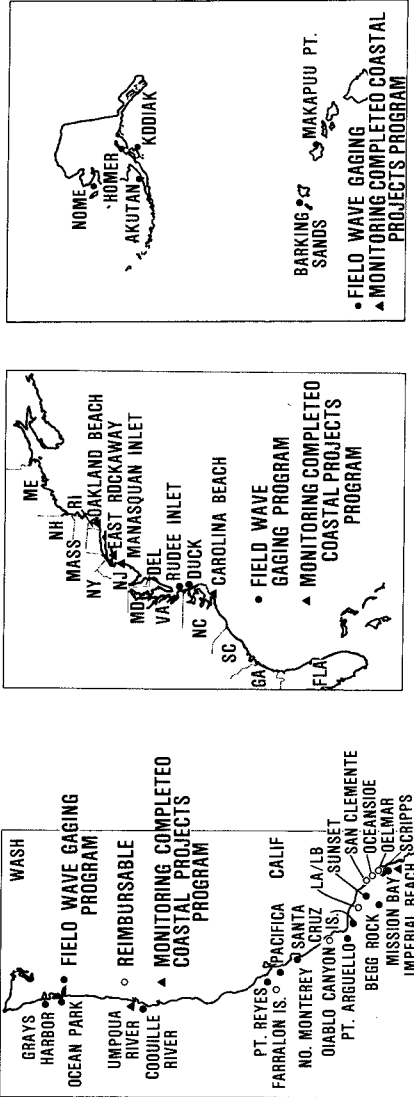

Figure 2. Data Collection Sites

## FIELD WAVE GAGING PROGRAM

Figure 3. System Status

Nearshore gages installed in support of specific projects supplement the data collected under the FWGP. On the Pacific coast, nine project-supported gages are operated through the FWGP network and the data reported by Scripps in the program's reports. The program, therefore, provides an existing system through which project-specific data can be collected, analyzed, and reported, taking advantage of the FWGP computers at Scripps. The system provides the considerable capacity and flexibility needed for coastal data collection and can accommodate any continuously reporting instrument. Tide, surge, current, wind, and wave data are being or have been collected on the system.

#### Related Data Collection Programs

Alaska's coastal data needs are unique. The State has approximately 54,500 km (33,900 miles) of coastline with a climate varying from temperate to arctic. With communities heavily dependent on the sea scattered along the entire coast, the State needed a planned approach to its coastal data collection efforts. In 1982, a cooperative agreement was signed between the State of Alaska and the Corps of Engineers to collect coastal wind and wave data. The goals stated in that agreement were, briefly, to collect, analyze, report, and archive coastal data collected by either party; to develop a plan for the collection of coastal data; and to develop instruments, telemetry systems, and analysis procedures suited to the needs and environment of Alaska (1).

Figure 2 includes the sites currently instrumented in Alaska. The Alaska Coastal Data Collection Program (ACDCP) is supported by funds from the State Department of Transportation and Public Facilities (DOT/PF), the Corps of Engineers, Alaska District, and the FWGP. Short-term (two to three years) data collection is planned to begin at 17 sites over the next 5 years.

Two types of stations have been developed: one for deep water and the other for nearshore measurements; both include a remote anemometer. For the deepwater sites, Waverider buoys are used. Nome is the only station currently in shallow-water operation. There the instrumentation consists of a pressure gage and current meter to provide directional wave data. Data from both station types are telemetered to a shore station and recorded on magnetic tape. Because data transmission over telephone lines is not reliable in Alaska, a meteor burst transmitter is used to send real-time data to the Corps office in Anchorage. The system uses meteor trails in the upper atmosphere as the medium from which the data are reflected. Meteor burst allows the data to be transmitted over great distances without the use of satellites or telephone lines and provides an inexpensive system check.

US Army Engineer District, Alaska, publishes data reports periodically as data are processed. To date, two reports have been produced for the station at Kodiak. The data reports provide the average wind speed and direction, maximum wind speed, and standard deviation of the wind speed and direction for each data collection. Both wind and wave data are reported every three hours. Wave data reported include the significant wave height, total energy in the spectrum, and the percent of the energy in frequency bands of 0.02148 Hz

width. As more stations become operational, the data reports will be published more frequently.

Another cooperative effort that receives some support from the FWGP involves a contract with the University of Florida to collect, analyze, and report wave data from the Florida coast. The gaging effort is funded by the Corps of Engineers through the Hurricane Surge Prototype Data Collection Work Unit and the FWGP, by the State of Florida, and by the US Nuclear Regulatory Commission. Eight sites in Florida are operated by the University as the Florida Coastal Data Network (FCDN) using bottom-mounted single pressure transducers. Recently, three P-U-V in situ recording meters were added to provide directional wave data.

The FCDN provides real-time data in support of the hurricane surge work unit. Data reports are produced monthly by the University of Florida for each of the sites operated under the contract. Both tables and plots are used to report the wave data, which are collected every 6 hours. Plots of maximum period and significant wave height versus time are included in the reports. The tables provide significant wave height, total energy in the spectra, and the percent energy in various period bands from 4 to 22+ seconds for each data collection (4).

#### Data Collection, Analysis, and Reporting

The data collection system developed by Scripps and used by the FWGP is based on burst rather than continuous sampling. While sampling frequency is field selectable, depending on the data to be collected, it is typically set at 1 hertz for ocean waves measured for the FWGP. The standard sample size is 1024 points, yielding 17 minutes of data. Normally each instrument is interrogated once every 6 hours, although certain critical stations are called every 3 hours and the data transmitted to the National Weather Service.

A block diagram of the collection and analysis system is shown in Figure 4. Signals from as many as eight input channels are received by a weatherproof shore station near the sensors. This station, which contains the data conversion and storage capability, control and power systems, and telephone interfaces, is modular. All electronics are on plug-in cards to facilitate the replacement of faulty components and minimize a station's down-time. Current incoming data are maintained in a digital buffer memory which expels the oldest words on a first-in first-out basis, ensuring that the most recent data set is in the buffer.

A control computer (a NOVA 1200 located at Scripps) initiates a telephone call to the shore station using an autodialer and normal telephone lines. The shore station, when called, locks the most current words in memory and transmits the data in a special 1200 Baud synchronous format to a digital data receiver at Scripps. Once all the data are transmitted, typically in slightly over one minute for four data channels, the shore station disconnects itself from the telephone line. Header information is then added, and the record is written on magnetic tape. During data transmission from the shore station, signal quality checks are performed. Failure of a quality check results in a second

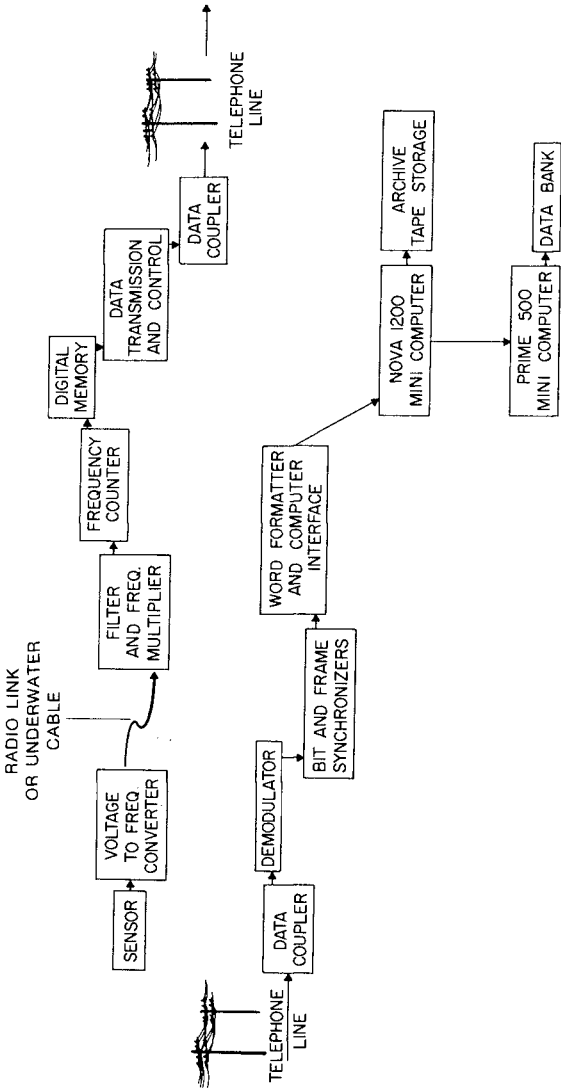

Figure 4. Data Collection and Analysis System

From Seymour, et.al., in press

call causing the immediate retransmission of the original data from the shore station. This protocol is important in the correction of transmission errors (9).

After the quality check, the raw data are put onto disks in a large mini-computer (a Prime 500 which serves as the central processing computer) for quasi-real-time analysis. The Prime and the NOVA are connected with a bidirectional serial link, allowing data and command flow in both directions. The NOVA can be remotely accessed through the Prime to make functions such as test calls, status checks, and raw statistics available from remote terminals.

Data analysis is composed of three phases. The first phase involves the receipt of the raw data from the NOVA and extensive data verification and editing in preparation for the second phase. An analysis phase performs the Fast Fourier Transform operations on the edited time series. The final phase operates on the analyzed data to produce the end products, monthly and annual reports.

In the first phase, an editing routine provides an automated data assurance scheme operating on the massive daily influx of data after their acceptance by the central computer. The editor is programmed to objectively recognize certain anomalies, to correct the more obvious ones, and to reject the others as bad data. It also compiles daily summaries and monthly statistics on the frequency and type of errors. The types of errors are spikes (the most frequent cause of data rejection), flat spots, mean shift exceedence, absence of zero crossings, and maximum and minimum wave height exceedence. Additionally, the editor filters the time series to remove tidal components and intercompares the individual sensor variances to evaluate acceptability of data for determining wave direction from the arrays.

Edited data for both gravity and infragravity waves are then Fourier transformed and the energy spectra calculated. Spectral values are grouped into period bins and summed to yield the variance. From the variance, the significant wave height is determined and the period band containing the maximum energy in the spectrum is identified. The data analysis routine also determines the percent of energy in each of nine period bands ranging from 4 to 22+ seconds.

Higgins, Seymour, and Pawka (3) describe the analytical method for extracting wave directionality from the sea surface slope components measured by the array. The method developed by Longuet-Higgins, Cartwright, and Smith (5) for use with a pitch-and-roll buoy is adapted for use with the array. An estimate of the longshore component of radiation stress,  $S_{xy}$ , can be extracted when surface elevation and components of sea surface slope are known at a point. The components of the slope are determined from differences between a pair of sensors. While only three sensors are required for this analysis, four are used for redundancy.

Routine analyses of wave direction involves calculation of a spectrum of the longshore component of shoreward-directed radiation stress, which, with the energy spectrum, allows the estimation of an apparent arrival direction for each band of

periods. Summing the radiation stress components over all frequencies yields total  $S_{xy}$ . From this, and the total energy, a significant angle of arrival for all the wave energy can be estimated (9).

In addition to the products previously discussed, the distribution of  $S_{xy}$  in the period bands is reported.

The significant data collected under the FWGP are available to users in three forms: direct access via remote terminals, data archives at Scripps and the US Army Engineer Waterways Experiment Station (WES), and monthly and annual reports. Data processed since the program's inception are directly available to any user with a computer terminal capable of remote telephone access of the Prime at Scripps. A user-friendly program has been developed to call up tabular and plotted data, including data for single or multiple stations on a single day, a single station on multiple days, or overplotted spectra to allow visualization of a storm's passage. Edited raw data are archived on tape at both Scripps and WES and can be made available to users under certain conditions.

Monthly and annual reports produced by Scripps provide the widest dissemination of wave data collected within the FWGP. After the first month of operation of the original program in 1975, a report was issued showing spectra and other wave parameters for Imperial Beach, CA. Every month since, analyzed data have been provided through these reports to a large group of public and private users. These data are summarized in an annual report which includes descriptive statistics on wave height and period as well as longshore sediment transport.

#### Future Effort

A nationwide network of index sites, including the Great Lakes, is the goal of the FWGP, and that goal will be pursued during the next few years. Growth of the program will be gradual, but the importance of obtaining long-term wave data should ensure that expansion.

#### Acknowledgement

The program described in this paper is an ongoing effort undertaken by WES for the Civil Works Program of the Corps of Engineers with the support of California, Florida, and Alaska. The author wishes to acknowledge the Office, Chief of Engineers, US Army Corps of Engineers for permission to publish this paper.

## CHAPTER TWENTY TWO

### IRREGULAR WAVE OVERTOPPING RATES

Scott L. Douglass\*  
A.M., ASCE

**ABSTRACT:** Methods for estimating wave overtopping of coastal structures are reviewed and compared with the very limited available data and with each other. The different methods yield results which can vary more than an order-of-magnitude. For vertical seawalls, the U. S. Army Engineer Shore Protection Manual method estimates more overtopping than Goda's method except in very shallow water. For sloped structures, the Shore Protection Manual method usually estimates less overtopping than Battjes' method and Owen's method. However, data for adequately evaluating how well these methods predict overtopping has not been published.

#### INTRODUCTION

Accurately estimating the amount of water which will wash over a coastal structure can be vital to design engineers. Building seawalls high enough to completely prevent overtopping is often unacceptable because of aesthetics and costs. For example, at Roughan's Point, Massachusetts, a coastal suburb of Boston, overtopping of the existing seawall causes flooding. A moderately higher seawall with improved backside drainage will reduce the flooding. In such situations, a reliable method for estimating overtopping rates for proposed seawall designs is imperative. Kobayashi and Reece (9) have pointed out that overtopping is also important in the design of arctic, gravel islands.

Overtopping is an extremely complex coastal phenomenon. Variables include structure characteristics (shape, height, slope, roughness, porosity, berm width, offshore slope, etc.) wave characteristics (height, period, direction, and the statistical descriptions of the wave field such as spectral widths and the correlation between height and period), water depth, wind speed and direction, air and water densities and viscosities, etc. Most overtopping

\*Hydraulic Engineer, Coastal Engineering Research Center, US Army Engineer Waterways Experiment Station, Vicksburg, Mississippi 39180-0631.

investigations have ignored the effects of local winds and wave direction in order to concentrate on the relationship between overtopping and the other variables.

#### METHODS FOR ESTIMATING OVERTOPPING

The US Army Corps of Engineers Coastal Engineering Research Center's (CERC) Shore Protection Manual (SPM) (17) presents a method for estimating overtopping due to irregular waves. The method uses results from three separate CERC investigations. Weggel (18) used Saville's (13) monochromatic wave overtopping data to derive an equation for overtopping due to monochromatic waves. Ahrens (2) extrapolates Weggel's equation to irregular waves by assuming that runup is Rayleigh distributed and by holding Weggel's empirical coefficients constant. These assumptions allow Ahrens to sum the overtopping contributions from each runup in an irregular sea.

Tsuruta and Goda (16) and Goda (7) use Saville's data and some Japanese data to generate dimensionless curves for monochromatic wave overtopping. The monochromatic wave curves are extrapolated to irregular seas by assuming that wave height is Rayleigh distributed and summing the overtopping contributions of each wave in the irregular sea. This method is called Goda's method in this paper.

Battjes (3) uses Saville's data to derive a different equation for monochromatic wave overtopping. Battjes then accounts for the irregularity of the seas by assuming deepwater wave height and length are jointly Rayleigh distributed. The overtopping contribution from each wave in the irregular sea is summed to estimate the overtopping rate.

All three of the methods use a form of what Tsuruta and Goda (16) call a "linear summation" procedure. They use an overtopping relationship derived for monochromatic waves and assume that the relationship holds for each component (wave or runup) in the irregular sea.

Recently, versions of the "summation" procedure have been presented which are computationally less direct. Kobayashi and Reece (9) and Gadd, et. al. (6) begin with assumed joint probability distributions of wave height and period. Then, a monochromatic runup formula is used to calculate the runup associated with each probability cell (H-T group). Thirdly, some form of Weggel's equation is used to calculate the overtopping contribution associated with each probability cell. And finally, all of these overtopping contributions are summed.

A different approach to estimating overtopping due to irregular waves has been taken by Owen (10, 11). He has related overtopping to irregular wave field parameters by conducting small-scale laboratory tests with irregular waves. However, Owen does not discuss scale effects in his 1:25 scale laboratory data. Aaen (1) found scale

effects at a 1:8 scale to be 60-150% and at a 1:10 to be 50-200%. Jensen and Sorensen (8) also suggest small-scale laboratory tests with irregular waves for estimating overtopping.

The rest of this paper focuses on four of the above mentioned methods:

SPM  
Goda  
Battjes  
Owen

The three basic questions which are addressed are:

- For what situations are the methods most applicable?
- How do estimates from the different methods compare?
- How good are the methods at estimating overtopping?

#### APPLICABILITY OF METHODS

Each of the four methods for estimating overtopping is applicable to specific design situations. The SPM method is limited by the range of situations which Saville tested: vertical and curved structures, smooth-slope structures, stepped structures, and a 1:1.5 slope impermeable quarrystone structure. While it may be necessary to extrapolate from these situations, particularly for composite walls and quarrystone structures at other slopes, Weggel derived his empirical coefficients only for those situations tested by Saville.

Goda's method is for vertical seawalls. He duplicated his work with seawalls covered with concrete blocks, but does not clearly define the situation.

Battjes' method is applicable to gently-sloped smooth structures. He did not attempt to apply the method to rough slopes.

Owen's method is for structures with slope between 1:1 and 1:4. Owen does not recommend using the method for situations outside of the range of wave and structure variables he tested. However, he does suggest an unverified way to apply his smooth-slope results to rough slopes.

These general regions of applicability are schematically represented in Figure 1.  $H_s$  is the offshore significant wave height and  $d$  is the water depth at the toe of the structure. The dashed portion of Battjes region represents the breaking wave limit, which will vary with wave steepness. Battjes' method is based on the assumption that the waves break on the structure.

Figure 1. General regions of applicability of methods for estimating overtopping.

COMPARISON BETWEEN METHODS

The method's estimates can be compared in design situations for which more than one method is applicable. Figure 1 shows that both Goda's method and the SPM method can be used for estimating overtopping over a vertical wall. The methods can be compared in dimensionless form as in Figure 2.  $F$  is the freeboard (the height of the structure above the still water level),  $g$  is the acceleration due to gravity, and,  $Q$  is the volume rate of overtopping per unit length of structure. The four  $d/H_s$  ratios correspond to situations tested by Saville. The vertical spread of the SPM method is the effect of the variability of peak wave period, which Goda ignores.

The relationship between SPM and Goda estimates is dependent on the relative depth,  $d/H_s$ . For relative depths of 3 and 1.5, the SPM method estimates more overtopping than Goda's method. For a relative depth of 0.75, the two methods yield similar results. For a relative depth of 0.4, i.e. very shallow water, the SPM method estimates less overtopping than Goda's method. This dependence on relative depth implies a dependence on wave breaking and appears to be a result of

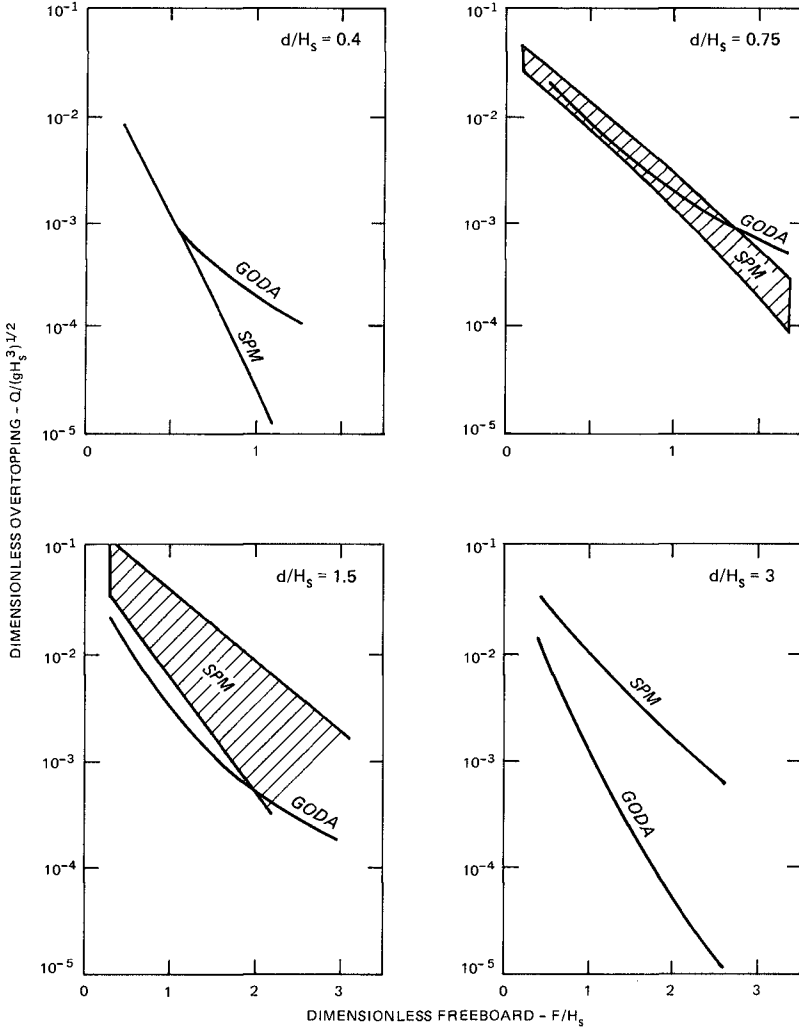

Figure 2. Goda's method and SPM method. Overtopping of a vertical wall.

the different approaches used to extrapolate monochromatic wave overtopping results to irregular seas.

Figure 2 clearly shows the sensitivity of overtopping to the freeboard. Since the freeboard is merely the difference between the structure height and the water level, overtopping is extremely sensitive to changes in either parameter. A varying water level, such as a tide or storm surge, will cause the overtopping rate to vary significantly with time.

Similar dimensionless plots can be generated to compare the SPM method with Battjes method for mildly-sloped, smooth structures. Figure 3 shows that Battjes method estimates more overtopping than the SPM method.  $\bar{T}$  is the average wave period. The spread of Battjes method is due to  $\kappa$ , a parameter which varies from 0 to 1 and is a function of the correlation between wave height and lengths.

Figure 1 shows that Owen's method can be compared with the SPM method. Figure 4 shows the comparison for 1:3 smooth slopes. Owen's method estimates more overtopping than the SPM method. The same result is found for both rough and smooth 1:1.5 slopes.

#### COMPARISON WITH DATA

The four overtopping methods should be evaluated by seeing how they agree with laboratory and field overtopping data. Unfortunately, no conclusive, comprehensive set of overtopping rates due to irregular waves has been published. Paape (12), Sibul and Tickner (14), and Tsuruta and Goda (16) conducted laboratory experiments before the present generation of irregular wave generators was developed. They could not generate a controlled, realistic irregular sea. Neither Owen (10, 11) nor Jensen and Sorensen (8) published their data. However, two studies provide rough "spot checks" of three of the overtopping methods.

Aaen (1) measured actual overtopping rates at a breakwater in Denmark. He then reproduced the structure and storm conditions in the laboratory at two scales, 1:8 and 1:10. The breakwater had a 1:2 slope of rounded sea stones. Figure 1 shows that Owen's method for rough slopes is applicable. The SPM method will be used for the sake of comparison by ignoring the difference in slope (1:2, not 1:1.5) and the difference in armor (rounded sea stone, not angular quarrystone). Aaen's data for these storms are plotted with the method's estimates in Figure 5.

The SPM method underpredicts Aaen's data and Owen's method overpredicts Aaen's data. Note that the relationship between the two estimates agrees with the trend in Figure 4; that is, for low overtopping rates, Owen's method estimates much more overtopping than the SPM method.

Figure 3. Battjes method and SPM method. Overtopping of a 1:6 smooth-slope structure.

Figure 4. Owen method and SPM method. Overtopping of a 1:3 smooth-slope structure.

Figure 5. Aaen's overtopping data with estimates by Owen's method and the SPM method.

There are several possible explanations for the discrepancies shown in figure 5. Considering the inherent assumptions in the method, the unverified wind correction factor, and the ignored differences in slope and stone, the difference between the SPM estimate and the data is not discouraging. The difference between Owen's estimate and the data could be due to the unverified wind and roughness corrections and to scale effects. It must be strongly pointed out that Aaen measured only small rates of overtopping. Conclusions from Aaen's data apply to overtopping rates which may be less than the design engineer is considering.

Fukuda, Uno, and Irie (5) measured actual overtopping rates at a seawall fronted by artificial concrete blocks. They found that Goda's curves for seawalls covered with artificial blocks overpredicted their data by between one and two orders of magnitude. Fukuda, et. al. believe this drastic difference is due to energy dissipation across their offshore slope (1:80), which was much flatter than Goda's offshore slope (1:10 to 1:30).

#### OTHER PARAMETERS WHICH EFFECT OVERTOPPING

Several parameters which effect overtopping are ignored in the four methods. Onshore winds should increase the overtopping rate at a seawall. The SPM recommends an unverified wind correction factor which varies from 1 to 3.2. Owen uses the SPM wind correction factor and the other two methods do not address the problem. It must be realized, however, that the SPM correction is merely an engineering judgement approximation of a very complex phenomenon. Gadd et. al. (6) discuss some qualitative trends in the wind effect and conclude that more data is needed to improve upon the SPM correction.

Very little information exists concerning the effect that angle of wave attack has on overtopping. In the absence of data, engineers have usually assumed that overtopping is maximum when waves hit the structure head on, i.e. perpendicularly, and tapers off to zero as the angle of attack lessens. However, Owen found that overtopping is maximum not when waves approach the structure perpendicularly, but at an angle of 15°. Owen (10, 11) has no explanation for his results. Similar results have been seen for monochromatic wave runup by Tautenhain, Kohlhasse, and Partenscky (15). Until data is available to better define this phenomenon, care should be taken to not assume too much overtopping reduction for oblique angles of wave attack.

#### CONCLUSIONS

There are a number of methods for estimating wave overtopping rates. Some of the methods are based on "summation" extrapolations of monochromatic wave overtopping theory. Some of the methods are based on small-scale overtopping tests with irregular waves. For vertical walls, the SPM method estimates more overtopping than Goda's

method except in very shallow water. For sloped structures, the SPM method generally estimates less overtopping than Battjes' method and Owen's method.

Better data is sorely needed. The US Army Engineer Coastal Engineering Research Center (CERC) plans to conduct site-specific and general research overtopping tests. The tests will begin this fall in CERC's two-dimensional flumes with irregular waves. Also, prototype data is needed to determine scale effects in overtopping modelling, and data is needed to better understand the effects of wind and angle of attack.

The question, "how well do the available methods estimate overtopping?," cannot be conclusively answered at this time. The methods discussed in this paper provide the best available estimate. Until better data is available, these estimates should be considered to be within, at best, a factor-of-three, and conservatively, an order-of-magnitude of the actual overtopping rate. This final conclusion is made considering:

- a. The lack of comprehensive, conclusive data and the discrepancies between the methods' estimates and the very limited published data
- b. The assumptions made in the derivations of the methods
- c. The factor-of-three confidence band that Owen claims for his method, which is the only method of the four based on irregular wave overtopping data
- d. The scale effects found by Aaen, and
- e. The order-of-magnitude difference between estimates from different methods

#### ACKNOWLEDGEMENTS

Much more detail about the existing overtopping estimation methods and the methodology of this investigation is being published in a US Army Engineer Waterways Experiment Station Technical Report (4). The results presented herein, unless otherwise noted, were obtained from the research conducted under the Wave Runup and Overtopping Work Unit, Coastal Structure Evaluation and Design Program of the United States Army Corps of Engineers by the Waterways Experiment Station, Coastal Engineering Research Center. Permission was granted by the Chief of Engineers to publish this information.

## CHAPTER TWENTY THREE

### RUN-UP OF PERIODIC WAVES ON BEACHES OF NON-UNIFORM SLOPE

Yoshinobu Ogawa\* and Nobuo Shuto\*\*

#### ABSTRACT

Run-up of periodic waves on gentle or non-uniform slopes is discussed. Breaking condition and run-up height of non-breaking waves are derived by the use of the linear long wave theory in the Lagrangian description. As to the breaking waves, the width of swash zone and the run-up height are obtained for relatively gentle slopes (less than  $1/30$ ), on dividing the transformation of waves into dissipation and swash processes. The formula obtained here agrees with experimental data better than Hunt's formula does. The same procedure is applied to non-uniform slopes and is found to give better results than Saville's composite slope method.

#### 1. INTRODUCTION

Attempts are recently made to establish, in the prediction of beach process, a two-dimensional model which is more realistic than the conventional one-line or two-line models [Watanabe(1981)]. In the modelling to be developed, no sufficient knowledges have yet been accumulated on the swash zone which is the most remarkable output of the beach process. As the first step to fill this lack, run-up of periodic waves is discussed both on uniform gentle slopes and on beaches of non-uniform slopes which are often seen at natural sandy beaches.

Many studies have been made on run-up of periodic waves on uniform slopes, as are summarized below. Run-up of periodic waves is roughly divided into two types; run-up of surging (standing) waves and that of breaking (progressive) waves.

For non-breaking waves, the run-up height and the breaking condition as a standing wave can be estimated well by the modified Miche's(1944) solution [Le Méhauté et al.(1968), Van Dorn(1966), Takada(1970)] and Miche's condition(1951).

On the other hand, for breaking waves, the run-up height is empirically correlated directly to the offshore wave characteristics and the beach slope [Hunt(1959), Savage(1958)]. This is partly due to a lack of

---

Aoba, Sendai 980, Japan

\*\* Professor, Dept. of Civil Eng., Tohoku University,  
Aoba, Sendai 980, Japan

knowledge about breaking waves. In addition, most of them deal with the run-up height on dikes which have relatively steep slopes.

Recently, some studies are performed on the size of the swash zone. Roos & Battjes(1976) showed from run-up experiments on relatively steep slopes (greater than 1/7) that the run-up height  $R$  was estimated well by Hunt's formula(1959) and that the run-down height  $R_r$  was expressed as  $R_r = R(1-0.4\xi)$ , in which  $\xi$  was the surf similarity parameter. Guza & Bowen(1976) and Van Dorn(1978) showed that the swash parameter  $\epsilon = a \sigma^2 / g s^2$  is almost constant for breaking waves. Although some people tried to discuss the run-up height in relation to the wave set-up [Van Dorn(1976), Michi & Watanabe(1982)], they did not formulate the results.

In the case of non-uniform slopes, one can use Saville's composite slope method (1958) to calculate the run-up height for breaking waves. Taylor(1980) applied this method to natural beaches by expressing beach profile as a parabolic curve. However, the physical meanings of this method is not always clear.

In the present study, the authors first obtain the run-up height of surging waves and the breaking condition as a standing wave on non-uniform slope by the use of the linear long wave theory in the Lagrangian description. The non-uniformity of profiles means steps, bars and foreshores with different inclination from those of inshore. Secondly, for breaking waves, we divide the wave deformation after breaking into two processes. One is the "Dissipation Process" and another is the "Swash Process". Combining these two processes in terms of wave height, we derive the run-up height on uniform gentle slopes. This technique is also applied to non-uniform slopes and is compared with Saville's method.

## 2. RUN-UP OF NON-BREAKING WAVES

Run-up height,  $R$ , of a linear standing wave on a uniform slope connected to the water of a constant depth,  $h$ , is given by the following equation, as was analysed by Shuto(1972) by using the Lagrangian description.

$$\frac{R}{H_i} = [J_0^2(4\pi\frac{L}{L}) + J_1^2(4\pi\frac{L}{L})]^{-1/2} \quad (1)$$

where  $H_i$  and  $L$  are the height and length of the incident wave in the channel of constant depth,  $l$  the horizontal distance between the shoreline and the toe of slope, and  $J_0$  and  $J_1$  the Bessel functions of the zeroth and the first order. As  $l$  tends to  $\infty$ , the relationship becomes

$$\frac{R}{H_i} = \sqrt{\frac{\pi\sigma}{s}} \left(\frac{h_1}{g}\right)^{1/4} \quad (2)$$

where  $\sigma$  is the angular frequency and  $s$  the angle of slope. In order to replace  $H_i$  by the height of incident wave in deep water  $H_0$ , the law of energy conservation is applied. Then Eq.(2) is reduced to Eq.(3) which is similar to Miche's solution(1944).

$$\frac{R}{H_0} = \sqrt{\frac{\pi}{2s}} \quad (3)$$

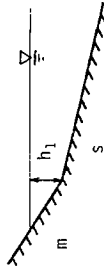

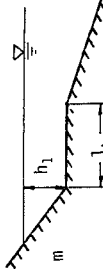

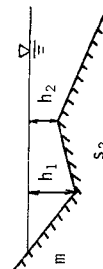

Table 1. Solutions of run-up height and breaking condition of standing waves.

$$\frac{R}{H_0} = \frac{1}{Z} \sqrt{\frac{\pi}{2S}}$$

$$\left(\frac{H_0}{L_0}\right)_{cr} = Z \sqrt{\frac{2S}{\pi}} \frac{m^2}{\pi}$$

$J_0, J_1, N_0, N_1$  : Bessel and Neumann function of the zeroth and the first order.

Profile	Value of coefficients
	$z = \sqrt{\left(\frac{J_0(d)N_1(e) - J_1(d)N_0(e)}{J_0(e)N_1(e) - J_1(e)N_0(e)}\right)^2 + \left(\frac{J_0(d)J_1(e) - J_1(d)J_0(e)}{N_0(e)J_1(e) - N_1(e)J_0(e)}\right)^2}$ $d = \frac{2\sqrt{2\pi}}{m} \left(\frac{h_1}{L_0}\right)^{0.5} \quad e = \frac{2\sqrt{2\pi}}{S} \left(\frac{h_1}{L_0}\right)^{0.5} \quad L_0 = \frac{g}{2\pi} T^2$
	$z = \sqrt{\left(\frac{u N_1(e) - v N_0(e)}{J_0(e)N_1(e) - J_1(e)N_0(e)}\right)^2 + \left(\frac{u J_1(e) - v J_0(e)}{N_0(e)J_1(e) - N_1(e)J_0(e)}\right)^2}$ $u = J_0(d) \cos k l_b - J_1(d) \sin k l_b \quad d = \frac{2\sqrt{2\pi}}{m} \left(\frac{h_1}{L_0}\right)^{0.5} \quad e = \frac{2\sqrt{2\pi}}{S} \left(\frac{h_1}{L_0}\right)^{0.5}$ $v = J_1(d) \cos k l_b + J_0(d) \sin k l_b$
	$Z = \sqrt{\left(\frac{u N_1(q) - v N_0(q)}{J_0(q)N_1(q) - J_1(q)N_0(q)}\right)^2 + \left(\frac{u J_1(q) - v J_0(q)}{N_0(q)J_1(q) - N_1(q)J_0(q)}\right)^2}$ $u = J_0(p) \frac{J_0(d)N_1(e) - J_1(d)N_0(e)}{J_0(e)N_1(e) - J_1(e)N_0(e)} + N_0(p) \frac{J_0(d)J_1(e) - J_1(d)J_0(e)}{N_0(e)J_1(e) - N_1(e)J_0(e)}$ $v = J_1(p) \frac{J_0(d)N_1(e) - J_1(d)N_0(e)}{J_0(e)N_1(e) - J_1(e)N_0(e)} + N_1(p) \frac{J_0(d)J_1(e) - J_1(d)J_0(e)}{N_0(e)J_1(e) - N_1(e)J_0(e)}$ $d = \frac{2\sqrt{2\pi}}{m} \left(\frac{h_1}{L_0}\right)^{0.5} \quad e = \frac{2\sqrt{2\pi}}{S_2} \left(\frac{h_1}{L_0}\right)^{0.5} \quad p = \frac{2\sqrt{2\pi}}{S_2} \left(\frac{h_2}{L_0}\right)^{0.5} \quad q = \frac{2\sqrt{2\pi}}{S} \left(\frac{h_2}{L_0}\right)^{0.5}$

A similar manipulation yields the following breaking condition of standing waves which is analogous to Miche's result(1951), from the breaking condition obtained by Shuto(1972).

$$\left(\frac{H_0}{L_0}\right)_{cr.} = \sqrt{\frac{2s}{\pi}} \frac{s^2}{\pi} \tag{4}$$

Run-up on a slope of more complicated shape can be obtained as follows. Divide the whole beach into segments of uniform slope with the inflection points of bottom slope as their end points. For each segment, solutions of the linear standing long waves in the Lagrangian description are determined, corresponding to its own slope. These local solutions are connected to build the solution over the whole slope. The continuation is carried out for the horizontal and vertical displacements of the water particles which are on the boundary between the two different slopes at the initial instant. As for the procedure, one may read the reference (22). Once the solution is established, the run-up height is correlated with the height of incident waves in deep water, as is shown above.

Solutions are obtained for bi-linear sloped beach, step-type beach and bar-type beach. Equations are summarized in Table 1. Numerical examples for the offshore slope  $s = 0.03$  and the foreshore slope  $m = 0.1$  are shown by circles and triangles in Fig.1. The dotted lines in Fig.1 are the result given by Eqs.(3) & (4), by setting  $s = m = 0.1$ . Even though the equations are functions of not only  $m$  but also  $s$ ,  $R/H_0$  and  $(H_0/L_0)_{cr.}$  are mainly governed by  $m$ . One may consider that the solutions of  $R/H_0$  (or  $(H_0/L_0)_{cr.}$ ) for  $m = 0.1$  and  $s = 0.03$  are between the values of Eq.(3) (or Eq.(4)) for  $s = 0.1$  and for  $s = 0.03$ . However, this is not

Fig.1(a) Numerical Examples of run-up height and breaking condition of standing waves (bi-linear sloped beach)

Fig.1(b) Numerical examples of run-up height and breaking condition of standing waves (step-type beach)

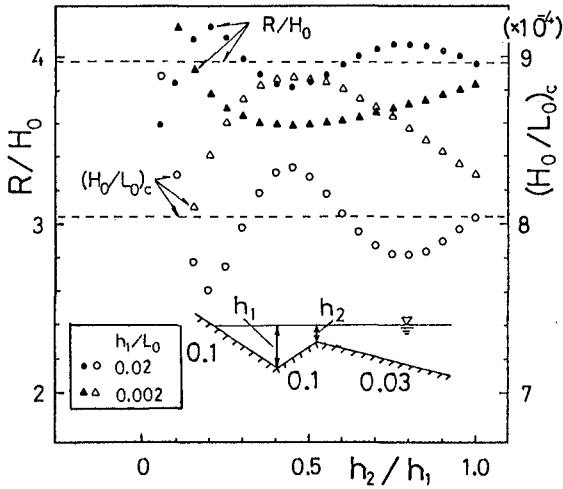

Fig.1(c) Numerical examples of run-up height and breaking condition of standing waves (bar-type beach)

true in case of the standing waves in contrast to the case of the breaking waves. This result suggests that the foreshore slope is the most important in problems of the run-up, the breaking condition and the reflection of standing waves.

3. RUN-UP OF BREAKING WAVES

Deformation of progressive waves after breaking is divided into the following two processes; i) the dissipation process in which the kinematic and potential energies are consumed due to breaking, and ii) the swash process in which the kinematic and potential energies alternates to each other on a dry bed. The run-up height and the width of swash zone are calculated by continuing the wave height between the two processes. Figure 2 gives the definition sketch.

3.1 Dissipation process: decay of wave height due to breaking

According to the experimental curves of Sasaki & Saeki(1974) for waves after breaking on a uniform slope, the decay in wave height is almost independent of the wave steepness. It is also shown in their results that if  $h/h_b$  is smaller than 0.5,  $H/H_b$  is linearly proportional to  $h/h_b$  with the coefficient of proportionality  $\beta = 0.6$ , independent of the beach slope. Assume that their experimental curves can be extended to the points where the curves intersect the beach profile. The height,  $R_r$ , of the points of this intersection which are hereafter called as the beginning points of run-up are given by

- $H_0$  : Offshore wave height
- $T$  : Wave period
- $L_0$  : Offshore wave length
- $H_b$  : Breaking wave height
- $h_b$  : Breaking water depth
- $s$  : Tangent of slope in the surf zone
- $H_s$  : Wave height at the shoreline of still water level
- $H_r$  : Wave height at the beginning point of run-up
- $m$  : Tangent of foreshore slope
- $R$  : Total run-up height above still water level
- $R_d$  : The width of swash zone
- $R_r$  : The height of the beginning point of run-up

Fig.2 Definition sketch.

$$\frac{R_r}{h_b} = \frac{1}{\beta} \left( \frac{H_s}{H_b} - \frac{H_r}{H_b} \right) \tag{5}$$

The wave height,  $H_r$ , at the shoreline of still water level is given by black circles in Fig.3, from experimental results of Sasaki & Saeki (1974) and Roos & Battjes (1976). It is expressed by

$$\frac{H_s}{H_b} = \begin{cases} 3.04 s^{1.07} & \text{for } 0.01 < s < 0.2 \\ 0.55 & \text{for } 0.2 < s \end{cases} \tag{6}$$

With these informations,  $R_r$  can be obtained as a function of  $H_r$ , the wave height at the beginning point of run-up if the breaking wave height  $H_b$  and the breaking water depth  $h_b$  are given.

For a non-uniform slope for which no simple relations similar to Eqs.(5) and (6) are available at present, numerical computation such as proposed by Mizuguchi (1980) may be used.

Fig.3 Relative wave heights  $H_s/H_b$ ,  $H_r/H_b$  and beach slope.

3.2 Swash Process: run-up of waves

Trajectory of the wave front when waves are climbing a uniform slope is given by Freemann & Le Méhauté (1964) as follows.

$$x_f(t) = -\frac{1}{2} gAm \left( t - \frac{u_s}{gAm} \right)^2 + \frac{1}{2} \frac{u_s^2}{gAm} \tag{7}$$

$$A = \frac{1+f/(a^2m)}{(1+2a)(1+a)} \tag{8}$$

where  $x_f(t)$  is the horizontal coordinate of the wave front measured from

the beginning point of run-up,  $t$  the elapsed time after the wave front passes the beginning point of run-up,  $u_s$  the water particle velocity of rarefaction waves at the beginning point of run-up,  $a$  the ratio of the wave propagation velocity  $c = \sqrt{g(h+\eta)}$  to the water particle velocity, and  $f$  the friction coefficient defined by  $\tau = \rho f u^2$ . According to the experiments of Iwagaki et al.(1966),  $a = 0.26$  and  $f = 0.005 - 0.01$  for a smooth bottom in case of  $m > 0.1$ .

Trajectory of the wave front when waves are descending is given as follows, on continuing the solution of Brandtzaeg(1964) with Eq.(7).

$$x_f(t) = \frac{u_s^2}{2gAm} - \frac{2z}{f'} \ln[\cosh \sqrt{\frac{f'g(m-\tan \gamma)}{2z}} (t-\zeta T)] \quad (9)$$

$(f' \neq 0)$

$$x_f(t) = \frac{u_s^2}{2gAm} - \frac{1}{2} g(m-\tan \gamma)(t-\zeta T)^2 \quad (f' = 0) \quad (10)$$

where  $\zeta T$  is the time when the maximum run-up height appears,  $T$  the wave period,  $z$  the thickness of water of descending waves,  $f'$  the friction coefficient and  $\gamma$  the angle between water and beach surface. With the assumptions that  $f = f'=0$  (or  $A = 1$ ) and that the water surface displacement at the shoreline varies linearly with respect to time, we have  $\zeta = 0.46$ .

The value of  $u_s$  is assumed to be given as follows in terms of  $H_r$ .

$$u_s = F\sqrt{gH_r} \quad (11)$$

Figure 4 shows empirical relationships between  $u_s$  and  $H_r$ . The experimental results are taken from one of the present authors(1982) for single bores on  $m = 1/20$ , Iwagaki et al.(1966) for solitary waves on  $m > 1/10$  and Roos & Battjes(1976) for regular wave trains on  $m = 1/3$  and  $1/7$ .

Fig.4 Relationship between  $u_s$  and  $\sqrt{gH_r}$  (for smooth fixed bottom)

It was assumed  $\zeta = 0.46$  in case of regular waves. From the figure, the coefficient of proportionality which is a kind of Froud number is 2.2 on an average for both single waves and regular wave trains. This is nearly equal to the wave front condition of Iwasaki & Togashi(1969).

From Eqs.(7) and (11),  $H_r$  and  $R_d$  are derived as follows.

$$H_r = \frac{gm^2T^2}{F^2} A^2\zeta^2 \tag{12}$$

$$R_d = \frac{gm^2T^2}{2} A\zeta^2 \tag{13}$$

Figures 5 and 6 compare the calculated results of  $H_r$  and  $R_d$  for  $F = 2.2$ ,  $f = 0.005$  and  $\zeta = 0.46$  with experimental results of  $R_oos$  &  $Battjes(1976)$ , Van Dorn(1976) and Michi(1982). Since the value of  $a = 0.26$  according to Iwagaki et al.(1966) makes the calculated value too big in case of a gentle slope, the followings are used for convenience.

$$a = \begin{cases} 0.26 & \text{for } 0.1 < m \\ 0.13 m^{-0.3} & \text{for } 0.01 < m < 0.1 \end{cases} \tag{14}$$

In the result of Van Dorn(1976) who discussed  $R_d$ , the calculated values were about twice the experimental results in case of a steep slope. From Eq.(13), swash parameter  $\epsilon = a_s \sigma^2/gm^2$  is calculated as  $\pi^2\zeta^2A$  ( $= 2.09 A$ ) and is found to be a function of  $s$  foreshore slope and friction factor.

Equation (12) (or Eq.(13)) shows that  $H_r$  (or  $R_d$ ) is mainly governed by the foreshore slope  $m$  and the wave period  $T$ , whereas  $H_s$  is a function of the slope  $s$  alone. For a comparison, values of  $H_r/H_b$  for different wave periods are drawn by dotted lines in Fig.3 which is originally given to show the relationship  $H_s$  and the slope angle.

Fig.5 Comparison of  $H_r$  between measured and calculated. (for smooth fixed bottom)

Fig.6 Comparison of  $R_d$  between measured and calculated. (for smooth fixed bottom)

3.3 Run-up on a gentle, uniform slope

Run-up height  $R$  is given by a sum of  $R_r$  and  $R_d$ .

$$\frac{R}{H_0} = \frac{0.46}{\beta} s^{-0.12} \left(\frac{H_0}{L_0}\right)^{-0.2} [3.04 s^{1.07} - \frac{2.94\pi\zeta^2 A^2}{F^2} s^{-0.09m^2} \left(\frac{H_0}{L_0}\right)^{-0.75}] + \pi A \zeta^2 m^2 \left(\frac{H_0}{L_0}\right)^{-1} \tag{15}$$

for  $0.02 < m < 0.33$ ,  $0.01 < s < 0.1$  and  $0.003 < H_0/L_0 < 0.07$

The first term on the right-hand side is  $R_r/H_0$  which is equal to the wave set-up and the second term is  $R_d/H_0$ , the width of swash zone. Breaking conditions are determined by the following formulas obtained from the same data as Goda(1970) used.

$$\frac{H_b}{H_0} = 0.68 s^{0.09} \left(\frac{H_0}{L_0}\right)^{-0.25} \quad \text{for } 0.01 < s < 0.1 \tag{16}$$

$$\frac{h_b}{H_0} = 0.46 s^{-0.12} \left(\frac{H_0}{L_0}\right)^{-0.20} \quad \text{for } 0.003 < H_0/L_0 < 0.07 \tag{17}$$

Fig.7 Comparison of calculated  $R/H_0$  with experimental data.

Figure 7 compares experimental results of Michi & Watanabe(1982), Van Dorn(1976), Sawaragi et al.(1976) and Savage(1958) with the calculated ones for  $\beta = 0.6$ ,  $F = 2.2$ ,  $f = 0.005$  and a obtained from Eq.(14). Calculated run-up heights agree better with experimental results than Hunt's formula(1959) does. Figure 8 shows the relative magnitude of  $R_r/H_0$  and  $R_d/H_0$  for  $s = 1/10, 1/30$  and  $1/90$ . The gentler the slope is and the greater the wave steepness is, the contribution of the wave set-up  $R_r$  is the greater, although the greater wave steepness does not always yield the greater  $R_r/H_0$ .

The discussion above is for a fixed bottom of smooth surface and is not directly applicable to a natural beach which is of movable and rough surface. According to Sawaragi's experiments(1962), effects of bottom roughness is not dominant on the breaking condition and is negligible for a natural, sandy beach.

Effects of bottom roughness in the swash process is shown in Fig.9. Equation (13) is used to calculate the run-up height for different values

Fig.8  $R_d/H_0$  vs.  $R_r/H_0$  for various slopes.

Fig.9 Effect of the value  $f$  on run-up height.

of  $f$  and the results are made dimensionless, divided by the run-up height on a smooth bottom for which  $f$  is 0.005. Tsuchiya et al.(1978) reexamined Savage's data(1958) and obtained the effect of roughness on run-up height, which is similar to Fig.9. However, we must take notice of the fact that  $f$  used here is somewhat different from the original definition of the bottom shear stress but is a virtual friction coefficient which includes several other effects such as turbulence effect caused by breaking in the name of the friction coefficient. No method is available to determine the value of  $f$  from hydraulic conditions near the bottom.

From prototype experiments by the Central Research Institute of Electric Power Industry, relationships similar to Fig.4, 5 and 6 are shown in Fig.10,11 and 12. As for the experimental channel, one may read the reference(8). All experiments were conducted with a constant still water depth of 4.5 m and on initial slope inclination of 1/20. The slope consists of movable sands with the median diameter of 0.27 mm. Foreshore slopes formed by waves ranged from 0.033 to 0.186. In these experiments, the value of  $F$  is also about 2 on an average. The friction coefficient is found to be 0.8 so as that calculated values of  $R_d$  and  $H_r$  give the best fit to the measured data. Values of  $f$  as well as  $\bar{a}$  should be experimentally determined, after all.

3.4 Run-up on a non-uniform slope

The same procedure is applied to the run-up on a non-uniform slope, based on the following assumptions.

- i) Dissipation process does not vary by changing foreshore profiles.
- ii) Water particle velocity is continuous at the point where profile changes and the value of  $a$  depends on local slopes.

Examples are given in case of bi-linear sloped beaches, the inflection point of which coincides with the shoreline. If  $R_r > 0$ , Eq.(15) can be used. For  $R_r < 0$ , the following equation is used.

$$\frac{R}{H_0} = \frac{F^2}{2A_2} \left( \frac{H_r}{H_0} \right) - \frac{A_1}{A_2} s \left( \frac{x_1}{H_0} \right) \tag{18}$$

$$\frac{x_1}{H_0} = \frac{-0.676}{8} s^{-1.21} \left( \frac{H_0}{L_0} \right) 0.05 [2.07s^{1.16} \left( \frac{H_0}{L_0} \right) - 0.25 \frac{H_r}{H_0}]$$

$$2\zeta \left( \frac{H_0}{L_0} \right)^{-1/2} = \frac{F}{A_1 s} \sqrt{\frac{H_r}{H_0}}^{1/2} + \sqrt{\frac{2}{\pi} \frac{A_1 s - A_2 m}{A_1 A_2 s m} F^2 \left( \frac{H_r}{H_0} \right) - 2A_1 s \left( \frac{x_1}{H_0} \right)}$$

where  $A_1$  and  $A_2$  are the values of  $A$  obtained from Eqs.(8) and (14) for  $s$  and  $m$ ,  $x_1$  the horizontal distance between the beginning point of dry bed and the inflection point of the slope.

Figure 13 shows comparisons of the calculated results with experimental results of Toyoshima et al.(1964) and Saville(1958). Full lines in Fig.13 are Eqs.(15) & (18) and broken lines are calculated by Saville's composite slope method(1958). The composite slope method always gives smaller values. The present method agrees fairly well with the experimental results, although the effect of the foreshore slope on the deformation of waves after breaking is not taken into consideration.

#### 4. CONCLUSIONS

Run-up of periodic waves is discussed, *considering the wave deformation*, especially for *gentle and non-uniform slopes* (with steeper foreshore slopes, steps and bars) which are often seen at *natural beaches*. Results are summarized as follows.

- (1) The run-up height and the breaking condition for non-breaking waves on non-uniform sloping beaches are derived as shown in Table 1. Foreshore slopes are found to be dominant in these values. The procedure to obtain the solution can be applied to understand the behavior of long period waves in the surf zone.
- (2) For breaking waves, run-up phenomena can be explained well by connecting dissipation and swash processes.
  - i) The width of swash zone is mainly determined by the foreshore slope and wave period. It can be calculated by Eq.(13) if the foreshore slope is within the range of  $1/3 - 1/50$ .
  - ii) For gentle uniform slopes ( $1/10 - 1/100$ ), the run-up height formula, Eq.(15), obtained by setting  $m = s$  can be used instead of Hunt's formula(1959) which is originally applicable to steeper slopes than  $1/10$ .
  - iii) The procedure to connect dissipation and swash processes is applied to calculate the run-up height in the case of steeper foreshore profiles which are generally found at natural beaches. The procedure gives not only better results than Saville's method(1958), but also a physically sound explanation of run-up. We can also obtain the size of the swash zone which is closely connected with the stability of dikes built near and above the shoreline and which is also important in estimating sand movement near swash zone.
  - iv) Further studies are necessary for wave run-up on more complicated slopes and for estimation of values of friction coefficient.

#### ACKNOWLEDGEMENTS

The authors express their thanks to Mr. R. Kajima, Mr. T. Shimizu and Mr. S. Saito, Civil Engineering Laboratory of the Central Research Institute of Electric Power Industry (CRIEPI) for their permission to use their data which were obtained in one of their special project. Only a part of the data was published, for example, at the 18th I.C.C.E. [see reference (8)]. A part of this research was supported by a grant from the Ministry of Education, Science and Culture, the Japanese Government.

## CHAPTER TWENTY FOUR

### EFFECTS OF MEASUREMENT ERROR ON LONG-TERM WAVE STATISTICS

by Bernard Le Mehaute<sup>1</sup> and Shen Wang<sup>2</sup>

KEY WORDS: Water waves, wave statistics

SUMMARY: An analysis of errors in the determination of extreme waves of low frequency of occurrence is presented. The result of the analysis provides a better understanding toward determining safety coefficients in the design of offshore structures.

ABSTRACT: The effect of sample size on confidence band in predicting the extreme wave height is related to the return period and the duration of the sample record length. An estimate of errors resulting from various methods of data acquisition is given. The uncertainties corresponding to various number of years of observation and various measurement errors are analyzed for various return intervals. It is shown that data accuracy and record length are equally important in long term wave predictions. At the present time, the determination of extreme event benefits more from relatively less accurate long-term hindcast calculation rather than short-term high quality measurements. In the long run, a long-term accurate measurement program is imperative if more definite descriptions of extreme events are sought.

## INTRODUCTION

The uncertainties in the determination of extreme wave heights from observations may result from three causes of errors:

1. Errors due to climatological variations and extrapolation of the statistical compilation of small sample to extreme wave events of low probability of occurrence.
2. Errors in measurements, visual estimates, or (hindcast) calculations of wave input data on which the wave statistics are established.
3. Errors resulting from the lack of knowledge on the functional relationship characterizing the "true" long-term, underlying distribution, particularly at low probability level.

In a paper by Earle and Baer (6), the effects of uncertainties resulting from causes 1 and 2 have been addressed and analyzed through a Monte Carlo simulation, assuming that the long-term distribution of wave heights was log-normal. Patruskas and Aagaard (19) addressed the problems in extrapolating historical storm data. In particular, they examined the errors resulting from causes 1 and 3. While it was impossible to assess accurately the effect due to the uncertainty in underlying distribution laws, they concluded that it should be less significant than the uncertainty resulting from small sample size. The error resulting from small size samples was investigated analytically by Wang and Le Mehaute (25). The fact that small size samples cannot accurately establish the underlying distribution was particularly discussed. Confidence bands of uncertainties were possibly determined at low probability level as a function of sample size, assuming the error due to other sources to be absolutely negligible and the population distribution to be Weibull.

The purpose of this paper is to establish a rationale by comparing various methods of data gathering and to establish the confidence bands of prediction for extreme wave events. This also allows us to answer a number of practical questions such as: to determine the "100-year wave", is five years of good reliable wave measurements better than say 20 years of more questionable hindcasted data or ship observations?

As such, this paper is considered as a sequel to the previous paper already mentioned (25). Considerations and assumptions which have been raised in that paper concerning duration between uncorrelated events, measurement intervals, return periods, etc., are therefore not repeated here. Recalled only is that the translation of long-term wave statistics from a variety of causes of oceanic events (hurricane, storm, local sea state, swell, etc.) into a single distribution - Weibull, log-normal or else - is a gross simplification. It may be justified by curve fitting and found good or bad, but it cannot be proven right or wrong on a rational basis. The actual distribution in fact represents a sum of different populations corresponding to different classes of oceanic events and each having its own characteristics. It also varies with water depth and becomes very site

specific in shallow water.

Different forms of distribution have been examined and reviewed by Isaacson (13). Ochi and Whelan (17) and Ochi (18) have attempted to rationalize some of these. Even though the fact of no well-proven law of distribution could be a significant cause of error at low probability level, this subject will not be considered in the present paper. Instead, the Weibull distribution considered in (25) will remain as the foundation in the present discussion. There is enough evidence to support the Weibull distribution at low probability level down to  $10^{-3}$ , below which the probability of exceedance curves tend to depart on the high wave height side from the Weibull distribution due to the superposition of rare classes of oceanic events such as winter storms or tropical depressions. Indeed the Weibull distribution may not be truly representative of the population distribution, any conclusion which is obtained with the Weibull distribution however is anticipated to be equally valid for other forms of distributions.

#### EFFECT OF SAMPLE SIZE

Under the assumptions made in (25) the probability of exceedance of wave height at a given location is given by

$$Q(h) = \exp [-h^\gamma] \quad (1)$$

where the variate  $h$  is defined by

$$h = \frac{H - H_0}{\bar{H}} \quad (2)$$

Here  $H$  is the significant wave height characterizing a sea state, typically obtained by analyzing a 20-minute continuous wave record;  $H_0$  is the so called location parameter signifying a lower bound of the wave height,  $H$  the scale parameter and  $\gamma$  the shape parameter which varies between 0.9 and 1.5. The parameter  $\gamma$  tends to be toward the lower limit in shallow water.

Confidence bands at any given level of  $Q(h)$  can be determined with respect to errors arising from small sample size. The widths of these bands are given in terms of the standard deviation of the sample quantile at various probability levels. Recalled from (25), the standard deviation is given by

$$\sigma_s = \frac{1}{f(h)} \left[ \frac{Q(h)[1-Q(h)]}{N} \right]^{1/2} \quad (3)$$

in which  $f(h)$  is the probability density function, which can be obtained by

$$f(h) = -\frac{d}{dh} Q(h) \quad (4)$$

Note that  $\sigma_s$  is dimensionless because  $h$  is dimensionless. Referring to Eq. 2, the absolute value of the standard deviation  $\sigma_s$  maybe obtained by multiplying  $\sigma_s$  with  $H$ .

$$\bar{\sigma}_s = \sigma_s \cdot \bar{H} \quad (5)$$

Let  $N$  be the size of the sample which may be defined in terms of the number of years of measurements  $Y$  and the time interval between uncorrelated events  $\Delta t$  (expressed in hours) so that

$$N = \frac{365 \times 24 \times Y}{\Delta t} \quad (6)$$

The sensitivity of the exact definition of  $\Delta t$  on the confidence band for  $h$  has been examined in (25). The confidence bands which define the error in  $h$  due to small sample size generally envelop the error resulting from an imprecise definition for  $\Delta t$ . This allows some flexibility in the choice of  $\Delta t$  to assimilate the number of observations  $N$  to the number of uncorrelated events. Even though a  $\Delta t$  of 6 hours is probably small for the latter, it is common practice to sample the sea state every six hours. This number will be retained in most cases of the following discussion.

The standard deviation relative to the variate  $h$  is now defined by

$$\sigma'_s(h) = \frac{\sigma_s}{h} = \frac{\bar{\sigma}_s}{H - H_0} \quad (7)$$

Equation 7 shows that  $\sigma'_s(h)$  is equivalent to the dimensional quantity of the standard deviation normalized by the variable  $(H - H_0)$  or  $H$  if  $H_0$  is zero. This normalized standard deviation therefore can be expressed in percentages of wave height  $(H - H_0)$  or  $H$ . Inserting  $Q(h)$  and  $f(h)$  from Eqs. 1 and 4 into 3, the normalized standard deviation is given by

$$\sigma'_s(h) = \gamma^{-1} h^{-\gamma} \left[ \frac{[1 - \exp(-h^\gamma)] \exp(h^\gamma)}{N} \right]^{1/2} \quad (8)$$

Let  $R$  be the return interval (in years); by definition it is given by

$$R = \frac{\Delta t}{Q(h) \times 365 \times 24} = \frac{1}{Q(h) v} \quad (9)$$

where  $v$  is the number of observations per year. At low probability levels  $1 - Q(h) \approx 1$ , Eq. 8 then can be written as

$$\sigma'_s = \frac{1}{\gamma \ln(Rv)} \left( \frac{R}{Y} \right)^{1/2} \quad (10)$$

This relation indicates that the error due to extrapolation from short

sample is proportional to the square root of the return period but inversely proportional to the square root of the sample record length. The fact that the accuracy of prediction requires a long record length is obvious. The uncertainty in predicting events of long return period being not very sensitive to the value of  $\nu$  or the definition of  $\Delta t$  has been discussed in (25).

#### ERRORS FROM MEASUREMENT OR HINDCAST - ERROR IN DATA SAMPLE

The analysis presented in the previous section has assumed that the sample data are accurate with no error. The uncertainty involved, therefore, comes only from the fact of finite short length of sample. In this section, the error and uncertainty in the data are particularly addressed.

The methods used to constitute the population sample on which wave statistics are established, are numerous and various. The errors made in gathering the data depends on the specific instruments and processes used to analyze the records. Specific information on each method can be found in the literature (3,4,5,7,12,15,16,19,20,21,23,24).

The primary methods which have been used include wave staff (continuous or step), pressure gage in shallow water, wave rider and accelerometer in deep water, visual observations and estimates from ships, hindcasts from weather maps, either storm by storm or systematically. Remote observations by radar from airplane or satellite have also been used recently, but the corresponding data do not provide any kind of long-term statistical information at this time.

For a given wave height the random errors corresponding to all methods are normally distributed and can be characterized by a standard deviation  $\sigma_M$ . The systematic error or bias is obtained by "calibration in comparing the results of a less accurate method with the most accurate for the same period of time. In general,  $\sigma_M$  is a function of the wave height, and increases with the wave height. As  $\sigma_s$ , a standard deviation expressed in percentages of the wave height  $H$ , is defined by

$$\sigma_M' = \frac{\sigma_M}{H - H_0} \quad (11)$$

and in general  $\sigma_M'$  can be assumed as a constant. It is not, however, for the case of wave measurements made by step wave staff where  $\sigma_M$  rather than  $\sigma_M'$  is a constant. Indeed, the error is a function of the distance between sensors on the wave staff, and for small amplitude waves, the recorded signal appears as a square function making Fourier analysis of the signal meaningless. Also in the case of wave rider, the response is influenced by the wave period and sometimes the phenomena of jerking due to poorly designed mooring attachments.

Before attempting to give an order of magnitude estimate for  $\sigma_M'$  a general remark applies: given a true signal - such as given nearly by a high quality continuous wave staff - any comparison between this signal

and the data given by the other methods in the time domain, generally exhibit very large errors. For example, comparisons of recorded time series characterized by an energy spectrum or more simply a significant wave height with hindcasted wave results, display large discrepancies corresponding to a  $\sigma_M$  near 50%, (4, 14).

If, instead of comparing the sea state in the time domain, both data are ranked statistically, the random error becomes very small by comparison and the only discrepancy left would be the sum of the systematic error or bias, and the "ranked random errors." This applies also to short-term wave analysis. For example, free surface waves determined from pressure gage differ significantly from free surface measured concurrently by a wave staff. But, when the results are ranked statistically, the two (Rayleigh) distributions are alike (Brebner & LeMehaute, 2). Much of the random errors in these comparisons must be attributed to phase shifts. Figure 1 illustrates an example of a comparison of data obtained by hindcast calculations with data obtained by measurements given by Carson and Resio (4). On the left the data is compared point by point in the time domain. On the right the data is first ranked statistically and the comparison is made by rank, leading to a much smaller deviation.

It has been mentioned that the most accurate method for acquiring wave data is a continuous wave staff. The only error is from the calibration of the wave recorder and the data analysis which translates a limited size sample, say 20 minutes, into a wave energy spectrum. For practical purposes, this method provides a negligible error and can be used to calibrate the bias in other methods of data acquisition.

Step wave staff yields too much of a large error for small wave heights as already mentioned. Buoys, wave riders and accelerometers have been used in deep water. They also give reliable data when properly calibrated as function of frequency.

The most common mode of wave measurement has been by pressure gage. The free surface is then obtained by convolution of the pressure signal based on the linear wave theory. The original method which was developed on a wave by wave basis leads to an underestimation of the surface wave height by 25 to 30% because of nonlinear convective effects and inadequate consideration to shorter waves. A more accurate procedure is to compute the spectrum of the pressure record and to compensate each frequency band of the spectrum for the effect of gage submersion as function of the relative depth (Harris, 9). With the proper method of analysis and compensation factor, the error is then very small, even in the time series presentation. For a pressure gage on the seafloor, the normalized standard deviation  $\sigma_M$  does not exceed 5% when the results are statistically ranked (see Harris (9), Homma et al (11), Grace (8)).

Statistical wave summaries from ship observations have often been the only source of long-term wave data. For this, they have been the most widely used. Unfortunately they are the most inaccurate, particularly for large amplitude wave which ships tend to avoid. However, when the results are ranked statistically, the discrepancies between measured

R in years	1	10	100
$\gamma = 1.0$	13.7	10.4	8.4
$\gamma = 1.2$	11.5	8.6	7.0
$\gamma = 1.4$	8.1	7.4	6.0

TABLE 1

 (assume  $\Delta t = 6$  hr)

Fig. 1. Case example of a comparison of the calculated (hindcast) data vs. measured data. On the top the comparison is made point by point in the time domain, on the bottom the data is initially ranked statistically.

and observed data appear much smaller (Hogden and Lumb (12), Bell (1)).

Many comparisons between ship observations and measurements are reported in the literature and a number of quite different formulae have been proposed to "calibrate" ship observations. The problem is not settled. Harris (10) has presented an analysis on the reasons for these discrepancies, which include, singularities of the codes, ship operational procedures, etc.

The uncertainty in statistical information from wave hindcasting is of a different nature. Here again, an abundance of literature can be found offering comparisons between hindcast data and measurements. Errors in wave hindcasting result from: 1) the state of the art in relating wind and sea state, and 2) inaccuracy of weather maps, and the interpretation of weather maps.

The most recent assessment of the state of the art formulation can be found in a report on the SWAMP (Sea Wave Modeling Project) experiment (22). In this report, a comparison of 10 different mathematical models of wave generation was done based on seven hypothetical test wind fields. The wide spread between the results of these models gives an indication of the uncertainties which remain, even though all these models are initially based on specific experimental data.

Many differences found in the model wave growth are attributed to the uncertainties as to whether the friction velocity  $u$  or the wind velocity  $U_{10}$  control the growth rate of waves. Also, uncertainty is due to the lack of accurate information on the value of the drag coefficient as well as on the relationship between  $u_*$  and  $U_{10}$ .

Furthermore, since the comparison of the model is based on hypothetical, simple wind field, results corresponding to real situations may be expected to exhibit more divergence than for the cases studied by SWAMP. Uncertainties due to the lack of accuracy of weather maps and their interpretation are also a significant cause of error. In theory, more than 50 years of weather maps have been archived and can be used for wave hindcasting. But in reality, only the last 30 years are considered reliable. The lack of enough pressure measurements in the southern hemisphere still hindered wave hindcast. In general, the accuracy is better for a small body of water where the fetch is limited, such as the Great Lakes. It is also better for the Atlantic Ocean than it is for the Pacific because of the interference of swell on local sea states. The worst hindcasting uncertainty is for the case of hurricanes and tropical storms.

Still when the results are ranked statistically the large discrepancy due to random error disappears, and wave hindcasting methods appear in a more favorable shape. One of the latest comparisons between hindcast vs measurements, excluding hurricanes, is due to Carson and Resio (4). It indicates that a 20% deviation is still possible.

As a conclusion of this broad and rapid survey, one will retain for the sake of simplicity, the following normalized standard deviations applicable when the sample populations are ranked statistically:

Direct wave measurement	$\sigma_M' = 0.05$	bias	0.00
Ship observations	$\sigma_M' = 0.20$	bias	0.05
Wave hindcast	$\sigma_M' = 0.15$	bias	0.05

COMBINED ERRORS DUE TO SHORT SAMPLE AND INACCURATE DATA

It has been assumed that the errors due to small sample size and the random errors from measurements were normally distributed and characterized by the normalized standard deviation  $\sigma_s'$  and  $\sigma_M'$ , respectively. Because of their independence and the convolution of the Gaussian functions, the total errors are also normally distributed and the total variance is given by:

$$\sigma'^2 = \sigma_M'^2 + \sigma_s'^2 \tag{12}$$

In the case of a Weibull distribution,  $\sigma_s'$  is given by Eq. (8), or approximately by Eq. (10).

If one retains this last formulation, it is found that the number of years Y required for predicting an event of return period R with a maximum uncertainty not greater than  $\epsilon$  (in terms of standard deviation) is given by

$$Y > \frac{R}{[\gamma \text{Ln}(Rv)]^2} \frac{1}{\epsilon^2 - \sigma_M'^2} \tag{13}$$

It is seen that there is a lower limit to the level of uncertainty,  $\epsilon = \sigma_M'$ , for which the required number of years Y approaches infinity. This indicates beyond a certain number of years Y, the error introduced by small sample size becomes less important than the accuracy limited by the error of the data. This is further evidenced if one writes:

$$\sigma' = \left[ \sigma_M'^2 + \frac{1}{[\gamma \text{Ln}(Rv)]^2} \left( \frac{R}{Y} \right)^{1/2} \right]^{1/2} \tag{14}$$

which allows us to determine the normalized total standard deviation  $\sigma'$  for various return interval R as a function of the number of years of observation Y for various values of the data errors  $\sigma_M'$ . The corresponding results calculated for  $\Delta t = 6$  hours,  $\gamma = 1, 1.4$ ,  $R = 20, 50, 100$  years, and various values of  $\sigma_M'$  are shown in Figs. 2, 3 and 4. These results compared well with the results of Earl and Baer (6) obtained by a Monte Carlo simulation. (The case  $\sigma_M' = 0$  yields the same results as the one presented in (25) except for the multiplier of 1.28 for insuring a confidence level of 90%). From these results the asymptotic value of  $\sigma'$  at  $\sigma' = \sigma_M'$  clearly appears.

The derivative  $\partial\sigma'/\partial Y$  yields the fact that as Y increases the gain in accuracy decreases much less rapidly when  $\sigma_M'$  is large than when,  $\sigma_M'$  is small. This reveals that long-term accurate measurements ( $\sigma_M' = 0.05$ ) corresponding to, for example,  $Y/R \approx 0.4$  (40 years for the 100-

Fig. 2

Fig. 3

Fig. 4

Fig. 2 Normalized standard deviation as function of the number of years of observations and relative measurement error  $\sigma_M$ .

year wave) seems to be a worthwhile investment since the normalized standard deviation decreases to 16%. It decreases rather slowly for longer periods of measurements.

On the other hand, for data with  $\alpha_M = 0.2$ , such as given by wave hindcasts or ship observations, processing more data than given by  $Y/R = 0.15$  (15 years for the 100 year wave) gains little accuracy. This result of course contradicts what is done in practice where there is a tendency to carry out small-term wave measurements and long-term hindcast. Therefore, it would appear that long-term hindcast (or ship observations) should only be considered as a temporary measure, not a substitute for long-term wave measurements. The measurement accuracy characterized by  $\alpha_M = 0.05$  is adequate since with this accuracy the error due to sample size is more significant. Figures 2, 3 and 4 also yield directly the number of years which give the same level of accuracy by the various methods. For example, it is seen from Fig. 3 ( $R = 100$  y,  $\gamma = 1$ ) that 40 years of hindcast ( $\alpha_M = 0.15$ ) is equivalent to 18 years of accurate measurements ( $\alpha_M = 0.05$ ) since both yield a value of  $\sigma$  of 0.20.

As a part of the presumption of this paper, it has been implicitly assumed that all the cases had the same underlying distribution of Weibull type in the above discussion. This assumption is justified because of the lesser significance of the exact distribution than the causes of small sample size and relatively larger errors from measurements. It must be noted, however, that in most cases extreme wave heights are determined from a multiplicity of information which may include both short-term measurement and long-term hindcast or ship observations, and the probability functions fitted by different methods are not necessarily the same even though they correspond to the same time period because of the inherent errors of the methods. If part of the hindcast period overlaps the measurement period, the measurements may certainly be used to "calibrate" the hindcast results. The correction factor, which is valid for the lower level of probability, may then correct, in part, the systematic error of the hindcast and modify the underlying distribution. This kind of calibration is particularly useful in shallow water where the wave climatology is site-specific and directional.

For the convenience of discussion without jeopardizing the accuracy of the outcome, we shall continue to assume a single underlying distribution applying to all methods of data acquisition. In particular, we consider a Weibull distribution with  $\gamma = 1$ , and the distribution of a combined error (in terms of standard deviation) due to joint causes of limited observation ( $Y$ ) and measurement inaccuracy ( $\alpha_M$ ) are presented in Fig. 5. This figure reveals the trade-off between the data accuracy and the record length. Specifically, it shows that a 5-year accurate record ( $\alpha_M = 0$ ) is equivalent to 20 years less accurate hindcasts ( $\alpha_M = 0.10$ ) for prediction of 5.7-year return waves. Particularly of interest is that, in long return period predictions, the long record of less accurate data is far more superior than short, accurate data. This result shows the extreme importance of record length on the extrapolation of long-term wave statistics. On the other hand, in Fig. 6, one may find that good measurements ( $\alpha_M = 0.05$ ) of 5 years are just

Fig. 5 Comparison of confidence bands about probability of exceedance curve based on 20 years of observations and measurement error  $\alpha_M = 0.10$ ; and 5 years of observations and measurement error  $\alpha_M = 0$ .

Fig. 6 Comparison of confidence bands about probability of exceedance curve. Corresponding to number of years of observations Y and relative measurement error  $\alpha_M$ :

$\alpha_M = 0.05$	Y = 5 years
$\alpha_M = 0.05$	Y = 10 years
$\alpha_M = 0.20$	Y = 40 years

as good as 40 years of ship observations ( $\sigma_M^2 = 0.2$ ) for 23-year return waves and good measurements of 10 years would predict 68-year return waves as the 40 years less accurate observations. In general, a high frequency event, say the 5-year or 10-year wave should be determined from 5 years of good measurements rather than 20 years of questionable hindcast. This figure, therefore, specifically emphasizes the importance of the measurement accuracy. It also indicates, however, that in order to improve the long-term predictions, long-term commitment of accurate measurements is imperative. At the present time, a deeper insight into extreme events can be provided only by lengthy hindcast, say 30 or 40 years, because of the nonexistence of long-term accurate measurements.

#### CLIMATOLOGICAL VARIATIONS

The foregoing discussion reveals indubitably two important errors which may be involved in long-term wave statistics, the error of extrapolation from short-term data and the error due to the inaccuracy in the data themselves. Consequently, it is not difficult to conclude that a long-term investment on the acquisition of accurate data is necessary, especially when there are only 5-7 years of good measurements available today. The improvement in the measurement accuracy always benefits wave analysis. The combination of error due to measurements and small sample size demonstrates that large measurement errors practically limit the accuracy of the prediction of extreme wave heights regardless of the number of years of observation. On the other hand, when the record length is longer than a certain period of time, the improvement in prediction accuracy becomes negligible. As shown in the foregoing analysis, a period of 30-40 years of good measurements appear to be sufficient for establishing 100-year wave statistics.

Statistical estimates can be improved by reducing the source of uncertainties. For the present problem, the reduction is limited by the facts of the data accuracy and sample extrapolation. The former is governed by the state of the art in wave measurements and data analysis; the latter is governed by the law of statistics. Still, there is an additional source of uncertainty attributed to the nature, the natural variations of the wave climate.

Now, assuming the natural climatology is ergodic and stationary and indeed governed by the statistical law of Weibull distribution, the result derived in Eq. (10) can also be used to determine the periodical climatological variations. Setting  $Y = R$  in Eq. (10), one obtains:

$$\sigma^*(R) = \frac{1}{\gamma \ln(Rv)} \quad (15)$$

This parameter, in theory, characterizes the climatological variation of  $R$  years for the Weibull nature. In particular, when  $R = 1$ , one obtains the annual climatological variation

$$\sigma^*(1) = \frac{1}{\gamma \text{Ln}(v)} \quad (16)$$

This parameter represents the characteristics of the nature indicating the spread of yearly climatological variations at a particular location. This parameter is unique under the assumption of Weibull distribution and the definition of  $\Delta t$ . The values of this parameter are tabulated in Table 1 for three values of  $R$  with  $\Delta t = 6$  hr. From this table, it is seen that  $\sigma^*(1)$  is on the order of 11%, for  $\gamma = 1.0 - 1.4$ . The result indicates that there is a variation of about 11% (in term of standard deviation) from year to year in the Weibull nature. This value reduces to about 9% for 10 years and 7% for 100 years. Indeed, when making an estimate on 100-year events in a Weibull world, there is always a 7% standard deviation from the expectation attributed to the climatological variations of the nature, regardless of the data quality or the sample length used for extrapolation. In other words, the average prediction accuracy is limited by the climatological variations of the nature. It becomes more evident to relate this parameter with the risk of exceedance. It is well known that the risk for a  $R$  year-wave to be exceeded in  $R$  years is

$$R_e = 1 - \left(1 - \frac{1}{R}\right)^R \quad (17)$$

which tends toward 0.63 or 63% when  $R$  is large. Knowing the climatological variation in  $R$  years makes it further possible to determine the standard deviations of the risk from expectations.

#### CONCLUSION

Large errors in the prediction of sea state, such as given by wave hindcast, limit the accuracy of the prediction of extreme event, and improvement in prediction accuracy with the number of years of observation becomes rapidly negligible. Long term measurements are only worthwhile if they are accurate. For an accurate prediction of extreme events, a long term program of accurate measurements is necessary, as it reduces both the error  $\sigma_s$  due to short sampling and  $\sigma_M$  due to measurement or hindcasting calculation.

The errors due to natural climatological variations are predictable, assuming a stochastic and Gaussian world. This error is of the order of 11% for the yearly wave and 7% for the hundred year wave. In a non-ergodic and unstationary nature, it could be larger. This parameter directly relates with the risk of exceedance and should be carefully taken into account in the design of offshore structures.

The uncertainty of prediction as well as the errors involved in short sampling and data accuracy is characterized in terms of standard deviation. Confidence bands of uncertainties for various levels of probability can be derived from the standard deviation under the law of normal distribution (25).

## Appendix

PROBABILITY OF EXCEEDENCE CURVE INCLUDING UNCERTAINTIES.

Both  $h$  and  $\sigma'_s$  can be expressed in term of  $Q$ . Indeed referring to equation (1).

$$h = [-\text{Ln } Q]^{1/\delta}$$

Also, referring to equation (8)

$$\sigma'_s = \frac{1}{\gamma \text{Ln } Q (\sqrt{Y})^{1/2}} \left( \frac{1-Q}{Q} \right)^{1/2}$$

Therefore, the total error  $\sigma'^2 = \sigma_M'^2 + \sigma'_s'^2$  can entirely be defined in terms of  $Q$ . Furthermore, multiplying  $\sigma'$  by a coefficient  $\alpha$  allows to calculate the uncertainty spread corresponding to various confidence levels. For example,  $\alpha = 0.84, 1.28, 1.65, 2.32$  corresponds to confidence level  $C_1 = 80, 90, 95, \text{ or } 99\%$  that the spread will not be exceeded. By adding  $\alpha\sigma'h$  to  $h$  gives the upper bound corresponding to these confidence levels. (By subtracting  $\alpha\sigma'h$ , the lower bound is obtained.) Accordingly, the upper bound characterizes a new probability of exceedence curve which is now defined by the function

$$h_E = h(1+\alpha\sigma) = [-\text{Ln}Q]^{1/2} \left\{ 1 + \alpha \left[ \sigma_M'^2 + \frac{1}{\gamma^2(\text{Ln}Q)^2 \sqrt{Y}} \left( \frac{1-Q}{Q} \right)^{1/2} \right] \right\}$$

It is an inverse Weibull distribution defining the upper bound due to statistical uncertainties. The inclusion of the correction due to these uncertainties establishes the basis for the determination of the safety coefficients for various confidence level  $C_1(\alpha)$ . As a result it appears that tradeoff or risk analysis for the design of offshore structures should rather be based on  $h_E(Q)$  instead of  $h(Q)$ . The importance of each cause of error, and the need for long term accurate measurements then become apparent.

## ACKNOWLEDGEMENTS

This study was sponsored by the National Science Foundation as part of a study under Grant No. CEE-7911930 and by the NOAA under contract No. NA83AA-D-00041. The authors acknowledge Dr. L. Baer for his encouragements and challenging discussions. M. Soldate reviewed the manuscript critically and is acknowledged for his pertinent remarks. Dr. Max Sheppard of Mobil Research and Development Corp., is also acknowledged for fruitful discussions during the course of this investigation.

## CHAPTER TWENTY FIVE

### On A Design Wave Spectrum\*

Paul C. Liu<sup>†</sup>, M. ASCE

We propose the use of a generalized representation for acquiring a design wave spectrum. The generalized form, free from any predetermined coefficients and exponents, requires only significant wave height and average wave period as input for practical applications. The usefulness of this representation has been demonstrated with over 2000 measured deep-water wave spectra recorded from NOMAD buoys in the Great Lakes during 1981.

#### Introduction

Since Neumann (1953) first introduced his representation for wind-wave spectra to facilitate wave prediction, coastal engineers have endeavored for over three decades to develop a realistic representation of wave spectra. The two-parameter spectrum of Bretschneider (1959), the fully developed spectrum of Pierson and Moskowitz (1964), and the fetch-limited spectrum of JONSWAP (Hasselmann et al., 1973) are notable examples. Among these, the JONSWAP spectrum is perhaps the one most widely used in wave modeling and engineering designs during the last decade.

All of these proposed spectral forms consist of a number of empirical coefficients and exponents that differ among various authors, while the overall forms are basically similar. The applicability and universality of these coefficients and exponents has frequently been the subject of question or dispute. For instance, the rear face of the spectrum in the high frequency range was first intuitively set by Neumann to be proportional to the -6th power of frequency. Later Phillips (1958) deduced from dimensional considerations that the exponent should be -5. The -5th power dependence on the high frequency side of the spectrum seems to have been substantiated by many laboratory and field measurements. Most of the spectral forms use the -5 formulation. More recently, however, Kitaigorodskii (1983) found theoretical as well as experimental evidence that the exponent should be -4 instead. The situation remains unsettled. Moreover, the widely used average JONSWAP spectrum consists of four numerical parameters, three of which are averaged from largely scattered empirical data points. When applying the formula with these empirical numbers in

---

\*GLERL Contribution No. 435.

<sup>†</sup>Oceanographer, NOAA/Great Lakes Environmental Research Laboratory, 2300 Washtenaw Avenue, Ann Arbor, MI 48104.

practice, it is seldom certain how close the representation is as compared to the actual modeling or design conditions.

In this paper, we propose an alternative approach by using a generalized form (Liu, 1983) that avoids predetermining any coefficient and exponents in the spectrum representation. They can all be obtained from known spectral parameters. Hence, if design wave conditions are given, relevant spectral parameters can be estimated and a design wave spectrum can be readily determined.

### The Spectral Form

The generalized spectral form given by Liu (1983) in representing a one-dimensional, single peak frequency wave spectrum is

$$S(f) = C_1(E/f_m)(f/f_m)^{-C_2}\exp[-C_3(f/f_m)^{-C_2/C_3}] \quad (1)$$

where  $E = \int S(f)df$  is the variance of the surface displacement,  $f_m$  is the frequency of the spectral peak, and  $C_i$ 's are dimensionless coefficients and exponents that can be determined from given spectral parameters.

To show how the  $C_i$ 's are determined, we note first in eq. (1) that for  $f = f_m$

$$C_1 = \exp(C_3)S(f_m)f_m/E \quad (2)$$

Furthermore from the definition of  $E$  and using the gamma function  $\Gamma$  with eqs. (1) and (2), we find

$$E/(S(f_m)f_m) = \exp[C_3 + (1 - C_3 + C_3/C_2)\ln C_3]\Gamma(C_3 - C_3/C_2)/C_2 \quad (3)$$

which is an equation for  $C_2$  and  $C_3$ . Now if we use the average frequency  $f_a$  defined by Rice (1944)

$$f_a^2 = [\int f^2 S(f)df]/[\int S(f)df] \quad (4)$$

and substituting  $S(f)$  from eq.(1) and using the gamma function again, we have another equation for  $C_2$  and  $C_3$

$$(f_a/f_m)^2 = \exp(2C_3)\ln C_3/C_2\Gamma(C_3 - 3C_3/C_2)/\Gamma(C_3 - C_3/C_2) \quad (5)$$

Thus we have two equations [(3) and (5)] that can be solved for  $C_2$  and  $C_3$  if the parameters  $E$ ,  $f_a$ ,  $f_m$ , and  $S(f_m)$  are given. Then  $C_1$  can be found from eq. (2) and the spectrum is fully determined.

The representation eq. (1) has been applied to over 2000 sets of deep-water wave spectra measured from NOMAD buoys moored in the Great Lakes with water depth ranging from 15 m to 250 m. Sample comparisons are presented in Liu (1983). It was found that the spectral form fits the measured spectra very well under a variety of wave conditions. The close fit was especially evident for large storm waves. Perhaps the spectra that eq. (1) does not fit well were those multimodal ones that occur mainly during the early stage of wave growth.

The process for solving eqs. (3) and (5) can best be achieved iteratively. Liu (1983) presented a workable empirical trial and error procedure. A more effective approach is to apply the iteration procedure using the Newton method to solve eq. (3) (Liu, 1984a; Fullerton, 1984) for  $C_3$  with an initial  $C_2$ . These values are then substituted into the right-hand side of the following equation obtained from eqs. (3) and (5)

$$C_2 = \exp[C_3 + (1 - C_3 + 3C_3/C_2)\ln C_3]\Gamma(C_3 - 3C_3/C_2)/D \quad (6)$$

where  $D = (f_a/f_m)^2 E / (S(f_m)f_m)$ . If the  $C_2$  calculated from eq. (6) is not nearly equal to the previous one, then the new  $C_2$  will be used for input and the procedure is repeated again until  $C_2$  converges.

### The Applications

The practical applications of the generalized spectrum form eq. (1) require the parameters  $E$ ,  $f_a$ ,  $f_m$ , and  $S(f_m)$  to be known. With these four parameters, all the useful spectral properties can be readily deduced. For example, the  $n$ th moment of the wave spectrum is given by

$$\begin{aligned} M_n &= (2\pi) \int f^n S(f) df \\ &= E(2\pi f_m)^n (C_1/C_2)^n \exp[(1-n)\ln C_3] \Gamma(Z) \end{aligned} \quad (7)$$

where  $Z = C_3 - (n+1)C_3/C_2$ . From eq. (7), the spectrum-width parameter is then

$$\begin{aligned} \epsilon^2 &= 1 - M_2^2 / (M_0 M_4) \\ &= 1 - \Gamma^2(C_3 - 3C_3/C_2) / [\Gamma(C_3 - C_3/C_2)\Gamma(C_3 - 5C_3/C_2)] \end{aligned} \quad (8)$$

Therefore, relevant spectral characteristics can generally be estimated if we know the four essential parameters.

Among the four parameters,  $E$  and  $f_a$  are obtainable from design wave information (e.g.,  $E = (H_{1/3}/4)$ , where  $H_{1/3}$  is the significant wave height). The parameters  $S(f_m)$  and  $f_m$  are in general, however, not readily obtainable without actual measurements. For practical applications, Liu (1983) found that for  $f_a$  and  $f_m$  in Hz,  $S(f_m)$  in  $m^2/Hz$ , and  $E$  in  $m^2$  the following empirical correlations exist for deep-water wave spectra

$$f_a = 0.82(f_m)^{0.74} \quad (9)$$

and

$$S(f_m) = 17.0(E)^{1.13} \quad (10)$$

which effectively reduced the necessary parameters to only two. Applying eqs. (9) and (10) in practice, we can always acquire a reasonably accurate deep-water design wave spectrum with only customarily available design wave conditions, e.g., a significant wave height and an average wave period. The applicability of eqs. (9) and (10) has been further corroborated with over 2000 measured wave spectra as shown in Fig. 1. These measured data, recorded from the eastern Lake

Figure 1. The correlations between  $f_a$  and  $f_m$  and between  $S(f_m)$  and  $E$ . The straight lines correspond to eqs. (9) and (10), respectively.

Superior buoy during 1981, consist of waves ranging from 0.2 to over 8 m in significant wave height. Although dimensionally inhomogeneous, the obvious existence of the empirical correlations eqs. (9) and (10) has provided a useful modification that simplifies and enhances the applicability of the generalized wave spectrum representation eq. (1).

#### Assessment of the Representations

To demonstrate the actual applicability of the generalized spectrum form, we use the following deviation index, D.I., defined in Liu (1983) as a measure of the accuracy of the representations:

$$D.I. = \sum_i \left[ \frac{S(f_i) - S_R(f_i)}{S(f_i)} \times 100 \right] \left[ \frac{S(f_i)\Delta f}{E} \right] \quad (11)$$

where  $S(f_i)$  and  $S_R(f_i)$  are, respectively, measured spectral density at frequency  $f_i$  and that calculated from eq. (1);  $\Delta f$  is the frequency interval used in calculating the spectrum. Simply stated, this deviation index is the sum of percentage deviations of calculated from measured and weighted by the relative magnitude of the measured spectral density. A perfect representation will yield a zero D.I. Hence, a smaller D.I. implies a better fit.

Based on over 2000 measured wave spectra recorded from the eastern Lake Superior NOMAD buoy during 1981, our representation with all four required parameters had an average D.I. of  $30.875 \pm 8.756$ . The modified application with only two parameters leads to an average D.I. of  $41.896 \pm 13.425$ .

For comparison, we also applied the JONSWAP representation to the same data set with the coefficients determined through fitting the measured spectrum. The resulted average D.I. is  $44.056 \pm 27.203$ . Furthermore, when the average JONSWAP representation with predetermined parameters is used, the average D.I. becomes  $101.31 \pm 82.022$ .

Since the data used in the analysis are from both large and small waves, it is of interest to eliminate the smaller waves for design purposes. For over 900 spectra with significant wave heights greater than 1 m, the average D.I.'s are  $28.510 \pm 6.720$  and  $38.136 \pm 11.011$ , respectively, for the original and modified applications of representation (1). Similarly, average D.I.'s of  $27.802 \pm 8.428$  and  $52.549 \pm 23.032$  are found for the JONSWAP and average JONSWAP representations, respectively.

From the above discussion, it appears that the JONSWAP representation gives a better fit for waves having a significant wave height greater than 1 m. However, JONSWAP only has the advantage when the spectra are given and the parameters can be obtained through fitting the known spectrum. For practical applications where a wave spectrum is not expected to be available, the proper JONSWAP parameters cannot be readily obtained; then the generalized representation is certainly

more advantageous. A comparison of the various average D.I.'s we have calculated makes it evident that the modified approach of eq. (1), which renders a reasonably accurate representation with only  $H_{1/3}$  and  $f_a$  as required inputs, is the most useful and feasible approach for acquiring a deep-water design wave spectrum.

#### The Equilibrium Range Exponent

The generalized wave spectrum representation eq. (1) is characterized by the nonpredetermined coefficients and exponents  $C_i$ 's. What is the significance of these  $C_i$ 's? Basically, they are simply scale factors for the spectrum. Liu (1983) found evidence that the  $C_i$ 's are correlated with the wave growth process; i.e., the  $C_i$ 's are large during early growth and approach some asymptotic value as waves become well developed. This is generally the case. We are particularly interested in  $C_2$ , which is the equilibrium range exponent corresponding to the high frequency side of the spectrum. Its exact value has been the subject of some controversy.

Fig. 2 presents a correlation between  $C_2$  and the significant wave height  $H_{1/3}$  based on the 2000 and more data sets used in this study. For smaller wave heights,  $C_2$  is generally larger and quite scattered. For larger wave heights, the scatter reduces significantly and  $C_2$  appears to cluster around the value 5, which is consistent with many of the previous studies. There is no indication, however, that the exponent  $C_2$  should approach a value of 4.

Figure 2. The correlation between  $C_2$  and  $H_{1/3}$ .  
The straight line represents  $C_2 = 5$ .

It should be noted that in most of the previous studies the equilibrium range exponent was generally obtained by fitting only the high frequency side of the spectrum, which basically ignores the total spectrum. The  $C_2$ 's deduced in this study relate to the entire spectrum and are therefore more representative of the true equilibrium range exponent.

#### Concluding Remarks

We have shown that the generalized form eq. (1) provides a reasonably accurate representation for the deep-water wave spectrum. The spectrum is fully determined from four internal parameters: the variance of the surface displacement  $E$ , the average frequency  $f_a$ , the frequency of the spectral peak  $f_m$ , and the energy density at the spectral peak  $S(f_m)$ . Because some of these parameters are not readily accessible, we have also found empirical correlations between  $S(f_m)$  and  $E$  and between  $f_a$  and  $f_m$  that can be used to reduce the essential parameters to two. This is useful in many coastal and oceanic engineering applications when spectral properties are needed and only design wave height and wave period are available.

The analysis presented here has concentrated on deep-water waves. One of the immediate interests related to coastal engineering problems is the finite depth effect. We have found from a separate analysis (Liu, 1984b) that, with four parameters given, the representation also applies satisfactorily to shallow-water waves. The depth clearly affects the spectral parameters but not the generalized form of representation. There is at present not enough shallow-water wave measurements to allow a more detailed analysis.

The contention that spectral characteristics can be obtained from given wave height and wave period can also lead to a simplified wave prediction process. That is, instead of using complicated spectral model predictions, a simpler model can be developed to predict wave height and wave period only. One such model has been developed for the Great Lakes (Liu et al., 1984; Schwab et al., 1984) with satisfactory results. Thus, by combining the output from this model with the generalized spectrum representation, we can obtain results similar to those produced from a general spectral model, but using a simpler approach and with greater computational economy.

## CHAPTER TWENTY SIX

### Shallow Water Waves: A Spectral Approach

Charles L. Vincent,\* M. ASCE

#### Introduction

Bouws et al. (1983, 1984) have shown that wind sea spectra in finite depth water can be described by a self-similar spectral equation that in the deep water limit is the JONSWAP spectrum (Hasselmann et al. 1973). This paper shows that the spectral parameter  $\alpha$  is linked to wave steepness, for wind sea and swell; presents a simple model for wave transformation across the surf zone; and shows that the spectral theory provides data similar to the results of Bretschneider (1958) for shallow water wave growth.

#### TMA Spectral Spectrum

Examination of the free wave spectrum of wind generated gravity waves in water of finite depth indicates that the shape of the spectrum may be specified by an equation (Bouws et al., 1983) which Bouws et al. termed the TMA-spectrum

$$S(\omega, H) = \alpha g^2 \omega^{-5} \exp[-5/4(\omega/\omega_m)^{-4}] \times \exp[-(\omega - \omega_m)^2 / 2\omega_m^2 \sigma^2] \times \phi(\omega_H) \quad 1$$

with

$$\phi(\omega_H) = \frac{(k^{-3}(\omega, H) \partial k(\omega, H) / \partial \omega)}{(k^{-3}(\omega, \infty) \partial k(\omega, \infty) / \partial \omega)} \quad 2$$

$$\omega_h = 2\pi f(H/g)^{1/2}$$

where the parameters  $\alpha, \gamma$  and  $\sigma$  can be derived by curve fit analysis to a particular spectrum or estimated by prognostic equations. Although the most useful form of the equation is in frequency space, Bouws et al. (1983, 1984) indicate that the spectrum is better expressed in wave number space because depth is included explicitly through wave number. The resulting equation has a simple form in which the spectral density is related to a constant power of wave number, i.e.

$$F(k) = \frac{\alpha}{2} k^{-3} \Psi(\gamma, \omega_m, \omega, \sigma) \quad 3$$

\*Chief Scientist, Offshore & Coastal Technologies, Inc., 10378 Democracy Lane, Fairfax, VA 22030

where  $\Psi$  is dimensionless. Equation 1 goes to the JONSWAP equation in deep water.

The prognostic equations for  $\alpha$  and  $\gamma$  are derived in terms of the wave number for the peak frequency of the spectrum, gravitational acceleration and wind speed (Table 1). The spectral equation was derived as an extension of the deep water similarity principles used to develop the JONSWAP equation to shallow water using the results of Kitaigorodskii et al. (1975). The results were checked against nearly 3000 wind sea spectra observed off the North Carolina coast and in the North Sea. The bottom slopes ranged from nearly flat to about 1:100, bottom materials ranged from fine to coarse sands, and wind speeds ranged up to 30 meters per second.

TABLE 1

## TMA PARAMETRIC RELATIONS

$$\alpha = 0.0078 \kappa^{0.49}$$

$$\gamma = 2.47 \kappa^{0.39}$$

$$\sigma = 0.7 \quad f \leq f_m; \quad \sigma = 0.9 \quad f > f_m$$

where

$$\kappa = \frac{U^2 k_m}{g}$$

U wind speed at 10m elevation, g gravitational acceleration  
wave number corresponding to peak frequency

## Steepness and Alpha

The general fit of the TMA spectrum to data implies that the Kitaigorodskii et al. (1975) wave number expression

$$F(k) = \alpha k^{-3/2} \quad 4$$

is a reasonable scaling of the spectrum up to the peak wave number (recognizing some modification due to the shape factors near the peak) if  $\alpha$  is allowed to vary. An approximation of the total energy in the spectrum may be obtained by integrating equation 4 from  $k_m$  to

$$E_t = \int_{k_m}^{\infty} F(k) = 1/4 \alpha k_m^{-2} \quad 5$$

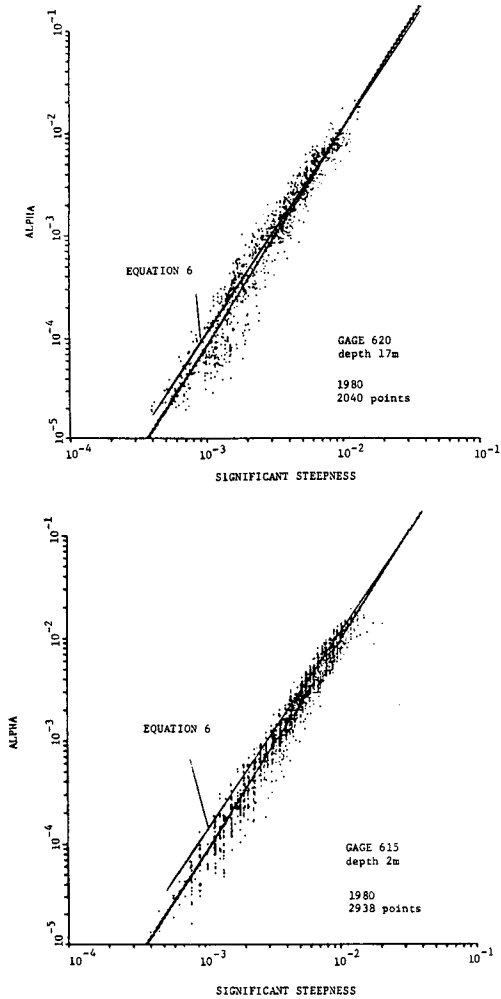

Figure 1. Alpha versus Significant Steepness. Theoretical equation (6) is compared to data taken at two average depths. Unlabelled line is the regression line for the data in each graph.

Figure 2. Depth Variation of Zero Moment Wave Height. The zero moment estimate of significant wave height  $H_{mo}$  is normalized by the offshore value (ratio denoted as  $H/H_0$ ) and plotted as a function of depth normalized by the offshore wave height (denoted as  $h/H_0$ ). Two field data sets and one laboratory data set are plotted. The equivalent variables are plotted for a monochromatic wave from laboratory tests with similar initial steepness.

By inverting equation 5 a relationship between  $\alpha$  and a steepness parameter  $\epsilon$  may be obtained

$$\alpha = 4E_t k_m^2 = 16\pi^2 \epsilon^2 \quad 6$$

where

$$\epsilon = E_t^{1/2} / L_m \quad 7$$

with

$$L_m = 2\pi / k_m \quad 8$$

Huang et al. (1980) had arrived at the same relationship for deep water. Equation 6 is valid for any depth where equation 4 holds. Figure 1 shows a plot of  $\alpha$  versus  $\epsilon$  from field data taken at the Coastal Engineering Research Center's Field Research Facility at Duck, North Carolina, for two average depths: 17m and 2m. Alpha was estimated by fitting equation 6 to both sea and swell spectra. The results indicate an excellent fit at high steepnesses. For low steepnesses there is some divergence. This results from a poor knowledge of depth over time in the surf zone and the irregularity of spectral shape for very low wave height conditions.

#### Energy Levels in the Surf Zone

Equation 5 was used by Vincent (1983) to derive an upper bound on energy in the surf zone by noting that the zero movement estimate of significant wave height is given by

$$H_{m0} = 4E_t^{1/2} = 2\alpha^{1/2} k_m^{-1} \quad 9$$

For depth limited conditions it is assumed that a linear shallow water dispersion relation

$$k_m = \omega_m (gh)^{-1/2} \quad 10$$

held and equation 9 becomes

$$H_{m0} = \frac{1}{\pi} (\alpha gh)^{1/2} f_m^{-1} \quad 11$$

If  $\alpha$  and  $f_m$  were constant across the surf zone (which is not generally the case) equation 11 would imply a square root of depth dependence for  $H_{m0}$ . Because of some variation of  $\alpha$  and  $f_m$ , some difference from square root dependence occurs. Figure 2 provides a comparison of field and laboratory data for high energy conditions compared to a monochromatic wave. The

SURF ZONE ALPHA

$$\alpha = 3.55 h / gT_m^2$$

Figure 3. Surf Zone Alpha. Alpha was calculated from a curve fit to the spectra of waves measured in the surf zone in the field and the laboratory and compared to the maximum value of alpha expected from theory.

results show that  $H_{mo}$  has a curvilinear form similar to the square root of depth and that its variation with depth is distinctly different than the monochromatic case. In the shallowest water the dependence is not much different from the monochromatic case. Since equation 9 is directly related to equation 6, the data in Figure 1 suggest that the upper bound derived is a good approximation.

#### Surf Zone ALPHA

The relationship between  $\alpha$  and  $\kappa$  given in Table 1 is valid where there is a relative balance between energy gain and loss in the spectrum during wave growth. As the wave field propagates into the surf zone, breaking dominates and the  $\alpha, \kappa$  relation is no longer valid. Mathematically for fixed  $f_m$  as  $H \rightarrow 0$   $\kappa$  becomes infinite as does  $\alpha$ . Equation 6 provides a link between spectral shape and steepness. In the surf zone, the wave train is largely nondispersive and the largest waves are limited by depth, so it is possible to estimate  $\alpha$  by relating the variance in the wave relative to its height and obtain a rough estimate on the maximum alpha for a given depth and peak frequency:

$$\alpha_{max} = 3.55hf_m^2/g \quad 12$$

Figure 3 provides a comparison of measured and estimated  $\alpha_{max}$  from field and laboratory data.

#### Simple Model for Surf Zone Wave Heights

Equation 11 provides an estimate for the upper bound for a wind sea. In order to model the spectrum across a shoaling and breaking region for an arbitrary wind and depth field requires a complex numerical model. For many purposes an assumption of a uniformly varying slope in the along shore direction is not an unreasonable first approximation. A simple one-dimensional numerical code embodying the TMA relationship and extension has been developed to provide an intermediate step between the simplest equation and a full scale model.

The following are the elements of the model:

- (1) Refraction and shoaling is given by the method of Longuet-Higgins (1957).
- (2) The spectrum at any depth is given by equation 1.
- (3) For wind seas  $\alpha, \gamma, \sigma$  are given in Table 1.

Figure 4. Comparison of Model Predictions to Field Data.

Figure 5. Comparison of Model Predictions to Laboratory Data.

- (4) For swell  $\alpha$  is provided by equation 6, with the wave steepness at a new computation estimated by projection of the next upstream wave steepness.
- (5) The maximum value of  $\alpha$  in the surf zone is given by equation 12.
- (6) If waves pass over a bar, and the depth then increases  $\alpha$  and  $\gamma$  remain fixed at the equilibrium values of the previous shallowest depth until a shallower depth is reached.
- (7)  $f_m$  remains fixed.

This model neglects bottom friction and overly simplifies the processes occurring. Its essential assumption is that once the depth becomes a dominant influence on the waves the spectrum rapidly approaches the equilibrium form.

The model allows input of initial TMA parameters and a peak wave direction. The directional spectrum is set to  $\cos 4\theta$  spread. Variation of this input may be made by reprogramming.

The model was run for a wind sea case using data from the CERC Field Research Facility Figure 4 and laboratory data from a CERC wave tank Figure 5. In both cases the simple model provided an approximation to energy decay across the shoaling region. Similar results using different field data and a more sophisticated numerical scheme are reported by Hubertz (1984).

#### Shallow Water Wave Growth Relationships

A discussion of deep water wave growth is required before the TMA spectrum can be related to the Bretschneider wave growth curves. In deep water, wind wave growth appears to stop for wave components whose speed is faster than the wind. In the open ocean for long duration winds the spectrum appears to reach an equilibrium fully developed form (Pierson and Moskowitz, 1964) with a peak frequency  $f$  with celerity  $C$  satisfying

$$U/C_m = 0.82$$

13

The observation that the peak frequency of spectrum occurs at a slightly lower frequency than would be expected from the constraint of zero wind input for  $C(f) > U$  has been explained by the nonlinear wave-wave interactions (Masselmann et al., 1976). Although atmospheric input ceases for waves with  $U/C < 1$ , the wave interactions can still shift wave energy to lower frequencies. If for a given  $U$ ,  $f_p$  is the frequency of waves such that  $U=C$ ,

Figure 6. Depth Limited Wave Period. Bretschneider's empirical curve is labelled B; theoretical curves are given for values of A of 0.82 and .9.

Figure 7. Depth Limited Wave Height. Bretschneider's curve for a friction factor of .01 is labelled B; theoretical curves corresponding to values of a of .082 and .09 for the depth limited period are provided.

once the peak frequency of the wind sea evolves to  $f_0$ , the frequency with maximum input from the wave-wave interactions are 0.8 to 0.9  $f_p$ , or approximately the peak frequency associated with the fully developed spectrum.

In shallow water of depth  $H$  the maximum celerity of waves is approximately  $(gH)^{1/2}$ . If  $H$  is sufficiently small, almost any wind speed  $U$  will exceed  $(gH)^{1/2}$ . Hence the mechanism for producing a cut-off to wave growth in deep water does not appear workable in shallow water. Yet the data of Bretschneider (1958) clearly suggest a cut-off value for the wave period. In essence this is a depth limited wave period which would be the shallow water analogy to the fully developed spectrum's peak frequency in deep water.

In the TMA spectrum when  $\omega_H$  is less than one, the spectrum approaches the  $f^{-3}$  saturation dependence suggested by Kitaigorodskii et al. (1975). Thus, a hypothesis for a limit on the peak frequency can be suggested. Assuming a flat bottom, as waves grow and the peak frequency decreases, the waves at the spectral peak ultimately reach a value of  $\omega_H < 2$  in which depth begins to influence wave growth. With continued development to lower frequencies  $\omega_H$  approaches 1 and waves near the peak of the spectrum approach the saturation limit, i.e. cannot grow more without breaking. Thus, allowing for some influence of the wave-wave interactions, the peak frequency should not become less than

$$\omega_{H,m} = 2\pi f_m (H/g)^{1/2} = A \quad 14$$

where  $A$  lies between 0.8 and 1.0. Nondimensionalization to include wind speed and algebraic rearrangement provides an equation for a depth limited period

$$T = gT/U = 2\pi(gH/U^2)^{1/2}/A \quad 15$$

with  $A$  between 0.8 and 1.0. A plot of equation 15 versus Bretschneider's data (Figure 6) indicates reasonable agreement when the uncertainty in  $A$  and the differences in  $T_m$  and  $T_s$  are considered.

Vincent and Hughes (1985) have taken equations 11 and 15 with the  $\alpha, \kappa$  relationship and calculated an estimate of the  $H_{mo}$  for depth limited conditions assuming a shallow water dispersion relation. The results are displayed in Figure 7 for two values of  $A$  and are within the general scatter of the data. Pinpointing the correct value of  $A$  requires a yet to be performed analysis of the shallow water wave-wave interactions.

## Summary

Natural wave trains may be described in several ways: approximation as a monochromatic wave, representation by probability distributions and representation by a spectrum. The TMA spectrum and its extensions discussed here provide a unified wave theory that spans a range of conditions including deep, intermediate and shallow water through a continuous variation of the parameter  $\kappa$  for wind seas. For swell, the parameter  $\epsilon$  appears equally useful. The theory provides a description of the free wave components of the spectrum even into the surf zone and provides a prediction of energy levels of the same quality as the other methods without a requirement of a site specific dissipation mechanism tuning. Further, the theory provides an explanation of the apparent depth limited wave period which when combined with the spectral shape parameters yields a reasonable approximation to the shallow water wave growth data of Bretschneider (1958).

One useful element of the approach is its direct connection to spectral models for wave forecasts and hindcasts.

## CHAPTER TWENTY SEVEN

### WAVE COHERENCE IN COASTAL WATERS

Steven A. Hughes\* , M.ASCE

**ABSTRACT:** The spatial variability of the near-shore wave field is examined in terms of the coherence functions found between five closely spaced wave gages moored off the North Carolina coast in 17 meters depth. Coherence was found to rapidly decrease as the separation distance increased, particularly in the along-crest direction. This effect is expressed as nondimensional coherence contours which can be used to provide an estimate of the wave coherence expected between two spatial positions.

#### INTRODUCTION

The coherence function between two spatially separated time series of ocean waves measures the extent to which the waves occurring at one position can be predicted from the wave field at the other position, assuming a linear dependence exists between the wave time histories at the two locations. The coherence function rapidly decreases as the distance between the two spatial positions increases. This decrease arises because most naturally occurring waves are not long-crested and the waves change form as they propagate. Ocean waves are conveniently described in terms of energy spectra, with empirically determined parameters relating the spectra between locations. In many applications a spectral representation of the wave field is sufficient, however, there are instances when it would be useful to estimate the wave coherence function between two positions. A case in point is an investigation by the Naval Civil Engineering Laboratory (NCEL) into ship motions and mooring forces for vessels anchored in coastal waters.

A mooring forces numerical model has been developed by the NCEL which simulates ship motions and resultant mooring loads under various mooring configurations and wave conditions, but field data are needed to verify the model's accuracy and to determine its limits of applicability. In the NCEL numerical model the wave field is to be applied at the ship's center of gravity. Since waves cannot be measured at this position, it is necessary in the course of a

---

\* Hydr. Engr., Coastal Engineering Research Center, U.S. Army Engineer Waterways Experiment Station, P.O. Box 631, Vicksburg, Mississippi 39180 USA.

field experiment to collect wave data a short distance away from the ship where the waves are free of excessive ship-induced interference. These waves, which are slightly different from those waves causing the ship motion, are used to drive the numerical model, producing a time history of the mooring loads.

Evaluation of the mathematical algorithms in the model can be performed by finding the coherence function between the measured ship response and the response predicted by the model. This response coherence is composed of the coherence due to the approximations made in the mathematical algorithms and the wave coherence between the position where the waves were measured and the ship's center of gravity. Therefore, it is necessary to either: 1) estimate or directly measure wave coherence as a function of spatial separation so that it may be factored out of the response coherence, or 2) position the wave gage in a location which helps maximize the wave coherence.

It was this application that prompted the NCEL to sponsor a month-long wave coherence experiment at the Coastal Engineering Research Center's Field Research Facility at Duck, North Carolina during the Spring of 1983. The primary objective of the experiment was to collect simultaneous wave data from an array of five closely spaced wave gages for events of wind seas, swell, and multi-directional wavetrains, and to then examine the spatial variability in the wave field. This paper presents the findings of the experiment.

#### DATA COLLECTION

Between April 23 and June 10, 1983, wave data were collected from an array of 5 Datawell Waverider wave gages moored in a depth of 17 meters. The array was positioned about 2 kilometers offshore of the Field Research Facility (FRF) at Duck, North Carolina (Fig. 1). The dimensions and orientation of the Waverider array, as shown in Fig. 2, were determined using a land-based laser surveying instrument during calm conditions after the array was installed. The local bottom slope in the area is on the order of 1:200, resulting in less than a meter difference in water depth over the site. All the buoys in the array were tethered to mooring lines of equal scope with the intent that any displacement due to a unidirectional current would result in a translation of the array with minimum distortion. There was some variation in the array dimensions and orientation due to wave induced excursions of the buoys, but these spatial differences are small compared to the dimensions of the array and should average out over the period of data collection.

Prior to deployment all the Waveriders were calibrated according to the manufacturer's recommendations using a ferris wheel arrangement, and all the gages met or exceeded the calibration specification required by Datawell. A check on two of the gages after the experiment indicated

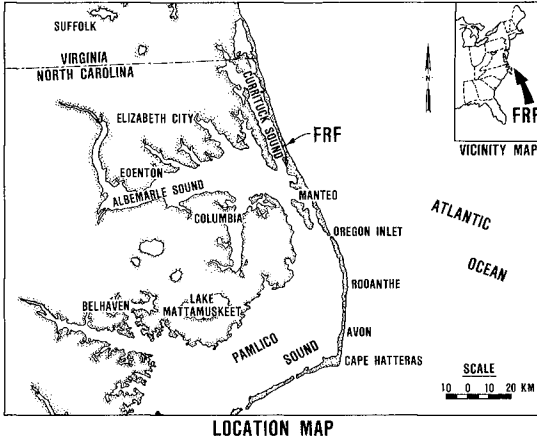

Figure 1. Field Research Facility Location Map

Figure 2. Waverider Wave Gage Array

that the calibration error for these two instruments was less than 4 percent.

The original data set is comprised of 38 data collection sessions lasting 80 minutes each. Each session involved the simultaneous recording of the wave height time series (as determined from buoy accelerations) from all gages at a sampling rate of 4 data points per second, resulting in a total record length of 19,200 data points per wave gage. The collection sessions were substantially longer than normal because it was realized that a fairly unique data set was being assembled and longer records might be of interest in future studies. The raw data were recorded by a digital computer and stored on magnetic tape.

The wave direction for each recording session was routinely obtained using an X-band imaging radar at the Field Research Facility, supplemented by visual observations. Mattie and Harris (5) report the direction measuring capability of the imaging radar to be accurate to within +4 degrees. During periods when two distinct wave trains were approaching from different directions, the direction of both the primary and secondary wave train was recorded. Pertinent weather data were noted during each recording session, and aerial photographs of the wave field were obtained several times over the duration of the experiment.

Realtime monitoring of the instruments during collection sessions helped insure that reasonable data were being obtained. Buoy number 2 (the buoy at the most southerly location on Fig. 2) produced erratic results from the onset of the experiment, and was replaced with a backup buoy as soon as possible. Consequently, the data from the first 22 collection sessions do not include results from this location. The 16 sessions after run number 22 include results from all locations in the array.

#### DATA ANALYSIS

Nine of the data collection sessions, representing a fairly broad range of conditions, were selected for detailed analysis (Table 1). For each selected data session the energy density spectrum for each gage was calculated and cross-spectral analysis was performed to determine the coherence and phase functions between all possible gage pairings. By definition the coherence function is given as

$$\gamma_{xy}(f) = \frac{|G_{xy}(f)|}{[G_{xx}(f) G_{yy}(f)]^{1/2}} \quad (1)$$

where

$G_{xx}(f)$  = autospectral density function of gage X,

$G_{yy}(f)$  = autospectral density function of gage Y, and

$G_{xy}(f)$  = cross-spectral density function between X and Y.

TABLE 1. Analyzed Data Set

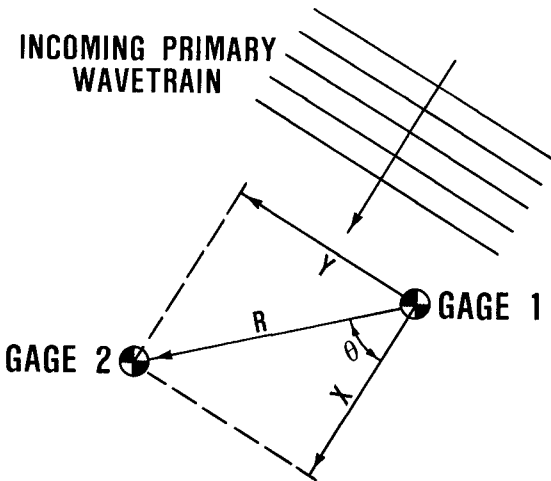

Figure 3. Reference Coordinate System

The coherence values are bounded between zero (no dependence) and one (complete linear dependence).

The data were processed with a fast Fourier transform routine using every other data point in the first 2048 seconds of the recorded time series. Thus the analysis subset contained 4096 points sampled at a 2 hertz rate (1/2 second interval). There is evidence that coherence estimates are not appreciably improved by increasing the length of the time series beyond 2048 data points (1). The resolution in the frequency domain is 0.0004883 hertz. Attention was concentrated on the frequency range 0- to 0.25-hertz since coherences at higher frequencies are expected to be quite small. Within this range spectral values are given at 512 discrete frequencies. A Tukey filter was applied to the cross-spectrum Fourier coefficients to increase the statistical stability of the results with only a minor loss in resolution. Coherence and phase were computed from the smoothed cross-spectral values.

Using the rather arbitrary criterion that coherence values greater than 0.7 indicate a meaningful coherence between gages, the results were examined, and it was found that about half (36) of the gage pairings had meaningful coherence in at least part of the frequency range. The autospectra and coherence functions for those gage pairings selected by this criterion are given in Hughes (3). The cases without meaningful coherences represented gage pairings with large spatial separation.

#### QUALITATIVE OBSERVATIONS

For each incident wave direction the distance vector separating any wave gage pairing can be resolved into a crest-parallel (along-crest) component, Y, and a crest-perpendicular (down-crest) component, X, as illustrated in Fig. 3. By comparing gage pairings with similar values for X and Y, several qualitative trends were observed. For example, Runs 3 and 7 (Fig. 4) and Run 6 (Fig. 5) have similar spatial separation for the selected gage pairings, and the coherence plots for these three runs are quite similar even though the autospectra differ considerably between runs. This comparison and other similar comparisons suggest that the coherence function is weakly, if at all, dependent upon the shape of the spectrum (compare Runs 3 and 7), the total energy contained in the spectrum, or the location of the spectral peak (compare Runs 3 and 6) for the range of conditions examined. Reasonably high coherence is observed at frequencies lower than the peak frequency so long as there is at least a small amount of energy present. The relatively high coherences at low frequencies could be attributed to the fact that waves at these frequencies are rendered less dispersive by the depth than waves at higher frequencies, and hence, can propagate with less alteration in form and celerity than higher frequency waves. These trends appear to be fairly consistent throughout the examined data. Run 5 (Fig. 5) was

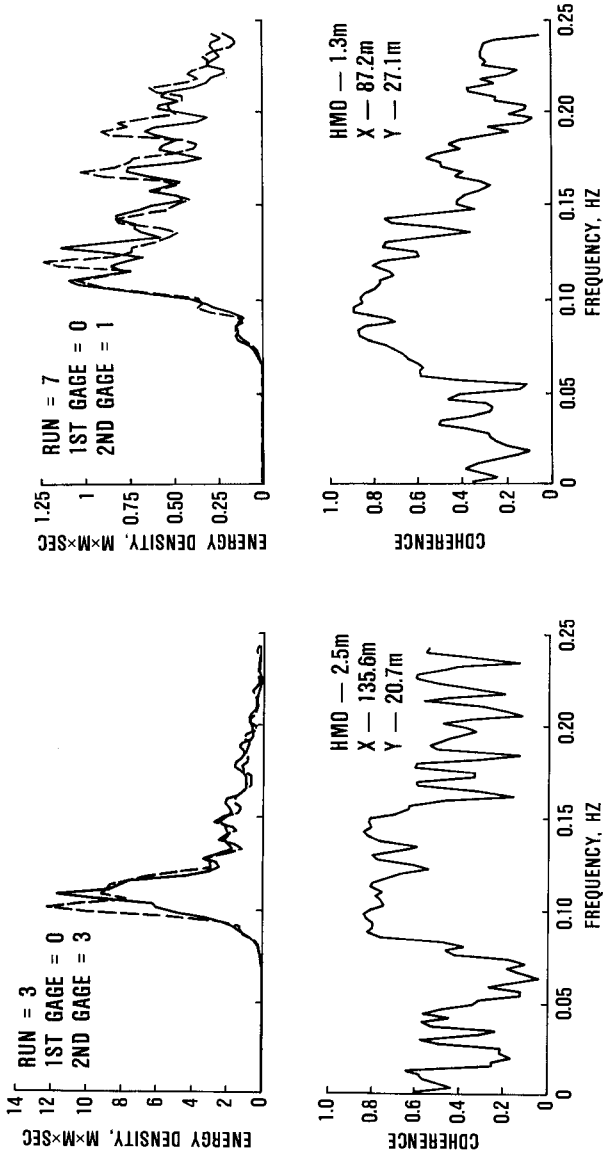

Figure 4. Comparison of Coherence Functions, Runs 3 and 7

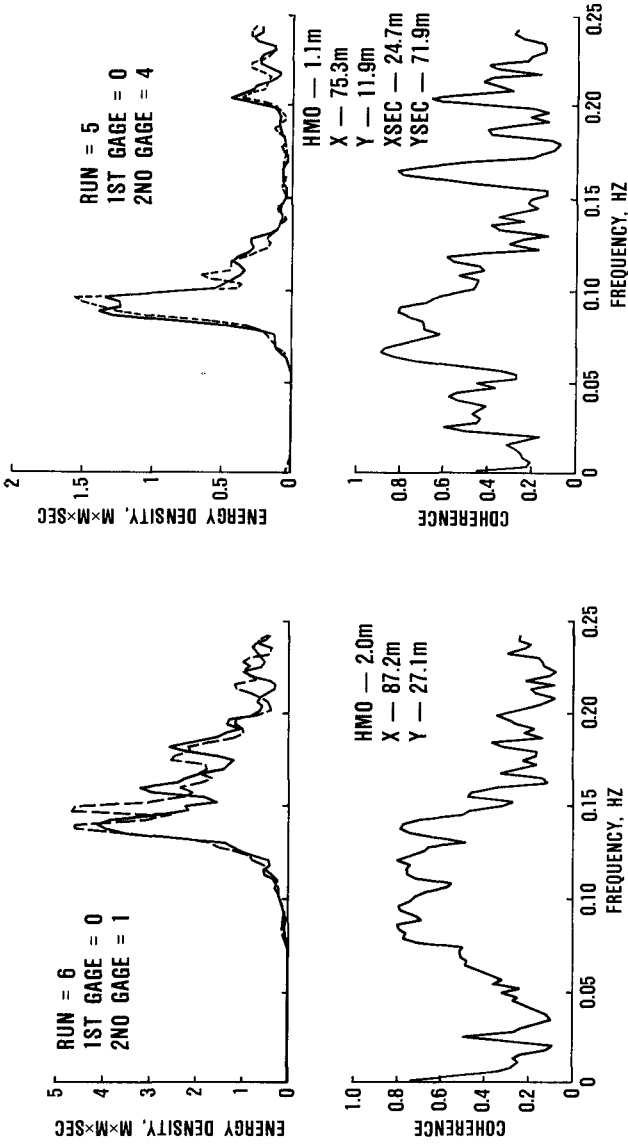

Figure 5. Comparison of Coherence Functions, Runs 6 and 5

included to illustrate the decrease in wave coherence caused by the visually observable presence of two wave trains propagating from different directions.

The most apparent influence on the wave coherence function is the spatial separation of the wave buoys. The observed trend is for a decrease in wave coherence, particularly at higher frequencies, as the spatial separation increases, and the trend is more evident with increases in along-crest separation than with down-crest separation. In other words the coherence found between gages separated by 30 meters in the down-crest direction will be somewhat better than the coherence between gages 30 meters apart in the along-crest direction.

#### WAVE COHERENCE CONTOURS

One of the goals of this study was to arrive at a method for estimating the wave coherence function in terms of the important parameters, which appear to be mainly frequency and spatial separation. A convenient way of incorporating frequency into the analysis was to nondimensionalize the along-crest ( $Y$ ) and the down-crest ( $X$ ) distances by the wavelength associated with each discrete frequency at the 17-meter water depth (linear theory). Then all discrete coherence values can be plotted against separation distances given in terms of relative wavelength. A survey of the discrete coherence values revealed that meaningful coherence values (greater than 0.7) were almost exclusively contained within the frequency range 0.08 - 0.16 hertz (wave periods 12.5 - 6.3 seconds). Since this frequency range covers the region where most coastal wave energy is concentrated, it was decided to limit the ensuing analysis to the discrete coherence values within this range.

Plotting of coherence values as a function of relative down-crest separation ( $X/L$ ) and relative along-crest separation ( $Y/L$ ) led to the subjective sketching of contours of equal coherence. These contours resembled those of an elliptic surface, suggesting that a satisfactory approximation might be obtained by the fitting of an elliptic surface to the data, i.e.,

$$\frac{(X/L)^2}{a^2} + \frac{(Y/L)^2}{b^2} = 1 \quad (2)$$

where  $a$  and  $b$  are some function of the wave coherence. Under the assumption that coherence decays exponentially as a function of the magnitude and direction of the vector separating the two positions, coherence can be expressed as

$$\gamma = e^{-f(R/L, \theta)} \quad (3)$$

where

$$\begin{aligned} \gamma &= \text{coherence,} \\ L &= \text{wavelength by linear theory,} \\ R &= (X^2 + Y^2)^{1/2}, \text{ and} \\ \theta &= \arctan (Y/X) \end{aligned} \quad (4)$$

The cylindrical coordinate system (Eqs. 4 and 5) is oriented so that the down-crest direction (X/L) corresponds to 0 degrees and the Y/L axis aligns with 90 degrees.

Transforming Eq. 2 into cylindrical coordinates and taking the square root of both sides yields

$$\frac{R}{L} \left[ \frac{\cos^2 \theta}{a^2} + \frac{\sin^2 \theta}{b^2} \right]^{1/2} = 1 \quad (6)$$

Taking the logarithm of Eq. 3 and rearranging gives

$$\frac{f(R/L, \theta)}{-\ln(\gamma)} = 1 \quad (7)$$

By equating Eqs. 6 and 7, it is seen that one expression for the unknown function,  $f$ , is

$$f(R/L, \theta) = \frac{R}{L} [(c \cos \theta)^2 + (d \sin \theta)^2]^{1/2} \quad (8)$$

where

$$c = \frac{-\ln(\gamma)}{a} \quad \text{and} \quad d = \frac{-\ln(\gamma)}{b} \quad (9)$$

and  $c$  and  $d$  are the constants to be determined from the coherence data.

After discarding coherence values less than 0.5, the remaining 4000 discrete values of coherence as a function of X/L and Y/L were used to determine the values of  $c$  and  $d$  which minimized the sum of the square of the errors between the observed and predicted coherence values. The data collected when multiple wave trains were approaching from different directions were not included in this formulation. The resulting "best-fit" equation is

$$\gamma = \exp\left\{-\frac{R}{L} [(0.18 \cos \theta)^2 + (0.39 \sin \theta)^2]^{1/2}\right\} \quad (10a)$$

or in rectangular coordinates,

$$\gamma = \exp\left\{-[(0.18 X/L)^2 + (0.39 Y/L)^2]^{1/2}\right\} \quad (10b)$$

There are certainly a multitude of other surfaces which could be fit to the data with equal or slightly better success, but the present solution offers reasonable simplicity. As an indication of the scatter present in the data, the root-mean-square error between the measured coherence and that predicted by Eq. 10 was calculated and found to be 0.126, which is quite large.

The coherence contours found from Eq. 10 are presented in Fig. 6 as a function of nondimensional along-crest separation distance (horizontal axis) and nondimensional down-crest separation distance (vertical axis). The contours are a crude estimate at best, however, they do provide a means of getting a first estimate of the wave coherence function between two locations. Fig. 7 is a plot of Eq. 10 for constant values of theta.

Fig. 8 shows four coherence plots from this experiment along with the estimate of coherence obtained from Eq. 10. The dashed portion of the estimate represents application of Eq. 10 outside the frequency range 0.08 - 0.16 hertz. The estimate for Run 8 is the product of the separate coherence functions determined for the primary and secondary wave directions. Eq. 10 is seen to reproduce a reasonable estimate for planning purposes.

The estimation technique was also applied to the data of Kuo, et al. (4) which were collected from a triangular array, 7 meters on a side, located in 15.5 meters depth. The estimate (see Fig. 9) is reasonable even well outside the frequency range used to establish the empirical constants. This is probably because of the close proximity of the gages.

## DISCUSSION

An empirical equation for estimating wave coherence in terms of spatial separation has been formulated using a select portion of the original data set, and thus, the limits of applicability have been defined. Within the frequency range 0.08 - 0.16 hertz, the empirical equation can be expected to provide a fair estimate of wave coherence. At higher frequencies the coherence decreases more rapidly than Eq. 10 would predict. This indicates that the parameterization of frequency in terms of wavelength is incorrect at higher frequencies.

There was no clear difference in wave coherence between conditions representing swell and storm seas in the data analyzed. Swell waves can be expected to be longer-crested and less dispersive and thus less sensitive to spatial separation, but this was not clearly evident in the data. This observation may be a consequence of the finite depth influence, and the difference between sea and swell might become more apparent in deeper water. Since the results were obtained in a water depth of 17 meters, it is reasonable to expect some signature of the depth in the coherence function. The high coherence values observed in the frequency range 0.08 - 0.10 hertz are quite possibly

Figure 6. Wave Coherence Contours

Figure 7. Coherence Curves of R/L Versus  $\theta$

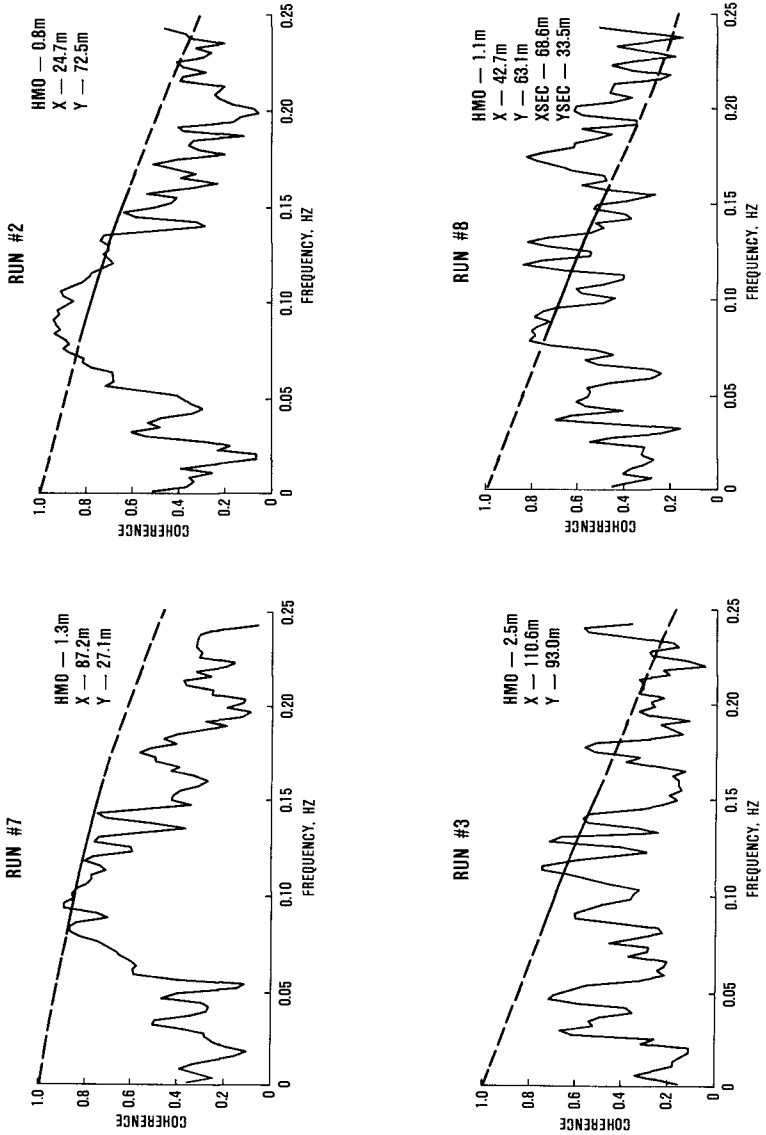

Figure 8. Coherence Estimates (This Experiment)

Figure 9. Coherence Estimates (Kuo, et al. Data)

related to the fact that waves at these frequencies have been rendered less dispersive by the finite depth. The observed decrease in coherence values at frequencies less than about 0.07 hertz may well be due to the minuscule amounts of energy at these low frequencies.

It must be emphasized that the equation for estimating wave coherence was obtained from data gathered in a water depth of 17 meters. It is expected that Eq. 10 could be applied at other water depths because of the nondimensionalizing by wavelength, however, more data are needed to support this generalization.

One interesting observation comes from comparing the theoretical wave coherence plots presented by Georgiadis and Hartz (2) with the empirical result given by Fig. 7. The theoretical coherence curves were obtained by assuming a JONSWAP spectrum in conjunction with selected directional spreading functions, and the results assume that the coherence function between two positions is strictly determined by the directional spreading. The theoretical curve which best follows the down-crest (0 degree) curve on Fig. 7 turns out to be the one found for a cosine to the sixth power. However, the corresponding theoretical curve for the along-crest direction (90 degrees) drops off to zero coherence before the value of  $R/L$  reaches 1.0. This is not the case for the empirical representation of the field data, as seen in Fig. 7. Thus, the along-crest coherence in shallow water is much better than predicted from the stated theoretical considerations. This could once again be a depth influence and possibly an indication that energy and directional spreading are not completely uncoupled in finite depth water.

Finally, the empirical equation presented for estimating the wave coherence function between two spatial locations should be used primarily as a planning tool due to the considerable variation present in the observed values. Attempts to use Eq. 10 to remove the effects of wave coherence from a system response might not be satisfactory in many cases. If the wave coherence between two positions is required during the course of an experiment, it is advisable to measure this coherence directly, using Eq. 10 as a planning guide.

#### SUMMARY

The Coastal Engineering Research Center has collected wave data from a closely spaced array of five wave gages at the Field Research Facility at Duck, North Carolina. The objective was to examine the spatial variability of the wave field in terms of the wave coherence function for a variety of incident wave conditions.

Qualitatively, the coherence function appears relatively independent of the shape of the spectrum, the spectral energy content, and the location of the spectral peak frequency for the range of conditions examined. The finite water depth at the site appears to render the lower fre-

quency waves less dispersive, and hence, more coherent so long as sufficient energy is present at those frequencies. The most apparent influence on the coherence is the spatial separation, and this effect was empirically quantified in terms of the relative wavelength. The resulting equation can be used to estimate the wave coherence function in finite depth water, but the uncertainty involved is substantial. A reasonable estimate is provided in the region between 0.08 - 0.16 hertz, but coherence is overestimated at higher frequencies. Consequently, these results are more suited for planning considerations.

## CHAPTER TWENTY EIGHT

### Field Studies of Run-up on Dissipative Beaches

Christopher T. Carlson\*, A.M. ASCE

#### Abstract

Field measurements of narrow-band incident wind waves and the resulting run-up were made photographically at two different natural sand beaches along San Francisco Bay. The run-up spectra derived from the field-measured time series show some energy at the incident-wave peak frequency, with the predominant run-up spectral energy concentrated in frequency bands below the incident-wave peak frequency. Observations of the swash time series recorded at both beaches indicate that the low-frequency run-up is generated on the beach face by the interaction between the run-up and backwash during the swash cycle.

Coherence analyses indicate that the offshore incident waves and run-up on the beach are not linearly correlated but that the run-up is correlated in the alongshore direction. The slopes of the log-log run-up spectra computed over the frequency band of the incident waves are all approximately -3. Statistical hypothesis tests were used to compare the empirical run-up cumulative distribution functions with both normal and Rayleigh distribution functions.

#### Introduction

The frequency band containing the dominant run-up spectral energy is generally not the same as the frequency band of the predominant incident-wave energy. For this reason, offshore wave statistics may not provide good estimates of the frequency distribution of wave energy expected at the shoreline or on the beach. A shift in the run-up spectral energy to frequencies lower than the predominant incident-wave frequencies has been observed for the run-up generated by a broadband incident-wave field. Field measurements of wave run-up reported in the open literature are very limited and most are by-products of edge wave or standing wave studies conducted on open ocean coasts where the incident-wave fields were usually swell dominated. The incident-wave/beach slope combinations generally produced highly reflective conditions, and the low-frequency (LF) run-up observed or measured during the experiments was attributed to modulation of the run-up by standing waves or edge waves present near the shoreline. No measurements have been reported for the run-up generated on a dissipative beach by narrow-band wind waves only.

\*Oceanographer, Sohio Petroleum Co., One Lincoln Centre,  
5400 LBJ Freeway, Suite 1200-LB 25, Dallas, TX 75240

LF swell-derived components in the run-up spectrum can often obscure other low-frequency contributions to the run-up that are developed on the beach by the higher-frequency wind waves in the incident-wave field.

### Objective

The objective of this study was to measure LF run-up generated on the beach face by the interaction between the run-up and backwash during the swash cycle. The experiments were designed to measure run-up on dissipative beaches exposed only to relatively high-frequency, narrow-band wind waves that broke near the shoreline by plunging. These conditions generally minimize or eliminate standing wave, edge wave, or very-low-frequency surf-beat components from the run-up that are derived from the swell component in an incident-wave field.

### Field Experiments

On 14 December 1977, incident wave and run-up measurements were made at the R.W. Crown Memorial State Beach on the eastern shore of San Francisco Bay (western shore of Alameda Island); similar measurements were subsequently made along the western shore of the bay on 14 May 1982 at Coyote Point Beach (Figure 1). Two separate field sites were selected to provide independent data sets for different beach slopes exposed to different incident wind-wave fields. It was necessary to avoid reflective beach conditions for which nonlinear perturbation of the incident-wave field by edge or standing waves might affect the frequency distribution of the run-up on the beach face. The field measurements were therefore conducted for dissipative beach conditions.

Beach reflectivity and inshore resonance may be characterized by the surf scaling parameter,  $\epsilon = a\omega^2/g \tan^2\beta$ , where  $a$  is the incident wave amplitude,  $\omega$  the radian wave frequency and  $\beta$  the beach slope. Reflective, dissipative and highly dissipative beach conditions are characterized by respective  $\epsilon$  values of less than about 2.5, greater than 2.5 and greater than 33. The moderately dissipative regime studied here, is identified by a relatively narrow surf zone, plunging breakers, and strong run-up. Beach reflectivity conditions for these field experiments yielded ideal  $\epsilon$  values of 6 (Alameda) and 19 (Coyote Point).

#### Alameda Beach

The Alameda Beach was composed of fine- to medium-grained silica sand and was openly exposed to westerly and southwesterly winds (Figure 1). The angle of wave approach was nearly normal to the shoreline as wind speeds increased from 3 m/s to over 5 m/s from 170

degrees true. A single breaker zone was located approximately 3 m (9.8 ft) from the shoreline, and all waves broke by plunging. The measurements were made during the peak of the afternoon high tide.

A 16-mm Bolex movie camera was used to simultaneously record time series of the offshore incident waves and the run-up on the beach face along a single line of 25 aluminum reference stakes. The reference stakes were positioned in a linear transect normal to the shoreline extending about 14 m (45.9 ft) in the offshore direction (Figure 2) and were used to calibrate the time series of the incident waves and run-up measurements. The camera was positioned on a 1-m (3.3 ft) high bluff just shoreward of the reference stake array.

Transit and level field survey methods and direct tape measurements were used to establish the position and elevation of the reference stakes relative to a fixed datum stake and the camera. The elevations were surveyed accurate to 0.3 cm (0.01 ft), as were the horizontal distances. Reference surveys that included offshore profiles were made both before and after the experiment and confirmed that no measurable change occurred in the offshore profile during the experiment. Agreement between the measured and computed heights and positions of the reference stakes was better than 1 cm (0.03 ft) in all cases. The Alameda beach had a nearly linear slope of approximately  $0.11 (6.2^\circ)$ , becoming nearly horizontal about 12 m (39.4 ft) offshore.

FIGURE 2 PLAN VIEWS OF ALAMEDA BEACH REFERENCE STAKE ARRAY SHOWING (a) REFERENCE STAKE NUMBERS AND SPACING BETWEEN STAKES AND (b) LOCATION OF CAMERA RELATIVE TO REFERENCE STAKE TRANSECT AND APPROXIMATE SHORELINE POSITION.

### Coyote Point Beach

The beach at Coyote Point was openly exposed to northerly and northwesterly wind waves (Figure 1) and the beach was composed of very small gravel and coarse sand. The beach slope was nearly constant in both the alongshore and offshore directions and formed a low-energy dissipative system with the incident-wave conditions present during the experiment.

The movie camera used for the Alameda field experiment was also used for the Coyote Point measurements. A two-dimensional grid of 80 wooden reference stakes arranged in 10 shore-normal transects provided the datum control for the Coyote Point experiment (Figure 3). Level and transit field survey techniques described for the Alameda measurements were used to establish datum control with the same accuracies. Three long transects and seven shorter ones crossed the beach face and extended offshore. The stakes located on the beach face were spaced closer together than those offshore to increase the available resolution for the run-up measurements. Figure 4 shows the orientation of the reference stake array relative to the camera, which is positioned at the origin of the plot. Also shown is a triangular array of three stakes located well seaward of the breaker zone and used for definition of the offshore incident-wave field.

To maintain continuity of the mean water level during the experiment, time series were recorded during the peak of the high tide. The winds were quite strong (about 8 m/s) and were nearly constant in their direction ( $250^{\circ}$  true) throughout the experimental period. The waves were nearly normal in incidence to the beach at the location of the reference stake array and plunging breakers were observed throughout the experiment. No visible signs of edge wave activity, such as beach cusps or regular alongshore spatial modulation of the run-up, were observed at any time during the experiment. Only one breaker zone was present near the shoreline.

### Data Analysis

Time series of the incident waves were derived from the 16-mm photographic record by digitizing the amplitude fluctuations of the waves where they passed the offshore reference stakes. Similarly, the run-up time series were developed from the movie record by digitizing the position of the leading edge of the run-up on the beach face.

The movie frames were digitized manually using an electronic photodigitizer. The oblique photographic image was projected onto a Tektronix 4956 Graphics Tablet connected to a Tektronix 4052 terminal; an electronic pad with crosshairs was used to digitize the photograph. The digitized points were stored on cassette tape and subsequently transferred from the Tektronix terminal to a DEC VAX 11-782 computer for processing and analysis.

The leading edge of the run-up on the beach face was digitized in the photographs along the reference stake transect. It was relatively easy to identify the position of the leading edge of the run-up in the photographs due to the presence of seafoam on the beach. The seafoam provided an effective tracer of run-up in the photographs since it closely followed the moving shoreline. In addition, the flow pattern around other inundated reference stakes was readily evident and proved helpful in verifying the continuity of the swash layer on the beach face. The run-up time series were calibrated into physical units directly from the photographs by using the surveyed reference stake positions. The positions of the reference stakes computed from the photographs agreed to within 2.5 cm (0.08 ft) of the measured positions.

The incident-wave amplitude time series were developed by digitizing the fluctuating water surface at the stakes. As with the digitized run-up time series, the product of digitizing was a digital time series of oblique photo coordinates in arbitrary digitizer units. No calibrations were available for the middle of the unmarked offshore reference stakes, near the mean water level, where the waves passed the stakes, thus precluding direct calibration. Photogrammetric analysis techniques were used to calibrate the incident-wave time series. The equivalent vertical photograph method of analysis (2,8,13) was used to compute the real ground coordinates of the offshore reference stakes and to calibrate the wave amplitude time series.

All incident-wave and run-up time series data computed from the Alameda and Coyote Point photographs were processed identically using standard digital time series analysis techniques. The results of four primary categories of processing are presented; spectral analysis, coherence and phase analysis, computation of spectral slopes, and statistical hypothesis testing on the empirical cumulative distribution functions (CDFs). Both chi-square ( $\chi^2$ ) and Kolmogorov-Smirnov (KS) goodness-of-fit tests were used to compare the empirical CDFs to both normal and Rayleigh distributions.

Results

Alameda Beach

Due to preset camera exposure rates, the raw time series data were recorded at 10.66 Hz and were subsequently down-sampled to 5.33 Hz during the digitizing process. A total of 1024 time series points were processed for both the incident waves and run-up, representing approximately 192 s of data. A 128-point FFT window was used, which corresponded to a 24-s time series segment, giving a Nyquist frequency of 2.67 Hz and a spectral resolution of 0.042 Hz. The use of a 50% spectral overlap with the power-normalized Hanning window produced 26 equivalent degrees of freedom for the spectral estimates (12).

Figure 5 shows the power spectral density (PSD) computed for (a) the incident waves recorded at reference stake 19 (Figure 2) and (b) the run-up recorded on the beach face plotted against frequency in Hertz. The predominance of LF run-up spectral energy at frequencies not containing high energy densities in the incident-wave spectrum is striking. The absolute magnitude of the power in the run-up spectrum is greater than that of the incident-wave spectrum. This is because the component of swash motion measured parallel to the plane of the beach face was recorded in these experiments and is reported here. If the vertical component of run-up had been computed, the absolute magnitude of the run-up spectral values would have been smaller, but the frequency distribution of the energy would remain the same.

FIGURE 5 ALAMEDA BEACH (a) INCIDENT-WAVE AND (b) RUN-UP SPECTRA WITH THE ASSOCIATED (c) COHERENCE AND (d) PHASE.

The frequencies of the dominant peaks in the spectra are indicated on the plots. The frequency resolution is 0.042 Hz, and the absolute position of any given spectral peak with respect to frequency may vary by a single resolution cell in either direction. The 0.42-Hz peak in the wave spectrum can be assumed to match the 0.37-Hz peak in the run-up spectrum. Guza and Thornton (6) also report the presence of a peak in the run-up spectrum at the incident-wave frequency for run-up measured on steep beaches with narrow surf zones. The wave spectrum is virtually devoid of energy at the 0.083- and 0.25-Hz frequencies containing the majority of the energy in the run-up spectrum. Conversely, the run-up spectrum does not exhibit energy at frequencies higher than about 0.5 Hz, whereas significant wave energy is present at frequencies greater than 0.5 Hz.

The incident-wave and run-up spectra were recomputed using a log-log format. Spectral slopes were then computed for these spectra over the so-called saturation frequency band of the incident wind waves by using a linear least-squares regression analysis. The slope computed for the wave spectrum is -1.9 and for the run-up spectrum is -3.2. The saturation band was defined over the frequency band of the incident wind waves that broke near the shore (6,7). Since the data recorded for the Alameda and Coyote Point field experiments contained only wind-wave characteristics, the saturation region of the spectrum was defined as all frequencies equal to and greater than the incident-wave peak frequency.

Figure 5 also shows the (c) coherence squared and (d) phase computed between the incident-wave and run-up time series. Following Bendat and Piersol (4), the 95% confidence limits are given in the Appendix (Table A-1) as a function of coherence. At the 5% level of significance ( $\alpha = 0.05$ ), the hypothesis that  $\gamma_{xy} = 0$  results in an acceptance region for the variable equal to 0.19. The coherence is generally low across the entire frequency band, and the phase is random, indicating that the waves and run-up are not linearly correlated. This lack of linear coherence between the offshore incident waves and the run-up on the beach face is not surprising and has been observed by others. The coherence between the time series was computed both with and without compensation for the spatial separation between the measurement locations.

The CDFs were computed for the Alameda incident waves and run-up. Two different data formats were used in comparing the empirical CDFs with normal and Rayleigh CDFs. For hypothesis testing of the measured data with respect to the model normal distribution, the incident-wave and run-up amplitude time series were converted to time series of standard deviations using:  $x(t) = (x(t) - E[x(t)]) / \sigma_x$  where  $E[\ ]$  is the expected value and  $\sigma_x$  is the standard deviation. Prior to computing the Rayleigh CDFs, the run-up and incident-wave time series were redefined for the comparisons using:  $x(t) = x^2(t) / \langle x^2(t) \rangle$ .

With the exception of the Rayleigh distribution for the waves, the empirical distributions provide a very close fit to both the normal and Rayleigh distributions and it might be tempting to conclude that

both distributions provide a good fit to the data. A KS goodness-of-fit test was used to quantify the agreement between the empirical, normal, and Rayleigh distributions. Only the incident-wave and normal CDFs appeared to be statistically the same with respect to the KS test statistic. That is, the two CDFs were not statistically different based on the KS test statistic. It should be emphasized here that these statistical tests do not indicate the distribution to which the empirical data conform; rather, the tests identify model statistical distributions from which the empirical distribution is not different. It is also possible that some other statistical distribution, not tested here, may fit the empirical run-up and incident-wave distributions.

#### Coyote Point Beach

The Coyote Point reference stakes were numbered consecutively in the offshore direction from 1 to 15 in transect 1 (Figure 3). The incident waves were measured at four offshore locations, which included reference stakes 10 and 15 in transect 1 and points A and B in the offshore reference stake triangle shown in Figure 4. The waves were steepening or just beginning to break as they reached stake 15; the largest waves broke by plunging just seaward of stake 15, while the smaller waves broke by plunging just shoreward of stake 15. The waves measured at stake 10 were actually bores moving shoreward toward the beach. The run-up was measured along transects 1, 3, 5, and 6 spanning an alongshore distance of approximately 3.5 m (11.5 ft).

The Coyote Point series data were recorded at 14 Hz and were downsampled to 3.5 Hz during digitizing. All eight time series were time-registered. Spectral analysis of these data was accomplished using 36-s, 128-point FFTs, producing a spectral resolution of 0.027 Hz and a Nyquist frequency of 1.75 Hz. The 50% spectral overlap, Hanning window, and other processing techniques described for the Alameda data were used to produce the spectra with 23 equivalent degrees of freedom.

The incident-wave spectra computed for the data recorded at offshore stakes A and B and along transect 1 at stakes 10 and 15 are shown in Figure 6. The spectral peak frequencies between all four of the spectra agree to within 1 frequency resolution cell. The spectra measured at all four locations are uniformly narrow-band, with one primary frequency. Virtually no LF energy is observed in any of the incident-wave spectra measured either well offshore at stakes A and B or nearer the shoreline at stakes 10 and 15.

A net decrease in wave height was observed across the reference stakes moving shoreward in order B-A-15-10. Respective rms wave heights of 10.0, 9.7, 8.6 and 5.1 cm (0.33, 0.32, 0.28, 0.17 ft) were computed for these locations both directly from the time series variance and by integration of the spectra from zero to the Nyquist frequency. Agreement between the two methods was uniformly better than 1%. Some transfer of spectral energy from lower to higher frequencies is observed in the spectra computed for stakes 10 and 15.

FIGURE 6 COYOTE POINT INCIDENT-WAVE SPECTRA MEASURED AT REFERENCE STAKES (a) B, (b) A, (c) 15 AND (d) 10

FIGURE 7 COYOTE POINT RUN-UP SPECTRA MEASURED ALONG REFERENCE TRANSECTS (a) 1, (b) 2, (c) 5 AND (d) 6

The run-up spectra measured at reference transects 1, 3, 5 and 6 are shown in Figure 7. The predominance of the LF energy in each run-up spectrum is the most noteworthy feature. The spectral peak frequency of the incident waves was approximately 0.38 Hz and although each of the measured run-up spectra show some energy at this frequency, the predominant run-up energy is located at much lower frequencies as observed for the Alameda Beach data. The 0.14 Hz spectral peak is observed in all of the run-up spectra measured at Coyote Point. A peak at 0.22 to 0.25 Hz (1 resolution cell apart) is observed in the run-up spectra measured at transects 1, 3 and 5.

The predominant run-up and backwash motions at frequencies 0.14 and 0.38 Hz were readily observed along all of the transects analyzed here. Although the frequency resolution of all four run-up spectra is identical, there appears to be a loss of fine structure detail in the spectra moving from transect 1 to transect 6. This is attributed to the increased distance between the measurement point and the camera location (Figure 4), coupled with the photographic resolution of the small 16-mm film. During analysis, it was increasingly difficult to observe the fine structure of the swash motions as transects located further from the camera were analyzed. For this reason, the continuum of energy located in frequency bands surrounding the dominant 0.14- and 0.38-Hz peaks in the run-up spectra recorded at transects 3, 5 and 6 is not as pronounced as in the spectrum recorded at transect 1. The basic shape of the energy continuum surrounding the 0.14-Hz spectral peak is conserved in the spectra measured at transects 1, 3 and 5 as is the total energy in the spectra. The rms run-up computed in the plane of the beach face at transects 1, 3, 5 and 6 was respectively 50.3, 55.2, 53.4 and 55.4 cm (1.65, 1.81, 1.75, 1.82 ft).

The spectral slopes were also computed over the saturated frequency band of the breaking incident wind waves for the run-up and incident-wave data recorded at Coyote Point. The slopes given in Table 1 compare favorably with the slopes computed for the Alameda data and show good agreement with slopes reported recently by others (6,7) for measurements made at beaches exposed to both swell and wind waves simultaneously. The slopes of the incident-wave spectra decrease in the shoreward direction. This appears to be explained by the transfer of energy in the spectrum from lower to higher frequencies as the waves shoal and break.

Table 1  
COYOTE POINT SPECTRAL SLOPES

Run-up Location	Slope	Wave Location	Slope
1	-2.8	B	-3.1
3	-3.0	A	-3.0
5	-2.9	15	-2.7
6	-3.1	10	-1.8

To estimate the onshore-to-offshore correlation between the run-up and the incident waves, the coherence and phase were computed between the run-up measured at reference transect 1 and the incident waves measured at reference stakes B, 15 and 10. Figure 8(a) shows the coherence squared and the phase computed between the run-up and the waves measured at offshore stake 15. The acceptance region for  $\gamma_{xy} = 0$  at the 95% confidence interval is 0.21. These results are typical of those computed between measurements made at the other locations. In each case, the correlation between the incident waves and the run-up is low.

The alongshore correlation in the run-up was also examined by computing the coherence and phase between all combinations of the run-up time series measured at transects 1, 3, 5 and 6. The coherence and phase between the run-up measured at transect 1 and 3 shown in Figure 8(b) is representative of all transects. Phase in the run-up correlations is generally random above 0.4 Hz, and coherence is low. Coherence squared was generally high between all four run-up transects across the lower frequency bands containing the predominant run-up spectral energy, reaching a maximum of approximately 0.8. The alongshore correlation in the run-up tends to decrease, however, with increasing separation between measurement points. Across all transects, the coherence remains consistently high near 0.14 and 0.38 Hz, the frequencies of the dominant peaks in the run-up spectra. The phase is nearly constant and is approximately zero in the band of frequencies less than 0.3 Hz, where the coherence is high, indicating that the time series are in phase.

FIGURE 8 COYOTE POINT COHERENCE AND PHASE BETWEEN THE RUN-UP ALONG TRANSECT 1 AND THE (a) INCIDENT WAVES AT STAKE 15 AND (b) THE RUN-UP ALONG TRANSECT 3

The CDFs computed for the run-up measured at transects 1, 3, 5 and 6 and for the incident waves measured at stake A were compared to model normal and Rayleigh distributions using  $X^2$  and KS statistical hypothesis tests. In each instance, the fit between the normal and data-derived run-up CDFs is very close. The KS tests results show that the null hypothesis cannot be rejected at the 95% confidence interval in any of the tests, and thus a normal distribution is not statistically different from the distribution of the Coyote Point run-up data for all four transects reported here. The observed value of the  $X^2$  statistic was less than the expected value in each case, and thus, the  $X^2$  test also confirms that the Coyote Point run-up data are not different from a normal distribution at the 95% confidence interval.

When tested against a Rayleigh distribution, the tests show that the Coyote Point run-up is statistically different from a Rayleigh distribution at the 95% confidence interval. The distribution of wave heights measured at A is statistically different from both the Rayleigh and normal distributions at the 95% confidence interval but is not different from a normal distribution at 99%.

#### Discussion

Two different field sites were selected, each with similar yet statistically different incident-wave and beach slope conditions, and in both cases low-frequency wave run-up was observed with similar characteristics. A small percentage of run-up energy was observed at the incident-wave peak frequency, but the largest percentage of the run-up energy was located at frequencies that were significantly lower. The fact that some run-up spectral energy is located at the predominant incident-wave frequency indicates that although wave-breaking by plunging is highly nonlinear, there is some memory involved whereby incident-wave frequency information is transferred to the run-up. The mechanism for this transfer may be the collision between the seaward-moving backwash and the shoreward-moving incident bore.

Observations of the run-up made during the field experiments revealed a typical swash-cycle scenario. A wave broke by plunging in the shallow water near the shoreline forming a bore that traveled a very short distance before running up the beach. Before this first wave reached the run-up limit and began its backwash, a second or even third wave plunged and surged up the beach face over the top of the moving layer of water created by the first wave(s). The backwash generated by the combination of these earlier waves would often attenuate the run-up of the subsequent wave, producing a modulation of the swash. Because a spectrum of incident-wave frequencies was present, albeit a narrow one, the relative timing between the run-up and backwash was not constant, thus creating the spectrum of low run-up frequencies.

The red-shift observed in run-up spectra may be caused by different mechanisms. The beach can behave as a low-pass filter to

the incident waves when exposed to a broadband spectrum of incident-wave energy. When exposed to both long swell waves and shorter wind waves, the longer waves produce the dominant, large run-up excursions, and the run-up generated by the shorter waves becomes embedded in the long-wave run-up. As a result, the run-up spectrum shows a prominent peak at the long-wave frequency, as well as at other frequencies.

Unlike the run-up field data reported in the open literature, however, the Alameda and Coyote Point run-up measurements were made for wind-wave conditions exclusively. The Alameda and Coyote Point incident-wave fields were narrow-band in frequency and contained only one predominant wind-wave component. The peak in the run-up spectrum coincident with the incident-wave peak frequency was not produced by long waves masking the run-up generated by shorter waves. Instead, the incident wind waves produced components in the run-up at their characteristic frequency and at lower frequencies through the interaction of the run-up and backwash during the swash cycle. If the beach were simply acting as a low-pass filter to the incident waves, the run-up spectral energy would be observed primarily at the wind-wave frequency only. There was no broadband distribution of incident-wave energy to be low-passed by the beach, but instead only one predominant forcing frequency.

No regular alongshore modulation of the run-up was observed at any time during the field experiments. The mean shoreline remained straight, and no edge wave derived cusps or regularly spaced deposits of seafoam or debris were observed along the shore. The time series of the run-up measured at transects 1, 3, 5 and 6 all showed approximately the same mean value. Thus, no quantitative alongshore variability of the mean run-up was observed over the 3.5-m (11.5 ft) distance between transects 1 and 6.

Huntley et al. (7) proposed a universal form for swash spectra. They observed an  $f^{-4}$  frequency dependence over the saturated portion of the run-up spectrum corresponding to the wind-wave band. Thornton (10) and Guza and Thornton (6) reported swash measurements for which an  $f^{-3}$  frequency dependence was observed. While a -3 slope was measured for the Alameda and Coyote Point run-up spectra, these data do not identify whether the same mechanisms produce both the -3 and -4 spectral slopes. These data do, however, support the idea of a saturated run-up spectrum.

Both normal and Rayleigh distributions appear to provide reasonable models for the run-up amplitude distribution. Webber and Bullock (11) indicate laboratory measured run-up was best described by a normal distribution. Battjes (3) suggests that run-up is more appropriately modeled using a Rayleigh distribution based on an assumed Rayleigh distribution for the incident-wave heights and squared wave periods. Sawaragi et al. (9) used a Weibull distribution in their run-up distribution model and Ahrens (1) assumed a Rayleigh distribution for the run-up in his proposed method for predicting the run-up due to irregular waves. Formal statistical hypothesis test

results are often not reported in the open literature for comparisons between empirical data and a chosen model probability distribution. The agreement may not be acceptable quantitatively based on formal hypothesis tests. If the run-up distribution model proposed for use in a predictive capacity does not match the field conditions, the accuracy of the prediction may not be acceptable.

#### Conclusions

Field measurements of narrow-band, incident wind waves and the resulting run-up on the beach face were made at two different natural beaches. The run-up spectra measured at both beaches show LF energy concentrated at frequencies much lower than the frequency band of the predominant incident waves. No LF energy was observed in any of the incident-wave spectra measured either offshore or near the shoreline. No continuous offshore-to-onshore red-shifting of spectral energy was observed. Photographic observations of the swash cycle on the beach face indicate that the interaction between the run-up and the backwash appears to be the source of the low-frequency energy.

Coherence between the incident waves and the run-up is very low across the surf zone. Although some run-up spectral energy is present at the dominant incident-wave frequency, the coherence level in this frequency band is not statistically significant. Some incident-wave information appears to be transmitted to the run-up, but linear coherence estimates do not identify the mechanism.

An equilibrium region of the run-up spectrum appears to exist over the frequency band of the incident waves. Run-up spectra measured during both field experiments show consistent  $-3$  slopes over the frequency band defined by frequencies greater than or equal to the incident-wave peak frequency.

The CDF computed for the Coyote Point run-up amplitude data is not statistically different from a standard  $(0,1)$  normal distribution. The Alameda run-up was statistically different from both normal and Rayleigh distributions, although qualitatively the data were more nearly normally distributed.

## CHAPTER TWENTY NINE

### A Nonlinear Model of Irregular Wave Run-up Height and Period Distributions on Gentle Slopes

Toru SAWARAGI\* and Koichiro IWATA\*\*

Member, JSCE and ASCE

#### ABSTRACT

This paper discusses the probability distributions of irregular wave run-up height and period on gentle slopes.

Assuming that the long period component appeared on the run-up oscillation corresponds to the incident envelope wave period, a nonlinear model to estimate the probability distributions of run-up heights and periods is proposed.

Laboratory experiments on gentle slopes of 1/15, 1/30 and 1/40, and field measurements on a natural sandy beach with swash slopes of 1/6 to 1/14 were performed to examine the proposed model. The proposed model is shown to agree with the experiments.

#### 1. INTRODUCTION

The elucidation of irregular wave run-up mechanism on a gently sloping beach is one of the important Coastal Engineering problems. The run-up oscillation presents a shoreward boundary condition for the onshore-offshore sediment transport which results in the change of beach profile, and a precise prediction of the swash oscillation, especially run-up heights give a significant information for the construction site of dikes, beach nourishment works, etc.,

So far, investigations have been performed to verify the nature of the swash oscillation on gentle slopes from field measurements<sup>1)-4)</sup> and laboratory experiments<sup>5)-9)</sup>. Most of the foregoing researches have pointed out that the swash oscillation has long period components which are not included in an incident wave outside the surf-zone, and the power level in the low frequency range of the swash oscillation becomes larger than that of the incident individual wave.

Some theoretical models<sup>10)-13)</sup> to predict a probability distribution of run-up heights have been proposed. All the foregoing models, however,

---

\*\* Associate Professor, Dr. of Eng., Dept. of Civil Eng., Nagoya Univ., Aichi 464, Japan

assumed that run-up heights of individual waves in an irregular wave train indicate the values following a formula proposed for a regular wave, such as Hunt's equation<sup>14</sup>). Therefore, the long period component observed in field and laboratory measurements has not been taken into consideration. In this sense, the foregoing models should be called a "linear model". Then, a "nonlinear model" considering the long period components is expected to be settled down.

With this situation, the present paper is intended to propose a nonlinear model to evaluate the probability distribution of the run-up height and period of irregular waves on gently sloping beaches, from engineering purposes in mind.

First of all, the nature of wind wave-generated run-up oscillations on a sandy beach is discussed. Secondly, two-component composite waves showing a strong wave grouping are treated and the effect of wave groupiness on the run-up oscillation is revealed in laboratory flume. Lastly, the irregular wave-induced swash oscillation is investigated in an indoor wave tank. Based on the experimental fact that the long period on the swash oscillation is highly correlated with the incident envelope wave period, the probability distribution of swash oscillation periods is proposed to be given by a combined distribution of the incident individual wave and their envelope wave periods. By extending the idea, the probability distribution of run-up height is also proposed to be given by a combined distribution of the incident individual waves and their envelope waves-induced run-up height distributions. The proposed model is shown to agree with experiments.

## 2. FIELD MEASUREMENT

### 2-1. Measurements

Field measurements were conducted at Kanaiwa Beach, Ishikawa Pref., in Honshu Island, during Sept., 1981 and Nov., 1983. The Kanaiwa Beach which faces to the Japan Sea is moderately well sorted sandy beach and the sand has a diameter of 0.5 mm and the coefficient of permeability of the beach is 0.124 cm/s.

A typical beach face topography is shown in Fig.1. The local beach slope where the run-up oscillation was measured was between 1/14 and 1/6. The slope in the surf-zone and just offshore was more gentle ( $< 0.01$ ). Bar-trough topography was in general weak or absent, and the beach bottom counter was relatively uniform in the longshore direction (see Fig.2).

The change of tidal level at Kanaiwa Beach was so small enough to be constant during 45 min measurement. The swash oscillation was measured at three different locations (O, R and L in Fig.2), where the distances between R and O, and O and L were about 300 m. Most of the run-up oscillation data were collected at location O.

The run-up meter was a capacitance wire, and its length was 50 m and the diameter was 2 mm, and it was supported about 0.5 cm above the bed. Sand level changes required raising and lowering the support wood stakes. The run-up meter was calibrated before and after each data acquisition by shorting the wire at three different locations.

Nanao Harbor Construction Office at 1st Harbor Construction Bureau of Transportation Ministry has been measuring regularly 20 min wave data at 2 hours intervals at the depth of 20 m with the ultrasonic-type wave gauge

( see Fig.2 ). The tidal level has been also measured by the Office at the adjacent Kanazawa Port. In this research, the wave and tidal data measured by the Nanao Harbor Construction Office were used as an incident wave and an initial stillwater level, respectively.

The run-up oscillation was recorded on a magnetic tape with 45 min. The wave and run-up oscillation were cut discretely at 1 Hz intervals and a power spectrum was calculated by FFT method with 1024 points. The incident individual and envelope waves were defined by the zero-upcrossing method. On the other hand, the individual wave of run-up oscillation was defined here both by the zero-upcrossing and trough-to-trough methods. This is due to the following reason. The zero-upcrossing method is very objective, but it sometimes fails to define small waves which donot cross the mean water level. On the other hand, the trough-to-trough method is subjective, in general, and it can define noise-like small waves. Thus, both definitions have its own merits and demerits. Since there have been little discussions on which definition is better, this paper uses the two definitoins.

### 3-2. Results and Discussions

Fig.3 is one example indicating an incident wave profile at the depth of 20 m and the corresponding run-up oscillation measured at the location O. It can be pointed out that the run-up oscillation has flat crests and sharply edged troughs in general.

Fig.4 shows an effect of the swash zone slope  $S$  on the non-dimensional period of run-up oscillation  $\bar{T}_R/\bar{T}_I$ , where  $\bar{T}_R$  is the mean period of the run-up oscillation and  $\bar{T}_I$  is the mean period of incident individual waves. The mean period of run-up oscillation defined by the trough-to-trough method as well as by the zero-upcrossing method becomes longer with decreasing of the swash zone slope  $S$ .  $\bar{T}_R/\bar{T}_I$  defined by the zero-upcrossing

Fig.1 Typical beach topography

Fig.2 Measuring locations

method is about two times larger than those defined by the trough-to-trough method. The reason is that the former method neglects short period waves which do not cross the mean water level, on the other hand the latter method defines noise-like short period waves.

Thus, the swash oscillation cycle becomes longer than the incident individual wave periods on gentle slope such as 1/14 in our field measurement. The mechanics of generation of the long period component have been pointed out as follows<sup>1)-8)</sup>.

- (1). marked decay of wave energy around a spectral peak frequency by wave breaking ( see Fig.5 ),
- (2) amplification of long period components by nonlinear wave-wave interactions in the surf-zone,
- (3) nonlinear wave-wave interaction on the swash zone, i.e. large bores overtaking and capturing smaller ones in the up-rush and downrush process,
- (4) edge wave or standing long long wave, et..

Therefore, a new model considering the long period component for predicting the swash oscillation is needed to be established.

Fig.5 indicates that the power spectral shape(A) of the run-up oscillation in low frequency range resembles approximately to that of the incident envelope wave(A'). On the other hand, the spectral shape(B) of the run-up oscillation in high frequency range (> 0.1 Hz ) can be seen to correspond to that of the incident individual wave (B'). From Fig.4 and Fig.5, we assume here that the probability distribution of run-up oscillation  $P_{R}(T_R)$  is, for 1st approximation, given by a combined distribution of the incident individual wave period distribution  $P_{I}(T_I)$  and the incident

Fig.3 Incident wave and swash oscillation

Fig.4 Effect of swash beach slope on period of run-up oscillation

Fig.5 Power spectra of incident individual and envelope waves and run-up wave

envelope wave period distribution  $P_{rE}(T_E)$ , as expressed by Eq.(1).

$$P_{rR}(T_R) = \alpha P_{rI}(T_I) + \beta P_{rE}(T_E) \tag{1}$$

$$\alpha + \beta = 1$$

In Eq.(1),  $\alpha$  and  $\beta$  are weight coefficients. In case of  $\alpha = 1$ , the swash oscillation periods equal the incident individual wave periods and there is no long period component. On the other hand,  $\beta = 1$  presents a situation where only long period components appear on the run-up oscillation. Therefore,  $\beta$  is an index showing a degree of nonlinear interaction in the surf and swash zones.

Fig.6 shows that the probability distribution of run-up oscillation period can be estimated by Eq.(1) for moderate values of  $\alpha$  and  $\beta$ . The value of  $\beta$  for the zero-upcrossing wave is generally larger than that for the trough-to-trough wave.

### 3. TWO-COMPONENT COMPOSITE WAVE

#### 3-1. Equipment and Procedure

Experiments were conducted to examine the effect of wave groupiness on run-up heights and periods on gentle slopes. In the experiments, an indoor wave tank in 0.75 m width, 0.9 m height and 30 m length was used. At one end of the wave tank, a uniform slope was installed. The slopes of 1/40, 1/30 and 1/15 were used in this experiment. At the other end of the tank, a flap-type wave generator was set, which is controlled by an electric dynamic shaker. The electric dynamic shaker is activated by an electric voltage input. Throughout the experiments, the stillwater depth was kept constant ( 73 cm ) in front of the wave board.

Two-component composite waves were generated by composing two monochromatic waves ( [  $H_1, T_1$  ] and [  $H_2, T_2$  ] ) with use of a multi-wave composer, where  $H$  and  $T$  are the wave height and period, respectively. Wave periods of  $T_1$  and  $T_2$  were changed from 0.67 sec to 1.47 sec and were chosen to be almost equal each other in order to produce grouping or beat waves.  $H_1$  and  $H_2$  were also determined to have almost an equal value. The envelope wave period  $T^*$  and height  $H^*$  were 3.1 sec to 47.0 sec and 2.0 cm to 15.8 cm, respectively.  $T^*$  and  $H^*$  are indicated in Fig.7(c). The number of experimental waves were about 70.

The incident water surface profile was measured by a capacitance-type wave gauge, and a time history of the run-up oscillation was measured by the run-up measuring instrument<sup>13)</sup> which was set along the surface of slope bed. All the measured wave profiles were recorded onto magnetic tapes in about 120 sec.

Incident individual and envelope waves were defined by the zero-up-crossing method which is more objective than the trough-to-trough method. The run-up wave which is discussed in this paper is a *time history of run-up wave front* ( swash oscillation ) measured by the run-up measuring instrument. The run-up oscillation waves were defined by the zero-up-crossing and trough-to-trough methods.

#### 3-2. Results and Discussions

##### (1) Time history of run-up oscillation

Fig.7 shows some typical examples of time histories of incident two-component composite waves and their corresponding run-up oscillations. As indicated in Fig.7(a), (b) and (c), incident individual wave periods do not, in general, appear on a time history of the run-up oscillation with decreasing of the bottom slope. And, the period of run-up oscillation becomes to close to the incident envelope wave period  $T^*$  with decreasing the beach slope( Fig.7(c)). This is very different from the case of the regular wave as in Fig.7(d). The physical explanation of this seems to be following. Since the individual wave heights change gradually and regularly with the beat period, the nonlinear wave-wave interaction, e.g. big waves overtaking and capturing smaller waves in the run-up and run-down process occur regularly and smoothly in the swash zone, which smooths out variation generated by incoming incident individual wave components. Therefore, it can be understood that the time history of the swash oscillation shows a change of the mean water level. Its oscillation period comes to close to the incident envelope wave period with decrease of the bottom slope.

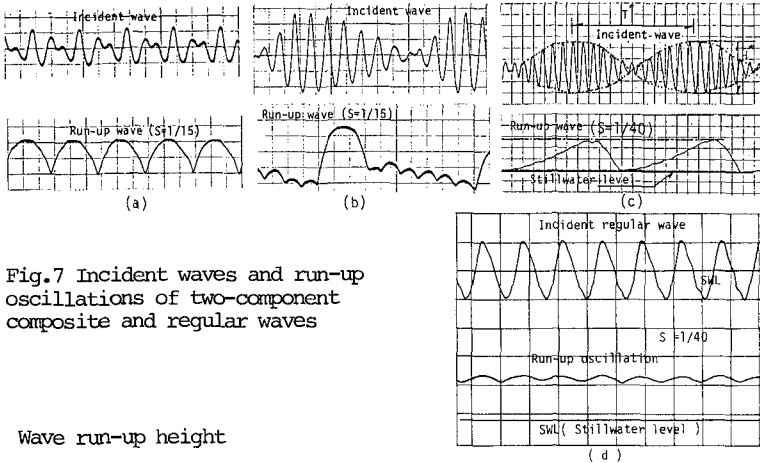

Fig.7 Incident waves and run-up oscillations of two-component composite and regular waves

(2) Wave run-up height

The run-up height is defined by a vertical distance of the run-up oscillation crest from the stillwater level. Based on a dimensional consideration, the run-up height  $R$  is dominated by 6 physical quantities,

$$R = F ( T^*, H^*, T_1, h, g, S ) \tag{2}$$

here,  $h$  is the stillwater depth,  $g$  is the gravitational acceleration, and  $S$  is the beach slope. From Eq.(2), a non-dimensional run-up height  $R/H^*$  is governed by 4 factors;

$$R/H^* = F ( H^*/L_o^*, T^*/T_1, h/L_o, S ) \tag{3}$$

where,  $L_o^* = gT^{*2}/2\pi$  and  $L_o = gT_1^2/2\pi$ .

The run-up height  $R$  of the two-component composite wave increases with increasing of  $H^*$  and  $T^*$ , in general, as indicated in Fig.8. This is very similar to the case of the regular wave<sup>13</sup>). The run-up height of two-component waves are generally higher than those of the regular waves. Putting it in another way, a grouping wave is apt to produce higher run-up height than the regular wave which does not show a grouping wave. The same thing can be said from Fig.9, where the wave height and period of the regular wave are equal to the maximum wave period and height among the incident individual waves. This experimental fact would imply that the run-up height of irregular waves becomes possibly higher than that of the regular wave.

By the way, the non-dimensional run-up height of the two-component composite wave  $R/H^*$  decreases as the incident envelope wave steepness  $H^*/L_o^*$  becomes larger, as indicated in Fig.10. In our experiments, the effect of  $h/L_o$  on  $R/H^*$  was little (the figures are not presented in this paper). From Fig.10, the non-dimensional run-up height  $R/H^*$  can be approximated by the following equations.

$$R/H^* = 0.05 ( H^*/L_o^* )^{-0.1} \quad \text{for } S = 1/40$$

$$\left. \begin{aligned}
 R / H^* &= S \sqrt{H^0/L^0} && \text{for } H^0/L^0 \geq 0.05 \\
 &= 0.15 && \text{for } H^0/L^0 < 0.05 && \text{for } S=1/30 \\
 \\
 \text{where, } H^0/L^0 &= 0.766 (T^*/T_1)^{2.18} (H^*/L_0^*) \\
 \\
 R / H^* &= S \sqrt{H^0/L^0} && \text{for } H^0/L^0 \geq 0.022 && \text{for } S=1/15 \\
 &= 0.45 && \text{for } H^0/L^0 < 0.022 \\
 \\
 \text{where, } H^0/L^0 &= 0.309 (T^*/T_1)^{2.18} (H^*/L_0^*)
 \end{aligned} \right\} (4)$$

Eq. (4) will be used for calculating run-up heights caused by the incident envelope waves in an irregular wave train in the next section.

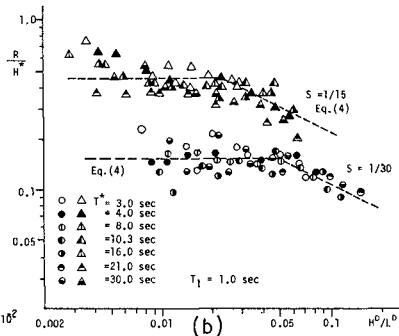

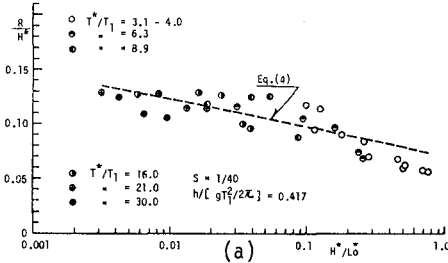

Fig.10 Non-dimensional run-up height of two-component composite wave

4. IRREGULAR WAVE

4-1. Equipment and Procedure

Experiments were carried out by using the same wave tank and instruments used for two-component composite wave experiments.

Irregular waves were generated to have a Bretschneider spectrum. In this work, 11 random waves (W.-1 - W.-11) were produced, and their power spectral and statistical quantities are given in Table 1. Time histories of incident individual and envelope waves and run-up waves were cut discretely, respectively, at each 0.05 sec, 0.5 sec, and 0.2 sec intervals, and the corresponding power spectra were calculated by BT-method with data of 4000 and freedom of 40, data of 6000 and freedom of 60 and data of 2400 and freedom of 30, respectively.

Incident individual and envelope waves were defined by the zero-upcrossing method. The run-up waves were defined both by the zero-upcrossing and trough-to-trough methods.

Table 1. Experimental waves

Wave	$H_{1/3}$	$\bar{H}$	$T_{1/3}$	$\bar{T}$	$Q_p$	$H_0/L_0$	S

$H_{1/3}$ : significant wave height,  $\bar{H}$ : mean wave height,  $T_{1/3}$ : significant wave period,  $\bar{T}$ : mean wave period,  $Q_p$ : spectral peakedness,  $H_0/L_0$ : equivalent deep water wave steepness, S; beach slope  
Unit: cm for  $H_{1/3}$  and  $\bar{H}$ , and sec for  $T_{1/3}$  and  $\bar{T}$

4-2. Results and Discussions

(1) Time history and power spectrum of run-up oscillation

Fig.11 shows time histories of run-up oscillation. Different from the regular wave, the irregular wave-caused run-up oscillation contains long period components which are not included in the incident wave at the wave board. Therefore, this fact shows that the assumption "run-up heights of individual waves in an irregular wave train indicate the values following the formula, such as Hunt's formula, deduced for the regular wave" is not established on the gentle slopes of 1/15, 1/30 and 1/40.

Fig.11 Time histories of incident wave and run-up oscillation

Fig.12(a) shows one example of power spectra of run-up oscillations. The remarkable feature of run-up oscillation is a marked increase of power density in a low frequency range than the spectral peak frequency of the incident individual wave. A predominant power peak is always recognized to appear at a little lower frequency side than the power spectral peak frequency of the incident individual wave. This is due to the reason of rapid decay of the wave energy around the spectral peak frequency by wave breaking and nonlinear wave-wave interactions in the swash and surf zones, etc..

The power spectral shape of run-up oscillation in a low frequency band is very similar to that of the incident envelope wave, different from the spectral shape of the incident individual wave. This would imply that the long period components which are supposed to be caused by nonlinear interactions including wave-wave interaction can be estimated from incident envelope wave periods. Typical examples are the cases of two-component composite waves discussed in the previous section.

Therefore, it may be possible to assume that the power spectrum of run-up oscillation is constructed by the two components, i.e. the individual wave and its envelope wave power spectra.

By the way, as indicated in Fig.12(a) and (b), the spectral slope of the run-up wave on high frequency range is proportional to  $f^{-4}$  (  $f$ ; frequency ). This fact coincides with experiments of Sutherland et al.<sup>6)</sup>

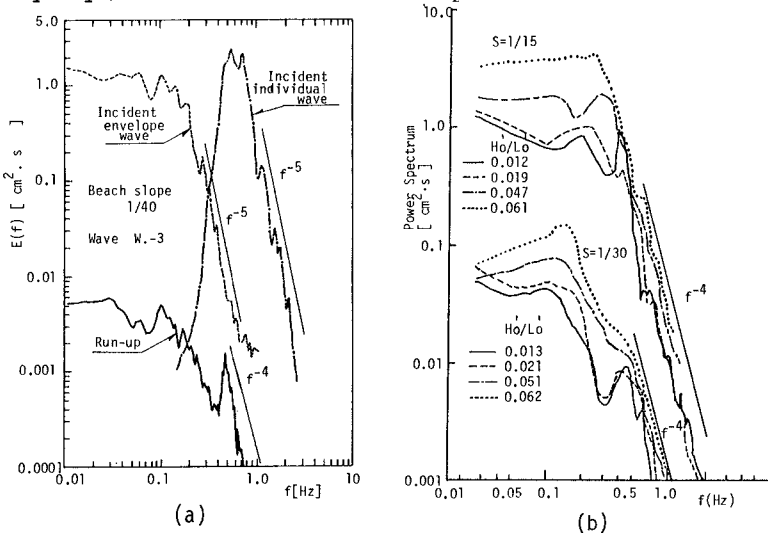

Fig.12 Power spectra of run-up oscillation on gentle slopes

(2) Distribution of run-up wave period

The distribution of run-up wave periods ( run-up oscillation periods ) is different from  $T^2$ -Rayleigh distribution which is usually observed for the incident individual wave, as indicated in figure 13. The run-up

wave periods distribute comparatively widely from short periods to long periods, and the distribution becomes to have two peaks with increasing of individual wave steepness  $H_0/L_0$ , as in Fig.14. The second peak period appears in the period domain corresponding to the incident envelope wave period.

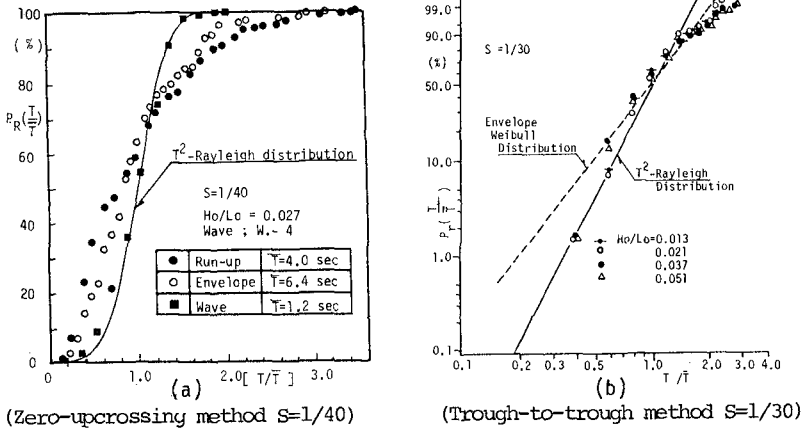

Fig.13 Cumulative distribution of period of run-up oscillation ( $T$  ; mean wave period )

Fig.14 Probability distribution of period of run-up oscillation ( Waves defined by zero-upcrossing method )

As already cited in this paper, the foregoing theoretical distributions for run-up heights are strongly based on the assumption of "Equivalency". The assumption is, however, inconsistent with experimental facts described above.

Since the period of long period components of run-up waves almost equals incident envelope wave periods and the spectral shape of swash oscillation

in low frequency resembles that of the incident envelope wave, this paper uses the following assumption. That is, the long periods are appearances of incident envelope wave periods, and the occurrence frequency of short periods (individual wave periods) and long periods (envelope wave periods) on the run-up oscillation is probabilistic, because of extreme complexity of nonlinear wave-wave interaction in the surf and swash zones.

Following the above-mentioned assumption, the probability density function of run-up wave period,  $P_{rR}(T)$  is defined here, like the field measurement, by a following combined probability density function,

$$\left. \begin{aligned} P_{rR}(T) &= \alpha P_{rI}(T) + \beta P_{rE}(T), \\ &= \alpha \left[ \frac{m_{I1}}{n_{I1}} T^{m_{I1}-1} \exp\left(-\frac{1}{n_{I1}} T^{m_{I1}}\right) \right] + \beta \left[ \frac{m_{E1}}{n_{E1}} T^{m_{E1}-1} \exp\left(-\frac{1}{n_{E1}} T^{m_{E1}}\right) \right] \\ \alpha + \beta &= 1, \end{aligned} \right\} (5)$$

here,  $P_{rI}(T)$  and  $P_{rE}(T)$  are the probability density functions of the incident individual and envelope wave periods, respectively. Since there are no established expressions for  $P_{rI}(T)$  and  $P_{rE}(T)$ , they are given by Weibull probability density functions. In Eq. (5),  $n$  and  $m$  are, respectively, a scale and shape parameters,  $\alpha$  and  $\beta$  are weight coefficients whose meaning is the same as in Eq. (1), and subsuffixes  $R, I$  and  $E$  indicate quantities regarding the run-up, incident individual and envelope waves. The subsuffix  $l$  shows quantities concerning incident wave periods.

The mean of the largest  $l/k$  wave period,  $\bar{T}_{l/k}$  is defined by Eq. (6).

$$\bar{T}_{l/k} \int_{\bar{T}_{l/k}}^{\infty} P_{rR}(T) dT = \int_{\bar{T}_{l/k}}^{\infty} T P_{rR}(T) dT \quad (6)$$

From Eqs. (5) and (6),  $\bar{T}_{l/k}$  is expressed by

$$\bar{T}_{l/k} = \frac{\left[ \alpha n_{I1}^{1/m_{I1}} \Gamma\left(\frac{1}{m_{I1}} + 1, \frac{1}{n_{I1}} \bar{T}_{l/k}^{m_{I1}}\right) + \beta n_{E1}^{1/m_{E1}} \Gamma\left(\frac{1}{m_{E1}} + 1, \frac{1}{n_{E1}} \bar{T}_{l/k}^{m_{E1}}\right) \right]}{\left[ \alpha \exp\left(-\frac{1}{n_{I1}} \bar{T}_{l/k}^{m_{I1}}\right) + \beta \exp\left(-\frac{1}{n_{E1}} \bar{T}_{l/k}^{m_{E1}}\right) \right]} \quad (7)$$

where,  $\Gamma\left(\frac{1}{m_{j1}} + 1, \frac{1}{n_{j1}} \bar{T}_{l/k}^{m_{j1}}\right)$ ,  $j=I$  and  $E$ , are incomplete Gamma functions.

Figure 15 shows some comparisons between calculations and experiments. As indicated in Fig. 15, agreement of the estimated values using Eq. (5) with experimental values is good for moderate values of  $\alpha$  and  $\beta$  in both waves defined by the zero-upcrossing and trough-to-trough methods. The run-up oscillation period defined by the zero-upcrossing method is, in general, longer than that defined by the trough-to-trough method. The reason is, as mentioned already, that the zero-upcrossing method cannot define small period waves which do not cross the mean water level, on the other hand, the trough-to-trough method is apt to define or pick up noise-like short period waves.

Following comparisons between calculations and experiments, it seems that correspondence between estimated values and experiments for the zero-upcrossing method-defined wave is better than that for the trough-to-trough

method-defined wave .

In calculating Eq. (5), the scale and shape factors of  $n$  and  $m$  were determined, by a least square method, to fit best the incident experimental wave.  $\alpha$  and  $\beta$  were also decided by the least square method in order for the estimated value of Eq. (5) to agree with experimental distributions.

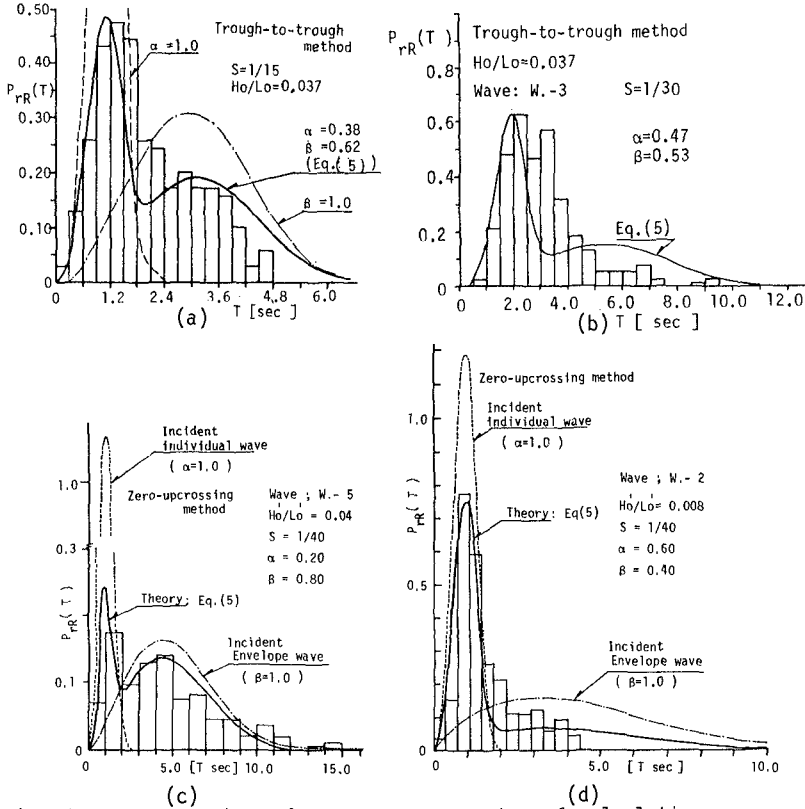

Fig.15 Some comparisons between measurements and calculations ( probability distribution of run-up wave period )

The values of  $\beta$  thus determined are shown in Fig.16, where  $H_o/L_o$  is the incident significant wave steepness (for an individual wave) in deep water depth and  $S$  is the beach slope. The value of  $\beta$  which implies a degree of nonlinear interaction increases with increasing of  $H_o/L_o$  and decreasing of  $S$ . That is, the gentler the beach slope and the steeper the wave steepness become, the more long period components are generated. Due to the shortage of experimental values, we cannot propose an empirical expression for  $\beta$  in relation to  $H_o/L_o$  and  $S$ . Further elaborate experiments are needed to set up an experimental formular for  $\beta$ , which will be done in the near future by the present authors.

Fig.16 Variation of  $\beta$  with  $H_o/L_o$  and  $S$  ( T-T;Trough-to-trough method, ZUC;Zero-upcrossing method )

(3) Distribution of run-up heights

The distribution of run-up heights is, like that of run-up wave period, assumed to be given by a combined distribution of the incident individual wave-induced run-up height distribution and the incident envelope wave-induced run-up height distribution.

The probability density function  $P_{rR}( R )$  of run-up height distribution is then given by Eq. (8a) and Eq. (8b).

$$P_{rR}( R ) = \alpha P_{rI}( R ) + \beta P_{rE}( R ) \tag{ 8a }$$

( for trough-to-trough method )

$$P_{rR}( R ) = \alpha \frac{P_{rI}( R )}{\int_{R_0}^{\infty} P_{rI}(R) dR} + \beta \frac{P_{rE}( R )}{\int_{R_0}^{\infty} P_{rE}(R) dR} \tag{ 8b }$$

( for zero-upcrossing method )

where,  $\alpha$  and  $\beta$  are weight coefficients determined by Eq. (5), and  $R_0$  is the vertical distance of the mean water level from the stillwater level.

$P_{rI}( R )$  is the probability density function of run-up heights induced by the incident individual waves, and Eq. (9) proposed by the authors<sup>13)</sup> is used for  $P_{rI}( R )$ .

$$P_{rI}( R ) = K_1( R ) \int_0^{\infty} K_2( R ) dt \tag{ 9 }$$

$$K_1( R ) = [2P(S) h^{Q(S)} (g/2\pi)^{1/2-Q(S)} ] [ \frac{m_{I2}}{n_{I2}} \frac{m_{I1}}{n_{I1}} R^{2m_{I2}-1} ]$$

$$\left. \begin{aligned} P(S) &= 4.56 \times 10^{-2} \times S^{-0.133} \\ Q(S) &= 5.85 \times 10^{-3} \times S^{-1.246} \quad (\text{for } 1/10 \leq S \leq 1/40) \\ a(S) &= 2(1/2 - Q(S)) \end{aligned} \right\}$$

In Eq. (9), subsuffixes 1 and 2 indicate quantities regarding the incident wave period and height, respectively.

$P_{rE}(R)$  is the probability density function of run-up heights produced by the incident envelope wave. Eq. (4) is adopted here as  $P_{rE}(R)$ , for the 1st approximation. In case of  $S=1/40$ ,  $P_{rE}(R)$  is expressed by Eq. (10).

$$\left. \begin{aligned} P_{rE}(R) &= K_3(R) \int_0^\infty K_4(t) dt \\ K_3(R) &= \frac{b(S)}{1-C(S)} \frac{m_{E1}}{n_{E1}} \frac{m_{E2}}{n_{E2}} R^d(S) \\ d(S) &= (m_{E2} + 2C(S) - 1) / (1 - C(S)) \\ K_4(t) &= t e^{e(S)} \exp\left[-\frac{1}{n_{E1}} t^{m_{E1}} - \frac{1}{n_{E2}} R^j(S) t^{-2j(S)C(S)}\right] \\ b(S) &= 0.137, C(S) = 0.100, e(S) = m_{E1}^{-1} - [2C(S)m_{E2}/(1-C(S))] \\ j(S) &= m_{E2}/(1-C(S)) \end{aligned} \right\} (10)$$

In cases of  $S=1/15$  and  $S=1/30$ , we can deduce similar but a little different expressions, which are not presented in this paper because of limited pages.

By the way, using the same definition as in deriving Eq. (7), the mean of the largest  $1/k$  run-up height  $R_{1/k}$  is expressed by

$$\bar{R}_{1/k} = \frac{\alpha \int_{R_{1/k}}^\infty R P_{rI}(R) dR + \beta \int_{R_{1/k}}^\infty R P_{rE}(R) dR}{\alpha \int_{R_{1/k}}^\infty P_{rI}(R) dR + \beta \int_{R_{1/k}}^\infty P_{rE}(R) dR} \quad (11a)$$

( for trough-to-trough method )

$$\bar{R}'_{1/k} = \frac{\alpha \int_{R_{1/k}}^\infty R P_{rI}(R) dR + \beta' \int_{R_{1/k}}^\infty R P_{rE}(R) dR}{\alpha \int_{R_{1/k}}^\infty P_{rI}(R) dR + \beta' \int_{R_{1/k}}^\infty P_{rE}(R) dR} \quad (11b)$$

$$\alpha' = \alpha \int_{R_0}^\infty P_{rI}(R) dR, \quad \beta' = \beta \int_{R_0}^\infty P_{rE}(R) dR$$

( for zero-upcrossing method )

Thus, as described above, the probability density function of run-up wave heights  $P_{rR}(R)$  can be calculated by putting Eq. (9) and Eq. (4) or Eq. (10) (in case of  $S=1/40$ ) into Eq. (8a) or Eq. (8b).

Fig.17 shows some comparisons between calculated values and experiments. Run-up waves in Fig.17 are all defined by the trough-to-trough method. The correspondence of the calculated values to the experimental values is, in general, good on the slopes of 1/15 and 1/30. In particular, quantitative agreement of calculations with experiments is recognized on the slope of 1/15 ( see Fig.17(a) and (b)). On the beach slope of 1/30, however, the discrepancy between calculated values and measurements is sometimes observed for steep waves such as W.-10 ( see Fig.17(d)) and W.-11 listed in Tabel 1. This may be partly caused by the reason that Eq. (4) is not the best formula for estimating the envelope wave-induced run-up heights.

In calculating Eq. (8a),  $m_{I1}$ ,  $m_{I2}$ ,  $m_{E1}$ ,  $m_{E2}$ ,  $n_{I1}$ ,  $n_{I2}$ ,  $n_{E1}$  and  $n_{E2}$  were all determined by the least square method with use of incident wave statistics measured in our experiments.

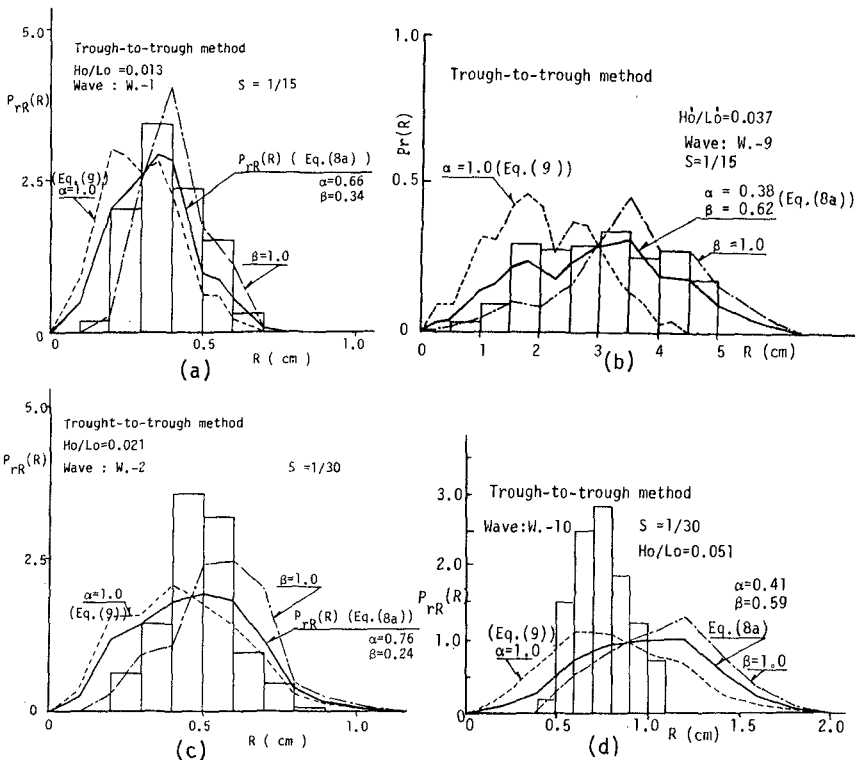

Fig.17 Comparisons between calculations and experimental values ( Trough-to-trough method )

Fig.18 shows some comparisons between measurements and calculations. In Fig.18, waves are defined by the zero-upcrossing method. The agreement of calculated values with experimental values is also good, like the case for waves defined by the trough-to-trough method. However, in some cases on the slope of 1/15; the calculated values of W.-10 and W.-11 do not correspond well to the experiments. The reason may be the same as that described for waves defined by the trough-to-trough method.

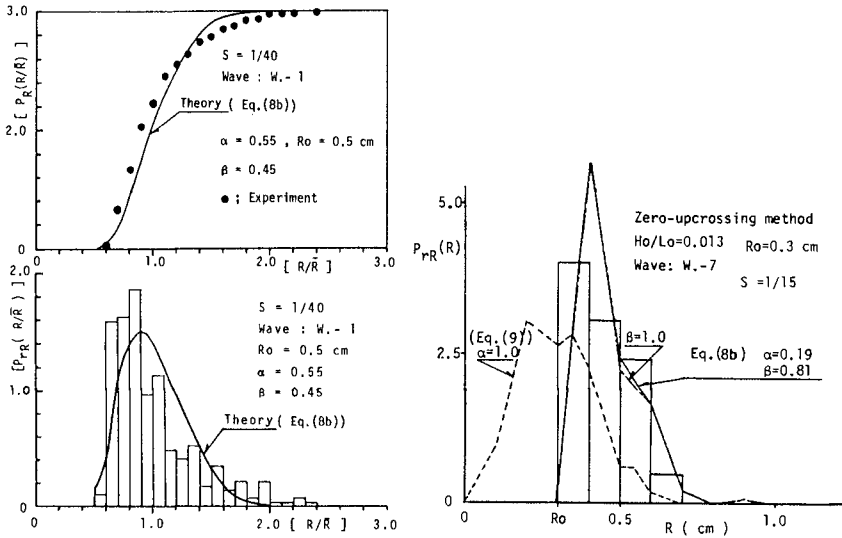

Fig.18 Comparison between measurements and calculations  
( Zero-upcrossing method )

In the calculations,  $m_{T1}$ ,  $m_{T2}$ ,  $m_{E1}$ ,  $m_{E2}$ ,  $n_{T1}$ ,  $n_{T2}$ ,  $n_{E1}$ , and  $n_{E2}$  were all the same values as those for waves defined by the trough-to-trough method.  $R_0$  was decided as the mean value over 8 minutes.

(4) Extreme distribution of run-up height and period

The estimation of the maximum values of run-up height  $R_{max}$  and period  $T_{max}$  is usefull for engineering purposes.

The maximum run-up wave period  $T_{max}$  is defined by

$$N ( 1 - P_r ( T < T_{max} ) ) = 1 \tag{12}$$

In Eq.(12),  $N$  is the number of wave ,  $P_r ( T < T_{max} )$  is the cumulative probability that  $T$  does not exceed  $T_{max}$ .

From Eq. (5) and Eq. (12),  $T_{max}$  can be determined by solving the following equation,

$$\alpha \exp\left(-\frac{1}{n_{I1}} \frac{m_{I1}}{T_{max}}\right) + \beta \exp\left(-\frac{1}{n_{E1}} \frac{m_{E1}}{T_{max}}\right) = \frac{1}{N} \quad (13)$$

The same argument is applied to the maximum run-up height  $R_{max}$ . The maximum run-up height  $R_{max}$  is obtained by solving the following equations.

$$\alpha \int_{R_{max}}^{\infty} P_{rI}(R) dR + \beta \int_{R_{max}}^{\infty} P_{rE}(R) dR = 1/N \quad (14a)$$

( for trough-to-trough method )

$$\alpha \int_{R_{max}}^{\infty} P_{rI}(R) dR + \beta \int_{R_{max}}^{\infty} P_{rE}(R) dR = 1/N \quad (14b)$$

( for zero-upcrossing method )

One example of calculations is given in Fig.19. As indicated in Fig.19, the correspondence of the calculation using Eqs.(5)-(14) to the experiment is not bad.

Fig.19 Nondimensional maximum run-up height and period ( Zero-upcrossing method )

5. CONCLUDING REMARKS

In this paper, the distributions of the run-up height and period of irregular waves on gentle slopes of 1/15, 1/30 and 1/40 are mainly discussed from engineering viewpoint. The theoretical distributions of run-

up heights and periods which consider long period components generated by nonlinear wave-wave interactions in the surf and swash zones are proposed.

The theoretically estimated values are seen to agree with experiments. The proposed model is, however, largely based on the assumption that the long period components can be represented by the incoming envelope wave periods. It should be stressed that the energetic investigations on mechanics of long period wave generation by wave-wave interactions in relation to the incident wave characteristics are needed to develop more elaborate theoretical distributions for the run-up oscillation.

## CHAPTER THIRTY

### A Dynamical Expression of Waves in Shallow Water

Y. Tsuchiya<sup>1</sup>, M. ASCE and T. Yasuda<sup>2</sup>

Making the assumptions that solitons are one of the most elementary excitation in random nonlinear waves in shallow water and that the waves have a coherent dynamic structure of solitons, we attempt to describe the swell-like waves theoretically by deriving the asymptotic multi-soliton solution for the KdV equation. Formulations of the random wave profiles and internal properties are also made. We conclude from the comparisons between observed and theoretical results of the propagation characteristics of the swell-like random waves and their water particle velocities, that the waves in shallow water have a coherent dynamic structure of solitons and that the theoretical expression for the waves has practically sufficient accuracy in estimating their propagation.

#### 1. INTRODUCTION

One of the outstanding features of swell-like waves propagating on shallow water is the coupling between their nonlinearity and randomness. How to express them theoretically is clearly of basic importance for coastal engineering because of the need to accurately calculate forces on coastal structures and to rationally estimate design waves and so on. Various attempts have been made to formulate them theoretically, for example, by using the nonlinear spectral analysis based on a perturbative approach from a linear mode, which was developed by Tick(1959), Phillips (1961) and Hasselmann(1962). However, the application of the nonlinear spectral analysis requires much labor because the nonlinear effects of the waves are remarkably stronger than those of ocean waves. As the result, the design of coastal structures is generally carried out by using the individual wave method which is a mere statistic approach and has no basis of the dynamics.

The coupling between nonlinearity and randomness of the waves makes their dynamics seriously difficult, because it provides active exchanges of energy among different modes and brings the above perturbative approach to the chaotic situation. From the new viewpoint of the dynamics of nonlinear waves, therefore, another approach may be needed in establishing the dynamics of the waves, instead of the usual perturbative approach mentioned above.

In this study, we attempt to propose a dynamical expression of the swell-like waves based on soliton modes, including simultaneously both effects of their nonlinearity and randomness. Further, applicability of the expression to field waves is examined by comparing it with observed data of wave propagation in the field.

2. WAVE EQUATION OF SWELL-LIKE WAVES IN SHALLOW WATER

Consider swell-like waves in shallow water of uniform depth and define the two-dimensional coordinate system as shown in Fig. 1. By assuming that viscosity is ignorable in the swell-like waves, we derive the equations governing them as

$$\left. \begin{aligned} \nabla^2 \Phi &= 0 \\ \Phi_t + (\Phi_x^2 + \Phi_z^2) / 2 + gz' |_{z=h+z'} &= 0 \\ \eta_t + \Phi_x \eta_x - \Phi_z |_{z=h+z'} &= 0 \\ \Phi_z |_{z=0} &= 0 \end{aligned} \right\} (1)$$

where  $\phi$  is the velocity potential,  $z'$  the water surface displacement from the mean water level,  $x$  and  $z$  the coordinate system,  $t$  the time,  $h$  the water depth, and  $g$  the acceleration of gravity.

Furthermore, assuming that the effects of nonlinearity and frequency dispersion of waves are of the same order and considering progressive waves of temporal evolution, we introduce the so-called Gardner-Morikawa transform

$$\xi = \epsilon^{1/2} (x^* - t^*), \quad \tau = \epsilon^{3/2} t^*, \quad x^* = x/h, \quad t^* = t\sqrt{g/h}, \quad z^* = z/h, \quad \epsilon = (h/L)^2 \quad (2)$$

and the perturbed solution

$$\left. \begin{aligned} z' / h (= \epsilon \eta) &= \epsilon \eta_1 + \epsilon^2 \eta_2 + \dots \\ \Phi / h \sqrt{gh} &= \epsilon^{1/2} \Phi_1 + \epsilon^{3/2} \Phi_2 + \dots \end{aligned} \right\} (3)$$

where  $L$  is the representative wave-length.

By substitution of Eqs. (2) and (3) into Eq.(1), we can rewrite Eq. (1) as

$$\eta_\tau + 3 \eta \eta_\xi / 2 + \eta \xi \xi \xi / 6 = \epsilon F(\eta, \eta_\xi, \Omega_\tau, \dots) + O(\epsilon^2) \quad (4)$$

$$\Omega_\xi - \eta = \epsilon (\eta \xi \xi / 2 + \eta^2 / 2) + O(\epsilon^2) \quad (5)$$

The relation between the new velocity potential  $\Omega$  and the original one  $\phi$  is given as

$$\Phi / h \sqrt{gh} = \epsilon^{1/2} (\Omega - \epsilon z^{*2} \Omega_\xi \xi / 2 + \dots) \quad (6)$$

Fig. 1 Coordinate system and symbols used

Taking  $\epsilon = 0$  in Eq.(4), we obtain the well-known Korteweg de Vries(KdV) equation as the lowest order equation of the swell-like waves as

$$\eta_\tau + 3\eta\eta_\xi/2 + \eta\xi\xi\xi/6 = 0 \quad (7)$$

Fig. 2 which was calculated by the authors(1982) indicates the comparison of wave transformation in evolution process between the numerical solutions of Eqs.(4) and (7) and the experimental results obtained by giving sinusoidal waves a initial condition of waves. From this figure, it can be considered that the second order correction when compared with that of the first order is relatively small for the wave transformation and that the soliton development can sufficiently be explained by the KdV equation. Hence, from the viewpoint that the swell-like waves should be described as simple as possible, we may use the KdV equation as the governing equation.

Fig. 2 Comparison between numerical and experimental wave profiles

### 3. WAVE SOLUTION OF THE KDV EQUATION BASED ON SOLITON MODES

#### 3.1 Elementary Excitation in the Wave Field Governed by the KdV Equation

We can derive the solution of the KdV equation perturbed from a sinusoidal wave solution by using Stokes expansion as

$$\left. \begin{aligned} \eta &= A \cos \theta + (3A^2/4\gamma) \cos 2\theta + (27A^3/64\gamma^2) \cos 3\theta + \dots, \\ \gamma &= (2\pi h/L)^2, \quad \theta = 2\pi x/L - \omega t \end{aligned} \right\} \quad (8)$$

where A is the Ursell number and  $\omega$  the angular frequency. The above expression describes that a sinusoidal wave becomes an elementary excitation of the wave field to be governed by the KdV equation. It is, however, noticed that the reduction of higher order terms requires much labor and that the number of sinusoidal modes is undetermined. We may conclude that sinusoidal waves are inadequate as elementary excitation in the wave field to be governed by the KdV equation.

The exact stationary solution of the KdV equation is known as cnoidal waves which is given as

$$\eta = A \left[ \text{cn}^2 \left\{ (\sqrt{3A}/2k) \vartheta \right\} - (E/K + k^2 - 1)/k^2 \right] \quad (9)$$

where  $\vartheta = (x/h - ct/h)$ , c is the wave-celerity, K and E the complete elliptic integrals of the first and the second kind, respectively, of

which the modulus is denoted by  $k$  and  $cn$  the Jacobian  $cn$ -function. Eq. (9) describes the stationary waves which is simpler than Eq.(8), although it contains an elliptic function.

It is well-known that Eq.(9) expresses a solitary wave(soliton), when the wave-period of cnoidal waves is taken infinite, as

$$\eta = A \operatorname{sech}^2 \left\{ (\sqrt{3A}/2) \vartheta \right\} \quad (10)$$

This means that the cnoidal waves contain solitons as their limiting and are rather elementary than solitons. However, using the relation between Jacobian  $dn$ -elliptic and hyperbolic functions obtained by Toda(1970)

$$\operatorname{dn}^2 \chi = (\pi/2K')^2 \sum_{l=-\infty}^{\infty} \operatorname{sech}^2 \left\{ (\pi K/K') (\chi/2K - l) \right\} - k/2KK' + E/K \quad (11)$$

we can transform Eq.(9) into

$$\eta = \sum_{l=-\infty}^{\infty} a \operatorname{sech}^2 \left\{ (\sqrt{3a}/2) \vartheta - l \pi K/K' \right\} - (4aK'^2/3\pi^2) \left\{ 3(E/K) + 2k^2 - 2 \right\} \quad (12)$$

where

$$\left. \begin{aligned} \vartheta &= \varepsilon^{-1/2} (\xi - c^* \tau) = (x/h - ct/h), \quad c = 1 - (2aK'^2/\pi^2) \left\{ 3(E/K) + k^2 - 2 \right\}, \\ a &= A(\pi/2kK')^2, \quad \varepsilon = (h/L)^2 \end{aligned} \right\} \quad (13)$$

Eq.(12) shows that a cnoidal wave train with the amplitude  $A$  consists of a periodic sequence of pulse-like waves, that is, solitons with the amplitude  $a$ , and that the cnoidal wave train can be expressed by making solitons its elementary excitation. As the modulus  $k$  becomes large, the number of solitons expressing a single wave crest of the cnoidal wave decreases. When the value exceeds about 0.98,  $a$  is approximated by  $A$  so that the influence of the adjacent waves become negligible and the cnoidal waves can be expressed as the regular train of solitons with the same amplitude. This means that periodic wave motion can be expressed by using a particle-like waves such as solitons, and that solitons are superior to cnoidal waves as elementary excitation in the wave field governed by the KdV equation. We, therefore, may describe theoretically nonlinear random waves in shallow water by making solitons elementary excitation.

### 3.2 Expression of the Swell-Like Waves Based on Soliton Modes

It is possible to express approximately the swell-like waves by the perturbed approach from sinusoidal modes as made by Freilich and Guza (1984). However, the calculation becomes very complicated, so that the approach is not applicable to explain nonlinear random waves completely. Some attempts[Nakamura and Matsuno(1980) and Hirota and Ito(1981)] were carried out of the theoretical expression of nonlinear random waves by making cnoidal waves elementary excitation, but they merely succeed in the case of two-periodic waves in shallow water. Consequently, the approach making solitons elementary excitation may give the sole and possible expression of nonlinear random waves in shallow water. Hence, considering that the swell-like waves in shallow water are the typical nonlinear random waves, we assume that the swell-like waves have a coherent

dynamic structure making solitons elementary excitations, that is, the soliton structure, as far as concerned with the dominant portions of them. In order to describe theoretically the swell-like waves under the above assumption and the condition of nondegeneration, we derive the exact multi-soliton solution of the KdV equation satisfying the continuity condition for wave profiles around the mean water level(1984) as

$$\eta = (4/3) (\log F)_{\xi\xi} - \eta_0 \tag{14}$$

where

$$F = \lim_{N \rightarrow \infty} \det \left| \delta_{ij} + \frac{2B_i}{B_i + B_j} f_i \right|, \quad 1 \leq i, j \leq N \tag{15}$$

$$\left. \begin{aligned} f_i &= \exp \{ B_i (\xi - c_i \tau - \tilde{\delta}_i) \}, \quad B_i = \sqrt{3A_i} \\ c_i &= A_i/2 - 3\eta_0/2 \end{aligned} \right\} \tag{16}$$

in which both of  $A_i$  and  $\tilde{\delta}_i$  are integral constants,  $A_i$  denotes the amplitude of a soliton expressing its energy level,  $\tilde{\delta}_i$  the phase constant determining the position of the soliton with the amplitude  $A_i$ ,  $c_i$  the wave-celerity of the soliton, and  $\delta_{ij}$  Kronecker's  $\delta$ . And,  $\eta_0$  is a statistical quantity defined as an ensemble mean of solitons satisfying the continuity condition and given as

$$\eta_0 = \lim_{\zeta \rightarrow \infty} (2/3\zeta) (\log F)_{\xi} \Big|_{-\zeta}^{\zeta} \tag{17}$$

under the assumption that disturbances exist at infinity and the period of observation( $\xi: -\zeta - \zeta$ ) is sufficiently long to describe the wave phenomena.

In analyzing the swell-like waves with the soliton structure, we may assume the following relation for spacings between the crests of solitons, which states that interactions of solitons are negligibly small.

$$|\xi_i - \xi_j| > \beta, \quad e^{-\beta} \ll 1, \quad -\infty < \dots < \xi_i < \xi_j < \dots < +\infty \tag{18}$$

where  $\xi_i$  is the coordinate of the crest position of the soliton with the amplitude  $A_i$  at  $\tau = \tau_0$ . Under the above assumption, Eq.(15) can asymptotically be rewritten as

$$F = \prod_{i=1}^{\infty} \{ 1 + f_i \exp(-B_i \Delta_i) \} \tag{19}$$

where

$$\Delta_i = -(1/B_i) \log \left\{ \prod_{j=1}^{i-1} (B_i - B_j)^2 / (B_i + B_j)^2 \right\} \tag{20}$$

Substituting Eq.(19) into Eq.(14), we can obtain the asymptotic expression of the swell-like waves based on soliton modes as

$$\eta = \sum_{i=1}^{\infty} A_i \operatorname{sech}^2 \vartheta_i - \eta_0, \quad \vartheta_i = (\sqrt{3A_i}/2) (\xi - c_i \tau - \delta_i), \quad \delta_i = \tilde{\delta}_i + \Delta_i \tag{21}$$

This expression asymptotically agrees with the exact solution of the KdV equation even when the value of  $\tau$  is finite not but  $\tau \rightarrow \infty$ , only if the

relation of Eq.(18) is satisfied. It is emphasized that this expression admits arbitrary degeneration of the amplitudes of solitons and is independent of evolution type. Moreover, we can easily determine the integral constants  $A_i$  and  $\delta_i$  from the observed data of swell-like waves by using the asymptotic solution, although it is very difficult to determine them and transform the exact solution with unknown constants into the particular solution expressing actually the swell-like waves as far as the exact solution is used.

Taking into account these facts in addition to that the usual swell-like waves can be expressed by the asymptotic multi-soliton solution as the authors recently pointed out(1984), any wave motion to be governed by the KdV equation may asymptotically be expressed as a train of solitons with various amplitudes under the assumption of Eq.(18). Macro-scopic properties of the waves then may uniquely be described by using the ensembles of  $A_i$  and  $\delta_i$ .

3.3 A Complete Orthonormal System

If the right-hand side of Eq.(21) is transformed into a linear combination of orthonormal system,  $\{\phi_i\}$ , by using Schmidt's method, it becomes a complete orthonormal system because Eq.(21) is a solution of the swell-like waves having a soliton structure. Eq.(21) is then rewritten by the linear combination of complete orthonormal systems

$$\eta = \lim_{N \rightarrow \infty} \sum_{i=1}^N A_i \psi_i(\vartheta_i) - \eta_0 = \lim_{N \rightarrow \infty} \sum_{i=1}^N A_i \sum_{l=1}^i c_{il} \phi_l(\vartheta_i) - \eta_0 \tag{22}$$

where

$$\psi_i = \text{sech}^2 \vartheta_i$$

$$\phi_i = \psi_i / \|\psi_i\|,$$

$$\phi_l = |F| \cdot G(\psi_1, \dots, \psi_{l-1})^{-1/2} \cdot G(\psi_1, \dots, \psi_l)^{-1/2}, \quad (l \geq 2)$$

$$|F| = \begin{bmatrix} (\psi_1, \psi_1) & & (\psi_1, \psi_l) \\ \vdots & & \vdots \\ (\psi_{l-1}, \psi_1) & \dots & (\psi_{l-1}, \psi_l) \\ \psi_1 & \dots & \dots & \psi_l \end{bmatrix}$$

$$G(\psi_1, \dots, \psi_l) = \begin{vmatrix} (\psi_1, \psi_1) & \dots & (\psi_1, \psi_l) \\ \vdots & & \vdots \\ (\psi_l, \psi_1) & \dots & (\psi_l, \psi_l) \end{vmatrix}$$

$$c_{il} = D_{li} (d_{11} \cdot d_{22} \dots d_{ll})$$

(23)

in which  $(\psi_i, \psi_j)$  is the dot product defined by

$$(\psi_i, \psi_j) = \int_0^\infty \psi_i \psi_j d\xi \tag{24}$$

and  $D_{1j}$  a cofactor of  $d_{1i}$  element of the matrix [D] defined by

$$[D] = \begin{bmatrix} d_{11} & 0 \\ \vdots & \ddots \\ d_{N1} & \dots & d_{NN} \end{bmatrix} \quad (25)$$

where

$$\left. \begin{aligned} d_{li} &= \left| \sum_{j=1}^{l-1} d_{ji}(\psi_l, \phi_j) / \left| \psi_l - \sum_{j=1}^{l-1} \phi_j(\psi_l, \phi_j) \right| \right|, \quad (l > i \geq 1) \\ d_{li} &= 1 / \left| \psi_l - \sum_{j=1}^{l-1} \phi_j(\psi_l, \phi_l) \right| \end{aligned} \right\} \quad (26)$$

4. EXPRESSION OF THE INTERNAL PROPERTIES OF SWELL-LIKE WAVES BASED ON SOLITON MODES

4.1 Reduction of the Velocity Potential

Not only the number of solitons but both of the amplitude  $A_i$  and the integral constant  $\eta_0$  are invariant, so that the wave-celerity  $c_i$  also become invariant and each soliton propagates with a constant speed. We then introduce the following transform of variables into each soliton.

$$\sigma_i = \xi - c_i \tau \quad (27)$$

Assuming that both  $\eta_i$  expressing the wave profile of the soliton with the amplitude  $A_i$  and  $\Omega_i$  being the velocity potential are functions of  $\sigma_i$ , we obtain the relations

$$\left. \begin{aligned} \partial \eta_i / \partial \tau &= -c_i \partial \eta_i / \partial \sigma_i, \quad \partial \eta_i / \partial \xi = \partial \eta_i / \partial \sigma_i \\ \partial \Omega_i / \partial \tau &= -c_i \partial \Omega_i / \partial \sigma_i, \quad \partial \Omega_i / \partial \xi = \partial \Omega_i / \partial \sigma_i \end{aligned} \right\} \quad (28)$$

Substituting Eqs.(27) and (28) into the relation between  $\Omega$  and  $\eta$  derived from Eqs.(5) and (6),

$$(\partial \Phi / \partial x) / \sqrt{gh} = \varepsilon \eta + \varepsilon^2 \{ \eta^2 / 2 + (1/2)(1 - \alpha^{*2}) \partial^2 \eta / \partial \xi^2 + \partial \Omega / \partial \tau \} + \dots \quad (29)$$

which may be transformed to

$$\begin{aligned} (\partial \Phi / \partial x) / \sqrt{gh} &= \sum_i \eta_i - \eta_0 + \left( \sum_i \eta_i - \eta_0 \right)^2 / 2 + (1 - \alpha^{*2}) / 2 \sum_i \partial^2 \eta_i / \partial \sigma_i^2 \\ &\quad - \sum_i c_i (\eta_i - \eta_0) + \dots \end{aligned} \quad (30)$$

It is found that the water particle velocities of the waves having the soliton structure have the particle-like property to be governed directly by the amplitude of each soliton and the periodic property dependent on the ensemble of solitons through the continuity condition for wave profiles.

#### 4.2 Expression of the Water Particle Velocities

Substituting Eq.(21) into Eq.(30) and evaluating the velocity potential of the waves to the second-order approximation, the horizontal and vertical velocities in the Eulerian coordinates  $u$  and  $w$  are obtained respectively as

$$\begin{aligned} \frac{u}{\sqrt{gh}} = & \sum_i A_i \operatorname{sech}^2 \vartheta_i - \eta_0 + \sum_i A_i \operatorname{sech}^2 \vartheta_i \left[ \frac{\eta_0}{2} + \frac{A_i}{2} \left\{ 2 - 3 \left( \frac{z}{h} \right)^2 \right\} - \frac{9}{4} A_i \left\{ 1 - \left( \frac{z}{h} \right)^2 \right\} \operatorname{sech}^2 \vartheta_i \right] \\ & + \frac{1}{2} \left( \sum_i A_i \operatorname{sech}^2 \vartheta_i \right)^2 - \eta_0^2 + \frac{1}{2N} \eta_0 \sum_i A_i \end{aligned} \quad (31)$$

$$\begin{aligned} \frac{w}{\sqrt{gh}} = & \frac{1}{2} \left( \frac{z}{h} \right) \sum_i \sqrt{A_i^3} \operatorname{sech}^2 \vartheta_i \tanh \vartheta_i \left[ 2 + \left\{ \left( \frac{z}{h} \right)^2 - 1 \right\} A_i (3 \operatorname{sech}^2 \vartheta_i - 1) \right. \\ & \left. + 2 \sum_j A_j \operatorname{sech}^2 \vartheta_j + 2 \eta_0 - A_i \right] \end{aligned} \quad (32)$$

Further, those in the Lagrangian coordinates  $U$  and  $W$  are expressed as

$$\frac{U}{\sqrt{gh}} = \frac{u}{\sqrt{gh}} + 2 \sum_i \sum_j \frac{\sqrt{A_i A_j}}{c_i} \tanh \vartheta_i \Big|_0^\infty \tanh \vartheta_j \operatorname{sech}^2 \vartheta_j + \eta_0 t^* \sum_i \sqrt{3 A_i^3} \tanh \vartheta_i \operatorname{sech}^2 \vartheta_i \quad (33)$$

$$\begin{aligned} \frac{W}{\sqrt{gh}} = & \frac{w}{\sqrt{gh}} - \left( \frac{z}{h} \right) \left( \sum_i \sum_j \frac{A_j \sqrt{3 A_i}}{c_i} \tanh \vartheta_i \Big|_0^\infty \operatorname{sech}^2 \vartheta_i (3 \operatorname{sech}^2 \vartheta_j - 2) \right. \\ & \left. - \frac{3}{2} \eta_0 + \sum_j A_j^2 \operatorname{sech}^2 \vartheta_j (3 \operatorname{sech}^2 \vartheta_j - 2) - \sum_i \sum_j \frac{A_i \sqrt{3 A_j^3}}{c_i} \operatorname{sech}^2 \vartheta_i \operatorname{sech}^2 \vartheta_j \tanh \vartheta_j \right] \end{aligned} \quad (34)$$

#### 4.3 Expression of the Mass Transport Velocities

In this study, the expression of the velocity potential has been derived under the assumption of Eq.(28) as shown already, so that the water particle velocity is independent of the restriction caused by the so-called Stokes' definition of wave-celerity. The mass transport velocities can then be defined both in the Eulerian and Lagrangian coordinates. Denoting the observed period as  $T^*$ , the mass transport velocity in the Eulerian coordinate:  $\bar{u}$  is defined as

$$\frac{\bar{u}}{\sqrt{gh}} = \frac{1}{T^*} \int_0^{T^*} \frac{u}{\sqrt{gh}} dt^* \quad (35)$$

Rewriting Eq.(31) into the expression of  $N$  solitons which are included in observed data within the period of  $T^*$  and introducing this into Eq.(35), we obtain

$$\frac{\bar{u}}{\sqrt{gh}} = \frac{1}{2T^*} \int_0^{T^*} \left( \sum_i^N A_i \operatorname{sech}^2 \vartheta_i \right)^2 dt^* - \frac{1}{2} \eta_0^2 - \frac{1}{2T^*} \left\{ 1 - \left( \frac{z}{h} \right)^2 \right\} \sum_i^N \frac{\sqrt{3 A_i^3}}{c_i}$$

$$\begin{aligned} & \times \left\{ 2 \tanh \vartheta_i \Big|_0^{T^*} - \tanh \vartheta_i (\operatorname{sech}^2 \vartheta_i + 2) \Big|_0^{T^*} \right\} \\ & - \sum_i^N c_i \left\{ \frac{\eta_0}{N} + \sqrt{\frac{A_i}{3}} \frac{2 \tanh \vartheta_i}{c_i T^*} \Big|_0^{T^*} \right\} \end{aligned} \quad (36)$$

By the same means, the mass transport velocity  $\bar{U}$  in the Lagrangian coordinates is derived by the horizontal velocity for the observed period as

$$\begin{aligned} \frac{\bar{U}}{\sqrt{gh}} &= \frac{\bar{u}}{\sqrt{gh}} + \frac{2\eta_0}{T^*} \sum_i^N \frac{1}{c_i^2} \sqrt{\frac{A_i}{3}} \left\{ \frac{\sqrt{3}A_i}{2} c_i t^* \operatorname{sech}^2 \vartheta_i + \tanh \vartheta_i \right\} \Big|_0^{T^*} \\ & - \frac{2}{T^*} \sum_i^N \sum_j^N \frac{A_j}{c_i c_j} \sqrt{\frac{A_i}{3}} \tanh \vartheta_i \Big|_0 \operatorname{sech}^2 \vartheta_j \Big|_0^{T^*} + \frac{2}{T^*} \sum_i^N \sum_j^N \frac{\sqrt{A_i A_j}}{c_i} \\ & \times \int_0^{T^*} \tanh \vartheta_i \tanh \vartheta_j \operatorname{sech}^2 \vartheta_j dt^* \end{aligned} \quad (37)$$

5. APPLICATION TO FIELD WAVES

5.1 Soliton Analysis and Synthesis of Observed Data

For expressing theoretically observed waves on soliton modes, we must decompose them into a number of solitons to determine their amplitude  $A_i$  and phase constant  $\delta_i$ . Then, employing these values of  $A_i$  and  $\delta_i$  into Eq.(21) may yield a theoretical expression of the waves with a soliton structure.

Under the assumption that the right-hand side of Eq.(23) is a complete orthonormal system, moreover, the ensemble of the amplitude  $\{A\}$  by making the inner product between the theoretical wave profile  $\eta$  given by Eq.(23) and the observed wave profile  $Y$  can be calculated by

$$\begin{Bmatrix} A_1 \\ \vdots \\ A_N \end{Bmatrix} = \begin{bmatrix} d_{11} & \cdots & d_{N1} \\ \vdots & \ddots & \vdots \\ 0 & & d_{NN} \end{bmatrix} \begin{Bmatrix} (Y + \eta_0, \phi_1) \\ \vdots \\ (Y + \eta_0, \phi_N) \end{Bmatrix} \quad (38)$$

5.2 Accuracy of the Expression of the Swell-Like Waves

An observation of the swell-like waves was carried out on the 7th of March, 1981, by using the wave observation system, at the Ogata Wave Observatory, Disaster Prevention Research Institute, Kyoto University.

Fig. 3 describes the position of the wave gauges of capacitance type installed along the observation pier 315m long in the offshore direction. The water depths at which the wave gauges are installed are shown in the figure. Wind speed and direction during the observation were about 3m/s and S, respectively. Incident waves were long crested and approaching parallel with the pier as swell-like waves suffering from no influence of wave breaking.

A comparison of power spectra computed by the FFT method between the waves observed at P. 1 and P. 2 is shown in Fig. 4 with their values of skewness and kurtosis of the water surface displacement. And, the Ursell

(a) Plane view of observation pier

(b) Side view of observation pier and wave gauges installed

Fig. 3 Positions and number of installed wave gauges

number( $U_r$ ) at P. 1 calculated by the zero-up crossing method is 45.9. The power spectra exhibit pronounced secondary peaks at frequencies about twice the main peak frequencies due to nonlinear interaction among sinusoidal modes. It is considered from this figure that the waves are swell-like with fully developed nonlinearity. Low frequency components of the waves have considerable energy which is probably due to water surface displacements with long periods, such as surf-beat, independent of the soliton modes. Mechanism of their excitation is different from that of the waves. The approach based on soliton modes can therefore be applied to the observed data, if the low frequency components under 0.04Hz are excluded with a numerical low-cut filter of critical frequency of  $f_c = 0.04$ Hz.

Fig. 4 Spatial variation of power spectra

Fig. 5 shows comparisons of wave profiles between the data observed at P. 1 and P. 2 mentioned above and the theoretical results obtained by the expression of Eq.(21). Clearly, Eq.(21) has sufficient accuracy in expressing the wave profiles under the swell-like sea condition.

Fig. 5 Comparisons of wave profiles between the observed data and the theoretical results

One of the comparisons between the observed data and the theoretical profiles of the waves propagated from P. 1 to P. 2 is shown in Fig. 6. This figure states that this approach can express the propagation of the waves, as well as the wave profiles with satisfactory accuracy.

Fig. 6 Comparison of wave propagation between the observed and theoretical data

Figs. 7 and 8 show another comparison on swell-like waves with the Ursell number 22.4 at P. 1. The observed data in these figures were obtained by the same observation system under the similar sea condition and analyzed as well. The expression has sufficient accuracy, so that the dominant part of these waves have the soliton structure for which the formulation can be made by the soliton modes.

Fig. 7 Comparisons of wave profiles between the observed data and the theoretical results

Fig. 8 Comparison of wave propagation between the observed and theoretical data

### 5.3 Extensive Application to Waves Under the Various Sea Conditions

Observations of waves were carried out by use of both the array consisting of nine capacitance-type wave gauges installed along the observation pier mentioned above and the line array of four ultra-sonic-type wave gauges installed at the offshore end of the pier to obtain directional spectra. Fig. 9 shows the positions of the wave gauges at which the water depths are also shown. Fig. 10 indicates the changes in wind speed and direction within a period of the observation and the relation between them together with the data numbers of which abbreviation is expressed by DNO.

Fig. 11 shows some comparisons of wave profiles at the points of U<sup>4</sup>, CW5, CW7 and CW9 between the observed data of DNOs 27, 31 and 34 and the theoretical results by soliton modes. The Ursell numbers at U<sup>4</sup> of DNOs 27, 31 and 34 are 4.7, 18.0 and 11.1, respectively. We may conclude that the expression by soliton modes has sufficient accuracy in expressing the wave profiles under various sea conditions, as far as their

dominant portions are concerned, although the influence of wave breaking is not negligible in these comparisons where about a few ten's percent or more of the waves are broken.

Fig. 11 Comparisons of wave profiles in a period of growing state to damping, one between the observed data and the theoretical results

Fig. 11 Comparisons of wave profiles in a period of growing state to damping one between the observed data and the theoretical results

5.4 Accuracy of the Expression of Internal Properties

An observation of horizontal water particle velocities of the swell-like waves with the Ursell number 19.6 was carried at Ajigaura coast facing the Pacific ocean by Horikawa et al. The velocities were measured at the water depth of 2.28m by using an electro-magnetic current meter which is installed at the height of 0.62m above the sea bottom.

Fig. 12 shows part of the comparison of the velocities between their observed data and the theoretical result calculated by Eq.(31). Fig. 13 also shows similar comparison of wave profiles. It is found from these

Fig. 12 Comparison of horizontal water particle velocity between the observed data and the theoretical results

Fig. 13 Comparison of wave profiles between the observed data and the theoretical results

results that the expression of the water particle velocity based on soliton modes has accuracy similar to that for wave profiles as far as the expression of wave profiles has sufficient accuracy.

## 6. CONCLUSIONS

From the viewpoint that the soliton is one of the most elementary excitation in the nonlinear random waves, we have attempted to describe swell-like waves in shallow water theoretically by deriving the asymptotic multi-soliton solution under the assumption that the waves have a coherent dynamic structure composed of solitons alone. The expressions of wave profiles and internal properties such as water particle and mass transport velocities were derived by using the asymptotic solution, independently of both the evolution type and the degeneration of the amplitudes.

Further, applicability of the expressions by soliton modes was examined by comparisons between observed and theoretical wave profiles and internal properties. We conclude from these comparisons that the expressions by soliton modes practically have sufficient accuracy in expressing various properties of the swell-like waves.

## 7. ACKNOWLEDGEMENT

Figs. 12 and 13 were drawn from the wave data observed by Professor Horikawa et al. of Tokyo University and their permission for publication is gratefully acknowledged.

## CHAPTER THIRTY ONE

### PREDICTION METHOD FOR THE WAVE HEIGHT DISTRIBUTION OFF THE WESTERN COAST OF TAIWAN

Frederick L. W. Tang\*  
Jea - Tzyy Juang\*\*

#### Introduction

Taiwan Strait locates on the continental shelf of the western Pacific Ocean. The water depth is less than 100 meters. Furthermore, the bathymetry of the eastern side namely the offing of western coast of Taiwan shoals gradually. In consequence, in case of the wind blows from the north to south, waves in the deeper part of the strait refract to be north west direction while they are approaching the shore and local waves directly generated by the wind still keep the same direction of the wind. The situation is shown in Figure 1.

From September to April of the next year, anticyclones come from Mongolia causes monsoon in this area. The wind velocity in the monsoon sometimes exceeds 20 meters per second, but it is around 10 meters per second in general. However, the duration of winds over 5 meters per second has been recorded more than 50 days. Engineering works such as towing caissons for building breakwater as well as dredging offshore have to be done in these days. Furthermore, navigation operations should not be stopped unless the wind is too strong. Of course, waves are forecast every day, however, more precise information about the probability of the occurrence of certain wave height is of great significance.

In last conference, the authors submitted a probability density function of wave heights in this area. This distribution model is to be remended by considering energy loss in this paper, and concrete forecasting procedure is submitted for engineering and navigation practice.

#### The Distribution Model

In last conference which was held in Capetown the authors ( Tang et. al. 1982 ) submitted a probability density function of wave heights off the western coast of Taiwan namely the eastern side of Taiwan Strait. The bathymetry of this area is rather flat and the prevailing wind direction is almost in the longshore direction. Waves in this area are considered to be the combination of the refracted waves from the deeper sea in the central part of Taiwan Strait and the local waves generated directly by the wind. The wave height is proportional to the square root of the sum of energies from refracted and local wave.

Fig.1 Wind and wave situation in the winter

Fig.2 Relationship between  $k$  and  $n$

From such an assumption the wave height probability distribution was to be worked out as follows :

$$\psi(H) = \frac{H}{a-b} \left[ \exp\left(-\frac{H^2}{2a}\right) - \exp\left(-\frac{H^2}{2b}\right) \right] \quad (1)$$

where  $a$  : energy of the refracted waves,  $a = 4 \sigma_1^2$   
 $b$  : energy of the local waves,  $b = 4 \sigma_2^2$   
 $\psi(\cdot)$  : probability density function  
 $H$  : wave height  
 $\sigma_{1,2}^2$  : area under the wave spectral density function curve, subscript 1, 2 denote the refracted and local wave respectively.

The ratio between the mean wave height  $\bar{H}$  and the combined energy  $\sigma$  is

$$k = \frac{\bar{H}}{\sigma} = \sqrt{2\pi} \cdot \frac{1 - n^{3/2}}{(1-n)\sqrt{1+n}} \quad (2)$$

where  $\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$ ,  $n = \frac{b}{a} = \left(\frac{\sigma_2}{\sigma_1}\right)^2$

when  $n \rightarrow 0$ , it means that no local wave existing,  $k = \sqrt{2\pi}$ , as shown in Fig.2.

Above equation fits the reality better than Rayleigh's distribution in comparison with the measured data as shown in Fig.3.

#### Modification of The Model

In navigation and engineering practice, the wave height distribution must be predicted in advance of operation and being much more accurate is required.

In equation(1), the ratio of  $\sigma_1$  and  $\sigma_2$  is to alter the steepness and location of the peak of the curve sensitively. In addition, the wave energy dissipation should also be taken into consideration.

Denoting  $E_1$ ,  $E_2$  to be the wave energy of refracted and local wave respectively, considering the energy dissipation, the total wave energy  $E$  at the location of interest is assumed to be the following linear combination.

$$E = r E_1 + c r E_2 ; 0 < r \leq 1, c > 0, c r \leq 1 \quad (3)$$

From probability transform and convolution integration operations the revision of equation(1) is worked out as follows :

$$\psi(H) = \frac{H}{r(a-cb)} \left[ \exp\left(-\frac{H^2}{2ra}\right) - \exp\left(-\frac{H^2}{2crb}\right) \right] \quad (4)$$

The expected value namely the average wave height and the variance, can be calculated respectively as

$$\bar{H} = \sqrt{\frac{\pi}{2}} \cdot \frac{r^{1/2}}{a-cb} \left[ a^{3/2} - (cb)^{3/2} \right] \quad (5)$$

$$\sigma_H^2 = 2r(a+cb) - \frac{\pi r}{(a-cb)^2} \left[ \frac{a^3 + c^3 b^3}{2} - (cab)^{3/2} \right] \quad (6)$$

Fig.3 New probability density curve and measured data

The skewness and kurtosis of the curve are also to be evaluated as follows.  
Skewness :

$$\sqrt{\beta_1} = \frac{1}{\left\{ 2(a+cb) - \frac{\pi}{(a-cb)^2} \left[ \frac{a^3+c^3b^3}{2} - (c \cdot a \cdot b)^{3/2} \right] \right\}^{3/2}} \cdot \frac{\sqrt{\pi/2}}{a-cb} \cdot \left\{ 3 \left[ a^{5/2} - (cb)^{5/2} \right] - 6(a+cb) \left[ a^{3/2} - (cb)^{3/2} \right] + \frac{\pi}{(a-cb)^2} \left[ a^{3/2} - (cb)^{3/2} \right]^3 \right\} \quad (7)$$

Kurtosis :

$$\beta_2 = \gamma^{-3} = \frac{1}{\left\{ 2(a+cb) - \frac{\pi}{(a-cb)^2} \left[ \frac{a^3+c^3b^3}{2} - (cab)^{3/2} \right] \right\}^2} \cdot \left\{ 8(a^2+cab+c^2b^2) - \frac{6\pi}{(a-cb)^2} \left[ a^{3/2} - (cb)^{3/2} \right] \cdot \left[ a^{5/2} - (cb)^{5/2} \right] + \frac{6\pi(a+cb)}{(a-cb)^2} \left[ a^{3/2} - (cb)^{3/2} \right]^2 - \frac{3\pi^2}{4(a-cb)^4} \left[ a^{3/2} - (cb)^{3/2} \right]^4 \right\} - 3 \quad (8)$$

And the ratio k becomes

$$k = \frac{\sqrt{2\pi} \left[ 1 - (cn)^{3/2} \right]}{(1-cn)\sqrt{1+cn}} \quad (9)$$

For evaluating the influence of coefficients k, r, c, on the shape of the curves, several calculations are made and illustrated in Figures 4, 5, 6.

These coefficients, however, should be determined by calculations of refraction effect, friction of sea bottom as well as wave-wave interaction. Such computations are too complicate to be done. Besides, the theories have not yet fully developed. Approximate evaluations are to be carried out by comparing calculated curve and measured data as shown in Fig.7.

Through these comparison, coefficient r, which represent the ratio of remainder of energy after dissipation, should be taken to be 0.95, and the coefficient c, which denotes the ratio of energy loss of refracted and local waves is of minor significant, so it can be consider as unity. The coefficient k, its definition is shown in equation(2)and(9), is merely the function of the ratio of local wind wave energy and the refracted wave, which will depend on the weather situation and can not be decided in advance and will not be a constant. The probability density function is as follows in consequence.

$$f(H) = \frac{H}{0.95(a-b)} \left[ \exp\left(-\frac{H^2}{1.9a}\right) - \exp\left(-\frac{H^2}{1.9b}\right) \right] \quad (10)$$

Prediction Procedure

If the weather forecasting data are available, the waves and wave height distribution off the western coast of Taiwan are to be forecasted as follows.

Fig.4 Coefficient k influences the shape of distribution (1)

Fig.4 Coefficient k influences the shape of distribution (2)

Fig.5 Coefficient r influences the shape of distribution(1)

Fig.5 Coefficient r influences the shape of distribution(2)

Fig.6 Coefficient c influences the shape of distribution(1)

Fig.6 Coefficient c influences the shape of distribution(2)

Fig.7 The measured data and the new distribution curve in comparison to Rayleigh's

Waves come from the East China Sea and Taiwan Strait are evaluated by Liang's (1976) element wave prediction model

$$E_I = \frac{2}{\pi G} \int_r \int_\theta \bar{\xi}(r, \theta) \bar{U}^2(r, \theta) \cos^2[\beta(r, \theta)] \cdot \exp\left(-\frac{0.08 r}{\bar{U}^2}\right) dr d\theta \quad (11)$$

- $E_I$  : wave energy in the point of interest.
- $G$  : group velocity
- $\bar{U}(r, \theta)$  : wind velocity at 10 meters above sea level.
- $\beta(r, \theta)$  : the angle between the wind direction and the line.

Such definitions are illustrated in Fig.8.

In practical calculations,  $\bar{\xi}$  can set to be constant.  $H_{1/3,1}^2$  is to replace  $E_I$  and  $T_{1/3,1}$  can calculated from fetch and wind velocity.

$$H_{1/3,1}^2 = \frac{2\bar{\xi}}{\pi G_{1/3}} \sum_r \sum_\theta \bar{U}^2(r, \theta) \cos^2[\beta(r, \theta) \exp\left(-\frac{0.08 r}{\bar{U}^2}\right) \Delta r \Delta \theta \quad (12)$$

$$T_{1/3,1} = \frac{0.0552 \cdot \pi \cdot \bar{U}}{g} \left(\frac{g F}{\bar{U}^2}\right)^{0.3269} \quad (13)$$

The local wave height  $H_{1/3,2}$  and period  $T_{1/3,2}$  are to be computed by following formula ( Tang, 1970 )

$$H_{1/3,2} = \frac{0.26 U^2}{g} \tanh\left\{0.578 \left(\frac{g D}{U^2}\right)^{3/4}\right\} \tanh\left\{\frac{0.01 \left(\frac{g F}{U}\right)^{1/2}}{\tanh\left[0.578 \left(\frac{g D}{U^2}\right)^{3/4}\right]}\right\} \quad (14)$$

$$T_{1/3,2} = \frac{2.8 \pi U}{g} \tanh\left\{0.52 \left(\frac{g D}{U^2}\right)^{3/8}\right\} \tanh\left\{\frac{0.0436 \left(\frac{g F}{U^2}\right)^{1/3}}{\tanh\left[0.52 \left(\frac{g D}{U^2}\right)^{3/8}\right]}\right\} \quad (15)$$

- where  $U$  : local wind velocity
- $g$  : gravitational acceleration
- $D$  : water depth
- $F$  : fetch length

The wave height  $H_{1/3}$  can be calculated by

$$H_{1/3} = \sqrt{r H_{1/3,1}^2 + c \cdot r \cdot H_{1/3,2}^2} \quad (16)$$

According to Liang (1982) the period in this case can be calculated as follows

$$T_{1/3} = \frac{H_{1/3,1}^2 \times T_{1/3,1} + H_{1/3,2}^2 \times T_{1/3,2}}{H_{1/3,1}^2 + H_{1/3,2}^2} \quad (17)$$

Examples of such prediction are shown in Fig.9

Finally, since

$$a = 4 \sigma_1^2 = 4 \left(\frac{H_{1/3,1}}{3.8}\right)^2 \quad (18)$$

Fig. 8 Illustration of element wave method

Fig.9 Results of wave prediction (1)

Fig.9 Results of wave prediction (2)

Fig. 10 Predicted wave height distribution

$$b = 4 \sigma_2^2 = 4 \left( \frac{H_{1/3, 2}}{3.8} \right)^2 \quad (19)$$

after substitute into equation(10), the wave height distribution can be predicted as Fig.10.

#### Conclusion

The wave height distribution of the waves generated by monsoon is to be predicted by following procedure.

1. Calculate the waves by element wave prediction method from weather data.
2. Calculate local waves by empirical formulas.
3. Add wave energies linearly but the coefficient of energy remainder is considered.
4. Calculate a and b by equations (18) and (19)
5. Substitute a, b to equation (10), the probability density equation is obtained.

These distribution model only can be applied in monsoon season, because the wind direction remains to be constant and the waves are moderate. Navigation and offshore engineering activities have to be done if the probability of waves exceeding certain height is negligible. However, during typhoon assailing, wave directions change frequently, navigation should be stop and no engineering work would take place. Neither the necessary to predict the probability of wave height nor the above model can be applied in such a case.

If the bathymetry and climate situation are similar to the offing of western coast of Taiwan, namely the sea bottom shoals gradually and the wind direction along the shore such as the southern part of German bight, this model might be adoptable.

## CHAPTER THIRTY TWO

### METHOD FOR ESTIMATING DIRECTIONAL WAVE SPECTRUM IN INCIDENT AND REFLECTED WAVE FIELD

by

Masahiko Isobe\* and Kosuke Kondo\*\*

#### ABSTRACT

The relationship between the directional spectrum and the cross-power spectra in an incident and reflected wave field differs from the situation with no reflected waves because the phase lag between the incident and reflected waves is not random. Extra terms, which may be called phase interaction terms, exist. Hence standard methods for estimating the directional spectrum are not applicable. In the present study, the MLM is modified for this situation and the method is termed the MMLM (Modified Maximum Likelihood Method).

The validity of the MMLM is examined by numerical simulation. The results indicate that the MMLM has a high resolution power. Formulas to determine the reflection coefficient are derived and their accuracy and suitability are examined.

#### 1. INTRODUCTION

This paper describes a method to measure the directional spectrum in an incident and reflected wave field and to determine the reflection coefficient of a structure in a directional sea. The directional spectrum represents the energy distribution in wave direction, so that in principle the incident and reflected wave energies can be separated by measuring the directional spectrum near a structure and then the reflection coefficient can be determined. However, standard methods of estimating the directional spectrum are not valid because the phase lag between the incident and reflected waves is not random. Therefore, these methods should be modified for application in such a situation.

Many methods have been proposed for directional spectrum estimation. These are the DFT method (Direct Fourier Transform Method; Barber, 1963), parametric methods (Longuet-Higgins et al., 1963; Panicker and Borgman, 1974), the MLM (Maximum Likelihood Method; Capon,

1969), and others. Of all the proposed methods of calculation, the MLM has the highest resolution power, so that it is favorable to use to separate the incident and reflected wave energies. Therefore, in the present study, the MLM is modified to estimate the directional spectrum in an incident and reflected wave field.

Numerical simulations were carried out to examine the validity of the MMLM. By this means, accuracies of various formulas to determine the reflection coefficient could be examined.

The MLM was originally applicable only to wave gage arrays, but recently it has been extended for use with mixed gage arrays such as a pitch-roll buoy system, a clover-leaf buoy system, a wave gage plus current meter system, and so on (Isobe et al., 1984; Oltman-Shay and Guza, 1984). Hence it is also possible to extend the present method to mixed measuring systems.

## 2. DERIVATION OF MMLM

### 2.1 Relationship between Directional Spectrum and Cross-Power Spectra

Suppose that the wave amplitude is small, and that the water surface elevation can be expressed as the superposition of component waves with wavenumber (vector),  $\mathbf{k}$ , and angular frequency,  $\sigma$ . The water surface elevation due to the incident waves,  $\eta_i$ , at the point,  $\mathbf{x}$ , and the time,  $t$ , can be expressed as:

$$\eta_i(\mathbf{x}, t) = \int_{\sigma} \int_{\mathbf{k}} e^{i(\mathbf{k}\mathbf{x} - \sigma t)} Z(d\mathbf{k}, d\sigma) \quad (1)$$

This was called the spectral representation by Koopmans (1974). From the physical point of view,  $Z(d\mathbf{k}, d\sigma)$  means the amplitude which represents the energy within  $[\mathbf{k}, \mathbf{k} + d\mathbf{k}]$  and  $[\sigma, \sigma + d\sigma]$ . The quantity  $Z$  is a complex number. The absolute value of  $Z$  gives the amplitude of the component waves and the argument gives the phase at  $\mathbf{x} = \mathbf{0}$  and  $t = 0$ . Since the phase lag between different wave components can be assumed to be random,  $Z(d\mathbf{k}, d\sigma)$  and  $Z(d\mathbf{k}', d\sigma')$  are independent for  $\mathbf{k} \neq \mathbf{k}'$ , i.e.,

$$\langle Z(d\mathbf{k}, d\sigma) Z^*(d\mathbf{k}', d\sigma') \rangle = 0 \quad (\mathbf{k} \neq \mathbf{k}') \quad (2)$$

where the symbol  $\langle \rangle$  denotes the ensemble mean. The wavenumber-frequency spectrum,  $S(\mathbf{k}, \sigma)$ , represents the power density (square of the amplitude), and is therefore defined as:

$$\langle Z(d\mathbf{k}, d\sigma) Z^*(d\mathbf{k}, d\sigma) \rangle = S(\mathbf{k}, \sigma) d\mathbf{k} d\sigma \quad (3)$$

where the symbol  $*$  denotes the complex conjugate. The wavenumber vector,  $\mathbf{k}$ , is expressed by the wavenumber,  $k$ , and the wave propagation direction,  $\theta$ . Hence, the wavenumber-frequency spectrum is a function of  $k$ ,  $\theta$ , and  $\sigma$ . For water surface waves, since  $k$  is uniquely determined from  $\sigma$  by the dispersion relation, the spectrum becomes a function of  $\theta$  and  $\sigma$  and is called directional spectrum.

As shown in Fig. 1, if waves are reflected at the y-axis, the water surface elevation due to the reflected waves,  $\eta_r$ , can be expressed as:

$$\eta_r(\mathbf{x}, t) = \int_{\sigma} \int_{\mathbf{k}} r e^{i(\mathbf{k}_r \mathbf{x} - \sigma t)} Z(d\mathbf{k}, d\sigma) \quad (4)$$

where  $\mathbf{k}_r$  denotes the vector symmetrical to  $\mathbf{k}$  with respect to the reflection line, and  $r$  is the reflection coefficient which can be a function of  $\mathbf{k}$  and/or  $\sigma$ . Even though the amplitude of the reflected waves may change by the factor  $r$ , the phase on the reflection line is the same as that of the corresponding incident waves. Therefore the phase lag between the incident and reflected waves is not random. Let  $\mathbf{x}_r$  be the vector symmetrical to  $\mathbf{x}$ , then Eq. (4) can be written as:

$$\eta_r(\mathbf{x}, t) = \int_{\sigma} \int_{\mathbf{k}} r e^{i(\mathbf{k} \mathbf{x}_r - \sigma t)} Z(d\mathbf{k}, d\sigma) \quad (5)$$

From Eqs. (1) and (5), the total water surface elevation,  $\eta = \eta_i + \eta_r$ , can be expressed as:

$$\eta(\mathbf{x}, t) = \int_{\sigma} \int_{\mathbf{k}} [ e^{i(\mathbf{k} \mathbf{x} - \sigma t)} + r e^{i(\mathbf{k} \mathbf{x}_r - \sigma t)} ] Z(d\mathbf{k}, d\sigma) \quad (6)$$

Thus the complex amplitude,  $X(\mathbf{x}, d\sigma)$ , which represents the energy in  $[\sigma, \sigma + d\sigma]$  at the point  $\mathbf{x}$ , becomes

$$X(\mathbf{x}, d\sigma) = \int_{\mathbf{k}} [ e^{-i\mathbf{k} \mathbf{x}} + r e^{-i\mathbf{k} \mathbf{x}_r} ] Z^*(d\mathbf{k}, d\sigma) \quad (7)$$

The cross-power spectrum,  $\Phi_{mn}(\sigma)$ , between the water surface elevations at  $\mathbf{x} = \mathbf{x}_m$  and  $\mathbf{x} = \mathbf{x}_n$  is defined as the ensemble mean of the product of the complex amplitude,  $X(\mathbf{x}_m, d\sigma)$ , the the complex conjugate amplitude,  $X^*(\mathbf{x}_n, d\sigma)$ . That is,

$$\Phi_{mn}(\sigma) d\sigma = \langle X^*(\mathbf{x}_n, d\sigma) X(\mathbf{x}_m, d\sigma) \rangle \quad (8)$$

If  $m = n$ , then  $\Phi_{mn}(\sigma)$  represents the power spectrum, and if  $m \neq n$ ,  $\Phi_{mn}(\sigma)$  represents the cross spectrum. Substitution of Eq. (7) into Eq. (8) yields

$$\begin{aligned} \Phi_{mn}(\sigma) d\sigma = \int_{\mathbf{k}} \int_{\mathbf{k}'} [ e^{i\mathbf{k} \mathbf{x}_m + r e^{i\mathbf{k} \mathbf{x}_m}} ] [ e^{-i\mathbf{k}' \mathbf{x}_n + r e^{-i\mathbf{k}' \mathbf{x}_n}} ] \\ \times \langle Z(d\mathbf{k}, d\sigma) Z^*(d\mathbf{k}', d\sigma) \rangle \end{aligned} \quad (9)$$

From Eqs. (2) and (3), Eq. (9) becomes

$$\Phi_{mn}(\sigma) = \int_{\mathbf{k}} [ e^{i\mathbf{k} \mathbf{x}_m + r e^{i\mathbf{k} \mathbf{x}_m}} ] [ e^{-i\mathbf{k} \mathbf{x}_n + r e^{-i\mathbf{k} \mathbf{x}_n}} ] S(\mathbf{k}, \sigma) d\mathbf{k} \quad (10)$$

This is the relationship between the wavenumber-frequency (or directional) spectrum and the cross-power spectrum in an incident and reflected wave field and will be used to derive the basic formula for

Fig. 1 Definition sketch of incident and reflected wave field.

Fig. 2 Co-spectrum for Mitsuyasu-type directional distribution functions.

Fig. 3 Result of directional spectrum estimation by the standard MLM in incident and reflected wave field.

estimating the directional spectrum. The product of the first terms in the two brackets in Eq. (10) represents the incident wave component and the product of the second terms represents the reflected wave component. The other two products are extra terms describing the interaction of the incident and reflected wave fields. Since these terms appear because the phase lag between the incident and reflected waves is not random, they may be called phase interaction terms.

2.2 Magnitude of Phase Interaction Contribution

Before proceeding to the discussion of the directional spectrum estimation, it is worth examining the relative magnitude of the phase interaction terms. Any combination of terms in the brackets in Eq. (10) has the following form:

$$\phi(\mathbf{X}) = \int_{\mathbf{k}} e^{-i\mathbf{k}\mathbf{X}} S(\mathbf{k},\sigma) d\mathbf{k} \tag{11}$$

Mitsuyasu et al. (1974) proposed a standard directional distribution function with two parameters,  $\theta_0$  and  $s$ , as:

$$S(\mathbf{k},\sigma) = \left[ \cos \frac{\theta - \theta_0}{2} \right]^{2s} \tag{12}$$

If Eq. (12) is substituted into Eq. (11), the following result can be obtained after some manipulation:

$$\frac{c(\mathbf{X})}{c(\mathbf{0})} = J_0(kR) + 2 \sum_{l=1}^{[[s/2]]} (-1)^l \left[ \frac{s!}{(s-2l)!} \right] \left[ \frac{s!}{(s+2l)!} \right] \times J_{2l}(kR) \cos\{2l(\theta_0 - \theta)\} \tag{13}$$

$$\frac{q(\mathbf{X})}{c(\mathbf{0})} = 2 \sum_{l=0}^{[(s-1)/2]} (-1)^l \left[ \frac{s!}{(s-2l-1)!} \right] \left[ \frac{s!}{(s+2l+1)!} \right] \times J_{2l+1}(kR) \cos\{(2l+1)(\theta_0 - \theta)\} \tag{14}$$

where  $[[x]]$  denotes the maximum integer not larger than  $x$ ,  $J_n$  is a Bessel function of the  $n$ 'th order, and  $c$  and  $q$  are the co- and quadrature-spectra:

$$\phi(\mathbf{X}) = c(\mathbf{X}) - iq(\mathbf{X}) \tag{15}$$

and

$$\mathbf{X} = (R \cos\theta, R \sin\theta) \tag{16}$$

Figure 2 shows the relative co-spectrum as a function of relative distance  $R/L$  ( $L$ : wave length) for  $\delta = \theta_0 - \theta = 0^\circ$  and  $30^\circ$ . For the quadrature-spectrum, the shapes of the curves are similar to the co-spectrum, but the maximum and minimum occur at the zero-crossing points of the co-spectrum. Thus the amplitude of  $\phi$  becomes the envelope of the curve. Therefore, the relative magnitude of  $\phi$  is small for large

relative distance, unless the directional distribution is very narrow ( $s$  is large) and the principal direction almost coincides with the direction of the distance vector ( $\theta = \theta_0$ ).

For the phase interaction terms, we have  $\mathbf{X} = \mathbf{x}_{nr} - \mathbf{x}_m$ ,  $\mathbf{x}_n - \mathbf{x}_{mr}$ , so that  $R$  becomes about twice the distance between the measuring point and the reflection line. Hence the phase interaction terms generally become small if the wave gage array is located far from the reflection line. Therefore, if the structure is long enough, the incident and reflected directional spectrum can be observed in the far field by applying the standard methods of estimation.

Figure 3 is an example of a numerical simulation which shows the effect of the phase interaction terms. The peak incident wave direction is  $150^\circ$  and the reflection coefficient is 1, so that a spectral peak due to reflected waves appears at  $\theta = 30^\circ$ . The separation distance in the 3-sensor linear wave gage array are  $0.2L$  and  $0.4L$ . The estimated directional spectra by the standard MLM are shown by the dashed lines for the cases that the distances between the nearest wave gage and the reflection line are  $0$ ,  $L$ ,  $2L$ , and  $\infty$ . The accuracy becomes higher as the distance increases. This is because the phase interaction terms become small. However, a 3-sensor array may not be sufficient to measure a bimodal directional spectrum.

### 2.3 Formula for Estimating the Directional Spectrum

In this subsection a formula for estimating the directional spectrum is derived from the relationship between the directional spectrum and the cross-power spectra, as given by Eq. (10). The maximum likelihood technique is used and the process is similar to that given by Davis and Regier (1977), and Isobe et al. (1984).

Let

$$\gamma_{on}(\mathbf{k}) = e^{-i\mathbf{k}\cdot\mathbf{x}_{om}} + r e^{-i\mathbf{k}\cdot\mathbf{x}_{mr}} \quad (17)$$

and

$$T_{mn}(\mathbf{k}) = \gamma_{on}^*(\mathbf{k}) \gamma_{on}(\mathbf{k}) \quad (18)$$

Then Eq. (10) can be rewritten as follows:

$$\phi_{mn}(\sigma) = \int_{\mathbf{k}'} T_{mn}(\mathbf{k}') S(\mathbf{k}', \sigma) d\mathbf{k}' \quad (19)$$

In general, the estimated wavenumber-frequency spectrum, denoted with a caret as  $\hat{S}(\mathbf{k}, \sigma)$ , can be formally expressed as a linear combination of the known cross-power spectra:

$$\hat{S}(\mathbf{k}, \sigma) = \sum_m \sum_n \alpha_{mn}(\mathbf{k}) \phi_{mn}(\sigma) \quad (20)$$

where  $\Sigma$  means a summation over all measuring points and the  $\alpha_{mn}(\mathbf{k})$  are coefficients. Then, substitution of Eq. (19) into Eq. (20) yields

$$\hat{S}(\mathbf{k}, \sigma) = \int_{\mathbf{k}'} S(\mathbf{k}', \sigma) w(\mathbf{k}, \mathbf{k}') d\mathbf{k}' \tag{21}$$

where

$$w(\mathbf{k}, \mathbf{k}') = \sum_m \sum_n \alpha_{mn}(\mathbf{k}) T_{mn}(\mathbf{k}') \tag{22}$$

Equation (21) indicates that the estimated wavenumber-frequency spectrum is a convolution of the true wavenumber-frequency spectrum and the window function,  $w(\mathbf{k}, \mathbf{k}')$ , which is expressed by Eq. (22).

Now  $\alpha_{mn}$  is assumed to be of factorable form as

$$\alpha_{mn}(\mathbf{k}) = \gamma_m(\mathbf{k}) \gamma_n^*(\mathbf{k}) \tag{23}$$

Then Eqs. (20) and (22) become

$$\hat{S}(\mathbf{k}, \sigma) = \sum_m \sum_n \gamma_m(\mathbf{k}) \phi_{mn}(\sigma) \gamma_n^*(\mathbf{k}) \tag{24}$$

and

$$w(\mathbf{k}, \mathbf{k}') = \sum_m \sum_n \gamma_m(\mathbf{k}) T_{mn}(\mathbf{k}') \gamma_n^*(\mathbf{k}) \tag{25}$$

Substitution of Eq. (18) into (25) yields

$$w(\mathbf{k}, \mathbf{k}') = \left| \sum_m \gamma_m(\mathbf{k}) \gamma_{\text{cm}}^*(\mathbf{k}') \right|^2 \tag{26}$$

which shows the value of the window function is non-negative. Then the estimated directional spectrum is always non-negative because the integrand in Eq. (21) is non-negative.

The window function is normalized by putting

$$w(\mathbf{k}, \mathbf{k}) = 1 \tag{27}$$

In order for  $\hat{S}(\mathbf{k}, \sigma)$  to closely approximate  $S(\mathbf{k}, \sigma)$ , it is seen from Eq. (21) that  $w(\mathbf{k}, \mathbf{k}')$  should approach the Dirac delta function as closely as possible. Since  $S(\mathbf{k}, \sigma)$  and  $w(\mathbf{k}, \mathbf{k}')$  in Eq. (21) are non-negative, this can be attained by minimizing the value of  $\hat{S}(\mathbf{k}, \sigma)$ :

$$\hat{S}(\mathbf{k}, \sigma) \rightarrow \min. \tag{28}$$

From Eqs. (24), (25), (27), and (28), this problem becomes as follows:

$$\frac{\sum_m \sum_n \gamma_m(\mathbf{k}) T_{mn}(\mathbf{k}) \gamma_n^*(\mathbf{k})}{\sum_m \sum_n \gamma_m(\mathbf{k}) \phi_{mn}(\sigma) \gamma_n^*(\mathbf{k})} \rightarrow \max. \tag{29}$$

This is equivalent to the problem of finding the maximum eigenvalue for given matrices,  $\phi_{mn}$  and  $T_{mn}$  such that

$$\sum_n T_{mn} \gamma_n^* = \lambda \sum_n \phi_{mn} \gamma_n^* \tag{30}$$

and hence

$$\sum_m \sum_n \phi_{lm}^{-1} T_{mn} \gamma_n^* = \lambda \gamma_l^* \tag{31}$$

where  $\phi_{lm}^{-1}$  is the inverse matrix of  $\phi_{lm}$ . From Eq. (29), the maximum eigenvalue,  $\lambda_{max}$ , is inversely proportional to the estimated directional spectrum:

$$\hat{S}(k, \sigma) \propto 1/\lambda_{max} \tag{32}$$

It can be seen from Eq. (18) that any vector orthogonal to  $\gamma_{0n}$  is an eigenvector with eigenvalue  $\lambda = 0$  in Eq. (31). Hence the only possible choice of  $\gamma_n$  for a positive eigenvalue is of the form

$$\gamma_n = \gamma_{0n} + \gamma_{0n}^\perp \tag{33}$$

where  $\gamma_{0n}^\perp$  is a vector orthogonal to  $\gamma_{0n}$ . If Eqs. (18) and (33) are substituted into Eq. (31) and then multiplied with  $\gamma_{0l}$  from the left, the maximum eigenvalue,  $\lambda_{max}$ , can be obtained as

$$\lambda_{max} = \sum_m \sum_n \gamma_{0m} \phi_{mn}^{-1} \gamma_{0n}^* \tag{34}$$

As seen from Eq. (17),  $\lambda_{max}$  is a function of  $r$ . In order to determine the value of  $r$ , a relationship which is strictly satisfied in the uni-directional case was derived. That is

$$d\lambda_{max} / dr = 0 \tag{35}$$

This relationship is assumed to be valid in a general case and then substitution of Eq. (17) and (34) into Eq. (35) yields

$$r_0 = - \frac{\sum_m \sum_n \phi_{mn}^{-1}(\sigma) [ e^{ik(x_n - x_{nr})} + e^{ik(x_{nr} - x_n)} ]}{2 \sum_m \sum_n \phi_{mn}^{-1}(\sigma) e^{ik(x_{nr} - x_{nr})}} \tag{36}$$

Since the value of the reflection coefficient is non-negative the estimated reflection coefficient becomes

$$\hat{r} = \begin{cases} 0 & (r_0 \leq 0) \\ r_0 & (r_0 > 0) \end{cases} \tag{37}$$

Finally, from Eqs. (17), (32), (34), and (37), the estimated directional spectrum becomes as follows:

$$\hat{S}(\mathbf{k}, \sigma) = \begin{cases} \kappa / \left[ \sum_m \sum_n \Phi_{mn}^{-1}(\sigma) e^{i\mathbf{k}(\mathbf{x}_n - \mathbf{x}_m)} \right] & (r_0 \leq 0) \\ \kappa / \left[ \sum_m \sum_n \Phi_{mn}^{-1}(\sigma) e^{i\mathbf{k}(\mathbf{x}_n - \mathbf{x}_m)} \right. \\ \left. - \frac{\left\{ \sum_m \sum_n \Phi_{mn}^{-1}(\sigma) \left[ e^{i\mathbf{k}(\mathbf{x}_n - \mathbf{x}_{nr})} + e^{i\mathbf{k}(\mathbf{x}_{nr} - \mathbf{x}_m)} \right] \right\}^2}{4 \sum_m \sum_n \Phi_{mn}^{-1}(\sigma) e^{i\mathbf{k}(\mathbf{x}_{nr} - \mathbf{x}_{mr})}} \right] & (r_0 > 0) \end{cases} \quad (38)$$

where  $\kappa$  is a proportionality constant which can be determined from the relationship between the directional spectrum and the power spectrum. This relationship can be obtained by putting  $m = n$  in Eq. (10). The result is

$$\Phi_{mn}(\sigma) = \int_{\mathbf{k}_i} \left[ \hat{S}(\mathbf{k}_i, \sigma) + 2 \sqrt{\hat{S}(\mathbf{k}_i, \sigma) \hat{S}(\mathbf{k}_r, \sigma)} \cos \mathbf{k}_i(\mathbf{x}_m - \mathbf{x}_{nr}) + \hat{S}(\mathbf{k}_r, \sigma) \right] d\mathbf{k}_i \quad (39)$$

where  $\mathbf{k}_i$  represents the wavenumber vector within the incident wave direction and  $\mathbf{k}_r$  is the reflected wavenumber vector corresponding to  $\mathbf{k}_i$ . The symbol  $\hat{S}(\mathbf{k}_r, \sigma) = r^2 \hat{S}(\mathbf{k}_i, \sigma)$  represents the reflected wave spectrum. If Eq. (38) is substituted into Eq. (39), the equation for determining the value of  $\kappa$  can be obtained for each measuring point. Hence  $\kappa$  can be obtained by the least square method.

Equation (38) was derived by modifying the standard MLM for use in an incident and reflected wave field. Therefore, the present method is named the MMLM (Modifiend Maximum Likelihood Method).

The procedure for calculating the directional spectrum by the MMLM is summarized as follows:

- 1) For a given data set, compute the cross-power spectra,  $\Phi_{mn}(\sigma)$ , for all possible combinations.
- 2) For a fixed value of  $\sigma$ , determine  $k$  from the dispersion relation and the compute the directional spectrum by using Eq. (38), except for  $\kappa$ . The computation range of the wave direction includes both the incident and reflected wave directions.
- 3) Determine the value of  $\kappa$  from Eq. (39); then the directional spectrum is completely determined by Eq. (38).

### 3. NUMERICAL SIMULATION

#### 3.1 Procedure of Numerical Simulations

Numerical simulations were performed to examine the validity of the MMLM. The procedure is similar to the one used for examining the EMLM (Isobe et al., 1984). Since from the theoretical viewpoint the energies distributed among the wave frequency can be separated by cross-power spectral analysis, the directional spectrum is described as a function of only the wave direction,  $\theta$ .

The procedure for the numerical simulation is as follows:

- 1) Specify a functional form for the directional spectrum,  $S_{\theta}(\theta)$ , and reflection coefficient,  $r(\theta)$ . Here, the Mitsuyasu-type directional distribution expressed by Eq. (12) is used. To fabricate a bimodal distribution, two Mitsuyasu-type distribution functions with different  $\theta_0$  and  $s$  are superimposed.
- 2) Calculate  $\phi_{mn}$  for a given wave gage array from Eq. (10). For the power spectra,  $\phi_{mm}$ , a fraction of the total incident wave energy is added as a noise component.
- 3) Calculate  $\hat{S}_{\theta}(\theta)$  from Eq. (38) and compare to  $S_{\theta}(\theta)$ .

#### 3.2 Results

Figure 4 shows an example of the numerical simulation. A 3-sensor linear wave gage array in which the gages are set at  $(x, y) = (0.2L, 0)$ ,  $(0.4L, 0)$ ,  $(0.8L, 0)$  is used. This arrangement is the same as in Fig. 3. For all the figures in this paper, the reflection line coincides with the  $y$ -axis. The solid line represents the true (given) directional spectrum. The peak direction of the incident waves is  $150^\circ$  and the reflection coefficient is 1, so that the spectral peak due to the reflected waves appears at  $\theta = 30^\circ$ . The estimated results are shown for various values of  $\epsilon$ , the ratio of the noise power to the total incident wave energy. The resolution power decreases with increasing noise component; however, the MMLM has higher resolution power than the (standard) MLM for the same amount of noise (cf. Fig. 3).

Numerical simulations were carried out for a wide range of wave gage arrangements in order to study adequate arrangements. Results were similar to the case of the standard MLM. The minimum and maximum distance between wave gages should be about  $0.2L$  and  $1.5L$ . As can be seen from Fig. 5, the resolution power increases as the number of wave gages increases. The detailed shape of the array does not influence the result very much. This is quite different from the DFT method.

Figure 6 shows one problem in the MMLM. If the wave gages are located far from the reflection line, spurious peaks can appear in the estimated spectrum, as shown in the figure. This occurs when the modes of the standing waves at the measuring points are the same for the true and spurious peak direction. It should be possible to remove these false peaks after calculation, since they are always very sharp and recognizable. If one wave gage is located within  $0.2L$  from the

Fig. 4 Influence of noise on the resolution power of the MMLM.

Fig. 5 Comparison among true and estimated directional spectra for various wave gage arrays.

Fig. 6 Example of spurious peaks resulting from the MMLM.

reflection line and another one is about  $0.2L$  from the first one, this trouble can be avoided.

From these results, linear arrays in which the distances between the reflection line and the wave gages are  $0.2 l$ ,  $0.4 l$ ,  $0.8 l$ ,  $1.6 l$ , ..... ( $l$  is the minimum wave length to be observed.) can be recommended. However, as will be seen later in Fig. 7(a), a 2-dimensional array is necessary to improve resolution power near the normal direction.

Figure 7 shows the results for various true directional spectra. The numbers of wave gages used are 2, 3, and 4. The array types are linear and the locations of gages are indicated in Fig. 7(a). Figure 7(a) corresponds to normal incidence. Accuracies are not high because the resolution power of the linear array in the array direction is low. A 2-dimensional array is necessary to improve resolution power in this direction. The peak incident wave direction is  $120^\circ$  for Fig. 7(b). Three or four-sensor arrays may have sufficient accuracy. Figure 7(c) shows the results for a uni-directional case. If the noise component is excluded, the estimated spectra should approach the true spectrum. However, since the relative noise amount of 1% was added in the numerical simulation, the resolution power for the smaller number of gages decreases significantly. Figure 7(d) corresponds to a broad spectrum. The estimated spectrum by the 4-sensor array becomes bimodal. In order to avoid this, the distance between the wave gages should be reduced. Figure 7(e) is for the bimodal incident wave spectrum. The 4-sensor array gives an accurate estimation even in this case. The reflection coefficient for Fig. 7(f) is 0.5 and the MLM is valid.

Figure 8 shows the result for a complex situation. The incident directional spectrum is bimodal and the reflection coefficient changes with direction as indicated by the solid line in the lower figure. It can be seen that many wave gages are necessary for this case.

### 3.3 Estimation of Reflection Coefficient

There are several possible ways to estimate the reflection coefficient. Equation (37) gives an estimation of the reflection coefficient at the peak direction,  $\theta_m$ . This can be defined as a representative reflection coefficient, denoted by  $r_m$ :

$$r_m = r(\theta_m) \quad (40)$$

A second definition is as the square root of the ratio between the reflected and incident spectra estimated at the peak direction:

$$r_{sm} = \sqrt{\hat{S}(\theta_{mr}) / \hat{S}(\theta_m)} \quad (41)$$

where  $\theta_{mr}$  is the reflected wave direction corresponding to the incident peak direction. A third definition is as the square root of the ratio between the integrated reflected and incident wave energy:

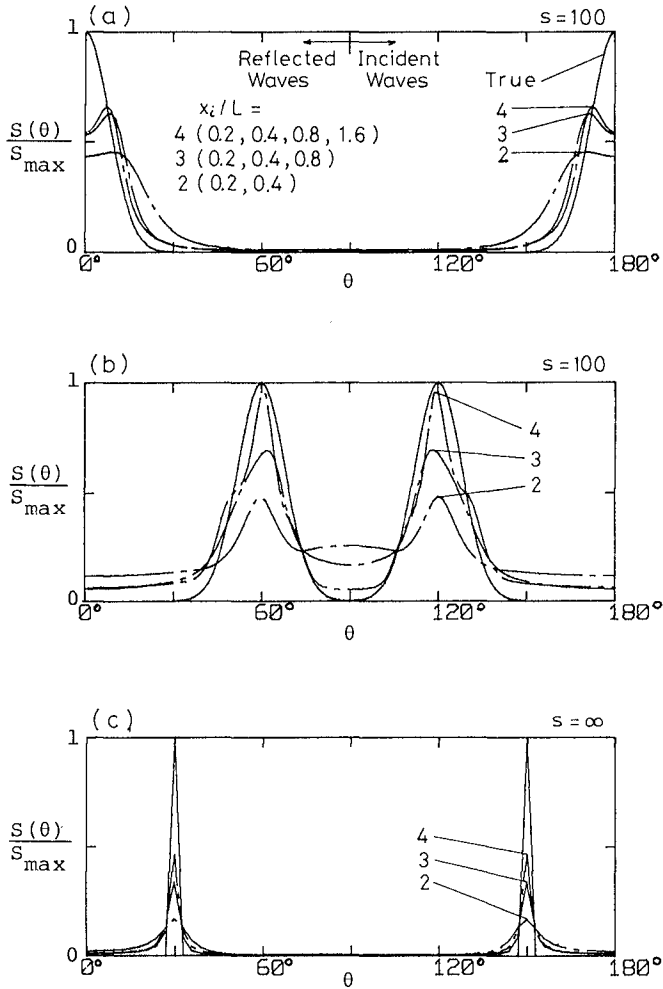

Fig. 7 Comparison among true and estimated directional spectra for various true spectra. (continued)

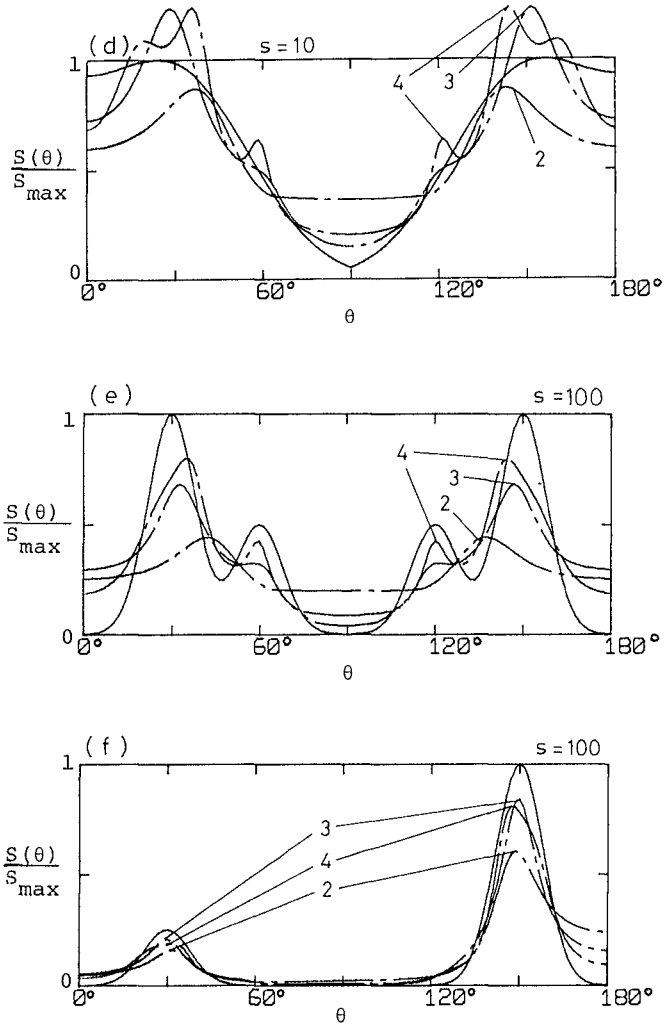

Fig. 7 Comparison among true and estimated directional spectra for various true spectra.

Fig. 8 Comparison among true and estimated directional spectra and reflection coefficients for a complex wave field.

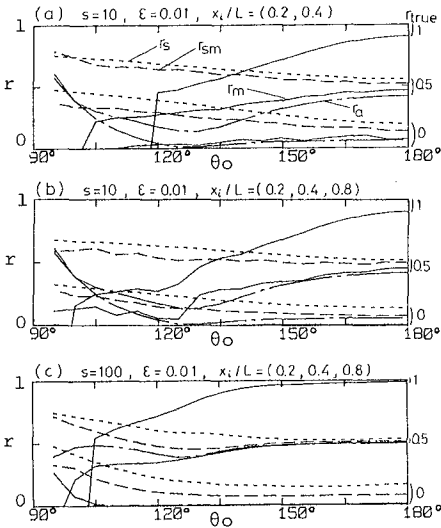

Fig. 9 Comparison among true and estimated reflection coefficients.

$$r_s = \sqrt{\frac{\int_{\text{ref.}} \hat{S}(\theta) d\theta}{\int_{\text{in.}} \hat{S}(\theta) d\theta}} \quad (42)$$

For the uni-directional case, the reflection coefficient can be calculated from data records at two points (Goda and Suzuki, 1976, for example). When the two points are on the x-axis, this can be written by using the results of a spectral analysis as

$$r_a = \sqrt{\frac{1 + c^2 - 2c \cos(kd \cos\theta_0 - \Delta)}{1 + c^2 + 2c \cos(kd \cos\theta_0 - \Delta)}} \quad (43)$$

where  $c$  is the ratio of the power spectra,  $\Delta$  is the phase lag, and  $d$  is the distance between the measuring points.

Figure 9 compares the true and estimated reflection coefficients. The Mitsuyasu-type directional distributions were used with  $s = 10$  for Fig. 9(a) and (b) and  $s = 100$  for Fig. 9(c). For true reflection coefficients of 0, 0.5 and 1, the estimated values are plotted against the peak incident wave direction. The solid, dashed, dotted, and chain lines indicate the values of  $r_m$ ,  $r_{sm}$ ,  $r_s$  and  $r_a$ , respectively. As seen from Fig. 9(a), a 2-sensor array may not be sufficient. If a 3-sensor array is used,  $r_m$  gives a fairly accurate value when the true reflection coefficient is small, whereas  $r_{sm}$  is relatively accurate for large values. However, the error is large when the peak incident direction is nearly parallel to the reflection line.

#### 4. CONCLUSION

In an incident and reflected wave field, extra terms which may be called phase interaction terms, appear in the relationship between the directional spectrum and the cross-power spectrum. If the wave gage array is located near the reflection line, this contribution becomes significant and therefore the standard MLM is not applicable. The MLM was modified for estimating the directional spectrum in such a situation and the method was named the MMLM (Modified Maximum Likelihood Method). The final result is expressed by Eq. (38).

Numerical simulations were carried out to examine the validity of the MMLM. The results demonstrated that the MMLM has high resolution power and can separate incident and reflected wave energies. The resolution power increases with increasing number of wave gages, but the effect of the detailed wave gage arrangement is small. In general, the minimum and maximum distance between the wave gages should be about  $0.2L$  and  $1.5L$ . However, these criteria depend upon the number of gages and the width of the directional distribution. Spurious spectral peaks appear if the wave gages are located far from the reflection line. If the wave gages are located at  $0.2l$ ,  $0.4l$ ,  $0.8l$ ,  $1.6l$ , ... ( $l$  is the minimum wave length to be observed) from the reflection line, the array is effective for wide range of wave length. A 2-dimensional array is necessary to improve the resolution power near the direction normal to the reflection line.

Various formulas to estimate the reflection coefficient were examined. As long as the peak incident wave direction is not coincident with the reflection line, the reflection coefficient,  $r_m$ , determined directly by the MMLM is accurate for small values of the true reflection coefficient, whereas the reflection coefficient determined from the resulting power ratio of the incident and reflected waves,  $r_{sm}$ , is accurate for large values.

## CHAPTER THIRTY THREE

### CALCULATION OF DIRECTIONAL WAVE SPECTRA BY THE MAXIMUM ENTROPY METHOD OF SPECTRAL ANALYSIS

Michael J. Briggs,\* M. ASCE

#### Abstract

Two analysis techniques for calculating directional wave spectra from measured pressure and biaxial current components were inter-compared using data from the 25 October 1980 Atlantic Remote Sensing Land Ocean Experiment (ARSLOE) storm. The two methods are the conventional Fast Fourier Transform (FFT) method and a Maximum Entropy Method (MEM). The MEM is a nonlinear data adaptive method of spectral analysis which is capable of generating higher resolution spectral estimates from shorter data records than conventional FFT methods. The MEM has shown good agreement with the frequency and directional wave spectra calculated using conventional methods.

#### Introduction

The accurate calculation of directional wave spectra is important in the coastal zone for determination of coastal erosion, littoral sediment transport, diffraction and refraction of waves, and interaction with marine structures. One of the top research priorities of the National Research Council's Workshop on Wave Measurement Technology conducted in Washington in 1981 was the development of more efficient analysis techniques for the calculation of directional wave spectra (6). Considerable interest was generated at the ASCE Conference on Directional Wave Spectra Applications held in Berkeley on the Maximum Likelihood Method (MLM) for calculating directional spectra (8). Borgman (1) presented a proposal during the Second Workshop on Maximum Entropy and Bayesian Methods in Applied Statistics for comparisons of directional wave spectra instrument systems and analysis methods. Among the methods discussed were the conventional FFT, MEM, MLM, variational fitting, and linear programming. The four latter methods are all data-adaptive procedures which are capable of generating a higher resolution spectral estimate from shorter data records than conventional FFT methods. The primary objective of this paper is to demonstrate the promise of the MEM as a technique to increase directional resolution in directional wave spectra estimates.

Grosskopf (7) reported the results of an intercomparison of five different measurement systems and analysis techniques for calculating directional wave spectra from data obtained during the ARSLOE

---

\* Coastal Engineer, Coastal Engineering Research Center, US Army Engineer Waterways Experiment Station, Vicksburg, Mississippi.

experiment. The five measurement systems included two pressure/biaxial current meter arrays belonging to the Coastal Engineering Research Center (CERC) and Woods Hole Oceanographic Institution (WHOI), respectively, a Scripps  $S_{xy}$  array, an NHL triaxial current meter array, and a CERC X-Band Surface imaging radar (XERB). In this paper, an intercomparison with the CERC pressure/biaxial current meter (PUV) array is presented. Data representative of storm conditions during 25 October 1980 of the ARSLOE experiment are used.

#### Techniques Used

In 1965 Cooley and Tukey sparked a revival of the Fast Fourier Transform (FFT) which had been known for years but was not practical until the advent of the high speed digital computer. The direct method of calculating spectral estimates involving magnitude squaring of the transform of windowed data records became popular. Unfortunately, this method unreasonably assumes the data to be zero outside the selected number of points and repeats itself periodically.

In 1967, Burg (3) introduced the concept of MEM of autospectral analysis. Entropy is a measure of the information content contained in a signal. Maximizing entropy, therefore, maximizes the information transmitted in a signal. The concept involves finding a spectral estimate corresponding to the most random or unpredictable time series whose extended correlation function satisfies the constraint that it agrees with known values. Since then researchers have successfully applied MEM to such diverse fields as geophysics, neurophysics, and ocean engineering. Campbell (4) accurately estimated natural frequency and damping ratio parameters and their 95 percent confidence limits for offshore platforms. The multichannel MEM was shown to be a useful tool in mode shape identification of offshore structures (2). Houmb (9) showed that MEM is a powerful tool for estimation of wave spectra and proposed a data acquisition system based on the technique.

In conventional FFT analysis of PUV arrays, the data are windowed and Fourier transformed; and the variance lost due to windowing is restored to the line spectra. The auto and cross-spectra terms are calculated from the line spectrum and used to obtain the first five directional Fourier series coefficients (truncated series representation for three independent measurements). These coefficients are usually band or ensemble averaged to decrease the variance of the estimate. Finally, the directional wave spectrum is calculated from the averaged coefficients using a smoothing or weighting function such as Longuet-Higgins, et al. (11) to eliminate negative side lobes.

Because the MEM is data adaptive, it does not suffer from the "bias vs. variance" tradeoff due to finite record length requirements of conventional methods. When calculating spectral estimates at one frequency, it is able to adjust itself to be least disturbed by power at neighboring frequencies. In this paper, the MEM method is used instead of conventional FFT techniques to calculate the auto- and cross-spectra for input to the directional Fourier series coefficient algorithm. Other portions of the algorithm are unchanged.

## Multichannel Maximum Entropy Method of Spectral Analysis

In order to assist understanding of the multichannel MEM algorithm, a brief review of the single-channel MEM model as a prediction error (PE) filter will be presented. An error series,  $e(n)$ , is defined as the difference between the desired signal,  $d(n)$ , and the actual signal,  $y(n)$ . The desired value is chosen as the input signal advanced one time unit ahead. The actual signal represents past values of the input signal. These past or previous values of the time series are used to predict the next value. According to least squares theory, a mean square error or error power,  $P(L)$ , is defined as the expected value of the square of the error signal. The energy contained in this error power must be minimized in such a way that the input signal is whitened as the filter order is increased. The Normal or Wiener-Levinson equations are obtained as a result of this minimization and are given by

$$[R]\{A\} = \{P\} \quad (1)$$

where

$[R]$  = matrix of autocorrelation coefficients, 0 to 1 lags

$\{A\}$  = column vector of prediction error filter coefficients

$\{P\}$  = column vector of prediction errors

The Normal equations are then solved by the Levinson-Durbin recursion to obtain the PE filter coefficients,  $A$ . The MEM spectral estimate,  $S_x$ , defined between the Nyquist frequency,  $f_{ny}$ , is then given by

$$S_x(f) = |A(f)|^2 S_w(f) \quad -f_{ny} \leq f \leq f_{ny} \quad (2)$$

$$= \frac{2\sigma^2(L)\Delta}{\left| 1 - \sum_{m=1}^L A(m) \exp(-j2\pi f m \Delta) \right|^2}$$

where  $\sigma^2(L)$  or  $S_w(f)/2\Delta$  is the prediction error or white noise variance and the denominator is the magnitude squared of the Fourier transform of the PE filter coefficients. The  $\Delta$  is the time increment in seconds between sampled data points.

Thus, the single-channel MEM filter can be written in a form familiar to engineers. The MEM spectral estimate,  $S_x(f)$ , (i.e. output spectrum) is the product of the prediction error spectrum,  $S_w(f)$  (i.e. input spectrum), and the magnitude squared of the transfer function of the PE filter,  $A(f)$ . The MEM spectral estimate is obtained by (1) calculating the PE filter coefficients out to the desired filter order of length  $L$  (as determined by Akaike's Final Prediction Error (FPE) or other suitable model order criterion), (2) calculating the PE due to a white noise signal at filter order  $L$ , (3) taking the magnitude squared of the Fourier transform of the PE coefficients, and (4) performing the operations indicated in Equation 2.

For the multichannel MEM algorithm, the development is analogous to the single-channel case. The expected mean square values of forward and backward errors of length  $M$  ( $M \leq L$ ) are minimized for the optimum filter. As a result, the Normal equations for the two-channel case forward filter coefficients,  $CF$ , are given by

$$[RF] \{CF(M,m)\} = \{V\} \quad (3)$$

where

$[RF]$  = forward R-matrix, Toeplitz, square block submatrices

$\{V\}^T$  = forward power matrix,  $[P(M) \ 0 \ 0 \dots 0]$

$m$  = coefficient number

The  $R_4$  element or  $2 \times 2$  submatrix of the RF matrix for a lag of 4 for the two-channel case is

$$\{R_4\} = \begin{bmatrix} R_{11}(4) & R_{12}(4) \\ R_{21}(4) & R_{22}(4) \end{bmatrix} \quad (4)$$

where the diagonals are the autocorrelations and the off-diagonals are the cross-correlations between channels 1 and 2.

The single-sided multichannel MEM spectral estimate matrix is a function of the Fourier transform of the forward filter coefficient matrix and is given by

$$G(f) = 2\Delta [CF^{-1}(1/z)]^* P(M) [CF^{-1}(1/z)] \quad (5)$$

where  $z = \exp(-j2\pi f\Delta)$ . Equation 5 reduces to Equation 2 for the single channel case if matrices are replaced by vectors and vectors by scalars. The inverse matrix operations become divisions, and the product of the filter coefficients with their complex conjugates gives the magnitude squared as before.

#### Directional Wave Spectral Theory

The directional wave spectrum is given by

$$S(\sigma, \theta) = S(\sigma) D(\sigma, \theta) \quad (6)$$

where  $S(\sigma)$  is the one-dimensional frequency spectrum

$$S(\sigma) = \int_0^{2\pi} S(\sigma, \theta) d\theta \quad (7)$$

and  $D(\sigma, \theta)$  is a directional spreading function which satisfies

$$\int_0^{2\pi} D(\sigma, \theta) d\theta = 1 \quad (8)$$

For a pressure/biaxial current meter combination (PUV), the derivation of the wave directional spectra is analogous to that of Longuet-Higgins et al. (11) and Cartwright (5) for heave-pitch-roll buoys. The water surface elevation is given by

$$\eta(x, y, t) = \int_{-\infty}^{\infty} \int_0^{2\pi} A(\sigma, \theta) \exp [i\psi(x, y, t, \sigma, \theta)] d\theta d\sigma \quad (9)$$

The dynamic wave pressure and horizontal u- and v-water particle velocities in the x and y directions are, respectively,

$$p(x, y, t) = \int_{-\infty}^{\infty} \int_0^{2\pi} A(\sigma, \theta) K_p(\sigma) \exp [i\psi(x, y, t, \sigma, \theta)] d\theta d\sigma \quad (10)$$

$$u(x, y, t) = \int_{-\infty}^{\infty} \int_0^{2\pi} A(\sigma, \theta) K_u(\sigma) \cos \theta \exp [i\psi(x, y, t, \sigma, \theta)] d\theta d\sigma \quad (11)$$

$$v(x, y, t) = \int_{-\infty}^{\infty} \int_0^{2\pi} A(\sigma, \theta) K_u(\sigma) \sin \theta \exp [i\psi(x, y, t, \sigma, \theta)] d\theta d\sigma \quad (12)$$

where

$$A(\sigma, \theta) = \text{amplitude spectrum} = \sqrt{2S(\sigma)d\sigma} \sqrt{D(\sigma, \theta)d\theta} \quad (13)$$

$$\psi(x, y, t, \sigma, \theta) = \text{random phase angle} = \sigma t - k_x x - k_y y \quad (14)$$

$$K_p(\sigma) = \gamma \frac{\cosh k(h+z)}{\cosh(kh)} \quad (15)$$

$$K_u(\sigma) = \sigma \frac{\cosh k(h+z)}{\sinh(kh)} \quad (16)$$

The single-sided autospectra for pressure and u- and v-velocities are, respectively,

$$G_{pp}(\sigma) = \int_0^{2\pi} S(\sigma, \theta) K_p^2(\sigma) d\theta \quad (17)$$

$$G_{uu}(\sigma) = \int_0^{2\pi} S(\sigma, \theta) K_u^2(\sigma) \cos^2 \theta d\theta \quad (18)$$

$$G_{vv}(\sigma) = \int_0^{2\pi} S(\sigma, \theta) K_u^2(\sigma) \sin^2 \theta d\theta \quad (19)$$

The single-sided cross-spectra are given by

$$S_{pu}(\sigma) = \int_0^{2\pi} S(\sigma, \theta) K_p(\sigma) K_u(\sigma) \cos \theta d\theta \quad (20)$$

$$S_{pv}(\sigma) = \int_0^{2\pi} S(\sigma, \theta) K_p(\sigma) K_u(\sigma) \sin \theta d\theta \quad (21)$$

$$S_{uv}(\sigma) = \int_0^{2\pi} S(\sigma, \theta) K_u^2(\sigma) \sin \theta \cos \theta d\theta \quad (22)$$

Since a PUV gage has only three independent measurements, only the first five directional Fourier coefficients can be derived. They are expressed as

$$A_0(\sigma) = \frac{S_{pp}(\sigma)}{2\pi K_p^2(\sigma)} = \frac{S_{uu}(\sigma) + S_{vv}(\sigma)}{2\pi K_u^2(\sigma)} \quad (23)$$

$$A_1(\sigma) = \frac{S_{pu}(\sigma)}{\pi K_p(\sigma) K_u(\sigma)} \quad (24)$$

$$B_1(\sigma) = \frac{S_{pv}(\sigma)}{\pi K_p(\sigma) K_u(\sigma)} \quad (25)$$

$$A_2(\sigma) = \frac{G_{uu}(\sigma) - G_{vv}(\sigma)}{\pi K_u^2(\sigma)} \quad (26)$$

$$B_2(\sigma) = \frac{2S_{uv}(\sigma)}{\pi K_u^2(\sigma)} \quad (27)$$

Ideally, the number of directional Fourier coefficients would be infinite, and perfect frequency and directional resolution would be obtained. However, due to the limited number of coefficients, a loss of resolution and negative side lobes results in a broadened spectra with lost total energy (variance). A binominal weighting function given by Longuet-Higgins et al. (11), although ensuring a non-negative directional spectra, still results in some loss of directional resolution. It is given by

$$S(\sigma, \theta) = A_0 + 2/3(A_1 \cos \theta + B_1 \sin \theta) \\ + 1/6(A_2 \cos 2\theta + B_2 \sin 2\theta) \quad (28)$$

Some of the statistical parameters which are compared in this paper are significant wave height, peak frequency, peak wave direction, and peak directional spread. The significant wave height is related to the zeroth moment of the directional wave spectrum by

$$H_{mo} = 4.0 \sqrt{M_0} \quad (29)$$

where  $M_0$  is the sum of the energy or variance over all frequencies and directions. The peak frequency is the center frequency of the band containing the maximum energy. The peak wave direction is the mean direction the waves travel toward in the band of maximum energy. It is defined as

$$\bar{\theta}(\sigma) = \arctan \left[ \frac{B_1(\sigma)}{A_1(\sigma)} \right] \quad (30)$$

The peak directional spread is an estimate of the spread of energy about the peak wave direction. It is given by

$$\theta_s(\sigma) = \left\{ 2 - \frac{2 \left[ A_1^2(\sigma) + B_1^2(\sigma) \right]^{1/2}}{A_0(\sigma)} \right\}^{1/2} \quad (31)$$

#### Description of Arsløe Experiment

The ARSLØE was conducted during October and November 1980 by CERC's Field Research Facility (FRF) at Duck, NC (see Figure 1). The purpose was to evaluate various types of in situ and remote sensing

Figure 1. CERC Field Research Facility (FRF)

Figure 2. CERC FRF pier bathymetry

devices for measuring directional wave spectra in shallow water. All in situ instruments were installed on or near the end of the FRF pier (see Figure 2).

A major storm moved through the area during the period 23-25 October 1980. A total of 15 data records during the hours of 0915 to 1415 on 25 October was selected for intercomparisons with the CERC FFT and MEM directional wave spectra programs. The weather conditions during this time period were characterized by winds of 10-15 m/s (22-34 mph). Wind directions were initially from the northeast, then from the east followed by a rapid shift southward then around to the west and north-west (12). Figure 3 shows the mean current speed and direction during this time as determined from the PUV data records.

The gage used for software comparisons in this paper is the CERC PUV gage: a Model 551 Marsh McBirney biaxial current meter with a Bell and Howell pressure gage. The table below summarizes the sampling parameters used. The water depth at this location was 5.5-6 meters (18.0-19.7 ft) (see Figure 2).

#### Sampling and Analysis Parameters

Sampling Frequency, Hz	4
Burst Interval, min	20
Total Number of Points per Record	4096
Record Length, sec	1024
Bandwidth, Hz	0.00781

#### Results and Discussion

Intercomparisons are made between the directional wave spectra and moment generated parameters calculated by the CERC and MEM analysis methods for the 15 data records collected during the period 25 October 1980. For the MEM auto- and cross-spectra estimates, a constant model order (filter length L) was selected for each record based on the results for each from Akaike's FPE criterion. Figures 4, 5, and 6 are sample plots of frequency and peak directional wave spectral estimates for records 12, 13, and 14 (i.e., 1315, 1335, and 1355), respectively. The solid curve in all figures corresponds to the FFT-generated spectral estimates; the dashed line represents the MEM spectral estimates. The table on the following page compares the results for the significant wave height, peak frequency, peak wave direction, and peak directional spread for these three data records. Figures 7 and 8 are time series plots of significant wave height, peak frequency, peak direction, and peak directional spread for all of the 15 data records intercompared.

In general, the MEM frequency spectral estimates are smoother than those of the FFT, with the peaks shifted slightly in frequency. Records 13 and 14 peak frequencies differ by one bandwidth interval (which is the minimum resolveable with the band averaging procedure used). As a

result, the significant wave height and peak frequency time series curves (Figure 7) agree quite well.

Comparison of MEM and FFT Method

Record No.	Hs, M		fp, Hz		$\bar{\theta}$ , deg TN		$\theta_s$ , deg	
	FFT	MEM	FFT	MEM	FFT	MEM	FFT	MEM
12	3.39	3.39	0.0898	0.0898	256.9	255.1	20.2	8.3
13	3.45	3.53	0.0820	0.0898	265.0	257.3	10.7	24.1
14	3.21	3.20	0.0820	0.0742	261.7	269.0	10.7	45.7

The MEM peak directional spectral estimates intercompare less favorably, however. The ARSLOE data used here were characterized by a combination of factors which would tend to increase the variability of the peak directional spread estimates (see Figure 8). Among these factors were unsteady wind conditions, reflections from the beach, and pier effects. Irregular bathymetry, short-term disruptions in wave patterns, and shallow-water induced spatial variability as reported by Grosskopf et al. (7) have a pronounced effect on the data analysis.

Figures 4 and 5 agree reasonably well with some slight shifts in direction being apparent. Figure 6, however, indicates two peaks of differing amplitude occurring at the same peak frequency. This bidirectional wave spectrum of two wave trains agrees with results obtained by XERB radar during the ARSLOE experiment. More than one wave train occurring at the same wave frequency was resolved by the XERB but not by the other systems using conventional FFT analysis methods (12).

Jefferys (10) demonstrated the substantial effect reflections and phase locking have on the spread predictions even for MLM methods. Phase locking occurs when two waves of the same frequency but differing amplitudes and directions are produced. Even when the amplitudes were equivalent, only a unimodal spectrum was produced. As the amplitude of one of the waves is decreased, the peak remains unimodal but shifts slightly. When the waves were no longer identical in frequency but still equal in amplitude, the bidirectional nature of the waves could be resolved. This would explain the differences in the MEM-generated peak directional spectra of Figures 4, 5, and 6.

#### Conclusions

In general, the MEM and CERC FFT method intercompared reasonably well. Comparisons were made with frequency and directional wave spectral estimates, significant wave height, peak frequency, peak wave direction, and peak directional spread. The MEM spectral estimates were generally slightly shifted in frequency and direction. The MEM tended to resolve multiple wave trains of similar frequency coming from different directions better than did the FFT method. The lack of band averaging in the MEM also tended to make the spread calculations more erratic. Further research with MEM and other data adaptive methods should be encouraged.

## CHAPTER THIRTY FOUR

### DESCRIPTION OF NATURAL SEA STATES

#### REQUIREMENTS TO THE REPRODUCTION IN MODELS

H. LUNDGREN<sup>1</sup>

ELIAS DAVIDSEN<sup>2</sup>

#### ABSTRACT

In order to attain a satisfactory reproduction in physical and numerical models of Nature's sea states, much development of the description of these sea states has to take place. This paper gives a *discussion* (i) of the problems that can be considered as solved today, and (ii) of the problem areas where much research is still needed.

Firstly, the paper presents the basic definition of the *directional spread* of energy (for a given frequency) as derived from a field record. This definition is necessarily a statistical one and leads directly to the determination in practice of the directional spectrum.

Secondly, the parameterization of spectra is discussed and it is proposed to express one-dimensional storm spectra by means of the *four parameter F.I.-spectrum*, which is more manageable than the JONSWAP-spectrum.

Thirdly, it is concluded that the first order components of any spectrum have *random phases*.

#### 1. INTRODUCTION

In the modelling of a coastal engineering problem it is, of course, desirable to work with the best reproduction of the natural sea states. The degree of sophistication, however, depends on the size of the project and the type of model used.

For economic reasons, the study in *physical models of smaller projects* must be confined to the *1-D f-spectrum*, i.e. the one-dimensional frequency spectrum giving wide-crested waves, i.e. waves with (infinitely) wide crests.

The input wave data will often be given as, say, the

---

<sup>1</sup>Professor, Dr.Techn., Institute of Hydrodynamics and Hydraulic Engineering, Technical University of Denmark, Building 115, DK-2800 Lyngby - Denmark. Consultant to Danish Hydraulic Institute.

<sup>2</sup>M.Sc., Harbour Engineer, Government Engineering Office, Faroe Islands.

100 year storm, where  $H_s$  and  $f_p$  (peak frequency) have been found by *extrapolation* of wave statistics, based on (i) actual wave records, or (ii) meteorologically based wave hind-cast models, or (iii) a combination of both, for example, involving the forecast of extrapolated 'historical' storms.

It is quite usual to prescribe a *spectrum* corresponding to the average parameters determined during the JONSWAP-project. Because of the special characteristics of this project (offshore wind), this method is not in general completely satisfactory. It would seem better to parameterize the locally recorded spectra and to extrapolate the parameters to 100 years.

In order to obtain reliable results from models of *larger projects*, it is necessary to reproduce the 2-D ( $f, \theta$ )-*spectrum*, i.e. the directional spectrum giving narrow-crested waves. For physical models it is more expensive to work with the directional spectrum because of the large number of wave generators required and the equipment to control them. On the other hand, in a numerical model, when first established, the extra work involved in the use of the 2-D spectrum is often not essential.

In models of *disturbance inside harbours* the directional spread of wave energy can influence the diffraction considerably, cf. Sand et al., 1983 (Ref. 15). For *rubble mound breakwaters* preliminary tests have shown that unidirectional waves may give results on the conservative side in shallow water (see the reference in Lundgren, 1983 (Ref. 8)). On the other hand, recent failures of major breakwaters indicate that the directional spread may give catastrophic 3-D effects, perhaps as a result of the occurrence of freak waves. For *vertical and composite breakwaters*, which may be exposed also to shock forces, one could imagine that the directional spread of energy would give a higher local force but a smaller total force on a long caisson.

The *determination of directional spectra* is discussed in Sec. 2 in terms of what can be characterized as a complete analysis of the 3-D structure of waves. Unfortunately, rather many papers have dealt with computer simulations of directional spectra, and very few have given actual directional distributions from recorded data. Therefore, it would be premature to propose an empirical formula covering the essential part of the energy in directional spectra for storm waves. On the other hand, such a *parameterized formula* is definitely a prerequisite for the extrapolation to rare events. In addition, there is a great need for studies of the *spectrum development because of shoaling and currents*.

For *1-D spectra* the situation is considerably simpler. In this area several parametric formulae have been proposed. The JONSWAP-formula is the most frequently used. It has five parameters and exhibits a discontinuity in curvature

at the peak. In Sec. 3 a four-parameter spectrum (without discontinuities) is proposed for use in typical storm situations. It is called the *F.I.-spectrum* because it was conceived in connection with the analysis of thousands of spectra recorded around the *Faroe Islands* in the North Atlantic. A complete *procedure* for the determination of the *F.I.-parameters* is described in the Appendix.

In recent years many papers have been published about the *grouping of waves*. This is discussed in Sec. 4, and it is contended that all information about the grouping of first order components is inherent in the (directional) spectrum. It is therefore proposed that the international discussion of grouping be discontinued. Related to the grouping is the occurrence of *long waves*, a second order effect that is decisive for harbour resonance and for drift forces. In Sec. 4 the imminent necessity of recording long wave directional spectra is pointed out.

In some models it is sufficient to reproduce the first order components of the (directional) spectrum applying random phases. In other models, however, the higher order effects involved in the *wave shapes* must be included, as briefly discussed in Sec. 5.

## 2. DETERMINATION OF DIRECTIONAL SPECTRA

A survey of the methods hitherto used for the determination of directional spectra is given by Lundgren, 1984 (Ref. 9), as Opening Address at the Symposium on Description and Modelling of Directional Seas, organized June, 1984 by Danish Hydraulic Institute & Danish Maritime Institute.

If a fixed support of instruments cannot be provided, a pitch-roll buoy can be used. It records the water surface elevation  $\eta$  together with two slopes,  $\eta_x$  and  $\eta_y$ , of the water surface. If a fixed support, for example, an offshore platform is available,  $\eta$  can be recorded by a wave radar from above or an echo sounder from below, at the same time as two horizontal velocities,  $u$  and  $v$ , are recorded by a current meter placed below the deepest trough.

In principle, there is little difference between analysing the set  $(\eta, \eta_x, \eta_y)$  and the set  $(\eta, u, v)$ . The latter will be used as basis for the discussion below.

There are two different methods of analysis:

- A. The correlation method, which requires knowledge of all 3 time series,  $\eta(t)$ ,  $u(t)$  and  $v(t)$ , in one vertical. This method can deliver approximate information about only 4 parameters of the directional distribution of energy at each frequency.
- B. The complete FFT-method, which - for practical purposes - requires knowledge of only 2 time series,  $u(t)$  and

$v(t)$ . This method will deliver the most complete information about the directional distribution that can be obtained from the data recorded.

The *correlation method* was first developed by Longuet-Higgins et al., 1963 (Ref. 7). It is based on the 6 auto- and cross-spectra,  $S_{\eta\eta}, S_{uu}, S_{vv}, S_{\eta u}, S_{\eta v}, S_{uv}$ . From these can be derived the first 5 coefficients,  $a_0, a_1, b_1, a_2, b_2$ , in the fourier series development with respect to the direction  $\theta$ . A special correction had to be introduced in order to eliminate the negative side lobes, which would correspond to propagation of negative energy in directions away from the mean direction.

In recent years the correlation method has been further elaborated in a number of papers, cf. for example, Kuik and van Vledder, 1984 (Ref. 5), who give approximate formulae for 4 directional parameters, viz. the circular mean direction, standard deviation, skewness and curtosis. The basis is still the 6 spectra. The same applies to a recent paper by Isobe et al., 1984 (Ref. 4), who describe an extension of the maximum likelihood method to an arbitrary combination of instruments as wave gauges, current meters etc.

The principle of the *complete FFT-method* was first proposed by the senior author in February 1978 and worked out in details by Dr. S. E. Sand, cf. Sand and Lundgren, 1979 (Ref. 14) and, particularly, Sand, 1979 (Ref. 13). It can be described as follows: The FFT-analysis of the three time series delivers - at a particular frequency  $\omega = 2\pi f$  - the fourier coefficients  $A_\eta, B_\eta, A_u, B_u, A_v, B_v$ , where the three A pertain to  $\cos \omega t$  and the three B to  $\sin \omega t$ . ( $A_u, A_v$ ) constitute the velocity vector of a wavelet, for which the energy corresponds to  $|A_u, A_v|^2 = A_u^2 + A_v^2$ . If  $A_\eta$  is positive, the wavelet has a crest for  $t = 0$ , and the vector indicates the direction of energy propagation. If  $A_\eta$  is negative, the wavelet has a trough for  $t = 0$ , and the vector has to be rotated  $180^\circ$  in order to give the direction of energy. In this simplified description the numerical value of  $A_\eta$  is an (unused) redundant. It is possible to utilize it in a least square method (Ref. 13).

In 1984 the FFT-method has been further elaborated in connection with the analysis of data from the North Sea where the wave radar (recording  $\eta$ ) for practical reasons could not be placed vertically above the current meter. For simplicity, only the latter was used in the analysis. For a strong storm without essential swell the major part of the energy propagates within  $\pm 90^\circ$  from the mean direction. Therefore it is easy to distinguish between crests and troughs.

The explanation below will be illustrated with a one hour record from 1983-10-16 with practically constant wave weather with  $H_{m0} = 5.8$  m. With a scanning per 0.5 s there is 7200 data available. Traditionally, this can be divided into 14 subseries, each of 512 data. Each subseries gives

a frequency resolution of  $\Delta f = 1/256$  Hz. For each frequency there are four fourier coefficients,  $A_u, B_u, A_v, B_v$ . The total set of fourier coefficients for all frequencies gives a *complete, deterministic description* of the variation of the velocities (u,v).

Hence, for each subseries there is at each frequency *only* two energy vectors

$$|A_u, A_v| \cdot \{A_u, A_v\} \quad \text{and} \quad |B_u, B_v| \cdot \{B_u, B_v\} \quad (2-1)$$

Seen from a deterministic point of view, these vectors represent the energy spread for the subseries considered. Thus, for 14 subseries there are 28 vectors. This ensemble will already give some idea of the statistical spread of energy.

Much more directional information can be obtained, however, by the method of *overlapping subseries*. Overlapping was introduced by Welch, 1967 (Ref. 17) for reduction of the variance by the determination of spectra. Assuming a  $\cos^2$ -data taper for the subseries and a large number of subseries, giving a variance of one of the spectral value at a certain frequency, the use of overlapping will, according to Welch's formulae, reduce the variance as indicated in Table 1.

Table 1: Reduced variance by overlapping

Overlap of each subseries with the previous one	50%	66.7%	75%	80%	83.3%
5% taper each end	0.730	0.683	0.667	0.660	0.656
10% - - -	0.709	0.660	0.645	0.639	0.636

By 50% overlap the computer work is doubled and the variance reduced to about 70%. For the determination of 1-D spectra it does not pay to go any further.

For 2-D spectra, however, the situation is completely different. Here, *overlapping time series will increase the directional information decisively*. Whereas the one hour record mentioned above gave 28 vectors at each frequency for 14 non-overlapping subseries, an 85% overlap (i.e. a shift of  $0.15 \cdot 512 = 77$  data for each subseries) will give 87 subseries, or 174 energy vectors.

This is illustrated by Fig. 1, showing the directional distribution at the peak frequency 102 mHz. The trough vectors have been rotated  $180^\circ$ , and each vector is referred to one of 180 boxes, each  $1^\circ$  wide. For smoothing, a triangular window with a base width of only  $5^\circ$  has been applied.

Fig. 1 Directional distribution for 85% overlapping

Fig. 2 Directional distribution for 95% overlapping

For comparison, the directional distribution for 95% overlapping is shown in Fig. 2. It is seen to be much smoother. In both cases a 10%  $\cos^2$ -taper has been applied at the ends of a subseries.

It is a fundamental fact that the 1-D spectrum of a field record can be defined only statistically, by a sufficiently long record or by a spectral window. Analogously, the overlapping method leads to the very statistical definition of the directional distribution of energy in a field record.

If the length of the velocity vector  $(A_u, A_v)$  is squared, the vector  $(A_u, A_v) \cdot (A_u^2 + A_v^2)^{1/2}$  is obtained. It is proportional to the energy. Thus, each of these vectors defines an "energy point" in the plane where  $\theta = 0$  is the u-axis and  $\theta = 90^\circ$  the v-axis. Half the points correspond to crests of wavelets, the other half to troughs, which - on the whole - are in the opposite directions.

The first principal axis, with direction  $\theta_0$ , is the mean energy direction. It is found from the equation

$$\tan 2\theta_0 = \frac{\sum A_u A_v (A_u^2 + A_v^2) + \sum B_u B_v (B_u^2 + B_v^2)}{\sum (A_u^2 - A_v^2) (A_u^2 + A_v^2) + \sum (B_u^2 - B_v^2) (B_u^2 + B_v^2)} \quad (2-2)$$

Before Figs. 1-2 were plotted, the coordinate system was rotated the angle  $\theta_0$ , so that the mean energy is in direction  $0^\circ$ . In addition, all energy vectors with directions between  $90^\circ$  and  $270^\circ$  were assumed to correspond to troughs and were rotated  $180^\circ$ . This method implies that the small amount of energy that propagates in directions beyond  $+90^\circ$  or  $-90^\circ$  is mirrored in these directions. At frequencies far from the peak frequency, or if essential swell is involved, it is necessary to include information from the fourier series of  $\eta(t)$  in order to determine the full distribution over  $360^\circ$ .

It should be noted that with the method developed in 1978 a good resolution of the spectrum with respect to frequencies was accompanied by a poor resolution with respect to directions and vice versa. With the overlapping method a *good resolution* can be obtained simultaneously in frequencies and directions.

With this method it should also be possible to study the spectral properties that give rise to *freak waves*.

Excellent *deterministic reproduction* of the 3-D structure of waves may be obtained by means of 60 wave generators, as shown by Agee and Sand, 1984 (Ref. 1).

### 3. F.I.-SPECTRUM

Four waveriders placed around the Faroe Islands have delivered a comprehensive material, for the analysis of which the so-called F.I.-spectrum has been chosen

$$S(f) = A_p (f/f_p)^{-\varphi_1} \exp\left[-B_p (f/f_p)^{-\varphi_2}\right] \quad (3-1)$$

This formula is a generalization of the P-M-spectrum, for which  $\varphi_1 = 5$  and  $\varphi_2 = 4$ . The Ochi-spectrum is the sum of two similar terms, both with  $\varphi_2 = 4$ . At the 19th ICCE in Houston, 1984, Liu (Ref. 6) has, independent of the present authors, reported the use of a formula that differs from (3-1) only in the symbols.

The F.I.-formula can be fitted with good accuracy to more than 95% of all spectra of larger waves. It has only four parameters, because the powers of  $f_p$  may be included in  $A_p$  and  $B_p$ .

A procedure for the determination of  $A_p$ ,  $B_p$ ,  $\varphi_1$ ,  $\varphi_2$  is described in the Appendix. It is based on the moments of (3-1), which can be expressed by means of the  $\Gamma$ -function, see Eq. (A-4). This circumstance has previously been utilized by Ochi and Hubble, 1977 (Ref. 11) and by Houmb, 1984 (Ref. 3). The advantage of using the moments is that they have a much smaller variance than the individual spectral values  $S(f)$ .

An example of an F.I.-fit is shown in Fig. 3 for a 20 minute record with 9 non-overlapping subseries, each of 256 data. (With a 10% data taper it is recommended to use 55% overlapping, cf. Table 1, Sec. 2.) The abscissa is the frequency number  $i = f/\Delta f$ , where  $\Delta f = 1/128$  Hz. The moment  $M(n)$  in (A-2) and its derivatives in (A-12/14) have been taken at  $n = -2$ , with summations extending from  $i_{\min} = 5$  to  $i_{\max} = 30$ .

The spectrum of the wave record is shown with dots. For this spectrum, with  $H_{m0} = 11$  m, the values  $\varphi_1 = 3.5$  and  $\varphi_2 = 10.6$  have been found.

Fig. 3 F.I.-spectrum

#### 4. WAVE GROUPING AND LONG WAVES

It is well known that there is a steadily ongoing *multi-exchange of energy* (or rather wave action) between infinitely many combinations of four wave number vectors. Because of this exchange, *the phases of the infinite number of first order wave components are random*. It is excluded to define a "phase spectrum".

Hence, the *grouping of waves* in a stochastic ensemble of shorter and longer groups is determined uniquely by the spectrum. On the average, a narrow spectrum gives long groups and a wide spectrum short ones. A very long wave record is required in order to obtain a complete statistical picture of the grouping.

For a *steady wave state* the grouping is associated with a pattern of *second order long waves* (SOLW) in such a manner that the long waves have troughs where the short waves are high, and crests where the short waves are small. Formulae for the SOLW for an arbitrary directional sea in arbitrary depth were given by Sharma and Dean, 1979 (Ref. 16). Independently, Ottesen Hansen et al., 1981 (Ref. 12) established the corresponding formulae for a unidirectional sea. The SOLW have frequencies and wave number vectors equal to the differences between frequencies and wave number vectors of pairs of first order wave components.

In practice, however, *all wave states are unsteady*. Because of the movement and the change of the wind field, the change in water depth and current as the waves propagate, wave-wave interaction and energy decay, there is a continuous change of the (directional) spectrum. Since the characteristic frequencies of the long waves are the differences between frequencies of the short ones, the long waves can only gradually adjust themselves to the changing short wave spectrum. If, for instance, the wind field changes direction, the short waves may turn relatively fast, whereas

the long waves will turn much more slowly. Hence, it is possible to speak of a *partial separation* of the long waves from the short ones.

The long waves are responsible for harbour resonance and will often be the dominant cause of drift forces, cf. Lundgren et al., 1982 (Ref. 10). Hence, there is an *urgent need for good records of directional spectra of long waves*. Since long waves have a much larger directional spread than the short ones, it is necessary to determine their distribution over the full circumference of  $360^\circ$ . This cannot be done with a pitch-roll buoy because of its poor response for low frequency heave motions. Therefore, it is necessary to record three time series ( $\eta, u, v$ ) with a fixed installation and analyse the data with the overlapping method.

#### 5. WAVE SHAPE EFFECTS

The spectrum represents the superposition of a large number of small sinusoidal components. In contrast to sine curves, high waves have *elevation skewness*, i.e. the crest height is larger than the trough depth, and they may have *slope skewness*, i.e. the wave front is steeper than its back.

In some model tests, for example with vertical and composite breakwaters, it is necessary to also reproduce the natural wave shapes. The deviations from the "sinusoidal" shapes are *second order short waves* (SOSW), generated by the first order components through the nonlinear surface conditions or the bed slope. The SOSW have frequencies and wave number vectors equal to the sums of frequencies and wave number vectors of pairs of first order wave components, cf. Sharma and Dean, 1979 (Ref. 16).

Because of the high frequencies of the SOSW, they have a good possibility of adjusting themselves to the local first order wave conditions, provided that the bed slope is not too large. By abrupt changes, however, a *partial separation* may take place. This was shown by Biésel, 1963 (Ref. 2) in connection with the diffraction of regular high waves into a harbour model and the refraction across a shoal. In both cases the height of the first order waves changes over a rather short distance and, if the first order wave is reduced to 90%, the corresponding SOSW is reduced to 81%. Therefore, some SOSW energy is released and diffracted/refracted in a different manner.

A particularly strong nonlinear effect is present in *freak waves*, where a very high 3-D crest is surrounded by troughs of normal depth, cf. Fig. 4.

North Sea,  
1981-11-25

#### ACKNOWLEDGEMENTS

The large Faroe Islands Wave Project has been executed under the auspices of and vigorous support from Mr. M. A. Helmsdal, Government Engineer, Head of Public Works. The wave recorders were installed with the valuable assistance of the Faroe Islands' Coast Guard. The instrumentation, programming and data analysis have profited greatly from the cooperation with Mr. Flemming Lindenstrøm and Mr. Signar Heinesen and their keen interest in the project.

The results presented in this paper could not have been produced without valuable support from management and staff members of Danish Hydraulic Institute, including the use of North Sea data available in the institute. Special thanks go to Mr. Ebbe W. Frederiksen and Mr. Bjarne Donslund for their work with 1-D and 2-D spectra.

## APPENDIX: DETERMINATION OF F.I.-PARAMETERS

From the FFT-analysis the empirical spectrum  $S(f)$  is determined at the equidistant values  $f = i \cdot \Delta f$ , with  $i = 1, 2, 3, \dots$ . For simplicity, the spectrum is considered a function of the *frequency number*  $i$ , i.e.

$$S(i) = A i^{-\varphi_1} \exp[-B i^{-\varphi_2}] \quad (\text{A-1})$$

Expressed in frequency numbers, the moment of order  $n$  is

$$\begin{aligned} M(n) &= \sum_{i=1}^{\infty} i^n S(i) \approx \int_0^{\infty} i^n S(i) di \\ &= A \int_0^{\infty} i^{n-\varphi_1} \exp[-B i^{-\varphi_2}] di \end{aligned} \quad (\text{A-2})$$

After introduction of the parameter

$$z = z(n) = (\varphi_1 - n - 1) / \varphi_2 \quad (\text{A-3})$$

and the substitution  $t = B i^{-\varphi_2}$ , (A-2) may be written

$$M(n) = A \varphi_2^{-1} B^{-z} \int_0^{\infty} t^{z-1} e^{-t} dt = A \varphi_2^{-1} B^{-z} \Gamma(z) \quad (\text{A-4})$$

the infinite integral being the definition of the gamma function.

Hence, the problem is, from a knowledge of the moments  $M(n)$ , to determine the four parameters  $A, B, \varphi_1, \varphi_2$ . Since  $\varphi_1$  and  $\varphi_2$  through the parameter  $z$  are 'well hidden' under the  $\Gamma$ -function, this is a seemingly difficult problem. It may be tackled in the following manner: The *logmoment*  $P(n)$  is introduced by taking the logarithm of (A-4)

$$P(n) = \ln M(n) = \ln A - \ln \varphi_2 - z \ln B + \ln \Gamma(z) \quad (\text{A-5})$$

In the following,  $M(n)$  and  $P(n)$  are considered functions of the *continuous variable*  $n$  and may be differentiated with respect to  $n$ .

Since  $z'(n) = -\varphi_2^{-1}$ , the first derivative of (A-5) is

$$P' = P'(n) = M'/M = \varphi_2^{-1} \ln B - \varphi_2^{-1} \psi(z) \quad (\text{A-6})$$

where

$$\psi(z) = \Gamma'(z) / \Gamma(z) \quad (\text{A-7})$$

is the digamma function, also called the psi function.

The derivative of (A-6) is

$$P'' = M''/M - (M'/M)^2 = \varphi_2^2 \psi'(z) \quad (\text{A-8})$$

where  $\psi'(z)$  is the trigamma function. Finally, the derivative of (A-8) is

$$\begin{aligned} P''' &= M'''/M - 3 (M''/M) (M'/M) + 2 (M'/M)^3 \\ &= -\varphi_2^3 \psi''(z) \end{aligned} \quad (\text{A-9})$$

where  $\psi''(z)$  is the tetragamma function.

In (A-8) and (A-9) both  $\varphi_2$  and  $z$  are unknown. Therefore,  $\varphi_2$  is eliminated by introducing the *ratio function*

$$R(z) = (P''')^2 / (P'')^3 = (\psi'')^2 / (\psi')^3 \quad (\text{A-10})$$

where  $P$  is differentiated with respect to  $n$  and  $\psi$  with respect to  $z$ . In principle,  $R(z)$  may be tabulated from published tables of the  $\psi''$  and  $\psi'$  functions.

Assuming that  $P'''$  and  $P''$  have been calculated from the given spectrum for a chosen value of  $n$ , the *procedure* is now: Calculate the value of  $R$  from the first expression in (A-10), and find the corresponding value of  $z$  as the *inverse function*

$$z = z(R) \quad (\text{A-11})$$

from the table mentioned. In practice, no table is needed because an approximate formula for  $z(R)$  is given below.

According to (A-6,8,9), the derivatives  $P'$ ,  $P''$ ,  $P'''$  of the logmoment  $P$  can be found from the moment  $M$  and its derivatives  $M'$ ,  $M''$ ,  $M'''$ . For these derivatives the following formulae are easily derived from (A-2)

$$M'(n) = \sum_{i=1}^{\infty} \ln i \cdot i^n S(i) \quad (\text{A-12})$$

$$M''(n) = \sum_{i=1}^{\infty} \ln^2 i \cdot i^n S(i) \quad (\text{A-13})$$

$$M'''(n) = \sum_{i=1}^{\infty} \ln^3 i \cdot i^n S(i) \quad (\text{A-14})$$

Based on analyses of a number of Faroe Island spectra, the present authors recommend the following *procedure*:

(a) In the sums (A-2,12,13,14) choose  $n = -2$ . ( $n = -1$  has been found not to reproduce a sharp peak in the spectrum sufficiently well.  $n = -3$  has been found to give practically the same spectral shape as  $n = -2$ .) In order to compare the F.I.-parameters for different storms, it is advantageous to use the same  $n$  for all spectra.

(b) The summations in (A-2,12,13,14) must *not* start from  $i = 1$ . The reason is that the left hand side of the F.I. spectral shape is very steep down to extremely small values. Therefore, if the empirical spectrum has points above this steep slope - for example, because of the presence of some swell - such points would influence the F.I.-parameters in a *most disturbing* manner if they were included in the summations. In most cases the following rules may be applied:

- (i) To the left of the maximum,  $S_{\max}$ , of the given spectral values all points are included for which  $S(i) > 0.25 S_{\max}$ .
- (ii) Below  $0.25 S_{\max}$  at least one more point is included but

otherwise the summations stop at the value  $i_{min}$  for which

$$S(i_{min}) - S(i_{min}-1) < 0.8 [S(i_{min}+1) - S(i_{min})] \quad (A-15)$$

this inequality indicating that the steep slope does not continue further to the left.

(c) The summations (A-2,12,13,14) need only extend to a value,  $i_{max}$ , for which the spectral values are so small that they do not influence the sums essentially. In this respect the value  $n = -2$  helps in reducing the influence of large  $i$ -values.

(d)  $M, M', M''$  and  $M'''$  are calculated.

(e)  $P', P''$  and  $P'''$  are calculated.

(f)  $R$  is calculated from (A-10).

(g)  $q$  is calculated from

$$q = \left(1 - \frac{R}{4}\right)^{\frac{1}{2}} \quad (A-16)$$

(h)  $z$  is calculated from the approximation

$$Rz = 1.8024 q + 0.7906 q^2 - 1.5920 q^{4.640} - 2.252 q^{3.379} (1-q)^{1.589} \quad (A-17)$$

The error on  $z$  according to this formula is numerically less than 0.17% for  $z < 1.5$  and less than 0.29% for all  $z$ .

(i) Calculate  $\Gamma(z)$  from the formula

$$1/\Gamma(z) = \sum_{k=1}^{\infty} c_k z^k \quad (A-18)$$

where

k	$c_k$	k	$c_k$

(j) Calculate  $\psi(z)$  from the formula

$$\psi(z) = -\gamma - \frac{1}{z} + \sum_{m=1}^{10} \frac{z}{m(z+m)} + z \Sigma_2 - z^2 \Sigma_3 + z^3 \Sigma_4 - \dots \quad (A-19)$$

where

$$\gamma = 0.57721 56649 \quad \text{and} \quad \Sigma_k = \sum_{m=11}^{\infty} m^{-k} \quad (A-20)$$

[The formula for  $\psi(z)$  has been derived by differentiation of the logarithm of Euler's infinite product for  $1/\Gamma(z)$ . Since  $\psi(z)$  has simple poles at the points  $0, -1, -2, \dots$ , the convergence of the series (A-19) has been improved by separating the first 11 poles with their respective residues.] The numerical values of  $\Sigma_k$  are \*)

$$\begin{aligned} \Sigma_2 &= 9.516\ 633\ 568 \cdot 10^{-2}; & \Sigma_3 &= 4.524\ 917\ 486 \cdot 10^{-3}; \\ \Sigma_4 &= 2.866\ 502\ 175 \cdot 10^{-4}; & \Sigma_5 &= 2.041\ 379\ 870 \cdot 10^{-5}; \\ \Sigma_6 &= 1.549\ 542\ 998 \cdot 10^{-6}; & \Sigma_7 &= 1.224\ 317\ 311 \cdot 10^{-7}; \\ \Sigma_8 &= 9.942\ 690\ 896 \cdot 10^{-9}; & \Sigma_9 &= 8.236\ 974\ 0 \cdot 10^{-10}; \\ \Sigma_{10} &= 6.927\ 213 \cdot 10^{-11}; & \Sigma_{11} &= 5.89777 \cdot 10^{-12}; \\ \Sigma_{12} &= 5.0683 \cdot 10^{-13}; & \Sigma_{13} &= 4.388 \cdot 10^{-14}; \\ \Sigma_{14} &= 3.80 \cdot 10^{-15}; & \Sigma_{15} &= 3.3 \cdot 10^{-16}. \end{aligned}$$

(k) Calculate  $\psi'(z)$  from the formula

$$\psi'(z) = \sum_{m=0}^{10} \frac{1}{(z+m)^2} + \Sigma_2 - 2z \Sigma_3 + 3z^2 \Sigma_4 - 4z^3 \Sigma_5 + \dots \quad (\text{A-21})$$

(l) Find  $\varphi_2$  from (A-8) as

$$\varphi_2 = \left[ \psi'(z) / P''(n) \right]^{\frac{1}{2}} \quad (\text{A-22})$$

(m) Find  $\varphi_1$  from (A-3) as

$$\varphi_1 = z \varphi_2 + n + 1 \quad (\text{A-23})$$

(n) Find B from (A-6) as

$$\ln B = P'(n) \varphi_2 + \psi(z) \quad (\text{A-24})$$

(o) Find A from (A-4) as

$$A = M(n) \varphi_2 B^z / \Gamma(z) \quad (\text{A-25})$$

(p) Plot the graph of  $S(i)$  according to the F.I.-formula (A-1) and compare with the given spectral values. In special cases it may be necessary to choose another value of  $i_{\min}$  than given by the rules (i) and (ii) under item (b) above. In some cases another value than  $n = -2$  may have to be chosen; see (a) above.

(q) Calculate the peak frequency from

$$i_p = \left[ B \varphi_2 / \varphi_1 \right]^{1/\varphi_2} \quad (\text{A-26})$$

and the peak spectral value from

$$S_p = A i_p^{-\varphi_1} \exp\{-\varphi_1 / \varphi_2\} \quad (\text{A-27})$$

\*) The last few decimals in these values are not reliable.

## CHAPTER THIRTY FIVE

### NON-GAUSSIAN CHARACTERISTICS OF COASTAL WAVES

Michel K. Ochi\* and Wei-Chi Wang\*

#### ABSTRACT

This paper presents the results of a study on non-Gaussian characteristic of coastal waves. From the results of the statistical analysis of more than 500 records obtained in the growing stage of the storm, the parameters involved in the non-Gaussian probability distribution which are significant for predicting wave characteristics are clarified, and these parameters are expressed as a function of water depth and sea severity. The limiting sea severity below which the wind-generated coastal waves are considered to be Gaussian is obtained for a given water depth.

#### INTRODUCTION

The profile of wind-generated waves observed in coastal waters is significantly different from that observed in deep water because of finite water depth effects, and the difference is particularly pronounced in severe seas. In general, time histories of coastal waves show a definite excess of high crests and shallow troughs in contrast to those of waves in deep water as demonstrated in Figure 1. This implies that waves in coastal waters where the effect of water depth on wave characteristics is present cannot be considered as a Gaussian random process. Hence, clarification of the non-Gaussian characteristics of coastal waves is highly desirable to provide a basis for statistical prediction of wave characteristics such as wave height, breaking, groupiness, etc.

The purpose of this study is to clarify the non-Gaussian properties of coastal waves which depend on water depth as well as sea severity. In particular, effort is made to clarify the extent to which coastal waves deviate from a Gaussian random process for a given water depth in order to develop more accurate and rational prediction techniques of random wave characteristics. To achieve this goal, a statistical analysis is carried out on wave time histories obtained during a storm by the Coastal Engineering Research Center (CERC) in the Atlantic Ocean Remote Sensing Land-Ocean Experiment (ARSLOE) Project.

Figure 1: Comparison of coastal and ocean wave profile

The paper consists of three sections. The first section summarizes the results of the statistical analysis based on the non-Gaussian probability density function. From analysis of more than 500 wave records measured at various water depths during the growing stage of the storm, it is found that two parameters associated with skewness and kurtosis, respectively, involved in the Longuet-Higgins' non-Gaussian probability density function are significant for predicting wave characteristics in finite water depth. The second section presents the results of the analysis in which these two parameters are expressed as a function of water depth and sea severity (significant wave height). The third section discusses the limiting sea severity below which wind-generated coastal waves can be considered Gaussian. It is shown that coastal waves in seas for which the parameter representing the skewness is less than 0.2 can be considered as a Gaussian random process irrespective of water depth.

#### PROBABILITY DISTRIBUTION OF WAVE PROFILES

As stated in the introduction, waves in coastal waters cannot be considered as a Gaussian random process, and hence a non-Gaussian probability density function has to be applied for representing the wave profile. Several probability density functions have been introduced to describe non-Gaussian random processes. These can be categorized as being derived from two different approaches: one based on probability theory in which no specific consideration is given to the wave profile, the other based on an approximation to the wave profile. The Gram-Charlier probability density function (Cramér 1946) derived from the concept of orthogonal polynomials is a well-known example of the former approach. Since Hermite polynomials are orthogonal with respect to the normal distribution,

the probability density function is expanded in a series of Hermite polynomials. The Edgeworth series probability density function (Edgeworth 1905) is derived following the same basic concept as the Gram-Charlier series but the series expansion method is different and the expanded terms are expressed in terms of cumulants. On the other hand, the Longuet-Higgins series probability density function (Longuet-Higgins 1963) is derived by applying the cumulants generating function. In his approach, the integrations involved in the derivation are expressed in terms of Hermite polynomials. Although these three probability density functions are derived by applying different theorems in probability theory, the results are similar.

In contrast to the approach considered for the above three probability density functions, Tayfun (1980) and Huang et al. (1980) (1983) derived probability density functions based on the approximation that waves can be expressed as a Stokes expansion to the 2nd and 3rd order components. This is certainly one way to present non-Gaussian characteristics of coastal waves. However, an important object of the present study is to clarify the extent to which coastal waves deviate from a Gaussian random process; hence, it may be well not to impose any preliminary form on wave profile representation in analyzing data obtained in coastal waters. Hence, the following non-Gaussian probability density function derived by Longuet-Higgins is considered in the present study:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{x^2}{2\sigma^2}} \left[ 1 + \frac{\lambda_3}{3!} H_3\left(\frac{x}{\sigma}\right) + \frac{\lambda_4}{4!} H_4\left(\frac{x}{\sigma}\right) + \frac{\lambda_5}{5!} H_5\left(\frac{x}{\sigma}\right) + \dots \right] \quad (1)$$

where,  $\sigma^2$  = variance of wave deviation from the mean

$$\lambda_3 = \kappa_3 / (\sqrt{\kappa_2})^3 = \text{skewness}$$

$$\lambda_4 = \kappa_4 / (\kappa_2)^2 = \text{kurtosis} - 3$$

$$\lambda_5 = \kappa_5 / (\sqrt{\kappa_2})^5$$

$\kappa_j$  = cumulants

$H_n\left(\frac{x}{\sigma}\right)$  = Hermite polynomial of degree n

In applying the above probability density function to the analysis of coastal waves, the following remarks are made:

(1) The probability density function given in Equation (1) at times becomes negative for large negative x depending on the value of  $\sigma$ . However, this should not cause any trouble in practice, since the

x-values where the function becomes negative are usually outside the range where the histogram exists as will be shown later.

(2) The accuracy of a function which is expressed in the form of a series increases with increase in higher order terms, in general. However, this is not the case for the probability density function given in Equation (1). The results of comparisons between histograms and the probability density function have shown that higher order terms do not necessarily yield better agreement. Therefore, it is highly desirable to examine terms of the series which significantly contribute to the distribution.

In order to clarify questions that might surface from the above remarks, more than 500 wave records measured at various water depths during the growth stage of the storm in the ARSLOE Project are analyzed. Details of wave data used in the present study are summarized in the Appendix.

Figure 2 shows an example of a comparison between the probability density function given in Equation (1) with a histogram of the wave profile obtained at a water depth of 1.4 m. The significant wave height is 2.05 m which is considered to be severe for this water depth. Four variations of the probability density function are compared with the histogram. These four variations represent, respectively, the first term of the series (which is the normal distribution), the first two terms (including the parameter  $\lambda_3$ ), the first three terms (including the parameters  $\lambda_3$  and  $\lambda_3^2$ ), and the first four terms (including the parameters  $\lambda_3$ ,  $\lambda_3^2$ , and  $\lambda_4$ ). As can be seen in the figure,

(1) The histogram deviates substantially from the normal distribution.

Figure 2: Comparison between observed histogram, Gaussian distribution (heavy line), and Non-Gaussian distribution: Water depth 1.4 m, Significant wave height 2.1 m

(2) The probability density function becomes negative for large negative  $x$ . However, the magnitude of the negative probability density function is relatively small; on the order of 2 percent or less. Furthermore, the negative density occurs outside the range of the histogram. Therefore, it will not cause any serious problem if we assume this negative probability density to be zero and, in turn, normalize the entire probability density function so that the area of the density function becomes unity.

(3) The probability density function which includes the parameter  $\lambda_3$  only agrees reasonably well with the histogram.

(4) The agreement with the histogram becomes poor if the term with the parameter  $\lambda_3$  is included in addition to the  $\lambda_3$ -term in the probability density function. Although not included in Figure 1, the same trend is obtained if the term with the parameter  $\lambda_4$  is included in addition to the  $\lambda_3$ -term.

(5) The probability density function consisting of terms with the parameters  $\lambda_3, \lambda_3^2, \lambda_4$  agrees well with the histogram.

(6) The addition of the parameter,  $\lambda_5$ , to the probability density function does not yield any appreciable change in the shape of the probability density function.

The same trend as stated above was also observed for many other wave records obtained at various water depths in various sea severities. Some examples are shown in Figures 3(a) through 3(c) for which the water depth ranges from 3.7 m to 8.8 m.

Figure 3: Comparison between observed histogram, Gaussian distribution (heavy line), and non-Gaussian distribution:

(a) Water depth 3.7 m, significant wave height 2.45 m

(b) Water depth 6.0 m, significant wave height 2.60 m

(c) Water depth 8.8 m, significant wave height 3.55 m

ANALYSIS OF PARAMETERS OF THE PROBABILITY DISTRIBUTION FUNCTION

It was shown in the previous section that  $\lambda_3$  and  $\lambda_4$  in Equation (1) are the significant parameters which govern the non-Gaussian probability density function for representing the distribution of wave profiles. Since the non-Gaussian characteristics of coastal waves depend on water depth and sea severity, it may be well to examine these parameters as a function of water depth and sea severity.

It was first thought that the parameter  $\lambda_3$  was a function of significant wave height and wave period. However, wave records show that  $\lambda_3$  appears to depend on significant wave height only. To substantiate this, an example of the variation of significant wave height, water depth, and the parameter  $\lambda_3$  with time during the growing stage of the storm are shown in Figure 4. The data were obtained at an average water depth of 1.4 m during the storm. As can be seen in the figure, the water depth varies with time by a substantial amount due to the tide. This results in an increase and decrease in significant wave height with the same period as the tide but the magnitude at high tide increases consistently during the growing stage of the storm. The time history of the magnitude of the parameter  $\lambda_3$  computed at hourly intervals (although a few points are missing) demonstrates nearly the same pattern as that of the significant wave height. Thus, it is clear that the parameter  $\lambda_3$  has a functional relationship with significant wave height.

Figure 4:

Variation of water depth, significant wave height, and skewness with time: Water depth 1.4 m

The parameter  $\lambda_3$  computed from records measured at various water depths is plotted against significant wave height, and some examples are shown in Figures 5(a) through 5(c). It is noted that the results presented in these figures are at locations where waves were measured, and that the water depth given in each figure is the average water depth during the storm at that location (see Figure 13

(a) Water depth 2.0 m

(b) Water depth 3.7 m

(c) Water depth 8.8 m

Figure 5:  
Parameter  $\lambda_3$  as a function of significant wave height

in the Appendix). Included in each figure is the functional relationship between  $\lambda_3$  and significant wave height expressed in the form of  $\lambda_3 = a(H_s)^b$ , where  $H_s$  is the significant wave height and the coefficients "a" and "b" are obtained by drawing the average line in the figure.

The coefficients "a" and "b" obtained from Figure 5 are plotted against the (average) water depth and the results are shown in Figure 6(a) and 6(b), respectively. As can be seen in these figures, the values of the coefficients "a" and "b" evaluated at a location where the water depth was in the range of 5.5 m to 6.0 m deviate from the average line drawn in the figure. That is, for a given significant wave height, the skewness evaluated from the record is greater than that evaluated by using the values obtained from the average line. This implies that the water depth of 5.5 m to 6.0 m appears to be the breaker depth during the storm, and hence the non-Gaussian characteristics of the waves in this particular water depth range are relatively more pronounced.

Figure 6: Parameters "a" and "b" as a function of water depth

The coefficients "a" and "b" are expressed as a function of the average water depth,  $h$ , as shown in Figure 6, and thereby the parameter  $\lambda_3$  can be evaluated in terms of water depth and sea severity as follows:

$$\lambda_3 = 1.16 e^{-0.42h} \cdot H_s^{0.74} h^{0.59} \quad (2)$$

where,  $h$  = average water depth in meters  
 $H_s$  = significant wave height in meters

Next, the parameter  $\lambda_4$  is evaluated from the records and its values are plotted against the parameter  $\lambda_3$  as shown in Figure 7. Several interesting features of the results shown in the figure are apparent. These are,

(1) There is considerable scatter in the values of  $\lambda_4$  for values of  $\lambda_3$  less than 0.2. These are values obtained from records taken at locations where the water depth is relatively deep; on the order of 15 to 25 meters. Although the values of  $\lambda_4$  vary considerably for  $\lambda_3$  less than 0.2, the shape of the distribution appears to be very close to that of the normal distribution. As an example, Figure 8 shows a comparison between the non-Gaussian probability density function with  $\lambda_3 = 0.2$  and  $\lambda_4 = -0.15$  and the normal probability density function in the standardized form. As can be seen, there is no difference between these two probability density functions. From the results of many similar comparisons, it may safely be concluded that the non-Gaussian presentation of coastal wave profiles (in standardized form) with a value of  $\lambda_3$  less than 0.2 can be approximated by the Gaussian probability density function (in standardized form).

Figure 7:  
Parameter  $\lambda_4$  as a function of parameter  $\lambda_3$

Figure 8:  
Comparison between normal probability distribution and non-Gaussian distribution with  $\lambda_3 = 0.20$  and  $\lambda_4 = -0.15$

(2) The largest value of the parameter  $\lambda_3$  obtained in the present analysis is 1.26 with the parameter  $\lambda_4$  of 1.98. This is observed in a severe sea of significant wave height 2.31 m at a water depth of 1.97 m. Figure 9 shows the histogram of the wave profile together with a portion of the wave record.

Figure 9: Histogram, probability distribution and portion of wave record for significant wave height 2.31 m at water depth 2.0 m

(3) There is some scatter in the  $\lambda_4$ -values for a specified  $\lambda_3$ . For example, the value of  $\lambda_4$  spreads from 0.45 to 0.90 with an average value of 0.70 for  $\lambda_3 = 0.8$ . However, the difference in the  $\lambda_4$ -values for a specified  $\lambda_3$  does not seriously affect the shape of the non-Gaussian probability density function. For instance, Figure 10 shows a comparison between three probability density functions having the same  $\lambda_3$ -value (0.8), but with values of  $\lambda_4$  of 0.45, 0.70 and 0.90. Included also in the figure is the Gaussian probability density function. As can be seen, the shape of the non-Gaussian probability density functions computed by Equation (1) differ significantly from that of the Gaussian density function, but there is no substantial difference between the shapes of the non-Gaussian distributions. In other words, the scatter in the  $\lambda_4$ -values for a given  $\lambda_3$  does not result in any serious difference in the shape of the probability density function.

From the discussion and subsequent conclusions stated in Items (1) and (3) above, the relationship between  $\lambda_3$  and  $\lambda_4$  can be formulated by taking the average value of  $\lambda_4$  for a specified  $\lambda_3$ -value. That is,

$$\lambda_4 = \begin{cases} -0.15 + 1.10 (\lambda_3 - 0.20)^{1.17} & \text{for } 0.2 < \lambda_3 < 0.5 \\ -0.15 + 1.10 (\lambda_3 - 0.20)^{1.17} + 1.48 (\lambda_3 - 0.50)^{1.47} & \text{for } \lambda_3 > 0.5 \end{cases} \quad (3)$$

Figure 10: Comparison between normal probability distribution and non-Gaussian distribution with  $\lambda_3 = 0.80$  and  $\lambda_4 = 0.45, 0.70,$  and  $0.90$

#### NON-GAUSSIAN PROPERTIES AND WATER DEPTH

As discussed earlier, the non-Gaussian characteristics of wind-generated coastal waves depends on water depth as well as sea severity. That is, even though the water depth is shallow, waves may still be considered to be a Gaussian random process if the sea severity is mild. Therefore, it may be of considerable interest to examine the limiting sea severity below which wind-generated coastal waves are considered to be Gaussian.

In the discussion of Figure 8, it was stated that the non-Gaussian presentation of coastal wave profiles with a value of  $\lambda_3$  less than 0.2 can be approximated by the Gaussian probability distribution, where  $\lambda_3$  is expressed as a function of water depth and sea severity in Equation (2). Therefore, it may be well to confirm whether or not the significant wave height which yields  $\lambda_3 = 0.2$  computed from Equation (2) for a given water depth represents the limiting sea severity below which the seas can be considered to be a Gaussian random process.

For this, histograms of the wave profile obtained at various water depths are examined to find the severest sea state (significant wave height) below which the histograms approximate a normal distribution. As an example, Figure 11 shows the histogram as well as a portion of the wave record obtained in a sea of significant wave height 1.52 m at a location of water depth 7.0 m. This is the largest significant wave height below which Gaussian characteristics were observed during the storm at this location. The computed value of the parameter  $\lambda_3$  is 0.19. A similar analysis was made at various water depths and the results are shown in Figure 12. Included also

Figure 11: Histogram, probability distribution and portion of wave record for significant wave height 1.52 m at water depth 7.0 m

Figure 12: Largest significant wave height below which non-Gaussian characteristics are expected as a function of water depth

in the figure are the lines indicating various  $\lambda_3$ -values computed from Equation (2). As can be seen, the largest significant wave height below which Gaussian characteristics are observed for water depths up to 15 m agrees well with the line for  $\lambda_3 = 0.20$ .

It is noted that the largest significant wave height observed at a water depth of 24.4 m was 4.34 m during the storm, and that all histograms of the wave profile obtained at this location approximate a normal probability distribution. It thus appears that the sea severity at this location did not reach a level during the storm to produce non-Gaussian characteristics. Thus, although confirmation could not be made for a water depth of 24 m, it may safely be concluded from Figure 12 that coastal waves in seas for which the parameter  $\lambda_3$  (skewness) is less than 0.2 can be considered as a Gaussian random process irrespective of water depth.

#### CONCLUSIONS

This paper presents the results of a study on non-Gaussian properties of coastal waves. From the results of statistical analysis of more than 500 records obtained in the growing stage of the storm, the following conclusions are drawn:

1. Time histories of coastal waves show a definite excess of high crests and shallow troughs, in general, and waves are considered to be a non-Gaussian random process. The non-Gaussian characteristic depends on water depth and sea severity.
2. The parameter  $\lambda_3$  which represents the skewness of the wave profile is the dominant parameter affecting the non-Gaussian characteristics of coastal waves, and that the combination of the parameters  $\lambda_3$ ,  $\lambda_2$ , and  $\lambda_4$  (where  $\lambda_4 = \text{kurtosis} - 3$ ) best represent the non-Gaussian probability density function (see Equation 1) applicable to coastal waves.
3. The parameter  $\lambda_3$  can be evaluated from Equation (2) as a function of water depth and sea severity. However, the non-Gaussian presentation (in standardized form) of coastal wave profiles with a value of  $\lambda_3$  less than 0.2 can be approximated by the Gaussian probability density function (in standardized form).
4. The parameter  $\lambda_4$  can be evaluated from Equation (3) as a function of  $\lambda_3$ .
5. From the conclusion stated in Item 3, it is possible for a given water depth to evaluate the limiting sea severity below which wind-generated coastal waves are considered to be Gaussian. That is, coastal waves in seas for which the parameter  $\lambda_3$  (skewness) is less than 0.2 can be considered as a Gaussian random process irrespective of water depth.

ACKNOWLEDGEMENTS

Part of this study was carried out under the sponsorship of the Office of Naval Research, Ocean Technology Program through Contract N00014-83-K-0157 to the University of Florida in connection with a project on prediction of wind-generated waves in finite water depth. The authors would like to express their appreciation to Dr. Silva, Office of Naval Research, for his encouragement and valuable discussion received during the course of this project.

APPENDIX: WAVE DATA

The wave data used in the present study were obtained by the Coastal Engineering Research Center (CERC), U.S. Army, at its Field Research Facility, located at Duck, North Carolina. The Field Research Facility has a 550-meter-long research pier extending into the Atlantic Ocean, equipped with seven Baylor resistance-type wave gages (see Figure 13). Extensive wave measurements were made at this site for two months in 1980 under the Atlantic Ocean Remote Sensing

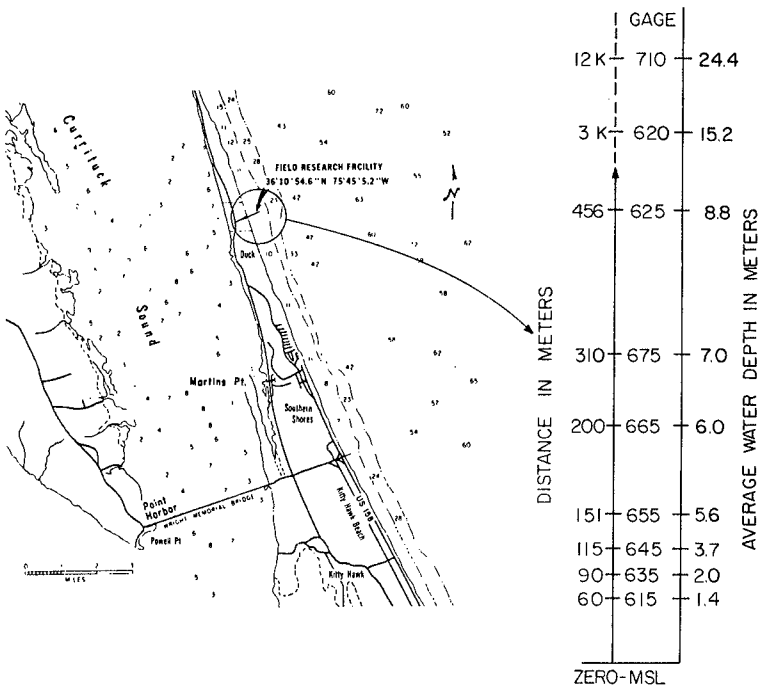

Figure 13: Coastal Engineering Research Center (CERC) Field Research Facility, Duck, North Carolina (By courtesy of CERC)

Land-Ocean Experiment (ARSLOE) Project. The details of this project may be found in several publications, Vincent and Lichy (1981), for example.

During October 23-25, an extratropical cyclon moved directly through the experimental area with wind speeds on the order of 10-15 m/sec. Continuous wave records were taken by the CERC Field Research Facility during the storm. The wave data analyzed in the present study are those recorded at the seven locations along the research pier and an additional two buoys (wave riders) located offshore along the extended line of the pier. The location of the wave gages and wave riders as well as the average water depth measured on October 21 and 27 by CERC are given in the figure.

## CHAPTER THIRTY SIX

### STATISTICAL PROPERTIES OF SHORT-TERM OVERTOPPING

Akira Kimura\* and Akira Seyama\*\*

#### 1. INTRODUCTION

It has been recognized recently that large waves tend to form a group in random sea waves. Overtopping tends to occur particularly when a group of high waves attacks a sea wall. If the capacity of a storage reservoir inside the sea wall is not sufficiently large enough to store a total amount of overtopping brought about by a single group of consecutive high waves, and if a drainage facility is not large enough to pump out sufficient water from the storage reservoir before the next overtopping starts, there is a danger of flooding inside the sea wall. Hence, storage and drainage facilities should be planned to be able to cope with the total amount of overtopping produced by a single group of high waves which overtop the sea wall consecutively. The term "short-term overtopping" referred in this study is that caused by a single group of high waves (see Fig.1). This study aims to clarify the following points:

- (1) the statistical properties of the amount of short-term overtopping,
- (2) the method to evaluate a security factor inside a sea wall against flooding by overtopping and an extension of the theory to the short-term overtopping from a comparatively long sea wall.

#### 2. PROBABILITY DISTRIBUTION OF SHORT-TERM OVERTOPPING

Short-term overtopping from a vertical (steep) sea wall located off a breaking zone is investigated in this paper. Following three assumptions are made to introduce statistical properties of short-term overtopping amount from a sea wall:

- (1) characteristics of an overtopping of zero-up-crossing wave from a sea wall can be approximated by a existing theory for periodic wave,

\* Associate Professor, \*\* Professor of the Dept. of Ocean Civil Engg., Faculty of Engg., Tottori Univ., Tottori, Japan

Fig.1 Explanation of the short-term overtopping and schematic illustration of the sea wall, storage reservoir and drainage pump

- (2) characteristic of an overtopping is not affected by neighboring waves but can be evaluated only by properties of an individual wave,
- (3) statistical distribution of wave height can be approximated as the Rayleigh distribution.

Beside above assumptions, wave period of overtopping waves are assumed to be constant, since high waves in random sea tend to have a constant wave period as recent studies on the joint probability distribution of wave height and period have pointed out<sup>4),7)</sup>.

The overtopping equation by Kikkawa et al.<sup>5)</sup> was applied in this study. They gave a simple overtopping equation in terms of a wave height, period and properties of a sea wall as follows.

$$q' / TH\sqrt{2gH} = 2/15 \cdot m_0 k^{3/2} (1 - Z/kH)^{5/2} \tag{1}$$

in which  $q'$ : overtopping amount of a wave from a unit length of a sea wall,  $H$ : incident wave height just outside a sea wall,  $T$ : wave period,  $Z$ : sea wall height,  $m_0, k$ : constants which characterize a shape and location of a sea wall (for a vertical sea wall located off a breaking zone, the value of

$m_0=0.5, k=0.6$  are recommended by Kikkawa et al.<sup>5)</sup>,  $g$ : gravitational acceleration. From eq.(1) an overtopping amount of the mean wave ( $\bar{H}, \bar{T}$ ) in case of  $Z=0$  is given by

$$\bar{q} = \sqrt{8}/15 \cdot m_0 k^{3/2} g^{1/2} \bar{T} \bar{H}^{3/2} \tag{2}$$

q' in eq.(1) is normalized with  $\bar{q}$  to yield

$$q = q'/\bar{q} = th^{3/2} (1 - \frac{z}{h})^{5/2} \tag{3}$$

in which  $t=T/\bar{T}$ ,  $h=H/\bar{H}$  and  $z=Z/k\bar{H}$ .

Analyzing the results presented by Goda<sup>4)</sup>, it appears that wave periods of high waves tend to distribute around 1.1 times of the mean wave period. t is put equal to 1.1 in this study. Thus a normalized overtopping amount is given only in terms of h when the properties of the sea wall are given. An amount of a short-term overtopping brought about by n high waves  $(h_1, h_2, \dots, h_n)$  which overtop the sea wall consecutively is determined as

$$q_0 = \sum_{i=1}^n q(h_i) \tag{4}$$

in which  $q(h_i)$  ( $i=1,2,\dots,n$ ) is given by eq.(3).

If the above-mentioned n wave heights are classified into following ranks

$$\begin{array}{lll}
 \text{rank} & 1 & : \quad 0 < h_i \leq z \\
 & " & 2 & : \quad z < h_i \leq z + \Delta h \\
 & \dots & \dots & \dots \dots \dots \dots \dots \\
 & " & j & : \quad z + (j-2)\Delta h < h_i \leq z + (j-1)\Delta h \\
 & \dots & \dots & \dots \dots \dots \dots \dots
 \end{array} \tag{5}$$

and if these n waves belong to the ranks  $j_1, j_2, \dots, j_n$  respectively and since the time series of zero-up-crossing wave height has close properties to those of the Markov chain<sup>6)</sup>, the probability that they appear in this order is given as

$$p(j_1, j_2, \dots, j_n) = p_{j_1} p_{j_1 j_2} \dots p_{j_{(n-1)} j_n} \tag{6}$$

in which  $p_{j_i}$ : probability that wave  $h_i$  belongs to the rank  $j_i$ ,  $p_{j_i j_{(i+1)}}$  ( $i=1,2,\dots$ ): probability that consecutive two waves belong to the rank  $j_i$  and  $j_{(i+1)}$  in this order respectively and so on. These probabilities are given as follows in this study<sup>6)</sup>.

$$P_{ji} = \int_{z+(ji-2)\Delta h}^{z+(ji-1)\Delta h} P(h) dh \quad (7)$$

and

$$P_{jij(i+1)} = \frac{\int_{z+(ji-2)\Delta h}^{z+(ji-1)\Delta h} \int_{z+[j(i+1)-2]\Delta h}^{z+[j(i+1)-1]\Delta h} P(h_1, h_2) dh_1 dh_2}{\int_{z+(ji-2)\Delta h}^{z+(ji-1)\Delta h} P(h) dh} \quad (8)$$

from the third assumption,  $P(h)$  and  $P(h_1, h_2)$  are given as<sup>6)</sup>

$$P(h) = \pi h/2 \cdot \exp(-\pi h^2/4) \quad (9)$$

$$P(h_1, h_2) = h_1 h_2 \cdot I_0[h_1 h_2 \rho/A] \cdot \exp[-(h_1^2 + h_2^2)/\pi A]/A \quad (10)$$

and

$$A = 4/\pi^2 - \rho^2$$

in which  $I_0$ : modified Bessel function of order 0,  $\rho$ : the correlation parameter which has the following relation with the correlation coefficient of the consecutive two wave heights<sup>1), 6)</sup>.

$$\gamma_h = \{E(\pi\rho/2) - (1/2)(1 - \pi^2\rho^2/4)K(\pi\rho/2) - \pi/4\} / (1 - \pi/4) \quad (11)$$

in which  $\gamma_h$ : correlation coefficient of consecutive wave heights,  $K$  and  $E$ : complete elliptic integrals of the 1st and 2nd kinds. When  $\Delta h$  in eq.(5) is sufficiently small, eqs.(7) and (8) can be replaced by eqs.(7)' and (8)'<sup>6)</sup>.

$$P_{ji} = \pi h_i/2 \cdot \exp(-\pi h_i^2/4) dh \quad (7)'$$

and

$$P_{jij(i+1)} = 2h_{i+1}/\pi A \cdot I_0(h_i h_{i+1} \rho/A) \cdot \exp[-(h_i^2 + h_{i+1}^2)/\pi A + \pi h_i^2/4] dh \quad (8)'$$

The probability that a short-term overtopping amount becomes  $q_0$ , when the above mentioned  $n$  waves overtop consecutively

in this order from a unit length of the sea wall, is given as

$$P_1(q_0) dq = \int \int \dots \int_D p_{j1} p_{j1j2} \dots p_{j(n-1)jn} dh_1 dh_2 \dots dh_n \tag{12}$$

where D is the region which is determined as

$$D : q_0 < \sum_{i=1}^n q(h_i) \leq q_0 + dq \tag{13}$$

D is schematically shown in Fig.2 when n=2 for example.

Fig.2 Region D (hatched area)

Region D (hatched area) the boundaries of which are given by the equations

$$\begin{aligned} \sum_{i=1}^2 q(h_i | t) &= q_0 \\ \sum_{i=1}^2 q(h_i | t) &= q_0 + dq \\ h_1 &> z \quad h_2 > z \end{aligned}$$

in which z: normalized sea wall height (eq.3). No over-topping takes place when an incident wave height is not larger than z. Since the region D and the probabilities  $p_{ji}$  and  $p_{jij(i+1)}$  in eq.(12) have complex forms, this equation is integrated numerically in this study. In such a case, the

more number of waves in a high wave group increases the longer becomes the computing time. But if a sea wall height is not so low, the expected run of waves in the longest high wave group which may appear during a single storm period is not so large. From the theory of a run of waves<sup>6)</sup>, the probability distribution of a run of high waves is given as

$$P_2(\ell) = p_{22}^{\ell-1} (1-p_{22}) \quad (14)$$

where  $p_{22}$ : probability that consecutive two waves exceed the threshold wave height  $h_*$ , which is given by

$$P_{22} = \frac{\int_{h_*}^{\infty} \int_{h_*}^{\infty} P(h_1, h_2) dh_1 dh_2}{\int_{h_*}^{\infty} P(h) dh} \quad (15)$$

$P(h)$  and  $P(h_1, h_2)$  are given by eqs.(9) and (10) respectively. Therefore, the probability that a run of high waves does not exceed  $\ell_* - 1$  is

$$P_3(\ell_* - 1) = \sum_{\ell=1}^{\ell_* - 1} p_{22}^{\ell-1} (1-p_{22}) = (1-p_{22}^{\ell_* - 1}) \quad (16)$$

Among  $N$  sets of independent high wave runs, the probability that no run exceeds  $\ell_* - 1$  is given by  $(1-p_{22}^{\ell_* - 1})^N$ . Therefore the probability that at least one run exceeds  $\ell_* - 1$  is given by  $1 - (1-p_{22}^{\ell_* - 1})^N$ . In the same manner, the probability that at least one run exceeds  $\ell_*$  is  $1 - (1-p_{22}^{\ell_*})^N$ . Probability distribution of the maximum run among  $N$  sets of high wave runs becomes  $\ell_*$  is given as<sup>8)</sup>

$$\begin{aligned} P_4(\ell_*) &= (1-p_{22}^{\ell_*})^N - (1-p_{22}^{\ell_* - 1})^N \\ &= \exp[N \cdot \ln(1-p_{22}^{\ell_*})] - \exp[N \cdot \ln(1-p_{22}^{\ell_* - 1})] \end{aligned} \quad (17)$$

in which  $\ln$ : natural logarithms.  
Its expectation is<sup>8)</sup>

$$\begin{aligned}
 E(\ell_*)_{\max} &= \sum_{\ell_*=1}^{\infty} \ell_* (1-p_{22}^{\ell_*})^N - \ell_* (1-p_{22}^{\ell_*-1}) \\
 &= \sum_{n=1}^N \frac{(-1)^{n+1} N C_n}{1-p_{22}^n} \\
 &\approx -[\ln(N) + 0.5772] / \ln(p_{22}) + (2p_{22}+1)/(3+3p_{22})
 \end{aligned} \tag{18}$$

Fig.3 shows probability distribution of the maximum run among 1000 sets of high wave runs, for example, for several threshold wave heights. (the value of  $\rho$  in eqs.(10) and (8)' is about 0.25 in case of the Pierson-Moskowitz type random waves). Solid lines in Fig.4 show the relation between  $E(\ell_*)_{\max}$  and  $N$  when the same value of  $\rho$  and  $z$  as Fig.3 are used. From this figure, the expected maximum run during a single storm is evaluated as follows. The mean interval of a run of high waves (mean total run) is given as<sup>6)</sup>

$$\bar{\ell}_0 = \frac{1}{1-p_{11}} + \frac{1}{1-p_{22}} \tag{19}$$

where

$$p_{11} = \frac{\int_0^{h_*} \int_0^{h_*} P(h_1, h_2) dh_1 dh_2}{\int_0^{h_*} P(h) dh} \tag{20}$$

$p_{22}$  is given by eq.(15).

The total number of waves which arrive during a single storm of duration  $I_e$  is  $N=I_e/(\ell_0 T)$  ( $\ell_0$ : mean total run). Substituting this value into eq.(18), the expected value of the longest run can be evaluated. For example, in case of  $h_* = h_{1/10}$  ( $=H_{1/10}/H=1.80$ ),  $T=10s$  and  $I_e=24$  hours in the Pierson-Moskowitz type random waves,  $N$  is about 860.  $E(\ell_*)_{\max}$  can be calculated by eq.(18) or read off from Fig.4 as about 4.3. In case of the non-dimensional sea wall height  $z=5$ ,  $E(\ell_*)_{\max}$  is about 2.5. For the practical use these values should be raised to the next whole number.  $n$  in eq.(12) for above examples are 5 and 3.

Fig.5 shows an example of a cumulative distribution of the short-term overtopping amount  $q_0$  which is given by

Fig.3 Probability distribution of the maximum run (N=1000)

Fig.4 Relation of  $E(\ell_*)_{\max}$  and N

Fig.5 Cumulative distribution of the short-term overtopping amount  $q_0$  ( $z=3, n=6$ )

$$C_1 = \int_0^{q_0} P_1(q) dq \quad (21)$$

when  $z=3.0, n=6$  are used for the Pierson-Moskowitz type random waves.

The security factor  $C_1$  against a temporal flooding by a single short-term overtopping inside the sea wall can be read off from this Fig.5 in terms of a capacity of the storage reservoir  $q_c$ . For example, when a normalized capacity of the reservoir ( $q_c/\bar{q}$ ) is 0.3,  $C_1$  is about 0.998 in this case (dotted line in Fig.5).

### 3. SECURITY FACTOR AGAINST FLOODING

The total run of high waves is determined by a sum of a pair of one high wave group and the next one low wave group. Therefore if an amount of a short-term overtopping  $q_0$  brought about by a single high wave group is pumped out until the next overtopping starts (within a total run), no flooding inside the sea wall takes place. When a drainage pump the capacity of which per 1 wave period ( $1.1T$ ) equals  $q_c/r$ , is facilitated inside the sea wall (it takes  $r$  times of the wave period to pump out water of volume  $q_c$  (Fig.1) from the reservoir) and if the next total run is longer than  $r+1$ , no overtopping takes place.

Since the probability distribution of the total run is given as<sup>6)</sup>

$$P_5(\ell_0) = \frac{(1-p_{11})(1-p_{22})}{p_{11}-p_{22}} (p_{11}^{\ell_0-1} - p_{22}^{\ell_0-1}) \quad (22)$$

The probability that a total run exceeds  $r$  ( $\ell_0 \geq r+1$ ) is given as

$$C_2(r) = \sum_{\ell_0=r+1}^{\infty} P_5(\ell_0)$$

$$= \frac{(P_{11}-1)P_{22}^r - (P_{22}-1)P_{11}^r}{P_{11} - P_{22}} \tag{23}$$

Since the expected maximum run of high wave of which length equals  $n$  is being discussed now, the total run is always longer than  $n$ . Therefore

$$C_2(r) = 1 \quad (r < n) \tag{24}$$

Finally, the security factor during a single storm inside the sea wall is given by  $C_1(q_c)C_2(r)$  when the given capacities of the storage reservoir and drainage pump per 1 wave period are  $q_c$  and  $q_c/r$ , respectively. Fig.6 shows examples of the security factor  $C_1C_2$  when the given  $q_c$  can cope with 99% of short-term overtoppings ( $C_1=0.99$ ) among entire short-term overtoppings brought about by high wave groups of length 6 (Fig.5). The parameter in the figure is the normalized sea wall height  $z$ .

Fig.6 Security factor in the case drainage pump is facilitated ( $C_1=0.99$ )

## 4. SPATIAL DISTRIBUTION OF WAVE HEIGHTS

Short-crestedness of random waves has to be taken into account to cope with the short-term overtopping from a comparatively long sea wall. In this study, such a long sea wall is divided into sections in which the water surface profile along the sea wall can be assumed to be uniform within the individual sections but independent of those of other sections. Overall security inside the sea wall is derived from the synthesis of the securities of all sections. In this respect, a simultaneous spatial correlation coefficient of wave profile along the sea wall may be a good property to determine the above mentioned range along the sea wall.

Short crested random wave profile is usually expressed as<sup>3)</sup>.

$$\eta(x,y,t) = \sum_{i=1}^{m_f} \sum_{j=1}^{m_\theta} \sqrt{2S(f_i)G(f_i,\theta_j)} \Delta f \Delta \theta \cdot \cos(k_1 \cos \theta_j x + k_1 \sin \theta_j y - 2\pi f_i t + \epsilon_{ij}) \quad (25)$$

in which  $m_f$ ,  $m_\theta$  : numbers of partitions of the energy spectrum  $S(f)$  and directional function  $G(f,\theta)$ ,  $\Delta f$ ,  $\Delta \theta$  : interval of  $S(f)$  and  $G(f,\theta)$ ,  $k_1$  and  $\theta_j$  : wave number and direction of propagation,  $\epsilon_{ij}$  : initial phase. Directional

function used is of Mitsuyasu type<sup>9)</sup>.  $S_{\max} = 50$  at non-dimensional water depth  $d/L_{1/3} = 0.1$ . Fully developed wind wave directional spectra usually take around this value of

$S_{\max}$  in this water depth range<sup>3)</sup>. ( $L_{1/3}$ : significant wave length), significant wave period is 5s and main direction of wave propagation is normal to the sea wall.

Fig.7 shows an example of a simultaneous spatial correlation coefficient along the infinitely long straight sea wall when a bottom slope is uniform and x-axis is set on the sea wall, y-axis is normal to the sea wall.

$$R(x_0, y_0) = \int_{t=0}^{\infty} \eta(x,y,t) \eta(x+x_0, y+y_0, t) dt \quad (26)$$

This correlation coefficient  $R$  was approximated with the following function  $R'$  (dotted line in Fig.7) in this study.

$$R'(x) = \begin{cases} 1 & ; L_c \leq |x_0| \\ 0 & ; \text{otherwise} \end{cases} \quad (27)$$

where  $L_c$  was selected so that the integration of

$R(x_0) - R'(x_0)$  from  $x_0=0$  to the point where  $R(x_0)$  first takes on 0, becomes 0. The long sea wall is divided into sections, the interval of which is  $2L_c$ . If there are topographical configurations on the sea bottom, the local change of  $L_c$  due to the refraction, diffraction and shoaling<sup>3)</sup> should be changed locally. To cope with the spatial changes in wave height and  $L_c$  due to sea bottom configuration, probability distribution  $P_1$  (or cumulative distribution  $C_1$ : Fig.5) for individual sections should be transformed so that they are expressed in terms of the real (not normalized) amount of short-term overtopping by multiplying  $2L_c \bar{q}$  to the horizontal axis at individual sections.

Fig.7 Spatial correlation coefficient of wave profile along the sea wall ( $S_{max}=50, d/L_{1/3}=0.1, T_{1/3}=5s$ )

5. SECURITY FACTOR INSIDE THE COMPARATIVELY LONG SEA WALL AGAINST FLOODING

In case the sea wall is divided into  $M$  independent sections and simultaneous amount of short-term overtoppings brought about by a single group of  $n$  consecutive waves from individual sections are  $q_1, q_2, \dots, q_M$ , respectively, the probability that the overall amount of a short-term overtopping becomes  $Q$  is

$$P_6(Q) = \iiint \dots \int_S P_{11}(q_{*1}) P_{12}(q_{*2}) \dots P_{1M}(q_{*M}) dq_{*1} dq_{*2} \dots dq_{*M} \tag{28}$$

in which  $P_{1i}(q_{*i})$  ( $i=1, 2, \dots, M$ ): probability that an amount of the short-term overtopping at the section  $i$  becomes  $q_{*i}$ ,  $S$ : the region where

$$S : Q < \sum_{i=1}^M q_{*i} \leq Q+dQ$$

Since  $P_{1i}$  are introduced numerically in this study, eq.(28) is rewritten as

$$P_6(Q) = \sum_{i_1=0}^{i_Q} \sum_{i_2=0}^{i_{Q_1}} \sum_{i_{M-1}=0}^{i_{Q_{M-2}}} P_{11}(i_1 \Delta q) \dots \cdot P_{1(M-1)}(i_{M-1} \Delta q) P_{1M}(i_{Q_{M-1}} \Delta q) \tag{29}$$

in which

$$i_m \Delta q = q_m, \quad i_Q \Delta q = Q, \quad i_{Q_m} \Delta q = i_Q \Delta q - \sum_{j=1}^m i_j \Delta q$$

( $m=1, 2, \dots, M-1$ )

When an amount of a single overall short-term overtopping  $Q$  is less than the capacity of the storage reservoir  $Q_0$ , no flooding inside the long sea wall takes place. This probability is given by

$$P_7(Q_0) = \text{Prob.}[Q \leq Q_0]$$

$$= \sum_{i_1=0}^{i_{Q_0}} \sum_{i_2=0}^{i_{Q_1}} \dots \sum_{i_M=0}^{i_{Q_{M-1}}} P_{11}(i_1 \Delta q) \dots P_{1M}(i_M \Delta q) \tag{30}$$

in which

$$i_{Q_0} \Delta q = Q_0$$

When the drainage pump the capacity of which per 1 wave period is  $Q_u$  (it takes  $r_u$  times of one wave period to pump out water of the volume of  $Q_0$  from the reservoir :  $r_u=Q_0/Q_u$ ) is facilitated, no overtopping takes place as far as the simultaneous total runs at all sections are longer than  $r_u+1$ . Since the probability that a total run exceeds  $r$  is given by eq.(23), the simultaneous probability that total runs at all sections exceed  $r_u$  is given as

$$P_8(r_u) = \prod_{i=1}^M C_{2i}(r_u) \quad (31)$$

Suffix  $i$  refers to the properties of the section  $i$ . Totally, the security factor against flooding inside the sea wall becomes

$$P_7(Q_0)P_8(r_u) \quad (32)$$

Supplemental security can be incorporated into eq.(32) even in the case a certain amount of water is left unpumped from the reservoir. Because if the total amount of unpumped water from the reservoir and that brought about by the next short-term overtopping do not exceed  $Q_0$ , no flooding takes place. When the total run of the first high wave group becomes longer than  $r_u - j$  at every section, an amount of  $jQ_u$  is left unpumped from the reservoir at most. And in case the next short-term overtopping is  $Q'$ , to pump out the total amount of  $Q' + jQ_u$  within the second total run, the second total run should exceed  $j + \ell' + 1$  ( $\ell' = Q'/Q_u$ ). Therefore the security against flooding in this case becomes

$$P_7(Q_0 - jQ_u)P_8(r_u + j) \quad (33)$$

The maximum possible amount carried over to the second total run is  $Q_0 - (n+1)Q_u$  because the minimum total run is  $n+1$  in the present discussion. The security against flooding when a single carry-over of water to the next total run is permitted, is given as

$$\sum_{j=0}^{n+1} P_7(Q_0 - jQ_u)P_8(r_u + j) \quad (34)$$

## 6. DISCUSSION

The overtopping equation by Kikkawa et al<sup>5)</sup> was used in this study. But to the extent which the three assumptions made in section 2 holds, other overtopping equations which are suitable for various situations considered may be utilized.

The method to divide the long sea wall into independent sections used in this study is found not always appropriate one. Therefore a more effective method needs to be introduced<sup>2)</sup>.

Some supplemental security factor was discussed in the last part of the section 5. Further supplements are possible, however, in the same way by allowing carry overs of unpumped amounts from the reservoir to occur more than twice. Needed supplements should be determined in accordance with the degree of accuracy of the assumptions made for various situations considered.

## CHAPTER THIRTY SEVEN

### Shallow-Water Spectral Wave Modeling

Robert E. Jensen, PhD\*

#### ABSTRACT

A parametric shallow-water spectral wave modeling technique is developed and is tested against extensive field measurements of wave height, period and spectral shape. The wave model considers wave growth and finite water depth mechanisms such as spectral wave shoaling, wave-bottom interactions, wave-wave interactions and wave breaking. The key to this approach is that the resulting wave conditions are provided by transformation mechanisms rather than transforming spectral components during wave propagation. Thus long-term wave hindcasts can be performed economically without the loss in accuracy.

#### INTRODUCTION

The predictions of shallow-water wave characteristics have become a focal point of research activities across the world. Because construction, shipping, and dredging operation costs have drastically increased over the years, coastal engineers have been faced with more accurately defining the shallow-water wave climate. A better understanding of shallow-water wave growth and transformation mechanisms is slowly evolving through controlled wave-measuring programs such as ARSLOE [Vincent and Lichy (21)]. However, not all of the questions have been answered, and it will take some time before all shallow-water wave transformation mechanisms are quantified [Vincent (19)]. In light of this, the shallow-water wave modeling technique employed in this study adopts recently derived mechanisms currently available. The main intent in the development of the wave model is to describe the physical processes as accurately as possible while simplifying the computational procedures to a degree where shallow-water wave hindcasting is economically feasible. The wave model is designed to compute wave conditions (frequency spectra and various wave parameters derived from the spectra) at site-specific locations. Study areas are restricted to semi-enclosed bodies of water. Also, wind conditions are assumed to be uniform over the area and remain constant for a given duration. Wave propagation is assumed to be restricted to the direction described by the winds, and the bottom topography is represented by straight and parallel bottom contours. The model is applied to Saginaw Bay, Michigan.

#### THEORY

Hasselmann et al. (7) introduced a parametric model of wind-wave generation relating the rate of energy growth to nondimensional

\*Research Hydraulic Engineer, US Army Engineer Waterways Experiment Station, Coastal Engineer Research Center, Vicksburg, Miss. 39180-0631.

characteristics of the wind field. The energy growth (in space or time) is governed by a self-similar process and verified through extensive prototype data [Hasselmann (5), Hasselmann et al. (7)]. In these studies, the dominant energy input to the forward face of the spectrum is related to convergence of energy flux due to nonlinear, resonant wave-wave interactions (Fig. 1) of the form described by Hasselmann (6). Studies by Mitsuyasu (13, 14) and Kitaigordskii (11) also displayed similar results.

Fig. 1. Schematic representation of the nonlinear wave-wave interactions

The rate of wave growth under ideal conditions of fetch limitations or duration limitation and a stationary wind field can be computed [Hasselmann et al. (7)]. For growth along a fetch the solution is

$$E_o = 1.6 \times 10^{-7} U^2 \frac{F}{g} \tag{1}$$

and for growth through time, it becomes

$$E_o = 4.3 \times 10^{-10} U^{18/7} g^{-4/7} t^{10/7} \tag{2}$$

where  $E_o$  is the total energy resulting from a wind speed  $U$  [assumed to be overwater wind conditions adjusted to 33 ft (10m) elevation], blowing over a given fetch length  $F$ . The gravitational

acceleration is denoted by  $g$ ;  $t$  is the time since the wind began to blow.

Two additional pieces of information are required to quantify the distribution of  $E_0$  given in the form of an energy density spectrum. The nondimensional peak frequency,  $\tilde{f}_m$ , and the Phillips' equilibrium constant  $\alpha$  [Phillips (17)] and are written as

$$\alpha = 0.076\tilde{X}^{-0.22} \quad (3)$$

and

$$\tilde{f}_m = 3.5\tilde{X}^{-0.33} \quad (4)$$

where  $\tilde{X}$  is the nondimensional fetch length

$$\tilde{X} = \frac{gF}{U^2} \quad (5)$$

Although Hasselmann, et al. (7) found that wave growth followed the parametric forms defined in terms of distance and time, it will be shown that for all wave generating conditions in Saginaw Bay, wave growth is adequately described only by spatial variations. Therefore, it becomes a matter of comparing the prototype results (wave height, period and spectral shape) to the hindcast model that employs Eqs. 1 and 4.

The parameterization of the wave growth is restricted such that when the nondimensional peak frequency attains a value of 0.13 or less, a fully developed sea state is achieved and wave growth is halted. Over long fetch lengths and low wind speeds, this condition can occur with some degree of regularity. Thus Eqs. 1, 3-5 are then redefined by

$$Q = K \sum_{i=1}^{10} \zeta_i \quad (6)$$

where  $K$  is defined as the nonvarying parameters (and constants),  $Q$  is defined as the dependent parameters, and  $\zeta_i$  is recognized as the independent parameters ( $F$  and  $\tilde{X}$ ) found in Eqs. 2-5. The parameter  $i$  is the increment counter. After each discrete fetch length  $F_i$ , the nondimensional peak frequency is evaluated to determine if  $\tilde{f}_m < 0.13$ . If this occurs wave growth is terminated, and wave decay is initiated for the remainder of the fetch length. Wave decay is parameterized following the work conducted by Bretschneider (1) and Mitsuyasu and Kimura (15) for the peak frequency  $f_m$  (where  $f_m = \tilde{f}_m g/U$ ) while the total energy decay rate follows that described by Jensen (10).

Wave conditions generated in Saginaw Bay also must consider dispersion effects resulting from finite water depth conditions. When the water depths vary from  $F_i$  to  $F_{i+1}$ , the conservative transformation mechanisms of shoaling and refraction must be considered. Wave shoaling is determined from the evaluation of group speed determined by linear theory. Wave refraction is neglected under the assumption

that: the bottom topography is assumed to be straight and parallel for every fetch length. Considering the water depths in Saginaw Bay and peak wave periods ( $T_p = 1/f_m$ ) in the range of 2 to 8 sec, wave-refraction effects (and subsequent "errors") would be on the order of 2 to 25 percent in terms of the wave direction. This is assuming that the angle between the wave crest and bottom contour is at most,  $30^\circ$ . The initial direction of wave propagation is limited to 18 angle classes at  $10^\circ$  increments (because of the wind data employed in this study); thus the accuracy in the resultant refracted wave condition, by similarity, also would be constrained to the 18 angle classes.

Finite water depth conditions also lead to bottom dissipation effects on the growing seas. Energy losses associated with bottom friction are empirically modeled using the following sets of equations developed by Bretschneider (2).

The second theoretical aspect of wave model deals primarily with the distribution of the total energy ( $E_o$ ) in the form of a one-dimensional discrete frequency spectrum  $E(f)$ . Through the use of similarity principles, Kitaigorodskii, Krasitskii, and Zaslavaskii (12) extended Phillips' deepwater hypothesis [Phillips (17)] of the equilibrium range in the spectrum of wind-generated surface waves to finite depth conditions. The spectral form is defined by

$$E(f) = \alpha g^2 (2\pi)^{-4} f^{-5} \phi(\omega_h) \quad f \geq f_m \quad (7)$$

where  $E(f)$  is the energy density at each discrete frequency band  $f$  and  $\phi(\omega_h)$  is a nondimensional function dependent on  $\omega_h$  given by

$$\omega_h = 2\pi f(h/g)^{1/2} \quad (8)$$

The function  $\phi(\omega_h)$  varies from 1.0 in deep water to 0.0 when  $h = 0.0$  as shown by Fig. 2. When  $\omega_h$  is less than 1.0,  $\phi(\omega_h)$  can be approximated by:

$$\phi(\omega_h) \approx \frac{1}{2} \omega_h^2 \quad (9)$$

and therefore,

$$E(f) = \frac{1}{2} \alpha g h (2\pi)^{-2} f^{-3} \quad f_j \geq f_m \quad (10)$$

or, the spectral shape changes from  $f^{-5}$  to  $f^{-3}$  in the tail of the energy density spectrum, and more importantly, becomes a function of the water depth.

The forward face of the spectrum is assumed to be represented by:

$$E(f) = \alpha g^2 (2\pi)^{-4} f_m^{-5} \exp \left[ 1 - \left( \frac{f}{f_m} \right)^4 \right] \phi^*(\omega_h) \quad f < f_m \quad (11)$$

where  $\phi^*(\omega_h)$  is evaluated from the  $\omega_h$  defined at  $f_m$ . Field and laboratory data by Goda (4), Thornton (18), Ou (16), Iwata (8), and Vincent (20) support the form given by Eq. 7. The verification of Eq. 11 is supported by Garcia and Jensen (3), Jensen (9, 10).

Figure 2. The universal dimensionless function  $\phi$  (solid curve) and the function  $\omega_h^2/2$  (dashed curve), from Kitaigorodskii, Krasitskii, and Zaslavskii (12).

The parametric representation of wave growth assumes a dynamic balance between atmospheric sources and transfers of energy resulting from wave-wave interactions (Fig. 1). This parameterization was based on deep-water wave conditions, Hasselmann et al. (7). During the Saginaw Bay study, it was determined that over moderately short fetch lengths [10 to 20 nautical miles (18.5 to 37 km)], this deep-water growth rate expression (Eq. 1) consistently underpredicted the total energy found in the measured data. The only theoretically consistent location to add the energy would be on the forward face of the spectrum (Fig. 3). The function,  $E(f,h)_{THEORY}$  is the saturated spectrum based on Eqs. 7 and 11, and  $E(f,h)_{WEIGHTED}$  is the spectrum based on  $E_0$  after wave growth. This process also shifts  $f_m$  to a lower frequency which has been noticed in field data. As the fetch length increases, the relative amount of added energy decreases, where eventually no additional energy is incorporated into the resulting spectrum.

It has been shown that the water depth greatly influences the spectral shape and in so doing will influence the maximum wave conditions. The parametric formulation follows the work conducted by Vincent (20). The depth limiting maximum wave condition is given by,

$$H_m = 4 \int_{f_c}^{\infty} E_m(f) df \quad (12)$$

where

$H_m$  is the maximum wave condition;  $f_c$  is the lower frequency bounding the total energy (equal to  $0.9 f_m$ ); and  $E_m(f)$  is defined from Eq. 10. Integrating Eq. 12 the absolute limit on the wave condition at a particular water depth is obtained, where

$$H_m = \frac{(\alpha gh)^{1/2}}{\pi f_c} \quad (13)$$

Fig. 3. Construction of the final energy density spectrum (solid symbols) caused by shallow-water wave generation

In summary, the physical process governing wave generation and transformations has been theoretically determined using available, state-of-the-art techniques. It must be emphasized that not all shallow-water transformation processes have (or can be) measured to determine their relative effect on the total energy, spectral shape, and peak frequency. Therefore the development of the wave model as employed in this study attempts to model the physics of the problem in a general sense while maximizing computational efficiency.

#### VERIFICATION

In all wave hindcasting studies, comparisons to gage measurements are a necessary element in the development of a wave model. The initial calibration test was conducted on a data set that contained the largest wave conditions measured during the wave gaging portion of this study.

The wave gages were deployed in April 1981 shortly after the bay became ice-free (Fig. 4). Early on 10 May 1981, winds began to increase and by noon were steady at 25 to 30 mph (11.1 to 13.4 m/s) from a direction of about  $40^\circ$  east of north. The winds held a remarkably constant speed and direction for about a day and a half before beginning to diminish. The predominant direction coincided with the axis of the bay and alignment of the gage array, the most favorable condition for generation of the largest waves and for studying changes in the wave climate.

Fig. 4. Saginaw Bay wave gage and hindcast station locations, (Note: 1 mile = 1.61 km)

Because of the constancy in the wind speed and direction during the period 10-12 May 1981, any variation in the wave climate would be a function only of the wind speed. Fig. 5 shows the wind data obtained at the Saginaw Projects Office, of the U. S. Army Engineer District, Detroit, during this period of time. The anemometer elevation was about 60 ft (18.3 m) and located about 3 miles (4.8 km) south of Station 1.

Results of the comparisons for gage sites 1 and 2 are shown in Fig. 6 where  $H_{mo}$  is the characteristic wave height and  $T_p$  is the peak period defined as:

$$H_{mo} = 4 \int_0^{\infty} E(f) df \quad (14)$$

$$T_p = f_m^{-1} \quad (15)$$

Fig. 5. Wind data used for verification test,  
(Note: 1 mph = 0.447 m/s)

There is a slight phase difference between the measured and hindcast data sets. This is due to the wave model assumption that wave conditions are generated instantaneously, i.e., there is no time-dependency associated with the effects of wave propagation on the wave climate. The small-scale temporal fluctuations in the measured data cannot be simulated in the wave model because of the assumption of uniform wind conditions.

Energy density comparisons are also made between the measured and hindcast data. It is helpful to recognize that a spectral representation of the wave phenomena is an estimate of the actual wave conditions existing at a specific point in space and time. To illustrate this, all measured wave spectra are plotted with an accompanying 90 percent CHI-squared distribution confidence band. Although numerous comparisons were performed, a limited number of Station 1 results are presented. The three energy density spectral plots shown in Figs. 7-8 represent three phases in the 10-12 May 1981 storm; Fig. 7 illustrates the initial growth phase, and the peak of the storm; Fig. 8 illustrates the final decay stage. The wave model spectral results are adjusted in time to compensate for the lag associated with the wave propagation. The adjustment varies from 2 to 4 hours depending on propagation time.

The energy plots [ $E(f)$  versus  $f$ ] are plotted in a nondimensional frequency domain defined by  $f/f_m$  where  $f_m$  is the frequency at the spectral peak. The greatest discrepancy in the comparison of measured and hindcast peak frequencies was one discrete frequency band or 0.0156 Hz. Figs. 7-8 show that from initial growth to final decay,

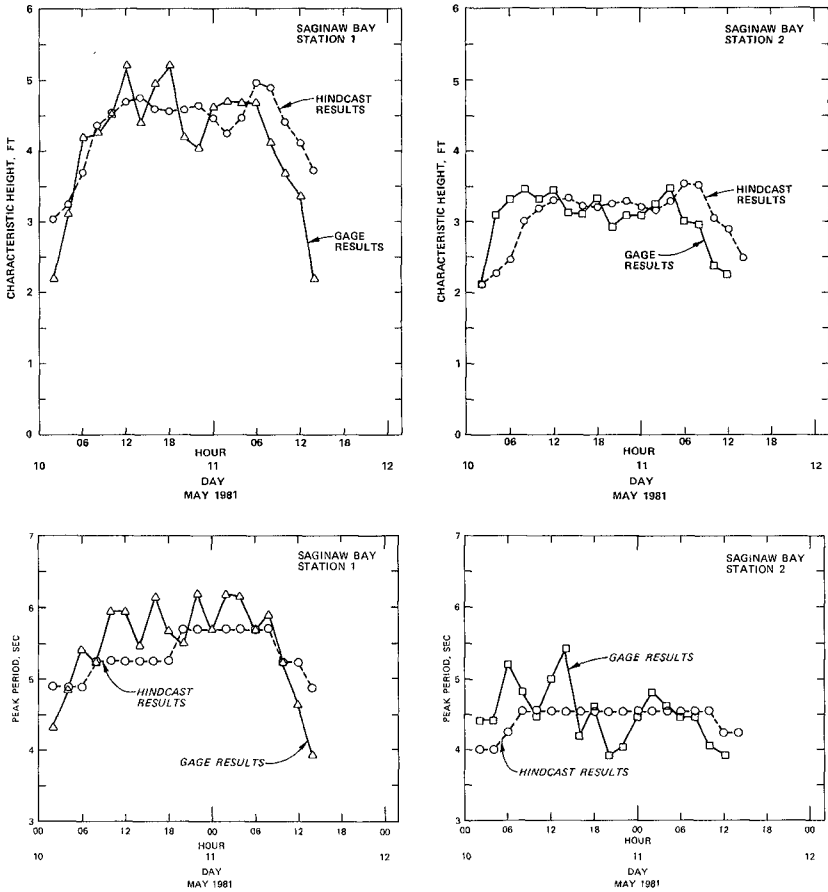

Fig. 6. Comparison of wave height and period for hindcast and measured conditions, (Note: 1 ft = 0.305 m)

Fig. 7. Comparison between measured and hindcast wave spectra estimates for Station 1, 1600 hours, 10 May 1981 and 400 hours, 11 May 1981, (Note:  $1 ft^2 = 0.093 m^2$ )

Fig. 8. Comparison between measured and hindcast wave spectra estimates for Station 1, 1000 hours, 11 May 1981,

(Note:  $1 \text{ ft}^2 = 0.093 \text{ m}^2$ )

the wave model energy density spectrum follows the measured spectrum to within the 90 percent confidence limits. The forward face of the measured spectra conforms with the assumption of the spectral shape defined in Eq. 11. The tail of the hindcast spectra conforms with the measured data except for small-scale temporal variations in the measured data and the extreme tail of the distribution, i.e., when  $f/f_m > 2$ . The discrepancy between the measured and hindcast spectra when  $f/f_m > 2$  is a characteristic of a pressure sensing gage system such as used in this study. Assuming a linear transformation exists between the recorded pressure response and the free surface, individual wave component frequencies greater than 0.35 Hz will be increasingly damped with water depth. Thus representation of the energy density at frequencies greater than  $\approx 0.35$  Hz are very approximate. The relative energy at frequencies greater than 0.35 Hz is plotted but represents only an unknown fraction of the energy in a particular wave record.

The secondary peaks displayed in the measured spectra may be caused by several different mechanisms such as secondary wave trains propagating into the area or backscattering due to variations in bottom topography, the decomposition of finite amplitude waves into secondary harmonics, or in artifact of the analysis procedure.

#### CONCLUSIONS

Many more comparisons were performed than are presented here without adjustment of coefficients or modification to the hindcast model to account for changes in location. The comparisons convincingly demonstrate the ability of the wave model to accurately hindcast wave conditions in Saginaw Bay to within  $\pm 0.5$  ft ( $\pm 0.15$ m) significant height and  $\pm 1.0$  sec peak period. Moreover, the theoretically derived spectral shapes generally conform within the 90 percent CHI-squared confidence limits of the measured spectra, [Garcia and Jensen (3)].

The wave model has been extensively used in other site specific hindcast studies [Jensen (9, 10)]. The mechanisms describing the physical processes found in the wave model have remained unchanged from study to study. The differences between the hindcast and prototype wave estimates were found to closely approximate the aforementioned ranges.

#### ACKNOWLEDGMENTS

I would like to thank the Office, Chief of Engineers for permission to publish this manuscript and the U. S. Army Engineer, Detroit District for sponsoring the project on which this work was accomplished. Ms. Janie Daughtry assisted in preparing this report.

## CHAPTER THIRTY EIGHT

### A Typhoon Wave Hindcasting Technique

N.K. Liang\*      C.C. Chien\*\*

#### ABSTRACT

The typhoon wave forecasting technique proposed by C.L. Bretschneider (1) is a good simple method. However, the measured maximum wave height at Nan-Wan Bay (at southern tip of Taiwan) of Ida typhoon is about twice of the hindcasted maximum wave height. In general, the hindcasted maximum typhoon wave height arrives earlier than the measured data for Bretschneider's method as well as the other methods, such as Tang's and Ijima's methods. And as the typhoon is approaching the station, the hindcasted wave heights are smaller than the measured ones. On the contrary, as the typhoon is leaving the station, the hindcasted wave heights are greater than the measured heights. In order to improve these defects, the typhoon swell proposed by Liang (7) is superimposed upon the typhoon wind wave according to the energy conservation principle. The modified wave period is calculated by the energy-weighted method.

In this paper 8 typhoons are as examples to show that the new method has amended the above-mentioned defects.

## 1. INTRODUCTION

There are approximately 4 typhoon wave hindcasting techniques : (1) Wilson's graphical method (2) Tang's numerical technique. (3) Ijima's tracing method, and (4) Bretschneider's empirical method. Liang (3) has used Tang's method to hindcast typhoon wave at South Taiwan strait of Typhoon Elsie (Oct., 1975). The result is that the hindcasted peak wave arrived 7 hours ahead of the measured data. And the hindcasted peak wave height is 2 meters less than the measured one. However, Tang's method is proved to be quite good for typhoon wave on shoaling beaches.

Tsai (10) has used Ijima's tracing method to hindcast waves of typhoons Nina (Aug., 1975), Betty (Sept., 1975), Bess (Sept., 1971) and Judy (May, 1966). The results show that in the approaching period the measured wave heights are much higher than those of hindcasted wave heights, and vice versa for the leaving period. However, the hindcasted peak wave heights are close to the measured ones. Therefore, Ijima's method can be used to determine the design wave.

Bretschneider's empirical method is very simple. Liang & Lin (4) have used it to hindcast waves of Typhoon Vera (July, 1977). It was found that in the initial stage the hindcasted wave heights are higher than the measured data and the hindcasted peak wave height is close to the measured one. The former result may be due to the sheltering effect of the land. However, Liang has hindcasted wave of Typhoon Ida (July, 1980). The measured wave heights are much higher than the hindcasted data (Fig. 7). The reason is that Typhoon Ida's center did not pass through the wave station at Nan-Wan (at the southern tip of Taiwan) as Typhoon Vera did. Therefore, more typhoon swell energy overlapped on the typhoon wind wave for the latter case.

Hou, Kou & Tzeng (2) have modified Bretschneider's method by reducing the R value (radius of maximum wind speed) and found that the hindcasted peak wave heights are close to the measured ones. But, if the variation of the typhoon track changes greatly, the hindcasted data do not match the measured data, such as for Typhoon Judy (Fig. 1).

This paper is going to use Bretschneider's method to calculate typhoon wind wave and Liang's typhoon swell method to estimate typhoon swell. Then, by the energy superposition principle and wave energy weighting method, the typhoon wave height and wave period are estimated.

## 2. THEORY

A simple introduction of Bretschneider's method and Liang's method is as follows:

(A) Typhoon wind wave hindcasting method (for area within the radius  $10R$ )

(1) Typhoon wind field

$$\frac{U_r}{U_R} = -\frac{1}{2} \frac{fR}{U_R} \frac{r}{R} + \left[ \left( 1 + \frac{fR}{U_R} \right) \frac{R}{r} e^{\left( 1 - \frac{R}{r} \right)} + \left( \frac{1}{2} \frac{fR}{U_R} \frac{r}{R} \right)^2 \right]^{\frac{1}{2}} \quad (1)$$

in which,

- r radius of typhoon measured from typhoon center.
- R radius of maximum wind speed.
- f Coriolis force coefficients.
- U<sub>r</sub>, U<sub>R</sub> Geostrophic wind speed at radius r or R.

By Graham and Nunn, an empirical formula for maximum wind speed radius is as follows:

$$R' = \{ 28.52 \tanh [ 0.0873 ( \phi - 28 ) ] + 12.22 \exp [ ( p_o - 1013.2 ) / 33.86 ] + 0.2 V_F \times 1.852 + 37.22 \} / 1.852 \quad (N.M.) \quad (2)$$

in which,

- φ latitude
- p<sub>o</sub> typhoon center atmospheric pressure in mb
- V<sub>F</sub> typhoon moving speed in knots

Here, R is modified by the following equation

$$R = R' - [ ( U_{R'} - 100 ) / 6 + 6 ] \quad (3)$$

where

$$U_R = K \sqrt{\Delta p} - 0.5 fR \quad (4)$$

$$K = -\phi / 7.5 + 70 \quad (5)$$

after Liaw (8), typhoon center atmospheric anomaly in inches of mercury column is as follows:

$$\Delta p = \frac{1}{33.86} \left[ 1000 + \frac{(1000 - p_o)}{10} p_o \right] \quad (6)$$

The mean (10 minute) sea surface wind speed at 10 meter height at radius R is as follows:

$$U_{RS} = 0.865 U_R \quad (7)$$

for moving typhoon

$$U_{RSS} = U_{RS} + \frac{1}{2} V_F \cos \theta \quad (8)$$

in which,

- θ angle between the line connecting typhoon center and wave station and the direction of typhoon motion

Similarly, we have

$$U_{rs} = 0.865 U_r \quad (9)$$

$$U_{rss} = U_{rs} + \frac{1}{2} V_F \cos \theta \tag{10}$$

(2) Estimation of wave height and wave period

For stationary typhoon, the wave height at radius R is

$$H_R = K' \sqrt{R \cdot \Delta p} \quad (\text{ft}) \tag{11}$$

$K'$  is a function of  $\frac{fR}{U_R}$  and can be approximated by the equation:

$$K' = 7.59 - 41.21 \left( \frac{fR}{U_R} \right) + 160.51 \left( \frac{fR}{U_R} \right)^2 - 219.32 \left( \frac{fR}{U_R} \right)^3 \tag{12}$$

$$\frac{T_o}{U_{RS}} = 0.4 \tanh \left\{ \ln \left( \frac{1 + \frac{40 H_R}{U_{RS}^2}}{1 - \frac{40 H_R}{U_{RS}^2}} \right)^{0.5} \right\}^{0.6} \tag{13}$$

$$T_R = (4/5)^{\frac{1}{4}} T_o \tag{14}$$

$T_R$  is the wave period at radius R.

$H_r$  is the wave height at radius r,  $H_r/H_R$  is a function of  $r/R$  and  $fR/H_R$  (1).  $T_r$  is the wave period at radius r.

$$\frac{T_o}{U_{rs}} = 0.4 \tanh \left\{ \ln \left( \frac{1 + \frac{40 H_r}{U_{rs}^2}}{1 - \frac{40 H_r}{U_{rs}^2}} \right)^{0.5} \right\}^{0.6} \tag{15}$$

$$T_r = (4/5)^{\frac{1}{4}} T_o \tag{16}$$

For moving typhoon,

$$H_{RS} = H_R \left( 1 + \frac{\frac{1}{2} V_F \cos \theta}{U_{RS}} \right)^2 \tag{17}$$

$$H_{rs} = H_r \left( 1 + \frac{\frac{1}{2} V_F \cos \theta}{U_{rs}} \right)^2 \tag{18}$$

(B) Typhoon swell estimation (for radius r greater than 10R)

After Liang (7), the swell height is as follows:

$$H_s = C H_{RS} \frac{R}{\sqrt{DD}} \quad (\text{Meter}) \tag{19}$$

DD distance between typhoon center and station in N.M.  
 C a constant, about 0.11

The swell period is as follows:

$$T_s = C' T_{RS} \quad (20)$$

$C'$  is always greater than 1 and empirically equal to

$$C' = 0.0021 \left( \frac{DD \cdot T_{RS}}{R \cdot U_{RSS}} \right)^2 + 0.0021 \left( \frac{DD \cdot T_{RS}}{R \cdot U_{RSS}} \right) + 1.21 \quad (21)$$

The time lag for the swell to arrive the station is:

$$T_{lag} = \frac{DD}{1.516 \times T_s} \quad (\text{hours}) \quad (22)$$

As the typhoon moves to the station,  $T_{lag}$  decreases; and as the typhoon moves away from the station,  $T_{lag}$  increases. By using the principle of energy flux conservation, a swell wave height correction coefficient  $\lambda$  is obtained (7).

$$\lambda = \left( \frac{T_D}{T_{D'}} \right)^{\frac{1}{2}} \quad (23)$$

in which

$T_D$  Duration of swell if the typhoon were stationary

$T_{D'}$  The real duration

The swell wave height is then as follows,

$$H_s' = \lambda H_s \quad (24)$$

By the principle of energy conservation, the typhoon wave can be estimated as follows:

$$H_{1/3} = (H_s'^2 + H_w^2)^{\frac{1}{2}} \quad (\text{meter}) \quad (24)$$

$$T_{1/3} = \frac{H_s'^2 T_s + H_w^2 T_{rs}}{H_s'^2 + H_w^2} \quad (\text{sec}) \quad (25)$$

where

$$H_w = 0.3048 \text{ Hrs} \quad (\text{meter}) \quad (26)$$

### 3. COMPARISONS OF HINDCASTED AND MEASURED DATA.

In the paper 8 typhoons are used to check the different models by the measured wave data. The typhoons and the wave stations are shown in Table 1.

Table 1

Typhoon	Time	Wave Station	Water Depth
Judy	May, 1966	Kaoshiung Harbor	12 m
Agnes	Sept., 1971	Taichung Harbor	19 m
Bess	Sept., 1971	Taichung Harbor	19 m
Nina	Aug., 1975	Su-Ao Harbor	28 m
Betty	Sept., 1975	Su-Ao Harbor	28 m
Elsie	Oct., 1975	South Taiwan Strait	104 m
Vera	July, 1977	Keelung Harbor	38 m
Ida	July, 1980	Nan-Wan Bay	16 m

Because the wave stations are not at deep sea (except Elsie Typhoon), shoaling effect is considered. The measured data and hindcasted data of the above eight Typhoons are shown in Fig 1 - Fig 8.

#### 4. CONCLUSIONS

This paper proposes a new typhoon wave hindcasting method which has improved several defects of the other models. Basically, this method is based on Bretschneider's method and Liang's typhoon swell method. Which is also partially originates from Bretschneider's method. Hence, it is sure that, (1) Bretschneider's method is a good typhoon wave predication method. (2) The effect of swell has not been considered in Bretschneider's method. Finally, there are two other things which should be further studied. One is R value (radius of maximum wind speed). Another is the wave period. However, the method proposed in this paper can be used in the wave climate prediction.

## CHAPTER THIRTY NINE

### INFLUENCE OF EL NINOS ON CALIFORNIA'S WAVE CLIMATE

Richard J. Seymour, M.ASCE (1)

R. Rea Strange III (2)

Daniel R. Cayan (3)

Robert A. Nathan AM.ASCE (4)

#### ABSTRACT

Waves with exceptional height and periods caused severe damage along the coast of California in 1982-83. Because these large wave events coincided with a strong El Nino-Southern Oscillation (ENSO) climatic anomaly, which occurs 20-25 times per century, there was interest in determining if the extreme waves resulted from the ENSO or its related features. The meteorological setting featured a very large and intense low pressure zone over the north-central Pacific. Associated with this Pacific-wide pattern, a series of large mid-latitude storms developed at about weekly intervals and produced exceptionally long fetchs directed at the California Coast.

Two time series of extreme wave events, using buoy data after 1981 and hindcasts before, were used covering the period from 1900 to 1984. One series considered waves with significant heights greater than 3 m (10 ft) and the second for those greater than 6 m (20 ft.) These were compared with a time history of ENSOs for the same period. A strong association was established between northern hemisphere winters during ENSO years and large wave events in Southern California. Strong ENSO winters had the largest storm waves, moderate ENSOs less intense waves, and weak ENSOs tended not to have storm waves greater than the threshold value used in this study. The correlation between large waves and ENSO years is significant at the 1% level. The correlation between lack of large waves and non-ENSO years is significant at the 0.5% level.

Because of the great southerly extent of the most energetic storms, a large number of energetic wave trains approach the coast from the west, rather than the northwest, as previously assumed by many. ENSO winters are responsible for producing all of the wave events in this study with both heights greater than 6 m and periods of peak energy longer than 19 seconds.

Five out of nine eastern Pacific tropical storms making landfalls on California in the 85 year period occurred during the late northern summer of ENSO years.

## INTRODUCTION

During the Winter of 1982-83, a series of extraordinary storms attacked the coast of California. Shoreline damage was severe, particularly in Southern California, and was accompanied by unusual coastal plain flooding in many areas. The extreme sea levels causing this flooding and an assessment of the nearshore waves and their impacts are discussed in two papers in these proceedings (see Flick and Cayan, 1984 and Walker, Nathan, Strange and Seymour, 1984.) The wave fields associated with these storms attracted particular attention because of the extremely long peak periods as well as the great wave heights. To many observers, the number and intensity of these storms exceeded that of any winter within memory.

The year 1982, which immediately preceded the most intense storms during January-March of 1983, was climatologically exceptional. We now know that a very strong El Nino - Southern Oscillation (ENSO) event began in the late spring of 1982. At the time, the time sequence of equatorial oceanic warming and trade wind reversal was several months later than most previous ENSOs, causing lively debate among oceanographers and climatologists as to whether there really was an ENSO occurring (see Kerr, 1983.) The impact of ENSOs on productivity in South American coastal waters has been well studied for many years. Only recently, motivated in part by the extreme nature of the 82-83 ENSO, have scientists understood the global impacts of the event, including droughts and excessive rainfall over large areas outside of the tropics. (For a review of ENSO see Philander, 1983.) There was a second major climatological perturbation almost coincident with the onset of the ENSO - the eruption of the Mexican volcano, El Chichon. Although its total ejected mass was much smaller than, say, Mount St. Helens, it was one of those rare eruptions that results in very large quantities of sulfuric acid in the stratosphere. This contaminant, with a long persistence, spread completely around the globe in a broad band straddling the equator. There is evidence from historical climate records that this kind of eruption can have pronounced effects on global climate (see Sigurdsson, 1982.) The superposition of the strong ENSO and El Chichon makes it very difficult to sort out the climatic effects of each event. The severity of the 1982 ENSO may even have been augmented by the influence of the El Chichon cloud, but our present level of understanding of climatology does not allow us to confirm or reject such interactions.

Volcanos rarely vent sulfides all the way to the stratosphere, but ENSOs occur perhaps 20 times in a century. It is therefore important, from a wave climatology standpoint, at the least to determine if ENSOs are likely to have been paramount in driving these severe storms. Therefore, the authors decided to test the relationship between ENSOs and large wave events by comparing time series from historical records.

### THE 1982-83 LARGE WAVE EVENTS OFF CALIFORNIA

The NOAA observation buoy moored at approximately 35 N latitude and 121 W longitude measured six large wave events, each related to a massive storm in the Pacific Basin, that occurred in the period from December, 1982 to March, 1983. The significant wave height exceeded 6 m (20 ft) in each of these events, as shown in Table I. These observations were made in deep water in unsheltered offshore locations.

The storm of 10 February, 1983, which produced the longest periods of this series, was studied in detail (see Earle et al., 1984.) Using all of the NOAA buoy data, this work showed that the significant wave height at the site closest to the storm was 12.9 m (43 ft) and that there was considerable energy up to periods as long as 25 seconds. This energy level would predict a maximum wave height of about 24 m (79 ft.)

In later sections of this paper, it will be shown that these storms rank as very extreme events in recent history.

### THE METEOROLOGICAL SETTING

From a meteorological standpoint, the 1982-83 ENSO winter was most extraordinary, especially over the Pacific and adjacent continental margins. Not only was the Gulf of Alaska-Aleutian low pressure center unusually deep (as is often the case with northern hemisphere ENSO winters), but the low was, on average, large enough in areal extent and displaced eastward sufficiently to affect the West Coast and particularly California. This has not always been the case with ENSO winters (see Namias and Cayan, 1984.) Figure 1 shows the departure from normal of the 700 millibar (mb) height surface for winter, which is nearly equivalent to the anomalous pressure pattern at about 3 km (10,000 ft) aloft. It is shown to be abnormally low (negative) in a broad region centered in the southern Gulf of Alaska, and very high (positive) in the central Pacific subtropics. Symptomatic of this pressure distribution were the frequent massive and vigorous storms that tracked across the central North Pacific to make landfall along virtually the entire West Coast of the United States. In a more usual winter, storms would be confined to landfalls at latitudes much further north.

The anomalous atmospheric angular momentum associated with these wind fields was studied by Rosen et al., (1984). This work shows that the transfer of angular momentum between the earth and the atmosphere was sufficient to change the length of the day by a few milliseconds during the winter of 1982-83.

Note that, although these storms were associated with an ENSO (a tropically based phenomenon), they were definitely extratropical disturbances. This is shown in Figure 2 by the cyclone tracks for March 1983. Figure 3 shows an infrared satellite image of two of the March 1983 storms. The storm fronts show greater development and a more southerly displacement than usual. Also note that there is no obvious connection of these storm systems with the tropics.

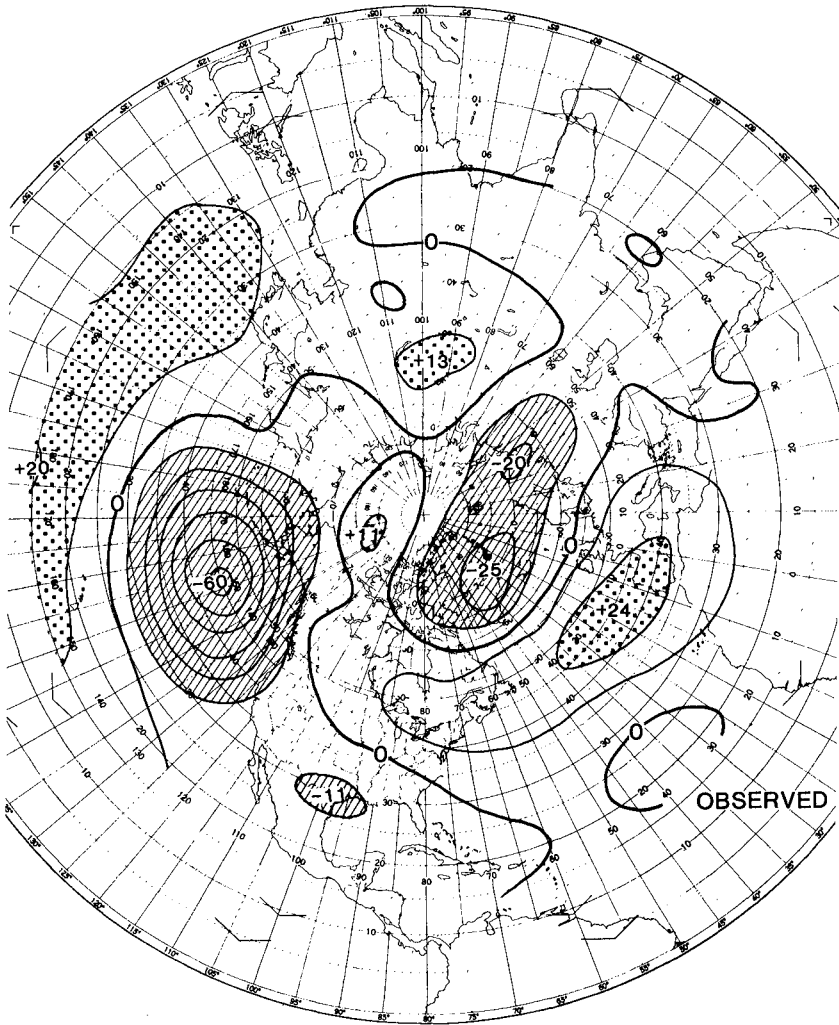

FIGURE 1

Winter 1982-1983 mean 700 mb. height anomaly in tens of feet. This is roughly analogous to the sealevel pressure anomaly. Winter is defined as December through February. Anomaly calculated against mean of 1947-1972 winters.

27 JAN 83	7.3	22	279
10 FEB 83	6.7	25	281
01 MAR 83	8.2	20	258

These very large and intense low pressure centers resulted in fetches on the order of 1000 km (550 nm) and wind speeds up to 30 m/s (60 kts.) Previous empirical models, still widely used today, would predict peak periods of only about 17 seconds for such conditions. Contemporary spectral wave generation models containing nonlinear wave interaction terms, however, are capable of predicting the very long periods actually generated in these storms.

It can be seen from Figure 1 that the wind vectors can be expected to rotate to the north as the storms approach the continent. In typical winters, this northward shift occurs (on average) about 2200 km (1200 nm) offshore. At this point, the winds no longer continue to increase wave height. Dispersion causes the swell to decay over these long distances, reducing the height of the waves as they approach the shore. During the winter of 1982-83, because of the very large size of the low pressure zone and the increased strength of the westerlies, the average decay distance was reduced to about 1600 km (900 nm.) These factors account for the increase in the swell height during these storm wave events. It should also be noted that the locally generated waves may be travelling north almost orthogonally to the swell, producing a very confused sea state in deep water.

#### HISTORICAL WAVE DATA FOR THE CALIFORNIA COAST

Systematic wave measurements in deep water off the West Coast of the United States have been available only since 1980. Therefore, any meaningful historical assessment must depend largely upon wave hindcasts. Contemporary hindcasts, based upon reliable pressure field data and satellite imagery, can provide wave energy spectra and directional estimates with satisfactory accuracy for engineering analyses. However, for pre-satellite years, and particularly prior to the mid-1940's, the meteorological data become less satisfactory and the accuracy of the wave hindcasts is degraded. There are a number of storm hindcast studies that have been performed for the California

Coast (e.g., see Marine Advisers, 1960 and Meteorology International, 1977.) These works suffered from short observation periods and, in at least one case, from serious methodological problems. The earlier works used a singular wave approximation, compared with the spectral approach now employed by contemporary hindcasters. Rather than attempting to patch together the work of several hindcasting studies in an attempt to acquire a long enough time history, we decided to use the work of a single hindcaster which spanned the whole interval from the inception of meteorological data (approximately 1900) to the advent of continuous deep water measurements in late 1980. One of us (RRS) has prepared such a series. It was hindcast for a location in Southern California at a latitude of about 35 N. This series was an attempt to identify wave trains expected to have a significant impact on the shoreline. Therefore, it included only those events with deep water approach directions in the zone between SW and WNW. Waves approaching more obliquely would be diminished considerably by refraction as they approached the shore. Further, the waves were ranked by their power (energy multiplied by period.) This resulted in a list of 59 storms in which the resulting offshore significant wave height exceeded 3 m (10 ft), all having periods equal to or exceeding 12 seconds. The tropical cyclone of September, 1939, a major wave event in Southern California, was added for a total of 60 storms. These storms are listed in Table II.

A second series was obtained by considering only the very largest events. The threshold significant wave height was raised to 6 m (20 ft.) The second series contains only 18 storms because of its higher limit value, as shown in Table III.

It should be clearly recognized that the possible quality of hindcast decreases with the age of the data, particularly prior to the 1950's. It is likely that some major storms in the early years were excluded because there was insufficient pressure field resolution and accuracy to estimate the real wind speeds. This is particularly true for small, intense storms like tropical cyclones. It is almost impossible to hindcast these storms prior to the availability of satellite imagery. However, since no series of this length had previously been published, and since the work used a consistent methodology throughout, we felt that they would make a valuable contribution to our knowledge of the wave climate off California.

#### HISTORICAL RECORDS OF ENSO CONDITIONS

Using anomalies in the surface barometric pressure in the Indian and Pacific Oceans, combined with observations of fisheries in Peru and other similar data, Quinn et al. (1978) were able to develop a series of ENSO events covering more than 200 years. They also rated each event as strong, moderate or weak. The ENSOs since 1900 from this record are shown in Table IV. Quinn et al.'s ENSO series identifies events according to their onset years. For our purposes, it is the winter following the onset, when the mid-latitude connections are strongest, that would have possible consequences for Pacific waves.

In four cases, one year adjustments were made in the onset years suggested by Quinn et al. The 1929 onset was changed to 1930 and the 1905, 1914 and 1939 onsets were changed to two year spans (1904-05, 1913-14, and 1939-40, respectively.) The basis for this was the timing of the peak of the Southern Oscillation (as determined from the Santiago-Darwin anomaly.) The onset year was adjusted to provide a uniform condition throughout the series in which the peak of the pressure anomaly occurred in the Spring or Summer. In addition, the

TABLE IV  
 ONSET YEARS OF ENSOS, 1900-1984  
 (From Quinn et al., 1978)

1969	Weak
1972	Strong
1976	Moderate
* 1982	Strong

\* Modified from Quinn et al.

1969 ENSO was reclassified from weak to moderate, in the context of this study, because the pressure anomaly persisted for more than a year. The 1982 ENSO, which occurred after the Quinn et al. paper, was classified by us as strong. The ENSO predictions for the first half of the century are expected to be of higher quality than the wave hindcasts, since they did not depend upon the density of pressure measurements.

#### CORRELATIONS BETWEEN ENSO YEARS AND LARGE WAVE EVENTS

As was observed in 1982-83, increased storminess as a result of an ENSO condition would likely occur during the winter following onset. Therefore, storms in January through April of the year following the onset could be assumed to have been influenced by the ENSO.

Applying this criterion to the time series of ENSOs and of large wave events produces the following results. For the basic wave series, 32 of the 60 wave events were associated with ENSOs. For the series of very large waves, 12 of the 18 wave events were associated with ENSOs.

Not all ENSOs resulted in large wave events. Table V shows a comparison between the occurrence of large storms and the ENSO strength categories of Quinn et al.

Table V shows that all seven strong ENSOs resulted in a wave event where the height exceeded 3 m (10 ft) with an average of 2.1 such events per ENSO. Three out of seven of these strong ENSOs produced wave heights over 6 m (20 ft) for an average of 1.3. All but one of the nine moderate ENSOs yielded waves above 3 m, with an average of 1.7 events per ENSO. Only two of these produced waves above 6 m and the average dropped to 0.3. Two of the five weak ENSOs met the lower height limit with an average of 0.4 occurrences per ENSO. Weak ENSOs produced no wave events exceeding the 6 m limit.

Table V shows a consistent series of relationships between ENSOs and large wave events. Strong ENSOs result in significant numbers of storms with waves exceeding both the 3 m and the 6 m thresholds. Moderate ENSOs produce storms with waves exceeding the 3 m limit, but not the 6 m value. Weak ENSOs have only a slight tendency to produce storm waves that exceed the 3 m threshold.

Eliminating the weak ENSOs, a total of 16 strong and moderate events were recorded in the 85 year period considered. Allowing for the three multi-year events, there were 19 ENSO years during the 85 year interval that would be classified as greater than weak events. Considering the 3 m (10 ft) threshold wave events, there was an average of 0.71 events per year over all years. During the moderate or strong ENSO years, there was an average of 1.58 events per year. Applying the Student's t test to determine the probability of the mean during these ENSO years exceeding the mean over all years by this amount, the probability was shown to be about 0.01 (one chance in a hundred.) The mean value of large wave events during non-ENSO years was found to be 0.45. The probability of the mean being this much lower than the mean over all years was found, by Student's t test, to be less than 0.005 (five chances out of a thousand.) Thus, the incidence of large wave events in association with ENSOs and the reduction in large storm waves during non-ENSO years are established statistically with little question.

#### WAVE APPROACH DIRECTIONS AND CHARACTERISTIC PERIODS

Because of the frequent winter storms that are spawned by the Aleutian Low during most years, it has generally been assumed that the track for major storms affecting California is usually out of the northwest. Table II shows, however, that a large number of severe storm waves come out of the west. This is shown in Figure 4, which plots the incidence of wave approach directions for the Table II series. A strong peak is found at about 285 deg. for both the total data set and also the ENSO year subset. The ENSO year occurrences also are observed to fall off rapidly at approach directions slightly north of this peak.

TABLE V  
ASSOCIATION OF ENSOS AND LARGE WAVES

Conventional wisdom has also suggested that severe storms along the California Coast produced periods of peak energy of no greater than about 19 seconds. The storms of 1982-83 showed very clearly that this limit was much too low. Figure 5 depicts the incidence of peak periods in the very large wave events contained in the Southern California series. It can be readily seen from Figure 5 that all storms that produced peak energy wave periods greater than 20 seconds were associated with ENSO years. This is, of course, consistent with the meteorological setting during most ENSO events in which there are very long fetches directed at the California Coast.

#### TROPICAL STORMS

The pronounced warming of the surface waters along the California Coast during a strong El Nino condition could be expected to allow the northward excursion of tropical cyclones (hurricanes) in late summer and early fall to latitudes excluded in non-ENSO years. As previously noted, it is not generally possible to develop a wave hindcast series

FIGURE 4

Number of occurrences of major wave events from various approach directions for events in Table II.

FIGURE 5

Number of occurrences of major wave events with the energy spectra peaked at various wave periods. Events are from Table II.

for these storms which are so small in diameter compared to a typical extra-tropical cyclone. However, Court (1980) has compiled a record of hurricane tracks since 1900. This was extended through 1983 using DeAngelis (1983). The tracks of these storms are shown in Figure 6. Of all of the hurricanes observed in this period, only nine made landfalls in California. Five of these nine were in ENSO initiation years, when warm water would be expected along the West Coasts of Mexico and California during the Fall hurricane season. One of these was the storm of 25 September, 1939, which is one of the events in the basic series. Therefore, the data suggest that late summer and fall hurricane-driven wave events in Southern California are much more likely in ENSO years than during the intervening periods.

#### DISCUSSION AND CONCLUSIONS

A very convincing statistical relationship has been demonstrated between ENSOs and the large wave events that dominate the wave climate of Southern California. Because ENSOs also tend to increase sea level along the California Coast in rough proportion to their intensity, the coastal damage resulted from large waves will be exacerbated during ENSO events.

The scheme adopted by Quinn et al. (1978) for designating the intensity of the ENSOs is in good qualitative agreement with the number and intensity of large hindcast wave events in California.

ENSOs appear to be among the more predictable of the major global climate events. Therefore it may be possible to forecast severe winter wave climates with some skill for the California Coast.

FIGURE 6

Tracks of tropical cyclones (hurricanes) that made landfalls in Southern California during the period 1900-1983.

Wave periods much longer than typically assumed for this coast were recorded. These very long periods have particular significance both for wave runup intensity and for drastic intensification of mooring loads on large floating structures with the potential for reaching a near-resonant condition at approximately 0.04 hz.

## CHAPTER FORTY

### RUN-UP OF RANDOM WAVES ON GENTLE SLOPES

Hajime Mase\* and Yuichi Iwagaki, M.ASCE\*\*

#### ABSTRACT

This paper investigates the following characteristics of run-up of random waves on gentle slopes experimentally: (1) the run-up wave energy spectrum, (2) the ratio of the number of run-up waves to that of incident waves, (3) the relationship between the representative run-up height, the deep-water wave steepness and the beach slope, (4) the run length of run-up heights, and (5) the effect of wave grouping on representative run-up heights.

Main results are summarized in the chapter of conclusions.

#### 1. INTRODUCTION

Wave up-rush and back-rush on beaches are significant external forces for the change of beach profile near the shoreline. Besides, the height of wave run-up is important in determining for the height of coastal structures such as seawalls, dykes and surge barriers, and is the limit of onshore side for on-offshore and littoral sand transports.

A number of studies for run-up of random waves on steep slopes, as well as for run-up of monochromatic waves, have been performed, because front faces of traditional coastal structures are generally steep and accurate design data of wave run-up on steep slopes have been needed. Recently, seawalls and dykes with gentle slopes have been recommended, if possible, from the reason that sand beaches in front of the structures with steep slopes are apt to be lost during storms and from the reason of a good view and utilization of the beaches. However, studies for run-up of random waves on relatively gentle slopes like natural beaches are very few.

When a beach slope becomes gentle, a period of one cycle of up-rush and back-rush of a wave becomes long and the interaction between a back-rush and a subsequent up-rush (or, overtaking and capturing of bores on beaches) becomes remarkable. The characteristics of run-up of random waves will depend on the time series of waves coming to the shoreline, and also on wave grouping of incident waves in deep water.

The purpose of this paper is to examine the following characteristics of run-up of random waves on gentle slopes experimentally by using random waves with two different groupiness factors defined by Funke and Mansard<sup>1</sup>), but with the same spectrum of Pierson-Moskowitz type: (1) the run-up wave energy spectrum, (2) the ratio of the number of run-up waves to that of incident waves, (3) the relationship between the representative run-up height, the deep-water wave steepness and the beach slope, (4) the run length of run-up heights, and (5) the effect of wave grouping on representative run-up heights.

## 2. EXPERIMENTS

A series of tests was carried out in a 50cm wide, 27m long and 75cm deep wave flume. At one of the ends of the wave flume, a random wave generator is installed. Beach slopes were selected as 1/5, 1/10, 1/20 and 1/30. The depth of water,  $h$ , in a uniform section of the flume was kept 45cm, but 43cm only in the case of a 1/30 beach slope. The outline of experimental apparatus is shown in Fig.1.

Fig.1 Experimental apparatus.

A wave gauge of capacitance type was used as a run-up meter, which was installed in a groove (3cm wide and 1cm deep) along a centerline of the slope to coincide the height of the capacitance wire (2.2mm diameter and 2m long) with the slope surface, see Photo.1. The run-up meter was calibrated by moving every 10cm along the slope surface. The calibration curve was closely approximated by a straight line. Additional calibrations of the run-up meter were done comparing

Photo.1 Run-up meter.

Fig.2 Comparison of run-up heights by run-up meter and by visual observation with scale.

run-up heights measured by the run-up meter and by a visual observation with a scale. Both run-up heights were nearly the same. An example of the comparison is shown in Fig.2, and the correlation coefficient of both run-up heights is about 0.99. We believe that the run-up meter used here is sufficient to measure run-up of random waves.

Random waves used here were simulated<sup>2)</sup> to have Pierson-Moskowitz type spectra with six kinds of peak frequencies of 0.4, 0.5, 0.6, 0.8, 1.0 and 1.2Hz, and with two kinds of groupiness factors of 0.74 (Case 1) and 0.53 (Case 2), based on the study of Funke and Mansard<sup>1)</sup>. Electric signals for generating the random waves have been recorded by an analog data recorder. Three kinds of input levels of the electric signals were used to generate random waves with the peak frequency from 0.4 to 0.8Hz (in Cases 1 and 2) and two kinds were used for random waves with the peak frequency of 1.0Hz (in Cases 1 and 2) and 1.2Hz (in Case 1). A series of totally 30 tests were carried out for each beach slope.

Water surface variations were measured by using five wave gauges of capacitance type at water depths of 45 (40cm for a 1/30 beach slope), 20, 15, 10 and 5cm (W-1 ~ W-5).

Both of water surface variations and run-up variations (shoreline oscillations) were recorded simultaneously by an analog data recorder. The records were digitized by an A-D converter at the sampling interval of 0.04 second. The numbers of data are 40 000, 31 000, 26 500, 19 500, 15 500 and 12 500 for cases of random waves with peak frequencies of 0.4, 0.5, 0.6, 0.8, 1.0 and 1.2Hz. The numbers of individual waves at the wave gauge W-1 in each record are from 650 to 900.

### 3. EXPERIMENTAL RESULTS AND CONSIDERATIONS

#### 3.1 Characteristics of incident waves

Table 1 shows representative quantities of waves measured at the wave gauge W-1 (40cm water depth), and the wave height and wave steepness in deep water,  $H_0$  and  $H_0/L_0$ , calculated from the significant wave, for the experiments of a 1/30 beach slope. Individual waves are defined by the zero-up-cross method.

Fig.3 shows two examples of energy spectra of incident waves, in which (a) is for S30-Case 1-7 and S30-Case 2-7, and (b) for S30-Case 1-13 and S30-Case 2-13. The energy spectra of waves with the same case number of Cases 1 and 2 are almost the same except in the region of low frequency smaller than 0.3Hz. The difference of energy spectra in the low frequency region depends mainly on long waves generated by short waves with the different wave groupiness factors.

Fig.4 shows the groupiness factor,  $GF$ , against the deep-water wave steepness  $H_0/L_0$ . The average values of  $GF$  in Cases 1 and 2 are 0.73 and 0.57 respectively, while the expected values of  $GF$  are 0.74 and 0.53<sup>2)</sup>. Random waves with a small  $GF$  cannot be well reproduced in a wave tank when the deep-water wave steepness is larger than 0.03 (this corresponds to  $kh > 1.36$ ,  $k$ : the wave number), which is discussed in another paper<sup>3)</sup>.

Statistical properties of random waves related to wave groups have been examined in the previous paper<sup>2)</sup>.

Fig.3 Energy spectra of incident waves at the wave gauge W-1 in case of 1/30 beach slope. (a)  $f_p=0.6$ Hz, (b)  $f_p=1.0$ Hz.

Fig.4 Groupiness factor of incident waves at the wave gauge W-1. Groupiness factor was defined by Funke and Mansard<sup>1)</sup> to represent wave groupiness.

### 3.2 Energy spectrum of run-up waves (run-up variations)

Huntly, Guza and Bowen<sup>4)</sup> remarked that run-up wave energy spectra have a universal 'saturation' form of  $f^{-4}$  dependence for the frequency region over which incident waves are large enough to break. Guza and Thornton<sup>5)</sup> mentioned that run-up wave energy spectra in the saturation region show a  $f^{-3}$  dependence and spectral energy densities are independent of incident wave energies. The difference of both results is the  $f^{-4}$  or the  $f^{-3}$  dependence, which is considered as the effect of beach slopes by Guza et.al.

Fig.5 shows run-up wave energy spectra when the energies of incident waves with the peak frequency 0.6Hz (Case 1) are changed, for 1/5, 1/10, 1/20 and 1/30 beach slopes. It is seen from these figures that run-up wave energy spectra are saturated and show the  $f^{-4}$  dependence in the region of high frequency independently of incident wave energies and of beach slopes.

Fig.6 shows the relationship between the beach slope and the spectral energy density of run-up waves in the saturation region, in which values of the spectral energy density are plotted by the mean value and the standard deviation. It is found from this figure that the spectral energy density at a given frequency in the saturation region depends on the beach slope and is nearly proportional to  $\tan^4\theta$ .

These results of run-up wave energy spectra such as the  $f^{-4}$  and  $\tan^4\theta$  dependence are the same as those estimated from the theoretical consideration by Huntly et.al<sup>4)</sup> and Guza et.al<sup>5)</sup>.

Fig.5 Run-up wave energy spectra. (a)  $\tan\theta=1/5$ , (b)  $\tan\theta=1/10$ , (c)  $\tan\theta=1/20$ , (d)  $\tan\theta=1/30$ .

Fig.7 Definition method of run-up waves.

Fig.6 Relationship between beach slope and spectral energy density of run-up waves in saturation region.

**3.3 Individual wave analysis of run-up waves**

**(1) Definition of an individual run-up wave**

There are several definition methods of an individual wave of run-up wave such as a zero-up-cross, a zero-down-cross, a crest-to-trough and so on. The number of individual run-up waves and the representative run-up heights change with the definition method. Fig.7 shows an example of definition of an individual wave, in which (a) is the crest method, (b) the zero-up-cross method. The number of run-up waves by the crest method is two waves more than that by the zero-up-cross method. In our experimental results, the ratio of the number of individual run-up waves defined by the zero-up-cross method to that by the crest method is from about 0.4 to 0.9 depending on the

beach slope, and the ratio of significant run-up height is about 1.1 and the ratio of mean run-up height is about 1.2.

In the following sections, an individual run-up wave is defined by the crest method.

(2) Number of individual run-up wave

In the case of gentle slopes, it takes place that a wave (bore) coming to the shoreline cannot run up if the back-rush of a preceding wave (bore) is large and that a wave (bore) running up on the beach face is overtaken and captured by a subsequent wave (bore) before the wave (bore) reaches a maximum run-up height. Therefore, the number of run-up waves (the frequency of run-up waves) will be reduced compared to that of incident waves. Fig.8 shows the ratio  $\alpha$  of the number of run-up waves to that of incident waves at the wave gauge W-1. The experimental data can be well arranged by the surf similarity parameter,  $\xi (= \tan\theta / \sqrt{H_0/L_0})$ , as shown in Fig.8. The ratio  $\alpha$  becomes small as  $\xi$  becomes small (or the beach slope becomes gentle and the deep-water wave steepness becomes large). In this result, the effect of wave grouping is not clear.

Fig.8 Ratio of the number of run-up waves to that of incident waves.

(3) Representative run-up heights

According to the dimensional analysis, the height of run-up,  $R$ , on an impermeable, smooth slope is expressed as follows:

$$\frac{R}{H_0} = f\left(\frac{H_0}{L_0}, \tan\theta, \frac{h_0}{H_0}\right), \quad (1)$$

in which,  $h_0$  is the water depth at the toe of a slope. When  $h_0/H_0$  is larger than 3.0, the effect of  $h_0/H_0$  is negligible<sup>6)</sup> and Eq.(1) becomes

$$\frac{R}{H_0} = f\left(\frac{H_0}{L_0}, \tan\theta\right). \quad (2)$$

Hunt<sup>7)</sup> proposed the following equation for run-up heights of monochromatic waves based on the experimental data:

Fig.9 Relationship between representative run-up heights and deep-water wave steepness. (a)  $\tan\theta=1/5$ , (b)  $\tan\theta=1/10$ , (c)  $\tan\theta=1/20$ , (d)  $\tan\theta=1/30$ .

(c)

(d)

Fig.9 (c) (d) (Continued).

$$\frac{R}{H_0} = \tan\theta / \sqrt{H_0/L_0} \quad (3)$$

In this paper, representative run-up heights of random waves are examined based on Eq.(2), in which  $H_0$  and  $L_0$  are taken as the significant wave height and wave length in deep water (see Table 1).

Fig.9 shows the relationship between the representative run-up heights ( $R_{max}$ : maximum run-up height,  $R_{1/3}$ : significant run-up height,  $\bar{R}$ : mean run-up height) and the deep-water wave steepness. Straight lines were drawn parallel to each other in all figures, so as to represent the tendency of the experimental data of which the deep-water wave steepness is larger than 0.008. The gradient of the lines is  $-0.37$ , which is a little different from  $-0.5$  by Hunt. In the cases of smaller deep-water wave steepness than 0.005 for  $1/20$  and  $1/30$  beach slopes, the values of  $R_{1/3}/H_0$  and  $\bar{R}/H_0$  are a little smaller than the values by the straight lines. Especially for the  $1/5$  beach slope, all representative run-up heights are considerably smaller than the values by the straight lines in the region of smaller deep-water wave steepness than 0.008. Although we used the same electric signal to generate random waves, the significant wave height at the wave gauge W-1 in the case of the  $1/5$  beach slope was large compared with the results in other gentler slopes  $1/10$ ,  $1/20$  and  $1/30$  due to the wave reflection at the slope. The larger value of  $H_0$  causes the smaller values of  $R_{max}/H_0$ ,  $R_{1/3}/H_0$  and  $\bar{R}/H_0$ . When we use the mean value of  $H_0$  obtained in other gentler slopes, the run-up heights are plotted with triangular shape symbols (in Fig.9(a)) represented well by the straight lines.

Fig.10 Relationship between run-up heights and beach slope.

The maximum run-up height in Case 1 of which the groupiness factor is about 0.73 is about 10% larger than that in Case 2 of which the groupiness factor is about 0.57. However, there is little effect of wave grouping on other representative run-up heights of  $R_{1/3}/H_0$  and  $\bar{R}/H_0$ .

Fig. 10 shows the relationship between the representative run-up heights and the beach slope  $\tan\theta$ , in which experimental data are plotted by the mean value and the standard deviation. It is seen from this figure that the representative run-up heights increase as the beach slope becomes steep. The gradients of the straight lines are 0.69 for the significant and mean run-up heights, and 0.77 for the maximum run-up height.

(4) Experimental formula for run-up height of random waves

Here, we formulate the run-up height by the following two equations:

$$\frac{R}{H_0} = a(\tan\theta)^b (H_0/L_0)^c, \quad (4)$$

$$\frac{R}{H_0} = d(\tan\theta/\sqrt{H_0/L_0})^e. \quad (5)$$

The coefficients in Eqs. (4) and (5) are determined by the least squares method, based on the experimental data of which the deep-water wave steepness is larger than 0.008 for the 1/5 beach slope and larger than 0.005 for the 1/20 and 1/30 beach slopes.

Table 2 shows the result, in which  $\sigma$  denotes the standard deviation of the difference between the experimental value and the formula. The standard deviation in Table 2(b) is almost the same as that of Table 2(a). We propose the simple experimental formula for run-up heights of random waves, represented by the surf similarity parameter of Eq. (5).

(5) Run length of run-up heights

The highest wave in a wave record does not appear alone but usually appears with several high waves. Such a phenomenon was firstly studied by Goda<sup>8)</sup>. On the other hand, the highest run-up appears singly very often. Table 3 shows the distribution of run length of run-up heights exceeding the significant run-up height and the mean run-up height, based on all 120 test runs containing 54 244 run-up waves. The mean length of runs of run-up heights is 1.18 for  $R > R_{1/3}$  and 1.95 for  $R > \bar{R}$ , which is smaller than the mean length of runs of wave heights (1.42 for  $H > H_{1/3}$  and 2.37 for  $H > \bar{H}$ ). The mean length of conditional runs of run-up heights containing the highest run-up is 1.15 for  $R > R_{1/3}$  and 1.78 for  $R > \bar{R}$  (2.37 for  $H > H_{1/3}$  and 4.82 for  $H > \bar{H}$ ). The highest run-up occurs when the preceding back-rush is small, and the subsequent run-up height is reduced by the back-rush of the highest run-up. Therefore, the highest run-up is apt to appear alone.

(6) Effect of wave grouping on run-up heights

It was demonstrated by Carstens, Torum and Traetteberg<sup>9)</sup> and Johnson, Mansard and Ploeg<sup>10)</sup> that random waves with large wave grouping cause larger wave run-up and therefore severer damage to rubble mound breakwaters than waves with poor wave grouping. Van Ooschot<sup>11)</sup> reported that random waves with a large spectral width parameter cause larger wave run-up than waves with a small spectral width parameter, which means random waves with poor wave grouping

cause larger wave run-up. In our results, the maximum run-up height in Case 1 (large wave grouping) is about 10% larger than that in Case 2 (poor wave grouping). However, there is little effect of wave grouping on the significant and mean run-up heights.

Fig.11 shows the groupiness factor at the wave gauge W-5 in 5cm water depth, which shows the degree of wave grouping before waves run up. It is seen from this figure that the values of  $GF$  in cases 1 and 2 become small compared with the results shown in Fig.4 and the difference of wave grouping between in Cases 1 and 2 diminishes due to wave breaking in the surf zone.

Fig.11 Groupiness factor at the wave gauge W-5 after wave breaking.

The change of wave grouping in shallow water has been investigated by the authors (2), (3), (4).

In the experiments by Carstens et.al and Johnson et.al, it seems that since the slope of a breakwater is very steep such as 1:1.25 and 1:1.5, the properties of wave grouping are not changed on the slope and the effect of wave grouping on wave run-up and stability of the breakwater was remarkable.

#### CONCLUSIONS

This paper examined the characteristics of wave run-up of random waves on gentle slopes experimentally by using random waves having the same spectrum and two different groupiness factors. Main results of this paper are summarized as follows:

1) Run-up wave energy spectra show a  $f^{-4}$  dependence in the region of high frequency (saturation region) independently of incident wave energies and beach slopes, and also show a  $\tan^4\theta$  dependence in the saturation region.

2) The ratio of the number of run-up waves to that of incident waves at the deepest water (45cm or 40cm in our experiments) becomes small as the beach slope becomes gentle and the deep-water wave steepness becomes large. The experimental data can well be arranged by the surf similarity parameter as shown in Fig.8. Reducing of the number of run-up waves is caused by overtaking and capturing of bores in the surf zone and on the beach face, and by large back-rushes suppressing

following running up waves.

3) A linear relation is obtained when two pairs of representative run-up heights vs. deep-water wave steepnesses and representative run-up heights vs. beach slopes are plotted on a log-log scale. We propose the simple experimental formula for run-up heights of random waves represented as a function of the surf similarity parameter by Eq. (5).

4) The highest run-up of each test run appears singly very often because the highest run-up occurs when the preceding back-rush is small, and the subsequent run-up height is reduced by the back-rush of the highest run-up.

5) The maximum run-up height of random waves in Case 1 of which the groupiness factor is about 0.73 is 10% larger than that in Case 2 of which the groupiness factor is 0.57 on the average. However, there is little effect of wave grouping on other representative run-up heights  $R_{1/3}/H_0$  and  $\bar{R}/H_0$ . This is due to the fact that the difference of wave grouping of random waves between in Cases 1 and 2 becomes small in very shallow water by wave breaking in the surf zone in the case of gentle beach slopes.

## CHAPTER FORTY ONE

### On the Sequential Behaviour of Sea-States

A. Sánchez-Arcilla \*

#### Abstract

Probability distributions theoretically derived for gaussian, stationary processes are applied here to the sequential behaviour of sea-states. This behaviour defined by the curve of evolution of significant wave-height,  $H_s(t)$ , is characterized by variables such as: intensity of storm peaks, time between beginnings of storms, average duration of calms and storms, average number of consecutive storms, expected value of the extremal storm peak, etc.

The distributions obtained for these variables have been tested with 5 years of wave data, recorded in the north coast of Spain. The agreement obtained is satisfactory in most cases, showing the validity of the approach and its applicability to situations in which only a limited amount of data is available. However, in cases where a large volume of data exists, empirically selected distributions could provide a marginally better fit.

#### 1. Background

Short-term analysis of wave records apply random process theory, (20), (1), to the curve of sea surface elevations,  $\eta(t)$ . The curve must be continuous, random, stationary and gaussian (for most results) to allow application of this technique. The results so obtained are probability distribution functions (PDF's) for variables such as wave-height ( $H$ ), wave period ( $T$ ), etc. in terms of a few (compact) parameters. These theoretically derived PDF enable a straightforward prediction of a wide range of characteristic values provided some basic parameters are known (e.g. mean value, variance, etc.).

The sequential behaviour of sea-states shall be defined here by the curve of evolution of  $H_s$  (significant wave-height) with time:  $H_s(t)$ . Any threshold level defines in this curve a sequence of calms (periods in which  $H_s$  is below the

---

\*Professor, Coastal and Harbour Eng. Dept. Univ. Politécnica de Catalunya. Jordi Girona Salgado, 31.08034 Barcelona. Spain

threshold) and storms (opposite event) whose analysis is the aim of the paper. However, to use random process theory for this purpose,  $H_s(t)$  must be continuous, random, stationary and gaussian.

A continuous evolution of  $H_s(t)$  and its first derivate is physically much more realistic than with a step-wise shape. This, in spite of having obtained  $H_s(t)$  from a set of values calculated from stationary, i.e.  $H_s$  constant, time periods. The difficulty is more apparent than real because an  $H_s(t)$  curve, with a continuous slope may be obtained from stationary periods by lagging  $\Delta t$  at the intervals. If  $\Delta t$  goes to zero the successive  $H_s$  values may be as close as desired, obviating the step-wise shape problem.

It is quite reasonable to assume  $H_s(t)$  is random since the stationary wave fields are generated by random winds. On the other hand, it is easy to understand that  $H_s(t)$  is not stationary in an average (typical) year. Nevertheless it is possible to hypothesize shorter, stationary periods (e.g. months) and test with wave data the validity of this hypothesis. In the paper the stationary periods selected have been months (from January to December) and winter (1st. October to 31st. March) and summer (1st. April to 30th September) seasons. In these periods the sequence of calms and storms obtained could be assumed to be homogeneous since the energy density (variance) of the  $H_s(t)$  curve was found to be reasonably constant.

The PDF of the  $H_s(t)$  process should be Gaussian to allow application of what has been called random process theory. However the long-term PDF of  $H_s$  is usually taken to be Weibull (16) with 3 free parameters for the fit. A Gaussian PDF can also be assumed empirically, providing only 2 free parameters for the fit, and therefore, an (expected) slightly worse visual agreement with data. In figure 1 and 2 the fit of 4 randomly selected months (out of the 5 years of wave data used in the paper) to a Weibull and Gaussian PDF, respectively, is shown. The agreement is acceptable in both cases and the predictions of  $H_s$  for a fixed probability level are very similar except in the tails of the distributions.

An acceptable fit of registered  $H_s$  values to the Gaussian PDF would allow application of random process theory such as is done in short term analyses. An important difference will be the spectral width of the process which, for this sequential behaviour analysis, turns out to be broad-banded in all cases. Apart from this, however, there is a close similarity

Figure 1 : Fit of the empirical distribution of  $H_s$  (as obtained from data) to a Weibull PDF for 4 randomly selected months.

Figure 2 : Fit of the empirical distribution of  $H_s$  to a Gaussian PDF for the same 4 months of figure 1.

between both problems. As an illustration, local maxima in a wave record (short-term) would correspond to local storm peaks (sequential-behaviour), the zero-up-crossing wave period to the time between beginnings of storms, etc. A more detailed review of common points between both types of analysis, together with a summary of some of the empirical models used for storm analysis, may be found in (21).

## 2. Theoretical results compared with wave data

The data used for calibration are 6 years (1.975 to 1.980) of continuous wave recording near the entrance of the Bilbao Harbour in the north of Spain. The average depth at the recording location was 30 m., with records of 10 to 20 minutes every 3 or 4 hours, depending on the year.  $H_S$  was obtained by standard statistical analysis (Tucker's method). For part of the records  $H_S$  was also calculated with a standard spectral analysis, based on the FFT approach.

The first thing to check was the PDF of the  $H_S(t)$  process. A Gaussian distribution was proposed and a satisfactory visual fit was found for all stationary periods considered (months and winter and summer seasons). Quantitatively, the Gaussian PDF was found acceptable in 96.15% of cases, with a significance level of 0.05, applying a Kolmogorov-Smirnov goodness-of-fit test.

The spectral width of the process, measured by the  $\xi$  parameter, (13),(4) to facilitate comparisons between statistical and spectral analysis, was found to be between 0.90 and 0.99 except in 5 months in which it varied between 0,87 and 0,90. This means that the  $H_S(t)$  process is broad-banded for all stationary periods considered.

In these conditions the PDF of storm peaks,  $H_M$ , (local maxima) should be Gaussian, (21). An illustration of the fit obtained appears in figure 3. Negative values of  $H_M$  are, simply, values of  $H_M$  smaller than the mean value of  $H_S$  for the stationary period considered,  $H_{mean}$ . In other words, the height of storm peaks was measured from the  $H_{mean}$  level. The total range of  $H_S$  variation between two successive up-crossings of  $H_{mean}$  (i.e. range of  $H_S$  variation between storms defined with respect to  $H_{mean}$ ) should, for a gaussian process, follow a Rayleigh PDF irrespective of  $\xi$  (9). This total range shall be denoted  $H$  and is equivalent to the wave-height concept (zero-up-crossing definition) in short-term analysis. Figure 4 shows the fit obtained for 4 random months. The agreement was satisfactory for all stationary

Figure 3 : Fit of the empirical distribution of  $H_M$  (intensity of storm peaks) to a Gaussian PDF for 4 randomly selected months.

Figure 4 : Fit of the empirical distribution of  $H$  (range of  $H_S$  variation in a storm) to a Rayleigh PDF for the same 4 months of figure 3.

periods considered.

The zero-up-crossing wave period of short-term problems,  $T$ , corresponds here to the time between beginnings of storms (defined with respect to  $H_{S, \text{mean}}$ ). Three PDF were used for  $T$ : Bretschneider, (3), CNEXO, (5), and Longuet-Higgins (14). Only the last two provided a satisfactory fit for winter and summer seasons (figures 5 and 6), while giving a poor fit for monthly periods. This was attributed to the small size of  $T$  samples obtained for monthly periods. The poor agreement found for Bretschneider's PDF could be due to the lack of an  $\epsilon$  dependance for this distribution, the other two being  $\epsilon$ -dependent, (21).

The average number of storms (defined with respect to an arbitrary threshold  $H_S = h$ ) per unit time,  $n(h)$ , is identical to the average number of up-crossings of level  $h$ , per unit time, in short term analyses. It may, therefore, be written as, (2) :

$$n(h - H_{\text{mean}}) = \left(\frac{m_2}{m_0}\right)^{\frac{1}{2}} \exp\left(-\frac{(h - H_{\text{mean}})^2}{2m_0}\right)$$

in which  $m_0$  and  $m_2$  are, respectively, the zero and second order moments of the spectral density function of the  $H_S(t)$  process. If alternatively,  $\bar{T}$  (average value of  $T$ ) is known  $m_2$  may be evaluated from  $m_0$  and  $\bar{T}$  by considering that, for  $h = H_{\text{mean}}$

$$\bar{T} = \frac{1}{n(0)} = \left(\frac{m_0}{m_2}\right)^{\frac{1}{2}}$$

From these expressions it is easy to see that (21), the average duration of calms and storms, defined for an arbitrary threshold  $h$ , may be calculated as:

$$\bar{d}_S(h) = \frac{(1 - P(h))}{n(h - H_{\text{mean}})}$$

$$\bar{d}_C(h) = \frac{P(h)}{n(h - H_{\text{mean}})}$$

in which:

$\bar{d}_S(h)$  : average duration of storms at level  $h$ .

$\bar{d}_C(h)$  : average duration of calms at level  $h$ .

$P(h)$  : Prob ( $H_S \leq h$ )

Figure 5 : Fit of the empirical distribution of  $T$  (time between beginnings of storms) to a CNEOX PDF for 4 randomly selected seasons.

Figure 6 : Fit of the empirical distribution of  $T$  to a Longuet-Higgins PDF for the same 4 seasons of figure 5.

These formulae for  $\bar{d}_s$  and  $\bar{d}_c$  have been tested for all months and winter and summer seasons finding a qualitative fit in all cases. Figure 7 shows the agreement obtained together with predictions for  $\bar{d}_s$  and  $\bar{d}_c$  calculated from the empirical model of (10).

The PDF of the  $d_s(h)$  and  $d_c(h)$  variables was found (empirically) to agree well with a 3-parameters Weibull distribution (figure 8), as reported by other authors, (11), (12).

The number,  $j_1$ , of consecutive storms (defined with respect to  $H_{mean}$ ) exceeding level  $h$  is equivalent to the number of waves in a group exceeding a threshold  $h$  in short-term analyses. The number,  $j_2$ , of storms between groups exceeding level  $h$  is likewise equivalent to the number of waves between groups.

Three different expressions were tested for the mean values of  $j_1$  and  $j_2$ ,  $E(j_1)$  and  $E(j_2)$ . The formulae proposed by Nolte, (15), Ewing (7), and Goda (9) were found to give a very poor agreement with recorded data. This was attributed to existing differences between the  $H_s(t)$  process and the standard sea-surface elevation process. Furthermore the PDF of  $H$  used in the predictions of  $j_1$  and  $j_2$  could also introduce additional errors. It was, thus, decided to use Goda's formulae which provided a marginally better fit than the other two, reformulated in terms of the PDF of  $H_s$  instead of using the PDF of  $H$ . The original formulae can be written as (9):

$$E(j_1) = \frac{1}{P}$$

$$E(j_2) = \frac{1}{P} + \frac{1}{Q}$$

in which  $Q$  is the probability of occurrence of the event ( $H > h^*$ ) and  $P$  is :  $P = 1 - Q$ .

For a process symmetric with respect to  $H_{mean}$  the reference level  $h^*$  of the variable  $H$  can be written in terms of the reference level  $h$  of the variable  $H_s$  as:

$$h^* = 2(h - H_{mean})$$

Moreover  $H$ , for a symmetric process, may be expressed as:

$$H = 2(H_s - H_{mean})$$

Figure 7 : Average duration of storms versus the threshold level, as obtained from registered data, the proposed model and the model of (10).

Figure 8 : Fit of the empirical distribution of  $d_s$  (duration of storms) to a Weibull PDF for 4 randomly selected winter seasons.

Hence :

$$Q = \text{Prob} (H > h^*) = \text{Prob}(H_s > h) = 1 - F(H_s)$$

$$P = F(H_s)$$

Substituting these equations in Goda's formulae the fit improves significantly though remaining still qualitative (figure 9).

The PDF of the extremum of  $H_s$  in a stationary interval of duration  $D$  may be obtained following the approach proposed in (6):

$$\phi_1(h) = \text{Prob} (H_s \text{ extr.} \leq h) = (F(h))^n$$

in which :

$$F(h) = \text{Prob} (H_s \leq h)$$

$$n(h) = \frac{D}{d_s(h)} = \frac{D}{1 - F(h)} \lambda (h - H_{\text{mean}})$$

The extremal distribution may be alternatively obtained treating storm occurrences as a Poisson process. The corresponding PDF, as used in short-term analyses, is shown in (1) and can be written as :

$$\phi_2(h) = \text{Prob} (H_s \text{ extr.} \leq h) = \exp \left[ -D \left( \frac{m_2}{m_0} \right)^{\frac{1}{2}} \exp \left( - \frac{(h - H_{\text{mean}})^2}{2m_0} \right) \right]$$

The distribution so obtained is only valid for  $h > H_{\text{mean}}$ , requiring extrapolation out of this region. A comparison of predictions obtained using  $\phi_1(h)$  and  $\phi_2(h)$  is shown in figure 10. To test these predictions with wave data the mean value of the extremum has been evaluated from  $\phi_1$  and  $\phi_2$ , being denoted, respectively,  $E_1$  and  $E_2$ .

An alternative estimate of this mean value,  $E_3$ , has been obtained applying the formula proposed in (4) for the expected value of the highest of  $N$  maxima. This expression, valid for large  $N$  and broad-banded gaussian processes, may be written as:

$$E_3 = H_{\text{mean}} + m_0^{\frac{1}{2}} \left[ m + \frac{0,5772m}{1 + m^2} \right]$$

$$m = \left( \ln \left( \frac{N}{2\pi} \right) - \ln \ln \left( \frac{N}{2\pi} \right) \right)^{\frac{1}{2}}$$

Figure 9 : Mean values of the number of consecutive high storms ( $j_1$ ) and storms between groups of high storms ( $j_2$ ) as a function of the threshold level for defining high storms.

Figure 10 : Comparison of theoretical predictions of the extremal  $H_s$  value in a stationary period (randomly selected winter/summer seasons).

Figure 11 : Mean of the extremal  $H_s$  value in a stationary period as obtained from theory ( $E_1$ ), versus the corresponding value calculated from data (for a random winter season).

in which  $N = \frac{N_o}{r}$  ( $N_o = D \left( \frac{m_2}{m_o} \right)^{\frac{1}{2}}$ ) is the total number of local maxima for a process symmetric with respect to  $H_{\text{mean}}$ . This expression is easily obtained considering that the proportion of negative maxima is  $(1 - \alpha)$ , with  $\alpha$  given by  $\alpha = \frac{1}{2} (1 + r)$ , (1).

These three theoretical estimates for the mean value of the extremum have been tested with wave data showing a reasonable agreement in winter seasons (figure 11). The fit obtained for summer periods is significantly worse, probably due to the poor definition (in a probabilistic sense) of maxima in these seasons.

### 3. Concluding remarks

A satisfactory fit has been obtained for the theoretical distributions of  $H_M$  (storm peaks),  $H$  (range of  $H_S$  variation in a storm) and  $T$  (time between beginning of storms). Theoretical expressions for  $\bar{d}_c(h)$  (average duration of calms),  $\bar{d}_s(h)$  (average duration of storms),  $j_1(h)$  (number of consecutive storms) and  $j_2(h)$  (number of storms between groups exceeding level  $h$ ) show a qualitative agreement with wave data in all cases. Moreover, the fit obtained for these variables is also quantitatively correct in a high percentage of the stationary periods considered.

Theoretical expressions for the average value of the extremum of  $H_S$  in a stationary interval (month or winter/summer season) provide a good fit with data except for summer months and seasons.

The agreement between theory and data appears to be significantly improved when using results of the statistical analysis of the time-series  $H_S(t)$  (instead of results from spectral analysis) for the parameters of the theoretical expressions. All figures shown in the paper have been obtained with results from statistical analysis.

### 4. Acknowledgments

The author wants to express his acknowledgment to the Harbour Laboratory R. Iribarren for permission to use the wave data included in this paper. He is also indebted to Dr. J.J. Egozcue and J.R.-Marín, from the University of Barcelona for their help in handling and processing the data.

## CHAPTER FORTY TWO

### LOW FREQUENCY OSCILLATIONS ON THE DUTCH COAST

by

F. Gerritsen<sup>1</sup> and J. van Heteren<sup>2</sup>

#### 1. INTRODUCTION

During several months in 1981 and 1982/1983 two extensive programs of field measurements were carried out at Egmond on the Dutch North Sea coast, one during the spring of 1981 and the other during the winter of 1982/83.

In these programs researchers of the Dutch "Rijkswaterstaat", of The Delft University of Technology and of the Delft Hydraulics Laboratory cooperated in the planning and execution of the measurements and are now involved in data analysis and evaluation of results.

During the year 1983 the senior author spent a sabbatical year with the Rijkswaterstaat in the Netherlands and joined the team effort in analyzing the data.

Reference is made to other papers presented at this conference, highlighting some aspect of this research program: Van Heteren and Stive (1984), Derks and Stive (1984).

The present paper deals with low frequency oscillations in the surfzone and their potential impact on certain aspects of coastal morphology.

The conclusions of this paper have to be considered as tentative and should be followed by further study.

Its main intention is to point to certain possible relationships regarding coastal morphology so that in future measurements the program can be designed in such a way that certain relationships can clearly and unmistakably be identified.

The programs of measurements carried out in 1981 and 1982/83 were primarily designed to evaluate the usefulness and accuracy of various types of instruments in the surfzone. The measurements were never designed for the use we have made of them and results may therefore not be fully conclusive and thus subject to discussion.

Nevertheless the authors found their tentative findings of sufficient interest to share them with their colleagues.

<sup>1</sup> Professor and Chairman, Dept. of Ocean Engineering, Univ. of Hawaii

<sup>2</sup> Staff member, Rijkswaterstaat, Hellevoetsluis, The Netherlands

In the group of low frequency oscillations a distinction has been made between edgewaves and surf beat in this paper.

Edgewaves are characterized as waves propagating parallel to the shoreline and surf beat as waves travelling perpendicular to the shoreline. It is known to the authors that often low frequency oscillations are considered to be in the surfbeat frequency range, without distinction for direction.

For the purpose of studying their effect on coastal morphology a distinction in the two types of waves as discussed above is meaningful.

## 2. VARIOUS TYPES OF LOW FREQUENCY OSCILLATIONS IN THE SURFZONE

Many phenomena play a role in the generation of low frequency oscillations in the nearshore zone.

In this paper we will limit ourselves to the discussion of some relevant aspects of this subject.

### Wave groups and mass transport

In recent years the presence of wave groups in a wave train has been recognized as an important feature, both in the development of coastal processes and in the design of coastal structures, such as breakwaters. In the past the study of the phenomena of wave groupiness has developed along two different lines; one is the correlation aspects of sequential waves in an observed or simulated wave record, the other is the analysis of the modulations in mean energy of a wave record. In this study a third approach is followed: the analysis of low frequency oscillations through spectral analysis.

Two important phenomena may be observed in wave groups:

- (1) a lowering of the mean waterlevel associated with high waves in the group and a rising of the mean waterlevel in the group of low waves. This phenomena arises from the concept of energy conservation.
- (2) a modulation in mass transport associated with the sequence of groups of high and low waves.

Outside the surfzone the first aspect demonstrates itself as a coupled long wave, which travels shoreward with the groupspeed of the waves, having a  $180^\circ$  phase difference with the center of the group of high waves. This wave is coupled to the wave height modulation of the group. At the breaking point the coherence of wave groups is destroyed; the low frequency wave is released from the group, travelling as a free wave toward the coastline, from which it is reflected in seaward direction. The reflected waves travels through the surfzone to deep water as a free wave.

With respect to the modulation in mass transport the breaking of high waves of a group induces larger onshore directed mass transport than the breaking of low waves. This phenomena again induces a free travelling long wave in the breaking zone, with a phase difference of

180° with respect to the first wave. The two waves cannot be distinguished from one another because they have the same frequency, associated with the group period.

### Surf beat

The low period oscillation that is induced by the above described phenomena is here called surf beat. Inside the surfzone the surfbeat demonstrates itself as a standing wave of low period. In this zone both the incoming and reflected wave travel with the speed of a free travelling long wave,  $c = \sqrt{gh}$ . Outside the surfzone the incoming wave has the speed of the group velocity and the reflected wave that of a free travelling long wave. The seaward propagating free wave is often larger than the incoming forced wave (7).

It has been established that the amplitude of the surfbeat waves is dependent on the wave amplitude of the incoming wave.

According to Munk (11) the ratio of the amplitudes of long period oscillations to wind wave amplitude is about 1:10. This is probably valid for areas outside the surfzone. Inside the surfzone the ratio can be higher depending on depth and location (10).

### Progressive edge waves

For a long time edge waves were regarded as a subject of pure hydrodynamical interest, with no or little practical significance. In more recent years, however, it has been established that the presence of edge waves can be of fundamental importance in the dynamics and sedimentology of the nearshore zone through their interaction with ocean swell and surfbeat to produce circulation cells and ripcurrent patterns.

Reports of the occurrence of edge waves in the literature indicate that they may come in vastly different dimensions (9).

Observations at Egmond in 1981 and in 1982/83 suggest that edge waves are also present along the Dutch coast.

Where surf beat waves were identified as waves which have their crest parallel to or almost parallel to the shoreline, edge waves have their crests perpendicular to the shoreline. A solution for the edge wave formulation for gently sloping beaches with constant inclination  $\beta$  can be obtained from the linearized shallow water equations (9).

The condition of trapping is reflected in the form of the dispersion relation, which for the shallow water wave approximation is given by

$$\sigma_n^2 = gk(2n + 1) \tan\beta \quad (n = 0, 1, 2, \dots) \quad (1)$$

where  $\tan\beta$  is the beach slope and  $n$  the edgewave mode.

The solution for a progressive edge wave is of the form

$$\zeta(x, y, t) = F(y) e^{i(kx - \sigma t)} \quad (2)$$

in which the x-direction is parallel to the coast and the y-direction perpendicular to the coast positive seaward.  $k$  is the longshore wave number and  $\sigma$  the angular frequency. The function  $F(y)$  depends on the mode of the edgewave.

Edge waves have velocities in the x and y-direction, respectively parallel and perpendicular to coastline.

Trapping of edgewaves can also occur with different coastal profiles. A profile which is more realistic than the straight beach (from 0 to  $\infty$ ) has the form

$$h = h_0 (1 - e^{-\alpha y}) \quad 0 < y < \infty \quad (3)$$

The behavior of edge waves for such a profile was studied by Ball (1). It can be shown (Huntley, (6)) that the entrapped modes must obey the condition:

$$\sigma_{CR} = [n(n+1)]^{1/2} \alpha \sqrt{gh_0} \quad (4)$$

Experiments by Huntley (6) have furthermore shown that the frequencies of spectral peaks in the spectrum can be identified with the frequencies  $\sigma_{CR}$  for the consecutive modes. For a given offshore profile this can be expressed by:

$$f_{CR} = \text{const.} [n(n+1)]^{1/2} \quad (5)$$

where  $f = \sigma/2\pi$ . This expression could be verified for the North Sea Coast near Egmond.

#### Cell circulation

A standing edge wave has surface variations according to:

$$\zeta(x, y, t) = F(y) \cos kx \sin \sigma t \quad (6)$$

Standing edge waves are of particular relevance to coastal morphology.

Both theoretically and experimentally it can be shown that standing edge waves induce a nearshore cell circulation. Kaneko (8) developed a numerical simulation for cell circulation under the influence of standing edge waves on a sloping beach. He considered three conditions:

- (a) Cell circulation due to edge waves only.
- (b) Cell circulation due to superposition of edge wave and leaky-mode wave (with crest parallel to shoreline) with leaky mode having half the period of the edge wave (subharmonic edge wave). Leaky mode waves are defined as waves, which are not trapped to the coast.
- (c) Cell circulation due to superposition of edge wave and leaky-mode wave of the same period (synchronous edge wave).

The leaky mode waves of interest here are the surfbeat waves. The numerical circulations showed that in the cases (a) and (b) the circulation cells which developed, had the same form whereby two circulatory

cells developed each in size equal to one half the wave length of the edge wave. In the second case the velocities were considerably stronger than in the first case. The third case (c) showed a different behavior. Two cells developed along the full length of the edge wave whereby circulatory velocities became fairly strong in case the amplitudes of the two waves had equal value.

3. ANALYSIS OF MEASUREMENTS

Measurements

For a complete description of the measurements reference is made to Derks (2). In 1982/1983 two parallel traverses A and B were erected. Traverse A contained four platforms, traverse B only piles.

In Figure 1 the offshore profile in Traverse A and the measuring stations (A1 - A9) are shown.

Figure 1: Depth-profile and measuring stations Traverse A, Stations A1 - A9.

Waves were measured with resistance gages where supporting piles were available and with wave buoys in deeper water. For currents various types of sensors were used.

### Digital filtering

A low pass filter has been developed, which suppresses the energy of wind wave frequencies of the spectrum. In order to remove the high frequency oscillations from a waterlevel or velocity record, a moving-average procedure is applied. The length of the record section to which the averaging is applied must be long enough to filter out the high frequency oscillation but short enough to retain the type of oscillations in which we are interested. As a general measure an averaging period of one to two times the peak period of the wave spectrum is an adequate procedure. The application of a moving average system in the time-domain corresponds with a frequency response in the frequency-domain.

If the window function in the time domain has a length  $2\tau$  and a height of  $1/2\tau$  then the frequency response function is

$$H(f) = \frac{\sin 2\pi f\tau}{2\pi f\tau} \quad (7)$$

This function has zero crossings for  $f\tau = 0.5, 1.0, 1.5, \dots$ . If a number of moving average procedures are applied in series, one finds the impulse response by convolution of the individual weighting functions and the frequency response as the product of the individual frequency response functions.

Based on the above described procedures various low pass filters were designed and applied to selected data. For the 1982/83 observations the original time series was sampled at a frequency of 10 Hz.

It was found that a reduction of the number of data points in ratio 1:24 could be applied without loss of relevant information. ( $\Delta t = 2.4$  sec).

Characteristics of the selected low pass filter were the following:

- (1) Use of the running average procedure 3 times in series with equal block length. This corresponds to a filtering characteristic

$$H(f) = \left( \frac{\sin 2\pi f\tau}{2\pi f\tau} \right)^3 \quad (8)$$

- (2) Selection of block length  $2\tau$  in such a manner that

$$H(f) = 0.5 \quad \text{at } f = \frac{1}{4T_p},$$

where  $T_p$  is the peak period of the wave or velocity spectrum. This condition gives  $2\tau = 1.465 T_p$ .

- (3) A further reduction of data points in sequential time series in ratio 1:8. The characteristic low pass filter obtained in this way is shown in Figure 2-a.

In addition a high pass filter of the form of Figure 2-b was applied to remove low frequency trends such as the tide. The combined effect is shown in Figure 2-c.

Figure 2. Numerical filter characteristics ( $T_p = 7.5$  sec).

### Required resolution of low pass filter

In the beginning of the study measuring series of about 1800 seconds in length were used for analysis. In order to obtain sufficient accuracy (10 subseries) the resolution step could not be smaller than  $\Delta f = 0.0029$  Hz. It appeared that this type of resolution would smooth most of the edge wave energies. To overcome this problem a longer length of time series was required. For this five hour records were selected which reduced the resolution step to  $\Delta f \approx 0.0006$  Hz. A five hour time series also has serious drawbacks. It is likely to violate the requirement of stationarity of the low frequency oscillations due to changes in tide and wave conditions over that period. In the future record lengths of 3 hours will be utilized. This period is selected before and after high water to have minimal effect of the tide on the low frequency phenomena.

## 4. RESULTS OF INVESTIGATIONS

The results of the investigations relate to three different aspects of the problem:

- (1) The characteristics of the low frequency spectra (both waterlevel and velocities)
- (2) The effect of low frequency oscillations on horizontal circulation (spacing of rip currents)
- (3) Relationship of low frequency oscillations to beach profile characteristics

### Low frequency spectra

The analyzed data included the measurements of Spring 1981 as well as of Winter 1982.

Space limitations do not allow us to present the results of both measurement series. In this paper only results of 1982 will be presented.

For this paper the measurements of 10 December 1982 were selected. This series is characterized by significant wave heights ( $H_s = 4\sqrt{m_0}$ ) and peak periods as follows:

Sta A9 :	$H_s = 2.56$ m	$T_p = 7.5$ sec
Sta A8 :	$H_s = 2.18$ m	$T_p = 6.95$ sec
Sta A6 :	$H_s = 2.14$ m	$T_p = 7.5$ sec
Sta A5 :	$H_s = 1.64$ m	$T_p = 6.75$ sec

The low pass filter, described in section 3 is based on a peak period for the offshore waves of 7.5 sec.

The wave spectrum in Sta A5 is presented in Figure 3.

The results of the low frequency spectra obtained by applying the low and high pass filters are presented in Figures 4 through 7.

Figure 3. Wave spectrum in Station A5

In figure 4 the low frequency wave spectra are shown for stations A2, A3, A4, and A5 (stations 2-5 in traverse A).

The type of oscillations present in these spectra include the surfbeat types (waves travelling perpendicular to the shoreline) and the edgewave types (waves travelling parallel to the shoreline).

Without further information the distinction between these two types of oscillations is difficult to assess.

To assist in the distinction of these types the following additional information was utilized.

- (a) Directional information obtained from horizontal velocity components;
- (b) Phase spectra (phase of wave in one station compared to the next station).
- (c) Coherence spectra, giving correlation between one oscillation and another.
- (d) Horizontal circulation patterns.

By considering the above information in addition to the low frequency spectra the following picture emerges:

In almost all low frequency spectra a dominant peak occurs at a frequency between 0.0012 and 0.0033 Hz (This peak is clearly dominant in Figure 6<sup>a</sup> and 7<sup>a</sup>). This peak is attributed to the zero mode edge wave. The sharp peaks visible e.g. in Figure 4 are contributed to edge wave peaks of higher modes. The peaks in Stations A2, A3, and A4 are superimposed on three broad bands of low frequency energy. The middle one, between frequencies 0.012 Hz and 0.024 Hz contains the largest amount of energy and is believed to represent the major surfbeat mode.

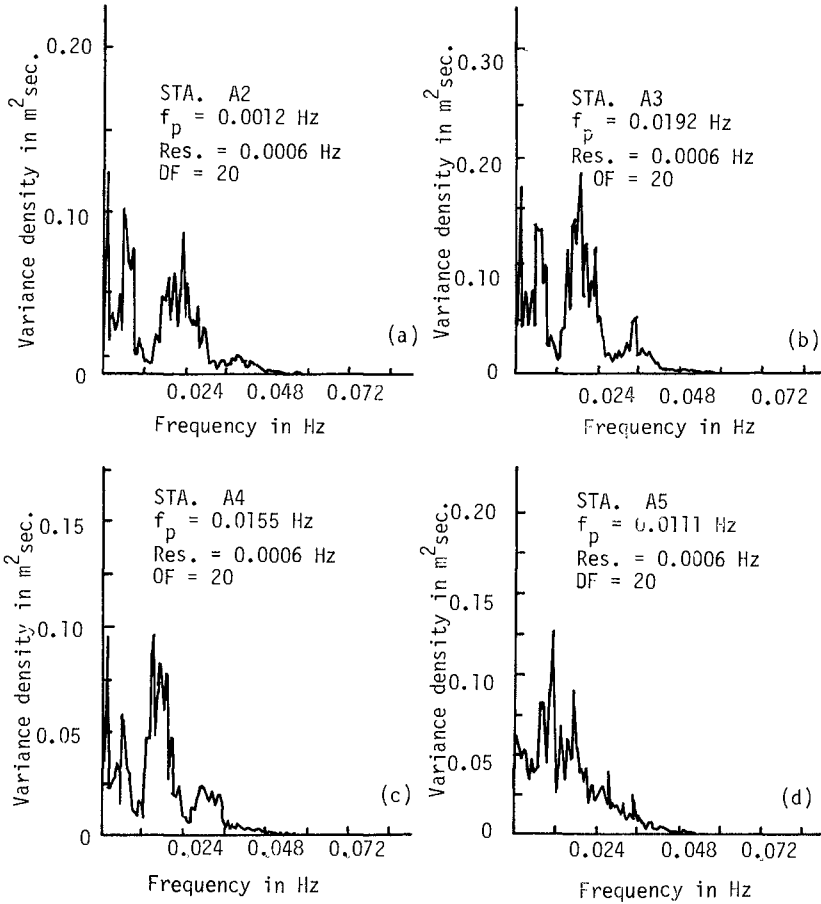

Figure 4: Low frequency wave spectra for stations A2 - A5

Figure 5. Low frequency wave spectrum for Sta. A3 for different resolution and degrees of freedom

The bands on either side also contain surfbeat energy. It is of interest to consider the frequency at which the major surfbeat energy has its maximum density and to relate this to the peak frequency of the offshore waves:

Figure 6. Low frequency spectra for velocity components (a) Perpendicular to coast; (b) parallel to coast

Figure 7. Low frequency spectra for velocity components  
 (a) perpendicular to coast;  
 (b) parallel to coast

In station A5,  $f_p = .1483$  Hz.

For stations 2-4 we have ( $f_{ps}$  denoting the peak of the surfbeat energy):

Sta A2:  $f_{ps} = 0.024$ ;  $f_p/f_{ps} = 6.2$

Sta A3:  $f_{ps} = 0.019$ ;  $f_p/f_{ps} = 7.8$

Sta A4:  $f_{ps} = 0.015$ ;  $f_p/f_{ps} = 9.9$

with an average value (for stations 2 to 4) of 8.0.

In order to compare total energy values for the three different surfbeat modes it must be realized that due to the application of the filter, energies in the higher frequencies are undervalued compared to the values corresponding to the lower frequencies. Since the filter characteristics are known this can be compensated for. However, this is not necessary where spectra are used to identify where peaks occur. In this study this compensation was not applied.

Keeping this in mind and going from Station A4 to Station A2 there is a shift of energies to lower frequencies in a relative perspective. The highest variance density ( $0.18 \text{ m}^2/\text{sec}$ ) is present in Station A3; this value however includes some edge wave energy as well. The sharp peaks in the spectra for stations A2 and A4 are also considered to represent edge wave energy. The grouping of surfbeat energy is less distinct at Station A5 (Figure 4d). The individual peaks are also considered edge wave peaks.

One method to filter edge wave energy is to use a larger resolution frequency step ( $0.0019$  Hz) and obtain a higher degree of accuracy (Degrees of freedom = 60). See Figure 5, showing an example of this approach for Station A3.

Figure 6 and 7 present the low frequency spectra for onshore and alongshore velocity components for Stations A3 and A4.

It is to be noted (Figure 6<sup>a</sup>) that where surfbeat energy is high ( $f \sim 0.02$  Hz) onshore velocities are low. This corresponds with the situation at standing waves, at a location close to the nodal point.

An example of the calculated phase spectrum between surface elevations of Stations A2 and A3, is presented in Figure 8. Both edge wave peaks of low frequency and surfbeat peaks have phase = 0, as expected (standing waves). The coherence function for the same quantities is shown in Figure 9, showing high coherence for the very low frequency oscillation as well as the surf beat modes.

The resolution of 0.0019 Hz used for the analysis in Fig. 8 and 9 smoothes the edge wave energy and therefore does not allow identification of edge wave peaks.

Figure 8. Phase spectrum (waterlevel) for Stations A2 and A3

Figure 9. Squared coherence function (waterlevel) for Stations A2 and A3

Figure 6<sup>a</sup> and 7<sup>a</sup> have been used to plot the (assumed) edgewave frequency peaks as a function of the mode number. The results are plotted in Figure 10 and validate the relationship given in equation (5), with the value of the constant equal to 0.0031.

Figure 10. Edge wave frequency peaks as function of mode number for velocities perpendicular to coast. (reference Figure 6(a) and 7(a)).

Massel and Musielak (10) found for the Baltic Coast at Lubiatowe for the constant value 0.0041, which is somewhat higher but of the same order of magnitude.

An offshore profile of exponential shape is given by relation (3):

$$h/h_0 = 1 - e^{-\alpha y}$$

If  $h_0 = 16\text{m}$  and  $\alpha = 0.001315$  (obtained from equation(5)) a reasonable approximation for the offshore profile at Egmond is obtained.

#### The effect of low frequency oscillations on horizontal circulation

In section 2 a description is given of possible circulation patterns induced by edgewaves or by edge waves and surfbeat waves combined.

With respect to ripcurrent distances along the Dutch Coast reference is made to Ten Hoopen and Van Driel (5). They found that along the Dutch coast ripcurrent distances varied from 150 to 1850m with an average distance of 785m. Aerial photographs of the Egmond coastline in 1981 show an average distance of rips of about 1300-1400m whereas the 1983 photographs showed shorter distances, 600-700m. Unfortunately there is no extensive information available for the circulation patterns and rip current distances at the date of the measurements except some local observations near the measuring site showing ripcurrent distances of 500-700m.

In view of the characteristics of the low frequency spectra, discussed above, it is feasible that a zero mode edge wave occurs by itself or simultaneously with a surf beat wave of double frequency, a situation corresponding with respectively the conditions (a) or (b) of the combi-

nation listed in section 2. The length of the complete circulation cell is than half of the wave length of the edge wave. Taking 700m as the distance between ripcurrents the zero mode edge wave length is then 1400m and the corresponding frequency for the zero mode edge wave (equation (1) for  $n = 0$ ) is:  $\sigma = 1.92 \times 10^{-2}$  rad/sec and  $f = \sigma/2\pi = 0.0031$  Hz. The corresponding first mode is  $f(1) = f(0)\sqrt{3} = 0.0053$ Hz.

The value  $f(0) = 0.0031$  Hz corresponds with the major low frequency peak in Figure 6a (Station A3). In this figure the next peak is either at  $f = 0.004$ Hz or  $0.005$ Hz. The assumption of a zero mode edge-wave peak at  $f \sim 0.003$  corresponding to a wavelength of 1400m therefore appears to be in general agreement with observed rip current patterns.

Relationship between low frequency spectra and beach profile characteristics

It is beyond the scope of this paper to discuss the various mechanisms that contribute to the formation of longshore bars and troughs. In this study we will only investigate if the dimension of troughs between offshore bars has any relationships with the major surfbeat wave. It is suggested that the following mechanism may play a part in the bar and trough formation. During high wave conditions (storms), waves break on the second bar. During this process due to variable mass transport a surfbeat type standing wave is induced with its nodal points at the first and second bar (see Figure 11).

Figure 11. Schematic offshore profile

If such a concept would be correct the following relationship should be valid:

$$T = 2\lambda_2 \left[ \frac{1}{\sqrt{gh_2}} \right] \tag{9}$$

whereby  $T$  is the dominant surfbeat period and  $\lambda_2$  the distance between first and second bar.

The overbar signifies the average value over the trough of  $\left[ \frac{1}{\sqrt{gh_2}} \right]$ . In first approximation the above expression for  $T$  can be written as:

$$T = \frac{2\lambda_2}{\sqrt{gh_2}} \tag{10}$$

Expression (10) was tested for a significant number of profiles during different times of their development. See also Nanninga (12). It was found that for most of the observations the value of  $T$  ranged from 75 to 85 sec.

Observations during storms on December 21 and December 27, 1982 showed a peak period of waves offshore of 9.0 sec.

The conditions during storm are selected because it is assumed that under those conditions bedforming activities occur. The ratio of the values of  $T$  found above and the peak period during storms then ranges between 8.3 and 9.5, which is similar to the ratio found in section 4 for station A3 and A4 (respectively 7.8 and 9.9).

In station A5 which is located in the trough between first and second bar, an (assumed) surfbeat peak occurs around  $f=0.011$  Hz corresponding to a period of 90 seconds. The above suggests a fairly good correlation between the period  $T$ , defined above and the period at which surfbeat energy peaks. It is suggested that further investigations are in order to validate this relationship.

For the channel between first bar and coastline two possibilities are open:

- (1) The width of this channel could correspond to  $1/4$  wave length with an anti-node located at the coastline. In that case,  $T$  would range from 110 - 130 sec. and does not correspond to the same surfbeat peak period. However there is a possibility that a correlation with the surfbeat mode at lower frequencies may be found.
- (2) The width of this channel could correspond to  $1/2$  of the local wave length with an offshore bar starting to develop near the shoreline. In that case  $T$  would range from 55-65 sec. which is 6.1 to 7.2 times the peak period. This is close to the observed values listed in 4 for Station A2 and A3 (respectively 6.8 and 7.8).

## 5. CONCLUSIONS

- (1) It is concluded that low frequency oscillations in the surf-zone may contribute in different ways to bedforming conditions of the Dutch North Sea coast.
- (2) Evidence is found of the following specific influences of low frequency oscillations on the Dutch coastline:
  - (a) Edge waves in possible combination with surfbeat are likely to influence horizontal circulating patterns and the spacing of rip currents.
  - (b) Surfbeat oscillations seem to have a bedforming influence on the offshore profile.

## 6. ACKNOWLEDGEMENTS

The authors wish to thank A.P. Roskam for assistance in computer programming and data analysis.

The senior author wishes to express his appreciation to the Dutch Rijkswaterstaat for the opportunity to participate in their studies.

## CHAPTER FORTY THREE

### VERIFICATION OF KIMURA'S THEORY FOR WAVE GROUP STATISTICS

J.A. Battjes<sup>1</sup> and G.Ph. van Vledder<sup>1</sup>

#### ABSTRACT

North Sea wave records, obtained in conditions of active wave generation, have been analyzed with respect to the distribution of the length of wave groups. The results are compared to a theory by Kimura, in its original form as well as with the addition of a new spectral wave groupiness parameter, based on the theory of Gaussian processes. The results lend support to the validity of Kimura's theory; this in turn implies further evidence that the phenomenon of wave groups in sea waves can by and large be explained, both qualitatively and quantitatively, in terms of the linear, random phase model for the wave motion, even in conditions of active wave generation.

#### INTRODUCTION

The occurrence of groups of high waves in a seastate is a phenomenon of practical and theoretical interest. Two principal lines of approach have been used for the investigation of wave groupiness. One approach considers the wave envelope, the other uses the sequence of wave heights. In this paper, the latter approach is followed. A wave group is defined as a sequence of wave heights ( $H_n$ ;  $n=1,2,\dots$ ) in excess of a given threshold value ( $H_x$ ), preceded and followed by a height below that level. The length of a group ( $N$ ) is defined as the number of heights in that group.

Goda (ref. 5) derived an expression for the probability distribution of  $N$ , assuming all wave heights to be stochastically independent, each being Rayleigh distributed. This theory systematically underpredicts observed group lengths in wind waves. This is due to the neglect of dependence between wave heights. As shown by Rye (ref. 11) and others, successive wave heights are positively correlated. This was taken into account by Kimura (ref. 9). His theoretical results are in good agreement with results from numerical simulations (Kimura, ref. 9) as well as from field observations in old, narrow-banded swell (Goda, ref. 6).

A shortcoming of Kimura's formulation is that the parameter determining the groupiness is not defined in terms of the energy spectrum of the underlying process. However, a spectral shape parameter which is appropriate for this purpose can in fact be defined (Battjes, ref. 3), using Arhan and Ezraty's calculations of the joint pdf of consecutive wave heights (ref. 1), which in turn were based on Rice's theoretical results on envelope statistics (ref. 10).

Dept. of Civil Engineering, Delft University of Technology,  
Stevinweg 1, 2628 CN Delft, The Netherlands

The purpose of the present paper is to present results of an empirical check of Kimura's theory, including the spectral parameter referred to above. The check is based on analyses of North Sea wave records obtained during conditions of active generation. The presentation in this proceedings paper is kept brief. A full account will be published elsewhere.

RESUME OF KIMURA'S THEORY

Considering a sequence of random wave heights ( $H_1, H_2, \dots$ ) as a Markov process, Kimura (ref. 9) derives the following expression for the probability distribution of the group length ( $N$ ) :

$$P(N) \equiv \Pr \{N = N\} = (1 - q) q^{N-1} \tag{1}$$

in which  $q \equiv \Pr\{H_{-n+1} > H_* \mid H_n > H_*\}$  (2)

For a given threshold value  $H_*$ , the conditional probability  $q$  can be expressed in terms of the joint probability density function (pdf) of two consecutive wave heights ( $H_1, H_2$ ), for which Kimura uses the two-dimensional Rayleigh pdf. This pdf has one shape parameter,  $\kappa$ , say (Kimura's parameter  $\rho$  equals  $\frac{1}{2}\kappa$ ). The coefficient of linear correlation between  $H_n$  and  $H_{n+1}$  (denoted as  $\gamma$ ) can be expressed in terms of  $\kappa$ , with the result

$$\gamma = \frac{E(\kappa) - \frac{1}{2}(1 - \kappa^2)K(\kappa) - \pi/4}{1 - \pi/4} \tag{3}$$

in which  $K(\kappa)$  and  $E(\kappa)$  are the complete elliptic integrals of the first and second kind, respectively. Kimura uses this to estimate  $\kappa$  from a wave record via  $\gamma$ , which can be calculated directly from the given sequence of wave heights. (A direct time-domain estimate of  $\kappa$  is possible on the basis of the fact that  $\kappa^2$  equals the coefficient of linear correlation between  $H_n^2$  and  $H_{n+1}^2$ , as shown by Battjes (ref. 2).) Alternatively, one can use an approach developed by Arhan and Ezraty (ref. 1) and express  $\kappa$  in terms of the energy spectrum  $E(f)$  of the surface elevation (Battjes, ref. 3) :

$$\kappa = k(\tau) \quad \text{for } \tau = T_z = (m_0/m_2)^{1/2} \tag{4}$$

in which

$$k(\tau) \equiv \left| \int_0^\infty E(f) e^{i2\pi f\tau} df \right| / m_0 \tag{5}$$

In these expressions,  $m_0$  and  $m_2$  are the zeroth- and second moments of  $E(f)$  about  $f=0$ , and  $T_z$  is the mean zero-crossing wave period.

It is pointed out that this direct, spectral estimate of  $\kappa$  obviates the need to use the correlation coefficient of successive wave heights. Nevertheless, the results to be given below are presented in terms of  $\gamma$  for purposes of comparison with previous results. To this end, values of  $\kappa$  obtained from (4) and (5) have been transformed to values of  $\gamma$  using (3).

## WAVE DATA

An empirical check was made of Kimura's theory, based on an analysis of 33 wave records, collected in the southern North Sea using a Waverider buoy in swell and wave growth situations. These included some JONSWAP data as well as data of the severe storm of January 3, 1976 (described by Harding and Binding, ref. 8 and by Bouws, ref. 4). The wave records consist of time series (sampling rate 2 Hz) with a duration of approximately 20 minutes.

## ANALYSIS AND RESULTS

In the time domain, each wave record was analysed to obtain a sequence of zero upcrossing wave heights. Each of these sequences was used to estimate the coefficient of correlation between consecutive wave heights, denoted as  $\gamma_t$  (t for time domain). Furthermore, frequency distributions of group length were determined for two threshold values, viz. the mean wave height and the significant wave height, here defined as the mean of the one-third highest wave heights ( $H_{1/3}$ ). In this paper, results for  $H_{\kappa} = H_{1/3}$  only are presented.

Each record was Fourier-analysed via a direct FFT-method with a partial Hanning data window in the time domain, to obtain estimates of the variance spectral density.

In the spectral domain, values of  $\kappa$  were calculated using (4) and (5). The integration limits for this calculation were 0.045 Hz and 0.505 Hz. Values of  $\kappa$  were substituted in (3) to obtain spectral estimates of the correlation coefficient  $\gamma$ , denoted as  $\gamma_s$  (s for spectral domain).

The number of wave groups per record was too small to allow meaningful conclusions about the group length distribution per record. Therefore, all records with more or less the same value of  $\gamma$  were pooled, using a class width equal to 0.1 ( $\gamma$  between 0 and 0.1, between 0.1 and 0.2, etc.). The frequencies of observations of the group length  $N$  ( $N=1, N=2, \dots$ ) for all records with  $\gamma$  in a given interval were added so as to obtain an estimate of the group length distribution  $P(N)$  for the given range of  $\gamma$ . These were compared with the theoretical distributions.

For each observed pooled distribution the sample mean group length was calculated, and compared with Kimura's theoretical prediction for it, using either the time-domain estimate of the correlation coefficient of successive wave heights ( $\gamma_t$ ) or the spectral estimate ( $\gamma_s$ ), obtained via  $\kappa$ . The results are given in the figures 1 and 2, respectively.

The whole observed distribution of the group length is compared to the predicted one in figure 3 for two classes of  $\gamma_s$ . For other classes comparable agreement was obtained.

## DISCUSSION

Kimura's theoretical prediction of the mean group length ( $\mu_N$ ), using the time-domain estimate of  $\gamma$  as input, is in excellent agreement with the observations (figure 1). The agreement is slightly less in case the spectral estimate of  $\gamma$  is used (figure 2). In this case, there appears to be some tendency of underprediction, particularly for cases of high correlation. Removal of the bound higher harmonics from the spectrum,

Figure 1 - Block diagram: sample mean group length ( $\mu_N$ ) and 90% confidence band vs. time domain estimate of  $\gamma$ . Curve:  $\mu_N$  vs.  $\gamma$  according to Kimura's theory.

Figure 2 - Block diagram: sample mean group length ( $\mu_N$ ) and 90% confidence band vs. spectral domain estimate of  $\gamma$ . Curve:  $\mu_N$  vs.  $\gamma$  according to Kimura's theory.

Figure 3 - Group length distribution for  $H_{*} = H_{1/3}$ ; records pooled according to values of spectral estimate of  $\gamma$ . Dots: observed values. Lines: theoretical values of  $\gamma_s$  at the limits of the class interval of the observations. (The lines have been drawn only for the purpose of visualisation; only the values for integer  $N$  have meaning.)  
 Fig. 3a: class interval  $0.2 < \gamma_s < 0.3$ ; fig. 3b: class interval  $0.3 < \gamma_s < 0.4$ .

as was done by Goda (ref. 6) using the theory for nonlinear wave-wave interactions by Tick (ref. 13) and Hamada (ref. 7), would result in less underprediction. This is because removal of the bound high-frequency energy from a given spectrum results in a narrower spectrum and a corresponding higher value of  $\kappa$ . The use of this higher value of  $\kappa$  in the estimation of the groupiness is legitimate because the principal effect of bound higher harmonics is wave profile distortion, and much less changes in wave height. An analysis along these lines of the data used in this study is carried out at the time of writing. Quantitative results are not yet available.

The theoretical prediction of the group length distribution is fair or good, as can be seen in the examples shown in figure 3. It is emphasized that the theory used in these predictions, and in those of the mean group length as well, does not contain any adjustable parameter.

The fair degree of agreement between theory and observations observed above lends further support to the validity of Kimura's theory, even in cases of active wave generation in storms. This in turn implies further evidence, in addition to that already presented by Rye and Lervik (ref. 12) and Goda (ref. 6), that the essential features of wave groups in sea waves can be explained on the basis of the linear, Gaussian model.

#### CONCLUSIONS

An analysis has been made of a series of North Sea wave records, including records obtained during storms. The analysis was aimed at an investigation of wave group statistics. The following conclusions were obtained:

- (1) The probability distribution and expected value of the length of groups of waves with height exceeding  $H_{1/3}$ , predicted by Kimura's theory, are in good agreement with observed frequency distributions and sample mean values.
- (2) The preceding conclusion holds for Kimura's theory in its original formulation, utilizing the correlation coefficient between consecutive wave heights estimated in the time domain, as well as in an alternative formulation, utilizing a spectral groupiness parameter based on Rice's theory for wave envelope statistics.
- (3) The preceding conclusions imply that the essential features of wave groups at sea, even in stormy conditions, can be explained on the basis of the linear, Gaussian model for the wave motion.

#### ACKNOWLEDGEMENTS

The authors thank E. Bouws of the K N M I (Royal Dutch Meteorological Institute) for providing the wave records used in this study.

## CHAPTER FORTY FOUR

### CALIBRATION AND VERIFICATION OF A DISSIPATION MODEL FOR RANDOM BREAKING WAVES

J.A. Battjes\* and M.J.F. Stive\*\*

#### ABSTRACT

A model describing the average rate of energy dissipation in random waves breaking in shallow water, published previously by the first author and Janssen (1978), has been applied to an extensive set of data for the purposes of calibration and verification. Both laboratory and field data were used, obtained on beaches with a more or less plane slope as well as on barred beaches, and for a wide range of wave conditions. Optimal values have been estimated for an adjustable breaking waveheight-coefficient in the model; these appear to vary slightly but systematically with the incident wave steepness, in a range which is physically realistic. A parameterization of this dependence allows the use of the model for prediction. Applied to the present data set, the correlation coefficient between measured and predicted rms wave heights is 0.98, with an rms normalized error of 6% and a bias which does not differ significantly from zero.

#### 1. INTRODUCTION

The principal physical process in the surfzone is the dissipation of the energy of incident windwaves and swell, due to wave breaking. Because of the randomness of wind-generated waves the occurrence of breaking at a fixed location is itself a random process. Realistic models for the prediction of the onshore variation of wave energy and radiation stress should take this randomness into account.

Battjes and Janssen (1978), hereafter referred to as BJ, presented an approach in which the mean local rate of energy dissipation is modelled, based on that occurring in a bore and on the local probability of wave breaking. The result is used as a sink in the energy balance, which is subsequently integrated to obtain the wave energy as a function of onshore distance. A few laboratory experiments performed by BJ, including cases with a bar-trough profile, indicated a very promising degree of agreement.

Thornton and Guza (1983) have presented a refinement of BJ's model, which however has negligible consequences for the predicted rms-variation. They also made a comparison between calculated and measured rms wave heights, using field data of low swell incident on a gently sloping, almost plane beach. Again, good agreement was found, with an rms relative error of about 9%.

The range of bottom profiles and incident wave parameters in the measurements referred to above is too restricted to allow a systematic investigation of the model performance and of the optimum values of the adjustable parameters. It was therefore decided to carry out an extensive calibration and verification of the model. The present paper briefly presents the results of this investigation. A full account will be published elsewhere.

The paper is made up as follows. A resume of BJ's model is given first. Then the observational conditions and procedures are described. The results are used for estimation of adjustable model coefficients as a function of the independent parameters (particularly the incident wave steepness). Finally, an overall assessment of the model performance with parameterized coefficients is presented, followed by a discussion.

## 2. RESUME OF BATTJES AND JANSSEN'S MODEL

In this section, we present a summary of BJ's model for reference in the remainder of this paper.

The essence of BJ's model is the estimation of the time-averaged rate of dissipation of wave energy per unit area due to breaking ( $\bar{D}$ ). Two aspects are distinguished: the rate of energy dissipation in periodic breaking waves, and the probability of occurrence of breaking waves of given height in a random wave field.

The energy dissipation in breaking waves is modelled after that in a bore of the same height. For periodic waves with frequency  $f$  and breaking waveheight  $H_b$  in water of mean depth  $h$ , BJ arrive at the following order-of-magnitude estimate for the mean dissipation rate per unit area:

$$D \sim \frac{1}{2} f \rho g H_b^2 \quad (1)$$

For application to random waves, the expected value of  $D$  (written as  $\bar{D}$ ) must be estimated, taking into account the randomness of the waves and the fact that not all the waves passing the point considered are breaking. In this estimate, BJ have used characteristic values for the frequency and the breaking waveheights, and they have derived a prognostic equation for the local fraction of breaking waves.

The characteristic frequency used in the following is  $f_p$ , the frequency at the peak of the energy spectrum of the incident waves.

The mean square of  $H_b$  is equated by BJ to the square of the nominal, depth-limited height of periodic waves ( $H_m$ ) in water of the local mean depth. BJ use a Miche-type expression for  $H_m$ , adapted through the inclusion of a parameter  $\gamma$  to account for influences of bottom slope and mean wave steepness:

$$H_m = 0.88 k_p^{-1} \tanh(\gamma k_p h / 0.88) \quad (2)$$

in which  $k_p = 2\pi/L_p$  is the wavenumber calculated on the basis of the linear theory dispersion equation for gravity waves with frequency  $f_p$ .

To determine the local fraction of breaking waves ( $Q$ ), BJ assume that the cumulative probability distribution of all waveheights (breaking or non-breaking) is of the Rayleigh-type, cut off discontinuously at  $H = H_m$ . This was shown to imply the following relation between  $Q$  and  $H_{rms}/H_m$ , in which  $H_{rms}$  is the rms of all waveheights:

$$\frac{1 - Q}{-\ln Q} = \left( \frac{H_{rms}}{H_m} \right)^2 \quad (3)$$

Substituting the approximations mentioned above in the averaged equation (1), and writing the order-of-magnitude relation in the form of an equation, gives

$$\bar{D} = \frac{1}{4} \alpha Q f_p \rho g H_m^2 \quad (4)$$

in which  $\alpha$  is a coefficient which is expected to be of order 1. It is pointed out that  $\bar{D}$  varies with  $H_{rms}$  through  $Q$ .

To close the model,  $\bar{D}$  is used as a sink in the wave energy balance, which in its most reduced form (statistically steady, uniform alongshore, no other sources or sinks than  $\bar{D}$ ) can be written as

$$\frac{\partial P_x}{\partial x} + \bar{D} = 0 \quad (5)$$

$P_x$  is the onshore energy flux per unit width, approximated as  $E c_g$ , in which  $E = \frac{1}{8} \rho g H_{rms}^2$  and  $c_g$  is the group velocity according to the linear theory for  $f = f_D$ .

The energy balance (5) is integrated simultaneously with the balance of onshore momentum (not reproduced here), resulting in the simultaneous determination of the onshore variation of  $H_{rms}$  and of the set-up of the mean water level ( $\bar{\eta}$ ).

### 3. OBSERVATIONS

Empirical data from various sources have been collected for calibration and verification of the theoretical model. These include laboratory data and field data, obtained for a variety of wave conditions and bottom profiles. The original data of BJ are included also.

All laboratory data used herein have been collected in wave flumes, using mechanically generated random waves. The field sites and conditions were selected so as to have more or less statistically uniform conditions alongshore and normal incidence (for the principal wave propagation direction). Direct wind influence was negligible in all cases considered here except one.

The laboratory bottom profiles include plane slopes and a schematized bar-profile in concrete, as well as concave and barred profiles in sand. Two field sites on the Dutch coast were used, one on a beach near Egmond, the other on a shoal in the mouth of the Haringvliet estuary. The beach has a typical double bar system. The measurements in the Haringvliet estuary were conducted in a line across an elongated shoal, with more or less parallel depth contours over a distance of about 5000 m. The minimum depth over the shoal is 0.1 m below Mean Sea Level, and about 1.5 m below Mean High Water Level.

For each combination of incident waves and bottom profile, measurements were made of the bottom profile, the mean water level, the rms wave height and the peak frequency at an offshore reference point, and the rms wave heights at various points in the profile. In some cases the variation of mean water level with distance onshore was measured also. The surface elevation signals were analyzed to estimate the variance,  $\sigma^2$ , and its spectral distribution. The measured variances were used to estimate  $H_{rms}$  according to

$$H_{rms} = 8^{\frac{1}{2}} \sigma. \quad (6)$$

A resume of the independent parameters is given in Table 1. The columns 4, 5 and 6 list the values of  $h$ ,  $H_{rms}$  and  $f_p$  in the offshore reference point (indicated with the subscript  $r$ ). Values of a mean deep-water wave steepness  $s_o = H_{rms}/L_{Op}$  are listed in column 7, based on  $L_{Op} \equiv g/(2\pi f_p^2)$  and a deep-water value of  $H_{rms}$  calculated from the values in the reference point using linear shoaling theory for periodic waves with frequency  $f_p$ , i.e.  $H_{rms}_o = H_{rms}_r (c_{gr}/c_{go})^{\frac{1}{2}}$ . The parameter  $\hat{\gamma}$  in column 8 will be explained below.

## 4. MODEL CALIBRATION

The energy balance and the momentum balance have been numerically integrated with respect to the onshore distance ( $x$ ) for each case listed in Table 1, using chosen values of  $(\alpha, \gamma)$ . The peak frequency  $f_p$  and the coefficients  $(\alpha, \gamma)$  were kept constant with respect to  $x$ . Each integration gives two functions  $\eta(x)$  and  $H_{rms}(x)$  shoreward of the reference point, which can be compared to the measurements. Repeating the integration for several choices of  $(\alpha, \gamma)$ , optimal values of these coefficients have been estimated, such that a maximum agreement is obtained between computed and measured  $H_{rms}$  values.

The coefficients  $\alpha$  and  $\gamma$  can formally be varied independently of each other. However, in the calibration process just described there is a dependence between the two since in this process the model is forced to simulate a certain energy dissipation, which depends on  $\alpha$  and  $\gamma$  through its proportionality to the product  $\alpha Q H_m^2$  (see eq. 4). Therefore, there is effectively only one degree of freedom in tuning the model to a measured waveheight variation. The calibration was in fact carried out by estimating optimal values of  $\gamma$  (denoted as  $\hat{\gamma}$ ) under the constraint  $\alpha = 1$ . The resulting values of  $\hat{\gamma}$  are listed in column 8 of Table 1. They fall in the range from 0.60 to 0.83, which is physically realistic.

Fig. 1 Estimated values of breaker height coefficient  $\hat{\gamma}$  vs. deep-water steepness  $s_0$ ; data points: optimal value per case; full curve parameterization given by eq. 7.

It is known that the process of wave breaking in shallow water is influenced by the incident wave steepness and by the bottom slope. It was therefore investigated whether the estimated  $\hat{\gamma}$ -values varied systematically with these parameters. No significant variation of  $\hat{\gamma}$  with beach slope could be found. However, there did appear to be a systematic dependence of  $\hat{\gamma}$  on the deep-water steepness  $s_0$ , as can be seen in Fig. 1. A tanh-function has been fitted to these data, with the result

$$\hat{\gamma} = 0.5 + 0.4 \tanh(33 s_0) \quad (7)$$

This relation, indicated in Fig. 1 by the full line, can be used for purposes of prediction.

##### 5. EVALUATION OF MODEL PERFORMANCE

In order to gain an impression of the overall performance of the model, we have applied it again to each of the 20 cases considered, this time using the parameterization (7) described above. The model was found to be quite realistic in the simulation of the observed rms waveheights. Some examples of the results are shown in the Figs. 2 through 4. A comparison of normalized computed and measured  $H_{rms}$  values in the zone of wave shoaling and breaking covering all 20 cases is given in Fig. 5. The correlation coefficient is 0.98; the model bias based on the best-fitting proportional relationship is 0.01, and the rms relative error, normalized with the mean value of all measured values of  $H_{rms}/H_{rms_0}$  shown in Fig. 5, is 0.06. These numbers confirm in a quantitative sense the high degree of realism possessed by the model for the prediction of the waveheight variation in areas of wave breaking. The good model performance is remarkable in view of the complexity of the physical processes involved, and the relatively simple concept on which the model is based.

The maximum set up also is well predicted (Fig. 2), but in areas of large set-up gradient the predicted rise is systematically too far seaward. This phenomenon has been noted previously by Battjes (1972) and by BJ. It suggests that the decrease in momentum flux lags behind the decrease in wave energy as measured through the variance of the surface elevation. A possible explanation for this phenomenon would be a relative surplus of kinetic energy in the area of intensive wave energy dissipation. This might consist partly of a surplus of kinetic wave energy (coherent with the surface elevation) and partly of turbulence energy. The latter possibility can be investigated by adding turbulent Reynolds stresses to the radiation stresses, e.g. on the basis of the model for turbulence in the surf zone presented by Battjes (1975). However this matter has not been pursued in the present study.

Fig. 2 Results for case 5 (laboratory); profiles of bottom elevation below MWL<sub>r</sub> ( $d$ ), mean water level above MWL<sub>r</sub> ( $\bar{\eta}$ ) and rms wave-height ( $H_{rms}$ ) vs. distance normal to shore ( $x$ ); data points: measured values with offshore reference value encircled; full curves: computed values of  $\bar{\eta}$  and  $H_{rms}$ , based on parameterization of  $\gamma$  given by eq. 7.

Fig. 5 Comparison of calculated and measured rms waveheights, normalized with the deep-water value. The calculated values are based on the parameterization given by eq. 7. The straight line is the least squares best-fit proportional relationship.

## 6. DISCUSSION

The model calibration described above is based on situations of one-dimensional wave propagation. However, the key element in the model is the estimate of the mean energy dissipation in random waves due to breaking, which is believed to apply equally well in cases of two-dimensional wave propagation.

In the situations used in the calibration described herein, there were no significant sources or sinks of energy between deep water and the surfzone. In these situations, a parameterization of the model coefficient(s) in terms of a characteristic deepwater wave steepness is meaningful, as in eq. 7. In applications, more complicated situations may arise, in which processes other than pure shoaling play a non-negligible role between deep water and the surfzone. Examples are

wave refraction, and energy dissipation in the near-bottom boundary layer. For such situations, we use the following procedure.

We distinguish areas of negligible breaking and areas of significant breaking. (In barred profiles, more than one area of significant breaking may occur). Somewhat arbitrarily, we define an area of significant breaking as the region of space (in the horizontal plane) where  $H_{rms}/h > 0.25$ . This corresponds roughly with  $H_{rms}/H_m > 0.35$ , approximately the limit above which the fraction of breaking waves is no longer negligible.

In a process of numerical integration along a wave ray in water of decreasing depth, in which refraction and various energy sources and sinks can be taken into account, the dissipation due to breaking is neglected as long as  $H_{rms} < 0.25 h$ . At the point where  $H_{rms} = 0.25 h$ , the local value of  $H_{rms}$  is converted to an equivalent deep-water value using linear shoaling only (i.e.  $H_{rms_o} = (c_g/c_{g_o})^2 H_{rms}$ ). This value is used to determine  $\hat{\gamma}$  according to eq. 7; the value of  $\hat{\gamma}$  so obtained is used in the integration of the energy balance (including the dissipation due to breaking according to eq. 4) across the area of non-negligible breaking downwave of the point of transition (i.e., as long as  $H_{rms}/h > 0.25$ ).

## 7. CONCLUSIONS

A calibration is performed of a theoretical model for the wave energy dissipation and resulting wave energy variation in random breaking waves. The theoretical model has effectively one adjustable parameter. Optimal values of this coefficient have been determined. These vary slightly in a physically realistic range with the incident wave steepness. A parameterization of this dependence is presented so that the model can be used for prediction. Using this parameterization, the overall performance of the model has been evaluated. The coefficient of correlation between predicted and observed  $H_{rms}$ -values is 0.98; the model bias is not significantly different from zero, and the rms relative error is 0.06. The maximum set-up of the mean water level also is well predicted.

## ACKNOWLEDGEMENT

The authors wish to express their gratitude to H. Derks, M.W. Dingemans and J. van Overeem, who supplied additional information on the measurement results obtained by them in their respective studies. Furthermore M.W. Dingemans is thanked for his support in developing the numerical model.

## CHAPTER FORTY FIVE

### WAVE GROUP ANATOMY OF OCEAN WAVE SPECTRA

Warren C. Thompson<sup>1</sup>, Arthur R. Nelson<sup>2</sup>, and Dean G. Sedivy<sup>3</sup>

#### ABSTRACT

This paper inquires into the questions of how wave groups are related to the wave spectrum, and how they differ in sea versus swell. Some results are presented in the form of a wave group model for sea spectra and for swell spectra. The models were developed from statistical analysis of a large number of wave records and apply to deep water only.

#### INTRODUCTION

A universal characteristic of sea (wind waves) and swell is the occurrence of sets of consecutive quasiperiodic larger waves called wave groups; these occur at intervals of approximately one to two minutes, vary in their energy and length, and are preceded and followed by generally nondescript low waves.

Wave groups have been recognized by coastal engineers in recent years as the cause of damage and destruction to vessels, offshore platforms, and shore structures due to high wave runs and to their periodicity. They constitute the principal components of the wave spectrum which the coastal engineer uses, yet information on their relationship to the spectrum has been quite incomplete. A further reason for interest in wave groups is their relationship to sea versus swell, or more specifically to initial wave steepness ( $H'_0/L_0$  in linear wave theory), particularly because the initial wave steepness controls many shallow-water wave variables, including breaker type, breaker height and depth, wave runup and overtopping, and beach profile response.

With these areas of practical concern in mind, we explore in this paper the following questions:

- (a) How are wave groups related to the wave spectrum?  
(Or, given a spectrum what can be said about the

characteristics of the wave groups occurring in the wave field?)

(b) How do wave groups differ in sea versus swell?

Some preliminary answers are given herein in the form of simple wave group models for sea and swell spectra. The models were constructed from statistical analyses of a large number of wave records for their wave group characteristics. The models apply to deep water only. Study of wave groups in shoal water is more complex due in part to differential shoaling of the various frequencies composing the spectrum and we have not probed this area in any depth. Such a study should logically follow and benefit from data developed for deep water.

In this paper a definition of wave group is given, wave group measures and associated wave record measures are specified, and some results from statistical analyses are presented leading to the models. The wave group definition was developed by Sedivy (1978), who also performed exploratory statistical analysis of wave records obtained from bottom pressure sensors in shallow water on the open California coast. Nelson (1980), applying this definition, probed wave group characteristics in deep water from a statistical analysis of records from a surface sensor on the California coast. It is Nelson's analyses that primarily provided the basis for constructing the deep water wave group models presented. The studies by Sedivy and Nelson were conducted at the Naval Postgraduate School in Monterey, California.

#### WAVE GROUP DEFINITION AND MEASURES

The analytical definition of the wave group presented by Sedivy (1978) is based on a comparison of the energy content in the group with that in the record, where energy is represented in terms of the statistical variance of the wave heights occurring in the group and in the record.

The procedure for identifying groups first involves computation of the variance of the whole record. The record, in digitized form, is then reanalyzed using a window of short duration over which a short-term variance is computed and plotted at the window midpoint. The window is moved along the wave record from beginning to end at one digital step at a time and produces a running short-term variance curve. The result of this procedure is illustrated in the upper diagram of Figure 1 for the record of mature swell shown. Those portions of the wave record where the running short-term variance values exceed the record variance indicate wave energy in excess of the record energy and identify possible wave groups.

Figure 1: WAVE RECORD (lower) AND VARIANCE ANALYSIS (upper)  
 (from Nelson, 1980)

In choosing a suitable window width  $W$  for computing the short-term variance, the finding by Thompson (1972) and by Smith (1974) that the average period of the waves in prominent wave groups approximates the spectral peak period  $T_R$  of the wave record indicates that  $W$  should be an integer multiple of  $T_R$ . Sedivy experimented with real and artificial wave records  $T_R$  and settled on  $W = 2T_R$  as optimum. Nelson (1980) conducted additional experiments by varying  $W$  over the range from  $1/2$  to 4 times  $T_R$ . He found that wave groups having high energy relative  $T_R$  to the record energy were identified by all window widths and that the window width seldom affected the number of waves in the group. In low energy groups, however, as  $W$  was increased from  $1/2 T_R$  to  $4 T_R$  the number of groups identified decreased by approximately 50% and the number of waves per group increased somewhat. Nelson concurred with the choice of  $W = 2 T_R$  and concluded that it gives a short-term variance curve that is relatively smooth yet is reasonably sensitive to lower energy groups.

In addition to the requirement that the short-term variance must exceed the record variance, Sedivy specified three limitations on the definition of a wave group. First, the group must be composed of whole waves as defined by successive upcrossings of the mean water level by the wave-form. Since the short-term variance curve does not ordinarily cross the record variance "line" at an upcrossing, this specification was satisfied by placing the wave group boundaries at the first zero upcrossing met in moving away from the center of the wave group in either direction. Second, a wave group must contain a minimum of two waves; this limitation requires a minimum of order to the wave heights against a random wave field, and also rules out many occurrences where the short-term variance curve only just manages to rise above the record variance for a brief interval of time. Third, adjacent wave groups must be separated from one another by at least one-half the window width, otherwise they are treated as a single group; this condition was specified in order to prevent the possibility of including a given wave in two separate wave groups.

Following identification of the wave group using these procedures, various wave group characteristics may then be measured. Those wave group variables (designated with subscript  $G$ ) that are dealt with in this paper, along with wave record measures (subscript  $R$ ) and group-to-record parameters, are as follows:

#### Wave group measures

$T_G$  Mean wave group period--average of the periods of the individual waves composing the group, computed from the group duration divided by the number of waves in the group; the waves composing a group tend to be periodic so that  $T_G$  approximates this periodicity.

- $V_G$  Mean wave group variance--computed by averaging the digital short-term variance values over the group duration.
- $N_G$  Number of waves per group--given by the number of intervals between upcrossings within the group.

Wave record measures

- $T_R$  Spectral peak period--reciprocal of the frequency of maximum energy density obtained from spectral analysis of the record (using the Fast Fourier Transform with four windows).
- $V_R$  Wave record variance--computed by digital time-series analysis (and checked by spectral analysis): the significant wave height  $H_R$  is related to the record variance by the relationship  $H_R = 4 \sqrt{V_R}$ .
- $G_R$  Significant wave steepness--defined and described below; used in this study to categorize wave records by wave type, e.g., sea, young swell, mature swell, and old swell.

Group-to-record parameters--In order to compare wave group measures among records having different peak periods and energy levels, the group period and group variance were normalized by referencing them to the corresponding record measures as follows:

- $T_G/T_R$  Relative group period.
- $V_G/V_R$  Relative group variance.

The significant wave steepness of the record  $G_R$  was used as a measure of the wave type (Thompson and Reynolds, 1976). It is defined by analogy with the steepness  $H/L$  of monochromatic waves in deep water as given by the linear wave theory, where the linear theory wave height  $H$  and period  $T$  are replaced by the significant height of the record  $H_R$  and spectral peak period  $T_R$ , as follows:

$$\frac{H}{L} = \frac{H}{\frac{g}{2\pi} T^2} \quad \equiv \quad \frac{H_R}{\frac{g}{2\pi} T_R^2} = G_R$$

The wave type is then defined in terms of the significant wave steepness according to the table below:

Wave type	$G_R$	Significant height reduction ( $H_D/H_F$ )	Swell decay distance (naut. mi.)
Sea	1/12-1/40	1.00	0
Young Swell	1/40-1/100	1.00-0.50	0-250
Mature Swell	1/100-1/250	0.50-0.25	250-1600
Old Swell	< 1/250	< 0.25	> 1600

$H_F$  = significant height in generating area  
 $H_D$  = significant height at decay distance

The range of wave steepness for sea given in the table was evaluated from the Sverdrup-Munk-Bretschneider (SMB) wave generation graph (Bretschneider, 1958). The wave steepness boundaries between the types of swell were determined by specifying swell height reductions of 0.50 and 0.25 relative to the significant height of the waves in the fetch (column 3), and assuming wave generation in extratropical storms of average size. These height reduction factors, when entered into the SMB swell decay curves, yield both the swell steepness boundaries (column 2) and the approximate swell decay distances from the generating area (column 4). Since swell steepness diminishes with increasing travel time as well as travel distance from the generating area, the significant steepness may be considered a measure of the relative age of the swell (column 1), and provides the basis for designating swell as young, mature, or old.

#### WAVE RECORDS ANALYZED AND SOME RESULTS

The wave group models presented herein were constructed from the results obtained from statistical analysis of a large sample of ocean wave records. The wave records were recorded at an open ocean station off the central California coast that is exposed to an array of wave dimensions typical of the major oceans, ranging from locally generated wind waves to swell that has decayed over thousands of travel miles. The wave data were recorded by a Datawell Waverider accelerometer-type buoy and were digitized on magnetic tape at a sampling interval of one second. Each record analyzed was of 1,024 seconds duration, or approximately 17 minutes.

The sea surface sensor was positioned in a water depth of approximately 30 fathoms (55 meters). At that depth the linear theory shoaling coefficient  $K_G$  for 18-second waves, the longest spectral peak period dealt with, is 0.91. This

value of the coefficient places the relative water depth  $d/L_0$  for waves of 18-second period toward the deep water boundary of the intermediate relative depth zone as conventionally defined. Accordingly, we consider the findings of this study to effectively apply to deep water for all wave periods dealt with.

A large number of wave records were screened from which 338 unimodal records were selected for analysis which met criteria requiring a single spectral peak and a relatively narrow bandwidth. These criteria were chosen to avoid complication in the selection of a short-term variance window used to identify wave groups and also to ensure as fully as possible that the waves in each record originated in a single generating area in order for the wave type to be determined.

The selected records are well distributed in their characteristics and cover spectral peak periods from 4 to 18 seconds, significant wave heights from 0.6 to 3.4 meters, and significant wave steepnesses from 1/15 (young sea) to 1/530 (very old swell). The 5,598 wave groups identified in these records were then statistically examined for their properties and relationships.

To convey an idea, in the limited space available, of the nature of the findings from these analyses, we now look at some of the results obtained by Nelson (1980). By way of example we will focus on the measure  $N_G$ , the number of waves composing a group, and examine its frequency of occurrence with respect to other factors as displayed in a series of graphs.

In Figure 2 the graph shows the cumulative frequency of occurrence, in percent, of  $N_G$  in different parts of the wave spectrum. The position of a wave group in the spectrum is determined by its relative group period  $T_G/T_R$ ; values of the ratio near unity place the group close to the spectrum peak whereas groups having ratios  $\ll 1$  and  $\gg 1$  lie, respectively, well into the high frequency tail and the low frequency tail. The six curves in the figure are seen to form a tight-bundle, and we draw the conclusion from this and other data that the percentage distribution of  $N_G$  is fundamentally the same in the tails of the spectrum as at the peak, i.e., the spectrum can be sliced at any wave frequency and the percentage distribution of  $N_G$  among the wave groups occurring there can be expected, for a large group population, to be the same. The histograms for these six sets of data (not shown) are Rayleigh-like in form.

The distribution of  $N_G$  with respect to the relative energy content of wave groups  $V_G/V_R$  is shown in the cumulative distribution graph in Figure 3. As may be expected from the wave group definition, groups with the lowest energy content have an average group variance approximately equal to the record variance ( $V_G \doteq V_R$ ). It is evident from this

Figure 2: CUMULATIVE DISTRIBUTION OF  $N_G$  FOR  $T_G/T_R$  BANDS  
 (from Nelson, 1980)

Figure 3: CUMULATIVE DISTRIBUTION OF  $N_G$  FOR  $V_G/V_R$  BANDS  
 (from Nelson, 1980)

figure that  $N_G$  is sensitive to the relative energy content of wave groups. The lowest energy groups most frequently contain 2 waves, the minimum taken to constitute a group, and seldom contain more than 4 waves. The highest energy groups, on the other hand, rarely contain 2 waves, most frequently have 6 waves, and exceed 10 waves in 10% of occurrences. Histograms for the six energy levels (not shown) appear as nested curves having a Rayleigh-like form in which the distribution becomes less peaked and extend over a wider range of  $N_G$  as the group energy level increases.

The frequency of occurrence of  $N_G$  with respect to wave type, represented by wave steepness intervals, is illustrated in the cumulative distributions shown in Figure 4. It may be concluded that the older the swell the larger tends to be the number of waves in a group at any given probability level. The associated histograms (not shown) also have a Rayleigh-like form.

#### WAVE GROUP MODELS

##### Sea Model

Figure 5 presents a model of the relationship between wave groups and the energy density spectrum for the case of waves under generation by the wind in deep water.

The reader's attention is directed to the table in the lower part of the figure which describes the three areas of the spectrum. The table indicates that most wave groups in a large population are concentrated about the frequency of maximum energy density of the spectrum, i.e., their relative group periods  $T_G/T_R$  lie at or close to 1.0. In moving away from the peak and toward the tails of the spectrum, group periods deviate increasingly from the spectral peak period and the number of groups falls rapidly. Groups are rare at values of  $T_G/T_R < 0.7$  and  $> 2.0$  (Figure 6).

Wave groups falling in the tails of the spectrum not only occur infrequently but they also have a low relative energy level in which the average group variance is close to the variance of the record. As the spectral peak is approached, low energy groups increase in occurrence and are joined by groups containing increasing amounts of energy. At and very close to the peak of the spectrum are found those groups with the highest energy levels but also the greatest occurrence of groups at all energy levels.

With regard to the number of waves per group, the percentage distribution of  $N_G$  is the same in all parts of the spectrum (noted in Figure 2). Thus, the percentage frequency of occurrence of groups having, for example, ten or more waves is the same in the spectrum tails as at the peak, but groups actually occur much less frequently in the tails.

Figure 6: CUMULATIVE DISTRIBUTION OF  $T_G/T_R$  FOR  $G_R$  BANDS  
(from Nelson, 1980)

Directing attention to the statement to the left of the diagram in Figure 5, it may be noted further that in wave groups containing increasing amounts of energy relative to the wave record, the group period tends to approach the spectral peak period and the number of waves in the group tends to increase.

#### Swell Model

A general wave group model for swell in deep water is also presented in Figure 5. Swell is similar to sea in that the highest energy groups are most closely concentrated about the spectral peak and, indeed, control the position of the peak. However, swell contains many lower energy groups that differentially trail well into the high frequency tail of the spectrum. As a result, the most frequently occurring group period in a large population shifts away from the spectral peak toward shorter periods increasingly with increasing swell age.

The latter situation is illustrated in the cumulative distributions in Figure 6. The three swell curves represent normal distributions with similar standard deviations, but are displaced successively toward lower values of  $T_G/T_R$  with increasing swell age. For old swell, the median of the distribution is located at  $T_G/T_R \doteq 0.7$ . This means that in old swell having a spectral peak period of 14 seconds the most frequently expected group period should be about 10 seconds, although these are not the groups having the highest energy.

Swell groups are commonly observed to contain short waves due to apparent phase changes and other effects, and these bias the group period. Accordingly, when wave groups are filtered to remove anomalously short waves, most group periods increase substantially with the result that the median  $T_G/T_R$  value in any large population is shifted back toward unity for all swell types. A similar effect can be achieved by raising the record variance level that the running short-term variance must exceed in the definition of the wave group. This redefinition would have the additional effect of reducing the number of groups occurring in a given recording period and the number of waves per group.

Referring once again to Figure 5, the frequency of occurrence of the number of waves per group in swell is similar to that in sea in that the percentage distribution of  $N_G$  appears to be the same in all parts of the spectrum, and also in that  $N_G$  tends to increase as relative energy in groups increases. However, as the swell age increases the number of waves per group increases for any given percentage frequency of occurrence.

Further illustration, from a different perspective, of the relationship of swell groups to the wave spectrum is

given in Figure 7 for a mature swell record. For each wave in the record the square of the height is plotted against the reciprocal of its wave period. Since wave energy is proportional to  $H^2$ , the graph is effectively a plot of energy versus frequency for every wave. Waves belonging to wave groups are coded according to the relative energy of the group; all waves occurring in the intervals between wave groups are designated "interval" waves and are separately identified. The curve shown in the figure is the wave spectrum (the energy scales of the  $H^2$  values and the spectrum differ).

The manner in which the individual waves contribute to the wave spectrum is readily apparent in the figure. All waves having high and moderate energy lie close about the spectral peak frequency, and all are members of wave groups. There is also a number of low energy wave group members and these are clustered in the frequencies of highest energy density, although a few lie well into the high frequency tail. The interval waves, all of low energy, are most densely concentrated in frequencies above the spectral peak frequency, but extend well out along the high frequency tail in decreasing number and with diminishing range of energy. The occurrence of individual waves on the low frequency end is cut off sharply in this record.

The close association of individual waves with the wave spectrum shown can also be readily demonstrated by cumulating the  $H^2$  values with frequency and constructing a histogram from this cumulative distribution having the same frequency interval as the wave spectrum. This  $H^2$  histogram, if plotted in Figure 7, would resemble the wave spectrum closely (not shown due to clutter).

#### CONCLUSION

We hope that the wave group models for sea and swell presented herein will give practicing coastal engineers a better feel for wave spectra and the nature of the waves composing them, and that these models might also bring to the attention of theoreticians some areas that can benefit from application of their talents.

We recognize that the models are preliminary and believe that a great deal more is yet to be learned about wave groups from purely statistical analysis. Further work that profitably can be pursued includes: (1) Additional investigation of the relationships between swell groups and the wave spectrum in deep water, (2) examination of group-to-group relationships in deep water and how they are related to sea and swell, and (3) inquiry into all of the above relationships in shallow water.

## CHAPTER FORTY SIX

### SWASH ON A NATURAL BEACH

Masaru Mizuguchi \*

#### Abstract

A field measurement was conducted in order to clarify the swash motion on a natural beach. It is found on this particular beach, which had a rather steep foreshore slope, that cross spectra calculated between the surface elevations, onshore velocities and the swash agree very well with those given by linear long two-dimensional standing wave theory in the lower frequency region than a certain value. This finding together with the observed  $f^{-4}$  ( $f$ ; frequency) high frequency saturation in swash spectra encourages a partial reflection model to describe the fluid motion in the inner surf zone, including the swash. The model developed shows a good agreement with the observed results, in which being employed an analogy to regular waves for the criticality of wave reflection. This model makes it possible to predict the swash spectrum for a given incident wave spectra and a given beach profile, as far as wave breaking takes place on a foreshore slope.

#### 1 INTRODUCTION

The boundary zone between the land and the sea provides interesting wave phenomena known as wave run-up. It is this zone where the incident waves show the swash motion which includes both the up-rush and the down-rush. Wave set-up due to wave breaking outside the swash zone contributes only to the mean water level change and the position of the mean swash motion, namely the shoreline.

The understanding of the wave dynamics in the swash zone on a natural beach is important in order to give a reasonable boundary condition at the shoreline when one tries to simulate the two- or three-dimensional beach transformation due to waves. Conventional assumption that the wave height is linearly proportional to the water depth gives zero wave height at the shoreline, resulting neither wave motion nor sand movement. This is clearly not what we observe in the field or in the laboratory, although one can imagine an extreme case where the wave energy would be completely dissipated before it arrives the swash zone on a very gentle beach.

On the other hand recent field observations reveal that the long period fluctuation may prevail among the fluid motion in the surf zone, especially near the shoreline (Guza & Thornton, 1982; Mizuguchi, 1982b). The long period motion is supposed to be a standing wave in the on-offshore direction, no matter if it is a two-dimensional one or a three-dimensional one like an edge wave. The long period standing wave form an antinode at the shoreline, exhibiting swash oscillations. There has been some discussions whether the observed long period fluctuations are

---

\* Associate Professor, Dept. of Civil Eng., Chuo Univ., Bunkyo-ku, Tokyo JAPAN 112

two- or three-dimensional. It is critically higher mode or cut-off mode edge waves that were employed to fit the data by Huntley (1976) and Sasaki & Horikawa (1978). It is shown, e.g. by Hotta et al. (1980), that the higher mode edge waves do not quantitatively differ from the two-dimensional standing waves as far as the fluid motion in the near-shore zone is dealt with. Therefore in this paper only two-dimensional motion is assumed as is done by Suhayda (1974).

This study comes from the first motivation mixed with the second findings. That is to test a hypothesis based on the linear long standing wave theory against a field experiment.

## 2. SWASH OF REGULAR WAVES

The wave run-up on a somewhat artificial beach has been studied for a long time and of their main concern has been the highest point of the up-rush. For example see Hunt (1959). The long history of the studies on its dynamics can be looked at from the following two viewpoints. There are a group of papers in which they looked at the swash motion as the highly nonlinear process and treated it as a bore on a dry bed. For example Shen & Meyer (1963). This approach indicates that the wave front shows a parabolic motion on a frictionless plane beach and that the total excursion width  $Y$  is given by the following relation for regular waves (Van Dorn, 1976).

$$Y = 1/18gT^2 \tan^2 \beta \quad (1)$$

where  $g$  is the gravitational acceleration,  $T$  is the wave period and  $\tan \beta$  is the bottom slope.

Another long history can be traced back to Lamb (1932). The swash motion is considered to be a standing wave on a sloping beach. The linear long wave theory gives the following well-known results for the water surface elevation  $\eta$  and the offshoreward velocity  $u$  for the perfectly reflected waves on a plane beach.

$$\eta = 2a_r J_0(z) \cos \sigma t \quad (2)$$

$$u = 2a_r \sqrt{a/h} J_1(z) \sin \sigma t \quad (3)$$

where  $z = \sqrt{\alpha x}$ ,  $\alpha = 4\sigma^2/g \tan \beta$  and  $2a_r$  is the amplitude of a standing wave at the shoreline. The  $x$  axis is taken offshoreward along the still water surface from the shoreline. The finite amplitude theory by Carrier & Greenspan (1956) shows that the amplitude of the swash motion does not differ from that given by the linear theory Eq.(2).

The standing wave solution, however, is no longer valid when the so-called swash parameter  $\epsilon_r$  which is defined as

$$\epsilon_r = 2a_r \sigma^2 / g \tan^2 \beta \quad (4)$$

exceeds a certain critical value  $\epsilon_{rc}$ . Miche (1951) argued that the surface slope at the shoreline should not be smaller than the beach slope and gave  $\epsilon_{rc} = 2$ . The finite amplitude wave theory gives  $\epsilon_{rc} = 1$  as

a necessary condition for the theory to yield a solution (Meyer & Taylor, 1972). The critical value  $r_c=1$  also corresponds to a condition that maximum downward acceleration of the swash is equal to the gravitational acceleration along the beach slope. Miche also proposed a hypothesis that the reflection coefficient for the incident waves on a plane beach may be given as follows.

$$r_0 = 2 / \epsilon_0 \quad \text{Eq. 11 of Guza} \quad (5)$$

$$\text{where } \epsilon_0 = \sqrt{2\pi} a_0 \sigma^2 / (g \tan^5 / 2 \beta) \quad \text{Guza Eq. of 1977} \quad (6)$$

and  $r_0$  is the reflection coefficient in deep water. The parameter  $\epsilon_0$  is equivalent to the swash parameter  $\epsilon_s$  and is calculated under the condition of perfect reflection, using the relation,

$$a_r = a_0 \sqrt{\pi / 2 \tan \beta} \quad \text{from setting } \epsilon_r = \epsilon_0 \quad (7)$$

Equation (5) simply states that the possible swash oscillation is always limited by his critical condition.

Guza & Bowen (1976) carried out detailed laboratory experiments in order to investigate the behaviour of the standing waves. They found (1) that the incident waves are perfectly reflected and the observed spatial distribution of the wave height agrees well with Eq.(3) when  $\epsilon_0 < 1$ , and (2) that Miche's hypothesis on the reflection coefficient given by Eq.(5) shows a reasonably good agreement with their experimental results when  $\epsilon_0 > 1.6$ , being taken into account the effect of bottom roughness. Their study confirmed that the swash oscillation can be considered at least on a rather steep beach as the antinode motion of two-dimensional standing waves, which survived wave breaking.

Comparing these two different approach to the regular wave swash, one may notice that Eq.(1) is quantitatively almost identical to Eq.(5). Substituting  $Y=2a_r$  into Eq.(1) gives  $\epsilon_r=2.5$ . Figure 1 compares the experimental data<sub>r</sub> by VanDorn (1976) with those two semi-theoretical results. It is clearly seen that the data agrees with Eq.(5) when the parameter  $L_0 \tan^2 \beta$  is large, in other words, high reflection coefficient.

Fig. 1 Total excursion of swash (VanDorn, 1976).

Handwritten notes on the left side of the page:

- $2a_r = 2 \cdot 60 = 120$
- $2a_r = 200 \cdot 2 = 400$
- $\epsilon_0 = 2.26 \cdot 10^6 \cdot 10^6 \cdot 10^6 / (9.8 \cdot 10^6 \cdot 10^6 \cdot 10^6) = 2.26$
- $\epsilon_r = 2.5$
- $L_0 \tan^2 \beta = 200$
- $L_0 \tan^2 \beta = 200$

icients can be expected. As the parameter decreases, Eq.(1) tends to show a better agreement, although the difference between the two lines is small as already pointed out. However it should be noted that, in a strict sense, the wave amplitude should affect the transition.

It is tempting from the above discussion to make a statement that the swash oscillation is, in any case, the antinodal motion at the shoreline of a standing wave, which survives its breaking on the slope. Practically, as pointed by Guza & Bowen (1976), Miche's criterion Eq.(5) provides the "surviving" ratio, as far as wave breaking occurs only on the foreshore slope. The following viewpoint can be added to support this tempting conclusion. It is not an unreasonable conjecture that the swash oscillation, which might be given through a complicated non-linear process on a gently sloping beach, plays a role to generate an outgoing wave by its periodic or unsteady forcing. The outgoing wave forms a standing wave, coupling with the incident wave. Hence the swash motion may well be treated as that of a standing wave at least as a first approximation. Therefore the following expression would be applicable to describe the wave motion near the shoreline not only for a steep (reflective) beach as confirmed by Guza & Bowen (1976) but also for a gentle (dissipative) beach, again as a first approximation.

$$\eta = a_i \{J_0(z) \cos \sigma t - Y_0(z) \sin \sigma t\} + 2a_r J_0(z) \cos \sigma t \quad (8)$$

$$u = \sqrt{a/h} [a_i \{J_1(z) \cos \sigma t + Y_1(z) \sin \sigma t\} + 2a_r J_1(z) \sin \sigma t] \quad (9)$$

where  $a_i$  is the amplitude of the progressive wave, which should change to be zero at the shoreline. The local reflection coefficient  $r = a_r / (a_i + a_r)$  varies with the on-offshore location as  $a_i$  does. The bottom profile in the field scarcely shows a plane beach. Then Eqs.(8) and (9) can be easily extended to the case of a complex beach profile by applying a multi-linear profile approximation.

### 3. A MODEL FOR IRREGULAR WAVE SWASH

For irregular waves, one, who put the stress on the high non-linearity of the process, may introduce a model based on the joint probability distribution of the wave heights and periods. For examples Battjes (1971) and Sawaragi & Iwata (1984). It is generally accepted that the swash motion on a gently sloping beach is described in such a model. However the long period fluctuation in the swash is significant as reported in many field experiments. The individual wave analysis clearly fails to be meaningful when the long period fluctuation exists, unless it is removed before the analysis is applied (Mizuguchi, 1982a).

Here a tentative model is proposed based on the previous discussion and illustrated schematically in Fig. 2. The model implies that the Fourier component of the irregular wave behaves independently even through the very nonlinear process like wave breaking, as far as the long period motion is concerned. It is trivial that this model has the shortcomings, as not only the real swash motion but also the waves near the shoreline show some nonlinearity. However it is worth trying to see how well the simple model based on a linear theory can describe a result obtained in a field experiment.

Fig. 2 A model for irregular wave swash

In relation to the critical condition for irregular wave reflection, there have been some field observations on the high frequency saturation of the swash spectra. Huntley et al. (1977) reported the form  $f^{-4}$  for the saturated high frequency range. Guza & Thornton (1982) found  $f^{-3}$  instead. When the concept of the critical condition could be applied for different frequency component independently, one can expect a kind of universal form for the saturated region, although it is not theoretically clear how the result for monochromatic waves is related to that on the irregular waves. The spectral shape of the high frequency region is also considerably affected by the profile of the main (peak frequency) component. The smoother the profile is, the smaller the power leaking to the high frequency region is. In addition, different techniques employed to measure the swash may produce different results (Guza & Thornton, 1984). Here we will not go further into this discussion.

#### 4. FIELD OBSERVATION

A field observation was carried out around noon on 9th Jan. 1982 at Yonezu-hama beach in Shizuoka Prefecture, Japan. The beach faces to the Pacific Ocean in south and has a straight extension of about 20 km. The beach cusp formation was observed on the previous day. However there remained only their ruins around the high water level on that day. The observation site was almost at the middle of the beach extension and the measuring section chosen on the line of the apex of a beach cusp ruin, so that the node of the edge waves had been expected if it had existed.

In Fig. 3 was shown the experimental setup with the bottom topography along the measuring section. Two artificial channels were placed, being extended into the water only to the position of the lowest run-down point, just covering the swash zone. The natural swash motion was measured between the two channels, by using the photographic technique. Small poles were placed standing on a line, every 50 cm, to give a scale. Several poles and two EMCM (Electro-Magnetic Current Meter) were also installed on the measuring section. The poles were photographed with 16mm camera, to obtain surface elevation records. Horizontal

Fig.3 Beach profile and experimental setup. The poles with a number in brackets denote those analyzed. The approximated profile to be used for the later analysis is so close to the measured one that one cannot see the difference.

velocities were measured with EMCM. The EMCM(on) was situated just on the step. The bottom profile was a typical bar-trough one with a step at the foot of the swash zone. The slope of the swash zone was  $1/9$ . The beach material of that zone was well-sorted sand with  $\sqrt{d_{75}/d_{25}}=1.7$  and  $d_{50}=0.4$  mm. Visual observation showed (1) that the incident waves were long-crested swells with some white caps due to the strong westerly wind, (2) that the average breaking point was on the offshoreward slope of the bar between the poles (25) and (26), and (3) that the broken wave reformed almost completely in the trough region and made surging type breaker on the foreshore slope. The measurement was done for the duration of 10min 22s with the sampling interval of 0.2s, yielding 3110 total data points.

Examples of the obtained raw data are shown in Fig. 4. This figure shows the following features; (1) Short period waves disappear almost suddenly in the swash record, although they are still seen in the surface elevation at the pole (10), which was in the swash zone. (2) Both at the two locations where the horizontal velocity was measured as well as the surface fluctuation, they are not correlated, in contrast to the in-phase relation for the progressive wave theory. (3) The downward motion of the swash, for instance that of about 60s from the beginning of the data, shows a very good correlation with the strong offshoreward velocity, and the upward motion does with onshore one. The latter two features indicate a fact that the long period fluctuations were significant, forming the swash oscillations as the antinode of standing waves.

Fig. 4 Examples of raw data obtained. The dotted line on the top denotes the swash on a artificial channel. The broken lines denote onshore velocity.

## 5. ANALYSIS OF THE DATA

First, the individual wave analysis was applied to the surface elevation data, partly for the purpose to show how inappropriate to apply the method automatically. The results obtained in Table 1 show peculiar behaviors of the wave transformation in the surf zone. As reported by Mizuguchi (1982a) the individual waves propagate independently in its literal sense in a normal circumstance, showing almost no change of the wave period distribution. However this results shows a considerable change of the wave period in the surf zone, being affected by the standing waves of significant magnitude. The standing waves have a node and antinode structure, which results in the dominance of shorter period waves at the node and longer period waves at the antinode. Table 1 shows that the significant node lay at the pole (16) where minima of both wave period and height were observed. Figure 4 also shows only

short period fluctuation at this position. This result shows that it is essential to separate the long period fluctuations which are of standing waves, in order to discuss the transformation of the progressive waves in the surf zone. Table 1 also shows that the significant breaking wave height and period were about 60cm and 7s respectively.

Secondly the obtained surface elevations were studied in the frequency domains. Figure 5 shows the two-sided power spectra of  $S(f)$  at the representative locations as well as that of the swash on the natural beach. There are following two points to be noted.

1) There are seen three distinct regions of the high frequency saturation. One is the  $f^{-3}$  law for the high frequency region of the incident wave spectra around the breaker line. This is consistent with the result reported by Thornton (1977), however the physical argument is, Second and third ones, which are more interesting here, are the  $f^{-1}$  observed in the intermediate frequency range from 0.2Hz to 0.5Hz in the surf zone, and the  $f^{-4}$  for the entire high frequency region of the swash. The simplest argument to give the  $f^{-1}$  law is to assume that the power spectra is determined by the depth-controlled wave breaking where the wave height is almost proportional to the water depth  $d$  as done by Sawaragi & Iwata (1980). This assumption yields the relation  $S_{\eta}(f) \approx d^2 f^{-1}$ , based on a dimensional analysis. This relation may hold only for the lower frequency than the limit of the long wave assumption. However in this observation the  $f^{-1}$  law is seen to the higher frequency range than this limit. Third one, high frequency saturation of the swash, has been recently investigated as already mentioned. It is useless to repeat the argument, unless one can add the more convincing model to describe the swash motion on a natural beach. Here it is taken for granted that there is a saturation for the swash spectra and the form obeys the  $f^{-4}$  law as obtained.

Fig. 5 Two-sided spectra of surface elevations at various points as well as of swash on natural beach.

2) The peak frequency of the swash is 0.1Hz as shown by the arrow. However the power corresponding to the peak almost disappears making a deep trough for the spectrum measured at the pole (13), which is just off the step at the foot of the swash zone. This fact suggests that the powers around the peak frequency are of standing waves.

Now it will be shown how well the linear long standing wave theory can describe the observed fluid motion including the swash. In the following three figures the results denoted by the solid lines for the perfect reflection model were calculated by using Eqs.(1) and (2) for the approximated multi-linear profile shown in Fig. 3. The dotted lines are those obtained by a partial reflection model which will be explained in the next section. Figure 6 shows the cross spectra between the surface elevations at the two different locations, (13) and (16), both of which were in the wave reforming zone. The agreement between

Fig. 6 Cross spectra between surface elevations at poles (13) and (16). The solid line denotes results for perfect reflection and the dotted lines those for a partial reflection model. Coherence is given by the ratio of transfer function to the root of power ratio.

Fig. 7 Cross spectra between surface elevation and onshore velocity at pole (21).

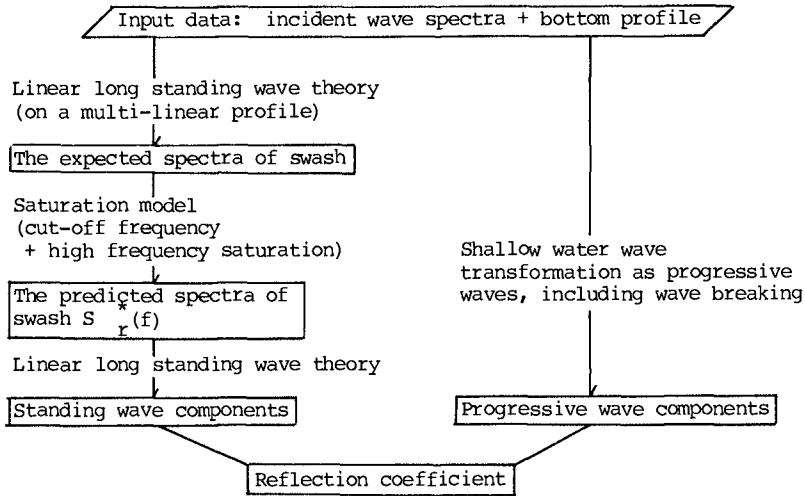

Fig. 8 Cross spectra between swash and surface elevation at pole (21).

the theory and the measurement is remarkably good for the lower frequency region than 0.1Hz, except very near the zero frequency. Figure 7 shows the cross spectra between the surface elevation and the onshore velocity at the point (21). In this figure one can obtain the same conclusion as in Fig. 6. The third figure, Fig. 8 shows the cross spectra between the swash and the surface elevation at the pole (21). The good agreement between the experiment and the perfect reflection model is only found around the peak frequency 0.1Hz, where the significant power of the spectra was observed. The following conclusions can be drawn from these three figures. (1) The long period fluid motion inside the surf zone is well described by the linear long standing wave theory. (2) The measured data in all of the figures shows large deviation from the theory in the higher frequency range beyond 0.1Hz. This corresponds to the inception of wave breaking. (3) In the low frequency range in Fig. 8, the swash motion tends to be about twice larger than that predicted by the theory, although the agreements are reasonably good in other two Figs. 6 and 7. This indicates that there might be taking place some nonlinear processes which work only in the swash zone to produce the longer period motion, transferring the energy from the shorter period one to the longer period one.

In concluding this section, it should be noted the magnitude of the power spectra of the alongshore velocity component was one-twentieth or less than that of the onshore component and can be maintained that there existed no significant edge waves.

Table 2 A model to predict the swash spectra as well as the reflection coefficient

6. PARTIAL REFLECTION MODEL AND THE SWASH SPECTRA

The observed swash motion as well as the fluid motion in the surf zone encourage the model discussed in the section 3. Table 2 illustrates the partial reflection model in terms of the flow of computation. The expected spectrum is defined as that which would be realized if all the incident wave powers were perfectly reflected. The concept of the saturation is introduced to calculate the predicted swash spectrum from the expected one. The assumption that the swash oscillations consist only of standing waves makes them equivalent evaluating the reflection coefficient at the specified location and determining the swash motion at the shoreline.

In order to obtain the predicted spectra, we exploit the following two results. First one is that there is a high frequency saturation. The  $f^{-4}$  law is employed here simply as it is the case observed. Second one is that the irregular wave trains may show a similar behavior as that of monochromatic waves in terms of the "surviving" process through the run-up. The method is not yet well established to relate properties of the irregular wave trains with those of the monochromatic waves. Here rms swash amplitude  $2a_r^*$  and mean frequency  $f^*$  are defined by the following relations after Longuet-Higgins (1969).

$$2a_r^* = \sqrt{2 \eta_r^2} = \int_0^\infty S_{\eta_r^*}(f) df \tag{10}$$

$$f^* = \left[ \int_0^\infty f^2 S_{\eta_r^*}(f) df / \int_0^\infty S_{\eta_r^*}(f) df \right]^{1/2} \tag{11}$$

These relations were applied to the measured swash spectra both on the natural beach and on the artificial channel. The representative swash parameter obtained by using these  $2a_T$  and  $f^*$  are respectively 1.18 and 1.50. These values are reasonably similar to those for the monochromatic waves so that the analogy between irregular waves and regular waves can be considered to work, as far as this experiment is concerned. However it could be wrong to take the zero frequency as the lower limit of the integral in Eqs.(10) and (11). The lower limit should be chosen such that the integral contains only the power of the spectral components affecting the phenomena considered. In this experiment the low frequency energy shown in Fig. 5 is not large and do not contribute to the integral. It is also true that the fact that the run duration of the experiment is the order of ten minutes automatically excludes the lower frequency energy contribution. The difference between the values on the natural beach and on the artificial channel is mainly due to the last moment up-rush which was only observed on the artificial channels as shown in Fig. 4. The reason should be attributed to the energy loss for the sand movement as well as peccolation on a natural beach.

Fig. 9 Representative swash parameters versus critical frequencies

Fig. 10 Comparison of predicted swash spectra with observed one

Then the critical frequency  $f_c$  for the predicted spectra which is defined as the highest frequency for perfect reflection or as the lowest frequency of the saturation range is calculated so that the representative swash parameter is equal to the observed value 1.18. Figure 9 shows the changes of estimated swash parameters  $\epsilon_{ri}$  versus different critical frequencies. Here four pairs of the data were used. It is necessary to use a pair of data to estimate the expected swash spectrum, as standing waves give nodes for particular combinations of a offshore location and a frequency. A practical method to have an average of the two quantities is needed, in order to avoid infinite transfer function that the nodes give. In Fig. 9 it is seen that the two results calculated by the pairs of the data in the trough region are almost identical, showing that there is no significant wave transformation in that zone. The critical frequency  $f_c$  for these data is determined 0.095Hz. The result based on the data at the pole (12) show smaller values and do not reach the measured swash parameter, indicating that the pole was actually located within the swash zone and some part of the energy was already dissipated before reaching the pole (12). The results from the offshoreward data, on the contrary, show larger value for the given critical frequency compared with the other results. The application of this model yields that the critical frequency  $f_c$  should be 0.075Hz.

Figure 10 shows the comparison of the three predicted swash spectra thus-obtained with the observed swash spectrum. The predicted results (denoted by the dotted line or the broken line) based on the data obtained in the trough zone agrees very well with the observed one, except in the frequency domain lower than 0.05Hz. The reason of this difference is already mentioned in the discussion for Fig. 8. The poorer agreement of the chain line may mean that the model shown in Table 2 should be applied only for the data obtained in the location between which and the shoreline there is no wave breaking except that on the foreshore slope.

As shown in Table 2, reflection coefficient at any location can be estimated either if the transformation of progressive wave components could be estimated or when wave spectrum is measured. In Fig. 11 are shown the reflection coefficients calculated by using the observed swash spectra together with the observed local spectra. The results based on the data in the trough region (denoted by open circles or open triangles) are supposed to show the reflection coefficients at the slope of swash zone. The higher reflection coefficients than unity in the low frequency region again correspond to the larger swash oscillation compared with the theory as shown in Fig. 8. The most reliable frequency region around 0.1Hz shows perfect reflection for the lower frequency than the critical frequency 0.095Hz and the decrease of the reflection coefficient following  $f^{-2}$  law in the higher frequency region. The  $f^{-2}$  law can be understood as follows. As discussed in the previous section the high frequency saturation due to the depth-controlled wave breaking results in the  $f^{-1}$  law. Then the expected swash spectra would be constant in that frequency region, as the linear long standing waves show the following behavior as  $\alpha x$  is large,

$$\eta = 2a_r J_0(\sqrt{\alpha x}) \sim f^{-1/2} \quad (12)$$

Taking this into consideration, the  $f^{-4}$  saturation law of the swash

Fig.11 Reflection coefficients observed

spectra simply indicate the  $f^{-2}$  dependence of the reflection coefficient at the slope. The reflection coefficients for the combination of the poles (25) and (26) cannot be free from the effect of wave breaking on the shoreward slope of the bar and are considerably smaller than those for the swash slope only. In Fig. 11 is also plotted the reflection coefficient calculated from the phase lag between the water surface elevation and the onshore velocity at the pole (21). The result shows a quantitative agreement with others. The surveying of the position of EMC was not so accurate that one should expect some errors for the reflection coefficients especially for high frequency region.

Returning back to Figs. 6-8, one can see the agreement improved between the results of this partial reflection model and the observed results. Especially in Fig. 7, where it is assumed that the progressive components of the incident wave do not change during the travel over the distance, the agreement is excellent. The partial reflection model gives slightly higher values than the observed ones in the high frequency region in Fig. 9. This is not significant and not worth of further consideration at present. However in Fig. 8 the observed velocity is considerably smaller in the higher frequency region than that calculated by the linear long wave theory. This corresponds to the fact reported by Guza & Thornton (1980) and Mizuguchi et al. (1980), that the linear (long) wave theory gives larger values of transfer function for the progressive waves from the water surface elevation to the onshore velocity in the nearshore zone. Nonlinearity can partly explain the difference, as the air entrained may account for the rest.

Finally Fig. 12 shows the result of the comparison of the proposed model to the data around the breaker line. The agreement is still good particularly around the peak frequency region. In this sense, it should be pointed out that the measured swash oscillation makes it possible to rather easily evaluate the standing wave components by applying the two-

Fig. 12 Cross spectra between surface elevations around breaker line.

dimensional liner long standing wave theory for the multi-linearly approximated bottom topography.

## 7 CONCLUSION

A model to describe the swash motion on a natural beach is developed based on three hypotheses. First one is that the swash oscillations are considered to be antinode motion of the linear long standing waves. Second one is that the swash spectra exhibit the high frequency saturation for which the observed  $f^{-4}$  law is assumed. Third one is that a concept of the saturation developed for the regular waves swash is also applicable to the irregular wave trains, as an appropriate method to make them related being employed. A field observation was conducted on a natural beach with a rather steep foreshore slope. The results, in a general sense, confirm the applicability of the model. With regard to the three hypotheses, first one is strongly supported by the observation. The validity of the concept of the saturation for the irregular waves is not so clear and needs further study, although the model works very well for this experiment. The minor discrepancy found in the very low frequency region suggests that there might be the cases where one should take into account nonlinearity to achieve a better agreements. It is plausible that the gentle slope of the swash zone provides such cases. Another limitation of this model is that the effect of wave breaking can not be included, which takes place in other area than the swash zone.

## CHAPTER FORTY SEVEN

### WAVE GROUPS IN THE FREQUENCY AND TIME DOMAINS

Rodney J. Sobey<sup>1</sup>, M.ASCE and W. Wayne Read<sup>2</sup>

**ABSTRACT.** The identification of wave groups in wave records is sought in terms of the classical linear analysis techniques in the frequency and time domains. Unwrapping and detrending of the phase spectrum identifies apparent order where none is assumed in the Gaussian random wave model. Similarly unexpected order is observed in the tail of the correlogram of both the wave record and the Rice envelope function. These aspects are strongly suggestive of wave grouping.

#### INTRODUCTION

Sophisticated design and analysis in coastal and ocean engineering requires a detailed description of incident sea conditions. Wave groups, a finite run of higher than normal waves, are frequently observed at sea and in wave records. They have an important impact on a wide range of coastal and offshore activities and some measure of wave groupiness needs to be included among the standard analysis and synthesis techniques routinely adopted by data collection authorities and coastal and ocean design groups. Despite the growing literature, the true nature and extent of wave grouping remains unresolved. There is sufficient evidence that wave grouping exists but insufficient evidence to confirm the nature and extent of these groups. Neither theoretical investigations nor numerical simulations can resolve these issues. The information must be sought initially from field data. Considerable recent research effort has focussed on the development of new analysis techniques to accommodate wave grouping. In contrast, the present paper will concentrate on linear wave theory and classical time series analysis techniques in the frequency and time domains. There is evidence to suggest that wave grouping is reasonably well described by these classical linear techniques.

### DATA SERIES FOR ANALYSIS

The basis of the present research is an extensive data base of deep water wave records assembled from sites off the eastern, western and southern coastlines of Australia. These are good quality records in computer compatible form. Data set A, obtained from the Maritime Services Board of New South Wales, comprises about fourteen hundred twenty-minute records off Newcastle and Botany Bay under generally winter storm conditions in the Tasman Sea. Data set B, obtained from Woodside Offshore Petroleum, comprises about three hundred twenty-minute records during six separate hurricanes on the North West Shelf. Data set C was obtained through Esso Australia for a site on the continental shelf of the Great Australian Bight. This region is exposed to Southern Ocean swell, recognized (Chelton, et al., 1981) as the most extreme wave climate in any of the world's oceans and the data set is an almost continuous record for several days of big, long-period swell. Together, these three data sets provide excellent samples of the common wave climate extremes.

Although the typical 20-minute wave record is the basic data series, considerable attention has recently been focussed on the data series of individual wave heights in the record, identified by the zero up-crossing method. Statistical parameters commonly extracted are  $R_H$ , the correlation coefficient between consecutive wave heights, and  $j_1$  and  $j_2$ , respectively the mean number of waves in a group and the mean number of waves between the start of one group and the start of the next group. Theoretical estimates consistent with the Gaussian random wave model have been developed by Goda (1970) for  $j_1$  and  $j_2$ , and Arhan and Ezraty (1978) for  $R_H$ . Field observations for  $j_1$  (Goda 1976, Su et al. 1982) and  $R_H$  (Arhan and Ezraty, Su et al.) are consistently above the theoretical values, although there is qualitative agreement in the trends. It is apparent that wave groups are rather longer and more coherent than predicted by the Gaussian random wave model. Battjes (1984) has, however, obtained adequate agreement between field records and a theory that is based on a finite lag one auto-correlation between consecutive wave heights.

As a sea state description, this data series of individual waves has considerable value, although the same cannot be said of its potential in the development of an appropriate sea state model. A predictive model is ultimately sought, in which the reversibility of analysis and synthesis is a required property. The data series of individual waves focusses attention on amplitude relationships and considers time relationships only in an averaged sense.

Much of the facility of the individual wave approach is implicit in the complex wave envelope  $A(t)$  introduced by Rice (1944, 1945). A carrier frequency,  $f_0$ , typically the

peak frequency  $f_p$ , is identified and removed from the record  $\eta(t)$ , such that

$$\eta(t) = \text{Real}[A(t) e^{i2\pi f_o t}] \quad (1)$$

In principle, the complex envelope function is the natural vehicle for wave group studies. No information is lost from the original record and attention is focussed on the envelope modulations. For typically narrow-banded sea states, the Rice envelope function  $|A(t)|$  is a good approximation to the wave envelope and the  $R_H$ ,  $j_1$  and  $j_2$  statistics are readily extracted.

#### FREQUENCY DOMAIN ANALYSIS OF DATA SERIES

The standard statistical summary in the frequency domain is the variance spectrum  $E(f)$  of the water surface time history  $\eta(t)$ . The common model of an irregular sea state, the Gaussian random wave model, was introduced by Rice (1944, 1945) as a model of random noise. The water surface time history is represented as the superposition of many linear waves of amplitude  $a_n = [2E(f_n)\Delta f]^{1/2}$  and random phase  $\phi(f_n)$ :

$$\eta(t) = \sum_n a_n \cos(2\pi f_n t + \phi_n) \quad (2)$$

The phase angle is randomly distributed over the range  $(-\pi, \pi)$ . This model has been the basis for analysis and design in coastal and ocean engineering for several decades.

There is a growing literature of detractors and defenders of the Gaussian random wave model. Rye (1983) and Goda (1983) argue that it is a sufficient description of wave grouping. Mollo-Christensen and Ramamonjiarisoa (1978), Hamilton et al. (1979) and Funke and Mansard (1980) propose supplementation to include wave grouping. Sobey and Colman (1982) have investigated a theoretical alternative, the nonlinear Schroedinger equation and the scattering transform. The field evidence is inconclusive, although the balance remains in favor of the Gaussian random wave model.

The intermediate step in the estimation of the variance spectrum is the complex Fourier transform  $F(\omega)$  of the wave record  $\eta(t)$ , defined as

$$F(\omega) = \int_{-\infty}^{\infty} \eta(t) e^{-i\omega t} dt \quad (3)$$

$F(\omega)$  is a complex function of the angular frequency  $\omega = 2\pi f$ , and may be represented as

$$F(\omega) = |F(\omega)| e^{i\Phi(\omega)} \quad (4)$$

where  $|F(\omega)|$  and  $\Phi(\omega)$  are respectively the amplitude and phase spectrums. The Gaussian random wave model assumes the phase spectrum to be completely random but Funke and Mansard (1981) have questioned whether it may indeed contain some useful information. Two problems are identified in interpretation of the phase spectrum, respectively phase unwrapping and phase trend removal, which may contribute to the apparently random character of computed phase spectra. These aspects will be considered separately.

### PHASE UNWRAPPING

Phase unwrapping refers to the modulo 2 operation on phase angles. The phase angle returned by the Fast Fourier Transform (FFT) algorithm is in the range  $-\pi$  to  $\pi$  and is termed the principal phase  $\Phi_p(\omega)$ . Any principal phase angle may in fact be  $\Phi_p(\omega) + 2n\pi$ , where  $n$  is any signed integer, without changing either the complex Fourier transform or the variance spectrum. The "true" phase is obtained by "unwrapping" the principal phase through addition or subtraction of multiples of  $2\pi$ ; this phase is called the unwrapped phase,  $\Phi_u(\omega)$ . The subscript  $u$  has been dropped but is implied in the subsequent discussion.

It remains to determine the signed integer  $n$ . The Schafer algorithm (Oppenheim and Schafer, 1975) assumes the unwrapped phase to be a continuous function of  $\omega$ , the only discontinuities being those introduced by the modulo  $2\pi$  operation in determining the principal phase. A discontinuity is defined to exist when the change in principal phase between adjacent values exceeds a given threshold. This process, however, is inconclusive and does not guarantee a unique result, as demonstrated by Tribolet (1977).

A unique result, however, does seem to be possible as the slope of phase spectrum is uniquely defined at all frequencies and uninfluenced by the modulo  $2\pi$  operation on the principal phase (Oppenheim and Schafer, 1975). Taking the natural logarithm of both sides of Eq. 4 and differentiating with respect to  $\omega$  gives

$$\frac{1}{F} \frac{dF}{d\omega} = \frac{d}{d\omega} (\ln|F|) + i \frac{d\Phi}{d\omega} \quad (5)$$

from which

$$\frac{d\Phi}{d\omega} = \text{Imag} \left( \frac{1}{F} \frac{dF}{d\omega} \right) \quad (6)$$

Similarly differentiating Eq. 3 with respect to  $\omega$  gives  $dF/d\omega$  as

$$\frac{dF}{d\omega} = -i \int_{-\infty}^{\infty} t \eta(t) e^{-i\omega t} dt \quad (7)$$

where the integral is recognized as the Fourier transform of  $t\eta(t)$ . The slope of the phase spectrum  $d\phi/d\omega$  is thus uniquely defined, at least in theory. Integration of Eq. 6 should yield the unwrapped phase spectrum but there are a number of problems in practice.

The first is a familiar one in discrete frequency domain analysis. The  $d\phi/d\omega$  estimates from the discrete Fourier transform of  $t\eta(t)$  are raw estimates and their erratic nature significantly complicates the numerical integration. Some theoretical assistance is available in that the principal phase prediction should be identical with that available from the Fourier transform of  $\eta(t)$ , but these discrete estimates are also raw estimates. Advantage can be taken of both estimates. The second problem is the specification of the phase and the phase gradient at zero or near zero magnitude points for the Fourier transform. This problem arises in the specification of the initial conditions for numerical integration of Eq. 6 and at any other frequency where  $|F(\omega)| \sim 0$  and  $1/|F(\omega)| \sim \infty$  in Eq. 6, a situation that is not uncommon given raw estimates of  $F(\omega)$ .

Tribolet (1977) considers the former problem in the context of the complex cepstrum, proposing an algorithm based on adaptive stepsize integration using the trapezoidal rule. If the difference between the unwrapped phase estimate and the principal phase estimate at each  $\omega$  is not sufficiently close to an integer multiple of  $2\pi$ , then the frequency interval  $\Delta\omega$  is continually halved until the specified accuracy is achieved. The discrete Fourier transform is used to estimate the Fourier transform by interpolation at intermediate points between those on the FFT raster. The initial phase was assumed to be zero, without discussion. The coding for this algorithm has been published and initial experiments utilized this code. Results were rather erratic for wave records and it was apparent that detailed consideration of the singular or near-singular points was essential.

These singular points can be accommodated by classical limit theory. L'Hospital's rule confirms that the principal phase and the phase derivative both exist and are given by

$$\phi_p(\omega) = \tan^{-1} \frac{F_I^{(k+1)}}{F_R^{(k+1)}} \quad (8)$$

$$\frac{d\phi}{d\omega} = \frac{1}{k+2} \frac{F_I^{(k+2)} F_R^{(k+1)} - F_I^{(k+1)} F_R^{(k+2)}}{F_R^{(k+1)} F_R^{(k+1)} + F_I^{(k+1)} F_I^{(k+1)}} \quad (9)$$

where  $|F^{(k)}(\omega)| = 0$ ,  $j = 0, 1, \dots, k$  and  $|F^{(k+1)}(\omega)| \neq 0$  and the bracketed superscripts represent differentiation with respect to  $\omega$ :

$$F_R^{(j)} + i F_I^{(j)} = \frac{d^j F(\omega)}{d\omega^j}$$

These higher derivatives can be calculated in a similar manner to Eq. 7, from the discrete Fourier transforms of  $t^j \eta(t)$  respectively. A further enhancement of the algorithm has been the adoption of Simpson's rule for numerical integration. Fourth order Runge-Kutta integration was initially utilized but Simpson's rule is numerically equivalent and has some coding advantages.

#### PHASE TREND REMOVAL

If the time origin of the record  $\eta(t)$  is shifted from  $t = 0$  to  $t = t_0$ , the Fourier transform of the origin-shifted record becomes  $F(\omega)e^{i\omega t_0}$ . The amplitude spectrum and hence the variance spectrum is not changed but the phase spectrum is changed by the addition of a linear trend  $\omega t_0$  to  $\phi(\omega) + \omega t_0$ . For an origin shift even as small as a few discrete record time steps  $\Delta t$ , this would impose a saw tooth variation on the principal phase, which potentially contributes to the random appearance of the principal phase spectrum. Although any linear trend is accommodated by phase unwrapping, the question of the "true" phase spectrum again arises. Interpretation of the phase spectrum will certainly be facilitated by the removal of any non-physical influences.

Funke and Mansard (1981) observe that a phase spectrum including a linear trend component will approach  $+\infty$  as  $\omega$  becomes very large and suggest that the correct choice of time origin (and this choice is arbitrary) will have zero slope,  $d\phi/d\omega \rightarrow 0$ , as  $\omega \rightarrow \infty$ . This is a compelling argument but there are difficulties in implementation. The phase spectrum is known only as far as the Nyquist frequency  $\omega_N = \pi/\Delta t$  and not to infinity. Also, energy levels beyond two to three times the peak frequency are very small for typical records and raw phase estimates are increasingly unreliable.

A reasonable compromise would be to take advantage of the phase estimates where they are expected to be most reliable, which is in the vicinity of the spectral peak. Accordingly the origin shift has been estimated from a least-squares curve fit of

$$\phi(\omega) = \phi(\omega = 0) + \omega t_0 \quad (10)$$

to the raw, unwrapped phase spectrum, weighted by the raw variance spectrum. This requires minimizing the sum

$$S(t_0) = \sum_i E(\omega_i) [\phi(\omega_i) - \phi(\omega = 0) - \omega_i t_0]^2 \quad (11)$$

where the  $\omega_i$  are the FFT raster points. The trend  $\omega t_0$  is then subtracted from the unwrapped phase spectrum. A number of variations on this approach and that suggested by Funke and Mansard (1981) were investigated but the Eq. 11 approach appeared to be the most consistent. This is recognized, however, as a subjective judgement.

Figures 1 and 2 are typical results from the phase unwrapping and detrending algorithms, showing the raw but unwrapped and detrended phase spectrum together with the raw variance spectrum. The results are presented non-dimensionally in terms of the peak frequency  $f_p$  and truncated at  $3f_p$  along the frequency axis. The oscillations in the tail of the phase spectrum are a computational effect in the phase unwrapping. A tolerance level must be set to define a near-singular point and to invoke the L'Hospital rule algorithm. These oscillations can be damped by appropriate choice of the tolerance level.

Similar results are consistently achieved, strongly indicating the existence of some coherent structure in the phase spectrum, against a background that has a distinctly random character.

#### TIME DOMAIN ANALYSIS OF WAVE RECORD

The standard statistical summary in the time domain is the correlogram  $R(\tau)$ , which forms a Fourier transform pair with the variance spectrum  $E(f)$ . In principle, both summaries describe the same information but from different perspectives. In practice, however, this equivalence becomes confused. The FFT algorithm yields the raw variance spectrum (Figures 1 and 2) which is then subjected to frequency domain smoothing, but the nature and extent of that smoothing is an especially subjective operation. Variations from a visually smooth result are commonly regarded as noise and given little attention; it remains possible that these variations from the smooth and expected result in fact describe wave grouping. This possibility is indeed sugges-

Fig. 1 Raw Variance and Unwrapped Phase Spectrum

Fig. 2. Raw Variance and Unwrapped Phase Spectrum  
in Deep Water off Botany Bay, 7:20 hrs  
on 9 July 1981

ted by the correlograms in Figures 3 and 4, corresponding to the same records as Figures 1 and 2, where  $\tau$  is the time lag and  $\sigma^2$  the record variance. The time lag scale is non-dimensionalized by the peak frequency, as were the frequency domain results. If the phase spectrum is indeed random, the envelope of the correlogram should go asymptotically to zero in about five wave periods. This is not observed in Figures 3 and 4 (solid line), where the dominant feature is the ordered tail. The correlogram is inherently smoothed in a reasonably unbiased manner and the ordered tail is strongly suggestive of wave groups. These are typical results for moderate sea states and were not specially selected for presentation.

It remains possible that the oscillations in the correlogram tail are a computational effect. It is well known (Kendall and Stuart, 1966) that the correlogram for short series can be unreliable and may not damp out as rapidly as expected; as a rule of thumb, only the first twenty percent might be given any credence. Wave records are moderately long series, typically 2048 points over seventeen minutes. Figures 3 and 4 present the correlogram for non-dimensional lags  $f_p$  up to twenty. This corresponds to approximately twenty waves, about one-fifth of a typical wave record of one hundred waves. Further Kendall and Stuart give the 95% confidence limits of the correlogram for a random process as

$$CL = -1/N \pm 2/(N)^{1/2} \quad (12)$$

where  $N$  is the number of points in the record. For  $N = 2048$ , the 95% confidence limits are  $-0.00 \pm 0.04$ . The amplitude of the oscillations in the tail of Figures 3 and 4 is of order 0.15, well outside the 95% confidence limits for a random process. This conclusion is not influenced by the adoption of the "unbiased estimator" for the autocorrelation, which uses the factor  $1/(N-k)$  in place of  $1/N$  in the estimation of  $R(\tau = k\Delta t)$ . In this case both the correlogram tail and the confidence limits are scaled up by the factor  $N/(N-k)$ .

#### TIME DOMAIN ANALYSIS OF RICE ENVELOPE FUNCTION

In the initial discussion of data series for analysis it was observed that the complex envelope function  $A(t)$  defined by Eq. 1 appeared to be the natural vehicle for wave group analyses. A procedure for extracting the complex envelope function from the wave record is described by Sobey and Colman (1983). It involves the computation of the discrete Hilbert transform  $\hat{\eta}(t)$  from the wave record  $\eta(t)$  using the FFT and inverse FFT algorithms. Then follows the definition of the pre-envelope function

$$\eta(t) + i \hat{\eta}(t) = A(t)e^{i\omega_0 t} \quad (13)$$

Fig. 3 Correlogram of Record and Rice Envelope Function in Deep Water off Botany Bay, 5:20 hrs on 9 July 1981

Fig. 4 Correlogram of Record and Rice Envelope Function in Deep Water off Botany Bay, 7:20 hrs on 9 July 1981

where  $\omega_0 = 2\pi f_0$  is the carrier frequency. The carrier frequency is identified as the peak frequency  $2\pi f_p$  and estimated as

$$f_p = \frac{\int f E^8(f) df}{\int E^8(f) df} \quad (14)$$

Multiplying both sides of Eq. 14 by  $\exp(-i\omega_0 t)$  recovers the complex envelope function  $A(t)$ . The Rice envelope is simply the modulus of  $A(t)$ .

Sample computations of the Rice envelope function and comparison with Rice envelope is simply the modulus of  $A(t)$ .

Sample computations of the Rice envelope function and comparison with the wave record confirm that it is indeed an excellent representation of the wave envelope. It is this property of the Rice envelope function that was used by Rice (1944, 1945) and later Longuet-Higgins (1952) to establish the Rayleigh distribution as an excellent approximation to the probability distribution for wave heights. In the context of wave grouping, the Rice envelope function very conveniently concentrates attention on the wave envelope and hence the wave groups. A similar identification of wave groups was the rationale for the definition of the SIWEH function by Funke and Mansard (1980).

The considerable attention recently given to the data series of individual wave heights might also be considered in the context of the Rice envelope function. Amplitude domain arguments led Rice and Longuet-Higgins to the Rayleigh distribution. Time domain or correlogram arguments appear to lead to  $R_H$  (the correlation coefficient between consecutive wave heights) and  $j_2$  (the average number of waves between the start of one wave group and the start of the next group). The correlogram of the Rice envelope function is shown as the dashed lines on Figures 3 and 4.

The initial exponential decay is closely related to typical statistics extracted from the data series of individual wave heights. In particular  $R_H$  might be defined as

$$R_H = R(\tau f_p = 1) / \sigma^2 \quad (15)$$

and  $j_2$  from the first zero crossing of the correlogram as

$$R(\tau f_p = 1/2 j_2) = 0 \quad (16)$$

Alternately the zero-crossing frequency rather than the peak frequency could be used in these definitions. The difference is typically small; the peak frequency has rather more dynamic significance while the zero-crossing frequency oc-

curs naturally in the theory of random noise. Note that  $R_H$  defined in terms of the zero crossing frequency is the parameter proposed by Battjes (1984) as the sole spectral shape parameter determining the group statistics.

The long period persistence in the tail of the Rice envelope correlograms is again suggestive of wave grouping.

### CONCLUSIONS

Evidence suggestive of wave grouping has been sought in the frequency and time domain. Ordered structures have been identified in the phase spectrum and in the tail of the correlogram, both for wave records and for the Rice envelope function. There is a reasonable expectation that wave grouping will be adequately described by these classical linear techniques of time series analysis.

## CHAPTER FORTY EIGHT

### SWASH ON STEEP AND SHALLOW BEACHES

R. T. Gnza<sup>1</sup>, E. B. Thornton (M. ASCE)<sup>2</sup>, R. A. Holman<sup>3</sup>

#### Abstract

Extensive field observations of swash on natural beaches are used to relate the magnitudes of swash oscillations to incident wave conditions and the beach slope. Swash fluctuations at wind wave frequencies (defined here as  $f > .05$  Hz) appear to be "saturated." As in laboratory experiments with monochromatic waves, wave breaking prevents the magnitudes of swash oscillations at incident wave frequencies from increasing past a certain level which depends on the beach slope. All data sets considered support this conclusion. In contrast, the magnitude of swash oscillations at surf beat frequencies (defined as  $f < .05$  Hz) varies between data sets. Possible reasons for the discrepancy are discussed. Despite their differences, all data sets show that motions at surf beat frequencies dominate the swash spectrum on dissipative beaches. As in previous studies, the frequencies of spectral hills and valleys in the spectra of surf zone sensors suggests that a significant fraction of the surf beat energy is contained in motions which are standing in the cross-shore direction. Preliminary analysis indicates that shoreward propagating surf beat is coupled to incident wave groups.

## INTRODUCTION

The location of shoreline water level (run-up) is important in coastal dynamics. Run-up is composed of a super elevation of mean water level (set-up) and of fluctuations about the set-up level (swash). The present work concerns swash oscillations on natural beaches. The objective is to relate the amounts of swash energy in low (i.e. surf beat) and high (i.e. incident wave) frequency bands to incident wave conditions and the beach slope. Previously unreported field data is supplemented by the extensive field observations of swash reported in Guza and Thornton [1982; in press] and Holman and Sallenger [in press], hereafter referred to as GT and HS. Taken together, these observations span a wide range of incident wave conditions (significant wave heights 20-400 cm, most energetic spectral period 6-20 sec) and beach morphologies (foreshore slopes .025-.125).

The GT swash data were collected on the California coast with a resistance wire gauge. HS used time lapse photography of run-up during a month long experiment at Duck, North Carolina. In all experiments, incident wave heights were calculated from pressure sensor data collected directly offshore of the run-up measurements. Each HS run was 35 minutes long, while GT runs varied between 35 and 256 minutes. Roughly 150 hours of run-up data are considered here.

Huntley et al., [1977] suggested that naturally occurring swash consists of "saturated" high frequency and "unsaturated" lower frequency components, corresponding roughly to the incident wave and surf beat frequency bands. Swash motions at wind wave frequencies are discussed first. Laboratory experiments and theories for monochromatic incident waves are briefly reviewed because they suggest nondimensional parameters useful in discussing this frequency band. As suggested by Huntley et al., [1977], the magnitudes of wind wave swash oscillations in field data are saturated, qualitatively similar to monochromatic laboratory wave results. Surf beat frequencies are considered next. Apparent discrepancies, between data sets, in the magnitude of surf beat swash oscillations are discussed. Finally, some preliminary results concerning the relationship between surf beat and incident wave groups are presented.

## WIND WAVE FREQUENCY BAND

Monochromatic results

Miche [1951] hypothesized that the amplitude of swash oscillations due to monochromatic incident waves is proportional to the amount of shoreline reflection and thus to the standing wave amplitude. Furthermore, the standing wave amplitude at the shoreline with incident wave breaking was assumed equal to the maximum value which occurs without wave breaking. Thus, a maximum swash oscillation supposedly occurs with incident waves just large enough to break. Further increases in incident wave height were hypothesized to increase the amplitude of the progressive component (which is dissipated by breaking and has zero shoreline amplitude), while the standing component and swash amplitudes remain constant (i.e., saturated). Carrier and Greenapan [1958] used the fully nonlinear, inviscid, shallow water

equations to study the maximum possible size a standing wave can attain on an impermeable sloping beach. A review of their work, and of the general problem of waves on a sloping beach is given by Meyer and Taylor [1972]. Carrier and Greenspan found that a standing wave solution is possible if

$$\varepsilon_s = \frac{a_o^s \sigma^2}{g \tan^2 \beta} \leq 1 \quad (1)$$

where  $\beta$  is the slope of a plane beach,  $\sigma$  is the radian frequency,  $2a_o^s$  the vertical swash excursion, and  $\varepsilon_s$  a nondimensional swash parameter. According to inviscid, linear theory, the standing wave amplitude at the shoreline is amplified, relative to the standing wave amplitude in deep water ( $a_\infty^s$ ) by [Stoker, 1947; Meyer and Taylor, 1972].

$$a_o^s = a_\infty^s \left| \frac{\pi}{2 \tan \beta} \right|^{1/2} \quad (2)$$

The deep water condition for a standing wave which will not break at the shoreline is given by, using (1) and (2),

$$\frac{a_\infty^s \sigma^2}{g} \left| \frac{\pi}{2} \right|^{1/2} \tan^{5/2} \beta \leq 1 \quad (3)$$

In terms of the deep water progressive wave amplitude  $a_\infty^s (= \frac{a_\infty^s}{2})$ , the criterion for total reflection of incident waves is [Meyer and Taylor, 1972]

$$\varepsilon_i = \frac{a_\infty^s \sigma^2}{g} (2\pi)^{1/2} \tan^{-5/2} \beta \leq 1 \quad (4)$$

Combining the Miche saturation hypothesis with inviscid linear theory for the maximum amplitude standing wave yields

$$\begin{aligned} \varepsilon_i, \varepsilon_i &< 1. \\ \varepsilon_s &= \\ 1, a_i &> 1. \end{aligned} \quad (5)$$

According to this model, if  $\varepsilon_i$  is small, then increasing the incident wave height (i.e.  $\varepsilon_i$ ) results in an increased swash excursion ( $\varepsilon_s$ ) and the swash is "unsaturated." For large  $\varepsilon_i$ , increasing the incident wave height results in a larger breaker height and steady set-up, but the swash oscillations ( $\varepsilon_s$ ) do not increase. The swash is "saturated."

Several laboratory experiments with monochromatic incident waves have confirmed the basic saturated swash hypothesis. There are, however, some differences in the observed maximum values of  $\epsilon_s$  [ $\sim 1.25$ , Battjes, 1974;  $\sim 2.0$ ; Van Dorn, 1978;  $\sim 3.0$ , Guza and Bowen, 1976] and in the proper nondimensional form for the incident waves ( $\epsilon_i$  in eq. 5).

Typical laboratory data are shown in Figure 1 based on the data of Guza and Bowen [1976]. For  $\epsilon_i < 1.0$ , there was no visible wave breaking and  $\epsilon_s = \epsilon_i$  as predicted by eq. 5. For  $1.0 < \epsilon_i < 9.0$  the swash motion ( $\epsilon_s$ ) increases slowly with increasing  $\epsilon_i$  until reaching a saturated value of  $\sim 3.0$  at  $\epsilon_i \sim 9$ . Further increases in  $\epsilon_i$  do not increase  $\epsilon_s$ . A modification of the Miche hypothesis (eq. 5) which better fits this data (Figure 1) is

$$\epsilon_i \quad ; \quad \epsilon_i < 1. \tag{6a}$$

$$\epsilon_s = \epsilon_i^{1/2} \quad ; \quad 1. < \epsilon_i < 9. \tag{6b}$$

$$3 \quad ; \quad \epsilon_i > 9. \tag{6c}$$

The  $\epsilon_i^{1/2}$  dependence occurs in a transition region between complete reflection and spilling wave conditions. The  $\epsilon_i^{1/2}$  functional form does not correspond to any theory and is only a convenient and simple fit to the data. For comparisons with other results it is useful to recast eq. 6 in terms of the Irribarren, or surf similarity parameter [Battjes, 1974]

$$\xi_\infty = \tan\beta \left| \frac{L_\infty}{H_\infty} \right|^{1/2} = \left| \frac{\pi}{2 \tan\beta} \right|^{1/4} \epsilon_i^{-1/2} \tag{7}$$

with  $L_\infty$  and  $H_\infty$  the deep water wavelength and height. The ratio of the vertical swash excursion ( $R^v = 2a_s^0$ ) to  $H_\infty$  is then

$$3\xi_\infty^2/\pi \quad ; \quad \xi_\infty < \xi_c/3 \tag{8a}$$

$$\frac{R^v}{H_\infty} = (2\pi\beta)^{-1/4} \xi_\infty \quad ; \quad \xi_c/3 < \xi_\infty < \xi_c \tag{8b}$$

$$(\pi/2\beta)^{1/2} \quad ; \quad \xi_c < \xi_\infty \tag{8c}$$

where  $\xi_c = \left| \frac{\pi}{2\beta} \right|^{1/4}$  is the minimum  $\xi_\infty$  value for complete reflection (corresponding to  $\epsilon_i = 1.0$  in eq. 7) and the small slope assumption has been made ( $\beta \sim \tan \phi$ ). Note that large waves correspond to large  $\epsilon_i$  (eq. 6c) and small  $\xi_\infty$  (eq. 8a).

Figure 1. Nondimensional swash ( $\epsilon_s$ , eq. 1) versus nondimensional incident wave height ( $\epsilon_1$ , eq. 4) for monochromatic lab data [Guza and Bowen, 1976].<sup>1</sup> Solid lines correspond to a modified Miche hypothesis (eq. 6).

Figure 2. Swash/incident wave height ratio ( $R^V/H_0$ ) versus surf similarity parameter ( $\xi_\omega$ ). — Eq. 8 for indicated values of  $\beta$ ; ---- eq. 9.

As shown in Figure 2, eq. 8 is qualitatively similar to the result of Battjes [1974] based on laboratory experiments with breaking waves on relatively steep slopes

$$\frac{R_v}{H_\infty} = 1.25 \frac{\xi_\infty^2}{\pi} \quad .3 < \xi_\infty < 1.9 \quad (9)$$

In fact, in the saturated range eq. 9 has the same functional form as the modified Miche model (eq. 8a). The difference in the constants corresponds to the different observed saturated values of  $\xi_\infty$  (1.25 and 3.0 in eq 9 and 8a, respectively). The important point here is that eqs. 8 and 9 describe a large amount of monochromatic lab data. Although run-up studies with random waves exist, the data are generally not analyzed in a form suitable for the present application.

#### Field Data; magnitudes

Figure 3 shows the field data superimposed on eqs. 8 (with  $\beta = 6^\circ$ ) and 9. The "significant" swash and incident wave heights ( $R_v$  and  $H_{s,\infty}$ ) are defined as four times the observed variance above  $s_{inc}$ .05 Hz and  $L_\infty$  (which appears in  $\xi_\infty$ ) is based on the incident wave frequency with the maximum power. Because run-up heights can have non-Rayleigh distributions, the significant heights in the present context are simply characteristic heights defined in terms of the variance. Figure 3 also shows the best fit straight line given by HS for that data only. Note that a linear dependence of  $R_v/H_\infty$  on  $\xi_\infty$  does not correspond to the  $\xi_\infty$  dependence of the fully saturated Miche (eq. 8a) or Battjes (eq. 9) models, but is consistent with the transition range suggested by the Guza and Bowen [1976] laboratory data (Figure 1, eq. 8b). However, the field data is clearly too scattered to define a particular functional dependence on  $\xi_\infty$ .

Some of the scatter in Figure 3 is due to the subjectivity of digitizing the HS films and to nonconstant elevations above the bed of the GT resistance wires [Holman and Guza, 1984]. In addition to these instrumental errors, there are more fundamental problems associated with the definitions of  $\xi_\infty$  and  $R_v$ . The  $L_\infty$  term in  $\xi_\infty$  (eq. 7) should probably be defined using the entire incident wave spectrum rather than only the most energetic spectral component. The frequency range for  $R_v$  (here  $f > .05$  Hz) might be more reasonably selected as the range of saturated frequencies, or as having a particular relationship to a characteristic incident wave frequency. The present choice of .05 Hz as the low frequency cut-off corresponds very roughly to a lowest frequency wave band. There are considerable experimental and conceptual shortcomings in the present work. Nevertheless, the clear decrease in  $R_v/H_\infty$  with decreasing  $\xi_\infty$  (Figure 3) further confirms the idea that saturation is a relevant concept for swash on natural beaches.

Figure 3. Ratio of observed significant swash height in the incident wave band ( $R_{s,inc}^V$ ) to significant incident wave height ( $H_{s,\infty}$ ) versus  $\xi_{\infty}$

## SURF BEAT FREQUENCIES

Field Data; magnitudes

In contrast to swash at wind wave frequencies, there are no comprehensive laboratory experiments which provide suggestions about the nondimensional parameters controlling the magnitude of swash oscillations at surf beat frequencies. Laboratory experiments have been hampered by both the generation of spurious free long waves (Bowers, 1977) and multiple reflections between the beach and wave generator [Flick et al., 1981]. Thus, although laboratory measurements with non-monochromatic incident waves do exist, the swash motions at surf beat frequencies are contaminated to an unknown degree. Work presented at the 19th ICCE (Kostense and Vis) describes the first variable depth experiments apparently free of both paddle generated free long waves and long waves re-reflected from the wavemaker. Such experiments, particularly when extended from two incident wave frequencies to a spectrum, will hopefully provide important insights into naturally occurring surf beat. There are no theories which claim to predict surf beat swash energy levels for a spectrum of incident waves. Bounded long wave theories [Longuet-Higgins and Stewart, 1962, 1964] are not valid in very shallow water. Symonds et al., [1982] model the generation of long waves in the surf zone, but the necessary extension of the model from a two frequency deterministic incident wave field to a random wave spectrum has not been done.

While theoretical work provides little guidance, field studies have indicated several general trends. The first is an apparent linear dependence between incident wave and surf beat energy levels [Tucker, 1950; Holman, 1981; Gnza and Thornton, 1982; in press]. Figure 4 shows the observed linear relationship between  $R_{s,IG}^V$  (the significant vertical swash excursion at infragravity frequencies) and  $H_{s,\infty}$  for the GT data. Figure 5 shows the same plot for the HS data. While there may be an indication of some dependence, the HS data are scattered. (Note that the GT data do fall within the general scatter of the HS data).

One reason for the great variability in the HS data lies in the longshore variability of the beach face slope. During the month the HS data were collected, the beach morphology was occasionally rhythmic with longshore length scales of several hundred meters. While these slope variations are small on an incident wave length scale (and the incident band data are correspondingly well behaved), they are large on the length scales associated with infragravity waves. The longshore variation of  $R_{s,IG}^V$  in the same data run, appears in Figure 5 as a wide range of  $R_{s,IG}^V$  values for the same  $H_{s,\infty}$ .

The second general trend that has been previously noted in the literature is that the presence of infragravity energy is in some way linked to the degree to which a beach is "dissipative" [Sasaki et al., 1976; and others]. Since  $s_i$  and  $\xi_\infty$  have been linked to the dissipative characteristics of a beach,  $H_{s,IG}$  plotted the non-dimensional infragravity band swash height,  $r_{IG} = R_{s,IG}^V/H_{s,\infty}$  against  $\xi_\infty$ . Figure 6 shows this plot, together with the best fit linear slope to the HS data. This parameterization does appear to reduce the scatter of the HS data. However, it also shows that the HS and GT data are systematically

Figure 5. Same as Figure 4, but data is from Holman and Sallenger [in press, reprinted with permission of AGU].

Figure 6.  $\frac{R_{s,IG}^V}{H_{s,\infty}}$  versus  $\zeta_{\infty}$   
 o, Holman and Sallenger [in press]  
 x, Guza and Thornton [1982; in press]  
 \*, Holman and Bowen [1984]

Solid line is best fit line to HS data.

different in this parameter space. While the HS data show a clear trend, the GT data show no significant slope when  $r_{IG}$  is regressed against  $\xi_\infty$ . Note that the linear dependence between  $r_{IG}$  and  $\xi_\infty$  in the HS data implies that  $R_{s,IG}^H/H_{s,\infty}$  (with the significant horizontal swash excursion  $R_{s,IG}^H = R_{s,IG}^V/\beta$ ) is independent of local  $\beta$ .

Perhaps the most important difference between the data sets are the inferred low Irriharren number (large waves) limiting values of  $r_{IG}$ . Based on linear regressions of  $r_{IG}$  against  $\xi_\infty$ , the limits are of the order of 0.1 and 1.0 for the HS and GT data sets respectively. Separate evidence from two highly dissipative beaches ( $\xi_\infty = 0.25$ ) tends to support the GT limit, with observed values of  $r_{IG}$  of at least 0.6 [Wright et al., 1982; Holman and Bowen, 1984].

A potentially simple explanation for the apparent discrepancy between the data sets lies in the rather arbitrary definition of the infragravity band. A cutoff frequency of 0.05 Hz may be generally appropriate for west coast swell, but may be too low for the higher frequency east coast waves. For Great Lakes data this cutoff would be ridiculous. It can be easily seen that variability in incident wave period could induce an artificial trend in a plot such as Figure 6, for a truly constant  $r_{IG}$ . For similar incident wave heights, shorter incident periods will be associated with smaller  $\xi_\infty$ , and will also have a smaller apparent infragravity energy since the fixed cutoff of .05 Hz will encompass a smaller portion of what may properly be considered true infragravity energy. Longer incident periods are associated with larger  $\xi_\infty$  and a proportionally larger  $r_{IG}$  since the .05 Hz cutoff encompasses more of the "true" infragravity energy. Thus the differences between the HS and GT data sets in Figure 6 may only represent the differences in incident wave frequencies encompassed by the data.

Summarizing, there are at least two potential factors contributing to the differences in the surf beat data sets. These are effects associated with three dimensional topography, and the arbitrariness of the present cut-off frequency separating the surf beat and wind wave bands. Note that altering the cut-off frequency will also alter the amount of wind wave energy, and improved agreement between the surf beat data sets may unfortunately be accompanied by increased differences in the wind wave band (Figure 3). Further research on this problem is clearly needed.

#### Field data: generation mechanisms

The idea that surf beat is a forced oscillation associated with incident wave groups originated with Munk [1949] and Tucker [1950]. They interpreted their low frequency observations, taken several hundred meters offshore, as being due to mass transport shorewards under high incident wave groups, with the release of low frequency free waves at the break point where the groups are destroyed by breaking. The long waves then reflect off the beach face and propagate offshore. Tucker [1950] found that high wave groups were correlated with troughs in the low frequency waves. The time lag of maximum correlation approximately equaled the sum of the travel times for incident wave groups to

propagate from the observation point to the break point, and seaward going long waves to return from the break point. Longuet-Higgins and Stewart [1964] subsequently showed that Tucker's observation that high wave groups were correlated with troughs in the low frequency waves agree with the predictions of second-order theory for forced waves if it is assumed that the long waves reflect at the beach. Munk's results were similar to Tucker's, except that with a similar time lag he found crests of long waves correlated with high wave groups, implying a  $180^\circ$  phase shift for the reflected long wave. Both Munk [1949] and Tucker [1950] imply that there is a small nonlinear forced long wave correction under shoreward propagating wave groups, and a larger seaward propagating low frequency wave released at the break point or beach face. In contradiction, Hasselman et al., [1962] presented evidence that the shoreward propagating nonlinearly forced motion is larger than any seaward propagating component. More recent observations suggest that incoming and outgoing waves are of roughly equal magnitude, forming a quasi-standing wave [Suhayda, 1974; and many others]. An example from the GT data set is shown in Figure 7 where measured surf beat run-up spectra are compared with numerical integrations of the long wave equations to predict the energy spectrum at offshore sensors, and the phase between offshore sensors and run-up meter. As in previous studies, valleys in the observed surf beat energy spectra at offshore sensors, and jumps in the relative phase between sensors, occur at the nodal frequencies of simple standing wave (either leaky or high mode edge wave) models.

The question of whether there are long waves associated with groups of incoming waves is addressed by calculating correlations between the two. The data considered here is from a 68 minute run at Torrey Pines on 21 November 1978. The envelope of the high frequency wind waves was obtained by squaring the wind wave time series, and then low pass filtering this signal. A similar approach has been independently taken by Kim and Huntley, and their results are also presented in this volume. Table 1 shows the maximum correlation, and the associated time lag, between the envelope of the deepest sensor (P4) and the envelope at other locations. The correlations are high for sensors outside the breaker region, seawards of W29 (Table 1). This indicates that well defined groups of waves propagate across the nearshore until shoaling and/or wave breaking radically alters the group structure. Theoretical travel times are approximated by using a group velocity equal to

$(gh)^{1/2}$ . These times are nearly equal to the observed times of maximum correlation except in very shallow water where bottom slope effects are not negligible, and the  $(gh)^{1/2}$  assumption breaks down.

Correlations between the low frequency motion and envelope at each sensor are also given in Table 1. At time lag 0, the correlation ( $C_2(\tau = 0)$ ) at the 5 deepest stations are all negative, as would be found with the bound long wave solutions of Longuet-Higgins and Stewart [1962, 1964]. Most of these correlations are barely significantly different than zero with 95% confidence. They are, however, comparable to the maximum correlations observed ( $C_2^{\max}$  in Table 1). At the shallowest three stations,  $C_2(\tau = 0)$  has substantially higher values

Table 1.  $C_1$  is the correlation between the wind wave envelopes at P4 and other sensors, and  $\tau_1^{\max}$  the time lag of maximum correlation, both observed and calculated.  $C_2$  values are correlations between the envelope and low frequency motion at the same sensor.  $C_2^{\max}$  is the maximum correlation (at lag  $\tau_2$ ), and  $C_2(\tau=0)$  the correlation at lag 0.

SENSOR	P4	P7	P7A	P10	P16	W29	P30	W38	W41
Offshore Location(m)	456.	360	303	233	159	103	73	47	17
Depth(cm)	1006.	736	669	553	381	173	130	85	47
$C_1^{\max}$	1.	.93	.92	.90	.87	.58	.50	.43	.43
$\tau_1^{\max}$ (sec) observed	0.	11	19	28	40	49	50	53	148
$\tau_1^{\max}$ (sec) theory	0.	10.	17.	26.	37.	48.	56.	64.	76.
$C_2^{\max}$	.16	-.20	-.14	-.18	-.30	-.17	.32	.51	.45
$\tau_2^{\max}$ (sec)	-225.	170	28	6.	4.	-91.	0.	4.	2.
$C_2(\tau=0)$	-.16	-.13	-.11	-.15	-.26	.00	.32	.46	.43

than at the deeper stations. The maximum correlations at the shallow stations occur at lags ( $\tau_2^{\max}$ ) very close to zero (a positive value of  $\tau_2^{\max}$  means the envelope leads the long wave). Curiously,  $C_2(\tau = 0)$  changes sign between deep and shallow water. The consistent pattern of correlations near zero lag suggests that there is a component of surf beat associated with local wave groups. However, the correlations are disturbingly low and there is no obvious indication of the outgoing long wave energy which contributes to the ubiquitous quasi-standing wave patterns observed by many investigators, and in this data set in particular (Figure 7).

Additional insights are obtained by using colocated pressure and current meters to decompose the long wave into seaward and shoreward propagating components. With  $\eta(t)$  and  $n(t)$  the long wave sea surface elevation and cross-shore velocity time series, plus and minus characteristic (PC(t), MC(t)) time series are defined as

$$PC(t) = (\eta + (\frac{h}{g})^{1/2} n)/2. \quad (10a)$$

$$MC(t) = (\eta - (\frac{h}{g})^{1/2} n)/2. \quad (10b)$$

If  $\eta$  and  $n$  are normally incident shallow water waves following the flat bottom dispersion equation, then PC(t) and MC(t) are the time series of shoreward and seaward propagating waves respectively. Figure 8 shows the time lags for maximum correlation between the envelope of sensor P10 (distance = 233 m) and PC and MC for the six available colocated pressure/current meters. The numbers on the figure are the values of the maximum positive and negative correlations. Correlation values between the P10 envelope and seawards propagating long wave characteristics are circled, while those between the envelope and the shoreward propagating wave are not circled.

In three cases ( $x = 233, 259, 47$  m) the time lag for one of the maximum correlations of the incoming characteristics was not between  $\pm 150$  sec., and these values are not shown. The solid lines on Figure 8 are the calculated travel times for groups of long waves to propagate from P10 to various locations, assuming reflection occurs at the shoreline and the phase speeds equal to  $(gh)^{1/2}$ . Incoming and outgoing long waves are both significantly correlated with the envelope at P10 ( $x = 233$  m). In fact, the maximum correlations of the outgoing long waves with the P10 envelope are comparable to those between the incoming long waves and the P10 envelope. Without the decomposition into incoming and outgoing long waves, the maximum correlations ( $C_2^{\max}$ , Table 1) are generally reduced because the envelope is correlated to both components, but with different time lags. Note the comparable magnitudes of the maximum positive and negative correlations between the seawards propagating long wave and the P10 envelope (circled values in Figure 8) at each position. Given their similar values, and the inaccuracies in the theoretical travel times in very shallow water, it is not possible to tell whether or not the outgoing long wave is phase shifted by  $180^\circ$

Figure 7. Upper panels compare measured surf beat elevation (A, —) and cross-shore velocity (B, —) energy spectra with predictions (.....) based on measured run-up spectra (A, ---) and hypothesis of standing long waves. Lower panels compare predicted (...) and measured (\*) phase difference between run-up and the offshore sensors (depth = 85 cm, x = 47 cm, 21Nov78, Torrey Pines Beach).

Figure 8. Time lags for maximum correlation between the wind wave envelope at a sensor 233 m offshore, and the seaward and shoreward propagating long waves at various offshore locations.

or not. It is clear, however, that both seaward and shoreward propagating components are correlated with the wind wave envelope. The variances of PC(t) and MC(t), at any particular location, differed by a maximum of 28%, with the shoreward propagating component larger at all positions. The average variance difference was 17%, or roughly an 8% difference in incoming and outgoing long wave amplitudes. This result is very preliminary, but the small differences in incoming and outgoing long wave amplitudes leads us to speculate that the outgoing long wave is simply the reflection of the incoming long wave. However, substantial improvements in several important aspects of the analysis, and consideration of a wider range of data sets are required before any firm conclusions can be reached. The present discussion demonstrates the potential value of decomposing the long wave into incoming and outgoing components and separately correlating these with the wind wave envelope.

## CHAPTER FORTY NINE

### MEASUREMENTS OF SURF BEAT AND SET-DOWN BENEATH WAVE GROUPS

J.K. Kostense\*

#### ABSTRACT

A laboratory study was conducted to measure the amplitudes of long waves in shallow water as induced by wave grouping. In a 55 m long wave channel with a plane beach at the end, two primary waves of nearly equal frequency were generated. Due to a sophisticated control of the wave paddle - including second order wave generation as well as active wave absorption at the paddle face - the wave action at the difference frequency was limited to an incident forced wave, propagating at the group velocity, and a reflected free wave generated in the surf zone. For the incident forced - or bound - wave, also known as set-down, the experimental results show good agreement with the existing theory. Furthermore, the experiments confirm qualitatively a theoretical model by Symonds et al. (1982) explaining two-dimensional surf beat as a result of the time-varying breakpoint of the incident primary waves.

#### 1 INTRODUCTION

Long period sea-level fluctuations of several minutes in the nearshore zone were first observed by Munk (1949) and Tucker (1950). Their field records revealed a correlation between the amplitude of these fluctuations, since then termed surf beat, and the amplitude of the incoming swell. The mechanisms by which surf beat is generated have been discussed since then.

Several more recent field studies revealed that three-dimensional free edge waves can account significantly for nearshore long period energy. Gallagher (1971) was able to show theoretically that edge waves can be generated and resonantly excited by nonlinear interaction of obliquely incident wave groups. However, since the first observations there has been some evidence that, apart from the resonant excitation of edge waves, two-dimensional surf beat due to normally incident waves also exists and contributes significantly to the long period energy.

Using the concept of radiation stress, Longuet-Higgins and Stewart (1962 and 1964) presented a theoretical explanation for the existence of a nonlinear forced - or bound - wave associated with grouped waves. This wave, propagating at the group velocity, results in a set-down beneath wave groups. For a constant water depth Bowers (1977) and Ottesen Hansen (1978) derived expressions for the velocity

---

\* Delft Hydraulics Laboratory, the Netherlands

potential and the surface elevation of the bound long wave, using a Stokes expansion of the wave equations to the second order.

Referring to Tucker's observations, showing at some distance offshore a time lag of several minutes between the envelope of the incoming swell and the measured long wave, Longuet-Higgins and Stewart (1962) suggested that the incident bound wave is reflected from the surf zone and is radiated seaward as a free long wave, resulting in two-dimensional surf beat. However, no mechanism was proposed for this phenomenon. More recently, Symonds, Huntley and Bowen (1982) presented a theoretical model explaining the generation of free long waves, radiating seaward from a plane beach, as a result of the time-varying position of the breakpoint of normally incident grouped waves. Shoreward of the breakpoint standing wave solutions are found. This model has been extended by Symonds and Bowen (1984) to describe the long wave solutions generated over any offshore profile, including barred topographies.

Apart from coastal processes, surf beat is of special importance for the resonant excitation of harbour basins and moored structures. However, until recently a correct reproduction of these waves in physical models has been hampered for two reasons. Firstly, if a wave paddle is programmed to produce the primary waves only, the boundary conditions at the paddle are not fulfilled for the bound long waves. This results in the generation of spurious free long waves, as already pointed out by Bowers (1977). Secondly, disturbances occur when reflected long waves are re-reflected from the paddle. Flick et al. (1980) show that for critical frequencies this may even result in resonance, which makes model testing on surf beat phenomena virtually impossible. In the following sections methods to prevent both types of disturbances are discussed. Moreover, experimental results on both set-down beneath wave groups and free long waves generated in the surf zone and radiated seaward, are presented.

## 2 EXPERIMENTAL SET-UP

The experiments were carried out in a glass-wall wave channel of the Delft Hydraulics Laboratory. The channel is 55 m long, 1.0 m wide and 1.2 m high.

Fig. 1 Sketch of the wave channel

The facility is equipped with a hydraulically driven cradle-type wave generator which was operated in the piston mode only. For all tests a primary wave system made up of two frequencies was generated in a water depth of 0.50 m. These waves broke on a plane cemented beach of a 1:20 slope (see Fig. 1).

## 3 WAVE PADDLE CONTROL

Excluding reflection from the beach, the first-order water surface elevation in the wave channel is given by:

$$\eta = \hat{\eta}_1 \cos(\omega_1 t - k_1 x - \phi_1) + \hat{\eta}_2 \cos(\omega_2 t - k_2 x - \phi_2) \quad (1)$$

Application of the classical wave paddle control for the generation of these bichromatic waves will induce a secondary wave motion at the difference frequency, which may consist of the following four components:

- incident bound wave :  $\zeta_{ib} \cos(\Delta\omega t - \Delta kx - \phi_{ib})$
- incident free wave :  $\zeta_{if} \cos(\Delta\omega t - \kappa x - \phi_{if})$
- reflected bound wave :  $\zeta_{rb} \cos(\Delta\omega t + \Delta kx - \phi_{rb})$
- reflected free wave :  $\zeta_{rf} \cos(\Delta\omega t + \kappa x - \phi_{rf})$

where  $\Delta k$ , the wave number of the bound waves, equals  $k_1 - k_2$ , and the wave number of the free waves  $\kappa$  is coupled to the wave group frequency  $\Delta\omega$  by the dispersion relation:

$$(\Delta\omega)^2 = (\omega_1 - \omega_2)^2 = g\kappa \tanh \kappa d \quad (2)$$

Ottesen Hansen (1978) shows that the amplitude of a bound wave is proportional to the product of the amplitudes of the corresponding primary waves. For the present study the 1:20 slope results in reflection coefficients for the primary waves of a few per cent. Therefore, the amplitudes of the reflected bound waves are negligible.

One of the objectives of the study was to measure the amplitude of the outgoing free long wave generated in the surf zone. To be able to do this, it is essential that all reflected low frequency energy is related to the outgoing free long wave only. However, without taking any precautions, and in spite of the mild slope of the beach, any incident free long wave will almost fully reflect due to its low steepness. Consequently, incident free long waves have to be avoided. In a wave channel there are two main reasons for the occurrence of these waves. Firstly, if a wavemaker is programmed to produce the primary wave system without the associated secondary bound wave, the boundary conditions at the paddle face are not fulfilled to second order. This results in the generation of spurious free long waves propagating onto the beach. Ottesen Hansen et al. (1980) give the theoretical expressions for these waves. Barthel et al. (1983) describe in detail how to correct the control signal for the wave paddle to second order, and verify this method, both for bichromatic wave systems and random waves. Secondly, free long waves reflected from the surf zone will re-reflect from the paddle face, resulting in another incident free wave. To prevent this, a recently developed device for active wave absorption has been applied. The special features of this electronic compensation are the capability of absorbing both primary and secondary waves and the independency of the mass of the paddle on the absorbing capacity.

The effect of second-order wave generation as well as active wave absorption on the resulting wave motion in the wave channel is illustrated in Figures 2a to 2d. These figures show respectively, from above to below, the control signal for the wave paddle, the wave signal recorded by the middle probe, and filtered low frequency signals at three increasing distances from the paddle (see Figure 1). Comparing these figures the effect of active wave absorption is obvious. The low frequency recordings obtained without absorption show instabilities - partly due to resonances in the channel - which almost completely vanish in the recordings obtained with absorption. An extra advantage of active wave absorption is the drastic reduction in time for a test series. Without absorption the low frequency water motion continues quite some time after the wavemaker is stopped, whereas with absorption one test can be started almost immediately after another. The effect of second-order wave generation can be seen best in the left-hand side of the figures, when the reflected waves are not yet interfering with the incident ones. If the wave generation is restricted to first order, the earliest long waves have different amplitudes at different positions. This is due to the interaction between the bound waves and the spurious free waves, which have different phase velocities. As shown in Figures 2c and 2d second-order wave generation results in equal amplitudes of the earliest waves at all positions, indicating that the spurious free waves are suppressed effectively.

#### 4 MEASURING PROCEDURES

Water surface elevations were measured by means of resistance type wave gauges. Although incident bound waves and reflected free waves can be distinguished using two probes only, it was decided to use a set of three probes to check the effectiveness of the suppression of the incident free waves. These probes were positioned above the horizontal bed at equal distances  $D$  (see Figure 1).

The analysis to obtain surf beat amplitudes is restricted to waves having the wave group frequency  $\Delta\omega$ . Thus, at a specific position  $x = x_A$  in the channel, the low frequency surface elevation  $\zeta_A$  can be written as:

$$\zeta_A = \zeta_{ib} \cos(\Delta\omega t - \Delta kx_A - \phi_{ib}) + \zeta_{if} \cos(\Delta\omega t - \kappa x_A - \phi_{if}) + \zeta_{rf} \cos(\Delta\omega t + \kappa x_A - \phi_{rf}) \quad (3)$$

The recorded signals were low-pass filtered. To obtain the local amplitudes at the fundamental, the low frequency signals were decomposed by means of a Fourier analysis. The Fourier series of the signal recorded at  $x = x_A$  can be written as:

$$\zeta_A = \frac{a_{0,A}}{2} + a_A \cos \Delta\omega t + b_A \sin \Delta\omega t + \dots \text{higher harmonics} \quad (4)$$

For positions  $x = x_B$  and  $x = x_C$  similar equations can be formulated, resulting in a set of 6 equations. For the applied analysis it is essential that the Fourier series refer to the identical time interval of the simultaneous signals. Choosing the origin of the  $x$ -axis at the

Fig. 2 Typical recordings for different wave-paddle control techniques

c. no active wave absorption; second order wave generation

d. with active wave absorption; second order wave generation

Fig. 2 (contd.) Typical recordings for different wave-paddle control techniques

middle probe, i.e.  $x_B = 0$ , after some trigonometry the following expressions can be obtained:

$$C_{ib} = \zeta_{ib} \cos \phi_{ib} = \frac{(a_A + a_C)/2 - a_B \cos \kappa D}{\cos \Delta \kappa D - \cos \kappa D} \quad (5)$$

$$S_{ib} = \zeta_{ib} \sin \phi_{ib} = \frac{(b_A + b_C)/2 - b_B \cos \kappa D}{\cos \Delta \kappa D - \cos \kappa D} \quad (6)$$

$$C_{if} = \zeta_{if} \cos \phi_{if} = \frac{(-b_A + b_C)/2 + a_B \sin \kappa D - C_{ib}(\sin \Delta \kappa D + \sin \kappa D)}{2 \sin \kappa D} \quad (7)$$

$$S_{if} = \zeta_{if} \sin \phi_{if} = \frac{(a_A - a_C)/2 + b_B \sin \kappa D - S_{ib}(\sin \Delta \kappa D + \sin \kappa D)}{2 \sin \kappa D} \quad (8)$$

$$C_{rf} = \zeta_{rf} \cos \phi_{rf} = a_B - C_{ib} - C_{if} \quad (9)$$

$$S_{rf} = \zeta_{rf} \sin \phi_{rf} = b_B - S_{ib} - S_{if} \quad (10)$$

The amplitudes of all long waves can be simply obtained from these expressions. The Fourier series were determined for 20 individual subsequent long waves. In this way, the average value as well as the standard deviation of  $\zeta_{ib}$ ,  $\zeta_{if}$ , and  $\zeta_{rf}$  could be obtained. Subsequently, the test was repeated with an adjusted control signal for the wave paddle. An extra long wave, having the same amplitude as the free incident wave obtained in the former test but with a phase shift of  $180^\circ$ , was generated. The test with an optimum control of the wave paddle, in other words the test resulting in the lower computed amplitude of the incident free wave - in most cases some tenths of a millimeter -, was selected for the final analysis. Sometimes, the original control was even better than the second one, suggesting that at the optimum control, the computed amplitude of the incident free wave should be considered as an indicator for the accuracy of the applied analysis instead of being considered as a real wave. Therefore, for the final analysis, it was assumed that there is no incident free wave at all, which means that the second term at the right-hand side of equation (3) is omitted. Now, the recordings of two probes suffice to compute  $\zeta_{ib}$  and  $\zeta_{rf}$ . Choosing the origin of the x-axis in between probes A and B yields the following set of equations:

$$C_{ib} = \zeta_{ib} \cos \phi_{ib} = \frac{(a_A + a_B) \sin(\kappa D/2) - (b_A - b_B) \cos(\kappa D/2)}{2 \sin\{(\kappa + \Delta \kappa)D/2\}} \quad (11)$$

$$S_{ib} = \zeta_{ib} \sin \phi_{ib} = \frac{(a_A - a_B) \cos(\kappa D/2) + (b_A + b_B) \sin(\kappa D/2)}{2 \sin\{(\kappa + \Delta \kappa)D/2\}} \quad (12)$$

$$C_{rf} = \zeta_{rf} \cos \phi_{rf} = \frac{(a_A + a_B)/2 - C_{ib} \cos(\Delta \kappa D/2)}{\cos(\kappa D/2)} \quad (13)$$

$$S_{rf} = \zeta_{rf} \sin \phi_{rf} = \frac{(b_A + b_B)/2 - S_{ib} \cos(\Delta kD/2)}{\cos(\kappa D/2)} \tag{14}$$

All presented results are obtained from the above set of equations.

A fourth probe was positioned above the slope just in front of the location where the highest waves break. In this way, it could be checked if the wave groups had the same modulation just before breaking as above the horizontal bed. No measuring devices were installed within the surf zone.

5 TEST PROGRAMME

The test conditions were selected to enable verification of the theoretical model presented by Symonds et al. (1982). They show that the zone between the minimum and the maximum positions of the breakpoint acts as a forcing region. Free long waves at the group period and harmonics are radiated away from this region both shoreward and seaward. As the waves which propagate shoreward are assumed to be fully reflected at the shoreline, standing waves are produced inshore of the forcing region. The reflected waves move through the forcing region and radiate seaward. Thus, the amplitudes of the resultant outgoing waves depend on the relative phase between the reflected waves and the waves radiated seaward directly from the forcing region. This is shown schematically in Figure 3 for the wave at the group frequency. The amplitude of this wave at the outer limit of the forcing

Fig. 3 Schematic representation of the results obtained by Symonds et al. (1982)

region, normalized by the variation about the mean of the steady state set-up, appears to be a function of the parameter  $\chi$  and the modulation ratio of the incident primary waves  $\hat{\eta}_1 / \hat{\eta}_2$ . The parameter  $\chi$  depends on the mean distance  $X$  between the breakpoint and the shoreline, the group frequency  $\Delta\omega$ , and the beach slope  $\beta$ .

Table 1 presents the test programme, which was divided up into five test series. For the tabulated values of  $\chi$  the mean position of the breakpoint had to be estimated. This quantity was obtained using the same equation as applied by Symonds et al.:

$$X = \frac{\hat{\eta}_1}{\gamma \tan \beta} \quad (15)$$

where the ratio of wave amplitude to water depth at breaking has been assumed to be  $\gamma = 0.4$  (see Bowen et al., 1968). The results of Symonds et al. imply among other things that the outgoing free wave does not depend on the individual primary wave frequencies  $\omega_1$  and  $\omega_2$ , but on their difference  $\Delta\omega$  only. To check this, series A and B, each repre-

sents one specific wave frequency  $\omega_1$ , were designed to cover the same set of values for the parameter  $\chi$ . In these series the variation of  $\chi$  has been obtained by a change of  $\omega_2$ . In series C and D the wave frequencies are fixed and, instead, the amplitudes of the primary waves are changed. In the model of Symonds et al. the breakpoint is taken to vary sinusoidally, implying a weak modulation of the primary wave system. Therefore, series A, B, C and D all have the same low ratio of modulation ( $\hat{\eta}_2/\hat{\eta}_1 \approx 0.2$ ). Of course, in nature far higher ratios are encountered. To obtain an idea of the effect of such modulations, series E was added to the programme.

Fig. 7 Comparison of measured bound waves with theory, all tests

6 RESULTS

For all the test series, the measured amplitudes of the incident bound long waves are shown in Figures 4 to 6. The solid lines in these figures represent the theoretical values as given by Ottesen Hansen (1978). Both for weakly and almost fully modulated wave signals, the agreement between measured and theoretical values is quite satisfactory. According to the theory, the amplitude of the bound long wave should be proportional to the product of the primary wave amplitudes  $\hat{\eta}_1$  and  $\hat{\eta}_2$ . As shown in Figure 6, this is confirmed by the measurements. In Figure 7 the measured values are plotted against the theoretical ones for all test conditions. The high correlation shown in this figure gives an indication of the accuracy of the measuring procedure applied.

Longuet-Higgins and Stewart (1962) have suggested that the incident bound wave is reflected from the surf zone and radiated seaward as a free long wave. Using this concept, one would expect some correlation between both waves. However, as shown in Figure 8, the correlation is very poor. Moreover, for some conditions the reflected wave is even higher than the incident one. Both results support the relevance of the model of Symonds et al.

Fig. 8 Relation between incident bound long waves and outgoing free long waves

Fig. 9 Measured outgoing free long waves for weakly modulated primary waves,  $\hat{\eta}_2/\hat{\eta}_1 = 0.2$

Fig. 10 Measured outgoing free long waves for almost fully modulated primary waves,  $\hat{\eta}_2/\hat{\eta}_1 = 0.8$

The measured amplitudes of the outgoing free waves are shown for each test series separately in Figures 9 to 11. The barred lines on these figures merely connect the measured values; they do not refer to any theory. Figure 9 shows that the results for series A and B compare quite well with one another, which is again in accordance with the model of Symonds et al. This model is also qualitatively confirmed by the results shown in Figure 11. This figure shows clearly that increasing the primary wave amplitudes, or, in other words, increasing the mean position X of the breakpoint, does not necessarily result in an increase of the amplitude of the outgoing wave. The results of the tests with almost fully modulated primary waves show the same trend as that found for the weakly modulated waves (see Figure 10).

To be able to compare the experimental results with the model of Symonds et al. in a quantitative way, some assumptions have to be made. Firstly, the mean position X of the breakpoint was not measured. This quantity was obtained using equation (15). Secondly, the experimental results are obtained at a water depth of 0.50 m, whereas the theoretical results refer to the amplitude of the outgoing wave at the outer limit of the wave breaking region. This amplitude was estimated as follows:

$$\hat{\zeta}_{rf,b} = \left(\frac{0.50}{d_b}\right)^{\frac{1}{2}} \cdot \hat{\zeta}_{rf} = \left(\frac{0.50 \gamma}{\hat{\eta}_1 + \hat{\eta}_2}\right)^{\frac{1}{2}} \cdot \hat{\zeta}_{rf} \tag{16}$$

Fig. 11 The effect of the average amplitude of the primary waves on the outgoing free long wave,  $\hat{\eta}_2/\hat{\eta}_1 = 0.2$

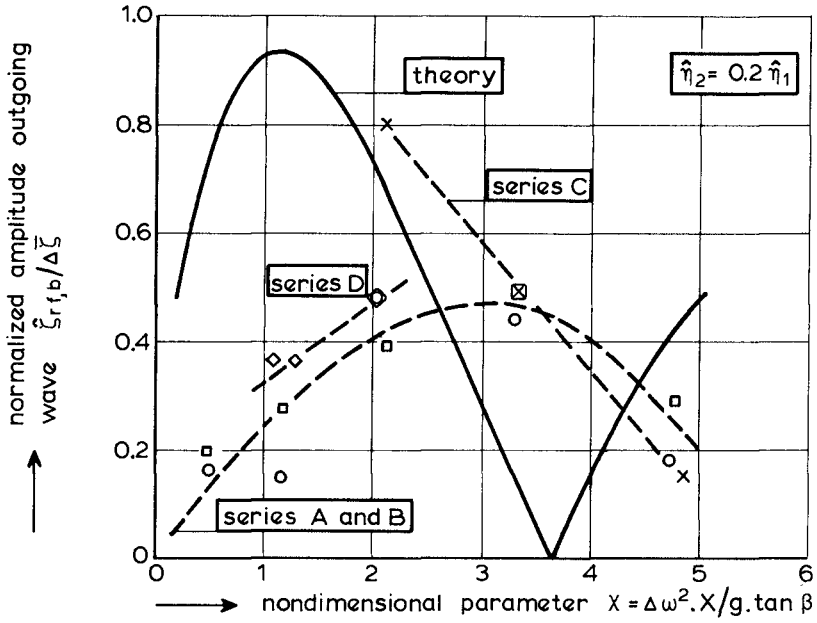

Fig. 12 Comparison of normalized outgoing long waves with the theory of Symonds et al., weakly modulated primary waves

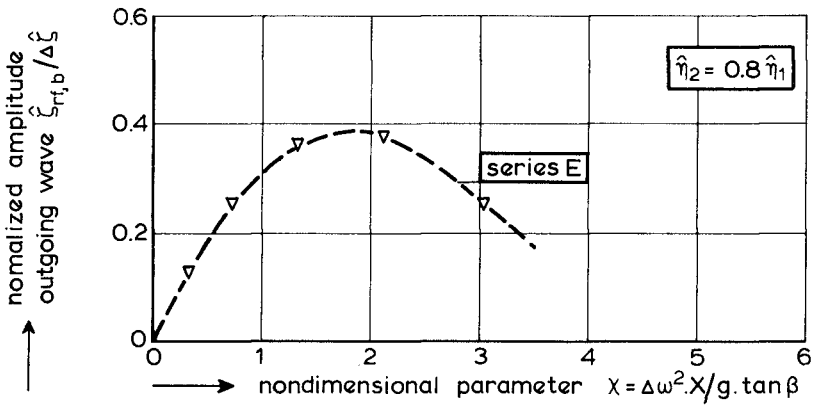

Fig. 13 Normalized outgoing long waves for almost fully modulated primary waves

Finally, the theoretical results are normalized by the variation about the mean of the set-up at the shoreline which would be obtained for monochromatic waves with the same amplitudes. Again in accordance with Symonds et al. this variation has been estimated to be:

$$\Delta \bar{\zeta} = \frac{3}{2} \gamma \hat{\eta}_2 \quad (17)$$

Using equations (15) to (17), the experimental results can be plotted against the theory. Figure 12 shows, in spite of a qualitative agreement, that the deviations are significant. It is presumed that this is due to the assumptions underlying the conceptual model. For instance, the bound wave associated with the incoming wave groups, has not been included in the model. Moreover, the formulation precludes any modulation of the primary waves inside the surf zone. Another major assumption of the theoretical model is that the long waves propagating shoreward are supposed to be fully reflected at the shoreline.

Symonds et al. also assume a sinusoidal variation of the break-point, which restricts a qualitative comparison between the theory and experiments to those tests carried out with weakly modulated primary waves. Nonetheless, for comparison, the normalized results of series E are presented in Figure 13. Studying Figures 12 and 13 reveals that the effect of the ratio of wave modulation qualitatively agrees with the theoretical trend presented in Figure 3.

## 7 CONCLUSIONS

Two-dimensional surf beat induced by bichromatic waves has been investigated experimentally. The following conclusions can be drawn:

- The wave action at the wave group frequency can be reproduced correctly, applying a sophisticated control of the wave paddle, including second-order wave generation and active wave absorption at the paddle face.
- Two-dimensional surf beat induced by incident wave groups should be considered as the result of two wave systems, viz. incident bound waves, propagating at the group velocity, and outgoing free waves, which are generated in the surf zone.
- The experiments confirm the theoretical values for the amplitude of the incident bound wave, which is often termed as set-down, as obtained with a Stokes expansion of the wave equations to second order.
- There is no correlation between the incident bound waves and the outgoing free waves.
- The theoretical model of Symonds et al. and the experimental results for the free waves, which are generated in the surf zone and radiated seaward, agree qualitatively.

## CHAPTER FIFTY

### THE PROBABILITY CHARACTERISTICS OF WAVES AND WAVE PRESSURES AT A VERTICAL BREAKWATER

Huang Peiji\* and Zhao Binglai\*\*

#### ABSTRACT

In this paper, under the condition of waves in front of a breakwater being not broken, studies were made on the characteristics of probability distribution of waves and wave pressures, the regularity of the spectral component attenuation with depth and the constitution of the high frequency band of wave pressure spectrum.

The distributions of wave heights in front of a vertical breakwater, the range of wave pressure fluctuation at different subsurface levels, and the wave periods have shown that they are practically invariable with depth and can be determined theoretically. The spectral constitution of wave pressure field and the regularity of attenuation of spectral components were analyzed at the vertical breakwater, and a new expression describing the equilibrium range of wave pressure spectrum was obtained.

#### 1. INTRODUCTION

Along with the exploitation of the offshore oil fields and marine minerals as well as with the advance of marine navigation and transportation, it is necessary to build up much more marine structures or wharfs. As for those structures, the vertical-wall type marine structure is still adopted widely in the engineering construction at present. In order to select the optimum conditions for structure of this kind, we must research on the probability characteristics of the waves and wave pressures in front of it. This work directly concerns the calculations of the stability and the strength for such structure. It is very important to investigate, under natural conditions, the probability characteristics of the waves and the wave pressures in front of it.

Since the late 1960's, the effects of sea wave on the vertical breakwater have been studied and observed abroad(9, 10,12). In recent years, we have observed the wave and its action on the vertical breakwater at a certain harbour(1,3). The breakwater of this harbour is situated in the open sea ,

---

First Institute of Oceanography, National Bureau of Oceanography, P.O. Box 98, Qingdao, China

and its body which is a caisson structure was placed on the basement. The sea bottom is comparatively even. The altitude of the basement is -6.0m and the tidal range 3--4m. The depth of water in front of the breakwater may reach about 10m at high tide. The observation station was built 40m from the head of this breakwater. The sensors which are used for measuring the wave pressure were mounted at different heights of the breakwater side facing the sea (its respectively altitudes are -5.2, -2.2, -0.2, +1.8, +2.8, and +3.8m, the altitude is regarded as zero at the tidal datum plane and is positive on the above and negative in the below). The resistance wire staffs are mounted on the breakwater side and on a location where it is 450m far from the breakwater in the open sea. The wave pressures at different heights on the breakwater side, the water surface elevations in front of it and the incident waves are synchro-recorded altogether continuously.

In this paper, as to the successive recordings of the waves and the wave pressure, we have carried on statistical and spectrum analyses on the basis of actually measured data in front of the vertical breakwater in this harbour. Meanwhile, we also investigated, without the wave breaking condition in front of the breakwater, the probability distribution characteristics of the wave and the wave pressure, the characteristics of the component of the wave pressure spectra attenuated with the depth, and the constitution of the wave pressure spectra in front of the breakwater.

## 2. THE PROBABILITY DISTRIBUTION OF WAVES AND WAVE PRESSURES IN FRONT OF THE BREAKWATER

The waves are random phenomena, the forces resulted from them also exhibit the stochastic behaviour. Therefore, when the interaction between the waves and the breakwater takes place, the wave height and the total pressure acted upon the breakwater, the intensity of pressure at any point on it and other dynamic parameters which characterize the action of wave on the breakwater, all these may be regarded as being of random quantities with the definite distribution law. In the case of deep water, this distribution law has ever been investigated by some researchers. They thought that the wave height in front of the breakwater, the range of wave pressure fluctuation at different heights on the breakwater, the crest value and the trough value of the total pressures all follow the Rayleigh Distribution(9,11). In the case of shallow water, this problem has not been studied yet.

### 2.1 The cumulative probability distribution function for both the wave height in front of the vertical breakwater and the range of wave pressure fluctuation at different heights on the breakwater

In the case of deep water, both the wave height in front of the breakwater and the range of wave pressure fluctuation

at any point on it follow the Rayleigh Distribution. In the case of shallow water, the wave height is no more in agreement with the Rayleigh Distribution. According to reference(2), we may obtain the following expressions:

$$F(h) = \exp \left[ - \Gamma^{K(H^*, B)} \left( \frac{1}{K(H^*, B)} + 1 \right) \left( \frac{h}{\bar{h}} \right)^{K(H^*, B)} \right], \quad (1)$$

$$K(H^*, B) = (5 - B)/(2 - 1.5H^*), \quad (2)$$

$$B = \begin{cases} \bar{C}/U = \bar{\tau}g/2\pi U, & \bar{C} \leq U \\ 1, & \bar{C} > U \end{cases}, \quad (3)$$

$$H^* = \bar{h}/d, \quad 0 \leq H^* \leq 0.5$$

here  $\bar{h}$  is the average wave height,  $\bar{\tau}$  the average wave period,  $d$  the water depth,  $U$  the wind velocity,  $g$  the gravitational acceleration,  $H^*$  the shallow water factor,  $B$  the stage factor of wind-wave growth. When  $B=1$ , the wind wave appears in a fully developed state. It is evident that the expression (1) is the Rayleigh Distribution, while  $H^*=0$ , and  $B=1$ .

In order to find out which kind of distributions will be reflected in the actually measured data, first of all, we have respectively computed the cumulative curve of the nondimensional wave height ( $h/\bar{h}$ ) and the nondimensional wave pressure range ( $p/\bar{p}$ ) at every recording, and then determined the values of the nondimensional wave height and the nondimensional wave pressure range which correspond to the cumulative probabilities as 1, 5, 10, 20, 30, 50, 70, and 90%. By making use of the values of every cumulative probability mentioned above, we have computed the points corresponding to the value  $K$  by the expression(2), and then plotted them on Fig. 1.

Fig. 1a illustrates the distribution of the actually measured wave heights on the vertical breakwater and Fig. 1b illustrates that of the range of wave pressure fluctuation measured at the basement layer of the breakwater. Other mediate layers have similar figures, too.

As seen from the above figures, the distances between the points of the actually measured data quite approximate the corresponding values of the theoretical cumulative probability in expression(1). Thus we may think that, in the case of shallow water, the wave height at the vertical breakwater and the wave pressure range at different heights on it are in agreement with the distribution law in expression(1). The distribution of wave pressure range, as a matter of fact, will not vary with the altitude of the measured points.

## 2.2 The cumulative distribution function of the surface wave period in front of the vertical breakwater and the wave pressure period at the different heights on it

Regarding the distribution of the wave period, analyses (6,8) of the researchers and results observed indicate that, under the first order approximation, the distribution curves

Fig. 1a Comparison of the empirical cumulative distribution (dots) of wave height with the value (line) calculated by eq.(1).

Fig. 1b Comparison of the empirical cumulative distribution (dots) of range of wave pressure fluctuation with the value (line) calculated by eq.(1).

of the nondimensional wave periods for the wind waves and the swell before the breaking area are, in fact, a constant no matter how deep the water is. Its distribution function is given as follows:

$$F(\tau) = \exp \left[ -\Gamma \left( \frac{5}{4} \right) \left( \frac{\tau}{\bar{\tau}} \right)^4 \right]. \quad (4)$$

To analyse the distributions of both the wave period in front of the breakwater and the wave pressure period at different heights on it, we have plotted the experimental cumulative distribution on the special coordinate paper such as Fig.2, whose curves denote the expression(4).

In Fig. 2,  $Z=0$  represents the distributions of the surface wave period in front of the vertical breakwater, and  $Z=-5.2\text{m}$ , the distributions of the wave pressure periods at the basement layer of the breakwater. There are also similar distribution for the mediate layers.

After analysing the experimental cumulative distributions of periods for the wave and wave pressure, it shows that, in the case of shallow water, the distribution of wave periods and wave pressure periods in front of the vertical breakwater may be calculated by expression(4), and that the distribution of period for the wave pressure does not vary with the altitudes of the measuring points practically.

Fig. 2a,b The comparison of the experimental cumulative distribution of wave period and wave pressure period(points) with the theoretical cumulative distribution(curves).

### 2.3 The cumulative distribution function of the total pressure

The total pressure is one of the most important characteristic quantities for the wave acted on the vertical breakwater. At present, research on the total pressure is mainly

based on the analysis to the values of crest and trough of single wave hitted against the breakwater.

To analyse the distribution characteristics of the total pressure, we have calculated the crest value,  $R^+$ , and trough value,  $R^-$ , of the total pressure corresponding to the phases of every wave crest and wave trough based on 27 successive recordings. Then we obtained the cumulative distribution curves of the total pressures for the nondimensional crest ( $R^+_i/\bar{R}^+$ ) and trough ( $R^-_i/\bar{R}^-$ ). Furthermore, we determined the values of the total pressures of the nondimensional crest and trough corresponding to cumulative probability of 1, 5, 10, 20, 30, ..., 90%. According to the following expression(5)

$$F(R^\pm) = \exp \left[ -\Gamma \frac{5-B}{2-1.5H^*} \left( \frac{2-1.5H^*}{5-B} + 1 \right) \left( \frac{R^\pm_i}{\bar{R}^\pm} \right)^{(5-B)/2-1.5H^*} \right], \quad (5)$$

we computed the above mentioned total pressures of the nondimensional crest value and trough value for every cumulative probability as well as the relative differences between them and the actually measured value. Thus we have respectively made statistics of the occurrence probability for the relative differences within the given range (-5--+5%, -10--+10%). Then the mean absolute difference was calculated and the maximum relative differences corresponding to cumulative probability were obtained. Their results are shown in table 1.

Table 1

relative error		cumulative probability %							
		1	5	10	20	30	50	70	90
-5--+5%	$R^+$	100	100	100	100	100	100	100	81.48
	$R^-$	98.30	100	100	100	100	100	98.30	74.07
-10--+10%	$R^+$	100	100	100	100	100	100	100	96.30
	$R^-$	100	100	90	100	100	100	100	100
maximum relative error	$R^+$	-4.109	3.84	4.32	4.96	4.09	4.211	4.34	10.25
	$R^-$	7.272	3.261	3.012	3.543	4.065	-4.211	5.633	-8.888
average absolute error	$R^+$	0.030	0.022	0.0237	0.0200	0.0248	0.014	0.0155	0.014
	$R^-$	0.035	0.0229	0.0203	0.0174	0.0181	0.0155	0.0155	0.0163

Table 1 shows that the occurrence probability corresponding to every cumulative probability is quite high within the relative differences at -5--+5%, while the lowest is 74.07%. As for the mean absolute difference, its maximum is not more than 0.035. Therefore, it is deemed that the distribution function of the total pressures for the crest and trough of the wave acted upon the vertical breakwater in shallow water may be calculated by expression(5) and may be of identical distribution law of wave heights in front of the vertical breakwater.

As for the above cumulative distribution function of every parameter, the analysed results are of importance. In the case of shallow water, making use of these distribution law, we might obtain the required values of the arbitrarily given cumulative probability by the average wave height known in front of the vertical breakwater, the mean range of wave pressure fluctuation at different heights on it, the mean wave period and the mean total pressure. They are very useful to the engineering calculations.

### 3. ATTENUATION OF WAVE PRESSURE WITH DEPTH

The problem of the wave and the wave pressure attenuated with depth was first investigated on the open sea and ocean(6,13) or in the offshore area without any obstacles(6). Since the beginning of the 1970's, there were research results of both the waves and the wave pressures attenuated with the depth in front of the vertical breakwater under the deep water condition(9,11). On the basis of the actually measured data, we have analysed and investigated the regularity of the wave pressure spectral component attenuated with the depth and the constitution of the high frequency portion of the wave pressure spectrum in front of the vertical breakwater.

#### 3.1 The spectral component of wave pressure attenuated with depth

According to the ordinate data picked out by the same time interval( $t=0.75\text{sec.}$ ) for both the wave profile in front of the breakwater and the wave pressure fluctuations at different heights on it, we have obtained their spectrum densities respectively.

We regarded the frequency spectrum of the wave pressure at the levels  $-0.2$ ,  $-2.2$ , and  $-5.2\text{m}$  as original data used for analysing the spectral component of the wave pressure attenuated with the depth, then we compared the actually measured results with that of the wave theory for small amplitude at the limited depth. The attenuation coefficient of spectral component varied with the depth may be obtained, within the limited depth, by the wave theory

$$r(\omega, Z, d) = \text{ch}k(d + Z) / \text{ch}k(d + Z_0), \quad (6)$$

where  $d$  stands for water depth in front of the vertical breakwater,  $k$  stands for wave number; it has to be satisfied with the expression as follows:

$$\omega^2 = gk \text{th} k d. \quad (7)$$

Fig.3 shows the comparison of the measured attenuation coefficient of wave pressure spectral component at the level of water layers being  $-2.2$ , and  $-5.5\text{m}$  respectively with the values calculated(curve) by the expression(6).

Fig.3 Comparison between the measured attenuation coefficient(dots) of wave pressure spectral components and the result(curve) of small amplitude wave theory

The above comparison shows that, within the whole range of  $0.5 < kd < 1.15$ , the low frequency components of the wave pressure spectra attenuated with the depth may be considered coincidence with the results of small amplitude wave theory for a limited depth. while  $kd > 1.15$ , the spectral component (corresponding to the high frequency portion of the wave pressure spectra) attenuated with the depth has a more even trend. This is due to the non-linear effect of the interaction between the wave and the vertical breakwater.

3.2 Equilibrium range of wave pressure spectrum varied with the depth

It is well known that there is a most important and specific hypothesis for the wind wave spectrum, namely, while the frequency is high enough, there is a range agreed with Phillips' equilibrium range(4,5,7). Within the equilibrium range, the wave energy is only related to the physical parameters characterized the mechanism of the wave crest breaking, but is independent of external factors of wind wave generation. If we only consider this range, in which the sea-water surface tension and sea-water molecular viscosity have no effect on the wave frequency, the constitution of the equilibrium range only depends on the frequency and the gravitational acceleration. Basing ourselves on the dimensional analysis, we may obtain:

$$S(\omega) = \beta g^3 \omega^{-5}, \tag{8}$$

where  $\beta$  is nondimensional constant, adopted as  $7.8 \times 10^{-3}$ (7).

At present, most measured wind wave spectra have primarily verified the expression(8) of the equilibrium range

worked out by Phillips(5,7). Until now we have studied very little of constitution of high frequency portion for the wave pressure spectra at different depth below the sea surface. In 1973, Цыплухин and Попов (14) analysed the wave pressure spectra at different depths on the vertical breakwater in the harbours of Сочи and Месхарис. They pointed out that, in the expression(8), the power of frequency varied with the depths from 5.0 of  $Z=-0.6m$  to 8.0 of  $Z=-11.2m$ . Such a result show that it is not proper to analyse by the dimension because the dimension of the spectrum density is varied with the power of the frequency in the expression(8).

We intend to investigate the constitution of the high frequency portion of the spectrum for both the wave in front of the breakwater and the wave pressure at different depth on it. We have plotted the points of the spectrum density values actually measured for the wave in front of the breakwater and the wave pressures at different depth on it onto the logarithmic paper, such as Fig. 4a shows the wind wave spectra in front of the breakwater, and Fig. 4b the wave pressure spectra at the level of  $-2.2m$ .

Fig. 4a, we see that the high frequency portion of the wind wave spectra in front of the vertical breakwater may be described by the expression(8)(rough inclined line in the Fig. ). From Fig. 4b, we see that the high frequency portion of wave pressure spectra almost parallelly deviates from the rough lines with the increase in depth. From this we may think that within the constitution of the equilibrium range of wave pressure spectrum, the power of the frequency is still equal to 5, and does not vary with the increase in depth, but its spectrum density values may get smaller with the increase in depth. From the expression(8), we may obtain:

$$\beta = S(\omega) \cdot \omega^5 / g^2, \quad (9)$$

Now we calculate the actually measured  $\beta$  values by expression(9), and then plot it (Fig. 5).

As an example, Fig. 5 gives the  $\beta$  values at the level of  $-0.2m$  through many observations; we can obtain similar diagram at other water levels, too. Since the tidal levels are not the same at each observation, the actual depths in every observation also are not the same at the level of  $-0.2m$ . Thus in Fig. 5, the  $\beta$  values measured in every observation always have some difference. While  $\omega > \omega_{max}$ , however, the  $\beta$  values actually measured in each time do not vary with the frequency primarily, and vary up and down at some  $\beta$  value. This is due to the errors in the observation and the spectrum analysis. As a result, after evaluating the average value of  $\beta$  actually measured at different depth, Fig. 6 is plotted with the average value of  $\beta$  as ordinate versus the nondimensional parameter  $Z\omega_{max}^2/g$  as abscissa. Here  $\omega_{max}$  is the spectral peak frequency.

Fig. 6 shows that, while the sea surface  $Z=0$ , the ave-

Fig. 4a,b The observed spectra of wave and wave pressure fluctuations at a vertical breakwater, declined line is expression(8).

Fig. 5 The values of wave pressure spectra at level  $Z = -0.2m$ .

Fig. 6 The relationship between the measured value  $\beta$  and the nondimensional parameter  $Z\omega^2 \max/g$ , of which the curve from the eq.(10).

range value of  $\beta$  is  $7.8 \times 10^{-3}$ . Since the value of  $\beta$  get smaller with the increase of  $Z\omega_{max}^2/g$ , we can obtain:

$$\beta = \beta_0 \exp[-4\pi Z\omega_{max}^2/5g], \quad Z\omega_{max}^2/g \leq 0.75 \quad (10)$$

where  $\beta_0 = 7.8 \times 10^{-3}$ .

The above analyses, indicate that the equilibrium range of the wave pressure spectra at different depth on the vertical breakwater varied with depth may be described by the following expression:

$$S_p(\omega) = \beta_0 \omega^{-5} g^2 \exp[-4\pi Z\omega_{max}^2/5g], \quad (11)$$

#### 4. CONCLUSION

The results of this study are concluded as follows:

1. In the case of shallow water, the cumulative distribution of range of wave pressure fluctuation at different heights on the vertical breakwater actually does not vary with the heights of the measuring points on the breakwater, and it may be described by the expression(1). The cumulative distribution of both the crest value and the trough value of total pressure acted upon the breakwater agrees with that of wave height, and it may be calculated by expression(5).

2. The cumulative distribution of wave period also does not vary with the heights of measured points on the breakwater; it just follows the distribution law of expression(4).

3. The analysis of the wave pressure spectra at different altitudes in front of the vertical breakwater shows that within the whole range of  $0.5 < kd < 1.15$ , the low frequency portion of the wave pressure spectra attenuated with depth may be calculated according to the small amplitude wave theory within a limited depth. When  $kd > 1.15$ , the spectral component of the wave pressure (corresponding to the high frequency portion of the wave pressure spectrum) attenuated with depth has a more even trend. Thus we may think that it related to the nonlinear effect of the interaction between the wave and the vertical breakwater. In order to obtain a clear explanation, it is necessary to establish a nonlinear model of the interaction between the irregular wave and the vertical breakwater.

4. The high frequency portion of the spectra for both the wave in front of the vertical breakwater and the wave pressure at different altitudes on it agrees with the Phillips' equilibrium range. With the increase in depth, the power of the frequency in the constitution of the equilibrium range is basically unchanged, but the value of  $\beta$  may get smaller with the increase in the nondimensional parameter and can be described by the expression(10).

## CHAPTER FIFTY ONE

### WAVE MEASUREMENT WITH DIFFERENTIAL PRESSURE GAUGES

by

Kevin R. Bodge<sup>1</sup> and Robert G. Dean<sup>2</sup>, M. ASCE

#### ABSTRACT

The potential error of estimating the small pressure gradient under a directional wave field through the subtraction or comparison of relatively large total-head signals from adjacent pressure transducers in an array is avoided through the use of differential pressure transducers which measure directly the pressure gradients. A device which utilizes four differential pressure transducers placed orthogonally about one absolute pressure transducer, (the "DPG"), was developed and field-tested at the U.S. Army Corps of Engineers Coastal Engineering Research Center Field Research Facility, Duck, North Carolina. The first five directional Fourier coefficients of the directional ocean spectra were developed from the DPG data, and although no other in situ directional wave monitors were available for comparison, the directional peak determined from the DPG agreed well with simultaneous High Frequency (HF) radar data. The DPG instrument is about one-half the size and less than one-sixth the weight of conventional pressure sensor arrays. The field establishment of the orientation of directional-measuring instruments is also discussed.

#### 1. INTRODUCTION

The "pressure-slope array" is a commonly used instrumentation technique to make in-situ point estimates of wave directionality. Such systems traditionally use a subsurface array of transducers which simultaneously measure the absolute pressure at a number of fixed locations under the wave field. Whereas the use of one pressure sensor to obtain wave height requires the measurement of the dynamic pressure sensed by a single gauge, the use of an array of pressure sensors to obtain wave direction requires intercomparison of the dynamic pressures sensed at adjacent gauges. The direction can be estimated by a number of methods. One is to cross-correlate each of the sensors' signals directly (2). Another is to calculate the

<sup>1</sup>Ph.D. Candidate, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611; Formerly, Research Assistant, Department of Civil Engineering, University of Delaware, Newark, DE 19711.

<sup>2</sup>Graduate Research Professor, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611; Formerly, Professor, Department of Civil Engineering and College of Marine Studies, University of Delaware, Newark, DE 19711.

pressure gradients between the sensors and cross-correlate this estimate of slope (4). In any case, the analysis methods are concerned with the difference in pressures sensed between points under the wave field. For a typical array, where pressure sensors might be spaced about 20 feet (6 m) apart, the instantaneous differences in the sensors' records due to wave action can be very small relative to the large total-head values that the sensors are required to record. Hence the pressure gradient across the array is calculated by comparing two large numbers in order to generate a very small number. This technique can lead to inherent inaccuracies, for example due to minor non-linear response or different noise levels in the sensors. The difference between adjacent sensor signals can be increased by enlarging the distance between transducers -- at the expense of a more physically unmanageable array, greater error in the assumption of linear surface slope, and possibly introduction of directional ambiguities for the higher frequencies present.

It is desirable, then, to measure directly the difference in pressure between two points. A differential pressure transducer (DPT) is ideally suited for this task. The DPT generates an electrical voltage proportional to the fluid pressure difference on opposite sides of a mechanical diaphragm, and can thus be considered an inherently more effective instrument for determining pressure gradient (and thereby wave direction) than conventional pressure sensors. Further, the variation with depth of the differential pressure is a maximum over a range of frequencies that is more representative of typical ocean gravity waves. For a pressure transducer located at height  $s$  above bottom, the dynamic pressure,  $P_{dyn}$ , can be expressed as a function of position  $(x,y)$  from linear theory, as:

$$P_{dyn}(x,y,s,t) = \gamma \frac{H}{2} K_p(s) \cos(k_x x + k_y y - \sigma t + \epsilon) \quad (1)$$

where  $K_p(s) = \frac{\cosh ks}{\cosh kh}$ , the pressure response factor

and  $H$  = wave height

$x,y$  = coordinate axes in the horizontal plane

$k_x = k \cos \theta$  = wavenumber in the x-direction

$k_y = k \sin \theta$  = wavenumber in the y-direction

$\theta$  = wave direction, measured counter-clockwise from the x-axis

$\sigma$  = wave frequency

$h$  = water depth

$\gamma$  = specific weight of seawater

$\epsilon$  = phase angle

The x- and y-components of pressure gradient are then:

$$dP(x,y,s,t) = -\gamma \frac{H}{2} k \begin{bmatrix} \cos \theta \\ \sin \theta \end{bmatrix} K_p \sin(k_x x + k_y y - \sigma t + \epsilon) \begin{bmatrix} dx \\ dy \end{bmatrix} \quad (2)$$

Figure 1 depicts the dynamic response of pressure for a DPT located in twenty feet (6.1 m) of water, three feet (0.91 m) off the bottom, with

Figure 1. Upper curve: signal from differential pressure transducer sampling 3 feet (0.9 m) along wave ray. Lower curve: difference of signals from two absolute pressure transducers separated 20 feet (6.1 m) along wave ray. (Both curves normalized by typical rated capacity of the measuring instrument.)

a wave height of 5.0 feet (1.5 m). The DPT is assumed to sample two points separated by three feet (0.91 m) coincident with the wave ray. The lower curve represents the difference in pressure monitored by two absolute pressure transducers separated by twenty feet (6.1 m) along the wave ray. The response of each system is normalized by typical values of the rated capacity of the instruments: 35 psia (2460 cm H<sub>2</sub>O) for the absolute pressure transducer and  $\pm 0.5$  psid (70.3 cm H<sub>2</sub>O total differential) for the DPT. The differential pressure signal utilizes a greater portion of the instrument dynamic range than the difference between adjacent absolute pressure gauge signals and reaches its greatest response for waves between four and six second periods for the deployment described. The maximum response of the DPT shifts to longer period waves with increasing water depth or instrument deployment depth. The response of the DPT was developed over a pressure sampling space, or gage length, of only three feet (0.91 m) -- less than one-sixth the gage length of conventional pressure sensor array systems. The differential pressure gauge concept, then suggests that more efficiently measured directional information can be obtained with a considerably smaller instrument than is presently used.

## 2. THE DIFFERENTIAL PRESSURE GAUGE DIRECTIONAL WAVE MONITOR

To test the effectiveness of an array using differential pressure transducers, the differential pressure gauge directional wave monitor

(DPG) was developed and tested under field conditions. The DPG samples the pressure about its center using an absolute pressure transducer and simultaneously samples the pressure gradient along four arms oriented orthogonally about the instrument center using four DPT's, (Figure 2). There are two redundant slope measurements made along each axis in case one of the arm sensors should fail or so that directional spectra calculated from different combinations of gauges might be compared. It was also hoped that the pressure curvature could be developed through the subtraction of collinear slope terms.

### 3. SELECTION OF TRANSDUCERS AND DPT ARM LENGTH

The selection of the arm length which establishes the pressure difference to be measured by the DPT is dependent upon three criteria: (i) the characteristics of the transducer, (ii) the error in approximating the water surface slope as a linear function between the two sampled points, and (iii) reasonable size limitations of the instrument. The third criterion limits the gage length per transducer to a maximum of about 5 feet (1.5 m) if one imposes a design constraint of easy instrument manageability. At such small spacings, the maximum error in linearly approximating the water surface slope between sampled points is less than one and one-half percent for the shortest waves of interest, (say 3.2 seconds). The necessary rated capacity of the transducer R, is a function of the maximum pressure gradients expected and the ability of the transducer to detect and report a pressure difference of a minimum wave condition beyond the ambient and electrical noise level. From Eq. (2), the gage length between sensors can be found from

$$\Delta x = \frac{R}{\gamma H k K_p} \quad (3)$$

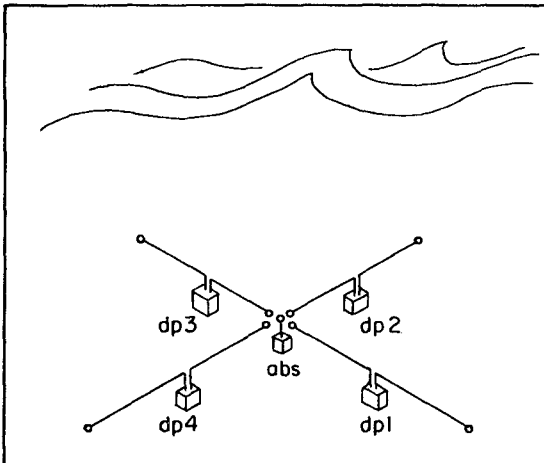

Figure 2. Schematic representation of the DPG directional wave monitor.

evaluated for the maximum wave height of interest (at the most sensitive wave frequency of the DPT at the selected deployment depth).

The site selected for field evaluation of the DPG was the United States Army Corps of Engineers Field Research Facility (FRF) at Duck, North Carolina, which is operated by the Coastal Engineering Research Center (CERC). The instrument was to be placed near and hard-wired to the Facility research pier. After examining the bathymetry near the pier, a nominal deployment depth of 20 feet (6.1 m) was selected. This indicated that the instrument would be most sensitive to waves of about 5 second period, (Figure 1). A design wave height of 16 feet (4.9 m) was chosen and considered with a gage length of 5 feet (1.5 m). This suggested the use of a  $\pm 0.6$  psid ( $\pm 42$  cm H<sub>2</sub>O) transducer which was unavailable. A  $\pm 0.5$  psid ( $\pm 35$  cm H<sub>2</sub>O) transducer was selected instead resulting in a gage length of 4.15 feet (1.27 m) from Eq. (3). The overall dimensions of the final instrument, then, became 9.75 feet (3 m) along each axis and 40 inches (1 m) in height to accommodate the electronics package. The sensors are approximately 3.9 feet (1.2 m) from the seafloor when the instrument is mounted in a supporting cradle.

#### 4. DPG HARDWARE

The in situ instrumentation is contained in a poly-vinyl chloride (PVC) structure that is secured to a steel cradle fixed to the seafloor. The PVC structure, or "instrument" as it is called hereafter, consists of a central tube, or "fuselage," and four arms that extend from near the top of the fuselage, (Figure 3). The fuselage section contains five pressure-sensing isolation diaphragms and a water-tight instrumentation cylinder that contains the pressure transducers. Each of the four arms contain a pressure-sensing isolation diaphragm near its end. The arms bolt into a PVC 4-pipe female junction within the fuselage so that the arms can be disconnected for greater ease in transportation, or potentially, a change in arm orientation. The ends of each arm and the top of the fuselage are punctured with 5/8 inch (1.6 cm) holes. Removable end-caps are fastened to the extreme ends of each arm and the fuselage in order to protect the isolation diaphragm sensors.

A typical DPT (Setra Systems Model 228) measures the pressure difference between the isolation sensor at the end of one arm and one of the five isolation sensors mounted within the fuselage near the center of the instrument. The fifth isolation sensor in the fuselage provides a signal measured by a Setra Systems Model 205-2 50 psia (3515 cm H<sub>2</sub>O) absolute pressure transducer. Each isolation sensor consists of a flexible 13 mil DuPont Fairprene® elastomer sealed to an acrylic housing by a 90-10 copper-nickel alloy ring and six Monel® bolts, (Figure 4). The exposed diameter of the elastomer is 1.625 inches (4.1 cm). The isolation sensors are connected to the transducers by flexible tubing -- 1/8 inch (3.2 mm) I.D. stainless steel armored teflon outside the water-tight cylinder and 1/16 inch (1.6 mm) I.D. nylon tubing inside. The tubing is back-filled with an ethanol-water mix (gin) such that the response time of a transducer to a static load placed on its isolation sensor was measured as 0.12 seconds for all sensors.

Figure 3. Rendering of the DPG instrument.

Figure 4. Assembly drawing of an isolation sensor chamber.

The instrument is anchored to the seafloor using a steel cradle which consists of two mutually perpendicular pieces of channel iron in plan view with a hole in the center, and legs to raise the channel off the seabed. The arms of the instrument fit into the channel and are made fast with heavy electrical cable ties. The cradle is anchored to the seafloor by chain that runs taut between each arm of the cradle and screw-anchors in the seabed. Alone, the cradle weighs about 200 pounds (91 kg) in air and about 280 pounds (127 kg) with the instrument attached (cable excluded).

The instrument is cabled to shore for power requirements and analogue data delivery. Eighty feet (24 m) of the seaward end of the cable is stripped of its armoring and stored in a plexiglass box immediately shoreward of the instrument. The top plate of the box is removable in order to access the extra cable if the instrument is to be moved or taken to the surface.

#### 5. CALIBRATION AND WAVE TANK EVALUATION

A relatively simple bench calibration system was designed consisting of two pressure chambers which secure around each isolation sensor of a DPT using a short length of motorcycle tire inner tube, (Figure 5). Each chamber is equipped with a pressure transducer and a bicycle tire valve. The two chambers are connected by tubing with a valve in the center to isolate, bleed, or allow the chambers to communicate with one another. The chambers are pressured with a bicycle tire pump and the pressures which are sensed simultaneously in each chamber and by the corresponding DPG transducer are recorded on a multi-channel strip chart. The response time for the DPG transducers was determined by measuring the passage of time between loading events as reported by the chamber transducers and by the DPG transducer. If an anomalous pressure difference or response lag was observed during a

Figure 5. The DPG bench calibration system. One pair of sensors shown for clarity.

calibration test, it was assumed that air was present in the lines and the isolation sensors and connecting tubing were re-back-filled and re-calibrated. After the final back-filling and calibration, each of the transducers on board the DPG was found to respond linearly (1:1) to the pressure loads imposed on its isolation sensors.

The tubing length of the arm sensors is four times greater than that of the center sensors so that an ambient temperature change induces a slight differential pressure across each DPT. (Volumetric expansion of a fluid is linearly proportional to the change in temperature and initial volume of fluid, so that the expanded volume in the arm sensors due to a temperature increase will be four times that of the center sensors.) Temperature changes under twenty feet (6.1 m) of ocean water are typically of low frequency, so it is assumed that any temperature-induced drift during a sampling interval will be interpreted as a very long period wave or as a mean which changes from record to record. If the mean of a DPT record was known at some measured ambient temperature, then for any other sampling interval, the record mean could be used to approximate the water temperature during the time of that record, (neglecting the small lag of the transducer readings due to the thermal mass of the instruments).

An early version of the DPG was tested in the Coastal Engineering Research Center's large outdoor wave tank at Fort Belvoir, Virginia. This initial version of the instrument used semi-rigid 1/8 inch (3.2 mm) I.D. sensor tubing, and it is believed that three of the four arm tubings broke during the instrument assembly; (the tubing was subsequently changed to a flexible type for the field evaluation). The absolute pressure gauge and differential pressure channel dP3 appeared to be in satisfactory order, however, and their signals were recorded on a strip chart while the instrument operated under large amplitude, regular waves generated for another test in progress. The wave profile recorded by the tank's resistance wave staffs indicated non-linear waves of 5 second period and crest-to-trough height between 3.0 feet (0.925 m) and 3.36 feet (1.025 m). Because of the highly non-linear nature of the waves, stream function theory (3) was used to calculate the water surface displacement inferred by the signals of the DPG's absolute pressure gauge — approximately 3.2 feet (0.98 m) from crest to trough with a period of 5 seconds.

The DPG orientation relative to the unidirectional wave train was approximated from the signal of dP3 for each of the two DPG orientations tested. The average total magnitude of the dP3 signal was estimated from the strip chart and the maximum differential pressure expected along the direction of wave travel  $s$ , was calculated from stream function theory. The angle  $\theta$  between the wave ray and the dP3 arm is then:

$$\theta = \cos^{-1} \left[ \frac{\left| \frac{dP}{dx} \right|_{\text{measured by dP3}}}{\left| \frac{dP}{ds} \right|_{\text{max. calculated}}} \right] \quad (4)$$

where  $(dP/ds)_{\max}$  is the value applicable for  $\theta=0^\circ$  from stream function theory. The orientation of arm 3 of the DPG was measured approximately by divers as  $55^\circ$  to the tank centerline, or wave ray, for the first tests and  $35^\circ$  for the second tests. The calculated angle from (4) using the instrument data was  $51.3^\circ$  and  $35.4^\circ$  for each of the two sets of tests, respectively. The directional agreement -- as well as the ease with which the instrument was installed and removed -- was encouraging. Details of the wave tank evaluation are given in Bodge (1).

#### 6. FIELD INSTALLATION AND ORIENTATION MEASUREMENT

The DPG field prototype was deployed at the CERC Field Research Facility on May 14, 1982, using the Facility's Coastal Research Amphibious Buggy (CRAB). The CRAB is a large tripod that is capable of driving across the beach and into the surf zone under its own power. The DPG was hoisted beneath the operator's platform, and the CRAB driven toward the end of the pier where the cable was mated to the instrument and then driven to the installation site where the instrument and cradle were lowered and secured to the seafloor by divers. The relatively small and lightweight DPG hardware, combined with the flexibility of the CRAB, afforded a very smooth installation -- despite less than ideal wave conditions.

The DPG is installed on the relatively stable 20 foot (6.1 m) depth contour, approximately 735 feet (224 m) south of the pier and 1800 feet (549 m) offshore. The orientation of the instrument was determined using a submersible digital compass mounted at the end of a five-foot (1.5 m) length of aluminum angle which was placed atop the end of each PVC instrument arm. In this way, the digital compass was at least six feet (1.8 m) from the steel cradle. Compass headings were recorded for each arm twice -- once by each of two divers -- and then averaged. The orientation of each arm was also measured by securing a diver's compass around the end of each arm using the compass wrist strap. Measurements were taken three times for each arm using two different wrist compasses and then averaged. All of the values recorded for each technique along each arm agreed reasonably well within a technique.

As an experiment, the divers' compasses were placed on an arm above the end of the steel channel and then slid towards the end of the arm. The heading changed as the compass moved across the end of the steel and then remained relatively stable. It was therefore thought at the time that the readings taken at the ends of the PVC arms were sufficiently far from the steel cradle to avoid magnetic bias. However, this was found not to be the case. Since each arm is perpendicular to its neighboring arm, adjacent arm bearings are constrained to be  $90^\circ$  apart. Although the digital compass measurements approximate  $90^\circ$  separation, those of the wrist compasses clearly do not, (Table 1).

If the measured orientation  $\beta_n'$  is expressed in terms of the actual orientation,  $\beta_n$ , of the arm and the error,  $\epsilon_n$ , associated with that arm that is introduced by the metal mass of the cradle, one can write:

Table 1: ORIENTATION HEADINGS* OF THE DPG ARMS					
ARM	WRIST COMPASS		DIGITAL COMPASS		RESOLVED
	apparent	actual	apparent	actual	averaged
1	228.33	241.75	238.80	241.89	241.82
2	155.33	151.75	153.90	151.89	151.82
3	78.00	61.75	61.20	61.89	61.82
4	325.33	331.75	333.65	331.89	331.82

\*Headings are with respect to magnetic north, 6/15/82.

$$\beta_n' = \beta_n + \epsilon_n \quad (5)$$

Since the compasses were placed upon each arm at about the same distance from the center of the instrument, and if one assumes that the effect of the metal mass upon the compass readings is the same for each arm (i.e., radially inward), then the errors associated with each of two collinear arms should be equal and opposite in sense. Accordingly,

$$\sum_{n=1}^4 \epsilon_n = 0 \quad (6)$$

If one expresses the actual orientation of each arm in terms of the arm with the smallest value of apparent direction, (arm 3, in this case), Eq. (5) may be written:

$$\beta_3' = \beta_3 + \epsilon_3 \quad (7a)$$

$$\beta_4' = \beta_3 + 90^\circ + \epsilon_4 \quad (7b)$$

$$\beta_1' = \beta_3 + 180^\circ + \epsilon_1 \quad (7c)$$

$$\beta_2' = \beta_3 + 270^\circ + \epsilon_2 \quad (7d)$$

From the sum of Eqs. (7) and substituting (6);

$$\beta_3 = \frac{1}{4} \left[ \left( \sum_{n=1}^4 \beta_n' \right) - 540^\circ \right] \quad (8)$$

The corresponding orientation for each of the other three arms may be found by successively adding  $90^\circ$  to the orientation of the adjacent arm. The agreement between the corrected averages of the arm headings as found using the expensive digital compass and the two simple wrist

compasses is surprisingly good, within  $0.3^\circ$  (Table 1). This investigation indicates the importance of establishing the inherent inaccuracies in a compass and/or of careful redundant checks of instrument orientation when working near a steel structure.

## 7. DATA ANALYSIS AND RESULTS

If only the absolute pressure signal  $P$ , and one slope signal from each of the two axes,  $dP_x$  and  $dP_y$ , are processed, then the DPG yields the same information as a heave-pitch-roll buoy. The first five coefficients in a Fourier series representation of the directional wave spectrum ("directional Fourier coefficients," or DFC's, for short), can be found using the analysis technique described by Longuet-Higgins, Cartwright, and Smith (4).

If the absolute pressure and the four slope signals are measured and the curvature across each axis established, the first seven DFC's could be developed by the aforementioned technique (4). However, attempts to calculate curvature through the subtraction of collinear slope measurements were generally unsuccessful. This is not surprising since it requires the calculation of very small curvature terms by subtracting two already small (measured) slope terms. In principal, differential pressure transducers can be used to measure directly pressure curvature, however, and this technique will constitute the subject of a future investigation.

If one directly cross-correlates the instrument's signals using the technique outlined by Borgman (2), among others, higher order DFC's can generally be obtained. If one directly cross-correlates the instrument's signals using the technique outlined by Borgman (2), among others, higher order DFC's can be obtained if the gages are separated sufficiently to allow estimation of an accurate separation-related phase difference in the signals of the two gages. If the gages are so closely located that it is impossible to obtain meaningful phase differences due to their separation, it is possible to estimate only the first five DFC's. If it is known that waves approach only over a limited range of directions, it is possible to modify the analysis procedure to improve the directional description substantially. Altering the orientation of the arms as shown in Figure 6 would appear to improve the quality of the directional distribution information for waves approaching over a limited range of directions.

Inspection of the time series signals from the submerged DPG indicated that one of the differential transducers along the instrument's x-axis was suspect. Accordingly, only the absolute pressure signal and one measure of slope along each axis were processed. In particular, the pressure slope along each axis was calculated by dividing each differential pressure signal by the gauge length between DPT sensors, and the absolute pressure and pressure slope time series were then transformed to the frequency domain. The linear pressure response function and a low pass filter were applied to obtain the water surface displacement and slope spectra, and the analysis technique mentioned above, (4), was utilized in order to calculate the first five directional Fourier coefficients.

Figure 6. Plan view of DPG proposed to potentially improve resolution of directional wave distribution.

For several data sets, directional spectra were calculated using  $P$ ,  $dP_x$ , and one of the  $dP_y$  signals -- and then re-calculated using  $P$ ,  $dP_x$ , and the other  $dP_y$  signals from the redundant y-axis differential pressure transducer. Agreement between the calculated spectra using the two different y-axis DPT signals was satisfactory (1).

No other *in situ* directional wave monitors were operational during the first few months following the DPG installation. Therefore, the wave height and period information calculated from the DPG's absolute pressure sensor were compared to height and period estimates from nearby surface-piercing Baylor gauges, (Table 2). The direction of peak wave energy reported by the DPG was compared to visual estimates and HF radar images of the wave fields, (Table 2). The agreement between observed and DPG-generated height, peak period, and directional estimates, (all taken from the spectra for the DPG estimates), is encouraging.

It is theoretically possible to develop the water surface displacement energy spectrum from the slope spectra of the differential gauges:

$$S_{\eta\eta}(\sigma) = \frac{S_{\eta_x\eta_x}(\sigma) + S_{\eta_y\eta_y}(\sigma)}{k^2} \quad (9)$$

where  $S_{\eta\eta}$ ,  $S_{\eta_x\eta_x}$ , and  $S_{\eta_y\eta_y}$  represent the auto-spectra of water surface displacement, and x-axis and y-axis slopes respectively. Theoretically, it is also possible to estimate the principal wave direction without the absolute pressure signal if one assumes that there exists only one wave direction  $\theta$  per frequency  $\sigma$ . Specifically,

		period	11.07	10.89 <sup>c</sup>

NOTES:  
 "dirxn" listed is the principal direction (peak energy), true north.  
 "H<sub>sig</sub>" is the significant wave height in meters.  
 "period" corresponds to the frequency band of greatest energy in seconds.  
<sup>a</sup>CERC Radar ( $\pm 2^\circ$ )  
<sup>b</sup>visual estimate from the end of the pier  
<sup>c</sup>CERC Baylor Gauge near the end of the pier

$$\tan 2\theta (\sigma) = \frac{2 S_{\eta_x \eta_y} (\sigma)}{S_{\eta_x \eta_x} (\sigma) - S_{\eta_y \eta_y} (\sigma)} \quad (10)$$

There exist four roots in the arc-tangent of  $2\theta$ , and it can be shown that two of these roots are associated with maxima (and separated by  $180^\circ$ ) and the other two (also separated by  $180^\circ$ ) are associated with minima and separated from the first two roots by  $90^\circ$ . Two of these roots (the minima) can be eliminated by considering the signs of the numerator and denominator. The remaining two might be resolved by considering the physical environment of the instrument deployment site; i.e., ruling out the possibility of dominant waves originating

from the beach. Equations (9) and (10) were tested on a frequency-by-frequency basis with DPG data and compared to the total energy from the absolute channel and the peak-energy direction found from the directional spectra, respectively. Agreement was poor (with errors often greater than 40% in energy and 70° in direction) -- presumably due to spectral leakage and because the noise of the differential pressure signals is potentially greater than that of the absolute pressure signals and because the wave energy is spread over many directions in reality.

Similarly, a directional estimate was considered (and found likewise unreliable) which uses only one differential pressure signal and the absolute pressure signal:

$$\theta(\sigma) = \cos^{-1} \frac{1}{k} \sqrt{\frac{S_{\eta_x \eta_x}(\sigma)}{S_{\eta\eta}(\sigma)}} \quad (11)$$

or

$$\theta(\sigma) = \sin^{-1} \frac{1}{k} \sqrt{\frac{S_{\eta_y \eta_y}(\sigma)}{S_{\eta\eta}(\sigma)}} \quad (12)$$

assuming one direction per frequency. Non-linearity in wavenumber,  $k$ , may contribute to the observed error of (11) and (12).

## 8. CONCLUSIONS

From the present work, it appears that differential pressure gauges provide an effective means of measuring the pressure gradient under a wave field -- enabling estimation of at least the first five coefficients in the Fourier series representation of the directional wave spectrum. The use of differential pressure sensors enables one to directly measure pressure gradients over small arrays instead of comparing large-valued point measurements of pressure over relatively large arrays. It appears that the development of higher order terms, such as curvature, are also best made directly.

## ACKNOWLEDGEMENTS

The DPG was reduced to practice under U.S. Army Corps of Engineers Coastal Engineering Research Center Contract No. DACW72-81-C-0025 and further supported by the Exxon Research Foundation while the authors were at the University of Delaware. The authors wish to thank James Coverdale, Ed Green, and Roland Essex of the University of Delaware Civil Engineering Shop Facility, Dr. Todd Walton of CERC, Curtis Mason and the staff of the FRF, and Brian Jacobs, "Chip" Fletcher, David Wiley, and Karen Francheschini for their dedicated assistance to the project.

## CHAPTER FIFTY TWO

### Prediction of Wave Group Statistics

Steve Elgar,<sup>1</sup> R.T. Guza,<sup>2</sup> and R.J. Seymour<sup>3</sup>

Two methods of numerically simulating random seas, given a target power spectrum, are discussed. Wave group statistics, such as the mean length of runs of high waves, produced by the different simulation schemes are compared. For a large number of spectral components, no significant differences are found in the wave group statistics produced by the two simulation techniques. Using the simulation techniques, it is shown that ocean gravity wave group statistics are not inconsistent with an underlying wave field composed of linearly superposed random waves. The majority of the field data examined were collected in 9-10 m depth, significant wave heights ranged from about 20 to 200 cm, and the spectral shapes ranged from fairly narrow to broad. For the 9-10 m depth data, observed mean run length, variance of run length, and the probabilities of runs of a given number of high waves were statistically consistent with the linear simulations. In contrast to the apparent linear behavior in 9-10 m depth, waves in 2-3 m depth showed substantial departures from the linear simulations.

#### Introduction

Groups of high waves are commonly observed in the ocean. A run or group of waves is defined as a sequence of waves, the heights of which exceed a particular level (Goda, 1970). It has been suggested that such runs of large waves effect coastal structures such as breakwaters (Burcarth, 1979) and pipelines (Dean, 1980), and influence the response of ships to the wave field (Pinkster and Huijsmans, 1982). Additionally, groups of waves can excite other fluid motions, which may in turn produce noticeable effects (Bowers, 1979).

There are several linear theories which predict wave group statistics, such as the mean group length, given only the energy spectrum. One such theory considers the wave field to be composed of a succession of discrete, independent waves, an assumption appropriate for broad band spectra. Results from the theory of runs are then employed to determine certain group statistics (Goda, 1970; Nagai, 1973). The mean length of such runs of waves greater than some critical height,  $H_c$  is (Goda, 1970)

$$E\{j\} = 1/(1-p) \quad (1)$$

where  $j$  is the number of discrete waves in a run,  $E\{\}$  is the expected value operator, and  $p$  is the probability that the height of a wave is greater than  $H_c$ . The standard deviation of run length is

$$\sigma\{j\} = p^{1/2}/(1-p) \quad (2)$$

For Rayleigh distributed wave heights, and for  $H_c = 4m_o^{1/2}$ , where  $m_o$  is the variance of the time series,  $p=0.1348$ . Thus, for these conditions

$$E\{j\} = 1.16$$

$$\sigma\{j\} = 0.42$$

On the other hand, for narrow band energy spectra, an expression for the mean length of runs can be derived from Rice's (1944, 1945) results for the envelope of a random process. For

<sup>1</sup> Research Assistant, Scripps Institution of Oceanography, A-022, La Jolla, CA 92093

<sup>2</sup> Associate Professor, Scripps Institution of Oceanography, Shore Processes Lab, A-009, La Jolla, CA 92093

<sup>3</sup> Head, Ocean Engineering Research Group, Institute of Marine Resources, SIO, A-022, La Jolla, CA 92093, M. ASCE

this case, the mean length of runs whose envelope lies above  $H_c/2$ , for the  $H_c$  given above, is given by (Vanmarke, 1972; Ewing, 1973)

$$E\{k\} = 1/2(m_2/2\pi\mu_2)^{1/2} \tag{3}$$

where  $m_2$  and  $\mu_2$  are the second moments of the spectrum about the origin and about the centroid, respectively, and  $k$  is the number of waves in the group, not necessarily discrete.

Extensive numerical simulations (Elgar, Guza, and Seymour, 1984) indicate agreement ( $\pm 10$  percent) with Goda's prediction of a constant mean run length, equation (1), for very broad spectra,  $Q_p < 2$ . Here  $Q_p$  is defined as (Goda, 1970)

$$Q_p = (2/m_0^2) \int_0^\infty f S^2(f) df \tag{4}$$

where  $f$  is frequency and  $S(f)$  is the power spectral density. Unfortunately, Elgar, et al. (1984) could find no simple shape parameter that quantitatively indicated the region of validity of equation (3). Indeed, for spectral shapes similar to those found in the ocean, neither of the theories described above adequately predicts mean run length. Consequently, in order to predict wave group statistics given an arbitrary spectral shape, a simulation procedure is utilized.

**Simulations**

The fundamental assumption of linear waves is that the sea surface can be represented as a linear combination of waves with random phases,

$$\eta(t) = \sum_{n=1}^N C_n \cos(\omega_n t - \phi_n) \tag{5a}$$

where  $N \gg 1$  and

$$C_n = (2S(f_n)\Delta f)^{1/2} \tag{5b}$$

are the Fourier amplitudes,  $\omega_n = 2\pi f_n$ ,  $f_n = n \Delta f$ , and  $\phi_n$  are random phase angles, uniformly distributed in  $[0, 2\pi]$ . An alternate expression for the sea surface is

$$\eta(t) = \sum_{n=1}^N a_n \cos(\omega_n t) + b_n \sin(\omega_n t) \tag{6}$$

where  $a_n$  and  $b_n$  are independent, Gaussian distributed random variables with zero mean and variance  $S(f_n)\Delta f$ . Simulations using equation (5), which will be referred to as a random phase scheme, have spectra that always exactly match the target spectrum,  $S(f)$ , while simulations with equation (6), a random Fourier coefficient scheme, have spectra with a statistical variation about  $S(f)$ . Both methods were implemented, and as discussed below, yield nearly identical results.

**Comparison of simulation schemes**

For the random phase scheme, Fourier coefficients were coupled with random phases produced by a numerical random number generator (equation (5)). An inverse fast Fourier transform of the unsmoothed spectrum results in a simulated time series with the identical spectral shape as the target spectrum, but with random phases. To obtain random Fourier coefficients (equation (6)), Gaussian distributed, zero-mean, unit-variance random variables were generated, and then multiplied by  $(S(f_n)\Delta f)^{1/2}$ , producing new Fourier amplitudes with the desired properties (Andrew and Borgman, 1982). Again, an inverse fast Fourier transform yields a simulated time series.

Rice (1944 and 1945), invoking the central limit theorem, points out that both representations (5) and (6) will yield the same statistics in the limit as  $N \rightarrow \infty$ . Nevertheless, both forms were used in the simulations because there is some question as to whether or not they produce the same results (Tuah and Hudspeth, 1982; Tucker, Challenor, and Carter, 1984).

Figure 1. Power spectral density of sea surface elevation in water 10 m deep. Circle, narrow band; asterisk, broad band. The spectra have 128 degrees of freedom, and the 90 percent confidence limits are indicated by the bars. (Reprinted with permission of AGU.)

Each set of random phases or coefficients, via the simulations described above, produces a time series whose properties are statistics which fluctuate about mean values. To compare the two simulation methods for a particular target spectrum, 100 simulated time series were produced for each simulation scheme, each with its own set of random phases or Fourier coefficients. This procedure was repeated for 29 target spectra, thus a total of 5800 time series were produced.

The target spectra used to compare the two methods of simulating random waves were obtained from field measurements at Santa Barbara, California during the Nearshore Sediment Transport Study, conducted in January and February, 1980 (Gable, 1981). The time series used for this study were obtained from bottom mounted pressure sensors in water approximately 10 m deep. These spectra represent a wide range of ocean conditions, including very narrow (by ocean standards) and quite broad band spectral shapes. Figure 1, and significant wave heights between 20 and 200 cm. With typical peak periods from 8 to 20 seconds, the wave steepness (product of significant amplitude and wave number of the spectral peak) is in the range 0.006 to 0.1. Some of the field data were characterized by swell from distant storms, others by locally generated seas, and a few had multiple-peaked spectra, representing a combination of sea and swell.

Each time series used in this study was 8192 s (2.27 hr) long and was band-pass filtered between 0.04 and 0.3 Hz. The bottom pressures were converted to sea surface elevation using linear theory. Individual wave heights were determined using a zero-upcrossing definition, and were considered to belong to a group if the crest to trough distance exceeded  $4m_0^{1/2}$ , the significant wave height. The mean period of the waves was about 10 s, so there are approximately 800 waves per record, and about 80,000 waves per target spectrum for each of the two simulation schemes. The mean length of runs of waves greater than the significant wave height in the simulations varies from about 1 to 2.5, and the number of groups in each time series is between 30 and 100. It was shown in Elgar, et al. (1984) that simulations with 100 realizations as described above are extensive enough to estimate the mean length of runs and the frequency distribution of the number of waves per group to within a few percent of their true values.

For each realization, the mean run length and the frequency distribution of the number of waves per group were calculated. These quantities were then averaged over the 100 realizations per target spectrum. Higher order moments, such as the variance of run lengths, were calculated from the averaged frequency distributions. Average values were calculated for each simulation scheme, and compared to determine if there are any statistical differences between the two simulation schemes. Figure 2 shows that the mean run lengths from the random phase and random coefficient schemes are visually very similar. To test if the collection of mean run lengths from the random phase scheme was statistically consistent with the collection produced by the random coefficient scheme, Student's t test for paired data was calculated. Essentially, this test examines whether or not the two treatments (random phase and random coefficients) of the same data (target spectrum) produce the same result (mean run length). The t statistic obtained will be exceeded about 25 percent of the time due to random fluctuations. Thus, there is no support for the hypothesis that the mean group lengths produced by the random phase scheme are statistically different than those produced by the random coefficient simulations.

Similarly, the variances of run lengths obtained from the random phase and coefficient methods were compared. Figure 3 shows the two simulation procedures have negligibly different run length variances. The ratios of the square of run length coefficients of variation (standard deviation normalized by the mean, random phase and random coefficient schemes) for each of the 29 target spectra were compared to tabulated values of Fisher's F distribution. None of the values exceeded the tabulated values at the 99 percent significance level.

Finally, the frequency distributions of the number of waves per group produced by each simulation technique for each target spectrum were compared. A chi-square test was used to test if the entire collection of frequency distributions produced by the random phase scheme differed significantly from those produced by the random coefficient scheme. The chi-square value obtained (with 77 degrees of freedom) is such that the hypothesis that the two collections of frequency distributions come from the same population can be accepted with more than 99 percent confidence. Indeed, as displayed in Figure 4, when corresponding frequency distributions

from each simulation method are compared, they are seen to be almost identical. A more detailed discussion of the variability and statistics of the frequency distributions can be found in Elgar, et al. (1984).

The parameters investigated above indicate that the random phase scheme produces wave group statistics which do not differ from the random coefficient scheme statistics any more than two collections of random coefficient (or random phase) generated statistics would differ from each other. Further discussion of the similarities of and differences between the two simulation procedures can be found in Elgar, Guza, and Seymour (in Press).

### Simulation-data comparison

In order to determine whether or not linear simulations (i.e., random phase or random Fourier coefficient schemes) are adequate for predicting ocean wave group statistics, several different comparisons of measured and simulated data were made. The simulation procedures are the same as described above, but in this case statistics from ensemble averages of the 100 simulation realizations are compared to the actual field data values for each target spectrum. One such comparison is of the mean length of runs. Figure 5 shows that the mean run lengths from the ocean data are visually well correlated with the mean run lengths from the simulations. As shown in Elgar, et al. (1984), the  $E[j]$  for the 100 realizations for each target spectrum are Gaussian distributed, and the field values of  $E[j]$  deviated from the simulation mean no more than would be expected for a Gaussian distribution, with 77 percent of the ocean  $E[j]$  falling within one standard deviation of the simulation mean.

To test if the entire collection of ocean  $E[j]$  were statistically consistent with the simulated  $E[j]$ , Student's *t* test for paired data was calculated (Elgar, et al., 1984). The value obtained will be exceeded about 50 percent of the time due to random fluctuations. Hence, the hypothesis that the ocean mean group lengths are statistically consistent with linear wave theory cannot be rejected, and the simulation procedure successfully predicts ocean mean group lengths given a target spectrum.

Similarly, the variances of run length obtained from the ocean data were compared with the corresponding variances produced by the simulations, Figure 6. Fisher's *F* distribution was used to compare the ratios of the square of run length coefficients of variation. As shown in Elgar, et al. (1984), the hypothesis that the run length variances come from the same population cannot be rejected. Thus, the simulation procedure correctly predicts field values of run length variance given the energy spectrum.

Finally, a comparison of the frequency distributions of the number of waves per group was made, as shown in Figure 7. The details of this comparison can be found in Elgar, et al. (1984). Again, the conclusion is that the simulation schemes are capable of predicting field probability densities given only the power spectrum.

All the above statistical tests were applied to both the random phase simulations and the random Fourier coefficient simulations, with negligible differences as expected. The values presented above are from the random phase simulations.

### Simulations of shoaling waves

The results presented so far indicate that the assumption of a linear, Gaussian process, as expressed by equation (5) or equation (6), produces statistics consistent with observations of ocean wave group statistics in 10 m depth. However, as waves shoal they are expected to become more nonlinear. Consequently, a linear representation, such as (5) or (6) should not necessarily produce wave group statistics consistent with observations of shoaled waves. That this is the case is shown in Figure 8. Values of  $E[j]$ , both observed and simulated (from the measured spectrum at the appropriate depth) are shown as a function of depth, from 10 m, through the breaking region (about 2 m), and into 1 m of water. The simulated run length varies during shoaling because of substantial changes in the observed spectrum. Simulations and observations are similar in 9-10 m depth, but as the waves shoal the observed  $E[j]$  becomes much greater than

Figure 8. Mean length of runs greater than the significant wave height versus depth of water. Asterisk, ocean field data; circle, simulations, bars indicate  $\pm 1$  standard deviation of simulated values. (Reprinted with permission of AGU.)

linear simulations predict. The ocean  $E[\eta]$  remains higher than the corresponding value from the simulations until the waves break. This trend occurs in many of the data sets, and requires a nonlinear model to be predicted from a given deep water spectrum (Elgar, et al., in preparation). Other group statistics observed in the field data are also inconsistent with the linear simulations, as described in Elgar, et al. (1984). Consequently, it is inappropriate to use the linear simulation technique to predict wave group statistics for very shallow water waves.

### Conclusions

The theoretical models which predict wave groups statistics given only the power spectral density are not appropriate for the vast majority of ocean spectra. On the other hand, wave group statistics such as the mean length of runs of high waves, the run length variance, and the frequency distribution of the number of waves per group can be predicted by a linear numerical simulation from the energy spectrum. The two methods discussed here, a random phase scheme and a random Fourier coefficient scheme, produce nearly identical statistics for the spectra and conditions considered in this study.

Although the linear simulations accurately predict wave group statistics in water 8-10 m deep, very substantial disagreement with the simulations was found for shoaled waves in 2-3 m depth. Thus, the linear simulation procedure is inappropriate to use in shallow water where nonlinearities are important.

## CHAPTER FIFTY THREE

### ESTIMATES OF LONG WAVES IN THE WESER ESTUARY

V. Barthel\* and E.R. Funke\*

#### ABSTRACT

Long waves of small amplitudes can excite harbour oscillations as well as the motion of floating structures or vessels. Field data from the Weser Estuary, German Bight of the North Sea were analysed with respect to waves with periods greater than 8 s. After preprocessing of the mostly noisy data records, special analysis incorporated the reconstruction of incorrectly recorded frequency components below .03 Hz and bivariate distributions of heights and periods. Results suggest that long wave activity increases towards the inner estuary. Grouping properties are dependent on wind direction and on directionality of the sea state. Further investigations and model studies for the response of travelling vessels to this wave climate are recommended.

#### 1.0 INTRODUCTION

It has been frequently suggested and generally accepted that long waves with a small amplitude can excite harbour oscillations. Pinkster (7) and Mansard and Pratte (6) demonstrated that significant motions of moored vessels can be induced as a result of these same waves. It is also being speculated that large vessels navigating with small underkeel clearance in restricted channels can hit bottom in response to these long waves. It is therefore important to know about and to understand long wave activity in coastal areas and estuaries.

Long waves in estuaries can appear as

- (a) free long waves, which are generated far from shore and travel at free wave velocity.
- (b) group-bound long waves, which represent a set-down under the wave group and travel at group velocity.
- (c) free long waves, which result from the shoaling process of bounded long waves.
- (d) reflected long waves, which derive from a reflection process of free or bounded long waves.

The existence of second order group-bound long waves as a result of the variation of radiation stress under a group of waves has already been shown by Longuet-Higgins and Stewart (5). Dependent on the amount

\*Hydraulics Laboratory, National Research Council, Ottawa, Ont. K1A 0R6  
Canada

of wave grouping the bounded long wave appears as a set-down under a group of larger waves and a set-up in between groups (Fig. 1). That this phenomenon is really present in nature can be shown by a low-pass filtering process presented in Figure 2 where the thick line superimposed on the measured wave train represents the second-order low frequency surface elevation. The encircled low frequency part of the variance spectral density is shown enlarged on the upper right part of the figure.

FIGURE 1: GROUP BOUNDED LONG WAVES - DIAGRAMMATIC SKETCH -

Long waves in deep water are typically considered to have periods longer than 30 seconds. However, as waves propagate into the shallower water of an estuary, there is a significant transformation of spectral energy towards the higher as well as the lower frequency part of the spectrum. As a result, long waves in estuaries may reasonably be considered as being those of periods longer than eight to ten seconds. This

FIGURE 2: BOUNDED LONG WAVES IN NATURAL WAVE TRAINS

investigation was also undertaken in support of navigation services in the Weser Estuary, part of the German Bight of the North Sea, for which a specific interest in wave activity beyond a certain threshold had been expressed. Discussions taking estimated or well-established response frequencies of different types of vessels into consideration resulted in a cut-off frequency of 8 s. For the purpose of this analysis long waves - in deviation from a conventional definition - shall be considered as those which exceed this given threshold.

The behaviour of long waves propagating in a uniform channel at constant water depth is well known (Barthel et al., 1983) (2). However, when approaching the shore with progressively decreasing depth of water, these waves change due to shoaling, refraction, diffraction and reflection in a manner which is not yet understood. It is suspected that, e.g. bounded long waves depart from the wave groups and proceed as free long waves in the shoaling process. To complicate matters, some long wave components tend to follow deep channels into the inner estuary without much change in characteristics.

## 2.0 Field Data

Field investigations were carried out in the Weser Estuary, German Bight of the North Sea, between 1975 and 1981 and results were partly reported by Barthel (1). This study was to provide sufficient wave climate information for the prediction of waves and form the basis for design of coastal structures. Waverider buoys were deployed in seven

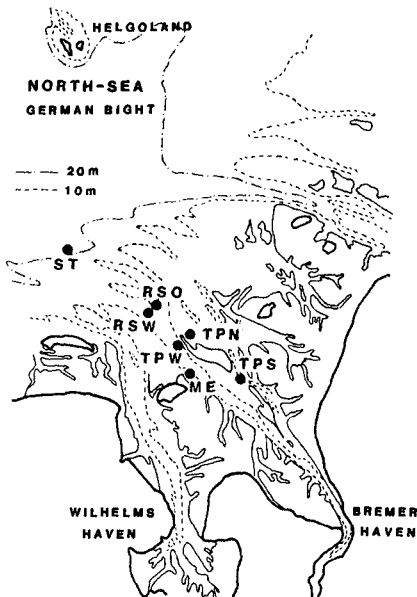

FIGURE 3: WESER ESTUARY WITH LOCATIONS OF MEASUREMENTS

different locations in the estuary, covering specific areas like the open sea, the edge of deep channels and the protected areas behind submerged bars (Fig. 3). This data set was also made available for the present investigation.

Data had been acquired for the conventional 20 minute periods and transmitted to shore for recording on digital magnetic tape. However, for reasons of cost, it had not been possible to record data from all buoys concurrently. Instead, data channels were selected consecutively for 20 minute periods. During different periods, different buoys participated in wave monitoring activity. Sometimes two, three or four buoys were selected consecutively so that the same buoy recorded every 40, 60 or 80 minutes. At other times a two-buoy sequence repeated every 60 or 80 minutes if one or two of the buoys in the sequence were inoperative.

### 3.0 INSTRUMENTATION

When the wave climate study was started in 1975 it could not be anticipated that the data might be used for long wave analysis. Consequently, the instrumentation selected which was most suitable for short wave measurements at that time, proved to be not ideal for this investigation.

The Waverider buoy has a dynamic response which starts dropping off at wave periods of 16 seconds. As Figure 4, which originates from the

FIGURE 4: WAVERIDER TRANSFERFUNCTIONS (WAVERIDER MANUAL)

Waverider Manual, shows, the buoy is totally incapable of recording periods greater than 50 seconds. Typically, measurements of periods longer than 30 seconds should not be relied upon.

A further disadvantage stems from the fact that the radio transmission is susceptible to corruption by radio interference. The buoys and their receiver station had to be located in the vicinity of harbour services which were using short wave communication systems. CB-amateur activity in the region is very high. Hence, many of the records are influenced by interferences which lead to statistical "outliers" or "glitches". In order to make use of as many of the limited number of records as possible, programs had to be developed to detect and correct these erroneous portions of records.

#### 4.0 PREPROCESSING OF DATA

The procedure GLTFX which was created to recognize and repair noise records can be summarized as follows: The data vector is being differentiated by simple differencing. The resultant derivative is subjected to statistical analysis for the definition of a threshold which permits the separation of derivatives contributed by noise spikes on the one hand and those contributed by the uncorrupted signal on the other. The derivative record is then searched and on the basis of this threshold, a noise derivative is identified with the additional proviso that the derivative of the noise spike must be shorter than a given period and that the noise spike must be associated with a derivative exceedence of one polarity followed immediately by another derivative exceedence of the opposite polarity.

Figure 5 shows an example of a noisy record with its derivative and

FIGURE 5: PREPROCESSING OF DATA

the switching function. The upper part shows the repaired wave record as a thick line superimposed on the original recorded time series of "surface elevations". As may be seen, the method can significantly improve the viability of wave data.

Another program was developed which can process erroneous prototype records and replace them by the best fitting quasi-synthetic time series. By using Fourier techniques, sinusoidal components are systematically removed from the original record until the variance of the extracted sum of sinusoids is greater than 90-95% of the RMS value of the original record. The superposition of all sinusoids at their computed amplitude and phase approximates the original function quite well.

By this method "glitches" and statistical "outliers" can be removed. However, since the process requires a comparatively long computation time, it can only be justified for very valuable records which cannot be recovered otherwise.

## 5.0 ANALYSIS OF WAVE DATA

### 5.1 Conventional Analysis

In order to assess the quality of data records after preprocessing, conventional analysis is applied on all records. This procedure incorporates:

- (a) Zero-downcrossing analysis, resulting in statistical parameters like  $H_s$ ,  $H_{max}$ ,  $T$ , etc.
- (b) Variance spectral density analysis giving peak frequency and RMS-values.
- (c) SIWEH-analysis as per Funke and Mansard (4) from which the groupiness factor  $GF$  is obtained.
- (d) Wave height probability distribution analysis including a comparison with model distributions.

After a visual control and selection process, data are subjected to a second analysis procedure.

### 5.2 Extended Long Wave Analysis

Since waves with a period longer than 33 s could not have been recorded correctly, all frequency components smaller than the given boundary were removed and replaced by a theoretical bounded long wave component. These second-order components were calculated using the method described by Ottensen-Hansen (7) and had been extensively tested for laboratory conditions (Barthel et al.) (2). The program uses Fourier techniques combining every possible combination of frequency pairs and their respective Fourier components. The second order surface elevations are given by

$$\eta_{nm}(t) = G_{nm}(f, \Delta f) \left[ (a_n a_m + b_n b_m) \cos(\Delta\omega_{nm}t) + (a_m b_n - a_n b_m) \sin(\Delta\omega_{nm}t) \right]$$

$G_{nm}(f, \Delta f)$  is the transfer function, the properties of which were extensively described by Sand (9). In order to save computational time the program lets the user remove all frequency pairs with an energy content below a defined threshold.

This procedure effectively reconstructs the long period portion of the energy spectrum which could not be correctly measured by the Wave-rider buoy. The low frequency part of the spectrum shown in Figure 2 is, in fact, a reconstructed, theoretical bounded long wave which adds remarkably to the energy content in this range. However, it accounts only for those long waves which belong to the category of "bounded long waves". It does not include any free long wave activity which may also be present in the natural sea state but has not been correctly recorded. Consequently the long wave activity computed and presented here represents an underestimation of the true situation.

Because of the specific interest in all "long wave" activity for wave periods longer than eight seconds, a special time series was constructed. The measured wave train was band-pass filtered between the low cut-off frequency of 0.03 Hz and the given boundary value of 0.125 Hz ( $T = 8$  s). The filtered time series was then superimposed with the "theoretical bounded long wave" and the resulting "long wave" subjected to the following analysis:

- (a) Zero-crossing analysis results in heights and periods of this artificial wave train. The effect of a wave field on a floating structure or travelling vessel can only be obtained by physical or mathematical modelling. However, certain boundary values (e.g. periods) are considered to initiate a - very often serious - response of a vessel. The RAO (response amplitude operator) of a vessel can be for example 0.6 for a frequency of .2 Hz and 1.0 for a frequency of 0.125 Hz. Therefore, a wave height  $H_R$  obtained from a measured wave train, which in Figure 6 as an example only consists of two superimposed frequencies, may not mean too much for a travelling vessel. The filtered, lower frequency component attached to a significantly smaller height  $H_F$ , however, can be of more consequence to its movement.
- (b) To evaluate the frequency of occurrence of pairs of height and period obtained from the zero-crossing analysis data are subjected to a bivariate distribution analysis resulting in a scatter diagram of heights and periods of the "long wave train". This procedure is performed on the data records of each station separately for a whole measurement period and results are accumulated in one data file to show the distribution of this specific period. Figure 7 shows the bivariate distributions of stations ST and RSW (42 records each) for the period of November 15-17, 1978. Leakage during the filtering process still lets waves appear in the region  $T < 8$  s. Due to the same filtering process, the asymmetry of a joint distribution as shown by Cavanie et al. (3) is not very distinct in this representation. As can be seen from the example, the maximum numbers of events occur within the periods of 8-10 s with heights from 0.4-1.0 m. These "long waves" may well

FIGURE 6: SUPERPOSITION OF LOW AND HIGH FREQUENCY COMPONENTS  
- SCHEMATIC PRESENTATION -

excite a travelling vessel to an extent which could cause dangerous situations. Multiple events in that period range go up to 3.6 m whereas very long waves ( $T > 22$  s) occur more than once with a height of .4-.6 m. However, it still remains to be accurately defined how these results have to be interpreted with respect to the behaviour of a certain type of vessel.

### 5.3 Distribution of Energy

Another method of showing the energy which is attached to certain frequency ranges is given with Figure 8. The cumulative distribution of spectral energy (RMS-value) for the frequency bands 0-0.05, 0.05-0.125, 0.125-0.25 and 0.25-0.5 Hz gives a very good indication of what is happening, e.g. in a storm. In the presented example the energy of "long waves" increases substantially with increasing wind velocity in both locations. However, real long wave activity for frequencies below .05 Hz ( $T > 20$  s) is much larger towards the inner estuary (RSW) than it is in deep water. This process of transfer of energy towards lower frequencies in storm situations could be observed quite often and appears to be enhanced with decreasing water depths. It implies that vessels moving into the estuary can expect more "long wave activity" and therefore possibly heavier motion towards the inner estuary where water depths normally provide less underkeel clearance.

### 5.4 Grouping Properties

The concentration of energy in a group of higher waves in superposition with a second-order slow drift oscillation of a ship due to very long waves can affect its stability especially if it starts to respond in a resonant rise. Grouping properties of the sea state in terms of the groupiness factor

$$GF = \frac{\sqrt{m_0 \epsilon}}{m_0}$$

JOINT FREQUENCY OF OCCURENCE DIAGRAM

JOINT FREQUENCY OF OCCURENCE DIAGRAM

FIGURE 7: BIVARIATE DISTRIBUTION OF H AND T

FIGURE 8: CUMULATIVE DISTRIBUTION OF SPECTRAL ENERGY

$m_{0E}$  = zeroth moment of the SIWEH spectral density

$m_0$  = zeroth moment of the SIWEH variance spectral density

SIWEH = Smoothed Intermediate Wave Energy History

as defined by Funke and Mansard (4), were determined for all records. The groupiness factor GF is the standard deviation of the SIWEH function about its mean normalized by its variance and gives a good indication of the concentration of higher and smaller waves in deviation from the Gaussian process. Table 1 presents the results of this specific analysis for different wind directions and the three main locations which were being looked at for navigation safety purposes. It appears that unusually high GF values only occur with certain prevailing wind directions (SE).

WIND DIRECTION	ST			RSW			TPW (TPN)

TABLE 1: GF AND H<sub>sig</sub> FOR DIFFERENT WIND DIRECTIONS FOR THE LOCATIONS ST, RSW AND TPW

Figure 9 shows the groupiness factors for only three wind directions. Interpretation of these results suggests that waves, generated by easterly winds, are not very much affected by topography and therefore only obey the boundary process of energy transfer from wind to water surface, which seems to govern or influence the grouping properties the most. On the other hand, waves penetrating the estuary are being affected by bottom-wave-interaction and superimposed by locally generated wind waves. Therefore, the grouping-process is disturbed and interrupted. Interaction of the group-bound long wave, which feels the bottom very early, and its constituent group could lead to a decay of the group. Finally, superposed wave fields coming from different directions can suppress grouping behaviour of the combined sea state.

Therefore, wave data used for groupiness analysis should be selected and treated very carefully. If superposed sea states like those shown in Figure 10 are being recorded, a separation of the two (or in some

FIGURE 9: AVERAGE AND MAXIMUM GF - VALUES FOR 3 WIND DIRECTIONS

FIGURE 10: DOUBLE - PEAK - SPECTRUM - RW 609

cases even three) partial spectra is necessary to obtain valid grouping properly results. For a series of twelve records for four locations double-peak spectra were separated by filter techniques. Combined and separated time series were subjected to a grouping analysis, the results of which can be seen in Table 2. The GF value is generally much higher for the partial wave fields than for the combined record. Moreover, bounded long wave energy in terms of RMS-values of the bounded long wave is up to 25% higher if determined for the separated wave fields rather than for the superimposed and recorded sea state. This shows very much the need for directional information for further investigations if also groupiness properties are to be determined.

### 5.5 Parameter Sampling

To show the collected parameters of each measurement series consisting of more or less consecutive recordings of participating buoys over the course of a strong wind episode, analysis results were plotted for each location showing the time series of

- wind direction and velocity
- significant and maximum height of the measured wave train
- groupiness factor GF
- significant and maximum height of the "long waves" with  $T > 8$  s

FIGURE 11: WESER WAVE PARAMETER - STATION RSW

- and the peak period (derived from spectral analysis) and average period (derived from zero-crossing analysis) of the "long waves".

Figure 11 presents the results for location RSW for the period of November 15-17, 1978.

#### 6.0 CONCLUSIONS

Analysis indicates that

- long waves with periods exceeding 8 s may well be in excess of 5 m in height.
- those waves of periods greater than 33 seconds, which provide only an underestimation of real long wave activity (theoretical bounded long wave) can reach .5 m in height.
- grouping of waves can be very much affected by decreasing water depth. With only wind-wave interaction groupiness is quite high, if waves travel offshore.
- grouping properties described by the groupiness factor  $GF$ , as defined by Funke and Mansard (4), are much more distinct for the directional components of a superimposed state than for the original record itself. This reflects on the theoretical energy content of the group bounded long wave as well.

It is recommended to perform further wave investigations in that area deploying measurement devices which are capable of recording the required range of frequencies. In addition to that, gustiness recordings and directional information are essential for a detailed analysis.

The response of different types of travelling ships to the existing wave climate has to be investigated in laboratory experiments.

## CHAPTER FIFTY FOUR

### SHOALING PROPERTIES OF BOUNDED LONG WAVES

E.P.D. Mansard\* and V. Barthel\*

#### ABSTRACT

Group bounded long waves which appear as a set-down under a group of high waves and a set-up in between groups are well described for constant water depth. However, their propagation into shallow water and their interaction with the constituent wave groups are not well understood and theoretically described yet. Therefore, model investigations were carried out to study shoaling properties of these second order waves in terms of amplitudes and phases. The tests give a good insight into the phenomenon and suggest distinct shoaling properties. Moreover, experimental results provide a valuable basis for future theoretical considerations.

#### 1.0 INTRODUCTION

Recent investigations have shown that model tests of harbour basins and moored ships are highly dependent on the correct reproduction of grouped sea states. Using the concept of radiation stress, Longuet-Higgins and Stewart (4) have established that a set-down of the mean water level occurs under wave groups with a corresponding set-up in between the groups. This results in a variation of the mean water level known as a Bounded Long Wave (BLW) with its period equal to that of the wave groups. The Bounded Long Wave, which travels with the group velocity, is of second order and therefore cannot be reproduced in a model just by application of the first order classical wave generation, since the boundary conditions required at the paddle are not being satisfied. As a consequence the following spurious long wave components are generated in a model in addition to the inevitably produced Bounded Long Wave:

- a free parasitic long wave which is opposite in phase to the bounded long wave,
- a free displacement wave generated due to the moving boundary of the paddle, and
- a free long wave generated by the first order local disturbances (negligible amplitude with respect to the above two).

These spurious long waves, which propagate at free wave celerities, can travel back and forth along the flume since they are almost fully reflected even from beaches with mild slopes. The resulting standing wave system could therefore lead to incorrect and unrealistic responses of test structures depending on their location. However, these free long waves can be reduced by including correct suppression terms in the

\*Hydraulics Laboratory, National Research Council, Ottawa, Ont. K1A 0R6  
Canada

wave generation. This is basically achieved by generating, along with first order waves, long wave components which are equal in amplitude but opposite in phase to those spurious contributions. The theoretical expressions of these contributions are given by Ottensen-Hansen et al. (6) and their successful suppression in a physical model is demonstrated by Barthel et al. (1). These suppression techniques used in model investigations of moored ship response (Mansard and Pratte) (5) and wave run-up on beaches (Barthel et al.) (2) have clearly established their importance in obtaining a realistic response of the structure in the model.

## 2.0 OBJECTIVES

This paper describes the continuation of the research program and deals with the shoaling properties of the group-bound long waves. Although these waves are small in amplitude, their shoaling effects can significantly influence the model response. Harbour oscillations are one of the examples where these effects can be greatly felt; the long waves penetrating the harbour can induce long period seiches or resonance causing thereby enhanced slow drift motions of moored vessels or other floating structures.

At present there is no description (either theoretical or experimental) of the shoaling properties of these waves. Model investigations were therefore undertaken at the Hydraulics Laboratory of the National Research Council of Canada to study the propagation of Bounded Long Waves on a mild slope.

## 3.0 EXPERIMENTAL SET-UP

Investigations were carried out in a flume of dimensions 67 m x 1.2 m x 1.2 m (see Figure 1), equipped with a hydraulically driven wave generator operating in piston mode. The horizontal part of the flume in front of the wave paddle was 9 m long with a mean water depth of 0.7 m. A slope of 1:40 covering a distance of 17 m was used for shoaling purposes. This slope was then followed by a 16 m long horizontal part with a water depth of 0.28 m. A porous beach with a 1:30 slope was to dissipate wave energy at the end of the flume.

Considering wave length and velocity of these long waves, the experiments should ideally be carried out in very long flumes; however, such flumes are generally not available. Moreover, the distances used in this set-up represent some of the commonly encountered dimensions in model studies.

The shoaling slope and the following constant depth portion were constructed of sand covered with a thin layer of floated concrete. But subsequently the entire concrete surface had to be painted in order to make it smoother since preliminary investigations indicated a high degree of breaking and viscous loss due to the roughness of the bottom.

The permeable beach at the end of the flume was made up of 2 to 3 cm angular stones in order to allow the waves to penetrate through the stones and thereby dissipate as much energy as possible before being reflected at the vertical end of the flume. During a set of preliminary investigations a beach, with a slope of about 1:20 was originally used.

Under that set-up the results displayed a high degree of reflection, which could be detected particularly in the phases of long waves: in the first portion of the sampled record, the set-down and the corresponding set-up were properly reproduced but after about 50 s the phases were corrupted due to reflection.

FIGURE 1  
EXPERIMENTAL SETUP IN THE 4' FLUME

The slope used in this study (1:30) provided an optimum "effective length" of the flume and at the same time guaranteed satisfactory absorption characteristics. Given the limited lengths of the constant depth zones, a satisfactory reflection analysis could not be carried out in the present configuration.

A set of nine twin wire capacitance gauges were used to monitor the waves of the salient locations of the set-up. Wave generation and data acquisition were controlled by an on-line computer.

#### 4.0 SELECTION OF TESTS

It has been shown by Barthel et al. (1) that the magnitude of bounded long waves and suppression terms used for the correct reproduction of bounded long waves change as a function of water depth and frequencies: higher amplitudes go with decreasing water depths and frequencies.

Since the amplitudes of the bounded long waves are generally very small in models ( a few mm), a careful selection of wave signals had to be done in order to obtain a distinct long wave with an amplitude well above the accuracy of the gauges and the signal noise level. As a result, a peak frequency of 0.43 Hz and a depth of water of 0.7 m were finally chosen since they provided reasonable amplitudes of the bounded long waves and at the same time an effective beach length for dissipation purposes. Jonswap spectra with three different characteristic wave heights (6 cm, 9 cm and 12 cm) were used on this study to establish the shoaling properties of the different amplitudes of the BLW. In addition, the amplitudes of BLW were varied by changing the grouping properties of the input wave which are described by the Groupiness Factor (GF), (Funke and Mansard) (3).

In a recent study Sand (7) has illustrated the direct relationship which exists between the bounded long wave and the Groupiness Factor. The Groupiness Factor, a measure of the wave group activity in a wave train, can be easily controlled in model tests using the synthesis techniques developed at the National Research Council of Canada (Funke and Mansard) (3). Using this technique, time series of 150 s with the same variance spectral density but with three different groupiness factors ( $GF = 0.60, 0.75$  and  $0.90$ ), were synthesised. This resulted in three combinations of bounded long wave amplitudes for each characteristic wave height. Besides varying the groupiness factor, the synthesis technique, indicated above, could also be used to control the ultimate shape of the bounded long wave spectrum in terms of peak frequency and width. For this study, a relatively narrow spectrum with a peak frequency of 0.05 Hz was used. Complete details of the various steps involved in this technique are well documented in the reference cited above.

Data sampling was always initiated a few seconds before the generation in order to monitor corruption of bounded long wave, if any, due to reflections. However, in order to be consistent with the length of the time series used in generation, the analysis was carried out only for a period of 150 s. The generation technique was such that the same driving signal was recycled every 150 s which meant that any part of the time series with a length of 150 s could be used in the analysis. For this study, it was decided to sample for a total period of 325 s and analyse two portions of the record: one from 25 s to 175 s and another 175 s to 325 s. The choice of 25 s as initial time was based on the propagation time of the waves up to the 9th wave gauge. The results presented in this paper correspond generally to the first section of the record while the second portion was useful to establish the effects of reflections, if any.

One of the main objectives of this study, besides establishing the shoaling properties of BLW, is to investigate the effects of spurious long waves on the amplitudes of long wave oscillations measured in the shallow water region. Hence each combination of input sea states described above was run with and without compensation for spurious long waves.

The compensation for the spurious long waves was performed, as indicated in Section 1.0, by generating long wave components equal in amplitude but opposite in phases to the spurious contributions. Generation of the suppression terms often requires large paddle excursions as illustrated in Figure 2. The graph presents two driving signals used for the generation of the same input sea state ( $f_p = 0.43$  Hz,  $HCHR = 12$  cm and  $GF = 0.9$ ). The driving signal corresponding to the classical wave generation (without suppression) is shown in Figure 2a while Figure 2b displays the signal with correct compensations for spurious long waves.

## 5.0 ANALYSIS TECHNIQUES

The various analysis techniques used in this study, can best be described with the help of the illustrations presented in Figure 3 displaying a sample of analysis results obtained for the first gauge with and without compensation for spurious long waves.

FIGURE 2

DRIVING SIGNALS FOR AN IRREGULAR WAVE TRAIN WITH AND WITHOUT SUPPRESSION OF SPURIOUS LONG WAVES

The wave train measured at the first gauge is shown together with the time series of measured and calculated long wave components. The spectra of these two long wave components are also presented in the same figure on the left hand side of the total spectrum.

The measured long waves (or the long waves prevailing in the model) were extracted from the total wave train by low pass filtering. Filtering was carried out using a time domain technique which convolved a data window with the input data. A 201 point Kaiser filter with a cut-off frequency 0.2 Hz was used for this purpose.

The expected (or calculated) long waves were obtained by theoretical relationships (Ottensen-Hansen et al.) (6) from the measured wave trains with a cut-off frequency excluding all the measured long waves (0.2 Hz).

Frequency domain analysis of these two long wave components and the measured wave train directly provided their corresponding spectral densities and RMS values. The closer the RMS value of the measured long waves is to the theoretical RMS value, the more successful is the spurious long wave suppression (see Fig. 3a). However, perhaps more important than matching the amplitudes of the measured long waves to their respective expected values, it is necessary to obtain a good agreement in phase. This is usually demonstrated by a distinct proper set-down and set-up of the mean water level with respect to the wave groups. Without any suppression, this agreement would be difficult to achieve

WAVE TRAIN WITH MEASURED AND CALCULATED

LDNG WAVE COMPONENTS

FIGURE 3

ANALYSIS OF THE LONG WAVE CHARACTERISTICS

partly due to the differences in velocities between the free and bounded long waves. To verify the phase agreement between measured and calculated long waves, a cross correlation technique was used as follows:

$$C_{\eta_{LM}\eta_{LT}}(\tau) = \frac{1}{T-\tau} \int_{-T/2+\tau}^{T/2} \eta_{LM}(t) \cdot \eta_{LT}(t+\tau) dt / (RMS_{\eta_{LT}} \cdot RMS_{\eta_{LM}})$$

where,  $\eta_{LT}$  = time series of theoretical (or calculated) long waves

$\eta_{LM}$  = time series of measured long waves

If optimum suppression is achieved, the analysis should indicate zero shift for maximum correlation. In practice the time shift  $\tau$  (TAU) for maximum correlation is never quite zero. However, this variable proves to be a fair measure of success of suppression of spurious long waves. The maximum cross correlation coefficient is also never quite 1 due to small variations in the RMS values of the long waves which are very small themselves.

## 6.0 ANALYSIS OF RESULTS

### 6.1 Comparison Between Measured and Calculated Long Waves

Figure 4 presents comparisons between measured and calculated long waves for four different locations in the flume. To illustrate the effectiveness of suppression, results from both types of generation (with and without suppression) are also included in this figure.

The characteristics of the bounded long wave, measured at the first gauge before any shoaling took place, are illustrated in Figure 4a. The measured amplitudes and phases of the long waves show good agreement with theory when compensation was applied. On the other hand, when no compensation was done, the amplitudes and especially the phases of the BLW are different from the theoretical predictions. To a certain extent, this figure demonstrates not only the effectiveness of suppression but also the minimal influence of reflection: If reflections were higher, it would be difficult to obtain such a good match in spite of compensation.

The long waves measured, at gauges 3 and 5, during shoaling, are presented in Figures 4b and 4c. In the case of generation with suppression, the phase agreement between theoretical predictions and measured values are more or less maintained, but differences in amplitudes can be detected. When no suppression was included, differences between theory and experiment are much larger in amplitudes as well as in phases.

Since a large amount of breaking was taking place between probes 6 and 7, the long waves measured at gauge 9 (Fig. 4d) show very little correlation between theory and experiment. This is possibly due to the fact that the long waves measured at the 9th gauge are a superposition of two different contributions:

- long waves released by breaking process, and

**FIGURE 4**  
**COMPARISON OF MEASURED AND CALCULATED**  
**LONG WAVES**

**FIGURE 4**  
**COMPARISON OF MEASURED AND CALCULATED**  
**LONG WAVES**

SHORT WAVE SPECTRUM RMS=0.03m, GF=0.90

- long waves which are bound to a grouped wave train reconstituted after breaking.

The calculated long waves presented in these figures for various locations of the flume, were computed using the local depth of water. But it should be pointed out that the theoretical relationships available now are strictly valid only for a constant depth of water. Hence the predictions which are presented here are only approximations of the true values. To calculate these true values it would be necessary to extend the existing theory by including terms for variable water depth and non-linear interactions between first order and bounded long waves. Since, at present, such a theory is not available, the equations of Ottensen-Hansen et al. (6) provide a useful comparison to the various trends in BLW behaviour.

#### 6.2 Amplitudes of the Measured Long Waves at Different Locations of the Flume

Figure 5 presents the variation of RMS values of the measured long waves along the flume. These results, only shown for the case of suppression of spurious long waves, illustrate very well some of the anticipated trends:

- The RMS value of the long waves increases with increasing wave height of the input sea state.
- For a given characteristic wave height of the spectrum (HCHR), an increase in GF results in large bounded long waves.

It is interesting to detect a reduction in the amplitudes of the long waves with increasing GF for the input sea states with HCHR = 9 and 12 cm at gauges 7, 8 and 9. This reduction could be attributed to the breaking of large waves due to the combination of high RMS value and large GF: a portion of the long wave energy could be expected to be dissipated with the breaking of short waves while the rest is released as free long waves.

Figure 6 presents a similar illustration of the amplitude of the long waves, but this time as a function of the amplitude of the measured short waves. With the amplitude of the long waves being proportional to the square of the amplitude of the primary wave train, the ratios of  $RMS_{LW}/[RMS_{SW}]^2$  are illustrated in Figures 6a and 6b. Figure 6a represents the ratio of the expected long wave, while the values actually measured are displayed in 6b. Results of  $RMS_{LW}/[RMS_{SW}]^2$  suggest that, for both cases of generation (SUP and UNS), this ratio increases towards the end of the flume. While this increase could be associated with the shoaling effect in the sloped area, it is not clear as to why the same tendency prevails in the post-breaking zone where the depth is constant (gauges 7, 8 and 9). A possible explanation could be the superposition of the long wave energy released during breaking process with the group-bound energy of the post-breaking time series. It could also be partly due to incomplete stabilisation process after breaking.

Because of additional free wave energy, the generation process without suppression generally results in a higher value of this ratio within the shoaling process.

**FIGURE 5**

**FIGURE 6**  
**RATIO  $\frac{RMS_{LW}}{[RMS_{sw}]^2}$  (SUP.+UNS.)**  
 3 GROUPINESS FACTORS,  $RMS(SW) = 0.03m$

The ratio of expected long wave  $RMS_{LWC}/[RMS_{SW}]^2$  increases much more rapidly on the slope than the measured one. In the post breaking zone, it decreases as anticipated to a more or less constant value. As discussed above, these variations are based on the estimations of the theoretical long wave. However, it is not clear why this ratio is slightly higher for the unsuppressed cases (2% on the average and 8% at probe 6). This appears to be partly due to slight changes in the spectral shape caused by the difference in breaking pattern. It has been observed that the omission of suppression causes waves to break in different regions than observed in the presence of correct suppression.

### 6.3 Cross-Correlation Between Measured and Theoretical Long Waves

The results of the cross-correlation analysis between measured and calculated long waves are presented in Figure 7. These results correspond to the input sea states of  $RMS = 0.03$  m generated with different groupiness factors, each with and without suppression. The full lines indicate the suppressed case while the dotted lines represent the other. The effectiveness of suppression is well evident in this figure, since for all three groupiness factors the generation without suppression results in a poorer correlation and larger time shift as opposed to the generation with correct suppression. As anticipated, the correlation between theory and experiment decreases in the post breaking zone due to the superposition of energy from the bounded long waves and the long waves released by the breaking process. However, it is not clear why the time shift tends to decrease in that zone.

Similar cross correlation analyses were carried out to establish the effects of wave height of the primary spectrum and the influence of decreasing water depths.

As expected, a higher correlation and a smaller time shift value were achieved with lower wave heights resulting in less wave breaking.

With a shallower water depth ( $d = 0.6$  m), the number of breaking waves was comparatively higher than in 0.7 m depth resulting in an increasing mismatch between expected and measured values. Distinctly higher phase shifts and lower correlation coefficients ( $TAU > 3$  s and  $corr < 0.3$  at gauge 7) reflected this result.

### 7.0 ENERGY BUILD-UP DUE TO REFLECTION

In order to establish the possible effect of reflection on the phases and amplitudes of BLW, the second portion of the record (175 s - 325 s) was subjected to similar analyses described above. The comparison of results of both portions of the records are presented in Figures 8 and 9 for two typical cases of GF. The cross-correlation between theoretical and obtained bounded long waves of both portions in Figure 8 show a good agreement in the TAU values while minor differences could be detected in the correlation coefficient. The match of the amplitudes of the long waves measured in different locations of the flume indicates a minimal effect of reflection (Fig. 9). In other words, the reflection coefficient was small enough not to substantially corrupt the progressive nature of the wave system in the set-up.

## 8.0 CONCLUSIONS

In the absence of a suitable theoretical description of bounded long wave propagation on a slope, this study provides useful experimental results on their shoaling properties. To date, the investigation suggests that

- there is a distinct trend in the increase of the BLW during shoaling.
- for nonbreaking waves, the relationship between BLW and GF is well documented.

In our experimental set-up, the classical wave generation, which does not include any suppression for spurious long waves, resulted in a higher magnitude of low frequency oscillations in the shallow region as opposed to those with suppression. However, this may not be true if the reflections had been high enough to set up a predominant standing wave pattern. Therefore it is recommended to suppress the spurious long waves in order to have a realistic model response. Further experiments are being carried out to study the effect of impervious beaches.

## CHAPTER FIFTY FIVE

### Numerical Simulations of the 1964 Alaskan Tsunami

James R. Houston<sup>1</sup> and H. Lee Butler<sup>2</sup>, A.M. ASCE

#### Introduction

Tsunamis are long-period water waves usually generated by earthquakes. They occur predominantly in the Pacific Ocean and can produce massive inundation and destruction. The last major tsunami that seriously impacted the United States was the 1964 Alaskan tsunami. This tsunami was generated in Alaska and caused damage in Alaska, the Hawaiian Islands, and on the west coast of the continental United States. It is the most documented of all tsunamis and the only tsunami for which there is information on the ground motion that generated the tsunami.

Numerical models have been used to simulate tsunami generation and propagation. A numerical simulation of the 1964 Alaskan tsunami that included deep ocean propagation was performed by Hwang et al. (1) and a comparison was made with a deep water gage at Wake Island. Houston (2) performed a numerical simulation of this tsunami including both deep ocean and nearshore propagation in the Hawaiian Islands and presented comparisons with tide gage recordings. Although Houston (2) demonstrated the ability of numerical models to propagate tsunamis from source regions to distant shorelines, the Hawaiian Islands considered in his simulation have a very short continental shelf and the conclusions of his study might not be applicable to typical continental areas that have significantly longer continental shelves.

There has been considerable controversy in recent years concerning the governing equations for tsunami generation, deep ocean propagation, propagation over the continental shelf, and land inundation. The importance of frequency dispersion and nonlinearity in tsunami propagation has been debated. However, research by a number of investigators in recent years has provided clear evidence of the relative significance of frequency dispersion and nonlinearities. The numerical simulation presented in this paper of the 1964 Alaskan tsunami and comparisons with tide gage recordings of this tsunami all along the west coast of the continental United States provide additional confirmation of the conclusions of these investigators. I show that for very large tsunamis such as the 1964 Alaskan tsunami, frequency dispersion is negligible during

<sup>1</sup>Chief, Research Division, Coastal Engineering Research Center, U. S. Army Engineer Waterways Experiment Station, P. O. Box 631, Vicksburg, MS 39180-0631.

<sup>2</sup>Chief, Coastal Processes Branch, Coastal Engineering Research Center, U. S. Army Engineer Waterways Experiment Station, P. O. Box 631, Vicksburg, MS 39180-0631

all phases of tsunami propagation except in rare circumstances when tsunamis exhibit a bore-like form in their final runup phase. Nonlinearities also are negligible except during tsunami land inundation, and they are not generally dominating even during inundation by non-bore waves.

It should be emphasized that the conclusions of this paper are valid only for spatially large tsunamis such as the 1964 Alaskan tsunami and for the first major waves recorded at distant locations. Frequency dispersion may be significant for the propagation of relatively short period tsunamis generated by ground displacements that are small and for the later waves of even large tsunamis. Waves near the tsunami source region may be influenced by details in the time-history of the ground motion or by small scale features of the permanent ground deformation.

#### Governing Equations

Tuck (3) made the following sweeping statement in a paper on models of tsunami propagation: "The linear long-wave equations are adequate to describe most of the tsunami generation, propagation and reception processes."

He primarily used intuitive arguments based upon the magnitudes of ratios of tsunami wave lengths and wave heights to water depths. Tuck (3) clearly stated that his conclusions applied only to large tsunamis such as the 1964 Alaskan tsunami, but the considerable disagreements with his conclusions that developed were a result of assumptions that his statement applied to smaller tsunamis.

Hammack (4) in a series of detailed laboratory experiments and calculations employing the Korteweg and deVries (KdV) equation (includes frequency dispersive and nonlinear terms) concluded that linear theory is applicable for determining tsunami generation for large tsunamis such as the 1964 Alaskan tsunami. In subsequent work using the KdV equation, Hammack (5) concluded ". . . the propagation of the lead wave of a two-dimensional tsunami is modeled by linear nondispersive theory for almost its entire trajectory. The KdV equation is valid, but unnecessary, while linear dispersive theory never applies." This trajectory was explained to extend from the source region to the vicinity of a beach. Nonlinearities were found to be negligible in the generation region and for deep ocean propagation. Frequency dispersion was shown to be negligible for the lead wave of the 1964 Alaskan tsunami until it propagated a length of time of approximately 100 hours (equivalent to a propagation distance of approximately 50,000 miles). Kajiura (6) in a separate analysis using linear but dispersive equations found "The remarkable similarity of results between dispersive and nondispersive theories is evident for  $P_a = 4$ ."  $P_a$  was defined as

$$P_a = 6(h/g)^2/t^3(b/h) \quad (1)$$

where

h = water depth

g = acceleration of gravity

t = time  
b = one-half the length of the major axis of an elliptical source region

Using parameters for the 1964 Alaskan tsunami,  $P_a$  decreases to a value of 4 after 105 hours. Thus Kajiura's analysis is in agreement with that of Hammack (4). Kajiura (6) also noted the calculations of Carrier (7) were in similar agreement.

The unimportance of nonlinearities and frequency dispersion for generation and deep ocean propagation of large tsunamis was confirmed by simulations of the 1964 Alaskan tsunami and comparisons of results with a deep water gage at Wake Island (1) and with tide gages in the Hawaiian Islands (2). These simulations did not confirm the negligibility of nonlinearities during propagation from the deep ocean to shore, since the Wake Island gage is in deep water and the continental shelf of the Hawaiian Islands is so short that the time scale for the growth of nonlinearities is small.

Hammack (5) considered tsunami propagation from the deep ocean to the nearshore area using the KdV equation and concluded that ". . . linear nondispersive theory can be used until the distance across the continental shelf (of uniform depth) that the lead wave propagates is given by . . . X = 200 miles." Goring (8) conducted laboratory experiments and calculations using Boussinesq equations (similar to the KdV equations, but allowing wave propagation in two directions) and also concluded ". . . the propagation of tsunamis from the deep ocean to the continental shelf-break and for some distance onto the shelf will be predicted as well by the linear nondispersive theory as by the nonlinear theories." The conclusions of Hammack (5) and Goring (8) may not be in agreement with calculations of Mader (9) who used a Simplified Marker and Cell (SMAC) code that included vertical accelerations and nonlinearities and a vertically integrated linear long wave code (SWAN). Significant differences were noted between the calculations of the SMAC and SWAN codes for long waves propagating over a simulated continental shelf (9). However, since experimental or field data are not presented, differences between the models noted by Mader (9) are likely attributable to inaccuracies of the solution techniques, methods of application, or boundary conditions rather than to differences in the equations solved.

Tsunamis are often portrayed as bore-like walls of water during their final stages as they inundate coastal areas. However, tsunamis only rarely appear as bore-like along coastlines distant from a source region. Instead they normally are described as having the appearance of "fast-rising" tides. In this form they are likely to be governed by nonlinear long wave equations that are successfully used for tidal inundation problems.

#### Simulation of the 1964 Alaska Tsunami

Tsunami generation and deep ocean propagation was simulated using a finite-difference numerical model (1). The model solves the linear long-wave equations on a spherical coordinate grid. One-third by one-third degree grid cells were used with the grid extending over much of the

north Pacific Ocean. The boundary condition employed on land boundaries of the grid was the component of the velocity normal to the boundary was equal to zero. On open (ocean) boundaries, a first-order approximation of total transmission was made.

The model solved an initial value problem starting with an uplift deformation of the water surface identical with the major features of the permanent deformation (permanent in the sense that the time scale associated with it is much longer than the period of the tsunami) of the seafloor following the 1964 earthquake. The transient movements within the time history of the ground motion of the 1964 earthquake were neglected because Hammack (4) has shown through laboratory experiments that these movements are unimportant in the far field for spatially large ground motions. Hammack (4) has further shown that the initial deformation of the water surface will closely approximate major features of the permanent deformation of the ocean floor, provided these features have characteristic lengths that are at least four times as great as the water depth (water depth was approximately 200 m in the tsunami source region of the 1964 earthquake). The neglect of smaller features is unimportant because Hammack (4) demonstrated in laboratory experiments such small-scale details produce waves negligible in the far field. These experiments (4) have great practical significance, since details of the time history of ground motion and small scale features of the ground deformation are unknown for the 1964 earthquake and other tsunamigenic earthquakes.

The permanent deformation of the ocean's bottom as a function of spatial location for the 1964 earthquake was adapted (1) from the field measurements of Plafker (10). It is identical to the uplift used earlier by others (1,2). Starting with this uplift as an initial condition, the numerical model propagated the 1964 tsunami across the deep ocean to the west coast of the continental United States.

The cell size of the deep ocean grid is too coarse to allow accurate simulations of tsunami propagation from the deep ocean to shore, since the tsunami wave length decreases in shallow water. Therefore, separate finite difference grids were used to propagate waves from a water depth of 500 m to shore. a variable rectilinear grid was used with grid cells that decreased in size as the water depth decreased. The smallest grid cells were less than 1 mi on a side. A finite-difference numerical model (11) was used to calculate nearshore propagation. The model uses a highly efficient implicit solution scheme that employs a centered, alternating-direction procedure. Nonlinear long wave equations including bottom function terms were solved. However, in agreement with the calculations of Hammack (5) and Goring (7) it was found that the results were insensitive to the nonlinear advective and bottom friction terms for reasonable values of bottom friction.

Figures 1-9 show comparisons between the numerical model calculations and tide gage recordings for nine tide gates on the west coast of the continental United States. These are all of the tide gages on the west coast that recorded the 1964 tsunami, except for gages in Puget Sound, the Columbia River, and San Francisco Bay (not covered by numerical grid). The tide has been extracted from all the comparisons except

the one at Crescent City, California. A tide gage record of the 1964 tsunami at Crescent City inferred by Wilson and Torum (12) is used for the comparison at Crescent City. In addition, an estimate by Wiegel (13) that differs somewhat from the estimate of Wilson and Torum (12) is presented. Each comparison is over a period of 1.5 to 2.0 hr.

Tide gages do not record tsunamis perfectly, but the heights and periods of the waves seen in Figures 1-9 are such that gage response is close to 100 percent (14). However, the standard sampling interval of tide gages is 6 minutes and this long sampling interval distorts the recorded wave form and can reduce apparent heights. Tide gages also experienced difficulties when gage limits were encountered. In addition to truncations of the waveforms as seen in Figures 2, 8, and 9, gage limit problems are seen in the inverted trough of Figure 8 and high frequency oscillations in the crests seen in Figures 2 and 8.

The wave form recorded at one location is remarkably different from those recorded at other locations. The waveforms for the 1964 tsunami calculated for the Hawaiian Islands (2) also show remarkable differences from gage to gage. The numerical calculations are in good general agreement with the waveforms. The shape of the waveforms, and wave heights and periods are in reasonable agreement in Figures 1-9 considering unknowns of the source region. Calculated maximum wave heights vary among the locations from as little as 1.5 ft to as much as 18.0 ft.

#### Land Inundation

The only gage location where the tsunami produced significant land inundation was at Crescent City, California. Figure 10 shows the numerical grid used to simulate land inundation at Crescent City. The grid was oriented such that the incident waves approached Crescent City from the direction predicted by Roberts and Kauper (15). The interaction of the tsunami with the Crescent City region was quite complex. For example, the Crescent City Harbor is protected by breakwaters, some of which were overtopped and others which were not. In the region there is a developed city area, mud flats, and an extensive riverine floodplain. Inland flooding was extensive in the floodplain area and extended as much as a mile inland. Sand dunes and elevated roads played a prominent role in limiting flooding in certain areas.

The input to the numerical model was a wave crest that, when propagated to shore, reproduced as accurately as possible the historical maximum elevation at the tide-gage location near the shoreline in Crescent City. There is some disagreement among investigators on the maximum elevation of the tsunami at the tide gage with estimates ranging from 18 to 20.7 ft above mean lower low water (mllw). A wave crest with an elevation of 19 ft above mllw at the tide-gage location was used in this simulation, based on a study by Keulegan et al. (16) that considered all available data and concluded the 19.0-ft level was the most likely.

There are several barriers in the Crescent City region. Wiegel (13) reports that there was little flow over the outer breakwater during the 1964 tsunami (Figure 10). Therefore, this breakwater was represented as a non-overtopping barrier. However, the breakwaters attached to Whaler

Figure 10. Numerical grid from Crescent City, California.

Island (Figure 11) were overtopped during a part of the tsunami and thus are represented as dynamic overtopping barriers. Similarly, Redwood Highway (Figure 11); and beach dunes along the crest were overtopped during the tsunami. Magoon (17) reported water flowed over these barriers with flow rates governed by weir equations.

Frictional effects in the numerical model are governed by Chezy frictional coefficients. Values of Manning's  $n$  suggested by Bretschneider and Wybro (18) for coastal terrain were used. Manning's  $n$  values were selected for very general categories of terrain, since detailed knowledge of vegetation and land roughness are not known. The ocean bottom, mud flats, and beaches were assigned a value of 0.024. Developed areas were assigned a value of 0.035 and the riverine flood-plain area and other heavily vegetated areas a value of 0.055. No attempt was made to force agreement of numerical calculations and historical recordings of elevations by varying local values of Manning's  $n$ .

The U. S. Army Corps of Engineers made surveys of the tsunami inundation at Crescent City in January, April, and May of 1965 (17). Figure 11 shows the location of 11 high-water marks recorded by the surveys. The tide gage was located near high-water mark No. 307 (Figure 11). Table 1 presents the measured elevations at the high-water marks and elevations calculated by the numerical model. The measured and calculated elevations are within 1 ft except at locations 307, 2, 3, and 5. However, Wiegel (13) reports that the measured elevation at

Table 1

High-Water Mark Number (Reference 17)	Measured Elevation mllw, ft	Calculated Elevation mllw, ft	Difference ft
302	18.35	17.95	+0.40
305	18.74	19.39	-0.65
307	20.70	19.45	+1.25
309	19.84	19.79	+0.05
312	19.41	20.23	-0.82
316	16.29	17.09	-0.80
1	15.90	15.43	+0.47
2	17.80	19.24	-1.44
3	19.30	18.89	+0.41
4	16.50	18.94	-2.44
5	20.50	19.13	1.37

location 307 was greater than the actual wave elevation by 1 to 2 ft due to local runup on a concrete wall. Thus the actual wave elevation and the calculated elevation are in good agreement at location 307. The measured elevation at location 4 is lower than the calculated elevation, since the measured high-water mark was inside a lumber building (17). Incomplete filling of the lumber building by water would result in lower elevations within the building than outside the building. Location 5 is almost 2 miles south of the tide gage. It is likely the wave approaching this shoreline had a greater elevation than the wave approaching the harbor area. The elevation calculated at this location could be increased by varying the incident wave form along the input boundary.

Figure 11. High-water mark locations for 1964 Tsunami (adapted from Magoon, 1965).

Figure 12. Inundation Lines, 1964 Tsunami (adapted from Magoon, 1965).

There is no apparent explanation for the disagreement at location 2, especially since there is good agreement at nearby location 1.

The agreement between the measured high-water marks and calculated elevations is quite good. The root-mean-square error is 0.7 ft (elevations at locations 307, 4, and 5 not included since differences attributable to factors other than the numerical model). Since the observed elevation at the tide gage used to choose an incident wave height is accurate to within no more than 0.5 to 1.0 ft, the agreement between measured and calculated elevations is good.

Figure 12 shows contour lines of the tsunami elevation above ground level within the developed area of Crescent City. The topography and tsunami elevations are known in much more detail in this developed area than any other area. The dotted parts of the measured elevation denote uncertain elevations. The contour lines for the calculated elevations were determined by linear interpolation. For example, if the elevation at the center of one cell was 9.0 ft above land and the elevation in an adjacent cell was 7.0 ft, the contour line was drawn halfway between the two cell centers. The agreement between the measured and calculated elevations shown in Figure 12 is good.

#### Conclusions

Linear long waves are adequate to simulate tsunami generation, propagation across the deep ocean, and propagation over the continental shelf of the west coast of the continental United States or the Hawaiian Islands when the uplift that generates the tsunami is large spatially (1964 Alaskan or 1960 Chilean tsunamis). Tsunamis usually appear as rapidly rising water levels along distant coastlines. Nonlinear long wave equations that include bottom function terms (typically used to model astronomical tides) can be used to model land inundation for tsunamis that appear as rapidly rising water levels. If information exists on the ground motion that generates a tsunami, the tsunami can be simulated over its complete path of propagation from a generation region up to terminal flooding at a distant coastline.

## CHAPTER FIFTY SIX

### A THREE-DIMENSIONAL MODEL OF THE BEAUFORT SEA

Shiao-Kung Liu\* and Jan J. Leendertse\*

#### Introduction

The Beaufort Sea borders the northern coasts of the United States and Canada. During the last decade, oil discovered at the Prudhoe Bay field contributes a substantial amount of the petroleum needs of the U.S. At present, it represents approximately 20 percent of the total domestic production. However, according to estimates made by the Department of the Interior, gas and oil lie under the Alaskan coastal waters (mainly in the Beaufort Sea) accounts for about 40 percent of the total domestic reserve.

To assist government agencies in their assessment of offshore oil exploration, the authors have been engaged, during the past nine years, in three-dimensional modeling work of the the Alaskan coastal area (Fig. 1). Results from the modeling work involving the Bering Sea and the Chukchi Sea have been reported at an earlier conference (Ref. 1).

This paper describes the formulation, coupling, and other essential aspects of the Beaufort Sea model (Fig. 2).

The Beaufort Sea, occupying a larger portion of the Alaskan coastal water, is dynamically interactive with other modeled areas. Most importantly, the exchange of water mass with the Chukchi Sea interconnects the Bering Sea through the Bering Strait (Fig. 3). Under certain weather conditions, ice in the Beaufort Sea can be transported toward the Bering Sea by an "ice breakout" process through the Bering Strait.

The purpose of the modeling work is to address coastal hydrodynamic-related problems, in general, as well as the following specific objectives:

- o Tidal and density-induced baroclinic circulation patterns;
- o Water and ice movements induced by wind, including storm-surges;
- o The behavior of oil movements under various spill scenarios; and
- o Providing boundary conditions for the near-shore models of higher spatial resolutions (Fig. 3).

#### The Methodology and Modeling System

Formulated on an elliptical horizontal grid and variable vertical grid, the three-dimensional model solves the equations of motion for water and ice, continuity, state, the balance of heat, salt, pollutant, turbulent energy density, the dynamics and thermodynamics of ice. The model computes the generation, melting, and the movements of ice together with the nonlinear vertical shear coupling during cooling and heating processes. This is achieved by means of a turbulence-closure technique in which the potential and kinetic energetics are monitored and

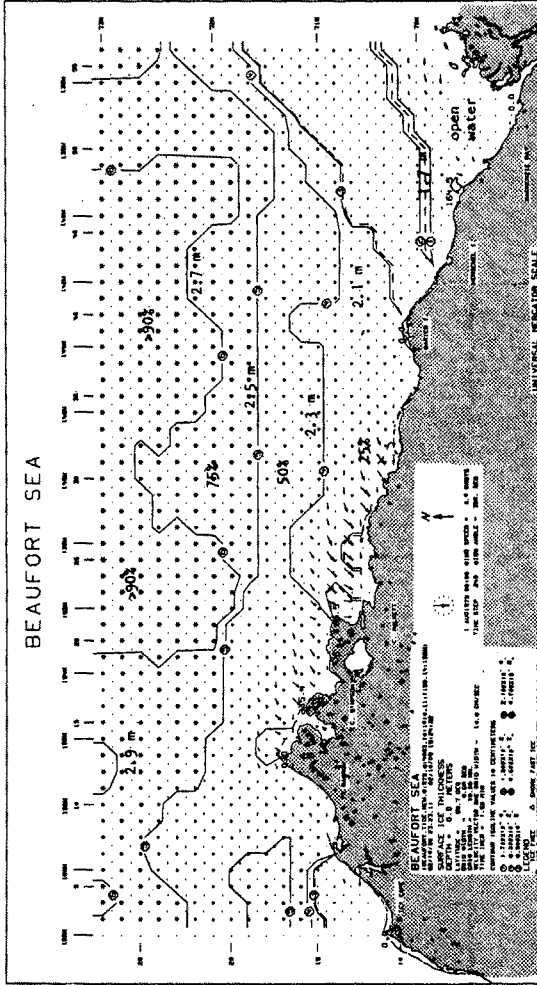

Fig. 2--Computational grid of the Beaufort Sea model plotted using the universal Mercator projection method. The map also shows the spatial distribution of ice concentration and ice thickness for the summer period.

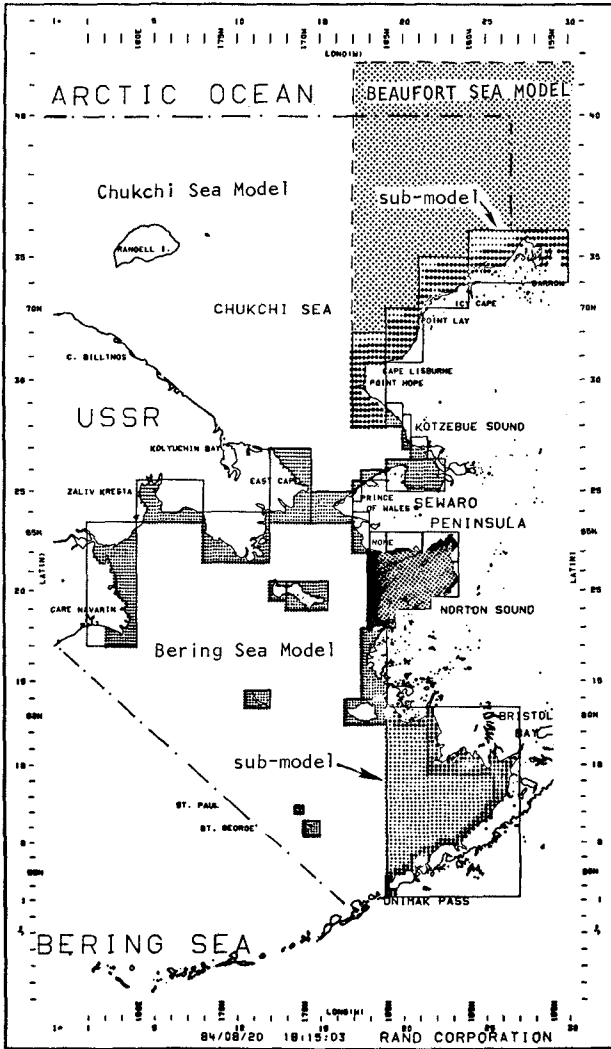

Fig. 3--Due to the interactive aspects, the western portion of the Beaufort Sea Model (shaded) is overlapped with the Chukchi Sea Model. This technique not only minimizes the boundary's effects on the computed residual currents but also would allow oil spill trajectory computations to be continued into the neighboring models. Submodels improve the near-shore resolution.

transferred in a closed form.

The hydrodynamic model is coupled to a two-dimensional stochastic weather model and an oil trajectory model. The important components and the flow of information are illustrated in Fig. 4.

The inclusion of the weather model is essential because the model covers the area where one of the world's major low pressure systems in the Northern Hemisphere (i.e. the Aleutian Low) is situated.

In developing the model we first treat the weather system over the modeled area as a stochastic process whose evolution is represented by a series of transitions between certain "state" of the process. When the number of the states is finite, the process is of the Markov type. It can be described or simulated if the probabilities of transition are known via the matrix of transitional probability. Also needed are the steady state behavior of the process chain and the amount of occupation time the chain spends in various states.

The required transitional probability matrices are generated using the daily synoptic weather data over the modeled area from 1945-1963. A  $11 \times 11$  matrix is determined for each oceanic season. Within the sampled period, 98 percent of the daily surface pressure pattern over Alaska can be classified into eleven types. The most frequent pattern (with 23 percent occurrence) during summer is a low pressure system with several centers over Alaska. Surface winds at various locations are analyzed for each weather type.

During the simulation with the stochastic weather model, wind fields generated by the Markov model are being interrupted by a storm track model which is of the Poisson type. The initial location of the extra-tropical-low is generated from a two-dimensional density function derived from the long-term observed data (Fig. 5). Figure 5 also gives the comparison between the wind rose generated from the model and those observed at three major weather stations showing zonal climatological variabilities. Detailed analyses of the probability distributions for the wind speed, direction, homogeneity and storm interruption are discussed in Ref. 2. Surface winds during the passage of a storm are computed by the gradient wind equation and modified for speed and veering angle according to local marine boundary layer stability conditions.

Another component of the modeling system is an oil-spill trajectory model which synthesizes the hydrodynamic responses of the coastal system obtained by the three-dimensional model under various forcing to compute the movement of oil resulting from simulations of the stochastic weather model. The 3-D model also provides energy densities and dispersion parameters for various layers for the oil trajectory computation. These trajectory computations have extended to eight months in elapse time at half-hourly intervals.

In addition to data synthesis, the oil trajectory model computes the surface and subsurface oil concentrations while the oil/weather processes take place.

#### Modeling Results

Our first step in the model development has been the determination of tidal and baroclinic residual circulation. The latter is caused by

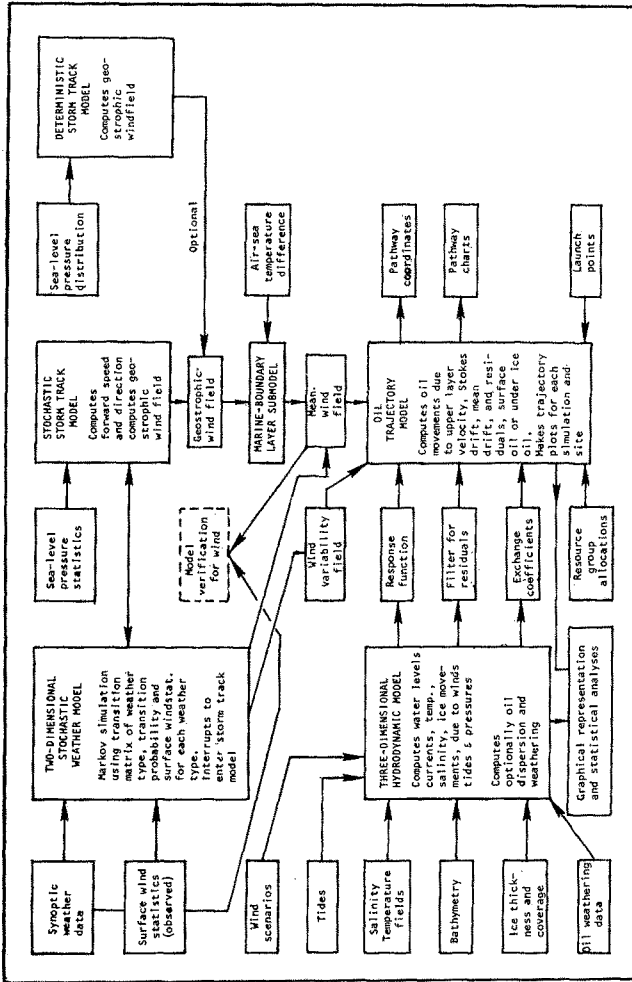

Fig. 4--Essential components of the two-dimensional stochastic weather simulation model; also showing their inter-relationship between the three-dimensional hydrodynamic model and the oil-spill trajectory model. Transitional probabilities of the weather states are derived from 19-year synoptic weather data.

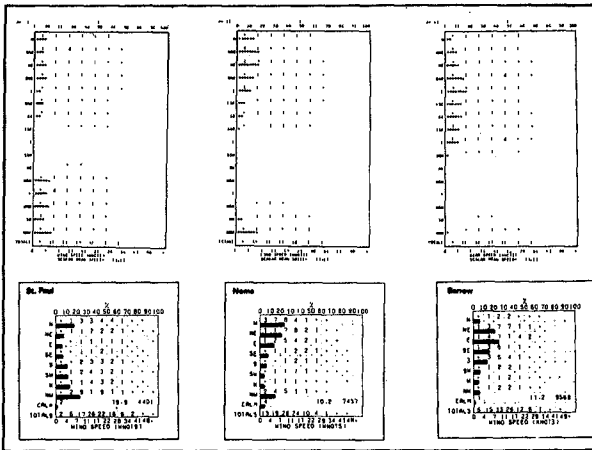

Fig. 5--Top graph shows the probability density function (pdfx10000) of the occurrence of extra-tropical cyclones within the modeled area. Lower graphs show the comparison between the wind roses generated by the long term simulation of the stochastic weather model and the observed wind roses at three ground stations for the month of July.

the density field and is interactive with the former. Originating from the Arctic Ocean, the tides in the Beaufort Sea generally move in a clockwise direction. The computed co-tidal chart for the semi-diurnal component is illustrated in Fig. 6. Also presented are the comparisons between the computed and the observed values at several locations. The agreement is generally quite good except near Herschel Island where the measured value is two centimeters higher. The difference may be attributable to the location of the gauge which, for practical reasons, was deployed behind the barrier island.

The computed tidal current ellipses, including baroclinic components for the surface layer is presented in Fig. 7. Figure 8, also for the surface layer, is the residual circulation pattern. The plotting scale for the current vector is two kilometers for each model grid-spacing.

The combined effects of residual circulation and the weather's effects can be illustrated by a map showing the trajectories of hypothetically spilled oil as they are released at various locations in the Beaufort Sea (Fig. 9), all under identical sequence of weather state. The daily movement of oil (depicted by a dot) reflects the local circulation as well as the evolution of weather states. The series of wind vectors plotted on top of the graph represent the 12-hour mean wind at Point Barrow. From Fig. 9, the shore's effect on the movement of oil is quite obvious.

In order to evaluate the risk (probability) associated with the oil development, a sequence of oil-spill scenarios have been selected at important locations representing platforms, pipelines, and transportation routes.

Figure 10 shows the comparison between trajectories of five satellite-tracked buoys deployed by the U.S. Coast Guard for a period of three months, and 30-day trajectories launched from five locations computed by the oil-spill trajectory model. They generally agree both in speed and in direction of movement.

Also needed for the evaluation of ecological impact, the concentrations of the spilled oil are computed. This computation includes the evaporation, dissolution, and spreading across the vertical layers.

Figure 11 shows the daily envelope of one-part-per-billion concentration contour of a hypothetical 30-day continuous spill of 500 barrels of crude oil per day under a summer condition. Loops in the plume's centerline indicating the occurrence of three low pressure centers move across the Bering Sea area. Under identical weather sequence, oil released from other areas, experiences an entirely different drift pattern.

The effects of shoreline and zonal climate difference on the movements of oil can be illustrated in Fig. 12. The peninsula in the figure exerts substantial influence on both near-shore residual currents as well as on the local wind pattern.

#### Conclusions and Discussions

Soon after the beginning of our modeling effort, it became clear that hydrodynamic computations per se cannot sufficiently address important policy issues. Other types of models such as for oil, ice, and weather related processes were needed. Weather models are of particular

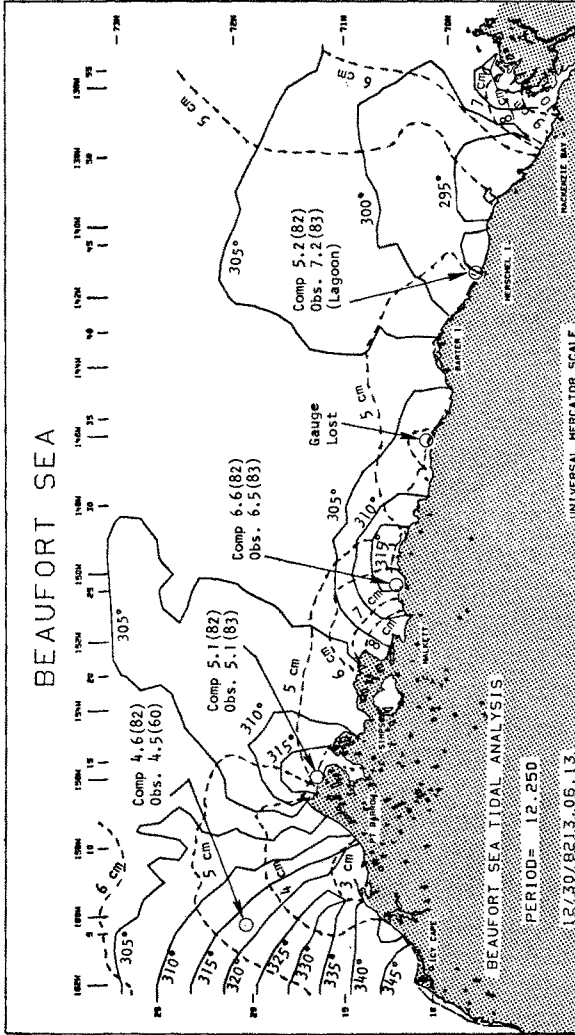

Fig. 6--Computed co-tidal chart for the semi-diurnal component in the Beaufort Sea showing amplitudes in cm and Greenwich phase in degrees. Computations were made in December 1982, and observations were made in September 1983 and published in 1984 (Pitman, 1984).

Fig. 8--Computed tidal and baroclinic residual current in the surface layer using a plotting scale of 2 km/day per grid space

Fig. 9--Thirty day oil spill trajectories launched from hypothetical spill locations. Near shore trajectories within the ice-free area tend to move downwind whereas the oil in the offshore area tend to have various turning angles depending on the local ice concentration.

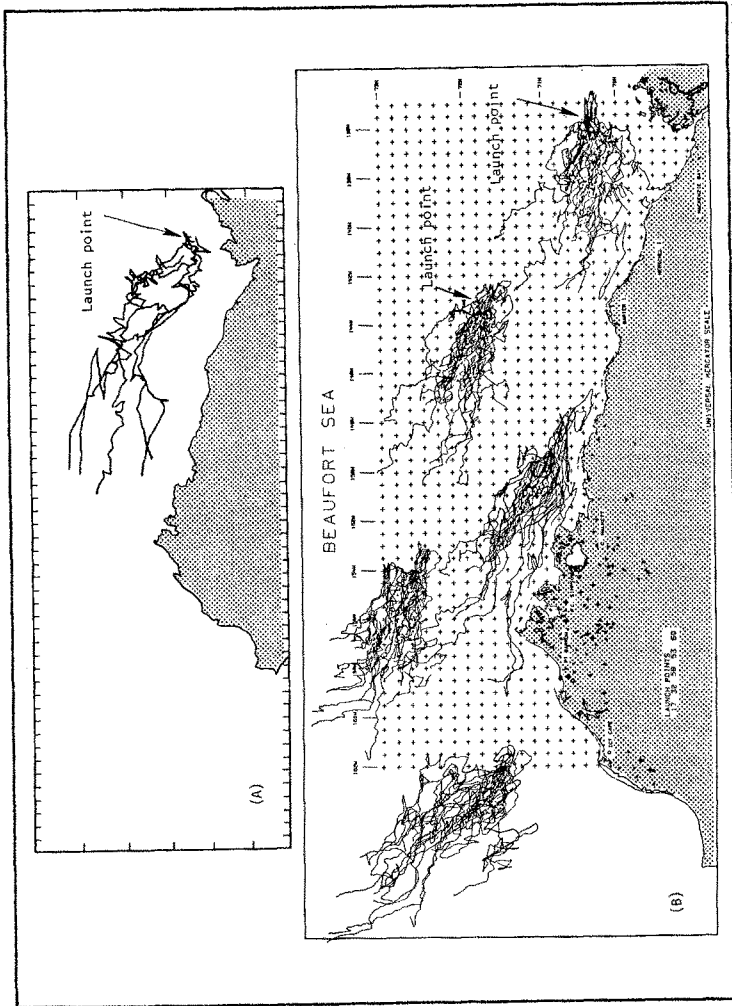

Fig. 10--Comparison between (A) trajectories of five satellite-tracked buoys deployed by the U.S. Coast Guard during the period between the months of August and October, 1979 from eastern Mackenzie Bay, Canada, and (B) 30-day trajectories launched from five locations computed by the oil spill trajectories model and the two-dimensional stochastic weather simulation model.

Fig. 11--Daily envelope of one-part-per-billion concentration contour of a hypothetical 30-day continuous spill of 500 barrels of crude oil per day under a summer condition.

Fig. 12--The effects of shoreline and zonal climatic difference on the movements of oil

importance as the weather is often the major driving force for the generation of currents, movement of ice, and the dispersal of oil.

The stochastic-type of weather model is more suitable for the coastal area than the steady-state type of model in which winds are randomly generated based on a given wind rose. The latter method can be used under open ocean conditions where the drift duration is long and the nonlinear dynamic effects induced by the coasts are less significant. In coastal areas, the sequential occurrences of weather types tend to govern the final landfall location, particularly where coastal features and orographic influences have to be taken into consideration.

Finally, numerical models are particularly useful in remote areas where observed data are scarce and difficult to obtain, such as the one reported here. A preliminary model, formulated according to fundamental parameters and existing data, would serve as a starting point. Results from the initial analysis would then indicate the data needs. It can also assist in designing an effective field sampling program.

With new data, the investigators can thence improve the model formulation and proceed in an efficient manner.

#### ACKNOWLEDGEMENTS

This study was supported by the U.S. Bureau of Land Management through interagency agreement with the National Oceanic and Atmospheric Administration, under which a multi-year program responding to the needs of petroleum development of the Alaskan Continental Shelf is managed by the Outer Continental Shelf Environmental Assessment Program (OCSEAP) office. Thanks also go to our Rand colleagues, A. B. Nelson for his excellent programming effort and G. Coughlan for paper preparation.

## CHAPTER FIFTY SEVEN

### Model Harbour Seiching Compared to Prototype Data

W A M Botes\*, K S Russell\*, P Huizinga\*

#### 1. INTRODUCTION

Since 1978 a finite-difference numerical model based on that developed by Leendertse and adapted for resonance studies (Russell and Huizinga, 1978) has been applied to investigate harbour resonance in Table Bay Harbour and several other South African ports.

During April 1981 three long-wave recorders were installed in the cooling water intake basin of the Koeberg Nuclear Power Station to determine the occurrence and magnitude of the long waves and to measure the corresponding response of the basin. Koeberg is situated on the west coast of South Africa, 30 km north of Cape Town and is exposed to the approaching cyclonic weather systems which experience has shown to be associated with the occurrence of long waves. An example of an approaching low pressure system with the location of Koeberg is shown in figure 1.

Figure 1. South Africa with approaching low-pressure systems, passing from west to east

Data were sampled over a period of two years and a paper on the characteristics of the long waves in the Koeberg basin was presented at the ICCE in 1982 by Botes, Russell and Huizinga (1982). In that paper the

\* National Research Institute for Oceanology, Stellenbosch, Republic of South Africa.

correlation between the occurrence of long-period waves and short-period waves was shown. During the sample period the recorders were switched to continuous mode during extreme weather conditions. These relatively long records could be analysed with a high degree of confidence and resolution for determining the response of the basin.

This paper presents further work using prototype results since they provide the basic data to calibrate and verify a numerical model of the Koeberg basin designed to study its resonance characteristics. This also allowed the investigation of aspects such as the sensitivity of the numerical model to grid sizes, computational time steps, friction, etc. The Koeberg intake basin provides an ideal configuration for the abovementioned investigations, as the basin is of medium size and situated on a straight coastline with a uniformly contoured seabed.

2. PROTOTYPE DATA SAMPLING

The water level recorders used consist of pressure transducers connected to magnetic tape recorders. Data were sampled at an interval of 1,0 s for a duration of 50 minutes every 12 hours. When resonance was visually observed the recorders were switched to continuous mode.

Three water-level recorders were installed in the basin and were in operation for the period April 1981 to March 1983. The characteristics of the long waves and the relation between the long- and short-period wave heights are described in Botes, Russell and Huizinga (1983). The long-period wave heights between 50 s and 110 s measured in the Koeberg basin are illustrated in Figure 2 where the wave height exceedance curves are drawn for the three recording positions.

Figure 2. Long-period wave height exceedances

The analysis of the data was based on the auto-covariance method and is described in Botes (1980).

### 3. THE NUMERICAL MODEL

#### 3.1 General

The computations for this numerical model were based on the approximation of the hydrodynamic equations (conservation of mass and momentum equations in terms of the water elevation and depth average velocity) by using finite-difference techniques. The finite-difference modelling scheme, originally developed by Leendertse (1967), was adapted at the CSIR to accommodate any harbour layout (Russell and Huizinga, 1978). The modifications included radiative open boundaries, based on the method of characteristics which could be applied to any of the model boundaries to permit the passage of reflected waves. The same type of boundary was constructed on the side of the model which faced the main long-wave direction for the input wave conditions.

Figure 3. Computational field of the numerical model

The model area of Koeberg was represented by a two-dimensional grid system ( $50 \times 50$ ) with a grid size of 30 m which was the largest grid size which could describe this particular harbour configuration accurately.

At each grid point the depth and bottom friction were described and the velocities and water level fluctuations were calculated.

The computational field of the model was described by a notation of "1"'s and "0"'s with which the harbour configuration, shoreline, boundaries, etc. could be defined. The model created a computational notation by scanning this field vertically and horizontally. The computational field is described in Figure 3.

### 3.2 Input Conditions and Output of the Model

A method was developed to incorporate a range of frequencies in one model run by simulating an input wave spectrum which could be obtained by the bandpass filtering of a white noise spectrum. During the model run, time-series recordings were made at selected grid locations. These time-series were analysed in the frequency domain and the amplifications between two locations were obtained by the direct relation between the spectral density estimates of the two selected locations. The analysis was based on the auto-covariance method and is described by Botes (1983).

The advantages of this method were that the model and prototype data could be compared directly for calibration purposes and that it led to impressive savings over an approach where individual regular long waves were used in the model.

Frequencies which caused high amplifications were identified and the model was then operated with a sine wave input, with frequencies similar to the identified peaks. Maximum water level fluctuations over the entire harbour area were obtained as well as velocity vector fields at certain time steps.

### 3.3 Selection of Grid Size and Time Step

The computational time and cost of such a numerical model is directly related to the grid size and the computational time step.

The grid size must be small enough to provide not only a sufficient description of the coastline and harbour geometry but also to describe the bottom topography accurately. Bottom profiles can be very irregular with deep, narrow channels as at the entrance of the Koeberg basin. For adequate description of the Koeberg basin a maximum grid size of 30 m was needed for this study.

The computational system is unconditionally stable and is consistent so that the solution of the difference equations converge to the solution of the differential equations, the "true solution", as the grid size and time-step approach zero.

The stability, convergency and accuracy of the scheme is described by Leendertse (1967). The computational time-step can be determined theoretically with a few guidelines such as the Courant criterion and wave description, for the minimum phase and amplitude deformation. However, there was still a need to determine the sensitivity of the model compared to prototype measurements. If various layouts for a harbour are to be tested for a preliminary study, considerable cost can be saved if a bigger time-step than that theoretically decided on, can be used as long as the results are within acceptable limits.

The accuracy of the model (amplitude) compared to prototype responses for various time steps was determined with this series of tests.

#### 4. RESULTS

##### 4.1 Calibration

As mentioned, the grid size is controlled by the harbour geometry and topography. Initially a grid size of 30 m was chosen. For an average depth of 7 m the wave celerity is:

$$C = \sqrt{gd} = 8,29 \text{ m/s}$$

where  $d$  = depth (m)  
 $g$  = gravitational acceleration ( $\text{m/s}^2$ ).

For the best first approximation to a value for  $\Delta t$  we can put the Courant number,  $C_r$ , equal to 1:

$$C_r = C \cdot \Delta t / \Delta l = 1$$

where  $\Delta l$  = model grid size (m)  
 $\Delta t$  = model time step (s).

For  $C = 8,29$  and  $\Delta l = 30$

$$\Delta t = \frac{30}{8,29} \approx 3,62$$

$$\Delta \tau = 4,0 \text{ s.}$$

With a time step of 4,0 s and a grid size of 30 m the model was run with a random input between 0,0075 Hz (133,3 s) and 0,026 Hz (38,5 s). For the shortest wave, that is 38,5 s, the wave description (number of points per wave length) was  $T/\Delta t = 9,6$  and  $L/\Delta l = 10,6$ , which according to Leendertse (1967) is approximately the lower limit for wave description before considerable phase shift will occur.

Figure 4. Prototype and model responses for  $\Delta t = 4,0$  s

The model responses between locations 1 and 2 are compared to the prototype data in Figure 4. The model topography was similar to the prototype topography that existed when the long waves were recorded.

The peak amplification at 0,015 Hz (66,67 s) compared well with the prototype data. This is the standing wave between the lateral arm and the shore side of the basin. Although the form of the total response wave tended to the shape of the prototype response curve, the correlation became worse from 0,013 Hz and lower. This is due to the lack of exact description of the topography in the outer basin which was still in the construction stage (dredging) during the time when the prototype data were recorded.

During 1978 an existing physical short-wave penetration model (scale 1:80) was used to investigate the response of the physical model to long waves.

This physical model had been constructed with a simplified harbour topography (a depth of 6,0 m throughout) and responded to a wave of 91 s. The numerical model responded to a wave of 85 s when an average depth of 6,0 m was also used in the model.

The resemblance between the velocity fields of the numerical and physical models is illustrated in Figure 5.

Figure 5. Velocity fields

Numerical model  
 $T = 85,7$  s

Physical model  
 $T = 91,0$  s

#### 4.2 Influence of Varying Time-steps on the Accuracy of the Model

As the grid size was fixed for the description of the layout it was attempted to increase the computational time-step in order to economize the model.

Although the shape of the response curve changed with a bigger time-step the peak response period and the magnitude of the amplification for the basin remained the same for a computational time-step of 6,0 s which resulted in a  $T/\Delta t$  of 6,4 and Courant number of 1,7. The result is illustrated in Figure 6.

Figure 6. Prototype and model responses for  $\Delta t = 6,0$  s

The influence of the time-step on the accuracy of the model is best illustrated when the amplifications and velocity fields over the entire harbour area for the peak period of 66,67 s are compared as illustrated in Figures 7a-f.

Figure 7a. Maximum amplifications  
 $\Delta t = 4,0$  s,  
 $T = 66,7$  s,  
 Input height = 0,1 m

Figure 7b. Maximum amplifications  
 $\Delta t = 6,0$  s,  
 $T = 66,67$  s,  
 Input height = 0,1 m

Figure 7c. Maximum amplifications  
 $\Delta t = 8,0$  s,  
 $T = 66,67$  s,  
 Input height = 0,1 m

Figure 7d. Velocity field  
 $\Delta t = 4,0$  s,  
 $T = 66,67$  s,  
 Input height = 0,1 m

Figure 7e. Velocity field  
 $\Delta t = 6,0$  s,  
 $T = 66,7$  s,  
 Input height = 0,1 m

Figure 7f. Velocity field  
 $\Delta t = 8,0$  s,  
 $T = 66,7$  s,  
 Input height = 0,1 m

From these figures it can be seen that a computational time-step of 8,0 s ( $T/\Delta t = 4,81$ , Courant number = 2,2), which is twice the theoretically determined time-step, can still be used when numerous preliminary tests are necessary to determine an optimum layout. This results in considerable savings on computer cost and time.

However, for a time step of 10,0 s ( $T/\Delta t = 3,85$ , Courant number = 3,0). As shown in Figure 8, there is no sign of the characteristic response of the basin when compared to Figures 7a-c.

Figure 8. Maximum amplifications

#### 4.3 Influence of the Magnitude of the Input Wave

As the long-wave amplitudes range between 10 and 50 cm in the prototype, the influence of the magnitude of the input waves to the model was investigated.

As experienced with the prototype data the model response was consistent, irrespective of the magnitude of the input waves as illustrated in Figure 9 and compared to Figure 7b.

Figure 9. Maximum amplifications  
 $\Delta t = 6,0 \text{ s}$ ,  $T = 66,7 \text{ s}$ ,  
 Input height =  $0,2 \text{ m}$   
 Amplifications are the values divided by 2

4.4 Influence of Water Depth

In relatively shallow areas in a harbour layout the water levels are of great importance when comparing model results to prototype data as illustrated in Figure 10 where the responses of the model for water levels at spring, mean and neap tides are compared with prototype data.

Figure 10 Model responses at different water levels compared to prototype data

## 5. CONCLUSIONS

- (1) The prototype data provided valuable information on wave-height exceedances, correlation between short and long-period wave heights, and response data to calibrate and verify the numerical model.
- (2) The numerical model could be calibrated with a computational time-step of 4,0 s.
- (3) Resemblance between the physical and numerical model results is very good.
- (4) For basic investigations with the response frequency, larger time-steps can be used in order to save cost and time.
- (5) For a wave description ( $T/\Delta t$ )  $< 4,8$  and a Courant number  $> 2,2$  the model results are completely inaccurate.
- (6) In relatively shallow harbours the response of the basin is strongly influenced by the water depths (tidal variation).
- (7) The response of a basin (i.e. pattern of oscillation and degree of amplification) is not influenced by the magnitude of the input wave height.

## CHAPTER FIFTY EIGHT

### Boundary Condition for Limited Area Modeling

H. Lee Butler<sup>1</sup>, and Y. P. Sheng<sup>2</sup>, M, ASCE

#### Abstract

A simple open boundary condition for limiting the computational domain in tidal simulations is presented. In modeling the impact of proposed coastal projects with a limited-area model, problems due to undesired reflection of gravity waves at open boundaries often occur. The boundary condition presented herein eliminates these problems in many instances and can be easily incorporated into a wide variety of models. The adapted procedure permits representation of appropriate forcing conditions while allowing propagation of internally-generated disturbances out of the open boundaries. Applications to real world engineering problems are presented.

#### Introduction

Numerical models are routinely used to assess the potential impact of proposed hydraulic or geometric modifications within coastal areas. A recurring problem in these applications is the establishment of appropriate boundary conditions for both baseline and improvement simulations. For tidal simulation by means of a vertically-integrated model, it is often sufficient to specify the surface elevation along the open boundaries based on existing tidal measurements at these boundaries. However, the presence of a proposed modification within the model domain may introduce enough disturbance to significantly alter the tidal conditions at the open boundaries.

In such a case, using existing tidal measurements at the boundaries of the limited-area model will lead to wave reflection and hence erroneous simulation results within the model domain. Traditionally, this problem has been resolved by moving the open boundaries to locations substantially further from the area of interest such that existing measurements there may be utilized without causing damaging wave reflections. This procedure leads to a much larger computational domain and hence extra computational cost. Moreover, there may exist little or no data at such far-away open boundaries and acquisition of such data can be expensive and difficult to obtain. In an effort to simulate the effect of tidal barriers in a limited-area model, Prandle (9) utilized the concept of Garrett (5) to objectively assess the validity of applying existing tidal measurements at various downstream boundary locations.

## Wave Separation/Radiation Boundary Condition

The approach used is based on the concept that tidal data at a given coastal location (e.g., the open boundary) can be represented by the superposition of an incident and an outgoing component. The present formulation is a variation of the approach given by Orlanski (8) which did not include any external forcing, and is somewhat similar to the port boundary condition used by Reid and Whitaker (10) in the limiting case of negligible spatial variation of the wave phase speed. The application of Reid and Whitaker's condition, however, requires the explicit estimation of the tidal impedance according to the empirical formula of Garrett (5). The estimation of tidal impedance in the presence of proposed structures is not a straightforward matter.

Consider the scalar wave equation (or Sommerfeld radiation condition) as given by

$$\frac{\partial \phi}{\partial t} + c \frac{\partial \phi}{\partial x} = 0 \quad (1)$$

where  $\phi$  is the surface elevation or fluid velocity and  $c$  is the phase velocity of the wave. Let Figure 1 describe an area within the computational domain where we desire to establish an open-boundary condition that permits any internally-generated disturbances to pass through the boundary without undergoing significant distortion and without influencing the interior solution. Let  $p$  and  $q$  represent the outgoing and

FIG. 1.-Typical Location for Applying the Wave Separation/radiation Boundary Condition

incoming tidal waves, respectively. The surface elevation ( $\eta$ ) at the boundary (B) is given by the superposition of  $p$  and  $q$ , or

$$\eta = p + q \quad (2)$$

Functional representations of  $p$  and  $q$  can be given in characteristic form as

$$p = f(x - ct) \quad \text{and} \quad q = g(x + ct) \quad (3)$$

Assuming flow through the open boundary is approximately normal to the boundary, the scalar wave equation can be used to approximate tidal behavior at B. Substituting the value of surface elevation given by expressions (2) and (3) into Equation 1 and evaluating the lefthand side at the boundary, we obtain

$$\begin{aligned} \frac{\partial(p+q)}{\partial t} + c \frac{\partial(p+q)}{\partial x} &= \frac{\partial p}{\partial t} + c \frac{\partial p}{\partial x} + \frac{\partial q}{\partial t} + c \frac{\partial q}{\partial x} \\ &= -cf' + cf' + cg' + cg' \\ &= 2cg' = 2q' \end{aligned} \quad (4)$$

The term  $q'$  is the time derivative of the incoming wave evaluated at B, i.e.,  $q'_B$  is given as

$$\left. \frac{\partial \eta}{\partial t} + c \frac{\partial \eta}{\partial x} \right|_B = 2q'_B \quad (5)$$

This formulation only requires knowledge of the incoming tidal wave. The proposed strategy is to (a) measure tidal elevation at the open boundary for some existing condition under various tidal events, (b) apply the interior hydrodynamic model under tidal forcing and evaluate the lefthand side of expression (5) to obtain  $q'_B$ , and (c) introduce proposed interior modifications for impact evaluation and apply Equation (5) as a forcing boundary condition at B.

In case of an open boundary on the left side of the computational domain, a corresponding condition can be derived as

$$\frac{\partial \eta}{\partial t} - c \frac{\partial \eta}{\partial x} = -2cf' = 2p' \quad (6)$$

If interior modifications to be investigated do not alter characteristics of the incoming tide, only a different combination of incoming and outgoing waves at the boundary will occur. The wave separation/radiation (S/R) open boundary condition prescribes the correct incident component,  $q$ , and allows the outgoing component,  $p$ , to be modified by any internally-generated disturbances. In the absence of tides, the S/R condition reduces to the simple Sommerfeld radiation boundary condition.

For simplicity, the above discussion has been given for the limiting case of subcritical flow and small amplitude wave. Extension of the basic concept to the more general case has been studied and will be

discussed elsewhere. The major difference is that the more general S/R condition involves both  $\eta$  and the velocity  $u$ .

Numerical Implementation

The S/R boundary condition application is not dependent on the type of numerical algorithm used for solving the equations of motion within the computational domain. In all application examples vertically-integrated two-dimensional implicit finite difference models were used (1,11). These schemes employ a three-time level alternating-direction implicit (ADI) algorithm to solve the equations of motion on a variable-stretched rectilinear grid. Any finite difference representation of Equation (5) or (6) must be consistent with the interior scheme. The ADI procedure in the models mentioned above uses the double-sweep method to efficiently solve for the dependent flow variables. For simplification we will consider the boundary to be parallel to the y-direction (Fig. 1) and hence only the x-sweep of the algorithm is affected. The index  $m$  ( $M$  in FORTRAN notation) will be used to mark the boundary location within a staggered grid system (Fig. 2). The grid stretching is of the exponential type and involves only a weighting factor ( $\mu$ ) with the second term in Equation (5). For the three time level ADI scheme (ADI3T)

FIG. 2.-Staggered Grid Cell Definition at the Open Boundary

used in Butler (1), Equation (5) in finite difference form is

$$\left(\frac{\partial \eta}{\partial t}\right)_{m+1/2}^k + \left(\frac{c}{\mu}\right)_{m+1/2}^k \left(\frac{\partial \eta}{\partial x}\right)_{m+1/2}^k = 2(q')_{m+1/2}^k \quad (7)$$

where  $k$  is the time step counter and  $\mu_{m+1/2}^k$  is the weighting factor to account for the grid stretching (variability).

If

$$z_{m+\frac{1}{2}}^k = \frac{2 \Delta t c_{m+\frac{1}{2}}^k}{\mu_{m+\frac{1}{2}} \Delta x} \quad (8)$$

and

$$F^k = 8 \Delta t q'_{m+\frac{1}{2}}^k + \eta_{m+1}^{k-1} + \eta_m^{k-1} + z_{m+\frac{1}{2}}^k \left( \eta_{m+1}^k - \eta_m^{k-1} \right) \quad (9)$$

then the ADI3T approximation for Equation (5) can be written as

$$\left( 1 - z_{m+\frac{1}{2}}^k \right) \eta_m^{k+1} + \left( 1 + z_{m+\frac{1}{2}}^k \right) \eta_{m+1}^{k+1} = F^k \quad (10)$$

The last interior equation evaluated adjacent to the boundary is of the form

$$-a_M \eta_M^{k+1} + \bar{a}_{M+\frac{1}{2}} u_{M+\frac{1}{2}}^{k+1} + a_{M+1} \eta_{M+1}^{k+1} = D_{M+\frac{1}{2}}^k \quad (11)$$

where the coefficients  $a$  and  $\bar{a}$  are defined in terms of known quantities and where  $a_M = a_{M+1}$ . Substituting the expression for  $\eta_{M+1}^{k+1}$  from Equation (10) into (11), one obtains

$$-\frac{2a_M}{1 + z_{M+\frac{1}{2}}^k} \eta_M^{k+1} + \bar{a}_{M+\frac{1}{2}} u_{M+\frac{1}{2}}^{k+1} = D_{M+\frac{1}{2}}^k - \frac{a_M F^k}{1 + z_{M+\frac{1}{2}}^k} \quad (12)$$

To implement Equation (12) as a boundary condition in the ADI model, only a few recursion coefficients in the solution algorithm need to be changed. Note that no restrictions have been made on grid cell dimensions or time step.

Actual implementation of the S/R boundary condition in areas of complex geometries may result in high frequency oscillations superimposed on the derivative of the incident wave,  $q'$ . This problem can be eliminated by applying a temporal smoothing formula. In some applications presented herein a central smoothing formula of degree 3 over a subrange of 13 time steps was effective (6).

#### Tests and Applications

As stated previously the S/R boundary condition was used in conjunction with a vertically-integrated model (WIFM or WES Implicit

Flooding Model) developed at the U. S. Army Engineer Waterways Experiment Station. The governing equations and computational scheme are explained in the paper by Butler (1). This model, as well as a two time level ADI model used by Sheng (11), were employed in performing extensive tests of the S/R boundary condition in idealized basins with simple geometry and bathymetry. These included one-dimensional model tests with parameter variations of (a) constant depth or sloping bottom, (b) fixed or variable grid spacing, (c) uniform flow or tidal forcing, and (d) the introduction of internal modifications. Also tested were two-dimensional basins with similar parameter variations. Once the boundary condition algorithm was coded to be consistent with the ADI models all tests were successful in radiating the outgoing wave components without reflection or without disturbing the incoming signal.

To demonstrate the application of the S/R condition, we present a simple example of wave propagation in a one-dimensional channel with a length of 10 spatial units. Consider an external forcing of  $\sin(2\pi t/100)$  on the right boundary with radiation at the left boundary. For simplicity, but without loss of generality, we assume that  $\Delta t = 1$ ,  $\Delta x = 1$ , and  $c = 1$ . Based on these boundary conditions and parameter values, the results of the one-dimensional wave equation along the channel at a particular instant of time are shown by the solid line in Figure 3.

The dashed line in Figure 3 was obtained by using the S/R condition on the right boundary. In the separation mode the model was run with the conditions just described in the last paragraph. The term,  $q'$  (Equation 5), was evaluated at each time step on the right boundary (using one-sided differences) and stored on a file. The model was then run in the radiation mode with Equation (5) as a boundary condition on the right boundary.

The slight discrepancy shown in Figure 3 is associated with the fact that the interior numerical scheme is based on central differencing while one-sided differences were used at the boundary in computing  $q'$ . When central differences were used in the separation mode to compute  $q'$ , the radiation mode results agreed exactly with the result obtained by external forcing.

The primary motivation for a S/R boundary condition was a project impact study involving a proposed navigation lock and flood-control structure at the Lake Pontchartrain, Louisiana, end of the Inner Harbor Navigation Canal (IHNC). This application was part of a comprehensive study to evaluate effects of the Lake Pontchartrain and Vicinity Hurricane Protection Plan (3).

Lake Pontchartrain is adjacent to and just north of the city of New Orleans, Louisiana. In addition to two natural pass connections to the Gulf of Mexico, there is a man-made canal, including the IHNC and Mississippi River-Gulf Outlet (MR-GO), which connects the southernmost part of the lake with the Gulf of Mexico. The Gulf Intracoastal Waterway

FIG. 3.—One-Dimensional Test of the S/R Boundary Condition

FIG. 4.—Vicinity and Gage Location Map for the Lake-IHNC Sectional Model

(ICWW) also joins with the MR-GO resulting in a highly complex lake-channel waterway.

A part of the study centered on investigating effects of the proposed lock and flow-control structure at the lake end of the IHNC. Figure 4 depicts the waterway subsystem geometry, location of the proposed structure (S), and locations of prototype measurement stations (P5 and P6). A numerical sectional model of the lake-IHNC complex was constructed and verified with tidal elevation and current data taken at locations P5 and P6. In addition, a physical hydraulic model of the same area was constructed, verified for existing conditions under steady state flow, and run for various flow rates and head differences between the lake and the IHNC. These results were used to define the structure hydraulic characteristics in order to permit proper numerical representation, and are reported by Butler, et al., (2). Results from the hydraulic model tests were used to verify the S/R boundary condition for peak flow conditions (near steady state).

The numerical sectional model of the lake-channel complex was calibrated and verified to simulate steady-state flow conditions generated in the undistorted hydraulic model of the same area. Frictional coefficients associated with barriers representing the existing bridge constriction at the lake entrance of the IHNC and those representing the lock/structure for various operating conditions were determined. In all cases the model was forced at the IHNC open boundary with discharge rates while lake levels were held at specified values.

Without changing any model parameters the numerical sectional model was forced with mixed tides (determined from analyzed constituent data at P5 and P6) at both the lake and IHNC open boundaries. Table 1 shows, for a series of average water levels in the lake and IHNC at peak flood conditions corresponding to a spring, mean, and neap tide, a comparison of discharge rates taken from the numerical and hydraulic model tests. Similar comparisons were noted for peak ebb discharge conditions.

TABLE 1. Comparison of IHNC Discharge Rates Predicted by the Hydraulic and Numerical Sectional Models for Existing Conditions

Tide Event	Water Levels (cm)		Discharge Rate ( $m^3/sec$ )	
	IHNC	Lake	Hydraulic	Numerical
Spring	12.8	2.4	490	496
Mean	7.9	1.2	408	382
Neap	1.5	-1.2	215	227

For each tide simulation the derivative of the incident wave at P6 was computed and stored for later use. Replacing the tidal forcing boundary condition at P6 with the S/R boundary condition resulted in identical model results throughout the computational domain. Figure 5 depicts a comparison of the elevation computed at the S/R boundary with analyzed prototype data for a mean tide.

FIG. 5.-Comparison of Analyzed Prototype Surface Elevation Data at Gage P6 with Computed Results at P6

FIG. 6.-Impact of the Lock/Structure System on Tidal Elevations and Discharge Rates in the IHNC

The proposed lock/structure was placed in the model and runs were made for the three tidal conditions mentioned above, using the S/R boundary condition as a forcing condition. Results for the mean tide condition with and without the lock/structure modification are shown in Figure 6a (tidal behavior in the IHNC) and Figure 6b (changes in IHNC discharge rates). Table 2 shows a similar comparison as in Table 1 for differences between the numerical and hydraulic model tests. The results indicate a very good agreement was reached for the near steady-state portions of the tidal cycle. What is significant is that a small change in channel discharge may be associated with a large change in tidal amplitude in the IHNC. This is expected since the constriction of the lock/structure system in a fully-open operating condition reduces the existing cross-sectional area of the IHNC lake entrance by about 70 percent. Also as expected, the impact is significantly less during a neap tide event.

TABLE 2. Comparison of IHNC Discharge Rates Predicted by the Hydraulic and Numerical Sectional Models for Plan Conditions

Tide Event	Water Levels (cm)		Discharge Rate ( $m^3/sec$ )	
	IHNC	Lake	Hydraulic	Numerical
Spring	40.2	3.7	408	405
Mean	28.0	3.4	317	328
Neap	6.1	0.0	161	164

A second application of the S/R boundary condition involved its use as a simple radiation boundary condition. To implement such a condition one need only input a zero derivative for  $q'$  at the open boundary. The radiation condition was applied in a generalized numerical model for longshore currents (12). The vertically-integrated long wave equations were modified to include radiation stresses defined in terms of the local values of the wave height, wave number, and wave direction. For the bottom friction a linear formulation, similar to that of Longuet-Higgins (7), was used in all applications. The solution algorithm is similar to that used in WIFM and is computed on a variable-spaced rectangular grid. A wall condition was assumed at the still water line along the beach. A zero-gradient flux condition was used at the open-sea lateral boundaries extending seaward from the beach. Of primary concern was the selection of a proper boundary condition for the seaward boundary, parallel to the shore.

Use of a fixed elevation or wall boundary condition on the offshore boundary will develop transients in the numerical solution. Such transients are evident in the results (Fig. 7) present by Ebersole (4). If transients are present that reflect between the shore and the offshore boundary, a steady condition of no flow in the onshore and offshore direction is not achieved. If steady state is assumed, grid cells will have small but steady currents in onshore and offshore directions that will produce steady erosion and deposition when these currents are used as input to sediment transport models.

FIG. 7.-Velocity with Transients in the Offshore Direction (4)

FIG. 8.-Velocity in the Offshore Direction Using the S/R Boundary Condition (12)

To eliminate the problem with transients, the S/R boundary condition was used as a simple radiation condition. Figure 8 shows a test (12) similar to the one run by Ebersole, except using the radiation boundary condition. Velocity in the offshore direction reached a steady zero velocity after approximately 6 minutes. Similar results were obtained for wave setup and the longshore velocity component. All tests demonstrated how well the S/R condition worked.

#### Conclusions and Remarks

The successful application of this type of boundary condition in various idealized and practical investigations has resulted in cost-effective analysis by permitting a reduction in model limits. The efficient numerical scheme and the ability to vary spatial coordinates at the boundary allows for realistic and easy application to a large number of coastal impact studies. Current research is aimed at expanding the S/R boundary condition approach to more complicated two- and three-dimensional model problems. In addition, the condition has been recently developed for application on a generalized curvilinear grid. These developments will be reported in forthcoming articles.

## CHAPTER FIFTY NINE

### Is Surf Beat Forced or Free?

David A. Huntley and Chang S. Kim\*

#### Abstract

Although many field experiments have shown that surf beat motion, with periods longer than incident wave periods, becomes the dominant feature of the nearshore velocity field as the shoreline is approached, the nature of this motion is still not fully understood. This paper describes a field experiment on a sheltered beach which was designed to distinguish between long wave motion directly forced by the incident wave envelope (as suggested by Longuet-Higgins and Stewart, 1962), and wave motion which is only weakly coupled to the local incident waves and therefore essentially free.

The results for on/offshore flows show that low frequency surf beat (frequency less than 0.03 Hz) is strongly correlated with the wave envelope, suggesting the dominance of forced wave motion at these frequencies. In a higher frequency band, between 0.06 and 0.095 Hz, the correlation is generally much lower, suggesting that free wave motion, possibly subharmonic edge waves, is significant in this band.

The longshore flows are much more weakly correlated to the envelope of either the longshore or on/offshore components of the orbital velocity. This is consistent with previous observations that edge wave motion dominates the longshore surf beat motion.

#### Introduction

It is now clear that water motion with periods substantially longer than incident wave periods generally dominates the velocity field near the shore, and may be the controlling mechanism for changes in coastal morphology in response to waves (Bowen and Huntley, 1984). However, despite extensive field and theoretical work, the precise nature of this long period motion is still unclear.

\* Department of Oceanography  
Dalhousie University  
Halifax, Nova Scotia  
B3H 4J1 Canada

Figure 1 shows schematically the possible forms of low frequency motion which have been suggested for the nearshore zone. Broadly they fall into two categories, occurring either as forced waves or free waves.

Forced motion is generated directly by the incident waves. Longuet-Higgins and Stewart (1962) showed theoretically, using the radiation stress concept, that there should be a depression of the mean water level under high waves and a corresponding rise in mean water level under low waves. Hence if incident waves are "groupy", i.e. have an alternating sequence of high waves and low waves, they will carry with them a forced wave component at the frequency of the wave groups.

Free wave motion, on the other hand, is presumed to have an existence which is decoupled from the local incident waves. It can, in principle, take a number of different forms. Free edge waves are trapped to the coast and propagate parallel to the shoreline. Although such edge waves at surf beat periods are probably generated by the groupy structure of the incident waves, their growth rate is relatively slow and depends upon a spatial average of the incident wave structure, in contrast to the immediate and local response of the forced waves (Gallagher 1971, Bowen and Guza 1978). Free waves might also be "leaky" in the sense of being able to propagate towards or away from the shoreline. There is no evidence that significant free long wave energy propagates to the shoreline from deep water, but free wave motion may be generated within the nearshore zone itself. For example Symonds et al (1982) show how the varying position of the breakpoint for groupy incident waves can generate freely propagating long waves at the group period. They predict a shoreward propagating long wave which reflects at the shoreline to set up standing wave motion in the surf zone, and a seaward propagating free wave seawards of the breakpoint. It has also been suggested that the forced wave brought to the breakpoint by incident wave groups might be released at the breakpoint and travel seawards and perhaps shorewards as a free wave, though the mechanism for this is not clear (Tucker, 1950, Longuet-Higgins and Stewart, 1962).

Surprisingly little published data addresses the problem of distinguishing between these possible forms of long period motion in the field. A number of studies confirm that edge waves contribute to the long period energy (e.g. Holman, 1981; Huntley et al., 1981). For example, Huntley et al (1981) show unambiguous evidence that edge wave motion dominates in the alongshore components of velocity, though the on/offshore velocities

showed additional energy which could not be clearly related to edge wave motion.

This paper describes field measurements of nearshore velocities designed to distinguish between forced and free long wave motion. In order to measure significant incident wave groups the measurements were made just seawards of the breakpoint. The test of whether the long period motion is forced or free then becomes simply a question of the degree of correlation between the local incident wave envelope and the long period motion at a point; if forced motion dominates the correlation should be very high while if free wave motion is significant the correlation should be correspondingly low.

### Theoretical considerations

#### Forced waves

Longuet-Higgins and Stewart (1962) showed theoretically that mean water level,  $\zeta$ , under wave groups and the onshore component of radiation stress,  $S_{xx}$ , are related by

$$\zeta = - S_{xx} / \rho(gh - c_g^2) + \text{const} \quad (1)$$

where  $\rho$  is the density of water,  $g$  the gravitational acceleration,  $h$  the local water depth and  $c_g$  the incident wave group velocity. Equation 1 should be valid where the wave group wavelength is long compared to the water depth. Since  $S_{xx}$  is proportional to the square of the incident wave amplitude equation (1) predicts a relative depression of mean water level where the wave amplitude is high.

As the incident waves travel into shallow water their group velocity tends to the wave phase velocity and the denominator in equation 1 tends to zero, suggesting very large changes of mean water level. At small Ursell numbers the shallow water form of (1) can be written

$$\zeta \sim -3/4 \frac{ga^2}{\sigma^2 h^2} \quad (2)$$

where  $a$  is the wave amplitude and  $\sigma$  is the wave radian frequency. However the large mean water level changes predicted by this formula are clearly inappropriate in the nearshore zone. As Longuet-Higgins and Stewart (1962) pointed out, not only is the small Ursell number condition violated, but also the shallow water resonance implied by equation (1) must be properly treated.

Unfortunately, although there has been some theoretical work addressing this problem (e.g. Foda and

Mei 1981) there is as yet no accepted theoretical prediction of water level changes under wave groups in shallow water. Nevertheless, for the purposes of this study we assume that, although the forms of equations 1 and 2 are not valid where our measurements were made, the mean water level response in shallow water will still be proportional to the square of the incident wave amplitude since the varying radiation stress remains the agent driving the forced waves.

The measurements discussed in this paper are of velocities rather than sea level changes. The only change this might make to the discussion above is in the sign of the long wave response relative to the wave envelope. For elevations the depression of mean water level under high waves results in the negative sign on the right hand side of equations 1 and 2. Under such a depression the forced velocity is in the opposite direction to the group propagation direction. In the discussion below we take the positive  $x$  direction to be the seaward-pointing normal from the shoreline, so that offshore flows under shoreward propagating wave groups are positive. Hence, while for elevation measurements we would expect to find a negative correlation between wave envelope and mean sea level (assuming positive sea level changes to be upwards), for our current measurements we would expect a corresponding positive correlation.

### Free waves

As we have shown in Figure 1 there are several different forms that free wave motion might take, but each is decoupled in some way from an immediate local response to incident wave groups.

Edge wave generation is generally considered to take one of two basic forms. Pairs of edge waves can be generated by the instability of a single incident wave component reflected at the shoreline, the most rapidly generated being zero mode edge waves at the subharmonic of the incident waves (Guza and Davis 1974; Guza and Bowen 1975). Edge waves can also be generated by the long period groupiness structure of the incident waves (Gallagher 1971, Bowen and Guza 1978). Theoretical and laboratory work on these generation mechanisms has been limited to monochromatic incident waves, but even in these studies edge wave growth rates have been found to be relatively slow (e.g. an e-folding time of 10 incident wave periods for the fastest growing subharmonic edge waves). On natural beaches with a stochastic spectrum of incident waves the growth rates should be substantially reduced below these monochromatic values and edge wave

Figure 1. Possible forms of long waves on sloping beaches. The top three lines represent free wave modes and the bottom represents the forced wave.

Figure 2. Location of Queensland beach.

amplitude is therefore expected to correspond to a time average of incident wave conditions rather than to the immediate local wave conditions. In addition, as Bowen and Guza (1978) point out, edge waves generated by incident wave groups will be linked only to that component of the groupiness whose spatial as well as temporal structure matches that of the edge wave. Again this suggests a low correlation between edge wave amplitude and local incident wave envelope.

Free waves generated by a time-varying breakpoint (Symonds et al. 1982) are clearly linked to the incident wave groupiness. However there are a number of reasons why correlation to incident wave amplitude may be small. The amplitude of the seaward propagating free waves is frequency dependent with free wave amplitude going to zero for some group frequency components. At each group frequency component, free waves at a range of harmonic frequencies are also predicted. In addition, for a sensor seawards of the breakpoint, there will be a time lag between the wave envelope and the long wave response corresponding to the travel time to the breakpoint and back. Without a more complete quantitative theory it is not possible to estimate the significance of the first two of these factors, and the third may be too small to detect in our data (see the discussion below). However a strong correlation over a broad frequency range would seem unlikely in this case.

### Field Observations

Measurements of the nearshore velocity field were made at Queensland Beach in St. Margaret's Bay, Nova Scotia, on the 25th and 26th June, 1979. Queensland is a pocket beach with direct exposure to the Atlantic in only a very narrow range of directions around normal incidence to the beach (Figure 2). The shoreline is essentially straight, about 170 m long, and is terminated at one end by a headland and at the other by a reef of bedrock which extends several tens of meters offshore. The local beach slopes in the region where the currents were measured varied between 0.08 and 0.10.

The flow field was measured using Marsh-McBirney electromagnetic flowmeters mounted on the single tripod at three heights above the bed (10, 45 and 100 cm). Each sensor, measuring two orthogonal axes of flow with a response time of about 0.2 s, was aligned to measure the onshore and longshore components of flow. Figure 3 shows the position of the tripod on which flowmeters were mounted, the mean run-up position visually observed midway

through each data run and tidal variation during the measurements.

Winds during the experiment were generally mild and variable in direction. Near-normally incident waves approached the shoreline with noticeable groupiness. Generally the significant wave heights were between 40-60 cm near the tripod, which was located 10-25 m from the shoreline. Most of the waves broke inshore of the sensors.

#### Data Acquisition and Analysis

Spectra of the measured currents show two consistent spectral troughs. A trough near 0.095 Hz, present in all spectra, is taken to separate the incident wave energy, centered at 0.12 Hz, from the low frequency motion. A second spectral trough is found near 0.06 Hz, and its frequency is independent of offshore distance for the range of distances shown in Figure 3. This trough separates the low frequency band into a higher frequency band which we term "subharmonic" and a lower frequency band which we term "surf beat". For all segments of the data there is significant long period energy. Long wave energy varies from 2% to 11% of the total incident wave height, the largest values occurring nearest the breakpoint.

A Kaiser-Reed (1977) filter is used to separate time series of velocity into low- and high-passed components, with the division at 0.095 Hz. To obtain the wave envelope, the high-passed time series is squared and then low-passed through the same filter. Means of both the wave envelope and the long period time series are then calculated and removed.

Cross-spectra between wave envelope and low frequency wave motion were computed using the IEEE cross-spectral algorithm described by Carter and Ferrie (1979). Each time series of 4096 data points was partitioned into 7 segments of 1024 data points with a 50-percent overlap, giving a frequency resolution of 0.0029 Hz. Nuttal (1971) shows that the number of degrees of freedom,  $n$ , for 50% overlapped data segments is given by:

$$n = 3.82 N_d - 3.24$$

where  $N_d$  is the number of disjoint (non-overlapping) segments. For our data runs this gives  $n = 12$ .

Cross-correlations between the two series were also calculated for time lags up to  $\pm 200$  seconds, to determine

Figure 3. Tripod deployment and the variation of mean run-up positions with the tide.

Figure 4. Sample segments of time series. From the bottom in ascending order the original data, the corresponding wave envelope, the very low frequency surf beat motion and, on top, the motion at sub-harmonic period.

any non-dispersive time lag between the series. The 95% significance level for cross-correlation is related to the effective number ( $N^*$ ) of independent points within each series. The number of independent points can be estimated from the auto-correlation of the product of the two series by (Garrett and Toulany, 1981),

$$(N^*)^{-1} = (N)^{-1} + \sum_{j=1}^{N'} (N-j) R_{11}(j) \quad (3)$$

where  $N$  is the actual number of observation,  $R_{11}(j)$  is the lagged auto-correlation of the product and  $N'$  is the number of lags up to the first zero crossing of  $R_{11}$ . Throughout our runs  $N^*$  lies in the range 150-600. The corresponding 95% confidence limits on zero correlation ranges between 0.18 to 0.10.

#### The On/Offshore Flow Response to Incident Wave Groups

The lowest plot of figure 4 is a segment of the time series of onshore velocity for run Q141, showing noticeable wave groupiness. Above this, in ascending order, are the corresponding wave envelope, the very low frequency surf beat motion and, on top, the wave motion at subharmonic periods. Clearly the surf beat energy is positively correlated with the wave envelope.

Figure 5 shows an example of the spectra, coherence and phase of wave envelope and long period motion. The cross spectra suggest that we can identify three spectral bands, a surf beat band (0.003 - 0.03 Hz), an intermediate band (0.03-0.06 Hz) and a subharmonic band (0.06-0.08 Hz).

In the surf beat band the coherence between the incident wave envelope and the long period motion is consistently above the 95% confidence level and the phase is close to zero degrees across the entire frequency band. These features occur in the surf beat band throughout the data set. They suggest that locally forced wave motion strongly dominates the on/offshore flow in this frequency band.

In the subharmonic band, on the other hand, the coherence is generally weak with a phase which, if not entirely random, varies significantly across the band. This suggests that free wave motion is significant in this band. This is not the case for all data runs, however. Where subharmonic energy occurs as a narrow high energy peak a corresponding narrow peak in coherence can occur, with again a phase close to zero degrees (Figure 6). Clearly this suggests that forced wave motions can occur

Figure 5. Cross-spectra between wave envelope and low frequency wave motion for Q112.

Figure 6. As Figure 5, but for Q141.

in a narrow frequency band within this "subharmonic" band, but the significance of this observation is not yet clear.

In the intermediate band between the lowest frequency band and the subharmonic band no consistent conclusion could be reached, the cross spectra suggesting the presence of both forced and free motion with neither dominating.

Figure 7 summarizes the band-averaged coherences and phases for the complete data set, for both the low frequency surf beat band and the subharmonic band. These confirm the conclusions discussed above. In the surf beat band the coherence averages about 0.8, suggesting that the long period energy is about 80% forced by the wave envelope. The phase, as expected from the Longuet-Higgins and Stewart (1962) theory, is very close to zero degrees. In contrast, the subharmonic band shows coherence values which, while sometimes above the 95% confidence level on zero coherence, are much lower, with an average value of around 0.55. The average phases are also scattered. Although definitive conclusions cannot be drawn from coherence values so close to the 95% level, it would appear that the forced wave motion can account for, at most, 55% of the long period energy present in this frequency band.

Cross-correlations between the incident wave envelope and the long period motion were also computed for the lowest frequency surf beat band to identify any time lags between the wave envelope and the long period response. Figure 8 shows the average cross-correlation function for the complete data set. The 95% confidence level is estimated as about 0.10. As expected, the largest correlation occurs at zero lag and the correlation drops rapidly for non-zero lags. In Figure 8 a positive lag implies that wave envelope leads the long period motion. In the case where the forced wave is released as a seaward propagating free wave at the breakpoint, the positive lag between wave envelope and long wave response was around 10 s for the present data set. This is too small to be clearly separated from the peak at zero lag, but the rapid decay of the peak at positive lag is suggestive of only a small seaward component, if any. The secondary, barely-significant peak at a positive lag of about 35 s is intriguing. It will be further mentioned in the following section.

#### The Longshore Flow Response

Huntley et al. (1981) used data from a California beach to show that the longshore component of flow was

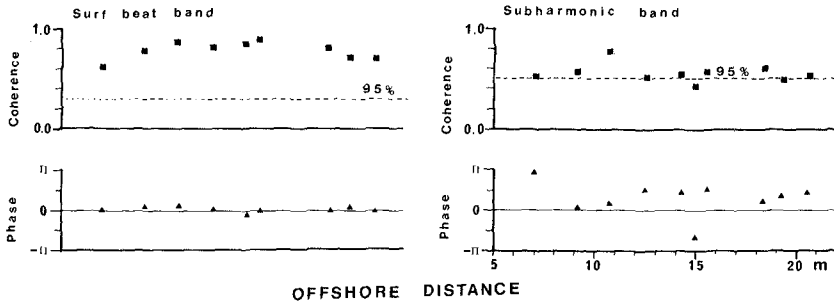

Figure 7. Band-averaged coherences and phases at surf beat and subharmonic frequencies.

Figure 8. Cross-correlation between wave envelope and low frequency motion.

Figure 9. Cross-correlation between incident wave envelope and longshore surf beat energy.

dominated by free edge wave motion. It is therefore of some interest to ask whether the present data set is consistent with this observation or whether there is evidence for forced longshore motion correlated with incident wave groups.

Calculated cross-correlations between longshore current envelope and the longshore surf beat flow are low, below the 95% confidence level, for all time lags. Thus there is no evidence for longshore motion forced by longshore groupiness. However cross-correlation between the on/offshore envelope and the longshore surf beat flow does show a significant, though low, peak at a positive lag of around 35 s (Figure 9). This surprising result may be related to the peak at a similar lag observed in the on/offshore correlation (Figure 8). These observations and possible explanations for them will be the subject of a subsequent paper.

#### Discussion

This study clearly shows that, outside the surf zone, the long period surf beat motion at frequencies below 0.03 Hz is dominated by the locally forced response to the incident wave groupiness. This is contrary to the suggestion of Bowen and Guza (1978), based on laboratory and theoretical studies, that the free edge wave response should dominate.

Other studies of long period motion have emphasized its on/offshore structure, which is generally found to be consistent with shoreline-reflected standing waves or with edge waves (Suhayda, 1974; Huntley, 1976; Holman, 1981). The present data set cannot provide definitive evidence for or against the presence of a seaward propagating wave which could combine with the incoming forced wave to provide standing wave motion. The observed cross-correlation of figure 8 does not suggest the presence of an outgoing free wave at a lag expected for the wave envelope to travel to the breakpoint and a free wave to return to the sensor location, but the expected lag is within the peak centered at zero lag so no firm conclusions can be drawn. If there is a smaller seaward propagating component on Queensland Beach it may be related to the absence of long swell waves characteristic of many of the other sites studied.

The present data set is limited to measurements outside the surf zone, whilst many previous studies have concentrated on measurements within the surf zone. For data run Q151, when the sensor tripod was closest to the breakpoint, the cross-correlation between surf beat motion

and wave envelope was significantly lower than for runs further offshore. This is consistent with the observed saturation of wave amplitude on breaking, which reduces incident wave groupiness inside the surf zone. Thus previous measurements from within the surf zone which have emphasized the presence of edge waves will have been unable to identify forced wave motion by a direct correlation with the local wave envelope. It would be particularly interesting to correlate long period motion inside the surf zone with incident wave envelope just outside the breakpoint, to try to identify any free wave motion inside the surf zone released by wave breaking.

The lack of evidence for dominant free edge waves motion in the on/offshore flows on this relatively steep beach may require some modification of the hypothesis that edge waves are the most significant controlling factor for nearshore coastal geomorphology (Bowen and Huntley, 1984). However even small on/offshore standing wave components will be very significant in providing the mean flow divergences and convergences needed to create erosion and deposition. The observations of edge wave motion in the longshore flows (Huntley et al., 1981) is also consistent with the present data set and provides a further important component contributing to flow divergence and convergence.

## CHAPTER SIXTY

### EXTREME SEA LEVELS ON THE COAST OF CALIFORNIA

Reinhard E. Flick<sup>1</sup> and Daniel R. Cayan<sup>2</sup>

#### 1. INTRODUCTION

During the winter of 1982-1983, a combination of high tides, higher than normal sea level and storm-induced waves were devastating to the coast of California. Damage estimates for public and private property destruction in the coastal counties of California total over \$100,000,000.

Much higher than average sea levels played a very important contributory role in the flooding damage. This report describes and examines the oceanographic and meteorological conditions prevailing during winter 1982-1983, and attempts to put them into perspective using historical information at San Diego. Emphasis is placed on the processes and forces that contribute to extreme sea levels in the hope that better understanding of these and more complete information on historical extremes will help the engineer in design and in assessment of risk.

The unusually high sea levels were due to a combination of higher than normal mixed layer temperature associated with a strong, 2-year El Nino, storm surge due to low atmospheric pressure and persistent onshore winds, and the cumulative effect of steady, "global" rise in relative sea level. Higher than average high tides coincided to an unusual extent with the peak sea levels reached during the numerous storms between November 1982 and March 1983. Important cyclical variations occur in California's tide regime and the consequences of these on extreme tides have not been considered previously.

#### 2. ASTRONOMICAL TIDES

During the time of the winter 1982-1983 storms, newspaper accounts of the damage referred to predictions of much higher astronomical tides in the early part of the next decade and led to increased public concern as to the future safety of many coastal structures. These concerns are unfounded since studies have shown that there are crucial differences in the California tide regime compared with those that were used as the basis for the alarming forecasts (Zetler and Flick, 1985).

Tides along the coast of California are of the "mixed" type meaning that the diurnal constituents are of the same order of magnitude as the semidiurnal components. This is crucial for explaining the

---

<sup>1</sup> California Department of Boating and Waterways, and  
Scripps Institution of Oceanography, La Jolla, CA

<sup>2</sup> Scripps Institution of Oceanography, La Jolla, CA

nature of the extreme ranges of tides. Different criteria determine the time of occurrence of maximum mixed tides as opposed to semidiurnal tides, which dominate, for example, the east coast of the U.S.

"Spring tides" are large semidiurnal tides that occur twice each month around the time of full and new moon. Spring tides tend to be larger than average twice each year during the equinoxes, that is, during the spring and autumn seasons. In contrast, "tropic tides" are large diurnal tides that also occur twice each month, but around the times of maximum lunar declination. Solar declination has a similar influence, and as a consequence, the tropic tides occurring in winter and summer (during maximum solar declination) are larger than average. In addition, the earth's yearly closest approach to the sun (perihelion) occurs during the northern hemisphere winter, thus increasing yet further the magnitude of the tropic tides that occur around December and January.

Figure 1. Predicted extreme high astronomical tide for four California ports through 2000. The extremes are dominated by the mixed tidal regime (Zetler and Flick, 1985).

Because of the complexities in the mixed tide regimes, the best way of forecasting times and heights of extreme tides is to prepare standard harmonic predictions and extract the desired extremes for tabulation. This has been done for the monthly extreme high tides at four California ports through the year 2000, and is shown in Figure 1 (from Zetler and Flick, 1985). The details of the interactions governing the variability of extreme predicted tides as well as tables of data corresponding to Figure 1 are given in Zetler and Flick (1985) and Zetler and Flick (in prep).

The effect of tropic tides dominates the extremes so that maximum tides occur in summer and winter. This maximizes the likelihood of coincidence of high tide levels with storm-induced sea level extremes. A second feature evident in Figure 1 is the regular 4.4 year beat which raises high tides about 0.5 foot every 4.4 years compared with times in between. This cycle peaked in 1982-1983 and contributed to the high levels observed.

### 3. MEAN SEA LEVEL

Recent studies of global mean sea level rise indicate a most probable value of about 0.5 foot/century (Hicks et al, 1983; Aubrey and Emery, 1983; Barnett, 1983; and many others). These estimates have a great deal of uncertainty and variability depending on how the analysis is done and due to a large number of other factors: errors in measurement, poor spacial distribution of stations around the world, wide variations in record length, wide variability of ground motions relative to sea level, etc.

Yearly mean values are likely contaminated very little by tidal errors and are very useful for displaying secular trends and longer term departures from the trends. Figure 2 shows annual average sea level at San Diego relative to MLLW computed over the 1960-1978 epoch, also shown in the figure. The light line is a least squares fit to all the data points and indicates an upward trend of 0.7 foot/century between 1906-1983. This is comparable to the global rate of rise and is typical of all long-term California stations, except for a few where

Figure 2. Secular increase in relative sea level at San Diego is close to global "average" of around 0.5 foot/century. Large positive departures are associated with major El Niño events.

local uplift or subsidence effects dominate the relative sea level signal.

Extreme estimates of rapidly accelerating rise in future mean sea levels have been published, and expressed as a mean rate, range as high as 10 feet/century to the year 2100 (Hoffman, 1983). These estimates depend upon a widely varying range of assumptions, or "scenarios," involving global warming and subsequent ice cap retreat and thermal expansion of the oceans. In our opinion, it is very difficult to know how much weight to assign to such extreme predictions and therefore how much to allow for them in design. On the other hand, it seems prudent to allow for at least the current rise of between 0.6-0.7 foot/century over the life of any particular planned coastal improvement.

Another feature of annual mean sea levels displayed in Figure 2 are the episodic (2-4 year) positive departures from the linear trend. These are shown shaded and are very pronounced in 1914, 1930-1931, 1941, 1957-1959 and 1982-1983, comprising 5 episodes in about 70 years of record. All these periods coincide with or are near in time to strong El Nino events. While there is no ability to forecast the year of onset, duration, and intensity of future El Nino occurrences, the historical record suggests that for engineering purposes, it would be sensible to design for the prolonged high sea level stands that occur during major episodes. The data in Figure 2. suggests these major events have an average return period of 14 years with departures from the trend on the order of 0.2 foot for durations of 2-3 years.

Seasonal variations in mean sea level are often displayed using monthly mean sea levels. The extremely unusual and persistent sea level heights reached during the 1982-1983 El Nino off San Diego are illustrated in Figure 3. The solid line shows the "average" seasonal cycle of sea level computed over the 19-year tidal epoch from 1960-1978. The light vertical bars around each average monthly data point show +/-1 standard deviation, indicating the typical variability of the fluctuations. The amplitude of the seasonal cycle is about 0.5 foot, with a variability of about 0.1-0.2 foot. This seasonal sea level cycle in San Diego is clearly related to seasonal heating and cooling of the ocean (Reid and Mantyla, 1976). On average, the water temperature is coolest in spring, leading to lower levels, and warmest in autumn, leading to higher levels. The light dashed line in Figure 3 shows the monthly averages for 1982. Until about July, observed sea level was close to normal, but by fall and early winter it exceeded the 1960-1978 average by up to 0.5 foot, or about 3 standard deviations. This condition persisted through 1983, illustrated in Figure 3 with the light solid line. Sea level finally returned to near normal in December 1983. The small vertical arrow labelled "trend" shows the increase in yearly mean sea level between 1969 (middle of the 1960-1978 epoch) and 1983. The magnitude of this increase is 0.1-0.2 foot or about 0.5 of a typical standard deviation. This shows that the unusually large deviations in 1982-1983 from the 1960-1978 mean were only due in small part to the cumulative secular increase.

Figure 3. Seasonal cycle of sea level at San Diego associated with cooling in spring and warming in autumn. Curves for 1982 and 1983 show large departure from 1960-1978 average.

#### 4. METEOROLOGICAL INFLUENCES

The winter of 1982-1983, now commonly known as "El Nino Winter," was in many respects the most severe storm season in several decades along the North American Pacific Coast (Quiroz, 1983). The unusually active North Pacific storm conditions were associated with anomalously warm water in the eastern tropical Pacific that had its beginnings in the Summer of 1982 and by northern Winter, 1982-1983, had developed into the most intense such warmings of any within about a century of quantitatively recorded data.

Winter atmospheric conditions during El Nino events show a tendency for anomalously low barometric pressure in the region south of the Aleutian Islands, extending into the Gulf of Alaska, and higher than normal pressure in the North Pacific subtropics (Namias, 1976; Dickson and Livezey, 1984). This pressure distribution is associated with heightened storm activity across the central North Pacific. However, the pattern is not clear-cut along the West Coast: in some winters the storms take a northward course into British Columbia and Alaska, while in others they take a southward trajectory into Oregon and California (Namias and Cayan, 1984). As a measure of this activity during the winter of 1982-1983, the average westerly winds across the North Pacific subtropics were almost twice their normal speed. The

high winds and long fetch produced by these conditions during 1982-1983, caused the unusually long and high waves that pounded the California coastline (Seymour et al, 1984). The influence of atmospheric pressure and high winds during the winter 1982-1983 season on sea level is illustrated in Figure 4. The upper curve shows daily maximum observed sea level with each monthly maximum, shown circled. The second curve shows the anomaly, or the difference between the observed daily maximum and the predicted highest tide each day. This curve is very close to the daily mean sea level (curve 3) implying that the exceedence over the predicted tide is more or less constant over time scales of 1 day. The dashed line under the daily mean sea level shows the long-term (1960-1978) monthly mean sea levels and illustrates the approximate 0.5 foot excess due to the large-scale El Nino condition.

Figure 4. Daily observations at San Diego during winter 1982-1983. Storm episodes are marked with increased wind speed and anomalously low barometric pressure (bottom two curves).

The lowest 2 curves in Figure 4 show average daily wind speed and surface barometric pressure anomaly at San Diego. The storm episodes stand out clearly (9-10, 16-19, 29-30 Nov; 7-9, 22-23, 29 Dec; 17-19, 27-29 Jan; 2-4, 7-8, 24-27 Feb; 1-5, 17-18, 21-24 Mar) and these are highly correlated with the sea level anomalies. In general, the direct influence of lowered atmospheric pressure in the winter's storm events through the inverse barometer effect contributed about 1/3 of the observed anomalies of sea level. The average of surface pressure anomalies during the storms is in the range of 7-10 mb, with a maximum of 18 mb below normal on 3 March 1983.

Maximum winds recorded at San Diego during this time period were 39 mph on 1 December 1982. The wind direction (not shown) associated with high sea level anomalies varies from one event to the next. High sea level events were found under conditions of east, south, southwest and northwest wind. The largest anomalies (2-3 Mar 1983) occurred under southerly winds at San Diego. It is not known how open ocean wind conditions may differ from those measured at San Diego's Lindbergh Field.

In the five month winter 1982-1983 period shown, three of the five monthly high predicted tides (30 November 1982, 27 January 1983, and 1 March 1983) were coincident with unusually large anomalous daily average sea level (0.8, 0.7, 0.9, respectively). For any given month, with about 6 days of large sea level anomalies and only about 3 days of near monthly maximum predicted tide, the probability of these coinciding (assuming the two phenomena are independent) is about  $6/30 \times 3/30 = 1/50$ . The fact that this coincidence was realized in 3 out of 5 chances between November and March is even more unusual, and illustrates the extraordinary nature of this winter. This suggests a very small likelihood that such a concentrated run of severe winter months having high tides amplified by large non-tidal anomalies will recur with great frequency, even given sympathetic large-scale conditions.

## 5. MONTHLY EXTREME SEA LEVELS

Many published studies describe changes in mean sea level and their possible causes, but very few have concentrated on the extremes of sea level (Disney, 1955; Smith and Leffler, 1980). From an engineering viewpoint, the rationale behind such investigation is simple: the extreme sea level dictates design since it is what floods property and causes damage. Monthly sea level extreme values are routinely tabulated as one of the products of the National Ocean Service, NOAA. Plots have been prepared (Figures 5, 6, 7) each showing (at San Diego) observed monthly extreme sea level, maximum predicted tide on the date of the observed extreme, and two versions of the anomaly defined as the difference between the observed level and predicted tide. Movement of the tide station, installed in 1906, and other complications causes the analysis of the anomalies to be limited to the period 1940-1983.

The highest value of sea level recorded at San Diego is 8.35 feet above MLLW on 27 January 1983. The largest contribution to this level was from the extreme tide (7.6 feet) with the remainder due to the processes discussed above. Analysis in this study was limited to the statistics of the monthly anomalies at the time of maximum monthly sea level. In this sense, the statistics should not be expected to follow extreme value form since they are not the extremes drawn from the population of all (hourly or daily, say) exceedence values. Instead, they form a conditional sample from this population, the condition being that the total sea level be the monthly maximum.

The two versions of the anomaly plotted in Figures 5, 6, 7 are the "raw" anomaly, which is simply the difference between the observed sea level and the tide, and the "adjusted" anomaly which was corrected for a linear fit to the trend in sea level (shown in Figure 2). The raw anomaly figures show a secular increase which reflects the trend in the observed monthly extremes and the fact that the tide predictions do not include any trend. In effect, the "adjusted" anomalies represent the exceedence of the maximum sea level over the tide and the secular trend. To derive statistical estimates of future absolute

Figure 5. Monthly extreme sea level at San Diego 1926-1945 showing predicted tide on day of observed monthly maximum. Anomaly is difference between observed and predicted. Lower trace is anomaly adjusted for secular trend shown in Figure 2.

Figure 6. Monthly extreme sea level at San Diego 1946-1965. See Figure 5.

sea level heights, the estimate of exceedence must be added to the tide prediction plus an estimate of the increase due to the trend in mean sea level.

Several statistical analyses of the adjusted anomaly data have been carried out. First, Figure 8 shows the median anomaly as a function of month of year for the period 1940-1983. There is a clear seasonal variation with larger than normal anomalies in December through April, with median values around 0.1 to 0.15 foot. During the summer and in October and November, the median of the highest monthly sea levels are very close to the predicted tides with median anomalies not significantly different from zero. In September, there is a significant peak, with median anomalies over 0.1 foot higher than predicted tides at maximum sea level. This is apparently attributable to extratropical low pressure systems that are frequently observed west of San Diego in September. These systems cause depressions in atmospheric pressure of about 5-10 millibars compared with seasonal normals, roughly accounting for the magnitude of the anomalies.

Figure 7. Monthly extreme sea level at San Diego 1966-1983. See Figure 5.

A return period statistic has been computed, and the results are shown in Table 1. The return period of any particular anomaly size can be defined as  $T$  where  $T = R/N$ , and  $R$  is the record length in months and  $N$  is the number of occurrences of that size in the record. Table 1 shows that the return period for 0.3 foot anomalies is about 20 months, or just under 2 years. Anomalies of 0.5 foot occur on average about every 50 months (4 years). The longer interval, larger anomalies have not recurred often enough to derive stable statistics, and not too much faith should be put in their return period. On the other hand, anomalies on the order of 1 foot are certainly possible, since they have been observed at San Diego, and at other stations on the California coast.

An added complication in the recurrence of the largest anomalies exists because their occurrence is not independent. Examination of the dates of occurrence of the 12 largest adjusted anomalies (greater than or equal to 0.6 foot) shows that 3 groups, containing 9 events cluster together (March, April and October 1941; January, February 1958, January 1959; and November 1982, January 1983). This is consistent with the observations that a large portion of the exceedence is related to the sympathetic, large-scale and persistent El Nino conditions.

Table 1

San Diego Sea Level Anomalies, 1940-1983

Adjusted Anomaly (ft)	Number of Occurrences	Return Period (mo.)
-0.4	4	132.0
-0.3	32	16.5
-0.2	58	9.1
-0.1	100	5.3
0.0	103	5.1
0.1	99	5.3
0.2	59	8.9
0.3	28	18.9
0.4	22	24.0
0.5	11	48.0
0.6	4	132.0
0.7	2	264.0
0.8	1	528.0
0.9	3	176.0
1.0	1	528.0
1.1	1	528.0

Figure 8. Median adjusted anomaly statistics, San Diego 1940-1983. Peak in September is associated with extra-tropical low pressure systems.

## 6. CONCLUSIONS

This investigation confirms the unusual nature of the 1982-1983 winter. Although individual months with relatively high sea level anomalies can be isolated, and some years exist with clusters of such anomalies, the concentrated run of extreme events that occurred in 1982-1983 is virtually unprecedented in the California sea level record. That is not to say that winters such as 1982-1983 won't happen again, but such recurrence should be quite rare.

Unusually high tides coincided with storm events to cause coastal flooding. The mixed tide regime in California predictably causes peak tides in summer and in winter. This maximizes the chances for such coincidences.

Sea levels in excess of predicted high tides during Winter 1982-1983 were the result of 1) large-scale meteorological and oceanic influences broadly known as "El Nino" that produced (among other effects) a tendency for anomalously high sea levels along the West Coast, probably contributing in the neighborhood of 0.1 to 0.4 foot in excess of normal. 2) Frequent vigorous North Pacific storms affected hundreds of miles of the West Coast over durations of 1-4 days. These heightened sea level by lowering surface barometric pressure via the "inverse barometer effect" (as much as 0.6 foot, but usually about 0.2 to 0.3 foot), and strong winds that piled up coastal waters.

## ACKNOWLEDGEMENTS

Financial support from the California Sea Grant College Program under Project R/CZ-69, NOAA, Grant No. NA80AA-D-00120 and from The Quest for Truth Foundation of Seattle, Washington is very gratefully acknowledged.

## CHAPTER SIXTY ONE

### New aspects concerning the increase of sea level on the German North Sea coast

Hans Rohde\*

#### ABSTRACT

The development of MThw on the German North Sea coast is probably related to the development of the climate. Other important contributing factors are discussed. For the last 20 years a relatively steep rise of MThw level is recognizable. An even steeper rise as a result of climate changes appears possible within the next 100 years. With regard to the great importance for coastal engineering, the necessity of attentive observation and international cooperation among different scientific disciplines is stressed.

#### 1. INTRODUCTION

The development of the water level changes on a coast is of great importance for coastal engineering. In general the water level in the oceans and also on the coasts has risen more than 100 m since the maximum of the last ice age about 20,000 years ago, when huge masses of water were stored in large ice-covered areas. The steepest increase amounted to 2 m per century (2 cm/a) (5) (12) (18) (10). This rise was caused primarily by the melting of the ice and the subsequent increase of the water volume in the ocean. All other influences on the development of the water level changes on the coasts were negligible by comparison.

The steep rise of water level ceased about 6,000 years ago. With the flattening of the water level curve other influences on the development of water level on the coasts became evident. The development wasn't uniform. Oscillations can be found which can differ in locality as well as with time as described by many authors (12) (10) (13).

The development of the water level changes on a coast depends essentially on three superimposed effects:

- 1) The height of mean sea level in the ocean: Its development with time depends primarily on the general behavior of the temperature and hence on the ratio between the volume of mainland ice and the volume of sea water (development of the climate).
- 2) The wind conditions: They depend essentially on atmospheric pressure conditions (meteorological conditions in general) and can change with time.
- 3) The geographical and geological conditions of the specific coastal region. Changes of the morphology or the topography - natural as

\*Dr.-Ing., Director of the Coastal Engineering Department of the Federal Institute of Waterways Engineering (Bundesanstalt für Wasserbau), Moorweidenstraße 14, D-2000 Hamburg 13, FR Germany

well as man-made - can produce a change in the development of water level. Tectonical changes of the sea-bottom and of the coast may also contribute to the water level changes.

These three factors are interdependent. A worldwide change of temperature can cause changes in the atmospheric circulation which affect the abundance and the paths of low-pressure systems. Changes of the wind-field and of the wind set up on the coast can be the consequence. A changing angle of attack of the sea against the coast can cause changes of the coastal configuration.

## 2. DEVELOPMENT OF WATER LEVEL FOR THE LAST 2,000 YEARS ON THE GERMAN NORTH SEA COAST

Figure 1 depicts schematically the probable development of MThw (Mean tidal high water, MThw) on the German North Sea coast for the last 2,000 years. If the levels of MThw and MThw (Mean tidal low water, MLW) change in the same direction and the shape of the tidal curve re-

Figure 1. Probable behavior of MThw on the German North Sea coast for the last 2,000 years (schematic)

mains constant, the development of MThw will be in accordance with the development of the "Mean Sea Level". But in most cases the shape of the tidal curves were affected by changes of the meteorological, topographical and morphological conditions. The influences of these factors are different on the levels of MThw and MThw.

The curve of Figure 1 consists of three sections:

- 1) The period till the middle of the 16th century (dotted line): The data arise from geological and archaeological investigations. They are relatively uncertain in their magnitude and temporal classification. The topographical conditions of the coast are of great importance and are not exactly known for this period.
- 2) The period from the middle of the 16th century until the end of the 18th century (dashed line): There are already data of water levels on the German North Sea coast, namely of the height of severe and very severe storm surges. Figure 2 shows some sites on the German North Sea coast for which these data are known.

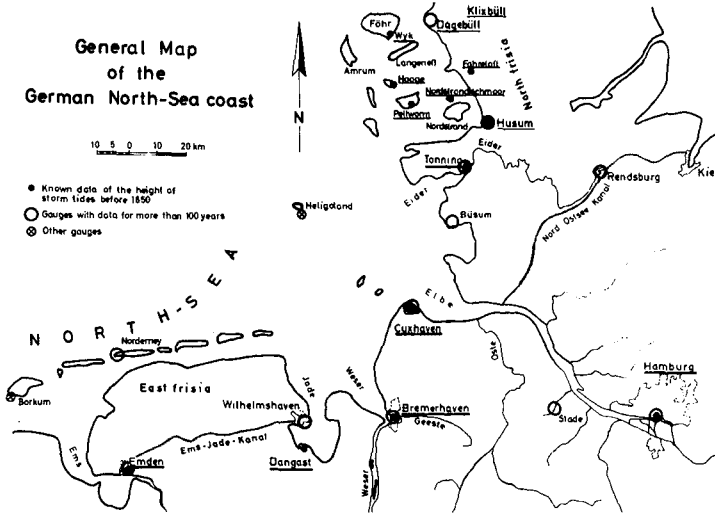

Figure 2: General map of the German North Sea coast with the sites of gauges and storm surge data

Figure 3: Maximum flood levels at Dangast and Wilhelmshaven since 1570 (15)

Figure 3 depicts the development of the maximum flood levels for one of these sites (Dangast/Wilhelmshaven) since 1570. One can recognize that the limiting line of the peaks of the highest storm surges 28.5 cm per century. A similar increase between 20 and 30 cm per century can be found at the other investigated sites (15) (16). Because the shape of the coast and the climatic conditions didn't change essentially in this

period, one may suppose that the level of the highest storm surges remains constant with respect to MThw and thus the increase of MThw also amounts to 20 - 30 cm per century i.e. an average of 25 cm per century.

- 3) The period from the end of the 18th century until present time (solid line): The shape of the coast and the climate have not changed fundamentally in this time. For this period records of some gauges are available (Figure 2). In the middle of the 19th century there were already as many gauges on the German North Sea coast as there are today (14). As long as gauges are not or only slightly affected by morphological changes of their environment, one can recognize an average increase of MThw of 25 cm per century. About 60 or 70 years ago the slope of the MThw curve began to decrease. The flat run of the curve is most pronounced on such gauges on which the man-made influences on the development of MThw are small (15) (16).

The graph in Figure 1 is in good agreement with the curve of temperature-development in Central England for the last 1000 years (7) (8) and a similar curve given by Benoist et al. (2) for the Antarctic. High water levels correspond to relatively high temperature, low water levels to a relatively low temperature. At the beginning of the second millennium A.D. the water level on the coast was relatively high. The height of the "Little Ice Age" was about 1600 A.D. and the water level was relatively low. This confirms assumptions that the development of water level change, shown in Figure 1, depends essentially on gradual changes of the climate (11). How much the water levels are influenced by other factors can only be determined from the careful analysis of gauge records. It was already said by (15) that the rise of MThw - see lower curve in Figure 4 - and correspondingly the rise of Mean Sea Level as well as the increase of the maximum flood levels - see upper curve in Figure 4 - depends essentially on changes of the climate. The frequency of the high

Figure 4: Development of water level on the German North Sea coast since the 16th century (15)

tides oscillates with long periods as the curve in the middle of Figure 4 shows. The oscillations depend on changes of the wind conditions and have meteorological causes (19).

3. ANALYSIS OF WATER LEVELS ON THE GERMAN NORTH SEA COAST FOR THE YEARS 1951 - 1980

For five gauges on the German North Sea coast - Borkum, Emden, Wilhelmshaven, Bremerhaven and Cuxhaven (Figure 2) - an exact analysis was made for the period from 1951 to 1980. Figure 5 shows as an example the frequency distribution of all Thw of the two years with the lowest MThw (1960) and the highest MThw (1967) at Cuxhaven. High water levels are produced by winds blowing towards the coast (from the directions north and west), low water levels by winds blowing away from the coast (from the directions south and east). In order to eliminate the influence of west winds on MThw, all Thw with a level of more than 50 cm above the arithmetical mean of all Thw for each year (MThw) were omitted. The hatched parts of the curves in Figure 5 show the omitted Thw. The number

Figure 5: Frequency distribution of Thw at Cuxhaven for the years 1960 and 1967

of these high levels, caused by west winds, was much higher in 1967 than in 1960, a year with a relatively large number of low east wind tides. A new arithmetical mean was computed with the rest of the Thw for each year (MThw). All Thw, influenced by onshore winds were disregarded in the computation of this new mean.

Figure 6 shows for Cuxhaven, as one example, that the differences between MThw and  $\bar{MThw}$  are small. The figure also shows the 5 year overlapping means and their regression lines (A and B), determined by the method of the least squares. A clear increase of the  $\bar{MThw}$  is recognizable which is only a little less steep than the increase of MThw. The

Figure 6: MThw and  $\overline{MThw}$  at Cuxhaven 1951 - 1983

slopes of the regression lines of the 5 year overlapping means of MThw and  $\overline{MThw}$  are collated for all 5 above mentioned gauges in the Columns 1 and 4 of Tabel 1.

	MThw	> MThw + 1 m number	+ 1 m level	$\overline{MThw}$	$\geq \overline{MThw}$ + 1 m number	+ 1 m level
	1	2	3	4	5	6
Borkum-Südstrand	0.23	0.12	0.37	0.20	0.18	0.27
Emden	0.23	0.18	0.42	0.20	0.17	0.59
Wilhelmshaven	0.22	0.09	0.50	0.19	0.17	0.32
Bremerhaven	0.22	0.14	0.51	0.18	0.22	0.30
Cuxhaven	0.22	0.17	0.55	0.17	0.26	0.29

Table 1: Slope "b" of the regression lines  $y = a + bx$  of the 5 year overlapping means 1951 - 1980

Now all Thw with a higher level of 1 m or more above the regression lines of MThw (line B in Fig. 6) were selected. These Thw are visible in Figure 5 for the years 1960 and 1967 on the right hand side and are shaded black in the frequency distribution curve. The upper graph in Figure 7 shows the annual number of these high Thw, the 5 year overlapping means and their regression line for Cuxhaven. In comparison with the number of the Thw  $\geq 1$  m above  $\overline{MThw}$  (line B in Fig. 6) the number of Thw  $> 1$  m above the yearly MThw (line A in Fig. 6) is also given (dashed line in Fig. 7). The number of the last mentioned Thw is 330 for the whole period 1951 - 1980, the number of the Thw  $\geq 1$  m above  $\overline{MThw}$  is 426. The

Figure 7:  $Thw > MThw + 1\text{ m}$  and  $\overline{Thw} \geq MThw + 1\text{ m}$  at Cuxhaven 1951 - 1981 (number and mean level)

mean levels, which are computed from the Thw with a level of 1 m or more above  $\overline{MThw}$ , the 5 year overlapping means and their regression line are shown in the lower graph of Figure 7 for Cuxhaven.

The mean level of the high Thw increases as well as their number for the period 1951 - 1980. This applies also for the  $Thw \geq 1\text{ m}$  above line B in Figure 6 and for the  $Thw > 1\text{ m}$  above line A in Figure 6 and has proved to be true for all 5 gauges as Table 1 shows (see Columns 2, 3, 5 and 6). The rise of the levels of the high Thw is remarkably steeper than the increase of  $\overline{MThw}$  or  $MThw$ , as the comparison of Column 3 with Column 1 and of Column 6 with Column 4 shows. This result doesn't change if the  $\overline{MThw}$  are not computed for the hydrological year (November to October) but for the year September to August.

The comparison between the Columns 1 and 4 in Table 1 shows that the greatest part of the rise of  $\overline{MThw}$ , observed on the German North Sea coast, is independent from the increase of the high Thw's which are influenced by west winds. The influence of the high tides on the rise of  $\overline{MThw}$  is relatively small. Therefore it is permissible, as a first approximation, to look at the rise of the common yearly  $\overline{MThw}$  for comparisons of the development of mean water level on the coast. This is important because the elimination of all tides influenced by stronger west winds has not been done for all gauges and for longer periods.

As Figure 7 shows, the number and the mean level of the high Thw is increasing. The last section of the middle curve in Figure 4 also shows this because a good correlation between the number of the high Thw in each year and the highest level of Thw in the same year exists. The factor of correlation lies between 0.61 and 0.73 for the five mentioned gauges. The middle curve in Figure 4 also gives an approximated scale

for the frequency of high tides. Periods with a high frequency of high tides always have been followed by periods with a lower frequency.

#### 4. POSSIBLE FUTURE DEVELOPMENTS

As already mentioned above and as described in previous papers, the records of most gauges on the German North Sea coast show an average rise of 25 cm per century since the beginning of the observations. Since about 1920, the curves of the 19 year overlapping means of MThw on several gauges became less steep (15) (16). In such cases where the decrease of the slope was less strong, effects of man-made influences are probable (e.g. dredging in the estuaries or the construction of dams). It seemed to be possible that the less steep increase of the MThw-curve could turn over in a gradual decreasing curve. Because a correlation between the development of temperature and water level obviously exists, a maximum of the water level curve could come after a maximum of the temperature. Some observations of temperature pointed out such a development (7) (15) (16) (19). The decrease of the temperature and of the water level could be the beginning of a new "Little Ice Age" or even a new major ice age.

Recently a turning-point seems to be recognizable. The graphs of MThw of all gauges on the German North Sea coast rise steeper again during the last years. Figure 8 shows the curves of the 19 years overlapping means of MThw at Emden, Cuxhaven and Büsum. The figure which was published already in (15) (16) has been expanded for the years up to 1983. Moreover the time-scale has been shifted in such a way that the mean values refer to the last year of the period respectively (e.g. mean value of 1932/50 = 1950). These three gauges show a very flat graph of

Figure 8: 19 year overlapping means of MThw at Emden, Cuxhaven and Büsum

MThw from 1920 to 1965. In the last years a steeper rise of the graphs is apparent. The slopes of the regression lines are quoted for the three periods 1871/89 - 1912/30, 1912/30 - 1947/65 and 1947/65 - 1965/83. Such a recent increase can also be observed on other gauges on the coast and in the estuaries (compare Columns 1 and 2 with Column 3 in Tabel 2).

		MThw			MTnw
		till 1955	1873-1955	1956-1983	1956-1983
		1	2	3	4
Emden	(1857)	0.25	0.23	0.54	-0.33
Wilhelmshaven	(1873)	0.23	0.23	0.37	-0.15
Cuxhaven	(1843)	0.25	0.24	0.51	-0.21
Büsum	(1871)	0.22	0.21	0.62	-0.25
Husum	(1870)	0.30	0.28	0.63	-0.09
Dagebüll	(1873)	0.28	0.28	0.65	-0.32

Table 2: Slope "b" of the regression lines  $y = a + bx$  of MThw in 3 different periods and of MTnw in the last period

Figure 9 gives a schematic curve of MThw generated by the graphs in Figure 8. The dashed line shows the development which seemed to be possible on the basis of the less steep graph of water level after 1920. On the basis of the new steeper rise one cannot exclude a development described by the dotted line. In the opinion of some climatologists an increase of the mean temperature of the atmosphere by 4° C during the next 50 or 100 years could be possible as a result of air pollution,

Figure 9: Schematic graph of MThw on the German North Sea coast since the middle of the 19th century and possible future developments

increase of carbon dioxide concentration etc. Such an increase of temperature would cause a change of the ice conditions in the polar regions. A rise of the sea level by some meters could be the consequence (1) (3) (4) (9).

There is no exact proof to date that the steeper rise of MThw, observed on the gauges on the German North Sea coast, is already the result of the beginning of a general increase of temperature. But such a development cannot be excluded. On the other hand a more or less decrease of MThw has been observed on most gauges on the German North Sea coast (see Column 4 in Table 2), that means an increase of the mean tidal range (MThb). If the rise of MThw had climatic causes, a simultaneous rise of MThw would be probable. Therefore it is possible that the increase of MThb - rise of MThw and a simultaneous decrease of MThw - has oceanographic causes. Investigations of Siefert (20) provide some hints of generally changing tidal conditions in the North Sea. But such a change can also be the consequence of the rising sea level. Investigations about this problem by means of a numerical model have been started already.

## 5. CONCLUSIONS

The knowledge of the probable development of the water level on the German North Sea coast - in general on all flat coasts - is of greatest importance for coastal engineering. In Germany an increase of MThw of 25 cm per century has been taken as a basis for dimensioning of coastal protection constructions (e.g. dykes or storm surge barrages) (6). If instead one had to reckon with a rise of MThw of 2 m or more in the next 100 years and with at least the same increase of the storm surge levels, all coastal protection works would be ineffective. It is doubtful that an elevation of the dykes for such a water level rise would be possible everywhere. As one can conclude from the development of MThw at all locations on the German North Sea coast for the last 400 years in connection with the development of temperature in Central England (7) (8), an increase of 2 m or more would be thinkable in the case of an increase of the temperature of about 4° C. The increase of temperature is assumed to be 1° C since the culminating-point of the "Little Ice Age". In the same period MThw rose about 1 m (Fig. 1). Some scientists even speak of a possible rise of mean sea level of 5 or 6 m during the next 100 years (3) (4).

Therefore it is necessary to intensify investigations in order to predict the probable development of the global sea level as well as that of certain coastal sections for the next 100 years as exactly as possible. Three routes of research are deemed necessary:

- 1) One has to analyse all the factors responsible for the development of water level in the ocean and on the coasts as exactly as possible. This demands an extensive and close co-operation of the different scientific disciplines of climatology, meteorology, oceanology, glaciology, geodesy and coastal engineering. This co-operation has to be international. Coastal engineers should contact such projects as the International Climate Research Program and the Project No. 200 of the International Geological Correlation Program "Sea-Level Correlation and Applications". The results of these projects are of greatest practical importance for coastal engineering.

- 2) One has to analyse all records of gauges on the coasts or near the coasts as far back in time as possible. The aim must be to discover relationships between the development of water level and other factors, e.g. climate and wind set up. Such relationships can be of importance for the estimation of the water level behavior in the future. In the Federal Republic of Germany the records of many gauges are available. They go back up to 180 years. But only the youngest data are available for an analysis with automatic data processing (ADP). We started to convert, at least for the most important gauges, the older data - all daily Thw and Thw level and time - to automatic data carriers. This requires careful examinations of the data. The older the data are, the more difficult become these examinations. Such investigations should also be done by all countries which possess gauge-records for long time periods.
- 3) One should try to erect new gauges at a greater distance away from the coast in order to receive water level records which are free from coastal influences. Also Ausubel (1) suggests an expansion of the present global tide gauge network. The new gauges have to have firm foundations: any vertical movement of the stations should be impossible. The water levels have to be recorded exactly for some decades. The German Coastal Engineering Board (KFKI), in which the federal authorities and the authorities of the German States work together, plans the construction of three such gauges in the North Sea (17). Figure 10 shows the sites of these gauges. They are situated at a distance of 25 to 35 km from the German North Sea coast in a water depth between 15 and 25 m below chart datum. The geo-

Figure 10: Sites of the three planned gauge-stations in front of the German North Sea coast

logical and morphological parameters are such that firm foundations are possible and movements are very unlikely. Gauge devices are planned which will stand on the sea-bottom and be fixed onto piles which are driven 10 or 20 m into the sea-bed. The devices work on the pressure transducer principle. The costs for the construction of the stations are not very high compared to the management and maintenance costs for several decades. The problem of an exact reference of the gauge-records to the altitude datum of the mainland is still unsolved. At first one can dispense with this reference. The gauge-stations are also of importance for other branches of research and practical tasks, e.g. for an exact surveying of the depths of the off-shore region and for storm surge research. The final design of the stations has not been completed. We hope to obtain the necessary financial support shortly so that the gauges may be operational by 1986 or 1987.

## CHAPTER SIXTY TWO

### SHORT-CRESTED BREAKING WAVES

P.C. Machen<sup>1</sup>

#### Abstract

The likely effects of short-crested (sc) breaking waves on ships and structures are summarised in the case of the simplest non-trivial sc sea at medium/high crossing angle. Typical experimental data of sc breaking wave-height and sc water particle speeds are given at model-scale.

#### 1. INTRODUCTION

In recent years, more attention has been devoted to extreme waves (e.g. 15). It is suggested that there are at least two classes of extreme waves, which frequently may break:

- a) "Tail of the distribution" - type waves where two or more waves are temporarily superposed (16).
- b) Current-wave interaction, producing high steepness waves (14, 17, 26). To these should probably be added a third category:
- c) Short crested waves, in particular where high waves come together from two or more directions at middle or high crossing angle. An inshore example is given in Figure 1.1

Figure 1.1: Near-shore short-crested breaking wave formed from two obliquely-crossing waves.

Little attention has been paid to the last of these. Salter (23) formed a three-dimensional deep-water plunging wave by arranging that the phases of waves from an array of generators came into coincidence at a point. Halliwell and Machen (10) pointed out that short-crested (sc)

<sup>1</sup> Senior Research Associate, University of Newcastle upon Tyne, U.K.

breaking waves could be higher than long-crested and gave some results for shallow water. Hsu and Silvester (12) and Hsu (13) compared these results with predictions based on a third-order perturbation analysis.

The term 'short-crested' sea is often used to describe any sea having components from more than one direction, but in this paper the simplest non-trivial case will only be considered, that is a sc sea composed of two equi-amplitude equi-period waves crossing obliquely. It is to be expected that before breaking the finite-amplitude standing wave research reported in the 1950s and 1960s may be relevant. A step towards three-dimensional behaviour was made by Verma and Keller (28), and a third-order perturbation analysis of two obliquely-crossing waves was made by Hsu et al (11). Roberts (21) generalised and extended the analysis of the resonance behaviour of steady sc waves, using the preferred term "harmonic resonance".

In this paper, we begin in Section 2 by examining the loss of HMS COBRA in 1901 to which sc waves may have contributed. After some general discussion of sc breaking waves, some results are given in Section 3 from an experimental facility of two intersecting channels and sc steepness is compared with limiting long-crested steepness. The measurement of sc water-particle speed is considered in Section 4 where some success with a hot-film anemometer is reported.

## 2. THE IMPORTANCE OF SHORT-CRESTED BREAKING WAVES FOR SHIPS AND STRUCTURES

In a wind-sea, the angles between directional components are small and whitecapping will accord to normal criteria. The short-crestedness of the sea might be described as of low entropy. On the other hand, if we imagine two separate long-crested waves (associated perhaps with a swell or highly peaked spectrum) crossing obliquely at medium or high angle, then a high energy event with modified breaking criteria is possible.

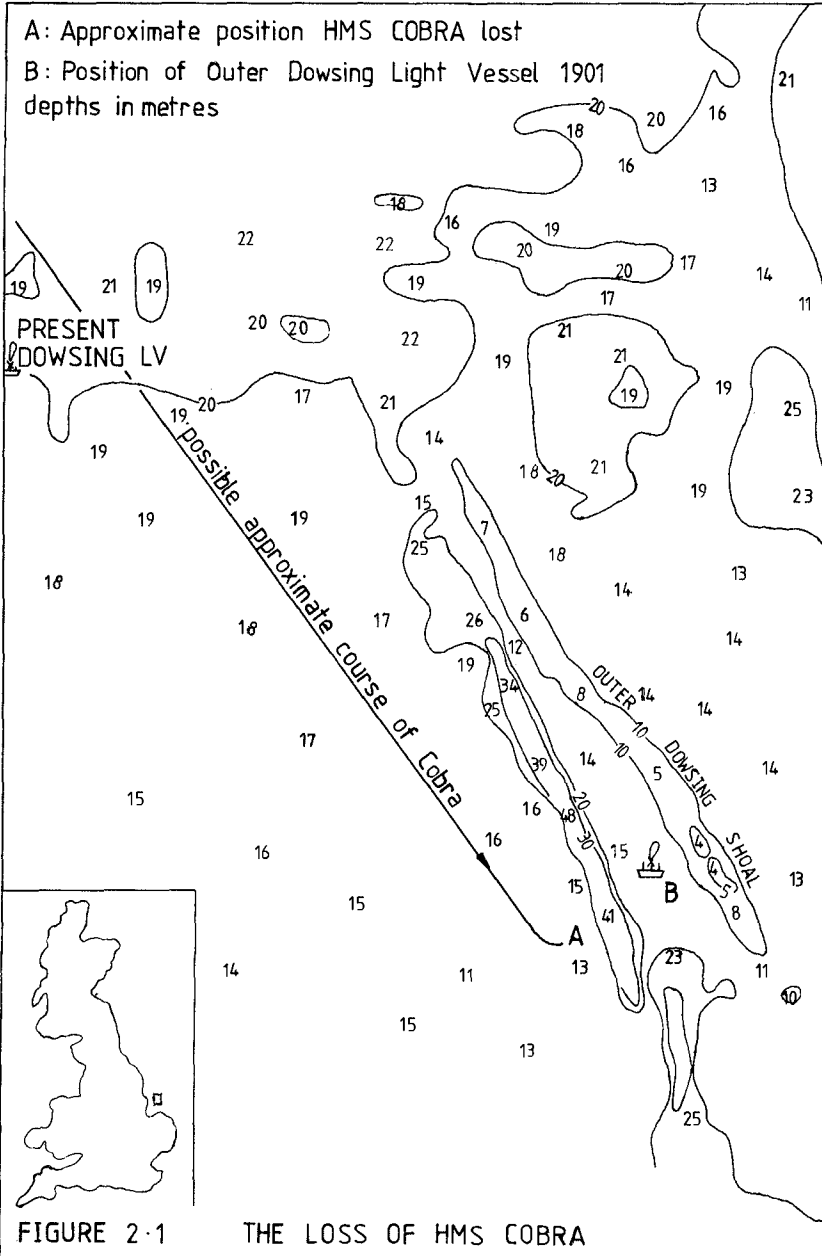

In the case of such a crossing event the secondary wave flux can be produced by refraction around a shoal, by reflection from a deep-channel or structure, or by similar action through the action of a current regime. Clearly in these cases the secondary source is an image source. High crossing waves due to an image source are in practice likely to be rather localised.

Equally a secondary source could be real in the sense of wave flux from a second storm or from a wind-shift, but there is some experience that the short steep seas caused by very strong winds attenuate quite quickly when the wind drops or changes direction (see for instance Fig. 2 of (22), (6) and (8)); a secondary real wave flux is therefore only likely to be of the same order as a high primary source in a localised region of time and space.

### 2.1 Loss of HMS COBRA

Pierson (19) discussed the loss of two trawlers in the North Sea, suggesting that crossing waves could be to blame. Recently Faulkner et al (7) re-examined the loss of the torpedo-destroyer HMS COBRA in the North Sea in 1901 (their principal interest being in the structural aspects of the vessel). In the case of COBRA, more information is available

regarding the position of the ship than in Pierson's and there is eye-witness evidence that it was lost in a crossing sea. The mate of the light vessel 2nm ( $3\frac{1}{2}$ Km) to the north-east reported winds NNW Force 6, the helmsman wind NW, and heavy rolling was experienced when heading slightly north of east. In spite of the sea being described by the light vessel mate as only "middling rough" the ship was seen to execute three terrific plunges with waves breaking over her fore-castle and the ship broke in two. Survivors described the sea as "a heavy sea, a cross sea, not a regular sea, the wind one way and the tide another, as though there had been a change in the wind" (7).

There was some ambiguity about the exact position but the COBRA was near the Outer Dowsing Channel, the general alignment of which is NNW/SSE (Fig. 2.1). At this point the west bank of the channel is steep with chart depths of 15m and 40m top and bottom respectively, and its lie is  $N16^{\circ} W$  over a 3Km length. Waves from the NW/NNW would have been obliquely incident on the discontinuity, and those of middle and higher period would have been reflected. A simple analysis by Snell's law indicates that, at the state of the tide at the time, waves from the NW would have been reflected for periods of 8 sec and more; from the NNW, of 5 sec and more. Faulkner et al (7) estimated the characteristic wave period as 7 sec.

A crossing-wave regime would have been set up near the discontinuity. 7-sec waves would have implied a depth-to-wavelength ratio of about 0.24, and the primary wave flux, the reflected secondary component(s) and any swell would have been approximately superimposed until a breaking limit were reached. There remains some doubts, however, whether the short-crested seas were breaking, what contribution additional swell made, what effect tidal currents had, and to what extent the present-day chart indicates the bathymetry of 1901.

## 2.2 Summary of Short-crested Breaking Effects

There are other examples of the importance of short-crested wave effects both offshore and inshore, but restrictions of space preclude inclusion here. The effects of sc (breaking) waves on ships and structures are as follows:

- a) The sc pyramidal or breaking waves may present a vessel or structure with a steeper than expected wave environment, which may exceed normal steepness criteria before reaching instability.
- b) Along the centre-line of the sc wave the wavelength is  $L \sec \alpha$  ( $\alpha$  being defined in Figure 3.1) and a ship steaming in that direction is more likely to be entirely in a trough immediately before the bow is struck by the three-dimensional crest. (In two dimensions, an abnormal length of trough has been advanced as an important factor in the casualties off the South African coast (17)).
- c) The sc wave profile speed may be high (higher by a factor of the order of  $\sec \alpha$ ).
- d) At breaking a sc jet or inverted saucer of water may issue from the crest. Little information is available about maximum water-particle speeds, but behaviour is likely to depend partly upon  $d/L$ . Some results

are given in Section 4.

- e) Silvester (25) discussed the effects of crossing waves on sediment movement. Increased sediment transport can accompany crossing waves.
- f) There are likely to be consequences for fatigue calculations.

3. SC BREAKING WAVES - THEIR MODELLING AND HEIGHT

3.1 Modelling

Although it might be expected by symmetry and neglecting energy losses at the wall, that two obliquely-crossing waves would be analytically the same as one wave obliquely reflected from a straight vertical wall, if the wall is of finite length the diffracted wave must be included. High energy crossing events are likely to be localised and the diffracted wave may have to be included in some general sc breaking waves. There are, therefore, two alternative crossing-wave circumstances which can be modelled, one including the diffracted wave (Set-up A) and the other not (Set-up B).

The decision which to model will be significant as the diffracted wave may be important for a considerable distance (2). Clearly A can be modelled by reflecting waves from a straight vertical wall, or alternatively by bringing together waves from two intersecting channels. B could be modelled in a large basin with an array of wave generator elements with their phases set such that two obliquely-crossing waves were generated, but depending upon the scale a diffracted wave may still make a significant contribution. There are further possible modelling problems.

The basin at the University of Western Australia has some attractive features (25) and perhaps lies somewhere between A & B. For reasons of finance and the need for a local facility, an A-type basin was built at Newcastle (Figure 3.1), in which the angle  $\alpha$  is variable. It is however not an ideal facility and suffers from the following deficiencies: diffraction of wave energy takes place into the adjacent channel which is then subject to reflection at the paddle; the test aperture is rather limited; and the channels, being of finite width, can support standing waves, in spite of cross-wave filters.

3.2 Short-crested Instability Criteria

As  $\alpha$  is varied (theoretically) between  $0^\circ$  and  $90^\circ$ , the sc behaviour changes from being purely progressive to purely standing. In the general case, the two principal instability criteria, as summarised in (10) & (13) are:

a) Kinematic:  $u_{max} > f(C_s)$  ..... (3.1A)

b) Dynamic:  $v_{max} > h(g)$  ..... (3.1B)

Where  $u_{max}$  and  $v_{max}$  are maximum water particle speeds parallel to the basin centre-line and vertically upwards respectively,  $f(C_s)$  is some function of short-crested celerity and  $h(g)$  is a function of gravitational acceleration. Here the terms kinematic and dynamic are preferred as used by Hsu (13) after Dean (5).

Clearly when  $\alpha$  is high, the dynamic condition is likely to dominate.

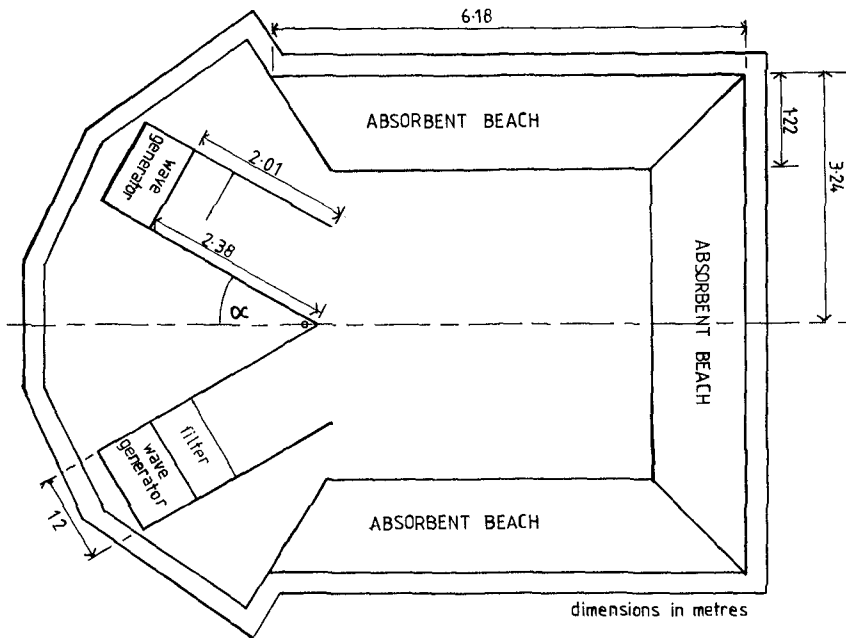

FIGURE 3.1 TWO-CHANNEL BASIN

Hsu (13) found a third-order solution to the dynamic stability criterion at all  $d/L$  from 0.05 to 0.5 for  $70^\circ \leq \alpha \leq 90^\circ$ . In the range  $55^\circ < \alpha < 70^\circ$  he found the stability equation unsatisfied in a number of  $d/L$  values. On the other hand at lower values of  $\alpha$  it may be expected that the kinematic condition will be dominant. In Equation (3.1A)  $f(C_s)$  may be approximately equal to  $C_s$ , or alternatively a long-crested kinematic condition may be more appropriate. In this respect Hsu (13) found that for part-range of  $d/L$  a maximum value of  $u$  occurred which was less than  $C_s$ , finding it questionable that  $u_{\max}$  was a valid criterion for the highest wave where it was less than  $C_s$ .

The author has watched a large number of in-shore sc breaking waves and there appears to be a maximum value of  $\alpha$  for a forward-breaking sc wave which is of the order of  $45^\circ$ . For wave-loading and slam considerations the kinematic condition is probably the more important criterion, but for ships experiencing pyramidal seas both conditions are likely to be of interest.

### 3.3 Short-crested wave height

In the model basin the sc breaking wave-height ( $H_{bs}$ ) varied with the parent wave steepness ( $K\bar{H}$ ), and there appeared to be a particular value of  $K\bar{H}$  which gave the highest acceptable value of  $H_{bs}$ . At values of  $K\bar{H}$

FIGURE 3-2 SC BREAKING STEEPNESS FOR 35°

FIGURE 3-3 RATIO TO MICHE LIMITING VALUES FOR 35°

higher than the optimum, one of two circumstances applied, either  $H_{bs}$  decreased with the sc breaking wave being "pushed through" because of high energy concentration, or unacceptable spilling occurred in the channels. An envelope curve of  $H_{bs}/L_1$  versus  $d/L_1$  was plotted for  $\alpha = 35^\circ$  (Figure 3.2); two values of channel width ( $W = 1200$  &  $1100\text{mm}$ ) and two values of  $d$  ( $145$  and  $121\text{mm}$ ) were used. The bracketted points are those where, at one  $d/L_1$ ,  $W$  was changed but the  $KH$  setting was not re-optimised. A series was also carried with a higher frequency cross-wave filter. The data is compared with limiting progressive steepness (according to Miche, and Cokelet (3)) and limiting standing wave steepness (24)). Fig. 3.3 shows the ratios of the experimental data points to the Miche value ( $r_m$ ) and limiting standing wave ( $r_s$ ):-

$$\left( \begin{array}{c} r_m \\ r_s \end{array} \right) = \left( \begin{array}{c} 1/0.142 \\ 1/0.22 \end{array} \right) \frac{H_{bs}}{L_1 \tanh Kd} \dots\dots\dots (3.2)$$

Compare Figure 3.3 with Roberts' conclusion that deep water sc waves could be up to 60% steeper than progressive waves (21).

Daemrich et al (4) found that for  $\alpha = 20^\circ$  the height of a Mach Stem breaking wave did not exceed the predicted Miche limiting value for progressive waves. Further work needs to be done, but this may indicate the sensitivity of behaviour to variation of  $\alpha$  in the range  $20^\circ$ - $30^\circ$  (21 Fig. 4).

#### 4. WATER PARTICLE SPEED MEASUREMENTS

##### 4.1 Experimental Method

Available was a Thermo-Systems Inc. 1054 Constant Temperature Anemometer, with which conical hot-film probes (1231W) were used.

Breaking waves represent a hostile environment for hot-film anemometry. The problem of air entrainment was however likely to be less severe if measurements were made only up to the location where the front face of the sc waves became vertical.

Regarding the air-water interface, there have been conflicting views. Baldy et al (1) felt that the exploration, by fixed probes, of the air and water flows near the interface was "not generally feasible" and went on to use a wave-follower mounting. Wills (29) used a fixed hot-wire probe at the interface, but he was interested in the air flow above the surface. His discussion of the problems facing the experimenter at the air/water interface is illuminating. Van Dorn and Pazan (27) recognised that the frequency response of the equipment was sufficiently high for an equilibrium value to be measured within a small distance of the probe traversing from air to water (in their case  $0.1\text{mm}$ ).

To measure velocity on the water-side of the interface is easier than on the air-side. The reason for this is that if measurements are made on the airside a high overheat may be necessary to rapidly evaporate the water film and this degree of overheat may increase the rate of accretion of any contamination from the water-surface onto the sensing element.

In the two-channel basin a water-surface suction and filtering system was used to reduce contamination, but it was still likely to be a major

problem. It was decided to use a low value of overheat to reduce accretion, and the lowest value which would give adequate sensitivity to flow was used. 4% overheat was chosen. The usual heat balance equation is:

$$\frac{e_b^2 R}{(R + R_3)^2} = \left[ A + B (\rho V)^{\frac{1}{n}} \right] (T_s - T_e) \dots\dots\dots (4.1)$$

where  $e_b$  is the bridge voltage, R the probe resistance,  $R_3$  the resistance in the other bridge arm,  $\rho$  density, V speed,  $T_s$  the sensor operating temperature,  $T_e$  the water temperature and A, B constants. For good sensitivity to flow variation, a high  $T_s$  is required, that is high overheat. The choice of a low overheat of 4% necessitated close control of  $T_e$  to be maintained.

A simple test of the probe traversing the interface was conducted (at an overheat of 4%) at a constant speed in a towing tank. By means of a suitable mounting and a string and pulley, the probe was caused to traverse a number of times the water surface which had previously been

Fig. 4.1 Towing Tank Trial

swept clean, Figure 4.1 showing the bridge output voltage. The acceleration of the carriage to 1 m/s is clear, followed by traverses of the interface. The evaporation of the water film can just be seen. Upon successive immersion a consistent value of  $e_b$  was evident. The record was made on a heat recorder of bandwidth to about 50Hz which will therefore filter high frequency transients.

A calibration rig was constructed alongside the basin and water was drawn from the central area of the basin and discharged onto one of the absorbent beaches (Figure 4.2). The calibration rig had similarities to that used by Goodman and Sogin (9) who demonstrated that heat transfer was not affected by whether the flow was turbulent or laminar. In the calibration rig for the present work, Reynold's Numbers were in the range  $1.5 \times 10^4$  to  $4 \times 10^4$ . Temperature increase through the calibration rig was about  $0.05^\circ\text{C}$  which was equivalent to a change in speed of the order of 1%.

One would expect two principal reasons for changing calibration, dirt accumulation on the probe and temperature variation.

a) Dirt accumulation: Richardson and McQuivey (20) proposed that a dirty probe behaved as a clean probe at lower overheat, but Morrow and

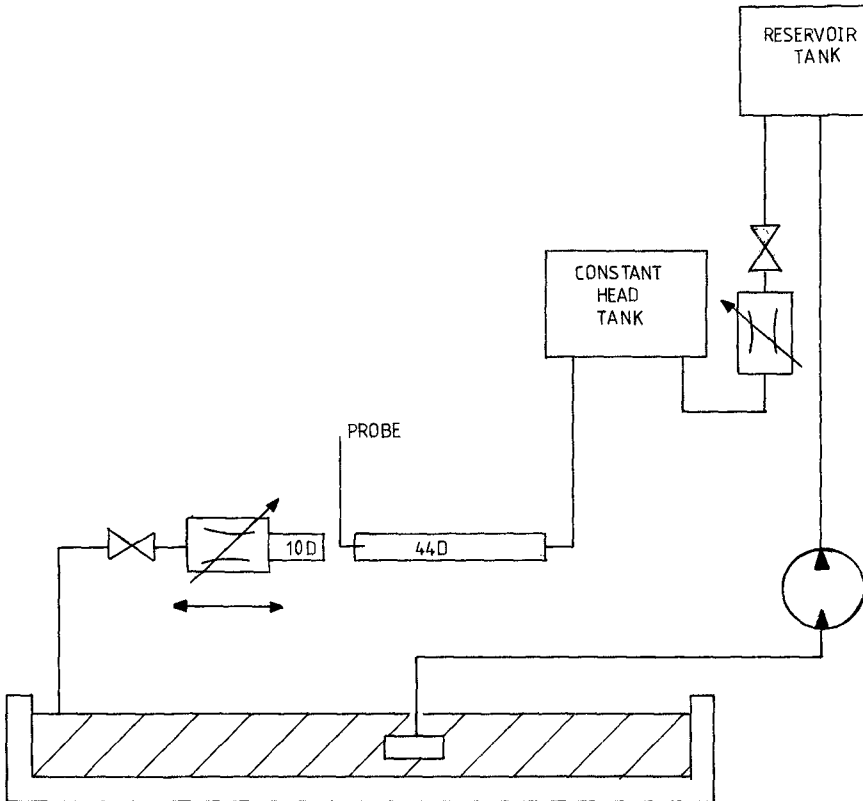

FIGURE 4-2 CALIBRATION RIG

Cline (18) concluded this was untrue. Because of the anticipated high drift from water surface contamination a second simple test was conducted with a highly contaminated water surface, at an overheat of 4%. The probe was mounted such that it was wetted by the crests of a series of waves. The output was monitored and it was noted that for the condition of the water at the time, rapid degradation occurred when the drying time between wave crests exceeded 0.7sec., but no degradation occurred for less than 0.6sec. This drift was probably due to the progressive accretion of water surface contamination onto the probe. Therefore for subsequent measurements small wave periods were chosen and the probe calibration was re-checked and the probe cleaned after every measurement.

b) Temperature variation: One standard method of allowing for a change of  $T_e$  by varying overheat slightly for the same  $e_{b0}$  was unsatisfactory in this case for the degree of control required. It can be easily shown from Equation (4.1) that for the same probe setting and the same flow one would

expect an approximately linear relationship between  $e_b^2$  and  $e_{bo}^2$ . Experimental confirmation is given in Figure 4.3 where the middle group of points relates to small changes in  $T_e$  and the low and high values are a result of dropping and raising overheat slightly, that is varying  $T_s$ . This linear relationship was used to correct measured values of  $e_b^2$  to a base

FIGURE 4-3 VARIATION OF  $e_b^2$  WITH  $e_{bo}^2$  FOR CONSTANT FLOW

value of  $e_{bo}^2$  the square mean zero-flow measurement before and after calibration. The procedure also corrected for variations in other resistances. In Table 4.1 Runs 1 and 2 were calibration runs for a cleaned probe at differing water temperatures with similar values of  $e_b^2$  after correction. For comparison Run 3 shows the calibration run for a lightly contaminated probe. The base value of  $e_{bo}^2$  was 17.56.

#### 4.2 Results

Profiles of maximum total water particle speed  $U/C_1$  were measured along the basin centre-line (average of 5 consecutive waves), with the right-angled probe pointing towards the channel apex. Figures 4.4a and b show the development of the  $U/C_1$  profile (shown by the circled points) for  $d/L_1 = 0.34$  at four distances from the apex ( $X/L_1$ ). The corresponding sc  $L_1$  wave profiles are also shown. For comparison the horizontal speed profiles ( $u/C_1$ ) in a hypothetical long-crested wave of this height according to Van Dorn's hyperbolic equation is shown (27):

$$\frac{u}{C} = \frac{a}{b} \frac{z^1}{1-z^1} + \frac{u_0}{C}$$

Where  $z^1$  is the fractional ordinate from trough to crest at which  $u$  is given,  $a$  &  $b$  are arbitrary constants 0.10 and 1.125 respectively.  $u_0/C = 0.20$  and  $C$  is the wave celerity.

In Figures 4.5 to 4.7,  $U/C_1$  profiles are shown at breaking for  $d/L_1 = 0.29$ , 0.24 and 0.19. Differing values of  $d$  and  $W$  were used. It is seen that there is good consistency of the  $U/C_1$  profiles at breaking of the four values of  $d/L_1$ . Measurement accuracy is estimated as  $\pm 15\%$ .

Table 4.2 summarises the maximum values of  $U(U_{max})$  found for each  $d/L_1$ , and compares it with linear pattern speed ( $\sec\alpha$ ) and with a measured estimate of sc celerity  $C_s$ . It will be seen that maximum water particle speeds were less than pattern speeds except for  $d/L_1 = 0.24$  for which there was variation in the sc jet speed; at these values of  $d/L_1$  this is qualitatively not in disagreement with Figure 4 of (13). However higher speeds later in the breaking process cannot be ruled out.

Further work is desirable on the crest values of  $U$  as breaking develops: measurements are required at lower  $d/L_1$  values; and an increase of scale is desirable.

$d/L_1$	$\sec\alpha$	Measured $C_s/C_1$	Measured $U_{max}/C_1$
0.34	1.22	1.33	0.83
0.29	1.22	1.31	0.89
0.24	1.22	1.31	0.82-1.28
0.19	1.22	1.39	0.78

#### 1. Introduction

An artificial wave-absorber (wave-absorbing quay) has come to be widely used to counteract excessive wave action on ships and structures in harbors. Its two-dimensional characteristics on wave absorption have been investigated with several types of the wave-absorbing quay theoretically as well as experimentally, e.g., Jarlan (5), Terret, Osorio and Lean (9), Ijima, Tanaka and Okuzono (3), and Ijima and Okuzono (4), but the effects on the wave reduction in harbors seem to be not fully clear. This may be due to the lack of analytical methods for solving wave-induced oscillations in harbors with the wave-absorbing quay.

When the side wall in the harbor basin is assumed to be perfectly reflective, many theoretical methods for solving wave-induced oscillations in harbors have been presented: Ippen and Goda (2) solved the problem of a rectangular harbor by using the Fourier Transform technique. Hwang and Tuck (1) presented powerful method, which is applicable to arbitrary shaped harbors, by using integral equation (source distribution along the boundary) for the expression of the velocity potential. A similar method to that of Hwang and Tuck, but more suitable one for numerical computation, was presented by Lee (6), who used integral equation separately in the harbor basin and in the open sea. Raichlen and Naheer (8), Mattioli (7), and Yoshida and Ijima (10) presented the methods being applicable to the harbors of arbitrary shape and variable depth by further extending Lee's method.

On the other hand, when the side wall in the harbor basin is partly or wholly composed of the wave-absorbing quay, a new boundary condition, replacing the usual solid boundary

condition  $\partial\phi/\partial\nu=0$  ( $\phi$  is the velocity potential and  $\nu$ , the normal to the boundary), is needed, and it can be expressed as  $\partial\phi/\partial\nu=\Omega\phi$ . The characteristics of the coefficient  $\Omega$  depend on the nature of the wave-absorbing quay, and  $\Omega$  generally takes complex values, in which  $\Omega=0$  gives perfect reflection and  $\Omega=ik$  ( $k$  is the wave number) gives perfect absorption. It is obvious that  $\Omega$  can not be determined either by theoretical approach or by experimental approach only, and both the approaches are required. And, If the boundary condition on the wave-absorbing quay is obtained, the methods presented so far for solving wave-induced oscillations can be directly extended to the harbors with the wave-absorbing quay.

The aim of this investigation is to derive the boundary condition on the wave-absorbing quay, and to check that the methods for perfectly reflective harbors are applicable to the harbors with the wave-absorbing quay by using the obtained boundary condition.

2. Theoretical Formulation

Figure 1 shows schematic drawing of the harbor with the wave-absorbing quay: an arbitrary shaped harbor of a flat bottom is directly connected to the open sea. The boundary line on the harbor basin as well as the straight coastline are assumed to be perfectly reflective except that on the wave-absorbing quay. If there is no wave-absorbing quay in the harbor, the problem is reduced to a usual harbor resonance problem, which has been already solved by, e.g., Hwang and Tuck (1), Lee (6), etc. The following theoretical formulation is devoted to derive the boundary condition on the wave absorbing quay.

The type of the wave-absorbing quay considered in this investigation is illustrated in figure 2. This type of the wave-absorbing quay is now widely used in practice. It comprises a uniformly perforated vertical wall and a water chamber behind the wall.  $b$  and  $d$  indicate the thickness of the wall and the length of the water chamber, respectively. The water chamber is further divided into small chambers along the perforated wall with partition walls.

The fluid region in front of the perforated wall is indicated as region (0), and the fluid region in the water chamber, as region (1). In each region, physical quantities such as the wave amplitude, the fluid velocity, etc., will be expressed with either subscript 0 or subscript 1 from now on.

The fluid is assumed to be inviscid and incompressible and the fluid motion to be irrotational; then, the velocity potential of the fluid motion can be expressed as

$$\Phi=(ga/\sigma)\phi \exp(i\sigma t) \dots\dots\dots(1)$$

where  $g$  is the gravitational acceleration,  $a$  and  $\sigma$  are the amplitude and the angular frequency, respectively, of the incident wave, and  $\phi$  is a non-dimensional function which satisfies the Laplace equation,

$$\nabla^2 \phi = 0 \quad \dots\dots\dots(2)$$

Assuming that the waves are shallow water waves, and that the distance between the adjacent partition walls is much smaller than the incident wave length so that the fluid motion in the  $y$ -direction can be negligibly small in each water chamber, we can express the distribution of the wave amplitude  $\zeta_1$ , and the horizontal fluid velocity  $u_1$ , as follows:

$$\zeta_1(x) = \eta \cos \{k(x+b+d)\} \quad \dots\dots\dots(3)$$

$$u_1(x) = -i(\eta g k / \sigma) \sin \{k(x+b+d)\} \quad \dots\dots\dots(4)$$

where  $\eta$  is the unknown amplitude of the standing wave in each water chamber. In the region (0), the distribution of the wave amplitude  $\zeta_0$  and the horizontal (in the  $x$ -direction) fluid velocity  $u_0$  can be expressed with the potential function  $\phi$  as follows:

$$\zeta_0 = -ia\phi \quad \dots\dots\dots(5)$$

$$u_0 = (ga/\sigma) \cdot \partial\phi/\partial x \quad \dots\dots\dots(6)$$

We assume that the energy dissipation caused by the wave-absorbing quay is represented by linearized fluid resistances proportional to the fluid velocity and to the fluid acceleration in the holes. Then, the equation of the fluid motion in the holes can be expressed as

$$\frac{dU}{dt} = -\frac{1}{\rho} \frac{\partial p}{\partial x} - \mu_1 U - \mu_2 \frac{dU}{dt} \quad \dots\dots\dots(7)$$

in which  $\rho$  is the fluid density,  $U$  is the fluid velocity in the holes,  $\mu_1$  and  $\mu_2$  are the coefficients of the fluid resistances proportional to the fluid velocity and to the fluid acceleration, respectively, and  $\partial p / \partial x$  is the pressure gradient in the holes, which is assumed to be given by the water level difference across the perforated wall as

$$\frac{\partial p}{\partial x} = \rho g \exp(i\sigma t) [\zeta_0(0, y) - \zeta_1(-b)] / b \quad \dots\dots\dots(8)$$

Then substituting equation (8) into equation (7), and writing the fluid velocity  $U = U_0 \exp(i\sigma t)$ , we have

$$U_0 = \frac{ig[\zeta_0(0, y) - \zeta_1(-b)]}{\sigma b[(1 + \mu_2) - i(\mu_1/\sigma)]} \dots\dots\dots(9)$$

The mass continuity must be satisfied both at the front (x=0) and at the rear (x=-b) of the perforated wall, and because the width of each water chamber is assumed to be much smaller than the incident wave length, the mass continuity equation can be expressed on each water chamber as follows:

$$U_0 V = u_0 \quad (x=0) \quad \dots\dots\dots(10)$$

$$U_0 V = u_1 \quad (x=-b) \quad \dots\dots\dots(11)$$

where V is the porosity ratio (the ratio of the hole area to the whole area of the perforated wall). In equation (10), the midpoint of the chamber width may be used as the value of y-coordinate in  $u_0$ .

From these mass continuity conditions and equations (4) and (6), the unknown quantities  $U_0$  and  $\eta$  can be expressed by  $\partial\phi/\partial x$  as follows:

$$U_0 = (ga/\sigma V) \cdot \partial\phi/\partial x \quad \dots\dots\dots(12)$$

$$\eta = i\{khV/\sigma \sin(kd)\} \cdot (ga/\sigma V) \cdot \partial\phi/\partial x \quad \dots\dots\dots(13)$$

Thus, substituting equations (3) and (5) into equation (9), and eliminating the unknown quantities  $U_0$  and  $\eta$  by using equations (12) and (13), we obtain the equation,

$$\frac{\partial\phi}{\partial x} = \left[ \frac{\cot(kd)}{k} - \frac{b}{V} \{(1 + \mu_2) - i(\mu_1/\sigma)\} \right]^{-1} \cdot \phi \quad \dots\dots\dots(14)$$

This gives a relation between the potential function  $\phi$  and its normal derivative  $\partial\phi/\partial x$ , and therefore can be used as the boundary condition on the wave-absorbing quay. However, this equation contains two coefficients of the fluid resistances,  $\mu_1$  and  $\mu_2$ , which have to be rationally determined before we use equation (14) for numerical calculations. They can be determined by sub-empirical way from theoretical and experimental approaches.

In order to estimate the values of the coefficients, we consider the case that a plane monocromatic wave is incident on the wave-absorbing quay, which is now assumed to be infinitely long, at an angle  $\theta$  with x-axis as shown in figure 2. The distribution of the wave amplitude  $\zeta_0$  and the horizontal fluid velocity  $u_0$  can be expressed in this case as follows:

$$\zeta_0(x, y) = a \exp(iky \sin \theta) \times [\exp(ikx \cos \theta) + K \exp(-ikx \cos \theta)] \dots (15)$$

$$u_0(x, y) = -\frac{agk \cos \theta}{\sigma} \exp(iky \sin \theta) \times [\exp(ikx \cos \theta) - K \exp(-ikx \cos \theta)] \dots (16)$$

in which K is the complex reflection coefficient of the wave absorbing quay: the absolute value |K| means the reflection coefficient and its argument means the phase angle of the reflected wave. The rest of equations, that is, the equation of motion in the holes, the mass continuity equation at the perforated wall, and the equation of  $\zeta_1$  and  $u_1$  remain valid.

Therefore, using equations (15) and (16) for equations (5) and (6), respectively, and following the same procedure just used to derive the equation (14), we can obtain the following equation,

$$|K| \exp(i\epsilon) = \frac{\cos \theta (\cot(kd) - kb\alpha) - i(1 - kb\beta \cos \theta)}{\cos \theta (\cot(kd) - kb\alpha) + i(1 + kb\beta \cos \theta)} \dots (17)$$

in which  $\alpha = (1 + \mu_2)/V$ ,  $\beta = (\mu_1/\sigma)/V$ , and  $\epsilon$  is the phase angle of the reflected wave.

Equation (17) gives a relation between the coefficients of the fluid resistances, the reflection coefficient and the phase angle. Since it is a complex equation, the coefficients of the fluid resistances can be determined provided that the reflection coefficient and the phase angle are known. In order to simplify the equation, we introduce the following variables,  $x = kb\alpha (= kb(1 + \mu_2)/V)$ ,  $y = kb\beta (= kb(\mu_1/\sigma)/V)$  and  $m = \cot(kd)$ . Furthermore, we assume that the coefficients  $\mu_1$  and  $\mu_2$  are independent of the incident wave angle. Then, equation (17) can be written as

$$|K| \exp(i\epsilon) = \frac{(m-x) - i(1-y)}{(m-x) + i(1+y)} \dots (18)$$

Separating this into the real part and the imaginary part, we have two equations for x and y,

$$x^2 + y^2 - 2mx - 2\{ (1+\gamma)/(1-\gamma) \} \cdot y + (1+m^2) = 0 \dots (19)$$

$$\delta(x^2 + y^2) - 2(m\delta + 1)x + (\delta m^2 + 2m - \delta) = 0 \dots (20)$$

in which  $\gamma = |K|^2$  and  $\delta = \tan \epsilon$ .

Consequently, solving equations (19) and (20) simultaneously, we have

$$\left. \begin{aligned}
 & \left\{ \begin{aligned}
 y &= \frac{A(\delta^2+1) \pm \sqrt{(\delta^2+1)(A^2-1)}}{(\delta^2 A^2+1)} \\
 x &= \delta A y + (m-\delta)
 \end{aligned} \right. & (\delta \neq 0, \pm\infty) \\
 \\
 & \left\{ \begin{aligned}
 y &= 1/A \\
 x &= m \pm \sqrt{1-y^2}
 \end{aligned} \right. & (\delta = \pm\infty) \\
 \\
 & \left\{ \begin{aligned}
 y &= A \pm \sqrt{A^2-1} \\
 x &= m
 \end{aligned} \right. & (\delta = 0)
 \end{aligned} \right\} \dots\dots\dots (21)$$

in which  $A=(1+\gamma)/(1-\gamma)$ . The radical sign which gives  $|K| \cdot \exp(i\epsilon)$  when  $x$  and  $y$  are substituted into equation (18) should be chosen: the other set of  $x$  and  $y$  gives  $|K| \cdot \exp(i\epsilon+\pi)$ .

3. Theoretical and Experimental results

Before conducting the theoretical calculations and the wave basin experiments, we first made two-dimensional wave tank experiments on wave reflection for a specific wave-absorbing quay to determine the resistance coefficients.

The properties of the model wave-absorbing quay were as follows: The thickness of the perforated wall was 6cm; the length and the width of each water chamber were 10cm and 6cm, respectively; the perforated wall had circular holes (14mm diameter) distributed uniformly and its porosity ratio  $V$  was 0.19.

The model was set at one end of the wave tank (water depth  $h=0.35m$ ) which is 18m long, 0.3m wide and 0.6m deep, with a flap type wave generator at the other end, and the reflection coefficient  $|K|$  and the distance  $x^*$  between the wall and the node were measured. The phase angle can be obtained from  $x^*$  by the relation  $\epsilon=4\pi(x^*/L)-(2n+1)\pi$  ( $n=0, \pm 1, \pm 2, \dots$ ;  $L$  is the wave length). The measured values are shown in figure 3, in which the white circle and the black circle indicate  $|K|$  and  $x^*/L$ , respectively.

Using the measured reflection coefficients and phase angles, we calculated the coefficients  $\mu_1/\sigma$  and  $\mu_2$  through equation (21), and the results are shown in figure 4. Figure 3 shows that the wave absorption characteristic of this model wave-absorbing quay is good for  $kh$  near 1.8, but relatively bad for  $kh$  less than 1.4. This corresponds to the results in figure 4 that both  $\mu_1/\sigma$  and  $\mu_2$  increase rapidly as  $kh$  decreases, and thus the boundary condition (equation (14)) approaches to the solid boundary condition  $\partial\phi/\partial x=0$

which means no wave absorption.

Of course the wave absorption characteristics differ greatly depending on the combination of the values of  $b$ ,  $d$  and  $V$ , but the scope of this investigation is to derive and to verify the boundary condition, and not to investigate the effective wave-absorbing quays, only single model of the wave-absorbing quay was used.

In succession from the two-dimensional wave tank experiments, we conducted theoretical calculations and wave basin experiments for two model harbors with the wave-absorbing quay. The shapes of the model harbors and the locations of the wave-absorbing quay are illustrated in figure 5 (model-1) and in figure 7 (model-2). The wave-basin (20m long 9m wide 0.6m deep) in the laboratory of Civil Engineering Hydraulics, Kyushu University, was used. The water depth was kept 0.35m throughout the experiments. The incident wave height and the wave heights at several points in the model harbors were measured, and Amplification Factor (indicated by  $A$ ), defined as the ratio of the wave amplitude in the harbor basin to the incident wave height, was calculated.

As for the method for solving wave-induced oscillation in harbors, we used the method presented by Yoshida and Ijima (10) only because the computer program was available. The method is based on the direct use of Green's Identity Formula in three-dimension for the expression of the velocity potential of the wave motion in the harbor basin, thus the method itself is applicable to the harbors of arbitrary shape and variable depth.

The comparisons between the theoretical and experimental results on the Amplification Factor are shown in figures 5 and 6 for model 1, and in figures 7 and 8 for model 2. The broken lines and the black circles indicate the theoretical and the experimental values, respectively. In addition, theoretical results in the case of no wave-absorbing quay were also shown for model-1 with solid line. comparison.

Figures 5 and 6 and figures 7 and 8 show very good agreements between the theory and the experiment. This confirms that the boundary condition (equation (14)) and the values of the coefficients  $\mu_1/\sigma$  and  $\mu_2$ , determined through equation (18) and two-dimensional experiments, properly represent the wave absorption effects of the wave-absorbing quay in harbors. The results also show that the boundary condition is practically applicable up to "Intermediate depth waves" inspite of shallow water wave approximation used for the derivation of it.

#### 4. Conclusions

To solve wave-induced oscillations in harbors with wave absorbing quays, we have derived a boundary condition on the wave-absorbing quay in the form as  $\partial\phi/\partial x = \Omega\phi$ . The coefficient  $\Omega$  contains two unknown coefficients of the fluid resistances,  $\mu_1$  and  $\mu_2$ . We have further derived a relation between the two coefficients and the complex reflection coefficient of the wave-absorbing quay, and have shown that  $\mu_1$  and  $\mu_2$  can be determined sub-empirically from the relation and the experimental data on wave reflection of the wave-absorbing quay.

The validity of the boundary condition was confirmed by comparing analytical results with the data obtained by wave basin experiments. Scale effects on  $\mu_1$  and  $\mu_2$ , however, have not been considered, thus further investigations on them may be needed to use the boundary condition on actual harbors.

## CHAPTER SIXTY FOUR

### The Physical Basis of The Mild-Slope Wave Equation

Lars Behrendt\*

Ivar G. Jonsson\*\*

#### Abstract.

The mild-slope wave equation is derived by demanding minimum in total wave energy.

By demanding conservation of wave energy, two different functionals for the finite element solution of the mild-slope wave equation are constructed. The first functional is based on a finite/infinite element formulation, and the second one is based on a hybrid finite element formulation. Both functionals are constructed in a straight-forward way that leads to a better physical understanding of the functionals and a full understanding of each separate part of them.

#### 1. Introduction.

Waves of arbitrary length propagating in an area of varying depth may be described by the mild-slope wave equation. This equation was first derived by Berkhoff (1972). Later an alternative derivation was given by Smith and Sprinks (1975). A detailed discussion can be found in Jonsson and Brink-Kjær (1973).

Berkhoff (1972) solved the mild-slope wave equation by using the finite element method. Chen and Mei (1974) formulated a hybrid finite element method that, contrary to Berkhoff's formulation, leads to a symmetric stiffness matrix, which is almost a necessity when dealing with larger element grids. Their formulation has later been used in a generalized version by Houston (1981) and Tsay and Liu (1983).

Bettes and Zienkiewicz (1977) solved the mild-slope wave equation by using a simple finite/infinite element method based on a variational formulation different from the one used by Chen and Mei (1974).

In this paper is given a derivation of the mild-slope wave equation based on energy considerations. Then it is demonstrated how — by generalizing the approach used to derive the wave equation — one can construct the functionals used in both the hybrid element and in the finite/infinite element methods when solving the wave equation. General intermediate depth theory will be used, and energy dissipation along an absorbing boundary is included.

## 2. Basic Theory.

When the fluid is assumed to be ideal, it is possible to describe the motion of small amplitude surface gravity waves by the complex velocity potential  $\phi$  :

$$\Phi(x,y,z,t) = \phi e^{-i\omega t} \frac{\cosh k(z+h)}{\cosh kh} \quad (1)$$

where  $x$  and  $y$  are horizontal co-ordinates,  $z$  is the vertical co-ordinate,  $t$  is the time,  $h$  is the local water depth,  $\omega$  is the angular frequency and  $k$  is the wave number. Quantity  $\phi = \phi(x,y)$  is a two-dimensional complex potential function.

The complex wave amplitude  $\eta$  is :

$$\eta = \frac{i\omega}{g} \phi \quad (2)$$

and the instantaneous complex surface elevation  $\xi$  is :

$$\xi = \eta e^{-i\omega t} \quad (3)$$

When one deals with a complex potential, a complex wave amplitude and a complex surface elevation, it is only natural also to introduce complex energies.

The complex potential energy of the wave motion per horizontal unit area is defined by :

$$E_p \equiv \int_0^{\xi} \rho g z \, dz \quad (4)$$

and after some calculations one finds :

$$E_p = -\frac{\rho}{g} e^{-2i\omega t} \frac{1}{2} \omega^2 \phi^2 \quad (5)$$

The complex kinetic energy per horizontal unit area is defined by :

$$E_k \equiv \int_{-h}^0 \frac{1}{2} \rho (\nabla_3 \phi)^2 \, dz \quad (6)$$

$\nabla_3$  being the three-dimensional gradient operator. After some calculations this can be written as :

$$E_k = \frac{\rho}{g} e^{-2i\omega t} \frac{1}{2} [c c_g (\nabla\phi)^2 + \frac{1}{2}(1-G)\omega^2 \phi^2] \quad (7)$$

$c$  being the phase velocity,  $c_g$  the group velocity and  $\nabla$  the horizontal gradient operator.

The total complex wave energy of the wave motion per unit area is the sum of the potential energy (5) and the kinetic energy (7) :

$$E = \frac{\rho}{g} e^{-2i\omega t} \frac{1}{2} [c c_g (\nabla\phi)^2 - \frac{c_g \omega^2}{c} \phi^2] \quad (8)$$

The complex energy flux through a section characterized by normal  $n$  is per unit length :

$$E_f = \int_{-h}^0 p^+ u \, dz \quad (9)$$

where  $p^+$  is the excess pressure :

$$p^+ = -\rho \frac{\partial\phi}{\partial t} \quad (10)$$

and  $u$  is the horizontal particle velocity in the  $n$ -direction :

$$u = \frac{\partial\phi}{\partial n} \quad (11)$$

Inserting (10) and (11) in (9) and integrating one finds :

$$E_f = \frac{\rho}{g} e^{-2i\omega t} i\omega c c_g \phi \frac{\partial\phi}{\partial n} \quad (12)$$

It is noted that the energies (5), (7) and (8) and the energy flux (12) are all functions of time  $t$ . When dealing with the corresponding quantities in ordinary, real-value wave theory one uses the mean value over one wave period. When one deals with a complex energy and energy flux this has no meaning, since these mean values will all be zero. However, after some simple calculations one easily realizes that the absolute values of the complex energies are equal to twice the value of the corresponding real quantities. The same result is found for the energy flux.

### 3. The Wave Equation.

An area of calculation, A, is shown in Fig. 1.

Fig. 1. Area of calculation A in the horizontal plane.

Inside area A some wave scattering structure, area B, is located. The water depth in area A may vary. For simplicity it is assumed in this chapter that the boundary of area B,  $\partial B$ , is fully reflecting leading to the boundary condition :

$$\frac{\partial \phi}{\partial n_B} = 0 \quad \text{along } \partial B \quad (13)$$

It is also assumed that the outer boundary of area A,  $\partial A$ , is lying at infinity. Far away from the central part of area A, the Sommerfeld radiation condition must be fulfilled :

$$\lim_{r \rightarrow +\infty} \sqrt{r} \left( \frac{\partial \phi}{\partial r} - ik \right) \phi^S = 0 \quad (14)$$

where  $\phi^S$  is the velocity potential of the scattered wave field.  $\phi^S$  may be found from the total potential  $\phi$  by the expression :

$$\phi = \phi^i + \phi^S \quad (15)$$

where  $\phi^i$  is the known velocity potential of the incident wave motion. What (14) says is in fact that the scattered wave system should be outgoing at some distance from the central part of area A.

The total complex wave energy in area A,  $E_A$ , can be found from (8):

$$E_A = \frac{\rho}{g} e^{-2i\omega t} \iint_A \left[ cc_g (\nabla\phi)^2 - \frac{c}{g} \frac{\omega^2}{c} \phi^2 \right] dx dy \quad (16)$$

Since the wave motion by definition is stationary  $E_A$  must also be stationary. This means that the first variation of  $E_A$  must vanish, i.e.

$$\delta E_A = 0 \quad (17)$$

Using Green's theorem one finds from (16) :

$$\delta E_A = \frac{\rho}{g} e^{-2i\omega t} \left\{ - \iint_A \delta\phi \left[ \nabla \cdot (cc_g \nabla\phi) + \frac{c}{g} \frac{\omega^2}{c} \phi \right] dx dy + \int_{\partial A + \partial B} cc_g \delta\phi \frac{\partial\phi}{\partial n_A} ds \right\} \quad (18)$$

The line-integral in (18) along  $\partial B$  vanishes by introducing (13). It can be argued that also the integral along  $\partial A$  can be ignored. Hereafter by combining (17) and (18) one gets :

$$\iint_A \delta\phi \left[ \nabla \cdot (cc_g \nabla\phi) + \frac{c}{g} \frac{\omega^2}{c} \phi \right] dx dy = 0 \quad (19)$$

This must hold for any  $\delta\phi$ . Therefore the term in the square brackets must be zero everywhere in area A :

$$\nabla \cdot (cc_g \nabla\phi) + \frac{c}{g} \frac{\omega^2}{c} \phi = 0 \quad (20)$$

This is the mild-slope wave equation.

So, for the total complex wave energy in the area of calculation to be stationary the mild-slope wave equation is the necessary and sufficient demand.

However, from physical reasoning one can tell that for a known incident wave system there will be no stationary situation except the one that represents the minimum in wave energy. Therefore, the mild-slope wave equation is also a consequence of the total wave energy in the area of calculation being minimized.

4. Two Functionals.

4.1. General Remarks.

For many practical purposes it is convenient not to deal with an area of infinite extension as that shown in Fig.1., but instead to split the horizontal plane in an inner area A, and an outer area R reaching to infinity as shown in Fig.2. Thus, it is possible to treat the inner and the outer area in separate ways as will be done in the following sections.

Fig.2. Areas of calculation A and R in the horizontal plane.

Again, inside area A some wave scattering structure B is located. For generality, the boundary of this area, ∂B, may be partially absorbing :

$$\frac{\partial \phi}{\partial n_B} + i k \alpha \phi = 0 \quad \text{along } \partial B \quad (21)$$

where  $\alpha$  is an absorption coefficient. For waves incident at a right angle to the boundary, (21) results in reflected waves with the reflection coefficient  $(1-\alpha)/(1+\alpha)$ . Thus,  $\alpha=1$  corresponds to full absorption of waves incident at a right angle, and  $\alpha=0$  corresponds to a fully reflecting boundary.

Over the boundary ∂A which now is not at infinity, the velocity potential has to be smooth which leads to the boundary conditions :

$$\phi_R = \phi_A \quad \text{along } \partial A \quad (22)$$

$$\frac{\partial \phi_R}{\partial n_A} = \frac{\partial \phi_A}{\partial n_A} \quad \text{along } A \quad (23)$$

where  $\phi_A$  and  $\phi_R$  are the potentials in area A and R respectively.

In the outer area R the velocity potential can be expressed as :

$$\phi_R = \phi^i + \phi^S \quad (24)$$

where again  $\phi^S$  must satisfy the radiation condition (14) leading to the vanishing of  $\phi^S$  and its derivative at the boundary of area R,  $\partial R$ .

4.2. A Simple Element Formulation.

A simple element formulation is here understood as a formulation that only involves element shape functions to describe the solution to the problem. The mild-slope wave equation has been solved by use of such a method by Bettes and Zienkiewicz (1977) where infinite elements were used in the outer area R, and ordinary finite elements were used in the inner area A. Hereby Bettes and Zienkiewicz were able to extend the integration to cover the entire x-y plane.

Using the results from section 2 and 3 will now demonstrate how one in a new and easily understandable way can construct the functional used by Bettes and Zienkiewicz (1977) in their finite/infinite element formulation.

The total complex wave energy in area A is given by (16). In a quite similar way the total energy in area R,  $E_R$ , may be found. Energy is lost along the partially absorbing boundary  ${}^R\partial B$ . This is described by an energy flux through the boundary. Hereby the following equation describing conservation of total complex wave energy arises :

$$\frac{\partial}{\partial t} (E_A + E_R) + \int_{\partial B^A} E_f^A ds + \int_{\partial B^R} E_f^R ds = 0 \quad (25)$$

where  $E_f^A$  is positive as a flux out through the boundary  $\partial B$  meaning the direction  $n$  in (12) should be  $n_A$  ( $=-n_B$ ).  $E_f^R$  is positive as a flux out through the distant boundary  $\partial R^A$ , i.e.  $n$  should be  $n_R$ .

Integrating (25) once with respect to time  $t$  yields :

$$E_A + E_R + \int_{\partial B} \left[ \int E_f^A dt \right] ds + \int_{\partial R} \left[ \int E_f^R dt \right] ds = \text{Constant} \quad (26)$$

Using (12) and (21) the integral along  $\partial B$  in (26) can be calculated :

$$\int_{\partial B} \left[ \int E_f^A dt \right] ds = -\frac{\rho}{g} e^{-2i\omega t} \int_{\partial B} \frac{1}{2} i\omega c_g \phi^2 ds \quad (27)$$

Using (12) and (24) the integral along  $\partial R$  in (26) can be written as :

$$\int_{\partial R} \left[ \int E_R^R dt \right] ds = -\frac{\rho}{g} e^{-2i\omega t} \left\{ \int_{\partial R} cc_g \frac{1}{2} \phi^i \frac{\partial \phi^i}{\partial n_R} ds \right. \\ \left. + \int_{\partial R} cc_g \frac{1}{2} \phi^S \frac{\partial \phi^S}{\partial n_R} ds + \int_{\partial R} cc_g \frac{1}{2} \phi^i \frac{\partial \phi^S}{\partial n_R} ds \right. \\ \left. + \int_{\partial R} cc_g \frac{1}{2} \phi^S \frac{\partial \phi^i}{\partial n_R} ds \right\} \quad (28)$$

As in (18) it can be argued that these integrals along  $\partial R$  can be ignored.

Introducing (24) in the expression for  $E_R$  one gets :

$$E_R = \frac{\rho}{g} e^{-2i\omega t} \left\{ \iint_R \frac{1}{2} [cc_g (\nabla \phi^i)^2 - \frac{c_g \omega^2}{c} (\phi^i)^2] dx dy \right. \\ \left. + \iint_R \frac{1}{2} [cc_g (\nabla \phi^S)^2 - \frac{c_g \omega^2}{c} (\phi^S)^2] dx dy \right. \\ \left. + \iint_R [cc_g \nabla \phi^i \cdot \nabla \phi^S - \frac{c_g \omega^2}{c} \phi^i \phi^S] dx dy \right\} \quad (29)$$

The first integral in (29) is stationary, and it can therefore be discarded. The second integral contains the velocity potential  $\phi^S$  of the scattered wave field which is to be modelled by special shape functions in the outer area  $R$ . The third integral in (29) may be rewritten as follows :

$$\iint_R [cc_g \nabla \phi^i \cdot \nabla \phi^S - \frac{c_g \omega^2}{c} \phi^i \phi^S] dx dy = \\ \int_{\partial R + \partial A} cc_g \phi^S \frac{\partial \phi^i}{\partial n_R} ds - \iint_R \phi^S [cc_g \nabla^2 \phi^i + \frac{c_g \omega^2}{c} \phi^i] dx dy \quad (30)$$

Again the line integral in (30) along  $\partial R$  can be discarded. Furthermore assuming the water depth in the outer area  $R$  to be constant, the second integral on the right hand side of (30) vanishes, since  $\phi^i$  naturally must be a solution to the wave equation.

Hereafter the integrated energy equation (26), with (16), (27) and (29) introduced, gives the functional (omitting the unimportant factor  $\frac{\rho}{g} e^{-2i\omega t}$ ) :

$$\begin{aligned}
F(\phi) = & \iint_A \left[ \frac{1}{2} c c_g (\nabla \phi)^2 - \frac{c_g \omega^2}{c} \phi^2 \right] dx dy \\
& + \iint_R \left[ \frac{1}{2} c c_g (\nabla \phi^S)^2 - \frac{c_g \omega^2}{c} (\phi^S)^2 \right] dx dy \\
& - \int_{\partial A} c c_g \phi^S \frac{\partial \phi^i}{\partial n_A} ds \\
& - \int_{\partial B} \frac{1}{2} i \alpha \omega c_g \phi^2 ds = \text{Constant} \quad (31)
\end{aligned}$$

By taking the first variation of (31) it is found that :

$$\delta F(\phi) = 0 \quad (32)$$

$F(\phi)$  is exactly the functional used by Bettes and Zienkiewicz (1977). By finite/infinite element discretization (32) can be expressed as a system of linear equations, which easily can be constructed and solved on a computer. When solving (32) one finds the function  $\phi$  — or, more precisely, a close approximation to the true  $\phi$ -function — which with the preconditions introduced fulfils the energy conservation equation (25). So, from a physical point of view, what really happens in this finite/infinite element formulation is that the conservation of total complex wave energy in the entire plane is ensured.

#### 4.3. A Hybrid Element Formulation.

A hybrid element method is a combination of a conventional element method and some other method. The mild-slope wave equation was initially solved by Berkhoff (1972,1975) using a hybrid element method. A slightly different hybrid element formulation was introduced by Chen and Mei (1974) solving the shallow water wave equation. Later this formulation in its intermediate depth version has been used by Houston (1981) and by Tsay and Liu (1983). The basic principle of the Chen and Mei method is that while the inner area A (see Fig.2.) is divided into finite elements, a semi-analytical solution to the mild-slope wave equation is used in the outer area R to represent the velocity potential  $\phi^S$ . Hereby integration over the outer area R can be avoided.

Using the same new procedure as in the previous section, a functional for the hybrid element formulation as originally given for shallow water by Chen and Mei (1974) will now be constructed. However, as in the previous section, intermediate depth theory will be used, and an absorbing boundary condition will be included.

Conservation of total complex wave energy is again the starting point. However, since the two areas of calculation are going to be treated in two separate ways, it is necessary to describe the conservation of energy in two separate equations. This leads to the following energy conservation equation for the inner area A :

$$\frac{\partial E_A}{\partial t} + \int_{\partial A + \partial B} E_f^A ds = 0 \quad (33)$$

and for the outer area R :

$$\frac{\partial E_R}{\partial t} + \int_{\partial A + \partial R} E_f^R ds = 0 \quad (34)$$

$E_f^A$  and  $E_f^R$  are energy fluxes positive out of areas A and R, respectively. From (33) and (34) one gets by integration :

$$E_A + \int_{\partial A + \partial B} [ \int E_f^A dt ] ds = \text{Constant} \quad (35)$$

$$E_R + \int_{\partial A + \partial R} [ \int E_f^R dt ] ds = \text{Constant} \quad (36)$$

The integral in (35) along the partially absorbing boundary  $\partial B$  can be calculated according to (27). The integral in (35) along  $\partial A$  can be calculated :

$$\int_{\partial A} [ \int E_f^A dt ] ds = - \frac{\rho}{g} e^{-2i\omega t} \int_{\partial A} \frac{1}{2} cc_g \phi_A \frac{\partial \phi_A}{\partial n_A} ds \quad (37)$$

Using Green's theorem one may write the wave energy in the outer area,  $E_R$ , as :

$$E_R = \frac{\rho}{g} e^{-2i\omega t} \left\{ - \iint_R \frac{1}{2} \phi_R [ \nabla \cdot (cc_g \nabla \phi_R) + \frac{c_g \omega^2}{c} \phi_R ] dx dy + \int_{\partial A + \partial R} \frac{1}{2} cc_g \phi_R \frac{\partial \phi_R}{\partial n_R} ds \right\} \quad (38)$$

Now, introducing the precondition that  $\phi_R$  must fulfil the mild-slope wave equation (20), it is seen from (38) that  $E_R$  may be written as :

$$E_R = \frac{\rho}{g} e^{-2i\omega t} \left\{ \int_{\partial A} \frac{1}{2} cc_g \phi_R \frac{\partial \phi_R}{\partial n_R} ds + \int_{\partial R} \frac{1}{2} cc_g \phi_R^i \frac{\partial \phi_R^i}{\partial n_R} ds \right\} \quad (39)$$

where again integrals along  $\partial R$  containing  $\phi^S$  or its derivative have been discarded.

When in addition assuming the water depth in the outer area R to be constant, it can be shown that :

$$\int_{\partial A} cc_g \phi^S \frac{\partial \phi^i}{\partial n_R} ds = \int_{\partial A} cc_g \phi^i \frac{\partial \phi^S}{\partial n_R} ds \tag{40}$$

The integral along  $\partial A + \partial R$  in (36) can be calculated :

$$\begin{aligned} \int_{\partial A + \partial R} [ \int E_f^R dt ] ds = & - \frac{\rho}{g} e^{-2i\omega t} \left\{ \int_{\partial A} \frac{1}{2} cc_g \phi^S \frac{\partial \phi^S}{\partial n_R} ds \right. \\ & \left. + \int_{\partial A + \partial R} \frac{1}{2} cc_g \phi^i \frac{\partial \phi^i}{\partial n_R} ds + \int_{\partial A} cc_g \phi^i \frac{\partial \phi^S}{\partial n_R} ds \right\} \end{aligned} \tag{41}$$

where (40) has been used and some integrals along  $\partial R$  again have been discarded.

By use of (27) and (37) to (41), energy equation (35) may now be written as :

$$\begin{aligned} \frac{\rho}{g} e^{-2i\omega t} \left\{ \iint_A \frac{1}{2} [ cc_g (\nabla \phi_A)^2 - \frac{c_g \omega^2}{c} \phi_A^2 ] dx dy \right. \\ \left. - \int_{\partial A} \frac{1}{2} cc_g \phi_A \frac{\partial \phi_A}{\partial n_A} ds - \int_{\partial B} \frac{1}{2} i \alpha \omega c_g \phi_A^2 ds \right\} = \text{Constant} \end{aligned} \tag{42}$$

and energy equation (36) may be written as :

$$\begin{aligned} \frac{\rho}{g} e^{-2i\omega t} \left\{ \int_{\partial A} \frac{1}{2} cc_g \phi_R \frac{\partial \phi_R}{\partial n_R} ds - \int_{\partial A} \frac{1}{2} cc_g \phi^S \frac{\partial \phi^S}{\partial n_R} ds \right. \\ \left. - \int_{\partial A} \frac{1}{2} cc_g \phi^i \frac{\partial \phi^i}{\partial n_R} ds - \int_{\partial A} cc_g \phi^S \frac{\partial \phi^i}{\partial n_R} ds \right\} = \text{Constant} \end{aligned} \tag{43}$$

Now it is time to include the matching boundary conditions along  $\partial A$ , (22) and (23). This is done by using (22) in the first integral in (43) and (23) in the second integral in (42). The reason for this choice is that when it comes to actual calculations,  $\phi_A$  will be represented by finite element shape functions, and therefore the derivative of  $\phi_A$  will in general only be an approximation to the true one and should therefore be avoided. On the other hand,  $\phi_R$  will be represented by an analytical series solution containing some unknown constants. The derivative of  $\phi_R$  will therefore be known exactly.

It is noted that the third integral in (43) only contains  $\phi^i$  and its derivative. Thus, it is stationary and therefore unimportant.

Now, by adding the two expressions (42) and (43), omitting the unimportant factor  $(\rho/g)\exp(-2i\omega t)$  and taking advantage of the unimportance of the stationary integral, one gets the 'hybrid functional' :

$$\begin{aligned}
F_H(\phi) = & \iint_A \frac{1}{2} [c c_g (\nabla \phi_A)^2 - \frac{c_g \omega^2}{c} \phi_A^2] dx dy \\
& + \int_{\partial A} c c_g [\frac{1}{2} \phi^S - (\phi_A - \phi^i)] \frac{\partial \phi_R}{\partial n_A} ds \\
& - \int_{\partial A} \frac{1}{2} c c_g \phi^S \frac{\partial \phi^i}{\partial n_A} ds \\
& - \int_{\partial B} \frac{1}{2} i \alpha \omega c_g \phi_A^2 ds = \text{Constant} \quad (44)
\end{aligned}$$

Similarly to (32) one finds by taking the first variation of (44) :

$$\delta F_H(\phi) = 0 \quad (45)$$

$F_H$  is the functional first derived in its shallow water version by Chen and Mei (1974). The present formulation is more general since intermediate depth theory has been used, and an absorbing boundary condition has been included. Again it can be concluded that the basic demand expressed in (45) used in finite element calculations simply ensures conservation of total complex wave energy in the entire horizontal plane.

### 5. Discussion.

Two different functionals, each corresponding to its own element formulation, have been derived. When constructing the functional in section 4.2, constant water depth was assumed in the outer area. When constructing the functional in section 4.3, it was necessary to assume that  $\phi^S$  fulfil the wave equation in the constant water depth outer area. When making the actual calculations, this is ensured by representing  $\phi^S$  by a semi-analytical solution to the Helmholtz equation. This equation is the constant water depth version of the mild-slope wave equation. For practical use the two formulations have the same assumptions behind the functionals. The variational formulation described in section 4.3 is more complicated than the one in section 4.2, but that argument should not be used to downgrade the hybrid element method since this formulation only has to be gone through once. The authors of the present paper believe that when using efficient programming, i.e. mainly sparse-matrix handling techniques, there will be no significant difference in the cost of running the two models.

Finally an example of the results of diffraction calculations that one can get using the finite element method is shown in Fig.3 and Fig.4. Fig.3 shows the relative wave amplitude in and just outside a harbour. The incoming waves are approaching the coastline at a right angle and all boundaries are fully reflecting. Fig.4 shows the instantaneous surface elevation at a chosen time where the sum of the incident and the reflected waves has zero elevation everywhere outside the harbour. Therefore, what is seen outside the harbour at this moment is

alone the surface elevation of the scattered wave field.

More results including absorbing boundary conditions and superposition of waves can be found in Skovgaard et. al. (1984).

Fig.3. Harbour, relative amplitudes.

## 6. Conclusion.

The mild-slope wave equation has been derived by demanding minimum of total wave energy in the area of interest. This approach provides a new physical understanding of the mild-slope wave equation.

A functional for a simple element method and a functional for a hybrid element method have been derived from a general energy conservation principle. In both cases the procedure is straight-forward, and there is no need for any trial-and-error methods. Hereby a full understanding of each single part of the functionals is obtained and also a better understanding of the physical basis of the finite element method for the calculation of diffraction of small water waves.

## CHAPTER SIXTY FIVE

### Steep Unsteady Water Waves: An Efficient Computational Scheme

J W Dold and D H Peregrine

School of Mathematics, University of Bristol,  
University Walk, Bristol BS8 1TW, England.

A new method for computing the unsteady motion of a water surface, including the overturning of water waves as they break, has been developed. It is based on a Cauchy theorem boundary integral for the evaluation of multiple time derivatives of the surface motion. The numerical implementation of the method is efficient, accurate and stable.

#### 1. Introduction

Longuet-Higgins and Cokelet [2] first described a means of computing steep surface motions and the overturning of water waves in 1976. Since then their method has been used and modified by various authors ([1] to [8]). A useful discussion of most of the techniques available to date is given by Baker et al [1]. The water motion is assumed to be inviscid and irrotational; the necessary solution of Laplace's equation for the velocity potential is cast into some form of boundary integral; and the free surface boundary conditions are used to advance the calculations in time.

Most of these methods have been found to suffer from a "sawtooth" numerical instability [7], which is usually controlled by some kind of smoothing. They can also be computationally expensive; using an implementation of the method of Longuet-Higgins and Cokelet, New [4] found that about 20 hours of processor time on a Honeywell level 68 (multics system) computer were needed to determine, with reasonable accuracy, the motion of a breaking wave to the

point at which the jet strikes the lower surface.

The method described here uses Cauchy's theorem for analytic functions of a complex variable to formulate the boundary-integral equation in a form suitable for efficient solution by iteration. The same equation is used to find extra time derivatives of the surface motion at each step. For a given accuracy the resulting truncated Taylor series is used to estimate the maximum acceptable time-step, and to perform the time stepping.

The method is found to be both stable and very accurate for steep steadily-propagating waves. Unsteady waves can only be checked against other numerical solutions. Comparisons with solutions obtained using the approach of Longuet-Higgins and Cokelet give clear indications that this method is more accurate. Furthermore the program for this method is found to run an order of magnitude faster, for given accuracy.

## 2. Outline of Method

Incompressible irrotational flow is described by a velocity potential satisfying

$$\nabla^2 \phi = \phi_{xx} + \phi_{yy} = 0 \quad (1)$$

where

$$\underline{u} = \nabla \phi. \quad (2)$$

It is assumed that the fluid is bounded below by an impermeable flat bottom at  $y = -h$ . The appropriate boundary condition for  $\phi$  is

$$\phi_y(x, -h, t) = 0. \quad (3)$$

With these conditions governing the behaviour of the body of the fluid it is possible to focus attention on the fluid surface alone; as described in section 4, a boundary-integral equation can be used to summarise the whole fluid's behaviour in terms of its surface properties. In particular the normal and tangential gradients of  $\phi$  at the surface can be determined, knowing only the surface values of  $\phi$ . This gives the velocity  $\underline{u}$  from (2). The kinematic condition, that a surface particle moves with its

own velocity, shows that the instantaneous movement of the surface is then fully determined; if  $(X, Y)$  marks a particle on the surface then the rates of change of  $X$  and  $Y$  are given by

$$\frac{D}{Dt} (X, Y) = \underline{u} = (\phi_x, \phi_y). \quad (4)$$

To follow the motion of the surface further it is also necessary to know the way in which  $\phi$  varies. Bernoulli's equation gives the rate of change of  $\phi$  on the surface as

$$\frac{D\phi}{Dt} = \frac{u^2}{2} - (P/\rho + gY) \quad (5)$$

where  $P$  takes the value of the surface pressure which for many practical purposes may be taken as a constant, the actual value of which makes no difference to the motion of the fluid.

Most existing numerical schemes for following the movement of the fluid surface make use of this formulation with the following basic algorithm.

Given  $(X, Y, \phi)$  on the surface at the time  $t$ :

- i) solve  $\nabla^2 \phi = 0$  with  $\phi_y(x, -h, t) = 0$  to obtain  $\nabla \phi$  on the surface and hence evaluate  $D(X, Y, \phi)/Dt$
- ii) time-step to obtain  $(X, Y, \phi)$  on the surface at the time  $t + \Delta t$ , and repeat.

### 3. Extended Approach

Equations (1) and (3) can be successively differentiated with respect to time to yield the following equations and bottom conditions:

$$\begin{aligned} \nabla^2 \phi_t &= 0 & \text{with } \phi_{ty}(x, -h, t) &= 0 \\ \nabla^2 \phi_{tt} &= 0 & \text{with } \phi_{tty}(x, -h, t) &= 0 \end{aligned} \quad (6)$$

etc.

Clearly  $\phi_t, \phi_{tt}$  and all similar Eulerian derivatives of

$\phi$  satisfy Laplace's equation and the bottom condition just as  $\phi$  does. In the same way therefore it is possible to solve for the gradients of these derivatives and obtain the corresponding Eulerian rates of change of velocity, for which they are the appropriate potential functions. This can be seen by differentiating (2). Extension of the kinematic condition (4) to obtain  $D^2(X,Y)/Dt^2$  etc. is also straightforward. Similarly, differentiation of Bernoulli's equation (5) gives the corresponding Lagrangian rates of change of  $\phi$  on the surface.

In order to determine these higher derivatives it is necessary to obtain  $\phi_t, \phi_{tt}$  etc. on the surface. By using Bernoulli's equation once again and expressing the result in terms of Lagrangian, rather than Eulerian derivatives of pressure, these can be found in terms of known variables. For example,

$$\phi_{tt} = - \left[ \underline{u} \cdot \left( \underline{u}_t + \frac{D\underline{u}}{Dt} \right) + \frac{DP}{Dt}/\rho + g \frac{DY}{Dt} \right]. \quad (7)$$

Thus the Eulerian derivatives of  $\phi$  are given once  $P, DP/Dt$  etc. are specified. For a constant surface pressure all Lagrangian derivatives of  $P$  at the surface would simply be zero.

The algorithm for calculating the surface motion can thus be extended in the following way

Given  $(X, Y, \phi)$  on the surface at the time  $t$ :

- i) solve  $\nabla^2 \phi = 0$  with  $\phi_y(x, -h, t) = 0$  to obtain  $\nabla \phi$  on the surface and evaluate both  $D(X, Y, \phi)/Dt$  and  $\phi_t$
- ii) similarly use  $\phi_t$  to obtain both  $D^2(X, Y, \phi)/Dt^2$  and  $\phi_{tt}$
- iii) proceed in the same way to calculate up to a chosen order of time derivative
- iv) time-step, using Taylor series in  $X, Y$  and  $\phi$  with some backward differencing, to obtain  $(X, Y, \phi)$  on the surface at the time  $t + \Delta t$ , and repeat.

A scheme using calculations up to  $D^3/Dt^3$  in this algorithm has been implemented numerically.

Some immediate advantages are found with this approach. Firstly, it is possible to take larger time steps for a given accuracy. Secondly, the derivatives are calculated for the same surface profile,  $(X, Y)$ . This means

that the solutions are all obtained using exactly the same boundary-integral kernels. Both of these result in an improvement in numerical efficiency and hence shorter computer running times. It is also useful to have more detailed information calculated about the surface motion at each time step.

4. Integral Equation

For a variety of reasons it was decided to use Cauchy's integral theorem as the means of solving Laplace's equation. Its use leads to a fairly simple formulation in which the singularities in the integral kernels are easily taken into account. This contrasts with the more cumbersome logarithmic singularity found with approaches which use Green's identity. In addition the Cauchy formulation is soluble by iteration which can be a quick method of solution.

(i) Cauchy's Integral Theorem

Figure 1: Closed contour

For  $\phi$  satisfying Laplace's equation within the contour C, illustrated in figure 2, the complex potential gradient,  $\phi_u - i\phi_v$ , is an analytic function of the variable,  $w = u + iv$ . The following useful expression of the principal value form of Cauchy's integral theorem is then satisfied.

$$\phi_n = \frac{1}{\pi} \int \text{Im} \left[ \frac{W_s}{W' - W} \right] \phi_n' ds' + \frac{1}{\pi} \int \text{Re} \left[ \frac{W_s}{W' - W} \right] \phi_s' ds'. \quad (8)$$

In this equation the arclength derivative,  $W_s$ , of the surface position,  $W(s)$ , is the complex unit tangent, and

$\phi_s$  and  $\phi_n$  are the tangential and inward normal gradients of  $\phi$ , respectively.

(ii) Application

Figure 2: Physical plane

In the complex representation of the physical plane,  $z = x + iy$ , the complex gradient of the potential becomes

$$q = \phi_x - i \phi_y \tag{9}$$

and the bottom condition (3) can be satisfied by adopting the "reflection" condition,

$$q(Z^* - 2ih) = q^*(Z), \tag{10}$$

with the fluid assumed to extend continuously below the bottom to the reflection of the complex surface,  $Z$ , in the bottom.

It is useful at this point to assume that the system is periodic in  $x$  so that only a finite length of surface need be considered. No generality is lost in taking the spatial period to be exactly  $2\pi$ . The periodic surface  $Z(\xi)$  in the  $z$  plane is then transformed to a closed contour  $W(\xi)$  in the  $w$  plane by the conformal

transformation,

$$w = e^{-iz} = u + iv. \tag{11}$$

Applying the formula (8) to this contour and the transformation of the reflected contour leads to the following integral equation

$$\begin{aligned} \phi_v = \frac{1}{\pi} \int \operatorname{Im} \left[ \frac{W_\xi}{W-W'} + \frac{W_\xi}{W-e^{-2h/W'}*} \right] \phi_v' d\xi' \\ + \frac{1}{\pi} \int \operatorname{Re} \left[ \frac{W_\xi}{W-W'} - \frac{W_\xi}{W-e^{-2h/W'}*} \right] \phi_\xi' d\xi' \end{aligned} \tag{12}$$

where  $\phi_\xi$  is simply the derivative of  $\phi$  with respect to the parameter  $\xi$  along the surface, while  $\phi_v$  is the outward normal gradient of  $\phi$  scaled by  $|W_\xi|$ . Supposing that (12) can be solved for  $\phi_v$ , the complex potential gradient of  $\phi$  in the physical plane is then given by

$$\phi_x + i\phi_y = \frac{W^*W_\xi}{|W_\xi|^2} (\phi_\xi + i\phi_v). \tag{13}$$

(iii) Numerical Solution

In order to solve equation (12) numerically it is now convenient to identify  $\xi$  as a point label parameter with  $X(\xi)$ ,  $Y(\xi)$  and  $\phi(\xi)$  defined on the surface for integral values of  $\xi$ . Derivatives with respect to  $\xi$  can be estimated using either central difference or Fourier series methods. By considering a Taylor expansion for  $W'$  the singular part of the integral kernels in (12) can be seen to be of the form

$$\frac{W_\xi}{W-W'} = \frac{1}{\xi-\xi'} + \frac{W_\xi\xi}{2W_\xi} + O(\xi'-\xi). \tag{14}$$

Since  $(\xi - \xi')^{-1}$  is real this makes it clear that only the kernel comprising the real part of  $W_\xi / (W - W')$  is genuinely singular, and since

$$\lim_{\xi' \rightarrow \xi} \frac{\phi_\xi' - \phi_\xi}{\xi - \xi'} = -\phi_{\xi\xi} \tag{15}$$

the effect of this singularity in the integral is easily

determined. It can thus be shown that the formula

$$\int \operatorname{Re} \left[ \frac{W_\xi}{W-W'} \right] \phi'_\xi d\xi' \approx \sum_{\xi' \neq \xi} \operatorname{Re} \left[ \frac{W_\xi}{W-W'} \right] \phi'_\xi + \operatorname{Re} \left[ \frac{W_{\xi\xi}}{2W_\xi} \right] \phi_\xi - \phi_{\xi\xi} \tag{16}$$

can be used to provide a numerical estimate for this integral. Taking account of the other non-singular components of (12) the integral kernels were expressed in matrix form. Given any potential function  $\phi(\xi)$  on the surface, the derivatives  $\phi'_\xi$  and  $\phi_{\xi\xi}$  were estimated numerically and the matrix equations were solved iteratively for  $\phi_v$ .  $\nabla\phi$  was then obtained using equation (13).

5. Accuracy, Stability and Speed

The resulting scheme for following the free surface motion was tested in a number of cases and was found to show no sign of the "sawtooth" numerical instability. Figure 3 shows one such test using 32 points to follow the propagation of a steep steady surface wave in deep water (with  $ak = 13/32$  or about 92% of the highest wave) for ten wave periods. It is interesting to note the particle drift of nearly twice the wavelength,  $\lambda$ , with the triangle  $\Delta$  marking the same particle. The results are just as should be expected to within an accuracy of about  $\lambda/10^4$ . This accuracy reflects an accuracy in the phase speed for the calculated wave of about 0.005%.

Figure 3: Steep surface wave ( $ak \approx 13/32$ ) after 10 wave periods using 32 points.

On a Honeywell level 68 (multics system) computer the program took about 2 minutes of C.P.U. time per wave period to execute this calculation, a running time which could have been reduced with fewer points and/or larger time steps at the sacrifice of some accuracy. The examples shown in figures 4 to 6 below each took about 20 to 30 minutes of C.P.U. time to calculate, and may be compared with the 20 hours, or so, experienced by New [4].

There are some limitations to the method. It was found that it is not always possible to reliably calculate progressively higher and higher derivatives. This is particularly so in regions of large strain rates, such as under the jet of a breaking wave, where the spreading out of surface particles leads to a reduced ability to resolve the wave profile. Since higher derivatives vary more dramatically in this region they are found to be the first to suffer from a loss of resolution. One can still proceed making use only of lower order derivatives.

Another region where a lack of resolution was encountered is at the tip of a jet such as can be seen in figure 6. The shape of this jet tip reflects a situation in which the point marked with the triangle  $\Delta$  is being accelerated into the fluid while points nearby are being accelerated outwards. Smoothing was used to control the motion in this case. It is not clear whether this observed tendency reflects a growing numerical instability or whether a genuine physical phenomenon, such as a breaking up of the jet tip, is taking place.

6. Some Examples of Results

For the examples presented below the acceleration due to gravity was given the value unity. Except in cases of zero gravity no generality is lost by this choice.

- i) Figure 4 shows the detail of a very small jet formed at the crest of a breaking wave which was generated by suddenly imposing a mean water depth of 2.5 (where the wavelength is  $2\pi$ ) on the otherwise deep water travelling wave of figure 3. After about two wave periods this causes the small jet to form at the crest of the wave. It is interesting to compare the profile at the wave crest with the  $120^\circ$  angle shown by the dotted line in figure 4.

Figure 4: Formation of a "spilling breaker" by introducing finite depth into the wave in figure 3.

ii) By contrast figure 5 shows the development of a very large plunging breaker arising from an initial large amplitude travelling sine wave. Figure 6 shows a detail of the jet tip of this wave taken as far as the computation would allow.

Figure 5: Massive plunging breaker from an initial travelling sine wave of amplitude 0.844, in deep water.

Figure 6: Detail of the tip of the jet in figure 5.

- iii) A curious example of surface motion leading to both the formation of a vertical jet and a plunging breaker is shown in figure 7. The initial conditions leading to this are illustrated by the dotted lines, showing a stretching of the surface in one region and a convergence and focussing of the motion of the surface in another.

Figure 7: Surface motion arising from the symmetric, periodic, initial conditions in shallow water, of a flat surface with strongly convergent (and divergent) flow, as indicated by the dotted lines.

## 7. Conclusions

The use of higher derivatives and the use of Cauchy's integral theorem have led to an efficient numerical scheme for calculating the motion of steep surface waves. The efficiency of the program means that it can now be used in a wide variety of ways. It is already well suited to fundamental studies of nonlinear wave phenomena such as breaking. With little further development it could be used for assessing forces on structural elements or vessels which are small compared with the dimensions of the wave. This type of computation could replace the "design wave" concept where steep steady waves are currently used. For this application some measure of breaker "strength" should be developed.

## CHAPTER SIXTY SIX

### EXPLICIT SOLUTIONS TO PRACTICAL WAVE PROBLEMS

by

Peter Nielsen\*

#### ABSTRACT

Explicit formulae are provided for wave problems covered by linear wave theory. Two goals are pursued. The first is to provide a faster and more flexible tool than usual wave tables. The second is to provide explicit, analytical solutions to problems that have so far demanded time consuming numerical integrations. As an example we solve the problem of wave height variation due to refraction, shoaling and energy dissipation over a soft mud bottom. The obtained explicit solutions are accurate enough for practical purposes and require very little computational effort, in fact they will enable the engineer to solve many wave problems with a handheld calculator. Another advantage of analytical solutions is that they are always much more instructive than numerical results.

#### INTRODUCTION

Determination of local parameters like wave length,  $L$ , celerity,  $c$ , and height,  $H$ , for linear waves involves solution of the dispersion relation

$$k_0 h = kh \tanh kh \quad (1)$$

for finding the local wave number  $k$  at the depth  $h$ ;  $k_0$  is the deep water wave number given by

$$k_0 = 4\pi^2/gT^2 \quad (2)$$

Since (1) is a transcendental equation,  $k$  or  $kh$  has to be found either by an iterative numerical method or by using a wave table. This is a troublesome process considering the limited accuracy with which linear wave theory represents the physical reality. See Figure 1.

On the other hand linear wave theory is often the only practical option so we will still want to use it, but preferably in a

---

\*Assistant Professor, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, Florida, 32611.

Figure 1: Measured values of the shoaling coefficient  $H/H_0$  compared to linear theory (After Brink Kjaer and Jonsson 1973). The error is of the order 10 percent.

mathematical form which is no more complicated than the accuracy of the theory justifies. In other words, there is no reason to solve equation (1) to seven significant digits every time we need a value of  $kh$ .

In the following we shall see how  $kh$  and many other functions related to linear waves can be expressed very simply in terms of  $k_0h$ , and thus become explicit functions of the water depth.

Not only is it possible to write linear wave functions in terms of  $k_0h$ , but it turns out that these formulae are very simple and adequate for practical use.

Take of example the function

$$F(k_0h) = \frac{1}{\frac{c}{c_0} \cosh^2 kh} \quad (3)$$

which occurs in relation to the problem of wave energy loss over a soft mud bottom. This apparently complicated function becomes

$$F(k_0h) = (k_0h)^{-0.5} [1 - 0.5 k_0h + \dots] \quad (4)$$

the accuracy of which is better than 1 percent for  $k_0h < 0.92$  that is in depths up to 14 meters for an 8 second wave.

The advantage of using the explicit form (4) is not just to make the evaluation of F easier, in fact the main advantage is that the explicit expression makes it possible to evaluate integrals like

$$I = \int_{h_1}^{h_2} Fdh \tag{5}$$

analytically. With this ability we are able to give analytical solutions to many wave problems in intermediate depths, for which explicit solutions have so far only been possible in shallow water.

The improvement of accuracy compared to using shallow water formulae all the way is by no means trivial.

Figure 2: Comparison of the two approximations (4) and (6) to correct values  $F(k_0h)$  given by (3).

Figure 2 shows equation (4) as well as the shallow water expression

$$F_S(k_0h) = (k_0h)^{-0.5} \tag{6}$$

compared to correct values. We see that the improvement by adding just one more term is remarkable. And the accuracy of equation (4) is probably a lot better than the accuracy by which physical parameters of a natural mud bottom can be described.

The efficiency of formulae like (4) as simple and accurate approximations was first pointed out by Nielsen (1982).

AN ALTERNATIVE WAVE TABLE

Most coastal engineers are familiar with the use of wave tables for linear waves.

WAVE TABLE

Figure 3: A wave table provides discrete values of commonly used wave parameters in terms of  $k_0h$  or  $h/L_0$ .

The general form of wave tables is illustrated in Figure 3 and is based on the fact that the dependence of linear wave parameters on the depth  $h$  can be expressed in the form

$$P = P_0 F(k_0 h) \tag{7}$$

where subscript "o" denotes deep water properties. For example, the local wave speed is given by

$$c = c_0 \tanh kh = c_0 G(k_0 h) \tag{8}$$

The function  $G(k_0h)$  does not have an exact explicit form in terms of usual functions but it is of course possible to construct explicit approximations to  $G(k_0h)$  with any degree of accuracy. The aim of the following is to suggest a standard method for providing such approximations and give a few examples.

The most commonly used form of approximations to transcendental or implicitly given functions are MacLaurin series or power expansions around zero. For example

$$\tanh x = x - \frac{1}{3}x^3 + \frac{2}{15}x^5 - \dots \quad (9)$$

However, such expansions do not exist for functions like  $G(k_0h)$  in equation (8), because  $G(k_0h)$  is not analytical at  $k_0h=0$ .

It is therefore necessary to use a different form of expansions. We choose the form

$$G(k_0h) = G_s(k_0h)[1 + a_1k_0h + a_2(k_0h)^2 + \dots] \quad (10)$$

where the subscript  $s$  stands for shallow water. The coefficients  $a_1$  are constants.

The shallow water expressions are always power functions of  $k_0h$ , but the power is often not an integer. Still, functions of the form (10) are convenient in the sense that they are easy to integrate.

Let us now consider the most fundamental example:

$$F(k_0h) = kh \quad (11)$$

i.e., we want to write  $kh$  in the form

$$kh = F_s(k_0h)[1 + a_1k_0h + a_2(k_0h)^2 + \dots] \quad (12)$$

The fundamental relation between  $kh$  and  $k_0h$  is the dispersion relation

$$k_0h = kh \tanh kh \quad (1)$$

First we find  $F_s(k_0h)$  by letting both  $kh$  and  $k_0h$  approach zero. We find

$$F_s(k_0h) = \sqrt{k_0h} \quad (13)$$

Next, the coefficients  $a_1$  are found by inserting

$$kh = \sqrt{k_0 h} [1 + a_1 k_0 h + a_2 (k_0 h)^2 + \dots] \tag{14}$$

into the dispersion relation, using the expansion (9) for the hyperbolic tangent. The result is

$$kh = \sqrt{k_0 h} [1 + \frac{1}{6} k_0 h + \frac{11}{360} (k_0 h)^2 + \dots] \tag{15}$$

This formula is accurate enough for most practical purposes. For  $k_0 h < 0.31$  which corresponds to 5 meters of water for an 8 second wave, the relative error is less than 0.01 percent. For  $k_0 h < 0.63$  the error is less than 0.07 percent, and even for  $k_0 h = 2.5$ , corresponding to 40 meters of water for an 8 second wave the relative error is only 0.44 percent.

### ALTERNATIVE WAVE TABLE

	<u>1% Limit <math>k_0 h</math></u>
$kh = \sqrt{k_0 h} [1 + \frac{1}{6} k_0 h + \frac{11}{360} (k_0 h)^2]$	2.72
$\tanh kh = \sqrt{k_0 h} [1 - \frac{1}{6} k_0 h]$	1.62
$C_g/C_0 = \sqrt{k_0 h} [1 - \frac{1}{2} k_0 h + \frac{7}{72} (k_0 h)^2]$	2.09
$K_s = (k_0 h)^{-0.25} [1 + \frac{1}{4} k_0 h + \frac{13}{288} (k_0 h)^2]$	1.34
$\frac{1}{\sinh kh} = (k_0 h)^{-0.5} [1 - \frac{1}{3} k_0 h]$	1.54

Figure 4: An alternative wave table, the column to the right shows the limiting values of  $k_0 h$  below which the accuracy is better than one percent.  $k_0 h = 1.5$  corresponds to a depth of 24 meters for an 8 second wave.

Once we have an expression for  $kh$  it is straightforward to obtain similar expressions for different functions of  $kh$  like

$$\frac{c_g}{c_o} = \tanh kh \left[ 0.5 + \frac{kh}{\sinh 2kh} \right] \tag{16}$$

and

$$K_s = H/H_o = \sqrt{0.5 c_o / c_g} \tag{17}$$

$c_g$  is the local group velocity.

Figure 4 shows five commonly used functions and the limits below which the relative error is less than one percent.

All the formulae shown above are tuned to the needs of nearshore coastal engineering work in that they are exact in the shallow water limit. In deep water it is necessary to use another type of expansion. The small parameter is no longer  $k_o h$  but  $\exp(-k_o h)$  or  $\exp(-kh)$ .

Figure 5: Relative error of (15) and (18), and of some truncated versions.

Again based on the dispersion relation (1) we find the following deep water approximation for kh:

$$kh = k_0 h [1 + 2e^{-2k_0 h}] \tag{18}$$

Figure 5 shows the relative errors of eq. (18) and (15) and of some truncated versions.

DISSIPATION PROBLEMS

Explicit formulae are necessary for analytical evaluation of integrals. For example the integral

$$I = \int_{h_1}^{h_2} \sinh kh \, dh \tag{19}$$

cannot be evaluated analytically because kh is an implicit function of h. Such integrals occur frequently in coastal engineering and the only way of evaluating them has so far been by numerical integration.

Figure 6: Definition diagram for wave height predictions over straight parallel bottom contours.

One of the most common problems for coastal engineers is to predict wave height variation due to shoaling, refraction and different sorts of energy dissipation. Such calculations are based on energy flux ( $E_f$ ) considerations and if the bed contours can be assumed straight and parallel as in Figure 6, the fundamental differential equation is

$$\frac{d}{ds} (E_f \cos \alpha) = D_E \cos \alpha \tag{20}$$

where  $D_E$  is the energy dissipation per unit area, and  $s$  is the distance measured along the wave orthogonals.

If the sea bed consists of sand and the effects of winds are neglected, most energy dissipation will be due to bed friction and the solution can be based on

$$D_E = \frac{2}{3\pi} \rho f_e u_{b,\max}^3 \quad (21)$$

where  $f_e$  is Jonsson's energy dissipation factor (Jonsson, 1966), and  $u_{b,\max}$  is the wave induced velocity amplitude near the bed.

The solution, as given by Nielsen (1984), is

$$H_2 = \frac{H_1 \sqrt{\frac{c_{g1} \cos \alpha_1}{c_{g2} \cos \alpha_2}}}{1 + H_1 \frac{k_o f_e}{3\pi} \sqrt{\frac{c_{g1} \cos \alpha_1}{c_o}} J} \quad (22)$$

where  $J$  is given by

$$J = \int \frac{k_o h_2}{k_o h_1} \frac{c_o^{1.5} \cos^{-1.5} \alpha}{c_g^{1.5} \sinh^3 kh} \frac{dx}{dh} dk_o h \quad (23)$$

It turns out that the fairly complicated integrand in (23) has a reasonably simple approximation of the form (10) so that the solution can be evaluated on a handheld calculator with sufficient accuracy for practical purposes. In fact the accuracy of the approximate solution which takes about 100 program steps on an HP-15c is probably far better than the accuracy of any available procedure for prediction of the energy dissipation factor  $f_e$ .

Figure 7 shows wave height variation due to refraction, shoaling and friction, calculated with numerical evaluation of  $J$  on a major computer and by the explicit solution

$$J = \frac{k_o^{1-1/p}}{pA^{1/p}} \left\{ \frac{(k_o h_1)^{1/p-2.25}}{\frac{1}{p} - 2.25} \left[ 1 - \left(\frac{h_1}{h_2}\right)^{2.25-1/p} \right] \right\}$$

$$\begin{aligned}
 & + \frac{(\delta - \frac{1}{4})(k_o h_1)^{1/p-1.25}}{\frac{1}{p} - 1.25} \left[ 1 - \left(\frac{h_1}{h_2}\right)^{1.25-1/p} \right] \\
 & + \frac{(\mu - \frac{\delta}{4} - \frac{61}{480})(k_o h_1)^{1/p-0.25}}{\frac{1}{p} - 0.25} \left[ 1 - \left(\frac{h_1}{h_2}\right)^{0.25-1/p} \right] \} \quad (24)
 \end{aligned}$$

Figure 7: Comparison between the explicit solution (equations 22 and 24) and a numerical solution. The shown example corresponds to \$T = 8s\$, \$f\_e = 0.1\$ and a beach profile given by \$h = 0.1(x\_o - x)^{2/3}\$.

The beach profile is assumed to have the form

$$h = A(x_o - x)^p \quad (25)$$

and the coefficients  $\delta$  and  $\mu$  represent the effects of refraction via Snell's law. They are given by

$$\delta = \frac{0.75 \sin^2 \alpha_1}{k_o h_1 (1 - \frac{1}{3} k_o h_1)} \quad (26)$$

$$\mu = \frac{1.4 \sin^4 \alpha_1}{(k_o h_1)^2} - \frac{1}{3} \delta \quad (27)$$

$\alpha_1$  is the initial angle between wave crests and bed contours.

#### ENERGY DISSIPATION OVER A MUD BOTTOM

Waves propagating over a bed of soft mud will tend to induce a wave motion in the mud and thus feed energy into the mud at a rate of

$$D_M(t) = -p(t) \frac{dn}{dt} \quad (28)$$

where  $p$  is the pressure at the interface and  $n$  is the local elevation of the deformed interface. See e.g., Gade (1958).

If the pressure has the form

$$p(t) = p_o + p_1 \cos \omega t \quad (29)$$

and the interface elevation is given by

$$\eta(t) = \eta_o - \eta_1 \cos(\omega t - \phi) \quad (30)$$

Then the time averaged energy flux downwards through the interface is

$$\overline{D_M} = \frac{1}{T} \int_t^{t+T} -p(t) \frac{dn}{dt} dt \quad (31)$$

$$= \frac{1}{2} p_1 \omega \eta_1 \sin \phi \quad (32)$$

And introducing the mud response parameter (Tubman and Suheyda, 1976)

$$M = \frac{\rho g \eta_1}{P_1} \tag{33}$$

we get

$$D_M = \frac{1}{2} M \sin \phi \frac{\omega p_1^2}{\rho g} \tag{34}$$

For linear waves we have

$$P_1 = \rho g \frac{H}{2} \frac{1}{\cosh kh} \tag{35}$$

and thus the energy flux into the mud can be written

$$D_M = \frac{\pi \rho g M \sin \phi}{4T \cosh^2 kh} H^2 \tag{36}$$

WAVE HEIGHT VARIATION OVER A MUD BOTTOM

For sinusoidal waves propagating over a mud bottom equation (20) becomes

$$\frac{d}{ds} \left( \frac{1}{8} \rho g H^2 c_g \cos \alpha \right) = - \frac{\pi \rho g M \sin \phi}{4T \cosh^2 kh} H^2 \cos \alpha \tag{37}$$

which has the solution

$$\left( \frac{H_2}{H_1} \right)^2 = \frac{c_{g1} \cos \alpha_1}{c_{g2} \cos \alpha_2} \exp(M \sin \phi I) \tag{38}$$

with

$$I = \int_{s_1}^{s_2} - \frac{2\pi}{T} \frac{ds}{c_g \cosh^2 kh} \tag{39}$$

To evaluate this integral we must bring the integrand to an explicit form in terms of the independent variable.

If  $h$  varies monotonically with  $s$ , we can change the variable of integration into  $k_0 h$ . From Figure 6 we get

$$ds = \frac{d k_0 h}{k_0 \frac{dh}{dx} \cos \alpha} \quad (40)$$

and since  $c_0 k_0 = 2\pi/T$  we find

$$I = - \int_{k_0 h_1}^{k_0 h_2} \frac{d k_0 h}{\frac{dh}{dx} \frac{c_g}{c_0} \cos \alpha \cosh^2 kh} \quad (41)$$

Now using the alternative wave table (Figure 4) and a bit of algebra we find

$$\frac{1}{\frac{c_g}{c_0} \cosh^2 kh} \approx (k_0 h)^{-0.5} [1 - 0.5 k_0 h] \quad (42)$$

the accuracy of which is discussed in Figure 2. Since most natural mud bottoms are quite flat it is not very restrictive to assume constant bed slope and straight, parallel contours. Then Snell's law gives

$$\frac{1}{\cos \alpha} = [1 - (\frac{c}{c_1})^2 \sin^2 \alpha_1]^{-0.5} \quad (43)$$

and we use

$$\frac{c}{c_0} = \tanh kh \approx \sqrt{k_0 h} (1 - \frac{1}{6} k_0 h) \quad (44)$$

to get

$$\frac{1}{\cos \alpha} = [1 - \beta k_0 h (1 - \frac{1}{3} k_0 h)]^{-0.5} \quad (45)$$

where

$$\beta = \frac{\sin^2 \alpha_1}{k_0 h_1 (1 - \frac{1}{3} k_0 h_1)} \quad (46)$$

After some algebra we then get

$$I = - \frac{dx}{dh} \int_{k_o h_1}^{k_o h_2} \left[ (k_o h)^{-0.5} + \frac{1}{2} (\beta-1)(k_o h)^{0.5} + \left( \frac{3}{8} \beta^2 - \frac{5}{12} \right) (k_o h)^{1.5} \right] dk_o h \quad (47)$$

and

$$I = - \frac{dx}{dh} \left\{ 2(k_o h_1)^{0.5} \left[ \left( \frac{h_2}{h_1} \right)^{0.5} - 1 \right] + \frac{1}{3} (\beta-1)(k_o h_1)^{1.5} \left[ \left( \frac{h_2}{h_1} \right)^{1.5} - 1 \right] + \left( \frac{3}{20} \beta^2 - \frac{1}{6} \beta \right) (k_o h_1)^{2.5} \left[ \left( \frac{h_2}{h_1} \right)^{2.5} - 1 \right] \right\} \quad (48)$$

This formula together with (38) provides a very simple tool for predicting wave height variation over a soft mud bottom, and because the solution is explicit we can quite easily use it "in reverse", i.e.: If the final wave height,  $H_2$ , is known we can solve directly for  $M \sin \phi$ .

DISCUSSION

A set of simple explicit formulae have been provided (Figure 4) for easy calculation of linear wave properties. These formulae provide a handy alternative to wave tables, thus the basic

$$kh = \sqrt{k_o h} \left[ 1 + \frac{1}{6} k_o h + \frac{11}{360} (k_o h)^2 + \dots \right] \quad (15)$$

can easily be memorized by people who deal with linear waves frequently.

The major advantage of introducing explicit formulae is probably that it makes it possible to give analytical solutions to problems that involve integration. Such a solution to the problem of wave height variation due to shoaling refraction and frictional dissipation was given by Nielsen (1984) and a similar solution has been given above for the case of energy absorption by a soft mud bottom.

The accuracy of the solution (38) and (48) will depend on the depths  $h_1$  and  $h_2$  and on the starting angle  $\alpha_1$ . An error estimate can

be obtained by comparing discrete values of the integrands in (41) and (47).

At the presentation of this paper, Dr. O. Skovgaard of the Technical University of Denmark pointed out that a reduction by 20% or more in computing time could be obtained by using (15) as the first estimate in iterative procedures for determination of  $kh$ . It could be added that extra accuracy gained by iteration is often of no practical consequence because of the limited accuracy with which the physical environment can be described and of the crudeness of other underlying assumptions. - This is a matter of opinion, but it seems reasonable to omit iteration and rely entirely on (15) at least in the "debugging" phase for big wave programs.

#### ACKNOWLEDGEMENT

The present study was supported by the U.S. Office of Naval Research, Coastal Sciences Program, Task No. 388-189, Contract No. N00014-83-K-0198 through the Virginia Institute of Marine Science and University of Florida.

## CHAPTER SIXTY SEVEN

### THE INTERACTION OF SMALL AND FINITE AMPLITUDE LONG WAVES AND CURRENTS

By F. Raichlen,<sup>1</sup> F.ASCE, and J. J. Lee,<sup>2</sup> M.ASCE

#### INTRODUCTION

The interaction of waves and currents is important for many engineering problems. For example, when considering forces on marine structures, the velocity and acceleration field must be defined, and thus the manner in which a current interacts with small and finite amplitude waves must be understood. When the current is large and oblique to the waves, the direction of the force on an offshore structure may change significantly with depth introducing a torsional moment. Wave refraction and the concomitant attenuation or amplification of waves are also affected by offshore currents. An example is the effect on incident waves of offshore currents induced by the discharge of cooling water from coastal-sited power plants. This current can modify the direction and magnitude of approaching waves, and by these changes the breaking waves at the shore and the nearshore sediment transport associated with these waves may be changed.

A number of theoretical studies have been conducted on various aspects of wave-current interactions; see Peregrine (1976). One theoretical study, Thomas (1981), will be used in this investigation. Careful experiments in this area are limited; several are: Iwagaki and Asano (1980), Sarpkaya (1957), and Thomas (1981). Each of these has given attention to certain aspects of small amplitude wave-current interactions. The experiments are difficult to conduct because of the problems inherent in introducing waves into a flume with a steady-uniform current or conversely a current into a wave tank with permanent waves. Certain features of these experimental problems can be seen through the following two examples. If a plunger-wave machine were used and located at one end of a flume in which a steady current is flowing, although the waves would be developing as they interact with the current, the previously steady current would be changed to an unsteady one by the periodic blockage of the flow by the plunger. If the waves are generated at one end of the tank and allowed to develop, and a current is introduced from the bottom of the tank, this current must expand to the full depth of the flow; hence, the waves propagate on a developing current. Therefore, comparisons to theory are, to some extent, difficult to realize, because the theory generally assumes wave-current interactions when each is fully developed.

This study basically had two objectives. The major objective was

<sup>2</sup>Professor of Civil Engineering, University of Southern California, Los Angeles, CA.

whether simple linear superposition could be used to describe wave-current interactions with weakly nonlinear finite amplitude waves. In essence, the question raised is: could the water particle velocities measured under a wave without a current be added to those measured with the current alone to yield the total velocity similar to that which was determined experimentally for the combined wave and current. The second was to investigate, using a simple means of introducing a current into the wave tank and withdrawing it, the effect of the configuration of the current inlet/outlet arrangement on the water particle velocities associated with the wave during the interval of wave development. For the possible currents generated in this study, conclusions could be drawn relative to these two questions.

This study is primarily experimental. The numerical method proposed by Thomas (1981) has been applied to the periodic wave measurements; as mentioned, this analysis will not be described herein, and the interested reader is referred to that publication for a discussion of the method. In this paper attention will be devoted to the experimental results and the question of superposition; results obtained using the numerical method proposed by Thomas (1981) will be included only as an adjunct to these.

#### EXPERIMENTAL EQUIPMENT AND PROCEDURES

##### Wave generation and measurement

Experiments have been conducted in a 40 m tilting tank which is 0.60 m deep and 1.10 m wide. The tank has glass sidewalls throughout with a stainless steel bottom which is flat to within approximately  $\pm 0.1$  mm. Circular rails attached to the top of the walls of the tank form precision tracks for an instrument carriage to which a wave gage can be attached. The wave machine used in this study is a vertical bulkhead generator located at one end of the tank and is driven by an electro-hydraulic system. The servo system which controls its motion consists of a servo controller, a function generator, and a feedback device. The function generator is a nonlinear function synthesizer with a microprocessor which stores a list of binary numbers corresponding to an arbitrary signal. The maximum voltage amplitude and the time are divided into 4096 parts; using these data a smooth signal can be obtained.

The motion of the wave machine was programmed for these experiments using the method described by Goring and Raichlen (1980) for the generation of long-nonlinear waves with a bulkhead wave generator. The boundary condition on the face of the plate for this technique is that the wave propagates away from the plate as it moves. Thus, the usual assumption of a negligible plate motion relative to its mean position is not necessary.

The variation of the water surface profiles with time were obtained using a parallel wire, resistance wave gage composed of 0.25 cm diameter stainless steel wire spaced 0.4 cm apart.

##### Inlet and outlet structures

The inlet and outlet structures were each constructed of lucite and were essentially boxes resting on the bottom of the tank extending

across the width of the tank (110 cm), 61 cm in the direction of wave propagation, and 13.75 cm high. Inflow (or outflow) was brought into (or taken from) the flume by means of a 10.2 cm dia. pipe connected to one end of the inlet/outlet box. Straight vanes were used in the box to divide the front of the box and the pipe into six equal areas. Even with this attempt to distribute the flow uniformly across the width of the flume, flow separation occurred within the box leading to non-uniform flow conditions at the box exit. Nevertheless, as it will be shown, the velocity became well distributed through the depth of the tank at the measuring location.

Two pump-piping arrangements were used for these experiments. In the case of periodic waves the discharge was 0.02 cubic meters per second using a pump-piping system that permitted the flow to be reversed. In the experiment with solitary waves, where a larger velocity was desired, a discharge of 0.028 cubic meters per second was realized, but only adverse flows were possible, i.e., the box nearest the wave machine always collected the flow.

In the case of periodic waves the water depth was kept at 30.2 cm for all experiments and for the solitary waves the depth was maintained at 17.42 cm. For the latter, the smaller depth was necessary so that the mean current velocity would be a significant percentage of the water particle velocities in the wave. Considering the physical arrangement the water depth over the boxes was small for the solitary wave case and wave breaking occurred over the box; this will be discussed.

#### Measurement of water particle velocities

A two-dimensional laser-Doppler velocimeter (LDV) employing the reference beam technique was used to measure the water particle velocities at a location 21.6 m from the wave generator for experiments with periodic waves and 23.6 m from the wave generator for the solitary wave investigation. (These two locations are near the middle of the wave tank.) Two reference beams and a scattering beam were generated using a 5 mW helium-neon laser, and these were optically focused near the center of the wave tank. To provide a means for defining the direction of the velocity components the LDV was equipped with a frequency shifter consisting of two Bragg cells (which operate at a nominal frequency of about 40 MHz) and a frequency synthesizer with phase-locked loops. The frequency shift between the reference beams and the scattering beam created by the Bragg cells was 86.92 KHz. The laser and its associated optics were mounted to a carriage which was isolated from the wave tank. This permitted the laser to be moved vertically through the depth and along the wave tank in the direction of wave propagation.

#### PRESENTATION AND DISCUSSION OF RESULTS

In this section the results obtained using the LDV will be presented for both periodic and solitary waves. (The periodic waves generated were weakly nonlinear cnoidal waves.) For periodic waves the experimental results are compared to the velocities obtained from the linear superposition of independently measured velocities and to the numerical theory of Thomas (1981). The comparison of the results of experiments with solitary waves will be made only to the results obtained by the linear superposition of measurements of the wave alone and the current alone.

Cnoidal waves

Velocity profile for steady current alone

Measurements of the current velocity were made at the various depths at the same location where the wave measurements would be taken; 21.6 m (about 71.5 depths) from the wave machine. The velocity distribution is shown in Figure 1 where the abscissa is the velocity and the

ordinate is the relative distance from the bottom. A universal velocity distribution is fitted to the data, for both favorable and adverse currents, with the assumption that the von Karman constant was 0.4. Since the flume was horizontal, the flow must be nonuniform and an independent estimate of boundary shear stress is not possible. Therefore, the coefficient B and the shear stress are obtained from the fitted line in the semi-logarithmic plot, the mean velocity U is obtained from the spacial integration of the velocity distribution. It is recalled that the coefficients in the velocity distribution expression normally used are A = 5.75 and B = 2.5; hence, the velocity distributions measured are in fair agreement with the usual logarithmic profile.

Figure 1 Velocity Distribution of Current Alone with Experiments with Periodic Waves.

(However, the boundary shear stress obtained in this manner gives small values of the Darcy-Weisbach friction factor so that full interpretation of the profile is difficult.)

Velocities for the wave without a current

Two sets of experiments were conducted to investigate the kinematic properties of the cnoidal waves, which were to be used in the current-wave experiments, propagating in the tank without the current. It was realized early in the experimental program that the inflow box near the wave machine could create an effect on the wave even though the velocity and wave measurements were made nearly 72 depths away.

Time histories of the water surface variation, the horizontal velocity, and the vertical velocity at mid-depth for the case without the inflow box are presented in Figure 2. (The cnoidal waves generated were weakly nonlinear with a wave period of 3.015 seconds and the ratio of wave height to depth of about 0.04.) It is noted that although the wave is not highly nonlinear, even with the large wave length to depth ratio (about 17), high frequency components are not apparent in either the water surface-time history ( $\eta$  vs  $t$ ) or the time history of the horizontal velocity ( $u$  vs  $t$ ). This primarily is due to the careful wave generation procedure used. For both the water surface and the horizontal velocity, the second, third, and fourth waves are similar and well formed. The theoretical cnoidal wave profile is shown in the upper

Figure 2 Water Surface, Horizontal, and Vertical Velocity-Time Histories at  $z/h = 0.5$  for No Current (Without inflow box in place).

Figure 3 Water Surface, Horizontal, and Vertical Velocity-Time Histories at  $z/h = 0.5$  for No Current (With inflow box in place).

portion of Figure 2, and it agrees reasonably well with the experiments. The magnitude of the vertical velocity,  $v$ , is significantly less than the horizontal velocity, i.e., of the order of about 20%, and its distribution appears skewed. The reason for this is not fully understood.

Similar time histories are presented in Figure 3 at mid-depth for the wave propagating over the inflow box but without a current. The primary effect is the vertical and the horizontal velocities are reduced compared to the corresponding conditions without the box. This may be an effect which is associated with the wave propagating over the box with only about five wave lengths to the measuring station.

In Figure 4 the variation of the maximum water particle velocities with relative depth measured under the crest of the wave is presented for the wave propagating in the bare tank and for the wave propagating in the tank with the inflow box; in the latter no current is imposed.

Figure 4 Depthwise Distribution of Maximum Horizontal Velocity Under the Second Crest of a Cnoidal Wave Train.

The most obvious effect of the box occurs at elevations which are between the bottom and mid-depth. In the case with the box the velocities tend to increase as the bottom is approached whereas without the box the velocities remain relatively constant through the depth. Thus, the box seems to have an effect on the wave with regard to the depthwise distribution of its kinematic properties, perhaps more so than its effect on the wave profile. The data are compared to predictions from cnoidal theory and from small amplitude wave theory, and it appears that within the limits of experimental accuracy, the experiments without the box agree with the results of the small amplitude wave theory somewhat better than with those from the cnoidal theory.

#### Waves with a favorable current

In this section experimental results obtained with the waves and the current traveling in the same direction (a favorable current) are presented. Similar to previous figures, the time histories of the water surface and the horizontal and vertical velocities at mid-depth are presented first in Figure 5. A comparison of Figure 5 and Figure 3 show that there is, at most, a difference of about 3% to 4% in the wave amplitude and the wave length between the second and third wave crest for the cases without and with the current. The crest height is reduced and the wave lengths are somewhat longer, as expected. Taken in totality, however, the effect of the current on the wave profile indeed is quite small and within the range of experimental error; results such as those obtained by Jonsson et al. (1970) indicate this also.

The depthwise distributions of the velocities are shown in Figure

Figure 5 Water Surface, Horizontal, and Vertical Velocity at  $z/h = 0.5$  for Wave and Current in Same Direction (Favorable Current).

Figure 6 Distribution of the Horizontal Velocity for Wave and Current in Same Direction (Favorable Current).

6; the data are presented for the wave alone, the current alone, and the measured total velocity. The solid curve is obtained from superposing the measured data corresponding to the wave alone and that from the current alone. The dashed curve is the total water particle velocity predicted by the numerical solution proposed by Thomas (1981) which is based on the water particle velocity under the wave obtained from small amplitude wave theory. Above mid-depth the data agree well with each approach, and below it is difficult to establish the better agreement.

#### Waves with adverse current

For these experiments the direction of the current was reversed and is denoted as adverse. Data similar to those obtained for favorable currents are presented in Figure 7 showing the time histories of the water surface and the horizontal and vertical velocities at mid-depth. A close examination of the wave record indicates that the waves are somewhat steeper than they were for waves without the current or for waves traveling on a favorable current (see Figures 3 and 5, respectively). Perhaps more apparent are changes in both the horizontal velocity and the vertical velocity in terms of the steepness of the time history. The greatest differences between the kinematics of the waves propagating on a favorable and adverse current appear to be associated with the variation with time of the vertical velocities. This might be expected due to the small magnitude of the vertical velocity compared to the horizontal velocity for long waves, and hence, its sensitivity to small changes in the wave.

The measured velocity distributions are presented in Figure 8 for the wave alone, the current alone, and the total velocity. As for the case of the favorable current, linear superposition has been used based on the measured values along with the numerical solution proposed by Thomas (1981). In this case, the numerical solution appears to agree better with the data than the results of simple linear superposition. However, the differences are not large enough so that general conclusions can be drawn.

#### Solitary waves

In this section results obtained from experiments with solitary waves under the influence of adverse currents will be presented and discussed. The wave height was determined by the conditions that on the one hand a limited pump discharge was available for the solitary wave-current interaction investigation while on the other wave particle velocities were desired which would be of the same order of magnitude as the available current. The maximum average current velocity possible was 14.9 cm/sec and, to satisfy these conditions, a wave with a relative height (height/depth) of about 0.3 was used. Due to pump and piping restrictions only an adverse current could be generated. The velocity distribution for this current is presented in Figure 9 where the ordinate is the relative distance from the bottom and the abscissa is the velocity. Each data point shown is the result of averaging 10 different velocity samples at that elevation. Since each sample has a duration of one minute, in essence the data point is a temporal average of about 10 minutes of record. The averaging was necessary because of low frequency velocity fluctuations which apparently were caused by the outlet/inlet configuration. The inferred shear stress yields a friction

Figure 7 Water Surface, Horizontal, and Vertical Velocity at  $z/h = 0.5$  for Wave and Current in Opposite Directions (Adverse Current).

Figure 8 Distribution of the Horizontal Velocity for Wave and Current in Opposite Direction (Adverse Current).

Figure 9 Velocity Distribution of Current Alone for Experiments with Solitary Waves.

factor smaller than predicted by usual means, but this is mitigated by the fact that the flume is horizontal and the current takes some distance to develop.

The solitary wave is generated using techniques developed in other experimental studies where excellently formed waves with a negligible oscillatory tail were realized, e.g., see Lee, Skjelbreia, and Raichlen (1982). Water surface time histories of waves propagating without and with the adverse current have been obtained at relative distances from the wave generation of:  $x/h = 15.5, 75.8,$  and  $135.5$ . In each case the wave broke as it propagated

over the outlet box and then reformed into a lead wave which appeared to be solitary in shape followed by a group of oscillatory waves.

It is important to investigate the reproducibility of the wave generation arrangement used in these experiments, since the LDV is an instrument which can measure velocities only at one point at a given time. Therefore, to obtain the depthwise velocity distribution, the experiments must be repeated relocating the LDV for each measurement. In Figures 10 and 11 the wave profile is shown 135.5 depths from the wave generator (at the velocity measuring station) for the cases without and with an adverse current, respectively. For both current conditions the profile consists initially of a wave similar to a solitary wave followed by an oscillatory tail. Each of these records is for six different experiments, and the reproducibility is evident; even small oscillations in the record generally are reproduced well. It is interesting that in comparing the amplitude normalized with respect to the depth, for the wave with the adverse current the leading wave is about 2% greater in height than for the wave without the current.

Wave profiles were measured at several locations along the tank and the travel times between  $x/h = 15.5$  and  $x/h = 135.5$  were determined to compare wave celerities for conditions without and with the adverse current; these are shown in Table 1. (The experiments with the same last digit in the experiment number should be compared, e.g., WPA1 to WPCL, and etc.) If the mean current (14.9 cm/sec) is subtracted from the measured wave speed without a current the resultant celerity is within about 2% of that measured.

In Figures 12 through 15 time histories of the horizontal velocities are presented as measured at four different elevations and 135.5 depths from the wave generator. In each figure the measured horizontal water particle velocity for the waves propagating on a current is presented along with the water particle velocity time history which has been obtained by subtracting the measured velocity of the mean current from the measured horizontal velocity of the wave alone. Hence, the

dashed curve corresponds simply to linear superposition. There are differences which are apparent in these comparisons; however, the differences between the results of linear superposition and the measured total velocity for the lead wave are not large. In nearly all cases, the maximum velocity at the wave crest is underestimated by superposition by less than 10% to 15%. However, the trailing waves are significantly affected by the current so that superposition does not define the velocity field well in that region. (It should be noted that results from the method of Thomas (1981) were not compared to the experiments, since inherent to that method is the assumption that the water particle velocities under the wave for the condition without the current can be defined in a linear manner from harmonic components.)

In Figures 10 and 11, in which the variation of the water surface elevation with time was presented, similar differences between the wave profiles without the current and with the current were evident. Since this effect was significant in the trailing region of the wave, in this region differences between the velocities obtained by linear superposition and those measured with the current would be expected. Therefore, it appears the current affects the oscillatory waves which trail the main wave more than it affects the lead wave, and, thus, the velocity for the oscillatory tail cannot be constructed by simple linear superposition.

Examples of the time history of the vertical velocity components are presented in Figures 16 and 17 for relative depths of  $z/h = 0.6$  and  $0.78$  at  $x/h = 135.5$  and in each figure for conditions without and with the current. (Note the vertical scales in Figures 16 and 17 are different.) Several features are apparent. The ratio of the maximum vertical velocities at these two elevations is close to the ratio of the elevations themselves demonstrating the variation with depth of the maximum vertical velocities would be reasonably linear as predicted by linear long wave theory. The vertical velocity time histories at each of these two depths for conditions without and with the current are similar especially with respect to the velocity associated with the leading wave. As with the horizontal velocities most of the effect appears to be related to the velocities corresponding to the oscillatory tail.

#### CONCLUSIONS

The following major conclusions may be drawn from this investigation:

Figure 16 Vertical Velocity Time History at  $z/h = 0.6$ .Figure 17 Vertical Velocity Time History at  $z/h = 0.776$ .

1. Even a very simple means of introducing a current into a wave tank for wave-current interaction studies can yield useful results. Indeed it may not be possible to investigate exactly wave-current interactions in the laboratory as the problem is formulated theoretically, since either the wave is developing on a permanent current or the current is developing while a permanent wave is propagating through it.

2. For engineering purposes, for waves of the order of magnitude investigated, linear superposition appears to adequately describe the maximum horizontal water particle velocities.

3. For the case of solitary waves where the oscillatory tail of the wave caused by the wave propagating over the inflow box was considerably changed by the current, the horizontal and vertical velocities were affected accordingly.

4. This investigation further demonstrates the importance of the LDV for "in situ" measurements of velocities in water waves.

#### ACKNOWLEDGMENT

The study was supported by the Naval Construction Battalion Center with technical coordination provided by Mr. Jerry Dummer. The LDV which was used in this study was developed in connection with an investigation sponsored by the National Science Foundation under NSF Grant CME79-12434. Mr. James Skjelbreia assisted in certain aspects of the data collection.

## CHAPTER SIXTY EIGHT

### COMBINED REFRACTION-DIFFRACTION OF NONLINEAR WAVES IN SHALLOW WATER

James T. Kirby,<sup>1</sup> Philip L.-F. Liu,<sup>2</sup> A.M.'s. ASCE

Sung B. Yoon<sup>3</sup> and Robert A. Dalrymple<sup>4</sup>, M. ASCE

The parabolic approximation is developed to study the combined refraction/diffraction of weakly nonlinear shallow water waves. Two methods of approach are taken. In the first method Boussinesq equations are used to derive evolution equations for spectral wave components in a slowly varying two-dimensional domain. The second method modifies the equation of Kadomtsev & Petviashvili to include varying depth in two dimensions. Comparisons are made between present numerical results, experimental data and previous numerical calculations.

#### Introduction

In recent years, the recognition of the need for an improvement on the predictive capabilities of standard refraction methods (for example, Skovgaard, et al., 16) has led to the development of several techniques for computing wave fields modified by the combined effects of refraction and diffraction. Among these methods, the parabolic equation method (PEM) appears to be particularly attractive in the study of wave propagation in open coastal regions since its usefulness depends on a nearly unidirectional propagation of waves with little backscatter. The method was first developed for monochromatic linear waves by Radder (14) and Lozano & Liu (12) and has been extended to include effects such as frictional dissipation (3) and wave-current interaction (1,6,9). Recently, the formulation has been extended to the case of second-order monochromatic Stokes waves (8,11,19). Iterative methods have been developed in order to model the gradual development of reflected wave components, both for the linear (10) and Stokes wave (7) formulations.

Waves in shallow water near the coastline are rarely monochromatic, and are subject to fairly strong nonlinear interactions due to near-resonances as the phase speeds of individual spectral components approach coincidence. In addition, the smallness of the ratio of water

depth to wavelength in such regions invalidates the assumptions underlying the Stokes theory and leads, instead, to a description of the wavefield based on the Korteweg-deVries or Boussinesq equations. For this reason, we have investigated methods for calculating the propagation and evolution of spectral wave components in an arbitrarily varying, two-dimensional domain, with the restrictions of shallow water and the parabolic approximation applied. The results of this study extend the PEM to the case of nonlinear waves in shallow water, and are applicable to the study of harmonic generation and spectral evolution as well as refraction-diffraction.

Two methods of approach are described. First, Boussinesq equations are used to derive evolution equations for spectral wave components in a slowly varying, two-dimensional domain. Secondly, we describe a similar modeling approach based on a version of the weakly two-dimensional Korteweg-deVries equation of Kadomtsev & Petviashvili (5) (hereafter referred to as the K-P equation). The present approach extends the K-P equation to include varying water depth in two dimensions. The resulting systems of coupled nonlinear partial differential equations for spectral wave components from two approaches are quite similar. These equations are written in finite difference form using the Crank-Nicolson method, yielding an initial-boundary value problem for the spatial evolution of each spectral mode.

The present model is used to examine the refraction of a cnoidal wave over a plane slope in a rectangular channel. Numerical solutions agree very well with previous analytical and numerical results. The formation of stem waves along the boundary and the development of a high-frequency modulation are observed and discussed. Comparisons are also made between the predictions of each model and the experimental data of Whalin (18) for his three second wave period case. The agreement between experimental data and numerical results is reasonable but not excellent. Both models predict much higher first harmonic amplitudes along the centerline of the tank. The prediction of the second and third harmonic amplitudes is seen to be better.

#### Nonlinear Shallow-Water Wave Equations and Parabolic Approximation

The Boussinesq equations, which include nonlinearity and dispersion to the leading order, are used as a basis of the first approach. Using  $\omega$  as the characteristic frequency,  $a_0$  as the characteristic wave amplitude and  $h_0$  as the characteristic water depth, we introduce the following dimensionless variables:

$$t = \omega t' \quad , \quad (x, y) = \frac{\omega}{\sqrt{gh_0}} (x', y') \quad , \quad z = z'/h_0$$

$$h = h'/h_0 \quad , \quad \vec{u} = \vec{u}' / \left[ \frac{a_0}{h_0} \sqrt{gh_0} \right] \quad , \quad \zeta = \zeta'/a_0 \quad (1)$$

where  $\zeta$  is the free surface displacement and  $\vec{u}$  represents the depth-averaged horizontal velocity vector. The quantities with prime denote dimensional quantities. If the scale of water depth is small in

comparison with the horizontal length scale and the wave amplitude is small compared with the water depth, i.e.,

$$\mu^2 = \omega^2 h_0 / g \ll 1 \tag{2}$$

$$\epsilon = a_0 / h_0 \ll 1 \tag{3}$$

the Boussinesq equations take the following dimensionless forms:

$$\frac{\partial \zeta}{\partial t} + \nabla \cdot [(h + \epsilon \zeta) \vec{u}] = 0(\epsilon^2, \epsilon \mu^2, \mu^4) \tag{4}$$

$$\begin{aligned} \frac{\partial \vec{u}}{\partial t} + \epsilon \vec{u} \cdot \nabla \vec{u} + \nabla \zeta = \mu^2 \left\{ \frac{1}{2} h \frac{\partial}{\partial t} \nabla [\nabla \cdot (h \vec{u})] - \frac{1}{6} h^2 \frac{\partial}{\partial t} \nabla (\nabla \cdot \vec{u}) \right\} \\ + 0(\epsilon^2, \epsilon \mu^2, \mu^4) \end{aligned} \tag{5}$$

where two small parameters,  $\epsilon$  and  $\mu^2$ , are assumed to be of the same order of magnitude. In the present study we also assume that the variation of water depth is small in a characteristic wavelength, i.e.,  $0(|\nabla h|) \leq 0(\mu^2)$ .

We shall study the propagation of a shallow water wave train which is periodic in time with the fundamental frequency  $\omega$ . The solutions can be expressed as a Fourier series

$$\zeta(x, y, t) = \frac{1}{2} \sum_n \zeta_n(x, y) e^{-int} \quad , \quad n=0, \pm 1, \pm 2, \dots \tag{6}$$

$$\vec{u}(x, y, t) = \frac{1}{2} \sum_n \vec{u}_n(x, y) e^{-int} \quad , \quad n=0, \pm 1, \pm 2, \dots \tag{7}$$

where  $(\zeta_{-n}, \vec{u}_{-n})$  are the complex conjugates of  $(\zeta_n, \vec{u}_n)$ . Substituting eqs. (6) and (7) into eqs. (4) and (5) and collecting the coefficients of different Fourier components yields the set of equations

$$-in \zeta_n + \nabla \cdot (h \vec{u}_n) + \frac{\epsilon}{2} \sum_s \nabla \cdot (\zeta_s \vec{u}_{n-s}) = 0(\epsilon^2, \epsilon \mu^2, \mu^4) \tag{8}$$

$$-in \vec{u}_n + (1 - \frac{\mu^2 n^2}{3} h) \nabla \zeta_n + \frac{\epsilon}{4} \sum_s (\vec{u}_s \cdot \vec{u}_{n-s}) = 0(\epsilon^2, \epsilon \mu^2, \mu^4) \tag{9}$$

where  $s = 0, \pm 1, \pm 2, \dots$ . From these two equations we can find the following lowest order relationships:

$$\vec{u}_n = -\frac{i}{n} \nabla \zeta_n [1 + 0(\epsilon, \mu^2)] \tag{10}$$

$$\nabla \cdot \vec{u}_n = in \zeta_n / h [1 + 0(\epsilon, \mu^2)] \tag{11}$$

for  $n \neq 0$ , and

$$\vec{u}_0 = -\frac{\epsilon}{2h} \sum_s \zeta_s \vec{u}_{-s} + 0(\epsilon^2, \mu^4, \epsilon \mu^2) \tag{12}$$

$$\zeta_0 = -\frac{\epsilon}{4} \sum_s \vec{u}_s \cdot \vec{u}_{-s} + O(\epsilon^2, \mu^4, \epsilon\mu^2) \tag{13}$$

For the case where water depth is a constant,  $h = 1$ , eqs. (8) and (9) reduce to those derived by Rogers & Mei (15).

Using eqs. (10) and (11) in eqs. (8) and (9) and eliminating  $\vec{u}_n$  gives

$$\begin{aligned} \nabla \cdot \left[ \left( h - \frac{\mu^2 n^2 h^2}{3} \right) \nabla \zeta_n \right] + n^2 \zeta_n = \frac{\epsilon}{2h} \left\{ \sum_s (n^2 - s^2) \zeta_s \zeta_{n-s} \right. \\ - h \sum_{s \neq n} \left( \frac{n+s}{n-s} \right) \nabla \zeta_s \cdot \nabla \zeta_{n-s} - 2h^2 \sum_{\substack{s \neq 0 \\ s \neq n}} \frac{1}{s(n-s)} \left( \frac{\partial^2 \zeta_s}{\partial x^2} \frac{\partial^2 \zeta_{n-s}}{\partial y^2} \right. \\ \left. \left. - \frac{\partial^2 \zeta_s}{\partial x \partial y} \frac{\partial^2 \zeta_{n-s}}{\partial x \partial y} \right) \right\} + O(\epsilon^2, \epsilon\mu^2, \mu^4) \end{aligned} \tag{14}$$

which constitutes a system of nonlinear equations for  $\zeta_n$  ( $n = 1, 2, 3, \dots$ ). Since eq. (14) is a differential equation of the elliptic type, appropriate boundary conditions must be assigned along the boundaries. Once  $\zeta_n$  ( $n = 1, 2, \dots$ ) are found, eq. (10) can be used to calculate the velocity vector  $\vec{u}_n$ . The mean free surface set-up or set-down,  $\zeta_0$ , is obtained from eq. (13).

We now consider the cases where the dominant wave propagation direction is known and is in the x-direction. The free surface displacement for the n-th harmonic can be written as

$$\zeta_n = \psi_n(x, y) e^{inx} \tag{15}$$

where  $\psi_n(x, y)$  denotes the amplitude function which takes both refraction and diffraction effects into account. Substitution of eq. (15) into eq. (14) yields

$$\begin{aligned} G_n \left( \frac{\partial^2 \psi_n}{\partial x^2} + \frac{\partial^2 \psi_n}{\partial y^2} \right) + (2in G_n + \frac{\partial G_n}{\partial x}) \frac{\partial \psi_n}{\partial x} + \frac{\partial G_n}{\partial y} \frac{\partial \psi_n}{\partial y} \\ + \left( in \frac{\partial G_n}{\partial x} - n^2 G_n + n^2 \right) \psi_n = \frac{\epsilon}{2h} \left\{ \sum_s [h s(n+s) + (n^2 - s^2)] \psi_s \psi_{n-s} \right. \\ - h \sum_{s \neq n} \left( \frac{n+s}{n-s} \right) \left[ \nabla \psi_s \cdot \nabla \psi_{n-s} + i s \psi_s \frac{\partial \psi_{n-s}}{\partial x} + i(n-s) \psi_{n-s} \frac{\partial \psi_s}{\partial x} \right] \\ - 2h^2 \sum_{\substack{s \neq 0 \\ s \neq n}} \frac{1}{s(n-s)} \left[ \frac{\partial^2 \psi_s}{\partial x^2} \frac{\partial^2 \psi_{n-s}}{\partial y^2} - \frac{\partial^2 \psi_s}{\partial x \partial y} \frac{\partial^2 \psi_{n-s}}{\partial x \partial y} \right. \\ - s^2 \psi_s \frac{\partial^2 \psi_{n-s}}{\partial y^2} + s(n-s) \frac{\partial \psi_s}{\partial y} \frac{\partial \psi_{n-s}}{\partial y} + i(2s \frac{\partial \psi_s}{\partial x} \frac{\partial^2 \psi_{n-s}}{\partial y^2} \\ \left. - s \frac{\partial \psi_s}{\partial y} \frac{\partial^2 \psi_{n-s}}{\partial x \partial y} - (n-s) \frac{\partial^2 \psi_s}{\partial x \partial y} \frac{\partial \psi_{n-s}}{\partial y} \right] \left. \right\} + O(\mu^4, \epsilon\mu^2, \epsilon^2) \end{aligned} \tag{16}$$

where

$$G_n = h - \frac{\mu^2 n^2 h^2}{3} \tag{17}$$

In principle, eq. (16) can be solved as a system of boundary value problems for  $\psi_n$ .

The amplitude function  $\psi_n$  is primarily a function of the water depth due to wave shoaling. Therefore,  $\psi_n$  varies slowly in the direction of wave propagation at the same rate as that of  $h$  in the  $x$ -direction. Thus

$$\frac{\partial \psi_n}{\partial x} \sim \frac{\partial h}{\partial x} \sim O(\epsilon, \mu^2) \tag{18}$$

$$\frac{\partial^2 \psi_n}{\partial x^2} \sim O(\epsilon^2, \mu^4, \epsilon \mu^2) \tag{19}$$

The diffraction effects are considered important. Hence,

$$\frac{\partial \psi_n}{\partial y} \sim O(1) \tag{20}$$

Using eqs. (18-20), we can simplify eq. (16) significantly to get

$$\begin{aligned} 2in \frac{\partial \psi_n}{\partial x} + \frac{\partial^2 \psi_n}{\partial y^2} + \frac{1}{G_n} \frac{\partial G_n}{\partial y} \frac{\partial \psi_n}{\partial y} + \left[ \frac{in}{G_n} \frac{\partial G_n}{\partial x} - n^2 \left( 1 - \frac{1}{G_n} \right) \right] \psi_n \\ = \frac{\epsilon}{2hG_n} \left\{ \sum_s [h s(n+s) + n^2 - s^2] \psi_s \psi_{n-s} - h \sum_{s \neq n} \left( \frac{n+s}{n-s} \right) \frac{\partial \psi_s}{\partial y} \frac{\partial \psi_{n-s}}{\partial y} \right. \\ \left. + 2h^2 \sum_{s \neq n} \frac{1}{n-s} \left[ s \psi_s \frac{\partial^2 \psi_{n-s}}{\partial y^2} - (n-s) \frac{\partial \psi_s}{\partial y} \frac{\partial \psi_{n-s}}{\partial y} \right] \right\} \end{aligned} \tag{21}$$

Significantly, we have converted a set of elliptic equations (16) into a set of parabolic equations, (21), which may be solved with efficient numerical techniques. For later use, we can rewrite eq. (21) in a dimensional form

$$\begin{aligned} 2in k_o \frac{\partial \psi_n}{\partial x} + \frac{1}{G_n} \frac{\partial}{\partial y} \left( \bar{G}_n \frac{\partial \psi_n}{\partial y} \right) + \frac{1}{G_n} \left( in k_o \frac{\partial \bar{G}_n}{\partial x} - n^2 k_o^2 \bar{G}_n + \frac{n^2 \omega^2}{g} \right) \psi_n \\ = \frac{1}{G_n} \left[ \frac{1}{2} \sum_s [k_o^2 s(n+s) + \frac{\omega^2}{gh} (n^2 - s^2)] \psi_s \psi_{n-s} - \frac{1}{2} \sum_{s \neq n} \left( \frac{n+s}{n-s} \right) \right. \\ \left. \frac{\partial \psi_s}{\partial y} \frac{\partial \psi_{n-s}}{\partial y} + \sum_{s \neq n} \frac{g k_o^2 h}{\omega^2 (n-s)} \left[ s \psi_s \frac{\partial^2 \psi_{n-s}}{\partial y^2} - (n-s) \frac{\partial \psi_s}{\partial y} \frac{\partial \psi_{n-s}}{\partial y} \right] \right] \end{aligned} \tag{22}$$

where

$$\bar{G}_n = h \left( 1 - \frac{n^2 \omega^2 h}{3g} \right) \tag{23}$$

is the dimensional form of eq. (17) and

$$k_0 = \frac{\omega}{\sqrt{g h_0}} \quad (24)$$

is the wave number associated with a reference constant water depth  $h_0$ .

The Crank-Nicolson method is used to rewrite the governing differential equations, (21), in a finite difference form. The forward difference scheme is employed in the x-direction, which is a time-like variable, and a centered difference scheme is used in the y-direction. Details are similar to those given by Liu and Tsay (11) and are omitted here.

#### An Alternate Approach Based on the K-P Equation

The application of the parabolic approximation to the more general Boussinesq equations involves an implied restriction to the case of waves with a unidirectional propagation direction and small transverse modulation. In this connection, it is of some interest to examine model equations with time dependence incorporated which embody the same basic assumption. For the case of shallow water and constant depth, an equation of this form has been developed by Kadomtsev & Petviashvili (5). The K-P equation may be written (following Bryant, 2) as

$$\frac{\partial}{\partial x} \left( \frac{\partial \zeta}{\partial t} + \frac{\partial \zeta}{\partial x} + \frac{3\epsilon}{2} \zeta \frac{\partial \zeta}{\partial x} + \frac{\mu^2}{6} \frac{\partial^3 \zeta}{\partial x^3} \right) + \frac{1}{2} \frac{\partial^2 \zeta}{\partial y^2} = 0 (\epsilon^2, \epsilon \mu^2, \mu^4) \quad (25)$$

The connection to the parabolic approximation may be seen by considering only  $O(1)$  terms and making the substitution

$$\zeta = \psi(x, y) e^{i(x-t)} \quad (26)$$

yielding (after assuming  $O(\partial^2 \psi / \partial x^2) \ll O(\partial \psi / \partial x)$ )

$$2i \frac{\partial \psi}{\partial x} + \frac{\partial^2 \psi}{\partial y^2} = 0 \quad (27)$$

which is the parabolic approximation of the Helmholtz equation (Yue & Mei, 19). The K-P equation, which extends the Korteweg-deVries equation to include weak transverse modulations, thus contains the same degree of information as the parabolic approximation.

Based on this correspondence, we may construct a version of the K-P equation for variable depth. Retaining dimensional quantities, the resulting model equation may be written as

$$\begin{aligned} \frac{\partial}{\partial x'} \left( \frac{1}{C'} \frac{\partial \zeta'}{\partial t'} + \frac{\partial \zeta'}{\partial x'} + \frac{1}{4h'} \frac{\partial h'}{\partial x'} \zeta' + \frac{3}{2h'} \zeta' \frac{\partial \zeta'}{\partial x'} + \frac{(h')^2}{6} \frac{\partial^3 \zeta'}{\partial x'^3} \right) \\ + \frac{1}{2h'} \frac{\partial}{\partial y'} \left( h' \frac{\partial \zeta'}{\partial y'} \right) = 0 \end{aligned} \quad (28)$$

where  $C' = \sqrt{gh'}$ . Neglecting  $y$  derivatives, the equation reduces to the form given by Johnson (4) after non-dimensionalization. Retaining only lowest order terms, making the substitution (where we drop primes for convenience),

$$\zeta = \bar{\psi}(x,y) e^{i(\int k dx - \omega t)} \tag{29}$$

$$\omega = C'k \tag{30}$$

and referencing the phase function to a constant value  $k_0$  (following Kirby & Dalrymple, 8) leads to the parabolic approximation

$$2ikh \frac{\partial \psi}{\partial x} + 2 kh(k-k_0)\psi + i \frac{\partial(kh)}{\partial x} \psi + \frac{\partial}{\partial y} (h \frac{\partial \psi}{\partial y}) = 0 \tag{31}$$

which is simply the shallow water limit of the linear approximation

$$2ik C_g \frac{\partial \psi}{\partial x} + 2k C_g(k-k_0)\psi + i \frac{\partial}{\partial x} (k C_g) \psi + \frac{\partial}{\partial y} (C_g \frac{\partial \psi}{\partial y}) = 0 \tag{32}$$

obtained by Kirby & Dalrymple (8). In eq. (32)  $C_g = \partial\omega/\partial k$  is the group velocity.

Before substituting a series expansion for  $\zeta$ , it is advantageous to alter the dispersive term  $\partial^3\zeta/\partial x^3$  by the following substitution

$$\frac{\partial^2 \zeta}{\partial t^2} - g \frac{\partial}{\partial x} (h \frac{\partial \zeta}{\partial x}) = 0(\epsilon, \mu^2) \tag{33}$$

yielding the modified equation

$$\frac{\partial}{\partial x} \left\{ \frac{1}{C} \frac{\partial \zeta}{\partial t} + \frac{\partial \zeta}{\partial x} + \frac{1}{4h} \frac{\partial h}{\partial x} \zeta + \frac{3}{\partial h} \zeta \frac{\partial \zeta}{\partial x} \right\} + \frac{h}{6C^2} \frac{\partial^3}{\partial t^2 \partial x} (h \frac{\partial \zeta}{\partial x}) + \frac{1}{2h} \frac{\partial}{\partial y} (h \frac{\partial \zeta}{\partial y}) = 0 \tag{34}$$

which has approximately the same dispersion relation as the set of equations (4) and (5). The parabolic approximation is obtained in similar fashion to the procedure of the previous section; we proceed using the slightly revised form

$$\zeta = \frac{1}{2} \sum_{n=-\infty}^{\infty} \bar{\psi}_n(x,y) e^{in(\int k dx - \omega t)} \tag{35}$$

to manipulate eq. (34) initially, after which a shift to a reference depth is employed (as in eq. 31) to obtain

$$2in k_0 \frac{\partial \psi_n}{\partial x} + \frac{k_0}{k \bar{G}_n} \frac{\partial}{\partial y} (h \frac{\partial \psi_n}{\partial y}) + \frac{1}{\bar{G}_n} \left[ \frac{in k_0}{2} \frac{\partial \bar{G}_n}{\partial x} - 2n^2 k_0 (k_0 - k) \bar{G}_n \right. \\ \left. + \frac{4}{3} \left( \frac{k_0}{k} \right) \frac{4}{g} \frac{\omega_n}{h} \right] \psi_n = \frac{3n^2 k_0}{4\bar{G}_n} \left[ \sum_{s=1}^{n-1} \psi_s \psi_{n-s} + 2 \sum_{s=1}^{N-n} \psi_{-s} \psi_{n+s} \right]; \\ 1 \leq n \leq N \tag{36}$$

where

$$\zeta = \frac{1}{2} \sum_{n=-\infty}^{\infty} \psi_n(x, y) e^{in(k_0 x - \omega t)} \quad (37)$$

and where  $\bar{G}_n$  and  $k_0$  are defined previously. The difference in the coefficients of  $\psi_n$  in eqs. (22) and (36) is accounted for by the fact that the substitution (37) is used throughout the entire process to obtain eq. (22) rather than the intermediate form, eq. (35).

Comparing eq. (36) to the corresponding equation (22), derived from the Boussinesq equation, we observe that the basic characteristics of these equations are the same. We remark, however, that in the approach using the K-P equation the nonlinearity is localized due to the original form of the equation (no  $y$ -derivatives in nonlinear term), and that the retention of only the lowest-order depth dependence in the  $y$ -derivative term implies a possible error in energy flux conservation and refraction for waves shoaling over a general two-dimensional topography. This latter effect could be alleviated by making the substitution  $\partial(\bar{G}_n \partial \psi_n / \partial y) / \partial y$  for the given term in eq. (36). However, numerical experiments for the case of Whalin's experiment (18) have shown that this effect is not important to the present study.

#### Refraction of Waves over a Plane Slope

Both of the models derived here are strictly applicable to the case of waves propagating over topography which is very slowly varying in comparison to the fundamental wavelength. Experimental data which satisfies this criterion is lacking due to the large wave basin needed. Therefore, we first compare the present model's results to a case for which computational results are available. Such a case has been provided by Skovgaard & Peterson (17), who used the properties of a very slowly-varying train of cnoidal waves to develop a theory for the refraction and shoaling of obliquely incident waves on a plane beach. This situation has also been studied recently by Madsen & Warren (13), who obtained a numerical solution for the case of waves propagating in a rectangular channel containing a plane slope oriented at an angle of  $26.6^\circ$  to the channel side walls. Madsen & Warren used a time-dependent, finite difference solution of a set of conservation laws equivalent to eqs. (4) and (5) to obtain their numerical results. Here, we use the parameters chosen by Madsen & Warren and study the same channel configuration; however, we neglect the lateral boundary damping employed by Madsen & Warren in order to study the details of the reflection process at the vertical, impermeable side walls. The computational domain is given by  $0 < x < 2154.5$ ,  $0 < y < 1534.5$ , with waves normally incident at  $x = 0$ . Slope-oriented coordinates are given by

$$\begin{aligned} x' &= (x - 420) \cos(26.6^\circ) - (y - 775) \sin(26.6^\circ) \\ y' &= (x - 420) \sin(26.6^\circ) + (y - 775) \cos(26.6^\circ) \end{aligned} \quad (38)$$

with water depth given by

$$h(x', y') = \begin{cases} 21 \text{ m} & ; \quad x' < 0 \\ (21 - 0.013 x') \text{ m} & ; \quad 0 \leq x' \leq 1076.9 \text{ m} \\ 7 \text{ m} & ; \quad x' > 1076.9 \text{ m} \end{cases} \quad (39)$$

Wave parameters for the problem are given by

$$\begin{aligned} T &= 17.3 \text{ s} = \text{wave period} \\ H &= 1.74 \text{ m} = \text{wave height at 21 m depth} \end{aligned}$$

which gives a deepwater wavelength  $L_0 = 467.1 \text{ m}$  and an Ursell number  $U_r = (H/2h)/(kh)^2 = 0.13$  in the deepwater portion of the channel. Initial conditions for the calculation are thus specified according to a third order Stokes wave at  $x = 0$ . A total of  $N = 6$  components are retained, and the computational domain is divided into a rectangular grid with  $\Delta x = \Delta y = 15.5 \text{ m}$ .

A plot of the model topography is given in Figure 1 along with a snapshot of the instantaneous water surface elevation, with contour increments of 1 m for bottom topography and 0.4 m for surface elevation. As the wave shoals, refraction effects are apparent in the center of the channel, and the wave develops from nearly sinusoidal form to shallow water profiles with narrow crests and broad troughs. The formation of a "Mach Stem" is apparent on the right boundary, where refraction turns the incident wave towards the wall, inducing a grazing-incidence reflection as in the study of Yue & Mei (19). Also apparent is the development of a high-frequency modulation, possibly consisting of an un-phaselocked higher mode, which evolves in the shallower portion of the tank. This short wave component causes a significant modulation of waveheight  $H(x, y)$  in the shallow ( $h = 7 \text{ m}$ ) portion of the domain.

A plot of normalized waveheight  $H/h$  versus normalized water depth  $h/L_0$  for  $y = 750 \text{ m}$  is given in Figure 2 in comparison to the refraction model of Skovgaard & Peterson (17) and the time-dependent numerical results of Madsen and Warren (13). The evolution of  $H/h$  is seen to be quite smooth up to the shallower depths, with the plotted points (corresponding to every fifth computational point) agreeing quite well with the refraction theory. In the shallow portion of the tank, the short wave modulation causes a significant variation in local wave height about the theoretical value. Wave height  $H$  was obtained by stepping the individual components through time to construct  $\zeta'(x, y, t)$  and then determining  $H(x, y)$  according to  $\zeta'_{\max} - \zeta'_{\min}$ .

Refracted angles of incidence between the wave and slope also agreed quite well with the refraction model and are not shown.

Plots of the water surface profile along the line  $y = 750$  and through the "Mach Stem" region  $y = 0$  are shown in Figures 3a and b, respectively. In both cases, results show the presence of separate peaks in the wave troughs; this was also noted in the results of Madsen & Warren and was attributed to truncation errors. The rapid evolution of a nearly uniform wave train is evident in the Mach-stem region in Figure 1. We remark that, due to the narrowness of the wave

Figure 1. Bottom topography and contours of instantaneous surface elevation at  $t = 0$ ; - - - bottom contours in increments of 1 m,  $7 \text{ m} < h < 21 \text{ m}$ , — contours of free surface elevation in increments of 0.4 m.

Figure 2. Normalized waveheight  $H/h$  as a function of  $h/L_0$ ; error bar  $\Phi$  at  $h/L_0 = 0.015$  indicates range of  $H$  values in shallow part of tank due to short wave modulation.

Figure 3. Free surface profiles for cnoidal wave refraction: (a) along  $y = 0$  m, sidewall and through Mach stem region, and (b) along  $y = 750$  m, near the centerline of channel.

crests, displacement of these crests away from actual computational grid points may contribute significantly to the modulation of crest elevations  $\zeta'_{\max}$  which is apparent in the plotted results.

We remark that increasing the number of modes without a further reduction of grid size did not significantly alter the results of this example. Tests with smaller grid size have not yet been conducted.

#### Wave Focusing By a Topographical Lens

Whalin (18) conducted a series of laboratory experiments concerning wave convergence over a bottom topography that acts as a focusing lens. The wave tank used in the experiments has the horizontal dimensions 25.603 m x 6.096 m. In the middle portion of the wave tank,  $7.62 \text{ m} < x < 15.24 \text{ m}$ , eleven semicircular steps were evenly spaced and led to the shallower portion of the channel (Figure 4). The equations approximating the topography are given as follows:

Figure 4. Topographical lens in Whalin's (18) wave tank experiments.

$$h(x,y) = \begin{cases} 0.4572 \text{ m} & (0 \leq x < 10.67 - G(y)) \\ 0.4572 + \frac{1}{25} (10.67 - G - x) \text{ m} & (10.67 - G \leq x \leq 18.29 - G) \\ 0.1524 \text{ m} & (18.29 - G \leq x \leq 21.34) \end{cases} \quad (40)$$

where

$$G(y) = [y(6.096 - y)]^{1/2} \text{ m} \quad (0 \leq y \leq 6.096 \text{ m}) \quad (41)$$

The bottom topography is symmetric with respect to the centerline of the wave tank,  $y = 3.048 \text{ m}$ .

A wavemaker was installed at the deeper portion of the channel where the water depth  $h_0$  is 0.4572 m. Three sets of experiments were conducted by generating waves with periods  $T = 1, 2, \text{ and } 3 \text{ secs.}$ , respectively. Different wave amplitudes were generated for each wave period. For the cases of  $T = 1 \text{ and } 2 \text{ secs.}$ , a second order Stokes wave theory (11) has been shown to describe the combined refraction-diffraction mechanisms adequately. The focusing of water waves by refraction led to a focal region, in which energy was transferred to the second harmonic. For the experimental set with  $T = 3 \text{ s}$  the Ursell parameter,  $U_r = (a/h)/(kh)^2$ , is generally greater than unity in the shallower water region, which indicates that the Stokes wave theory is no longer valid and the present shallow water wave theory should be used. In Table 1, we summarize the experimental data and the corresponding small parameters  $\epsilon$  and  $\mu^2$ . The water depth in the shallower region,  $h_1 = 0.1524 \text{ m}$ , has been used as the water depth scale.

Wave Period	Incident Wave Amplitude			$\epsilon = a_0/h_1$			$\mu^2 = \omega^2 h_1/g$
T(s)	$a_0$ (cm)						
3.0	0.68	0.98	1.46	0.0446	0.0643	0.0958	0.0682

Table 1. Experimental and Numerical Parameters

According to Whalin's report, the second and the third harmonic waves grow rapidly in the focal zone. In fact, the amplitude of the higher harmonics becomes larger than that of the first harmonic (see Figures 5 and 6). To study this problem, we obtain numerical solutions by using both approaches described above. In numerical computations for each model, five harmonics ( $N = 5$ ) are considered.

Owing to the symmetry of the problem with respect to the centerline of the wave tank, only one half of the wave tank is discretized. The computational domain starts from the wavemaker,  $x = 0$ , and ends at  $x = 22$  m. The no-flux boundary conditions are used along the side wall and the centerline of the wave tank, i.e.

$$\frac{\partial \psi}{\partial y} = 0 \quad \text{along } y = 0 \text{ and } 3.048 \text{ m} \quad (42)$$

for all  $n$ . The wave amplitude for the first harmonic waves at the wavemaker ( $x = 0$ ) is prescribed with the values shown in Table 1. The initial conditions for higher harmonic waves are zero.

In numerical computations different grid sizes are tested for the convergence of the numerical scheme. Numerical solutions presented here are obtained by using  $\Delta x = 0.25$  m and  $\Delta y = 0.3048$  m, although no noticeable differences are observed when the grid sizes are doubled.

In Figure 5a, numerical results based on the Boussinesq equation approach for the case with  $\epsilon = 0.0446$ ,  $\mu^2 = 0.0682$  and  $a_0 = 0.0068$  m are presented with experimental data. Wave amplitudes along the centerline of the wave tank are plotted. Since it is assumed that only the first harmonic waves are generated at the wavemaker, the wave energy in the higher harmonic components are sufficiently small over the constant depth region ( $0 < x < 8$  m). However, as waves start to refract over the topography and focus along the centerline of the tank, a significant amount of energy is transferred into higher harmonic components. The agreement between laboratory data and numerical solutions is reasonable. The numerical model overestimates the first harmonic amplitudes. The second and third harmonic wave amplitudes are in good agreement with reported data. (Several experiments with higher values of  $N$  indicated only minor changes for modes 1-3.) Results for the cases  $a_0 = 0.0098$  m ( $\epsilon = 0.0643$ ,  $\mu^2 = 0.0682$ ) and  $a_0 = 0.0146$  m ( $\epsilon = 0.0958$ ,  $\mu^2 = 0.0682$ ) are shown in Figures 5b and 5c, respectively. Again, the model uniformly overpredicts first harmonic amplitude along the channel centerline, although the amplitude of the second harmonic is well-predicted in both cases. The third harmonic amplitude is also well-predicted in Figure 5b. The high-amplitude case of Figure 5c indicates a tendency for the numerical result to undergo a recurrence behavior before the experimental maximum of  $\zeta_3$  is obtained.

Numerical results for the three cases presented above were also obtained using the K-P model with  $N = 5$ . Here,  $h_0$  and  $k_0$  are taken to correspond to the shallow portion of the tank. To compare these

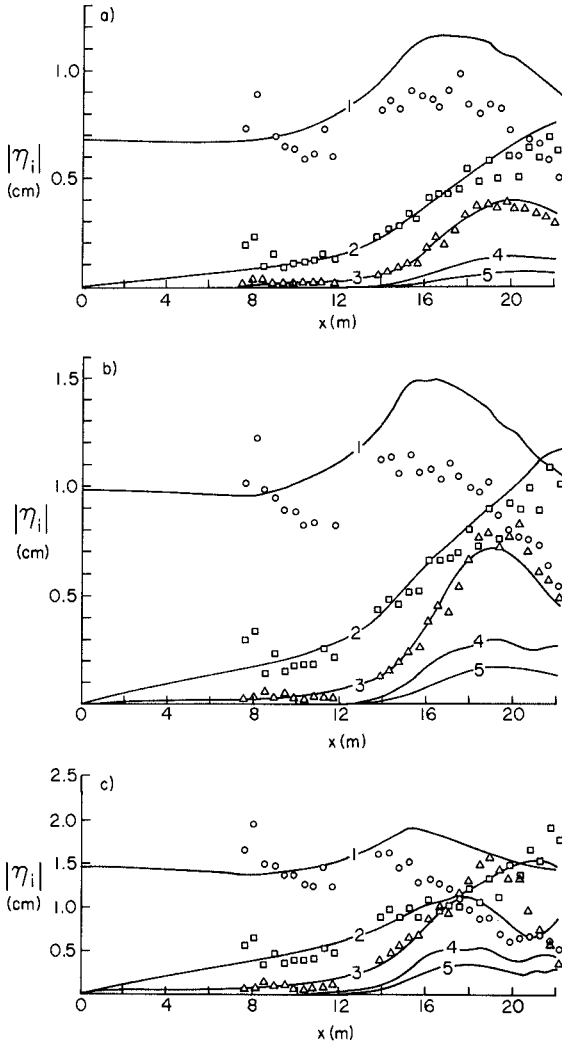

Figure 5. Harmonic amplitudes along centerline of Whalin's channel. a)  $a_0 = 0.68$  cm, b)  $a_0 = 0.98$  cm, c)  $a_0 = 1.46$  cm. Results using equation (21).

Figure 6. As in Figure 5. Results using equation (36).

two models, numerical solutions for the first three harmonics are shown in Figure 6a-c. For the low amplitude case  $a_0 = 0.68$  cm (Figure 6a), the results from the K-P model show an underprediction of second and third harmonic amplitudes, indicating the possible effect of the lowest-order  $y$  derivative term given in eq. (36). For the higher amplitude case (Figure 6b and c), nonlinearity becomes relatively more important and results of the two models are in closer agreement, with the exception that harmonic amplitudes grow somewhat more slowly in the K-P model. Both models are seen to be capable of predicting the essential features of harmonic generation in the focusing of a nonlinear wave. We remark that results of each model are sensitive to the choice of initial conditions, so that more detailed comparisons than those obtained here are not possible in the absence of detailed data in the vicinity of the wavemaker ( $x < 8$  m).

Finally, the evolution process described in the present cases occurs in the space of about two first harmonic wavelengths, indicating that the theoretical limitation to slowly varying topography and amplitudes is not restrictive in practice.

#### Concluding Remarks

The present study has demonstrated that the parabolic equation method may be successfully applied to the modeling of weakly nonlinear, weakly dispersive wave motions governed by the Boussinesq equations. The present study has been confined to the investigation of the propagation of monochromatic waves together with their nonlinearly-generated harmonics. However, given the necessary computer capacity, the method is directly applicable to the problem of modeling two-dimensional spectral evolution in shallow water.

In this study we have neglected the effects of frictional dissipation and wave breaking; the models in their present form are thus applicable to the region seaward of the surf zone. The inclusion of wave breaking effects in the models may be expected to be a non-trivial extension of the present results, since the models do not directly calculate the total wave height at each computational point.

#### Acknowledgements

This research was carried out with the support of the Office of Naval Research, Coastal Sciences Program (JTK and RAD) and New York Sea Grant Institute (PLFL and SBY). The possible utility of the K-P equation in the study of combined refraction and diffraction was suggested by Dr. J. L. Hammack.

## CHAPTER SIXTY NINE

### PROFILE ASYMMETRY OF SHOALING WAVES ON A MILD SLOPE

Paul A. Hwang\*, A.M., ASCE

#### Abstract

From limited experimental evidence, shoaling monochromatic waves seem to possess certain similarities. Specifically, the harmonic composition follows the trend of solitary or cnoidal waves, and the phase difference of harmonics vary with water depth monotonically. Based on the above observation a similarity model is constructed to study the asymmetric properties of shoaling waves. The implication of wave asymmetry on wave breaking is discussed.

#### Introduction

When the amplitude of a monochromatic wave becomes appreciable, the wave profile becomes asymmetric with respect to the horizontal axis, that is, a higher crest elevation than trough levels (Stokes, 1880). On shoaling water, in addition to the horizontal asymmetry, the wave form is obviously skewed with respect to the vertical axis with a steeper crest front than the crest rear face. Extensive studies have been conducted to study the wave asymmetry, especially for the case of breaking waves (McCowan, 1894; Munk, 1949; Iversen, 1952; Biesel, 1952; Ursell, 1953; Ippen and Kulin, 1955; Eagleson, 1957; Galvin, 1969; Goda, 1970; Hwang, 1982; Kjeldsen, 1981, 1983). Many studies of wave transformation at different stages of shoaling process also presented asymmetric information for nonbreaking waves (Iwagaki, 1968; Iwagaki and Sakai, 1972; Svendsen and Buhr-Hansen, 1978; Flick et al., 1981). The writer is especially interested in the approach of Flick et al. who performed harmonic analysis of the nonlinear shoaling waves. They found that both the amplitude and the phase spectra of a monochromatic shoaling wave vary with water depth in a deterministic fashion from the beach toe up to the breaking point: the amplitude spectrum resembles that of a cnoidal wave of the same height and the phase angle of each harmonic changes monotonically with decreasing water depth. Hwang (1982) applied harmonic analysis on breaking waves at different locations on sloping beaches, a very similar amplitude and phase spectral transformation was observed. It is speculated that certain similarity relationships of shoaling waves exist. The following presents an attempt to construct a similarity model for shoaling waves and to study their asymmetric properties.

\*Air-Sea Interaction Laboratory, College of Marine Studies, University of Delaware, Lewes, Delaware 19958.

## A Similarity Model

Flick et al. (1981) and Hwang (1982) studies wave profiles by Fourier decomposion

$$\eta = \sum_{n=1}^{\infty} a_n \cos(n\sigma t + \phi_n) \quad (1)$$

where  $\eta$  is the surface fluctuation,  $a_n$  the  $n$ -th component,  $\sigma$  the angular frequency,  $t$  the time coordinate and  $\phi_n$  the phase lag of the  $n$ -th component. They found that the variation of  $a_n$  with water depth follows closely the Fourier components of solitary or cnoidal waves (Figure 1a), and the phase of each oomponent changes monotonically with water depth (Figure 1b).

The amplitude spectrum of a cnoidal wave is given by (Cayley, 1895)

$$\frac{a_n}{H} = \frac{8}{3} k^2 h^3 n q^n \frac{1}{1 - q^{2n}} \quad (2)$$

where

$$q = \exp [-\pi K(1-m)/K(m)] \quad (3)$$

and  $K(m)$  is the complete elliptic integral of the second kind. The cnoidal parameter  $m$  is related to the wave parameters by the following relationship

$$m = \frac{3\pi^2 U_r}{4K^2(m)} \quad (4)$$

$U_r$  is the Ursell number defined as

$$U_r = H/k^2 h^3 \quad (5)$$

where  $H$  is wave height,  $k$  the wave number and  $h$  the water depth.

The amplitude spectrum of a solitary wave is given by (Gradshteyn and Ryzhik, 1980)

$$\frac{a_n}{H} = \frac{4n}{3U_r} \left( \sinh \frac{n\pi}{(3U_r)^{1/2}} \right)^{-1} \quad (6)$$

Eqs. (3) and (6) are plotted on Figure 1a along with experimental data. The difference between two theories is found insignificant in the range shown, and both theories agree with the trend of data reasonably well. In the following, we use Eq. (6) to calculate harmonic amplitudes due to its simplicity.

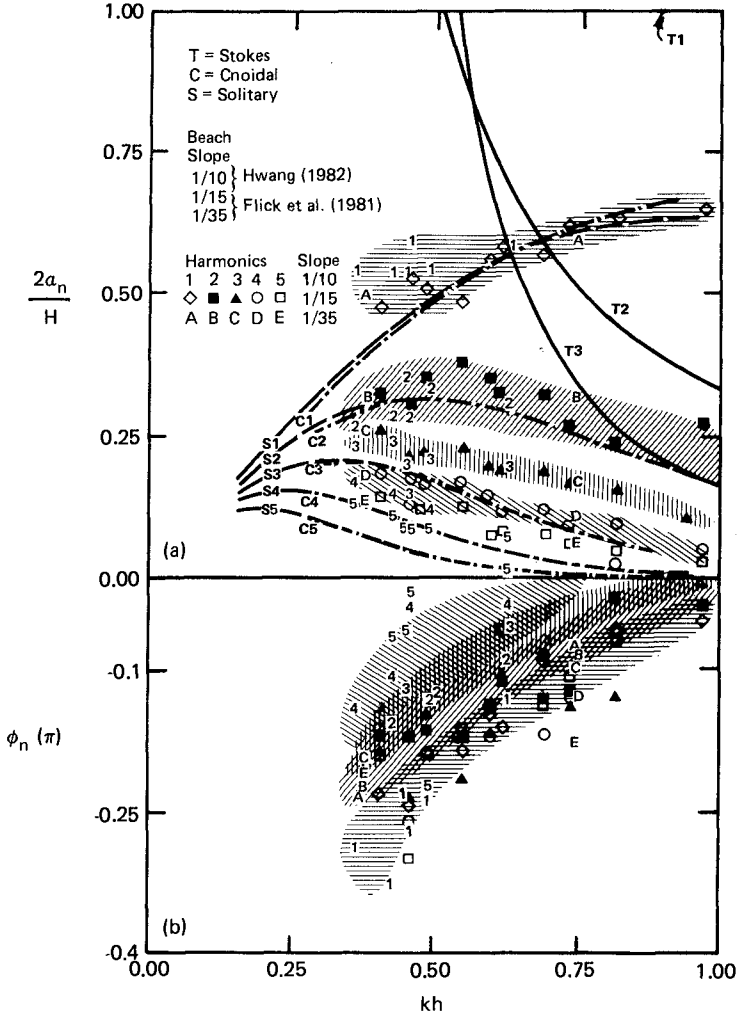

Figure 1 - Variation of (a) amplitude, (b) phase lag, of harmonics vs. kh.

Wave theories developed that considered the bottom slope modulation of the surface profile (Iwagaki, 1968; Chu and Mei, 1970; Iwagaki and Sakai, 1972; Guza and Davis, 1974) generally show poor agreement of the harmonic phase lags. The empirical relationship derived from the data in Figure 1b is used

$$\phi_n = -0.03 - 0.34(kh-1) \quad (7)$$

where  $\phi_n$  is expressed in  $\pi$ -radian. Alternatively,  $\phi_n$  can be expressed in  $Ur$  (Figure 2)

$$\phi_n = -0.05 - 0.052 Ur \quad (8)$$

Calculation shows little difference on the asymmetric properties (discussed in next section) using either equation. Eqs. (7) and (8) did not consider the variation of  $\phi_n$  with bottom slope or the harmonic numbers. From the limited data collected, the effect of bottom slope on  $\phi_n$  is very difficult to distinguish. Trying to establish a complete empirical relationship of  $\phi_n$  from such a small data set is probably not justified. The simplification employed therefore only gives a qualitative description. Eqs. (3) or (6) and (7) or (8) define a wave profile.

#### Wave Profiles and Asymmetric Factors

Figure 3 shows a few examples of the normalized wave profiles defined by Eqs. (6) and (7). For each profile, fifteen harmonics were included (Eq. 6). Due to the superposition of harmonics, the wave form is asymmetric with respect to the horizontal axis. The wave form is also skewed due to different phase lags among harmonics. The degree of asymmetry (both horizontal and vertical) increases with decreasing depth (or increasing  $Ur$ ).

There are many different parameters proposed to define the wave asymmetry (Iversen, 1952; Adeyemo, 1968; Iwagaki and Sakai, 1972; Kjeldsen, 1981, 1983, among others). The parameters  $\epsilon$ ,  $\delta$ ,  $\lambda$ , and  $\mu$  proposed by Kjeldsen (Figure 4) are adopted for the following discussion. The parameter  $\epsilon$  (the crest front steepness) is of special interest to this study since it represents the largest "local" steepness of the wave form and may dominate the wave breaking inception;  $\epsilon$  is related to the "global" wave steepness  $H/L$  (where  $L$  is the wave length) by

$$\epsilon = \eta'/L' = \frac{\eta'}{H} \frac{L}{L'} \frac{H}{L} \quad (9)$$

The factor  $\alpha_F = (\eta'/H)(L/L')$  can be interpreted as a "front steepness amplification factor," which defines the ratio between the crest front and the overall steepness. For a pure sinusoidal wave,  $\alpha_F = 2$ . Similarly, a "rear steepness amplification factor" can be defined as  $\alpha_B = (\eta'/H)(L/L'')$ . For nonlinear symmetric waves  $\alpha_F = \alpha_B > 2$ , and for asymmetric waves  $\alpha_F > \alpha_B > 2$ .

FIGURE 2 —Phase lag of the first harmonic vs.  $Ur$ .

Figure 3 — Normalized wave profile. Waves propagate toward left.

Figure 4 — Definitions of asymptotic parameters (reproduced from Kjeltdsen and Myrhaug, 1979).

Fig. 5 plots the asymmetry factors  $\alpha_F$  and  $\alpha_B$  with respect to the dimensionless water depth  $kh$ . Both vertical and horizontal asymmetry increase toward shallower water. The degree of asymmetry at any given depth ( $kh$ ) increases with wave nonlinearity ( $H/h$ ). The horizontal asymmetry  $\mu$  is found to be smaller than the corresponding symmetric wave of the same amplitude spectrum (compare the solid and the dashed curves of  $H/h=0.5$ , Fig. 5b), at the lowest  $kh$  range calculated, a reduction of 6% was shown. The vertical asymmetry factor  $\lambda$  is identically one for a symmetric wave. The slope amplification factors at the crest front  $\alpha_F$  and crest rear  $\alpha_B$  are plotted in Fig. 5c and d. As mentioned before,  $\alpha_F = \alpha_B = 2$  for a sinusoidal wave. Both  $\alpha_F$  and  $\alpha_B$  increase with wave nonlinearity, in which case, the crest region becomes narrower and trough region is elongated. For a symmetric wave  $\alpha_F = \alpha_B$ . When waves become asymmetric, the crest front becomes steeper and the crest rear becomes milder (compare dashed and solid curves for the case  $H/h=0.5$  in Fig. 5c and d).

Fig. 6 plots  $\lambda$ ,  $\mu$ ,  $\alpha_F$  and  $\alpha_B$  vs.  $Ur$ . Similar conclusions as those of Fig. 5 can be drawn.

#### Discussion and Conclusion

The amplitude and phase spectra of shoaling waves changes continuous with water depth. The former resembles the spectra of either cnoidal or solitary waves. A similarity model was constructed to study the asymmetric properties of shoaling waves using the solitary wave spectrum and an empirical relation of the harmonic phase lags with water depth.

As expected, the resulting wave profiles become more asymmetric both horizontally and vertically as water depth decreases or Ursell number increases. Compared with a symmetric wave of the same amplitude spectrum, the vertically asymmetry factor is always higher but the horizontal asymmetry factor shows a decrease. Due to the skewing of the wave profile, the crest front steepness is considerably greater than the overall wave steepness  $H/L$ .

The wave steepness is closely related to the breaking occurrence. In the classical studies of limiting (symmetric) Stokes' wave in deep water, the enclosing angle at wave crest was found to be  $120^\circ$  (Stokes, 1880). McCowan (1894) proved that the breaking angle of a wave in shallow water is still  $120^\circ$ . These results were confirmed by laboratory experiments and field observations (Gaillard, 1904, see eg. review of Kinsman, 1965). Michell (1893) showed that the corresponding maximum steepness  $H/L=1/7$  in deep water. When a wave moves into shoaling water, the limiting steepness decreases and becomes a function of both relative depth and the beach slope. Although this subject was studied extensively, the mechanism of wave breaking on a sloping beach is not yet clear. Subsequently, the breaking characteristics were generally expressed in terms of the ratio between the breaking wave height and water depth ( $H_b/h_b$ ), or the ratio between the wave height at breaking point and at deep water ( $H_b/H_0$ ). Many empirical formulas were proposed (Iversen, 1952; Galvin, 1969; Goda, 1970 among others). From the above short literature survey, it seems that the breaking angle is one of the rare breaking invariants (another invariant maybe the fluid particle

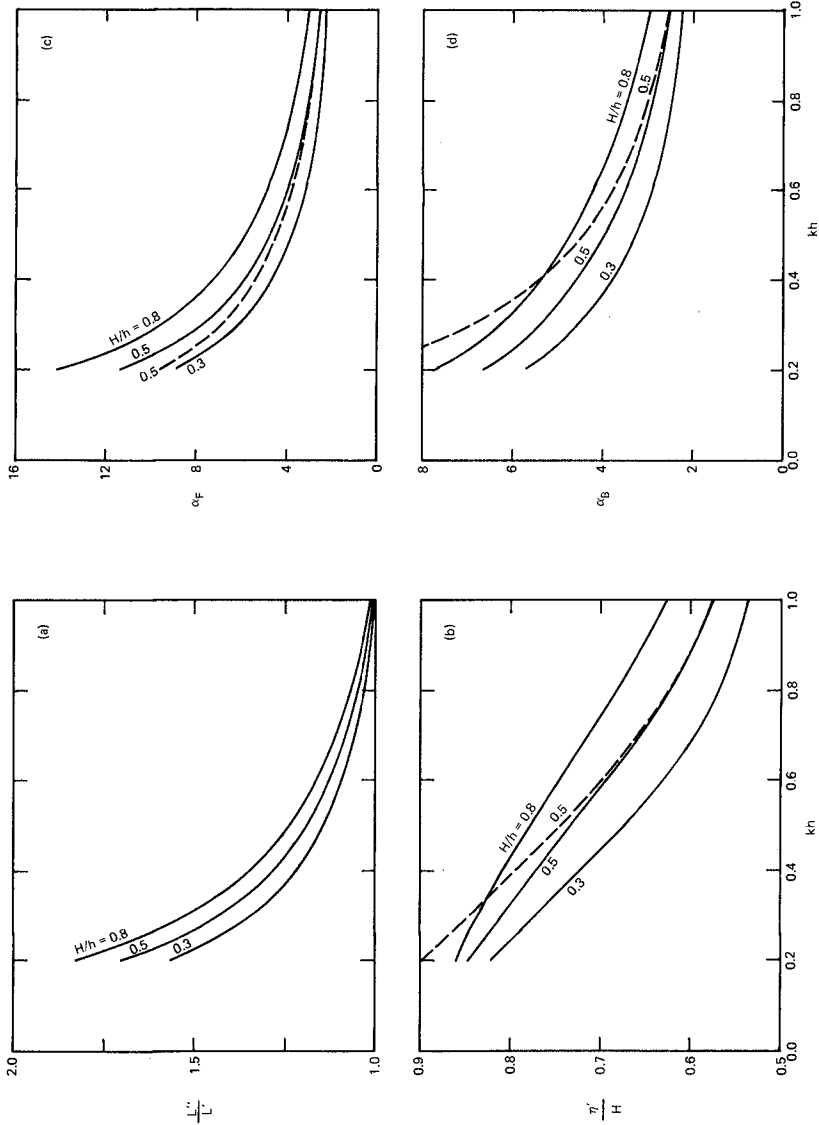

Figure 5 — Calculated asymmetric parameters. (a) Vertical asymmetry, (b) Horizontal asymmetry, (c) Front steepness amplification, and (d) Rear steepness amplification. Dashed line corresponds to the case of symmetric waves.

Figure 6 --- Same as Figure 5, except plotted against Ursell number  $U_r$

acceleration but this is very difficult to measure). For waves of vertically asymmetric profiles, the breaking angle is more closely related to the crest front and crest rear steepnesses. The crest front steepness is probably an important geometric index for "local" wave steepness. The local wave steepness was used by Longuet-Higgins and Smith (1983) in measurements of breaking probability.

## CHAPTER SEVENTY

### THE EXACT SOLUTION OF THE HIGHEST WAVE DERIVED FROM A UNIVERSAL WAVE MODEL

Yang Yih Chen<sup>1</sup> Frederick L.W. Tang<sup>2</sup>

#### ABSTRACT

The solitary wave is first established in this paper by extending the series solution of periodic gravity wave as the wavelength approaches to infinite. Then, the highest gravity wave of permanent type in finite depth of water is immediately analyzed. The maximum ratio of wave height to water depth is obtained as 0.854654..., and the angle at the crest for the considered highest wave is estimated to be 90°.

#### INTRODUCTION

Since Stokes (1847) developed the theory of oscillatory waves, the analysis for the periodic gravity waves of permanent form in the water has comprehensively been expanded, particularly, a very interested and important problem is the highest waves. However, up to now, all wave theories which have presented are not continuously available to describe the flow field of a wave motion in which both amplitude and wavelength vary from small to possible maximum in any fixed depth of water. Therefore, to solve this highest wave problem, several special wave theories have been employed, for example, as the cnoidal wave by Laitone (1960), the solitary wave by McCowan (1894), Yamada (1957), Lenau (1966) and Longuet-Higgins (1974), and an integral equation of wave motion by Byatt-Smith (1970) etc. The purpose of this paper is to establish a universal model which can adequately be used to analyze the waves motion in arbitrary uniform depth, from deep to shallow water, up to a solitary wave especially, and its wave height from small to just breaking; i.e. this model is adjustable to all the region for the periodic gravity waves of permanent type can be existed.

In §I, we recapitulate to formulate the series solution for the periodic gravity waves of permanent type in water of arbitrary uniform depth, which has been submitted in 19th International Conf. on Coastal Eng. In §II, the solitary wave similar to McCowan's type is established, in §III, §IV and §V, the structure of the highest waves is discussed.

1. THE NEW MODEL OF WATER WAVES

The solution of Laplace equation in water wave motion are to be set as follows:

$$\psi(x,y,t) = \sum_{n=1}^{\infty} C_n e^{-nk d} [e^{nk(d+y)} - e^{-nk(d+y)}] \cos nk(x-ct) \dots (1.1)$$

$$\phi(x,y,t) = \sum_{n=1}^{\infty} C_n e^{-nk d} [e^{nk(d+y)} + e^{-nk(d+y)}] \sin nk(x-ct) \dots (1.2)$$

$\psi(\cdot)$  : Stream function

$\phi(\cdot)$  : Potential

$C_n$  : constants to be worked out

$n$  : 1, 2, 3, .....

$e$  : exponential

$k$  : wave number,  $k=2\pi/L$

$L$  : wavelength

$d$  : water depth under  $x$  - axis

$c$  : wave celerity

The co-ordinate system is illustrated in Fig 1.

Figure 1 The coordinate system of wave motion

The motion is altered to be steady flow by adding an opposite velocity  $c$ .  $(x-ct)$  in above equations will be replaced by  $x$ , then

$$\psi(x,y) = -cy + \sum_{n=1}^{\infty} C_n e^{-nk d} [e^{nk(d+y)} - e^{-nk(d+y)}] \cos nkx \dots (1.3)$$

$$\phi(x,y) = -cx + \sum_{n=1}^{\infty} C_n e^{-nk d} [e^{nk(d+y)} + e^{-nk(d+y)}] \sin nkx \dots (1.4)$$

The equation of surface elevation is to be obtained by  $\psi(x, \eta) = 0$  as follows

$$\eta(x) = \sum_{n=1}^{\infty} \frac{C_n}{c} e^{-nk d} [ e^{nk(d+\eta)} - e^{-nk(d+\eta)} ] \cos nkx \dots\dots\dots (1.5)$$

$\eta$ : elevation of wave surface with reference to x axis

The constants are worked out by boundary conditions as shown in the previous paper published in Captain conference (19th proc. ICCE page 508-520).

The solution is as follows:

In deep water,  $d \rightarrow \infty$ , when  $n=1$ ,  $\dots\dots\dots (1.6)$

$$\psi(x, y) = -cy + \frac{c\theta}{Ke^\theta} e^{ky} \cos kx \dots\dots\dots (1.7)$$

$$\eta(x) = \frac{\theta}{ke^\theta} e^{k\eta} \cos kx \dots\dots\dots (1.8)$$

$$\theta = \frac{2\pi\delta}{1 + e^{-2\pi\delta}}, \quad \delta = \frac{H}{L}, \quad \text{the wave steepness.}$$

In water area of finite depth, when  $n=1$ ,

$$\psi(x, y) = -cy + c\eta_c \frac{\sin hk(d+y)}{\sin hk(d+\eta_c)} \cos kx \dots\dots\dots (1.9)$$

$$\eta(x) = \eta_c \frac{\sin hk(d+y)}{\sin hk(d+\eta_c)} \cos kx \dots\dots\dots (1.10)$$

and  $\eta_c$  is to be computed through following equation by Newton-Raphson's method

$$\delta = \frac{H}{L} = \frac{\eta_c}{L} \{ [1 + \cosh(2\pi\delta)] - \coth hk(d+\eta_c) \sinh(2\pi\delta) \} \dots\dots\dots (1.11)$$

$\eta_c$ : the elevation of wave crest above x-axis

wave celerity  $c$ , period  $T$  and the difference between still water level and the water depth of  $\psi(x, \eta) = 0$ , namely the depth under x-axis,  $\zeta = d_s - d$  have been worked out ( $d_s$  the depth of still water).

After elaborate experiments, the new model represents the reality very well. (19th Proc. ICCE page 510-520)

II. EXTENSION OF THE MODEL

For extending the new model to the region of solitary wave, the co-ordinate system is set as Fig-2.

Figure 2 The coordinate system of solitary wave

The equations expressing  $\psi, \phi, \eta$  are changed to be

$$\psi(x, y) = -c(y - h) + \sum_{n=1}^{\infty} C_n^1 (e^{nky} - e^{-nky}) \cos(nkx) \dots\dots (11.1)$$

$$\phi(x, y) = -cx + \sum_{n=1}^{\infty} C_n^1 (e^{nky} + e^{-nky}) \sin(nkx) \dots\dots\dots (11.2)$$

$$\eta(x, y) = \sum_{n=1}^{\infty} \frac{C_n^1}{c} [e^{nk(h+\eta)} - e^{-nk(h+\eta)}] \cos(nkx) \dots\dots\dots (11.3)$$

$$C_n^1 = C_n e^{-nk d}$$

let

$$K_n = \frac{2C_n^1}{c} \sinh[nk(h + \eta_0 + \epsilon_0)] \dots\dots\dots (11.4)$$

$\eta_0$  is the height of wave crest on water level and  $\epsilon_0$  is an constant,  $\epsilon_0 > 0$ .

Above equations become

$$\psi(x, y) = -c(y-h) + c \sum_{n=1}^{\infty} K_n \frac{\sinh(nky)}{\sinh[nk(h + \eta_0 + \epsilon_0)]} \cos(nkx) \dots (11.5)$$

$$\phi(x, y) = -cx + c \sum_{n=1}^{\infty} K_n \frac{\cosh(nky)}{\sinh[nk(h + \eta_0 + \epsilon_0)]} \sin(nkx) \dots\dots (11.6)$$

$$\eta(x) = \sum_{n=1}^{\infty} K_n \frac{\sinh[nk(h + \eta)]}{\sinh[nk(h + \eta_0 + \epsilon_0)]} \cos(nkx) \dots\dots\dots (11.7)$$

While  $L \rightarrow \infty$ ,  $k = \frac{2\pi}{L} \rightarrow 0$ , let  $k = d\tau$ ,  $nk = \tau$ ,  $K_n = K(\tau)$

$$\lim_{L \rightarrow \infty} \sum_{n=1}^{\infty} \frac{K_n \sinh\left(\frac{2n\pi}{L} y\right)}{\sinh\left[-\frac{2n\pi}{L} (h + \eta_0 + \epsilon_0)\right]} \cos\left(\frac{2n\pi}{L} x\right) \dots\dots\dots (11.8)$$

$$= \frac{1}{2\pi} \int_0^\infty LK(\tau) \frac{\sinh(y\tau)}{\sinh[(h+\eta_0+\epsilon_0)\tau]} \cos(\tau x) d\tau \dots\dots (11.8)$$

The integration should be a finite quantity even though the wave-length becomes infinitive, let

$$\lim_{L \rightarrow \infty} \frac{L \cdot K(\tau)}{2\pi} = \beta' \dots\dots\dots (11.9)$$

$\beta'$  will be a constant of finite value, consequently

$$\begin{aligned} & \lim_{L \rightarrow \infty} \sum_{n=1}^\infty \frac{K_n \sinh(nky)}{\sinh[(h+\eta_0+\epsilon_0)\tau]} \cos(nkx) \\ &= \beta' \int_0^\infty \frac{\sinh(y\tau)}{\sinh[(h+\eta_0+\epsilon_0)\tau]} \cos(\tau x) d\tau \\ &= \frac{\beta'}{2} \int_{-\infty}^\infty \frac{e^{i\tau x} \sinh(y\tau)}{\sinh[(h+\eta_0+\epsilon_0)\tau]} d\tau \dots\dots\dots (11.10) \\ & \quad i = \sqrt{-1} \end{aligned}$$

let

$$\tau (h + \eta_0 + \epsilon_0) = \pi \xi \dots\dots\dots (11.11)$$

$$\begin{aligned} & \lim_{L \rightarrow \infty} \sum_{n=1}^\infty \frac{K_n \sinh(nky)}{\sinh[nk(h+\eta_0+\epsilon_0)]} \cos(nkx) \\ &= \frac{\beta'}{2} \frac{\pi}{(h+\eta_0+\epsilon_0)} \int_{-\infty}^\infty \exp\left(-\frac{i\pi x \xi}{h+\eta_0+\epsilon_0}\right) \frac{\sinh\left(\frac{\pi y \xi}{h+\eta_0+\epsilon_0}\right)}{\sinh(\pi \xi)} d\xi \dots\dots (11.12) \end{aligned}$$

A complex integral as follows is invoked here, and which is integrated through the route in Fig. 3.

$$I = \int_{-\infty}^\infty e^{i\lambda_0 u} \frac{\sinh(a_0 u)}{\sinh(\pi u)} du \quad -\pi < a_0 < \pi \dots\dots\dots (11.13)$$

Figure 3 The contour of complex integration  $I, R_1 \rightarrow \infty, \delta_1 \rightarrow 0$

From mathematical operation, the integral is evaluated to be

$$I = \frac{\sin a_0}{\cosh \lambda_0 + \cos a_0} \quad -\pi < a_0 < \pi \dots\dots\dots (11-14)$$

As a result, it is proved that

$$\begin{aligned} & \lim_{L \rightarrow \infty} \sum_{n=1}^{\infty} \frac{K_n \sinh(nky)}{\sinh[nk(h + \eta_0 + \epsilon_0)]} \cos(nkx) \\ &= \frac{\pi \beta'}{2(h + \eta_0 + \epsilon_0)} \frac{\sin\left(\frac{\pi y}{h + \eta_0 + \epsilon_0}\right)}{\cosh\left(\frac{\pi x}{h + \eta_0 + \epsilon_0}\right) + \cos\left(\frac{\pi y}{h + \eta_0 + \epsilon_0}\right)} \dots\dots (11-15) \end{aligned}$$

put

$$\frac{\pi \beta'}{2(h + \eta_0 + \epsilon_0)} = \beta \dots\dots\dots (11-16)$$

The stream function and potential of the wave motion in the case of wave length approaching infinitive are to be obtained as follows:

$$\psi(x, y) = -c(y-h) + c\beta \frac{\sin(my)}{\cosh(mx) + \cos(my)} \dots\dots\dots (11-17)$$

$$\phi(x, y) = -cx + c\beta \frac{\sinh(mx)}{\cosh(mx) + \cos(my)} \dots\dots\dots (11-18)$$

Consequently, the wave profile can be expressed to be

$$\eta(x) = \frac{\beta \sin[m(h + \eta)]}{\cosh(mx) + \cos[m(h + \eta)]} \dots\dots\dots (11-19)$$

$$\text{where } m = \frac{\pi}{(h + \eta_0 + \epsilon_0)} \dots\dots\dots (11-20)$$

These equations identify with McCowen's theory. Therefore, the mathematical model submitted by the authors is proved to be able to represent the waves of symmetrical profile progressing in area of any water depth with any wavelength. So that this model can be nominated to be "universal".

III. EXACT SOLUTION OF FLOW FIELD IN SOLITARY WAVE

From the equations(II.17),(II.18) and (II.19), the partical velocity q can be calculated as follows:

$$q^2 = c^2 \left\{ 1 + \frac{m^2 \beta^2 - 2m\beta(1 + \cosh mx \cos my)}{(\cosh mx + \cos my)^2} \right\} \dots\dots\dots (III.1)$$

Expand and rearrange this equation, then substitute(II.17) to it, following expression is to be obtained.

$$q^2 = c^2 + m^2 [\psi(x, y) + c(y-h)]^2 \cdot \left[ \frac{1}{\sin^2(my)} - \frac{2}{m\beta} \right] - 2mc [\psi(x, y) + c(y-h)] \cot(my) \dots\dots\dots (III.2)$$

The partical velocity on the surface can be evaluated by substituting  $\psi(x, h+\eta) = 0$  to (III.2) and then have

$$(q^2)_{y=h+\eta} = c^2 \left\{ 1 - 2m\eta \cot[m(h+\eta)] + m^2 \eta^2 \cdot \left[ \frac{1}{\sin^2[m(h+\eta)]} - \frac{2}{m\beta} \right] \right\} \dots\dots\dots (III.3)$$

The water elevation in very distant location will have no disturbance, so

$$x \longrightarrow \pm \infty, \quad \eta = 0, \quad (q^2)_{x \rightarrow \pm \infty} = c^2 \dots\dots\dots (III.4)$$

Also from the dynamical boundary condition on the surface, the Bernoulli's constant Q can be evaluated as

$$Q = g(h+\eta) + \frac{1}{2} \left[ \left( \frac{\partial \psi}{\partial x} \right)^2 + \left( \frac{\partial \psi}{\partial y} \right)^2 \right]_{y=h+\eta} = \frac{1}{2} c^2 + gh \dots\dots (III.5)$$

so that

$$\left[ \left( \frac{\partial \psi}{\partial x} \right)^2 + \left( \frac{\partial \psi}{\partial y} \right)^2 \right]_{y=h+\eta} = (q^2)_{y=h+\eta} = c^2 - 2g\eta \dots\dots\dots (III.6)$$

From equations(III.3) and (III.6), another equation of wave profile can be worked out as follows

$$\eta(x) = \frac{2m \cot[m(h+\eta)] - 2g/c^2}{m^2 \left\{ \frac{1}{\sin^2[m(h+\eta)]} - \frac{2}{m\beta} \right\}} \dots\dots\dots (III.7)$$

Use the condition of  $X \rightarrow \pm \infty, \eta = 0$  again, c is to be calculated as follows

$$c^2 = \frac{g}{m} \tan(mh) \dots\dots\dots (III.8)$$

This is just the same as McCowan's theory (1891).

At  $x=0$ ,  $\eta = \eta_0 = H$ ,  $H$  is the wave height of solitary wave, from (III.19)

$$H = \beta \tan \left[ \frac{1}{2} m (h+H) \right] \dots\dots\dots (III.9)$$

and

$$m\beta = mH \cot \left[ \frac{1}{2} m (h+H) \right] \dots\dots\dots (III.10)$$

Substitute (III.8) and (III.10) to (III.7) in the case of  $\eta = H$  at  $x=0$ . Then we obtain

$$H = \frac{2m \cot [m(h+H)] - 2m \cot (mh)}{m^2 \left\{ \frac{1}{\sin^2 [m(h+H)]} - \frac{2 \tan \left[ \frac{1}{2} m (h+H) \right]}{mH} \right\}} \dots\dots\dots (III.11)$$

Rearrange this equation

$$\begin{aligned} & mH \{ 1 + \cos [m(h+H)] \} \\ &= 2 \{ \cot [m(h+H)] - \cot (mh) \} \cdot \sin^2 [m(h+H)] \cdot [ 1 + \cos m(h+H) ] \\ & \quad + 2 \sin^3 [m(h+H)] \dots\dots\dots (III.12) \end{aligned}$$

It is soon seen that, when the wave height  $H$  and the depth  $h$  of water are given,  $m$  can be worked out by solving this equation, then  $c$ ,  $\beta$  are also to be calculated through (III.8) and (III.9). The profile of solitary wave is to be delineated.

In this section, not any approximate calculation is used, so it can be called the exact solution.

IV. ON THE HEIGHT OF CRITICAL WAVE

When the crest particle velocity is equal to the wave celerity, the wave begins to break. The critical wave height is the height of wave just before breaking. In a coordinate system of steady motion the critical condition is that the particle velocity at the wave crest is zero. From (III.6)

$$c^2 = 2g\eta_0 = 2gH \dots\dots\dots (IV.1)$$

From (III.8)

$$c^2 = 2gH = \frac{g}{m} \tan (mh) , \quad mH = \frac{1}{2} \tan (mh) \dots\dots\dots (IV.2)$$

Substitute this equation to (III.12) and rearrange, following equation is obtained

$$\begin{aligned} & \frac{1}{2} \tan (mh) \left\{ 1 + \cos \left[ mh + \frac{1}{2} \tan (mh) \right] \right\} \\ & = 2 \left\{ \cot \left[ mh + \frac{1}{2} \tan (mh) \right] - \cot (mh) \right\} \\ & \quad \times \left\{ \sin^2 \left[ mh + \frac{1}{2} \tan (mh) \right] \right\} \left\{ 1 + \cos \left[ mh + \frac{1}{2} \tan (mh) \right] \right\} \\ & \quad + 2 \left\{ \sin^3 \left[ mh + \frac{1}{2} \tan (mh) \right] \right\} \dots \dots \dots (IV. 3) \end{aligned}$$

Solve this equation

$$mh = 1.070733 \dots \dots \dots (IV. 4)$$

Substitute to equation (IV.2)

$$mH = 0.915106 \dots \dots \dots (IV. 5)$$

Here the ratio of critical wave height to the water depth is worked out as follows

$$\frac{H}{h} = \frac{H}{d} = 0.854654 \dots \dots \dots (IV. 5)$$

This value is very agreement with those results obtained by Yamada (1957), Lenou (1966), Byatt-smith (1970), and Longuet-Higgins (1974). Also not any approximate computation is adopted in this section, this number is reliable and correct.

V. ON THE SHAPE OF CRITICAL WAVE

Substitute (II.19) (III.9) and (III.10) to equation (III.12), after complicated algebraical operation, following relationship in critical wave situation can be worked out.

$$mH = \sin [ m ( h + H ) ] \dots \dots \dots (V.1)$$

Now, to find the shape of the crest of critical wave, differentiate the wave profile with respect to x

$$\begin{aligned} \frac{d\eta}{dx} &= m \beta \left\{ \frac{\cos [ m ( h + \eta ) ]}{\cosh (mx) + \cos [ m ( h + \eta ) ]} + \frac{\sin^2 [ m ( h + \eta ) ]}{\{ \cosh (mx) + \cos [ m ( h + \eta ) ] \}^2} \right\} \\ & \quad + \frac{d\eta}{dx} - \frac{m\beta \sinh (mx) \sin [ m ( h + \eta ) ]}{\{ \cosh (mx) + \cos [ m ( h + \eta ) ] \}^2} \dots \dots \dots (V.2) \end{aligned}$$

Substituting equation (II.19) to this equation and simplifying

$$\frac{d\eta}{dx} = \frac{\frac{m\eta^2}{\beta \sin [ m ( h + \eta ) ]} \cdot \sin h ( mx )}{\{ m\eta \cot [ m ( h + \eta ) ] + \frac{m}{\beta} \eta^2 - 1 \}} \dots \dots \dots (V.3)$$

In critical case, x=0, η=H, using the relationship of (V.1)

$$\lim_{x \rightarrow 0} \left( \frac{d\eta}{dx} \right)_{\eta=H_{\text{critical}}} = \frac{0}{0} \dots\dots\dots (V.4)$$

The wave crest of critical wave is a singular point, using L'Hospital's rule and through some complicated operations, then, we obtain

$$\lim_{x \rightarrow 0} \left( \frac{d\eta}{dx} \right)^2 = \frac{mH}{m\beta \left[ \frac{\cos m(h+H)-1}{\sin m(h+H)} \right] + 2mH} = \frac{mH}{mH}$$

Immediately, we have

$$\lim_{x \rightarrow 0} \left( \frac{d\eta}{dx} \right) = \pm 1 \dots\dots\dots (V.5)$$

This means that the critical wave crest is a branch point, the slopes of left and right side are

$$\left( \frac{d\eta}{dx} \right)_{x=0^-} = -1 \quad \left( \frac{d\eta}{dx} \right)_{x=0^+} = +1 \dots\dots\dots (V.6)$$

Consequently, the crest is a summit where two symmetrical curves intersect, the slope angle of both side is 45°, as a result, the angle of the critical wave crest is 90° in stead of 120° stated by Stokes (1880) and identifies with Rankine's theory (1865).

The shape of the wave is illustrated in Fig. 4

Figure 4 The Structure of highest wave

CONCLUSION

The new model submitted in this paper is proved to be applicable to any wavelength and any water depth so it can be nominated to be "universal model".

The ratio of critical wave height to water depth derived from this model is

$$\frac{H}{d} = 0.8546 \dots$$

and the angle of the critical wave crest is  $90^\circ$ .

No approximate calculation is adopted in this theory, the solution is to be called "exact".

## CHAPTER SEVENTY ONE

### COMBINED REFRACTION-DIFFRACTION CALCULATIONS WITH DIRECTIONAL WAVE SPECTRA

P. Gaillard

SOGREAH, Grenoble, France

#### ABSTRACT

A method of calculation of the combined effects of wave refraction, diffraction and reflection in harbours of arbitrary shape and non uniform water depth, subject to periodic or random waves is presented. Examples of application are given and practical aspects on the wave spectrum discretisation are considered.

#### INTRODUCTION

The study of wave disturbance within harbours at the design stage has for many years been considered in terms of harbour response to various isolated unidirectional periodic waves both in laboratory scale models and numerical models. With the increasing application of wave measurement techniques giving information on the directional wave spectrum, a need is now felt to account for the directional spreading of wave energy, as well as for its frequency-wise distribution, in the design of ocean and coastal structures.

Numerical methods applying either refraction calculations (Collins et al [3]) or diffraction calculations in constant water depth (Goda et al [4], Nagai [6]) to directionally distributed random waves have formerly been published. However, methods involving both refraction and diffraction effects are required for engineering studies.

This paper presents a method of calculation of the combined effects of wave diffraction, reflection and refraction in harbours of arbitrary shape and non uniform water depth, which applies equally to periodic waves and random waves, conforming to a given directional wave spectrum.

This method has been applied since 1977 in studies of harbour projects involving periodic waves as offshore boundary conditions. It has recently been extended to account for prescribed irregular wave characteristics at the model boundaries.

## METHOD APPLIED WITH PERIODIC WAVES OR SPECTRAL COMPONENTS

The area investigated at the harbour site is discretised into a set of connected basins with constant water depths, these generally being unequal and conforming to the sea-bed topography. Within each of these domains, the problem is dealt with by a boundary integral element method as described by Barailler and Gaillard [1], Biesel and Ranson [2]. The refraction effects due to the sea-bed configuration are taken into account at the common boundaries between connected basins.

The excitation of the harbour by a periodic incident wave of angular frequency  $\omega$  induces a steady state dynamic response of the same frequency. The water surface elevation  $\zeta$  and the velocity potential  $\phi$  are accordingly expressed in the form:

$$\begin{aligned}\zeta(x,y,t) &= \text{Re} \left\{ \bar{\zeta}(x,y) e^{-i\omega t} \right\} \\ \phi(x,y,z,t) &= \text{Re} \left\{ \bar{\phi}(x,y,z) e^{-i\omega t} \right\}\end{aligned}\quad (1)$$

The unknown complex function  $\bar{\zeta}$  is, within each basin of constant depth  $h$ , a solution of the Helmholtz equation:

$$\nabla^2 \bar{\zeta} + k^2 \bar{\zeta} = 0 \quad (2)$$

with:

$$\omega^2 = gk \tanh kh \quad (3)$$

The function  $\bar{\phi}$  can be derived from  $\bar{\zeta}$  by the formula:

$$\bar{\phi}(x,y,z) = -i \frac{g}{\omega} \bar{\zeta}(x,y) \frac{\cosh k(z+h)}{\cosh kh} \quad (4)$$

The solution of (2) is expressed in the form of the boundary integral:

$$\bar{\zeta}_0 = -\frac{i}{4} \int_{\Gamma} \frac{\partial \bar{\zeta}}{\partial n} G_2(OM) ds \quad (5)$$

where:

$\Gamma$  is the boundary of the basin considered

$\partial/\partial n$  is the normal derivative taken positive inwards

$G_2(OM)$  the second Green's function associated with an arbitrary internal point  $O$  and a boundary point  $M$ , cf. fig. 1a.

$G_2(OM)$  is the solution of (2), which has a vanishing normal derivative along  $\Gamma$  and a logarithmic behaviour in the vicinity of  $O$ . When the domain is a half-plane, this solution is:

$$G_2(OM) = 2 H_0^{(1)}(kr) \quad (6)$$

$$\bar{\zeta}_0 = -\frac{1}{2} \int_{\Gamma} \frac{\partial \bar{\zeta}}{\partial n} H_0^{(1)}(kr) ds \tag{7}$$

where  $H_0^{(1)}$  is the Hankel function of the first kind and order zero. This formula can be applied to an arbitrarily shaped domain D by considering the combination of solutions associated with a discrete set of half-planes including D and bounded by the tangent to different sections of the boundary  $\Gamma$ . The area under investigation has to be subdivided into several basins of convex shape when necessary.

Furthermore, the normal derivative of  $\bar{\zeta}$  involved in (7) should be related exclusively to the waves entering into the basin considered. These waves may include:

- incoming waves with known characteristics, either given as basic data or derived from preliminary refraction calculations between the open sea and the harbour site. The sections of boundary where this occurs are referred to as main entrances;
- waves with unknown characteristics ab initio, which come from other connected basins or which are reflected from harbour structures. The sections of boundary where this occurs are classified as secondary entrances.

Fig. 1: Definition sketch

The method takes into account partial or total reflection from coastal structures and partial transmission when these are permeable or submersible, provided that the relevant coefficients are given. However, energy dissipation by bottom friction or wave breaking at locations other than these structures is not considered.

In the case of a reflective structure, the following boundary condition holds between the reflected (incoming) wave  $\bar{\zeta}_e$  and the incident (outgoing) wave  $\bar{\zeta}_s$ :

$$\bar{\zeta}_e = C_R \bar{\zeta}_s \tag{8}$$

$$\frac{\partial \bar{\zeta}}{\partial n} \bar{e} = - C_R \frac{\partial \bar{\zeta}}{\partial n} \bar{s} \quad (9)$$

$$\left( \frac{\partial \bar{\zeta}}{\partial n} \right)_p = - i \frac{k}{2} \int_{\Gamma} \left( \frac{\partial \bar{\zeta}}{\partial n} \right)_q H_1^{(1)}(kr_{pq}) \cos \Psi_{pq} ds \quad (10)$$

$$\Psi_{pq} = (\vec{n}_p, \vec{M}_p \vec{M}_q)$$

In the case of a permeable or submersible structure, the physical phenomenon can be complex because of the generation of harmonic wave components. As concerns the transmission of the fundamental component, the relationship between the outgoing wave in basin 1 and the incoming wave in basin 2, as shown in the figure 1b, is:

$$\bar{\zeta}_2 = C_T \bar{\zeta}_1 \quad (11)$$

$$\frac{\partial \bar{\zeta}}{\partial n} = - C_T \frac{\partial \bar{\zeta}}{\partial n} \quad \text{if } h_2 = h_1 \quad (12)$$

$$\left( \frac{\partial \bar{\zeta}}{\partial n} \right)_p = - M_{pq} \left( \frac{\partial \bar{\zeta}}{\partial n} \right)_q \quad \text{if } h_2 \neq h_1 \quad (13)$$

$$M_{pq} = \frac{k_2 \cos \Psi_{pq2}}{k_1 \cos \Psi_{pq1}} C_T \quad (14)$$

When the water depths in the adjacent basins are different, the direction of waves originating from a given boundary source,  $M_q$  varies according to Snell's law of refraction:

$$k_1 \sin \Psi_{pq1} = k_2 \sin \Psi_{pq2} \quad (15)$$

There is total reflection on the boundary if:

$$\Psi_{pq1} \geq \Psi_{1L} \quad \Psi_{1L} = \sin^{-1}(k_2/k_1) \quad (16)$$

This is observed for instance when waves propagating towards the shore encounter a navigation channel with an oblique incidence.

The complex parameters  $C_R$  and  $C_T$  have a modulus equal to the reflection or transmission coefficient of the structure and an argument equal to the phase lag introduced by the phenomenon considered. These parameters have to be derived from theoretical analysis or experimental investigations.

If the actual variation of water depth from one basin to another is gradual, i.e. with a sea-bed configuration of very mild slope which does not give rise to any appreciable wave reflection, the law of conservation of energy flux at the common boundary is applied.

$$\left| \bar{\zeta}_1 \right|^2 C_{g1} \cos \Psi_{pq1} = \left| \bar{\zeta}_2 \right|^2 C_{g2} \cos \Psi_{pq2} \quad (17)$$

This leads to the boundary condition (13) with:

$$M_{pq} = \frac{k_2}{k_1} \left[ \frac{C_{g1}}{C_{g2}} \frac{\cos \psi_{pq2}}{\cos \psi_{pq1}} \right]^{1/2} \quad (18)$$

The numerical calculation involves two steps:

- first, the solution of the system of equations resulting from the discretisation of the basin boundaries, the unknowns being the values of the normal derivative  $\partial \bar{\zeta} / \partial n$  in each basin at the centre of the boundary segments located on secondary entrances;
- then, the calculation of  $\bar{\zeta}$  in an arbitrary network of points by means of the discretised form of (7). This provides information on the spatial distribution of the local wave height  $2a$ , wave phase  $\theta$ , and diffraction coefficient  $K_d$  given by:

$$\bar{\zeta} = a e^{i\theta} \quad K_d = a/a_0 \quad (19)$$

where  $2a_0$  is the reference wave height given offshore or in the vicinity of the harbour entrance.

Additional information on the local wave direction  $\alpha$ , defined as the normal to the local constant phase line, and on the effective local wave number  $k_e$  is given by:

$$\frac{\partial \theta}{\partial x} = k_e \cos \alpha = \text{Im} \left\{ \frac{1}{\bar{\zeta}} \frac{\partial \bar{\zeta}}{\partial x} \right\} \quad (20)$$

$$\frac{\partial \theta}{\partial y} = k_e \sin \alpha = \text{Im} \left\{ \frac{1}{\bar{\zeta}} \frac{\partial \bar{\zeta}}{\partial y} \right\}$$

$$\left\{ \frac{\partial \bar{\zeta}}{\partial x}, \frac{\partial \bar{\zeta}}{\partial y} \right\} = -i \frac{k}{2} \int_{\Gamma} \frac{\partial \bar{\zeta}}{\partial n} H_1^{(1)}(kr) \left\{ \cos \mu, \sin \mu \right\} ds \quad (21)$$

$$\mu = (\vec{OX}, \vec{OM})$$

#### METHOD APPLIED WITH RANDOM WAVES

If the wave disturbance to be considered within the harbour results from random waves conforming to a given directional spectrum offshore, this spectrum is discretised into a finite set of directional and frequency-wise components. The harbour response to the excitation by each spectral component is calculated by the procedure described in the preceding section. This calculation gives:

- the diffraction coefficient  $K_d$  as a function of wave frequency  $f$ , initial wave direction  $\alpha_0$  and wave height  $a_0$ ; if the reflection and transmission coefficients of the structures involved in the study are considered as independent of the incident wave height,  $K_d$  will be independent of  $a_0$ , since the method is based on linear theory;

- . the correspondence between the local wave direction  $\alpha$  and the initial direction  $\alpha_o$  of the spectral component.

From these results, it is possible to derive the local directional spectrum and frequency spectrum at any selected point P, by means of the following expressions:

$$S(f, \alpha, P) = S_o(f, \alpha_o) K_p^2 \quad K_p^2 = \frac{C_{go} C_o}{C_{gp} C_p} \quad (22)$$

$$S(f, P) = \int_0^{2\pi} S_o(f, \alpha_o) [K_d(f, \alpha_o, P)]^2 d\alpha_o \quad (23)$$

where:

$S_o(f, \alpha_o)$  is the reference wave spectrum

$C_o, C_{go}$  are respectively the phase and group velocities at the location where the reference wave spectrum is specified

$C_p, C_{gp}$  are the phase and group velocities at point P

$K_d$  and  $K_p$  are theoretically related by:

$$K_d^2 = K_p^2 \frac{\partial \alpha}{\partial \alpha_o} \quad (24)$$

The spatial distribution within the harbour of various overall spectral properties can be derived from the spectral moments:

$$M_j = \int_0^\infty df \int_0^{2\pi} f^j S_o(f, \alpha_o) K_d^2 d\alpha_o \quad (25)$$

$$M_{pq} = \int_0^\infty df \int_0^{2\pi} k^{p+q} \cos^p \alpha \cos^q \alpha S_o(f, \alpha_o) K_d^2 d\alpha_o \quad (26)$$

The following spectral parameters are considered in the applications of the method which are presented here: the significant wave height  $H_s$ , the mean zero-upcrossing wave period  $T_m$ , the mean wave direction  $\theta_m$  and the mean spreading angle  $\theta_s$ , as defined by Goda, Miura and Kato [5]. These parameters are defined by:

$$H_s = 4 \sqrt{M_o} \quad (27)$$

$$T_m = (M_o/M_2)^{1/2} \quad (28)$$

$$\theta_m = \tan^{-1} (M_{o1}/M_{1o}) \quad (29)$$

$$\theta_s = \tan^{-1} \left\{ \frac{\sqrt{M_{o0} (M_{o1}^2 M_{2o} - 2M_{1o} M_{o1} M_{11} + M_{1o}^2 M_{o2})}}{M_{o1}^2 + M_{1o}^2} \right\} \quad (30)$$

The parameters associated with the reference wave spectrum are represented by  $H_{so}, T_{mo}, \theta_{mo}, \theta_{so}$ .

### EXAMPLES OF APPLICATION

Several examples of application of the above method to complex harbour layouts with periodic and random waves are presented here. Besides, practical aspects on the wave spectrum discretisation techniques are considered in the case of a breakwater gap.

#### Comparison with experimental data

Figure 2 shows the results of a comparative study of the wave disturbance within a harbour performed with a numerical model based on the above method and with a laboratory scale model at a scale of 1/150. The water depth ranges approximately between 31 m at the offshore boundary and 6 m in the nearshore zone of the harbour, and 24 diffraction basins were considered in the numerical model.

The results obtained for 12 s periodic waves are shown in the form of curves of constant relative wave-height, the latter being expressed in percentage of the reference wave-height offshore. The local wave direction, calculated by means of (20) (21), is also shown in figure 2b. A similar wave-height distribution is observed in both models.

#### Harbour access channel effect on wave propagation

The second example is an application of the numerical method to the study of the impact of a harbour extension scheme on the wave disturbance in Fos harbour (France). This study, performed at the request of the Marseilles Port Authority, is illustrative of the effect of harbour access channels on wave propagation.

Figure 3 shows the area investigated, the location of the harbour entrance channel being indicated by dashed lines. The results obtained for wave periods of 6 and 8 seconds are shown respectively in figure 3a and b, with the same presentation as in figure 2b. An enlarged view of the wave height and wave direction distributions in the harbour area is shown at the left hand side of the figure. A smaller mesh size of the calculation network has been used for this purpose.

This figure shows a marked effect of the wave period on the wave pattern. The reflection of the incoming waves on the outer side of the harbour access channel is observed with the higher period and this produces a favourable sheltering effect in the harbour area.

#### Wave spectrum discretisation techniques

In order to study the influence of the wave spectrum discretisation technique on the accuracy of results, numerical calculations have been done in the case of a breakwater gap in constant water depth with directional wave spectra representative of wind waves and swell respectively.

(a)

(b)

Fig. 2: Comparison of the wave-height distributions in a harbour obtained respectively with a laboratory scale model (a) and a numerical model (b) for 12 s periodic waves. In the latter model, the local wave direction is indicated by arrows.

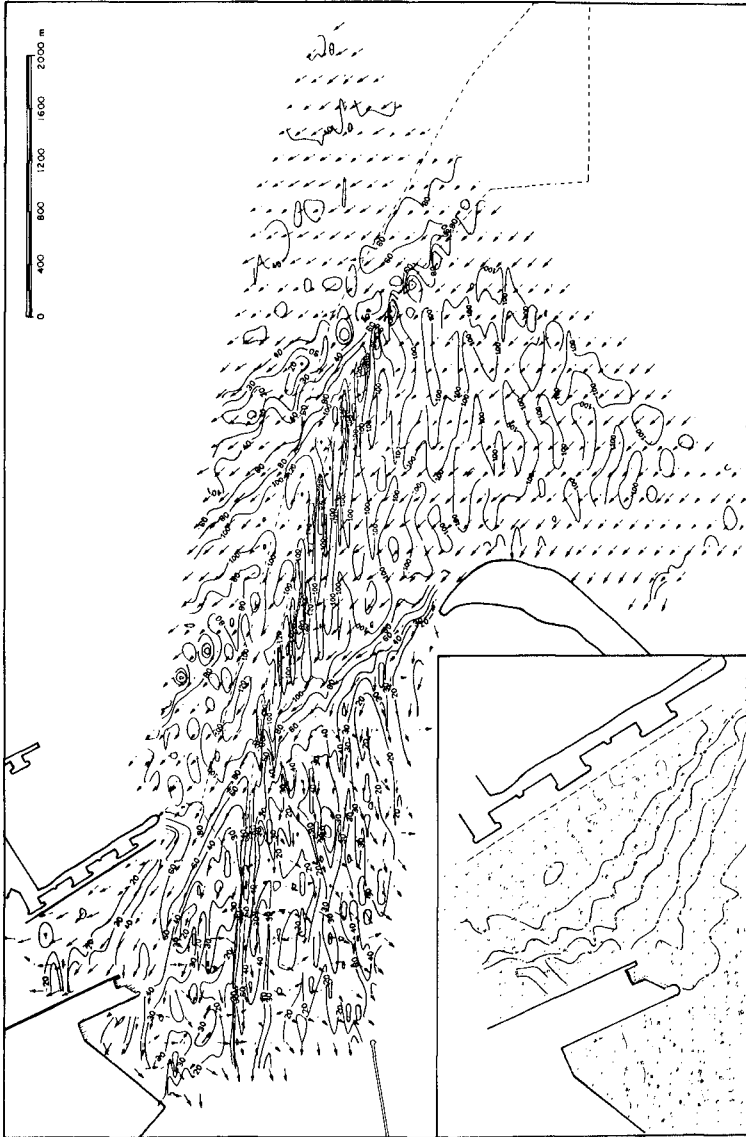

Fig. 3a: Wave-height and wave direction obtained with a numerical model of Fos harbour for waves of period  $T = 6$  s.

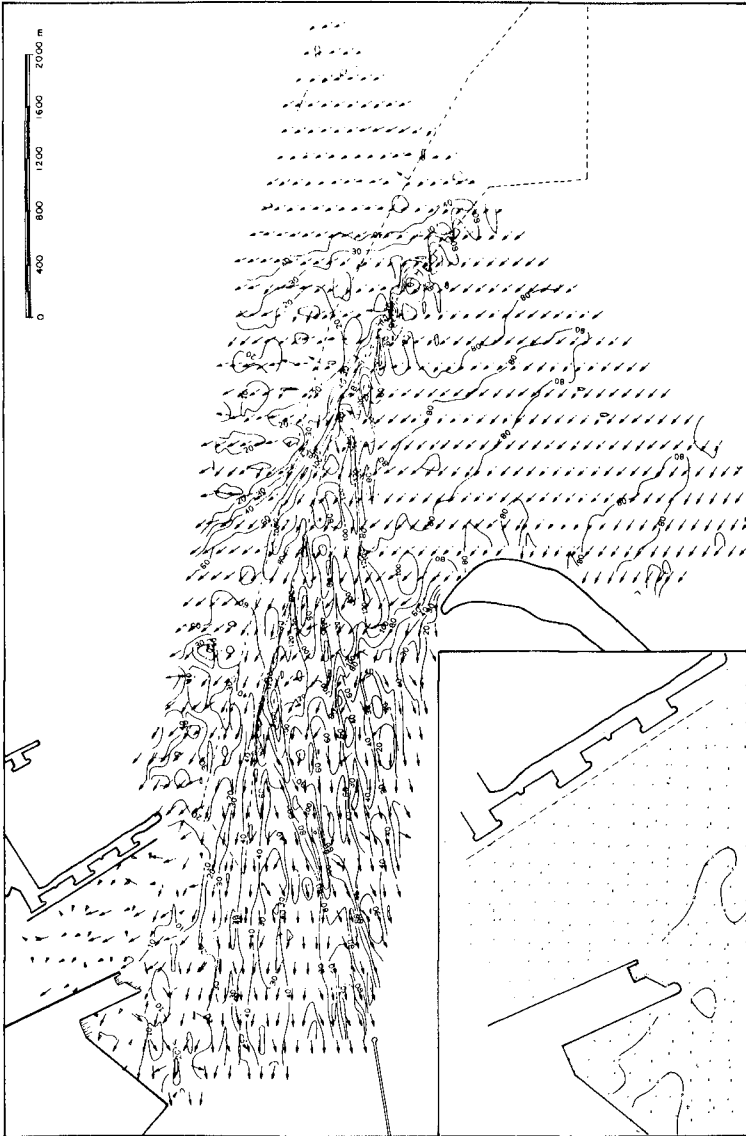

Fig. 3b: Wave-height and wave direction obtained with a numerical model of Fos harbour for waves of period  $T = 8$  s.

The incident wave spectra were chosen of the form proposed by Goda et al [4] :

$$S_o(f, \alpha_o) = \bar{S}_o(f) \cdot D(f, \alpha_o) \quad (31)$$

$$\bar{S}_o(f) = 0.312 H_s^2 T_p^{-4} f^{-5} \exp \left[ -\frac{5}{4} (T_p f)^{-4} \right] \quad (32)$$

$$D(f, \alpha_o) = C \left[ \cos \frac{1}{2} (\alpha_o - \theta_{mo}) \right]^{2s} \quad (33)$$

$$s = \begin{cases} s_{\max} (f/f_p)^5 & f \leq f_p \\ s_{\max} (f/f_p)^{-2.5} & f > f_p \end{cases} \quad (34)$$

where:

$T_p$  and  $f_p$  are the period and frequency of the spectral peak

$C$  is a normalisation constant.

In the example considered, the gap-width to wave length ratio corresponding to the spectral peak is approximately  $B/L_p = 1.81$ .

The results of two of the discretisation techniques implemented are reported here:

- The first one consists in a uniform allocation of wave energy to all frequency bands, this energy being lumped up at frequencies chosen in order to conserve the mean period defined by (28). The angular discretisation is done with a constant interval  $\Delta \alpha_o$  in a range of  $\pm \pi/2$  around the mean direction of the spectrum.
- The second technique is the same in the frequency domain. The angular discretisation is done with a constant interval, but the total range is reduced, the actual energy located beyond this range being allocated to the extreme angular components when this energy is lower than a given threshold value.

Figure 4 shows the distributions of the relative significant wave height  $H/H_{so}$  for the wave spectra corresponding respectively to  $s_{\max} = 10^0$  and 75. The full lines show the wave-height distribution resulting from the first technique with 204 spectral components, distributed in 12 frequency intervals. The dashed lines result from the second technique, which leads to the computation of 70 and 34 spectral components respectively for the broad and narrow spectra, with 6 frequency intervals. A good agreement of the results is found.

As concerns the mean wave direction  $\theta_m$ , indicated by arrows in figure 4, there is no discernible difference between the two techniques.

Figure 5 shows the distribution of the relative mean wave period  $T/T_m$  for the broad spectrum in the form of level curves. The results obtained with the first and second discretisation techniques are shown on the left and right hand sides of the gap centre-line respectively.

(a)

(b)

Fig. 4: Wave-height and wave direction behind a breakwater gap of relative width  $B/L = 1.83$  for random waves with: (a)  $s = 10$  (b)  $s = 75$ . The solid and dashed lines are related to the first and second discretisation techniques.

Fig. 5: Distribution of the mean wave period  $T_m/T_{m0}$  behind the breakwater gap for a directional wave spectrum with  $s = 10$ . See also legend of fig. 6.

Fig. 6: Distribution of the mean spreading angle  $\theta/\theta_0$  for the same wave spectrum. LHS and RHS show the results of the first and second discretisation techniques (204 and 70 spectral components respectively).

Figure 6 shows the distribution of the ratio  $\theta_s/\theta_{s_0}$  for the same case with a similar presentation.

Differences due to the discretisation technique are more pronounced with the mean wave period and the mean spreading angle than with the significant wave height distribution, although the results are of the same order of magnitude. This sensitivity to discretisation is connected with the presence of higher moments of the wave spectrum in the expressions used for calculating these parameters.

#### Study of a complex harbour layout with random waves

Figures 7 and 8 give an example of study of the wave disturbance in a harbour of complex shape with random wave characteristics given as boundary conditions. In this case, the reference frequency spectrum is of the Jonswap type and the angular dispersion function is of the form (33) (34) with  $s_{\max} = 50$ . This relatively narrow spectrum is discretised into 39 spectral components, distributed over 5 frequency bands, by the second technique just described.

Figure 7a shows the spatial distribution of the diffraction coefficient  $K_d$  associated with one of the spectral components considered, in the form of curves of constant  $K_d$  values. The local wave direction associated with this period is indicated by arrows.

Figure 7b shows the distribution of the relative significant wave height  $H/H_{s_0}$  in the form of level curves and arrows indicate the local mean wave direction defined by equation (29).

Figure 8a shows the distribution of the relative mean wave period  $T_m/T_{m_0}$ , as defined by equation (28) and figure 8b the distribution of the relative mean spreading angle  $\theta_s/\theta_{s_0}$ , defined by equation (30). In this particular case, the wave reflection on the harbour structures tends to increase the angular spread of the locally observed wave spectrum and this effect predominates over the adverse effect of wave diffraction in many parts of the harbour.

#### CONCLUSION

The method described provides an interesting means of evaluation of wave disturbance in harbour projects, in terms of wave spectral properties. The numerical calculations confirm the conclusion of other authors that the directional spreading of wave spectra is an important characteristic to account for in such studies, if sufficient information is available on the local wave climate.

The second wave spectrum discretisation technique presented here is recommended for selecting the spectral components to account for in the calculations. The number of components needed depends on the type of input wave spectrum and on the wave parameters required.

Fig. 7: Spatial distribution of: (a) coefficient  $K_d$  and wave direction  $\alpha$  for one spectral component, (b) significant wave height  $H_s/H_{s0}$  and mean wave direction  $\theta_m$  in a harbour of complex shape.

Fig. 8: Spatial distribution of (a) mean wave period  $T_m/T_{m0}$ , (b) mean dispersion angle  $\theta_s/\theta_{s0}$  in the harbour of figure 7.

The sensitivity analysis performed shows that the significant wave-height and mean wave direction are much less sensitive to the spectrum discretisation than the mean wave period and the mean spreading angle.

In practical applications, a careful choice of the reference directional wave spectrum is necessary, because of the marked influence of the angular distribution of energy on the wave pattern in sheltered areas and on the computer time required for these calculations.

## CHAPTER SEVENTY TWO

### A NUMERICAL SOLUTION OF BOUSSINESQ TYPE WAVE EQUATIONS

H. SCHAPER

W. ZIELKE

Institut of Fluid Mechanics  
University of Hannover  
Fed. Republic of Germany

#### 1. INTRODUCTION

Numerical models of short waves in shallow water, which are of particular interest for the calculation of the wave climate in harbours and coastal areas, have been presented by Abbott et al. (1978) and by Hauguel (1980). These models are based on the solution of the Boussinesq or Serre type equations. A recent discussion of the range of application for the equations has been presented by McCowan (1982).

Nevertheless, there is some uncertainty as to which terms in the differential equations are of importance, and how they are to be approximated. Therefore, no final judgement can presently be made on the accuracy and credibility of the solutions. Research on such models is still in progress and is of high theoretical and practical interest.

Some of the aspects of current research relate to the handling of nonlinear terms, the non-reflecting boundary conditions and the transfer capability of the models for spectral input. This paper will reflect on these points.

## 2. BASIC EQUATIONS

For simplicity, we will restrict ourselves to the one-dimensional case, for which the Boussinesq type equations read

$$(1) \quad \frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left( \frac{p^2}{h} \right) + g h \frac{\partial \zeta}{\partial x} = \frac{D}{2} \frac{h}{\partial x^2} \frac{\partial^3}{\partial t} \left( \frac{dp}{h} \right) - \frac{D^2 h}{6} \frac{\partial^3}{\partial x^2 \partial t} \left( \frac{p}{h} \right)$$

$$(2) \quad \frac{\partial \zeta}{\partial t} + \frac{\partial p}{\partial x} = 0$$

with  $D$  = mean water depth,  $\zeta$  = surface elevation,  $h = D + \zeta$   
 $p$  = flux per unit width,  $g$  = acceleration due to gravity.

For the actual calculation with a finite difference method, the third order terms on the right hand side of (1) have to be rewritten such that each term contains only derivatives of either  $p$  or  $\zeta$ . Two third order terms remain, as well as some 15 other terms with products of first and second order derivatives:

$$(1') \quad \dots = \frac{D^2}{3} \frac{\partial^3 p}{\partial x^2 \partial t} - \frac{D^2}{3} \frac{p}{h} \frac{\partial^3 \zeta}{\partial x^2 \partial t} + \text{product terms}$$

We assume that the product terms are small in comparison to the third order terms (Abbott et al., 1978). Equations (1') and (2) can be collected in matrix form

$$(3) \quad \frac{\partial w}{\partial t} + A \frac{\partial w}{\partial x} + B \frac{\partial^3 w}{\partial x^2 \partial t} = R$$

with

$$w = \begin{bmatrix} p \\ \zeta \end{bmatrix} \quad A = \begin{bmatrix} \frac{2p}{h} & gh - \frac{p^2}{h^2} \\ 1 & 0 \end{bmatrix} \quad B = \begin{bmatrix} -\frac{D^2}{3} & \frac{D^2 p}{3h} \\ 0 & 0 \end{bmatrix} \quad R = \begin{bmatrix} \frac{D^2}{h^2} D, x \\ 0 \end{bmatrix}$$

## 3. NUMERICAL APPROXIMATION

In order to implement the third order terms of (3), a two level scheme with central differences is used, the difference star being given in Fig. 1. The finite difference approximations of the partial derivatives are given by equations (4.a) - (4.c).

Fig. 1

$$(4.a) \quad \left. \frac{\partial w}{\partial t} \right|_i^{n+1/2} = \frac{w_i^{n+1} - w_i^n}{\Delta t} - \frac{\Delta t^2}{24} \frac{\partial^3 w}{\partial t^3} + O(\Delta^3)$$

$$(4.b) \quad \left. \frac{\partial w}{\partial x} \right|_i^{n+1/2} = \frac{w_{i+1}^{n+1} - w_{i-1}^{n+1} + w_{i+1}^n - w_{i-1}^n}{4\Delta x} - \frac{\Delta t^2}{8} \frac{\partial^3 w}{\partial x \partial t^2} - \frac{\Delta x^2}{6} \frac{\partial^3 w}{\partial x^3} + O(\Delta^3)$$

$$(4.c) \quad \left. \frac{\partial^3 w}{\partial x^2 \partial t} \right|_i^{n+1/2} = \frac{(w_{i+1}^{n+1} - 2w_i^{n+1} + w_{i-1}^{n+1}) - (w_{i+1}^n - 2w_i^n + w_{i-1}^n)}{\Delta x^2 \Delta t} + O(\Delta^3)$$

The third order correction terms are detected by Taylor series expansion of the used grid points.

At the boundary nodes 0 and N one sided difference stars have to be used and one coefficient of the correction terms is changed

$$(4.d) \quad \left. \frac{\partial w}{\partial x} \right|_0^{n+1/2} = \frac{(-3w_0 + 4w_1 + w_2)^{n+1} + (-3w_0 + 4w_1 - w_2)^n}{4\Delta x} - \frac{\Delta t^2}{8} \frac{\partial^3 w}{\partial x \partial t^2} + \frac{\Delta x^2}{3} \frac{\partial^3 w}{\partial x^3} + O(\Delta^3)$$

$$(4.e) \quad \left. \frac{\partial w}{\partial x} \right|_N^{n+1/2} = \frac{(w_{N-2} - 4w_{N-1} + 3w_N)^{n+1} + (w_{N-2} - 4w_{N-1} + 3w_N)^n}{4\Delta x} - \frac{\Delta t^2}{8} \frac{\partial^3 w}{\partial x \partial t^2} + \frac{\Delta x^2}{3} \frac{\partial^3 w}{\partial x^3} + O(\Delta^3)$$

Clearly all the correction terms cannot be approximated with the used 6-point star, because only a derivative of the kind  $\partial^3/\partial x^2 \partial t$  is possible. So the correction terms needed to be transformed into this form. As pointed out in literature (Peregrine, 1967, Abbott et al., 1978) the linearised equations (5) can be used and the transformations are given in (5.a) - (5.c).

$$(5) \quad \frac{\partial w}{\partial t} + L \frac{\partial w}{\partial x} = 0 \quad \text{with} \quad L = \begin{bmatrix} 0 & gD \\ 1 & 0 \end{bmatrix}$$

$$(5.a) \quad \frac{\partial^3 w}{\partial t^3} = L^2 \frac{\partial^3 w}{\partial x^2 \partial t}$$

$$(5.b) \quad \frac{\partial^3 w}{\partial t^2 \partial x} = -L \frac{\partial^3 w}{\partial x^2 \partial t}$$

$$(5.c) \quad \frac{\partial^3 w}{\partial x^3} = -L^{-1} \frac{\partial^3 w}{\partial x^2 \partial t}$$

Substitution of the finite difference approximations into equation (3) leads to

$$(6) \quad w_{,t} - \frac{\Delta t^2}{24} L^2 w_{,xxt} + A w_{,x} + \frac{\Delta t^2}{8} \underbrace{A L}_{L^2} w_{,xxt} + \frac{\Delta t^2}{6} \underbrace{A L^{-1}}_I w_{,xxt} + B w_{,xxt} = R$$

The product  $AL^{-1}$  can be replaced by the unit matrix, because  $L$  is the linearised form of  $A$ . The product  $AL$  is linearised to  $L^2$ , and all third order terms can be collected in matrix  $C$ .

$$(7) \quad w_{,t} + A w_{,x} + \underbrace{\left( B + \frac{\Delta x^2}{12} L^2 + \frac{\Delta x^2}{6} I \right)}_C w_{,xxt} = R$$

Now equation (7) can be rearranged with respect to the used grid points

$$(8) \quad \left[ -\frac{\Delta t}{4\Delta x}A + \frac{1}{\Delta x^2}C \right] w_{i-1}^{n+1} + \left[ I - \frac{2}{\Delta x^2}C \right] w_i^{n+1} + \left[ \frac{\Delta t}{4\Delta x}A + \frac{1}{\Delta x^2}C \right] w_{i+1}^{n+1}$$

$$= \left[ \frac{\Delta t}{4\Delta x}A + \frac{1}{\Delta x^2}C \right] w_{i-1}^n + \left[ I - \frac{2}{\Delta x^2}C \right] w_i^n + \left[ -\frac{\Delta t}{4\Delta x}A + \frac{1}{\Delta x^2}C \right] w_{i+1}^n + \Delta t R$$

and the coefficients of the unknowns can be collected in the matrices D, E, F, while the right hand side of (8) is collected in the vector G.

$$(9) \quad D_i w_{i-1}^{n+1} + E_i w_i^{n+1} + F_i w_{i+1}^{n+1} = G_i$$

Equation (9) is applied to all internal grid points 1...N-1. Similar equations can be performed for the boundary nodes 0 and N.

Neglecting the nonlinearity and the implementation of boundary conditions, which are described in detail later, a linear equation system of the following form arises.

$$\begin{bmatrix} D_0 & E_0 & F_0 & & & & & & & & \\ D_1 & E_1 & F_1 & & & & & & & & \\ & D_2 & E_2 & F_2 & & & & & & & \\ & & D_3 & E_3 & F_3 & & & & & & \\ & & & & & & & & & & \\ & & & & & & & & & & \\ & & & & & & D_{N-1} & E_{N-1} & F_{N-1} & & \\ & & & & & & D_N & E_N & F_N & & \end{bmatrix} * \begin{bmatrix} w_0 \\ w_1 \\ w_2 \\ w_3 \\ \vdots \\ \vdots \\ w_{N-1} \\ w_N \end{bmatrix} = \begin{bmatrix} G_0 \\ G_1 \\ G_2 \\ G_3 \\ \vdots \\ \vdots \\ G_{N-1} \\ G_N \end{bmatrix}$$

This system is solved very efficiently by a double sweep algorithm, taking into account the matrices  $F_0$  and  $D_N$ .

## 4. NONLINEAR TERMS

The differential equations are solved in the points  $*(i, n+1/2)$ . The matrices A and B, therefore, have to be evaluated at the time level  $n+1/2$ . A linearization by using the time level  $n$  can only be accepted, when calculating sufficiently long and shallow waves. The unknown values of  $W^{n+1/2}$ , arising in A and B, can be calculated explicitly from a Taylor series expansion

$$(10) \quad w_i^{n+1/2} = w_i^n + \frac{\Delta t}{2} \left( A \frac{\partial w}{\partial x} + B \frac{\partial^3 w}{\partial x^2 \partial t} - R \right) + \frac{\Delta t^2}{8} \frac{\partial^2 w}{\partial t^2} + \dots$$

by substitution of the differential equations (3) for  $\partial w / \partial t$ .

Some remarks should be made to this point:

- the third order terms of (3) are negligible, because of less influence;
- the second order term in (10) can also be neglected
- the convective parts of the first order terms of (3) cannot be neglected, especially in the calculation of high waves.

## 5. BOUNDARY CONDITIONS

It is of great interest for the practical application of numerical wave models, to introduce the waves at the boundary of the model using a time serie of the water elevation.

Such a condition is introduced by substitution of

$$(11) \quad \zeta_0 = f(t)$$

for either the momentum or the continuity equation at the node 0.

In this case, for example, the coefficient matrices will take the following form, where the coefficients of the remaining original equation are denoted by  $x$

$$\begin{matrix} \begin{bmatrix} x & x \\ 0 & 1 \end{bmatrix} w_0^{n+1} & + & \begin{bmatrix} x & x \\ 0 & 0 \end{bmatrix} w_1^{n+1} & + & \begin{bmatrix} x & x \\ 0 & 0 \end{bmatrix} w_2^{n+1} & = & \begin{bmatrix} x \\ f \end{bmatrix}^{n+1} \\ D_0 & & E_0 & & F_0 & & G_0 \end{matrix}$$

In the same way, a condition of total reflection may be introduced at the node N, which means

$$(12) \quad p_N = 0$$

$$\begin{matrix} \begin{bmatrix} 0 & 0 \\ x & x \end{bmatrix} w_{N-2}^{n+1} & + & \begin{bmatrix} 0 & 0 \\ x & x \end{bmatrix} w_{N-1}^{n+1} & + & \begin{bmatrix} 1 & 0 \\ x & x \end{bmatrix} w_N^{n+1} & = & \begin{bmatrix} 0 \\ x \end{bmatrix} \\ D_N & & E_N & & F_N & & G_N \end{matrix}$$

If waves are reflected from within the domain, non reflecting boundary conditions have to be used, which allow waves to leave the domain undisturbed. In this case, we use the equation given by Hanguel (1980), which he adopted from long wave theory.

$$(13) \quad p_n - c \zeta = -2c f(t)$$

with  $p_n$  flux normal to the boundary,  $\zeta$  water elevation,  $c$  wave celerity,  $f(t)$  water elevation of the incoming wave

Equation (13) may be slightly changed for simulation of partial reflection, occurring at breakwaters, for example. Naturally  $f(t)$  is equal to zero in this case, and with a reflection coefficient  $\gamma$  we get:

$$(14) \quad p_n - (1-\gamma) c \zeta = 0$$

Both conditions (13) and (14) are as well easily introduced as (11) and (12).

6. NUMERICAL RESULTS

Regular as well as irregular waves may be input, using the time function  $f(t)$ . For test calculations waves of permanent form, cnoidal waves, as well as their limiting case, solitary waves, are of particular interest.

Figures 2 and 3 show calculations of solitary waves where the coefficients are based only on the old time level  $n$ . As shown in Fig.2 for waves with an amplitude of 1 m, the errors due to the nonlinearity may be suppressed by using a very small time step (Fig. 2b). This was not possible for 2 m waves (Fig. 3).

The advantage of determining the coefficients from the time level  $n + 1/2$  (equation (10)) is shown in Fig. 4, for the case of 2 m waves and a time step of 0,625 sec.

Fig. 4

Fig. 5 shows calculations for a solitary wave of limited height. Again it should be noted, that the wave is fed into the system using a time function for the water elevation only.

Fig. 5

The behavior of the non-reflecting boundary conditions is shown in Fig. 6. In case (a) the reflection coefficient is zero and the wave leaves through the right boundary, located at  $x = 300$  m. In case (b) where  $\gamma$  is equal to one, the wave is totally reflected at the boundary and leaves the solution domain through the left boundary. In case (c) the reflection coefficient is 0,7 and the wave is partially reflected.

Fig. 6 c

Figure 7 shows the transformation of a solitary wave into several waves, due to its passing over a sloped bottom onto a shelf. These results are in good agreement with those of Hauguel (1980).

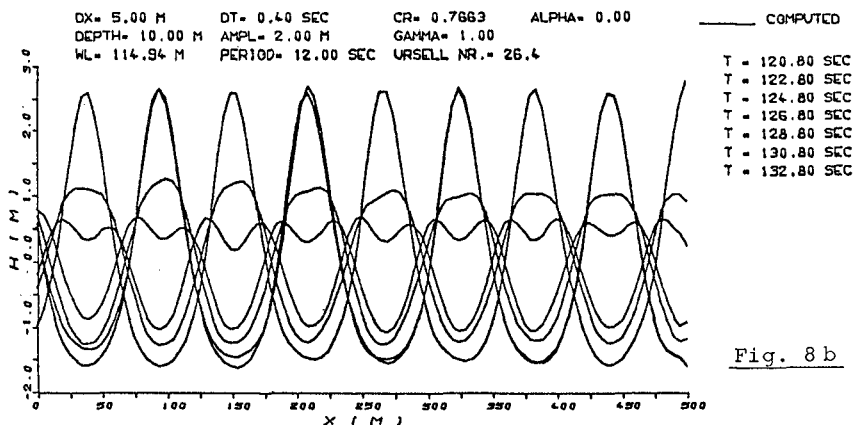

Fig. 7

Figures 8 a, b show the calculation of a cnoidal wave with a wave height of 2 m and a period of 12 sec. The water depth was held constant at 10 m.

Case (a), with a zero reflection coefficient, is again a test for the radiation condition at the right boundary.

In case (b), with total reflection, a standing wave results with a wave height of 4.30 m. The period of 12 sec and the wave length of 115 m remain unchanged. This example is a severe test of the left boundary condition.

One of the attractive features of a Boussinesq type wave model is the ability to calculate nonlinear irregular waves.

The transformation of a Jonswap spectrum into a time series is used as input to the numerical model (Fig. 9 a, c). The wave length at the peak frequency was approximately 50 m and the shortest components less than 30 m. The water depth was held constant at 10 m. Figure 9 b shows the water elevations at  $x = 200$  m and Figure 9 d the spectra, calculated with Fast Fourier Transformation.

The dotted lines in Figs. 9 a, b are obtained analytically from a superposition of the single frequency components. One can observe that some interaction between frequencies occurs in the numerical model. The results can be better understood, however, if one considers the frequency domain, which includes lower frequencies (Fig. 9 c). Only a comparison with experimental data can verify, whether these frequencies are physically meaningful. Experiments to obtain such data are planned for the near future.

The last test illustrates the essential differences between the results of a Boussinesq type wave equation and a shallow water wave equation. Fig.10 shows, that a hydraulic surge, under certain conditions, is transformed into a moving undular hydraulic jump.

These undulations are a result of the vertical accelerations included in Boussinesq type wave equations. Shallow water wave equations, which neglect vertical accelerations, would produce only a step in the water elevation, as indicated by the dotted line in Fig.10.

The frequencies, as well as the amplitudes of the undulations, are in good agreement with experimental results given by Favre (1935).

Fig. 10

## 7. CONCLUSIONS

Numerical solutions of Boussinesq type wave equations provide a powerful tool for the prediction of short waves in shallow water. They cover a wide range, including intermediate depth conditions and wave heights just before breaking.

Solitary and cnoidal waves, as well as irregular waves have been calculated. The necessary boundary conditions, such as total reflection, partial reflection and non-reflection have been successfully incorporated in the model.

The results presented in this paper are limited to the one dimensional case. Fig. 11 shows a result of the two dimensional version, currently under investigation.

## CHAPTER SEVENTY THREE

### INTERACTION OF NON-UNIFORM CURRENTS AND SURFACE WAVES

By Nabil M. Ismail, A. M. ASCE\*

#### ABSTRACT

Modifications of surface gravity waves and opposing nonuniform currents due to their interaction in coastal waters were experimentally and theoretically investigated. The flow field is modelled as a steady turbulent jet heads directly into the surface waves. Experimental results show that the net waves momentum flux is decreased as waves propagate into the jet which gives rise to mean water set-up towards the jet source. Opposing waves increase the spreading rate of the jet and causes vertical upwelling of the mean flow, near the bottom, towards the free surface. Theoretical predictions of the increase of the jet spreading rate and wave set-up agree with the experimental data. Wave-current interaction modifies significantly waves bottom flow pattern by focusing ambient nearshore waters on the jet outlet.

#### INTRODUCTION

Over a large portion of the world's oceans and seas, the spatial distribution of surface currents generated by winds, tides and ocean circulation is so great that an understanding of wave propagation on currents is very important. An example of these nearshore ocean processes is the interaction of surface waves, propagating towards the coast, with tidal flows out of bays, river flows, and cooling water discharges from power plants. Currents in coastal waters influence wave propagation significantly due to the strong current shear and in turn the waves modify the current. These wave and current modifications play an integral role in defining the near shore dynamic characteristics. In addition, the modifications have important implications in regard to prediction of coastal sediment transport, and mixing of materials dispersed into the surf zone. Furthermore, knowledge of changes of mean water level due to wave-current interaction is necessary for numerous engineering endeavors.

The present study is directly related to the interaction of waves coming from offshore and tidal flows out of bays. There has been very limited experimental work reported in the literature on the interaction of non-uniform currents with surface gravity waves which necessitates performing of a detailed experimental study on the subject.

\*Sr. Engr., Pipeline & Production Technology Division, Bechtel Petroleum, Inc., San Francisco, Calif.

The main purpose of this study is to explore experimentally and theoretically modifications of waves and non-uniform currents due to their interaction in coastal waters. The experiments were carried out for the more general of a steady turbulent jet heads directly into the surface waves. Experiments were limited to those cases for which the wave's particle oscillatory velocities are much larger than turbulent velocity fluctuations associated with the jet flow. Experimental measurements of velocity were made primarily along the longitudinal axis of the jet. The theoretical analysis and experimental work performed in this investigation were directed towards achieving the following objectives:

- o To determine experimentally modifications of the surface gravity waves; specifically, wave amplitudes and wave oscillatory water particle velocities
- o To determine experimentally and theoretically the modifications of the non-uniform flow (jet); specifically the distribution of the mean flow velocity profile over the water column, the change in the spreading rate of the turbulent jet, and mean water level
- o To assess, using a photographic system, the modifications of the bottom flow pattern resulting from either the waves forward mass transport or the jet bottom entrainment due to the interaction of one (waves or jet) with each other (jet or waves)

#### THEORETICAL BACKGROUND

The effect of large-scale fluid motion on wave propagation has been the subject of a number of relatively recent studies. The dynamics of these wave trains can be expressed in terms of the "wave action conservation principle" established by Bretherton and Garrett (2). It is given by

$$\frac{\partial}{\partial t} \left( \frac{E}{\omega_r} \right) + \nabla \cdot [(\vec{U} + \vec{C}_g) \frac{E}{\omega_r}] = 0 \quad \dots(1)$$

where  $\vec{U}$  is the nonuniform current velocity,  $\vec{C}_g$  is the vector wave group velocity,  $E$  is the wave energy density, and  $\omega_r$  is the waves intrinsic frequency.

Longuet-Higgins and Stewart (10) investigated two special cases of the general case considered by Bretherton and Garrett (2) using a perturbation expansion form for the solution. The first case is when the nonuniform current velocity  $\vec{U}$  in the direction of wave propagation and the horizontal variation of  $\vec{U}$  is compensated for by vertical upwelling from below. The second case is when the horizontal variation in  $\vec{U}$  is compensated for by a small horizontal inflow from the sides. The results of their work were a crucial advance in the theory of wave-current interaction.

Among the theoretical approaches followed is one which is a direct integration of the equations of motion with respect to the water depth and averaging over the phase of the fluctuating motion [Phillips (11)].

Crapper (3) considered the interaction of nonlinear deep water gravity waves and a steady nonuniform current, using the average Lagrangian method due to Whitham (12). His theoretical results showed that the rate of amplification of large waves is less than that of the essentially linear theory of Longuet-Higgins and Stewart (10).

Determining the back interaction of the wave field on the current mean flow is fraught with little difficulties. Hasselmann (5) and Garrett (4) emphasized that Phillips' approach yields the force exerted by the waves on the complete flow, consisting of the mean flow plus the wave field. Part of this force causes a change in the wave momentum rather than the momentum of the mean flow. Therefore, the rate of change of the wave momentum should be subtracted from the total force, in order to obtain the net force exerted by the waves on only the current flow. However for the purpose of analysis of the experimental results obtained in this study, a momentum balance of the complete flow is appropriate for the theoretical representation of the flow field.

#### Parameters Scaling

For the case of surface gravity waves propagating on a steady nonuniform flow, it is natural to consider the ratios of the independent parameters of the waves to those of the turbulent jet. Take  $L$ ,  $b$  the longitudinal and transverse distances, and  $U_*$ , the longitudinal surface velocity at  $y = b$ , as the characteristic lengths and velocity scales of the turbulent jet (Fig. 1). Take  $L$ , the wave length, and  $C$ , the wave phase speed as the characteristic length and velocity scales of the waves. These scales lead to non-dimensional group [Ismail (6)]

$$G = \frac{b}{L} \frac{L\sqrt{g\pi/L}}{U_*} = \frac{b}{L} \frac{C}{U_*} = \frac{r}{L} \quad \dots(2)$$

This group corresponds to the ratio of the radius of curvature,  $r$ , of the wave rays due to the refraction by the vorticity of the horizontal shear flow  $\xi$ , to the incident wave length  $L$ . The ranges of wave and current independent variables employed in the experiments were selected in a manner to keep the value of the parameter  $G$  larger than one. This restriction was done to focus on the direct dynamical aspects of interaction between the waves and the current.

Taking  $\alpha$  as number characterizing the ratio of the wave velocity fluctuation  $\tilde{u}_*$  to the jet characteristic surface mean velocity  $U_*$

$$\tilde{u}_* = \alpha U_* \quad \dots(3)$$

FIG. 1 Definition Sketch

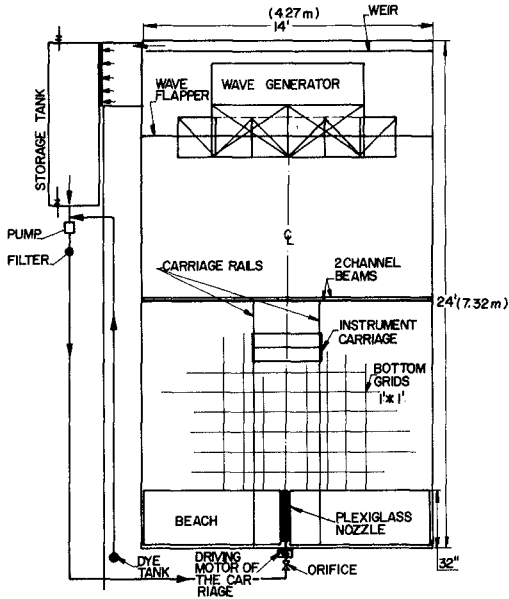

FIG. 2 Plan View of the Experimental Arrangements

For the case of waves propagating on currents in coastal waters,  $\alpha$  is roughly of the order 0.5-1.0.

Taking  $\beta$  as a number characterizing the ratio of the velocity scales of the turbulent fluctuations and the time mean longitudinal surface velocities can be written as

$$u'_* = (\overline{u'_i u'_i})^{1/2} = \beta U_* \quad \dots(4)$$

in which  $U_*$  is defined as  $U$  at  $y = b$ . On a spatial average,  $\beta$  is roughly of the order of 0.25.

Taking  $\epsilon$  as a number characterizing the relative water depth  $kh$  where  $k$  is the surface wave number and  $h$  is the water depth. Wave and current parameters are assumed to be uniformly distributed over the water depth for the range of the parameter  $\epsilon \approx 0.5-1.0$  considered in this analysis.

#### Momentum Balance of the Wave Current Flow

The equation describing the momentum balance of the complete flow follows that of Phillips (11), except we will be including the bottom shear stresses into the momentum considerations. Further, we expand the time mean horizontal velocity of the complete flow  $\bar{u}_i$  into the time average of the mass flux due to the current  $U_i$  and the wave mass transport velocity  $U_{mi}$  into the momentum balance for steady or quasi-steady complete flow to yield (9).

$$\begin{aligned} \frac{\partial}{\partial x_j} \int_{-h}^{\bar{\eta}} \rho U_i U_j dz &= -\rho g(\bar{\eta} + h) \frac{\partial \bar{\eta}}{\partial x_j} - \frac{\partial}{\partial x_j} S_{ij} - \\ &\frac{\partial}{\partial x_j} \int_{-h}^{\bar{\eta}} \rho (U_i U_{mj} + U_j U_{mi}) dz - \frac{\partial}{\partial x_j} \int_{-h}^{\bar{\eta}} \rho \overline{U'_i U'_j} dz + \bar{\tau}_j^B \dots(5) \end{aligned}$$

where the subscripts  $i$  and  $j$  refer to horizontal components of parameters. The terms of the right hand side of Eq. (5) represent parameters which could exert a force by the wave on the complete flow. These forces which contribute to the divergence of the current flow momentum  $\rho U_i U_j$  are respectively, the horizontal force due to the slope of the mean surface water level  $\bar{\eta}$ , the spatial gradients of the wave radiation stress  $S_{ij}$ , the convective momentum flux  $\rho U_i U_{mj}$ ;  $\rho U_j U_{mi}$  and the turbulent momentum flux  $\rho \overline{U'_i U'_j}$ . The last term,  $\bar{\tau}_j^B$ , represents the bottom shear stress.

Expressing each term of Eq. (5) in the scales introduced earlier one can approximate the momentum balance of the complete flow and partition it into separate mean flow and wave momentum balances. For the mean water level  $\bar{\eta}$ , one can argue that it is the sum of a wave

contribution  $\bar{\eta}_w$  and of a jet mean flow contribution  $\bar{\eta}_c$ . The approximate x-components of the momentum balance are as follows.

#### Mean flow momentum

$$\frac{\partial}{\partial x} \rho \bar{u}^{-2} + \frac{\partial}{\partial y} \rho \bar{u} \bar{v} = -\rho g \frac{\partial \bar{\eta}_c}{\partial x} - \frac{\partial}{\partial y} \rho \bar{u} \bar{v} - \frac{\partial}{\partial y} \rho \overline{u'v'} + \frac{1}{2} \rho \bar{f} u^{-2} \quad \dots(6)$$

The above equation, which governs the mean flow momentum in the stream wise direction, appears similar to the classical x-momentum equation for nonbuoyant jets in shallow water. However, there is a distinction which is manifested by the appearance of the second term on the r.h.s. of the equation. This term, which is due to wave refraction, represents the dominant force on the longitudinal momentum of the jet mean flow.

#### Wave momentum flux

$$\rho g \frac{\partial \bar{\eta}_w}{\partial x} + \frac{\partial}{\partial x} \rho (\bar{u}^2 - \bar{w}^2) + \rho g \frac{\partial}{\partial x} \frac{\bar{\eta}^2}{\bar{\eta} + h} = 0 \quad \dots(7)$$

In the above equation, the force due to the slope of the free surface  $\bar{\eta}_w$  would balance the difference between the two longitudinal gradients of the variance of the free surface and the isotropic waves momentum flux.

#### Jet spreading rate

The change of the spreading rate of the turbulent mean flow is determined by extending the scale analysis to the y-momentum equation to seek a relation between forces causing the spreading and the mean flow inertial terms (9). The increase of the spreading rate of the jet due to opposing waves is given by

$$\left(\frac{dB'}{dx}\right)_e = \frac{\frac{1}{2} \rho a_0^2 g / (C_0 - U_e) \cdot U_e}{0.122 \rho U_e^2 W_0} \quad \dots(8)$$

The numerator of the above expression can be thought of as the momentum action of the wave flow field on the jet flow, and is represented by the waves momentum density  $\frac{1}{2} \rho a_0^2 g / (C_0 - U_e)$  times the convection jet flow velocity  $U_e$ . The denominator of this expression is proportional to the initial jet momentum flux (at the efflux point).

#### EXPERIMENTAL STUDY

The ranges of the undisturbed design parameters  $a_0/L_0$ ,  $h_0/L_0$ ,  $W_0/L_0$ ,  $x/W_0$ , and  $U_e/C_0$  were selected in a manner such that the secondary circulation flow of the jet and due to the waves do not cause the deflection of the jet, and the turbulent intensities are smaller than the values of the wave-induced particle velocities. According to the scale analysis performed in the last

section, and also to the pilot experiments which were carried in the wave tank the ranges of the design parameters to be used were determined. These ranges are shown in Table 1.

TABLE 1. RANGE OF WAVE-CURRENT PARAMETERS

Experimental Design	Parameter (still water)	Range
wave amplitude/wave length:	$a_0/L_0$	0.0025-0.02
wave length/water depth:	$L_0/h_0$	4-12
nozzle width/wave length:	$W_0/L_0$	0.10-0.03
jet efflux velocity/wave phase speed:	$U_e/C_0$	0.07-0.10
longitudinal distance/nozzle width:	$X/W_0$	0-80

#### Experimental Arrangements

The series of laboratory experiments which were performed in this study used an idealized model in which a steady turbulent jet heads directly into surface waves. The water depth was kept constant (0.114 m). The location and orientation of the mechanical wave generator, the beach (with a slope of 1:7) and the alignment of the discharge nozzle were the same for all of the experiments. An overall plan view of the experimental arrangement is given in Fig 2.

The turbulent jet was generated by pumping water from the reservoir through a plexiglas nozzle which had inside dimensions of 3.8 cm wide by 11.0 cm high, 76.0 cm in length. Excess water in the wave tank flowed over a sharp-crested weir upstream of the wave generator. Using this weir allowed a closed system to form for circulating the water and maintaining steady-state flow conditions. The experimental facility is located at the Hydraulic & Coastal Engineering Laboratory, University of California, Berkeley.

#### Data Acquisition System:

The data acquisition system can be divided into three subsystems:

a. A photographic system consisted of a camera mounted on a movable base above the longitudinal axis of the wave tank. The camera was used to take a series of color photographs of the jet, which was made visible by dye injected into the flow. It was also used to take a sequence of photographs of the bottom flow pattern in the tank. This was done using the flow-visualization technique of dropping dye crystals (potassium permanganate particles, 0.50 mm-0.59 mm) to the bottom of the tank, and photographing the resulting dye streaks.

b. Parallel wire wave gages were used in conjunction with a Sanborn (Series 150) recorder in order to measure the surface water elevations as a function of time at a specific location in the wave tank. A Sanborn Carrier Preamplifier (Model 150-1100 AS) was used to

supply the 2400 CPS/4.5 volt excitation for the gages. The full bridge was provided by an isolation transformer to prevent electrical interference between neighboring wave gages.

c. A Cushing Inc. Model 612-P "velmeter" converter was used in conjunction with a miniature electromagnetic cylindrical sensor (Model 600-40). These were mainly used to measure the jet velocity at several locations along the centerline of the wave tank. The sensor was 0.74 cm in diameter, with its electrodes 0.8 cm away from its tip. The minimum time constant of the "velmeter" converter is 0.1 second.

#### Experimental Procedures

- a. Surface wave parameters were measured without the jet being discharged. Wave measurements included the time history of the water surface elevations at several points along the wave travel. No cross waves were found to exist for the range of waves generated, so that the waves were purely two dimensional. Dye crystals were dropped into the tank, near the bottom, for flow visualization of the waves bottom mass transport, and a time sequence of color photographs was taken.
- b. A turbulent jet was also generated separately. Sufficient time was allowed to pass for steady conditions of the jet to be developed. Dye was usually inserted in the jet for flow visualization. As for the case of the waves, color photographs were taken for the growth of the dye crystals on the bottom. Velocity measurements, using electromagnetic flow meter and the hot film sensor, were made at several locations along the longitudinal axis of the jet.
- c. Data on the wave-jet flow pattern was obtained by generating the waves followed by the jet flow opposing the waves. A steady state of the flow field was usually reached within a few minutes. As before, color photographs were taken for the bottom flow pattern.

#### Analog to Digital Conversion:

The analog outputs from the measuring devices were recorded, digitized, and then processed on a CDC 6400 computer. Tests with data samples of both the water surface elevations and instantaneous particle velocity, showed that the time series obtained in these experiments proved to be a weakly stationary ergodic random process. Choice of digitization time interval and record length requires a knowledge of the frequency range of interest for the particular parameter measured in the experiments. For water surface elevations the analog signal was digitized at a rate 10 samples per second. The time interval chosen for the velocity analog signal to be digitized was 20 samples per second. This was done as most of the energy within a spectrum lies generally within the low frequency band. It

has been found that over the range of wave frequencies generated in this study (0.8 - 1.4 Hz), approximately 100 seconds were sufficient for accurate estimate of time mean and spectral quantities.

## RESULTS

### Current Modifications

In this section, experimental results regarding the effect of opposing wave motion on the horizontal shear of the current  $\xi$  and on the modification of the rate of spreading of the jet are presented.

The experimental data taken along the longitudinal axis of the jet show that in the presence of waves mean velocities of the current near the bottom are decreased with a tendency of the current shear near the water surface to increase. As wave frequency and amplitude increase, the decrease of the mean velocities near the bottom becomes more prominent with an increase of the mean velocities near the water surface [Ismail, (6,8)].

The experimental data also indicate that there is a net decrease in the momentum density of the current along the jet longitudinal axis which is accompanied by an increase in the spreading rate of the jet. The increase of spreading rate of the jet was deduced experimentally using a photographic means and was compared with that derived theoretically (Eq. 8). The comparison shows that for linear waves the agreement between the theory and experiment is excellent for a distance less than  $2X/W_0 \approx 64$  [Ismail (9)].

### Surface Waves Modifications

Surface waves modifications due to the opposing non-uniform current are presented in the following subsections. First, the effect of the jet on the modification of wave amplitudes is presented. Second, modifications of the wave particle velocities by the current are presented, followed by modifications of the wave bottom mass transport.

### Wave amplitudes

The experimental results show that waves were decreased in length and increased in height as waves propagated into the jet. Waves were also shown to be refracted as they propagated into the jet. However, the degree of refraction was slight as the dimensionless parameter  $G$  was kept large in the design of experiments in order to focus on the direct dynamical aspects of the interaction.

Figures 3 and 4 show respectively the spectrum of the wave energy potential density for three waves of different characteristics in case of waves on still water and waves in the presence of the current. The results shown on Fig. 4 show that for waves of higher Ursell number the second and higher harmonics have larger normalized energy density. The amplification of wave amplitude due to the

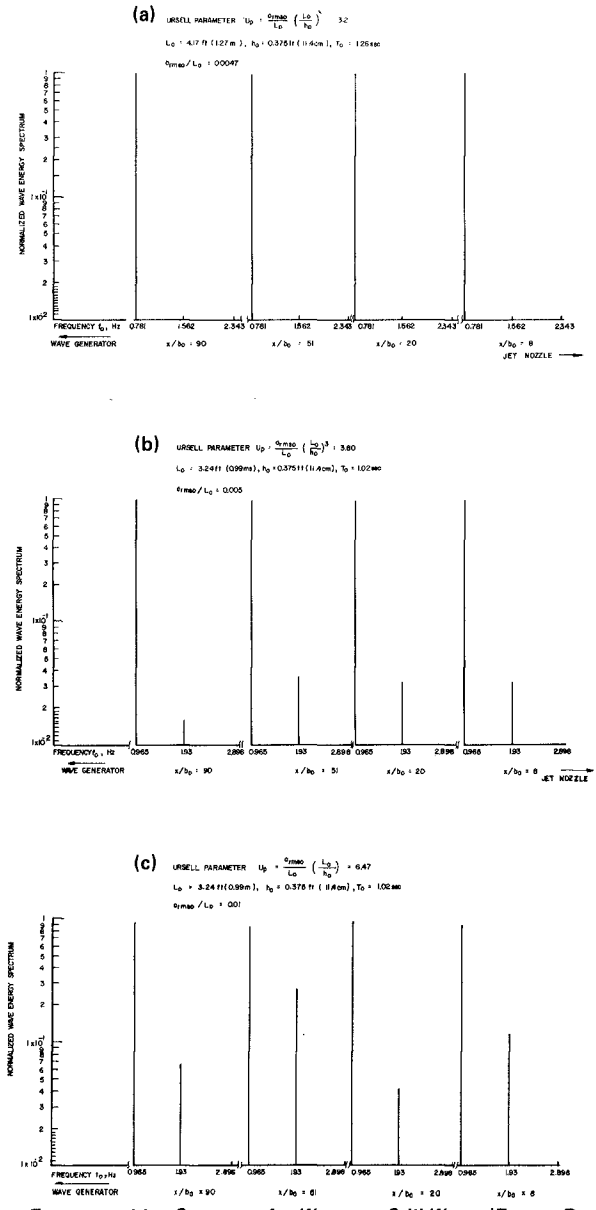

FIG. 3 Frequency Line Spectrum for Waves on Still Water (Energy Density is normalized by the Variance  $\overline{\eta^2}$ )

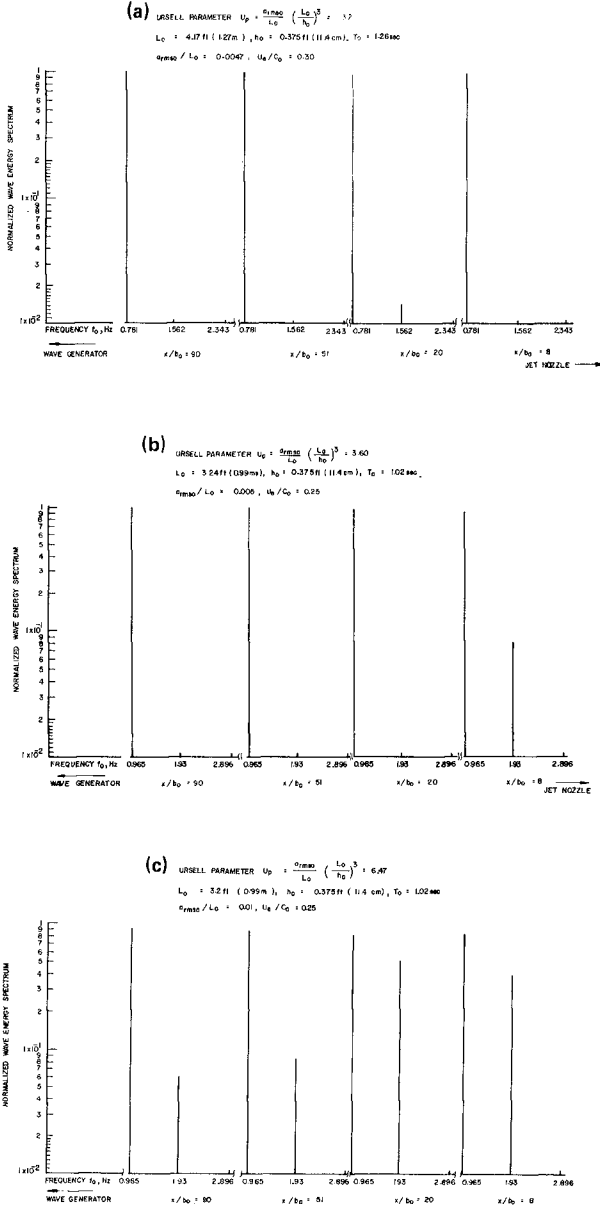

FIG. 4 Frequency Line Spectrum of Waves on a Jet (Energy Density, Normalized by the Variance  $\eta^2$ )

opposing current, represented by the rms of water surface elevation, along the jet axis for the same three runs is shown in Fig. 5. The variation of the dimensionless center line surface velocity  $U_c/U_e$  is plotted also on the same figure.

#### Wave particle velocities

The Eulerian particle velocities of waves  $\tilde{u}_i$  were obtained by subtracting the time mean of the measured instantaneous velocity  $\tilde{u}_i(x)$  from the phase averaged instantaneous velocity  $\langle u_i(x,t) \rangle$ . The process of phase averaging has the effect of rejecting the background turbulence and extracting the organized motion  $(\tilde{u}_i + \tilde{u}_i)$  and is defined by

$$\langle u_i(x,t) \rangle = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N u_i[(x,t) + nT] \quad \dots(9)$$

where T is the wave period and N is the number of waves examined.

The experimental results of velocity measurements along the jet longitudinal axis show that the wave particle velocities were increased in the presence of the opposing current. However, the magnitude of increase diminishes as the opposing waves approach the jet efflux point which results in having a gradient of wave momentum flux opposite to that induced by the variance of the free surface. Fig. 6 shows representative data of the gain of wave horizontal momentum flux at two Longitudinal positions on the jet axis.

#### Wave set-up

Theoretical predictions of change of mean water level due to wave set up  $\bar{\eta}_w$  were obtained by integrating Eq. (7) and making use of the experimental data of wave amplitudes in the presence of current. Theoretical values of wave particle velocities in the presence of opposing waves were obtained using a wave-current model which approximate the shear current by a constant vorticity current. The dispersion relation is given by Biesel (1) for small amplitude waves as

$$(U_s - C)^2 = \{[g + s(U_s - C)] \tanh kh\}/k \quad \dots(10)$$

where C is the wave phase speed and s the constant vorticity of the current. The dispersion relation was solved by iteration, for the wave number k, once the surface velocity  $U_s$  and the constant vorticity s of the current were determined from the measured current velocity profile. The wave particle velocities were obtained by a direct differentiation of the stream function of the combined wave-current flow. Fig. 7 shows the comparison between the theoretical predictions and experimental data of the change of the mean water level  $\bar{\eta}_w$  due to opposing waves.

FIG. 6 Relative gain of R.M.S. Wave Horizontal Particle Velocity

FIG. 7 Wave Set-up in the Presence of Opposing Non-uniform Current

### Wave bottom mass transport

The data obtained using the photographic system show that mass transport due to wave motion on the bottom and across the tank is in the direction of wave propagation. This can be seen in Fig. 8.a from the growth of the dye crystal vectors on the bottom. Here the waves are moving from under the clock in the photographs towards the lower front of the photo. Fig. 8.b shows a sample of the photographs taken for the jet and associated bottom secondary circulation.

The combined bottom mass transport pattern of the wave-jet flow system is shown in Fig. 8.c. It can be seen that the pattern of the waves forward mass transport at the bottom has been changed, due to the jet bottom flow. Within the jet zone of vertical shear it is found that the direction of the dye vector growth is dependent upon the relative strength of the waves to the jet. On the other hand, the mass transport pattern on the bottom and in the ambient water is directed towards the point of jet discharge. This modification of the flow pattern is induced by the jet secondary circulation. Thus, in prototype situations the jet secondary circulation derives bottom flow from the offshore zone towards the jet outlet.

### SUMMARY AND CONCLUSIONS

The major objective of the present study has been to investigate experimentally and theoretically the modifications of surface gravity waves and steady nonuniform current (jet) when they are propagated against one another in coastal waters. The design of the experiments allowed the turbulent velocity fluctuations associated with the current flow to be much smaller than the wave particle velocities.

The experimental results show that wave amplitudes, hence the wave potential energy, are increased as waves propagate into the jet. Also, wave particle velocities were increased. The longitudinal spatial gradient of the waves momentum flux due to particle velocity was found to be opposite and larger than that induced by the variance of the free surface. The net balance of wave momentum fluxes gave rise to a wave set-up at the jet source. These experimental results agree with the theoretical findings of Crapper (3) in that the rates of growth of large waves, on opposing nonuniform currents, are less than those rates for small amplitude waves. The difference in the rate of growth is a result of the fact that changes in energy propagate at a different speed from changes in wave number.

The experimental results indicate that the depth-averaged mean velocity of current, at the jet longitudinal axis, decreases in the presence of waves. This decrease is accompanied by an increase of the rate of spreading of the jet. Also the vertical velocity profile of the current is modified by the wave motion. While the mean velocity is decreased near the bottom, the mean velocity near the water surface is increased.

**FIG. 8** Photographs of the Bottom Flow Pattern in a Wave, a Jet, a Wave-Jet Flow.

Flow visualization of bottom flow pattern showed that in the presence of opposing waves the direction of the dye vector growth, within the jet zone of vertical shear, is dependent upon the relative strength of waves to the jet. On the other hand, the mass transport pattern on the bottom and in the ambient is focused on the jet outlet.

Scale analysis on the depth-averaged momentum equations yielded theoretical expressions of the increase of the jet spreading rate in the presence of waves and the wave-setup induced by the current's longitudinal rate of strain. Theoretical predictions obtained agree with the experimental data.

Wave-current interaction, through increasing the jet spreading rate and focusing the ambient bottom water on the jet outlet, have significant implications in regard to predicting mixing of thermal discharges in the marine environment and in analyzing the sediment budget at tidal inlets and river mouths.

#### ACKNOWLEDGMENT

The major part of this work constitutes a thesis presented by the author to the University of California at Berkeley, Calif., in 1981, in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The author expresses his deepest appreciation to Robert L. Wiegel of the University of California, Berkeley, and to Joseph L. Hammack of the University of Florida, Gainesville, for their guidance.

## CHAPTER SEVENTY FOUR

### A Finite Element Model for Wind Wave Diffraction

Ove Skovgaard\*   Lars Behrendt\*\*   Ivar G. Jonsson\*\*\*

#### Abstract

The applicability of a hybrid finite element model for the calculation of combined diffraction-refraction of small time-harmonic water waves is demonstrated. The model is valid for arbitrary water depths and wave lengths, i.e. it is based on intermediate depth theory (IDT). The model includes arbitrarily varying partial reflection along the boundaries. Superposition of waves (to simulate a spectrum approach) with different incident directions is demonstrated, and CPU-times and core memory requirements are given.

The model is verified and documented with respect to sensitivity of the model parameters in detailed tables, using the classical Homma island on a parabolic shoal. The wave period is here chosen in such a way that a small number of elements (larger than 500 and less than 2,000) is enough to get an accurate solution.

For a new simple, but realistic harbour geometry many detailed and accurate graphical results are given. The wave period ( $T = 9$  sec.) is here chosen so that it is representative for natural wind waves, and the size of the harbour is selected, so that the model gets a fairly large number of elements (of the order 10,000).

#### 1. Introduction

Small-amplitude time-harmonic waves of arbitrary length propagating in an area of varying depth may be described by the mild-slope wave equation. This equation was first derived by Berkhoff (1972). He solved the mild-slope wave equation by using a finite element method based on sources placed along the open boundaries. Chen and Mei (1974) formulated a hybrid finite element model (FEM) based on shallow water theory (SWT). This model was generalized to intermediate depth theory (IDT) by Houston (1981). Houston's hybrid FEM is restricted to full reflection along solid boundaries. In Behrendt and Jonsson (1984) a new derivation of the fundamental functional is presented. This new method includes partially absorbing boundaries and makes it straightforward also to include bottom friction.

In the present paper the hybrid functional by Behrendt and Jonsson (1984) (hereafter denoted by Paper I) is implemented, verified by comparison with exact solutions, and investigated for sensitivity of model parameters. The computational requirements and many detailed and accu-

rate results are illustrated for a new simple but realistic harbour geometry. In this harbour we demonstrate that partial reflection can be specified arbitrarily varying along solid boundaries (e.g. rubble mound breakwaters). This property is crucial for realistic modelling of wind wave diffraction in harbours. Another crucial property for practical applications is that superposition of waves with different directions and periods is computationally feasible.

2. The Hybrid Finite Element Model and its Implementation

This hybrid FEM is a combination of a simple finite element approach in area A (see Figs. 1 and 2) and a semi-analytical expansion in the outer area R (see Figs. 1 and 2), where we assume a constant water depth.

Figure 1. Sketch of model in the horizontally plane, infinite ocean.

Figure 2. Sketch of model in the horizontally plane, semi-infinite ocean.

Inside the circle or semi-circle  $\partial A$  the depth contours can be specified arbitrarily, but the change in depth over a wave length of the water waves has to be moderate. Along the "solid" boundary  $\partial B$  energy may be absorbed by specifying an arbitrarily varying absorption coefficient  $\alpha$  ( $0 \leq \alpha \leq 1$ ). Thus,  $\alpha = 1$  corresponds to full absorption of waves incident at a right angle, and  $\alpha = 0$  corresponds to a fully reflecting boundary. The partially absorbing boundary condition is the well-known Eq. (21) in Paper I.

The semi-analytical expansion in the outer area R of constant water depth is a solution to the classical Helmholtz wave equation (which is the constant water depth version of the mild-slope wave equation, see Paper I Eq. (20)) satisfying the Sommerfeld radiation condition (see Paper I Eq. (14)) at infinity. For the infinite ocean in Fig. 1 the expansion is:

$$\phi^S = \sum_{n=0}^{\infty} H_n^{(1)}(kr) [\alpha_n \cos(n\theta) + \beta_n \sin(n\theta)] \tag{1}$$

where  $\phi^S$  is the velocity potential of the scattered wave field (see Paper I Eq. (15)),  $H_n^{(1)}$  is the Hankel function of the first kind of order n, k is the wave number, and r and  $\theta$  are polar co-ordinates in the horizontal plane. The coefficients  $\alpha_n$  and  $\beta_n$  are determined by matching this solution with the solution in area A.

For the semi-infinite ocean in Fig. 2 the expansion is the same as in Eq. (1) with  $\beta_n \equiv 0$ ,  $n = 0, 1, \dots, \infty$ . Now  $\theta$  equals  $0^\circ$  or  $180^\circ$  along the infinite, fully reflecting straight coastline in area R. In the model the expansions are truncated at  $n = n_{\max}$  which is an input parameter to the model. The number  $n_{\max}$  depends on the desired accuracy of the solution and on the maximum distance  $r$  from the origo 0. For the classical Homma island, see Homma (1950), the necessary number  $n_{\max}$  has been studied in Appendix I in Skovgaard and Jonsson (1981).

The basic principle in the present finite element method is the minimization of a functional  $F_H(\phi)$ , see Eq. (44) in Paper I. This minimization is expressed in Eq. (45) in Paper I. The functional is discretized using finite elements in area A and using the expansion (1) describing  $\phi^S$  along  $\partial A$ . The finite elements chosen are simple triangular three-node elements with linear shape functions. This procedure results in a system of complex linear equations with a quadratic banded sparse symmetric coefficient matrix  $\{K\}$ . The maximum semi-bandwidth depends strongly on the chosen numbering of the nodes in the finite element grid. In the pioneering study by Chen and Mei (1974) the semi-bandwidth was also much dependent on the number of nodes along  $\partial A$ , and on 'nmax'.

### 3. An Example of Verification and Sensitivity: Homma's Island

Figure 3. Sketch of an idealized island on a parabolic shoal; (a) vertical; (b) horizontal.  $r_a = 10,000$  m,  $r_b = 30,000$  m,  $h_b = 4,000$  m,  $h_a = h_b(r_a/r_b)^2 = 4,000/9$  m.

Figure 4. Horizontal sketch of finite element grid over part of the shoal in Fig. 3. The grid covers the shoal for  $0^\circ \leq \theta < 360^\circ$  and  $r_a \leq r \leq r_b$ .

As an example from the verification program we have considered the classical Homma island surrounded by a parabolic shoal in an infinite ocean of constant water depth, see Fig. 3, and Jonsson et al. (1976), Table 1 and Eq. (1.1). A detail of the finite element grid is shown in Fig. 4.

The boundary  $\partial B$  is fully reflecting in this example. The boundary  $\partial A$  has been placed along the outer boundary of the shoal, i.e. area A is

Table I.

Calculated non-dimensional wave amplitudes  $A/A_i$  and phase angles  $\varphi$  for plane time-harmonic (of period  $T = 480$  sec.) incident waves around the Homma island in Fig. 3. Dimensionless radius  $r/r_a = 1, 2, 3,$  and  $9$ .  $\theta = 0^\circ, 30^\circ, \dots, 180^\circ$ . The values of phase angle  $\varphi$  are chosen in the interval  $0^\circ \leq \varphi < 360^\circ$ . For each of the 28 pairs of  $(r/r_a, \theta)$  three results are given in a column. The upper number is the exact solution, the middle number is the difference with a sign between the exact solution and our FEM-solution Nr. I. The lower number is the difference with a sign between the exact solution and our FEM-solution Nr. II. The rightmost column contains for each line a summation of the absolute values of the differences mentioned above.

the area covering the shoal. The geometry is symmetrical and it could be modelled by a semi-infinite ocean, but the finite element grid (Fig. 4) is not symmetrical, so we have to introduce an infinite ocean model.

Exact solutions using an orthogonal collocation method and IDT wave theory for this problem have been published in tabular form earlier, see Jonsson et al. (1976) and Skovgaard and Jonsson (1981). Here an exact solution for a new wave period ( $T = 480$  sec.) is given in Table I.

In Table I we have compared two finite element solutions (denoted by No. I and No. II) with the exact solution. FEM solution No. I is based on a very fine grid:  $\Delta\theta = 6^\circ$ , i.e.  $\theta = 0^\circ, 6^\circ, \dots, 360^\circ$ , and  $\Delta r/r_a = 0.1$  for  $1 \leq r/r_a \leq 2$ , and  $\Delta r/r_a = 0.2$  for  $2 \leq r/r_a \leq 3$ ,  $n_{\max} = 16$  (see Section 2). FEM solution No. II is based on a rather coarse grid:  $\Delta\theta = 10^\circ$ , i.e.  $\theta = 0^\circ, 10^\circ, \dots, 360^\circ$ , and  $\Delta r/r_a = 0.25$  for  $1 \leq r/r_a \leq 3$ ,  $n_{\max} = 11$ . The total number of elements is 1.800 and 576 in models No. I and II respectively.

Solution Nr. I was constructed in order to verify our model, i.e. verify the hybrid formulation, verify the functional, verify the discretization, and finally verify the implementation. Here the maximum distance (dimensionless with respect to local wave length,  $L_a = 31,648$  m and  $L_b = 93,959$  m) between neighbouring vertices of the triangular elements was of the order 0.05 for  $r/r_a = 1$  and 0.04 for  $r/r_a = 3$ , i.e. minimum  $20 \Delta s$  (see Fig. 4) per local wave length.

Solution No. II was constructed in order to measure the sensitivity of the finite element discretization. Here the maximum distance (dimensionless with respect to local wave length) between neighbouring vertices of the triangular elements was of the order 0.10 for  $r/r_a = 1$  and 0.06 for  $r/r_a = 3$ , i.e. minimum  $10 \Delta s$  per wave length near  $\partial B$  and minimum  $16 \Delta s$  per wave length near  $\partial A$ .

Solution No. I has a maximum error in  $A/A_i$  of  $-0.0324$  (corresponding to 1.37%) at  $r/r_a = 1$  and  $\theta = 0^\circ$  (point Q in Fig. 3, the centrepoint at the island in the shadow region). For the 28 results in Table I the mean error ( $1/28 \sum |\text{error}|$ ) is 0.0082, or relative mean error ( $1/28 \sum |\text{error}| / (A/A_i)_{\text{exact}}$ ) 0.58%. The rightmost column informs us that the sum of the errors along  $r/r_a = 1$  equals approximately the sum of the errors along the other three semi-circles  $r/r_a = 2, 3,$  and  $9$ . Note that for all considered 28 points there is no distinct pattern of the signs of the errors. The maximum error in phases  $\varphi$  is  $-1.69^\circ$  and it is found at  $r/r_a = 1$  and  $\theta = 30^\circ$  (which is not where the maximum error in  $A/A_i$  was found). The mean error in  $\varphi$  ( $1/28 \sum |\text{error}|$ ) is  $0.54^\circ$  for the 28 results.

These results for solution No. I did not change when  $n_{\max}$  was increased. This is in accordance with Skovgaard and Jonsson (1981), Fig. 24,

which showed that  $n_{\max} \gtrsim 12$  was enough for  $1 \leq r/r_a \leq 9$ . To describe our *hybrid* finite element solution we present the calculated expansion coefficients  $\alpha_0$ ,  $\alpha_n$ , and  $\beta_n$  for  $n = 1, 2, \dots, n_{\max}$  in Table II. First, in accordance with the reference mentioned above it was checked that the expansion coefficients in the table were in fact invariant to any increase in the number 'nmax'. Secondly, note that the largest  $\beta_n$ -coefficient is of the order of magnitude  $10^{-15}$  (the magnitude of the largest  $\alpha_n$ -coefficient is of the order of magnitude 1); this is in agreement with the fact that if a symmetrical grid had been used, all the calculated  $\beta_n$ -values should have been approximately zero, because for a semi-infinite ocean (Fig. 2) they are identically equal to zero.

Table II

Calculated expansion coefficients  $\alpha_0$ ,  $\alpha_n$ , and  $\beta_n$  for  $n = 1, 2, \dots, n_{\max} = 16$  in Eq. (1).  $T = 480$  sec., FEM-solution No. I.
