#### Numerical Method and Solution

We used the explicit finite scheme devised by Gray (1) to solve Eqs. 5 and 6. In this method the Lagrangian quadratic isoparametric elements are used, and the Simpson's rule is used to evaluate integrals over these elements. Leap-frog time differencing is used and the friction terms are evaluated at  $t - \Delta t$ . Because of the forced nature of the tidal flow, time-splitting of the solution is not a problem and no smoothing in time is needed. The combination of element type and numerical quadrature serves to greatly reduce the computational effort. Furthermore, the coefficient matrix is diagonal and computations can easily be done on a small computer.

One drawback of this scheme is the appearance of inter-

nodal oscillations in the computed solution due to the distortion of the dispersion relation of Eqs. 5-6 in their discretized forms(4). For our study these oscillations are negligible as far as the tidal elevation and tidal current are concerned. However, they will have effects on the suspended load computations. To filter out these internodal oscillations we used a nine-point smoothing operator at each time step. This operator was first tried on an example studied by Gray and Lynch(2) and its effectiveness was judged to be good (Fig. 2). The results shown in Fig. 2 are those along the axis of the domain during high water at the mouth. As is well known, this smoothing operation will have damping effects on the solutions, especially for the smaller length scale features. Since the  $M_4$  wavelength is significantly longer than the grid sizes used, the effect of smoothing on the  $M_4$  harmonic is probably not too great.

However, small scale spatial variations of the distributions of both the  $M_4$  current and the residual current associated with topographical features will no doubt be distorted. The good agreement of our results with the actual depositional patterns seems to support this assessment, since, as pointed out in the last section, both the  $M_4$  harmonic and the residual current are responsible for the net suspended load in Hangzhou Bay.

The study area is covered by 61 elements (Fig. 1). Because of the resolution limitation inherent in the choice of grid sizes, several deep narrow troughs along the northern coast have been ignored. To simplify the numerical treatment of the tidal flat along the middle of the southern shore we have modified the bathymetry there such that the water depth will be at least 0.5 m at low tides. The depth contours in Fig. 1 have been so modified. To lessen the distortion due to increased water depth, the value of the Chèzy coefficient over the tidal flat was chosen to be  $45 \text{ m}^{\frac{1}{2}}/\text{s}$  as compared to the value of  $75 \text{ m}^{\frac{1}{2}}/\text{s}$  elsewhere.

At both the east and the west boundaries the surface elevations are forced by the  $M_2$  constituents based on available data. Along the west boundary only one data station was available, and there we let the co-tidal line coincide with the boundary, which is compatible with available information. With a time-step of 1 minute integration of Eqs. 5-6 from zero initial values will yield periodic solutions stable to the third significant digits after three tidal periods. Comparisons are made between the computed surface elevation and the  $M_2$  harmonic constants at five stations (Table 1). The agreements are excellent for stations 1-3. The large error in amplitude at station 4 is probably caused by the neglect of a deep trough nearby, while the large discrepancies in phase at stations 4 and 5 are likely due to the accumulated effects of smoothing of

the deep troughs along the northern shore. In Fig. 3 the computed co-tidal lines and co-range lines in Hangzhou Bay plotted. They agree well with the existing measured results. Comparison of computed tidal current at a station in the northeast of the Bay with the harmonic constants of  $M_2$  there based on a 25-hour current measurement showed that the major axis of the computed tidal ellipse is lower by 25 per cent in magnitude and a  $3^\circ$  error in orientation.

As discussed in the last section both the residual current and the  $M_4$  harmonic are important for the suspended transport in Hangzhou Bay. Our computation results showed that, except for the lower corner next to the western boundary where it attains a value close to 0.05 m/s, the (Eulerian) tidal residual current reached a maximum value of about 0.04 m/s over the tidal flat. Elsewhere it is generally less than 0.03 m/s. In the eastern three quarters of the Bay the tidal residual current has an eastward component. In the western quarter of the Bay the residual current is mostly directed towards the west except its eastern area next to the south shore. However, as pointed out earlier in this section, smaller spatial variations are distorted because of the numerical smoothing operation. Therefore, at areas where the tidal residual currents are relatively small, their computed magnitudes and orientations are likely to be unreliable. In addition, no conditions were imposed on the tidal residual elevation at the open boundary, nor, for that matter, were they imposed on the  $M_4$  harmonic. The neglect of these conditions at the western open boundary is more questionable than at the eastern boundary. We have done some rough estimation of the effects on the residual current due to the tidal residual elevation at the western boundary, based on sea level data. The resulting residual current field is probably less than that due to a 7.5 m/s wind.

Eq. 3 implies that the grain-size dependence of the suspended load is through the factor  $w$  only, namely, the settling velocity of the particle. Suppose that  $D$  is the grain size and  $F(D)$  is the size-frequency distribution of the bed material at a station. The net suspended load of this bed material is then

$$\vec{Q} = \int_0^\infty \langle \vec{q} \rangle F \, dD = A \langle |\vec{U}|^3 \vec{U} \rangle, \quad (7)$$

where

$$A = 0.01 \left( \rho g / c^2 \right) \int_0^\infty (F/w) \, dD. \quad (8)$$

It is seen that  $A$  is independent of the tidal dynamics provided that the Chèzy coefficient is constant.

As argued in the Introduction the divergence of the spatial distribution of  $\vec{Q}$  may be used as a measure for the depositional patterns in Hangzhou Bay. In this approach the complication and uncertainty associated with solving

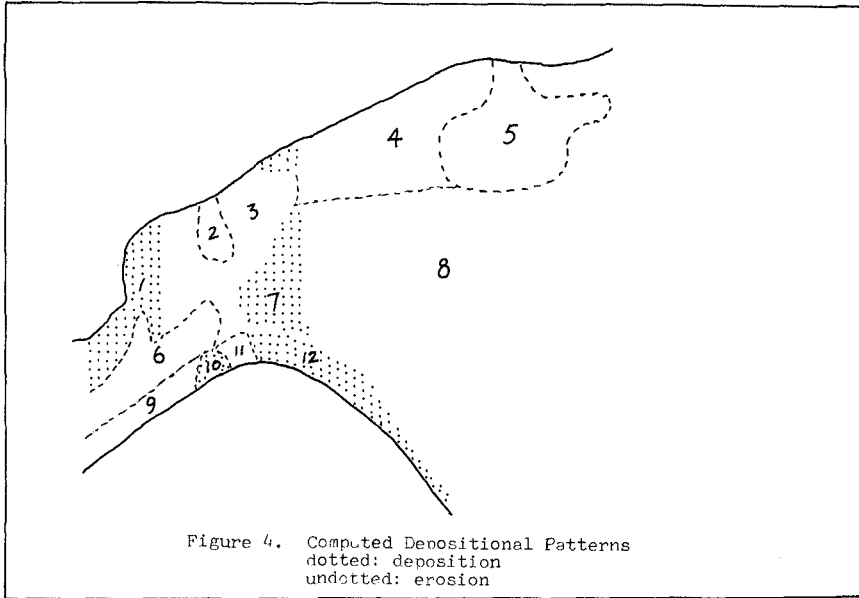

the sediment transport equation are avoided. The results are depicted in Fig. 4. Fig. 5 shows the depositional patterns in the western part of the Bay, based on surveys of topography between 1979 and 1982 during which period the discharge from Qiantangjiang was below normal. It can be seen that the numerical modelling results agree well with the measurements as far as the general patterns are concerned. Findings from other studies also supported our modelling results (Feng Yingjun, private communication). However, as anticipated earlier, the neglect of the deep narrow troughs along the northern coast caused large discrepancy locally.

To have some quantitative estimates of the deposition rate we computed  $\bar{Q}$  by assuming a uniform-size bed material, i.e.,  $\bar{Q} = \langle \vec{q} \rangle$ . Since the median size of the bed material is  $16 \mu\text{m}$  while that of the suspended sediment ranges from  $10$  to  $13 \mu\text{m}$ , we chose  $12 \mu\text{m}$  for computation purpose. Based on the computed results, in Fig. 4 the depositional and the erosional areas are further divided into subregions according to the variation of the value of the divergence. The maximum value of the divergence in each subregion is listed in Table 2. Since the divergence of  $\bar{Q}$  gives the depositional mass rate per unit area, the values listed in Table 2 are derived from the divergence by taking the specific gravity of the sediment to be 2.5. These values of annual depositional thickness are of the same order of magnitude as those estimated from available field study data, except at local areas along the northern coast due to reasons discussed earlier. We believe that refinement of grid sizes will probably improve the model prediction.

The computation also resulted in a net loss of  $1.2 \times 10^8$  ton of sediment from Hangzhou Bay to the ocean annually. Since Qiantangjiang has an annual suspended load of only 7 million tons, the balance has to come from either erosion in the estuary or replenishment of sediment in the upper reach of the Qiantangjiang Estuary from offshore sources. Available information seemed to support the latter mechanism. The Changjiang river discharges close to five hundred million tons of suspended sediment annually north of the Qiantangjiang. It is possible that sediment deposited at the mouth of Hangzhou Bay by Changjiang during summer will be transported upstream of the Bay in winter when the wind is strong.

## Conclusion

Hangzhou Bay is a well-mixed estuary where sediment transport is mainly through the suspended load. It is a shallow estuary with tidal action as the dominant transport mechanism. By using the Bagnold's formula for suspended load and taking the divergence of the distribution of the net suspended transport, a good measure of the depositional patterns in the Bay is obtained. The computed annual depo-

sition-erosion thickness over the Bay is also of the same order of magnitude as that obtained from field studies. Significant discrepancies occur only in small areas where deep narrow troughs have been neglected because of grid resolution limitation. The simple treatment of tidal flats by increasing its water depth and decreasing the Chèzy coefficient seems to be satisfactory.

In this study river runoff, wind effects, and other subtidal effects have been ignored. Only the  $M_2$  surface elevation oscillations are forced at the open boundaries. The results indicate that influence of the suspended sediment from Changjiang seems to be essential to the overall sediment budget in Hangzhou Bay.

## CHAPTER ONE HUNDRED FORTY SEVEN

### UNIFORM LONGSHORE CURRENT MEASUREMENTS AND CALCULATIONS

P.J. Visser\*

#### ABSTRACT

A description is given of laboratory experiments on uniform longshore currents and the comparison of the data with longshore current profiles predicted by a mathematical model. For the mathematical model it is assumed that longshore current generation takes place between the plunge line and the shoreline (instead of shoreward of the breaker line) and Battjes' (2,3) lateral friction model is applied. Good agreement between theory and laboratory data is achieved with realistic values of the bottom roughness.

#### 1. INTRODUCTION

When waves break at an angle to the coast, a mean current is generated parallel to the shoreline (see fig. 1). This longshore current is confined to a zone with a width of order two times the width of the surf zone. Longshore currents and the associated transport of sediment play a significant role in the erosion and deposition of sediment and the dispersion of pollutants.

Since the introduction of the concept of radiation stresses by Longuet-Higgins and Stewart (15), the theory of longshore currents has progressed considerably: Bowen (4), Thornton (18), Longuet-Higgins (13), James (8), Battjes (1), Jonsson, Skovgaard and Jacobsen (10), Liu and Dalrymple (12). In these theories the equations of motion are averaged over the water depth and over the wave period. Then, in a steady state, there is a balance of the longshore driving force, the bottom frictional stress and the lateral friction. The theoretical achievements obtained by these authors are considerable, although some of the assumptions are rather crude, for instance concerning the eddy viscosity outside the surf zone, the dissipation of wave energy inside the surf zone and the bottom friction.

- Measurements of longshore current profiles were done, both
- in the field: in the Nearshore Sediment Transport Study, see Seymour and Gable (16), and in more detail
  - in the laboratory by Galvin and Eagleson (7) and Visser (20,21).

\*Scientific Officer, Department of Civil Engineering, Delft University of Technology, P.O. Box 5048, 2600 GA Delft, The Netherlands.

Fig. 1 - The nearshore region.

Care must be taken in comparing Galvin and Eagleson's measurement results with theoretical longshore current profiles, since the measured currents were not uniform along the coast which was caused by the wave basin geometry and the recirculation system.

The measured longshore current profiles, which are compared in this paper with an improved longshore current model, are all uniform along the coast as a result of the application of the method for the adjustment of the proper longshore current in a wave basin proposed by Visser (19), see also Visser (20). In this method the wave basin geometry and the proper recirculation flow through the longshore current openings in the wave guides are determined such that the circulation flow between the wave guides  $Q_c$  (see fig. 2) is minimal.

The aim of the present investigation is to get more insight into the dynamics of longshore current generation by sea waves, i.e. dissipation of wave energy (longshore driving force) and production of turbulence by breaking, diffusion of turbulence and momentum (lateral friction), bottom frictional stress. The principal objective is a mathematical model for calculations of longshore currents being more reliable than the existing ones. The basic assumptions are uniformity in longshore direction, steady state conditions and the bottom contours are straight and parallel to the beach. The investigation is restricted to regular waves.

The scope of the present study is the comparison of longshore currents measured in a wave basin with the current profiles predicted by a mathematical model. In the latter it is therefore assumed that the angle of the beach slope is constant and that the positions of the breaker line, the plunge line and the wave set-up line are known (i.e. following from the measurements). The breaker line is here defined as the line on which the wave height is maximal. The plunge line is the line where the curly crest of a plunging breaker impinges on the preceding wave trough (see also fig. 1).

In the present mathematical model the longshore driving force is modeled taking into account the physical fact that dissipation of wave energy takes place between the plunge line and the shoreline instead of in the whole surf zone (that is shoreward of the breaker line). The bottom friction is modeled by considering the combined orbital and current velocity vector. In fact it is still unclear how to combine the orbital and current velocity near the bottom. Therefore different bottom friction models are applied. The lateral friction is modeled according to Battjes (2,3): it is one of the aims of this investigation to examine the applicability of the ideas proposed by Battjes.

## 2. EXPERIMENTS

### 2.1 Experimental arrangement

The experiments were performed in the 16.60 x 34.00 m<sup>2</sup> wave basin of the Civil Engineering Department of the Delft University of Technology. Opposite to the snake-type wave generator smooth concrete beaches were constructed with slopes 1:10 (fig. 2) and 1:20 (fig. 3), respectively. For the last experiment the 1:20 slope was roughened by bonding 5 - 9 mm gravel with a thin grout on the smooth concrete. The wave guide walls were composed of concrete elements and installed at angles of 15.4 or 31.0 degrees with the normal to the wave board.

To approximate the longshore current flow generated by a uniform wave field on a straight infinitely long and uniform beach, a wave basin configuration was chosen with longshore current openings in both wave guides and with an external recirculation  $Q_r$  which is completely effected by a pump. A distribution system was built in the longshore current opening of the upstream wave guide in order to increase the length along which the longshore current is uniform. The recirculation flow  $Q_r$  was distributed in this system according to the expected distribution of the longshore current flow and was readjusted if that turned out to be necessary. The correct width of the longshore current opening in the downstream wave guide and the proper rate of recirculation flow were determined experimentally, i.e. followed from the application of an experimental method with which it is possible to obtain the uniform longshore current in the present wave basin geometry, (see Visser (20) ).

### 2.2 Experimental procedure

The experimental procedure is given in table 1. Because of the rather fast spreading of dye in the breaker zone, it was not possible to follow the dye in this zone over distances exceeding about 1.0 m. In view of the accuracy, the number of observations per point was

Table 2 - Beach and wave field properties and quantities; the indices 0,1 and br refer to values on deep water, constant depth of the basin and the breaker line, respectively.

2.3 Experimental results

Seven experiments were performed, see table 2 ( $\alpha$  = slope angle, T = wave period). The results of the measurements of wave heights (H), angles of incidence ( $\theta$ ), (still water) breaker depth ( $d_{br}$ ), maximum wave set-up ( $\eta_m$ ), positions of the breaker line ( $x_{br}$ ) and the plunge line ( $p = x_{pl}/x_{br}$ ) with respect to the shoreline ( $x = 0$ ), and breaker types are also listed in table 2, see also fig. 1. The wave height and the angle of incidence on deep water were calculated from the measured values on constant depth part of the basin using linear wave theory and Snell's law.

The results of the mean water level measurements, see Visser (21), indicate clearly that the wave set-up starts at the plunge line instead of the breaker line. This is in conformity with experimental results of other investigators, for instance Bowen, Inman and Simmons (5). Consequently the transfer of momentum from waves to wave set-up and longshore current takes place shoreward of the plunge line, instead of shoreward of the breaker line in the whole surf zone, as often assumed. The mean water level measurements show further that the gradient of the wave set-up is more or less constant, as often observed on slopes with comparable steepnesses. The results of the wave height measurements in sections 1 and 2 indicate that in the breaker zone the wave height remains more or less proportional to the mean water depth, see Visser (21); this is also in agreement with other measurements on comparable slopes.

From the measured current velocities in three points per vertical, the depth-averaged current velocity in that vertical has been calculated. The depth-averaged longshore current velocities in the different sections have been given the present uniform longshore current profiles in the

sections 0,1,2 and 3 (experiments 1,2,3,4 and 7) and in the sections 0,1 and 2 (experiments 5 and 6). The uniformity of these longshore current profiles of each of the seven experiments is very satisfactory, see Visser (20); examples are given in fig. 4 (experiment 2) and fig. 5 (experiment 4). The depth-averaged and longshore-averaged measured current velocities are given in chapter 4 in combination with computed longshore current profiles.

Fig. 4 - Depth-averaged uniform longshore current velocities in experiment 2.

Fig. 5 - Depth-averaged uniform longshore current velocities in experiment 4.

As already described in Visser (19,20), the systematic error of the current velocity measurements is small (order 1%). The random error of the measured velocity in a point (following from 10 or 20 readings) is about  $\pm 4\%$  for the measurements in and near the surf zone. This gives for the depth-averaged velocity in this zone a random error of  $\pm 2.5\%$ . In view of the measuring technique (dye), both the systematic and random error are surprisingly small.

3. MATHEMATICAL MODEL

The equation of motion in longshore direction for the situation under consideration can be written as

$$\frac{dS_{xy}}{dx} - \frac{d}{dx} \left\{ \rho \mu_m h \frac{dV}{dx} \right\} + \tau_{by} = 0, \tag{1}$$

in which

$$\frac{dS_{xy}}{dx} = \frac{\sin \theta}{c} \frac{dF_x}{dx} = - \frac{\sin \theta}{c} D = \text{longshore driving force}, \tag{2}$$

$$\frac{\sin \theta}{c} = \text{constant according to Snell's law (c = phase velocity)}, \tag{3}$$

$F_x$  = flux of wave energy normal to the coast per unit length of shoreline,

$D$  = local rate of wave energy dissipation,

$x, y$  = coordinates in offshore, longshore direction, respectively,

$\mu_m$  = eddy viscosity (momentum),

$h$  = mean water depth,  $V$  = longshore current velocity,

$\tau_{by}$  = mean bottom frictional stress in y-direction.

3.1 Longshore driving force

If it is assumed that for  $x \leq x_{br}$

1. the wave height is proportional to the mean water depth,
2. the gradient of the wave set-up is constant,
3. the shallow water approximation of linear wave theory can be used and
4. the dissipation of wave energy takes place shoreward of the breaker line,

then the following simple model for  $D$ , see Battjes (2), can be derived

$$D = \begin{cases} 0 & \text{for } x > x_{br}, \end{cases} \tag{4}$$

$$D = \begin{cases} \propto x^{3/2} & \text{for } x \leq x_{br}. \end{cases} \tag{5}$$

The assumptions 1 and 2 are in agreement with the present observations. For the present model it is assumed that

1. the dissipation of wave energy takes place for  $x \leq x_{pl} = px_{br}$ ,
2.  $D$  is proportional to  $x^{3/2}$  for  $x \leq x_{pl}$ ,  $D = 0$  for  $x > x_{pl}$ ,
3. the transport of wave energy towards the shore = the transport of wave energy in x-direction on deep water given by linear wave energy =

$$(F_x)_o = \frac{1}{2} E_o c_o \cos \theta_o, \tag{6}$$

where  $E_o = \frac{1}{8} \rho g H_o^2$  = wave energy on deep water per unit area.

Then it follows from eq. (2) that:

$$\frac{dS_{xy}}{dx} = - \underbrace{\frac{1}{4} E_o \sin 2\theta_o}_I \cdot \underbrace{\frac{5}{2} \frac{x}{x_{pl}^{5/2}}}_{II} \quad \text{for } x \leq x_{pl} \quad (7)$$

The first part (I) of eq. (7) is the lateral thrust exerted by the waves on the longshore current. As emphasized by Longuet-Higgins (14), the expression for this total lateral thrust is exact and does not depend on the application of small amplitude theory to waves in the longshore current zone. The second part (II) of eq. (7) denotes the distribution of the lateral thrust across the region in which dissipation of wave energy takes place.

### 3.2 Bottom frictional stress

For the combination of a wave field and a mean current in y-direction, the mean bottom friction in longshore direction can be expressed, see Visser (21), as:

$$\tau_{by} = C \rho V^2 f(\theta, \xi \frac{u_m}{V}), \quad (8)$$

where

$$f(\theta, \xi \frac{u_m}{V}) = \frac{1}{T} \int_0^T \{ 1 + 2 \xi \frac{u_m}{V} \sin \theta \cos \omega t + (\xi \frac{u_m}{V})^2 \cos^2 \omega t \}^{\frac{1}{2}} \times \\ \times (1 + \xi \frac{u_m}{V} \sin \theta \cos \omega t) dt, \quad (9)$$

$C$  = a dimensionless bottom friction coefficient,

$u_m$  = maximum orbital velocity near the bottom,

$\xi$  = a dimensionless factor which depends on how the orbital and mean current velocity near the bottom are combined.

If the orbital velocity near the bottom and the depth-averaged longshore current velocity are combined then  $\xi = 1$ . Bijker (6) has proposed to combine the horizontal orbital and current velocity vector in the (hypothetical) boundary layer and arrives at (8) with (9) in which

$$\xi_B = \frac{p' \kappa}{\sqrt{C}} \approx \frac{0.16}{\sqrt{C}} \quad (p' \approx 0.4), \quad (10)$$

$$\text{where } C = \left( \frac{\kappa}{12 h} \right)^2, \quad (11)$$

with  $r$  = diameter of the bottom roughness elements,  
 is Nikuradse's expression for  $C$  for rough turbulent flow.  
 Bijker's model has been modified by Swart (17):

$$\xi_s = \sqrt{\frac{C'}{C}} = \left[ \frac{0.5}{C} \exp \{ - 5.977 + 5.213 \left( \frac{r}{a_b} \right)^{0.194} \} \right]^{\frac{1}{2}}, \quad (12)$$

in which  $C'$  corresponds with Jonsson's (9) wave friction factor  
 and  $a_b$  = amplitude of water particle excursion near the bottom.  
 For a linear wave theory is applied: this is justified as demonstrated  
 by Lemchauté, Divoky and Lin (11).

3.3 Lateral friction

The eddy viscosity is modelled according to Battjes (2):

$$\mu_m = M q l, \quad (13)$$

in which

$M$  = constant of order 1,

$q$  = characteristic turbulent velocity,

$l$  = characteristic length of turbulence (is set equal to  $h$ ). (14)

The turbulent velocity is calculated from Battjes' (3) balance of  
 turbulent energy

$$\rho h \epsilon - \frac{d}{dx} \{ \mu_e h \frac{d(\frac{1}{2} \rho q^2)}{dx} \} = D, \quad (15)$$

where

$\epsilon$  =  $q^3/h$  = mean rate of turbulent energy dissipation per unit mass, (16)

$D$  = local rate of wave energy dissipation which is set equal to the  
 rate of production of turbulent energy,

$\mu_e$  = eddy viscosity (energy) which is set equal to  $\mu_m$ .

Battjes (3) gives a local solution of eq. (15) in the neighbourhood of  
 the plunge line as defined in this paper. It is, however, possible to  
 give a complete analytical solution, see also Visser (21). Substitution  
 of (13), (14), (16) and the expressions for  $h$  (given in fig. 1) into (15)  
 leads to a differential equation with the following solution

$$q = \{ A_1 \left( \frac{x}{x_{p1}} \right)^{r_1} + \frac{D}{\rho} \}^{1/3} \quad \text{for } x \leq x_{p1}, \quad (17)$$

$$q = \{ A_2 (x - a)^{r_2} \}^{1/3} \quad \text{for } x > x_{p1}, \quad (18)$$

in which

$$A_1 = \frac{(x_{p1} - a) \left(\frac{dD}{dx}\right)_{p1} - r_2 D_{p1}}{\rho (r_2 - r_1) \left(1 - \frac{a}{x_{p1}}\right)}, \quad A_2 = \frac{(x_{p1} - a)^{-r_2} \{x_{p1} \left(\frac{dD}{dx}\right)_{p1} - r_1 D_{p1}\}}{\rho (r_2 - r_1)}, \quad (19)$$

$$r_1 = -0.5 + 0.5 (1 + 4B_1)^{\frac{1}{2}}, \quad r_2 = -0.5 - 0.5 (1 + 4B_2)^{\frac{1}{2}}, \quad (20)$$

$$B_1 = B_2 \left(1 - \frac{a}{x_{p1}}\right)^{-2}, \quad B_2 = 3M^{-1} \text{tg}^{-2} \alpha, \quad (21)$$

Fig. 6 - Calculated dimensionless turbulent velocity  $\tilde{q}$  as function of  $\tilde{x}$  for different  $M$  (applicable to experiment 3).

As example, fig. 6 shows the theoretical  $\tilde{q}$  for different  $M$  applicable to experiment 3.

3.4 Numerical model

Substitution of (7), (8) and (13) into (1) yields a second order non-linear differential equation which has to be solved numerically, see Visser (21). Because of the non-linearity, this has been done with an iteration procedure.

The boundary conditions are  $V = 0$  at  $x = 0$  and  $V = 0$  as  $x \rightarrow \infty$ . Since for  $x > 2 x_{br}$  the longshore current velocity  $V$  becomes very small, the boundary condition at  $x \rightarrow \infty$  has been rewritten as  $V =$  measured value at  $x \approx 2.5 x_{br}$ .

The numerical program has been checked with the aid of an analytical solution which can be derived for  $p = 1$ ,  $\theta =$  small and  $\xi u_m/V =$  large.

#### 4. COMPARISON OF MEASURED AND COMPUTED LONGSHORE CURRENTS

The rate of agreement between measured and computed longshore currents can be influenced by the choice of two coefficients in the mathematical model, i.e. the bottom friction coefficient  $C$  (through the diameter  $r$  of the roughness elements) and the lateral friction coefficient  $M$ . This is justified to a certain extent because  $r$  and  $M$  are not (exactly) known. But it is to be expected that

for the smooth slopes :  $r \approx 0.001$  m ( $C \approx 0.003$ ),

for the rough slope :  $r \approx 0.01$  m ( $C \approx 0.008$ ).

Further Battjes' (2,3) lateral friction coefficient  $M$  is expected to be of order 1.

The smooth concrete slopes 1:10 and 1:20 were constructed with the same materials, but in principle it is possible that the roughnesses of both slopes differ slightly due to 1) a small difference in workmanship and 2) the fact that the present measurements on the 1:10 slope have been preceded by other experiments on the same slope while the 1:20 slope was constructed especially for the present experiments (the roughness of a concrete slope increases generally in time).

In principle it is also possible to vary the factor  $p$  and to influence in this way the rate of agreement between measured and computed longshore currents; the computations, however, have been carried out with the measured value of  $p$ , see table 2.

The rate of agreement between measured and computed longshore current profiles, has been expressed in a standard deviation, see Visser (21). Thus, optimal values for  $M$  and  $r$  have been determined and the validity of the different bottom friction models (i.e. different expressions for  $\xi$ ) for the present application has been judged.

From the rate of agreement computations it follows that

- $M \approx 2.5 - 3.0$ , which is indeed of order 1,
- both  $\xi = 1$  and  $\xi = \xi_s$  give good agreement between measured and computed longshore current profiles with realistic values of  $r$ ; the general agreement obtained with  $\xi_s$  is somewhat better than with  $\xi = 1$ ,
- the agreement between measured and computed longshore current is very poor with  $p = 1$ .

Figures 7 and 8 show the measured and computed longshore current profiles of the seven experiments; these computed longshore current profiles are based on  $\xi = \xi_s$ , and further on  $M = 3.0$ ,  $r = 0.0012$  m for the smooth concrete 1:10 slope,  $r = 0.0004$  m for the smooth concrete 1:20 slope and  $r = 0.005$  m for the rough 1:20 slope. The agreement between measurements and theory is satisfactory, even very good in experiments 1 through 5, but less in experiments 6 and 7. The longshore current velocities in experiments 6 and 7 are smaller than in the other experiments: the less good agreement between measured and computed longshore current profiles in these experiments is probably caused by the fact that due to  $\xi = \xi_s$  in eq. (8) the bottom friction is over-estimated in the weak current situation, as it is also the case with  $\xi = \xi_b$ , see Visser (21).

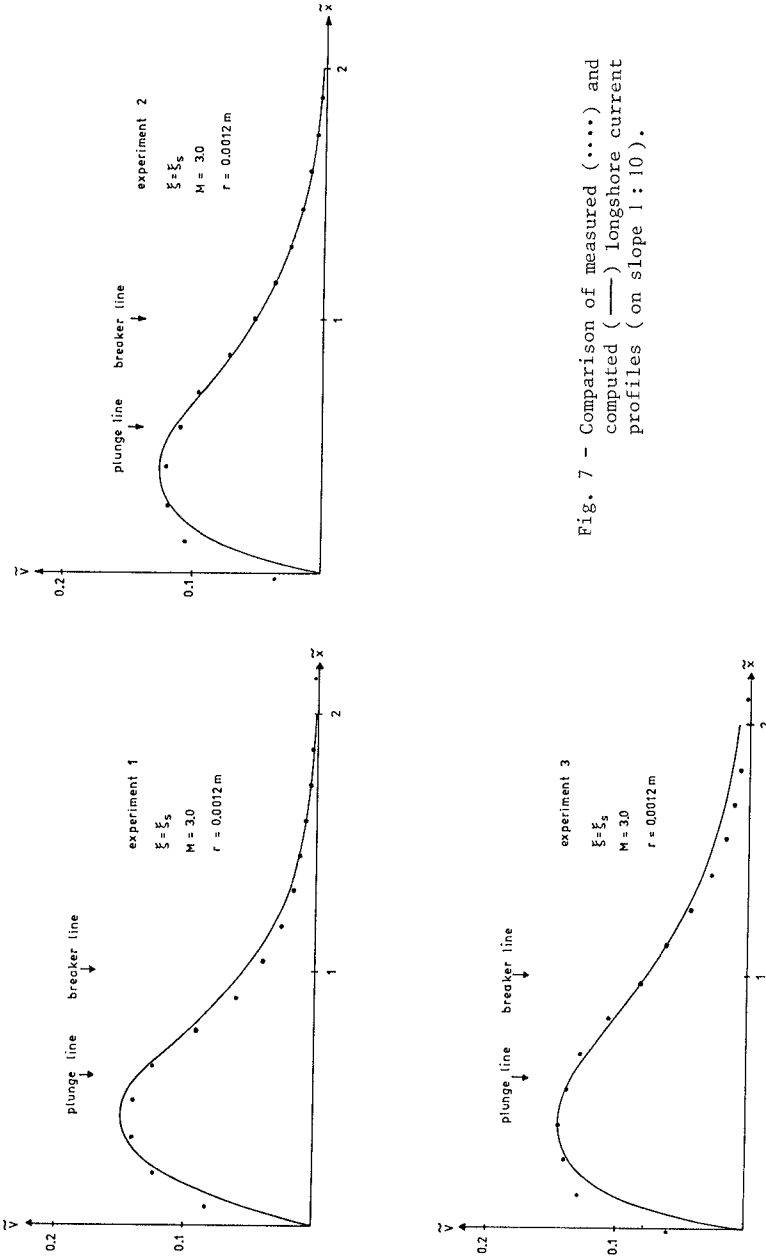

Fig. 7 - Comparison of measured (••••) and computed (—) longshore current profiles (on slope 1 : 10).

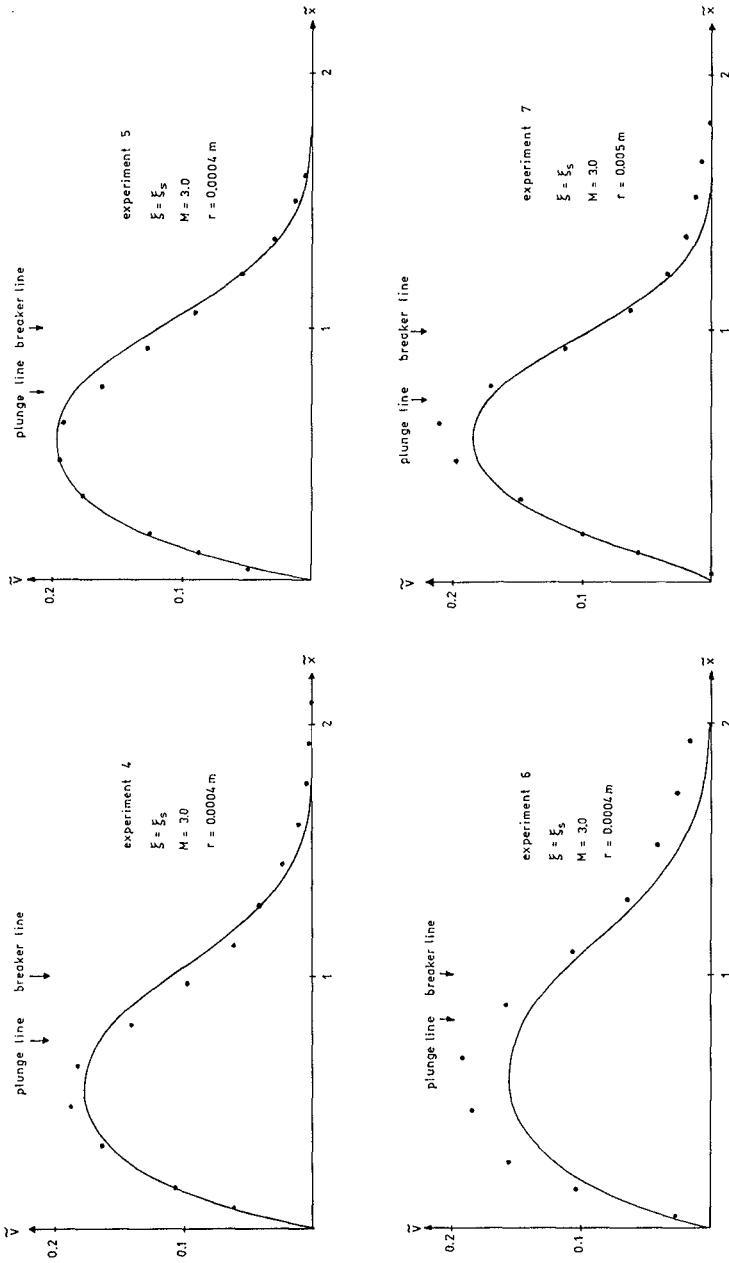

Fig. 8 - Comparison of measured (.....) and computed (——) longshore current profiles (on slope 1:20).

## 5 DISCUSSION AND CONCLUSIONS

The proposed mathematical longshore current model is more plausible on physical grounds than earlier models, in particular the formulation of the longshore driving force (action of this force shoreward of the plunge line) and the application of Battjes' (2,3) lateral friction model (in which the relevant properties of the horizontal turbulent momentum exchange are estimated taking account of the wave energy dissipation by breaking). This mathematical longshore current model has been verified by a number of longshore current measurements in a wave basin. The experimental set-up and execution has been extremely careful in order to obtain reliable results.

The conclusions from this investigation can be summarized as follows:

1. The data obtained from the present longshore current experiments are very usable to check the theoretical results: the rate of accuracy of the measurement results is high, the longshore current profiles are uniform and these were measured in detail.
2. The agreement between the longshore currents predicted by the mathematical model and the experiments is good. This good agreement has been achieved by using realistic values of the bottom roughness.
3. The present investigation confirms the utility of Battjes' (2,3) lateral friction model: best results have been achieved with  $M \approx 2.5-3.0$ , which is indeed of order 1.
4. The longshore current generation takes place between the plunge line and the shoreline (in plunging breakers), instead of in the whole breaker zone.
5. Bottom friction models in which the orbital and mean current velocity are combined, with a depth-dependent bottom friction coefficient and with  $\xi = 1$  or  $\xi = \xi_s$  can be used for the present application.

With respect to the last conclusion it is remarked that more research on this field is necessary because of the uncertainties regarding the real friction in case of combination of wave and current.

## CHAPTER ONE HUNDRED FORTY EIGHT

### Modeling of Nearshore Wave Driven Currents

Jon M. Hubertz<sup>1</sup>

#### Abstract

A nearshore current modeling system has been assembled which consists of a shallow water directional spectral wave model, an algorithm to convert directional spectral output from the wave model to radiation stress components and a current model to calculate nearshore wave-driven currents from the radiation stress field.

Wave-driven longshore currents have been hindcast at a coastal site for two wave conditions during a northeaster type storm off Cape Hatteras in October 1982. For one event, when local winds were strong, the calculated longshore current is only a fraction of what was measured. This discrepancy is attributed to a non-wave-driven component of flow which was present but not represented in the model. During the other event, winds were low and long period swell was present. In this case, the calculated and measured longshore flow agree well.

Both measured and calculated shore normal profiles of longshore current in each case show a generally uniform structure across the surf zone. This is in contrast to theoretical profiles based on monochromatic waves which show a maximum in longshore flow near the breaker line.

#### Introduction

The U. S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center (CERC) is sponsoring research to improve our capability to predict currents in the nearshore area. The prediction techniques which result from this program will then be available to support studies of sediment transport. A workshop held in the summer of 1982 on the subject of modeling nearshore currents provided a forum for discussion of what improvements are most needed to improve nearshore current models. One conclusion of the workshop attendees was that to predict wave-driven currents improvements were needed in transformation of the wave field from the input boundary of a model to the shoreline. It was concluded that acceptable predictions of wave-driven currents were possible only if the distribution of wave parameters in the model region was correct. We have concentrated recently on improving our ability to predict nearshore wave conditions.

Recent research on the transformation of shallow water wave spectra (2) has provided a promising technique to obtain nearshore wave

<sup>1</sup>Research Division, Coastal Engineering Research Center, U. S. Army Engineer Waterways Experiment Station, P. O. Box 631, Vicksburg, MS 39180

conditions. This technique has been incorporated in a two-dimensional directional spectral wave model. Output of the model is a directional spectrum at each grid point over the model region. Each spectrum is a function of wave angle, frequency and depth. These spectra are integrated over frequency and direction to provide an estimate of the three components of radiation stress at each grid point. This field of radiation stress components provides the driving force in a circulation model to predict longshore and cross-shore flows. The wave, radiation stress and current calculations are assembled as a nearshore current modeling system.

Field measurements at CERC's Field Research Facility (FRF) were made in cooperation with the United States Geological Survey (USGS) in the fall of 1982. They provide estimates of longshore and cross-shore flows as well as wave heights along a line normal to shore through the surf zone. Data sets such as these are quite valuable in studying nearshore processes and evaluating models. However, such data may contain the effects of a number of forcing functions such as waves, tides, winds, current fronts, etc. This makes it difficult to isolate particular components for individual study and for comparison to model results where all the processes in nature are not included. Each component in the modeling system is discussed in more detail below, as well as the field measurements and some model results.

#### Nearshore Current Modeling System

Shallow Water Spectral Wave Model.-The basis for the wave model is the model developed by Hsiao (5) to investigate wave energy dissipation in shallow water due to bottom effects. It computes over two horizontal dimensions and allows two-dimensional variation of depth. It is a steady state model which considers the balance of spectral energy among terms for advection of wave energy, refraction and shoaling effects, atmospheric input, bottom friction, percolation and nonlinear wave interactions. The wave number spectral balance equation of the model is:

$$\frac{\partial F(\bar{k}, \bar{x}, t)}{\partial x_i} \frac{dx_i}{dt} = S_A + S_N + S_F + S_P$$

where  $F(\bar{k}, \bar{x}, t)$  is the wave number spectrum and the lefthand side represents refraction and shoaling effects and the righthand side, source terms  $S_A$  - atmospheric input,  $S_N$  - nonlinear wave interaction,  $S_F$  - bottom friction and  $S_P$  - percolation. In addition to these terms, a modification to the model has been made to limit the spectral energy in shallow water by imposing a spectral shape called the TEXEL, MARSEN, ARSLOE (TMA) spectrum. This spectrum provides a favorable fit to about 2800 measured spectra from the three field experiments above. It is related to a quasi-equilibrium deep water spectral shape called the JONSWAP spectrum, (4) by the factor  $\phi$  which results in a quasi-equilibrium shallow water spectral shape. The  $\phi$  factor, (6) varies between zero and one as a function of nondimensional frequency  $W_h$  where  $W_h = 2\pi f \left(\frac{h}{g}\right)^{1/2}$  and  $h$  is depth,  $g$  gravity, and  $f$  is frequency.

A value of zero refers to zero depth and one to deep water. Thus the TMA spectrum can be expressed as:

$$E_{TMA}(f, h) = E_{JSWP}(f) \phi(f, h)$$

with JONSWAP parameters determined from the TMA shallow water data set.

This spectrum appears to account for the distribution of spectral energy in shallow water and with a minor correction even through the surf zone (Vincent, personnel communication). It is not understood at present what physical mechanisms it reflects, only that it approximates the wave spectrum nearshore. If one accepts this, it provides a method to specify spectral energy nearshore and through the surf zone. Thus one no longer has to rely on a monochromatic, single wave direction approach or specify breaking criteria to calculate the distribution of wave energy nearshore.

#### Calculation of Radiation Stresses

Another conclusion of the Nearshore Currents Workshop mentioned above was that the theory of radiation stress, (7) provides a simple and valid mechanism for the generation of nearshore wave driven currents. According to that theory, to second order for a progressive, linear, small amplitude wave, the radiation stress components are:

$$\begin{aligned} S_{xx} &= E \left[ \left( 2n - \frac{1}{2} \right) \cos^2 \theta + \left( n - \frac{1}{2} \right) \sin^2 \theta \right], \\ S_{xy} &= E n \cos \theta \sin \theta, \\ S_{yy} &= E \left[ \left( 2n - \frac{1}{2} \right) \sin^2 \theta + \left( n - \frac{1}{2} \right) \cos^2 \theta \right], \end{aligned}$$

where  $E$  is the wave energy density,  $n$  the ratio of group velocity to wave celerity and  $\theta$  the wave angle. Without recourse to an energy distribution, it has been common to express  $E$  as

$$E = \frac{1}{8} \rho g H^2$$

where  $\rho$  is water density and  $H$  is the root mean square wave height. Thus the radiation stress components depend strongly (as the square) on the distribution of wave height and a mean angle. The wave height in the nearshore has generally been taken as more or less constant up to a breaker line where it decreases rapidly with distance to shore. This results in strong gradients in the radiation stress field near the breaker line and hence strong currents and current shears in this area, if  $\theta$  has some nonzero value (zero indicating waves propagating normal to shore). This approach when combined with some type of lateral eddy viscosity or mixing function to smooth out the velocity field gives comparable results to theory and laboratory observations (1).

In place of the above approach, we have represented the radiation stress components as:

$$S_{xx} = \int_0^{\infty} \int_0^{2\pi} \left[ n \cos^2 \theta + \left( n - \frac{1}{2} \right) \right] E(f, \theta) \, d\theta df,$$

$$S_{xy} = \int_0^{\infty} \int_0^{2\pi} (n \sin \theta \cos \theta) E(f, \theta) \, d\theta df,$$

$$S_{yy} = \int_0^{\infty} \int_0^{2\pi} \left[ n \sin^2 \theta + \left( n - \frac{1}{2} \right) \right] E(f, \theta) \, d\theta df,$$

where in practice the integrals are replaced by summation of the integrands over the frequency and directional domains and  $E(f, \theta, \bar{X})$  is the three-dimensional wave spectrum as a function of position. The three components of radiation stress are calculated at each grid point of the nearshore current model and provide a stress field to generate wave driven currents with a circulation model.

#### Current Model

The wave driven current model was developed by Vemulakonda (8) and is based on the long wave model of Butler (3). In addition to radiation stress, it includes linear bottom friction, advection and lateral mixing terms. A radiation boundary condition is applied at the offshore boundary to permit transients developed during startup of the numerical solution to propagate out of the grid.

The equations for the conservation of mass and momentum, averaged over time (one wave period) and depth are:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial v}{\partial y} + g \frac{\partial \bar{\eta}}{\partial x} + \frac{1}{\rho d} T_{bx} + \frac{1}{\rho d} \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} - \frac{1}{\rho} \frac{\partial T_{xy}}{\partial y} = 0,$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + g \frac{\partial \bar{\eta}}{\partial y} + \frac{1}{\rho d} T_{by} + \frac{1}{\rho d} \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} - \frac{1}{\rho} \frac{\partial T_{xy}}{\partial x} = 0,$$

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x} (ud) + \frac{\partial}{\partial y} (vd) = 0,$$

where  $u, v$  are the  $x, y$  horizontal components of velocity,  $\bar{\eta}$  the mean free surface displacement,  $d$  the total depth,  $T_b$  bottom friction stress and  $T_{xy}$  lateral shear stress. These equations are solved using a three time level, alternating direction, implicit, finite difference scheme. The radiation stress field produced by the directional spectral wave model is input to the current model and held fixed while the current model is stepped to a steady state.

#### Model Simulation

A set of wave and current observations in the nearshore zone were obtained in the fall of 1982 at CERC's FRF in cooperation with the USGS.

Mean values of wave and current data were provided by the USGS (Sallenger, personnel communication) for comparison with the results from the near-shore current modeling system described above. These data were obtained along a line normal to shore and 457 m north of the FRF pier. The near-shore region modeled and location of wave and current observations in relation to the pier location are shown in Figure 1. Measurements were made with three electromagnetic current meters and a pressure sensor mounted on a sea sled which was pulled to various positions along the profile line shown in Figure 1. The three current meters were mounted 0.54, 0.99, and 1.74 m from the sea bed. Mean values of longshore and cross-shore flow over 34.1 minute intervals were measured at various distances from shore. Estimates of significant wave height were also made using the current data and pressure data independently.

A summary of mean current components and wave heights for measurements made on 10 October 1982 is shown in Figure 2. Early on the morning of 10 October 1982 a northeaster developed in the vicinity of Cape Hatteras. Winds from the northeast reached a sustained maximum of 13 m/sec at the FRF and waves grew to 2.5 m in the direction of the wind by Noon on October 10. Data shown in Figure 2 were collected from 1200 to 2000 hours Eastern Daylight Time (EDT) on 10 October while wind and wave conditions were approximately constant.

The mean longshore flow from the measured values during this period is about 80 cm/sec toward the south and fairly uniform along the shore normal profile out to the last measurement point at 285 m. Wave heights of 2 m were measured at the offshore station on the profile line and heights of 1 m at the station closest to shore. The profile of measured wave heights is shown in Figure 3 along with the wave heights calculated from the spectral model for the existing wind conditions. In the spectral model application, only Miles' mechanism for energy input from the wind and the TMA limiting spectral shape are imposed. The other options, (Phillips' term for energy input due to pressure fluctuations, bottom friction, percolation and nonlinear interactions) are turned off. A bottom profile as shown in Figure 2 is applied uniformly in the along-shore direction. The assumption of uniform alongshore bathymetry is based on the depth contours of Figure 1 in the model region. Both the wave and current model are capable of simulating arbitrary bathymetry. The upper and lower bars on the measurements of significant wave height indicate independent measures of significant height respectively from pressure and current meters on the sled at each station. The measured variation of wave height normal to shore is reproduced well by the spectral model.

Next, the radiation stress components were calculated as described above using the directional spectra at each grid point. The stress components were input to the current model as the only forcing term. The advective terms and the lateral eddy viscosity terms were turned off and the model was time stepped to a steady state. The alongshore current component as measured and calculated is shown in Figure 4. The general trend of both curves is similar although shifted in magnitude by a significant amount.

Figure 1. Location of the modeled region (dashed line) in relation to the FRP pier location (solid line over trough). Wave and current observations were made along the solid profile line within the modeled region.

Figure 2. Values of wave height ( $H_s$ ) derived respectively from current and pressure data at stations along the profile line. The time of observation and water level are indicated below values of  $H_s$ . Values of longshore flow shown are averages of values at 0.5, 1.0, 1.75 m above bottom.

Figure 3. Measured and calculated values of significant wave height along the profile line in the model regions.

Figure 4. Measured longshore flow and calculated value of the wave-driven component of longshore flow along the profile line in the model region.

Current measurements made from the end of the pier on the morning of 10 October, while the waves were developing, indicate a current toward the south of 55 cm/sec. The surf zone began about 200 m closer to shore than the end of the pier and there was little gradient in wave height near the end of the pier, so this longshore flow was probably not wave induced. There is not enough information to determine the origin of this component of current. A possibility is wind-induced flow. Estimating the surface wind drift as 3 percent of the wind speed would give a value of about 40 cm/sec. If the measured longshore flow in this case is not primarily due to wave driven current, it points out the need to identify and model all of the current generating processes in the nearshore region before one has a generally acceptable nearshore current model.

As this same storm moved offshore, winds at the FRF decreased and large long period waves generated offshore moved toward the pier from the east. On 12 October 1982 waves at the pier end were measured with a significant height of 3 m and peak period of 15 seconds. Such long period waves are extremely unusual on the U. S. East coast. Wave and current measurements were made along the same profile line as on 10 October and are shown in Figure 5. Longshore flow has now shifted northward in response to waves and winds from the southeast quadrant. The average magnitude from the measured values is now about 27 cm/sec. Values are uniform with distance from the shore out to the last measurement station 285 m from shore.

The bathymetric profile has changed from 10 October presumably due to the high wave activity of the previous two days. Figure 6 provides a comparison of the profile changes, showing the bar formation moving deeper and farther offshore.

The spectral wave model was run with the bathymetry appropriate for 12 October 1982. The results are shown in Figure 7. Again, there is good comparison between observed significant wave height and calculated values with a rather uniform decrease in wave height from 2.5 m at the offshore station to 1 m nearshore. The longshore component of flow produced by the current model for this wave height distribution is shown in Figure 8. There is better correlation between measurements and model results in this case leading one to assume that the longshore flow in this case is primarily wave driven.

Note that this longshore flow profile is not typical of theoretical profiles which increase from shore to a maximum inside the "breaker line" and then decrease to zero seaward in a distance about the same as from shore to the "breaker line." The more uniform distribution of longshore flow with distance from shore, as measured and calculated here, is attributed to the uniform decrease in wave height toward shore as observed and modeled in both of the cases considered. The exact physical processes and their relative importance in contributing to the decrease in wave height are unknown. Possibilities would certainly be breaking, white capping, bottom friction and nonlinear interactions. What percentage each of these plays and what other processes are involved remains unknown. It is likely that the key processes will vary

Figure 5. Values of wave height ( $H_s$ ) derived respectively from current and pressure data at stations along the profile line. The time of observation and water level are indicated below values of  $H_s$ . Values of longshore flow shown are averages of values at 0.5, 1.0, 1.75 m above bottom.

Figure 6. Bathymetric profiles along the profile line in the model.

Figure 7. Measured and calculated values of significant wave height along the profile line in the model regions.

Figure 8. Measured longshore flow and calculated value of the wave-driven component of longshore flow along the profile line in the model region.

for different beach and wave conditions. It is also likely that processes other than wave-driven flow will have to be considered when modeling nearshore currents at a given place and time.

#### Summary

A nearshore current modeling system has been assembled and used to hindcast the wave-driven component of longshore flow for two events at CERC's FRF where wave and current measurements are available. The modeling system is composed of a directional spectral wave model, an algorithm to calculate the components of radiation stress from the spectral wave model and a current model which uses the radiation stress components to calculate the nearshore wave-driven currents.

The first event hindcast was characterized by high winds and local wave generation. Measured longshore flow was relatively uniform in strength and direction from shore to the seaward most measurement station. The computed wave-driven component of flow was also relatively uniform in direction and speed, but only a fraction of the measured value. The discrepancy is attributed to processes other than wave-driven flow which were present but not modeled.

The second event was characterized by low winds and long period waves. The measured and hindcast longshore flow compare well in speed and direction indicating a condition of primarily wave-driven currents. Again, the longshore flow is generally uniform in speed and direction along the measurement profile.

The present nearshore current modeling system shows promise as a tool for studying and predicting nearshore current processes. Employing the directional spectral approach to specify the nearshore wave climate and radiation stress field appears to result in a more uniform cross-shore profile of longshore flow than a monochromatic approach. This is accomplished without resorting to lateral eddy viscosity or mixing parameters to smooth the profile. The more uniform profile is in agreement with the profiles measured at the FRF in October 1982.

A field measurement experiment to support nearshore wave and current model verification and to study nearshore processes is planned for the fall of 1986 at CERC's FRF. Interested investigators are invited to participate in the planning and execution of the experiment. A preliminary set of experiment objectives is available from the author.

#### Acknowledgments

I would like to acknowledge helpful discussions with Dr. Linwood Vincent on the wave model, Dr. Rao Vemulakonda on the current model and Dr. Abby Sallenger on the field measurements. This work was carried out under the Coastal Engineering Research Center's Nearshore Waves and Currents Work Unit, Harbor Entrances and Coastal Channels Program, Coastal Engineering Functional Area of Civil Works Research and Development. The author wishes to acknowledge the Office, Chief of Engineers, U. S. Army Corps of Engineers, for authorizing publication of this paper.

## CHAPTER ONE HUNDRED FORTY NINE

### Improved Formulas for Estimating Offshore Winds

S. A. Hsu\*

#### Abstract

On the basis of many pairs of simultaneous measurements of wind speed onshore,  $U_{\text{LAND}}$ , and offshore,  $U_{\text{SEA}}$ , in areas ranging from Somalia, near the equator, to the Gulf of Alaska, and under conditions ranging from breeze to hurricane, it was found that for operational use  $U_{\text{SEA}} = 3.93 U_{\text{LAND}}^{1/2}$  for  $U_{\text{LAND}} < 10 \text{ m s}^{-1}$  (or 20 kt); and  $U_{\text{SEA}} = 1.24 U_{\text{LAND}}$  for  $U_{\text{LAND}} \geq 10 \text{ m s}^{-1}$ . These formulas were developed mainly from theoretical considerations and were verified by field measurements.

#### 1. Introduction

Differences in onshore and offshore wind speeds have long been known to exist [see, e.g., (2), (15), (16)]. Marine meteorologists in the weather services are required to forecast offshore winds. Many studies related to coastal marine sciences and engineering require wind data or estimates for offshore regions. Yet in situ measurements over water are often lacking. Traditionally, wind measurements over land, preferably near coasts, have been used to estimate offshore winds. However, because simultaneous onshore and offshore observations do not always exist, systematic studies such as simple comparisons between these two environments are also lacking. Only recently the U.S. National Oceanic and Atmospheric Administration (NOAA) deployed a network of buoys for longer term measurements over the continental shelf as well as farther offshore. All of these buoys are located in or near U.S. coastal waters. However, there are still vast regions in other parts of the world where such a network does not exist.

\*Professor, Coastal Studies Institute, Louisiana State University, Baton Rouge, Louisiana 70803, U.S.A.

It is the purpose of this paper to synthesize various data sources and to provide simple formulas for operational use. Basic developments have been given in (9). Furthermore, because of the availability of wind difference measurements during hurricane conditions, as shown most recently by (12), the formulas originally proposed by (8) have been improved and extended from breeze conditions to hurricane-force winds.

## 2. Formulas

In order to understand and estimate wind speed differences across the coastal zone, two models, one theoretical and another semi-empirical, have been developed and verified using available data sets (9). The following discussion is based mainly on that paper.

Assuming that (1) mean horizontal motion occurs perpendicular to the coast and (2) the geostrophic wind does not change appreciably at the top of the planetary boundary layer (PBL), the equation of motion in the direction of the wind can be reduced so that

$$\frac{U_{SEA}}{U_{LAND}} = \left( \frac{H_{SEA} C_{D LAND}}{H_{LAND} C_{D SEA}} \right)^{1/2} \quad (1)$$

where  $U$ ,  $H$ , and  $C_D$  are wind speed, height of the PBL, and drag coefficient, respectively. Subscripts LAND and SEA stand for onshore and offshore environments, respectively.

Eq. 1 is based on equations of motion, which work fairly well for synoptic weather systems typically more than one day in time scale and at least 1,000 km (1 km = 0.54 nautical miles) in horizontal scale. These systems include anticyclones (high-pressure systems), monsoons, and trades. Their  $U_{LAND}$  values are generally less than  $10 \text{ m s}^{-1}$  ( $1 \text{ m s}^{-1} = 1.94 \text{ kt}$ ).

According to Large and Pond (10), the drag coefficient, reduced to 10-m height and neutral condition,  $C_{D SEA}$ , is independent of stability and fetch (for fetch/height  $> 800$ ) but increases with wind speed above

$10 \text{ m s}^{-1}$ . Using their measurements and many deep-water results of others, Large and Pond (10) obtained

$$10^3 C_{D \text{ SEA}} = \begin{cases} 1.2 & 4 \lesssim U_{10} < 11 \text{ m s}^{-1} \\ 0.49 + 0.065 U_{10} & 11 \lesssim U_{10} \lesssim 25 \text{ m s}^{-1} \end{cases} \quad (2)$$

where  $U_{10}$  is the wind speed at a height of 10 m over the water.

For typical low-relief topography and low mountains on land (peaks  $< 0.5 - 1 \text{ km}$ ), Garratt (4) obtained

$$C_{D \text{ LAND}} = 10 \times 10^{-3} \quad (3)$$

where  $C_{D \text{ LAND}}$  is the drag coefficient at a height of 10 m over the land surface.

According to Hsu (6), variation of  $H_{\text{LAND}}$  is much more pronounced than  $H_{\text{SEA}}$  because of larger diurnal variation in heating and cooling over land than farther offshore. This reasoning shows that the most important variable in Eq. 1 is  $H_{\text{LAND}}$ .

Following Blackadar (1), Plate (11), and many others, during neutral conditions

$$H_{\text{LAND}} = \frac{0.2 U_{* \text{ LAND}}}{f} \quad (4)$$

where  $U_{* \text{ LAND}}$  is the friction (or shear) velocity and  $f$  is the Coriolis parameter.

Note that, by definition,

$$C_{D \text{ LAND}} = \left( \frac{U_{* \text{ LAND}}}{U_{\text{LAND}}} \right)^2 \quad (5)$$

Substituting Eq. 5 into Eq. 4, one gets

$$H_{LAND} = \frac{0.2}{f} \cdot C_{D LAND}^{1/2} \cdot U_{LAND} \quad (6)$$

From Eq. 6, Eq. 1 can be written as

$$\frac{U_{SEA}}{U_{LAND}} = \left( \frac{f \cdot H_{SEA} \cdot C_{D LAND}}{0.2 \cdot C_{D LAND}^{1/2} \cdot U_{LAND} \cdot C_{D SEA}} \right)^{1/2} \quad (7)$$

In other words, for a given coastal zone, if one treats values of  $f$ ,  $H_{SEA}$ ,  $C_{D LAND}$ , and  $C_{D SEA}$  as known factors, as discussed above, then Eq. 7 becomes

$$\frac{U_{SEA}}{U_{LAND}} = A U_{LAND}^{-1/2} \quad (8)$$

where

$$A = \left[ \frac{f \cdot H_{SEA} \cdot C_{D LAND}^{1/2}}{0.2 \cdot C_{D SEA}} \right]^{1/2} \quad (9)$$

For  $U_{SEA} < 11 \text{ m s}^{-1}$  (or  $U_{LAND} \lesssim 10 \text{ m s}^{-1}$ ),  $C_{D SEA} = 1.2 \times 10^{-3}$  (10). In mid-latitudes,  $f \approx 10^{-4} \text{ s}^{-1}$ . Adopting the common value of  $H_{SEA} = 335 \text{ m}$  from Davenport [(12); see also Plate (11)] and  $C_{D LAND} = 10 \times 10^{-3}$  from Eq. (3),

we have

$$A = 3.74 \text{ m}^{1/2} \cdot \text{s}^{-1/2} \quad (10)$$

For weather systems such as hurricanes, the equations of motion do not work well because the centrifugal force is not considered. Under these conditions, the semi-empirical formula based on the power law wind distribution in the PBL [see, e.g., Plate (11)] may be employed. The power law states that

$$\frac{U}{U_H} = \left( \frac{Z}{H} \right)^P \quad (11)$$

where  $U$  at height  $Z$  and  $U_H$  at  $H$  are the velocity within and above the atmospheric planetary boundary layer (PBL), respectively. The thickness of the PBL is  $H$ , and  $P$  is an exponent [for details see, e.g., Sedefian (13)].

If we assume that  $U_H$  on top of the PBL does not change appreciably across the coastal zone and that  $Z = 10$  m, Eq. 11 becomes

$$\frac{U_{SEA}}{U_{LAND}} = \frac{10^{P_{SEA}}}{10^{P_{LAND}}} \times \frac{H_{LAND}^{P_{LAND}}}{H_{SEA}^{P_{SEA}}} \quad (12)$$

Adopting common values from Davenport [(2); see also Plate (11)],  $P_{SEA} = 0.10$  (at sea),  $P_{LAND} = 0.16$  (for flat and open country),  $H_{LAND} = 370$  m, and  $H_{SEA} = 335$  m, we find from Eq. 12 that

$$\frac{U_{SEA}}{U_{LAND}} = 1.25 \quad (13)$$

Eqs. 8 and 13 are our basis for data analyses.

### 3. Data Analyses

Many pairs of onshore and offshore measurements have become available recently [see Hsu (9)]. They are summarized in Table 1. Ratios of  $U_{SEA}/U_{LAND}$  were analyzed as a function of  $U_{LAND}$ . Note that in Hsu (9) wind speeds were below  $18 \text{ m s}^{-1}$ . The most recent data set was provided by Powell (12), who included hurricane-force wind measurements obtained during Hurricane Frederic in 1979. Although there are differences in measuring distances between onshore and offshore stations as well as lateral distance from the eye of the hurricane, the measurements are simplified here as shown in Table 1 for operational use.

### 4. Results

The results are shown in Fig. 1. It is interesting to note that

## Table 1 footnotes

- <sup>a</sup>From four geographic regions ranging from tropical to arctic (see Fig. 1 in Hsu, 1981).
- <sup>b</sup>Mean  $\pm$  standard deviation.
- <sup>c</sup>Total number of observational pairs (onshore and offshore).
- <sup>d</sup>Averaged data pairs between beach tower at Long Island, New York, and offshore Brookhaven National Laboratory buoy (from SethuRaman and Raynor, 1980).
- <sup>e</sup>U.S. Naval Coastal Systems Center platform offshore from Panama City, Florida, and NOAA Apalachicola station (see Hsu, 1979a).
- <sup>f</sup>Merchant ship observations vs. Mogadishu, Somalia (under conditions of general summer monsoon, but away from the Somali jet). For this experiment, see Fein and Kuettner (1980) and Hsu (1981).
- <sup>g</sup>Merchant ship observations vs. Gardo, Somalia (under conditions of Somali low-level jetstream).
- <sup>h</sup>Based on Powell (1982).
- <sup>i</sup>Mean  $\pm$  standard deviation averaged from five columns between (3) and (8)
- <sup>j</sup>Total areas studied. Note four areas already included in Fig. 1 in Hsu (1981).

when  $U_{LAND}$  is below  $10 \text{ m s}^{-1}$  the ratio of  $U_{SEA}/U_{LAND}$  follows the general trend of Eq. 8, whereas this ratio is a constant for  $U_{LAND} \geq 10 \text{ m s}^{-1}$ .

On the basis of Eq. 8, the dashed curve in Fig. 1 indicates that

$$U_{SEA} = 3.93 U_{LAND}^{1/2} \quad (14)$$

Note that the value of  $A$  ( $= 3.93 \text{ m}^{1/2} \cdot \text{s}^{-1/2}$  in Eq. 14) is in good agreement with the typical deduction, as shown in Eq. 10. The large standard deviation under low wind speed conditions is due to large variations in  $H_{LAND}$  and  $H_{SEA}$  because of large temperature differences across the coastal zone [see Hsu (6)]. In addition, averaging time, sampling rate, and heights were not uniformly reported in all pairs.

Under high wind speed conditions, say  $U_{LAND} \gtrsim 10 \text{ m s}^{-1}$ , we have

$$U_{SEA} \approx 1.24 U_{LAND} \quad (15)$$

as shown in Fig. 1. This equation is in excellent agreement with Eq. 13.

##### 5. Concluding Remarks

On the basis of many pairs of simultaneous measurements of onshore and offshore winds in regions ranging from the tropics to the Arctic and under forces ranging from breeze to hurricane, it is found that, for operational use:

For wind speed over land, i.e.,  $U_{LAND} < 10 \text{ m s}^{-1}$ ,

$$U_{SEA} \approx 3.93 U_{LAND}^{1/2}$$

and for  $U_{LAND} \geq 10 \text{ m s}^{-1}$

$$U_{SEA} \approx 1.24 U_{LAND}$$

The above formulas are useful over low-relief ( $< 0.5\text{-}1 \text{ km}$  in height) and open coasts. They may not be applicable for mountainous or cliffy

coast areas. Also, atmospheric mesoscale systems such as low-level jets under special conditions [see Hsu (7)], land- and sea-breeze systems (5), and coastal fronts during the winter season were not taken into account. Although there is still large scatter in the data points as shown in Fig. 1 and many smaller scale meteorological systems were not included because of the different physics involved, it is felt that for engineering applications these simplified formulas should be useful as a first approximation to this complex problem of onshore-offshore wind differences.

Acknowledgments. This study was sponsored in part by the Coastal Sciences Program, Office of Naval Research, Arlington, Virginia. Additional support was provided by the Louisiana Sea Grant College Program, a part of the National Sea Grant College Program maintained by NOAA, U.S. Department of Commerce.

Fig. 1. Ratio of  $U_{SEA}/U_{LAND}$  as a function of  $U_{LAND}$ . Data were based on Table 1. Vertical bars are the standard deviation, and numbers beside the mean point are the areas incorporated in the computations. Values on the right-hand side of the equations are mean and standard deviations, respectively.

## CHAPTER ONE HUNDRED FIFTY

### ASPECTS OF WAVE CURRENT BOUNDARY LAYER FLOWS

Felicity C. Coffey and Peter Nielsen

#### ABSTRACT

Field measurements of steady current profiles under the influence of waves are described, including a technique for obtaining an extra independent estimate of the friction velocity. Field and laboratory measurements are analysed for the effect on apparent bed roughness by superimposing waves on a current. Finally the applicability of the eddy viscosity concept to combined flows is examined. The conclusion is that in general, different eddy viscosities must be applied to different flow components.

#### INTRODUCTION

The process of sediment transport and the resulting erosion or sedimentation problems in coastal areas is most often the result of a combined effort by waves and steady (or quasi steady) currents. It is therefore desirable for the coastal engineer to be able to model the flow near a movable bed under combined flows. The aim of this paper is to review, what is known today about wave current boundary layer interaction, and what seems to be needed on the experimental side.

Waves and currents interact in two different ways. Firstly, there is the strong and fairly obvious shoaling and refraction effect on waves that propagate through areas with varying current speed. This effect results from interaction throughout the water column, and the current speed near the surface tends to be the most important. Secondly, there is the interaction in the bottom boundary layer, where the waves tend to dominate and modify the current distribution. The present paper deals entirely with the latter process.

Since short periodic flows develop thinner boundary layers in accordance with

$$\delta = \sqrt{\kappa_* T} \quad (1)$$

---

Coastal Studies Unit, Department of Geography, University of Sydney, N.S.W. 2006, Australia.

and thus penetrate better towards the bed, there is a general tendency for the waves to dominate this layer. In equation (1),  $\delta$  is the boundary layer thickness,  $\nu_T$  is the eddy viscosity, and T is the flow period.

The structure of the wave boundary layer is most often unaffected by even a fairly strong current, while the current profile always shows considerable influence from the waves under naturally occurring conditions. Figure 1 is a simplistic resume of the effects of waves on a steady current.

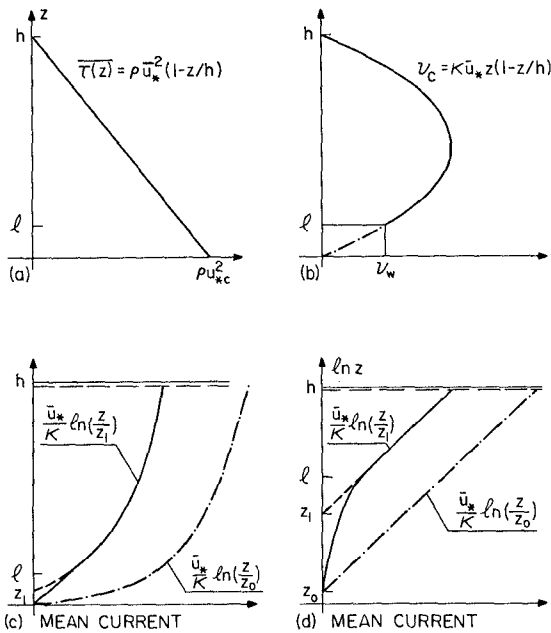

Figure 1: Influence of waves on the steady current profile. (b): The waves create extra eddy viscosity near the bed. (c) and (d): The upper part of the current profile maintains its logarithmic shape, but is shifted towards lower values, and the zero intercept is consequently increased considerably,  $z_1 \gg z_0$ .

It is easier to get a clear idea of what is going on if the steady friction velocity  $\bar{u}_*$  is thought of as a fixed

quantity. That is, we may think of flume experiments where the slope of the mean free surface is kept constant while different wave conditions are enforced.

We assume that the steady shear stress is linearly distributed (Figure 1a),

$$\tau(z) = \rho \bar{u}_*^2 (1-z/h) \quad (2)$$

Deviations from this may occur in the upper layers due to gradients in wave radiation stress, but such deviations will be small in and near the bottom boundary layer. The eddy viscosity induced by the undisturbed steady flow is assumed to have the form

$$\nu_T = \kappa \bar{u}_* z (1-z/h) \quad (3)$$

and (2) and (3) will lead to the familiar logarithmic current profile

$$\bar{u}(z) = \frac{\bar{u}_*}{\kappa} \ln \frac{z}{z_0} \quad (4)$$

where  $\kappa$  is von Karman's constant and  $z_0$  is the zero intercept (Figure 1c,d) of the logarithmic profile. The primary effect of superimposing waves on  $\bar{u}$  comes from increasing the mixing intensity in a thin layer near the bed (Figure 1b), which results in smaller velocity gradients for a fixed  $\bar{u}_*$ .

$$\frac{\partial \bar{u}}{\partial z} = \frac{\tau/\rho}{\nu_T} \sim \frac{\bar{u}_*^2}{\nu_T} \quad (5)$$

Thus the current velocity will grow more slowly with  $z$  through the lower layer when waves are present (Figure 1c,d). Outside the wave boundary layer, the waves will not contribute significantly to the eddy viscosity, and therefore, the shape of the current profile will be unchanged. It can be described by

$$\bar{u}(z) = \frac{\bar{u}_*}{\kappa} \ln \frac{z}{z_1} \quad (6)$$

Hence the only difference from the undisturbed current profile (4) is that  $z_0$  has been replaced by the considerably larger  $z_1$ .

Such changes of the outer steady current profile have been observed in the field by several authors e.g. Cacchione

and Drake (1982) and Grant et al (1983). Laboratory measurements by van Doorn (1981,1982) and by Kemp and Simons (1982,1983) also show this general trend.

The vertical extent of the logarithmic layer is from the top of the wave boundary layer to elevations where the waves or other phenomena start to cause deviations from the linear shear stress distribution, as seen in figure 2.

Figure 2: Steady current velocities in the presence of waves. In this case the intercept elevation was increased from  $z_0 = 0.07\text{cm}$  to  $z_1 = 0.51\text{cm}$  due to the presence of waves.

The relative change of the zero intercept ( $z_1/z_0$ ) depends mainly on the relative current strength  $\bar{u}_w/A\omega$ , but also on the relative roughness  $r/A$  and the direction of the currents relative to the waves.  $A$  is the semi excursion in the wave motion just above the wave boundary layer and  $\omega$  is the angular velocity ( $\omega = 2\pi/T$ ),  $r$  is the hydraulic roughness of the bed.

## FIELD EXPERIMENTS

In the literature combined wave current flows are approached from two perspectives. Namely, the influence of waves on a steady flow and the influence of a current on an oscillatory flow. Field observation of oscillatory boundary layers is generally a problem as it is difficult to fit accurate current meters into the thin wave boundary layer. Thus the field experiments presented here were concerned with the measurement of steady flows under the influence of waves.

Normally, the steady flow component in the field, as well as in the laboratory, shows a nicely logarithmic behaviour over a considerable fraction of the depth, (Figure 2) which gives us the friction velocity from the slope and an apparent roughness from the z-intercept, see Figure 1.

In our experiments the steady flow component was measured by an array of five Hales and Rogers propeller flow meters. The flow meters have an inner diameter of 6cm. Simultaneous readings were obtained by storing the voltage output of each flow meter in capacitors and reading alternatively from a digital display. The flow meter output was filtered electronically over a 100s time period and the sampling interval was approximately 1 minute.

Steady flow calibration of each flow meter was performed before and after each field experiment. The flow meters were found to have a very good, linear response. Experiments were also conducted to investigate the effects of waves on the instruments' steady flow response. These effects need to be taken into account when looking at the data.

Field sites with a strong unidirectional current in association with either parallel or normal wave propagation were selected in order to obtain well controlled field experiments. The codirectional and opposing currents to direction of wave propagation were observed in the tidal channel at Port Hacking, South of Sydney, Australia. The water depth ranged between 1.1 to 2.1m and the sediment diameter was approximately 0.28mm. The average wave period and significant wave height ranged between 7 to 10s and 20 to 61cm, respectively. Well rounded ripples were generally observed and were 2-6cm high and 9-40cm long.

To observe perpendicular currents to wave direction, experiments were carried out in rip feeder channels inshore of a bar. Palm Beach, Warriewood Beach and Warri Beach, near Sydney, were selected. During some experiments currents up to 1 m/s were experienced. The water depth was approximately 1.2m and the sediment, slightly coarser than that found in the tidal channel, had an average diameter of 0.46mm. The average wave period and significant wave height ranged between 7 to 11s and 25 to 50cm, respectively. Ripple geometry varied greatly. Large well rounded ripples with height 10cm and length 90cm were observed as well as small, sharp crested, wave generated ripples with height 2cm and length 10cm.

Time averaged values of the bed shear stresses were determined in the field by measuring the mean water surface slope using the so-called "Barometer". The "Barometer", Figure 3, consists of a set of vertical glass tubes which enable us to read the difference in mean water level between different locations. From the bottom of the tubes run plastic hoses out to different locations. The distance between the hose outlets is approximately 50 m. The tubes are connected at the top so that the air pressure is the same in all of them. We use two tubes for each location in order to check that the instrument is working satisfactorily. The water level should be the same in each pair. Water level oscillations within the tubes are not perceptible. The bed shear stresses or the friction velocity can be determined from the surface slope,  $S$ , via

$$\bar{u}_*^2 = -Sgh \quad (7)$$

Figure 3: The Barometer. Differences in mean water level between the various stations are shown by the water levels in the vertical glass tubes.

We can compare the friction velocity derived from the "Barometer" measurements with the friction velocity obtained from the observed velocity distribution. This is a valuable check. Note, however, that the "Barometer" can only be used in situations where the surface slope is the sole driving force of the current. In the situation where the waves arrive obliquely to the shoreline the radiation stress becomes a contributing driving force of the longshore current.

#### EMPIRICAL KNOWLEDGE ABOUT THE APPARENT ROUGHNESS, $z$ ,

Figure 4 shows tests 7-19 and laboratory data from the literature plotted for apparent roughness  $z$ , against relative current strength,  $\bar{u}_* / A\omega$ .  $z$  is nondimensionalized by the fixed bed roughness index,  $8\eta^2/\lambda$ , suggested by Nielsen 1983.  $\eta$  is the ripple height and  $\lambda$  is the ripple length. The relative current strength is the ratio between the current friction velocity  $\bar{u}_*$ , and the near bed horizontal velocity due to waves,  $A\omega$ . The results show that with increasing wave dominance  $z$ , increases. This has been observed by Kemp and Simons (1982,83). However, for the current following the waves, marked by the dots, the relationship is not clear and for perpendicular currents (the triangles) this relationship may not hold at all. Thus what we can see from this graph is that the relative orientation of waves and currents is important. More measurements are needed. The fixed bed roughness index appears to be a satisfactory scaling parameter for four of the perpendicular current observations, which flowed over sharp crested ripples. These lie in the vicinity of the laboratory data which used fixed roughness elements. However, the majority of field observations with well rounded ripples lie well below the laboratory data. This indicates that for these cases the relevant scaling parameter is the grain size rather than the ripple geometry.

#### WAVE BOUNDARY LAYER STRUCTURE

The wave induced velocity  $u(z,t)$  inside the wave boundary layer differs from the corresponding free stream velocity  $u_\infty(t)$  with respect to both magnitude and phase. This makes it somewhat complicated to describe the structure of the flow. We shall use the formalism suggested by Nielsen (in prep) which stresses the analogy in form of all oscillatory boundary layers with that of smooth, laminar oscillatory flow. For simplicity, we consider only simple harmonic flow

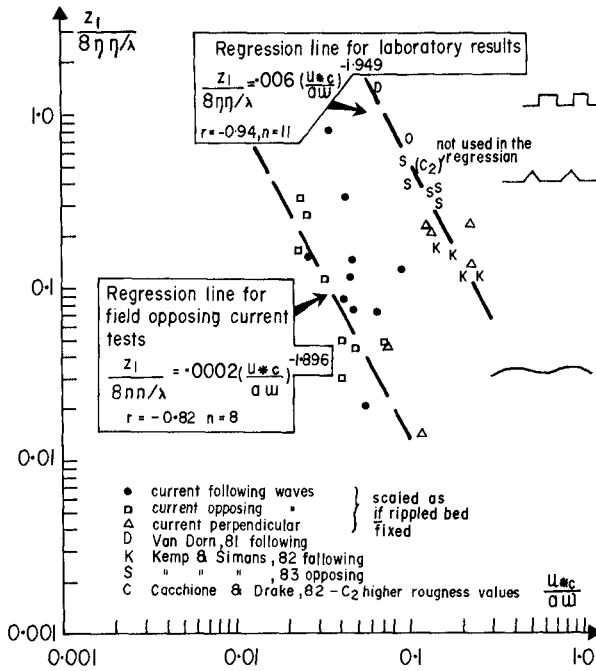

Figure 4: Field and laboratory data plotted for apparent roughness ( $30z_1$ ) against relative current strength,  $\bar{u}_* / A\omega$ .  $z_1$  is nondimensionalized by a fixed bed roughness index,  $8\eta^2/\lambda$ , given by Nielsen 1983, where  $\eta$  is ripple height and  $\lambda$  is ripple length.

With increasing wave dominance  $z_1$  increases. We find two populations of data. The upper set contains laboratory data and four field measurements of perpendicular flows with sharp crested ripples. The lower group consists entirely of field measurements where well rounded ripples were observed. This suggests that when the ripples are rounded, the hydrodynamic roughness is determined by grain size rather than ripple geometry.

or the first harmonic of more complicated flows, and define the non dimensional velocity deficit  $D(z)$  by

$$u(z,t) = [1-D(z)]A\omega e^{i\omega t} \tag{8}$$

$D$  is unity at the bed and zero at infinity, so that the free stream velocity corresponds to  $A\omega e^{i\omega t}$ .

For smooth, laminar flow,  $D$  is given by

$$D(z) = \exp[-(1+i)\frac{z}{\sqrt{2\nu/\omega}}] \tag{9}$$

see e.g. Lamb (1945). Equation (9) shows that argument and magnitude of  $D$  are two sides of the same thing in the sense that

$$\ln D = \text{Arg } D \tag{10}$$

Figure 5 shows the identity (10) for a rough turbulent oscillatory flow measured by van Doorn (1982).

Figure 5: The identity (10) which is an analytical result for smooth laminar flow holds for most turbulent flows as well.

As pointed out by Nielsen (in prep), this identity holds for many turbulent flows as well, with a slight generalisation in the form of D

$$D = \exp[-(1+i) \left(\frac{z}{z_t}\right)^p] \tag{11}$$

where the "Stokes' length"  $\sqrt{2\nu/\omega}$  is replaced by  $z_t$  which is approximately equal to  $0.095\sqrt{\nu A}$ . The slope parameter p varies smoothly from unity for very rough flows ( $A/r < 10$ ), to 0.32 for smooth turbulent flow.

The fact that very rough flows have the same slope parameter as smooth laminar flow, namely unity, is due to the fact that in both of these two cases there is only one vertical length scale involved. For smooth, laminar flow it is the "Stokes' length", and for very rough turbulent flows it is the bed roughness length.

The validity of (10) is not disturbed by superposition of a steady current, and the variation of D(z) changes very little, even with a fairly strong current. See Figure 6.

Figure 6: Variation of Arg D with z for different relative strengths of superimposed currents. The steady current induces very little change in the wave boundary layer structure.

## EDDY VISCOSITY IN OSCILLATORY FLOW

Shear stresses and velocity gradients in a turbulent flow are most easily related via an eddy viscosity

$$\nu_T = \frac{\tau/\rho}{\frac{\partial u}{\partial z}} \quad (12)$$

and it is therefore tempting to try and apply eddy viscosity models. It must be remembered however that  $\nu_T$  is only a formal tool without strictly defined physical meaning. This becomes very clear when one considers empirical data on oscillatory flows like the ones shown in Figure 7.

Figure 7: Time dependence of local shear stress and velocity gradient, both phase averaged. From Jonsson and Carlsen (1976) Test 1. The measurements were taken 45mm above a ripple crest.

The fact that the phase averaged values of shear stress and velocity gradients are out of phase (Figure 7) implies a somewhat radical behaviour of the eddy viscosity via the definition (12). Two interpretations are possible. One can either define the eddy viscosity as a real valued function of time, which will then have to vary approximately like  $-\tan \omega t + \text{constant}$ , see Horikawa and Watanabe (1967). The other option is to allow the eddy viscosity be a complex quantity. The latter option leads to a constant  $\nu_T$  if  $\tau$  and  $\frac{\partial u}{\partial z}$  are simple harmonic and the angle  $\text{Arg } \nu_T$  is then the phase shift between the two.

If we apply the second interpretation, measurements like the ones shown in Figure 5 correspond to complex eddy viscosities ( $\text{Arg } \nu_T \neq 0$ ). In fact the form given by eqs. (8) and (11) corresponds to a real valued  $\nu_T$  only when  $p=1$ . In that case the eddy viscosity is a real constant given by

$$\nu_T = \omega z_i^2 / 2 \quad (13)$$

## EDDY VISCOSITIES IN COMBINED FLOWS

Because of its simplicity the eddy viscosity model has been applied to combined flows by several authors in the past: Lundgren (1972), Grant and Madsen (1979) and Christoffersen (1982). All of these authors assumed the existence of a "common" eddy viscosity, which would apply to all flow components.

This assumption seems very reasonable, but it has never been proven. Only very recently, with the publication of the very detailed measurements by van Doorn (1981,1982) has it become possible to test it. The test result is stunning. It is very clearly negative, showing that steady and oscillatory components of the same flow correspond to very different eddy viscosities. See Figure 8.

Figure 8: Eddy viscosity estimates derived from steady and oscillatory components of the same flow. The steady component feels 3 times larger eddy viscosities inside the wave boundary layer than do the waves.

The eddy viscosity is estimated from the oscillatory component via equation (13).

The implication of Figure 8 is that future models of combined flows which are based on the eddy viscosity concept, must allow for the use of different eddy viscosities for different flow components.

Some might then say that the use of the eddy viscosity concept is a total over simplification, and that we must turn to other models of the stress strain relation, for example, the von Karman - Prandtl mixing length model

$$\tau = \rho l^2 \left| \frac{\partial u}{\partial z} \right| \frac{\partial u}{\partial z} \quad (14)$$

However the work of van Doorn (1983) and Nielsen (in prep) show that the non linear von Karman - Prandtl model which makes analytical solution impossible, is only marginally better than the linear-eddy-viscosity-model applied by Grant and Madsen (1979). Both models predict the flow phases rather poorly. See Throwbridge (1983) or Nielsen (in prep).

#### CONCLUSIONS

The major effect of waves superimposed onto a current with fixed  $\bar{u}_*$  is to reduce the current gradients inside the wave boundary layer. This leads to a shifting of the upper current profile towards smaller velocities. The shape of the upper current profile is unchanged because there is no wave induced mixing in this layer. One therefore finds (Lundgren, 1972) that the current profile above the wave boundary layer is logarithmic (Figure 2), and defines a friction velocity  $\bar{u}_*$ , by its slope and an apparent roughness ( $30z_i$ ) by its zero intercept  $z_i$ .

The apparent roughness in combined flows is generally found to be an order of magnitude larger than the Nikuradse roughness,  $30z_o$ , defined by a pure current over the same bed. Field and laboratory measurements shown in Figure 4 indicate that the roughness increase  $z_i/z_o$  depends strongly on the relative current strength,  $\bar{u}_*/A\omega$ . The dependence may be roughly described by

$$\frac{z_i}{z_o} \sim \left( \frac{A\omega}{\bar{u}_*} \right)^{1.9} \quad (15)$$

The dependence of  $z_i/z_o$  on the relative direction of waves and currents is so far unresolved. Thus there is a strong need for well controlled experiments with waves running at an angle to the current.

Analysis of high quality laboratory measurements reveals that the eddy viscosity concept can be applied to combined flows only with extreme caution. It is found that we must in general apply different eddy viscosities to different flow components. The measurements of van Doorn (1981,1982) show that the steady flow component feels an eddy viscosity three to four times larger than the one felt by the main oscillatory component.

## CHAPTER ONE HUNDRED FIFTY ONE

### A THEORETICAL AND EXPERIMENTAL STUDY OF UNDERTOW

J. Buhr Hansen\* and I. A. Svendsen\*

#### ABSTRACT

It is well known that on a three-dimensional beach large volumes of water carried shorewards by the breakers feed longshore currents, which eventually escape back through the breaker line, often as rip currents.

In a steady two-dimensional situation, however, the mass flux represented by (among other things) the surface roller in the breakers returns as a seaward current close to the bottom. This current is called the undertow.

In this paper theoretical results for the undertow are compared with the results of recent laboratory experiments.

#### 1. INTRODUCTION

Although known for years and described quite explicitly in texts on coastal morphology (see e.g Johnson 1919) the undertow seems for a long time to have escaped the attention of coastal engineers and scientists.

Undertow is the name used for the often very strong shore normal mean current which in a surf zone moves seaward below the level of the wave trough.

Clearly such a flow can only be maintained provided a similar flux of water is brought shorewards otherwise. This happens between crest and trough level in the broken surf zone waves. the situation is sketched in Fig. 1.

Fig. 1. The circulation flow in the vertical plane.

This circulation in the vertical plane represents a mechanism for maintaining the mass balance in the surf zone of a long beach. Another possible mechanism in the nearshore circulation is the three dimensional pattern of longshore and rip currents, which so far has received much more attention than the two dimensional circulation scheme in Fig. 1.

---

\* Assoc. Prof., Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark, DK-2800 Lyngby.

The purpose of the present paper is to discuss the physical processes responsible for the undertow. The discussion is supported by a theoretical model and recent laboratory measurements.

The undertow was observed experimentally by Bagnold (1940) and a qualitative analysis of the phenomenon was given by Dyhr-Nielsen and Sørensen (1970) in a descriptive paper which in essence contained most of the physical ideas pursued quantitatively in the following.

In the last few years the undertow has eventually attracted more attention. Thus Börekci (1982) presented a theoretical model based on the sinusoidal waves for the distribution over depth of this mean circulation, and an almost similar analysis was in fact given by Dally (1980).

Lately Louquet-Higgins (1983a,b) has considered several effects that may be caused by the strong pressure gradient from the set-up which also creates the undertow. In the last of the two papers in terms of convincing experimental demonstrations.

Finally Svendsen (1984b) presented a theoretical model based on the description of surf zone waves developed in Svendsen (1984a).

It may also be mentioned that laboratory values for the undertow can be extracted from the raw data of Stive and Winds experiments and were used by Svendsen (1984b). Also Guza (1984) reports that during the NSTS experiments at Californian beaches all current meters in the surf zone showed uniformly seaward going mean currents. This part of the data, however, has not been processed yet.

The theoretical model for the velocity profile of the undertow developed by Svendsen (1984b) differs from the models of Dally (1980) and Börekci (1982) in the way properties of the broken waves such as radiation stress and mass flux are determined.

The present paper will emphasize the physical aspects rather than mathematical details of the phenomenon, present some new measurements and also discuss the interaction with the bottom boundary layer, a point which was only briefly mentioned in Svendsen (1984b).

For several reasons an eulerian description has been chosen rather than a lagrangian. For one thing it is far simpler. Further all the measurements available are measurements at fixed points (i.e. eulerian descriptions). Most important, however, is the fact that the eulerian description is physically the more informative when mass balance, sedimenttransport etc. is considered.

## 2. THE MECANISM RESPONSIBLE FOR THE UNDERTOW

As mentioned in the introduction the undertow is a (strong) mean current which, superimposed on the oscillatory motion of the surf zone waves, moves seawards.

In this section is shown qualitatively that the undertow represents a balance between three equally important forces acting on the fluid particles.

For a start it is worth to recall that the turbulence created by the breakers spread downwards from the surface, where it was created, so that in the surf zone there is a substantial amount of turbulent kinetic energy present at all levels between bottom and surface. In such an environment a current like the undertow will generate large shear stresses which will tend to stop the current. Thus for the undertow to exist there must be a strong driving mechanism, which yields a seaward directed net force on each fluid particle.

It is well known that the depth- and time-averaged momentum balance

reads:

$$\frac{\partial S_{xx}}{\partial x} = -\rho g(h_0 + b) \frac{\partial b}{\partial x} - \overline{\tau}_b \quad (2.1)$$

where  $b$  is the set-up,  $\overline{\tau}_b$  is the mean bed shear stress, and the radiation stress  $S_{xx}$  is defined as

$$S_{xx} = \int_{-h}^{\eta+b} (\rho u^2 + p_D) dz - \frac{1}{2} \rho g \eta^2 \quad (2.2)$$

The dynamic pressure  $p_D$  is defined by

$$p_D = \rho g(z-b) + p \quad (2.3)$$

In this balance, however, the individual contributions are not equally distributed over depth. In (2.2) both  $u$  and  $p$  will in general vary over the depth and, in surf zone waves in particular, by far the largest contributions to  $S_{xx}$  (including the last term in (2.2) come from the region between trough and crest.

The  $\partial b/\partial x$  term in (2.1) on the other hand represents the pressure gradient from the sloping mean surface, and this contribution is the same at all  $z$ -levels. Fig. 2 shows the situation.

Fig. 2. The distribution of radiation stress and pressure gradients.

Consequently, if we consider a small fluid element at any  $z$ -level below trough level there will (in average over a wave period) be a net (seaward-directed) horizontal force on that fluid element equal to the difference between the local  $S_{xx}$ -contribution and  $g \partial b/\partial x$ . It is this net force which is driving the undertow. In Fig. 2 is also indicated the turbulent shear stress gradients which are responsible for preventing the current from accelerating indefinitely.

Thus a steady undertow establishes a balance between essentially three different forces: the radiation stress the pressure gradient due to set-up and the turbulent shear stresses created by the vertical variation of the undertow velocity in combination with the turbulence already present due to the breaking. The model used in the following is based on this balance. In principle it assumes (in addition to a situation steady in time) uniform conditions at different points in the shore normal direction. Since the depth varies this is clearly not quite true, but applies well to a gently sloping beach. The assumption corresponds to neglecting the convective accelerations in the shore normal direction, and on a steep beach this may not be acceptable.

3. THEORETICAL DESCRIPTION

From the description in Section 2 we realize that the undertow is associated with the strong set-up caused by wave breaking. Hence a proper quantitative description requires that the relevant characteristics of the surf zone waves are modeled suitably (see Svendsen, 1984a).

One of the important features is the mass or volume transport  $Q_s$  which occurs between crest and trough in the waves.  $Q_s$  is defined as (for definition of nomenclature see Fig. 3)

Fig. 3. Definition sketch.

$$Q_s = \overline{\int_{\eta_{tr} + b}^{\eta + b} u \, dz} \quad (3.1)$$

where  $\overline{\quad}$  indicates average over a wave period.

In broken waves this is found to be composed of two contributions (Svendsen, 1984a): one is the ordinary effect of non-linearity known from non-breaking waves. The other is caused by the surface roller which is equivalent to an amount of water directly following the wave as it propagates shorewards. Thus the average particle velocity in the roller equals the propagation speed  $c$  of the wave.

It is therefore assumed that the velocity variation in the waves can be approximated as shown in Fig. 4.

Fig. 4. a. Velocities in a breaker.  
b. Velocity profile used in this paper.

This is combined with the assumption that the change in shape of the waves can be neglected locally which implies that

$$I \equiv \int_{-h_0}^{\eta+b} u \, dz = c\eta \quad (3.2)$$

As written (3.2) also presumes that there is no net mass flux in the waves (two dimensional problem), and that  $\bar{\eta} = 0$  as indicated in Fig. 3.

When substituting these assumptions into (3.1) we get for the total Stokes drift (for derivation see Svendsen (1984 b))

$$Q_s = c \left( \frac{H}{h} \right)^2 \left( B_0 + \frac{A}{H^2} \frac{h}{L} \right) d_{tr} + O \left( \left( \frac{\eta}{h} \right)^3, \dots \right) \quad (3.3)$$

In this expression  $L$  is the "wave length" defined as  $c(x)T$ ,

$$B_0 \equiv \overline{(\eta/H)^2} \quad (3.4)$$

and  $A$  is the area in the vertical plane of the surface roller (see Fig. 4).

Measurements of  $A$  is only available for deep water breaking behind a submerged hydrofoil (Duncan, 1981) where it was found that

$$A \approx 0.9 H^2 \quad (3.5)$$

With no net mass (or volume) flux in the wave we also find the mean velocity  $U_m$  in the region below wave trough to be given by

$$U_m = - \frac{Q_s}{d_{tr}} \quad (3.6)$$

where  $d_{tr}$  is the water depth under the wave trough. With these results we have ensured the conservation of mass in the wave-current motion considered.

The equation of conservation of (horizontal) momentum is used on the form

$$\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial uw}{\partial z} = - \frac{1}{\rho} \frac{\partial p}{\partial x} \quad (3.7)$$

where viscous terms have been neglected. The balance described in Section 2 between three contributions then results in the following relation

$$\overline{\frac{\partial u^2}{\partial x}} \approx -g \frac{\partial b}{\partial x} - \frac{1}{\rho} \frac{\partial \bar{\tau}}{\partial z} \quad (3.8)$$

which is the time averaged momentum equation for a fluid particle.  $\bar{\tau}$  is the turbulent shear stress and  $u$  the turbulent mean velocity. (3.8) only applies below the level of the wave trough  $u$  may be divided into a wave part  $u_w$  (with  $u_w = 0$ ) and the undertow component  $U$ . It can then be shown that consistent with assumptions already introduced we have

$$\overline{u_w^2} \gg U^2 \quad (3.9)$$

so that (3.8) may be written as

$$\frac{1}{\rho} \frac{\partial \bar{\tau}}{\partial z} = \frac{\partial}{\partial x} \left( \overline{u_w^2} + gb \right) \tag{3.10}$$

The turbulent shear stress  $\tau$  is described by an eddy viscosity  $\nu_t$  such that

$$\tau = \rho \nu_t \frac{\partial (u_w + U)}{\partial z} \tag{3.11}$$

This is time averaged and we invoke that  $u_w$  to the first approximation can be assumed independent of  $z$ . Then we get

$$\bar{\tau} = \overline{\nu_t(t) \frac{\partial (u_w + U)}{\partial z}} = \overline{\nu_t(t)} \frac{\partial U}{\partial z} = \nu_t(t) \frac{\partial U}{\partial z} \tag{3.12}$$

which means we can apply the time averaged value for  $\nu_t$ . Then (3.10) can be solved directly which yields

$$U(z) = \alpha_1(x) \int \frac{z}{\nu_t(z)} dz + \beta_1(x) \int \frac{dz}{\nu_t(z)} + \gamma(x) \tag{3.13}$$

where

$$\alpha_1(x) = \frac{\partial}{\partial x} \left( \overline{u_w^2} + gb \right) \tag{3.13}$$

and  $\beta_1$  and  $\gamma$  are arbitrary integration functions to be determined by the boundary conditions.

Discussion of boundary conditions

To determine  $\beta_1$  and  $\gamma_1$  we need two conditions.

One seems fairly obvious: that the total volume flux represented by the undertow must equal  $Q_g$ . This can also be expressed as: the mean value of  $U(z)$  between trough and bottom must be  $U_m$ , that is

$$\int_{-h_0}^{\eta_{tr}} U(z) dz = U_m d_{tr} \tag{3.14}$$

As the second condition it will be natural to use the boundary value for  $U$  at the bottom. To do that properly, however, we must recall that at the bottom we have an oscillating boundary layer which averaged over time shows a steady streaming. Thus a consistent choice at this boundary will be either to use as the boundary condition the steady streaming velocity  $U_b$  at the top of the oscillatory boundary layer - and neglect the thickness of that layer so that  $U = U_b$  applies at  $z = -h_0$  - or to include the boundary layer in the solution. The latter necessitates that the boundary layer solution is carried to second order in the perturbation expansion.

Some aspects of this problem is discussed further in section 4 but for the time being it suffice to let

$$U(z) = U_b \text{ for } z = -h_0 \tag{3.15}$$

It may be worth briefly to examine some other possible boundary conditions for  $U(z)$ .

One possibility is to replace (3.14) by a boundary condition at the trough level  $z = \eta_{tr}$  where a proper description of the turbulence can yield a value for  $\bar{\tau}$  i.e. a condition on  $\partial U / \partial z$ .

When using the shear stresses at trough level as a boundary condition it becomes necessary to analyse the magnitude of the  $\partial \overline{uw} / \partial z$ -term in (3.6) ( $u$  and  $w$  being turbulent mean velocities) relative to the turbulent contributions to  $\bar{\tau}$ , and that requires a far more detailed description of the wave motion. The  $\overline{uw}$ -term also includes the convective accelerations caused by the decrease in wave height as the water depth decreases. This will cause  $Q_s$  to decrease shorewards giving a vertical flow downwards proportional (at trough level) to  $\partial Q_s / \partial x$ . The effect represents an enhancement of the horizontal shear stresses. In the present very crude model this effect has been considered included in  $v_t$  but would be necessary elements in a more detailed model.

Dally (1980) and Bökrci (1982) used both (3.14) and a condition for  $\bar{\tau}$  ( $z = \eta_{tr}$ ) and considered in addition the flow between trough and crest. In combination with sinusoidal waves (which they used) this is of limited relevance.

#### Solutions for two $v_t$ -distributions

The simplest possible evaluation of (3.13) is for  $v_t = \text{const}$ . Using the boundary conditions (3.14) and (3.15) thus yields

$$\frac{U(y) - U_b}{c} = \frac{1}{2} \frac{\alpha d_{tr}^2}{c} \left( \frac{y}{d_{tr}} \right)^2 + 2 \left( \frac{U_m - U_b}{c} - \frac{1}{3} \frac{\alpha d_{tr}^2}{c} \right) \frac{y}{d_{tr}} \quad (3.16)$$

where  $y = z + h$  is the distance from the bottom and

$$\alpha \equiv \frac{a_1}{v_t} \quad (3.17)$$

Our knowledge, however, of the turbulence generated by the breakers indicates that it spreads downwards from the surface while decaying. Hence  $v_t$  can be expected to decrease with distance from the surface. To model this we may use a  $v_t$  decreasing exponentially downwards, i.e.

$$v_t = Ne^{a(z - \eta_{tr})} \quad (3.18)$$

With the boundary conditions described above this yields the solution

$$U(z) = - \left( \frac{A_1}{c} + \frac{\alpha_1}{ca^2 N_0} ay \right) e^{-ay} + \frac{\gamma}{c} \quad (3.19)$$

where

$$A_1 = \frac{U_m - U_b}{M_1} - \frac{\alpha_1}{a^2 N_0} \left( 1 + ad_{tr} - \frac{ad_{tr}}{M_1} \right)$$

$$M_1 = \left( e^{-ad_{tr}} - 1 + ad_{tr} \right) / ad_{tr}$$

$$\gamma = U_b + A_1; \quad N_0 = Ne^{-ad_{tr}}$$

4. THE EFFECT OF THE PRESSURE GRADIENT ON THE BOTTOM BOUNDARY LAYER.

The relatively strong mean pressure gradient created by the set-up also changes the momentum balance in the bottom boundary layer. The equation for the mean flow may again be derived from (3.7) but using somewhat different approximations. As before we neglect the effect of the sloping bottom. A perturbation expansion is introduced by

$$u = u^{(1)} + u^{(2)} + \dots, w = w^{(1)} + w^{(2)} + \dots; p = p^{(1)} + p^{(2)} + \dots;$$

After averaging over a wave period and substitution of an eddy viscosity description for  $\tau$  based on a boundary layer viscosity  $\nu_{tb}$  this yields for the second order approximation

$$\frac{\partial}{\partial z} \left( \nu_{tb} \frac{\partial \overline{u^{(2)}}}{\partial z} \right) = \frac{\partial}{\partial z} \left( \overline{u^{(1)} w^{(1)}} \right) + \frac{\partial}{\partial x} \left( \overline{u^{(1)2}} + gb \right) \quad (4.1)$$

Here  $u^{(2)}$  represents the combined undertow and steady streaming in the boundary layer.

This is the equation describing the steady streaming in the bottom boundary layer. The first right term is the usual driving term for this flow (see e.g. Louquet Higgins 1953, 1957). This term tends to zero as we move away from the bottom, and we see that apart from this term the equation is almost the same as (3.8) describing the undertow. The additional differences being that the oscillatory component  $u^{(1)}$  is here  $u^{(1)}(z)$  and  $\nu_{tb}$  will in general be different from  $\nu_t$  for the undertow.

A similar equation (but with some terms included representing the effect of the sloping bottom) was derived by Börekci (1982), and the peristaltic pumping studied by Longuet-Higgins (1983) leads to an equation without the  $\overline{u^{(1)2}}$ -term. The orders of magnitude of the contributions to this momentum balance was discussed by Longuet-Higgins (1983).

Equation (4.1) may in fact be solved directly. For  $\nu_{tb} = \text{constant}$  the solution may be written

$$\overline{u^{(2)}} = \frac{1}{\nu_{tb}} \iint \frac{\partial}{\partial x} \overline{u^{(1)2}}(\xi) d\xi dz + \frac{g}{\nu_{tb}} \frac{db}{dx} \left( \frac{1}{2} z^2 + C_1 z + C_2 \right) + u_s(z) \quad (4.2)$$

where  $u_s$  is the steady streaming without the pressure gradient and with

$\frac{\partial}{\partial x} \overline{u^{(1)2}} = 0$ . Also for variable  $\nu_{tb}$  is the solution straightforward, however.

The boundary conditions to be satisfied by (4.2) is that at  $z = -h$  we have  $\overline{u^{(2)}} = 0$  and at the upper edge of the boundary layer  $\overline{u^{(2)}}$  approaches the undertow velocity  $U$ .

The solution used by Svendsen (1984b) corresponds to assuming the boundary layer infinitely thin and letting  $\overline{u^{(2)}} = U_b = u_s$  at  $z = -h$ . We see that in (4.2) this corresponds to neglecting the first two terms inside the boundary layer.

Equation (4.2) also shows, however, that if  $\nu_{tb}$  is small in comparison with  $\nu_{tb}$  between bottom and trough these terms may become far more important. Comparison of the eddy viscosities  $\nu_t$  found for turbulent

bores by Madsen & Svendsen (1983) with the eddy viscosities in an oscillatory boundary layer corresponding to the wave friction factors determined by Jonsson & Carlsen (1976) indicates that  $v_t$  may be significantly larger than  $v_{tb}$ . Further analysis is needed of this question, and also of the boundary layer under breaking waves rather than ordinary sine waves.

Using, however, a seemingly conservative estimate of  $v_{tb}$  which is 0.2 times a typical value of  $v_t$  in the region between trough and bottom, and constant over the boundary layer, then we get a mean velocity  $u^{(2)}$  at  $z = \delta$  ( $\delta \equiv (2v_{tb}/\omega)^{1/2}$ ) which on a slope  $h_x = 1/34$  is of the same order of magnitude as  $U_{bs}$  given by linear theory but of opposite sign. In other words: in the outer part of the bottom boundary layer the steady streaming is likely to be strongly seawards oriented. As it will be seen this result conforms well to the measurements presented in section 7. In the absence, however, of more precise information about this point we have chosen in the comparison with the measurements to show the effect which different values of  $U_b$  have on the undertow profile. This is done by showing theoretical results corresponding to  $U_b$ -values between + and -  $U_{bs}$  where  $U_{bs}$  is the (Eulerian) value from linear wave theory, i.e.  $U_{bs} = 3/16 c(H/h)^2$ .

#### 5. EXPERIMENTAL SET-UP

The experiments are carried out in a flume 32 m long, 60 cm wide, with a plane beach sloping 1:34.26 (see Fig. 5).

Fig. 5. Experimental set-up.

The motion of the piston type wave generator is controlled by a PDP 8 minicomputer, which generates a command signal of the form

$$\xi = e_1 \sin \omega t + e_2 \sin (2\omega t + \beta)$$

(Buhr Hansen, and Svendsen, 1974).

The water depth in front of the sloping beach is 36 cm, the wave period  $T = 2s$ , and the wave height  $H = 12$  cm. To obtain a stable test situation in the wave flume waves were generated for at least 20 min. before any recordings were taken.

The particle velocities are measured using a bi-directional micro-propeller current meter described in Basco et al, 1982. (see Fig. 6). However, for the undertow measurements special data logging and data-processing programmes were designed.

Fig. 5 Schematic illustration of the bi-directional, micro-propeller current meter showing the propeller, mounting, frame, and double electrodes to sense the blade passage for electronic interpretation. (From Basco et al. 1982).

The principle of operation of the current meter is that the propeller blades generate electric pulses when passing either of the electrodes A and B. The speed is determined directly from the length of the time interval between consecutive passages of the same electrode and the direction from the "position" of the pulse from the other electrode recorded in the same time interval.

The propeller is 5 mm diameter with 3 blades equivalent to approximately 5.2 mm peripheral distance between the blades. The propeller blade angle is  $45^\circ$  and the distance between the electrodes is 2 mm.

The time interval between consecutive pulses from one electrode varies from about 200 ms for velocities of 5 cm/s (about the lowest steady flow velocity that may be recorded) to about 15 ms for velocities of 50 cm/s (about the highest velocity observed in these experiments).

The datalogging programme run on a PDP 8/e minicomputer is designed to detect and store both the time of occurrence of pulses from the electrodes (accuracy 1/10 ms) and electrode identification. Notice that it is the leading edge of the pulses that is detected. Simultaneously the analog signal from a wave height meter and the analog output signal from the micro-propeller current meter are sampled. It is important to notice that the samples are triggered by the propeller blade pulses and consequently are unevenly spaced in time.

The analog current meter signal, however, is only used as support in the judging of the velocities calculated from the digital recordings. The reason is, that in oscillating flow - as in the present experiments - the online dataprocessing used to convert the propeller pulses to an analog signal yields a distorted velocity history because the output will always be the mean velocity recorded over the previous time interval, and the correct sign of the output may be delayed further.

The off line data processing programme is designed to convert all time intervals between two consecutive pulses from the same electrode

into water velocities. The speed is inverse proportional to the recorded time intervals (AA and BB respectively in Fig. 7).

Fig. 7. Timing diagram for propeller pulses under accelerating flow. (In the case of decelerating flow the AB/BA ratios indicated for AA will be valid for BB and vice versa).

The timing diagram in Fig. 7 further shows that the position of the B-pulse between two A-pulses and vice versa yields the sign (or direction) of the velocity: i.e.  $AB/BA \sim .62$  represents positive and  $AB/BA \sim 1.6$  negative velocities under constant speed. However, these well defined AB/BA ratios are found only when the propeller is running at a constant speed. In the case of accelerating/decelerating flow the AB/BA ratio may change considerably. The data processing programme is through a trial-and-error method found to yield the most reliable results when in the computer program we use  $AB/BA > 1.3$  in the AA case and 1.15 in the BB case to determine negative velocities.

When measuring in oscillating flow a special problem arises when the velocities are changing sign (the propeller changes rotational direction), and for some time the velocity remains below the minimum velocity that keeps the propeller running.

When the propeller changes rotational direction it may be observed through the registration of two consecutive pulses from one electrode without any pulse from the other electrode in the same period of time. In this case the velocity is set to zero for this period of time. However, the pulses have a width which is not negligible, and the change in rotational direction will in some cases take place while a pulse is High, and the changing direction of the flow is "only" detected as a sign shift of the calculated velocities. This causes some inaccuracy in the calculated velocity just after a sign shift, but occurs only when the velocities are small. When the velocities are changing rapidly, as it is the case around zero velocity, furthermore, the determination of the correct sign is uncertain. Around zero velocity a number of

obviously erroneous signs are observed.

Both these errors are of minor importance for the determination of the net velocity over the wave period, which is the result we are aiming at here.

Due to the presence of air bubbles in the water - and may be for other reasons as well - a few pulses are not detected by the computer. In the experiments this error occurred with a frequency of 2-4 per 1000 pulses. When appearing during a period of time with considerable velocities ( $> 10$  cm/s) it is corrected by the off-line processing programme. This programme also corrects single velocity values which have been assigned an obviously wrong sign when compared to preceding and following values both  $> 10$  cm/s.

It may be noticed that there is a time lag between the calculated velocities and the recorded surface elevations.

As the velocity measuring method is giving only mean velocities over the time intervals AA and BB respectively it is assumed that the measured velocities are representing the actual velocity in the middle of each time interval. The recorded analog signal from the wave height meter, however, corresponds to the instants of the propeller pulses, and the time series is consequently different from that of the velocities.

Each test comprises 2960 samples equivalent to a recording period in the range of 45 sec (22 wave periods) to 77 sec (38 wave periods).

## 6. DETERMINATION OF NET VELOCITIES AND WAVE DATA

For each test the two simultaneously recorded time series for horizontal particle velocities and surface elevations are analysed independently.

In both time series the individual waves in the recordings are separated through the determination of the zero-up-crossings of the signals and for each individual wave the time average value over the wave period as well as the RMS, maximum and minimum values are calculated. In turn these figures are averaged over the total number of waves included in the time series for each test. Fig. 8 contains a summary of all test results. (Only the experiments in the surf zone are analysed further in this paper).

Each test is associated with a specific horizontal position in the wave flume and a specific depth - or height over the bottom - where the velocity meter is located.

As all tests are performed using the same wave input, the recordings of surface elevations at any of the 6 horizontal positions are repeated a number of times, yielding a possibility of judging the inaccuracies involved in the recordings.

In the surf zone the variations in all surface wave data, e.g.  $\eta_{RMS}$ ,  $H$  and  $b$ , from wave to wave are very significant. Reliable results can consequently only be obtained when the results are averaged over a great number of waves. In these experiments, where one test run comprises 22 to 38 waves, all results are averaged over the total number of waves recorded.

Fig. 8. Summary of test results.

The resulting averaged  $\eta_{RMS}$  values are from test to test reproduced with a standard deviation below 1 mm. Just after breaking the averaged wave heights H are similarly reproduced with standard deviations about 4 mm. Before breaking, and further into the surf zone, however, the standard deviations on H are much smaller (about 1 mm). Similarly the set-down/set-up values are associated with standard deviations of .5-1 mm.

The analysis of the particle velocity measurements clearly reveals the very irregular and strongly turbulent velocity pattern expected after wave breaking. The resulting average net velocities at different positions and depths are given in fig. 8. Each of these net velocities are the averaged values over the 22 to 38 waves included in one test. The single wave net velocities reveal considerable variations, and the average value is within each test associated with a standard deviation about 10 mm/s outside the breaking point and 30-45 mm/s in the surf zone. Nevertheless, two of the tests in the surf zone have been repeated 4 times each, and from test to test the averaged net velocities vary only about  $\pm 5$  mm/s.

7. COMPARISON WITH MEASUREMENTS

To obtain numerical results from (3.16) or (3.19) for comparison with the measurements we first realize that these solutions have the parameters

$$v_t = \text{const.} : \frac{\alpha d_{tr}^2}{c}, \frac{U_m - U_b}{c}$$

$$v_t = Ne^{az} : \frac{\alpha(\eta_{tr}) \cdot d_{tr}^2}{c} = \frac{\alpha_1 d_{tr}^2}{cN}, \alpha d_{tr}, \frac{U_m - U_b}{c}$$

In the following we only consider the latter of the two models.

If we consider  $h$  as the known quantity in stead of  $d_{tr}$  this adds another parameter  $d_{tr}/h$  to the list.

Here the value of  $U_b/c$  has been discussed in Section 4.

For  $\alpha_1 = \partial/\partial x (\overline{u_w^2} + gb)$  we find with  $\frac{H}{h} \sim 0.6$

$$\frac{\partial}{\partial x} \overline{u_w^2} \approx \frac{\partial}{\partial x} c^2 \left( \frac{n}{h} \right)^2 \approx B_0 \left( \frac{H}{h} \right)^2 g h_x \approx 0.027 g h_x$$

$$\frac{\partial}{\partial x} gb \approx g \cdot 0.18 \cdot \frac{H}{h} h_x \approx 0.11 g h_x$$

so that  $\alpha_1 \approx 0.14 g h_x$ . The turbulence model used by Madsen & Svendsen (1983) yields  $v_t$ -values  $\approx 0.005$ - $0.010$   $ch$  depending on the characteristic parameters used. Thus we get for  $\alpha_1 d_{tr}^2 / c v_t$

$$\frac{\alpha_1 d_{tr}^2}{c v_t} \approx \frac{\alpha_1 h^2}{c v_t} \approx 14 - 27 h_x$$

In the present experiments this means

$$A = \frac{\alpha_1 h^2}{c v_t} = 0.4 - 0.8$$

Svendsen (1984b) used  $A = 0.4$  for Stive and Wind's 1982 experiments.

In the comparison with experiments we find that  $A = 0.2$  and  $0.4$  yield the best agreement (Fig. 9) but have shown a comparison including  $A = 1.0$  (Fig 10) which illustrates that the velocity profile is quite sensitive to the value of  $A$ . Clearly further investigations of this problem would be desirable.

The parameter  $ad_{tr}$  represents the decay of the turbulence downwards from the trough level.  $ad_{tr} = 1$  represents a bottom value of  $v_t$  which is 37% of the surface value, and  $ad_{tr} = 2$  similarly represent a reduction to 14% of the surface value.

Figs. 9 and 10 show comparison with the measurements described in section 5 and 6.

A number of observations can be made from the Figs. 9 and 10:

- a) The depth averaged value  $U_m$  of the undertow determined from the shoreward mass flux by (3.6) is generally in good agreement with the measured values
- b) The measurements going closer to the bottom indicates more clearly than those by Stive & Wind (used by Svendsen (1984b)) that the steady streaming in the boundary layer is likely to be in the seaward direction, and with  $U_b = -U_{bs}$  the theoretical results agree quite well with the measurements.
- c) The results appear to be very sensitive to the value of  $A$ ,  $A = 1.0$  being obviously too large. On the other hand the value of  $ad_{tr}$  has been found not to influence the theoretical results nearly as much.

Considering the relatively simple model and the uncertainties

Fig. 9. Comparison between experiments and eq. (3.19) with  $U_b = \pm U_{bs}$  and  $A = 0.2$  and  $0.4$ .

Fig. 10. Comparison between experiments and eq. (3.19) with  $A = 0.2, 0.4$  and  $1.0$ .

regarding at least the two important parameters  $U_b$  and  $v_t$  the agreement must be considered quite satisfactory.

The large seaward velocities near the bottom are considered of significant importance for the erosion of coastlines under storm conditions.

From (3.10) we see that the shear stress  $\tau$  varies linearly with  $z$  irrespective of  $v_t$ . We have for  $\tau$

$$\bar{\tau} = \rho v_t \frac{\partial U}{\partial z} = \rho(\alpha_1 z + \beta_1)$$

The eddy viscosity model also implies that the maximum value of  $U$  corresponds to  $\bar{\tau} = 0$ . In combination with the linear  $\bar{\tau}$ -variation this means that the relative height  $y_0/d_{tx}$  above the bottom of  $U_{max}$  indicates the magnitude of  $\bar{\tau}_b$  relative to the total shear stress variation. Thus the measurements in Figs. 9 and 10 corresponds to very small  $\bar{\tau}_b$ -values, whereas the measurements by Stive & Wind (1980) used by Svendsen (1984b) seem to indicate larger  $\bar{\tau}_b$ -values, though the scattering of the results and the lack of measurements sufficiently close to the bottom make a conclusion at this point uncertain.

## CHAPTER ONE HUNDRED FIFTY TWO

### SOME TECHNIQUES TO CALCULATE DESIGN CURRENTS IN SHELF AND STRATIFIED COASTAL WATERS

Stephen P. Murray\* and Myron H. Young\*\*

#### I. Introduction

Increasing use of marine environments for (a) petroleum-related structures (both explorational and production), (b) subsea mining (e.g., sulfur and salt), (c) brine disposal from onshore salt domes excavated for oil storage, and (d) offshore waste disposal has necessitated more frequent and more accurate predictions of current speeds and directions in coastal and shelf waters. No analytical techniques for such predictions of wind- and density-driven currents in coastal waters are presented at all in the Shore Protection Manual (1973). Wiegel (1964), however, does discuss wind-driven currents, but offers no modern methodologies for their application to coastal and ocean engineering problems.

Simple predictive models as outlined in this paper are especially valuable in feasibility studies, where the expense of a field measurement program is not yet justified. The prediction of oil spill trajectories is another important application for these procedures.

Three types of models are discussed in turn, all of which incorporate the critically important barrier effect of the coast on the current dynamics: (1) a constant eddy viscosity model, (2) an exponentially decreasing eddy viscosity model, and (3) a constant eddy viscosity model with cross-shore and longshore density gradients. The purpose of this paper is to evaluate these three models in terms of their recommended engineering usage and point out the important gaps for future research.

#### II. The Momentum Equations

As a first step in understanding the mechanics of the processes that drive these nearshore currents, we consider the three-component equations of motion with friction parameterized as a horizontally isotropic eddy viscosity:

\*Coastal Studies Institute, Louisiana State University, Baton Rouge, LA 70803.

\*\*Center for Wetland Resources, Louisiana State University, Baton Rouge, LA 70803.

$$\frac{du}{dt} = fv - \frac{g}{\rho} \int_{-\eta}^z \frac{\partial \rho}{\partial x} dz - g \frac{\partial \eta}{\partial x} + \frac{\partial}{\partial z} \left( K \frac{\partial^2 u}{\partial z^2} \right) \quad (1a)$$

$$\frac{dv}{dt} = -fu - \frac{g}{\rho} \int_{-\eta}^z \frac{\partial \rho}{\partial y} dz - g \frac{\partial \eta}{\partial y} + \frac{\partial}{\partial z} \left( K \frac{\partial^2 v}{\partial z^2} \right) \quad (1b)$$

$$0 = -\frac{1}{\rho} \frac{\partial p}{\partial z} + g \quad (1c)$$

In these equations  $u$  and  $v$  are speed components in the  $x$  and  $y$  directions, respectively,  $z$  is the vertical coordinate positive down,  $g$  is the acceleration of gravity,  $p$  is pressure,  $\rho$  is water density,  $\eta$  is the coordinate of the free surface positive upward from the mean level, and  $f$  is the Coriolis parameter. The term  $du/dt$ ,  $dv/dt$  on the left side of (1a) and (1b), respectively, are the accelerations that result from the forces (per unit mass) on the right-hand side of the same equation. These forces (from left to right in the equations) represent (a) the effect of the rotation of the earth, (b) the baroclinic pressure gradient force arising from horizontal density gradients ( $\partial\rho/\partial x$ ,  $\partial\rho/\partial y$ ) in the water mass, (c) the barotropic pressure gradient force arising from water surface slopes ( $\partial\eta/\partial x$ ,  $\partial\eta/\partial y$ ), and lastly (d) the force of internal friction parameterized with an eddy viscosity ( $K$ ,  $\nu$ , or  $N$ ).

In all three models that follow, the flow is considered quasi-steady, i.e.,  $\partial u/\partial t = \partial v/\partial t \approx 0$ , and locally uniform, such that the convective accelerations are also negligible and thus  $du/dt = dv/dt \approx 0$ .

### III. Constant Eddy Viscosity Model with

#### Negligible Horizontal Density Gradients

If the density gradients in the field are such that the baroclinic pressure gradient terms can be neglected, then (1a, b) can be written

$$K \frac{\partial^2 u}{\partial z^2} = -g \frac{\partial \eta}{\partial x} - fv, \quad (2a)$$

$$K \frac{\partial^2 v}{\partial z^2} = -g \frac{\partial \eta}{\partial y} + fu, \quad (2b)$$

where the coefficient of mixing of momentum (the eddy viscosity)  $K$  has been taken as independent of the vertical coordinate  $z$ . In shallow depths and in waters not strongly stratified in the vertical, this assumption of a three-dimensionally isotropic eddy viscosity is probably not overly restrictive. In this model  $x$  is the direction parallel to shore, positive to the right looking onshore, and  $u$  is the corresponding

speed component;  $y$  is the direction normal to the shore, positive on-shore, and  $v$  is the corresponding speed component;  $z$  is the vertical direction with an origin at mid-depth and positive downward. If the wind field is sufficiently uniform along the coast, we may expect no surface slopes in that direction, i.e.,  $\partial\eta/\partial x \approx 0$ ; then, using the complex velocity  $W = u + iv$ , Eq. (2) may be written

$$\kappa \frac{\partial^2 W}{\partial z^2} - fiW = i f G, \tag{3}$$

where  $G = -(g/f) \partial\eta/\partial y$  is independent of  $z$ .

If the presence of the coast is taken into account by setting

$$\int_{-h/2}^{h/2} v dz = 0 ,$$

i.e., there is no net transport toward or away from the shore, the solution of (3) is

$$W = C + A \sinh jqz + jC \frac{\cosh jqz}{\sinh j\lambda}, \tag{4}$$

where  $\lambda = 1/2 (qh)$ ,  $q^2 = 1/2 (f/K)$ ,  $j = i + 1$ ,  $A$  is a complex constant, and  $C$  and  $G$  are real constants.

The surface boundary condition is the usual quadratic wind stress rule:

$$\tau_s = K \rho \left[ \frac{\partial W}{\partial z} \right]_s = -\kappa_s \sigma Q^2 e^{i\alpha} . \tag{5}$$

The bottom boundary condition is not the usual Ekman "no-slip" condition, which tends to considerably underestimate current speeds in shallow water, but rather a quadratic bottom friction rule:

$$\tau_b = K_b \rho \left[ \frac{\partial W}{\partial z} \right]_b = -\kappa_b \rho R^2 e^{i\gamma}, \tag{6}$$

where  $\kappa_s$  and  $\kappa_b$  are friction coefficients for air-water and water-sea bottom, respectively,  $\sigma$  is air density,  $Q$  is the wind speed blowing at an angle  $\alpha$  to the shoreline, and  $R$  is the current speed making an angle  $\gamma$  to the shoreline.

The methodology of computing the current profile in the vertical (Murray, 1975) follows:

First, the angle  $\gamma$  that the bottom current makes with the shoreline is determined as the root of

$$\begin{aligned} & (\cosh 4\lambda - \cos 4\lambda) \sin \gamma \left( \frac{\rho}{\sigma} \cos \alpha \cos \gamma \right)^{1/2} \frac{g^2 \kappa_s^{1/2} K}{\kappa_s} \\ & + Q \{ \cos \alpha [ \sin (\gamma - \pi/4) \sinh 4\lambda - \cos (\gamma - \pi/4) \sin 4\lambda ] \\ & - 2 \cos \gamma [ \sin (\alpha - \pi/4) \sinh 2\lambda \cos 2\lambda \\ & - \cos (\alpha - \pi/4) \cosh 2\lambda \sin 2\lambda ] \} = 0, \end{aligned} \quad (7)$$

using the Newton-Raphson technique.

Then  $G$  is determined from

$$\begin{aligned} G = R \cos \gamma + \{ & D [ \cos (\gamma - \pi/4) \sinh 4\lambda \\ & + \sin (\gamma - \pi/4) \sin 4\lambda ] \\ & - 2E [ \cos (\alpha - \pi/4) \sinh 2\lambda \cos 2\lambda \\ & + \sin (\alpha - \pi/4) \cosh 2\lambda \sin 2\lambda ] \} \\ & \times (\cosh 4\lambda - \cos 4\lambda)^{-1}, \end{aligned} \quad (8)$$

where

$$R = Q \left( \frac{\kappa_s \sigma \cos \alpha}{\kappa_b \rho \cos \gamma} \right)^{1/2}, \quad (9)$$

$$E = \frac{\cos \gamma}{\cos \alpha} D, \quad (10)$$

$$D = \frac{\kappa_b R^2}{2^{1/2} q K}. \quad (11)$$

Moreover,  $C$ , a wholly real number in (4), is given by

$$C = \frac{-[\kappa_b R^2 \sin \gamma - (\sigma/\rho) \kappa_s Q^2 \sin \alpha]}{4Kq} \quad (12)$$

and the complex coefficient  $A$  may be written

$$A = \frac{-[\kappa_b R^2 e^{i\gamma} + (\sigma/\rho) \kappa_s Q^2 e^{i\alpha}]}{2K j q \cosh j\lambda}. \quad (13)$$

Substituting (8), (12), and (13) in (4) allows the determination of vertical profiles of  $u$  and  $v$  as a function of wind speed and wind direction with respect to the coastline, eddy viscosity, total water depth, latitude, and surface and bottom friction coefficients. Note

that  $\cos\alpha$  and  $\cos\gamma$  must have the same sign, i.e., alongshore components of wind and bottom drift are in the same direction. When winds are from a direction between  $\pi/2$  and  $3\pi/2$ , the sign of  $\gamma$  in (7) must be changed accordingly. The only poorly understood variable in this development is the eddy viscosity, which we calculated from the expression for a well-mixed surface layer (Neumann and Pierson, 1966):

$$K = 0.1825 \times 10^{-4} Q^{5/2} \rho^{-1} , \tag{14}$$

which, for wind speeds  $Q < 700$  cm/sec, is in good agreement with values shown in Munk and Anderson (1948).

The results of the constant eddy viscosity theory are shown compared to three field observations from unstratified coastal water in Figures 1, 2, and 3. The agreement between theory and observation is extremely encouraging for the purpose of practical prediction. Additionally, the

$$W = 8 \text{ m/sec} , \quad \alpha = 30^\circ$$

FIG. 1. Speed and direction of currents observed by Saylor (1966) under winds of 8 m/sec at  $30^\circ$  to the coastline compared to prediction of constant eddy viscosity theory, shown as light lines. Current direction is measured from parallel to shore-line, positive onshore.

FIG. 2. As in Fig. 1.

constant eddy viscosity model has recently been used by Dr. C. J. Sonu of Tek Marine Inc. to predict the trajectory of icebergs on the Pacific continental shelf ( $h \sim 30 \text{ m}$ ) with quite successful results (Sonu, personal communication, 1984).

An interesting point is the strong dependence of current speed on wind direction with respect to the coast. Figure 4 shows the approximately  $\cos^{1/2}$  response of current speed to wind angle, a result reported earlier by Bretschneider (1967).

#### IV. Variable Eddy Viscosity Theory

In wind-driven current systems the energy driving the current is diffusing downward from the surface, and in moderately stratified water we expect the eddy viscosity to decrease with distance from the surface. Figure 5 shows current speed profiles off the Florida Gulf Coast in moderately stratified water. Note the steep decrease of current speed with depth, suggesting a depth-dependent eddy viscosity, an idea supported by the numerical solutions of equation (2) discussed in Murray

FIG. 3. As in Fig. 1, except for measurements on 11 September under winds of 10 m/sec at  $73^\circ$  to the coastline.

(1975). A practical predictive equation incorporating this effect was not presented, however.

Witten and Thomas (1976) addressed this problem directly with an exponentially decreasing eddy viscosity of the form  $\nu = \nu_0 e^{-az}$ , where  $\nu_0$  is the surface eddy viscosity and  $a^{-1}$  is the e-folding length of the eddy viscosity. Since  $\lambda = ah$  is the ratio of depth to the e-folding length of the eddy, as  $\lambda$  gets smaller the eddy viscosity tends to be more uniform in the vertical. Large values of  $\lambda$  indicate a steep decrease of eddy viscosity with depth. As seen in Figure 6 at  $\lambda = 0.1$ , the surface value of the eddy viscosity is decreased only 5% at mid-depth, at  $\lambda = 0.5$  the decrease at mid-depth is 20%, and at  $\lambda = 1.0$  the decrease at mid-depth is 40%. In this model  $y$  is positive onshore,  $x$  is positive to the right looking onshore, and  $z$  and  $\eta$  are positive up. The complex horizontal momentum equation corresponding to (3) is

$$\frac{\partial}{\partial z} \left[ A \frac{\partial W}{\partial z} \right] - i f W = g \frac{\partial \eta}{\partial n} \tag{15}$$

where  $\partial/\partial n = \partial/\partial x + i \partial/\partial y$ . Witten and Thomas (1976) show that (15) can

FIG. 4. The effect of changing wind angle to the coast on the alongshore current for three wind speeds (water depth = 10 m) from Eq. (4).

be put into an inhomogeneous form of the modified Bessel equation. The general solution for W then is

$$W = \zeta [AI_1(i^{1/2}\zeta) + BK_1(i^{1/2}\zeta)] + i\frac{\partial\eta}{\partial n}, \tag{16}$$

where  $I_1$  and  $K_1$  are the modified Bessel functions of order one, and A and B are complex constants,  $\zeta = (2\alpha^{1/2}/\lambda) e^{-\lambda z/2}$ ,  $\alpha = fh^2/\nu_0$  is the reciprocal Ekman number, and  $\lambda = ah$  is the ratio of depth to e-folding length of the viscosity. The surface and bottom boundary conditions allow determination of the unknown constants A and B. Using the quadratic wind stress surface boundary condition the same as (5), but a "no slip" condition at the bottom, i.e.,  $W = 0$  at  $z = -h$ , the expressions for A and B are arrived at.

$$A = \frac{-\left\{ \frac{\lambda\tau}{2i^{1/2}} K_1 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} e^{\lambda h/2} \right] + \frac{\lambda i}{2\alpha^{1/2}} e^{-\lambda h/2} K_0 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} \right] \frac{\partial\eta}{\partial n} \right\}}{\left\{ K_0 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} \right] I_1 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} e^{\lambda h/2} \right] + I_0 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} \right] K_1 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} e^{\lambda h/2} \right] \right\}} \tag{17a}$$

$$B = \frac{\left\{ \frac{\lambda\tau}{2i^{1/2}} I_1 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} e^{\lambda h/2} \right] - \frac{i\lambda}{2\alpha^{1/2}} e^{-\lambda h/2} I_0 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} \right] \frac{\partial\eta}{\partial n} \right\}}{\left\{ K_0 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} \right] I_1 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} e^{\lambda h/2} \right] + I_0 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} \right] K_1 \left[ \frac{2(i\alpha)^{1/2}}{\lambda} e^{\lambda h/2} \right] \right\}} \tag{17b}$$

FIC. 5. Current speed (S) and direction ( $\theta$ ) with respect to the coast in moderately stratified water off the Florida Gulf Coast in the morning (solid dots and triangles) and the afternoon (open dots and triangles). Wind speeds are 3-4 m/sec. Note the severe kink in the afternoon speed profile due to decreased afternoon vertical mixing resulting from solar heating of the surface layer.

We solved for A and B by using the relationships between the Bessel functions and the Kelvin functions (Abramowitz and Stegun, 1972, eq. 9.9.1, 9.9.2). Using (14) for the near-surface eddy viscosity, the only unknown in (17) is the complex surface slope,  $\partial\eta/\partial n$ . At this point we call on our continuity condition  $\int_{-n}^{\eta} v dz = 0$ . Our solution procedure is to set the longshore slope  $\partial\eta/\partial x = 0$ , and guess a value for the cross-shore slope  $\partial\eta/\partial y$ , compute the constants A and B, and then compute the velocity profile from (16). Next, test to see if the continuity condition  $\int_{-n}^{\eta} v dz \approx 0$  is satisfied; if it is not, iterate values of the slope

FIG. 6. The effect of  $\lambda$  on the vertical profile of the eddy viscosity.

until the condition is satisfied and accept the values of  $\partial\eta/\partial x$ , A, B, and the velocity profile as the solution.

Figure 7 gives an example of the solution from the exponential eddy viscosity theory with  $\lambda = 0.1$  and  $0.3$ . Speeds are obviously far too low due to the no-slip bottom boundary condition. The constant eddy viscosity solution (4) is also shown for comparison. It gives a correct range of speed, but again the speed is too high near the bottom. In deeper water, Figures 8 and 9 show the two theories are tending to converge. The exponential eddy viscosity model probably gives a better representation of vertical current shear, but the actual magnitudes in the upper half of the water column are better represented by the constant  $\nu$  theory. At this point we recommend the constant eddy viscosity model for shallow water (<20 m) predictions and a judicious combination of both theories for deeper water applications.

FIG. 7. Current speeds predicted by exponential decaying eddy viscosity theory compared to constant eddy viscosity theory. Wind is 10 m/sec at 45° to coast.

FIG. 8. As in Fig. 7, except wind is 5 m/sec at 45° to coast (deep-water example).

Clearly, the most desirable predictive scheme would incorporate features from both models. We are currently at work on the analytical solution for the wind-driven current problem incorporating both a stress bottom boundary condition and an exponentially varying eddy viscosity.

FIG. 9. As in Fig. 8, except wind is 10 m/sec at 45° to the coast (deep-water example).

V. Constant Eddy Viscosity with Horizontal Density Gradient

In many coastal regions, intense rainfall on the local watersheds produces high runoff of fresh water to the coast through a multitude of river input sources that act somewhat as a line source of fresh water along the coast. These freshwater sources typically produce a brackish, turbid band of water that frequently moves at high speeds quasi-parallel to the coast. These baroclinic coastal boundary currents are known from the southeastern coast of the United States (Blanton, 1981), the Louisiana-Texas Gulf Coast (Lewis, 1979), the Alaskan coast (Schumacher and Reed, 1980; Royer, 1979), and the Caribbean coast of Nicaragua (Murray et al., 1982). One or two truly major rivers can also produce a baroclinic coastal current stream, as in the case of the Louisiana-Texas Gulf Coast, cited above, which is the result of the massive discharges from the Mississippi and Atchafalaya Rivers.

The essential difference in the dynamics between this model and the two discussed previously is the inclusion of the baroclinic pressure gradient term. Equation (1a,b) then reduces to

$$0 = fv - \frac{z+\eta}{\rho} \frac{\partial \rho}{\partial x} - g \frac{\partial \eta}{\partial x} + N \frac{\partial^2 u}{\partial z^2} \quad (18a)$$

$$0 = -fu - g \frac{\partial \eta}{\partial y} + N \frac{\partial^2 v}{\partial z^2} \quad (18b)$$

where in this model we take  $z$  positive down,  $\eta$  the sea surface coordinate positive up from the mean level,  $h$  the coordinate of the bottom,  $N$  the eddy viscosity,  $x(u)$  positive in the cross-shore direction toward the shore, and  $y(v)$  positive in the alongshore direction, to the left of an observer looking onshore.

Again defining the complex velocity  $W = u + iv$ , (18a, b) can be put in the complex form

$$\frac{\partial^2 W}{\partial z^2} = \alpha^2 W - \alpha^2 \frac{ig}{f} \left\{ (z+\eta) \frac{1}{\rho} \frac{\partial \rho}{\partial x} + S \right\} \quad (19)$$

where  $S$  is the complex slope  $= \partial \eta / \partial x + i (\partial \eta / \partial y)$  and  $\alpha^2 = if/N$ .

The solution to (19) is

$$W = A \exp \alpha(z+\eta) + B \exp -\alpha(z+\eta) + \frac{ig}{f} \left\{ \frac{z+\eta}{\rho} \frac{\partial \rho}{\partial x} + S \right\} \quad (20)$$

where  $A$  and  $B$  are complex constants to be determined by the boundary conditions. The cross-shore volume flux is given by the real part of

$$\int_{-\eta}^h W dz = \frac{A}{\alpha} (e^{\alpha h} - 1) - \frac{B}{\alpha} (e^{-\alpha h} - 1) + \frac{igh}{2\rho f} \left( \frac{\partial \rho}{\partial x} h + 2\rho S \right) \quad (21)$$

where terms in  $\eta$  are neglected as usual, as they affect the transport by only 0(0.1%).

The complex constants  $A$  and  $B$  and the cross-shore slope  $\partial \eta / \partial x$  are considered unknown in (20). Although often considered negligible, the solution can also include a longshore baroclinic pressure gradient.

The surface boundary condition  $\partial W / \partial z = -\tau_s / N$ , where  $\tau_s$  is complex, determines the first complex constant

$$A = B - \frac{ig}{\alpha f \rho} \frac{\partial \rho}{\partial x} - \frac{\tau_s}{\alpha N} \quad (22)$$

The bottom stress boundary condition

$$N\left(\frac{\partial W}{\partial z}\right)_h + \kappa\rho |W_h| W_h = 0 \quad (23)$$

and the continuity equation close the system by allowing computation of the constant B and the cross-shore slope  $\partial\eta/\partial x$ . For further details, see Murray and Young (1984).

The vertical current profile  $u$  and  $v$  can now be solved from (20) using observed or estimated values of the wind stress, eddy viscosity, water depth, cross-shelf density gradient, and longshore surface slope.

The model is evaluated by comparing our observations taken off the east coast of Nicaragua with the prediction of (20). Figure 10 shows the alongshore speed and salinity distribution in the turbid diluted coastal current found 20-30 km off the coast in this high-rainfall area (Murray et al., 1982). Our measurements of wind stress, water depth, and density structure allow us to compute a predicted velocity distribution and compare it to our field observations of current velocity. Eddy viscosities of  $N = 6 \text{ cm}^2/\text{sec}$  and longshore slopes  $\partial\eta/\partial y \approx 6 \times 10^{-8}$  are also estimated from the data. Pettigrew (1981) reports an eddy viscosity of  $\sim 10 \text{ cm}^2/\text{sec}$  for the east coast of the U.S., so  $5 \lesssim N \lesssim 15$  appears to be a good range for predictions for other coastal areas displaying similar hydrographic conditions. The longshore slope can be set = 0 unless knowledge exists to the contrary.

The distribution of the alongshore velocity component calculated from (20) and (21) under the wind stress, density gradients, and eddy viscosities associated with the field data presented in Figure 10 is given in Figure 11. Although minor details deviate, the agreement between theory and observation is extremely encouraging. For example, the magnitude and location of the current maxima at  $\sim 12$  km offshore and the offshore length scale of 15-20 km are all successfully reproduced. The offshore countercurrent of 5-10 cm/sec in both observations and theory is apparently the result of the slight longshore surface slope opposing the wind.

The theory assumes a density gradient that is constant with depth, and thus predicts significant southerly velocity components throughout the water column. In the observations, however, the density gradient weakens with depth, leading to some overprediction of the near-bottom velocities, but the first-order approximation of the longshore speed

FIG. 10. Alongshore current speeds (cm/sec) observed along east coast of Nicaragua (solid lines) and coincident salinity distribution (dashed lines), which delineate the baroclinic coastal current. Dots indicate data observation points. Basic southerly flow (off page) is bordered by a weak offshore countercurrent.

FIG. 11. Prediction of the distribution of alongshore current speeds from the theoretical model (20) under the field conditions shown in Fig. 10.

distribution, the goal of this paper, is clearly a good one.

#### VI. Summary

Three analytical models are presented that can be used to predict vertical profiles of coastal and inner-shelf currents when applied with careful consideration of the pertinent physical parameters in operation. Two of the models are driven solely by wind stress, while the third also incorporates density gradient effects.

An important result suggested by the successful comparison of our field data to theory is the possibility that considerable knowledge of the nearshore velocity distribution along coasts with simple geometry can be obtained, given data on local winds, from routine bathymetric and hydrographic (STD) surveys. An immediate application is the prediction of current structure for offshore petroleum operations and the trajectories of oil spill movements along many subtropical coasts as well as other high-runoff coasts such as the Pacific coast of Alaska.

## CHAPTER ONE HUNDRED FIFTY THREE

### Steady Flows In The Nearshore Zone

John W. Haines\*

#### Abstract

Field measurements using electromagnetic flowmeters on two natural beaches are presented. Mean flows are compared to theory. The horizontal and vertical structure are discussed.

#### Introduction

It has long been suggested that steady nearshore currents redistribute sediment entrained by the more energetic wave motions. This understanding has been the basis for many of the bulk sediment transport formulas developed. Coastal engineers have traditionally been concerned primarily with the shore parallel component of steady flows. Cross-shore flows generally are much smaller in magnitude and do not result in a large net transport of sediment. Nevertheless a large body of work has indicated that steady cross-shore flows generated by low frequency wave motions may generate various barred profiles (3). More recent work has indicated that quite small cross-shore mean flows can be quite significant for profile development and maintenance (2). The spatial structure of these mean flows has obvious implications for sediment transport and nearshore morphology. Theoretical models of the flow due to wind, wind waves and low frequency motions have been developed but field verification is lacking. Until field programs reliably measuring the magnitude and structure of nearshore flow fields are completed, application of these models to sediment transport estimates is unrealistic.

The work described here is a preliminary attempt to describe steady flows in the nearshore zone. Results from two field experiments will be presented. Particular attention will be paid to the vertical structure of such flows. Field measures of vertical structure have previously been neglected due to the expense and, perhaps,

\*Department of Oceanography  
Dalhousie University  
Halifax, Nova Scotia  
B3H 4J1 Canada

the questionable reliability of such measures. Knowledge of vertical structure is important for verification of theory as well as interpretation and use of single point measures. In addition, the offshore spatial structure will be described. Results to date indicate that commonly accepted ideas concerning steady nearshore flows may be difficult to support on all but the simplest of natural beaches.

### Background

Steady nearshore currents may result from a variety of generating mechanisms. Here we shall consider flows averaged on time scales long compared to the group or surf beat period. Wind and tidally forced flows are neglected where possible, although both mechanisms may result in significant flows. Of primary concern here are those currents driven by higher frequency, "wind wave", motions. While it is impossible to rigorously divide measured means into components based on forcing the condition of this study is such that flow associated with other forcing mechanisms should be small.

Measures of shore parallel flows have been more extensively reported than cross-shore flows. Theoretical treatments have been quite successful and are an integral part of longshore sediment transport models. Longshore flows have been modelled and observed to result from longshore gradients in the mean sea level due to low frequency edge wave motions. (5). A more prevalent mechanism is the forcing due to the oblique incidence of wind waves. This mechanism, as described by Bowen (6) and Longuet-Higgins (12) results in forcing due to gradients in the longshore component of the radiation stress. These models, which rely on empirical relations for frictional and lateral mixing effects have been found to compare quite favourably with experimental data (11).

The offshore structure of longshore flows depends primarily on the shore normal gradient of the radiation stress, and thus the wave shoaling and dissipation processes. The theories also describe an offshore dependence due to variation of lateral mixing. Field results seem relatively insensitive to the mixing parameterization chosen; probably because of the smearing effect of a finite bandwidth spectrum (15). The vertical dependence of longshore flows has been largely neglected by the above, depth averaged, treatment. Knowledge of the vertical structure is critical for attempts to estimate stresses acting on the bed. Simple riverine velocity profiles might be applied but in a wave dominated field such models are unlikely to be correct.

Theoretical treatment of cross-shore flows has advanced to levels well beyond our ability to verify in the field (i.e. 9). The theory of Longuet-Higgins (14) and the subsequent lab work of Russell and Osorio (16) has resulted in the commonly accepted picture of two dimensional nearshore flows. Near bed flows are assumed to be onshore outside the surf zone and offshore inside the breaker line (10). These wave generated mean flows result from the presence of viscous boundary layers and the associated production and transport of vorticity. The Longuet-Higgins theory for waves over a horizontal bed predicts, given a time invariant eddy viscosity, flows in the direction of wave propagation at the top of the bottom boundary layer. Above this the flow structure is quite sensitive to conditions at the free surface as well as the particular form of eddy viscosity chosen.

Seaward bottom flow within the surfzone may be attributed to the effects of a mean set-up (10), a mass flux to balance that associated with a translating bore (8) or a surface stress due to breaking waves. If we extend the Longuet-Higgins (13) model to include horizontal gradient terms then:

$$d/dx (\bar{u}^2) + d/dz (uw + u'w') = -d/dx (g\bar{\eta})$$

where  $u$  is the wave motion,  $u'$  the turbulent motion and  $\bar{\eta}$  is the mean change from still water. Further, allowing the depth to be a function of  $x$  and assuming

$$u'w' = -A_v \partial \langle u \rangle / \partial z \quad (\text{where } \langle u \rangle \text{ is the mean velocity})$$

we can solve for the mean flow. By assuming

$$\langle u \rangle = 0 \text{ at the bed, } A_v = \text{constant}$$

and

$$\int_{-h}^{\eta} u \, dz = 0$$

we arrive at

$$\begin{aligned} \langle u \rangle = & F(x) [f(z, z/\delta)]/A_v + A_v d(u_0^2/2)/dz [g(z, z/\delta)]/4\mu^2 \\ & + a_0^2 \sigma k [p(z, z/\delta)]/4 \sinh^2 kd \\ & + a_0 u_0 [q(z)]/d^2 \end{aligned}$$

where  $d = h + \bar{\eta}$      $u_0 = 3/4 \sigma a^2 k / \sinh^2 kh$

$$F(x) = g \frac{\partial \bar{\eta}}{\partial x} + \frac{\partial}{\partial x} (u^2_0 / 2) \quad \mu = (\sigma / 2A_v)^{1/2}$$

$$\sigma = \text{freq.} \quad k = \text{wavenumber} \quad h = \text{depth}$$

Even with the assumption that  $A_v$  is constant a number of solutions may arise depending on  $\frac{dh}{dx}$  and our method of solving for  $F(x)$ .  $F(x)$  represents the loss of energy by the waves. If we assume that  $a = \alpha h$ , where  $\alpha$  is a constant, in the surf zone we may solve for  $F(x)$  by assuming that the momentum flux from the waves results in a stress acting on the free surface. In that case

$$\langle U \rangle(x, z, t) = -3 g \alpha^2 d^2 \frac{dd}{dx} f(z) / (16 A_v)$$

$$+ \alpha^2 g \frac{dd}{dx} g(z) / (32\sigma)$$

$$+ 3\alpha^2 (gd)^{1/2} p(z) / 32.$$

The full solution allows bottom flows in either direction within the surf zone on beaches of realistic slope, with steeper beaches exhibiting offshore flow at the bed. The above solution, while supported by laboratory experiments (6,10), is probably wrong in its simplistic modelling of the bottom stresses, but it does illustrate that almost any velocity profile can be constructed if one manipulates  $A_v$  and the boundary conditions. As of yet there is a paucity of field data to constrain such models.

Quite a number of laboratory experiments measuring cross-shore flows have been completed. Most find the Longuet-Higgins solution to be accurate near the bed and less accurate towards the free surface. Russell and Osorio (16) for example found extremely good agreement for values of  $kd$  between 0.5 and 7.2. No significant effects of a sloping bed of .05 could be seen. Russell and Osorio also saw a reversal of the near bottom flow associated with breaking waves. Further experiments, summarized by Sleath (18) have shown that bed roughness and higher harmonics may decrease the velocity, and in one experiment reverse the flow.

It is readily apparent that the longshore and cross-shore theories of Longuet-Higgins have become quite entrenched. While the longshore current model seems to adequately predict the depth averaged flow little is known about the vertical structure. The laboratory work on cross-shore flows generally supports theoretical conclusions as to the direction of near bed flows but the magnitude of such flows as well as the flow structure above the bed are called into question (18). Reliable tests of the theory on natural beaches still need to be carried out.

Sediment transport models are quite sensitive to the mean velocity (2). Thus it is imperative that we make some effort to evaluate theories predicting mean flows. The spatial structure of this flow field also needs investigation if errors due to the use of point measures are to be estimated.

### Field Experiments

In order to study the vertical structure of mean flows a tripod mounted array of three Marsh-McBirney electromagnetic flowmeters were deployed on two Canadian beaches. The flowmeters were aligned to measure the two horizontal components of the flow. Velocity measures were taken at approximately 35 cm intervals with the bottom sensor ten to fifteen cm above the bed.

The initial experiment took place at Queensland Beach, Nova Scotia, a steep (slope = .1) sheltered pocket beach. Waves at Queensland are long crested and narrow banded in both frequency and direction. Lower frequency motions are quite energetic at times but all indications are that the beach is dominated by two-dimensional motions. Twenty to thirty minute data runs were taken at low and high tide over a two day period. The wave field was fairly stationary with  $kd \sim 0.25$ , wave amplitude about 35 cm and a wave period of 8 sec with pronounced group structure.

A subsequent experiment was carried out at Pte. Sapin, New Brunswick. Pte. Sapin is a fairly steep (.06) beach which quickly gives way to a wide, flat rock platform extending well offshore. Wave conditions are complex with two predominant directions of approach. Waves tend to be obliquely incident, short crested and rather broad-banded in frequency. Longshore transport of sediment is extremely vigorous in storm conditions, as witnessed by the sediment trapping of a breakwater immediately to the south. Any assumptions of two-dimensionality are suspect although no rip systems were observed. Run lengths were an hour in length taken over a variety of conditions. Wave heights ranged from .2 to 1.2 meters at the instrument position with periods from 3 to 8 seconds. Groupiness and angle of incidence varied over a similarly wide range. Ancillary data sets of wind speed and direction, offshore flow, and directional spectra were collected through the efforts of various researchers under the auspices of the National Research Council of Canada as part of the Canadian Coastal Sediment Study (C<sup>2</sup>S<sup>2</sup>).

There are a number of problems with the experiment as described. Working on steep beaches resulted in all data

sets being outside the surf zone. The deployment of only one tripod also prevented simultaneous measures at more than one point along an offshore line. In addition, single point measures yield insufficient information about the lower frequency motions present. These problems have been addressed as we prepare the next  $C^2S^2$  field study but they limit information content of this data set.

The Marsh-McBirney flow meter is a rugged device but it has some limitations. Firstly, it is unclear how near the bed or free surface such an instrument can be deployed. As well, the current meters must be separated by a similarly unknown distance. Our results indicate that ten centimeters is a safe distance; but one that is uncomfortably large for resolving near bed flows. In addition the EM flowmeter measures the Eulerian portion of the flow. For many applications the Lagrangian transport would be more meaningful. Estimates of the Lagrangian velocity indicate it is only slightly different but in cases of small velocities it may be a significant difference.

Recently the response characteristics of Marsh-McBirney flow meters has been questioned (1). Aubrey found that the current meters were unreliable in combined steady oscillatory flows. Errors in the measured mean were 1-6 cm/sec. Problems also arose in areas of large ambient turbulence. Aubrey questioned the reliability of such meters in calculating the higher moments as well. The accuracy of means measured in the field is difficult to estimate but some subjective evaluations can be made. More convincing arguments may be made for the reliability of the moments. The data was approached with some care and the current meter performance checked where possible.

### Results

The mean flows discussed here will be averages over an entire data run. Table 1 shows means averaged over shorter intervals and it is apparent that the means are fairly stationary over time scales of 15 minutes to an hour. The variance is also calculated. Since the records are highly autocorrelated the variance does not allow direct error estimates. Given the length of the data run the statistical uncertainty is nonetheless small with respect to possible sensor errors. The means are small in Table 1 and difficult to evaluate given the problems suggested by Aubrey (1). The variances are heartening with comparable magnitude for the two sensors and showing similar behaviours with time. The higher moments are similarly well behaved indicating that the electromagnetic flow meters are quite well behaved.

Sensor	Direction	Mean/Variance	(cms <sup>-1</sup> /cm <sup>2</sup> s <sup>±2</sup> )				
1	x	1.92/2.51	1.49/2.06	1.35/1.77	1.49/.87	1.54/1.69	
	y	-2.53/.14	-2.60/.13	-2.84/.14	-2.87/.15	-2.59/.14	
2	x	2.07/2.37	2.28/2.18	2.30/1.88	1.49/2.01	1.45/1.85	
	y	1.05/.15	-1.22/.14	-2.23/.14	-2.42/.17	-2.64/.17	

Table 1. Means and variance calculated for consecutive 10 minute data sections on two sensors at different heights. x represents on-offshore flow, positive off-shore.

Near normal wave incidence resulted in small longshore currents at Queensland. The cross-shore flows are plotted in Figure 1. Also plotted is the Eulerian part of the Longuet-Higgins solution. The agreement in the lower two-thirds of the water column is amazingly good. As the data points represent runs separated by up to 24 hours it appears a consistent, long term flow pattern exists. Real values of the velocity range from near zero to approximately 10 cm/sec. The agreement with theory suggests, once again, that the sensors may be quite reliable.

The only systematic deviation from theory is in the top of the water column. This is consistent with lab work (16, 18) and careful analysis of the data suggests it is not a sensor malfunction due to proximity to the free surface. The measured profile indicates, as expected, that the Longuet-Higgins model is inaccurate as one approaches the free surface. This is hardly surprising as the boundary conditions which apply are unknown.

The cross-shore data from Pte. Sapin, similarly plotted, bears no resemblance to the Longuet-Higgins solution (Figure 2). Dimensional velocities ranged from 0 to 9 cm/sec in magnitude. The profiles resulting show no consistency from run to run on the basis of kd values, wave direction or wind direction. In all cases bottom velocities are offshore and maximum velocities are significantly smaller than those predicted by the Longuet-Higgins theory. The question of three-dimensional effects can not be easily addressed. Calculation of the depth averaged flow required to balance the Stokes drift indicates that the measured flow is generally of the right order of magnitude with a tendency to be somewhat smaller. Under any circumstances the indication is strong that the Longuet-Higgins solution for bottom drift is not relevant even 3 to 4 surfzone widths offshore.

Figure 3 shows an indication of two profile types.

Figure 1. Cross-shore velocities at Queensland Beach. Solid line is the Longuet-Higgins solution for  $kd = 0.25$ . Onshore flows are negative.

Figure 2. Cross-shore velocities at Pte. Sapin, New Brunswick. Symbols represent different data runs separated by up to three weeks. Onshore flows are negative.

Figure 3. Total data of cross-shore means from Pte. Sapin. Note that all bottom flows are offshore.

This is rather a dangerous trick when working with only three data points in the vertical. The profile represented by the circles has onshore flow in the middle of the water column while the triangle profile exhibits offshore flow accelerated relative to the bottom velocity. The profile types are demonstrably not related to  $kd$  values, wave direction, or wind direction and speed. Figure 4, which shows the bottom velocities indicates that the profiles may be separated on the basis of non-dimensional distance offshore. It should be noted that the three inshore points represent a range of conditions from long waves to small values of dimensional distance offshore and include both extremes in values of  $kd$ . A similar plot could be constructed using the skewness of the velocity distribution rather than distance offshore. Thus it appears that the two profile types reflect some aspect of the shoaling process.

It should be noted in Figure 4 that the bottom velocity itself seems independent of the distance offshore. The profile shape and the direction of flow in the center of the water column are somehow related to wave asymmetry. This is to be expected as mean flows result from the vorticity generation associated with dissipation and shoaling. The data does not allow much speculation about near surface flows.

The cross-shore flows measured seem to change sensibly with wave conditions. Large waves generate large flows. Flows also increase towards the breaker line. The form of the velocity profile is stationary over fairly long time scales. Figure 5 shows results from three pairs of data runs. The pairs represent separations in time of two (crosses), four (circles) and nine hours (triangles). Wave conditions and dimensional velocities changed somewhat but the non-dimensional profile changes very little. Apparently similar conditions separated by longer periods (days to weeks) show quite dissimilar profiles. Figure 5 indicates that flow fields may be stationary over the duration of a storm event. The results again, give us some confidence in the performance of the flow meters.

Longshore flows at Pte. Sapin were variable ranging from 0 to 20 cm/sec. Depth averaged flows are plotted vs. the Longuet-Higgins (11) solution in Figure 6. Measured flows are certainly the right order of magnitude, tending to be somewhat large. This is partially due to wind driven currents also present. Flows are especially large far offshore and these flows probably contain a relatively large wind driven component as they represent small wave conditions. Pte. Sapin waves tend to be locally generated so it is especially difficult to separate wind and wave effects.

Figure 4 Bottom velocities from Pte. Sapin. Symbols are identical to those in Figure 3.

Figure 5 Velocity profiles from Pte. Sapin, see text for description of symbols.

Figure 6 Depth averaged longshore flows where  $V_0$  is the Longuet-Higgins solution and  $X_B$  is the distance to the breaker line.  $P$  is the mixing parameter as described in (12).

Figure 7 Longshore velocities vs. height above bed where  $\delta$  is the boundary layer thickness. Symbols represent different data runs.

Measured vertical structure is shown in Figure 7. Also plotted is the standard riverine  $Z^{1/7}$  formulation. Such a profile fits only when flows are most vigorous. Otherwise flows are somewhat surface intensified relative to the bottom with the maximum velocity in the middle of the water column. Again this may be due to the relatively greater importance of wind stresses during low wave conditions.

### Conclusion

The data collected so far leads to somewhat negative conclusions. On the simplest of beaches, such as Queensland, prediction of bottom velocities may be made with some measure of confidence. Pte. Sapin suggests that flows on more complex beaches are, at present, unpredictable and point measures of velocity are of questionable value.

Vertical and horizontal profiles are complex but may exhibit some systematic variation on a particular beach. Horizontal changes appear to be closely associated, as expected, with the shoaling process. Changes in the vertical are less well described. For further progress to be made we need to better measure the wave field present as well as gain a measure of the 3-D nature of the system. In addition, Lagrangian measurements, and simultaneous observations along a longshore transect would better constrain our results.

In a very subjective way it appears that EM flowmeters behave in a reasonable manner. Further work needs to be done to address this problem particularly.

Finally, our results are not inconsistent with those found by other researchers. Surf zone flows have been found by a number of researchers to be directed offshore in the lower and middle portions of the water column (7, 17). Our findings, although outside the surf zone, also exhibit offshore flows. Such flows need to be rigorously measured and explained, especially, as their impact on sediment transport raises obvious problems as to the maintenance of the bed profile.

### OSCILLATORY BOUNDARY LAYER FLOW OVER RIPPLED BEDS

Shinji Sato\* , Nobuo Mimura\*\* and Akira Watanabe\*\*\*

#### ABSTRACT

Characteristics of the oscillatory boundary layer flow above rippled beds were investigated through experiments and numerical calculations. Experiments were conducted in an oscillatory flow tunnel. Velocities above symmetric and asymmetric ripples were measured with split-hot-film sensors under conditions of both sinusoidal and asymmetric oscillations. The stress field in the boundary layer was evaluated based on the distributions of the measured velocity and Reynolds stress. Relations between vortex formation and turbulence were examined, and effects of the asymmetry of oscillatory main flow and of ripple form on the velocity field were discussed. Numerical calculations were carried out by integrating the Navier-Stokes equations with an implicit finite difference scheme. Formation of a lee vortex above ripples was simulated in the calculations. The bottom shear stress and the energy dissipation rate were estimated based on the results of the experiments and calculations.

#### INTRODUCTION

In order to understand the mechanisms of sediment movement as well as wave energy dissipation, it is important to investigate the characteristics of oscillatory boundary layer flow above rippled beds. The oscillatory flow over ripples is complex, since large vortices are formed in the leeside of the ripples and turbulence is produced intermittently. Quantitative understanding of the velocity and the stress field in the boundary layer is essential because of its relevance to various coastal processes such as sand transport, wave damping and mass transport.

Ripples take various shapes depending on the wave condition and the property of bed materials. It has been reported that the asymmetry of

\*\*\* Professor, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 JAPAN

both the ripple shape and the time history of velocity near the bottom exerts a strong influence on the direction and the amount of net sediment transport. In order to accurately estimate the net sediment transport rate, extensive investigations under the conditions of asymmetric oscillations are required.

A number of theoretical and experimental studies have recently been made on the velocity distribution in the oscillatory boundary layer over sand ripples. Some of them are briefly reviewed in the following. Sleath (1974) calculated the flow field by explicit numerical integration of the Navier-Stokes equations and suggested that the flow might remain laminar up to considerably high Reynolds numbers. Longuet-Higgins (1981) applied the inviscid discrete vortex method to the simulation of oscillatory flow over steep ripples. He estimated the value of the drag coefficient of a ripple from the momentum balance of the simulated flow and found the estimated value to be in good agreement with experiments. Toit and Sleath (1982) measured distributions of the horizontal velocity component over rippled beds by using a laser-doppler-anemometer and compared them with those given by available theories. Detailed measurements of the velocity field have been performed by Sawamoto et al. (1982) and by the present authors (1982), with the aids of improvement of measuring technique. However, since the oscillatory boundary layer over ripples involves the complex motion of unstationary inhomogeneous turbulence, a quantitative analysis is not yet satisfactorily accomplished.

The first objective of the present study is to understand the characteristics of the velocity and stress field in the boundary layer through experiments. The second objective is to develop a numerical model to calculate such complicated boundary layer flow with a good accuracy. The third objective is to evaluate the bottom shear stress and the energy dissipation rate based on the measured and calculated results.

#### EXPERIMENTAL FACILITIES, CONDITIONS AND PROCEDURE

Experiments were conducted in an oscillatory flow tunnel, which consists of a loop of closed conduits and a hydraulically-driven piston as illustrated in Fig. 1. The test section is 2m long, 24cm wide and

Fig. 1 Plan view of the oscillatory flow tunnel.

31cm in height. The motion of the piston is controlled through an electro-hydraulic servo-system, so that main flows of arbitrary velocity variation can be produced by inputting appropriate voltage signals. The period of flow oscillation is variable from 0.5s to 10.0s, and the maximum amplitude is 70cm at the test section. This facility enables us to make experiments under such realistic conditions as asymmetric back-and-forth motion and irregular oscillation with prototype scales. Preliminary tests were carried out in order to determine the typical size and shape of sand ripples. Well-sorted sand with mean diameter of 0.2mm was used as the bed material. Two-dimensional ripples with sharp crests and rounded troughs were observed for sinusoidal oscillations. The shape of these ripples was found to be well approximated by often adopted following equations.

$$x_0 = X - \left(\frac{\eta}{2}\right)\sin(2\pi X/\lambda) \tag{1}$$

$$z_0 = \left(\frac{\eta}{2}\right)\cos(2\pi X/\lambda) \tag{2}$$

where  $\eta$  is the wave height of a ripple,  $\lambda$  the wavelength,  $X$  an auxiliary parameter, and  $(x_0, z_0)$  represents the surface of ripples. Asymmetric ripples were observed for asymmetric oscillations as illustrated in Fig. 2. We selected several shapes of self-generated sand ripples as the representative geometry. Artificial ripples of the selected ripple geometry, both symmetric and asymmetric, were made of cement mortar for the following experiments.

The artificial ripples were installed on the bottom of the test section, and velocities were measured with split-hot-film sensors at about 100 measuring points close to the bed. Measuring points were arranged systematically in a vertical plane parallel to the main flow. The grid size was 1cm in the horizontal direction and 0.08cm to 2.0cm in the vertical direction.

The split-hot-film sensor consists of two platinum films on a single quartz fiber as shown in Fig. 3. The output from the two films provides a set of data of the magnitude of the velocity component normal to the axis of the fiber,  $U_N$ , and of the component normal to the split plane,  $U_N \sin\theta$ . The magnitude of the velocity component parallel to the split plane is calculated from these two values though its sign cannot be determined.

Fig. 2 Asymmetric oscillation and asymmetric ripples.

Fig. 3 Schematic diagram of a split-hot-film sensor.

Conditions of the present experiments are listed in Table 1, together with those of the previous experiments (cases H1 and H3) performed by Hamamoto et al. (1982). The period of oscillation is 4s and the wavelength of ripples is 12cm in all the cases. Cases 1 to 6 and H1 are for symmetric ripples under sinusoidal oscillation, and H3 is the case of asymmetric ripples under asymmetric oscillation. Prior to the velocity measurements, flow visualization was made in order to grasp characteristic features of the boundary layer flow of each case. It was found that cases 1 and 2 corresponded to the laminar flow condition. In cases 3 and 4, turbulence was detected in the leeside of a ripple and these cases were considered to be in transition. The flow in cases 5, 6, H1 and H3 was regarded turbulent through a full period.

Table 1 Experimental conditions.

Case	T(s)	$\hat{U}_0$ (cm/s)	$d_0$ (cm)	$\lambda$ (cm)	$\eta$ (cm)

$d_0$ : orbital diameter of the main flow

DATA ANALYSIS AND EXPERIMENTAL RESULTS

The velocity was decomposed into the mean velocity and turbulent fluctuations. It involves some uncertainty to define turbulence in unstationary flow, for the reason that there exist a number of fluctuating components of various frequency in the turbulent boundary layer. We assumed that the fluctuating components with higher frequency than a critical value might be attributed to turbulence. In order to determine the appropriate cut-off frequency, spectrum of the velocity record was calculated, and it was found that the power spectrum density showed an abrupt increase at 5Hz when the flow became turbulent. The higher frequency component than 5Hz of the velocity record was therefore defined as turbulent fluctuation. Equi-phase mean velocity components  $U$ ,  $W$  and products of turbulent fluctuations  $\overline{u'^2}$ ,  $\overline{w'^2}$ ,  $\overline{u'w'}$  were calculated by averaging equi-phase data over 30 periods.

In the following, discussions are concentrated mainly on case 6 because of space limitation. As stated before, the flow in case 6 was

Fig. 4 Time history of  $U$ ,  $W$ ,  $\overline{u'^2}$ ,  $\overline{w'^2}$ ,  $\overline{u'w'}$  measured above a crest and a trough (case 6).

turbulent through a full period. Coherent vortices began to be formed in the leeside of ripples when the velocity of the main flow reached its maximum. These vortices continued to develop until they were ejected after the flow reversal. The ejected vortices were transported over ripples during the next half period for a distance of twice the wavelength of a ripple. Figure 4 shows the time history of mean velocity components  $U$ ,  $W$  and products of turbulent fluctuation  $\overline{u^2}$ ,  $\overline{w^2}$ ,  $\overline{u'w'}$  measured at points about 0.3cm above a ripple crest and a trough. Values of  $\overline{u^2}$  and  $\overline{w^2}$  show two peaks in each half period, which corresponds to the passage of two vortices created in the leeside of the nearest and the neighboring ripples. Values of  $\overline{u'w'}$  above a crest show a strong peak according to the passage of the first vortex but they do not show a peak with the passage of the second vortex. It follows that turbulence maintains a coherent structure just after the vortex ejection and that, as the vortex moves upward, turbulence decays and diffuses to show locally isotropic features.

The stress fields were evaluated by the integration of the two-dimensional momentum equations.

$$\rho \left( \frac{\partial U}{\partial t} + \frac{\partial}{\partial x}(U^2) + \frac{\partial}{\partial z}(UW) \right) = -\frac{\partial P}{\partial x} + \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \tau_{xz}}{\partial z} \quad (3)$$

$$\rho \left( \frac{\partial W}{\partial t} + \frac{\partial}{\partial x}(UW) + \frac{\partial}{\partial z}(W^2) \right) = -\frac{\partial P}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \sigma_{zz}}{\partial z} \quad (4)$$

where  $P$  is the equi-phase mean pressure,  $\rho$  is the density of water, and  $\sigma_{xx}$ ,  $\tau_{xz}$  and  $\sigma_{zz}$  are the components of the Reynolds stress tensor defined by

$$\begin{aligned} \sigma_{xx} &= 2\mu \frac{\partial U}{\partial x} - \rho \overline{u'^2} \\ \tau_{xz} &= \mu \left( \frac{\partial W}{\partial x} + \frac{\partial U}{\partial z} \right) - \rho \overline{u'w'} \\ \sigma_{zz} &= 2\mu \frac{\partial W}{\partial z} - \rho \overline{w'^2} \end{aligned}$$

in which  $\mu$  is the molecular viscosity.

The equi-phase mean pressure  $P$  was evaluated by integrating equation (4) with respect to  $z$ . The mean pressure thus evaluated is the sum of the two components as follows.

$$P = P_I + P_D \quad (5)$$

$P_I$  represents the pressure due to the acceleration of the oscillatory main flow and is given by the following relation,

$$P_I = -\rho \int_{x_0}^x \frac{\partial U_0}{\partial t} dx \quad (6)$$

where  $x_0$  is a reference point of which pressure is set to be zero and  $U_0$  is the horizontal velocity of the main flow.  $P_D$  means the component originated from the presence of the wavy boundary and is responsible for drag and lift forces.

Figure 5 shows distributions of the equi-phase mean velocity vector, Reynolds stress and mean pressure ( $P_D$ ) in a half period. The flow is seen to be locally accelerated above a ripple crest and

Fig. 5 Distributions of the mean velocity vector, Reynolds stress and mean pressure (case 6).

decelerated above a trough. The process of generation and ejection of a lee vortex is clearly visualized. It is seen that the Reynolds stress is strong in the region of a lee vortex, and that, as the vortex is ejected upward, the area of high turbulence moves with it and then diffuses.  $P_D$  is lower in the vortex core and higher on the upstream side of a ripple crest where the separated flow reattaches to the boundary. Characteristic velocity and stress field is created in the oscillatory boundary layer over ripples through the formation of lee vortices and the local acceleration of the flow.

Time average of the equi-phase mean velocity over one period is not zero in general. Figure 6 gives the residual current in an Eulerian frame. A pair of circulation cells is seen for the case of symmetric ripples and sinusoidal oscillation, whereas a unidirectional flow appears for the asymmetric condition. These patterns of steady streaming seem to be strongly influenced by the formation of lee vortices. Symmetric cells in case 6 are due to the formation of symmetric lee vortices, while the formation of asymmetric lee vortices is responsible for the asymmetric flow pattern in case H3. Quantitative analysis of steady streaming is important because it plays an important role to determine the direction of sediment transport.

(a) symmetric condition (case 6).

(b) asymmetric condition (case H3).

Fig. 6 Velocity distributions of residual current.

NUMERICAL MODELING

The boundary layer flow was calculated by numerically integrating the two-dimensional vorticity equations. The governing equations are the same with those used in the calculation made by Sleath (1974). In the present study, the finite difference scheme and the description of the boundary conditions were improved, so that we could calculate the flow at higher Reynolds numbers with a good accuracy. The governing equations were expressed in an orthogonal curvilinear coordinate system  $(X, Z)$  in order to represent the wavy boundary, i.e. the shape of ripples. In this coordinate system, the two-dimensional vorticity equations are

$$\frac{1}{J} \frac{\partial \zeta}{\partial t} - \frac{\partial \psi}{\partial X} \frac{\partial \zeta}{\partial Z} + \frac{\partial \psi}{\partial Z} \frac{\partial \zeta}{\partial X} = \nu \nabla^2 \zeta \tag{7}$$

$$J \nabla^2 \psi = \zeta \tag{8}$$

in which  $\zeta$  is the vorticity,  $\psi$  the stream function,  $\nu$  the kinematic viscosity,  $J$  the Jacobian of transformation and  $\nabla^2$  the Laplace operator given by  $\nabla^2 = \partial^2/\partial X^2 + \partial^2/\partial Z^2$ . The relation between the coordinate system  $(X, Z)$  and the Cartesian coordinate  $(x, z)$  is defined as

$$x = X - \sum_n a_n e^{-\frac{2\pi}{\lambda} z} \sin \frac{2n\pi}{\lambda} (X - \phi_n) \tag{9}$$

$$z = Z + \sum_n a_n e^{-\frac{2\pi}{\lambda} z} \cos \frac{2n\pi}{\lambda} (X - \phi_n) \tag{10}$$

in which  $a_n$  and  $\phi_n$  are coefficients to be determined so that the curve,  $Z = 0$ , might give a good approximation of symmetric and asymmetric shape of wave-generated ripples.

The boundary conditions at the ripple surface and at the upper boundary are expressed by

$$\frac{\partial \psi}{\partial Z} = \psi = 0 \quad \text{on } Z = 0 \tag{11}$$

$$\psi = \hat{U}_0 \delta \cos \omega t, \quad \zeta = 0 \quad \text{at } Z = \delta \tag{12}$$

in which  $\delta$  is the height of the calculation domain,  $\hat{U}_0$  the velocity amplitude of the main flow, and  $\omega (= 2\pi/T)$  the angular frequency of the oscillation. Values of  $\psi$  and  $\zeta$  along the side boundaries are set to be periodic for the interval of a ripple wavelength.

The numerical integration was carried out by an implicit finite difference scheme, for the conditions of experimental cases 1 to 4 which corresponded to laminar flow or transition. Calculation was also conducted for the asymmetric oscillatory flow over asymmetric ripples, of which wavelength is 12cm and height is 1.7cm, with the value of stream function at the upper boundary given by

$$\psi = \hat{U}_0 \delta (0.8 \cos \omega t + 0.2 \cos 2\omega t) \tag{13}$$

Fig. 7 Comparison of the time history of horizontal velocity above a ripple crest (case 3).

In order to examine the validity of the numerical model, the calculated and experimental results were compared. Figure 7 gives a comparison of the time history of horizontal velocity component at a point 0.3cm above a ripple crest. Agreement between the calculation and the experiment is fairly good.

Figure 8 illustrates the calculated velocity vector in a half period for the case 3. Salient features of the oscillatory flow over rippled bed are reproduced, such as the local acceleration above a ripple crest and the vortex formation in the lee side. The steady streaming was also evaluated from the calculated flow field and it was concluded that characteristic features observed in the experiments were well reproduced for both symmetric and asymmetric conditions. The present model can thus simulate the flow field in which a lee vortex is formed and transition takes place.

The flow structure in a Lagrangian frame is also of interest concerning the sediment transport. In order to study the movement of water particles, a numerical experiment was conducted by using the result of the calculation for the asymmetric condition. Water particles were placed at grid points of the numerical calculation and the movement of the particles which started at the phase of maximum velocity of the main flow was traced in one period. Figure 9 shows an example of trajectories of particles which started from grid points above the steeper flank of a ripple. Figure 10 gives the final displacement of all particles after one period. Some particles were trapped in a lee vortex formed on the steeper flank and were transported leftward and upward with the vortex ejection. There occurred no trapping to a vortex

Fig. 8 Calculated flow field (case 3).

Fig. 9 Trajectories of water particles in one period.

Fig. 10 Final displacement of water particles.

on the milder flank. The resultant net transport of particles near bottom became leftward. Ripples on natural beaches have the steeper flank to the onshore direction and the milder flank to the offshore direction. Although this experiment does not incorporate the effect of the settling of particles nor the interaction between the fluid and particles, the result appears to provide a suggestion on the mechanism of sediment transport to the offshore direction.

#### EVALUATION OF THE BOTTOM SHEAR STRESS

The evaluation of bottom shear stress is essential for the problem of wave damping and sediment transport. The bottom shear stress was estimated by using the results of experiments and numerical calculations. The bottom shear stress was decomposed into following two components.

$$\tau_b = \tau_{bs} + \tau_{bd} \quad (14)$$

where  $\tau_b$  is the total shear stress,  $\tau_{bs}$  is the shear stress due to skin friction and  $\tau_{bd}$  is that due to form drag. The skin friction is

important in the study of sediment transport, while the total shear stress becomes important in the estimation of wave damping.

(1) Bottom shear stress due to skin friction

The skin friction at the bottom was calculated from the results of numerical modeling by the following relation,

$$\tau_{bs} = \mu \left\{ \frac{\partial}{\partial Z} \left( J \frac{\partial \psi}{\partial Z} \right) - \frac{\partial}{\partial X} \left( J \frac{\partial \psi}{\partial X} \right) \right\} = \mu \zeta_b \tag{15}$$

where  $\mu$  is the viscosity and  $\zeta_b$  is the vorticity at the bottom. Figure 11 shows the time history of  $\tau_{bs}$  in case 3 at various points along a ripple surface. Chain lines with two dots indicate the amplitude of the bottom shear stress on a flat plate under the same flow condition. The amplitudes of  $\tau_{bs}$  at a ripple crest (solid line) and at a trough (dotted line) are about 1.6 and 0.7 times the amplitude for a flat plate respectively. These ratios are almost the same with the rates of the local acceleration of the flow. Time mean values of  $\tau_{bs}$  over one period are seen to be negative on a flank of a ripple (broken line and chain line with one dot), which means steady shear stress is exerting in the direction from a trough to a crest.

It is very difficult to estimate the value of bottom skin friction from experimental results, since there is no measurement of velocity in the immediate vicinity of the bottom boundary. We made an attempt to evaluate the bottom skin friction at a crest using the value of shear stress estimated at a measuring point closest to the bottom. The shear stress at the bottom surface was expressed by integrating equation (3) as

Fig. 11 Calculated history of local bottom shear stresses (case 3).

Fig. 12 Comparison of the bottom shear stress at a ripple crest (case 3).

$$\tau_{zx}|_{z'=0} = \tau_{zx}|_{z'=z_1} - \int_0^{z_1} \left\{ \rho \left( \frac{\partial U}{\partial t} + \frac{\partial(U^2)}{\partial x} + \frac{\partial(UW)}{\partial z} \right) + \frac{\partial P}{\partial x} - \frac{\partial \sigma_{zx}}{\partial x} \right\} dz \quad (16)$$

where  $z'$  is the vertical distance from the bed,  $z$ , the height of the point closest to the bed and  $\tau_{zx}|_{z'=z_1}$ , the shear stress estimated at  $z'=z_1$ . The integral was evaluated by means of the trapezoidal rule, where the values of  $\partial U/\partial t$ ,  $\partial(U^2)/\partial x$ ,  $\partial(UW)/\partial z$  and  $\partial \sigma_{zx}/\partial x$  were assumed to be zero at the bottom and to change linearly within the domain of integration. The value of  $\partial P/\partial x$  was assumed to be constant in this domain. Figure 12 shows the time history of the bottom shear stress at a crest evaluated through the experiment (indicated by  $\circ$ ) and the numerical model (solid line). It is found that the bottom shear stress estimated through experiments shows a strong peak when a vortex passes. Scatter of plotted data implies the need to improve the validity of the assumptions and the accuracy of the pressure.

(2) Energy dissipation rate

Consideration of the energy budget of the mean flow leads to the following equation.

$$D = \rho \frac{dU_0}{dt} \psi_0 - \frac{1}{\lambda} \frac{\partial}{\partial t} \int \int \frac{1}{2} \rho (U^2 + W^2) dA \quad (17)$$

where  $D$  is the energy dissipation rate averaged over one wavelength of a

Fig. 13 Time history of the energy dissipation rate (case 6).

ripple and  $\psi_0$  is the value of stream function at the upper edge of the boundary layer.

Figure 13 gives the time history of  $D$  in case 6 evaluated from experimental data. The energy dissipation rate is large positive when the main flow is decelerated ( $0 < \omega t < \pi/2$ ), and becomes negative when accelerated ( $\pi/2 < \omega t < \pi$ ). This means that during the stage of the deceleration of the main flow the energy of the mean flow is dissipated through the generation of turbulence, and that a part of turbulence energy is transferred back to the mean flow during a certain period of the acceleration, which may correspond to the phenomenon of reverse transition.

The time mean value of  $D$  is conventionally related to the velocity of the main flow by

$$\bar{D} = \frac{1}{2} \rho f_e \overline{U_0^2} |U_0| \tag{18}$$

where  $f_e$  is the energy dissipation factor. Evaluation of the energy dissipation factor through experiments was also performed by Bagnold (1946) and Carstens et al. (1969). However, since their experimental conditions are quite different from those of the present experiments, we cannot compare our results with them directly. Values of  $f_e$  estimated through the present experiments and calculations are given in Fig. 14 together with values of friction factor given by Jonsson (1966). The quantity  $k$  represents the value of equivalent roughness and  $a_0$  is the orbital diameter of the main flow. Values of the energy dissipation factor are of the order of 0.05 and independent of the Reynolds number in the domain of the present study. The energy dissipation factor generally differs from the friction factor because there is a phase shift between the main flow velocity and the bottom shear stress. In the turbulent flow, however, this phase shift is so small that the

Fig. 14 Values of the energy dissipation factor.

values of  $f_e$  are regarded almost the same with those of the friction factor. By comparing the values of the energy dissipation factor and the friction factor in rough turbulent region of Fig. 14, we can estimate the values of equivalent roughness to be of the same order with the wave height of a ripple. Since there are only three data in rough turbulent region in the present study, more experiments under conditions of oscillatory flow are required to draw a generalized conclusion. It should also be noted that the energy dissipation due to sediment movement has to be taken into account under movable bed condition.

#### CONCLUDING REMARKS

It was concluded through experiments that lee vortices exert a strong influence on the velocity and stress fields of the oscillatory boundary layer above a rippled bed. The relation between the turbulence production and lee vortex evolution was quantitatively discussed based on the results of experiments under both symmetric and asymmetric conditions. The distribution of the residual current velocity was also presented. Using the numerical model developed, the boundary layer flow was accurately simulated up to considerably high Reynolds numbers. The bottom shear stress and the energy dissipation rate were evaluated through the results of experiments and numerical calculations. The authors intend to continue the work on the numerical modeling to make it possible to calculate the flow at higher Reynolds numbers based on the distribution of the measured Reynolds stress.

## CHAPTER ONE HUNDRED FIFTY FIVE

### VARIATION OF SEDIMENT SUSPENSION IN OSCILLATORY FLOW

Carsten Staub<sup>1</sup> Ivar G. Jonsson<sup>2</sup> Ib A. Svendsen<sup>3</sup>

#### ABSTRACT

Different syphon type suspended load probes were used together with a newly developed 'carousel' sampler for measurements of the instantaneous sediment concentration in turbulent oscillatory flow over a sand bed. Shields parameters were well above the rippled/flat bed transition region, resulting in intense sediment transport over a flat bed. The measurements were performed at different levels in a large oscillating water tunnel. They showed some characteristic features of the temporal concentration variation and of the variation with height of the mean concentration. Also a pronounced effect of the orientation of the suction tube relative to the flow was observed.

#### 1. INTRODUCTION

A large part of the sand in motion under waves on a sandy coast is carried in suspension. Thus, the suspended load plays an important rôle in the net transport of sediment.

Measurements of time-mean sediment concentrations have frequently been published during the last decades. In general, however, such information is not sufficient to determine the net sediment transport due to waves and currents. In a wave motion with a weak current (e.g. the on-shore/offshore problem) the net sediment transport may be caused by the difference between large sediment movements in opposite directions due to the predominantly oscillatory nature of the water flow. Thus, to determine this difference between two large numbers with any accuracy it is necessary to have detailed information about the temporal variation of the sediment concentrations.

The aim of the present experimental study is to provide measurements of the time variation of sediment concentrations above a sand bed under high shear conditions ('sheet flow'). Thus, the sand bed is (almost) plane during the experiments.

The Shields parameter is defined as

$$\theta = \frac{\tau_{b,\max}}{\rho g (s-1) d_{50}} \quad (1)$$

where  $\tau_{b,\max}$  is the maximum bed shear stress,  $\rho g s$  is the specific gravity of the sand grains,  $\rho$  being the density of water, and  $d_{50}$  is the median grain diameter. When  $\tau_{b,\max}$  is determined by (2) and (3) (see Chapter 3) the situations studied correspond to  $\theta$ -values of about 1.9 - 3.3 (with roughness  $K_N = 2.5 d_{50}$ , see comments in Chapter 3).

Measurements of time variation of sediment concentration have previously been reported by Nakato et al. (1977), Sleath (1982), and Bosman (1982). They all, however, measured the concentrations above a ripple bed corresponding to situations with smaller Shields parameters ( $\sim 0.1 - 0.8$ ), and they used electro-optical equipment.

The measurements presented in the following were carried out in a large oscillating water tunnel, using wave periods of 9.1 s and 6.8 s. The sediment concentrations were measured by letting a syphon probe suck out a sand-water mixture from a fixed point in the tunnel. A horizontal wheel with 18 cups covering the circumference was rotating under the outlet of the syphon, and the rotation was synchronized with the oscillation in the water tunnel. The sand-water mixture in each cup thus represents the concentration averaged over (about) one 18th of the oscillation period, giving a phase interval of  $20^\circ$ .

A limitation of this method compared with electro-optical methods is that rapid concentration fluctuations will not be represented in the results. It also involves some rather complicated phase corrections of measurements.

In Chapters 2 and 3 is given a more detailed description of the experiments, and the test parameters are listed in Table 1.

In Chapter 4 we discuss and analyze the experimental data in order to obtain the results presented in Chapter 5. These include variations of concentration and corresponding variations of the average-over-depth velocity, as well as mean concentration profiles.

## 2. EXPERIMENTAL FACILITIES

The oscillating water tunnel, in which the measurements of sediment concentration were performed, has been described by Lundgren and Sørensen (1958) and Jonsson and Carlsen (1976), but has since been modernized. Briefly, it consists of two cylindrical vertical risers and a horizontal part comprising a 10 m long test section with plexiglass walls and with a rectangular cross section (height  $\times$  width =  $36 \times 39 \text{ cm}^2$ ), see Fig. 1. In the experiments the bottom of the test section was covered with a 7 m long sand field. Thus, the inner height above the sand bed was about 30 cm. The water column was forced to oscillate by varying the air pressure above the water surface in the closed (southern) vertical riser. The air pressure was supplied by a hydraulically driven piston performing a sinusoidal oscillation under the control of an electric signal. The variation of the water level in the open (northern) riser was recorded by a capacitance-type wave gauge. From this record, the average-over-depth velocity,  $u$ , in the test section was determined by differentiating the record signal with respect to time.

Fig. 1. The oscillating water tunnel.

Fig. 2: Syphon probes with different types of intakes used in the experiments. Inner diameter of tubes is 1.6 mm. (Probe no. 6 has inner diameter 2.6 mm, see Table 1).

Fig. 3: The 'carousel sampler'. Two sets of cups placed on a horizontal wheel, 18 cups at each level. The outlets from the syphons are seen to the left.

'Wave' periods ( $T$ ) were 9.1 s and 6.8 s, and amplitudes in the test section ( $\alpha$ ) 1.8 to 2.1 m. Maximum flow velocities ( $u_{\max}$ ) were 1.3 to 1.9 m/s.

The probe for the concentration measurements was installed almost at the middle of the test section, see Fig. 1. A number of different probes were used in the experiments. Some of them are shown in Fig. 2. Each probe includes a stainless steel pipe supplied with an extension of plastic tubing with its outlet over the 'carousel sampler', as the horizontal wheel in Fig. 3 has been termed.

During an experiment the excess pressure in the tunnel continuously forced out a sand-water mixture through the probe. The 'carousel sampler' (Fig. 3) actually consists of two levels, each with 18 cups mounted along the circumference and rotating under the outlets of the double syphons used in most of the experiments. The rotation of the wheel was synchronized with the oscillation in the water tunnel. The revolutions of the wheel were recorded by a photo-electric cell, and corrections were made by a feed-back mechanism adjusting the velocity of rotation once every wave period.

Two different types of sand were used with median diameters 0.19 mm and 0.38 mm. Settling velocities at 18°C are about 0.021 m/s for  $d_{50} = 0.19$  mm, and 0.050 m/s for  $d_{50} = 0.38$  mm.

### 3. PROCEDURE

Before each test the level of the sand bed along the test section was measured. Sampling of suspension was begun a few minutes after the start of the oscillations to allow initial disturbances of bed and suspension to vanish, and each test then lasted for 6 - 13 minutes (Table 1). After each test the concentration of sand in the cups was determined by drying and weighing.

Ripples were not observed, but quite often some deviation from a plane horizontal bed was found. However, the associated bed slopes never exceeded 2° and usually were much gentler. The configuration was apparently caused by small irregularities in the flow conditions, perhaps partly related to the asymmetrical way in which the flow was driven. Variations of the bed level in the lateral direction were also recorded and found to be only a few millimetres.

Since the bed level sometimes changed during an experiment, the probe was not exactly at the same height above the sand bed during the whole test. Therefore, the bed level was measured before, during, and after each test, and an 'effective probe elevation' during the test was determined by averaging these three elevations. Both the average value and the range of variation are shown in Table 1 for each test. See also Figs. 8 and 9.

It may also be worth mentioning that there was no observation of local scour in cases where the probe was positioned close to the bottom.

The column 'probe pointing' in Table 1 shows the directions of the probe intakes - which are opposite to the directions of suction velocities. In most of the tests with the coarsest sand wider suction pipes were applied in order to avoid effects of partial or momentaneous blocking of the pipe. However, comparison of results obtained with wide and narrow suction pipes showed no such tendency. In some cases, however, clogging was observed, as demonstrated in the table.

Table 1: Test parameters for suspension measurements. Re directions

N(orth) and S(outh), see Fig. 1. Re details of probes, see Fig. 2.

The Shields parameter listed in the table is defined by (1), where maximum bed shear is determined by

$$\tau_{b,\max} = \frac{1}{2} f_w \rho u_{\max}^2 \quad (2)$$

The wave friction factor is determined from Swart's approximate formula based on the measurements by Jonsson and Carlsen (1976)

$$f_w = \exp\{-5.977 + 5.213 (\alpha/k_N)^{-0.194}\} \quad (3)$$

with the bed roughness  $k_N = 2.5 d_{50}$ . Quantity  $\alpha$  is the water particle amplitude of the oscillation.

The Shields parameters thus determined (Table 1) must be regarded with some reservation. Recent interpretations of the experiments by Carstens et al. (1969), see Grant and Madsen (1982), indicate much higher values for  $k_N/d_{50}$  than 2.5, for oscillatory flow associated with intense sediment transport over a flat bed. From their work one can quote figures as high as 210-240 for  $k_N/d_{50}$ . In this context note that the Shields parameter in Grant and Madsen's work is based on a wave friction factor, where roughness equals grain diameter; thus their Shields parameters - like the ones in Table 1 - are more formal than physical quantities. In conclusion, the 'real' Shields parameters must be expected to be much higher than listed in Table 1.

#### 4. INTERPRETATION OF MEASUREMENTS

The experimental data do not directly provide the information about sediment concentrations which we are aiming at. In the following it is described how the data were analyzed to obtain the experimental results presented in Chapter 5.

The sand-water mixture takes some time to pass through the suction system to the carousel. This phase shift or 'delay' must be accounted for when relating the concentrations to the water velocities in the test section. Also the effect of a varying sand-water mixture velocity in the suction system at  $T = 6.8$  s was considered, and the measurements were corrected accordingly.

Furthermore, the phase shift we are looking for is not just the delay of the water particles, but that of the sediment grains. These two phase shifts are not quite the same because on the non-uniform velocity distribution over the cross section of the pipes and tubes. The centre of the grains cannot get closer than half a grain diameter to the pipe walls where the velocities are lowest. Thus, if the sand grains are uniformly distributed over the remaining pipe cross section the average velocity of the sand through the suction system will be higher than the average velocity of the water. For a quantitative evaluation of this effect, however, we must estimate the velocity profile. From a few simple experiments the 'quickest' sand grains are found to pass through the suction system about 20% faster than the water, that is the maximum sand velocity is approximately 20% larger than the average water velocity. The experiments also indicated that this could be explained by introducing the velocity distribution

$$v = v_{\max} \left(1 - \frac{r}{R}\right)^{1/7} \quad (4)$$

where  $v$  is the velocity,  $r$  is the distance from the centre line, and  $R$  is the inner radius of the pipe (or tube). This well-known expression meets the requirement of a maximum velocity approximately 20% higher than the average velocity. In the tests we have used  $d_{50}/D = 0.10 - 0.13$ ,  $D$  being the inner diameter of the suction system. With the velocity profile given by (4), the difference between the delay of the sand and the delay of the water was found to be between  $2^\circ$  and  $10^\circ$ .

The average velocity,  $u$ , in the test section was determined by differentiating the wave-gauge registrations of the water level in the open vertical leg of the tunnel. As expected for a period of  $T = 9.1$  s, which is close to the natural period of the water column,  $u$  varies nearly sinusoidally (Fig. 4).

At a period of  $T = 6.8$  s, however, the deviation from a sinusoidal velocity variation is appreciable (Figs. 5 and 6). The wave motion corresponding to the flow in the tunnel is defined so that  $\omega t = 0$  ( $\omega = 2\pi/T$ ) at maximum velocity northwards (i.e. towards the open riser).

## 5. RESULTS

Some examples of the measured instantaneous concentrations,  $C_m$ , and the corresponding time variations of water velocities in the tunnel are shown in Figs. 4-6. All are tests with twin suction intakes oppositely directed and parallel to the flow (type 3 in Fig. 2), but located at the same level above the bed. The concentration variation curves are drawn through the measurement points, each corresponding to the sand concentration in one cup. The phase distance between these points is rather variable in Fig. 5 (test no. 28) due to a large variation in suction velocity in this particular test.

As expected the measured concentrations have two maxima during an oscillation period, one for each extreme in velocity. However, there is a considerable difference in magnitude between the two measured concentration maxima. Figs. 4-6 clearly show that the concentration measurements are very sensitive to the direction of the oscillatory flow (typically  $\pm 1.3$  to  $\pm 1.9$  m/s) relative to the suction velocity (typically 0.9 m/s). The effect is probably due to the fact that the heavier sand particles cannot quite follow the water in the large accelerations immediately around the intake of the probe.

Calibration tests for different types of suction probes in a stationary current have been made by Bosman (1982). These calibrations show that for a current directed towards the opening of the probe the true concentrations are up to about 30% larger than the measured concentrations, depending on the ratio between suction and flow velocity. None of Bosman's calibrations, however, were made with the opposite current direction. Qualitative considerations show that in this case concentration measurements will yield a large underestimate of true concentrations, and this is believed to be the reason for the above-mentioned differences between the two measured concentration maxima.

Therefore, in the following we consider measurements made when the current velocity opposes the intake velocity to be unreliable. In the tests with twin suction intakes we consider the at any instant highest of the two  $C_m$ -curves to be the best approximation to the actual concentrations, i.e. we change from one curve to the other one as soon as the

Fig. 4: The temporal variation of the sand concentration  $C_m$ , and the average-over-depth velocity  $u$ , in Test no. 10 (two oppositely directed suction pipes parallel to the flow, type 3 in Fig. 2). Test parameters in Table 1. N and S are North and South.

Fig. 5: The temporal variation of the sand concentration  $C_m$ , and the average-over-depth velocity  $u$ , in Test no. 28 (two oppositely directed suction pipes parallel to the flow, type 3 in Fig. 2). Test parameters in Table 1. N and S are North and South.

Fig. 6: The temporal variation of the sand concentration  $C_m$ , and the average-over-depth velocity  $u$ , in Test no. 41 (two oppositely directed suction pipes parallel to the flow, type 6 in Fig. 2). Test parameters in Table 1. N and S are North and South.

latter exceeds the former one<sup>4</sup>. This observation puts a question mark to the reliability of time-mean concentrations found in conventional experiments with single, longitudinally directed probe intakes. These should, according to the present experiments, be increased by at least 25-80% to get the actual mean concentrations in the flow (see, e.g. Figs. 4-6). Fig. 7 compares - for all three groups of test parameters - the time-mean concentrations of the actually measured suspension sample,  $\bar{C}_m$ , and the mean concentration,  $\bar{C}$ , determined by time-averaging the highest of two measured concentration variations. In the following only  $\bar{C}$  is considered.

In general, the time variation of concentration was 'peaky', with narrow maxima and broad minima, especially so for the coarse sand.

Mean concentration profiles are shown in Figs. 8 and 9. The range of variation of the height of the probe above the bed during each test is shown as a full line through the measurement point. A special procedure has been applied to determine the mean concentration in the tests with only a single suction tube directed parallel to the flow. The measured concentration variation was shifted 180° to simulate an oppositely directed probe, and the mean concentration was then determined from the at any time highest of the two concentration curves.

In addition to the grain size distribution of bed material a number of samples of suspended sand were analyzed. The median grain sizes for these are plotted in Fig. 10 versus the height of the probe above the sand bed. For the finer sand type, there is a clear tendency towards decreasing grain size at increasing height above bed, whereas no such variation appears in the results for the coarser sand.

## 6. CONCLUSIONS

- a. The time variation of sediment concentration at different heights over bed was measured in a large oscillating water tunnel (Fig. 1). Two types of sand were used with median diameters 0.19 mm and 0.38 mm. 'Wave' periods were 9.1 s and 6.8 s, and amplitudes were 1.8 to 2.1 m. Maximum velocities were 1.3 to 1.9 m/s corresponding to intense sediment transport over an approximately plane bed without ripples.
- b. The 'carousel sampler' (Fig. 3) with the probes in Fig. 2 proved to be well-suited for measuring 'instantaneous' sediment concentration in oscillatory flow (Figs. 4-6), although problems arise with phase corrections and calibration.
- c. The influence of the direction of probe intake relative to the flow on directly measured instantaneous concentration was large (Figs. 4-7). In situations where the flow direction opposed the direction of flow into the probe, the measured concentrations were found to be too small. This was accounted for by using probes with two oppositely directed intakes.

---

<sup>4</sup> Recently, C.H. Hulsbergen, Delft Hydraulics Laboratory, has performed experiments to determine the influence of suction velocity and probe direction on measured concentration (Bosman, 1984). When the report is published, the results will be used in a further adaptation of our measurements.

Fig. 7: Comparison of two methods to determine time-mean concentration  $\bar{C}$  in tests with two separate longitudinally directed (N-S) suction intakes.  $\times$ :  $\bar{C}$  determined as the mean concentration for the actually measured suspension sample ( $= \bar{C}_m$ ).  $\circ$ :  $\bar{C}$  determined as the mean value of the at any time highest measured concentration. —:  $d_{50} = 0.19$  mm,  $T = 9.1$  s. ---:  $d_{50} = 0.19$  mm,  $T = 6.8$  s. -·-·:  $d_{50} = 0.38$  mm,  $T = 6.8$  s.

Fig. 8: Time-mean concentrations  $\bar{C}$ , determined from the at any time highest measured concentration.  $d_{50} = 0.19$  mm,  $T = 9.1$  s and 6.8 s. Specifically for single longitudinally directed intakes:  $\bar{C}$  is determined from the at any time highest of curves  $C(\omega t)$  and  $C(\omega t + 180^\circ)$ . The range of variation of the bed level during the tests is marked by a full line through each test point.  $\Delta$ : intake pointing N;  $\nabla$ : intake pointing S;  $\triangleright$ : intake pointing E;  $\triangleleft$ : intake pointing W;  $\diamond$ : two intakes pointing N-S;  $\times$ : T-shaped intake;  $\circ$ : disc-shaped intake.

Fig. 9: Time-mean concentrations  $\bar{C}$ , determined from the at any time highest measured concentration.  $d_{50} = 0.38$  mm, and  $T = 6.8$  s. Legend, see Fig. 8.

Fig. 10: Median grain diameters of suspended sediment versus height above sand bed. o:  $d_{50}(\text{bed}) = 0.19$  mm,  $T = 9.1$  s. +:  $d_{50}(\text{bed}) = 0.19$  mm,  $T = 6.8$  s. □:  $d_{50}(\text{bed}) = 0.38$  mm,  $T = 6.8$  s.

- d. Also time-mean concentration profiles were found (Figs. 8 and 9).
- e. For the finer sand, grain size was found to decrease with height (Fig. 10).
- f. The time variation of concentration was 'peaky' with narrow maxima and broad minima, especially so for the coarse sand.
- g. The time variation of relative concentration was larger in experiments with coarse sand than with fine sand.

The experiments described in this paper were supported by the Danish Council for Scientific and Industrial Research. The authors also want to thank the staff at ISVA's workshops and laboratory for the skillful rebuilding of the oscillating water tunnel and for great help with the performance of the experiments.

## CHAPTER ONE HUNDRED FIFTY SIX

### SCALE EFFECTS IN LARGE COASTAL MOBILE BED MODELS

J.W. Kamphuis\* and R.B. Nairn\*

#### ABSTRACT:

A series of mobile bed model tests of a prototype circular sand island was performed to determine scale effects. It was found that scale effect was largely a function of mobility number with some secondary effects of Reynolds number, bedform and critical profile depth. It was concluded that a model series using prototype sand grain size is necessary at this time to effect successful extrapolation to prototype.

#### 1.0 INTRODUCTION

An extensive series of model tests was performed with circular islands consisting of sand only. The prototype modelled was an artificial island used for drilling purposes in the Canadian Beaufort Sea. It was located in 20 m of water, had a composite slope (mostly 1:12), a drilling platform of 50 m radius and nominally contained  $5 \times 10^6 \text{ m}^3$  of 0.2 mm diameter sand. (Figures 1 and 2 show the model basin and the prototype island profile.) To date 30 different mobile bed models have been built and tested, using scales of 50, 75, 100 and 200 and sand particle sizes of 0.56, 0.18, 0.17 and 0.105 mm. The island models were tested until they were completely submerged.

Erosion volumes were measured at prototype time intervals of 3, 12, 36, 108 and 216 hours, based on hydrodynamic scaling (Froude) relationships. Progression of erosion was also monitored by recording the time to reach several benchmark stations. These were the leading edge of the drilling platform, a post located at the centre of the island, the trailing edge of the platform and the disappearance of the island underwater. Erosion volume was also measured when the test reached the post and when the island became submerged. Thus, erosion rates could be calculated for particular prototype time intervals as well as over the morphological time interval required for erosion to reach the post and for the island to become submerged. In the present paper erosion volumes on the front half of the island only are considered in the analysis.

---

\* Department of Civil Engineering, Queen's University, Kingston, Canada, K7L 3N6

The prototype wave climate was simulated using 8 second monochromatic waves arriving from one single direction. Each model was built twice. One model was subjected to a wave height of 6.5 m, while the other was tested at a wave height of 4.75 m. Both of these are considered to be extreme storm wave conditions. Several models were built more than twice for replication of results, removal of testing errors and for tests with different wave heights.

This paper presents a description of how a series of model tests should be performed and interpreted. This study differs from previous scale effects investigations because a strong longshore sand transport gradient exists in this truly three dimensional problem.

## 2.0 DIMENSIONAL ANALYSIS

The primary objective of coastal mobile bed modeling is to determine prototype sediment transport rates and morphology. A functional relationship between sediment transport and its parameters may be postulated as follows:

$$Q = f(H, L \text{ or } T, D \text{ or } m, \rho, \rho_s, g, \lambda, \nu) \quad [2.1]$$

Here  $Q$  is defined as the volumetric rate of sediment transport. The wave is described by the wave height  $H$  at the toe of the structure and wavelength  $L$  which is a function of wave period  $T$ . Many authors have shown beach slope  $m$  is related to grain diameter  $D$ , therefore  $D$  and  $m$  are not independent parameters. The median grain diameter  $D$  is retained since it was varied in the tests. The geometric parameter  $\lambda$  describes the actual physical size of the model island, for instance the diameter of island. Time  $t$  should be included as a characteristic parameter but since the tests were carried out for distinct prototype time periods (e.g. 0 to 3 hrs. or time for erosion to reach the post) each test can be viewed separately, initially neglecting time effects.

The island tests were performed for storm conditions with plunging breakers which produce much suspended load. Under these conditions bed load moved by shear stress under unbroken waves does not amount to a significant proportion of the sediment transport and hence in the present tests, as well as in the prototype, sediment transport is mainly a result of suspended sediment movement in the surf zone. Since surf zone phenomena are characterized by rough turbulent flow it might be postulated that viscosity should not be included in Equation 2.1. However, as shown in sections 4.2 and 4.4 the morphology of the eroded form of the island is related to viscosity and hence it must be retained as a parameter. The dimensionless relationship for volumetric sediment transport rate  $Q$ , may be written as

$$\frac{Q}{H^3/T} = \phi \left( \frac{gH^2D^2}{L\nu^2}, \frac{H^2}{DL}, \frac{H}{L}, \frac{\lambda}{L}, \frac{\rho_s}{\rho} \right) \quad [2.2]$$

The influence of  $\rho_s/\rho$  has been discussed earlier - Kamphuis (1975a, 1982) and as a result all our coastal models use sand as a mobile bed material. Thus the influence of  $\rho_s/\rho$  was not tested in this series and  $\rho_s/\rho$  was kept the same as in the prototype. The island size  $\lambda/L$  was also kept constant and equal to the prototype value throughout these tests. Wave steepness  $H/L$  was varied in these tests, but in a geometrically similar model this ratio will also be the same as in the prototype.

This leaves the first two parameters which by virtue of the grain size  $D$  cannot be modelled correctly. Thus, these two parameters introduce scale effect. The first parameter is essentially a grain size Reynolds number, expressed in terms of the common wave parameters; the second is a mobility number or Shields parameter. The Reynolds number describes the boundary layer regime. The mobility number represents the ratio of inertia (or disturbing) forces to gravity (or restoring) forces and reflects actual amounts of sediment in motion as well as proportion of sediment in suspension. As scale decreases (larger models), the wave height increases and hence the Reynolds number and the mobility number will both increase resulting in more sediment movement and a larger proportion of material travelling in suspension.

### 3.0 MORPHOLOGICAL DEVELOPMENT

#### 3.1 Description of Morphology

All the island tests with monochromatic waves featured a similar pattern of morphological development. Throughout the tests, the incident waves formed plunging breakers in the vicinity of the radial facing directly into the waves. In most tests sediment agitation and suspension was observed beneath the plunging breakers within the surf zone. Strong longshore currents developed alongside the island forming a longshore trench. The current carried suspended sediment from the zone of plunging breakers and deposited it to form symmetrical wing bars extending out from either side of the back of the island (Figure 3).

Large unidirectional flow dunes clearly defined the location of the longshore current. These dunes abruptly changed to wave induced ripples just outside the breaker line. From the bedform it was apparent that the point of maximum longshore current closely coincided with the zone of greatest bed agitation. This supposition was confirmed with current velocity measurements.

#### 3.2 Rate of Morphological Development

Figure 4A shows cumulative erosion with time for one island test. It reveals that the erosion rate decreases with time as the island approaches dynamic equilibrium form or shape of minimum entropy. Replotting Figure 4A on a log scale as was done in Figure 4B shows a definite change in erosion rate when the leading edge of the erosion scarp infringes on the horizontal drilling platform.

During the erosion process, the waves on the front of the island tend to form an eroding profile which has a relatively constant shape and exhibits a critical depth below which no erosion takes place. The eroding profile has been fully formed at about the time that the erosion reaches the horizontal platform, hence the sudden decrease in erosion rate in Figure 4B. After that time the profile simply erodes back into the island as shown in Figure 5 but since the island is circular, there will be less and less material to erode as the profile approaches the centre of the island. This is reflected in the continuing decrease in erosion rate in Figure 4.

#### 4.0 DIAMETER EFFECTS

The inability to model grain size correctly in the model introduces scale effects as described in Section 2 which may be classified as Inertial Effects (incorrect mobility number) and Viscous Effects (incorrect Reynolds number).

#### 4.1 Inertial Effects

Dimensionless erosion rate is plotted as a function of the mobility number  $H^2/DL$  in Figures 6 and 7. If there were no scale effect, all points for constant sediment size and wave conditions would lie on a horizontal line. If the scale effect were purely a function of  $H^2/DL$ , Figures 6 and 7 would show a straight line. In fact, the lines are curved, indicating that scale effect is largely a function of  $H^2/DL$  but is also influenced by the other parameters. Since  $\rho_s/\rho$  and  $\lambda/L$  were not varied and since along any line in Figures 6 and 7  $H/L$  is constant, the curvature must be a function of the Reynolds number  $gH^2D^2/Lv^2$ . It may be seen in Figure 6 which shows erosion at constant (prototype) time using Froude scaling that as time increases, the curvature of the lines also increases, i.e. there are some secondary considerations. These may be explained directly from Figures 4 and 5. Smaller scale models are at a further state of erosion than larger scale models at any fixed time. This means the average erosion rate over such a period is less as may be inferred from Figure 4. Also the erosion rate is decreased because the constant eroding profile has progressed further into the island for these smaller scale tests, leaving less material to erode.

The latter two effects which may be called "time effects" can be removed by plotting erosion rate for a certain stage of morphological development as was done in Figure 7 where the average erosion rate to the post is plotted. This figure shows less curvature than Figure 6 and essentially the curvature is a result of viscous or Reynolds Number ( $gH^2D^2/Lv^2$ ) effect which is examined further in the next section.

Another way to investigate the effect of the mobility number on island erosion is to plot the time it takes to erode to a certain morphological stage. Figure 8 shows the time required to erode to the post. Once again it is seen that the lines for constant grain size are not straight but curved, reflecting the effect of viscosity.

One reason that sediment transport is highly dependent on mobility number is the fact that the amount of suspended load is closely related to mobility number. Sawaragi and Deguchi (1978) suggest criteria based on the dimensionless parameter  $H/D$  to distinguish between prominence of bed load versus suspended load.

$H/D < 125$	no suspension
$H/D > 200$	sediment is suspended (transition)
$H/D > 300$	suspended load exceeds bed load

The  $H/D$  parameter is identical to  $H^2/DL$  if the model is geometrically similar (then  $H/L$  will be the same in model and prototype). In the island tests  $H/D$  was greater than 300 in most of the finer sand tests (0.105 mm and 0.18 mm) indicating prevalent suspended load. The coarse 0.56 mm sand at all scales and the finer sands at 200 scale were transported almost entirely by bed load, quite unlike the transport mechanism in prototype. The modeling of prototype wave conditions which produce suspended load using typical model scales of 200 to 50 must therefore be performed with a model grain size smaller than 0.2 mm to 0.3 mm ( $H/D > 300$ ) to ensure suspended load is prevalent in the model.

#### 4.2 Viscous Effects

The effects of viscosity are not negligible as often assumed in coastal mobile bed modeling. Because of the flow reversals in wave mechanics often the flow regime in the boundary layer is smooth especially outside the breaking zone. Viscosity effects complicate the analysis in several ways.

Preliminary analysis indicated that the sediment transport increased with an increase in the grain diameter from 0.18 mm to 0.56 mm. It was shown in the previous chapter that bed load is dominant in this grain size range for the scales tested. In order to offer an explanation for this strange variation in sediment transport the boundary layer regime outside the surf zone must be examined. The Shields diagram for unidirectional flow shows that grains become increasingly mobile as the grain size increases from 0.2 mm to 0.6 mm (see Figure 9). This is the region of transition from laminar to turbulent flow in the boundary layer. In this region an increase in grain size intensifies the turbulence within the boundary layer which induces greater sediment mobility. For grain diameters greater than 0.6 mm (for unidirectional flow) the boundary layer flow is fully developed rough turbulent and increases in grain diameter do not cause further increases in sediment mobility. This same phenomenon exists for oscillatory fluid motion. When the island tests with the finer sands are plotted on the flow regime diagram developed by Kamphuis (1975), they indicate smooth flow in the boundary layer which is either laminar or in transition to turbulent. The coarser sand is in the transition region to rough turbulent (see Figure 10), and for the range of scales tested the flow in the boundary layer will be in transition for grain sizes between 0.3 and 4.5 mm. Within this transition zone an increase in grain diameter causes an increase in sediment mobility which translates to greater sediment transport

rates. Similar transition ranges have been suggested by Komar and Miller (1974) and Madsen and Grant (1976).

As the grain size Reynolds number,  $gH^2D^2/Lv^2$  becomes large the boundary layer will become turbulent and the effects of viscosity on bed load may be expected to become negligible. In Figures 7 and 8 there is less curvature through data points corresponding to the tests with smaller scales indicating a reduction in the Reynolds number effect. The remaining curvature is attributable to both remaining Reynolds number effect and secondary influences such as bedform and critical depth.

#### 4.3 Bedform Effect

In the tests with smaller scales and for the two finer sands the existence of bedform indicates that the boundary layer flow is rough turbulent and therefore the effects of viscosity should be minimal. The remaining curvature in Figures 7 and 8 may in part be attributable to bedform since it is a function of the ratio of orbital amplitude to grain diameter which varies with scale. While a varying size of bedform is present in the models, it will be different from the prototype, resulting in scale effect; in fact it is probable that in the prototype under the wave conditions being tested all bedform will be washed out.

The significance of this scale effect may be limited since it has been estimated that the wave energy loss due to the large turbulence brought into the water from the surface by the breaking wave was some hundred times the amount of energy dissipated due to bottom shear stress - (Sawaragi et al (1974)).

#### 4.4 Critical Depth Effect

The critical depth scale effect is important because it has a large impact on the amount of material eroded. Because of the measuring techniques adopted it was difficult to determine the critical depth of erosion accurately. However, if the cumulative erosion on the front half of the island is examined as in Figure 11 a more accurate idea of critical depth effect is obtained.

The cumulative erosion for the profile corresponding to the radial which is perpendicular to the waves displays identical trends observed in cumulative erosion of the front half of the island. This would indicate a variation in cumulative erosion with scale and grain size is largely a two dimensional effect related to critical depth. There is a slight increase in cumulative erosion or critical depth from 200 to 100 scale and then a decrease to the 50 scale. Direct observation of critical depth also confirms it decreases with scale.

Kamphuis (1984) has adapted an equation developed by Hallermeier (1980) for initiation of sediment to describe the critical depth of erosion as follows:

$$H_c = K D^{1/4} T^{3/2} \sinh(kd_c) \quad [4.1]$$

where  $K$  is a constant and  $H_c$  is a wave height which yields critical depth  $d_c$ . The average value<sup>c</sup> of  $K$  found in flume tests by Kamphuis was 0.12 and is identical to the average value of  $K$  for the island tests. This was somewhat fortuitous since the flume tests by Kamphuis were in fact in the middle range of the island tests (i.e. 100 scale). Both flume tests and island tests indicate critical depth is dependent on scale (or  $H^2/DL$ ) and on grain size Reynolds number and therefore  $K$  is not a constant.

The significance of this scale effect would be illuminated if the critical depth in prototype were known. Kamphuis (1984) has fitted a straight line to field results collected by Swart (1974) resulting in the following relation.

$$K = 0.125 + 0.037 H \quad [4.2]$$

Using this equation for  $K$ , the following prototype critical depths are estimated for a wave with an 8 second period using Equation 4.1:

D	Wave Height (m)	K (Eq. 4.2)	Prototype	Laboratory	
			Critical Depth (m) (Eq. 4.2)	Critical Depth (m) 200 scale	Critical Depth (m) 50 scale
0.20 mm	3	0.24	7.6		
	4.75	0.30	10.5	10.0	8.0
	6.5	0.37	12.0	12.0	10.0

The prototype critical depths are very similar to those found in the laboratory. This may indicate that the scale effect from critical depth is small.

## 5.0 THE USE OF REGULAR WAVES

The present tests were performed with regular waves which consistently produced plunging breakers. This very simple artificial wave climate allows a better understanding of the physics involved, but also results in much greater erosion rates than in the prototype case of irregular waves. The regular wave model creates a condition where all waves break at the same point and where the point of maximum longshore current velocity closely coincides with the point of greatest agitation of the bed, resulting in maximum sediment transport rate. For irregular waves, part of the wave spectrum results in spilling breakers, the longshore current velocity distribution is spread over a longer distance perpendicular to the beach and each wave does not break at the point of maximum value of longshore current. Tests which are now underway with irregular waves show that the trough and bar formed by the longshore current as well as the bedform in the

trough are not as pronounced. Also the waves refract further around the island, critical depths remain virtually the same, sediment transport rate is smaller by a factor of 3 to 4 and time to a certain morphological stage is greater by a factor 2.

## 6.0 EXTRAPOLATION TO PROTOTYPE

### 6.1 The Scale Series

The inability to scale down grain size correctly results in the most pronounced scale effect in coastal mobile bed models (Kamphuis 1982, 1975a). A complete understanding of this effect is very difficult because of incomplete theoretical understanding of the sediment transport mechanisms which involve sediment suspension, liquefaction of the bed, percolation and aeration of the surf zone. Also viscous and bedform effects introduce further complexities which are not fully understood. The results from a single physical model test of a previously untested coastal feature cannot therefore reliably describe a prototype e.g. how would one extrapolate from one single point in Figures 6, 7 or 8? One option remaining (until scale effect is fully understood) is a series of tests at different scales. The philosophy of the series of tests is to provide some understanding of the influence of scale effects in the range of scales tested as evidenced by Figures 6, 7 and 8 in the present tests and with this knowledge, attempt to extrapolate to prototype.

### 6.2 Validity of Extrapolation

The present series of tests has revealed the erosion (or sediment transport) rates of the front half of the island for model scales 200 to 50. Any attempt at extrapolation cannot be entirely dependable. However, in some cases extrapolation may be attempted with more confidence than others, for instance extrapolation of the 0 to 3 hr prototype time period (Figure 6A) or the morphological stage to the post, Figures 7 and 8, would be more reliable than longer prototype time periods, (Figures 6B and C) where curvature and differences between the lines of various grain sizes is much more severe. During the shorter prototype time period differences between erosion rates for different grain diameters are not large and the use of smaller grain sizes than the prototype sand aid in extrapolation because the values of  $H^2/DL$  for the finer sands will be greater and closer to the prototype value. It is apparent that the prototype grain diameter should be used in models if longer morphological time segments are used in the extrapolation because of the critical depth effect resulting from differing diameters is large (Figure 8).

Vellinga (1982, 1978) carried out a series of two dimensional dune erosion tests at different scales and grain diameters. In order to establish scaling relationships (based on the fall velocity parameter  $H/Tw$ ) Vellinga built models with different profile distortions and it was discovered that distortion was directly proportional to erosion. Therefore, Vellinga's results can be plotted using the parameters of the present paper by dividing the erosion quantity for a test by the initial profile distortion from a

prototype. The plots for three prototype time periods are shown in Figures 12A, B and C and these figures show the same trends observed for the island tests i.e. the longer time periods show more curvature and a greater difference between the different grain diameters. Vellinga's 5 hr prototype results were enhanced by a test at scale 5 in the Delta flume at Delft. These results have been plotted in Figure 12A and demonstrate that extrapolation is not outside the realm of consideration for shorter prototype time periods.

### 6.3 Extrapolation of Results

An attempt was made at extrapolation using two methods, extrapolating the dimensionless erosion rate for a short prototype time period and extrapolating over a morphological time segment. These two methods were employed to determine the time for the erosion scarp to reach the post at the centre of the island. For the first method an erosion rate was determined for 0 to 3 hrs for the prototype by extrapolation of Figure 6A. The second method was a direct extrapolation of the time to the post (Figure 8). The following results were obtained for regular waves with an 8 second period:

H(m)	time to reach the post (hrs)	
	method 1	method 2
6.5	2-3	3-6
4.75	3-5	5-10

The credibility of extrapolation is demonstrated by the fact that these separate methods yield results of the same magnitude.

The erosion of one prototype island in the Beaufort Sea was monitored by Esso Resources Canada with aerial photographs over the period of three storms in October 1980. During these storms which each lasted less than a day and featured significant wave heights of about 3 m and a wave period of 7 s the island was eroded from the edge of the drilling platform at the top of the 1 in 3 slope to approximately the centre of the island. It is estimated that each storm lasted about 6 hrs, hence the island was effectively subjected to approximately 18 hrs of waves with an approximate significant wave height of 3 m and period of 7 seconds. The extrapolation of model results with 3 m wave height and 8 second period for the morphological time period from the top of the 1:3 slope to the post yield an erosion time of 8 hours for the prototype. Since it was discovered in the model tests with irregular waves that the progression of erosion with the regular wave tests was about twice that with irregular waves, the above number needs to be doubled, giving an approximate estimated prototype erosion time of 16 hours. It must be stressed that both the prototype data and the extrapolation from the models are very approximate but the above comparison looks very promising.

## 7.0 CONCLUSIONS AND RECOMMENDATIONS

1. Scale effects are mainly due to the incorrect simulation of grain diameter.

2. The change in sediment transport rate with scale is primarily due to inertial effects.

3. Viscous effects and the existence of bedform and critical depth scale effects cause secondary influences which make direct extrapolation difficult.

4. To model a previously untested coastal feature, a series of tests must be performed which provides a basis for extrapolation of results to prototype.

5. The influences of the various scale effects have been identified within the scale series but their role in the zone of extrapolation is still relatively unknown. Further research is required at smaller scales.

6. Extrapolation can be performed with some degree of confidence for short prototype time periods and for morphological time segments.

7. Critical depth effects become large between different model grain diameters for the longer prototype times and extrapolation can only effectively be performed from models with the prototype grain size. Over short prototype time periods profile evolution and erosion rates are not much different for the different scales and extrapolation from different grain size curves is possible. Since critical depth effects are minimal in the early time periods finer grain sizes than prototype would help to close the gap on extrapolation to the prototype value of  $H^2/DL$ .

8. At lower values of  $H^2/DL$  or  $H/D$  (Sawaragi and Deguchi suggest a limit of  $H/D = 300$ ) sediment transport will be mainly by bed load in the laboratory and will not resemble a prototype which features predominant suspended load.

## 8.0 ACKNOWLEDGEMENTS

The work presented in this report was supported financially by a grant from the Natural Sciences and Engineering Research Council of Canada (NSERC). The junior author was also supported by an NSERC scholarship during his study at Queen's. The actual model testing involved many individuals and the authors are grateful for the support by this team of dedicated people.

### LOW-PROFILE BARRIER ISLAND OVERWASH AND BREACHING IN THE GULF OF MEXICO

Shea Penland and John R. Suter  
Louisiana Geological Survey  
Coastal Geology Program  
Box G, University Station  
Baton Rouge, La. 70893

#### ABSTRACT

An analysis of 17 tropical cyclone impacts along barrier islands in the Gulf of Mexico has led to the following conclusions: 1) tropical cyclones are the primary mechanism of barrier island overwash and breaching, 2) landward-directed and seaward-directed overwash flow can breach barrier islands, 3) storm track orientation to the shoreline controls the direction of barrier island breaching, 4) shore-normal and right-oblique hurricane impacts breach barrier islands by landward-directed overwash flow, and 5) left-oblique hurricane impacts breach barrier islands by seaward-directed overwash flow.

#### INTRODUCTION

The breaching of low-profile Gulf Coast barrier islands by hurricane impact is controlled by barrier island morphology, storm magnitude, and the type and intensity of other processes that operate on the system (Penland et al, 1980; Simpson and Reihl, 1981; Suter et al, 1982; Penland and Suter, 1984). Due to the asymmetry of the cyclonic wind field and the occurrence of the strongest winds in the northeast storm quadrant, orientation of the storm track to the shoreline controls the direction (landward or seaward) from which barrier island breaching occurs (Figure 1). Analysis of storm orientation and hurricane impacts using historical aerial photographs and tide gauge records of landfalls associated with hurricanes Flossy (1956), Audry (1957), Donna (1960), Carla (1961), Hilda (1963), Betsey (1965), Beulah (1967), Camille (1969), Celia (1970), Carmen (1974), and Eloise (1975) and field investigations of impacts associated with hurricanes Bob (1979), Claudette (1979), Frederic (1979), Allen (1980), Chris (1982) and Alicia (1983) leads to the development of three hurricane process-response models that explain the patterns of low-profile barrier island breaching identified on the Gulf

Figure 1. Distribution of pressure, surface winds, and waves within a typical northern tropical cyclone (Crutcher and Quayle, 1974).

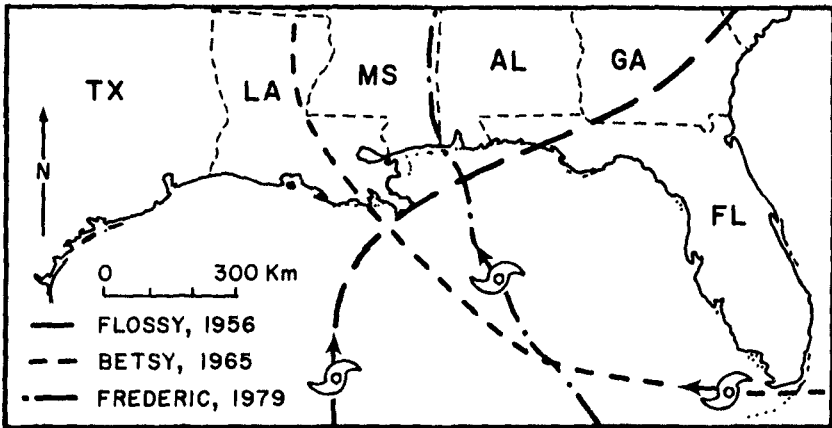

Figure 2. Hurricane Flossy represents a left-oblique impact, Hurricane Betsey represents a right-oblique impact and Hurricane Frederic represents a shore-normal impact.

Coast. These models are:

1. Shore-Normal Hurricane Impact.
2. Right-Oblique Hurricane Impact.
3. Left-Oblique Hurricane Impact.

Case studies for hurricanes Frederic 1979 (shore-normal impact), Flossy 1956 (left-oblique impact), and Betsey 1965 (right-oblique impact) are presented illustrating each type of hurricane impact (Figure 2).

#### LANDWARD-DIRECTED OVERWASH FLOW

For shore-normal hurricane impacts, peak surge and strongest winds occur pre-landfall and are focused onshore to the right side of the storm track. Landward oriented overwash features and barrier island breaches are concentrated to the right of the storm. Left of the storm, somewhat weaker winds are directed offshore. If the lagoon is sufficiently wide and shallow, offshore wind set-up can pile water against the backbarrier, creating the potential for minor seaward overwash, evidence of which may be masked by subsequent landward overwash flow. The breaching associated with hurricane Frederic (1979) at Dauphin Island and Gulf Shores in Alabama and at Perdido Key and Santa Rosa Island in Florida is representative of a shore-normal impact (Figure 3).

For right-oblique hurricane impacts, the peak storm surge precedes the storm and the strongest winds are directed onshore. In this situation major landward overwash and barrier island breaching takes place right of the storm. Because of the orientation of the wind field, the potential exists for minor seaward breaching to occur to the left of the storm. Hurricane Betsey (1965) is representative of right-oblique impact (Figure 4).

#### SEAWARD-DIRECTED OVERWASH FLOW

For left-oblique hurricane impacts, the peak storm surge follows landfall. Due to the orientation of the storm track, the strongest winds are initially directed offshore. This results in a significant water level set-up against the backside of the barrier island and leads to major seaward overwash and breaching left of the storm track. With hurricane passage the direction of overwash switches onshore, enlarging the breaches generated by the earlier seaward overwash. Hurricane Flossy (1956) is representative of a left-oblique impact (Figure 5).

## CONCLUSIONS

The analysis of 17 hurricane and tropical storm impacts along barrier islands on the U.S. Gulf Coast leads to the following conclusions:

1. Storm overwash associated with tropical cyclone impact is the primary mechanism of Gulf Coast barrier island breaching.
2. Barrier islands can be breached by landward-directed or seaward-directed overwash flow.
3. Storm track orientation to the shoreline controls the direction from which barrier island breaching occurs through overwash flow.
4. Shore-normal and right-oblique hurricane impacts breach barrier islands by landward directed overwash flow.
5. Left-oblique hurricane impacts breach barrier islands by seaward directed overwash flow.

## CHAPTER ONE HUNDRED FIFTY EIGHT

### A NUMERICAL HINDCAST OF STORM CURRENTS ON THE NORWEGIAN SHELF

Cortis K. Cooper, A. M. ASCE\*

#### INTRODUCTION

##### Objectives and Tasks

This paper describes an initial effort to model storm-driven currents and surge in the region indicated in Figure 1. The model results ultimately will be used in the design and operation of offshore oil platforms in the region.

The study consisted of four major tasks: 1) review of the data base and selection of the hindcast storms, 2) hindcast of the selected storms, 3) set-up and testing of the current model, and 4) hindcast of currents for the selected storms.

##### Description of Study Area

Current data were obtained from sites shown as solid circles in Figure 1. Each site consisted of an array of at least four Aanderaa current meters. Meters were typically placed at 50, 100, and 150 m below still water level, and at a few meters above the bottom.

Topographic effects play a major role in the shelf dynamics of the region. The Norwegian Trench is a dominant bathymetric feature with a characteristic depth of 300 m. Its outer edges are indicated by the dashed line in Figure 1. To the west of the trench, lies the Møre Plateau, a flat plane with an average depth of 150 m.

The worst storm conditions occur between late fall and early spring when the water column is generally well mixed. The region intersects the primary wintertime cyclone path and lies close to the average position of the polar front. Hence storms occur almost continuously during the winter season. Major storms in the region are extratropical, lasting for days. The region is too far south to be affected by the "polar low".

The frictional influence on shelf dynamics is relatively small, thus currents exhibit a strong inertial response (50 cm/s) during many storms. Within 50 km of the coast the response is affected by storm-induced alongshore pressure gradients.

The Norwegian Coastal Current is an important flow feature in the area. It flows from south to north through the Trench with a mean speed of 30 cm/s. However, the mean is occasionally interrupted by strongly baroclinic shelf waves which can generate surface currents of 150 cm/s (15).

\*Petroleum Research and Development, Conoco Inc., Ponca City, OK 74603.

Tidal currents are primarily semidiurnal and of order 40 cm/s in magnitude. The banks and submarine canyons are known to affect currents, sometime dramatically in the form of splitting and vortex shedding (12).

### Preview

The next section briefly describes the model formulation. Readers interested in more details should refer to Cooper and Pearce (9,10).

The third section describes the initial application of the model. During this phase of the study it was found that the model solution was dominated by a strong seiche. The seiche was caused by the reflective boundary conditions used in the initial grid system.

Following the difficulty with the boundary conditions, a review of existing techniques for specifying boundary conditions was performed and this is summarized in the fourth section. Readers should find this of general interest since a synthesis is absent in existing literature.

The fifth section describes the final grid system including a brief discussion of model sensitivity, and the sixth section presents some results from the storm hindcast, and discusses some of the reasons for the observed discrepancies between the model and data. The final section summarizes the previous sections, and describes the efforts presently underway to improve these efforts.

### MODEL FORMULATION

The model is based on the primitive barotropic equations. The form on which they are applied in this application is numerically similar to the shallow water wave equations.

Figure 1: Model grid used in initial runs. Element size is 15.7 km.

### Governing Equations

The model uses the linearized momentum equations:

$$0 = \frac{\partial u}{\partial t} + \frac{\rho_s}{\rho} g \frac{\partial \eta}{\partial x} - N_h (\nabla^2 u) - \frac{\partial}{\partial z} \left( N_v \frac{\partial u}{\partial z} \right) - fv + \frac{1}{\rho} \frac{\partial P_a}{\partial x} + \frac{g}{\rho} \int_0^z \frac{\partial \rho}{\partial x} d\xi,$$

$$0 = \frac{\partial v}{\partial t} + \frac{\rho_s}{\rho} g \frac{\partial \eta}{\partial y} - N_h (\nabla^2 v) - \frac{\partial}{\partial z} \left( N_v \frac{\partial v}{\partial z} \right) + fu + \frac{1}{\rho} \frac{\partial P_a}{\partial y} + \frac{g}{\rho} \int_0^z \frac{\partial \rho}{\partial y} d\xi,$$

where the symbols are defined as follows:

- t the time variable
- x, y the horizontal coordinates in a right-handed Cartesian coordinate system
- z the vertical coordinate, measured as positive downward from SWL
- u, v the horizontal velocity components in the x and y directions, respectively
- $\rho_s$  the density of the fluid, where the s subscript indicates the value at the surface
- g the gravitational constant (9.8 m/s)
- $\eta$  the water height of the free surface above SWL
- $N_h$  the horizontal eddy-viscosity coefficient
- $N_v$  the vertical eddy-viscosity coefficient
- f the Coriolis parameter  $[-2\omega \sin \phi]$  where  $\omega$  is the angular velocity of the earth and  $\phi$  the latitude
- $P_a$  the atmospheric pressure
- $\nabla^2$  the Laplacian operator  $\left[ = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right]$ .

Note that the vertical velocity is assumed negligible. The density-gradient term was neglected in this application since adequate hydrographic data was unavailable.

The other governing equation used in the model is the continuity equation

$$\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = \frac{\partial \eta}{\partial t},$$

where

U and V are the mass fluxes per unit length in the x and y directions, respectively.

### Boundary Conditions

The boundary conditions at the surface are

$$\tau_{sx} = \left[ -\rho N_v \frac{\partial u}{\partial z} \right] \Bigg|_{z=0}, \quad \tau_{sy} = \left[ -\rho N_v \frac{\partial v}{\partial z} \right] \Bigg|_{z=0},$$

where  $\tau_{sx}$  and  $\tau_{sy}$  are the specified shear stresses at the surface in the x and y directions, respectively.

At the bottom a linearized friction law is used

$$\tau_{bx} = [\rho c_b u] \Big|_{z=H}, \quad \tau_{by} = [\rho c_b v] \Big|_{z=H},$$

where  $\tau_{bx}$  and  $\tau_{by}$  are the bottom shear stresses and  $c_b$  is a drag coefficient.

There were insufficient observations to provide boundary conditions on the horizontal boundaries so assumptions had to be made. Initially it was assumed that

- the mass fluxes perpendicular to the coastline were zero;
- the alongshore surface gradient on the cross-shelf boundaries was zero
- the amplitude at the open ocean boundaries was the barometric water rise (i.e. the inverted barometer effect).

#### Numerical Solution Technique

The governing equations and boundary conditions are transformed using the Galerkin technique. A cosine is used as the basis function in this model. The technique explicitly eliminates  $z$  from the transformed equations and greatly simplifies the eventual solution process. The dependence of  $u$  and  $v$  on  $z$  is implicitly retained in the final equations and the  $u$  and  $v$  velocity profiles can be regained whenever desired. A summary of the transformation is given in Cooper and Pearce (9). The method was originally suggested by Heaps (17) and has been used by others (11).

The transformed equations are solved on a staggered finite difference grid system using a "leap-frog" explicit scheme attributed to Lilly (21).

The horizontal grid used in the initial model consisted of 30 X 20 elements of 15.7 km each as shown in Figure 1. The grid was a compromise between the resolution needed to model the steep topographic features in the region, and the long integration times needed to model the regional storms. A more extensive grid was considered but the additional expense was not felt justified given the preliminary nature of the study.

#### INITIAL APPLICATION

##### Model Setup

The model uses three empirical coefficients to parameterize turbulent processes: bottom friction, vertical eddy viscosity, and lateral eddy viscosity. Values for these coefficients were based on equations available in the literature.

The bottom friction coefficient was derived using a Manning's coefficient for "straight and uniform earth". This suggests a value for the model coefficient of roughly 0.2 cm/s.

The vertical eddy viscosity is typically the most influential parameter for relatively deep water areas such as the Norwegian coast. Estimates in the literature for  $N_V$  vary by several orders of magnitude, but many of these estimates can be quickly discarded because of poor quality. Cooper and Pearce (9) successfully used a relationship suggested by Townsend (30) in their application in relatively shallow water. Ramming and Kowalik (25) offer a similar expression for shallow water which gives a value of about one-half that suggested by (30). Both expressions are proportional to the water depth—a reasonable assumption for shallow water. However, as one moves into deeper water it can be soundly argued that  $N_V$  reaches an upper limit which is totally dependent on the primary energy source - in this case wind. Ramming and Kowalik (25) suggest the upper bound for  $N_V$  is given by:

$$N_V = 4.7 \times 10^{-4} W^2/f$$

where  $W$  is the wind speed.

Substituting reasonable values for the Norwegian shelf gives  $N_V = 40 \text{ cm}^2/\text{s}$  for a 10 m/s wind. The good experience with the Townsend relationship (30) suggests the doubling of the constant is in order, giving  $N_V = 80$  - the value used for these initial runs.

The model can include a vertical variation in the eddy viscosity, and this is particularly useful in the case of stratified oceans. There are also physical arguments which suggest the viscosity should vary in the vicinity of a sheared surface. For this application the viscosity was kept constant in the vertical because stratification was negligible during the storms of interest, and because field data has not yet resolved the variation of viscosity near the sea surface.

Figure 2: Modeled time series of surface elevation at the coast for initial model grid.

The horizontal eddy viscosity is primarily needed to account for subgrid turbulence, and advective terms. Previous experience by other modelers suggest a value on the order of  $10^8 \text{ cm}^2/\text{s}$  (29).

Since there were inadequate observations along the boundary, it was necessary to make some assumptions. Initially the conditions were specified as described in the previous section. Similar boundary conditions have been used in many shallow water current and surge models.

The model was forced with a spatially constant wind blowing from the south. Wind speed was ramped in time; that is it was increased from zero at model start-up to 10 m/s at 20 hours. No tidal forcing was included.

#### Model Results

Figure 2 summarizes the essential result from the early model runs. The figure shows a time series of surface elevation at a coastal location. An oscillation with a well defined period of 5.5 hours is evident.

The oscillation in the figure corresponds to the seiche period or fundamental free wave mode of the basin in the cross-shelf direction. This is easily shown by substituting the characteristic dimensions of the model basin into the analytic solution given in Lamb (19). Note that the open boundary is a node, and hence the analytic solution in (19) must be doubled.

The seiche is a numerical aberration which results from the ocean boundary conditions. These conditions reflect all incident wave energy (26). Hence, when the wind first starts, it generates free gravity waves within the model domain. These waves eventually impact the ocean boundaries and are reflected back into the model domain. The reflected waves serve to further excite the basin because their frequency is the fundamental mode.

It is clear from these results that a further refinement of the ocean boundary conditions is needed. Some of the alternatives are reviewed in the following section.

#### OVERVIEW OF HORIZONTAL BOUNDARY CONDITIONS

Having adequate data along the outer boundary of a geophysical fluids model is as rare as the proverbial hen's tooth. Thus assumptions must be made. A review of the literature revealed five types of boundary conditions which have been used in shallow water wave models: 1) variable specification, 2) telescoping, nested or stretched grids, 3) energy absorbing elements, 4) Sommerfeld radiation condition, and 5) free/forced wave modes.

Each of these is summarized below including: a description of the method, examples of previous applications, advantages, and disadvantages. It should be kept in mind that the discussion applies only to the shallow water wave equations.

#### Variable Specification

In this technique, one or more of the dependent variables are specified on the boundary. For the initial runs described above,  $\eta$  on the cross-shelf boundary is set to  $\eta$  at the internal element normal to the boundary at each

time step. In other words a one-sided spatial difference across one element is used. On the alongshore boundary,  $\eta$  is set to the inverted barometric rise - in essence a specified constant.

Variable specification has dominated surge modeling. For instance Beardsley and Haidvogel (1) specified  $\eta$  equal to the inverted barometer effect along all ocean boundaries. Forristall et al. (13) specified the flow normal to the boundary equal to zero on the alongshore boundary, and the gradient of the flow equal to zero on the cross-shelf boundaries.

The major advantage of this approach is that it is simple to implement in the code of a numerical model. In addition, the conditions perform reasonably well for forced steady-state flows such as Ekman transport because they will allow realistic alongshore pressure gradients to develop.

The major disadvantage of the approach is that it reflects incident waves. In the case of one-sided spatial differences or constants such as used in this model, the condition is totally reflective as concisely demonstrated by Reid (26).

Fortunately, for many applications reflections are not important. For example, in the case of storm surge models, the grid systems are in predominately shallow water. Two factors work in favor of the modeler: 1) the system is frictionally dominated so reflections are rapidly dampened, and 2) the travel time of long waves is large relative to the model integration time so reflections do not have time to hit the boundary and return to the coast (the primary area of interest). Reflections are also not a problem in quasi-steady or steady-state problems such as (10). Unfortunately, none of these factors apply for the Norwegian Shelf Model. In other words, the system is not frictionally dominated, nor is the integration time short. Furthermore, transient conditions are of major interest.

#### Telescoping, Nested and Stretched Grids

The basic idea common to these approaches is that the element size is a function of space.

In the stretched grid, the size changes smoothly and is "mapped" onto a constant element size using a transformation. Examples include Butler and Sheng (6) and Birchfield (2).

Telescoping grids change the element size suddenly. An example of a telescoping grid using three sizes of elements is given by Greenberg (16). The solution between the grids is coupled in time, allowing waves to propagate across the grid interfaces.

Nested grids solve the system several times. They begin by using a coarse grid, and the resulting solution is used to provide the boundary condition for a smaller "nested", fine scale grid which lies within the large grid. The method does not allow "feedback" from this "nested" grid to the large grid. The earliest example of such an approach is Reid and Bodine (27).

The advantages of these approaches are: 1) the open boundary is moved far away from the area of primary interest thus minimizing the influence of assumptions made at the boundary, and 2) the boundary can be moved to a

region where more reasonable assumptions can be made. Computational costs are minimized by using a larger element size in regions of less interest, or smaller gradients.

There are a number of problems with this approach besides the obvious inelegance and increase in computational cost. For instance, the technique will numerically distort waves as shown by Lewis et al. (20), and Browning et al. (4). In addition the nested grid does not influence the external one, and this is not realistic in general.

#### Energy Absorbing Elements

The basic idea in this approach is to dissipate wave energy when it hits the ocean boundary. This has been done in a number of ways. Busby and Timpson (5) added elements to the outer perimeter of their grid, and they specified large damping coefficients in these elements. These elements are the numerical analogue to "horse hair mats" used in laboratory wave tanks.

The approach is conceptually simple and easy to set up. However, it has a number of disadvantages in that it:

- requires extensive iteration in selecting the model damping parameters. It is not obvious a priori which parameters will minimize reflection and maximize energy absorption;
- is computationally expensive for the study of long wave phenomena because many damping elements will have to be added in order to get effective damping;
- distorts waves running tangentially to the boundary; and
- generates an artificial alongshore pressure gradient for the case of cross-shelf boundaries in the presence of wind forcing. This occurs because the alongshore Ekman transport will encounter undirectional resistance.

#### Sommerfeld Condition

This approach runs a close second in popularity behind the variable specification technique. The Sommerfeld condition can be written as:

$$\frac{\partial \phi}{\partial t} + c \frac{\partial \phi}{\partial x} = 0 \quad [1]$$

where  $\phi$  is either  $U$  or  $\eta$ ,  $c$  is the wave celerity, and the  $x$  direction is assumed normal to the boundary.

The Sommerfeld condition is the proper boundary condition for freely propagating waves at a boundary with infinite extent. Free waves are governed by the wave equation - a hyperbolic equation. The primitive barotropic equations in their full form lie somewhere between hyperbolic and parabolic, but degenerate into the wave equation in the absence of rotation, wind forcing and viscous effects. If these terms are neglected then the Sommerfeld condition does apply to the primitive equations.

An alternative form of the Sommerfield condition has often been used with primitive equation models:

$$U = c \eta + K \quad [2]$$

The equation can be derived by writing the Sommerfield condition for both  $U$  and  $\eta$ , then using the continuity equation to derive two differential equations - one in space and the other in time. The solution to the two equations is of the form [2]. The constant,  $k$ , is usually taken as zero based on physical arguments.

The value for  $c$  in [1] and [2] must be determined, and in general this requires knowledge of the dispersion relationship for the waves in question. Unfortunately, the relationship is not generally known. Orlanski (24), Camerlengo and O'Brien (7), and Miller and Thorpe (22) suggest methods to calculate  $c$  using one-sided differencing methods. However, for homogeneous fluids the value for  $c$  is generally taken as the shallow water wave speed,  $\sqrt{gH}$ , where  $H$  is the local water depth. This of course neglects rotational effects.

Vastano and Reid (40,41) used [1] in the study of tsunami response. They found that the technique was limited by the fact that [1] only radiates waves which hit the boundary at a normal angle - oblique waves will be partially reflected. Mungall and Reid (23) present a modification of [1] which allows radially spreading waves to scatter outward through a rectangularly bounded basin. Additional studies by Hebenstreit et al. (18) show the methods gives satisfactory results.

Reid and Bodine (27) appear to be the first to have used [2]. They studied the free wave propagation of storm surge in Galveston Bay. Wurtele et al. (42) used [2] to compare with the results from Vastano and Reid (40,41). Wurtele et al. (42) looked at the 2-D problem in a rectangular grid, and used the normal component of velocity at an internal grid to calculate  $\eta$  on the boundary. They found only weak reflections and no instabilities.

The obvious advantage of these radiation conditions is that they will allow free waves to propagate out of the model boundaries much as they would in the real world. Previous work clearly indicates that the conditions can be successfully used in the study of many practical free wave problems such as tsunamis.

The technique has some limitations in that it cannot include nonlinearities, rotation, or forced waves.

The last limitation is clearly indicated in the theoretical foundations of the Sommerfield condition; yet many investigators have ignored this fact. For example, Heaps (17) used [2] in the study of wind-driven surge in the Irish Sea. Similarly, Blumberg and Kantha (3) used a form of [1] to study wind-driven synoptic currents on the Eastern U.S. continental shelf.

Application of [1] or [2] to the forced wave problem is not theoretically justified, and can lead to substantial errors particularly in the case of quasi-steady or steady flow. The condition [1] or [2] requires that a pressure gradient be set up in order for flow through the boundary to exist. In the case of wind-driven flow it is clear that flow can occur through the boundary in the

absence of a pressure gradient. Thus when [1] or [2] is used in wind-forced problems, an artificial pressure gradient is established.

The errors which results when [1] or [2] is used for the forced wave problem are illustrated in Figure 3. The figure shows the velocity profiles in an infinitely long channel of constant depth with a constant wind stress. Two different types of models are shown. The linear profile denoted by "Galerkin" is the steady-state result for a constant eddy viscosity model. It can be generated using the Galerkin model by specifying  $\eta=0$  or  $d\eta/dx=0$  at the downwind boundary. The dashed profile denoted by "Galerkin w. rad." is the velocity profile using a radiation boundary condition. Note the velocity has been decreased by roughly a factor of two. This is caused by the artificial pressure gradient generated by the radiation condition. A similar result is found for the vertically averaged model, also illustrated in the figure.

#### Forced/Free Wave Solution

As was pointed out above, the Sommerfield radiation condition is not really appropriate for the study of wind-driven or forced flow. In an effort to remove the forced restriction, Røed and Smedstad (28) developed a method which separates the primitive barotropic equations into two modes: a local or forced mode, and a global or free mode. Using a specialized topography illustrated in Figure 4, Røed and Smedstad (28) were able to eliminate the need for any boundary conditions for the local solution. The boundary condition for the global solution is [1].

The modal approach is theoretically attractive. However, a number of major assumptions regarding topography were made by (28). It remains to be seen whether the technique can be applied to the more general case.

Figure 3: Comparison of profiles from two types of models using different downstream boundary conditions.

## REVISED GRID SYSTEM RESULTS

All of the techniques identified in the previous chapter were considered for this study. Most would have required extensive program recoding or expansion of the existing grid system. The costs associated with these changes could not be justified given the preliminary nature of the study.

A compromise was developed which could be quickly implemented. It consisted of adding 10 columns to the western boundary of the grid shown in Figure 1 resulting in a 30 x 30 grid. No wind stress was imposed on these additional elements, and dissipation parameters in the elements were increased. In addition a radiation condition in the form of [2] was implemented in the model code along the western boundary.

On the lateral boundary,  $dn/dx$  was set to zero as in the initial grid. Adding additional rows on the cross-shelf boundaries as was done on the western boundary would have generated an artificial alongshore pressure gradient for reasons cited in the previous section. Seiching tendencies in the alongshore direction were minimized by eliminating the alongshore bathymetric gradients. This is not unreasonable for this section of the coast.

The model was run using the same forcing as in the initial run (see the third section above). Figure 5 shows representative results using the same empirical coefficients as in the initial run. Comparing this figure to Figure 2 indicates that the radiation condition does substantially reduce the seiche. As indicated in Figure 6, further reduction is achieved by increasing the vertical eddy viscosity and bottom friction by an order of magnitude in the western 10 columns. The figure should be compared to 2 to see the substantial improvement obtained with the revised boundary conditions.

## HINDCAST RESULTS

Once the seiche was removed from the model, it was used to hindcast an actual storm event. Data was available for a major storm which occurred in late October 1974. Cardone (8) provided synoptic wind and pressure fields for the storm at six hour intervals. He used post-synoptic techniques, with data based on land, buoy, and ship data, as well as surface weather maps.

Figure 7 shows the wind vectors hindcasted by (8) near Bergen, on the Norwegian coast. Peak winds reached roughly 20 m/s. Wind direction was primarily from the north, shifting from northeast to northwest during the course of the storm. Spatial wind gradients were generally not large over the scale of the model grid.

Figure 4: Topography of basin used in the free/forced wave boundary condition studies of Roed and Smedstad

Figure 5: Modeled time series of surface elevation at the coast. Model grid is the same as Figure 2 except five additional columns have been added as well as a radiation boundary condition on western boundary.

Figure 6: Modeled time series of surface elevation at the coast. Model grid is identical to Figure 5 except five outer columns have been made highly viscous.

The wind and pressure fields were used to force the ocean current model. Everything else was the same as described in the previous section.

Figure 8 shows the comparison at station SN10 marked by the uppermost solid circle in Figure 1. The modeled results are shown as a dashed curve and the data as solid. Both data and model results are taken at 50 m below the still water level. The upper panel in the figure shows the alongshore component with positive indicating a northerly direction. The lower panel shows the cross-shelf component with positive indicating an easterly flow. Comparisons are also available at other depths and sites but these are qualitatively similar to Figure 8, and are not shown.

In general the model predicts the right order of magnitude of the current but there are clearly some major discrepancies. The model results are predominately in the wind direction, while the data are not obviously correlated with the wind. The results can not be substantially improved by varying the model parameters  $N_V$ ,  $c_b$ , or  $N_H$ .

Figure 7: Time series of hindcasted wind vectors at the coast for the storm of October 1974.

Figure 8: Comparison between modeled and observed currents at station SN10. Data is indicated by solid curve, and model by dashed curve.

The comparison is actually not as bad as it might first seem because the data still contain a relatively strong tidal signal, while the model contains no tidal forcing. An initial attempt was made to filter the tidal signal from the data, but this proved impossible using standard band-pass filters and least-squares or harmonic analysis. The reason for the difficulty is the nearly identical frequency of the inertial and tidal signal. One cannot apply any of these classical techniques without eliminating the inertial component, and of course this is not acceptable since a major portion of storm response of the shelf is inertial.

Figure 9 shows the modeled surface elevation at a central grid element on the coast. Two curves are shown. The dotted curve shows the result using the wind field provided by Cardone (8), whereas the solid curve used the same wind field but winds were updated every 30 minutes by interpolating the six-hour wind field. There are substantial differences between the two curves, indicating the dynamic sensitivity of the system. Much of this is due to the small role of friction in the basin.

Surge data had not been obtained at the time of this study for this particular storm. However, the magnitude of the modeled surge is consistent with other similarly severe storms (14).

#### SUMMARY AND CONCLUSIONS

The objective of the study was to make a first pass at modeling storm-driven currents and surge on the Southern Norwegian Shelf. A linear numerical model based on the barotropic primitive equations was used. Current data were available at several locations from some historical storms, and these were used to assess the model.

Figure 9: Time series of modeled surface elevation at the coast for storm of October 1974.

Friction was found to be of relatively little importance on the shelf, and storm response was strongly inertial. Stratification was generally negligible during the most severe storms, and hence the barotropic assumption was easily justified.

Preliminary application of the model to the shelf indicated the dominance of a seiche in the cross-shelf direction. The cause was traced to the reflective boundary conditions.

A fairly thorough review of the literature was undertaken in an attempt to find alternative boundary conditions which would eliminate the artificial seiche. Five types of conditions were identified, and examined. None of the conditions are universally applicable. One major finding is that many previous applications have used a radiation condition to study quasi-steady forced flow fields, and it is easily shown that this can generate substantial errors.

Eventually a boundary condition was found which eliminated the seiche. The configuration consisted of: 1) a highly viscous, unforced, outer western boundary, 2) a radiation boundary condition on the western boundary and 3) a simplified bottom bathymetry which eliminated alongshore oscillations.

Finally, the model was applied to hindcast currents during a major storm on the shelf. Results indicated the model gives the proper order of magnitude for both currents and surges. A more quantitative assessment was impossible because the data contained a strong tidal component which could neither be removed nor easily modeled.

Efforts are underway to improve the results described above. These improvements will include: 1) implementation of an improved boundary condition on all ocean boundaries, 2) expansion of the grid system to include the entire Norwegian Sea, 3) further data analysis to remove the tidal signal, or if this is not possible then tidal forcing will be included in the model, and 4) extension of the wind hindcasts to provide adequate model spin up.

## CHAPTER ONE HUNDRED FIFTY NINE

### REPRODUCTION OF NEARSHORE CURRENTS BY A MATHEMATICAL MODEL

Hiroyoshi Tanaka\* and Akira Wada\*\*

#### ABSTRACT

In order to cope with such environmental problems as shoreline change and diffusion of discharged warm water and contaminations in the surf zone, it is necessary to predict velocity vector field due to nearshore currents accurately.

The present study is aimed at establishing a mathematical model applicable to the prediction of nearshore currents on actual coasts which have complicated bottom configurations. First, to investigate the mechanism of nearshore current generation hydraulic experiments were carried out. By the experiment it was made clear that the generation of a longshore current depends mainly upon a difference in mean water level in the longshore direction. After investigating estimation of radiation stress terms on the basis of the information obtained from the basic experiments a mathematical model of nearshore currents was developed and validity of the model was verified by both hydraulic model tests and field survey.

#### I. INTRODUCTION

On a coast having a gentle slope the surf zone is relatively wide, and consequently physical phenomena such as breaking of waves, nearshore currents, etc. may have some effects on the diffusion and shoreline change in and near the surf zone. In the case where the nearshore currents fluctuate as wave condition changes hourly, the currents may exert a great effect on the advective diffusion of small time-scale. Meanwhile, in case that nearshore current pattern doesn't change very much even if wave condition varies to some extent, the currents may also have some effects on the shoreline change of long-term scale.

To cope with the aforementioned environmental problems in and near the surf zone, therefore, it is necessary to accurately predict the velocity vector field due to nearshore currents. Many mathematical models of nearshore currents<sup>1),2),3),4),5)</sup> have been proposed so far, but they have applied the small amplitude wave theory even to the estimation of physical phenomena in and near the surf zone. Consequently, none of the existing models may reproduce well the nearshore currents on actual coasts which have complicated bottom configurations. Recently, field surveys on nearshore currents have been carried out positively. Although those are very important from the standpoint of understanding the

\*\* Manager of Environment Department, Central Research Institute of Electric Power Industry, Abiko, Chiba Pref., Japan

actual phenomena it is very difficult to minutely grasp the mechanism and main characteristics of nearshore currents from complicated phenomena on a real coast.

In the present study, first, the mechanism of nearshore currents was clarified by hydraulic experiments. Especially, this experimental study attached great importance to the grasp of transient phenomena, regarding it as a clue for elucidating the physical processes and mechanisms.

Next, a mathematical model was developed for the prediction of nearshore currents in the field. In this model, estimation of radiation stress terms was mainly studied so that it was compatible with the mechanism of nearshore current generation. Then, validity of the present mathematical model was examined by comparing the results of the numerical simulation with those of the hydraulic model tests and the field survey.

## II. MAIN CAUSE OF NEARSHORE CURRENT GENERATION

### 2.1 Contents of the hydraulic experiments

The basin used for the present hydraulic experiments has dimensions of  $50\text{m} \times 22.6\text{m} \times 1.5\text{m}$ . On one end of the basin three units of wave generators are installed and on the other end there is a 1/150 non-distorted model of a certain actual sea region. Regular waves were used in the experiments. The normally incident waves were generated by the wave generator and the obliquely incident waves were made by a simple wave maker installed temporarily. As for the wave condition used in the experiments the ranges of the average breaking wave height and the wave period were 2.5~3.6cm (3.8~5.4m in the prototype) and 1.25~2.5s (15.3~30.6s in the prototype) respectively. Thus, the wave height and the wave period were exaggerated in the experiments compared with those appearing in the field, in order to grasp clearly the physical phenomena and processes in the surf zone.

Measurement of water surface level was made by using capacitance type wave gauge, and velocity and direction of nearshore currents were measured with ultra sonic current meters. Great precision was required in measuring wave set-up. Hence, after confirming that no zero drift took place during the measurement, one or several cycles of analog time series data of the water surface level written on pen recorder charts were traced on section papers and the elevation due to wave set-up was estimated by counting the area put between the time variation curve of the water surface and the still water level by means of 1mm section.

### 2.2 Experimental results and discussion

For the purpose of making clear the cause of nearshore current generation, the experiment was at first carried out by applying waves whose average breaking wave height and period were 3.6cm and 2.5s (5.4m and 30.6s in the prototype). Figure 1 shows the horizontal distribution of wave set-up in a steady state with the velocity vector field due to nearshore currents under the offing condition of normal incidence of waves. From the figure it can be seen that longshore currents are governed mainly by a difference in mean water level in the longshore direction. A result of the field survey<sup>6)</sup> carried out by Tokyo Electric Power Company is shown in Fig. 2. This result also tells the directions of longshore currents correlate with a difference in mean water level

Fig.1 Relation between velocity vector field due to neashore currents and horizontal distribution of mean water level (Experimental result)

Numerical figures: Values of mean water level (The base level is the lowest one)  
 [unit; cm]

Fig.2 Relation between longshore current directions and horizontal distribution of mean water level (Result of field survey)

in the longshore direction.

The above investigations were performed in steady state conditions.

Another kind of experiment was carried out in a transient state to examine the cause of longshore current generation. In this experiment the relation between the acceleration of a longshore current and the longshore gradient of mean water level was examined at the beginning of wave action, that is, at the time when the effects of friction force, eddy viscosity and inertia can be ignored. The several kinds of regular waves used in the experiment have 2.5~3.6cm in average breaking wave height, 1.25~2.5s in period and 0°~54° in incident angle. An example of the experimental results is shown in Fig. 3. Figure 3(a) shows how to obtain an initial acceleration  $\partial v/\partial t$  from the velocity change of a longshore current in a transient state and Fig. 3(b) shows how to obtain the initial force  $-g \cdot \partial \eta/\partial y$  from the initial difference in mean water level at two points near the velocity sampling point. From these figures it

is found that the acceleration  $\partial v/\partial t$  coincides with the value  $-g \cdot \partial \bar{\eta}/\partial y$  fairly well in the initial state. Figure 4 shows the relation between  $\partial v/\partial t$  and  $-g \cdot \partial \bar{\eta}/\partial y$  at the beginning of the action of various kinds of normally and obliquely incident waves. These data were obtained at various points in the surf zone to the exclusion of the region near breaking points. The experimental result clearly shows that even if waves have any incident angle the initial acceleration  $\partial v/\partial t$  agrees fairly well with the initial force  $-g \cdot \partial \bar{\eta}/\partial y$  based upon a difference in

Fig.3 Velocity change of a longshore current and a difference in mean water level in the longshore direction at the beginning of wave action

Fig.4 Relation between acceleration of a longshore current and force based upon a difference in mean water level in the longshore direction at the beginning of wave action.

mean water level. Also from this result it can be inferred that the generation of a longshore current depends mainly upon a difference in mean water level in the longshore direction.

### III. FEATURES OF MATHEMATICAL MODELS

#### 3.1 Mathematical model of wave field

The distribution of wave directions is calculated by using the following wave direction equation:

$$C \cdot \vec{i} \cdot \nabla \theta = - \vec{j} \cdot \nabla C \quad (1)$$

where  $C$ ,  $\theta$ ,  $\vec{i}$  and  $\vec{j}$  are wave celerity, wave direction, unit vector in the direction of wave ray, and unit vector in the direction of wave crest line, respectively. This equation shows that the wave direction varies with the spatial change of wave celerity determined by the distribution of water depths. However, as the wave ray method ignores the effects of reflection, diffraction, and energy transfer in the direction of wave crest line, it can be inferred that wave direction as well as wave height cannot be correctly estimated at the places where a space between neighbouring wave rays is very small or where wave rays cross. Hence, wave directions at such places are obtained by interpolating those in the surrounding area where the wave ray method is valid. Such handling as mentioned above removes an unnatural scattering of wave directions.

The plane distribution of wave heights is dealt with independently of wave direction, and the numerical simulation of wave heights is carried out on the basis of the following mathematical model.

Regarding the outside of the surf zone, basic equations are obtained by integrating the continuity equation and the momentum equations in the vertical direction and by applying the small amplitude wave theory. If the two-dimensional momentum equations are applied as it is, numerical instability is liable to occur because variables (water surface elevation and flow rate per unit width) widely fluctuate in a short period. From a physical viewpoint it can be considered that in the actual fluid momentum of waves is diffused due to eddy viscosity. Therefore, the momentum equations should be modified as follows.

$$\partial Q_x / \partial t = - C^2 \cdot \partial \eta / \partial x + K \cdot (\partial^2 Q_x / \partial x^2 + \partial^2 Q_x / \partial y^2) \quad (2)$$

$$\partial Q_y / \partial t = - C^2 \cdot \partial \eta / \partial y + K \cdot (\partial^2 Q_y / \partial x^2 + \partial^2 Q_y / \partial y^2) \quad (3)$$

where  $t$  is the time,  $x$  and  $y$  the horizontal co-ordinates,  $\eta$  the water surface elevation,  $Q_x$  and  $Q_y$  the flow rates per unit width in the  $x$ - and  $y$ - directions respectively, and  $C$  the wave celerity.  $K$  is the apparent horizontal eddy viscosity under the action of waves. By using the continuity equation  $\partial \eta / \partial t + \partial Q_x / \partial x + \partial Q_y / \partial y = 0$  and the momentum equations (2) and (3),  $Q_x$ ,  $Q_y$  and  $\eta$  are calculated from the offshore boundary to the breaking points. Since the result of calculation on the change in wave height is not based on the group velocity but on the wave celerity the actual wave height should be modified as shown below by introducing the coefficient  $f_s$  :

$$H = (\eta_{\max} - \eta_{\min}) (f_s / f_{s0}) \quad (4)$$

where  $\eta_{\max}$  and  $\eta_{\min}$  are the maximum and minimum of  $\eta$  respectively in a wave period. The modifying coefficient  $f_s$  is defined by the following equation :

$$f_s = (1+2kh/\sinh 2kh)^{-1/2} \quad (5)$$

where  $k$  is the wave number and  $h$  the water depth. The subscript  $o$  in Eq.(4) indicates the value of  $f_s$  for the offshore boundary.

The above argument cannot be applied to waves after breaking since it depends on the small amplitude wave theory. In this model, the wave height in the surf zone  $H$  was assumed as follows.

$$H = \gamma h \quad (6)$$

where  $\gamma$  is the ratio of wave height to water depth after breaking. To estimate the ratio  $\gamma$ , an experiment was carried out by using a non-distorted model of scale 1/150. Figure 5 shows the experimental results. The waves used in the experiment had frequencies extending over 0.4-1.2 Hz. The following information is obtained from Fig. 5.

- 1) The ratio of breaking wave height to breaking water depth  $\gamma_b$  (shown by the mark  $\bullet$ ) is about 0.8 even against any wave period.
- 2)  $\gamma$  immediately after breaking (shown by the mark  $\circ$ ) is smaller than  $\gamma_b$  and when the waves advance farther in the surf zone the ratio (shown by the mark  $\circ$ ) becomes much smaller.

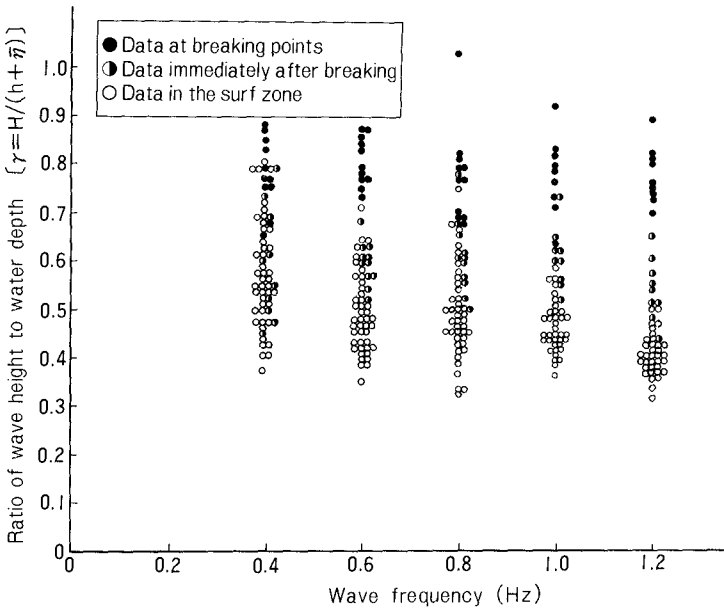

Fig.5 Ratio of wave height to water depth in the surf zone  
(Experimental Result)

3) In the frequency range of 0.4~1.2 Hz, the shorter the wave period, the smaller  $\gamma$  (shown by the mark O) is.

In the present study on nearshore currents, the waves concerned are regular waves (wave period 10.2s) and irregular waves (average wave period 7.3s). With regard to the regular waves, 0.4 is used as the ratio after breaking  $\gamma$  on the basis of Fig. 5 since the wave period 10.2s almost corresponds to the wave frequency 1.2 Hz on the hydraulic model of scale 1/150. In the present study, wave set-up  $\bar{\eta}$  has not been determined yet at the stage of calculating the wave field because the model of wave field is dealt with independently of that of nearshore currents. Ignoring the effect of  $\bar{\eta}$ , therefore, the wave height after breaking  $H$  is approximated by the following equation :

$$H = 0.4h \quad (7)$$

Regarding the irregular waves, 0.55 is used as the ratio of root mean square wave height to water depth in the surf zone and the value is selected based on the results of the field survey<sup>7)</sup>. Breaking wave height is assumed to be 80% of breaking water depth.

### 3.2 Mathematical model of nearshore currents

Basic experiments were conducted on the mechanism of nearshore current generation in parallel to the development of a mathematical model of nearshore currents. Judging from the information obtained by the experiments, it can be inferred that the greatest problem in our previous model<sup>5)</sup> lies in the estimation of radiation stress terms. One problem is the estimation of a wave field related to radiation stresses and another is applicability of the small amplitude wave theory to radiation stresses in and near the surf zone. Since the former problem was discussed in the foregoing paragraph, here follows a discussion on the development of a new mathematical model of nearshore currents in consideration of the latter problem.

The basic equations of the present mathematical model are depth averaged two-dimensional equations which are also averaged over one wave period.

$$\partial \bar{\eta} / \partial t + \partial \bar{M}_x / \partial x + \partial \bar{M}_y / \partial y = 0 \quad (8)$$

$$\begin{aligned} & \partial \bar{M}_x / \partial t + \partial (\bar{U} \bar{M}_x) / \partial x + \partial (\bar{V} \bar{M}_x) / \partial y \\ & = -g \cdot (h + \bar{\eta}) \cdot \partial \bar{\eta} / \partial x - R_x + K_h \cdot (\partial^2 \bar{M}_x / \partial x^2 + \partial^2 \bar{M}_x / \partial y^2) - \gamma_b \cdot \bar{U} \cdot \sqrt{\bar{U}^2 + \bar{V}^2} \end{aligned} \quad (9)$$

$$\begin{aligned} & \partial \bar{M}_y / \partial t + \partial (\bar{U} \bar{M}_y) / \partial x + \partial (\bar{V} \bar{M}_y) / \partial y \\ & = -g \cdot (h + \bar{\eta}) \cdot \partial \bar{\eta} / \partial y - R_y + K_h \cdot (\partial^2 \bar{M}_y / \partial x^2 + \partial^2 \bar{M}_y / \partial y^2) - \gamma_b \cdot \bar{V} \cdot \sqrt{\bar{U}^2 + \bar{V}^2} \end{aligned} \quad (10)$$

where  $x$  and  $y$  are the coordinates in the cross-shore and longshore directions,  $\bar{\eta}$  the mean water level,  $\bar{U}$  and  $\bar{V}$  the mean current velocities in the  $x$ - and  $y$ - directions,  $\bar{M}_x$  and  $\bar{M}_y$  the mean flow rates per unit width in the  $x$ - and  $y$ - directions,  $g$  the gravitational acceleration,  $h$  the water depth,  $R_x$  and  $R_y$  the radiation stress terms in the  $x$ - and  $y$ - directions,  $K_h$  the horizontal eddy viscosity coefficient, and  $\gamma_b$  the bottom friction coefficient.

a) Ry in the surf zone

Based on the basic experiments it is evident that in the surf zone longshore currents are generated mainly due to a difference in wave set-up in the longshore direction. It can therefore be inferred that the

contribution of  $R_y$  to longshore current generation is considerably small. It can be considered that if  $R_y$  is calculated by using the small amplitude wave theory as have been done so far the contribution of  $R_y$  to longshore current generation will be overestimated and consequently the numerical simulation will result in an unrealistic nearshore current field. It can also be supposed that  $R_y$  makes a small contribution to the generation of a longshore current which has a uniform velocity profile below the still water level but that it is connected with the longshore component of mass transport above the still water level. In the present model,  $R_y$  in the surf zone is ignored from an engineering standpoint. But near the breakwater not located in the longshore direction  $R_y$  is estimated with the same weight as that of  $R_x$ . In this case  $R_y$  may make an indirect contribution to the generation of a current because the breakwater interrupts the mass transport flow due to  $R_y$  and changes the mean water level.

b)  $R_x$  in the surf zone

The major cause of nearshore current generation is summarized as follows :

Wave set-up is formed so that it is almost in harmony with the radiation stress term  $R_x$  and usually it is not uniform in the longshore direction. Such a difference in the mean water level in the longshore direction generates a current, and it is important that the above mechanism is appropriately reflected in the mathematical model.

The basic experiments revealed the followings. In the surf zone, there is a narrow range where the mean water level is lower than the still water level but the range is very short in the cross-shore direction. In a very short distance from the breaking point, the mean water level turns out to be higher than the still water level, and the nearer the shoreline the higher the mean water level is. Because, at the place where the breaker line is prominent offshore (called the prominent place), wave set-up begins on the side more offshore than at the place where the breaker line is concave onshore (called the concave place), the mean water level of the prominent place is higher than that of the concave place at the same distance from a shoreline in the surf zone. Consequently, a longshore current flows from the prominent place to the concave one.

On the other hand, since in the previous mathematical model<sup>5)</sup> the wave height and radiation stress tensors  $S_{xx}$  and  $S_{xy}$  are overestimated after breaking,  $R_x$  is underestimated especially immediately after breaking. So, in the computational result, the gradient of the mean water level rise just after breaking is considerably small as compared with the actual phenomenon and the wave set-down range in the surf zone is long in the cross-shore direction. Hence, the model may produce a wrong phenomenon that a longshore current flows from the concave place to the wave set-down range in the prominent place and may distort the whole nearshore current system. Thus, one of the weak points of the previous model seems to be attributable to considerably overestimating radiation stress tensors  $S_{xx}$  and  $S_{xy}$ , especially near the breaking points.

From the above argument, it can be understood that the estimation of  $R_x$  in the surf zone is very important and that it governs the nearshore current pattern. In the present study, the radiation stress term  $R_x$  is estimated as follows by re-examining the existing formulas of radiation stress tensors :

The coefficient  $\alpha$  is determined as Eq.(11) on the basis of the result

of a basic experiment on the distributions of the mean water levels and wave heights in and near the surf zone under the wave condition of normal incidence. Then,  $R_x$  is approximated by multiplying  $R_{XS}$  by  $\alpha$ . Here,  $R_{XS}$  is the value obtained according to the small amplitude wave theory.

$$-g \cdot (h + \bar{\eta}) \cdot \partial \bar{\eta} / \partial x \approx \alpha \cdot (1/\rho) \cdot (\partial S_{XX} / \partial x) s \quad (11)$$

where  $\rho$  is the density of water.  $(\partial S_{XX} / \partial x) s$  is calculated according to the small amplitude wave theory by using the distribution of wave heights. The coefficient  $\alpha$  is inferred from a lot of experimental data related to high waves.  $\alpha$  is assumed to be 1 very near the breaking point and it abruptly decreases to 0.1 at a little more shoreward place where waves begin to be violently deformed to the bore-shape. In the range of  $1/3 \leq S/B \leq 1$  where the bore-shape is completely established  $\alpha$  is assumed to be 0.8 constant. Here,  $S$  is a distance from the breaker line and  $B$  the surf zone width.  $\alpha$  is also assumed to change in linear proportion to  $S$  between the two boundaries where  $\alpha = 0.1$  and  $\alpha = 0.8$ .

c)  $R_y$  on the outside of the surf zone

In the sea region where the small amplitude wave theory is valid the whole  $R_{YS}$  may contribute to current generation, but in the area where the finite amplitude wave theory has to be applied only a certain percentage of  $R_{YS}$  is assumed to contribute to nearshore current generation.  $R_y$  is assumed to be approximated by multiplying  $R_{YS}$  by  $\sqrt{(h-h_b)/(h_s-h_b)}$  because the percentage of  $R_{YS}$ 's contribution to current generation is difficult to estimate quantitatively even by an experiment. Here,  $h_s$  is the minimum water depth in the area where the existing model is applicable,  $h_b$  the breaking water depth and  $R_{YS}$  the value of  $R_y$  based on the small amplitude wave theory.

d)  $R_x$  on the outside of the surf zone

$R_x$  needs a thinking different from the discussion on  $R_y$  because the cross-shore component always has a boundary intersecting the direction. In the present study,  $R_x$  is estimated on the basis of the small amplitude wave theory on the outside of the surf zone from an engineering standpoint.

The above discussion on the estimation of radiation stress terms is summarized as shown in Table-1.

#### IV. CONDITIONS AND METHOD OF NUMERICAL SIMULATION

##### 4.1 Validity verification of the mathematical model by the hydraulic model

(1) Sea region concerned and mesh size for calculation

The numerical simulation was carried out with respect to the sea region shown in Fig. 6. This sea region is characterized by a gently sloping coast facing the Pacific Ocean and by existence of breakwaters. The results of calculations are compared with those of the hydraulic experiment. The comparison is made on the breaker line and the velocity vector field due to nearshore currents. The mesh size for calculation is 20m and the computational time step is 1/100 of wave period.

(2) Incident waves

The incident wave heights and periods are given by converting the values measured by the hydraulic model into those in the prototype. The average wave height and the wave period of usual waves are 0.77m and

Table-1 Estimation of radiation stress terms for calculating nearshore currents

$R_x$  ; Radiation stress term in the cross-shore direction

$R_y$  ; Radiation stress term in the longshore direction

$h$  ; Water depth

$h_b$  ; Breaking water depth

$h_s$  ; Minimum water depth in the area where the small amplitude wave theory is valid

$\alpha$  ; Coefficient determined by a basic experiment

Subscript s ; Value calculated on the basis of the small amplitude wave theory

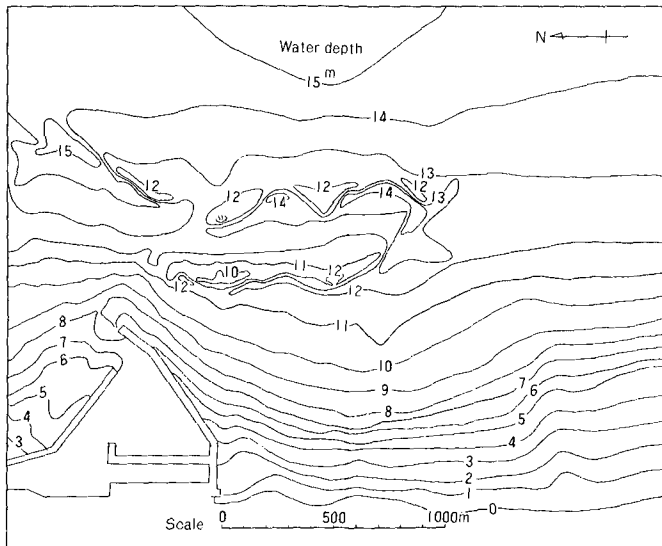

Fig.6 Bottom topography of the sea region concerned

10.2s at a distance 1 km from the shoreline. Those of high waves are 3.1m and 12.9s.

- (3) Horizontal eddy viscosity coefficients  $K_s'$  used for calculating wave fields

1  $m^2/s$  and 2.5  $m^2/s$  are used for calculating usual wave and high wave fields respectively on the basis of the preceding basic experiments.

- (4) Horizontal eddy viscosity coefficients  $K_h'$ s used for calculating nearshore currents

5  $m^2/s$  and 10  $m^2/s$  are used for calculating nearshore currents under the action of usual waves and those under high waves respectively on the basis of the preceding basic experiments.

- (5) Bottom friction coefficient  $\gamma_b$  used for calculating nearshore currents

On the assumption that the friction force is proportional to the square of current speed, 0.02 is taken as the non-dimensional bottom friction coefficient on the basis of the hydraulic model.

- (6) Method of numerical calculation

The wave field is first solved independently of nearshore currents by assuming that the interaction between waves and nearshore currents is small. Then, the computed wave field is used for calculating the values of radiation stress tensors. As the initial conditions, the mean water level and the flow rates are set equal to zero. On the offshore boundary, the mean water level is always equal to zero. At the breakwaters, on the shoreline and on the side boundaries,  $\tilde{M}_n = \partial\tilde{M}_t/\partial n = 0$ , where  $\tilde{M}_n$  and  $\tilde{M}_t$  are the flow rates per unit width, normal and tangent to the boundaries.

In the numerical calculation, the Leap-Frog and Lax-Wendroff schemes are applied in explicit form. The flow rates per unit width  $\tilde{M}_x$ ,  $\tilde{M}_y$  and the mean water elevation  $\tilde{\eta}$  are calculated every time step until they become steady.

#### 4.2 Validity verification of the mathematical model by the field survey

- (1) Sea region concerned and mesh size for calculation

Although the sea region concerned is the same as that described in 4.1 the bottom configuration surveyed in December, 1978 is applied. The sea region for calculation is 12.5km in the longshore direction and 0.8km in the cross-shore direction. The mesh size is 30m in the longshore direction and 20m in the cross-shore direction.

- (2) Incident waves

The applied waves were observed at almost the same time as that of nearshore current survey. The incident direction of waves is normal to the offshore boundary. Two kinds of regular waves are used for calculation. One is the significant wave whose wave height and period are 0.66m and 7.3s. The other is the root mean square wave whose wave height and period are 0.44m and 7.3s respectively.

- (3)  $K$  and  $K_h$

$K=1m^2/s$  and  $K_h=5m^2/s$  are used for the numerical simulation.

- (4)  $\gamma_b$

Since  $\gamma_b$  on the actual sandy coast may be different from that on a hydraulic model covered with mortar, we use 0.00637 which has been proposed so far.

- (5) Effect of the breakwater on wave energy dissipation

The energy dissipation coefficient  $v_d$  is defined by Eq.(12), and the

present mathematical model considers a decrease in wave height due to mounds of concrete armour units in front of the breakwater.

$$\partial(EC_{gx})/\partial x = -v_d k^2 E \quad (12)$$

where  $x$  is the coordinate in the cross-shore direction,  $E$  the wave energy density,  $k$  the wave number, and  $C_{gx}$  the  $x$ -component of group velocity. It is assumed that  $v_d=10^2 \text{ cm}^2/\text{s}$  along the breakwater normal to the shoreline,  $v_d=0 \text{ cm}^2/\text{s}$  at a distance of 400m from the breakwater, and that  $v_d$  linearly changes in the longshore direction between the two boundaries where  $v_d=10^2 \text{ cm}^2/\text{s}$  and  $v_d=0 \text{ cm}^2/\text{s}$ .

(6) Method of numerical calculation

The method is basically the same as that described in 4.1 (6).

## V. RESULTS OF NUMERICAL SIMULATION AND DISCUSSION

### 5.1 Breaker line and distribution of breaking wave heights

Validity of the mathematical model of wave height distribution on the outside of the surf zone has been examined by comparing the position of the breaker lines between the mathematical and experimental results.

As an example of the comparison Fig. 7 shows the breaker lines under the action of usual waves. From this figure it can be concluded that the two breaker lines agree fairly well except for the places where the breaker line is prominent offshore. In the prominent places where shoals grow, there may be some problems with regard to the breaking condition.

Fig.7 Comparison of the breaker line between the numerical and experimental results

Figure 8 shows comparisons between the results of the field survey and those of the numerical simulation regarding the distribution of breaking wave heights and breaker line. The significant wave trains are concerned in calculating wave field. The distribution of breaking wave heights calculated by the numerical simulation agrees fairly well with the result of the field survey at a long distance from the breakwater, but near the breakwater the calculated wave height is fairly larger than

that of the field observation. It can be considered that the result of the field survey was influenced by cooling water discharge from a foot of the breakwater. The surf zone width obtained by computation is a little smaller than the result of the field survey at the places where both results are almost equal regarding the breaking wave height. This may be due to the fact that the breaker line observed with the eye in the field corresponds to that of wave trains larger than the significant wave.

In conclusion, it can be said that the present mathematical model of wave field reproduces well the distribution characteristics of breaking wave heights and breaking positions on the actual coast.

Fig.8 Comparisons of the results of breaking wave height distribution and breaker line between the numerical simulation and the field survey

## 5.2 Velocity vector field due to nearshore currents

Figure 9 shows a comparison of the flow pattern due to nearshore currents under the action of usual waves between the numerical simulation and the hydraulic model test. Figure 10 shows a comparison of nearshore currents under the high waves between the calculation and the experiments.

The followings are revealed from Figs. 9 and 10.

(1) The computed result reproduces the following situation often found in the field. At the place where the breaker line is prominent offshore, the shoreward current is remarkable, while at the place where the breaker line is concave onshore the rip current is predominant.

Fig.9 Comparison of the result of nearshore current pattern under the action of usual waves between the numerical simulation and the hydraulic model test

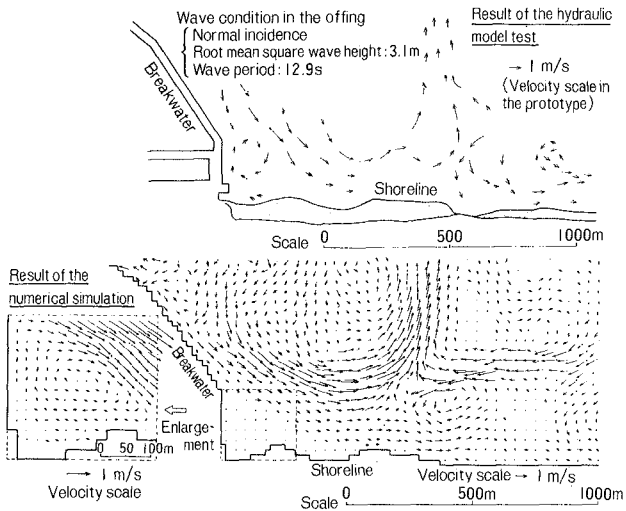

Fig.10 Comparison of the result of nearshore current pattern under the action of high waves between the numerical simulation and the hydraulic model test

(2) The mathematical result agrees fairly well with the experimental result regarding the following phenomena.

- a) A notable rip current reaching the offing at a distance of 800-900m from the foot of the breakwater
- b) Longshore currents in the surf zone
- c) A circulating flow near the breakwater

Next, Fig. 11 shows a comparison of nearshore currents between the present mathematical model and the field survey. The numerical simulation was carried out by using the regular wave condition of root mean square wave obtained from irregular waves in the field. The flow pattern in the field was obtained by using ball floats. Figure 12 shows the velocity vector field due to the previous mathematical model<sup>5)</sup> under the same computational conditions as those of the present model.

The followings are obtained from Figs. 11 and 12.

(1') Considering that a field survey cannot simultaneously grasp the whole flow pattern due to nearshore currents under irregular wave field varying from time to time and that the result may include uncertain factors, it can be said that the present mathematical model makes it possible to reproduce the characteristics of nearshore currents on the actual coast.

(2') The nearshore currents based on the previous mathematical model<sup>5)</sup> don't agree well with those obtained by the field survey especially in the surf zone. It can be understood that the present mathematical model has attained considerable improvement in the accuracy of prediction as compared with the previous model<sup>5)</sup>.

Fig.11 Comparison of the result of nearshore current pattern between the numerical simulation and the field survey

Fig.12 Calculated result of nearshore current pattern  
 on the basis of the previous mathematical model

## VI. CONCLUSION

Main conclusions are summarized as follows.

- (1) Basic experiments showed that longshore currents are generated mainly due to a difference in wave set-up in the longshore direction.
- (2) The results of the numerical simulations well reproduced velocity vector fields due to nearshore currents both under the action of usual waves and under that of high waves.
- (3) Validity of the present mathematical model is verified by both experiments and field survey and it is considered that the model is satisfactorily applicable to predicting nearshore currents in the field, though further study must be made to examine the validity of the model under obliquely incident waves.

## CHAPTER ONE HUNDRED SIXTY

### A TURBULENT TRANSPORT MODEL OF COASTAL PROCESSES

Y. Peter Sheng\*, Member ASCE

#### ABSTRACT

A second-order closure model of turbulent transport and recent model applications to some problems of practical importance in coastal engineering are presented. Particular examples considered are the turbulent wave boundary layer under a linear and a cnoidal wave; current-wave interaction within the bottom boundary layer; mixed layer dynamics; wind-driven currents in a channel. Comparisons are made between the computed results and field/laboratory data.

#### 1. INTRODUCTION

Turbulent transport plays a dominant role in many coastal processes, e.g., sediment dispersion, wave-induced currents in the surf zone, and forces on structures. The accurate prediction of these processes requires a sound understanding of the turbulent transport within various parts of the water column. Existing mathematical models of coastal processes generally utilize relatively simple eddy-viscosity concept to parameterize the complex turbulent transport phenomena. When sufficient data exist to establish the validity of the assumed eddy coefficients in the subject models, the model predictions for a particular application can give reasonable results. However, the required site-specific parameter tuning severely limits the predictability of eddy-viscosity models when little data exist and parameters must be extrapolated from much different flow situations. Moreover, turbulent quantities (e.g., shear stresses) computed by the eddy-viscosity models are often inaccurate due to the inherent model assumption that turbulence is always at local equilibrium condition. The lack of proper physics is why eddy-viscosity model often fails to faithfully simulate highly oscillatory and density-stratified flow situations which are often encountered in coastal waters.

This paper introduces a turbulent transport model (often called "second-order closure model") which allows accurate predictions of coastal processes when data is unavailable or hard to obtain. The basic turbulent transport model (4, 17, 18) retains the dynamic equations of the second-order turbulent correlations which affect the mean flow variables. The added physics contained in the second-order closure model allows direct computation of many of the turbulent transport phenomena without resorting to ad-hoc fixes. Following a brief description of the turbulent transport model, this paper presents some recent model simulations of various coastal processes including: turbulent wave boundary layer, current-wave interaction within the bottom layer, mixed layer dynamics and wind-driven currents.

2. A SECOND-ORDER CLOSURE MODEL OF TURBULENT TRANSPORT

The second-order closure model of turbulent transport as described herein has been originally developed by Donaldson and his colleagues at A.R.A.P. The model consists of dynamic equations for the mean flow variables as well as the second-order turbulent correlations (e.g.,  $\overline{u_i u_j}$ ,  $\overline{u_i \rho}$ , and  $\overline{\rho \rho}$ ). Models are developed for the unresolved third-order correlations appearing in the second-order correlation equations. Model constants are derived from analyzing a wide class of flow situations and remain invariant for new applications. As such, the model is often termed as an invariant model.

2.1 MODEL EQUATIONS

The model equations of motion for an incompressible fluid in the presence of both a gravitational and a Coriolis body force, with the mean variables denoted by capitals and the turbulent fluctuations by lower-case, may be written in general tensor notation as follows:

$$\frac{\partial U_i}{\partial t} + U_j \frac{\partial U_i}{\partial x_j} = - \frac{\partial \overline{u_i u_j}}{\partial x_j} - \frac{1}{\rho} \frac{\partial P}{\partial x_i} + g_i \frac{(\Theta - \Theta_0)}{\Theta_0} - 2 \epsilon_{ijk} \Omega_j U_k \tag{1}$$

$$\frac{\partial U_j}{\partial x_j} = 0 \tag{2}$$

$$\frac{\partial \Theta}{\partial t} + U_j \frac{\partial \Theta}{\partial x_j} = - \frac{\partial \overline{u_j \theta}}{\partial x_j} \tag{3}$$

$$\begin{aligned} \frac{\partial \overline{u_i u_j}}{\partial t} + U_k \frac{\partial \overline{u_i u_j}}{\partial x_k} = & - \overline{u_i u_k} \frac{\partial U_j}{\partial x_k} - \overline{u_j u_k} \frac{\partial U_i}{\partial x_k} + g_i \frac{\overline{u_j \theta}}{\Theta_0} + g_j \frac{\overline{u_i \theta}}{\Theta_0} \\ & - 2 \epsilon_{ikl} \Omega_k \overline{u_l u_j} - 2 \epsilon_{jlk} \Omega_l \overline{u_k u_i} \\ & + 0.3 \frac{\partial}{\partial x_k} \left( q \Lambda \frac{\partial \overline{u_i u_j}}{\partial x_k} \right) - \frac{q}{\Lambda} \left( \overline{u_i u_j} - \delta_{ij} \frac{q^2}{3} \right) - \delta_{ij} \frac{q^3}{12 \Lambda} \end{aligned} \tag{4}$$

$$\begin{aligned} \frac{\partial \overline{u_i \theta}}{\partial t} + U_j \frac{\partial \overline{u_i \theta}}{\partial x_j} = & - \overline{u_i u_j} \frac{\partial \Theta}{\partial x_j} - \overline{u_j \theta} \frac{\partial U_i}{\partial x_j} + g_i \frac{\overline{\theta^2}}{\Theta_0} - 2 \epsilon_{ijk} \Omega_j \overline{u_k \theta} \\ & + 0.3 \frac{\partial}{\partial x_j} \left( q \Lambda \frac{\partial \overline{u_i \theta}}{\partial x_j} \right) - \frac{0.75 q}{\Lambda} \overline{u_i \theta} \end{aligned} \tag{5}$$

$$\frac{\partial \overline{\theta^2}}{\partial t} + U_j \frac{\partial \overline{\theta^2}}{\partial x_j} = - 2 \overline{u_j \theta} \frac{\partial \Theta}{\partial x_j} + 0.3 \frac{\partial}{\partial x_j} \left( q \Lambda \frac{\partial \overline{\theta^2}}{\partial x_j} \right) - \frac{0.45 q \overline{\theta^2}}{\Lambda} \tag{6}$$

$$\begin{aligned} \frac{\partial \Lambda}{\partial t} + U_j \frac{\partial \Lambda}{\partial x_j} = & 0.35 \frac{\Lambda}{q^2} \overline{u_i u_j} \frac{\partial U_i}{\partial x_j} + 0.75 q + 0.3 \frac{\partial}{\partial x_i} \left( q \Lambda \frac{\partial \Lambda}{\partial x_i} \right) \\ & - \frac{0.375}{q} \left( \frac{\partial q \Lambda}{\partial x_i} \right)^2 + \frac{0.8}{q^2} q_i \frac{u_i \theta}{\Theta_0} \end{aligned} \tag{7}$$

where  $x_i$  are coordinate axes,  $t$  is time,  $U_i, U_j, U_k$  are the mean velocity components,  $u_i, u_j, u_k$  are the fluctuating velocity components,  $\rho$  is density,  $\Theta$  and  $\theta$  are mean and fluctuating temperatures,  $q$  is total fluctuating velocity,  $\Lambda$  is turbulent macroscale,  $\delta_{ij}$  is Kronecker

delta,  $\epsilon_{ijk}$  is alternating tensor,  $\Omega$  is earth's rotation.

In a first-order closure (or eddy viscosity) model, only the first three equations for the mean variables are resolved. The second-order correlations  $\overline{u_i u_j}$  and  $\overline{u_j \theta}$  appearing in the mean equations are parameterized as the products of eddy coefficients and the mean gradients,  $\partial u_i / \partial x_j$  and  $\partial \theta / \partial x_j$  respectively. The most complete second-order closure model, on the other hand, retains all the dynamic equations for the Reynolds stresses  $\overline{u_i u_j}$ , the heat fluxes  $\overline{u_j \theta}$ , and the temperature variance  $\overline{\theta^2}$ . To close the system, a dynamic equation for the turbulent macroscale  $\Lambda$  is introduced. It should be pointed out that many of the terms in the second-order correlation equations do not require any modeling. These include the turbulent production terms, the buoyancy terms, and the Coriolis terms. The third-order correlation and pressure correlation terms appearing in the original Reynolds stress equations have been modeled as a diffusion term and a tendency toward isotropy term. Model constants for the diffusion term, the tendency toward isotropy term, the dissipation term, and other modeled terms have been determined from analyzing a wide class of flow situations (13) and remain fixed for any new applications.

The complete second-order closure model as described by Equations (1) through (7) has been applied to simulate various atmospheric, oceanic, and laboratory problems of practical importance. The ability of the model to simulate a variety of flow situations with the same set of model constants has been successfully demonstrated. Simplified versions of the second-order closure model have also been formulated by retaining the dynamic equations for only part of the second-order correlation variables. For example, the quasi-equilibrium version retains the dynamic equations for  $q^2$  and  $\Lambda$ , while neglecting the diffusion and time evolution terms in other correlation equations. Such an approximation is valid so long as the turbulent time scale  $\Lambda/q$  is small compared to the mean flow time scale, and is being incorporated into a three-dimensional coastal current model (18).

Most of the following model applications utilize the one-dimensional version of the complete second-order closure model. Multi-dimensional versions of the second-order closure model have been utilized in numerous past and present applications, e.g., the detailed dynamics of wakes behind blunt bodies (5) and flow within the core of a tornado (14).

### 3. TURBULENT WAVE BOUNDARY LAYER

Detailed measurements in turbulent wave boundary layers are scarce. Johnson and Carlsen (9) measured the detailed flow within an oscillating water tunnel with a fixed rough bottom. In their Test I, an 8.39 sec wave with a maximum mean free stream velocity of 2 to 2.22 m/sec and a nearly sinusoidal time variation was imposed on a water depth of 23 cm. Vertical profiles of ensemble-averaged horizontal velocity within the water tunnel were measured at 15° intervals throughout several wave cycles. Multi-layered eddy-viscosity models (10,6,3) and time-varying eddy-viscosity models (8,21) were developed to achieve reasonable simulation of the mean flow variables measured

by Jonsson and Carlsen. Considerable efforts were spent in arriving at the "proper" eddy-viscosity formulation needed to yield good fit of the mean flow data. Using the complete second-order closure model, Sheng (17) successfully simulated Jonsson and Carlsen's turbulent wave boundary layer. Very good agreement was found between the simulated and measured mean velocity, phase lag and shear stress. In addition, model results revealed the transient behavior of a thin classic logarithmic layer modulated by the time-periodic pressure gradient. For simplicity, however, Sheng (17) assumed a sinusoidal free-stream velocity of 2 m/sec amplitude. In the present paper, based on harmonic analysis of the measured data, the following free-stream velocity is used:

$$U_f = A_1 + \sum_{i=2}^{13} \left\{ A_i \cos \left[ (i-1) \theta \right] + B_i \sin \left[ (i-1) \theta \right] \right\} \quad (8)$$

where  $A_i$  and  $B_i$  are coefficients determined from the harmonic analysis of Jonsson and Carlsen's free stream velocity. The boundary conditions for the mean and turbulent variables are basically the same as in Sheng (17).

The mean flow profiles at  $\phi=0^\circ$ ,  $45^\circ$ ,  $90^\circ$ ,  $135^\circ$  are shown in Figure 1(a), while those at  $\phi=180^\circ$ ,  $225^\circ$ ,  $270^\circ$ ,  $315^\circ$  are shown in Figure 1(b). Excellent agreement between the computed and measured data is apparent at all levels and all times. A slight mid-level velocity overshoot at peak free-stream velocity, which was found in the earlier results of Sheng (17), is now eliminated.

Vertical profiles of the Reynolds stress  $-\overline{\rho u w}$  are shown in Figures 2(a) and 2(b). Excellent agreement between the computed and measured results is found at  $\phi=0^\circ$  and  $180^\circ$ , while the worst agreement is found at  $\phi=90^\circ$  and  $\phi=270^\circ$ . This is because Jonsson and Carlsen's Reynolds stresses were not measure directly, but were computed indirectly from the mean flow data via the following equation:

$$\frac{\tau}{\rho} = - \int_0^z \frac{\partial}{\partial t} (U_f - U) dz \quad (9)$$

where  $d$  corresponds to  $\tau=0$  and was taken to be 17 cm. The Reynolds stresses calculated from Equation (9) are very sensitive to the numerical evaluation of the r.h.s., i.e., accuracy of time derivative and vertical profile of the mean velocity. The mean velocities were only measured at 15° intervals. Hence, one expects error in  $\tau$  to be the smallest when time variation of mean velocity is the smallest ( $\phi=0^\circ$  and  $180^\circ$ ) while error is the largest when time variation of mean velocity is the largest ( $\phi=90^\circ$  and  $270^\circ$ ). This explains the discrepancy found in Figure 2. In this regard, the second-order closure model can be used to guide the design of laboratory experiments by pointing out the needed temporal and spatial resolutions of data. Jonsson and Carlsen also calculated the eddy-viscosity values from

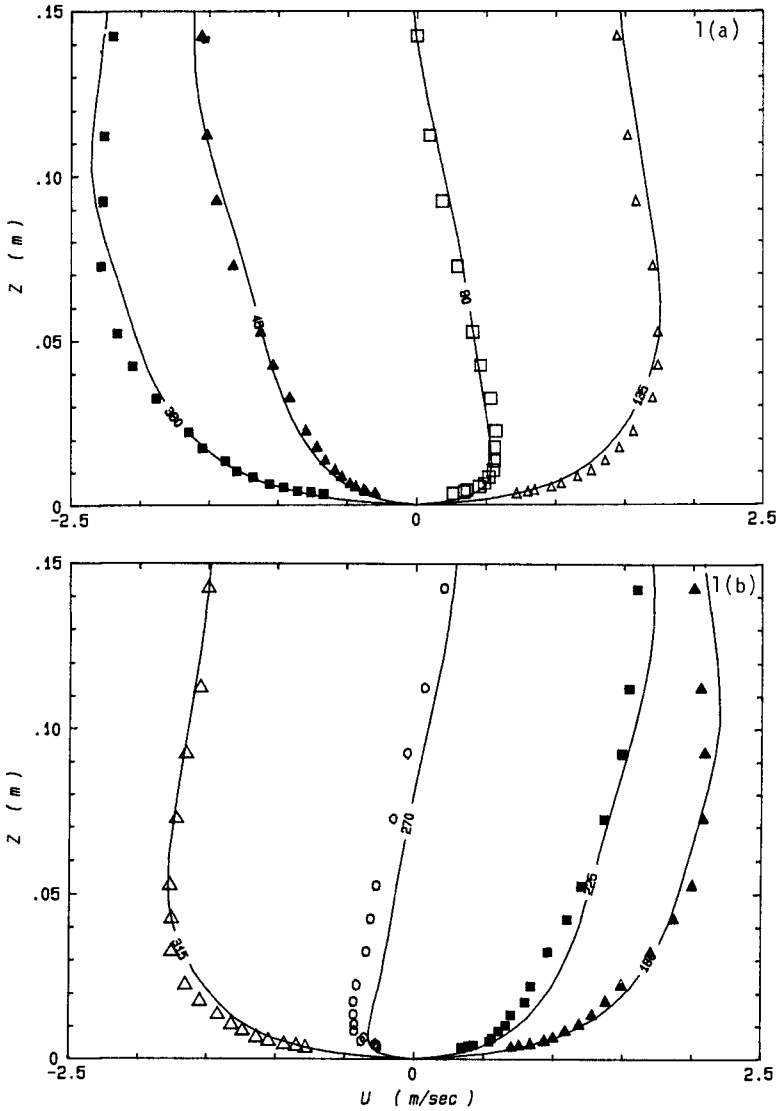

FIGURE 1. Mean velocity vs height in Jonsson and Carlsen's turbulent wave boundary layer (—: model results, symbols: data): (a) at  $\phi=0^\circ, 45^\circ, 90^\circ, 135^\circ$ ; (b) at  $\phi=180^\circ, 225^\circ, 270^\circ, 315^\circ$ .

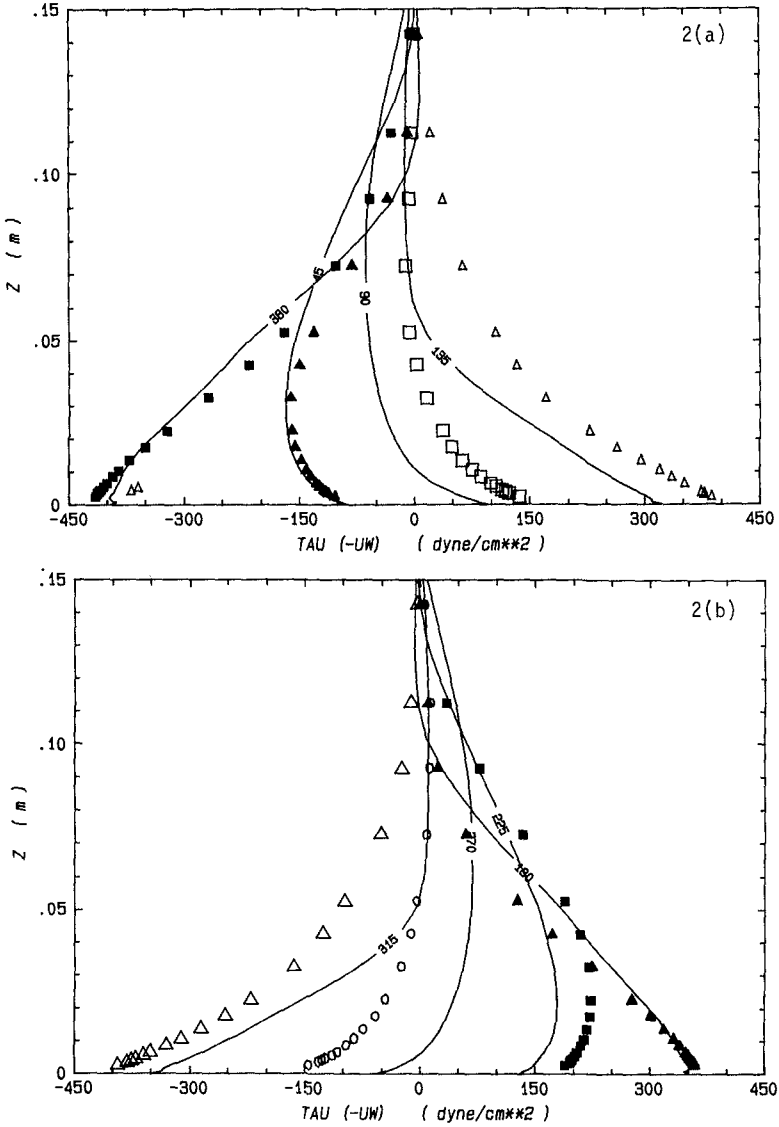

FIGURE 2. Reynolds stress vs height in Jonsson and Carlsen's turbulent wave boundary layer (—: model results, symbols: data): (a) at  $\phi=0^\circ, 45^\circ, 90^\circ, 135^\circ$ ; (b) at  $\phi=180^\circ, 225^\circ, 270^\circ, 315^\circ$ .

the calculated shear stresses and vertical gradients of the measured mean velocities. The resulting eddy viscosities are ill-behaved and often have negative values. Attempt to formulate an eddy viscosity model based on these ill-behaved eddy-viscosity values may lead to good fit of mean flow data, but will not provide physical insight of the turbulent transport processes.

Figure 3 presents the temporal variation of  $U_f$ ,  $U_{1cm}$ ,  $\tau_{bottom}$ ,  $\partial p/\partial x$  and  $z_{log}$  (thickness of the classic logarithmic layer). A phase lag of approximately 0.4 radians is found between  $U_f$  and  $U_{1cm}$  (the mean velocity at 1 cm above the bottom). Similar phase lag is also found between  $U_f$  and  $\tau_{bottom}$  (the bottom stress). The pressure gradient  $\partial p/\partial x$  balances the time variation of  $U_f$  exactly, and obtains maximum absolute value in the neighborhood of  $\phi=90^\circ$  and  $270^\circ$  but is approximately zero at  $0^\circ$  and  $180^\circ$ . The classical logarithmic layer is the layer within which the Reynolds stress  $-\overline{uw}$  varies less than 1% from its bottom value, and the log layer thickness lags behind the pressure gradient by approximately  $27^\circ$ . The maximum thickness of the log layer is only 2.5 cm, or 32 times the roughness height  $z_0$ . This rigorously computed value is substantially smaller than Jonsson and Carlsen's estimate of 6.3 cm and the fixed wave boundary layer thickness assumed by Grant and Madsen (7) in their current-wave boundary layer model.

#### 4. TURBULENT WAVE BOUNDARY LAYER UNDER A CNOIDAL WAVE

Waves in coastal waters are often nonlinear in nature, particularly when large sea swells are propagated onto very shallow waters. Linear wave theory is often inadequate to describe the wave under these circumstances and cnoidal wave theory has to be used. Cnoidal wave theory is based on the Korteweg-deVries equation (12) and its solution is basically different from those of higher-order Stoke's wave theories. Turbulent wave boundary layer underneath a cnoidal wave has not been previously investigated. The direct extension of the previously mentioned eddy-viscosity models to such cases is questionable. In the following, we present a simulation of the turbulent wave boundary layer underneath a cnoidal wave by means of the second-order closure model.

In a recent physical model study at CERC, the wave parameters within Humboldt Bay, California due to a 11-sec, 10-ft sea swell propagated from the Northwest were measured. Sharp-crested cnoidal waves were clearly observed over much of the Humboldt Bay. At a nearshore station in the vicinity of Buhne Point, the depth ( $d$ ) is only 2.65 m, and the wave height ( $H$ ) is 0.64 m. Values of  $d/gT^2$  and  $H/gT^2$  indicate that cnoidal wave theory should be used. The wave orbital velocities were computed by using the cnoidal wave theory and the linear theory and are shown in Figure 4(a). Based on Kajiura's empirical formula for the bottom friction coefficient underneath a linear wave, the computed bottom stresses over a wave cycle are shown in Figure 4(b). Excessively high bottom stress is found underneath the cnoidal wave.

The turbulent wave boundary layer underneath the cnoidal wave was computed by means of the second-order closure model and considering a water column of 20 cm above the bottom. Figure 5(a) shows the mean velocity profiles over the entire cycle at 45° intervals. The sharp-crested nature of the cnoidal wave is clearly manifested by these velocity profiles. Much of the temporal variation takes place during only half of the wave cycle while little variation is found during the other half cycle. The computed Reynolds stress profiles are shown in Figure 5(b). The Reynolds stresses are generally confined to a layer much thinner than what would be underneath a linear sinusoidal wave. Figure 6 shows the temporal variation of  $U_{\tau}$ ,  $U_{1cm}$ ,  $\tau_{bottom}$ ,  $\partial p/\partial x$  and thickness of the logarithmic layer. Compared to its linear counterpart, the logarithmic layer is thinner during the fast half cycle but somewhat thicker during the slow half cycle. The maximum bottom shear stress as shown in Figure 6 is little over 100 dyne/cm<sup>2</sup>, a value substantially less than the 180 dyne/cm<sup>2</sup> computed by using Kajiura's empirical formula for sinusoidal wave. More detailed computation of the cnoidal wave within the Humboldt Bay can be found in Sheng (20).

#### 5. CURRENT WAVE INTERACTION WITHIN THE BOTTOM BOUNDARY LAYER

Using an eddy-viscosity model, Grant and Madsen (7) produced a theoretical analysis of combined current and wave flow over a rough boundary, predicting an increase in apparent bed roughness and bottom shear stress when waves are superimposed on the current. Similar models and qualitative results have been produced by others (e.g., 2). As pointed out by Kemp and Simon (11), however, no detailed verification of the above eddy-viscosity models has been made. In addition, these models generally require ad-hoc assumptions on the wave boundary layer.

FIGURE 4. Orbital velocity and bottom stress at a station near Buhne Point in Humboldt Bay, CA due to a 11-sec (period) and 10-ft (wave ht.) sea swell propagated from the Northwest (—: cnoidal wave theory, ----: linear wave theory); (a) wave orbital velocity over a wave cycle, (b) bottom stress computed by using Kajiura's empirical formula.

FIGURE 5(b). Reynolds stress vs height within the turbulent bottom boundary layer under a cnoidal wave. The profiles are shown at 45° intervals over a wave cycle.

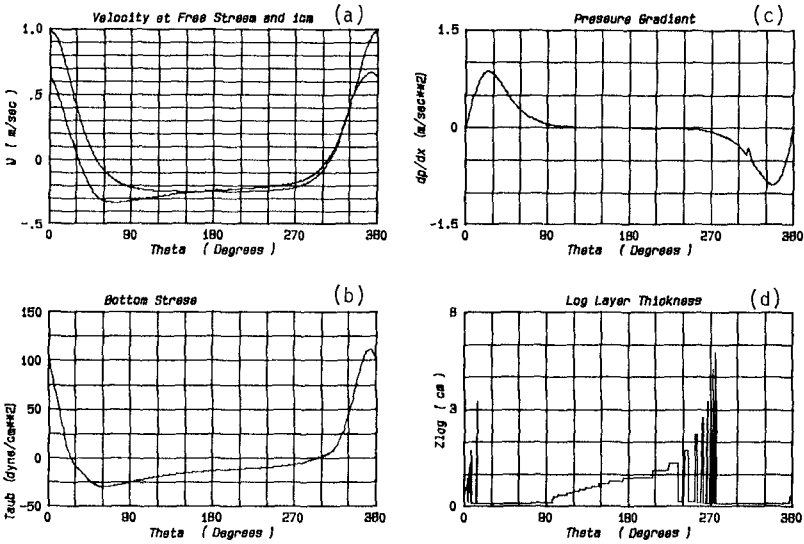

FIGURE 6. Temporal variation of (a) free stream velocity and velocity at 1-cm above the bottom, (b) bottom stress, (c) pressure gradient, and (d) thickness of log layer over one wave cycle in turbulent boundary layer under the cnoidal wave.

In this paper, we present some results on current-wave bottom boundary layer obtained with the second-order closure model. The first simulation is based on some data collected at a CODE site (C3) about 1 km off the California coast. Using  $z_0=0.2$  cm,  $U_{100cm}=10.21$  cm/sec,  $U_w=6.09$  cm/sec, and  $T_w=13.79$  sec, the model computed results (averaged over the wave cycle) within the bottom 1 m are shown in Figure 7. In the absence of any wave, the velocity profile shows a logarithmic variation with depth while the turbulent kinetic energy ( $q^2/2$ ) and Reynolds stress ( $-\overline{uw}$ ) are constant within the bottom boundary layer. When waves are superimposed on the current, the apparent roughness is increased to 0.5 cm while  $q^2$  and  $-\overline{uw}$  are increased by more than 50% near the bottom. The increase in  $-\overline{uw}$  is less than that produced by Grant and Madsen, which was found to be higher than that determined from the logarithmic velocity profile. If Kajiura's empirical formula was used for the bottom friction coefficient, one finds that the wave-induced bottom stress alone is on the order of 1.3 dyne/cm<sup>2</sup> which is much higher than our combined current-wave result.

The second model simulation is based on the current and wave data at a site in the Mississippi Sound (18) where  $z_0=0.1$  cm,  $U_{100cm}=20$  cm/sec,  $U_w=20$  cm/sec and  $T_w=2.5$  sec. The results shown in Figure 8

FIGURE 7. Simulated current-wave bottom boundary layer at a CODE site (C3). Vertical profiles of (a) mean velocity, (b) twice the turbulent K.E., and (c) Reynolds stress averaged over the wave cycle.  $z_0 = 0.2$  cm,  $U_{100} = 10.2$  cm/sec,  $U_W = 6.09$  cm/sec,  $T_W = 13.79$  sec.

FIGURE 8. Simulated current-wave bottom boundary layer at a site in the Mississippi Sound. Vertical profiles of (a) mean velocity, (b) twice the turbulent K.E., and (c) Reynolds stress averaged over the wave cycle.  $z_0 = 0.1$  cm,  $U_{100} = 20$  cm/sec,  $U_W = 10$  cm/sec,  $T_W = 2.5$  sec.

indicate the wave boundary layer is relatively thinner compared to the CODE simulation, although more than 50% increase is also found in the  $q^2$  and  $-\overline{uw}$  at bottom.

The results presented herein have great engineering implications.

The increased bottom shear stress due to the presence of the wave will lead to enhanced erosion of sediment while the increased turbulent intensity will lead to enhanced mixing of sediment within the water column. In a comprehensive laboratory study of current-wave interaction within the bottom boundary layer, Kemp and Simon (11) found significant phase shift between the turbulent intensity and the bottom stress. Earlier study by van Hoften and Karaki (22) found that presence of the wave may sometimes lead to reduction of the Reynolds stress. To further examine and understand such interesting phenomena, it is essential to use a dynamic turbulent transport model which requires little ad-hoc parameter tuning.

#### 6. MIXED LAYER DYNAMICS

Coastal processes may be affected by density stratification in coastal waters resulting from inhomogeneity in salinity, sediment concentration, and temperature. A predictive model capable of simulating stratified flow situations is highly desirable. Using the second-order closure model, we performed a simulation of the ocean mixed layer measured during MILE (MIXed Layer Experiment) by Miyake (16). Data obtained throughout a 32-day period starting August 2, 1977 exhibited significant temporal variations of the wind stress (between 0 and 5 dynes/cm<sup>2</sup>) and heat flux (diurnal heating and cooling cycle) at the ocean site. The model simulation was performed by using the measured temperature profile on August 2, 1977 as initial condition and the measured wind stress and heat flux during the subsequent 32 days as boundary conditions. As shown in Figure 9(a), the simulated mean temperature profile on the 32nd day agrees well with data. So are the simulated surface temperatures throughout the 32-day period in Figure 9(b). Despite the great variability of the weather, the model was able to correctly track the evolution of the thermocline throughout the simulation period.

More recently, a simplified version of the second-order closure model has been applied to simulate the mixed layer dynamics (19). This simplified model is comparable in complexity to the model of Mellor and Durbin (15) but contains more dynamics by allowing a spatially varying turbulence macroscale.

#### 7. WIND-DRIVEN CURRENTS

A simplified three-dimensional version of the second-order closure model was applied to simulate the wind-driven currents in a laboratory flume measured by Baines and Knapp (1). Figure 10 shows the model results at the middle of the flume obtained with the same  $U_*D/\nu(\sim 51,000)$  of the experiment. Both the mean horizontal velocity  $U$  and the vertical turbulent velocity  $w$  agree very well with measured data. Although the vertical eddy-viscosity  $A_V$  was not measured, the simulated peak  $A_V$  agree well with an estimated peak value based on the measured turbulence profile and a length scale approximately 20% of the water depth.

#### 8. CONCLUDING REMARKS

This paper presents a brief introduction of a second-order closure model of turbulent transport and recent model applications to simulate various coastal processes of practical importance. Due to the added

FIGURE 9 (a). Simulated and measured temperature profile at 32 days after the initiation of the MILE ocean mixed layer experiment.

physics contained in the model, the model was able to successfully simulate a variety of flow situations without having to perform extensive site-specific tuning of ad-hoc model parameters. Detailed simulations of the turbulent bottom boundary layers and the mixed layer demonstrated that the model may be used to (1) provide detailed understanding of the physical processes, (2) aid the design and interpretation of laboratory/field experiments, and (3) guide the development of first-order closure models (eddy-viscosity models). By combining the turbulent transport model with emerging high-quality laboratory/field data, further understanding on the turbulent current-wave boundary layer can be achieved. Research is also needed to extend the model to study (1) the dispersion of sediments, (2) the hydrodynamic forces on complex structures, and (3) the wave-breaking induced turbulence.

## CHAPTER ONE HUNDRED SIXTY ONE

### BOTTOM TURBULENT BOUNDARY LAYER IN WAVE-CURRENT CO-EXISTING SYSTEMS

Toshiyuki Asano\* and Yuichi Iwagaki\*\*

#### ABSTRACT

This study presents a new mathematical method calculating the water particle velocity in the wave-current co-existing systems. A boundary layer thickness  $\delta_w$  in the co-existing system is expected to be variable with the water particle velocity ratio of wave component to current component. In this method, the boundary layer equation is solved as a free boundary problem by treating  $\delta_w$  as an unknown boundary value. Several characteristics of the turbulent boundary layer such as the friction factor, friction velocity, boundary layer thickness, etc. are calculated by this method and the effect of the wave-current velocity ratio on them is discussed. Furthermore, the velocity reduction of the current due to wave superimposing is investigated.

In addition, near-bottom velocities are measured by a laser-doppler velocimeter in the pure current, the pure wave and the wave-current co-existing fields. These results are compared with calculated ones by this mathematical method.

#### 1. Introduction

Understanding of near bottom velocity characteristics in wave and current co-existing systems is of considerable importance for sediment transport in the nearshore region, and comprehensive study of the bottom shear stress in the field is essential in developing a more accurate theory to predict nearshore current systems.

Hydrodynamics near the bottom in the co-existing field is complicated because there are mutual interactions between a current and waves. Grant-Madsen<sup>4)</sup> proposed a theoretical model to describe the water particle velocity and the shear stress in the wave-current co-existing field, and pointed out that the current above the wave boundary layer feels a larger resistance due to the presence of the wave than in the pure current field. This is the first theoretical study to investigate

\*\* Professor, Kyoto University, M. of ASCE  
Yoshida-Honmachi, Sakyo-ku Kyoto 606, Japan

not only the wave deformation by a current but also the current deformation by waves. However, their analysis left some problems to be solved.

As an important problem, we point out that convective acceleration terms were neglected in their analysis. When the velocity potential in the wave-current co-existing field is introduced,  $U\partial u/\partial x$  term involved in the boundary conditions at the water surface should be considered because it is regarded to be the same order as the local acceleration term  $\partial u/\partial t$ . The velocity potential and the dispersion equation in the co-existing field can be deduced by considering this term.

Since the water particle velocity obtained by the boundary layer solution and that by the inviscid solution should be matched at a certain level from a bed, this term must be taken into consideration for the consistency in the analysis.

Another problem lies in how to determine the wave boundary layer thickness  $\delta_w$ . This model considers the co-existing field such a way that the current feels different eddy viscosities between inside and outside of the wave boundary layer. However, the current velocity can not be estimated as long as  $\delta_w$  is not determined. Grant-Madsen applied an existing knowledge on  $\delta_w$  in the wave boundary layer straightforwardly to the co-existing field. Therefore, the variation of the boundary layer thickness  $\delta_w$  with the wave-current composing ratio could not be considered in their analysis.

The present study proposes a new mathematical method to predict the water particle velocity in the co-existing field. By using this method, several characteristics of the turbulent boundary layer are calculated and discussed.

Finally, measurements on the near bottom velocity are carried out with a laser doppler velocimeter and the validity of this analytical method is examined by comparing with the experimental results.

## 2. Formulation of boundary layer equation in co-existing field

### (a) Basic assumption

This study is based on Grant-Madsen's model on the wave-current turbulent boundary layer. The basic idea of their model is briefly as follows:

The current is assumed to be a fully developed flow and the associated boundary layer extends over most of the depth. Meanwhile, the wave boundary layer is confined to a relatively thin region close to the bottom. The velocity distributions both for a wave component and a current component are schematically shown in Fig.1. Consequently, the shear stress inside of the wave boundary layer is composed of wave-current interacting effect. They assumed different eddy viscosities both for inside and outside the wave boundary layer regions as follows:

Fig.1 Profiles for eddy viscosity, wave and current components assumed in this model

$$\epsilon = \kappa |u_c^*|^2 z \quad z > \delta_w \quad (1)$$

$$\epsilon = \kappa |u_{cw}^*|^2 z \quad z < \delta_w \quad (2)$$

in which,  $\kappa$  is von Karman's constant,  $z$  the vertical coordinate,  $\delta_w$  the wave boundary layer thickness,  $u_c^*$  and  $u_{cw}^*$  the shear velocities for current and wave-current motions respectively.

This assumption on the eddy viscosity, which increases linearly with the height from the bed, is not sufficient to represent the turbulent boundary layer accurately.

For the wave turbulent boundary layer, Kajiura<sup>5)</sup> and Noda<sup>8)</sup> proposed the elaborate theories by introducing boundary layer stratifications. For the co-existing field, Tanaka-Shuto<sup>9)</sup> and Christoffersen<sup>3)</sup> presented the theoretical analyses on the basis of different assumptions on the eddy viscosity distribution from Grant-Madsen's model.

Their analyses are important for refinement of the Grant-Madsen's model; however, they did not solve the above mentioned problems. Since the primary concern here is to improve the essential weakpoints of Grant-Madsen's model, this study does not consider such modifications on the eddy viscosity, and starts the analysis under the same assumptions as Grant-Madsen's theory.

The shear stress inside the wave boundary layer is calculated by the sum of the wave and current components which are presented respectively as follows:

$$\tau_w = \rho \kappa u_{cw}^* z \frac{\partial u}{\partial z} \quad (3)$$

$$\tau_c = \rho \kappa u_c^* z \frac{\partial U}{\partial z} \quad (4)$$

While, outside the wave boundary layer, the shear stress is also obtained by replacing  $u_{cw}^*$  with  $u_c^*$  in Eqs.(3) and (4). The shear velocity in the co-existing field is assumed to be connected with the maximum bottom shear stress during a wave period  $\tau_{cw, \max}$ ; that is,

$$\tau_{cw, \max} = \tau_c + \tau_w, \max = \rho u_{cw}^{*2} = \rho \kappa u_{cw}^* z \left. \frac{\partial(u+U)}{\partial z} \right|_{\max} \quad (5)$$

in which,  $z_0$  is a constant and denotes a roughness height for fully turbulent flow.

#### (b) Solution for current component

Inside the wave boundary layer, the current velocity  $U$  is obtained from Eq.(4).

$$U = \frac{u_c^{*2}}{\kappa u_{cw}^*} \ln \frac{z}{z_0} \quad z < \delta_w \quad (6)$$

The current velocity at the outer edge of the wave boundary layer  $U_p$  is given by substituting  $z = \delta_w$  into Eq.(6).

$$U_p = -\frac{u_c^{*2}}{\kappa u_c^* z} \ln \frac{\delta_w}{z_0} \tag{7}$$

Outside the wave boundary layer, the relation between the current velocity  $U$  and the current shear stress  $\tau_c$  is represented with the eddy viscosity in Eq. (1) as follows:

$$\tau_c = \rho \kappa u_c^* z \frac{\partial U}{\partial z} \quad z > \delta_w \tag{8}$$

Thus, the current velocity distribution is found from Eqs (7) and (8).

$$U = \frac{u_c^*}{\kappa} \ln \frac{z}{\delta_w} + U_p = \frac{u_c^*}{\kappa} \ln \frac{z}{\delta_w} + \frac{u_c^{*2}}{\kappa u_c^* z} \ln \frac{\delta_w}{z_0} \quad z > \delta_w \tag{9}$$

(c) Solution for wave component

The governing equation in the wave boundary layer is as follows:

$$\frac{\partial u}{\partial t} + U \frac{\partial u}{\partial x} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{1}{\rho} \frac{\partial \tau_w}{\partial z} \quad z < \delta_w \tag{10}$$

,where the linearized convective acceleration term is involved on the left hand side.

Outside the wave boundary layer, the viscous term on the right hand side of Eq. (10) can be neglected. Thus the following equation is held at just outside the boundary layer:

$$\frac{\partial u_p}{\partial t} + U_p \frac{\partial u_p}{\partial x} = -\frac{1}{\rho} \frac{\partial p_p}{\partial x} \tag{11}$$

in which, the subscript 'p' denotes the value at  $z = \delta_w$ . The vertical pressure gradient is assumed to be negligible on the basis of the boundary layer approximation. The governing equation for the wave component inside the boundary layer is deduced from Eqs. (10) and (11):

$$\frac{\partial(u_p - u)}{\partial t} + U_p \frac{\partial u_p}{\partial x} - U \frac{\partial u}{\partial x} = -\frac{1}{\rho} \frac{\partial \tau_w}{\partial z} = -\frac{\partial}{\partial z} \left( \kappa u_c^* z \frac{\partial u}{\partial z} \right) \tag{12}$$

In the above equation,  $u_p$  is the water particle velocity at the boundary layer edge  $z = \delta_w$  and calculated from the small amplitude wave theory as follows:

$$u_p = \hat{u}_p \cos(kx - \sigma t) = \frac{H}{2} (\sigma - k \mathcal{O}) \frac{\cosh k \delta_w}{\sinh kh} \cos(kx - \sigma t) \tag{13}$$

in which,  $H$  is the wave height,  $\sigma$  the angular frequency,  $k$  the wave number,  $h$  the water depth.

(d) Free boundary problem on boundary layer equation

The wave component in the wave boundary layer is expressed as follows:

$$u = A(z) \cos(kx - \sigma t) + B(z) \sin(kx - \sigma t) \tag{14}$$

Substituting Eq. (14) into Eq. (12), and rewriting the functions  $A$

and  $B$  and their derivatives by  $\vec{\xi}$  and  $\vec{\eta}$  as

$$\vec{\xi} = \begin{pmatrix} A \\ B \end{pmatrix}, \quad \vec{\eta} = \begin{pmatrix} A' \\ B' \end{pmatrix} \tag{15}$$

we get

$$\frac{d\vec{\xi}}{dz} = \vec{\eta}, \quad \frac{d\vec{\eta}}{dz} = D\vec{\eta} + E\vec{\xi} + F \tag{16}$$

in which,

$$D = \begin{pmatrix} -\frac{1}{z}, & 0 \\ 0, & -\frac{1}{z} \end{pmatrix}, \quad E = \begin{pmatrix} 0, & -\frac{\sigma - kU}{\kappa U_{c_w}^* z} \\ \frac{\sigma - kU}{\kappa U_{c_w}^* z}, & 0 \end{pmatrix}, \quad F = \begin{pmatrix} 0 \\ -\frac{\sigma - kU_p \hat{u}_p}{\kappa U_{c_w}^* z} \end{pmatrix} \tag{17}$$

The boundary conditions for Eq. (16) are

$$\vec{\xi} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad z = z_0 \tag{18}$$

$$\vec{\xi} = \begin{pmatrix} \hat{u}_p \\ 0 \end{pmatrix}, \quad \vec{\eta} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad z = \delta_w \tag{19}$$

Eq. (19) shows that the problem we discuss here is a free boundary problem because  $\delta_w$  is an unknown value. The two point boundary value problem as shown in Eqs. (16) ~ (19) is interpreted to be equivalent to the following characteristic equation:

$$\frac{\partial \vec{\xi}}{\partial z} + \frac{\partial \vec{\xi}}{\partial \vec{\eta}} (D\vec{\eta} + E\vec{\xi} + F) = \vec{\eta} \tag{20}$$

This partial differential equation is the so-called invariant imbedding equation, of which value lies in its wide applicability to the numerical solution of various kinds of boundary value problems. The invariant imbedding method is an initial value method for boundary value problems obtained by boundary perturbation techniques<sup>(2),7)</sup>.

An initial value problem is derived from the partial differential equation Eq. (20) by using the following Riccati transformation on  $\vec{\xi}$ :

$$\vec{\xi}(z, \vec{\eta}) = G(z)\vec{\eta} + H(z) \tag{21}$$

Substituting the above in Eq. (20), we obtain

$$\frac{dG}{dz} + GD + GEG = I \tag{22}$$

$$\frac{dH}{dz} + GEH + GF = 0 \tag{23}$$

in which,  $I$  is a  $2 \times 2$  unit matrix and  $0$  is  $2$ -dimensional zero vector. The boundary condition of Eq. (18) is transformed as

$$G(z_0) = 0, \quad H(z_0) = 0 \tag{24}$$

in which,  $0$  is  $2 \times 2$  zero matrix.  $G(z)$  and  $H(z)$  in Eqs. (22) ~ (23) are easily calculated with the initial values shown in Eq. (24). Eq. (21) is

transformed as

$$\bar{\eta}(z) = G^{-1}(z)\{\xi(z) - H(z)\} = G^{-1}(z)\left\{\begin{pmatrix} \hat{u}_c(z) \\ 0 \end{pmatrix} - H(z)\right\} \quad (25)$$

Finally we can obtain the unknown boundary position  $z = \delta_w$  as a  $z$ -value when Eq.(25) is equal to 0. After the upper boundary point  $z = \delta_w$  is determined, the boundary value problem results in an initial value problem; that is, the solution of Eq.(16) can be calculated by the 'terminal condition' at  $z = \delta_w$  as shown in Eq.(19).

The shear velocity of the current  $u^*_C$  is estimated by the velocity distribution of the pure current. However, if only the average current velocity in depth  $\bar{U}$  is obtained for the co-existing system,  $u^*_C$  can be calculated alternatively by integrating Eq.(9) in depth and solving the resultant quadratic equation.

Thus,

$$u^*_c = \frac{-u^*_{c_w}\alpha_2 + \sqrt{u^*_{c_w}\alpha_2^2 + 4\bar{U}\kappa u^*_{c_w}(h-z_0)\alpha_1}}{2\alpha_1} \quad (26)$$

in which,

$$\begin{aligned} \alpha_1 &= h \ln \frac{\delta_w}{z_0} - (\delta_w - z_0) \\ \alpha_2 &= h \ln \frac{h}{\delta_w} - (h - \delta_w) \end{aligned} \quad (27)$$

On the other hand, the shear velocity for the co-existing system is defined by Eq.(5), and rewritten into the following equation with invoking Eq.(6):

$$u^*_{c_w}{}^2 = \kappa u^*_{c_w} z_0 \frac{\partial u}{\partial z} \Big|_{z=z_0} + u^*_{c_w}{}^2 \quad (28)$$

The above equation is a quadratic equation on  $u^*_{CW}$ , therefore if  $(\partial u / \partial z)_{z=z_0}$  is given,  $u^*_{CW}$  can be calculated. However,  $(\partial u / \partial z)_{z=z_0}$  is not known apriori, but obtained from the solution, consequently, several iterations are needed to obtain  $u^*_{CW}$ .

The boundary layer thickness  $\delta_w$  is defined as the height that the maximum shear stress  $\tau_{w,max}$  becomes 0. However it never coincides with exactly 0 unless  $z$  becomes infinitely large, so that, it is considered to be reasonable to define  $\delta_w$  as the  $\tau_{w,max}$  becomes very small relative to the value on the bottom.

In this study,  $\delta_w$  is defined as the height where  $(\partial u / \partial z)_{max}$  becomes 0.01 times of that on the bottom. Therefore,  $\delta_w$  is varied with the multiple rate, however the solution on the water particle velocity is not affected wherever  $\delta_w$  is, because only starting point differs in the calculation.

### 3. Calculating results and discussion

#### (a) Results on characteristics in wave boundary layer

In this section, several characteristics calculated by the above method are discussed and compared with those obtained by Grant-Madsen's theory.

Table 1 shows the results on several characteristics calculated from the both theories in the wave only field. The calculating conditions are as follows. The water depth  $h=30\text{cm}$ , the wave height  $H=10\text{cm}$ , the roughness height on the bottom  $z_0=0.1\text{cm}$  and the wave period  $T=2\text{sec}$  and  $1.25\text{sec}$  for case-I and case-II, respectively. The definition of the friction coefficient  $f_{cw}$  is:

$$\tau_{cw, max} = \rho u_{cw}^{*2} = \frac{\rho}{2} f_{cw} \bar{u}_p^2 \quad (29)$$

It is clear from Table 1 that the results by the authors' method agree with those by Grant-Madsen's theory. However, results on the non-dimensional wave boundary layer thickness  $\delta_w$  show some differences. In the present method,  $\delta_w$  is obtained by a solution of the free boundary problem. On the other hand in Grant-Madsen's theory  $\delta_w$  is assumed to be 2 or 4 times  $\kappa |u_{cw}^*| / \sigma$  (in this calculation  $\delta_w = 4\kappa |u_{cw}^*| / \sigma$ ), so that, the difference of the value is due to the estimation methods.

Table 2 shows the results in the wave current co-existing field. A little difference is seen between the results of Authors' and Grant-Madsen's, because a convective acceleration term is taken into consideration in our method.

Calculations without the convection term are also carried out by our method (indicated as Authors(2) in Table 2), and it is found that these results agree well with those by Grant-Madsen's theory.

Next, variations of the characteristics with the current velocity are discussed. Fig.2 shows the results on the friction coefficient  $f_{cw}$ , where the abscissa is a ratio of the depth averaged current velocity  $\bar{U}$  to the wave celerity  $c$  calculated from the dispersion equation in the co-existing system.

The figure shows that the values of  $f_{cw}$  differ between a following current and an opposite one even if the current has a same absolute velocity. The reason is that the water particle velocity on the bottom becomes larger in the following current co-existing field than that in the pure wave field, whereas in the opposite current co-existing field the water particle velocity on the bottom becomes smaller.

Fig.3 represents the results on the shear velocity  $u_{cw}^*$ , which shows the same tendency as  $f_{cw}$ .

Fig.4 shows the results on the non-dimensional boundary layer thickness  $\delta_w / (\kappa |u_{cw}^*| / \sigma)$ , which indicates that the value decreases with the current velocity and the property is different from Grant-Madsen's assumption that  $\delta_w / (\kappa |u_{cw}^*| / \sigma)$  is a constant independent of the current velocity.

The results on the phase precedence  $\theta$  of the bottom shear stress to the water particle velocity outside the wave boundary layer are shown in Fig.5. It is found that  $\theta$  decreases with the current velocity in the following current case, meanwhile  $\theta$  increases a little with the current velocity in the opposite current case.

Table 1 Calculated results for characteristic values of the boundary layer in the wave-only field.

Fig. 5 Phase precedence of bottom shear stress relative to water particle velocity outside boundary layer  $\theta$

Fig. 6 Non-dimensional current velocity reduction  $U_d / U$

**(b) Current velocity reduction**

As mentioned above, the current in the co-existing field experiences larger hydrodynamic resistance than that in the pure current field. Furthermore, the associated mean bottom shear stress is possible to differ from that in the pure current field. The current velocity without waves  $U_{n.w.}$  is expressed as the well known logarithmic law.

$$U_{n.w.} = \frac{u_c^*}{\kappa} \ln \frac{z}{z_0} \quad (30)$$

Meanwhile, the current velocity in the co-existing field is represented in Eq.(9). Thus, the reduction of velocity  $U_d$  due to wave superimposing above the wave boundary layer is obtained by subtracting Eq.(9) from Eq.(30) as follows:

$$U_d = U_{n.w.} - U = \left( \frac{u_c^*}{\kappa} - \frac{u_c^{*2}}{\kappa u_{cw}^*} \right) \ln \frac{\delta_w}{z_0} \quad (31)$$

The above equation shows that the reduction depends directly on the wave boundary layer thickness  $\delta_w$ .

This method treats  $\delta_w$  as a variable with the wave-current composing ratio and estimates it as a solution of the free boundary problem. Consequently, this method is rational to estimate the current velocity reduction. The calculated results on the non-dimensional reduction velocity  $U_d/U$  are shown in Fig.6.

**(c) Instantaneous water particle velocity**

Fig.7 and Fig.8 are the calculated results on the distribution of water particle velocity for a following and an opposite current cases respectively. The thin curves in the figure show the results calculated from the authors' method without the convective acceleration term. In addition, the results calculated from Grant-Madsen's theory are shown by the dotted curves for comparison. It is found from the figure that the convection term decreases the absolute values of water particle velocity in the following current case, and increases those in the opposite current case.

The effect of the convection term increases as  $U/c$  becomes large, because the ratio of the convective acceleration term  $U \partial u / \partial x$  to the local acceleration term  $\partial u / \partial t$  becomes  $U/c$ . In the actual nearshore regions, however, the value of  $U/c$  is usually small, therefore it occurs rather seldom that the convection term plays an important role.

**4. Measurements on near bottom velocity****(a) Experimental apparatus and procedure**

The experiment was carried out in a 27m long, 0.5m wide and 0.7m high wave tank, in which circulating flow could be generated by a power pump. The water depth was kept constant at 30cm. Test runs were conducted under the conditions that the wave period was 1.67sec, the wave height were 6.3 8.5cm. All the cases of current used in the tests were in the opposite direction to the wave propagation. Two dimensional

Fig.7 Distributions of horizontal water particle velocity in co-existing field (following current)

Fig.8 Distributions of horizontal water particle velocity in co-existing field (adverse current)

roughness elements of  $2\text{mm} \times 2\text{mm}$  in cross section and  $15\text{mm}$  interval were added on the bottom.

Water particle velocities were measured with a laser-doppler velocimeter, and at the same location water surface variations were detected simultaneously by a capacitance type wave gauge. The measuring points were located at the lowest  $1.4\text{mm} \sim 1.7\text{mm}$  above the top of the artificial roughness and at the highest  $100\text{mm}$  above that. The total measuring points were 21  $\sim$  23 for each test case. The test conditions are summarized in Table 3, and a schematical view of the experimental apparatus is shown in Fig.9.

**(b) Current component velocity**

The current component velocity in the co-existing system is defined as the time averaged velocity during a wave period. Fig.10 shows the current component velocities both in the pure current field and in the co-existing field.

The velocity reduction of the current component in the co-existing field is clearly seen from the figure.

The dotted line shows the calculated results from the authors' theory, where only the depth averaged velocity of the pure current and the wave conditions are given as inputs of the calculation.

**(c) Instantaneous water particle velocity**

Fig.11 shows the experimental results in the pure wave field, and the calculated results by the authors' and Grant-Madsen's theories are also shown for comparison.

The experimental results take larger values than the calculated ones at the phases 0 and  $\pi/4$  in the region of  $z < 2\text{cm}$ , and the distributions show over-shooting phenomena that the velocity in the boundary layer exceeds the outer velocity. Furthermore, the experimental results become smaller than the calculated ones especially at the phase  $3/4\pi$  and  $\pi$  in the region of  $z < 5\text{mm}$ .

Similar results were found in experimental results performed by Bakker and van Doorn<sup>1)</sup>, who measured water particle velocities under the similar experimental conditions to those of this study.

It also seems to be a reason of the disagreement that the water particle velocities under this test condition were not enough large to generate fully rough turbulent flow near the bottom.

Fig.12 shows the results in the wave-current co-existing field. The agreement between the calculated and experimental results seems to be better in the co-existing field than that in the pure wave field.

The reason can be explained by the fact that in the co-existing field the turbulent flow was produced close to the bottom due to superimposing current, while in the pure wave field under these experimental conditions the laminar sublayer occupied some width on the bottom.

In order to improve the mathematical model for predicting the experimental result more accurately, it is necessary to solve the

Fig.11 Comparisons between experimental results and theoretical ones in pure wave field

several important problems remained even in the pure wave boundary layer.

One important problem is the finite amplitude effect of waves on the water particle velocity in the wave boundary layer. Another problem lies in the assumption on the eddy viscosity. How to determine the roughness height  $z_0$  in oscillating flow is also one of the problems to be solved.

### 5. Conclusions

This study proposes a new mathematical method to predict near bottom water particle velocities in the wave-current co-existing field. Since this method is capable of expressing the variation of the boundary layer thickness with the wave-current velocity ratio, several characteristics of the boundary layer and the current velocity reduction due to superimposing waves can be estimated reasonably by this method.

Moreover, measurements on the water particle velocity above the artificial rough bottom were carried out in the pure wave, the pure current and the wave-current co-existing fields.

After comparing the calculated results with the experimental data, it was found that this method predicts well the experimental results, however some disagreements between them are obtained. These are partly due to the assumption on the eddy viscosity which is proportional to the height from the bottom, and in addition, due to neglecting the finite amplitude effect of waves.

### Acknowledgement

This study is part of the research sponsored by the Grant-in-Aid for Scientific Research of the Ministry of Science, Culture and Education. The authors wish to express their appreciation to Mr. H. Okamoto, former graduate student at Department of Civil Engineering, Kyoto University, for his assistance in performing the experiments.

## CHAPTER ONE HUNDRED SIXTY TWO

### NUMERICAL SIMULATION OF SECONDARY CIRCULATION IN THE LEE OF HEADLANDS

by

Roger A. Falconer<sup>1</sup>  
Eric Wolanski<sup>2</sup> and  
Lida Mardapitta-Hadjipandeli<sup>3</sup>

#### ABSTRACT

The paper gives details of a study to refine and further develop a two-dimensional depth average numerical model to predict more accurately the eddy shedding features often observed in the lees of headlands. Details are given of the application of the model to Rattray Island, just east of Bowen, North Queensland, Australia, where the strong tidal currents flowing past the island give rise to separation and hydrodynamic circulation in the lee of the island.

In the governing differential equations used to predict the secondary circulation, particular emphasis has been placed on the representation of the shear stresses associated with the free shear lateral mixing layer in the downstream wake of the headland. Use of an experimentally determined lateral velocity distribution in the shear layer, together with an eddy viscosity approach, have led to the use of a relatively simple turbulence model, including both free shear layer and bed generated turbulence. A comparison of the numerically predicted velocities with corresponding field measured results around Rattray Island has shown an encouraging agreement, although there were some differences. The main difference between both sets of results was that the vorticity strength of the secondary circulation predicted in the numerical model was noticeably less than that measured in the field.

## INTRODUCTION

The main objective of the research study outlined herein has been to refine and enhance a two-dimensional depth average numerical model, in an attempt to predict more accurately the tide induced eddy shedding features often observed in the lees of headlands. The model has been applied to Rattray Island, which is located just east of Bowen, North Queensland, Australia, with its geographical location being illustrated in Fig.1. This island is approximately 1.5km long, 300m wide and lies in well mixed water, having a typical depth of about 30m. Its longer axis is inclined at about  $60^\circ$  into the direction of the semi-diurnal tidal current, and strong tidal currents flowing past the island give rise to separation at the most northerly tip of the island and secondary circulation in the downstream lee.

A detailed field study has been undertaken by the Australian Institute of Marine Science to investigate the secondary circulation occurring around Rattray Island and to try and improve the existing knowledge of eddies shed by such headlands. In this study, outlined by Wolanski et al (1984), twenty six current meters were deployed at various sites in the south eastern lee of the island, as shown in Fig.2, with time series sea level recordings being taken around the island. Visual observations of the secondary circulation were also made using landsat imagery and aerial photography, and the surface temperature field was also measured at the time of the aerial observations. The recorded tidal ranges were generally about 3m and a strong south eastwards current was observed and measured during the rising tide. This south easterly current gave rise to a strong clockwise rotating eddy in the south eastern lee of the island. The eddy was observed to be very stable and about twice the size of the island for most of the rising tide. The surface temperature distributions and drogoue trajectories also confirmed the existence of this eddy which, from measurements, was found to be several kilometres long.

The numerical model being used to simulate this eddy shedding phenomenon, for similar hydrodynamic conditions, is of the two-dimensional depth integrated type, with the water surface slope and depth mean velocity fields being evaluated from the conservation equations of mass and momentum. Included in the momentum equations are the effects of the earth's rotation, bed and surface shear forces and a simple turbulence model to represent both bed generated and free shear layer turbulence. In the numerical model, particular emphasis has been placed on: (I) formulating the lateral turbulent shear stresses in the lee of the island, (II) accurately representing the island shape and the associated boundary derivatives, (III) representing the non-linear advective accelerations so that non-linear instabilities were avoided, and (IV) investigating the influence of the Coriolis acceleration on the open boundary conditions.

## GOVERNING EQUATIONS

### *Equations of Motions*

The appropriate equations of mass and momentum conservation were derived by vertical integration of the three-dimensional continuity and Navier-Stokes equations respectively, see Falconer (1976). Thus, for the mass conservation equation in the horizontal plane, integration yields:-

Fig.1 Location of Rattray Island and bathymetry (in fathoms)

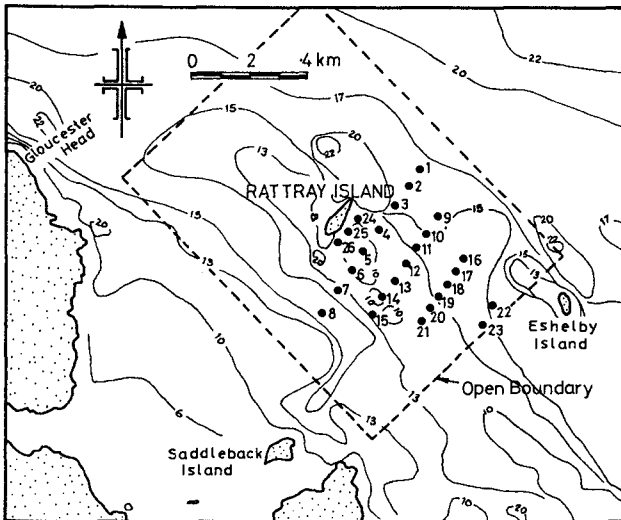

Fig.2 Area around Rattray Island showing location of current meters and model boundary

$$\frac{\partial \eta}{\partial t} + \frac{\partial UH}{\partial x} + \frac{\partial VH}{\partial y} = 0 \quad \dots\dots (1)$$

where  $\eta$  = water surface elevation above mean sea level,  $U, V$  = depth average velocity components in the  $x, y$  co-ordinate directions respectively, and  $H$  = total depth of flow.

Likewise, for an incompressible turbulent fluid flow on a rotating earth, the depth integrated equations for horizontal momentum in the  $x$  and  $y$  directions respectively, can be written as:-

$$\begin{aligned} \frac{\partial UH}{\partial t} + \beta \left[ \frac{\partial U^2 H}{\partial x} + \frac{\partial UVH}{\partial y} \right] - fVH + gH \frac{\partial \eta}{\partial x} - \frac{\tau_{wx}}{\rho} + \frac{\tau_{bx}}{\rho} \\ - \frac{1}{\rho} \left[ \frac{\partial H\sigma_{xx}}{\partial x} + \frac{\partial H\tau_{xy}}{\partial y} \right] = 0 \quad \dots\dots (2) \end{aligned}$$

$$\begin{aligned} \frac{\partial VH}{\partial t} + \beta \left[ \frac{\partial UVH}{\partial x} + \frac{\partial V^2 H}{\partial y} \right] + fUH + gH \frac{\partial \eta}{\partial y} - \frac{\tau_{wy}}{\rho} + \frac{\tau_{by}}{\rho} \\ - \frac{1}{\rho} \left[ \frac{\partial H\tau_{yx}}{\partial x} + \frac{\partial H\sigma_{yy}}{\partial y} \right] = 0 \quad \dots\dots (3) \end{aligned}$$

where  $\beta$  = correction factor for non-uniformity of the vertical velocity profile (assumed to be 1.016 for a seventh power law velocity distribution),  $f$  = Coriolis parameter,  $g$  = gravitational acceleration,  $\rho$  = fluid density,  $\tau_{wx}, \tau_{wy}$  = surface shear stress components due to wind action,  $\tau_{bx}, \tau_{by}$  = bottom shear stress components due to bed friction, and  $\sigma_{xx}, \tau_{xy}, \tau_{yx}, \sigma_{yy}$  = Reynolds stress components in the  $x, y$  directions respectively.

In the present study the effects of wind action have not been considered, and hence  $\tau_{wx}$  and  $\tau_{wy}$  have both been equated to zero. For the bottom stresses, the terms have been represented in a quadratic form (see Dronkers (1964)) giving:-

$$\left. \begin{aligned} \tau_{bx} &= \frac{\rho g U \sqrt{U^2 + V^2}}{C^2} \\ \tau_{by} &= \frac{\rho g V \sqrt{U^2 + V^2}}{C^2} \end{aligned} \right\} \dots\dots (4)$$

where  $C$  = Chezy roughness coefficient (defined by  $H^{1/6}/n$ , where  $n$  is the Manning roughness coefficient).

In the modelling of turbulent flows, particularly where secondary circulation and notable lateral velocity gradients exist, the direct shear stresses  $\sigma_{xx}$  and  $\sigma_{yy}$  are generally small in comparison with the lateral shear stresses  $\tau_{xy}$  and  $\tau_{yx}$ , see Kuipers and Vreugdenhil (1973).

Since this condition appeared to apply in this study, the direct stress components  $\sigma_{xx}$  and  $\sigma_{yy}$  have been neglected from the momentum equations (2) and (3) respectively. However, the significance and importance of the lateral shear stresses is not obvious in any study involving recirculating flows, and hence an analysis of the vorticity transport equation - corresponding to the momentum equations (2) and (3) - has been undertaken in an attempt to indicate the importance of these terms.

*Vorticity Transport Equation*

In order to obtain the appropriate depth mean vorticity transport equation from the momentum equations (2) and (3), the wind stresses and direct stresses were neglected and the momentum correction factor  $\beta$  was assumed to be unity for simplicity. Hence, differentiation of Eqs. (2) and (3) with respect to  $y$  and  $x$  respectively, and subtraction of the corresponding equations gives:-

$$\underbrace{\frac{\partial \omega}{\partial t}}_{(1)} + \underbrace{U \frac{\partial \omega}{\partial x} + V \frac{\partial \omega}{\partial y}}_{(2)} + \underbrace{(\omega - f) \left[ \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} \right]}_{(3)} + \underbrace{\left[ \frac{\partial}{\partial y} \left( \frac{\tau_{bx}}{\rho H} \right) - \frac{\partial}{\partial x} \left( \frac{\tau_{by}}{\rho H} \right) \right]}_{(4)} - \underbrace{\frac{\partial}{\partial y} \left[ \frac{1}{\rho H} \frac{\partial H \tau_{xy}}{\partial y} \right] + \frac{\partial}{\partial x} \left[ \frac{1}{\rho H} \frac{\partial H \tau_{yx}}{\partial x} \right]}_{(5)} = 0 \dots\dots (5)$$

where  $\omega$  = depth mean vorticity =  $\left( \frac{\partial U}{\partial y} - \frac{\partial V}{\partial x} \right)$

The various terms of Eq. (5) refer to:- (1) the time rate of change of vorticity, (2) advection of vorticity, (3) convergence or divergence of vorticity by the mean flow, (4) effects of bottom friction, and (5) moments of the lateral stresses about a vertical axis.

If a conventional control volume approach is adopted in analysing this equation, it can be shown that the generation of vorticity (or secondary circulation) is only affected by terms (3), (4) and (5) - see Flokstra (1977). Furthermore, the bottom friction term (4) can be shown to have a negative generation effect, i.e. it tends to dissipate any vorticity generated. Such an analysis therefore indicates that secondary circulation (or vorticity) in the lee of a headland, for example, can only be generated by:- (i) the advective terms (3), and (ii) the lateral shear stresses (5). Hence, in this study the representation and inclusion of the lateral shear stresses in the mathematical model is of considerable importance if secondary circulation is to be modelled with any degree of accuracy. In addition to the importance of the lateral shear stresses in recirculating flows, Kuipers and Vreugdenhil (1973) and Flokstra (1977) have shown that the use of a no-slip boundary condition at all solid boundaries is also important in generating vorticity in such flow fields.

*Formulation of Lateral Shear Stresses.*

Having established the importance of the lateral shear stresses in modelling secondary circulation, consideration was then given to formulating these terms as accurately as possible without the use of a multi-equation turbulence model, such as the  $k-\epsilon$  model. The disadvantages of using such refined turbulence models for tide induced secondary circulation are that:- (i) there is a lack of adequate tidal flow data for the empirical constants included in such models, and (ii) there is a significant increase in the computational effort required.

In adopting a simpler approach to the formulation of the lateral shear stresses, the turbulence in the mixing zone in the lee of the headland was first separated into its two components, namely:- (i) bed generated turbulence, and (ii) free shear generated turbulence arising between the main flow and the eddy as a result of relatively large horizontal velocity gradients. However, in the mixing region immediately downstream of the headland, free shear layer generated turbulence tends to dominate over bed generated turbulence and hence more emphasis has to be placed on this component.

In establishing a formulation for the free shear layer turbulence component, use has been made of some of the semi-empirical concepts and approaches developed from extensive experimental studies of the velocity field characteristics in wakes and jet flows. These investigations have been undertaken by a number of authors and are reviewed in Townsend (1956).

The pronounced horizontal velocity gradients occurring in the mixing region downstream of the headland have been approximated in the evaluation of the free shear layer stress components by assuming an observed universal velocity profile of the form given by Townsend (1956). Using the notation illustrated in Fig.3, this velocity profile can be simplified as outlined by Lean and Weare (1979) to give:-

$$U = \frac{U_1}{2} \left\{ 1 + \operatorname{erf} \left[ \frac{y}{x} \left( \frac{Rs}{2} \right)^{\frac{1}{2}} \right] \right\} \quad \dots\dots (6)$$

where  $U_1$  = free stream velocity and  $Rs$  = experimental constant  $\approx 288$ . In adopting an eddy viscosity approach, together with a Boussinesq representation of the shear stresses, observations suggest that a mean eddy viscosity can be applied across the shear layer, see Townsend (1956). In applying this approximation in the mixing layer, the resulting eddy viscosity can be shown to be of the following form:-

$$\epsilon_{\ell} \approx \frac{U_1 x}{2Rs} \quad \dots\dots (7)$$

where  $\epsilon_{\ell}$  = mean eddy viscosity across the mixing layer, and with the rate of spread of the mixing layer being assumed to be constant. In turn, it can be shown that the eddy viscosity, the length scale of turbulence and the width of the shear layer are all linearly dependent upon the longitudinal distance and independent of the lateral distance. Furthermore, although the eddy viscosity increases linearly with  $x$ , the maximum shear stress ( $\tau_{xy}$  at  $y = 0$ ) remains constant since the lateral

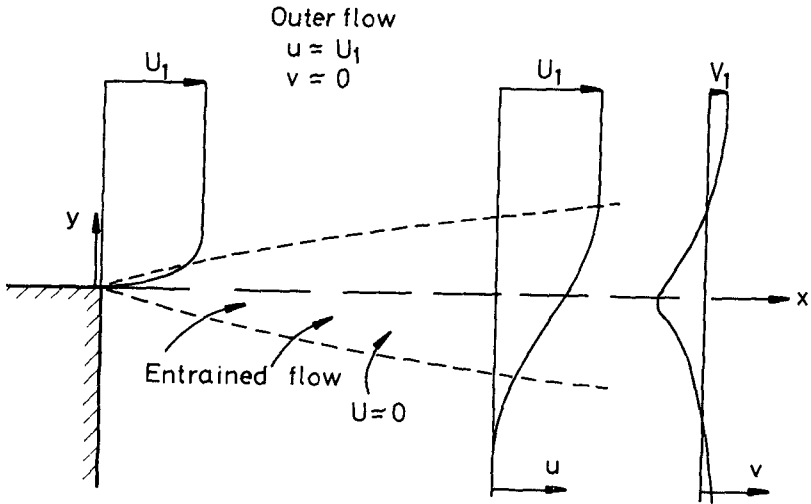

FIG.3 Typical velocity profile occurring in the mixing zone downstream of a headland.

FIG.4 Non-uniform grid spacing around headland for more accurate boundary representation.

velocity gradient  $\frac{\partial U}{\partial y}$  decreases linearly with x (see Lean and Weare (1979)) that is:-

$$\tau_{xy_{max}} = \rho \epsilon_b \frac{\partial U}{\partial y} = \rho \frac{U_1^2}{2} \frac{1}{\sqrt{2\pi R_s}} \approx 0.012 \rho U_1^2 \quad \dots (8)$$

For the bed generated component of turbulence, the vertical velocity profile can be approximated to a logarithmic form - for the purpose of closure of the momentum equations - with the result that the spatially varying eddy viscosity follows the well documented form, as reviewed by Fischer (1973):-

$$\epsilon_b \approx 0.16 U_* H \quad \dots (9)$$

where  $\epsilon_b$  = bed generated eddy viscosity and  $U_*$  = shear velocity =  $\sqrt{gU_s/C}$  - where  $U_s$  is the fluid speed.

In comparing the rate of production of turbulence in the mixing layer with that of the bed, Lean and Weare (1979) have shown that the bed generated turbulence becomes re-established in the mixing layer<sup>2</sup> when:-

$$\frac{x}{H} > \frac{2}{\pi} \frac{C^2}{g} \quad \dots (10)$$

Hence, combining both free shear layer and bed generated turbulence in the momentum equations, the resulting lateral shear stress representation used in the mathematical model can be summarised as follows:-

$$\tau_{xy} = \rho \epsilon \frac{\partial U}{\partial y} = \rho \left\{ \frac{U_1 x}{2R_s} + \frac{0.16 \sqrt{g} U_s}{C} \right\} \frac{\partial U}{\partial y} \quad \dots (11)$$

with the shear stress beyond the mixing layer, i.e.  $x > 2C^2H/(\pi g)$ , being defined simply by bed generated turbulence as:-

$$\tau_{xy} = \rho \left[ \frac{0.16 \sqrt{g} U_s}{C} \right] \frac{\partial U}{\partial y} \quad \dots (12)$$

The boundaries of the mixing layer in the lateral plane were obtained from equation (6), which was assumed to apply within the limits:-

$$0.05 U_1 < U < 0.95 U_1 \quad \dots (13)$$

and with shear generated turbulence again being equated to zero outside these bounds.

NUMERICAL SPECIFICATIONS

*Finite Difference Representations*

The finite difference equations corresponding to the governing differential equations were expressed in an alternating direction implicit form, with all terms being fully centred in time and space - except for the second derivatives of the velocity components immediately adjacent to the island boundary. The non-linear advective acceler-

ations and the second derivatives associated with the lateral shear stresses were time centred by iteration. The second order scheme, with accuracy  $O(\Delta t^2, \Delta x^2)$ , involved discrete values of the variables being represented using a space staggered grid scheme, in which water elevations and velocity components were described at different grid locations.

The only terms requiring special mention are the advective accelerations expressing the lateral transport of momentum in the x and y directions of the momentum equations, i.e. the UV product components of the advective accelerations in equations (2) and (3). These terms were represented in the finite difference scheme using the marker and cell technique, in that the spatial location of the velocity component in the direction of motion under consideration was governed by the direction of the perpendicular velocity component, see Williams and Holmes (1974). This representation was similar to that of upwind differencing and had the advantage that:- (i) the corresponding momentum flux was evaluated nearer to the position where it originated and (ii) no grid scale oscillations were apparent since this scheme included sufficient damping to counteract the occurrence of such oscillations.

In view of the significance of the headland shape on the characteristics of the downstream velocity field, the finite difference representation was refined immediately adjacent to the headland so that the island geometry could be represented as accurately as possible. Hence, instead of using a uniform grid space representation across the whole computational field, the first and second derivatives were adjusted, where necessary, within the grid squares around the headland so that the actual boundary location was defined in the model. An example of the boundary representation for the headland is illustrated in Fig.4, with the corresponding first and second derivatives in the y direction at point O being defined as (see Smith (1978)):-

$$\left. \frac{\partial U}{\partial y} \right|_O = \frac{1}{\Delta x} \left[ \frac{1}{\theta_1(1+\theta_1)} U_A - \frac{(1-\theta_1)}{\theta_1} U_O - \frac{\theta_1}{(1+\theta_1)} U_3 \right] \dots \quad (14)$$

$$\left. \frac{\partial^2 U}{\partial y^2} \right|_O = \frac{1}{\Delta x^2} \left[ \frac{2}{\theta_1(1+\theta_1)} U_A + \frac{2}{(1+\theta_1)} U_3 - \frac{2U_O}{\theta_1} \right] \dots \quad (15)$$

where the subscripts refer to the notation given in Fig.4. The resulting equations have leading errors of  $O(\Delta x^2)$  and  $O(\Delta x)$  respectively, and can be simplified for a no-slip boundary requirement since  $U_A = 0$  for the example given. Tests were undertaken on the application and comparability of this scheme with a regular grid representation for a one-dimensional flat bottomed estuary having similar dimensions and hydrodynamic boundary conditions as for the present study. The numerically predicted water elevations and velocities at the estuary head agreed to within a few percent for the irregular and regular grids, and compared favourably with the analytical results for linear waves (see Ippen (1966)) and the semi-analytical results for non-linear waves (see Proudman (1957)) - which included the effects of the advective accelerations and bottom friction. Hence, no marked numerical diffusion was expected to occur near the headland as a result of using such a

representation, and non-linear instabilities were not encountered in any of the subsequent simulations incorporating Eqs. (14) and (15) and similar representations for the other derivatives.

For the model simulations a mesh of 40 x 29 grid squares was used, with a grid spacing ( $\Delta x$ ) of 300m. At the centre of each grid square a representative depth between mean sea level and the bed was required, with the corresponding data being obtained from bathymetric charts provided by the Australian Institute of Marine Science. The resulting bathymetry used in the mathematical model can be seen in the isoparametric projection illustrated in Fig.5. Since no data was available concerning the characteristics of the bed roughness, all of the mathematical simulations were undertaken for an assumed Manning roughness coefficient of 0.025. This value of  $n$  appeared to be a reasonable choice based on Knight's (1981) measurements in the Conwy Estuary, where similar tidal ranges are experienced.

#### *Open Boundary Conditions*

The boundary conditions for the hydrodynamic model were taken from field measured water elevations and velocities recorded over a period of four tides. At the northernmost boundary water elevations were defined at 10 minute intervals using data recorded around the island perimeter, together with the inclusion of an approximate phase lag of  $L\sqrt{gH}$  - where  $L$  is the distance from the boundary to the island. Two representations of the lateral surface slope were considered in the simulations including:- (i) a horizontal water surface slope with  $\eta = f(t)$  only, or  $\partial\eta/\partial y = 0$ , and (ii) a surface slope governed by the Coriolis acceleration with  $\eta = f(y,t)$ . In both simulations the lateral velocity component along the boundary ( $V$ ) was assumed to be zero, which resulted in the latter and more accurate boundary representation being governed by the resulting form of the momentum equation (3), i.e.:-

$$\frac{\partial\eta}{\partial y} = -\frac{fU}{g} \quad \dots\dots (16)$$

On comparing the two simulations, the use of a horizontal surface slope gave unrealistic velocity field predictions, whereas from a purely observational viewpoint the second representation, i.e. Eq.(16), appeared to give realistic results.

At the western and eastern boundaries a free slip wall was assumed to exist, with only the lateral velocity component ( $V$ ) therefore being zero along the boundary walls. Finally, at the southernmost boundary velocities were defined, again at 10 minute intervals, from field measurements taken at site number 23, which was located as shown in Fig.2. The velocity along this boundary was assumed to be uni-directional, with the result that  $U = f(t)$  only and  $V = 0$ .

The open boundary water elevations and velocities required at every half timestep of 60 seconds were obtained by quadratic interpolation from the field data. The model simulations were always started from rest, i.e.  $U = V = 0$  everywhere, with the initial mean water elevation across the computational domain being coincident with the

Fig.5 Three-dimensional representation of the bathymetry around Rattray Island

elevation closest to the zero velocity condition obtained from field data.

#### NUMERICAL MODEL RESULTS

Although this study forms part of an on-going research programme on numerical modelling of secondary circulation around headlands, a number of model simulations have been undertaken to date which have allowed comparisons to be made with the field measurements and observations. In all of these simulations the same water elevation and velocity variations were applied at the open boundaries, with the model being run for up to 50 hours, i.e. almost four tides.

In the first of these simulations direct comparisons have been made between the field measured velocities at the current meter positions shown in Fig.2, and the numerically predicted velocities at the grid points closest to these meter positions. Synoptic current meter measurements at three different tidal phases are shown in Fig.6, with the corresponding numerical model predictions for the optimum island geometry being given in Fig.7. When the corresponding results of Figs. 6 and 7 are compared, it can be seen that the overall agreement between the predicted and the measured velocities and field observations is reasonably encouraging, with some distinct similarities. Firstly, the occurrence of the eddy in the lee of the island was first identified some 2 hours into the flood tide. This compared reasonably well with current measurements, in that Wolanski et al (1984) found that the current direction close to and in the lee of the island started to rotate clockwise after one hour into the flood tide. Further similarities between both sets of results were in the dimensions of the eddy, in that predictions and observations indicated that the eddy size was about the same width as the island and that the maximum length of the eddy was about twice the island width.

However, apart from these similarities, there were some important differences between both sets of results, with some of these differences forming the basis of current research in this field by the authors. The main difference between both sets of results was that the vortex strength of the eddy was noticeably less in the numerical model predictions. This was chiefly thought to be due to:- (i) the coarseness of the grid, which is presently being refined for future studies, and (ii) the reduction in size of the lateral shear stress gradient in the model as a consequence of using a finite difference representation for the velocity gradient in the mixing zone, i.e. Eq. (11) within the limits defined by Eq.(13), rather than the semi-empirical velocity gradient defined by Eq.(6). Secondly, the entrainment of the jet flow just downstream of the island tip, along the separation streamline, was found to be less marked in the numerical model - with this discrepancy also thought to be due to the previously mentioned inaccuracies. Finally, the centre of rotation of the eddy in the numerical model predictions was always observed to be too far west of the corresponding field measured and observed eddy centre. This discrepancy was thought to be due to inadequate consideration being given in the model to the flow conditions at the diametrically opposite island tip, where the influence of the separation phenomena on the downstream velocity field was known to be less pronounced.

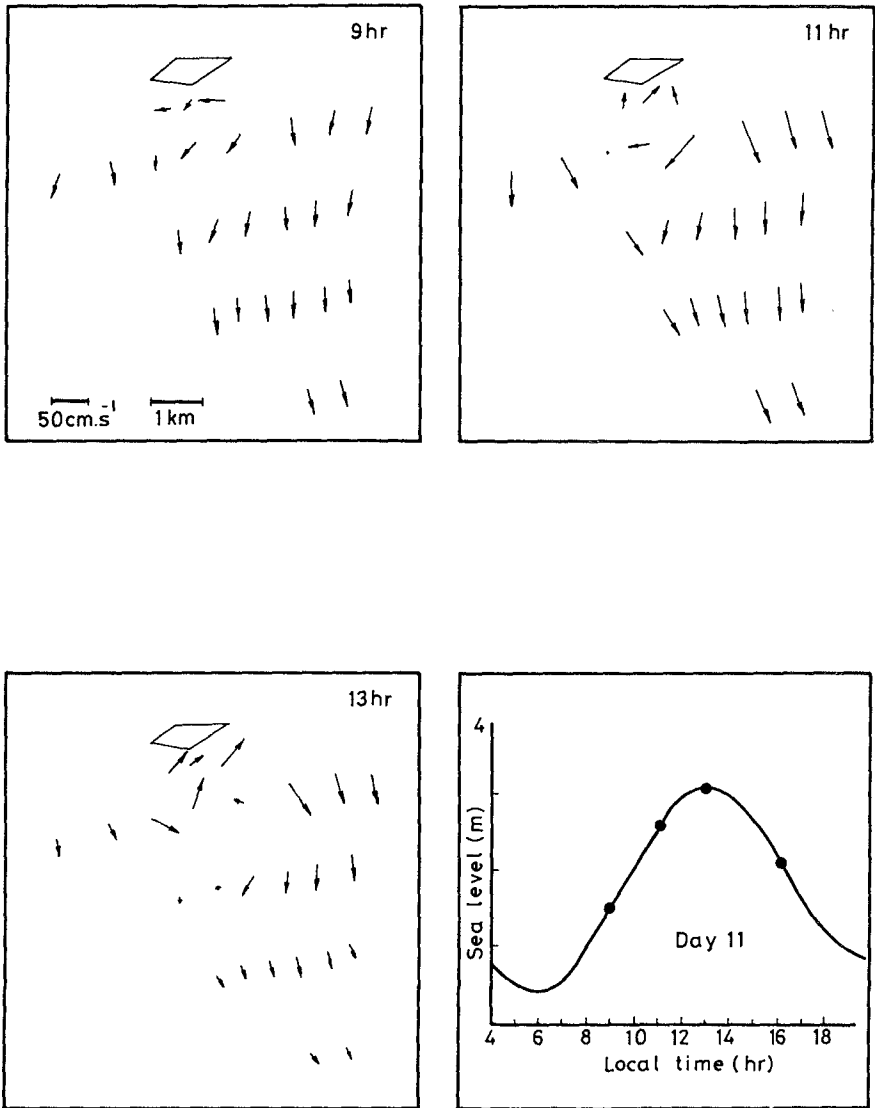

Fig.6 Field measured velocities at the measuring sites

Fig.7 Numerically predicted velocities near the measuring sites using a non-uniform grid around the island

Further similar tests and comparisons were undertaken for different grid representations of the island geometry, see Mardapitta-Hadjipandeli (1984). These tests included the adoption of:- (i) a regular square mesh, and (ii) impermeable thin plate walls for the island, although detailed comparisons with the results for the irregular mesh shown in Fig.7 indicated that the latter gave the closest similarity to the field measured results.

A series of tests were also undertaken to investigate the influence of the various terms of the equations of motion on the secondary circulation characteristics. These results were compared with the velocity field prediction for the whole computational field at 13.3 hours after the start of simulation, i.e. just after high tide, with the corresponding prediction being illustrated in Fig.8.

Although no field measurements have been taken in the northern lee of the island, comparisons were also made with the velocity field predictions at 18.5 hours, where the mathematical model results showed the existence of two well defined counter rotating eddies in the region, see Fig.9. The main results of this series of tests showed that no eddies occurred in either lee of the island when the advective accelerations and the lateral shear stresses were excluded from the model, see Fig.10, and that inclusion of the Coriolis term at the open boundary was essential for realistic velocity field predictions, see Mardapitta-Hadjipandeli (1984).

#### CONCLUSIONS

As part of an on-going research programme to develop a reliable mathematical model of secondary circulation in the lee of headlands, such a mathematical model is being developed and refined to predict the tide induced eddies, observed and measured in the field, around Ratray Island. The model includes a relatively simple zero-equation turbulence model, with particular emphasis being placed on the modelling of the free shear layer turbulence occurring in the mixing zone along the separation streamline - formed at the separation point at the island's most easterly tip. This component of the turbulence structure has been included in the model using an eddy viscosity approach, and a universal lateral velocity distribution, which is based on extensive field and experimental measurements for velocity fields in jet flows and wakes.

The numerical model predictions to-date have been compared with extensive field measurements and, although the agreement between both sets of results is reasonably encouraging, there are some important differences. These differences include:- (i) a weaker vortex strength, (ii) less entrainment into the mixing zone, and (iii) a difference in location of the centre of rotation of the eddy between the field measured and the numerically predicted results.

In addition to these comparisons, further tests have been undertaken to investigate the hydrodynamic phenomena being modelled. These tests showed that:- (i) exclusion of the Coriolis acceleration along the water level boundary gave unrealistic results, (ii) use of an irregular grid adjacent to the island gave improved results, with

MANNING NUMBER = 0.025  
TIDAL PERIOD = 12.6 HR

Fig.10 Numerically predicted velocities around Rattray Island at high water level excluding the advective accelerations

no indications of marked numerical diffusion, and (iii) no secondary circulation was predicted in the model when the advective accelerations and the lateral shear stresses were excluded. The latter conclusion from these tests confirmed the results of an analysis of the vorticity transport equation, where it was shown that the only terms generating vorticity in the model were the advective accelerations and the lateral shear stresses.

#### ACKNOWLEDGEMENTS

The model developments were undertaken at the Department of Civil Engineering, of the University of Birmingham, with the study being partially funded by a Science and Engineering Research Council research studentship.

This study in its present form would not have been possible without the use of extensive field data being made available by the Australian Institute of Marine Science, Queensland, Australia.

## CHAPTER ONE HUNDRED SIXTY THREE

### ACCURATE MODELLING OF TWO-DIMENSIONAL MASS TRANSPORT

Lance Bode<sup>1</sup> and Rodney J. Sobey<sup>2</sup>

Any numerical solution of the convective transport equation in an Eulerian framework will exhibit inherent numerical dispersion and solution oscillations. The magnitude of such numerical errors is often so severe as to destroy the value of many computed solutions. A successful and economical algorithm for the convective transport equation in one spatial dimension has been published recently by one of the authors (RJS), in which an exact solution is achieved by means of a moving coordinate system. The present study describes the extension of this work to the more important and challenging two-dimensional case.

#### INTRODUCTION

Numerical methods for the solution of the two-dimensional convection-dispersion or advective-diffusion equation (ADE) abound in the literature of fluid dynamics. In Cartesian coordinates  $(x,y)$  the ADE has the form:

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} = \nu \left( \frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial y^2} \right), \quad (1)$$

where  $C(x,y,t)$  is the field of the substance that is re-distributed passively by the velocity field  $(u,v)$ ,  $t$  is time and  $\nu$  is the diffusion coefficient. The equation may also contain source and reaction terms.

The attention given to ADE is a measure both of its importance and ubiquity. Physically, an initial distribution  $C(x,y) = C(x,y,0)$  is given and the solution describes the field of  $C$  at any subsequent time over the solution domain, under the dual influences of advection and diffusion. In many instances, and certainly in estuarine and coastal environments, Eq. (1) is advection-dominated, and diffusive effects are minor. To a first approximation,  $\nu$  can be ignored the problem reverts to passive scalar advection.

- 
1. Research Fellow, Department of Civil and Systems Engineering, James Cook University of North Queensland, Townsville, Q. 4811, AUSTRALIA.
  2. Associate Professor, Department of Civil Engineering, 412 O'Brien Hall, University of California, Berkeley, CA 94720, USA.

More importantly however, it is the advective rather than the diffusive terms in Eq. (1) that present numerical problems. Indeed, considerable attention continues to be devoted to the *one-dimensional* ADE (6,7,12,14,15), a sure indicator of dissatisfaction with the current 'state-of-the-art'. The reasons for this are well known, but often ignored. Most solutions of Eq. (1) are Eulerian, in that they use a fixed computational grid. As pointed out by Penton (6), solutions such as conventional finite difference or finite element schemes attempt to solve the equation, with no attempt to take account, let alone advantage, of the nature of the solution. In problems dominated by advection, the performance of Eulerian solutions is often most unsatisfactory. With many such schemes, numerical dispersion and solution oscillations completely degrade the value of the computed solution.

In view of the above, a satisfactory solution of the two-dimensional problem remains to be demonstrated. A successful and economical algorithm for the one-dimensional ADE has been presented recently by Sobey (15,16), in which an exact solution is achieved by means of a moving coordinate system. The present scheme is an extension of this Lagrangian scheme to two spatial dimensions. The primary aim in such an algorithm is to permit the accurate calculation of mass transport (biota, pollutants) in continental shelf waters. In such cases, the velocity field (u,v) that is applied to Eq. (1) would be provided by a conventional two-dimensional hydrodynamic model.

GOVERNING EQUATIONS

Setting  $v = 0$  in Eq. (1) gives the advection equation:

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} = 0 \quad (2)$$

As the prototype problem, Eq. (2) is to be solved on a square,  $-1 \leq (x,y) \leq 1$ , for  $t > 0$  where the initial field of C is a cone of unit height, radius  $r_0$  and initial location  $(x_0, y_0)$  - by convention (10,18) these parameters are  $r_0 = 1/4$ ,  $x_0 = -1/2$  and  $y_0 = 0$ . The initial conditions are:

$$C(x,y,0) = C_0(x,y) = \begin{cases} 1 - r/r_0, & r < r_0 \\ 0, & r > r_0 \end{cases} \quad (3)$$

where  $r = [(x-x_0)^2 + (y-y_0)^2]^{1/2}$ .

On the boundaries of the square, C is set equal to zero. The velocity field is solid body (anti-clockwise) rotation about the origin:

$$u = -\Omega y, \quad v = +\Omega x \quad (4)$$

where  $\Omega$  is the angular velocity. Perspective and plan views of the initial conditions are shown in Fig. 1.

Fig. 1 (a) Perspective and (b) plan views of initial cone configuration.

In the absence of diffusion ( $\nu = 0$ ), the cone should return, undistorted, to its original position after any integral number of periods,  $nT = 2n\pi/\Omega$ ; elements of the cone describe concentric circles with constant angular velocity  $\Omega$ , about the origin. The range of  $C$  should always remain  $[0,1]$ . The rotating cone problem has become the basic prototype problem for two-dimensional advection, and has been used widely as a test bed for numerical algorithms (3,4,10,18). It is undoubtedly demanding, since any dispersion (phase speed errors) immediately truncate the peak of the cone, as will be seen in the following section. However, if such schemes are to be capable of mapping the evolution of point-like sources such as a pollution outfall, then the requirement of high fidelity at short wavelengths is absolutely essential.

#### Jacobian Formulation

For incompressible flow a stream function  $\psi$  can be defined in the conventional manner by

$$u = -\frac{\partial\psi}{\partial y}, \quad v = +\frac{\partial\psi}{\partial x} \quad (5)$$

This allows Eq. (2) to be expressed as

$$\frac{\partial C}{\partial t} + J(C, \psi) = 0 \quad (2')$$

where  $J$  is the usual two-dimensional Jacobian. In this form the equation can be expressed in a variety of ways so that certain quantities are conserved throughout the region of integration. Use of this has been made in particular for finite difference schemes beginning with the work of Arakawa (1), discussed in the following section.

EXISTING TECHNIQUES

Two finite difference (FD) schemes, representative of existing techniques for the solution of Eq. (2) are reviewed below. In order that an objective comparison of the performance and economy of the various schemes can be made with the proposed scheme, these two algorithms have been programmed and selected results are presented.

Arakawa/Jacobian scheme

The Jacobian formulation of Eq. (2') has been used widely to evaluate the advective terms in numerical weather prediction models as well as in a variety of other fluid dynamical applications. For homogeneous boundary conditions in the absence of dissipation, it can be shown that a number of quantities, averaged over the region of integration, must be conserved. For two-dimensional incompressible flow, if  $\zeta$  is vorticity, then  $\bar{\zeta}$ ,  $\overline{\zeta\psi}$  (kinetic energy) and  $\overline{\zeta^2}$  (enthalpy) must be conserved, where the overbar denotes the continuous spatial average. Arakawa (1) was able to show that certain aliasing interactions were minimised by particular second order FD formulations for the Jacobian, resulting in the global conservation of  $\bar{\zeta}$ ,  $\overline{\zeta\psi}$  and  $\overline{\zeta^2}$ .

The Jacobian, denoted here by J - see also Ref. (10) - conserves all three quantities. Numerical experiments showed that this formulation prevented instabilities that had caused numerical schemes to 'blow up' and the use of Arakawa Jacobians has become widespread. It is a relatively simple matter to extend this scheme to produce Jacobians that are fourth order accurate spatially. One such formulation (1,10) also conserves all three quantities, and will be referred to as  $J_4$ . Although the conservative properties of  $J_2$  and  $J_4$  apply over the entire region of integration, this does not necessarily hold locally, with the result that the undesirable numerical dispersion can still be severe, particularly at the important shorter wavelengths.

Two basic spatial grid spacings are used,  $\Delta s = 1/8$  and  $1/16$ . These result in uniform  $17 \times 17$  and  $33 \times 33$  square grids applied to the given area of integration. These are denoted as cases A and B respectively. Both second order ( $J_2$ ) and fourth order ( $J_4$ ) Arakawa Jacobians are used, resulting in four cases altogether - A2, A4, B2 and B4. Time stepping is via the conventional 'leapfrog' scheme with periodic averaging to overcome time-splitting and appropriate re-initialisation. Thus, Eq. (2') is integrated by:

$$C_{i,j}^{n+1} = C_{i,j}^{n-1} + 2\Delta t J_{i,j}^n, \tag{6}$$

where  $J_{i,j}^n$  is either  $J_2(C)_{i,j}^n$  or  $J_4(C)_{i,j}^n$ . Temporal accuracy is of order  $(\Delta t)^2$ . The usual stability criterion applies to limit the size of  $\Delta t$  to  $\Delta t < \Delta s/v_{\max} = \Delta s/(\Omega\sqrt{2})$ .

In Fig. 2 the progress of the cone as it rotates through one complete revolution is shown for case A2. In all cases, the perspective views are rotated back to the original position, with the centre at  $(-1/2, 0)$ ,

**Fig. 2** Perspective views of cone at intervals of a quarter rotation for case A2 - see Table I.

for ease of comparison. The defects inherent in such a scheme are immediately apparent. In Fig. 2(a) after a quarter rotation, a wake is observed behind the cone proper for which only the 0.2 and 0.4 contours remain, even at this early stage - the range of  $C$  is  $[-0.25, 0.54]$ . This trailing wake continues to grow at the expense of the cone. By the end of one period - Fig. 2(d) - the structure of the cone is effectively unrecognisable, with the range of  $C$  now being  $[-0.31, 0.30]$ .

For some improvement, equivalent results for case B2 at twice the spatial revolution are presented in Fig. 3. Although a clear improvement, this second-order scheme is still totally inadequate. Numerical dispersion is so severe that short wavelength detail, particularly the cone's peak, trails behind in a wake of ever-increasing extent. After one revolution the original range for  $C$  of  $[0, 1]$  has become  $[-0.23, 0.52]$ . In Fig. 4, the results for case B4 (fourth order Jacobian with  $\Delta s = 1/16$ ) are presented after one and two revolutions. The range of  $C$  at these two times is  $[-0.13, 0.83]$  and  $[-0.16, 0.77]$  respectively. The well-recognised improvement with higher spatial order schemes (4,8,10) is apparent, but these results remain considerably short of theoretical expectations.

The overall results of these computations are listed in Table I. This gives the cone parameters (maximum and minimum values of  $C$  and the coordinates of the maximum  $C$  value) for the various cases at time  $t = 2T$ . These results can, to a limited extent, be compared with the results of a number of studies of the rotating cone problem that have been collated by Christensen and Prahm (3). Unfortunately, there is little uniformity amongst these, especially with regard to the times at which results are obtained. The present discussion will concentrate on the results at  $t = 2T$  - c.f. Ref. (10).

Fig. 3 As for Fig. 2, but case B2.

Fig. 4 Perspective views at (a)  $t = T$  and (b)  $t = 2T$  for case B4.

Lax-Wendroff Schemes

Consider the one-dimensional advection problem  $\partial C/\partial t + u (\partial C/\partial x) = 0$ , with  $u$  a constant. The standard Lax-Wendroff (LW) scheme (13) arises if,  $C^0$  is expanded as a Taylor series in time and the advection equation is then used to replace  $C_t$  and higher time derivatives by spatial derivatives. These are then approximated by centred FD approximations. Specifically, the one-dimensional scheme is:

$$C_i^{n+1} = C_i^n - \frac{\mu}{2}(C_{i+1}^n - C_{i-1}^n) + \frac{1}{2}\mu^2(C_{i+1}^n - 2C_i^n + C_{i-1}^n) \quad (7)$$

The LW scheme is both dissipative and quite strongly dispersive at short wavelengths (9). An equivalent two step scheme has also been derived (7). One advantage of the two-step formulation is the ease of extension to two or more spatial dimensions, as well as to higher spatial accuracy, as detailed in Gadd (7,8). In the second paper, Gadd noted that the scheme in two dimensions was not unconditionally stable and introduced a further modification. Like the fourth order Arakawa scheme above, calculations revert to second order at grid points adjacent to the boundaries. The final scheme (8) was shown to have a superior performance for the rotating cone problem over the earlier version.

Selected results for this scheme (8) and the standard second order LW method are presented. The cases that have been calculated are denoted by C and D for grid spacings of  $\Delta s = 1/8$  and  $1/16$  respectively, followed by the numbers 2 or 4 corresponding respectively to standard second order LW or the (fourth order) modified Gadd scheme (8). In Fig. 5 the progress of the cone over one rotation is shown for case D2. The overall impression is that these results are very similar to those exhibited by the corresponding second order Arakawa Jacobian experiments above. Quantitative details are listed in Table I. Again, doubling of spatial resolution does afford some improvement, but overall performance is poor. For example, after one revolution the C range in case D2 is  $[-0.20, 0.49]$  versus  $[-0.23, 0.52]$  for the corresponding case B2. In Fig. 6, case D4 is shown after one and two revolutions, the range for C at  $t = 2T$  being  $[-0.07, 0.76]$ , compared with  $[-0.16, 0.77]$  for the corresponding Arakawa case B4. The Gadd scheme is distinctly faster computationally, with two rotations for D4 taking 168 s on a DEC 10-21 mainframe versus 286 s for B4 - see also Table II. The performance of the Gadd scheme (8) does appear superior, since the negative values of C are not as extreme as those in case B4. However, it can be shown from Fourier analysis (9), that this can be attributed to increased dissipation and not necessarily to reduced dispersion at the shorter wavelengths.

It is apparent from Figs. 2-6 and Table I that the major problem is dispersion, although increased spatial accuracy in the representation of the advective terms can go a long way towards improving this situation. The effects of time differencing errors and spatial resolution are much less important. This defect (dispersion) is common to all Eulerian schemes; it is widely recognised and has been commented upon extensively, often in quite scathing terms (6,11,17). In spite of this, such schemes continue to enjoy widespread usage.

Fig. 5 As for Fig. 2, but case D2.

Fig. 6 As for Fig. 4, but case D4.

Spectral Methods

The major problem with the above FD methods, and indeed with all low order polynomial-based Eulerian methods is their failure to resolve spatial structure, particularly in the calculation of first derivatives. The spectral methods introduced by Orszag (10) have, by and large, been able to overcome this problem. They involve the expansion of the C field spatially in a set of suitable basis functions, chosen in general to satisfy the boundary conditions. Initial work used complex

two-dimensional Fourier series for the rotating cone problem which required the boundary conditions to be spatially periodic. Computations are sped up significantly by the use of the Fast Fourier Transform. Simple calculations reveal how with spectral methods, all available points enter the computation of derivatives, resulting in schemes that are markedly more accurate than second or fourth order FD methods. A substantial body of literature has arisen from this pioneering work of Orszag - see the review of Orszag and Israeli (11). The extension to less restrictive boundary conditions than the original periodic case follows with the use of alternative basis functions, such as Chebyshev polynomials.

There is, however, a major problem with spectral methods:- their lack of flexibility. The major motivation behind the present work was stated in the Introduction to be the need for an accurate algorithm for Eq. (1) where the velocity field ( $u,v$ ) is provided by a two-dimensional hydrodynamic model. Often, the boundaries of such models are extremely irregular, since they follow the coastline. Neither Eulerian FD models nor the present Lagrangian scheme have any difficulty in coping with this problem. On the other hand spectral models are totally unable to handle this situation; indeed, they are crucially dependent upon a regular (usually rectangular) geometry. A further related constraint is the lack of flexibility with respect to imposed boundary conditions. Even with regular boundaries, there is no simple way by which spectral methods could cope with, say, time-dependent input of  $C$  at a given point on the boundary, meant to model, for example, a pollutant discharge. Accommodation of this situation by Eulerian FD methods is again straightforward and will be shown below to be the case for the present method. Overall, although it can be demonstrated that spectral methods provide superior performance over more commonly used Eulerian FD schemes, they can offer little in the way of general application to hydrodynamic modelling of two-dimensional mass transport.

TABLE I

ACCURACY OF THE VARIOUS NUMERICAL SCHEMES (at  $t = 2T$ )

Scheme	Description	Spatial Order	Grid Dimensions	$C_{max}$	$C_{min}$

## MOVING COORDINATE ALGORITHM

It is widely recognised (6,11) that Lagrangian or moving coordinate numerical schemes are the 'natural' method for the solution of the advection equation, Eq. (1). Nevertheless, it would seem that the advantages offered by the simplicity of Eulerian schemes have been allowed to overshadow their considerable disadvantages as highlighted in the previous section. Lagrangian schemes have been proposed only rarely (5), but such work does not appear to have been carried appreciably further.

Lagrangian Solutions of the Advection Equation

Eq. (1) is mathematically equivalent to:

$$\frac{dC}{dt} = 0 \quad (8)$$

along

$$\frac{dx}{dt} = u \quad , \quad \frac{dy}{dt} = v \quad . \quad (9)$$

This is the Lagrangian scheme that forms the basis of the present work. There are complicating factors involved in the use of a Lagrangian scheme and these will be described below, but they are often over-stated. The almost trivial simplicity of Eq. (8) demands further attention. It simply states the well known physical fact that values of C are conserved in time along trajectories or characteristics that are the paths of the fluid particles. The actual integration of Eq. (9) can be performed by any suitable algorithm for ordinary differential equations, once the velocity field is specified. Standard fourth order Runge-Kutta is chosen in the present study.

The basis of Lagrangian schemes is reviewed by Book and Boris (2). A number of disadvantages of such schemes are stated, chief among which is the distortion of an initially uniform grid by a non-uniform velocity field. In specific numerical computations, the flow and hence the grid might become so distorted that the 'bookkeeping' involved in keeping track of the positions of the individual nodes ultimately becomes intractable. However, this argument loses sight of the fact that the very distortion of the grid mirrors the gradients in the flow: it is in regions where either C or the flow varies rapidly that grid points must be concentrated in order to effect an accurate solution. Lagrangian schemes adapt to this situation naturally; Eulerian schemes are simply unable to do so and their consequent and often severe loss of fidelity as the Nyquist limit is approached, can hardly be unexpected.

Previous Lagrangian schemes appear to have concentrated on situations where flow variables altered rapidly. These include flows involving shocks and other large gradients in the flow, for which they are ideal theoretically, but apparently impractical because of mesh distortion. In the present case the proposal is to apply the scheme to mass

transport calculations in slowly varying velocity fields. In this case, the computational grid does not become unmanageably distorted. More importantly, however, the gradients of  $C$  can be preserved accurately and do not suffer from the artificial diffusion and solution oscillations associated with Eulerian schemes. It needs to be recognised that in order to solve Eq. (9) for each element of  $C$ , the velocity field needs to be specified at the actual location of each of these points. For the solid body rotation of the present problem, simple linear interpolation will accomplish this exactly. For slowly varying velocities a low order bivariate interpolation scheme should suffice. This contrasts with the situation for Eulerian schemes where, on a fixed grid, spatial derivatives of  $C$  cannot be calculated accurately by low order Taylor series, especially in regions of high gradients (6).

Another problem that has been associated with Lagrangian schemes, and which has been believed to be to their detriment is associated with inflow and outflow boundaries. At the latter, grid points must leave the computational region; at the former, they must be created. This is by no means an insurmountable obstacle and will be discussed below.

If the solution of the full ADE, Eq. (1) is required, then the question incorporating diffusion on a possibly distorted Lagrangian grid, that may be both gaining and losing mesh points, is obvious. A proposed treatment of this important extension of the present problem is also discussed below. All of the above questions (i.e. method of integration of Eq. (9); boundary conditions and the addition or removal of grid points; incorporation of the diffusion step) have been addressed by Sobey (15,16) in an algorithm for the solution of the one-dimensional ADE. The results of this work were most encouraging, in terms of the high accuracy attained, the relative computational efficiency and the inherent flexibility of the scheme, and suggest that the extension of this Lagrangian approach to the more important and challenging question of two-dimensional advection should be equally worthwhile.

#### Sample Computations

Eqs. (8,9) were solved for the rotating cone problem, with the same spatial resolutions employed for the tests of the two main Eulerian schemes above. The results of these computations for the  $17 \times 17$  grid after two full rotations are presented in Table I and in Fig. 7. The timestep used for these results was  $1/16$  of the period of rotation. This corresponds to a dimensionless timestep of 4.5, compared with 0.5 used for the above Eulerian schemes. The error, which can be measured by the maximum error in the position of the grid elements at  $t = 2T$  was negligible ( $5 \times 10^{-5}$ ). It should be recalled that the range of  $C$  is always  $[0,1]$  with this scheme. It can be reduced by reducing the specified timestep in the solution of Eq. (9), but this increases the CPU time and the present parameters would appear to be satisfactory. The actual CPU times for the various schemes are shown in Table II and the moving coordinate scheme undoubtedly compares favourably with the much less accurate Eulerian methods. Should, on the other hand, the timestep be increased, inaccuracy results inevitably. For example, a dimensionless timestep of 18.0 results in errors of order unity in the position of grid elements at the boundary of the computational region.

Fig. 7 Perspective view of cone at  $t = 2T$  with the moving coordinate algorithm, with  $\Delta s = 1/8$ .

TABLE II

CPU TIMES FOR VARIOUS INTEGRATION SCHEMES ( $t = 2T$ )

Numerical Scheme	Dimensionless Timestep, $\lambda$	CPU(s)
Arakawa 2nd order	0.5	22.6
Lax-Wendroff 2nd order	0.5	10.9
Arakawa 4th order	0.5	32.3
Gadd (LW) 4th order	0.5	18.3
Moving Coordinates	4.5	6.7

$\lambda = v_{\max} \Delta t / \Delta s$ , with all results for a spatial grid of  $\Delta s = 1/8$ .  
 All computations performed on a DEC 10-21 mainframe computer.

Boundary Conditions

The specification of boundary conditions is exactly analogous to the treatment used in the method of characteristics, and is detailed in Sobey (15). For the rotating cone problem,  $C$  is specified as zero along the boundary of the square computational region, but more general boundary conditions can just as easily be accommodated. Outflow boundaries present no problem. If over a given timestep an element of  $C$  is adjudged to have passed out of the computational region, that element is simply removed from further consideration. At inflow boundaries, additional grid points can be created by integration back along the characteristics, Eq. (9), to the particular inflow boundary (15).

### Extension to the Advection-Diffusion Equation

The essence of this extension is the method of fractional steps employed by Sobey (15) for the one-dimensional ADE. Eq. (1) is equivalent to the following pair of equations:

$$\frac{\partial C}{\partial t} + u' \frac{\partial C}{\partial x} + v' \frac{\partial C}{\partial y} = 0 \quad , \quad (10)$$

$$\frac{\partial C}{\partial t} = \nu' \left( \frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial y^2} \right) \quad (11)$$

Addition of Eqs. (10) and (11) gives Eq. (1), the two-dimensional ADE, provided  $(u', v', \nu') = 2(u, v, \nu)$ . Thus, the full ADE can be thought of as separate, but simultaneous advection and diffusion steps, but with twice the given velocity and diffusion. Numerically, it is simpler to take the two steps as sequential. The solution of C at  $n\Delta t$  is advanced to  $(n+1/2)\Delta t$  by the numerical solution of Eq. (10), the present Lagrangian scheme. The field of C at this intermediate step is then used to solve the diffusion (or heat) equation, Eq. (11).

Because of the Lagrangian solution of the advection equation, this second step necessitates the solution of the diffusion equation on a non-uniform grid. Sobey (16) has presented an optimised solution of this equation in one dimension. The results obtained were most satisfactory, but the extension of this method to two dimensions poses additional problems, and a more pragmatic but less sophisticated approach may be warranted. Although Eulerian schemes have been effectively rejected for the solution of the advective step, there is no reason to do so for the diffusive step. The solution of Eq. (11) by standard low order Taylor series approximations, either FD or FE methods, is satisfactory in this case. Further work is currently being pursued on this important aspect of the problem.

### CONCLUSIONS

The moving coordinate method introduced in the present paper has been shown to have much higher accuracy than is available from conventional and widely-used Eulerian schemes. It is simple in both concept and implementation, and, in addition, it can be interfaced easily with hydrodynamic models used to provide the velocity field.

Extensions to include the diffusive component of Eq. (1) have to take account of the necessarily distorted computational grid. This has already been effected successfully for the one-dimensional equation - Refs. (15,16) - and an analogous procedure for the two-dimensional case has been proposed. With the slowly-varying velocity fields (e.g. continental shelf circulation) for which the method is intended, the mesh will distort, but not unmanageably so. Strategies have also been discussed for the removal or addition of mesh points, should they become too sparse or concentrated. It should be recalled however, that such

distortion mirrors the background gradients and gives a Lagrangian scheme natural advantages over any Eulerian approach. Overall, the present approach is meant to provide the first but also most important step towards the development of accurate and reliable methods for the solution of ADE problems in actual physical environments. Advection-dominated flows are the rule rather than the exception, yet too often the veracity of available solutions would appear to be compromised by an inadequate appreciation of the limitations of available numerical methods. A successful solution of the problem, based on the above principles, provides a resolution of this impasse.

#### ACKNOWLEDGEMENTS

This work has been supported in part by the Marine Sciences and Technologies Grant Scheme of the Australian government. The assistance of Mr. Lou Mason in the preparation of graphical output is also appreciated.

#### Abstract

This paper discusses the need to incorporate a reliability analysis in the design procedures for rubble mound breakwaters. Such an analysis is defined and a suggested approach is outlined. Failure mechanisms are analysed and categorized in Damage Event Trees. The probability of failure is computed using a level III simulation method to include time and cumulative effects and to account for skewed probability distributions. Typical outputs of the computer program are shown and compared with results according to traditional design approaches. The paper concludes that there is a definite need to include reliability analysis in the design procedures for larger breakwaters and such an analysis must consider the accuracy of design parameters and methods.

#### 1. Introduction

The design of rubble mound breakwaters is traditionally based upon a combination of experience, engineering skill and hydraulic model studies. The criteria for design are based on a design load having a return period in the order of 50 to 100 years. Under such a design load, typically damage may occur to between 2% and 5% of the armour units. When site information is unreliable the design condition may be defined more conservatively by applying an appropriate safety factor (Figure 1). Even so, a certain risk of failure in the lifetime of the breakwater still exists.

 BY EXACT METHODS (LEVEL III)

Fig. 3 Reliability Analysis Higher Levels

However, the probability and extent of damage is not established solely by the actual wave height exceeding the design wave height. Both the strength of the structure and the imposed loads are influenced by a number of other variables, some of which are a function of time. This results in a typical representation of the breakwater strength 'R' and the applied load 'L' as given in Figure 2. Failure principally occurs when the load exceeds the strength:  $'R-L < 0'$ .

For a breakwater, 'R' and 'L' are functions of a large number of parameters. 'R' is described by parameters which include geotechnical properties, armour weight, density and shape, crest height and slope angle. The load 'L' is a function of parameters which include the offshore wave height, period, direction and refraction. All of these parameters are not precisely defined, but have certain variations due to inaccuracies in studies and measurements, construction constraints, quality of workmanship etc. Furthermore, environmental conditions, including the wave parameters, have significant stochastic characteristics.

A better assessment of the probability of a given degree of damage, then according to the traditional approach outlined above, can be achieved by using more sophisticated probabilistic methods presently available, see Figure 3. The Joint Committee on Structural Safety (Reference 6) has structured the various methods for reliability analysis. In this respect the traditional design approach can be defined as level I. References 1 and 7 describe the application of a level II approach for rubble mound breakwaters. However in the level II method the computations are carried out utilizing a linearisation of the failure function  $'F = R - L'$  and utilizing assumptions for the shape of the probability functions. Also the method does not take into account accumulation of damage in subsequent storms.

This paper discusses the application of a computer program which computes the probability of failure on level III using a time domain simulation approach. Therefore, in contrary to the level II approach, it includes arbitrary statistical distributions of all variables and the response of breakwater structures depending on previous history of damages.

## 2. Failure Mechanisms

With traditional methods as well as with probabilistic approaches, gross errors must be avoided. Such errors may occur due to the neglect of one or more of the possible failure modes. For design conditions well within the existing field of experience this might not be important, but it can be critical when the design concepts are stretched beyond existing experience. Recent failures of deepwater breakwaters have exhibited evidence of neglect of certain failure modes through breakage of armour units and geotechnical instability of slopes.

<u>EXTERNAL EVENTS</u>	<u>MINOR EVENTS</u>	<u>MAJOR EVENTS</u>	<u>FAILURE EVENTS</u>
WATER LEVEL	SCOUR OF FORESHORE	DAMAGE FRONT ARMOUR	SETTLEMENT SLIDING AND OVERTURNING OF CROWN WALL
WAVES	EROSION OF TOE FILTER	DAMAGE REAR ARMOUR	EROSION OF UNDERLAYERS AND CORE
CURRENTS	VENTING THRU BREAKWATER	SETTLEMENT OF CORE AND SUBSOIL	GRADUAL DETERIORATION OF MOUND
TSUNAMIS	INSTABLE FRONT BERM	SLIDING FAILURE OF SLOPES AND SUBSOIL	
EARTHQUAKE	WASHING OUT OF FINES	EROSION AND UPLIFT OF BACKFILL	
		BREAKAGE OF PARAPET WALL	

Table 1 Damage Events

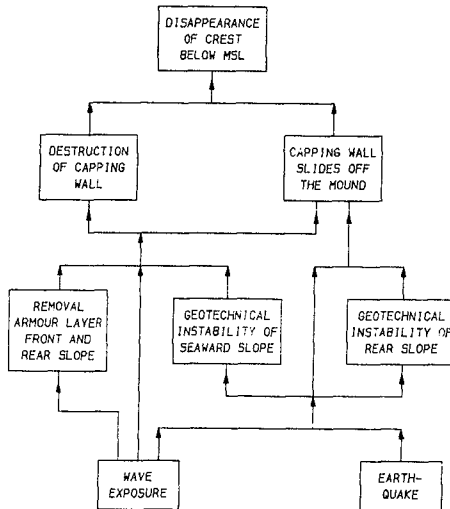

Fig. 4 Main Damage Event Tree

An important step in the probabilistic design method is to list all possible failure modes and to present the interrelation by use of a fault tree consisting of a number of successive or parallel events. Table 1 lists various damage events as they have occurred in failures of breakwaters. The relation between the various damage events is given in 'Damage Event Trees' as shown in Figures 4, 5 and 6. Figure 4 shows the main Damage Event Tree of a breakwater. Based on this, the Damage Event Tree is given for the geotechnical instability of the front slope (Figure 5). Figure 6 concentrates on the hydraulic damage of front and rear slopes.

Significant external loads on a breakwater structure are currents, waves, water level and seismic activities. These loads may cause events such as the hydraulic instability of front and rear armour, geotechnical instability of front and rear slopes, or the destruction or sliding of the capping wall either directly or as a consequence of damage to the slope. For each event the (partial) probability should be defined. Some events are independent whilst others are dependent. However, the total probability of failure of a breakwater is greater than the probability of a single event, for example, the hydraulic instability of the front armour layer only.

Considerations of the probability of failure lead to an important conclusion for the design of the components of a breakwater. If limited finance is available for reducing the overall failure probability, it should be invested in those components which show the largest reduction in overall failure probability for the given amount of money. Generally these comprise the relatively low-cost components to the breakwater which, however, may be vital to the stability of the structure. Examples of such components include filters and berms. The costs of safeguarding these components from failure are minor compared with the costs of achieving a similar increase in overall stability by improving major cost components such as armour or slopes. Hence, from the point of view of both risk analysis and cost, low-cost components may be designed such that the probability of their failure is negligible compared with the probability of failure of high cost items. This also simplifies the Damage Event Trees by virtually eliminating unknown factors and limiting consideration to failure mechanisms which can be quantified.

Figure 6 shows a simplified Damage Event Tree which indicates that, basically, only the problem of hydraulic instability of armour, due to waves, remains. Although not fully understood, hydraulic instability can be analyzed with reasonable accuracy using the results of hydraulic model tests in combination with a stability formula, as is shown in Section 4. The geotechnical response of the structure to external loads can be described by using methods as presented in Reference 2 and this paper does not consider this aspect further.

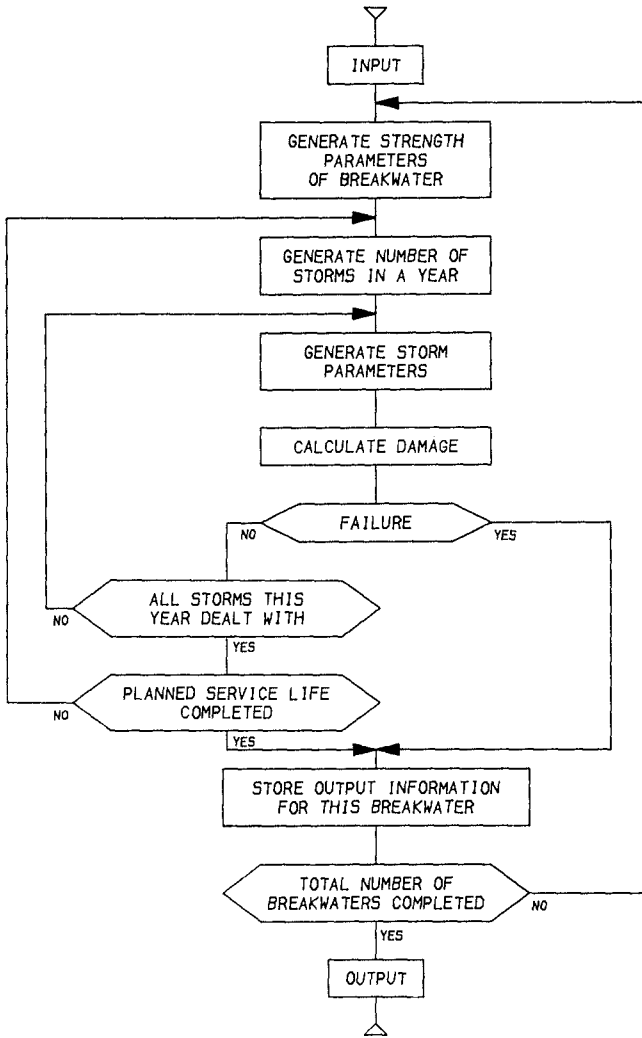

Fig. 7 Flow Diagram - Simulation Model

### 3. A Computermodel for Level III Reliability Analysis

As stated in References 1 and 7 considerable assumptions were necessary to compute the probability on failure. As a result the outcome is not very accurate, and is very limited.

A much more promising method is an approximatel level III approach based on a time domaine simulation of the service life of a large number of breakwaters from which the strength parameters are randomly generated from given statistical distributions. Figure 7 shows a flowchart of the computer program developed to handle this approach. Firstly the properties determining the strength of the breakwater are randomly selected from the given distributions, which can be of an arbitrary shape. Subsequently the impact of various generated storms is recorded over the service life of the breakwater with a range of options on accumulation of damage, historical effects and repair works. The program restarts by generating the properties of a new breakwater and subsequently recording the impact of newly generated storms, up to the required number of simulations.

The computational effort to obtain a reliable result strongly depends on the width of the statistical distributions. Checks on the accuracy are based on comparing the output of runs with various numbers of simulated breakwaters. It was found that for the presented case the computational effort was within acceptable limits.

The Software program can be expanded to include modules for geotechnical instability, (due, for example to wave action) and for seismic activity (generated independently according to given distributions); both simultaneous with the modules for hydraulic instability. In the following section a mathematical description is given of the relation between damage and input parameters for the hydraulic instability of the armour layer.

### 4. Mathematical Description and Quantification of Hydraulic Stability

In order to assess damage as a function of various input parameters, a mathematical description of hydraulic stability is required. This description is complex because it must take account of the load history, as exhibited by settlements of the armour and armour breakage. Although research on this subject continues, it is entering the stage of being used for engineering purposes (References 3, 4 and 9).

The damage function can be assessed using a combination of stability formulae (to include the effects of known parameters), and hydraulic model testing. Model tests help to assess the level of stability of the structure and verify the relationship between parameters, such as wave period, wave groupiness, the time history and the resulting

Fig. 8 Shape Factor

Fig. 9 Scatter Extreme Wave Heights

armour breakage. The graph shown in Figure 8 with damage along the 'y' axis and the Hudson Number 'Kd' along the 'x' axis illustrates. The Hudson Number is computed from the following equation:

$$Kd = \frac{\rho_c H^3}{W \left( \frac{\rho_c - \rho_w}{\rho_w} \right)^3 \cot \alpha}$$

with H = wave-height at the location  
of the breakwater without  
wave breaking  
 $\rho_c$  = density of concrete  
 $\rho_w$  = density of water  
W = armour weight  
 $\alpha$  = slope angle

The relationship in Figure 8 is shown as a function of the starting damage. Damage is expressed as the proportion of broken or displaced armour units related to the total number of units in the structure. Depending upon the sensitivity for wave parameters, tests should include the effect of spectral shape (peak period) and groupiness. Hence, extensive testing is required to provide the necessary input for the reliability analysis. The effects of small variations in input parameters, such as the weight and density of the armour unit and the slope angle, will produce damage of the order predicted by the stability formula. The wave-height excludes the effects of wave breakage (model testing will account for this phenomenon) but includes refraction, modelled numerically or physically.

For input into the model, the statistical distributions of the various parameters must be quantified. Table 2 gives a listing of the various parameters, the interrelation between the parameters, and the assumed modelling for the present study.

The estimated statistical distribution for parameters such as the armour weight is based on the allowable tolerances in the specifications and on the quality of supervision, specified measurement methods and expected quality of workmanship. Other parameters will depend on the quality and quantity of the studies carried out. For parameters describing environmental conditions, this factor for inaccuracy should be superimposed on the natural variation.

In the present study the joint probability distribution of wave-height, period, direction, groupiness and storm surge is equated to relations between the wave-height and other parameters. These other parameters are defined by a scatter parameter and the probability distribution of the wave height.

Particular emphasis should be laid on the scatter of the wave height distribution. Errors may occur due to:

- scatter and inaccuracies of the original data
- selection of probability function
- a considerable extrapolation outside the available period of observations

Table 2  
Listing of Parameters

<u>Parameter</u>	<u>Symbol</u>	<u>Relation</u>	<u>Modelling</u>
concrete density	$\rho_c$	independent	independent
density of water	$\rho_w$	"	"
slope angle	$\alpha$	"	"
armour weight	$W$	"	"
wave height offshore	$H_{so}$	} joint probability distribution of $H_{so}$ , $T$ , $s$ and $GF$	independent
storm surge	$s$		$s = F(H_{so})$
wave period	$T$		$T = F(H_{so})$
wave direction	$\phi$		independent
wave groupiness	$GF$		in model test
tide	$t$	independent	independent
refraction factor	$K_r$	depending on $\phi$ , $T$	$K_r = K_r(\phi, T)$
wave breaking	$K_b$	depending on $H, L,$ $T, s, t$	in model test
stability coefficient - damage relation	$K_d$	depending on $T, GF, s, K_r$	$K_d =$ $F(T, GF, s, t)$

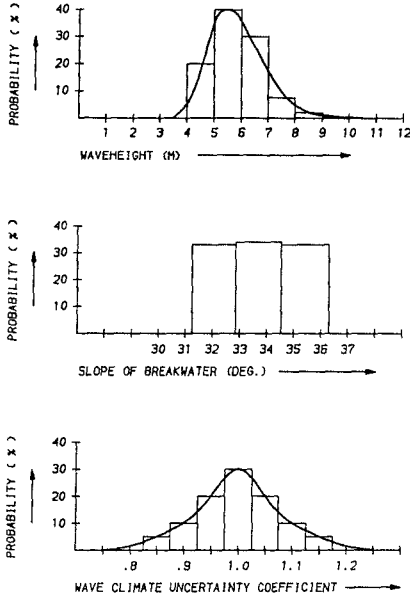

Fig. 10 Probability Density Functions

Fig. 11 Response of Structure to Wave Load

Fig. 12 Probability of Damage versus Time

Fig. 13 Probability of Repair versus Time

Fig. 14 Encounter Probability of Damage as Function of Service Life

This results in a large confidence band around the extrapolated function and gives standard deviations in the order of 10% to 15% of the average value, as shown in Figure 9 (References 5 and 8).

## 5. Application

An example of the application of the method as described above is shown in this section. It comprises a breakwater with a tetrapod armour layer of 25 tons. The wave climate is characterised by a 100 year return period wave-height of  $H_s = 8.5$  m.

Some examples of applied statistical distribution (wave-height, wave-height inaccuracy and slope distribution) are shown in Figure 10. The relationship between stability parameters and damage is assumed to be as in Figure 11. The concrete density is fixed on 2.43 T/m<sup>3</sup>.

Using the traditional level I approach, the design criterium was set at 3% damage in a 100 year event. Applying a 20% safety factor on the wave-height to include uncertainties, such as breakage of armour, the design wave-height is 10.2 m and, according to Figure 8, the criteria are satisfied.

The output of the level III simulation model is shown in Figures 12, 13 and 14. Figure 12 shows the number of breakwaters per year exceeding the 3% or 10% damage in a certain year of the lifetime. From this it can be seen that, although the traditional design approach suggests that the design criteria are satisfied, in closer reality many breakwaters (85%) will suffer more than 10% damage during a period of 50 years.

Figure 13 shows the number of breakwaters that would need to be repaired based on a 3% damage criteria after a given storm period. This shows that the probability of repair per year is 10%.

Figure 14 shows the encounter probability of damage in a certain service lifetime for a given level of damage. The design criterium based on a certain damage in an event with a 100 year return period results in an encounter probability of 39%. As shown in Figure 14 the encounter probability is much larger (99%). The damage belonging to the required encounter probability of 30% can be defined as severe.

In summary, it is essential that not only the wave-height but all parameters should be treated as statistical variables and that these variables must include the cumulative effects of damage.

## 6. Conclusions

The inaccuracy of the traditional design method is shown in establishing the real probability of damage. It is shown that a more reliable result can be achieved with the proposed level III approach, based on time domain simulation by utilizing a specially developed computer program.

The level selected for design and assessment of the failure probability is only reliable when all possible failure modes are included in the analysis. The neglect of an important mode will lead to an inadequate design. To avoid such errors the designer should be aware of causes and mechanisms of failures such as have occurred recently.

The proposed approach requires the designer to consider the accuracy of the various components of the study. This offers significant advantages over the traditional approach where the question of accuracy is not raised automatically. The proposed approach will further highlight those components where a large study effort is essential to minimize the risk of failure. Examples of these components are wave climate, wave refraction and structure response studies.

The reliability analysis also may lead to conclusions on the relative strengths of components of the breakwater. Components involving a relatively small financial investment can be designed with relatively high factors of safety and should not therefore have a significant contribution to the overall probability of failure.

In addition to variables in the design and in environmental conditions, further variables occur in the construction. Site conditions may impose variations between the design and the actual as-constructed structure. Also inconsistency in quality of the available material and inaccuracy of placement through available construction plant will inevitably play a certain role in the built-in safety of the final product. To what degree the variations will affect the overall quality is often difficult to conclude, in particular when such variation is sensitively related to the design assumptions. The proposed approach described herein will therefore prove to provide a very useful tool also for construction purposes.

## CHAPTER ONE HUNDRED SIXTY FIVE

### Rehabilitation Methods for Damaged Breakwaters

R.L. Croeneveld \*  
A. Mol \*  
E.H. Nieuwenhuys \*

#### Abstract

A number of studies have been undertaken recently to select optimum methods for rehabilitating damaged breakwaters in the Mediterranean and in the Atlantic Ocean. This paper outlines the approach to these studies and discusses the relative merits of the various concepts considered for repairing the damaged structures. Based on case studies of two projects, the paper also shows how the principle concepts have been successfully applied.

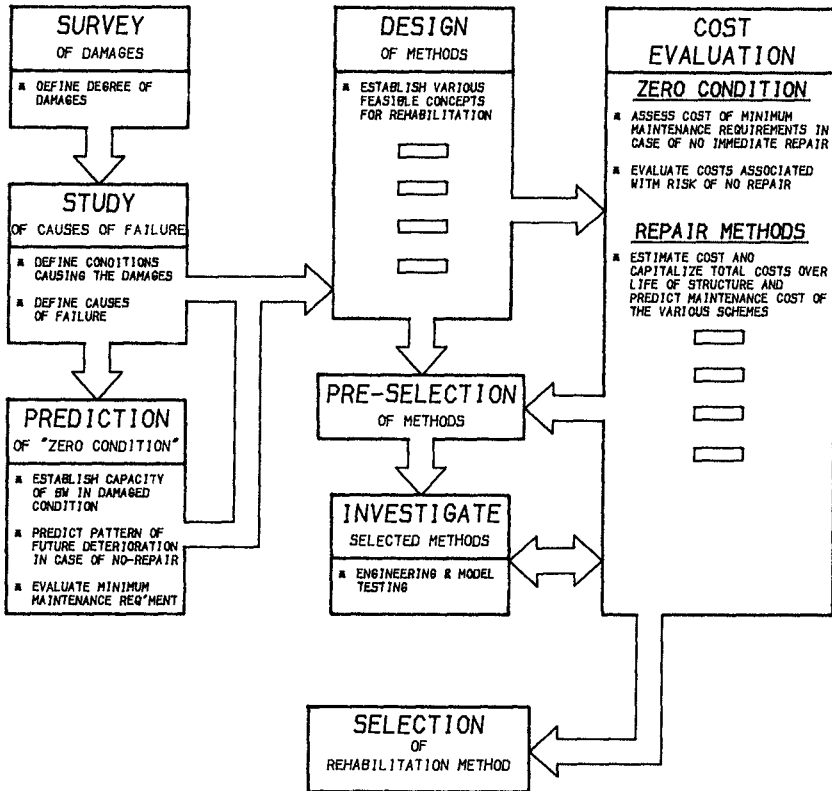

#### 1. Introduction

In recent years many deep-water breakwaters, protecting ports at exposed locations around the world, have exhibited damage to their armour systems or have in some cases suffered complete failure of whole sections. Studies have been carried out to define the causes of these failures and to select the most satisfactory method for rehabilitation in each case.

The optimum method for the rehabilitation of a breakwater depends on many factors which necessarily include:

- the cause of failure (inadequate design, unsatisfactory construction, or extreme environmental conditions)
- the degree and nature of the damage
- the geometry of the structure
- the local topography
- the availability of construction materials and equipment
- the acceptable level of risk to port operations or other facilities

FLOW DIAGRAM  
EVALUATION OF  
REHABILITATION METHODS  
FIGURE 1

- future requirements for port expansion or other construction works
- financial resources, cash-flow details and requirements on local and foreign elements of the rehabilitation costs

The basis for the evaluation of rehabilitation measures may be termed the "zero-condition" in which no immediate repair work is carried out. Under such a condition, the further deterioration of the breakwater is predicted and the likely additional financial burden, due to any associated restrictions in port operations or damage to other facilities, is assessed.

The general approach to a project study, in order to develop a satisfactory rehabilitation scheme, is shown in Figure 1. This indicates that the first step is to carry out a detailed survey of the historical damages to the breakwater. Wherever possible, this should be directly equated with the history of local environmental conditions. In addition, the causes of damage or failure should be determined as accurately as possible.

Together with the assessment of the "zero-condition", various feasible concepts for rehabilitation are developed, which provide possible permanent solutions. After a pre-selection the most attractive solutions are refined and optimized utilising laboratory model test studies.

The final selection of possible solutions and the "zero-condition" are then re-evaluated taking into account costs and all further relevant aspects including local availability of materials and plant and owner's cash flow policy.

This paper discusses this approach, for the study of any breakwater rehabilitation, in more detail and presents various concepts for repair. Examples of the application of the principle concepts outlined are shown, using case studies of projects along the Atlantic Coast.

## 2. Damage Survey and Causes of Failures

A detailed survey of a damaged breakwater is an essential element in establishing the cause or causes of the damage. The damage events are listed in Table 1. The external events which may be the direct causes of damage or failure of a breakwater are also listed.

Parallel with the breakwater survey the environmental conditions causing the damage have to be established using measurements, observations and, if necessary, hindcasting methods. In this respect, the severity of the event causing damage should be established as a matter of prime importance.

TABLE 1

DAMAGE EVENTS

<u>External Events</u>	<u>Minor Damages</u>	<u>Major Damages</u>	<u>Failure Damages</u>
Water level	Scour of Foreshore	Damage Front Armour	Settlement Sliding and Overturning of Crown Wall
Waves	Erosion of Toe Filter	Damage Rear Armour	
Currents	Venting thru Breakwater	Settlement of Core and Subsoil	Erosion of Underlayers and Core
Tsunamis	Instable Front Berm	Sliding Failure of Slopes and Subsoil	Gradual Deterioration of Mound
Earthquake	Washing Out of fines	Erosion and up-lift of backfill	
		Breakage of Parapet wall	

This study of the extent and causes of failure should also include the comprehensive collection of data on the design and construction stages. In this respect, major aspects to be investigated include:

- quality, extent and accuracy of the design studies
- possible neglect of any failure modes
- design parameters and safety factors
- differences between the design and the as-built condition of the breakwater

The damage or failure of a breakwater is frequently due to a combination of circumstances rather than to any single factor and it is important to identify as accurately as possible the precise causes of such damage of failure. If this is not done, there is a high inherent risk that further damage or failure will occur for the same unidentified reasons.

### 3. Study of the "Zero-Condition"

The severeness of a damage to a breakwater may be classified between two extreme conditions which are:

- a) damage of a nature which does not increase the risks of further damage/failure, and
- b) critical damage which places the breakwater at serious risk to further damage/failure.

Clearly, if the nature of any damage invokes a risk of complete failure, immediate measures will be required. In certain cases, however, the risk of further deterioration of a damaged breakwater may be small and the rate of further deterioration may be low. As an example of this, it is possible that a low percentage of armour units are found to be broken due to rocking and displacement. It is even possible that conditions exist which encourage further compaction of all units (so that they are less subject to rocking and displacement) whereby the broken units continue to be part of an integrated armour system. Under such conditions, the risks of further deterioration are diminishing.

A higher percentage of broken units may create serious weak spots in the armour. The broken units will not all be interlocked with the adjacent units and may be lifted. The secondary layer of armour will then be subjected to direct exposure. Such a condition will require repair, possibly by periodic replacement of broken armour units with new units.

The predictions of future damage can be verified through simulations by model tests, but it should be noted that many factors influencing the causes of failure are difficult or impossible to model. Most scale models are only concerned with the hydraulic behaviour of the armour and with immediate erosion problems. They do not address long term problems such as the loss of fine materials of the core material.

In order to establish the zero condition as a standard of comparison for other alternatives, an evaluation should be carried out in accordance with the following scope:

- define the damages
- investigate the causes of the damages
- evaluate the effect of the damage on the causes
- make a prediction of further damages in time
- estimate the risk of complete failure of the damaged area
- investigate the effect of the complete failure on the overall function of the breakwater with respect to port operations and safety
- evaluate the costs resulting from failure of part of the breakwater with respect to restrictions in port operations and damage to other port structures.

Relevant aspects to be taken into account in the comparison with other alternatives are:

- Owner's investment plan
- Project planning concerning port expansion or reconstruction work
- Availability of construction material and plant in the area

#### 4. Rehabilitation Methods

##### 4.1 General

The technical feasibility of methods of rehabilitation is related to the causes of the failures encountered and the extent of the damage. With respect to the extent of the damages, a classification is given in Table 2. This table shows a classification of damages resulting from hydraulic instability of the armour system.

The correlation between the percentage of displaced units and the description of damage given is based on average conditions.

TABLE 2

Classification of Damage	Percentage of Displaced Units	Description of Damage
(i) Minor	0 - 3%	A few individual units of top layer displaced, but no gaps in top layer larger than 4 units, bottom layer intact.
(ii) Moderate	3 - 5%	No gaps in top layer larger than 6 units, slight displacements of bottom units only
(iii) Major	5 - 30%	Top layer removed over large area, bottom layer over not more than 2 units.
(iv) Total	Over 30%	Armour and underlayers removed over large area, exposure of core material.

Typical concepts for repair (Methods 1 to 4) are set out below. Their application must be considered in the light of the causes of the damage or failure encountered. Figure 2 presents a diagram illustrating applications of each of these rehabilitation concepts. Each concept is related to the degree of damage and the magnitude of the external event (expressed in period of recurrence) which caused the damage.

Minor damage to a breakwater, is generally only noticed if the condition of the breakwater is regularly inspected. If damage is found, repair and strengthening measures may be necessary to avoid the risk of initiating a chain of events which leads to a major failure. If such a risk is not expected, it may be more economic to use the zero option and leave the damage unrepaired.

DAMAGE	RETURN PERIOD EXTERNAL EVENT		
	0-1 YR	10-25 YR	50-100 YR
MINOR	ZERO-CONDITION (0)		
	PROVIDE SHELTERING (4)	RESTORE ORIGINAL DESIGN (1)	
MAYOR	STRENGTHEN DAMAGED COMPONENTS (2)		
TOTAL	RECONSTRUCT RUBBLE MOUND (3)		

FIGURE 2

It is often difficult to strengthen individual components of a breakwater to avoid future minor damage. For example, repair is complicated if venting through the breakwater results in washing out of fine particles of the core material due to large permeability and insufficient filtering of the underlayers. In such cases the consequential risk of a major damage to the structure may be minimized by strengthening other components.

4.2 Repair by replacement of units (Method 1)

Damages classified under (i) and (ii) of Table 2 may be repaired by replacement of units of the same type and size, provided that such damage has been caused by events resembling the design conditions.

The feasibility of replacing the individual units should be considered case by case. Usually, if the units are of the interlocking type, the undamaged original units on the slope above the gap caused by the displaced damaged units, will need to be removed and replaced to provide adequate interlocking between individual elements.

Because the displaced units have most likely been removed from above or just below the water-line, the method of repair can in most cases be carried out with lifting equipment placed on the breakwater, provided that space is available. (Ref. Figure 3)

METHOD 1  
FIGURE 3

If the original units were too light, it may be possible to use reinforced units of the same type. This has the advantage that the units will be heavier and give better resistance against impacts due to initial movements and rocking. The amount of reinforcing steel may however be considerable and the solution may prove expensive. Moreover, the life of the reinforced units may be shortened by corrosion of the reinforcement when seawater seeps through cracks in the concrete. Compared with other possible repair methods, the use of steel reinforcement is seldom an attractive solution.

If heavier replacement units are preferred, a slight increase in dimensions can give a considerable increase in weight. It is likely however that this method will require continuous maintenance over a long period and will only be attractive if lifting cranes and labour are readily available when maintenance works are needed. The method can be economically attractive because:

- a) only those areas of the slopes and head of a breakwater, which are critically exposed, will be repaired and the areas where no damage occurs are left untouched
- b) the high direct investment costs are low and those costs required for the repair are spread over a long period

#### 4.3 Repair by replacement of Armour System (Method 2)

This method requires the replacement of the armour units by others of a different type and requires the removal of all original units. The method may be feasible if excessive maintenance to the original system is anticipated over the life of the structure, and capitalized costs of this maintenance exceed the cost of replacement. The underlying material should suit the new armour units and must be checked for layer thickness and compaction. It may be necessary also to place a new layer of secondary armour, in which case an adjustment of the slope may be considered. (Ref. Figure 4)

This method has been applied in cases in which the original choice of armour units proved to be inadequate. In particular this may occur, regarding the structural strength of units with a sophisticated interlocking form. The original units were possibly selected because similar but smaller units proved to be successful for breakwaters in shallower water with less wave action. However, the extrapolation to deepwater breakwaters often yields unsatisfactory results because the larger units have insufficient strength.

METHOD 2

FIGURE 4

#### 4.4 Repair by reconstruction of rubble mound (Method 3)

This method involves removal of the original armour and underlayers and placement of new layers after preparation of well-compacted core material and the placement of a suitable filter between core and armour material. (Ref. Figure 5)

METHOD 3

FIGURE 5

This ultimate solution may prove necessary to overcome serious problems such as:

- geotechnical instability e.g. slopes which are too steep in relation to the internal friction of the core, the underlayer material or the sub-soil.
- undue settlements of prime armour and crown due to the loss of core material through the armour system, caused by a lack of adequate filters, or erosion of sub-soil material near the toe of the breakwater because of a lack of sub-soil protection.

#### 4.5 Provision of sheltering against Critical Wave Condition (Method 4)

This method includes the following alternative solutions:

- a) Provision of an Underwater Berm attached to the Breakwater:

This underwater berm should be designed to reduce the energy of the waves, which may be critical to the stability of the slope. (Ref. Figure 6)

METHOD 4 , PROVIDE FOR SHELTERING

FIGURE 6

b) Provision of a Detached Underwater Breakwater:

In this case the additional structure reduces the wave conditions in front of the damaged breakwater to an acceptable level.

It is of interest to compare the merits of the above different methods in specific cases of breakwater projects. For this purpose, two case studies are discussed in this paper.

## 5. Case Studies

### 5.1 Case 1

This case study concerns a port along the Northern coast of Spain protected by two breakwaters.

The breakwaters are situated in waterdepths up to 20 m. The location is very exposed, in particular from north-westerly directions, but also from the North and occasionally from the East. Damage to the breakwaters occurred, however, under relatively quiet sea conditions. The first observations of damage were made soon after the completion of the construction of the breakwater. Damage was visually evident because armour units, which consist of 50 ton dolosse on slopes of 1:1.5 and 1:2, were broken.

Breakage of dolosse continued with time. Three years after the construction, over 3000 units were found broken, 17% of the total number of one breakwater and 25% of the total number on the other. In the areas with the greatest concentration of breakage the percentage was almost 50%. In addition, major cracks in the concrete crownwall of the South breakwater were found at several locations as a result of differential settlements.

EXISTING SECTION-N.B.

FIGURE 7

A study was undertaken covering an extensive scope including a re-evaluation of the wave climate at the particular location, site investigations, investigations of the causes of failure and evaluation of possible rehabilitation of the breakwaters.

Six alternative methods for rehabilitation of the North breakwater, of which the existing section is shown in Figure 7, were studied:

- (1) Removal of the existing 50 tons dolosse and replacement with a double layer of 90 ton concrete cubes placed at random. New rock armour underlayers would be placed. (Ref. Figure 8).

NEW SECTION N.B. - ALT.1  
FIGURE 8

- (2) Placement of a rock dike against the existing section and the voids between the dolosse would be filled with fine quarry run material or gravel whereby the existing dolosse would be left in place. Subsequently, new concrete armour similar to that considered for the first alternative would be placed over the rock dike at a slope of 1 to 2. (Ref. Figure 9).

NEW SECTION N.B. - ALT.2  
FIGURE 9

- (3) Installation of a berm at the toe of the breakwater to a level of about one third of the water depth whereby the dolosse would be left in place. New armour would be placed above the berm.
- (4) Installation of a wide berm attached to the breakwater as in alternative 3, but of sufficient size to absorb wave energy and thus reduce the energy acting on the slope of the breakwater. The dolosse would be left in place, except on the breakwater slope above the berm where the dolosse would be replaced by 60 ton solid cubes where necessary. (Ref. Figure 10).

NEW SECTION N.B. - ALT.4

FIGURE 10

- (5) Installation of an underwater breakwater in front of the existing breakwater at a distance sufficient to break up the waves before they reach the existing breakwater, which in principle remains unrepaired. The underwater breakwater would be designed such that the energy of the broken waves or, if unbroken, smaller waves would not cause further damage to the existing breakwater.
- (6) This alternative is the same as the alternative 5 with the exception that the underwater breakwater would consist of a series of concrete caissons in lieu of a rubble mound structure. (Ref. Figure 11)

NEW SECTION N.B.-ALT.6

FIGURE 11

The relative costs of the various alternatives compared to the most conventional type of repair defined in Alternative 1, are 140, 165, 65, 105 and 200 percent for the alternatives 2 thru' 6 respectively. These cost indications are given for a random section of the breakwater in deeper water. The final solution for the whole of the breakwater can of course be a combination of various methods, whereby the overall costs can be optimized. Alternative 1 could be applied for the deep water section, while the dolosse removed from that deep water section could be used as berm material as per the Alternative 4 solution for those sections which are less exposed.

The cost of alternative 2, whereby the dolosse would be left in place, is relatively high despite the fact that removal is not required. An important contribution in the costs is the special provision for pumping gravel between the dolosse to ensure that the underlayer of the new armour and sublayers would be properly compacted with a porosity as required within the overall system.

The cost of the Alternative 6 is high but includes the cost for repair of the head of the breakwater in accordance with Alternative 1. This has been done because the underwater breakwater would not provide effective protection for the head.

For both economical and technical reasons, the scheme finally selected for the rehabilitation of the North breakwater was in accordance with Alternative 1. The risk of exposure of the underlayers during construction, when the existing armour is removed, has been accepted.

For the rehabilitation of the South Breakwater, of which the existing cross section is shown in Figure 12, the possibilities were limited because this breakwater needed rehabilitation of the armour as well as strengthening to achieve better geotechnical stability. The alternatives considered were:

EXISTING SECTION - S.B.

FIGURE 12

- 1) Removal of the dolosse and placement of filter material over the existing core material at a slope 1 to 2, placing of a new underlayer and the installation of solid block armour units in sizes varying from 50-90 ton. (See Figure 13)

NEW SECTION S.B. - ALT.1  
FIGURE 13

- 2) A second alternative similar to the first, but with all new material placed at a slope of 1 to 3. The prime armour of block units would then be smaller than in Alternative 1. Furthermore, a berm at the toe of the seaward slope of the breakwater would be placed to a level of -12.0 m at waterdepth up to -20.0 m. (Ref. Figure 14)

The cost of the second alternative was estimated to be about 50% higher than the cost of Alternative 1. The second alternative was therefore selected for implementation.

NEW SECTION S.B. - ALT.2  
FIGURE 14

## 5.2 Case 2

This concerns the West Breakwater of the port of Sines, Portugal, located at the Atlantic coast, which was severely damaged during two storms in the winter period of 1978-1979. Figure 15 shows the layout of the breakwater divided in three sections:

- the Section between berth 3 and the shore protected with dolosse (Figure 16)
- the Section between berths 2 and 3 previously repaired with new 90 ton Antifer type blocks (Figure 17)
- the outer portion, severely affected and at present unrepaired (Figure 18).

The history of the damage of the breakwater was extensively described in Reference 1. The study was commissioned to evaluate the

WEST BREAKWATER, SINES PORTUGAL

FIGURE 15

DOLOSSE SECTION

FIGURE 16

EMERGENCY REPAIR  
FIGURE 17

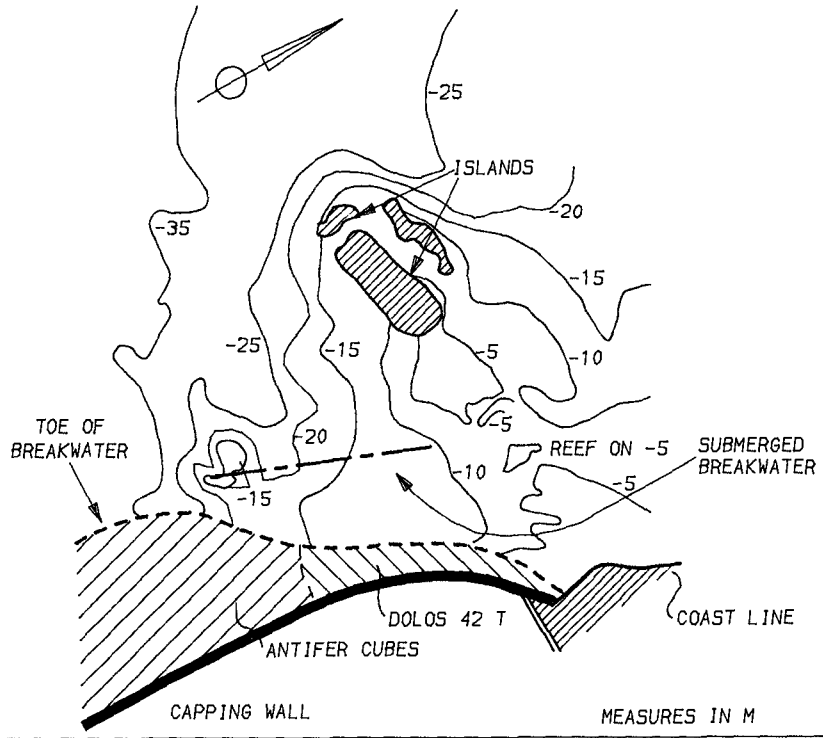

OUTER PORTION, PRESENT SITUATION  
FIGURE 18

earlier repaired sections, to propose mitigating measures if necessary, and to develop a rehabilitation method for the outer portion. Preliminary results were presented in Reference 2.

The conclusions of the study were as follows:

1. Close to the shore side of the breakwater the original section suffered hardly any damage. The repair should therefore be in accordance with Method 1 described above, and should be limited to replacement of new armour units where necessary. The units would then be of the same type as used in the original design.
2. The section armoured by dolosse, situated close to the previously repaired section, needed improvement. The most economic solution should involve closing the subsea trench south of the Perceveira Islands thereby eliminating the large waves which were penetrating through this trench from westerly directions. A plan and cross section are given in Figures 19 and 20.
3. The repair of the section between berths 2 and 3, where previous repairs had been made, should be in accordance with Method 2. The seaward slope should be modified by placing compact heavy cubes to a more gentle gradient.

ALIGNMENT SUBMERGED BREAKWATER IN FRONT OF DOLOSSE SECTION  
FIGURE 19

CROSS-SECTION IMPROVED DOLOSSE SECTION  
FIGURE 20

4. The outer portion of the breakwater should be rehabilitated by constructing a new rubble mound over the damaged structure (Figure 21).

In addition, with regard to the last part of the outer portion of the breakwater, a cost-benefit analysis is currently being carried out. Indications are that full reconstruction of this part is not justifiable at present. However, to provide the necessary protection of the port, the crest level of this part of the breakwater may have to be maintained on mean sea level.

REHABILITATION OUTER PORTION  
FIGURE 21

#### 6. Conclusive Remarks

- (1) Damage to a breakwater is often caused by a combination of events. Sufficient effort must be put into the rehabilitation study to recognise all causes so that the deficiencies of the breakwater can be correctly identified and satisfactory methods of rehabilitation can be selected.
- (2) To provide a basis for cost comparison of any rehabilitation method, the "zero-condition" excluding repairs should be studied. This study should include the predictions of further deterioration, the analysis of the costs associated with the risk of a partial failure of the breakwater and the long-term

maintenance requirements to minimize such risks. In some cases it can be justified, technically and economically, to postpone the repair work to suit the owner's requirements or to integrate it in the construction planning of new port facilities.

- (3) Simulation studies by physical or numerical models are an essential part of the overall study of a breakwater. Designers should be aware however of the limitations of such models. Overall conclusions must not be drawn from single model test results but from the interpretation of the study as a whole.

## CHAPTER ONE HUNDRED SIXTY SIX

### STABILITY OF BREAKWATERS WITH VARIATIONS IN CORE PERMEABILITY

G.W. Timco\*, E.P.D. Mansard\* and J. Ploeg\*

#### ABSTRACT

In setting-up a breakwater test in a laboratory flume, the conventional practice is to scale geometrically the armour units, under-layer rocks and core material based on the Froude scaling criteria. However, because some of the properties of the water are not scaled for a model test, the Reynolds scaling law is violated. This can result in improper water flow distribution through the model breakwater. To investigate this problem, a series of tests were performed with a model breakwater in which the permeability (and porosity) of the core was varied over a wide range, and the hydraulic response and breakage of the armour units were measured. It was found that the overall stability of the breakwater could be drastically affected if the flow in the core is scaled incorrectly.

#### 1.0 INTRODUCTION

Physical modelling of rubble-mound breakwaters is a common practice in many hydraulic laboratories. In order to model realistically these structures in a laboratory flume, there are several parameters which must be properly simulated since they can influence the test results. It has been shown, for example, that correct reproduction of the sea state must be made in both the time and frequency domain [6] and that the strength of the armour units must be properly simulated in the model regime [11] for the most reliable results. There are other factors, however, which to date have not been investigated, but which could influence the test results. In this paper, the effects on both the hydraulic and structural stability of a breakwater are investigated in terms of the permeability of the core material. This was done by comparing the response to the same storm conditions of a number of different breakwaters which were identical in all respects except for the permeability of the core.

#### 2.0 STATEMENT OF THE PROBLEM

In physical modelling, the forces involved in a specific interaction process are reduced but, by careful selection of the experimental arrangement, maintained in the same ratio as in the prototype. In this way, the interaction process can be investigated at reduced scale. This is highly desirable since model tests are much more economical to do than a corresponding full scale test, and it allows an examination of the process under controlled experimental conditions. For

\*Hydraulics Laboratory, National Research Council, Ottawa, Ont. K1A 0R6  
Canada

accurate results, however, it is important that all of the forces involved are scaled in the correct proportion. For model tests of rubble-mound breakwaters the forces of interest are gravity  $F_g = Mg = \rho g L^3$  where  $M$  is the mass,  $g$  is gravitational acceleration,  $\rho$  is the density and  $L$  is a linear dimension; the inertial forces  $F_i = Ma = \rho L^3 L t^{-2}$  where  $a$  is acceleration and  $t$  is time; and the viscous forces  $F_v = \mu p t^{-2} L^2$  where  $\mu$  is kinematic viscosity. The relationship between the gravitational and inertial forces is given by the Froude number ( $F_n$ )

$$F_n = \frac{v_p}{\sqrt{L_p g_p}} = \frac{v_m}{\sqrt{L_m g_m}} \quad (1)$$

where  $v$  is velocity and the subscripts  $m$  and  $p$  denote model and prototype respectively. Similarly, the relationship between the viscous forces and inertial forces is given by the Reynolds number ( $Re$ )

$$Re = \frac{L_p v_p}{\nu_p} = \frac{L_m v_m}{\nu_m} \quad (2)$$

To ensure total similitude in the model tests, both these numbers should be satisfied. This is virtually impossible to do unless a tank fluid can be found where (equating equations (1) and (2))  $\nu_p = \lambda^{3/2} \nu_m$  where  $\lambda$  is the linear scale factor of the model test. Since water is the normal working fluid in these tests, this is not accomplished and the viscous forces are not modelled correctly. For flow in the armour layer, it has recently been shown [4,9] that this is not a problem, even in tests with high scale factors. However, for flow in the filter layers and especially the core, this may not be the case due to the much smaller size of units and the correspondingly lower permeability of these regions. To test this is the purpose of the paper.

If the flow distribution in the core is not scaled correctly, this will influence the flow in the armour layer and consequently alter and distort the relative amount of wave energy dissipated in each of these regions. Because a breakwater dissipates the incident wave energy through rocking of the armour units and water turbulence within, the water flow and distribution should be the same in the model as in the prototype. If it is not, then the response of the armour units and energy dissipating processes are not properly reproduced in the model. This can affect the stability of the breakwater. This problem has been discussed by Yalin [12] who predicted that the restoring forces on the armour layer units will be scaled incorrectly and this could affect both the hydraulic and structural stability of the units. Burcharth [3] has suggested that this viscous effect will result in too high an internal water table within the breakwater. For the armour, this means that there will be a larger destabilizing pressure gradient and a reduction in the reservoir effect, thereby leading to larger overflow velocities.

### 3.0 EXPERIMENTAL APPROACH

The severity of this problem can be investigated using the physical modelling techniques which have been developed in this labora-

tory [8,10]. These techniques include: (1) the generation of realistic sea states in which both the variance spectral density and time domain characteristics of the wave field are correctly reproduced in the flume; (2) the use of a material to make the armour units in which the mechanical properties of concrete are scaled correctly for the model test (i.e. the strength of the armour units is scaled correctly based on the modelling laws). This material is a mixture of plaster-of-Paris, sand, iron ore and water. By varying the ratio of plaster to sand, the flexural (tensile) strength of the material can be altered over a wide range of interest ( $40 \geq \lambda \geq 15$ ); whereas by properly choosing the iron ore to sand ratio, the density of the material can be adjusted to that of concrete. Measurements of the mechanical properties of this material have shown that the flexural strength, density and fracture toughness are correctly scaled over a wide range of scale factors. The use of this material allows breakage of the armour units at realistic stress levels, thereby allowing an examination of the structural as well as hydraulic stability of the armour layer in the test; and (3) the use of a photographic technique which automatically takes pictures of the face of the breakwater with both a 16 mm movie camera at every wave trough and a 35 mm SLR camera at every 50 wave troughs. This gives a continuous record of the damage to the breakwater during a storm.

To investigate the influence of the permeability of the core, a very simple approach was taken as follows: A series of different model breakwaters of 0.9 m sections were built in a 1.8 m wide flume. In each case the slope and height of the breakwater, the size and type of the armour units, and primary and secondary underlayer stones were identical. The only difference was the permeability of the core. Each breakwater was subjected to identical storm conditions. After the storm, the damage to each breakwater was assessed in terms of both the number of armour units which either broke or had large displacements, and the amount of underlayer exposed. Since the breakwaters were identical in all respects except for the permeability of the core, any differences in their stability during storm conditions was attributed to differences in the viscous flow in the breakwater.

#### 4.0 TEST SET-UP

The tests were performed in a 1.8 m wide flume (see Figure 1) which was equipped with an hydraulically driven wave generator. The model breakwater was built with four individual layers comprising the core, primary and secondary underlayer and the armour layer. It was built with a 1:1.5 slope. In constructing the breakwater, the armour units were placed by hand in a random fashion with care being taken to ensure that it was of the same density and packing arrangement each time. For all of these tests, the armour layer consisted of dolos units of length 9 cm packed in two layers to a density of 330 units -  $m^{-2}$ . A cross-section profile of the model breakwater indicating the relative dimensions of each layer is shown in Figure 2. It should be noted that since the strength-simulated dolos units must be made individually, it was decided to limit the number of breakable units to 60 for each test. These were placed in a "nest" pattern centered about the mean water level in the centre of the model breakwater. The photographic equipment was set up to provide continuous documentation of the response of each breakwater to the storm conditions. After the storm, the flume was

FIGURE 1: WAVE FLUME WITH PROBE LOCATIONS

FIGURE 2: CROSS-SECTION PROFILE OF MODEL BREAKWATER

drained and the damage was assessed in terms of the number of broken and displaced armour units.

To alter the permeability of the core, three different core arrangements were used. To represent a very open core, the core was constructed from relatively large angular stones (diameter range from 3 to 6 cm). This was very porous with high permeability and an average Reynolds number of  $6 \times 10^3$ . To represent a more restrictive core, the core was constructed from much smaller angular stones (diameter range from 0.2 to 2 cm) with a correspondingly lower permeability and an average Reynolds number of  $1 \times 10^3$ . A core of this type is used in this laboratory in many tests of rubble-mound breakwaters since it is based on Froude geometric scaling of typical prototype cores. To represent a closed, restrictive core, a thin sheet of polyethylene plastic was inserted at the top of the core at the interface between the core and the secondary underlayer. This prevented flow within the core. In this case, all wave energy dissipated within the breakwater occurred in the armour layer and primary and secondary underlayer. This is the extreme case which represents zero permeability with a corresponding Reynolds number of zero for the core. These three cases were chosen simply to cover as wide a range of core permeabilities as possible. They are not meant to represent any particular prototype situation. This approach of looking at the response to a wide range of core permeabilities was taken since information on the permeability of prototype cores is scarce. Because of this, it is not possible at this time to know what the permeability, pressure and flow distribution should be within the core for a model test. In the present case, the permeability of the core is simply altered over as wide a range as possible in an attempt to determine the sensitivity to the core permeability of the overall stability of the breakwater.

In setting up the experiment, it was necessary to choose a suitable scale factor ( $\lambda$ ) for the test. When using the strength-reduced armour units, it is possible to scale the strength of the units over a wide range of scale factors (15 to 40). Based on the size of the armour units (285 gm dolos units), this would correspond to prototype dolos weights of 1 to 18 tonnes. Since it is known that there is a "size-effect" with concrete armour units such that the larger units will fracture much more readily than the smaller units for the same relative amount of movement [2], and since the problem of incorrect viscous flow becomes more severe with increasing scale factor, a test at any single scale factor produces limited information. Because of this, it was decided to perform the test series for scale factors at both  $\lambda = 15$  and  $\lambda = 40$ . These values bracket the range of scale factors which are typically used for model investigations of rubble-mound breakwaters. The first series was performed with the low scale factor ( $\lambda = 15$ ) since it is known that if there is a difference seen in these tests, it will be much worse at higher scale factors.

In order to test their relative stability, it is important that the storm conditions be identical for each test. This is accomplished since the flume is equipped with a hydraulically driven irregular wave generator which is controlled by an on-line computer. This wave generator can produce a variety of natural sea states and wave transients in the flume. Figure 3 shows the time and frequency characteris-

FIGURE 3: WAVE CHARACTERISTICS FOR THE TESTS

tics of the wave conditions generated for each of the test series. The reflection of the waves off of the breakwater was measured using an array of five gauges (see Figure 1) by the least squares method developed by Mansard and Funke [7]. The Smoothed Instantaneous Wave Energy History (SIWEH) which is shown in Figure 2 is used to determine the amount of wave grouping in the wave train [5]. Since the wave board in the flume is controlled by an on-line computer, these wave conditions could be stored and generated in each of the test series. In all tests, the storm conditions were run for 45 minutes.

## 5.0 RESULTS

The results of the tests for series I and II are tabulated in Tables I and II respectively. These tables list the information on the set-up for each test, as well as the damage sustained by the breakwater due to the storm. Note that the reflection coefficient (R) of the primary spectrum ( $R = \sqrt{E_R/E_I}$  where  $E_R$  and  $E_I$  are the total energies of the reflected and incident spectra respectively) was similar for all three types of core. This indicates that, regardless of the type of core, the overall energy transmitted into or dissipated at the front face of the breakwater was always the same (91-93% of the total incident energy) within experimental accuracy.

For test series I at  $\lambda = 15$  representing one ton dolosse, both the regular core and open core had very little damage done to the armour layer due to the storm. There were relatively few broken units or large scale displacements of the dolosse. There was virtually no difference in response between these two cases at this scale factor. For the case of the impermeable core, on the other hand, the response of the breakwater and amount of damage was quite different. In this case there was considerable rocking, displacement and breakage of the units. The destruction was so severe that in several places the underlayer was exposed since a considerable number of dolos units rolled off the face of the breakwater to the toe. This can be seen in Figure 4. During the storm, the whole face of the breakwater was almost continually under water since it took considerably longer for the water to drain off the breakwater than in the other two cases. In many instances for the impermeable core, the water from one wave would still be on the face of the breakwater when the next wave would hit. This caused a constant state of agitation of the dolos armour units. In observing the tests, it was evident that the response of the armour units to improper viscous flow was in agreement with the predictions by Yalin [12] and Burcharth [3] as discussed earlier. The complete hydraulic and structural stability of the armour layer was drastically influenced due to the improper viscous flow in the core.

For test series II at  $\lambda = 40$  representing 18 ton dolosse, the test with the impermeable core was not repeated. Since there was extensive damage for this case at the lower scale factor, there would be considerable damage for any similar test at a higher scale factor representing larger dolosse. For the open and regular core at the low scale factor, there was no difference in response between these two cases. Since the problem of improper viscous flow should become more severe with increasing scale factor, these two cases were repeated at the higher scale factor of  $\lambda = 40$ . At this scale factor, there was a signi-

ificant difference in the response of the breakwaters. As summarized in Table II, there was considerably more damage to the breakwater built with the regular, less-porous core.

## 6.0 DISCUSSION

These tests clearly show two things. First, the permeability of the core has a very definite effect on the overall stability of a rubble-mound breakwater. The core clearly plays an important role in the overall energy dissipating process of the breakwater. Secondly, for model testing of rubble-mound breakwaters, the influence of incorrect scaling of permeability is a function of the scale factor of the test such that it increases with increasing scale factor because of the size effect. Care must be taken to scale as nearly as possible this aspect of the breakwater for a model test. The generally accepted method of preventing viscous effects is to construct the breakwater such that the Reynolds number for the flow exceeds a certain value (typically  $10^3$  [12]). Recently Burcharth [3] has pointed out that this criterion is not satisfactory for two reasons. First of all, a single value of a Reynolds number cannot represent the complicated and unsteady flow which occurs in the prototype. Secondly, the permeability of prototype cores is very difficult to predict since the permeability is sensitive to small variations in grading and separation of the material when dumped. In general, the prototype flow field is poorly known.

In order to try to minimize this problem, more emphasis must be placed in examining the geotechnical stability of prototype breakwaters [1]. Correct scaling of this property can only be accomplished once tests of the permeability, flow and internal pressure in the prototype core are measured and understood. If this were done, correct viscous flow should be obtainable directly for model tests which use very large armour units. For those tests in which smaller armour units (i.e. high scale factor) are used, a solution may be to run an appropriate math model to determine the internal pressure field and, by adjusting the core permeability, calibrate the small-scale physical model to reproduce correctly the calculated internal pressure field [3]. This type of approach, although it is not ideal, should result in better model-prototype conformity.

The present tests have implications to the understanding of the behaviour and design of prototype breakwaters. First of all, the difference in the results clearly shows that the core plays an important role in the overall energy dissipating properties of a rubble-mound breakwater. Secondly, the tests show that the relative stability of the armour layer can be enhanced if the core is made more porous. If it were, it would assume a relatively higher percentage of the wave energy dissipated within the breakwater than a less porous core. This would decrease the amount of wave energy which would be dissipated in the armour layer and consequently make the armour layer more stable. Of course, this aspect would have to be incorporated into the design of the breakwater with due consideration to the geotechnical stability of the structure.

## 7.0 SUMMARY

Based on the results of the present tests, it is clear that incorrect viscous flow in the core can influence the hydraulic and structural stability of the breakwater. Care must be taken, therefore, to scale this viscous flow as correctly as possible. If this is done, model tests of the stability of rubble-mound breakwaters would be more reliable since they would then be relatively unbiased by viscous effects.

## 8.0 ACKNOWLEDGEMENTS

The authors would like to thank George Ashe for overseeing the construction of the breakwaters and for technical assistance during the tests, and to Rob Bowen for making the strength-reduced armour units.

## CHAPTER ONE HUNDRED SIXTY SEVEN

### PHOTOGRAMMETRIC MONITORING OF DOLOS STABILITY, MANASQUAN INLET, NEW JERSEY

Jeffrey A. Gebert<sup>1</sup> and James Clausner<sup>2</sup>

#### ABSTRACT

Photogrammetry has been applied as a technique to monitor the stability of dolosse on the Manasquan Inlet, New Jersey jetties. These jetties were rehabilitated between 1979 and 1982 with 16-ton steel-reinforced dolosse. The jetties have been exposed to a number of storms since 1982, including a design-level storm in March 1984. The photogrammetric measurements have provided a detailed record of the magnitude and direction of dolos movements in response to these storm events. Standard leveling techniques have been used to check the accuracy of the elevation data derived from photogrammetry. This paper describes the methods used in this monitoring effort and the results obtained from the photogrammetric measurements. Also presented are data on the structural integrity of the steel-reinforced dolosse.

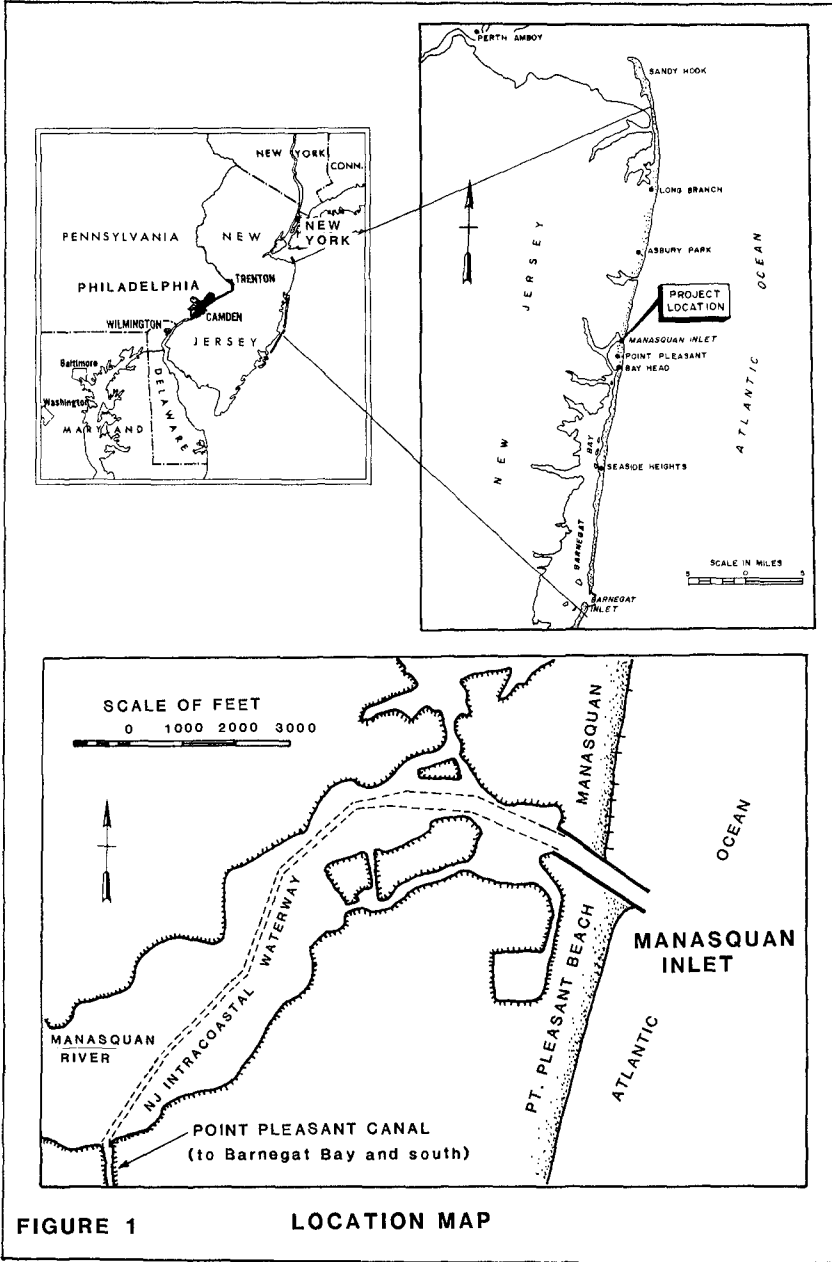

#### INTRODUCTION.

The Federal navigation project at Manasquan Inlet, New Jersey consists of a channel stabilized by parallel jetties, and provides the northernmost connection between the Atlantic Ocean and the New Jersey Intracoastal Waterway. Manasquan Inlet is located about 40 miles (64 km) south of New York City and about 60 miles (96 km) northeast of Philadelphia (Figure 1). The inlet is used year-round by a large commercial and party boat fishing fleet, and is most heavily used in summer when there is a large influx of recreational boaters.

Construction of the original rubblemound jetties and dredged channel was completed in 1931. The jetties are about 1200 feet (366 m) long, spaced 400 feet (122 m) apart, and protect the 250 feet (76 m) wide by 14 feet (4.3 m) deep (MLW) channel. Over the 1935 to 1975 period, the jetties suffered recurrent storm-related damages, primarily to the head sections of the jetties. In this period there were no less than nine contracts awarded for rehabilitation of one or both jetties. These rehabilitation efforts typically consisted of placement of additional and larger stone armor units, such that by 1975 the original 2-ton (1816 kg) stone size had been upgraded to 12-ton (10,896 kg) units in the most exposed portions of the jetties.

**FIGURE 1**                      **LOCATION MAP**

Despite the increase in stone size, the jetties continued to experience damage. This led to the 1978 investigation of alternative rehabilitation methods which concluded that dolosse would be used along the seaward portions of the jetties. Hydraulic design criteria of the U.S. Army Corps of Engineers in effect in 1978 resulted in required armor unit weights of 16 tons (14,528 kg) for dolosse and about 60 tons (54,480 kg) for quarystone given the design breaking wave height of 25 feet (7.6 m). Dolosse were selected as armor units because 60-ton quarystone was beyond the practical range of stone sizes available at this site. The jetties were rehabilitated under two separate contracts, with the south jetty completed in December 1980 and the north jetty in December 1982. A total of about 1300 steel-reinforced, 16-ton dolosse were used in the rehabilitation of the two jetties.

#### MONITORING PROGRAM

The effectiveness of the jetty rehabilitation has been observed and evaluated since 1982 through a monitoring program which is part of the U.S. Army Corps of Engineers Monitoring Completed Coastal Projects (MCCP) program. The monitoring program is a cooperative effort of the Coastal Engineering Research Center of the U.S. Army Engineer Waterways Experiment Station and the Philadelphia District of the U.S. Army Corps of Engineers. The Manasquan Inlet monitoring program has included the following types of measurements:

- o recording wave gage ("Waverider")
- o recording tide gage
- o littoral environment observer (LEO)
- o inlet tidal prism
- o hydrographic surveys of inlet and adjacent beaches
- o side scan sonar
- o aerial photography
- o photogrammetric mapping of dolosse
- o dolos elevations by leveling

This paper describes the procedures used and results obtained in the application of photogrammetry to monitor the stability of the dolosse since initial placement, and also presents findings regarding the structural integrity of the steel-reinforced dolosse.

## PHYSICAL/ENVIRONMENTAL CONDITIONS

Manasquan Inlet is located at the mouth of the Manasquan River, a small stream which originates 17 miles (27 km) above the inlet and is tidal for 5 miles (8 km) upstream of the inlet. At a point 2 miles (3 km) upstream of the inlet, the Manasquan River intersects the Point Pleasant Canal, a man-made channel which extends south 2 miles (3 km) and provides a hydraulic connection to the head of Barnegat Bay. Shark River Inlet is located 6 miles (10 km) north of Manasquan Inlet and is the only breach in the coastline from Manasquan north to Sandy Hook. The first inlet south of Manasquan is Barnegat Inlet, at a distance of 23 miles (37 km).

The hydraulics of Manasquan Inlet are tidally dominated, with a 4.0 feet (1.2 m) mean tidal range and semi-diurnal tides. The spring tidal prism has been measured to be on the order of  $3.5 \times 10^9$  cubic feet ( $9.9 \times 10^6$  cubic meters). The offshore contours are approximately shore parallel out to a depth of 40 feet (12.2 m), and there is no ebb shoal present. Since 1982 the actual depths in the navigation channel between the jetties range from 15 to 20 feet (4.6 to 6.1 m). From the outer ends of the jetties, the bottom drops off to a depth of 30 feet (9.1 m) below mean low water within about 500 feet (152 m) of the north jetty.

The beaches adjacent to Manasquan Inlet (Manasquan to the north, Point Pleasant Beach to the south) are formed against a headland of sandy Atlantic Coastal Plain sediments. The net longshore transport direction is to the north, as evidenced by the shoreline offset shown in Figure 2.

Prior to 1880, when the first timber jetties were built at Manasquan Inlet, the inlet location had been unstable within a zone extending several thousand feet (about 1 km) north of the present location. The first jetties failed by 1886, and no further attempts were made to stabilize the inlet until 1922, when the state of New Jersey built new timber jetty structures. These also failed and the inlet closed naturally on several occasions between 1922 and 1930. The inlet was closed in 1930 at the time that construction began on the present Federal navigation project.

## DOLOS STABILITY MONITORING

Background. In view of the historic problems with maintaining the integrity of the quarystone armor layers of the jetties, and also in view of the relative lack of prototype experience with dolosse on the U.S. east coast, a technique was needed to accurately monitor the performance of the dolosse at Manasquan Inlet and to verify the validity of the design procedures and assumptions used in the rehabilitation effort. Therefore, as an experiment in the Manasquan Inlet monitoring program, the use of precision photogrammetry was proposed as a means to answer the following questions:

**FIGURE 2**  
**MANASQUAN INLET**  
**24 JUNE 1983**

1. Do the dolosse move, particularly under storm conditions?
2. If they do move, then how far, and at which locations on the jetties?
3. Do dolos movements compromise the predicted project performance?
4. How accurate are the photogrammetric measurements and what is the resolution (vertical and horizontal) of photogrammetry in this application?
5. Was jetty rehabilitation with dolosse successful? and
6. Is photogrammetry a cost-effective method of monitoring the stability and performance of armor units on coastal structures?

The following sections provide the answers to these questions developed as of September 1984.

Procedures. The initial step in constructing photogrammetric maps of the south and north jetties at Manasquan Inlet was to establish primary targets on stable portions of the jetties and adjacent land area. The targets were surveyed in from nearby geodetic and vertical control benchmarks, and were visible in the aerial photography. These primary targets were used to define the horizontal (x and y) and vertical (z) datums to which all measurements on the dolosse are referred. The primary targets on the jetties were located along the centerline of the concrete cap. Each concrete cap section is a monolith 20 feet (6.1 m) square by 6 feet (1.8 m) thick, weighing 180 tons (163,000 kg), and supported by the core material of the jetty. The primary targets were surveyed periodically to determine their stability as reference points.

Low altitude black and white aerial photography was obtained with a shore-parallel flight line at an altitude of 600 feet (183 m), resulting in a contact scale of 1:1200 (or 1 inch = 100 feet). The photographic flights were scheduled to coincide with times of low tide and high sun angle conditions. All photography in this monitoring program was obtained with the same precision cartographic camera, a Zeiss RMK A 15/23. A total of three exposures were required to prepare the photogrammetric maps of the jetties; the southern and middle exposures were used for the stereo model of the south jetty, and the middle and northern exposures were used for the stereo model of the north jetty.

The final step in constructing the photogrammetric maps was compilation. A Kern PG 2-AT stereo restitution instrument was used to compile the selected features, in this case the plan view outlines of the dolosse, concrete cap sections, and armor stone. These features were superimposed on a grid based on the New Jersey State Plane Coordinate System, which graphically defined location and orientation of features in the horizontal plane. Vertical data were recorded numerically as spot elevations at selected points on the

same features. Using an enlargement factor of 20 times the contact scale, the finished scale of the maps was 1:60 (or 1 inch = 5 feet). A portion of a south jetty map is shown in Figure 3.

The photogrammetric maps were plotted on stable-base transparent drafting material. In this manner, the stability of a dolos from one flight date to the next was determined by overlaying and registering the two maps, then visually comparing the location of the feature of interest on the earlier and later dates. If a dolos moved in the time interval, the horizontal component of movement was evident as a displacement of the outline of the dolos, which was then scaled from the 1:60 maps. Experience with a number of Manasquan Inlet jetty maps has shown that horizontal movements of as little as 0.3 feet (9 cm) can reliably be detected. The vertical component of movement was determined by comparison of the spot elevation data for a particular point. A later section of this report addresses the accuracy and resolution of the vertical measurements.

Data Obtained. Aerial photography suitable for photogrammetric mapping was obtained on the dates indicated with a "P" in Table 1. Also shown are the dates of the three most significant storm events which have occurred during the course of the Manasquan Inlet monitoring program. The symbols "S" and "N" refer to the south and north jetties respectively, and the numbers (1,2, etc) refer to successive photogrammetric maps prepared for each jetty. Note that a north jetty map was not prepared from the 9 January 1982 photography because the north jetty rehabilitation was in progress at the time.

DATE		SOUTH JETTY	NORTH JETTY
P	9 Jan 1982	S 1	-
	24-26 Oct 1982	Storm	
P	29 Jan 1983	S 2	N 1
	12-13 Feb 1983	Storm	
P	15 Sep 1983	S 3	N 2
P	27 Mar 1984	S 4	N 3
	28-30 Mar 1984	Storm	
P	9 May 1984	S 5	N 4

The initial maps for the south jetty (S1) and north jetty (N1) are the most detailed of the maps prepared in this monitoring program. Spot elevations were determined at two or three locations

on all fully visible dolosse and cap sections, with one or two elevations determined for partially visible dolosse and armor stones. Maps S1 and N1 together document the location, orientation and elevation of 754 dolosse, about 57% of the 1326 units placed on the two jetties during the 1979 to 1982 rehabilitation. The remaining 43% of the dolosse were not mapped because they were either underwater or beneath the top layer of dolosse, and thus not visible in the photography. Subsequent photogrammetric maps have typically included from 20 to 30% of the 754 dolosse shown on maps S1 and N1. This smaller sample size reduces the cost of map compilation, while still obtaining representative coverage of armor units on the two jetties.

Leveling Measurements. As a check on the accuracy of photogrammetric methods which were previously untested in mapping armor units, standard leveling techniques have been used to record two or three spot elevations on a representative sample of both dolosse and armor stones. These level data were obtained for 65 south jetty dolosse on 27 April 1982, 14 March 1983, and 8 September 1983, and for 95 north jetty dolosse on 15 March, 9 June and 7 September 1983.

Prior to the 7-8 September 1983 leveling and 15 September 1983 photography, the comparisons of photogrammetric and standard leveling data suggested that accuracy of the photogrammetrically derived elevations was on the order of  $\pm 0.3$  feet (9.1 cm). However, there were two factors identified which could have been contributing to the differences between leveling and photogrammetric elevation data. The first factor was that the dates of leveling differed by as much as 2 or 3 months from the closest dates of photography. It was possible that dolos movement occurred during such periods, which would then contribute to apparent differences between photogrammetric and leveling measurements on the same point. For example, note that the February 1983 storm occurred in the six-week interval between the January 1983 photography and the March 1983 leveling. The second factor was that prior to September 1983, there were no visual targets on the dolosse to insure that the field leveling crew and the photogrammetrist were observing exactly the same point when measuring an elevation. Features such as "center of face of vertical fluke", for example, were the nominal targets used by the surveyors and photogrammetrist for spot elevations. If such surfaces are inclined relative to the horizontal, as are almost all dolos surfaces on a jetty, then small differences in horizontal location can contribute to comparable differences in measured elevation.

The best data set for determining the accuracy of the photogrammetric elevations was obtained in the period 7-15 September 1983, when both leveling measurements and aerial photography were performed. For these observations, one-foot (30 cm) black targets (crosses) were painted onto 111 dolosse distributed over the two jetties, assuring that both the field crew and the photogrammetrist would determine elevations at exactly the same points within a storm-free period of 8 days. Elevations were determined to the nearest 0.01 foot (3 mm) for both methods. Comparison of the elevation data from the two methods demonstrated that 84% of the photogrammetric

values were within  $\pm 0.1$  feet (3 cm) of the elevations determined by leveling, and 98% were within  $\pm 0.2$  feet (6 cm). The largest discrepancy between the two methods at any point was 0.27 feet (8.2 cm). These findings strongly suggested that earlier uncertainties regarding accuracy and resolution of the photogrammetric elevations were due to the time interval between measurements and the lack of point targets on the dolosse. These findings also showed that photogrammetry was capable of accurately resolving a scale of movement of individual armor units which would permit a detailed evaluation of dolos stability.

The leveling data were essential in verifying the accuracy of the photogrammetric elevations. However, the leveling data do not provide any information on horizontal displacement, whereas both elevation and planimetric data are provided by photogrammetry. Nevertheless, the leveling data summarized below in Table 2 suggest a relationship between dolos movement and storm exposure. Note that level measurements on the south jetty were obtained from April 1982 to September 1983, during which time two northeasters occurred (October 1982 and February 1983). The north jetty level measurements were obtained between March and September 1983, a relatively storm-free period. The data in Table 2 show that the south jetty dolosse experienced more frequent and greater downward vertical displacements than did the north jetty dolosse.

$\Delta z$ (feet)	SOUTH JETTY April 1982 to September 1983	NORTH JETTY March 1983 to September 1983
$\Delta z = 0$	3	18
$0 < \Delta z \leq 0.1$	22	32
$0.1 < \Delta z \leq 0.2$	1	3
$0.2 < \Delta z \leq 0.3$	1	3
$\Delta z > 0.3$ (Total upward)	2 (26)	1 (39)
$-0.1 \leq \Delta z < 0$	36	35
$-0.2 \leq \Delta z < -0.1$	13	6
$-0.3 \leq \Delta z < -0.2$	11	0
$\Delta z < -0.3$ (Total downward)	11 (71)	2 (43)

Note: positive  $\Delta z$  is upward movement, negative is downward.

Photogrammetric Measurements - Results through September 1983.

South jetty maps S1, S2, and S3 and north jetty maps N1 and N2 were prepared from aerial photography obtained through 15 September 1983. As previously discussed, these photogrammetric maps did not achieve as high a degree of accuracy in measuring dolos movement as did later maps due to the lack of point targets on the dolosse. However, analysis of the photogrammetric displacement data through September 1983 did show that 65% of the 250 observed points were within  $\pm 0.3$  feet (9.1 cm), and 91% were within  $\pm 1.0$  feet (30.5 cm) of their initial elevations. The maximum vertical change detected was a drop of 4.2 feet (1.3 m) on a dolos at the head of the south jetty. Ninety percent of the vertical displacements which exceeded 1.0 feet (30.5 cm) occurred on dolosse at the heads of the two jetties. The largest horizontal displacement detected was about 6.0 feet (1.8 m) on a dolos on the channel side of the south jetty. The next largest horizontal displacement was only 3.5 feet (1.1 m), and also occurred at the head of the south jetty. The mean horizontal movement of all monitored dolosse through September 1983 was about 1.0 feet (30.5 cm). The movements were predominantly rotation around the vertical axis (yaw) and displacement in a downslope direction relative to the jetty structures.

Photogrammetric Measurements - September 1983 through May

1984. All photogrammetric measurements on maps for this period utilized the dolos targets established in September 1983 and are therefore assumed to be of comparable accuracy. Note from Table 1 that the time interval from 15 September 1983 to 27 March 1984 was relatively storm-free, whereas the interval from 27 March to 9 May 1984 was not. Measurements of vertical and horizontal displacements over these two intervals reinforced the earlier findings that dolos movements were predominantly related to storm effects.

In the six-month period from 15 September 1983 to 27 March 1984, the mean vertical displacement for all points monitored on the two jetties was -0.15 feet (-4.6 cm) and only 10% of the monitored dolosse experienced detectable horizontal displacements, the largest of which was about 1 foot (30.5 cm).

Between 28 and 30 March 1984, an intense coastal storm affected the mid-Atlantic states. During the 29th, there was a maximum of about 4.5 feet (1.4 m) of storm surge above the predicted tide levels. The maximum still water elevation recorded at the long-term tide gage at Atlantic City, about 50 miles (80 km) to the south was only 0.1 feet (3 cm) below that attained during the March 1962 "storm of record". The maximum stage recorded at Manasquan was 0.2 feet (6.1 cm) below that at Atlantic City on 29 March 1984. However, coastal damage was less in March 1984 because the highest waves coincided with only one high tide, in contrast to the "five high tide" duration of the March 1962 storm. The wave gage at Manasquan, located about 1 mile (1.6 km) northeast of the inlet where the depth is about 50 feet (15.2 m), recorded a maximum 20-minute significant wave height of 22 feet (6.7 m) with a corresponding peak period of about 11.5 seconds. The peak of the wave record coincided with the maximum of the ocean stage, and thus exposed the jetties to what is believed to be the equivalent of the design storm. The significant

wave height at the gage exceeded 20 feet (6.1 m) for 5 hours and exceeded 10 feet (3.0 m) for 30 hours. Note that the 27 March 1984 photography was obtained only 24 hours before the arrival of the first storm effects at Manasquan.

The mean vertical displacement of all monitored dolosse due to the March 1984 storm was -0.46 feet (-14 cm). Table 3 summarizes the elevation change data from this storm, and utilizes the same notation as in Table 2. Approximately 3% of the dolosse moved in excess of 1.0 feet (30.5 cm) vertically, with a maximum value of a 2.03 feet (62 cm) drop.

$\Delta z$ (feet)	SOUTH JETTY	NORTH JETTY
$\Delta z = 0$	3	4
$0 < \Delta z \leq 0.1$	3	23
$0.1 < \Delta z \leq 0.2$	0	7
$0.2 < \Delta z \leq 0.3$	1	0
$\Delta z > 0.3$	2	0
(Total upward)	(6)	(30)
$-0.1 \leq \Delta z < 0$	24	26
$-0.2 \leq \Delta z < -0.1$	22	10
$-0.3 \leq \Delta z < -0.2$	14	10
$\Delta z < -0.3$	31	20
(Total downward)	(91)	(66)

The largest horizontal displacement caused by the March 1984 storm was 7.0 feet (2.1 m) at the head of the south jetty. There were 3 other dolosse which moved about 5 feet (1.5 m) horizontally. Altogether only 9% of the monitored dolosse moved in excess of 2 feet (61 cm) horizontally, with 31% moving from zero to 2 feet. About 60% of the dolosse experienced no detectable horizontal displacement.

Dolos Breakage. As a result of the March 1984 storm, 3 dolosse broke on the north jetty, all within a zone about 35 feet (10.7 m)

wide at the head of the structure. Two of the breaks resulted in the loss of some concrete from the shank portions of the dolosse, but the presence of the epoxy-coated reinforcing steel kept the dolosse substantially intact. The third north jetty dolos suffered a hairline crack through one fluke. One south jetty dolos, located near the head on the channel side of the structure, broke at the junction of the shank and a fluke. This dolos is also essentially intact because of the reinforcing steel.

Prior to the March 1984 storm, one other dolos at the head of the north jetty had broken. Therefore, a total of 5 out of the 1326 dolosse (only 0.4%) used in the 1979 to 1982 rehabilitation have broken despite exposure to the design storm event. It is interesting to note that of the five dolosse which have broken, only one has experienced a net horizontal displacement in excess of 2 feet (0.6 m) from its initial location. Other dolosse have moved greater distances, up to 7 feet (2.1 m) between dates of photography, yet have not broken.

Based on several years monitoring at Manasquan Inlet, it is evident that steel-reinforced dolosse in a weight range up to 16 tons can exhibit a degree of mobility on the jetty surface in response to storm conditions, yet not incur significant damage due to breakage of individual units.

## CONCLUSIONS

Photogrammetry has been found to be a highly useful technique for monitoring the stability of armor units on coastal structures. The application described in this paper has involved dolosse, but the technique would be equally applicable for monitoring structures with quarystone or other concrete armor units. Comparison of photogrammetric measurements with standard land survey techniques has shown that photogrammetry provides a degree of accuracy and resolution more than adequate to evaluate armor unit stability. At the scale of mapping used in this project, vertical accuracy of  $\pm 0.1$  feet (3.1 cm) and horizontal accuracy of about  $\pm 0.3$  feet (9.1 cm) have been attained. Periodic photogrammetric mapping of a coastal structure would permit detection of incipient or progressive failure along any visible portion of the structure before such a problem was readily detected by other means. This would allow for early assessment and possible correction of the problem.

Photogrammetry offers several advantages over conventional land survey techniques. First, it is possible to map armor units at or near the waterline of the structure which would be inaccessible or too hazardous to access on foot. Secondly, photogrammetry is flexible in that all the information needed to perform the photogrammetric mapping can be obtained almost instantaneously, permanently and at a fixed cost with one aerial photographic flight. The mapping itself can then be performed at any time thereafter, or not at all, depending on available resources, need for

information, etc. In contrast, land survey methods capable of obtaining the location, orientation, and elevation data for mapping every visible armor unit are labor-intensive and would require considerably more time and expense than the photogrammetry. If the land survey measurements are not made on a given date, they are then permanently lost. Thirdly, the standard data product of photogrammetric mapping is graphical, and thus readily interpreted with respect to location and magnitude of any armor unit displacements.

Despite the relatively short period of monitoring at Manasquan Inlet since completion of the jetty rehabilitation, monitoring measurements have shown that the jetties have already been exposed to their design level storm event (in March 1984). The photogrammetric measurements have documented that the dolosse do move, particularly in response to storm exposure. These measurements have quantitatively shown which dolosse have moved, how far, and in which direction. However, there is presently no indication that the range of dolos displacements experienced to date has in any way compromised the effectiveness of the most recent rehabilitation project. The photogrammetric measurements have also shown that none of the monitored dolosse has experienced a displacement, either horizontal or vertical, in excess of about 70% of the unit dimension (11 feet, or 3.4 m) of a 16-ton dolos.

The rehabilitation of the Manasquan Inlet jetties with these units has been fully successful to date. The overall performance of the jetties and in particular the low percentage of broken dolosse in response to the March 1984 storm serve to verify the design and construction procedures utilized in the rehabilitation of the jetties.

The initial photogrammetric maps prepared for the Manasquan Inlet jetties provide a complete and somewhat unique set of baseline data against which future performance of the dolosse can be readily compared. The information obtained by monitoring of the dolosse and jetties at Manasquan Inlet should provide an important quantitative contribution on prototype structure performance to complement the more extensive body of knowledge on armor unit stability derived from physical model studies.

#### ACKNOWLEDGEMENTS.

The research reported in this paper has been funded by the U.S. Army Corps of Engineers Monitoring Completed Coastal Projects (MCCP) program. Support by the office of the Chief of Engineers and the Coastal Engineering Research Center, Waterways Experiment Station is appreciated. The authors also wish to express appreciation to Mr. David K. Nale of A.D.R. Associates, Pennsauken, N.J. for continued valuable technical advice on the photogrammetric aspects of this work, and to Mrs. Clare McAneny for assistance in manuscript preparation.

## CHAPTER ONE HUNDRED SIXTY EIGHT

### SHIP-WAVE ATTENUATION TESTS OF A PROTOTYPE FLOATING BREAKWATER

Ronald E. Nece<sup>1</sup>, F. ASCE and Norman K. Skjelbreia<sup>2</sup>

#### ABSTRACT

Limited data are presented for the ship-wave attenuation of a prototype concrete pontoon floating breakwater. Results are compared with wave attenuation performance of a breakwater of identical cross-section and similar anchoring configuration as predicted by model tests using monochromatic waves. Field test procedures and limitations are described.

#### Introduction

Often the most severe wave climate impressed on floating breakwaters used in sheltered waters may originate not from wind-generated waves but from ship or boat waves. This paper presents limited boat wave attenuation test results for a prototype concrete pontoon breakwater. These specific tests were conducted as part of a U.S. Army Corps of Engineers prototype test program initiated to establish design criteria for floating breakwater applications in semi-protected coastal waters, lakes, and reservoirs.

The prototype testing program was established to obtain field information on, among other things, wave transmission characteristics, anchor loads, and structural forces. In particular, this paper describes the boat wave attenuation performance of a particular type of floating breakwater quite commonly used in semi-protected waters of the North Pacific coast in the United States and Canada.

Data from model tests using monochromatic waves typical to laboratory tests of such floating structures were available for a breakwater of identical cross-section and comparable anchoring scheme. Some data on wind wave performance of the prototype structure discussed in this paper also were available. This paper then takes the opportunity to compare, even if on a limited basis, laboratory, wind wave, and boat wave data for the same breakwater. Reasons why the test results are limited are indicated, and why boat wave performance tests of prototype floating structures may be limited in general is discussed.

### Description of Test Site and Breakwater

The prototype structure was installed at a test site at West Point, near Seattle, in Puget Sound, Washington. The site was in an exposed location, selected so that within the time frame of the tests the structure would be exposed to wave conditions more severe than those existing at sites currently considered as suitable for floating breakwaters. The water depths at the site varied between 40 and 50 feet (12.2 and 15.2 m) at mean lower low water (MLLW), the diurnal tide at the site is 11.3 feet (3.5 m) and the currents are variable.

The prototype breakwater consisted of two rectangular modules, each 75 feet (22.87 m) long and 16 feet (4.96 m) wide, with a draft of 3.5 feet (1.07 m) and a freeboard of 1.5 feet (0.46 m). During the boat-wave tests, the two modules were rigidly fastened together to form a single, 150-foot (45.73 m) long structure. The breakwater was anchored in place by 10 anchor lines attached to H-piles embedded in the sand and gravel bottom. Anchor lines consisted of 1-3/8-inch (35-mm) stud link chain at each end, with a one ton clump weight attached to minimize lateral displacement of the breakwater. The anchor lines had a minimum scope of 1 vertical to 4.5 horizontal, and were pre-tensioned to  $5,000 \pm 1,000$  pounds ( $22,200 \pm 4,450$  N). The breakwater is shown schematically in Figure 1.

Waves were measured by resistance-wire wave staffs mounted on spar buoys equipped with damping plates and having natural periods in heave and roll of 18 and 12 seconds, respectively, both much greater than periods of either windwaves or boatwaves at the test site. For the tests discussed in detail here the wave gages were located as shown in Figure 2; they were attached to the breakwater anchor lines. The gages were connected to a microprocessor-based data acquisition system designed to handle 80 analog input channels from wave gages, and force, pressure, and motion measuring transducers used in the monitoring project. Strip-chart records were also obtained during the boatwave tests. Details of the breakwater design and the instrumentation have been provided respectively by Nelson et al. (5) and Christensen (2).

### Boat-Wave Tests

Two tests are discussed here; each involved a different vessel.

The test discussed in more detail used a U.S. Coast Guard utility boat with a modified deep 'V' planing-type aluminum hull and having the following dimensions: length, 40.7 feet (12.4 m); beam, 13.4 feet (4.1 m); maximum draft, 4.9 feet (1.5 m); full load displacement, 15 tons. Nominal speeds for the constant speed, straight line courses run during the test were 12, 16, and 20 knots; at the 16-knot speed the boat is just beginning to plane and generates its largest waves.

Vertical photographs were taken during the boat runs, using a conventional aerial camera. The plane elevation was about 1,000 feet (305 m), so that the nominal scale was 1:2000. Those timed, sequential photographs which included the moving boat and the breakwater provided the necessary measure of boat speed, with the breakwater providing the

Figure 1. Schematic drawing of breakwater.

Figure 2. Wave gage locations.

horizontal scale, as well as boat direction and sailing line distance with respect to the breakwater. An example photograph is shown in Figure 3. A pipe-tire breakwater, not discussed in this paper, also appears in Figure 3. Successful photographs were not obtained for all runs. Boat speed was determined from the photographs for only one (the 16-knot) speed, so the same ratio between measured speed and that indicated by on-board instrumentation was assumed in the reduction of data. The actual speeds were thus determined to be 11.1, 14.9, and 18.6 knots. Boat wave patterns were obtained for the two higher speeds; the wave pattern angles for the "12-knot" speed had to be estimated by extrapolation. Where aerial photos were not available (when, for example, the airplane and the boat did not pass the breakwater at the same time) boat directions and distances from the breakwater were estimated on the basis of the test design and visual observations from the boat and breakwater. The breakwater corner 'A' identified in Figure 2 and in definition sketch Figure 4, was used as the reference point in distance measurements and calculations. Incident wave properties were defined at the position of the incident wave gage, as shown in Figure 4.

Wave angles  $\beta$ , and therefore  $\theta$  (measured with respect to the sailing line direction) of the diverging waves which were the dominant waves in the boat-wave pattern were measured at various distances from the sailing line on the aerial photographs. The solid lines on Figure 5 for the 14.9 and 18.6-knot speeds are each based on over twenty individual measurements of wave crest directions on a photograph; as indicated previously, the curve for the 11.1-knot speed was obtained by extrapolation.

The nearness of the wave staff to the breakwater posed a problem with respect to measurement of  $H_i$ , the height of the incident wave. To avoid possible effects of wave reflection from the breakwater, the following procedure was adopted. On the strip-chart records used in the present data analysis, the boat wave envelope was identified, and the vertical distance from the crest of the second wave in the boat-wave envelope to the following trough (using the gage scale factor) was defined as  $H_i$ . This is illustrated in Figure 6, traced from an expanded plot produced from the data acquisition system. The sampling rate was 4 Hz; frequencies below 0.1 Hz and above 0.8 Hz were filtered out to eliminate electronic drift and high frequency noise, respectively. Wind waves at the site were generally in the 2 to 4-second period range. The representative trace in Figure 6 was obtained from a separate piling-mounted wave gage located 150 feet (45.7 m) from the end of the breakwater opposite to the end containing point 'A', and on the longitudinal axis of the breakwater, so that there were no reflected waves. The record was obtained during tests using a 110-foot (33.5 m) tug, as described below. Figure 6 indicates that the error in the definition of  $H_i$  was small. The height  $H_t$  of the transmitted wave was the maximum wave height measured at the gage 'behind' the breakwater. Figure 6 shows the boat-wave envelope, and also indicates that at the time of the test the wind-waves were small enough so that for purposes of the present test the boat-wave heights could be measured directly from the strip-chart records.

Figure 3. Vertical aerial photograph, Coast Guard utility boat.

Figure 4. Definition sketch.

Figure 5. Wave crest direction vs. distance from sailing line, Coast Guard utility boat.

Figure 6. Representative wave trace (marine tug) and selected value of incident wave height  $H_1$ .

Figure 7 indicates the measured decay of wave height with normal distance  $y$  from the sailing line, for each of the three boat speeds. This decay is comparable to that reported by Sorensen for a Coast Guard cutter of length and speed range close to that of the boat used in the present test (8). Wave half-periods (time from crest to trough of the boat waves, as measured at the staff gage) ranged between 1.2 and 1.4 seconds, also comparable to the values reported by Sorensen.

The second test mentioned here utilized a marine tug having the following dimensions: length, 110 feet (33.5 m); beam 34 feet (10.4 m); draft, 10 feet (3.1 m); displacement, 193 tons (gross). The nominal speed was 11 knots for all runs. Aerial photographs were taken for some runs; however, the photographs were taken at oblique angles from a small airplane by a hand-held camera. Figure 8 is an example of these oblique photos. General features of the boat-waves as they acted upon the breakwater were visible, but vessel speeds and wave angles could not be determined. Consequently, no detailed treatment of the wave height data could be made. More details of this test, and of two other short boat-wave tests of the prototype breakwater in which aerial photography was not employed have been given by Skjelbreia (7).

#### Model Data

Model tests had been conducted on a floating breakwater proposed for (but not eventually, so constructed) a site near East Bay, Olympia, on Puget Sound Washington. Results, here all expressed in equivalent full-scale values, were reported by Carver (1). Monochromatic waves only were used in the 1:10 scale model tests.

Two configurations were tested, as shown in Figure 9. The cross-section of Plan 2 is identical to that of the prototype breakwater used in the boat wave tests. Anchoring systems are similar but not identical and the East Bay water depths are less than at West Point, so the East bay tests did not fully model the prototype of the present tests. Trends in wave transmission characteristics, however, would be expected to be similar. Conventional two-dimensional test results are shown in Figure 9 in the form of transmission coefficient  $C_t$  vs.  $L/W$ , where

$$C_t = H_t / H_i$$

$$W = b_{\text{breakwater width}}$$

$$L = \text{length of incident wave.}$$

To remain within the range of wave heights measured in the Coast Guard boat tests,  $H_i$  values of only 1.5 and 2 feet (0.46 and 0.61 m) from the model test data, were used in plotting Figure 9.

Plan 1 was also tested with waves having crests at an angle of obliquity  $\theta$  with respect to the face of the breakwater. Information concerning these tests is shown in Figure 10. Transmitted wave heights plotted in Figure 10 were maxima measured at the wave gage location shown; measurements from this gage were used because it most closely

simulated the location of the transmitted wave staff in the boat wave tests.

### Results of Prototype Tests

In order that the boat wave data be compared with laboratory data such as shown in Figure 10, it is necessary that  $\alpha$  and  $L$  be determined for the divergent waves of the boat wake which were the incident waves at the breakwater. Since it has long been established, e.g. (4) that boat wave patterns depend upon vessel speed and hull form (3), the aerial phototographs were necessary. Wave periods and water depths at the test site allowed deep-water equations for linear wave theory to be employed in the analysis.

Since the Kelvin-type wave pattern as a whole moves with the vessel, the wave crest (phase velocity) of the divergent wave is

$$C_D = V_s \cos \theta$$

in the direction normal to the wave crest as shown in Figure 4. Using the deep-water relations, the other wave properties are obtained:

$$T_D = \frac{2\pi C_D}{g} = \frac{2\pi V_s \cos \theta}{g}$$

$$L_D = \frac{g T_D^2}{2\pi} = \frac{2\pi V_s^2 \cos^2 \theta}{g}$$

The period  $T_D$  is not that recorded by a stationary wave gage as the diverging waves pass it. Wave lengths so calculated for the boat wave tests did agree well with wave lengths measured directly from the aerial photographs. The quality of the photographs was such, however, that wave crest angles could be measured more accurately than lengths; hence, the procedure followed.

Results of twelve passes of the boat past the breakwater are recorded in Table I. As noted, boat directions and distances from the breakwater could be obtained from only four photographs; other values are best estimates. To conserve space, only the foot units originally used are tabulated. Calculated incidence angles  $\alpha$  are listed, and compared with values estimated by an observer on the breakwater and with those few which could be measured from the photographs. Disparities in results indicate the need for a complete set of good quality photographs if a good, full set of data is to be obtained.

Wave transmission results are plotted as a function of wave length in Figure 11, and in conventional dimensionless form in Figure 12. The  $L$  and  $T$  in both figures apply to the diverging waves as they reached the incident wave gage. For the shorter boat waves, the transmission coefficient agrees with the results from the monochromatic wave model tests. For longer wave lengths  $L_D$ , however,  $C_t$  values for the boat

waves appear to be larger than those for the model tests. There is no discernible relationship of  $C_r$  to the obliquity angle  $\alpha$ , within the  $\alpha$  range indicated. The data are too limited for conclusive statements. One possible reason for the differences in  $C_r$  at the longer wave lengths could be the differences in the anchor line tensions.

Figure 13 shows some results reported by Nelson and Broderick (6) for wind waves at the prototype structure. The wave crests were essentially parallel to the breakwater axis for waves generated by southerly winds. The incident wave gage used was the pile-mounted gage referred to earlier, so that wave reflections from the breakwater posed no problem. The period shown is that at the spectral energy peak, obtained from spectral analysis of 2,048-point, approximately 8-1/2 minute records. The significant wave height was taken as four times the variance (standard deviation squared) of the wave record, an approximate result for calculations based on the Rayleigh distribution function (9).

No correlation of boat wave data from the test using the marine tug are given in this paper. Incident waves were of the order of magnitude 2-3 feet (0.6-0.9 m) as typified by the trace in Figure 6, and transmitted wave heights were approximately 0.5 foot (0.15 m). It was difficult to separate the transmitted boat-waves from the surface chop on the "transmitted" side of the breakwater on the day of the tests, just as it was difficult to identify the transmitted boat waves by visual observation. There was water on the deck of the breakwater when it was impacted by the waves generated by the tug. This breaking of waves on the breakwater provided an additional wave attenuation mechanism which may not have been relatively so significant in the laboratory studies; hence, wave attenuation by the prototype was greater than would be predicted by the laboratory model tests. Again, differences in anchor line restraint could be a major cause for the differences in performance of the laboratory model under monochromatic waves and the prototype breakwater subjected to boat waves.

### Conclusions

The limited data did not allow identification or separation of effects of the many variables involved in correlating wave transmission performances of a floating breakwater for continuous, monochromatic waves typical of model studies and for the finite envelope of waves experienced in boat wakes.

It appears that for shorter wave lengths (say  $L/W = 2$  or less) boat wave transmission of a breakwater can be predicted reasonably well from monochromatic wave model tests. At many sites where floating breakwaters may be feasible, this range of  $L/W$  might cover the anticipated range of boat waves that might be generated by smaller vessels such as pleasure craft.

For  $L/W > 2$ , results reported here are not conclusive. For the Coast Guard boat waves, transmitted waves were greater than predicted using the model test results, while the opposite was true for the tug-generated waves. This difference is perhaps due mostly to non-similitude in the anchoring systems. The pre-tensioned anchor lines

Figure 13. Wind wave data.

in the prototype may have kept the breakwater, while responding to the boat wave envelope, from achieving the motions obtained under continuous waves in the laboratory. For waves of moderate height the model data were not conservative, while they were for higher steeper waves which broke over the prototype.

In almost all cases for both model and prototype wave crests were inclined at angles of 30 degrees or less from the breakwater longitudinal axis. No significant effect of wave incidence angle on wave transmission was detected in the field test data.

Aerial photography is an important, and almost necessary, component of a comprehensive field test of the behavior of a floating structure to ship-generated waves. Tests involving aerial photography require careful planning and coordination, and must be responsive to such constraints as visibility conditions, sea state, and perhaps, elevations at which the aircraft used are allowed to fly if other air traffic is a concern. These requirements indicate why availability of such data may, in general, be limited.

#### Acknowledgements

The testing program was conducted under the direct supervision of the Seattle District, Corps of Engineers. Monitoring of the prototype performance was performed by the Department of Civil Engineering, University of Washington.

## CHAPTER ONE HUNDRED SIXTY NINE

Case History of a Spaced Pile Breakwater at Half Moon Bay Marina  
Auckland, New Zealand

P.S. HUTCHINSON\*  
A.J. RAUDKIVI\*\*

### Introduction

Half Moon Bay Marina is a privately owned small boat harbour located on the Tamaki Estuary of the Auckland Harbour. The marina was built in 1970 for 485 boats moored to floating marina berths, Fig. 1, and is sheltered by a spaced pile breakwater.

Figure 1 : View of Half Moon Bay Marina

- \* Partner, Bruce Wallace and Partners Consulting Engineers,  
P.O. Box 9123 Auckland, New Zealand
- \*\* Professor of Civil Engineering, University of Auckland,  
New Zealand

The marina is well protected by land from the prevailing south-westerly winds and from the north-easterly gales which are experienced in the region, Fig. 2. However, the marina entrance is exposed to the less frequent north-westerly and westerly winds blowing across the Tamaki River. For winds from a northerly direction at high tides the calculated significant wave height is 1 metre with a 3 second period and 0.7 metres with a 2.7 second period with westerly winds. During low water the fetch is further reduced to the relatively narrow width of the estuary by the drying shallows at the opposite side of the river.

Figure 2 : Location map of the marina showing the narrow sector of exposure to wind waves

Because of space restriction and cost it was not desirable to use a cover breakwater to protect the entrance and no such shelter was provided. The entrance to the marina was kept narrow, at 33 m width, in order to minimise the amount of wave energy entering. However, even with this narrow entrance full height waves can enter the marina and affect the boats and outer marina berths.

#### Aims

The object of the breakwater design was to provide shelter for the marina at least cost. A stone breakwater in the 4 m deep water would have been very expensive and would have occupied an unacceptable width of the river channel. A steel sheet pile breakwater would have been even more expensive and would have both reflected waves across the navigation channel and deflected some of the tidal flow. Floating breakwaters were considered but were not considered to provide a sufficiently positive breakwater. The final design used a spaced pile breakwater which has proved satisfactory when used in conjunction with robust steel tube marina berths in the area facing the entrance.

## Breakwater Design

Model tests to a 1:12 scale, were carried out in a wave flume at the Auckland University School of Engineering, and showed that a 50% reduction of wave height could be obtained by using vertical 300 mm timber piles spaced 37 m apart. This spacing gave a horizontal force of 22 kN per linear metre of breakwater. The force on a solid breakwater would have amounted to 53 kN per metre. These results compare well with those reported by Grüne and Kohlhasse (1) and Hayashi et al. (2).

This reduced load from spaced piles allowed a breakwater to be built using treated pine piles supported on an orthodox plumb and raker pile structure, Fig. 3.

Figure 3 : Typical cross section of the breakwater

It was also found that a barrier 2 m deep, 1.5 m behind the spaced pile breakwater provided very effective additional wave energy dissipation without significantly increasing the loading. The water level in this gap oscillated gently up and down. With this additional skirt the wave height transmitted was reduced to 30%. However, this secondary barrier was not used in final design.

### Breakwater Construction

Site investigations showed that there was no firm ground at a reasonable depth on which to found point bearing piles. It was therefore decided to use friction piles. To assess their friction capacity a factor of safety was applied to the shear strengths of the clays encountered. The 6 mm thick 380 mm diameter plumb and raker piles at 6 m spacing were driven using a 1 ton hammer striking on a pad about 2 m of sand and gravel in the bottom of the pile. The piles were filled with sand to 3 metres below the top and the top portion was filled with concrete reinforced to connect the piles to the cast in situ cap which supported the longitudinal precast concrete beam.

The upper 10 m of piles were sandblasted and treated with epoxy tar. The lower sections of the piles, which were in the harbour bed, were left untreated.

The spaced timber piles were prefabricated ashore into 6 m long panels and placed by a crane into position. The panels were supported by the precast concrete at the top and were fixed to the vertical steel piles at the lower end.

### Breakwater Maintenance

Virtually no maintenance has been required during the first twelve years of the breakwater's life, except that in 1983 it was found that some of the timber piles were loose and inspection by divers found that the bolts fixing the piles to the lower walings were pulling out. It was also found that the U bolts used to fasten the lower end of the panels to the vertical steel piles had failed.

In 1984 a contract for NZ\$56,000 was let for the repair of the breakwater. A detail, using 19 mm mild steel plate and 36 mm mild steel bolts was used to replace the original U bolts and timber yokes. The exposed steel bolts and nuts were wrapped in 'Denso tape'. It was found that the original 19 mm bolts and their threads were sound and that in all cases the nuts had corroded, sometimes completely, leaving the thread intact. The vertical piles bolted to the horizontal walers had also come loose due to the corrosion of the nuts with the bolts again left relatively intact.

Analysis of the steel has shown that different steels had been used to make the nuts and bolts and this led to an electrolytic action and corrosion of the nuts.

The pinus radiata piles had been treated with a copper chrome treatment to a concentration of 22 lbs per cubic foot (350 kg per m<sup>3</sup>). To date there has been no indication of marine borer attack of the piles.

### Marine Design

The floating marina was constructed using timber walkways supported on fibreglass pontoons. In New Zealand, because of the frequent strong winds experienced, boats are usually moored in marinas to float

clear of piles and the marina structure, using four mooring lines, Fig. 4. With this method of mooring boats need little supervision and fenders are not required. At Half Moon Bay it is only the marina berths near the entrance where the sea condition has caused deterioration of the timber marina structure. During northerly winds the waves which enter the marina through the entrance, combined with the half wave height entering through the spaced pile breakwater, cause a considerable amount of wave disturbance over the area just inside the entrance.

Figure 4 : Typical dimensions of the marina, showing the four line mooring system

The end fingers near the entrance have now been replaced using continuous 600 mm diameter steel pipe, Fig. 5, to support the walkway and fingers. This construction was first used over 20 years ago when the first marina berths were built by the Auckland Harbour Board at the Westhaven boat harbour.

#### Conclusion

A spaced pile breakwater has provided satisfactory economical shelter to a 485 boat marina. Only near the entrance did the original timber structure of the marina berths deteriorate due to wave action and it has been necessary to replace the light timber and fibreglass marina and fingers with more robust continuous 600 mm diameter steel pipes. Boats are moored to float clear of the fingers and do not require fenders.

## CHAPTER ONE HUNDRED SEVENTY

### NEW TYPE BLOCKS FOR SEAWALL SLOPE PROTECTION

Osamu Toyoshima\*

#### 1. INTRODUCTION

Japan is a mountaineous country, and coastal areas have been looked upon quite valuable.

In most cases, shorelines were slightly advancing until 1950, although there are some exceptional coasts which have been under continuous erosion for more than a thousand years.

However, in the last thirty years, beaches began to be eroded one after another, and the countermeasure against beach erosion has become one of the most important problems in the national land preservation.

Since the early 1960's, many seawalls against the beach erosion have been constructed. The table shows the amounts of the shore protection works constructed in the last twenty years.

Total length of the coastline of Japan	34 064 km		
Year	1962	1972	1982
length of seadikes	1818 km	2566 km	2889 km
length of seawalls	2686 km	4752 km	5665 km
number of groins	5448	8747	9790
number of detached breakwaters	205	544	2831

Seadikes have been extended gradually year by year, seawalls and groins show great elongation. And, detached breakwaters also show a remarkable development in the last ten years. The elongation percentages of these shore protection works in these twenty years is seadikes 1.59, seawalls 2.11, groins 1.80 and detached breakwaters 13.81.

Most of the seawalls constructed before 1975 were vertical ones, and mechanism of beach erosion had not exactly been known those days. As a result, some of the seawalls even encouraged the beach erosion contrary to expectation.

The author then, proposed new types of seawalls. The first type was the "Block faced seawall" whose front slope was covered with some artificial concrete blocks such as armour units, and the second type was the "Lattice type seawall".

---

\* Prof. Dr. Faculty of Marine Sci. & Tech. Tokai University  
Orido 3-20-1, Shimizu-shi, 424, JAPAN

The details of these works were presented by the author, on the 16th I.C.C.E., titled "Effectiveness of seawalls with rough slope".

Block faced seawalls have been used on several coasts in Japan for the past ten years or so. Most of these seawalls have turned out to be successful, in spite of the fact that they have to be connected with extra hooks to attain sufficient solidarity.

Recently, the author invented a new type of concrete blocks for slope protection works of seawalls, which need no hooks for connection, named "Lotus-Uni".

This paper describes the characteristics of "Lotus-Uni" and experimental works of seawalls using them.

## 2. DEFECTS OF VERTICAL TYPE SEAWALLS

Fig.1 Typical vertical type seawall

In Fig.1,

- ① is the shore just after the construction of the seawall.
- ② incident waves were violently reflected on the steep front slope of seawalls, and foreshore and the toe of seawalls were washed out with the reflected waves like this.
- ③ then, sand is completely washed out.

And furthermore, by the water pressure difference ( $h$ ) between outside and inside of the seawall facing, not a little amount of sand are drawn out with jet streams like A and B in Fig.1 through the small hall in the seawall facing.

Photo.1 Backfill sand is drawn out

Photo.1 shows a typical case where the backfill sand is drawn out. Soon after these phenomena, vertical type seawalls collapsed like Photo.2

Photo.2 Vertical type seawalls collapsed

### 3. AN EXAMPLE OF BLOCK FACED SEAWALLS IN SHIZUOKA COAST

After many field experiences, the author pointed out that, the problems to be considered for the new seawalls were as follows;

- 1) to decrease the reflected waves from the front of seawalls as much as possible.
- 2) to make the front face more rough.
- 3) to make the front face permeable.
- 4) some partial collapses should be allowed, but never be destroyed the whole body of the seawalls.
- 5) repair and reinforcement should be easy.
- 6) structure should be simple and low cost.

The author proposed block faced seawalls as a new type seawalls, and the first large-scale works have been carried out on the restoration works of collapsed seawalls in Shizuoka Coast under the author's guidance.

Fig.2 shows the previous structure and cross section of Shizuoka Coast before the destruction which occurred in March 1977. Since the 1970's, the Shizuoka Coast has turned into a erosive coast. The seawalls of this coast were constructed before 1970.

Fig.2 Structure and cross section before the destruction

In Fig.2,

- ① is the shore when the seawalls were constructed in 1961.
- ② just before the destruction in March 1977.
- ③ just after the destruction.

After the first destruction in March 1977, the seawalls in Shizuoka Coast have been broken down by the violent waves one after another. The position of collapsed seawalls are shown in Fig.3.

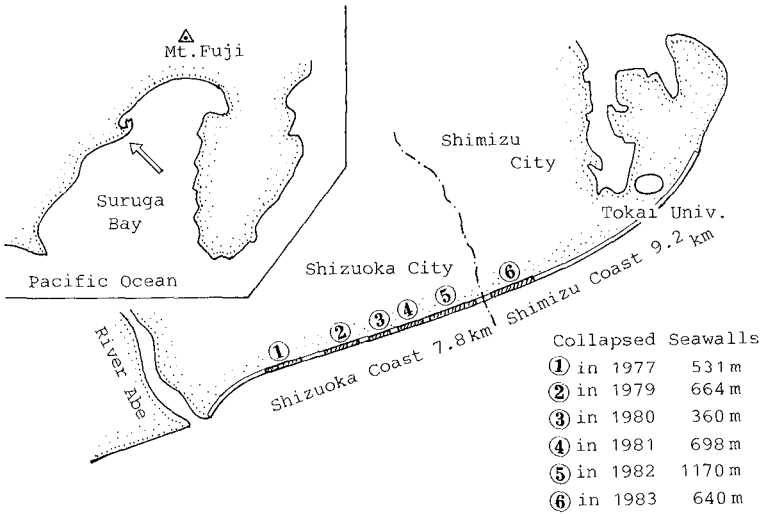

Fig.3 Position of collapsed seawalls

Instead of usual concrete facing, concrete block facing works was used as the restoration works, according to my proposal. Fig.4 shows the structure of the restoration works using the block facing.

Fig.4 Structure of restored seawalls with block facing

In Fig.4,

- ① is the shore at the starting works, in August 1977.
- ② is the shore at the completion of the works, in May 1978.
- ③ is the shore in May 1984.

Before the destruction, the beach had been eroded year by year. But, after the restoration works, the beach finely recovered and sand accumulated as about ten years ago.

Photo.3 shows the seawalls in 1978 one year after the restoration works. Four blocks are under the beach, and six are seen.

Photo.4 is the later view of the coast. The blocks are covered with sand up to the second step, then eight blocks are under the sand beach. Now the beach looks very stable.

Photo.3 Restoration works completed (1978)

Photo.4 The beach recovered finely (May 1984)

We have been talking about the first destruction in Shizuoka Coast, the position (1) in Fig.3.

After this restoration works, another destructions from the position (2) to (5) occurred consecutively, and all of them are restored in the same way as the above.

All of these restored seawalls were never destroyed again, and these block faced seawalls have proved to be successful.

However, they had to be connected with extra hooks to attain sufficient solidarity.

Recently, the author invented a new blocks, which need no hooks for connection, named "Lotus-Uni".

#### 4. CHARACTERISTICS OF THE "LOTUS-UNI" BLOCK

Fig.5 shows the plane and profile of the Lotus-Uni block. The block has three models according to its weight. Each model has same face, only the thickness is different.

Fig.5 Lotus-Uni block

Model	B	L	H	Weight
50H			50 cm	2 ton
75H	1.5 m	1.5 m	75 cm	3 ton
100H			100 cm	4 ton

Photo.5 Lotus-Uni block ( Model 50H, 2 ton)

The blocks have good close connection with one another, and there is no necessity for hooks (Fig.6).

Even if a block (black one in Fig.7) is removed, there is little room to move for the six blocks around(hatched), because blocks are holding mutually.

Fig.6 Facing style      Fig.7 Remove a block(black one)

## 5. NEW TYPE SEAWALLS FACED WITH "LOTUS-UNI"

### 5.1 Characteristics

Standard cross section of the seawalls faced with Lotus- Uni is shown in Fig.8.

Fig.8 Seawalls faced with Lotus-Uni block

Characteristics of this type seawalls are as follows.

- 1) There is no use for foundation, cut-off walls or steel sheet piles.
- 2) Blocks differ only in thickness, and different type of blocks can be used together on one slope as Fig.8.
- 3) The structure of this type of seawalls have flexibility, roughness, looseness, and chain connection like gabions. Once faced, these blocks shall hardly be decomposed by wave powers.

### 5.2 Example works

An experimental work of the new type seawall using Lotus- Uni block has been carried out on Muroran Coast, Hokkaido prefecture, Japan, facing the Pacific Ocean.

In this work, model 50H (2 ton) block is used on all the slope. The cross section of the work is like Fig.8.

There are no foundation and other shore protection works. The grade of the front slope is 1:3, and the number of blocks per slope is nine.

Photo.6 Soon after the completion (1982)

Photo.6 shows the seawall soon after the completion in 1982. The foundation blocks were set on the shoreline of the low water level, and there was no foreshore in front of the seawall. The uprush runs up with sand and gravel on the slope.

Photo.7 Uprush are sucked into the holes

Some of the uprushes are sucked into the holes of the block, and the back rush decreases.

The velocity and the volume of the backrush become slow and small. Then, the reflected waves become weaker, and the erosive beach turn into an accumulative one.

Photo.8 Gravel are left on the toe of the seawall

Sand and gravel, came from the offshore and included in the uprush, are left on the slope, in the holes and the toe of the slope of the seawall.

Eight or nine blocks are seen on the slope.

Photo.9 One year after the photo.8

More than ten meters long foreshore has grown in front of the seawall. Four or five block are to be seen, and five or four blocks are under the sand beach.

Sand has accumulated gradually and surely.

Photo.10 The latest view of the beach (1984)

The shoreline has advanced substantially, and the sand beach has grown extensively.

#### 6. CONCLUSION

The author invented a new type blocks for seawall slope protection. Now, twenty or more experimental works using the Lotus-Uni block are being carried out in Japan for the countermeasures against the beach erosion.

The collapsed seawalls in Shimizu Coast, the position(6) in Fig.3, were restored with Lotus-Uni block lately.

Most of these works are apparently successful.

## CHAPTER ONE HUNDRED SEVENTY ONE

### DETAILED DESIGN OF A WAVE ENERGY CONVERSION PLANT

G de F Retief<sup>1</sup>, FPJ Müller<sup>2</sup>, GK Prestedge<sup>3</sup>,  
LC Geustyn<sup>4</sup>, DH Swart<sup>5</sup>

#### ABSTRACT

A preliminary assessment of wave energy conversion by means of the Stellenbosch Wave Energy Converter (SWEC) has indicated the viability of this system as a supplementary source of electric power.

In order to refine the preliminary estimates of the cost of power delivered, detailed design of a 770 MW (rated output) installation at a site 60 km north of Cape Town has been undertaken.

This paper describes the power conversion characteristics of the SWEC at the proposed site, structural design of the collector arms and generating tower for both mass gravity or piled solutions, a construction scenario involving a casting harbour in nearby Saldanha Bay and the towing and placement of 53 m long precast modules, and finally an assessment of the environmental impact of the proposed 40 km array on the adjacent coastline.

The proposed system is found to be both technically and economically feasible and offers a useful contribution towards future electric power supply.

#### 1. INTRODUCTION

The Stellenbosch Wave Energy Converter (SWEC) is a shallow water device developed over a number of years to meet the specific requirements for wave power utilisation along the south western coast of South Africa. An analysis of the wave power resource along this coast as well as a full description of the development of the SWEC are presented in Retief et al. (1982).

- 
1. Professor, Ocean Engineering, University of Stellenbosch, Stellenbosch, South Africa, 7600.
  - 2,4. Research Engineer, Ocean Engineering Research Group, University of Stellenbosch, South Africa, 7600.
  3. Associate, Watermeyer, Legge, Piesold & Uhlmann, P O Box 6433, Roggebaai, South Africa, 8012.
  5. Sediment Dynamics Division, National Research Institute for Oceanology, C.S.I.R., P O Box 320, Stellenbosch, South Africa, 7600.

The objective of the present project was to produce an in-depth analysis of a potential application of the SWEC with reliable projections of future costs and operation management. The site chosen had been identified in the previous study as one of the more favourable locations for wave power conversion and the overall design philosophy described in Retief et al. (1982) was adhered to throughout this investigation.

Although the general characteristics of the device had been determined in the previous study a further series of field and hydraulic model studies were required for the determination of design parameters and power conversion characteristics specific to the site. Model studies of the rectified airflow, generated by the SWEC, led to a detailed design of the air turbine/power generation system. A theoretical analysis of prevailing littoral processes provided input for an environmental impact assessment of the proposed array on the adjacent coastline. Sedimentation in the immediate vicinity of the converter was studied both theoretically and empirically. Final costing was based on a construction and management scenario developed in conjunction with a team of coastal engineering consultants and contractors.

## 2. CONVERTER CONCEPT

A typical converter unit, which would form part of the total power conversion array, is shown in Figure 1. For the site under consideration in this project the unit is to be installed in an average water depth of 14 m (i.e. 2 m submergence), approximately 1,5 km off-shore. The two collector arms forming the "V" are 160 m long orientated at 45° to the predominant direction of energy flux at the site. Each arm comprises three precast concrete modules, each containing four chambers in which the water level oscillates. Each oscillation chamber is connected via rectification flap valves to the high and low pressure, closed-system air ducts which merge at the apex of the "V" to form the two legs of the generator tower. An axial flow air turbine mounted horizontally in the tower cabin converts the differential pressure between the two air ducts to mechanical power which in turn drives an alternating current electric generator. The module section shown in Figure 1 relates to the gravity design option - the alternative piled option is shown in Figure 14.

## 3. PROPOSED SITE

The proposed site for the converter array is shown in Figure 2. This 40 km long stretch of coastline, consisting of North and South Bays, is directly exposed to the almost unrefracted south westerly swells which are the cause of the peak levels of wave energy occurring along this section of the Southern African coast (Geustyn, 1983).

The study area has been well instrumented in the past and reliable wave height and direction data for the site are available. Mean annual wave power levels of about 30 kW/m are found in-shore at the generator site, which is conveniently situated, between the urban growth points of Saldanha and Cape Town, near to the national electric power network. The converter array will consist of 154 "V" units with a 770 MWe rating and mean winter capacity of 450 MWe.

FIGURE 1: Typical Layout of Wave Energy Converter

The two bays comprise sandy beaches with an average off-shore slope of 1:100, bounded at each end by a rocky headland. Nett littoral drift is northwards. Off-shore currents are weak and variable and the mean tidal range is 1,0 m diurnal.

A variety of analyses were performed on the available wave data - typical seasonal distributions of wave power were presented in Retief et al. (1982), wave direction characteristics are shown in Figure 3 and long term fluctuations (measured over a five year period at a station at the southern end of the array in 23 m water depth) are shown in Figure 4. The long term analysis produced a maximum deviation from the five year mean of  $\pm 5\%$  for the mean annual power level and  $\pm 20\%$  to  $30\%$  for the mean seasonal power level. As with all forms of fluctuating alternative energy sources a feasibility study of wave power utilisation should include an analysis of the probable occurrence and duration of periods during which the power available falls below some prescribed demand level. Figure 5 shows a Weibull distribution, based on five year's data, of the return period and duration of "calm" events where "calm" is defined by the level of wave power not exceeded during that period.

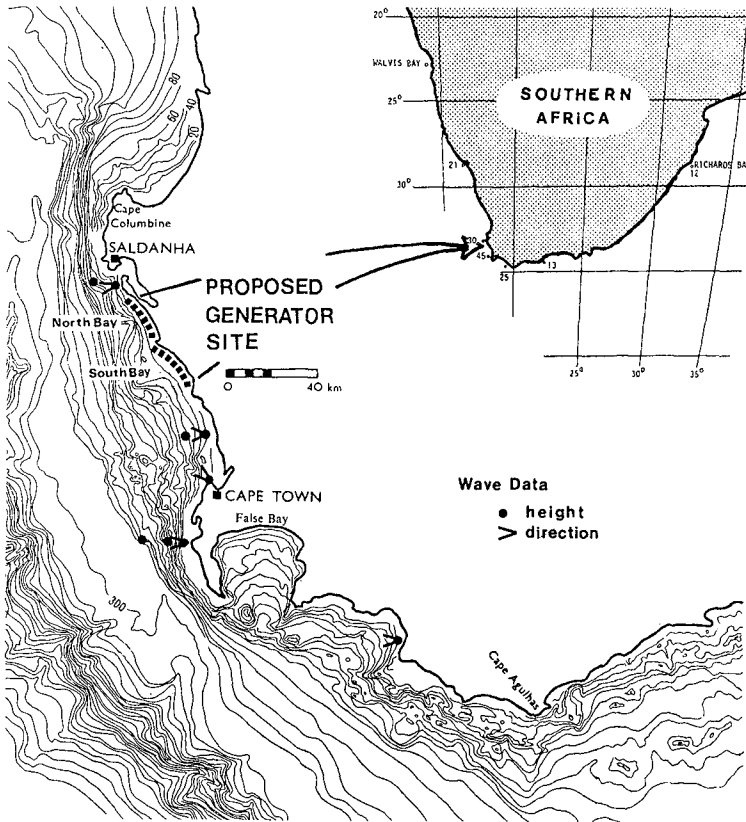

FIGURE 2: Proposed Generator Site

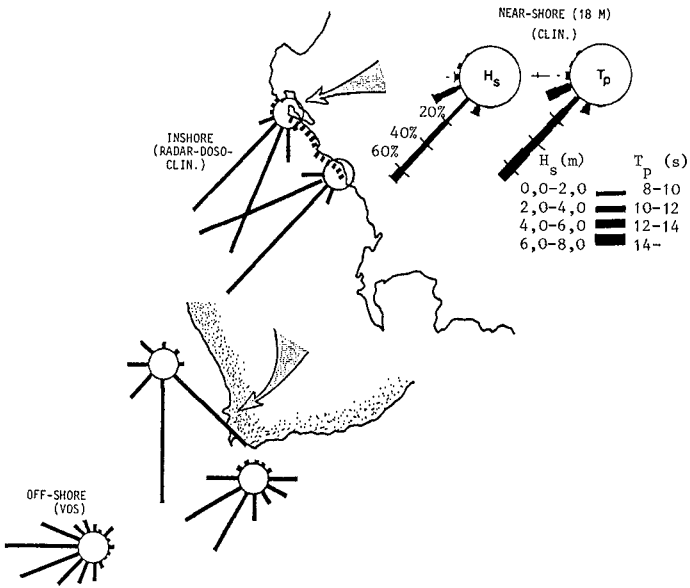

FIGURE 3: Wave Direction Analysis

FIGURE 4: Seasonal and Yearly Variation in Wave Power

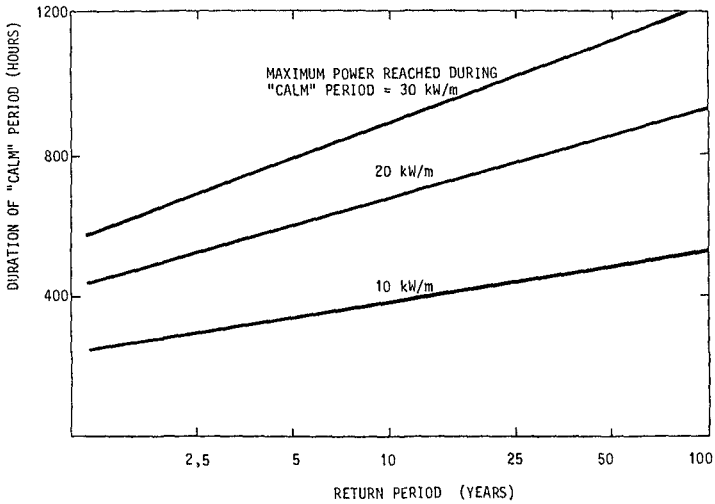

FIGURE 5: Duration of "Calm" Periods vs. Return Period

4. MODEL STUDIES

The physical and theoretical models which were used in the optimisation of the converter array design are summarised in Table 1.

Hydraulic Models	1:60	3-D	Irregular Wave	Conversion Design
				Sediment Studies
	1:50	2-0	Regular Wave	Internal Geometry
	1:100	2-0	Regular / Irregular	Structural Design
Theoretical Studies	LINREF Model (Crowley 1984)			Wave Refraction
	Regression Model (Swart 1976)			Extent of On-/Off-shore Transport
	Analysis based on Evans (1982)			Collector Arm Optimisation

TABLE 1: Model Studies for Converter Design

4.1 Power Conversion

Figure 6 shows the 1:60 scale three-dimensional model of a "V" unit being tested in the irregular wave tank of the National Research Institute for Oceanology of the South African Council for Scientific and Industrial Research. A schematic section of the model in Figure 8 shows the submerged oscillation chamber scaled according to Froude and the airflow system constructed to Reynolds scaling above water level.

Parameters monitored continuously by computer included air pressure at various locations, airflow in both collector arms, and water level both inside and outside the collector arms. The airflow throttle was set at an optimum pressure/flow ratio of 30 pascals per  $m^3/sec$ . Although the air system was not a correct reproduction of the prototype unit, non-linear duct losses are greater at model scale than at full scale (especially for irregular wave spectra at higher energy periods) and the results were considered to be conservative.

An example of a typical Pierson Moskowitz test spectrum is shown in Figure 7. Variables considered in the test series included water depth/structure height, submergence depth, angle of wave attack, swept angle of "V", collector arm geometry, incident and transmitted wave characteristics.

FIGURE 6: Three-dimensional Irregular Wave Tests

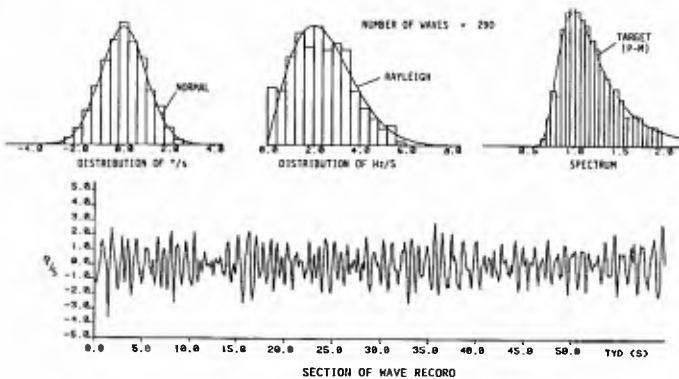

FIGURE 7: Analysis of Generated Irregular Waves

FIGURE 8: Schematic Diagram of Three-dimensional (1:60 scale) Model

The "V" shape of the collector arms not only enhances wave power conversion capability by reflecting "trapped" energy from one arm to the other, it also transmits the greater proportion of the unconverted energy shorewards. This relatively high transmission coefficient reduces the potential impact of the device on the shoreline, and is probably caused by non-linear effects along the collector arm which reduce the effective reflection angle of a wave slug.

In studying the frequency response of the "V" for different collector arm lengths it was found that the converter responds optimally to the zero crossing period,  $T_z$ , of the spectrum and not the peak or energy periods as had been expected. As the SWEC is not a tuned resonator it can be theorised that optimum "coupling" with the incident wave profile would occur at a period which reflects average fluctuation of the water surface ( $T_z$ ).

Directional sensitivity produced very favourable results when compared with the narrow direction spectrum measured at the proposed site. Figure 9 shows that 90% of the wave directions measured at the site fall within the 95% direction dependent conversion efficiency.

The percentage occurrence of power generated at discrete power intervals for one "V" converter is shown in Figure 10. This analysis was based on a 22 month wave record from the proposed site. The average rate of power conversion for the 22 month period is 2,2 MWe per "V", while the winter average was found to be 2,9 MWe per "V" (450 MWe winter average for the full array). The available and generated power in percentage exceedence form is given in Figure 11.

FIGURE 9: Relative Conversion Efficiency with Direction

FIGURE 11: Cumulative Power Exceedence (Available and Generated)

## 4.2 Stability Design

The SWEC has a relatively complicated form compared with the cylinders or spheres for which wave force data have previously been published. As no data were available for structures with water depth to structure height ratios as low as 1,4 (an area where modelling of the free surface becomes significant) it was decided to revert to a two-dimensional model study as a first attempt at determining design forces. The tests were conducted at scales of 1:100 and 1:60 and are described in Morrison and Geustyn (1984). Figure 12 shows peak values of the normalised horizontal force ( $f_x$ ) acting on the converter plotted against a dimensionless wave amplitude for various water depth/structure height ratios, where:

$$f_x = F_{x\max} / \rho g a a_0$$

and

$$a = \text{structure height}$$

$$a_0 = \text{amplitude of incident linear wave } (= H/2)$$

$$k = \text{wave number}$$

The measured curves are compared with those of previous similar studies and are found to display similar trends but with a more rapid reduction in force for higher  $ka$  values due probably to the compliant nature of the front face caused by the opening.

By ignoring wave period and assuming a linear relationship between wave height and applied force Morrison et al. were able to compile a set of simple design curves for various water depths, which were used in the later structural design.

FIGURE 12: Horizontal Wave Force on Structure. Theoretical and Measured (Morrison & Geustyn 1984)

To resist forces acting on the structure two design options were pursued. The one made use of a mass gravity solution which was model studied at a scale of 1:60 (Figure 13). The other solution entailed a theoretical analysis of a piled structure. Both were based on a maximum wave height/depth limited design condition. The design of the generator tower was handled in a similar manner. The force on the deck slab due to water column deceleration against the entrapped air cushion was determined by analytical modelling.

The finally selected sections are shown in Figure 14. Both would be placed by barge onto a prepared rubble bed. The gravity section is designed to be fully stable, immediately after placement, in the flooded mode. The mass surcharge introduced by the backfill, which is later placed by barge, is designed to accommodate the instability introduced by pumping air into the system when power generation commences. As the construction window on the piled option is more limited, driving of the 1,5 m diameter steel piles from a jack-up rig would commence immediately after placement. Both sections caused severe erosion of the seaward toe and a bitumen grouted apron of 2 t selected rubble was found to solve this problem. After the units have been secured on the bed the air ducts will be joined underwater by means of a flexible coupling specially designed for this purpose.

#### 4.3 Sediment Studies

Sediment deposition and erosion in the immediate vicinity of the converter was studied in the three-dimensional 1:60 scale model, qualified by a theoretical prediction of seabed stability. It was found that under the predominant wave conditions the position off-shore is such

FIGURE 13: Two-dimensional (1:60 scale) Stability Tests

FIGURE 14: Alternative Installation Methods

as to be beyond the dynamic sediment swept prism. Under storm conditions a bar was found to occur in the apex of the "V". Further long term build-up or dissipation of this mound has yet to be determined in a more rigorous analysis of the processes involved. The possible need for a sand by-pass or maintenance pumping station has thus not yet been determined. From the data of wave transmission across the converter, determined in the 1:60 scale three-dimensional model, an estimate was made of the overall impact that the array would have on the prevailing on-shore/off-shore sediment processes in the bays. The anticipated seawards shift of the beach line is likely to be between 10 m and 20 m. An anomalous situation could occur at each end of the array due to a discontinuity in long-shore drift rates. To reduce this effect the array is planned to extend as far as the bordering headlands in each bay.

#### 4.4 Airflow System Design

The rectification valves mounted in the plenum chamber above each oscillating water column will consist of 300 mm high plied rubber or neoprene flaps, with directional reinforcing, housed in a removable module. A buoyant splash flap will be installed at each valve opening immediately below the air cushion chamber. It is anticipated that an annual clean-up of the valves will be required to remove marine growth. This will probably entail removal of the complete valve module and its replacement with a serviced module while the converter is in a flooded mode.

Each collector arm will have an airflow throttle control, housed in the generator tower, to damp vertical displacement of the water surface in the oscillation chamber and limit power conversion during storm events. A typical example of airflow surging through the turbine caused by wave-beat is shown in Figure 15.

#### 4.5 Electro-Mechanical Power Conversion

Design parameters for the 3.5 m diameter, 8 m long axial flow variable pitch turbine are summarised in Figure 16. Airflow speeds of up to 100 m/sec will be experienced at the turbine. To counteract water drop erosion of the blades a nickel-aluminium-bronze or stainless-steel tipped G.R.P. construction is being considered. Anticipated maintenance includes an annual cleaning and inspection and 25 year replacement of the turbine. Conversion efficiency of the electro-mechanical system is estimated at 75%.

The variable pitch constant speed turbine will be directly coupled to a 5 MVA, 22 kV synchronous electric generator. The "V" units will be interconnected in groups of six, with each group connected directly to the national electricity supply grid by means of a 1.5 km long 22 kV, 35 MVA seabed cable.

FIGURE 15: Typical Wave Train with Resulting Airflow through Turbine

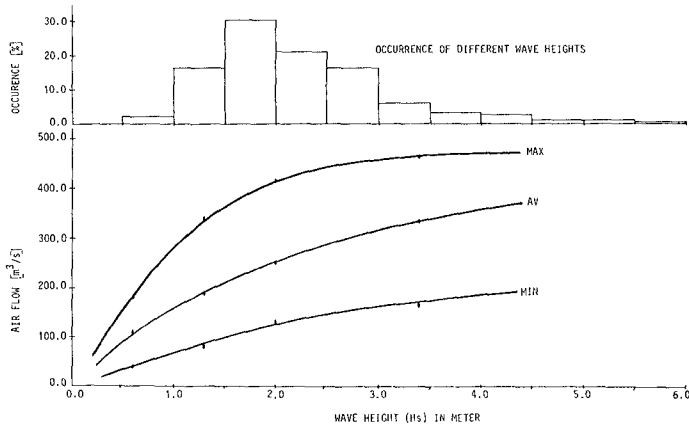

FIGURE 16: Airflow vs. Wave Height

5. LAYOUT AND CONSTRUCTION

A full set of wave refraction diagrams covering five deepsea directions ( $180^{\circ}$ ,  $210^{\circ}$ ,  $240^{\circ}$ ,  $270^{\circ}$ ,  $300^{\circ}$ ) and six periods (10,5; 12,3; 13,9; 15,2; 16,4; 17,5 secs) were compiled for the proposed site. This analysis identified the distribution of wave power along the shore, the long-shore energy flux along the 15 m contour and the optimum orientation for installation of the converter units. Figure 17 is an example

of the most dominant south westerly swell ( $240^{\circ}$ , 12,3 sec) approaching North Bay with a series of typical direction roses used for optimum converter orientation.

Figure 18 shows an artists rendering of the construction phases envisaged. Construction of the complete array has been planned to extend over a five year period after an initial preparation lead time of two years. The precast modules will be assembled in a specially constructed casting harbour within Saldanha Bay and towed to site suspended from a placement barge. The lowering of units onto the horizontal berm will commence at the apex of the "V". Each subsequent unit will be winched up to the previously placed unit to a tolerance of 500 mm and the flexible duct connectors will be installed, followed by the ballast rubble or piling by jack-up rig. The turbine/generator unit will be winched up directly into the tower cabin from a transport barge which will be temporarily moored between the tower legs.

FIGURE 17: Converter Orientation Studies

FIGURE 18: Construction Scenario

## 6. MAINTENANCE AND COSTING

Apart from the annual servicing of the flap valves and generator unit, maintenance of the converter is expected to be relatively low and not to exceed an average present day cost of (RSA) 0,6 cents per kWh over the design lifetime of 50 years. Marine growth in the submerged section of the oscillating chamber is expected to stabilize at a thickness of 120 mm and has not been found to affect conversion efficiency. Water is expected to accumulate in the air ducts and turbine chamber and will be drained to collector points and automatically pumped out. An optimum air volume in the converter will be maintained by an electricaly driven air pump housed in the generator tower. Navigation lights will be mounted at each end of the "V" and on the generator tower.

As the "elasticity" of the national electricity supply network can easily accommodate the expected variability in supply from this relatively minor source of power, costing has been based on total utilisation of the output from the converter array, which for an average year is 2,2 GWh of power delivered to the network (i.e. 14300 MWh per "V" per year).

The capital cost of a single "V" unit (based on the gravity option which was found to be less than the piled structure) is estimated at (RSA) R8,3 m. The projected cost of power delivered covers a range of values depending on the combination of financial parameters assumed. For an economic horizon of 30 years, an interest rate of 15% and an inflation rate of 12%, the present day cost of power delivered (discounted at 10%)

ranges from 2,6c/kWh (for a power tariff coupled to inflation) to 4,3c/kWh (for a tariff increase rate equal to 80% of inflation rate).

These figures compare very favourably with the present cost of nuclear power (RSA 5,6c/kWh) and coal fired power (RSA 4,7c/kWh) for the same area (SAICE, 1984).

## 7. CONCLUSION

The proposed 770 MW (rated output) wave power converter has been studied in sufficient detail to establish both a predictable means of implementation at what is considered to be a reliable estimate of the costs involved. An attempt has been made throughout the study to adopt a conservative approach to those areas which are as yet unproven. The system proposed is however well within the capability of present day technology and as there is scope for further reduction in the projected costs (by more rigorous optimisation of the civil engineering design vis-a-vis power conversion) the SWEC is considered to be a viable and attractive supplementary source of power.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge the financial and technical support of their sponsors and the various organisations who made their time and facilities available for this study.

## CHAPTER ONE HUNDRED SEVENTY TWO

### STRUCTURAL DESIGN PROCEDURES FOR CONCRETE ARMOUR UNITS

Kevin R. Hall, P.Eng.\*, W.F. Baird, P.Eng.\* and D.J. Turcke, P.Eng.\*\*

#### ABSTRACT

A rational design procedure for rubblemound breakwater protection which will ensure both the structural integrity and hydraulic stability of individual concrete armour units and the overall armour system is presented. The procedure involves new experimental techniques for measuring strains in model concrete armour units in a hydraulic model of a breakwater subjected to simulated prototype wave attack and analytical techniques for determining equivalent prototype loads on units. Selected design loads are used to define the resultant stress distribution to allow the designer to take the necessary measures to ensure the structural performance of the unit in a breakwater environment.

#### INTRODUCTION

In recent years, extensive damage has occurred to the armour layers of many breakwaters. In many cases this damage has led to a partial or complete failure of the entire breakwater structure including the core, filter layers and superstructure. In some instances, breakage of individual concrete armour units has been identified as the cause of the damage to the armour layer. This individual unit breakage has clearly demonstrated the inadequacy of existing procedures for successfully designing the armour layer of the breakwater.

Although specific concrete units such as the dolos and tetrapod can be identified as being more prone to structural failure, many other types of units including cubes have been observed to break in the breakwater environment. For this reason it is not sufficient to eliminate the use of units such as the dolos or to design the armour layer with large cubes placed on very flat slopes (to restrict motion). This does not achieve the desired objective of breakwater design which is to provide a safe, reliable, structure as economically as possible.

Existing design procedures must be updated to reflect the current state of the art in other scientific disciplines such as structural design, instrumentation techniques and materials modelling.

A review of existing breakwater design procedures reveals that designers have, consciously or not, accepted that undefined tensile

\* W.F. Baird & Associates, Coastal Engineers Ltd., 1390 Prince of Wales Drive, Suite 309, Ottawa, Ontario, K2C 3N6, Canada

\*\*T& C Engineering, Cartwright Point, Kingston, Ontario

stresses can occur in the armour units since movement of the units has been accepted. The procedure outlined in this paper has been developed so that these previously undefined stresses can now be determined and the appropriate action taken to ensure both the structural integrity and hydraulic stability of the armour units.

Several of the technical studies required to develop this rational design procedure are described in this paper. It is important to note that the design procedure was developed using existing technology from other areas of engineering, such as materials modelling, instrumentation, finite element methods and structural design techniques. These technologies were adapted for use in a hydraulic model and to take into account the uniqueness of a breakwater environment. These studies considered the following:

- A review of instrumentation or measuring techniques that could be adapted for use in a hydraulic model study to define the loads (or resulting stresses or strains) that occur on an armour unit. The instrumentation techniques reviewed included accelerometers and high speed photography to define unit movements and load cells, strain gauges, photoelastic techniques and full field strain measuring techniques to determine stress or strain levels in the units. The practicality of working at specified scales and in a hydraulic environment precluded the effective use of some of the identified techniques. As a result of this review, a system utilizing strain gauges placed at strategic locations on the model armour units used in the hydraulic model and directly measuring the strain level during simulated prototype wave attack was selected.
- A review of model materials was undertaken. Selection of a material was made in relation to the scaling down of prototype properties so that the requirements of similitude between the model and prototype are met. However, since the displacement related to the deformation of the prototype units is small, a certain level of strain distortion is permissible in the model and it was therefore advantageous to select a material with a low modulus of elasticity (resulting in a magnification of the low level strains in the model). A reinforced epoxy resin was selected which permitted the use of acceptable geometric scales with an appropriate scaling of material properties.
- A series of specifications for the design of the instrumentation system were developed based on the model material, hydraulic testing techniques, anticipated strain levels and minimum performance criteria.
- A thorough assessment of the reliability and repeatability of the instrumentation system was made for a range of static, dynamic and combined static-dynamic loading. A number of prototype tests described in the literature were duplicated to assist in assessing the accuracy of the system.
- Analysis of measured model data was completed using finite element procedures. Post processing colour graphics capabilities were developed to assist in presenting the data.

Each of these technical studies is described in more detail in the following sections. The component studies have been integrated into a rational design procedure. This is used to produce a design for a breakwater armour layer which is made both economical and reliable by combining structural integrity with hydraulic performance.

OVERVIEW OF THE DESIGN PROCEDURE

The rational design procedure involves techniques to define the loadings imposed on a model armour unit on a breakwater subjected to simulated prototype wave attack and subsequently, using conventional structural engineering techniques to determine the resulting stress distribution in the armour unit. A detailed design of the individual units can then be undertaken using standard structural engineering procedures that utilize reinforcing (bar, fibre and prestressing) or make use of changes in the geometry of the unit. A general outline of the overall design procedure is given below. The procedure is illustrated in Figure 1.

Fig. 1 Design Chart

Initially, it is necessary to fully understand the environmental conditions to which the breakwater is exposed, of which the most important parameter is the wave climate.

The choice of armour unit is up to the designer and should depend upon a number of variables including economics, material availability, form availability and construction equipment availability. Initially, the design should be developed using a hydraulic model study so that the armour units are not displaced from the armour layer under the design wave conditions. The assumption will be made at this point that each unit has sufficient strength to resist the applied forces.

Model armour units instrumented with a number of strain gauges placed at strategic locations on the unit are placed at random through the design test section. Values of strain are recorded continuously throughout the testing. Tests are undertaken for a variety of instrumented unit placement locations. From the results of the measured data, a history of the internal forces and moments occurring at the instrumented cross-section can be derived. The measured internal forces will include dynamic loads resulting from wave action on the breakwater, from collision between adjacent units and from static loads that are imposed by adjacent units or as a result of differential settlement of the structure.

Simplified equivalent external load conditions and constraints are derived, using numerical analysis, from the internal forces and moments

determined at the instrumented cross-section. The equivalent loads produce the selected measured stress (strain) distribution at the instrumentation location. Because of the random nature of the applied loads in a breakwater environment, it is necessary to undertake a statistical interpretation of the measured data. For each set of strains measured (flexure, torque, shear and axial) a frequency of occurrence distribution is determined. Extreme events from a selected set of strain data are combined with the other corresponding strains to determine equivalent design loads.

The design loads are applied to a finite element model of the armour unit to calculate the resulting stress distribution within the armour unit. The armour unit can now be structurally designed to resist the applied loadings using conventional structural engineering procedures. This may include the use of reinforced concrete, fibre reinforced concrete, prestressed concrete, the use of alternative materials or modification to the geometry of the unit (development of a new unit or armour layer system).

If additional changes to the design are implemented as a result of construction constraints and limitations, then the process of defining the loads in the hydraulic model would be repeated for the new design. The result of this procedure is the development of a breakwater armour design which provides the most economical solution combined with optimum hydraulic and structural performance.

#### DESCRIPTION OF THE COMPONENTS OF THE PROCEDURE

##### 1. Model Material Selection

Selection of the appropriate model material was based on the fundamental requirements of similitude between the model and prototype. This requires that the relationship between certain strength characteristics of the model material and the geometric scaling factor (in relationship to prototype) be properly assessed. A static dimensional analysis was carried out (Hall 1984, Baird et al, 1983) which showed that for complete similarity the geometric scaling must be identical to the material scaling. However, since the displacements related to the deformations of the prototype are sufficiently small, and not critical to the overall behaviour of the breakwater, some strain distortion and differences in Poisson's ratio is permissible. The results of the dimensional analysis yield,

$$\Theta_m = \frac{E_p}{E_m} \frac{h_m}{h_p} \Theta_p \quad (1)$$

where,  $\Theta$  = strain level;  $E$  = modulus of elasticity;  $h$  = geometric linear dimension; the subscript m denotes model and the subscript p denotes prototype.

Clearly, the choice of model size or geometric scale has a direct influence on the expected model strain levels. Since the strain gauging system has a limited resolution, the model material was selected so that the strains induced in the relatively small scale hydraulic model

studies would be of sufficient magnitude to be measured by the gauges.

Consequently, the following general requirements were identified. The material should:

- 1) have approximately the same density as concrete
- 2) be linear, elastic, homogeneous and isotropic
- 3) have a strength that would produce minimum model strain levels in the order of 50 microstrains to ensure that the behaviour of the units could easily be monitored within the resolution of the instrumentation
- 4) have reproducible mechanical properties
- 5) be easily strain gauged
- 6) be easy to use in a casting process
- 7) be relatively inexpensive.

Three major types of material are available for the construction of elastic models - plastics, cementitious materials and metals. It was determined that plastics meet most of the general requirements. Metals could not be found with the critical combination of the correct density and the desired elastic modulus required to ensure measurable strains and cementitious materials could not provide the long term stability required in a hydraulic environment and they are not easy to strain gauge.

There are a wide variety of thermoplastics and thermosetting plastics available with a diverse range of chemical composition and mechanical properties. Thermosetting plastics were identified as the best available material for the following reasons:

- 1) thermosetting plastics have a limited development of heat of polymerization which assures a homogeneous hardening process and results in a relatively consistent modulus throughout the material.
- 2) the relatively lower shrinkage that occurs in epoxy compounds after casting results in a significant decrease in the internal stresses.
- 3) the density, elastic modulus and curing rate can be easily modified by adjusting the amount of hardener or adding an inert material (filler) dispersed homogeneously throughout the model unit.

The material used to construct the model armour units was a steel fibre reinforced epoxy resin which had a bulk density of approximately 2000 kg/cubic metres and a Young's Modulus of Elasticity of 5 GPa.

## 2. Design of the Instrumentation System

The selection of the type of strain gauges and their placement location on the model armour units requires careful consideration since the forces acting on the unit and hence the stress/strain distributions are unknown. The design of the instrumentation has the fundamental objective of providing an economical, efficient strain gauging system capable of withstanding the environment in which it is operating. This design can only be achieved by taking into account the following

fundamental issues:

- 1) Environmental Operating Conditions - Factors such as temperature fluctuations, abrasion and hydraulic considerations.
- 2) Loading-Environment - Qualitative loads must be identified, such as static loads due to mound settlement, self-weight and weight of adjacent units and dynamic loads due to interunit and projectile collisions and hydrodynamic impact pressures.
- 3) Geometry - The geometric size of the model unit and the material used to construct the unit must be optimized.
- 4) Gauge Location - The density and placement of the strain gauging array must be selected to ensure adequate definition of stresses induced by torsional, flexural, shear, and axial loading conditions.
- 5) Strain Level - The possible magnitude of strains that will occur in the model must be defined so that the appropriate instrumentation can be selected.
- 6) Installation - The method of installing the gauges and subsequent water-proofing of the system must be defined.

Based on the requirements listed above and on a review of available strain gauging techniques and systems the following type of instrumentation package was developed.

For bending, torque and shear measurements, the gauge type used is a Vishay Micro-Measurement No. EA-06-125TW-120. The characteristics of this gauge type are as follows:

- constantan (A-alloy) in self-temperature-compensated form
- flexible polyimide backing
- self-temperature-compensation number = 06 in/in/degrees F
- 3 mm (.125 in) gauge length
- grid and tab geometry "TW"
- 120 ohms resistance

The gauge type used to measure axial strains is an EA-06-125TE-120 and differs from the EA-06-125TW-120 gauge only in its grid and tab geometry.

The gauge arrays should all be self-temperature-compensating (full bridge) to eliminate the effects of apparent strain in the system.

The EA series of gauges are a constantan (A-alloy) foil in combination with a tough, flexible polyimide backing, which is capable of operating in a temperature of -75 to +175 degrees Celcius. The constantan alloy has a high strain sensitivity (gauge factor) which is relatively insensitive to strain level and temperature and its resistivity is high enough to achieve suitable resistance values in very small grids. The polyimide backing is a tough, flexible carrier and can be contoured readily to fit very small radii. This backing is also

capable of very large elongation and can be used to measure plastic strains in excess of 20%.

Strain gauge performance is easily degraded by the effects of moisture damage and as a result, gauges require varying degrees of protection according to the severity of the environment in which they operate. For use in a hydraulic model study, the gauges will be subjected to a changing wet-dry environment and may be susceptible to abrasion; therefore, a good protection system is required. The work completed to date has used a system protected with Micro-Measurement M-Coat-G, a polysulfide modified epoxy compound and M-Coat B, a solvent thinned nitrite rubber compound. This system was found to provide excellent protection to the strain gauges.

### 3. Data Measurement

The instrumented model armour units are placed in the model breakwater which is subjected to simulated prototype design waves. Several considerations must be made at this point.

The random placement of armour units in the armour layer, results in a random pattern of constraint points and loading locations, and as a consequence, the forces acting on a unit will show a large variability based on the units location within the armour layer.

Therefore, it is important to determine the number of units and their placement within the armour layer required to accurately provide a definition of the stress envelope describing all possible unit locations on the breakwater. That is, it is necessary to understand how many instrumented units are required in a given test and how many tests are required (each test will require the test section to be rebuilt) to define this envelope.

Observations of prototype structures indicate that the most extensive breakage of prototype units occurs in the vicinity of the mean water level where the wave induced velocities in the armour layer are the greatest. This would indicate that forces on individual units are probably the largest in this area.

As the breakwater is tested, output from the gauges is a continuous voltage readout. Typically, voltage signals are relayed through a signal conditioner-amplifier and filtered through a high speed data acquisition. Experience has shown that a sampling rate of 100 to 200 samples per second (per channel) provides a suitable definition of the dynamic loads, although more study is required in this area. The signal can then be converted to a digital signal and stored on a computer for subsequent analysis.

In any particular test of a breakwater, in which the instrumented units are placed, the time history of the strains from all gauges is recorded simultaneously, resulting in a large quantity of data. The data must be pre-processed so that the design loads (at a desired level of exceedance) can be determined with a minimal amount of numerical analysis.

Several alternatives have been used; however, this is an area in which more research will be conducted in a future study to optimize this part of the design process. In one technique, equivalent load conditions on each instrumented unit are determined for each wave event based on the measured strains. Resultant stress values are then calculated for selected locations in the armour unit. However, because of the large number of events it is necessary that some preselection of the data be undertaken. Alternatively, statistical interpretation of the measured strain data can be made. For each set of strains measured (i.e. either flexure, torque, shear or axial strain) a frequency of occurrence distribution would be determined. Extreme events from a selected set would then be combined with the other corresponding strains to determine equivalent design loads and resulting stress distributions.

#### 4. Data Analysis and Presentation

The objective of the design procedure is to take the strain components measured during the hydraulic model tests and derive, using numerical analysis, loads that can be used for the structural design of the concrete armour units.

Finite element methods and colour graphics postprocessing are used extensively to determine the loads and view the stress distributions throughout the unit. The finite element technique is well established as a powerful tool capable of carrying out complex dynamic non-linear material and geometric analysis. The graphics package permits the analyst to quickly see the flow of stress throughout the model and verify that the model is behaving correctly.

Using the numerical techniques, simplified equivalent load conditions that produce the selected measured stress distributions at the instrumented section location are determined. These equivalent loads or, in fact, imposed boundary conditions are selected in such a way as to maximize the internal generalized forces and moments which are viewed as contributing most to the failure of prototype units at preselected locations.

Figure 2 shows a finite element grid model developed for a dolos.

Several techniques are available for viewing the resultant stress distribution in the armour units including stress flow diagrams which show the magnitude and location of tensile and compressive stress flow patterns and stress block techniques which indicate the intensity of surface stresses in the various elements. Figures 3, 4 and 5 show stress flow patterns for the dolos, tetrapod and tribar units for predetermined load conditions.

#### 6. Model-Prototype Relationship

The relationship between model and prototype is of fundamental importance to the design procedure. Two techniques are available; the first approach is to relate model strains directly to prototype strains and then determine the appropriate loads, while the second approach consists of first determining the model loads and then calculating the

Fig. 2 Discretized Dolos

Fig. 3 Stress Flow Diagram - Dolos

Fig. 4 Stress Flow Diagram - Tetrapod

Fig. 5 Stress Flow Diagram - Tribar

prototype values of load and strain. A discussion of both approaches is made below.

In the first approach the ability to relate strains between the model and prototype requires that the model material replicates all the fundamental material properties of the prototype. As a result, with the model material selected, which is essentially homogeneous linear elastic, model and prototype strains can only be related up to cracking for both unreinforced and reinforced concrete prototype units. This type of simplified relationship has been developed and is presented in Hall (1984).

For those units that are reinforced this structural model will not provide direct prototype strain information. In addition, any complete relationship must also take into account the static and dynamic attributes of both the model and prototype materials. Consequently, a direct relationship between model and prototype strains is both complex to develop and limited in its range of application.

An alternative to the above is the second approach which only involves establishing a model to prototype load relationship. Essentially, this method requires that the model material be well defined, that is both the static and dynamic properties be established, and the model loads be determined from the measured model strains. Once these loads are defined, the appropriate model to prototype load factor, based on the geometric scale, can be used to determine the equivalent prototype loadings.

It is important to note that there has been no restriction placed on the prototype material, since the determination of these loads did not require a prototype material definition.

Consequently, this approach can be applied to reinforced concrete units or units made of any other material. Thus the analysis and design of prototype units can be based on the appropriate codes of practice once these design loads are determined.

#### EXAMPLE APPLICATION

In this section of the paper an example of the design and performance of an instrumented model armour unit is given. The units used as an example are 110 mm dolos units which were subjected to extensive testing consisting of singular static and dynamic loadings in a dry environment and hydraulic model testing using both regular and irregular waves. Complete details of the tests are given in Hall et al (1984).

The design of the instrumentation package for the dolos unit required careful consideration since the forces acting on the unit and hence the strain distribution were unknown.

An approximation of the strain levels anticipated in the model dolos units was made using finite element analysis in which simplistic loading cases were imposed on a discretized dolos unit. Based on the results of

this analysis, it was anticipated that strain levels would be in the order of 40 to 200 microstrains for 110 mm units constructed of steel fibre reinforced epoxy resin.

The instrumented unit is shown in Figure 6.

Single point static loads were applied at a number of locations on the unit to place the instrumented section in pure flexure, torsion and axial strain and combined flexure, shear, torque and axial strain conditions. The units were restrained in a fixture designed to provide a solid restraint without inducing apparent stress within the units. Figure 7 shows a sample of the load versus strain curve for a typical test and indicates a linear relationship for both the loading and unloading curves.

A number of tests were performed in which an instrumented unit was placed in an armour layer and consequently, subjected to multiple static loads. Variation was made in the number of layers of dolos, placement density and slope of the armour layer. Figure 8 shows the response for one particular set up and illustrates the variation of static strain with a change in slope of the armour layer.

A number of dynamic tests were also undertaken in a dry environment. These tests consisted of short duration single event dynamic impacts created by dropping the unit onto one of its flukes or fluke ends. Figure 9 shows the type of tests conducted and Figure 10 shows a typical response. The sharp response at the moment of impact is clearly visible in Figure 10. However, the magnitude of the induced strains measured at the centre of the shank of the dolos are relatively small. Subsequent numerical analysis has shown that strain levels near the fluke-shank interface may be 3 to 5 times larger than those in the middle of the shank during this type of loading event.

The most interesting example of the use of instrumented units is given by observing the performance of the instrumentation during a breakwater model test in which the test section is subjected to simulated prototype waves. The units were subjected to both static loads, resulting from self-weight, the weight of adjacent units and mound settlement and readjustment, and dynamic loads resulting from hydrodynamic forces and impact with adjacent units. The instrumented units were placed at random within the breakwater armour layer. The test section was initially subjected to low wave conditions which were increased in small increments until significant armour unit movement was observed. Figure 11 shows the instrumented units in a typical test set up. Figure 12 shows the breakwater being subjected to wave attack.

Figure 13 shows an example of the output measured during a test conducted with regular waves. The repeatability of the strain signal at the same period as the period of the waves is excellent and illustrates the capability of the instrumentation. The strain level recorded exhibited a marked increase with an associated increase in wave height.

Figure 14 illustrates the response of the instrumented unit during tests ran with irregular wave conditions having a peak model wave period

Fig. 14 Strain Response - Irregular Wave Test

of approximately 2 seconds. Both the magnitude of the peak strain levels and the period between peaks is irregular and in fact, in some instances, the strain levels exhibit a groupiness similar to that observed in the irregular wave trace.

The following comments can be made with respect to the performance of the instrumentation used during these tests:

- 1) individual strain levels exceeding the tensile cracking strain level for concrete were recorded in wave conditions in which armour unit motion was observed.
- 2) the response of the instrumentation in irregular waves exhibited excellent repeatability in phase with the period of the waves.
- 3) the instrumentation is not affected by the hydraulic environment of the breakwater.
- 4) the instrumentation is not affected by abrasion occurring as a result of adjacent units moving over the surface and colliding directly onto the gauges.
- 5) the lead wires from the gauges do not affect the movement of the instrumented units or the units adjacent to them.

In general it is concluded that the strain gauging system provides a viable system of measuring strain levels in model armour units subjected to simulated prototype wave attack in a hydraulic wave flume.

#### CONCLUSIONS

A rational procedure for designing concrete armour units so that the structural and hydraulic performance can be simultaneously guaranteed has been presented. The various aspects that require consideration when designing the instrumentation and developing the prototype design criteria were discussed. The general objectives of utilizing this design procedure is to permit the widespread use of precast concrete units throughout the design life of the structure and represent a least cost investment.

A procedure for defining the loads that occur on a breakwater which enables the engineer to structurally design the unit has been developed and its performance evaluated.

Based on the design loads, the designer can determine the size of unit required, and the necessity for reinforcement (and type of reinforcement required). If necessary the geometry of the unit can be altered to reduce the occurrence of stress concentrations. This may ultimately result in the development of new units which optimize the combined structural and hydraulic performance.

In addition, if fatigue analysis is required, the defined loads can be employed to determine the expected life of a unit so that estimates of maintenance costs over a given period of time, related to replacement of armour units, can be determined.

Alternatively, these procedures could be used to develop codes of practice for concrete armour unit design which would provide a

description of the design loads for the many types of armour units used in breakwater design and for many of the variations in the physical environment of a breakwater.

#### ACKNOWLEDGEMENTS

The authors would like to thank the National Research Council of Canada, Hydraulics Laboratory and Public Works Canada for funding of various parts of the development of the overall design procedure.

## CHAPTER ONE HUNDRED SEVENTY THREE

### THE DESIGN OF BREAKWATERS USING QUARRIED STONES

W.F. Baird, MASCE, P.Eng.\* and K.R. Hall, AMASCE, P.Eng.\*

#### 1.0 Introduction

The majority of rubble mound breakwaters built in North America that use quarried stones in their armour layer contain either one or two layers of armour stone, one or two filter layers and a core of quarry run.

Preparation of a design normally involves use of the Hudson equation and may be supported by physical model tests. Once the design wave conditions are defined the size of armour stones are only a function of the outer slope of the breakwater.

In this paper an alternative approach to the design of quarried stone breakwaters is discussed. The basic principal involved in this concept is the use of locally available materials. It is established that the greater the thickness of the armour layer, the smaller the stones that are required to provide stable protection against wave action. Therefore, the thickness of the armour layer for a specific breakwater is determined by the gradation of the available armour stones and the incident wave climate. The final cross-section makes allowance for the practical considerations of breakwater construction. New concepts for breakwaters that have resulted from the use of this alternative design procedure are described. Construction of these breakwaters in 1983-84 has demonstrated that significant cost savings are obtained.

#### 2.0 Traditional Design

The traditional design approach is described in many texts, and in greatest detail in the U.S. Corps of Engineers Shore and Protection Manuals (4). A breakwater design that may result from the use of this procedure is shown in Figure 1.

A number of possible difficulties with the construction of this design can be identified and include the following:

- Large Armour Stones Required. At many locations the wave climate dictates (through the design formula) large stones that may be very expensive to obtain or are not available.

In the latter case the designer must specify concrete armour units which will significantly increase the cost of the project.

\* W.F. Baird & Associates, Coastal Engineers Ltd., 1390 Prince of Wales Drive, Suite 309, Ottawa, Ontario, K2C 3N6, Canada

Figure 1. Example of Conventional Armour Stone Breakwater

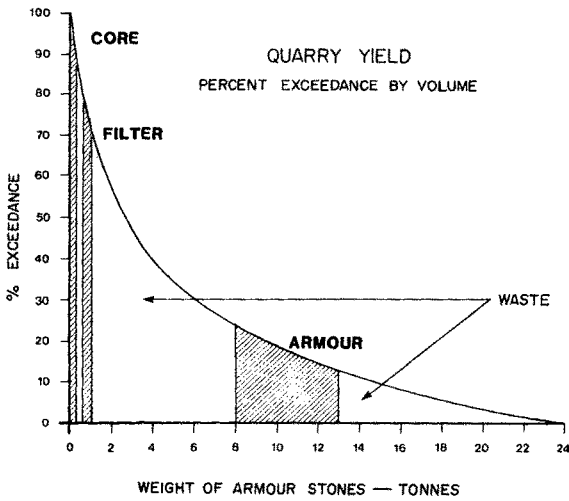

Figure 2. Quarry Yield and Stone Weights Required By Conventional Breakwater

- Wastage at the Quarry. The volume of armour and filter stones of the specified weights used may represent only a small percentage of the volume that must be quarried to obtain these stones. This problem is illustrated in Figure 2, which shows the yield of a typical quarry and the range of stone weights that can and cannot be used for a breakwater. This breakwater is designed for a significant wave height of 5 m and has a front slope of 2 horizontal to 1 vertical.

The relative proportions of material required to build this breakwater in 12 m of water are compared to the relative proportions of the usable volumes of the quarry yield in Table 1. In this example, over-production of armour stones will be required to produce the required volume of core material, although quite often the converse is true.

- Costly Quarry Operations. The quarry operation must be geared to produce armour stones, filter stones and core material. This may require differing blasting procedures. All other material that results from the quarried operations must be sorted and placed in a waste pile.
- Difficult to Construct. Placing continuous layers of armour and filter stones to specified tolerances for location and slope below water requires very careful supervision and inspection, which may be restricted by poor visibility. This may be very problematic in deeper water and/or at locations where there is little calm weather. Construction problems may also be associated with requirements to place core, filter and armour material in close succession to avoid damage to a partly built breakwater by wave action. The supply of materials along the breakwater can cause major logistical problems.
- Speed of Construction. The rate of placement of armour stones on a traditional breakwater is limited by crane operations, which are relatively slow.

The conventional design procedure based on the Hudson formula provides very little flexibility to the designer to overcome these problems and provide what could be a more cost effective design.

### 3.0 Alternative Design Approach

The basis of the design procedure described in this section is the optimization of the use of locally available material and the preparation of a design that requires relatively simple but effective construction methods.

The objective of the design process is to prepare a least cost and stable breakwater.

In order to develop the design, the following procedure is used:

- i) Study the properties of locally available stones.
- ii) Define the range of sizes of the locally available material, typically the gradation of curve of a quarry.

TABLE 1

COMPARISON OF RELATIVE PROPORTIONS OF MATERIAL VOLUMES  
REQUIRED FOR BREAKWATER TO THE USABLE QUARRY YIELD

	Percent of Breakwater Volume	Percent of Usable Quarry Yield
Armour	25	36
Filter	25	26
Core	50	38

TABLE 2

COMPARISON OF STONE SIZES POSSIBLE WITH BERM DESIGN  
AND CONVENTIONAL DESIGN

Design Significant Wave Height (Metres)	Range of Armour Stone In New Design (Tonnes)	Stone Weight For Conventional Design (Tonnes)	
		Slope	
4	0.2 - 1.1	1:1.5	1:2
		7.1	5.3
6	0.7 - 3.5	24	18
8	1.8 - 8.4	57	43

Note: The size of armour stones used in the proposed concept should be dictated by the yield of the local quarry and may be larger than shown. The above indicates possible lower limits that may be considered.

- iii) Use the smaller fraction of the available material for the core of the structure, as illustrated in Figure 3.
- iv) Use the large fraction of the available material for the armour, as illustrated in Figure 3.
- v) Determine the shape and dimensions of the armour protection, which typically involves increasing the thickness of the armour layer, so that during design wave conditions, a stable structure is obtained. This activity is completed using physical hydraulic model studies. As the dimensions of the armour protection are determined, the relative sizes of core material and armour material (items iii and iv) will vary to accommodate changes in the relative percentages of armour stone and core material required.
- vi) Finalize the geometry of the cross-section of the armour to allow for simple construction operations.

The design concept that has resulted from this approach contains armour stones placed in the form of a horizontal berm as illustrated in Figure 4. It is the horizontal dimension "L" that is to be determined in the model studies. This dimension is a function of the armour stone gradation and incident wave height. In Figure 4 comparison is made between a conventional breakwater and this alternative design when designed for the same wave conditions. This breakwater concept has the following features.

- The armour stones can be less than one-fifth the weight of the stones required in a conventional design, as illustrated in Table 2. However, the important point is that the concept is intended to make use of the available stones and not necessarily the use of smaller stones.
- Maximum use of quarry yield, as illustrated in Figure 3.
- Simple Design. Filter layers and toe scour protection berms are usually not required.
- The quarry operation consists only of blasting and sorting the stones into two categories (the larger fraction and the smaller fraction).
- The breakwater can be built using land based equipment only. In most cases a dump and push operation can be utilized and no crane placement is required. Plenty of room is available on the breakwater for construction roads. Wave action during construction is relatively of little concern.
- Construction tolerances can be relaxed and the requirement for extensive underwater inspection can be replaced by relatively simple surveys.
- The performance of the breakwater when subjected to waves exceeding the design condition is significantly better than the performance of a conventional structure exposed to similar conditions. The structure

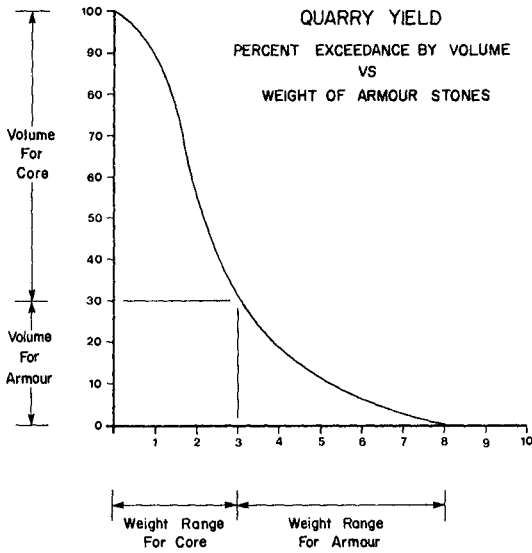

Figure 3. Quarry Yield and Stone Weights Required By Berm Breakwater

Figure 4. Example of Berm Breakwater Compared to Conventional Breakwater

will not fail in a rapid catastrophic manner.

- The total volume of the structure, compared to a conventional structure, depends on the depth of water and the size of stones available. Typically, it may be 10 to 20 per cent greater in depths of 10 to 20 metres.
- The cost of construction of this breakwater in Canada has been found to be between 50 and 70 per cent of the cost of an equivalent traditional structure.

The improved performance of the structure compared to conventional structures is achieved because of the permeable berm of armour stones that consolidates into a well 'nested' and armoured surface. In the following discussion the main armour protection, which is in the form of an armour stone berm, is referred to as the berm.

The relatively high porosity of the berm allows the waves to propagate into the armour stones and dissipate their energy over a large area within the berm. In a conventional two stone armour layer, the flow produced by the incident wave is restricted by the relatively impermeable filter and core and, consequently, there are large velocities produced by the wave uprushing or downrushing within the narrow armour layer. In the berm the flow has a larger area into which it can move and as a result localized velocities are greatly reduced thereby decreasing the external hydrodynamic forces applied to the stones. A considerable increase in stability is achieved as a consequence of this dissipation of wave energy within the permeable berm of armour stones.

The berm also increases its stability as a result of progressive wave action exceeding a threshold that will cause motion of the stones in the berm. The berm is consolidated as a result of nesting of stones and this increases the shear strength of the berm. This nesting process also results in an increase in the frictional restraint on individual stones. Depending on the size of stones available and the design wave conditions, movement of stones on the outer surface may occur to varying degrees. Movement takes place during the early stages of exposure to wave action. The stones eventually find a geometrically similar space in the berm surface into which they nest. The result of this process is a natural armouring of the outer layer of the berm. A typical armoured profile is illustrated in Figure 5, where it can be seen that the final profile has been consolidated to approximately 85 to 90 per cent of the as-placed volume.

Although the final shape of the cross-section may be similar to the 'S' shape profile reported by other investigators (3), there are several subtle differences. The berm does not change profile below a certain depth. Stones are not rolled out of the top of the berm and carried down to the seabed. The berm is consolidated because the stones that move eventually find a geometrically similar void into which they nest. Also, the profile of the berm is quite regular through the water line, typically in the order of 1:5, whereas an 'S' shaped profile tends to have a curvature to it in the region of the waterline.

Figure 5. Profile Development on Berm Breakwater

Figure 6. Cross-section of Unalaska Design

Figure 7. Cross-section of Codroy Breakwater

A formula to assist with the design of this concept of breakwater cannot be introduced because of the site specific nature of each design.

#### 4.0 Summary of Recent Experience

In the following section some designs that have been developed are summarized.

##### i) Runway Extension, Unalaska, Alaska

Protection against a design significant wave height of 10.5 m was required for a runway extending into a maximum water depth of 17 m. The armour consisted of a 23 m wide berm of 3.5 to 17 tonne stones. This design is reported in references (1) and (2). The cross-section is illustrated in Figure 6.

This design was prepared for Dames & Moore, Anchorage, who were responsible to the State of Alaska for this project.

##### ii) Helguvik Bay, Iceland

The breakwater was designed for a significant wave height of 6 m in a water depth of 20 m. The armour consisted of a 14 m wide berm of 1.7 to 7 tonne stones.

The design was prepared for Bernard Johnson Inc. of Bethesda who were responsible to the U.S. Navy for this project.

##### iii) Codroy, Newfoundland

The breakwater was designed for a maximum wave height of 6.8 m. The armour consists of a 12 m wide berm of 0.5 to 4.0 tonne stones. This breakwater is illustrated in Figures 7, 8, and 9.

Construction was completed in the summer of 1984. The work was completed for the Department of Public Works of Canada.

##### iv) North Bay, Ontario

The breakwater is designed to protect a marina. The design significant wave height is 1.5 m and the maximum water depth is 5 m. The breakwater was built out of 2 to 750 kg stones. The breakwater is illustrated in Figure 10.

Construction was completed in the summer of 1984. The work was completed for the Department of Public Works of Canada.

##### v) Breakwaters in Iceland

Four breakwaters based on this concept were built in Iceland by the Harbour and Lighthouse Authority in 1983-84. Contractors were invited to bid on conventional designs as well as the berm design. The berm design was found to be significantly less expensive.

Figure 8. Codroy Breakwater After Construction. Breakwater Extends From Beach (in foreground) to an island

Figure 9. Berm of Codroy Breakwater During Construction Showing 0.5 to 4.0 Tonne Stones

### 5.0 Model Investigations

The designs described above, with the exception of the Icelandic Harbour and Lighthouse Authority breakwaters, were based on extensive model investigations. These studies involved in excess of sixty complete tests (simulating a full storm profile) in three dimensions using irregular waves at scales between 1:30 and 1:50, and have considered the following variables:

- stone sizes and gradations
- width of the berm
- wave attack at an angle to the breakwater
- changes in water levels
- duration of storm and storm profile
- more than one consecutive design storm
- angular and rounded stones
- crest elevation and overtopping

Verification of the prototype performance of these structures has been the subject of discussion during the review of all of these designs. Review of the literature shows that extensive prototype data describing the performance of quarried stone structures of a similar nature exist. Since the 1800's many breakwaters have been built by dumping all quarried material at the breakwater site. The breakwater at Cherbourg, France; Plymouth, England; Fishguard and Holyhead, Wales; Aldernay, Channel Islands; Port Elliot and Encounter Bay, Australia are some examples where a major part of the structure was built in this way. Extensive surveys of many of these structures exist, although difficult to obtain, and provide support to the performance of the structures observed in the model tests. The question is whether the hydraulic model studies undertaken of these site specific designs fully represent the prototype processes. Consequently, in the development of these designs the size of the model, the simulation of storm waves, and the properties of the stones were very carefully reviewed.

### 6.0 Conclusions

The following conclusions can be drawn:

- i) The potential of quarried stones for protecting breakwaters from wave action is not realized with traditional designs.
- ii) Quarried stones could be used at many locations where expensive and problematic concrete units have been used in the past.
- iii) Significant cost savings compared to conventional structures can be achieved because of minimum wastage of available material, use of smaller stone sizes and simple construction methods. Cost savings of between 50 to 70 per cent of the cost of conventional structures have been achieved in Canada.
- iv) Improved stability, compared to traditional designs, is achieved for wave conditions equal to, or exceeding, the design event.

- v) The design for a specific project depends on the characteristics of the local quarry and the wave climate of the site.
- vi) The traditional design with two layers of armour stones can be considered a special case of this more general concept.

## CHAPTER ONE HUNDRED SEVENTY FOUR

### FATIGUE IN BREAKWATER CONCRETE ARMOUR UNITS

Hans F. Burcharth <sup>★</sup>

#### ABSTRACT

The reliability of rubble mound breakwaters depends on the hydraulic stability and the mechanical strength of the armour units. The paper deals with the important aspect of fatigue related to the strength of concrete armour units.

Results showing significant fatigue from impact tests with Dolosse made of unreinforced and steel fibre reinforced flyash concrete are presented. Moreover universal graphs for fatigue in armour units made of conventional unreinforced concrete exposed to impact load and pulsating load are presented. The effect of fibre reinforcement and the implementation of fatigue in a stochastic design process are discussed.

#### INTRODUCTION

Many of the recent failures of large rubble mound breakwaters are due to unexpected fracture of the concrete armour units. Traditionally the design process is based on hydraulic model tests and the design criterion chosen with consideration only to the hydraulic stability. Although progress has been made during the last years there exists no consistent armour layer design method in which both the hydraulic and the mechanical stability are considered. A discussion on the state of the art of this problem is given in Burcharth, 1983 (ref. 1 and 2).

The different types of loads on armour units and their origin are listed in Fig. 1.

TYPES OF LOADS		ORIGIN OF LOADS
STATIC	}	Weight of units
		Prestressing due to: Settlement of underlayers Wedge effect and arching due to movements under dynamic loads
ABRASION	}	Suspended material
DYNAMIC	Impact	Rocking/rolling of units Missiles of broken units Placing during construction
	Pulsating	Earthquake Gradually varying wave force
THERMAL	}	Stresses due to temperature differences during hardening process Freeze-thaw
CHEMICAL	}	Corrosion of reinforcement Sulfate reactions etc.

*Fig. 1. Types of loads on armour units.*

<sup>★</sup> Professor of Marine Civil Engineering, University of Aalborg, Denmark.

This paper deals with fatigue due to repeated dynamic loads from the waves. Fatigue is the reduction in material strength by increasing number of load cycles.

FATIGUE

The waves will cause *pulsating* (gradually varying) flow forces and also *impact* forces when the units are rocking. The number of cycles of wave loadings will be in the order of 200 million during a 50 years' period in the North Atlantic period. Since 1903 it has been known that concrete shows significant fatigue. Considering the high stress level in the large slender types of units such as Dolosse and Tetrapods it is important to evaluate the fatigue effect on the stability.

Fig. 2 shows the results from uniaxial fatigue tests with small specimens by Tepfers et al., 1979 (ref. 3 and 4), Fagerlund et al., 1979 (ref. 5), Zielinski et al., 1981 (ref. 6). The size of the specimens were 150 mm cubes, 100 mm and 74 mm diameter cylinders.

Fig. 2. Fatigue. Uniaxial impact and pulsating loading of small specimens (Tepfers et al. 1979, Fagerlund et al. 1979, Zielinski et al. 1981).

The results of the static test shown in Fig. 2 compare very well to the results by Tait et al., 1980 (ref. 7) for 25 kg model Dolosse of 300 mm height exposed to a pulsating load which created mainly uniaxial tensile stresses in the critical section, see Fig. 3.

Impact tests by M.G.A. Silva, 1983 (ref. 8) with full scale cubes in the range 1 ton to 27 tonnes also revealed significant fatigue as shown in Fig. 4. In the tests one cube impacted side to side a resting cube of the same size.

From the above mentioned tests it is seen that impact loads create the most drastic reduction in strength. Regarding the application in practical breakwater design of the tests presented in Fig. 2 and 3 it might be argued that the size of the specimens could be too small to re-

Fig. 3. Fatigue. Uniaxial pulsating tension loading of model Dolosse of 300 mm height (Tait et al. 1980).

Fig. 4. Fatigue. Impact tests with full scale cubes (M. G. A. Silva 1983).

present the properties of prototype concrete. Also the stresses are uniaxial whereas in prototype the stresses in critical sections are often flexural stresses. To evaluate these questions series of impact fatigue flexural stress tests with 200 kg Dolosse were performed at the University of Aalborg from 1981 to 1983. Both unreinforced and steel fibre reinforced concrete were tested.

FATIGUE TEST SET UP AND TEST PROGRAMME

The test set up is shown in Fig. 5.

Fig. 5. Set up of Dolosse impact fatigue tests.

The support of the Dolos compares to the set up used in prototype dynamic testing of Dolosse proposed by Burcharth 1980 and 1981 (ref. 9 and 10) and since widely used by other researchers. The set up is designed to generate mainly flexural stresses in the critical sections of the stem and the leg near the stem/leg corner. The pendulum was automatically operated by a hydraulic piston which could be set to any draw back distance from which the pendulum was released, thus reaching a specific impact speed. The number of impacts were recorded automatically. The operating speed was approximately one impact per 2 sec, somewhat dependent on the draw back distance.

Apart from disintegration also the first sign of crack and a specific width of the crack were taken as failure modes to be registered. This necessitated careful visual observation of the Dolosse throughout the tests.

To prevent material scale effects the size of the Dolosse was chosen such that concrete with normal size of aggregates could be used. This resulted in a Dolos height of 790 mm, a stem diameter of 261 mm giving a waist ratio of 0.33 and a mass of approximately 200 kg. The diagonal of the stem leg corner fillets was 48 mm.

A total of 45 Dolosse were tested included some pilot tests. Two types of concrete, unreinforced flyash concrete and steel fibre reinforced flyash concrete, were tested. The specifications and the material properties are listed in Table 1.

Table 1. Specifications of concretes.

	Unreinforced units	Steelfibre reinforced units
Cement content kg/m <sup>3</sup>	380 portland	435 portland flyash cement
Flyash kg/m <sup>3</sup>	125	
Sand kg/m <sup>3</sup>	525	788
4-8 mm pebbles kg/m <sup>3</sup>	80	none
8-16 mm pebbles kg/m <sup>3</sup>	1095	416
16-32 mm stones kg/m <sup>3</sup>	none	416
Water cement ratio	0.45	0.40
Additives	app. 4% air in Dolosse	3.3 kg plastisizer BV 40 app. 6% air in Dolosse
Reinforcement kg/m <sup>3</sup>	none	160, Wirex steel fibre 45 × 1 mm plain round (2% by volume)
Mean static compressive strength 100 × 200 mm cyl. $\bar{\sigma}_c$ N/mm <sup>2</sup>	44.4	27.0 *)
Mean static tensile strength 100 × 200 mm cyl. splitting test $\bar{\sigma}_{T \text{ split}}$ N/mm <sup>2</sup>	3.65	3.47 *)
Mean modulus of elasticity determined by ultrasound measurement $\bar{E}$ N/mm <sup>2</sup>	4.4 × 10 <sup>4</sup>	
Mean mass density of concrete in Dolosse $\bar{\rho}$ kg/m <sup>3</sup>	2330	2300

\*) Absolute values not fully representative for the Dolosse concrete strength due to boundary effect of the small cylinders on the concrete containing large fibres and coarse aggregates. This resulted in app. 4% higher air content and accordingly lower strength properties for the cylinder specimens. On this base the strength of the concrete in the Dolosse is estimated to  $\bar{\sigma}_c = 30$  N/m<sup>2</sup> and  $\bar{\sigma}_T = 3.85$  N/mm<sup>2</sup>.

A fairly high fibre content of 160 kg per m<sup>3</sup> of concrete or 2% by volume was used to make sure that it was well above the limit where fibre has no effect. According to full scale tests with 30 t Dolosse (static test and drop test) conducted by the author a steel fibre content below 70 kg/m<sup>3</sup> has only negligible effect on the strength.

Pilot's tests with beams reinforced with various types of steel fibres showed that a fibre length of app. 45 mm ensured a good toughness. A somewhat smaller diameter of the fibre than the applied 1 mm would probably have been more effective in terms of toughness per kilo of steel.

Although the amount of fibres was high no problems with mixing of the fibres were observed and the distribution of the fibres in the concrete Dolosse was good. However, the air content came out higher than expected and the strengths lower.

The age of all units when tested were approximately one year.

**THEORETICAL CONSIDERATIONS ON THE PROCESSING AND REPRESENTATION OF THE TEST RESULTS**

In fatigue tests each specimen is exposed to repeated load representing a specific stress range,  $\Delta\sigma$ .

Neglecting the influence of the rate of strain on stress and the variation of Poisson's ration Burcharth 1981 (ref. 10) derived formulae for the maximum tensile stress in a Dolosse exposed to impact load in a drop test and a pendulum test. Taking the waist ratio as a constant (0.33 in the present tests) the two formulae is given by

$$\frac{\sigma_T}{mghH^{-3}} \sim \left(\frac{E}{\rho gh}\right)^{0.5} \tag{1}$$

where  $\sim$  means proportional to

- $\sigma_T$  the max tensile stress
- m the pendulum mass (or the Dolos mass in the drop test)
- h the pendulum fall height (or the Dolos centre of gravity fall height in the drop test)
- H the Dolos height
- g the gravitational constant
- E the dynamic or static modulus of elasticity
- $\rho$  the mass density of pendulum and Dolos

In this it is assumed that for each type of concrete there is a constant ratio between the dynamic and the static modulus of elasticity. Thus the variation of this ratio with the stress level and the amount of internal fracture is neglected.

Eq. (1) is based on the assumption that the duration of the impact  $\Delta t$  can be taken as the time which elapses for a longitudinal shock wave to travel from the point of impact to a free edge of the concrete and back again, i.e.  $\Delta t$  is proportional to a characteristic length, H. However, actual recordings of the impact time in the present tests showed bigger values of  $\Delta t$ . A reanalysis based on the assumption of  $\Delta t$  being half of the natural period for the first mode of vibration of the Dolos when hit revealed good agreement between measured and calculated values of  $\Delta t$ . Fortunately this finding do not change eq. (1) as also the vibration model involves proportionality between  $\Delta t$  and a characteristic length.

Since the stresses range from approximately zero for each impact in the tests, the maximum stresses also represent the stress range. Thus in eq. (1)  $\sigma_T = \Delta\sigma_T$ .

The present fatigue test results are presented in diagrams where the ratio of the ultimate dynamic tensile stress range for N Impacts,  $\Delta\sigma_N$  to the same quantity for one impact,  $\Delta\sigma_{N=1}$

is plotted against the number of impacts at failure,  $N$ . Since the stresses were not directly recorded in the tests the ratio  $\Delta\sigma_N/\Delta\sigma_{N=1}$  was determined from the impact speed (or fall height) of the pendulum as follows:

For a system with constant values of  $g$ ,  $m$  and  $H$  eq (1) reduces to

$$\Delta\sigma_T \sim \left(\frac{Eh}{\rho}\right)^{0.5} \quad (2)$$

Moreover since  $\rho$  and  $E$  were approximately constants for each type of concrete we get

$$\Delta\sigma_T \sim h^{0.5} = \frac{v}{(2g)^{0.5}}, \quad (3)$$

where  $v$  is the pendulum impact velocity.

Since the material properties of concrete produced to identical specifications vary, corrections for this variation should be implemented in the results. For this reason 6 cylinders (100 x 200 mm) were cast from the batch of each Dolos. 4 or 3 cylinders were used to determine the splitting tensile strength,  $\sigma_{T\text{split}}$  and 3 or 4 cylinders were used to determine the compressive strength,  $\sigma_C$ . As testing of the cylinders and the corresponding Dolos took place at the same time it is assumed that the mean values  $\bar{\sigma}_{T\text{split}}$  and  $\bar{\sigma}_C$  characterize the actual strength properties of the Dolos.

In the impact fatigue tests the relevant strength property is the dynamic tensile strength  $\sigma_{T\text{dyn}}$  and not  $\sigma_{T\text{split}}$  which, due to the splitting test procedure, is a static tensile strength property. However, in what follows the reasonable assumption of proportionality between the two tensile strengths is used for each specific type of concrete.

To make it possible to compare fatigue in Dolosse of different concrete strength, corrections for the variations as found from the cylinder splitting test can be made by means of eq. (3). Thus a measure of a characteristic stress range for a tested Dolos is

$$\Delta\sigma_a = k \frac{h_a^{0.5}}{\sigma_{T\text{split},a}} \quad (4)$$

where  $k$  is an unknown constant and indices  $a$  corresponds to a specific Dolos.

From this we obtain

$$\frac{\Delta\sigma_{N,a}}{\Delta\sigma_{N=1,b}} = \frac{h_{N,a}^{0.5} / \sigma_{T\text{split},a}}{h_{N=1,b}^{0.5} / \sigma_{T\text{split},b}} \quad (5)$$

where indices  $b$  refers to a specific Dolos.

It should be noted that the use of eq. (4) in the present tests is somewhat invalidated by the uncertainty on estimating  $\sigma_{T\text{split}}$  from relatively small cylinders, cf. the footnote in Table 1. However, the test result presented by the graphs in Figs. 8 - 10 are based on eq. (5) which is not significantly biased because  $\sigma_{T\text{split}}$  appears both in the nominator and the denominator.

$h_{N=1}$  in eq. (5) could not be found directly from a test because it is impossible to determine the pendulum speed which in just one impact on an untested unit causes exactly the ulti-

mate stress where the first crack appears. Therefore  $\Delta\sigma_{N=1}$  was determined by extrapolation to  $N = 1$  of the fatigue test results in a log-linear representation, see Figs. 6 and 7.

TEST RESULTS

Fig. 8 shows the result of the fatigue tests with unreinforced Dolosse.

Fig. 8. Fatigue. Impact loaded Dolosse of unreinforced flyash concrete. Flexural stress.

The ordinate represents the ratio between two dynamic stresses, namely the ultimate dynamic stress range for N impacts to the same quantity for one impact, N = 1. Very often in such Wöhler diagrams the denominator is the static strength (cf. Fig. 2), but the presentation in Fig. 8 demonstrates the fatigue effect more clearly.

The full line corresponds to the first sign of crack, thus representing the design graph. The dotted line shows the state of disintegration. No sign of damage or indentation of the impacted Dolos-surfaces was seen in the test series with unreinforced concrete.

The results for the fibre reinforced units are shown in Fig. 9.

Fig. 9. Fatigue. Impact loaded Dolosse of steel fibre reinforced fly ash concrete. Flexural stress.

The full line corresponds to the first sign of crack and the dotted line to a crack width of 1 mm. For design purpose, the full line should be used since a crack width of 1 mm implies fast corrosion of the tiny steel fibres. If non-corrosive fibres are used cracks of some size might be acceptable. By large numbers of impacts an indentation was clearly seen on the impacted surface — quite contrary to the case of unreinforced concrete.

A comparison of the fatigue properties of the two types of concrete is presented in Fig. 10.

Fig. 10. Comparison of fatigue in impact loaded Dolosse of unreinforced and steel fibre reinforced flyash concrete. Flexural stress.

It is seen that the fatigue effect is smaller in the fibre reinforced units as it stabilizes at a stress range twice as big as for the unreinforced units for  $N \geq 10^5$ . This better performance is properly partly due to the development of a more soft impact surface, cf. the observed indentation.

Fig. 11 shows a comparison of the ultimate impact energy at the first sign of a crack. The impact energy, taken as the maximum kinetic energy of the pendulum, is dimensionless by dividing by  $gMH$ , where  $g$  is the gravitational constant,  $M$  the mass of the Dolos and  $H$  the height of the Dolos.

It is seen that, the fatigue life of the steel fibre reinforced concrete is the best of the two except for small number of impacts. However, the difference is fairly small and probably much smaller than most people expect since it is often said in the literature that fibres increase the energy absorbtions at failure many times, compared to plain concrete.

For example in ref. (11) a factor of "at least ten times" is related to a steel fibre content of  $100 \text{ kg/m}^3$ .

The reason for this discrepancy is the fact that most testing of fibre reinforced concrete reported in the literature is done with rather slender specimens, such as beams, where large deflection creates only very small cracks, contrary to what is the case with stiff bodies like Dolosse and Tetrapods. Another important reason is that in the case of armour units failure must be defined as the appearance of a crack, while in the concrete literature failure of tested specimens is usually taken as the state of complete disintegration or some high level of deformation.

 M AND H MASS AND HEIGHT OF DOLOS.  
 g GRAVITATIONAL CONSTANT.

Fig. 11. Fatigue. Comparison of ultimate impact energy for impact loaded Dolosse of unreinforced and steel fibre reinforced flyash concrete. Flexural stress.

The effect of steel fibres on the fatigue life and on the impact strength of slender armour units seems to be small and is certainly much smaller than the effect of similar quantities of steel in a conventional bar reinforcement, cf. also discussion of reinforcement in ref. (1).

In Fig. 12 the results of the present flexural impact tests with unreinforced concrete (Fig. 8) are shown together with the results of the uniaxial impact tests with small specimens (Fig. 2).

Fig. 12. Fatigue. Unreinforced concrete. Impact load.

It is seen that the graphs almost collapse into one single graph which then represents a universal curve for fatigue of *impact* loaded unreinforced concrete. Moreover, the graphs in Figs. 2 and 3 representing fatigue due to *pulsating* uniaxial loads fall into one graph. Because it seems most likely that also in this case fatigue due to pulsating flexural load follows this graph one can then produce two universal graphs as shown in Fig. 13, one representing fatigue by impact load and one representing pulsating load.

Fig. 13. Fatigue in conventional unreinforced concrete. Uniaxial and flexural stress.

Having in mind the uncertainties on the important parameters involved in rubble mound breakwater design, the graphs in Fig. 13 are regarded accurate enough for practical design of armour layers made of conventional unreinforced concrete blocks. It should be noted that the ultimate *impact load* strength for one cycle is in the order of 1.4 and 1.5 times the ultimate *pulsating load* strength in the case of uniaxial tension and compression respectively, cf. Fig. 2. For flexural stresses a factor of app. 1.4 should be used.

The ultimate pulsating load strength properties for one cycle can be taken equal to the static ones.

**IMPLEMENTATION OF FATIGUE IN THE DESIGN PROCESS**

The fatigue life is usually evaluated according to the *Palmgren-Minor accumulated damage theory* on the basis of a propiate Wöhler diagram, e.g. Fig. 13.

The Palmgren-Minor rule expressing the cumulative damage ration, D reads

$$D = \sum_{i=1}^K \frac{\eta_i}{N_i} \leq 1 \quad , \quad (6)$$

where  $\eta_i$  is the number of cycles within the stress range interval  $i$ ,  $N_i$  is the number of cycles to failure at the same stress range derived from the Wöhler diagram and  $K$  is the total num-

ber of stress range intervals. This implies that the number of stress cycles and the corresponding stress ranges throughout the lifetime of the structure, i.e.  $\eta$ ,  $N$  and  $K$  in eq. (6), must be estimated. This again means that the *load history* and the *relationship between the load and the stresses* must be established.

Pure deterministic calculations are impossible. More realistic is a *stochastic* approach.

In breakwater engineering the load history is closely tied up with the wave history. In most places a reasonable estimate on the wave history can be obtained from hindcast studies or observations. The wave history may be presented as the variation in significant wave height,  $H_s$  with the time,  $t$ , see Fig. 14.

Fig. 14. Wave history.

The wave period which is also of great importance is included in this representation if a relationship between wave height and period is established; for example is a power relationship often found. Only waves or storms over a certain size will contribute to the stability conditions of the armour block. The cut-off level, shown as a dotted line in the figure, depends on many things of which the type, the size, the material strength properties and the location on the structure of the armour blocks are the most important. The cut-off level will be relatively low for complex types of units, especially for the big ones where the stresses are high due to their own weight alone. The cut-off level might vary with time due to change in the strength properties of the concrete or change in hydraulic stability, for example caused by abrasion of the blocks.

The storm history can be modelled as a weakly stationary, stochastic process with a specific intensity, and following a specific extreme distribution, for example a Weibull distribution. Further, if independence between storm event is assumed the starting times of the storms can be characterized by a Poisson counting process. The wave heights are Rayleigh distributed in intervals of stationarity.

The stresses in an armour unit can be split into three terms, cf. Fig. 1: The *static* stresses mainly due to gravity, the *pulsating* stresses due to flow forces generated by the waves and the *impact* stresses generated when units are rocking, displaced and hit by other units. The problem is to find the stress transfer functions i.e. the relationship between the stresses and the wave action on the specific location of the breakwater structure, as illustrated in Fig. 15.

Fig. 15. Realization of wave induced stresses in an armour unit.

Due to the random placement of the armour units the stress transfer functions must be characterized by reference values (as for example the mean) and the distribution functions as illustrated on Fig. 16.

Fig. 16. Qualitatively illustration of dependence of stress transfer frequency functions on wave parameter.

The static stress field might be established from strain gauge measurements on large scale model armour layers in the dry combined with similarity considerations.

The dynamic stress field is much more difficult to assess. Because prototype measurements are very difficult and expensive the problem must be studied in large scale hydraulic models mainly by strain gauge measurements. The huge amount of work necessary to meet the needs of the practical designer calls for international sponsorship and cooperation.

In a consistent design process the above discussed strength aspects must be linked to the hydraulic stability aspects. Ref. (12) titled "Stochastic design of rubble mound breakwaters" deals with this problem taking into account also impact fatigue based on an estimated simple stress transfer function.

#### ACKNOWLEDGEMENTS

The study was sponsored by The Danish Council for Scientific and Industrial Research. The cooperation of Mr. Sven Hvid Nielsen and Mr. J.Kr. Jehrbo Jensen, the help of Aalborg Portland Cement and Concrete Laboratory in preparing pilot tests with fibre reinforced beams and the discussions with Prof. D. Krajinovic and Dr. A.J. Zielinski are gratefully acknowledged. N.B. Beton Aps and S.N. Simonsen & Co. are thanked for the supply of concrete and fibres.

## CHAPTER ONE HUNDRED SEVENTY FIVE

### Stability of Armour Units in Flow Through a Layer

Alex C. Thompson \*  
Hans F. Burcharth \*\*

#### Abstract

As part of a program to study the hydraulics of wave attack on rubble mound breakwaters tests were made on model armour units in a steady flow through a layer laid on a slope. The flow angle has little effect on stability for dolosse or rock layers. The head drop at failure across each type of layer is similar but the dolosse layer is more permeable and fails as a whole. There was no viscous scale effect. These results and earlier tests in oscillating flow suggest a 'reservoir' effect is important in the stability in steep waves.

#### Introduction

Many types of concrete unit for armouring rubble mound breakwaters have been designed to try and achieve a good stability to weight ratio and low costs of production. The designer of a breakwater often finds it difficult to choose between these different units as no systematic information on their stability exists. The physics behind the differences in stability of slender and bulky units is still poorly understood despite the large number of model tests and investigations of flow in rubble mound structures that have been performed.

Generally for units of the same weight and density, slender ones like dolosse exhibit a better hydraulic stability than bulky ones like cubes. However the different types of armour do not respond in the same way to changes in wave characteristics. Whillock and Price (7) for example, showed that oblique wave attack can dislodge dolosse much more easily than waves approaching at right angles and Burcharth (3) has demonstrated that the stability of a dolosse slope decreases as the wave period increases. Both effects are in contrast to the behaviour of slopes made of rocks.

It is thought that the explanation for this is the 'reservoir effect' by which the greater volume of voids in a dolosse pack can absorb a larger fraction of the uprushing wave than a rock slope. This idea emerged from work by the present authors (4) on oscillating flow over the surface of dolosse and rock layers. They found that the dolosse were only slightly more stable than stones of the same weight in this fully submerged flow, a similar result to that of Brebner (2) who tested dolosse and rocks in steady flow. The present work investigated the stability of dolosse and rocks on a slope in flow from underneath at various angles to the layer. The flow is uni-directional and through the

Figure 1 Throughflow Test Rig

layer. The object was to see if the differences in stability of slender and bulky units could be due to a difference in their response to flow through the cover layer, rather than to flow parallel to the surface. It was thought that at some instants of the wave motion on a breakwater the flow emerging through the slope may have a similar effect to the test flow.

A secondary object was to examine a further scale effect which might arise in models of rubble mound breakwaters, if flow through the layers was important as well as flow over the surface. To this end a scale model of the relevant parts of the main rig was made and tested.

#### Experimental Method

Layers of dolosse and rocks laid on a slope were subjected to flow through the slope, and through the layer. The head drop and flow rate at which the layer failed, as defined below, were found for different slope angles,  $\alpha$  and flow angles,  $\beta$ . A sketch of the apparatus is shown in fig. 1.

The test rig consisted of a plywood board thickness 20mm, width 0.9m and height 1.2m which formed the test slope. This was mounted so that its slope could be varied between  $15^\circ$  and  $45^\circ$  in the high head flume at the Hydraulics Research Station, Wallingford. This is a glass sided flume with a wooden floor and cross-section of 0.9 x 0.9m. Rubber seals were arranged round the edge of the board so that flow took place only through a hole of dimensions 0.6m wide by 0.34m deep in the lower half of the board, under the area covered by the armour units. The bottom units rested on a wooden ledge running the width of the board, and all units lay on an expanded metal mesh covering the board and the flow opening. In the flow opening one of three sets of vanes fixed at angles of  $20^\circ$ ,  $45^\circ$  and  $90^\circ$  to the slope could be mounted. These were made from aluminium plates of thickness 3mm and length 150mm mounted with a gap of 20mm between each in a rigid frame made from 12mm plastic plates. The flume was supplied with water from a large sump via a pump feeding a constant head tank. The water then flowed through a control valve into the inlet tank of the flume, over a 'V' notch where the discharge was measured, into a settling section through various screens and into the working section of the flume. The slope was mounted halfway along the 10m working length and at the end of the flume an adjustable over-shot tailgate allowed the water level downstream of the test slope to be varied.

The armour units used for the test were plastic dolosse with metal bars embedded in the limbs to give a weight of 130 gms, a height of 70cm and an average density of  $2.40 \text{ gm/cm}^3$ . The rock was selected from a supply of crushed rock by eye to match a number of individually weighed rocks and to have a reasonably cube-like shape. The average weight of the rocks was then found to be 124 gm and the density  $3.0 \text{ gm/cm}^3$ .

The number of dolosse used was 297 and the same number of rocks were employed in building a test layer. A single layer of units was used, placed by hand starting from the bottom of the slope but with no overall system of laying other than to get all the units in an area of 0.9m x 0.5m and to fill any obvious holes. This area was chosen so that the flow opening was covered, the full width of the channel occupied by units and because initial trials with the units showed that the number used filled this area naturally. The photographs 1 and 2 show views of the layers as completed.

The procedure for each test was to set the slope at the desired angle using a protractor in the form of an adjustable set square with a spirit level attached to it. The layer of units was then laid as described above and the flume filled using a slow rate of flow to avoid a large head drop across the slope before the flume downstream of the slope filled up. The rate of flow was then increased slightly and the water levels immediately upstream and downstream of the slope measured, while the slope was observed closely for signs of failure. The water levels were measured with point gauges attached to metre rules. The rules were held against the metal rails at the top of the flume, which had been accurately levelled, and read from the top edge of the rails. This system was adopted to follow the fast change in water levels which occurred after increasing the flow, so that the levels at the point of failure could be measured. As soon as holes appeared in

Photo 1 Dolosse layer.

Photo 2 Rock layer.

the layer the water levels would change again. The experiment was performed with two observers so that the water levels could be followed and so that one was always watching the slope. After these levels had been measured the water level upstream of the V notch was read using a pointer gauge mounted on a calibrated screw in a stilling tube. If the slope had not failed the flow rate was increased slightly and further readings taken.

The occurrence of failure was usually quite obvious but with careful control of the flow rate different stages could be observed, and the conditions just prior to failure established. Without close observation and control the failure flow could be exceeded giving complete collapse of the dolosse layer or large holes in the rock layer, as the first change noted. With a layer of dolosse a slight settling down the slope could be observed before failure, followed by the opening of gaps in the layer at a slightly larger flow, this is the failure condition and any further increase in flow would usually result in all the dolosse sliding down and off the slope. Occasionally larger gaps would open before total failure happened. With a layer of rocks the indication of failure was the displacement of individual rocks from their original position to positions lower down the slope, leaving holes in the layer. When 2 or 3 rocks had been moved in this way the flow could be increased without increasing the head drop and further rocks would move leaving more holes, as the flow was raised. The displacement of 2-3 rocks was taken as the failure condition for rock slopes. The rock layers never slid right off the slope as the dolosse layer often did.

Once the failure condition had been determined the flume was emptied, the slope angle changed and the layer rebuilt for another test. Slope angles  $\alpha$  of  $43.5^\circ$ ,  $36.7^\circ$ ,  $23.6^\circ$  and  $18.6^\circ$  were tested, first with dolosse and then with rock. The next set of vanes was then fitted to the test rig and the tests repeated so that results were obtained for vane angles  $\beta$  of  $90^\circ$ ,  $45^\circ$  and  $20^\circ$ . The head loss through the apparatus without a layer of armour units in place was found so that the head drop across the layer of units could be estimated.

After the main test had been completed a scale model of the apparatus was built based on the size of small dolosse available. These weighed 14.5 gm and had a height of 3.7cm. A plate to fit over the original flow opening was built, containing an opening scaled down in the ratio  $3.7/7.0 = 0.486$ . A set of vanes set at  $\beta = 90^\circ$  was also built to this scale and a step to hold the bottom of the layer. Expanded metal mesh of very nearly the correct scale (0.5) was used for the base of the layer. The flow and head drop at failure was found for the dolosse layer and for a layer of 14.5 gm stones, using this scaled down version of the original test.

A short series of tests which we refer to as 'overflow' tests was performed by blocking the hole in the sloping board and letting water flow over the top. The layers were built on the top half of the board supported by a new step fixed above the original opening. Layers of the large units were tested at several slope angles. In each run the slope of the board was set and the layer was built in the same way as for the throughflow test. The flow rate was gradually increased until the layer failed or the maximum flow rate was reached. The depth of flow above

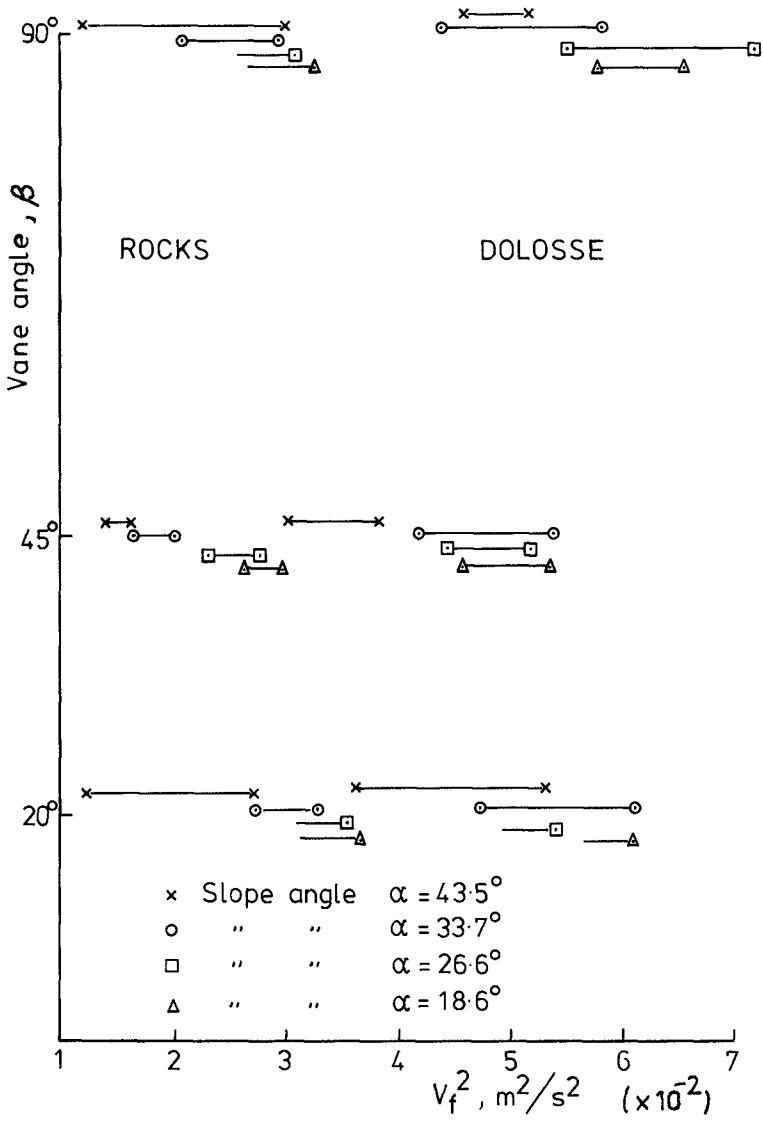

Figure 2 Filter Velocity Squared at Failure

the board and the flow rate were measured at several settings below failure. Depth was measured using a rule looking through the glass side of the flume half way down the slope where water surface is roughly parallel to the bed. This measurement was inevitably approximate until the water surface was well above the surface of the layer and became smooth.

#### Test Results

The test results were plotted in three graphs shown in figs. 2, 3 and 4. In the first of these the square of the filter velocity,  $V_f^2$ , at failure was plotted against vane angle,  $\beta$ . These results for the large units only. The slope angle  $\alpha$  was indicated by the different symbols shown in the figure and the failure condition is indicated by a range of values in some cases.  $V_f$  was defined as the discharge at failure divided by the area of the opening in the slope. This plot shows that the vane angle had little effect on the stability of either type of layer. The dolosse could withstand a higher filter velocity but this was because the permeability was higher as discussed below. It is interesting that the effect of slope angle,  $\alpha$ , is not great, with only  $\alpha = 43.5^\circ$  giving obviously lower  $V_f^2$  at failure, in this figure.

The second plot, fig. 3, shows the hydraulic gradient,  $i$ , across the layer at failure, versus the slope angle. This is expressed in a non dimensional form as follows. The hydraulic gradient  $i$  was calculated from:

$$i = \frac{(\Delta H - VL)}{t} \quad (1)$$

where  $\Delta H$  = total measured head loss  
 $VL$  = Vane loss of same flow rate  
 $t$  = thickness of layer

The layer thickness,  $t$ , is difficult to measure directly but an average value was found from the equation

$$t = \frac{W'N}{A(\rho_s - \rho)g(1 - n)} \quad (2)$$

where  $W'$  = submerged weight of a unit  
 $N$  = number of units in layer  
 $A$  = area covered by layer  
 $n$  = porosity of layer  
 $\rho_s$  = density of armour unit material  
 $\rho$  = density of water

A critical hydraulic gradient  $i_c$  was calculated for the condition that the pressure force across the layer is equal to the component of the weight of units and water in the layer at right angles to the layer. This gives the expression

$$i_c = - \left( \frac{\rho_s}{\rho} - 1 \right) (1 - n) \cos \alpha \quad (3)$$

Equations (1), (2) and (3) were then combined to give the quantity

$$\frac{i}{i_c} = \frac{(\Delta H - VL) \rho g A \left(\frac{\rho_s}{\rho} - 1\right) (1 - n)}{W'N \left(\frac{\rho_s}{\rho} - 1\right) (1 - n) \cos \alpha}$$

i.e.

$$\frac{i}{i_c} = \frac{\rho g (\Delta H - VL) A}{W'N \cos \alpha} \quad (4)$$

Figure 3 shows  $i/i_c$  versus slope angle  $\alpha$ . These results are for a vane angle  $\beta$  of  $90^\circ$  and include the tests on the small units. For the two lowest slope angles  $\alpha$  of  $18.6^\circ$  and  $26.6^\circ$  the layer fails for  $i/i_c$  between 0.85 and 1.0 for rocks and dolosse of both sizes tested. At  $\alpha = 33.7^\circ$  there was slightly more variation in the results with most layers failing at  $i/i_c$  between 0.8 and 1.0, and the small dolosse failing at  $i/i_c$  between 0.75 and 0.8. At the highest slope  $\alpha = 43.5^\circ$ , all layers except the small stones failed at lower values of  $i/i_c$  between 0.65 and 0.8. Although rock and dolosse layers failed at similar values of  $i/i_c$  the mode of failure was different. In rock layers individual units were removed from the layer leaving holes and were deposited lower down the slope. Dolosse layers failed by the whole layer sliding down the slope. Sometimes a slight settlement or bowing out of the layer can be seen shortly before the complete collapse.

The third graph, fig. 4, gives the head drop across a layer  $(\Delta H - VL)$  against the filter velocity squared,  $V_f^2$ . Results for the small units are plotted scaled up according to a Froudian law using the length scale  $\lambda = 0.486$ . The results for large rocks and large dolosse fall on straight lines indicating that the flow is turbulent and viscous scaling effects are absent in this size of model. The results from the small units fall mainly on or below the same lines.

The results of the overflow tests are given in table 1. Both types of layer dolosse and rock failed in a similar way. A few units were removed from the layer soon after the water covered most units. The flow could then be increased without further losses until a level where units began to be removed again, and once 2 or 3 had been removed the layer failed completely, being progressively washed away by the flow. A dolosse layer that was slightly looser in build than normal failed by sliding at a low flow rate, when the water just covered most units. The water which flowed through the layer and out at the toe never removed any units from the outflow region, with either dolosse or rock.

#### Interpretation of Results

The first fact apparent from the results is that the angle of flow at the bottom of the layer,  $\beta$ , does not affect the failure conditions of dolosse or rock. The higher stability dolosse under attack by steep waves is not due to an effect of the angle of flow through the layer.

The results did show a difference in permeability between dolosse and rock but an equal drop in total head across the layers required to produce failure. The critical head gradient  $i_c$  is much lower for

Figure 3 Hydraulic Gradient at Failure.

dolosse than rock but must act over the greater thickness of the dolosse layer. For example calculating  $i_c$  from equation (2) we find

For rock  $(\frac{\rho_s}{\rho} - 1) = 1.65, n = 0.4, i_c = 0.99 \cos \alpha$

For dolosse  $(\frac{\rho_s}{\rho}) = 1.4, n = 0.6, i_c = 0.56 \cos \alpha$

It is perhaps surprising that the angle of slope does not influence the head gradient at failure more than the  $\cos \alpha$  factor, at lower slopes than  $\alpha = 43.5^\circ$ . This is particularly so for rock where at  $\cot \alpha$  term appears in Hudson's Equation. This may be due to the placing of the rock layer by hand, rather than pell-mell dumping. Dolosse layers are often laid at steeper slopes and their structure does seem to make them less sensitive to slope than rock layers. The type of failure in throughflow, blanket as opposed to individual movement, may mean that dolosse layers will be more resistant to a localised critical head gradient. Certainly the gradient required to remove individual dolosse must be greater than that measured in the present experiments.

If it can be shown that the head gradient across the cover layer is near the critical value in a breakwater attacked by waves then these differences may explain the differences in stability between bulky and slender units in waves. Some evidence on this is provided by the results of Bavends et al (1). Calculations and measurements on a large physical model of Sines breakwater repaired section, both give the pressures in the region of maximum outflow. The wave height of 20m is sufficient to cause some damage according to the results of Mol et al (6). The parameter  $\xi = \tan \alpha / \sqrt{H/L_0}$  can be estimated as between 2.05 and 1.083 if the wave period is in the same range, 22 to 16 secs. as that used by Mol et al. (6). The pressures under the first filter layer and above the cover layer are given. Calculating the thickness of the two armour layers and the filter layers from the details given by Barends the head gradient can be estimated as  $i \approx 0.44$ . This is well below the critical value. Evidence from the overflow experiment described above is that water rushing down through the cover layer and then out at the toe of the slope is unable to dislodge either dolosse or rocks. Finally in model tests on breakwater sections with a cover layer of dolosse damage occurs with single units being removed. That is, a different type of failure than in the throughflow test takes place. All this suggests that on a conventional design of rubble breakwater the cover layer is not damaged by throughflow before other types of damage start. In an earlier series of tests, Burcharth and Thompson (4) the authors showed that fully submerged layers of dolosse and rock have about the same stability in oscillatory flow parallel to the surface of the layer. It is suggested that the good stability of dolosse in steep waves is due partly to interlocking and partly to a reservoir effect. That is, the large voids in the dolosse layer absorb a significant proportion of the uprushing wave, and this water then runs down within the layer so that it cannot remove units from the layer.

Calculations by Koutitas (5) on a breakwater section of uniform permeability, indicate that hydraulic gradient  $i$ , can exceed the critical values found in the present tests. Throughflow might therefore cause damage in a breakwater with unusually permeable underlayers. This point can probably be explored by further calculations.

The measurements of head drop across the layers show no evidence of a scaling effect due to viscosity. The points predicted by scaling up results from the small units using Froude scaling fall close to the results from the large units. The units span the usual range of sizes used in models except in giant flumes. The Reynolds number of the flow through the small rock is  $V_p D / \nu = 1.9 - 5.2 \times 10^3$ . This is just above the limit of  $2 \times 10^3$  for viscous effects in porous media suggested by Yalin (8). In the region of high outflows through the cover layer there should therefore be little viscous scale effect in models. A possible scale effect of a different sort is the force exerted in building the models. This will be relatively greater in small models where the units are placed by hand and could be responsible for the high strength of the small rock layer at  $\alpha = 43.5^\circ$  in the present results. A similar effect was noted in the oscillatory flow tests.

## CHAPTER ONE HUNDRED SEVENTY SIX

### Stability of Rubble Mound Slopes under Random Wave Attack

J.W. van der Meer\* and K.W. Pilarczyk\*\*

#### Abstract

The objective of the present research project is to give new practical design formulae for rubble mound slopes under random wave attack. The study is based upon a series of model tests. More than two hundred tests have been performed in order to vary systematically all the relevant variables. The main shortcomings in Hudson-type formulae have been solved as a result of the present series of investigations. Stability formulae are given which include the influence of wave period, number of waves, armour grading, spectrum shape, groupiness of waves and the permeability of the core.

#### Introduction

The use of coarse materials, such as gravel and natural stone for slope revetments, is very common in civil engineering. In recent years, there has been an increasing demand for reliable design formulae, to cope with the ever growing dimensions of the structures and the necessity to move into more hostile environments.

In 1981, the Netherlands Public Works Department commissioned the Delft Hydraulics Laboratory to perform a systematic study with the objective of developing design rules for both statically and dynamically stable slope revetments. The first results of this study, the design data for statically stable revetments, are given in this paper. Design criteria for dynamically stable gravel revetments have been reported earlier [5]. Research on profile development for rock material is still in progress. Reference should be made to [7] for a preliminary review of the complete study.

The Hudson formula is well known because of its simplicity. In the last decade, however, it has been found by many users to have a lot of shortcomings. It does not include the influence of the wave period and no data are available for random waves. The study of Ahrens [1] in a large wave tank showed the importance of the wave period on the stability of riprap. The tests, however, were performed with regular waves. Evaluation of Ahrens' data by Pilarczyk and den Boer [7] produced stability formulae which included the wave period. Losada

and Giménez-Curto [6] gave formulae for stability of rubble mound slopes under regular wave attack which also included the wave period.

An extensive investigation has been performed by Thompson and Shuttler [9] on the stability of rubble mound slopes under random waves. One of their main conclusions was, that within the scatter of the results, the erosion damage showed no clear dependence on the wave period. Reanalyzing their data, the authors, however, have found a very clear dependence on the wave period! The analysis also showed that only steep waves were used with a small range of wave periods. The work of Thompson and Shuttler has, therefore, been used as a starting point for the present research. By performing tests with longer wave periods, the dependence of erosion damage on wave period has been confirmed for a wider range of conditions. In addition the dependency on other variables has been investigated.

#### Governing Variables

A design formula for armour units should give a method of determining the minimum mass of individual armour units for given mass densities, required for stability as a function of all the variables involved. In the following the average mass of graded rubble is referred to as  $W_{50}$  or to the nominal diameter,  $D_{n50}$ , where:

$$D_{n50} = (W_{50}/\rho_a)^{1/3} \quad (1)$$

where:  $D_{n50}$  = nominal diameter (m)  
 $W_{50}$  = 50% value of the mass distribution curve (kg)  
 $\rho_a$  = mass density of stone (kg/m<sup>3</sup>)

The relative mass density of the stone in water can be expressed by:

$$\Delta = \rho_a/\rho - 1 \quad (2)$$

where:  $\Delta$  = relative mass density (-)  
 $\rho$  = mass density of water (kg/m<sup>3</sup>)

As shown by many authors there are a large number of variables affecting armour stability. The primary variables are shown in Table 1.

The wave height can be normalized by dividing the significant wave height,  $H_s$ , by the relative mass density and the nominal diameter. This dimensionless wave height is the same as the often used stability number  $N_s$  and reduces the Hudson formula to a very simple form:

$$H_s/\Delta D_{n50} = (K_D \cot \alpha)^{1/3} \quad (3)$$

The wave period can be related to external processes, waves breaking on a slope, by the dimensionless surf similarity parameter,  $\xi_z$ , where:

$$\xi_z = \tan \alpha / \sqrt{2\pi H_s/g T_z^2} \quad (4)$$

Table 1 Primary variables affecting armour stability

variable	symbol	dimension
nominal diameter	$D_{n50}$	m
relative mass density	$\Delta$	-
significant wave height	$H_s$	m
average wave period	$T_z$	s
slope angle	$\alpha$	degr
damage level	$S_2$	-
number of waves	$N$	-
armour grading	$D_{85}/D_{15}$	-
spectrum shape	$\epsilon_{5\%}, Q_p$	-
groupiness of waves	$G.F., J_1, J_2$	-
permeability of core	-	-

Plots of  $H_s/\Delta D_{n50}$  or  $N_s$  versus  $\xi_z$  are used by many authors to show the influence of wave period on armour stability. The wave period  $T_z$  can be related to internal processes as initiation of damage and transport of material, by coupling it to the nominal diameter:

$$\text{dimensionless wave period} = \sqrt{g T_z^2 / D_{n50}} \quad (5)$$

This wave period is also used in the investigations of van Hijum and Pilarczyk [5], on the stability of gravel beaches. Using (5) instead of (4) means that the influence of the wave height and the wave period on stability can be treated independently.

The dimensionless damage level,  $S_2$ , is described by:

$$S_2 = A_2 / D_{n50}^2 \quad (6)$$

where:

- $A_1$  = accretion above water level [m<sup>2</sup>]
- $A_2$  = eroded area of the profile [m<sup>2</sup>]
- $A_3$  = accretion below erosion area [m<sup>2</sup>]

A physical description for  $S_2$  is the number of cubical stones with a side of  $1 D_{n50}$ , eroded over a width of  $1 D_{n50}$ . The "no damage" criterion of Hudson and Ahrens is taken generally to be when  $S_2$  is between 1 and 3 stones eroded and "failure" of the slope is assumed when  $S_2$  is between 8 and 17. The exact value of  $S_2$  is dependent to some extent on the slope of the revetment.

#### Test Equipment, Materials and Procedure

All tests were conducted in a 1.0 m wide, 1.2 m deep and 50.0 m long wave flume with test sections installed about 44 m from the

random wave generator. This wave generator is capable of performing both translatory and rotational motions by means of a hydraulic actuator, programmed by a closed loop servo-system. The command signal of this loop is obtained from a punched tape, representing a random signal with a predetermined wave energy spectrum. A new system developed by the Delft Hydraulics Laboratory was used to measure and compensate for reflected waves at the wave board. With this system standing waves and basin resonance are avoided.

For the investigation a surface profiler was developed with nine gauges placed 0.10 m apart on a computer controlled-carriage. The surface along the slope was measured every 0.040 m. Depending on the slope angle every survey consisted between 500 and 1600 data points. Successive soundings were taken at exactly the same points using the relocatability of the profiler. An average profile was calculated and plotted by computer and used for determining the erosion damage,  $S_2$ .

Broken stone was used for the armour layer, the main characteristics of which were:  $W_{50} = 0.123$  kg;  $\rho_a = 2630$  kg/m<sup>3</sup>;  $D_{n50} = 0.036$  m; layer thickness 0.080 m. The sieve analysis curves were straight lines on a log-linear plot, see Fig. 1. Two gradings were used with  $D_{85}/D_{15} = 2.25$  (riprap) and 1.25 (uniform stones) respectively. The filter layer was defined by  $D_{n50}$  (armour)/ $D_{n50}$  (filter) = 4.5 and  $D_{85}/D_{15} = 2.25$ . The thickness of the filter layer was 0.02 m. This layer was placed directly on a slope constructed of mortar when an impermeable core was being tested. When a permeable core was tested the armour layer was placed directly on this core.

Each complete test consisted of a pre-test sounding, a test of 1000 waves, an intermediate sounding, a test of 2000 more waves and a final sounding. After each complete test the armour layer was removed and rebuilt. A test series consisted generally of 5 tests with the same wave period, but different significant wave heights. Wave heights ranged from 0.05 m to 0.26 m and wave periods from 1.3 to 3.2 seconds. A water depth of 0.80 m was applied for all tests. A damage curve was drawn for  $N = 1000$ , and  $N = 3000$ , for each test series, as shown in Fig. 2. From this the  $H_s/\Delta D_{n50}$  value was taken for three damage levels and the surf similarity parameter,  $\xi_z$ , given in (4) was calculated. The following three damage levels were chosen:

Fig. 1 Sieve curves

- start of damage (the  $H_D=0$  for Hudson)
- intermediate damage
- failure: filter layer is visible.

Fig. 2 Example of damage curves

Test Programme

Results

The influence of the primary variables on armour stability, shown in Table 1 is discussed below and new practical stability formulae, obtained from the results, presented.

Influence of Number of Waves

In the investigation of Thompson and Shuttler [9] profiles were sounded after each 1000 waves, up to  $N = 5000$ . Analyzing their results gives the relationship between damage and number of waves shown in Fig. 3. Data points are based on 50 tests and are independent of slope angle, wave period and damage level. Since a clear relationship was found between  $S_2$  and  $N$ , it was decided to decrease the total number of waves in the present study to  $N = 3000$  and to conduct one intermediate sounding after  $N = 1000$ . Analyzing the ratio of damage after 3000 and 1000 waves and using the damage after 3000 waves as a reference, gave a new point (\*) in Fig. 3. The difference between the two investigations is small.

The relationship between  $S_2$  and  $N$  can be described by the following formula:

$$S_2(N) = 0.014 \sqrt{N} * S_2(5000) \tag{7}$$

Since (7) is a square root function it is easy to find a parameter which describes the influence of the number of waves on the damage. This parameter is  $S_2/\sqrt{N}$ . The constant 0.014 becomes a part of a stability coefficient. The parameter  $S_2/\sqrt{N}$  can be used for  $N$  in the range of, approximately, 1000 to 7000. For  $N < 1000$  a linear relationship fits the data better, see Fig. 3. It is, however, very clear that with random waves a stable profile is not found with less than

Fig. 3 Influence of number of waves on damage:  $S_2/\sqrt{N}$

10,000 waves. This is very different to regular waves where equilibrium is generally found within 1000 - 2000 waves.

#### Influence of Wave Period and Slope Angle

The extent of damage depends on the slope angle. More stones have to be displaced for gentler slopes before the failure criterion is reached. From the investigations the lower and upper damage levels were determined as shown in Table 3.

Table 3 Lower and upper damage levels

$\cot\alpha$	start of damage	failure
2	$S_2 = 2$	$S_2 = 8$
3	$S_2 = 2$	$S_2 = 12$
4	$S_2 = 3$	$S_2 = 17$
6	$S_2 = 3$	$S_2 = 17$

The  $H_s/\Delta D_{n50}$  and  $\xi_z$  values for the three damage levels have been plotted for each slope angle and for  $N = 3000$  in Figs. 4 and 5. Although there is a little scatter the influence of the wave period is very clear, especially for the gentler slopes. The influence of the wave period is evidently larger for breaking waves ( $\xi_z < 2.5 - 3.5$ ) than for non-breaking waves ( $\xi_z > 2.5 - 3.5$ ).

#### Influence of Armour Layer Grading

For slopes with  $\cot\alpha = 3.0$  and  $\cot\alpha = 4.0$  the tests were repeated with different grading of the armour. The wide grading with,  $D_{85}/D_{15} = 2.25$  (riprap), was replaced by a narrow grading with  $D_{85}/D_{15} = 1.25$  (uniform stones). Test results are plotted on Figs. 4b and 5a (open symbols). No difference in damage was found for the two gradings. It can be concluded that the grading of the armour within the range tested has no influence on the stability and that the armour layer can be described by the nominal diameter,  $D_{n50}$ , only. This conclusion is in contrast to the use of different  $K_D$  values for riprap ( $K_D = 2.2$ ) and for uniform stones ( $K_D = 3.2$ ). It should be stated that the difference between the Hudson formula and the work of Ahrens [1] can not be explained by the different grading of the armour. Probably, this difference is due to the difference in core permeability of the two investigations.

#### Influence of Spectrum Shape and Groupiness of Waves

The main part of the present series of tests was conducted with a Pierson Moskowitz (PM) spectrum. The test series with a slope angle with  $\cot\alpha = 3.0$  were performed with both a very narrow spectrum and a wide spectrum. Although the last word has not yet been written about the description of spectrum shape and groupiness of waves the following parameters give a reasonable idea.

$$\epsilon_{5\%} = (1 - m_2^2/m_0 m_4)^{0.5} \quad (8)$$

Fig. 4a Cot  $\alpha = 2.0$

Fig. 4b Cot  $\alpha = 3.0$

Fig. 4 Stability formulae and test results for  $N = 3000$  and an impermeable core

Fig. 5a Cot  $\alpha = 4.0$

Fig. 5b Cot  $\alpha = 6.0$

Fig. 5 Stability formulae and test results for  $N = 3000$  and an impermeable core

$$Q_p = \frac{2}{m_0} \int_0^\infty f[S(f)]^2 df \tag{9}$$

$$GF = \text{groupiness factor} = (m_{0,\text{group}})^{0.5} / m_0 \tag{10}$$

$$\bar{j}_1(A) = \text{mean length of wave group above level A} \tag{11}$$

$$\bar{j}_2(A) = \text{mean total length of wave group (Goda [3])} \tag{12}$$

where:  $\epsilon_{5\%}, Q_p$  = spectral width parameters  
 $m_n$  = nth spectral moment of the energy density spectrum  
 $f$  = frequency  
 $S(f)$  = energy density as function of  $f$   
 $m_{0,\text{group}}$  = spectral moment of the SIWEH spectrum (Funke and Mansard [2])

Parameter values for the narrow, PM and wide spectra mentioned above are given in Table 4.

Table 4 Spectral parameters and groupiness of waves

parameter	narrow spectrum	PM spectrum	wide spectrum
$\epsilon_{5\%}$	0.10 ± 8%	0.39 ± 3%	0.59 ± 5%
$Q_p$	13.4 ± 14%	2.60 ± 3%	1.47 ± 11%
GF	0.99 ± 8%	0.77 ± 6%	0.72 ± 8%
$\bar{j}_1(H)$	5.43 ± 12%	2.60 ± 3%	2.16 ± 6%
$\bar{j}_2(H)$	12.6 ± 13%	5.60 ± 3%	4.76 ± 3%
$\bar{j}_1(H_s)$	2.95 ± 6%	1.54 ± 5%	1.35 ± 5%
$\bar{j}_2(H_s)$	22.0 ± 6%	11.3 ± 6%	10.3 ± 6%

The difference in width of the three spectra is clear. A strong wave groupiness was present for the narrow spectrum. Some groupiness existed for both the PM and wide spectrum but the difference between the GF factors is small. Although the width of the wide spectrum is much larger than for the PM spectrum ( $\epsilon_{5\%} = 0.6$  and  $0.4$  respectively), the groupiness of waves was almost the same ( $0.72$  and  $0.77$  respectively).

Test results for the narrow and wide spectrum are shown, for  $N = 3000$ , in Fig. 6.

Using the average wave period,  $T_z$ , for calculating  $\xi_z$  (4) gives good agreement between the test results for a narrow and a wide spectrum. It can be stated, therefore, that stability is not influenced by the spectrum shape or by the groupiness of waves. This conclusion was also reached for the profile development of gravel beaches, by van Hijum and Pilarczyk [5]. Wave runup and rundown, however, depend strongly on the groupiness of waves.

open symbols : wide spectrum,  $\epsilon_{5\%} = 0.59, GF = 0.72$   
 closed symbols : narrow spectrum,  $\epsilon_{5\%} = 0.10, GF = 0.99$

Fig. 6 Influence of spectrum shape and wave groupiness on stability

Fig. 7 Influence of core permeability

## Influence of Core Permeability

Tests were performed on a slope with  $\cot \alpha = 3.0$  with a permeable core. The armour layer was constructed directly on the core. The relative dimensions of the core were  $D_{n50}(\text{armour})/D_{n50}(\text{core}) = 3.2$  and  $D_{85}/D_{15} = 1.5$ . Test results are shown in Fig. 7.

The difference in results with an impermeable core (dotted lines) is appreciable which means that its influence on the stability is large. This was also found by Hedar [4] in 1960 for regular waves. Although stability is higher with a permeable core the same trend for the influence of wave period is shown.

## New Practical Stability Formulae

The list of variables given in Table 1 can be shortened using the results described above. The influence of the number of waves is given by  $S_2/\sqrt{N}$ . Armour grading, spectrum shape and wave groupiness have no influence on the stability and can, therefore, be deleted. The stability of rubble mound slopes can then be described by the following dimensionless variables:

$$H_s/\Delta D_{n50}; \xi_z \text{ or } \sqrt{g T_z^2/D_{n50}}; \cot \alpha; S_2/\sqrt{N}; \text{ permeability}$$

Stability formulae are given below for an impermeable core (lower boundary). The permeability of the core can be included in the formulae by adjusting coefficients. There is distinct difference between breaking and non-breaking waves, see Figs. 4 and 5, and different formulae have, therefore, to be applied for  $\xi_z < 2.5 - 3.5$  and for  $\xi_z > 2.5 - 3.5$ . Non-linear regression analysis gives the following stability formulae for an impermeable core.

for breaking waves:  $\xi_z < 2.5 - 3.5$

$$H_s/\Delta D_{n50} = 4.4 (S_2/\sqrt{N})^{0.22} \xi_z^{-0.54} \quad (13)$$

for non-breaking waves:  $\xi_z > 2.5 - 3.5$  and  $\cot \alpha < 3$

$$H_s/\Delta D_{n50} = 1.25 \sqrt{\cot \alpha} (S_2/\sqrt{N})^{1/6} \xi_z^{0.1} \quad (14)$$

for non-breaking waves:  $\xi_z > 2.5 - 3.5$  and  $\cot \alpha > 3$

$$H_s/\Delta D_{n50} = 1.25 \sqrt{3} (S_2/\sqrt{N})^{1/6} \xi_z^{0.1} \quad (15)$$

Eqs. (13), 14 and (15) become straight lines on log-log paper as shown in Fig. 8.  $H_s/\Delta D_{n50}$  is plotted in this figure against  $\xi_z$  and lines for several damage levels,  $S_2$ , are given for  $N = 3000$ .  $\xi_z^{-0.54}$  and  $\xi_z^{0.1}$  give the slope for the lines and also the influence of the wave period.

The damage level to be taken for design depends on the wave conditions, but must always be within the limits mentioned in Table 3. For storms with a recurrence interval of a few years  $S_2$  can be taken close to the lower limit ( $S_2 = 2 - 3$ ), for very severe storms an intermediate or even the upper limit should be chosen. Figures can be drawn with (13) (14) and (15) for any number of waves required. The stability formulae are also plotted in Figs. 4 and 5, and show good agreement with the test results.

Another way of describing the influence of the wave period is to use the variable  $\sqrt{g T_z^2/D_{n50}}$  instead of  $\xi_z$ . The following simple power function has been found for breaking waves:

$$\boxed{H_s / \Delta D_{n50} * \sqrt{g T_z^2 / D_{n50}} * \tan \alpha = 31 (S_2 / \sqrt{N})^{1/3}} \quad (16)$$

The correlation coefficient, in this case, is 0.90. The formula is based on the actual test results but with the restriction  $S_2 > 2$ . 225 data points were used for the regression analysis. Fig. 9 gives (16) for all test results. 156 data points could be used from Thompson and Shuttler [9] and 171 data points from the present investigation. The results of four different slope angles and two gradings are summarized in the figure.

The following relationships between wave height and damage for constant wave period, slope angle and number of waves can be determined from (14), (15) and (16).

$$S_2 = A H_s^3 \quad \text{for breaking waves} \quad (17)$$

$$S_2 = A H_s^6 \quad \text{for non-breaking waves} \quad (18)$$

where: A = a constant

A third and sixth power function are found. From (17) and (18) it can be concluded that for non-breaking waves the curve is steeper and the damage more progressive. This is also clear in Fig. 4a.

Although it seems that (13) is very different from (16), equation (13) can be rewritten in almost the same form as (16):

$$(H_s / \Delta D_{n50})^{1.35} * \sqrt{g T_z^2 / D_{n50}} * \tan \alpha = 39 (S_2 / \sqrt{N})^{0.41} \quad (19)$$

Using this formula the relationship between wave height and damage becomes:

$$S_2 = A H_s^{3.3}, \quad (20)$$

which is almost the same as found in (17). The agreement between (13) and (16) is good.

Higher stability was found for the permeable core, but with the same trend for the influence of the wave period, see Fig. 7. This

Fig. 8 Stability formulae for  $N = 3000$  and an impermeable core

Fig. 9 Stability formulae and test results for breaking waves ( $z_2 < 2.5$ )

makes it possible to use the same stability formulae (13) to (16) but with adjusted coefficients. For a permeable core the formulae become:

$$H_s/\Delta D_{n50} = 5.8 (S_2/\sqrt{N})^{0.22} \xi_z^{-0.54} \quad (13a)$$

$$H_s/\Delta D_{n50} = 1.65 \sqrt{\cot \alpha} (S_2/\sqrt{N})^{1/6} \xi_z^{0.1} \quad (14a)$$

$$H_s/\Delta D_{n50} = 1.65 \sqrt{3} (S_2/\sqrt{N})^{1/6} \xi_z^{0.1} \quad (15a)$$

$$H_s/\Delta D_{n50} * \sqrt{g T_z^2/D_{n50}} * \tan \alpha = 49 (S_2/\sqrt{N})^{1/3} \quad (16a)$$

The increase of stability for (13a), (14a) and (15a), is 32% and for (16a) 58%. Since there is no known simple parameter which describes the permeability of a structure it is left to the engineers judgement to use (13) to (16) or (13a) to (16a) or even intermediate values. The stability formulae (13a) to (16a) are shown on Figs. 7 and 9 and correspond well with the test results. Further investigation is still necessary with other values of core permeability and with other slope angles in order to solve this problem.

#### Conclusions

1. Based on more than two hundred tests and on the work of Thompson and Shuttler [9] practical design formulae have been developed for rubble mound slopes under random wave attack.
2. The stability, in a dimensionless form, has been determined using
  - the significant wave height:  $H_s/\Delta D_{n50}$
  - the average wave period:  $\xi_z$  or  $\sqrt{g T_z^2/D_{n50}}$
  - the slope angle:  $\cot \alpha$
  - the damage as function of number of waves:  $S_2/\sqrt{N}$
  - the permeability of the core.
3. Within the conditions tested the following had no influence on the stability:
  - the grading of the armour
  - the spectrum shape
  - the groupiness of waves.

## Notation

$H_s/\Delta D_{n50}$	= dimensionless wave height	
$\xi_z$	= surf similarity parameter: $\xi_z = \tan \alpha / \sqrt{2\pi H_s/gT_z^2}$	
$\sqrt{gT_z^2/D_{n50}}$	= dimensionless wave period	
$S_2/\sqrt{N}$	= dimensionless damage as function of number of waves	
$A_2$	= area of erosion profile	(m <sup>2</sup> )
$D_{n50}$	= nominal diameter; $D_{n50} = (W_{50}/\rho_a)^{1/3}$	(m)
$D_{15}$	= 15% value of sieve curve	(m)
$D_{85}$	= 85% value of sieve curve	(m)
GF	= groupiness factor	(-)
$H_s$	= significant wave height	(m)
$K_D$	= stability coefficient	(-)
N	= number of waves	(-)
$N_s$	= stability number; $N_s = H_s/\Delta D_{n50}$	(-)
$Q_p$	= parameter for spectral width	(-)
$S_2$	= damage level; $S_2 = A_2/D_{n50}^2$	(-)
$T_z$	= average wave period	(s)
$W_{50}$	= 50% value of mass distribution curve	(kg)
g	= acceleration due to gravity	(m/s <sup>2</sup> )
$\bar{j}_1$	= mean length of wave group	(-)
$\bar{j}_2$	= mean total length of wave group	(-)
$\alpha$	= slope angle	(degr)
$\Delta$	= relative mass density; $\Delta = \rho_a/\rho - 1$	(-)
$\epsilon_{5\%}$	= variable for spectral width	(-)
$\rho$	= mass density of water	(kg/m <sup>3</sup> )
$\rho_a$	= mass density of stone	(kg/m <sup>3</sup> )

## CHAPTER ONE HUNDRED SEVENTY SEVEN

### Surveys of Coastal Structures Using Geophysical Techniques

John R. Dingler and Roberto J. Anima\*

Coastal engineers have long relied upon bathymetric surveys to determine the extent of underwater damage to jetties and breakwaters. Though such surveys supply important information about variations in water depth around structures, they alone do not show in sufficient detail the nature of the material on the structure, the extent of subbottom features, or the nature of the subbottom upon which the structure sits. However, by conducting bathymetric surveys in conjunction with other remote-sensing techniques and diving observations, it is possible to obtain more complete knowledge of the subsurface condition of coastal structures.

During the summer of 1983 and the spring and summer of 1984, we conducted side scan sonar and shallow subbottom surveys in conjunction with bathymetric and diving surveys along three northern California coastal structures to determine the condition of the structures before extensive damage occurred. Then, we evaluated the applicability of the data collection techniques for condition surveys in general.

Two of the structures surveyed are the parallel jetties that protect the entrance to Humboldt Bay, California, and the third structure is the outer breakwater at Crescent City, California. Bathymetric records and sonographs from Humboldt Bay show deep holes along much of the inside of the south jetty and off the heads of both jetties. The subbottom record from inside Humboldt Bay shows a subsurface fault, the extension of which would run under the south jetty.

Sonographs from Crescent City show significant bedrock outcrops throughout the area outside the breakwater, making it difficult in places to identify the toe of the structure. The subbottom record shows that pockets of sand exist amidst the bedrock, but they are generally less than 2 m (6 ft) in thickness.

We found that the side scan sonar is an excellent tool for defining the toe of the structure; also, when waves are low, it can be useful in determining armor types and the slope of structures. Our subbottom system provided information on fault and bedrock locations; however, other systems need to be tested to see if any of them can locate buried armor near the structures.

\* Oceanographer and Geologist, respectively, United States Geological Survey, 345 Middlefield Road, Menlo Park, CA 94025.

## INTRODUCTION

Currently, it is difficult to evaluate the condition of a coastal structure before it fails. Damage from individual waves or storms may slowly undermine structural integrity, eventually causing a seemingly sudden failure and necessitating stop-gap repair measures until more permanent, and usually costly repairs, can be undertaken. Although coastal structures are built to withstand a prespecified wave (usually the significant wave according to the U.S. Army, 1973, p. 7-168), the combination of wave activity, tidal currents, and longshore transport slowly causes structural weakening. When damage becomes severe enough--usually after a visible failure of the structure--engineers inspect the structure above water and conduct a localized bathymetry survey to assess the damage. Prefailure surveys to determine the condition of a structure are rarely, if ever, conducted.

The cost of repairing coastal structures is high; consequently, techniques are needed to determine their integrity. Recently, the Los Angeles District of the Corps of Engineers initiated a program to determine the present condition of man-made structures along the California coast. During the summer of 1983, we conducted geophysical surveys in the vicinity of the jetties at Humboldt Bay, California, and the outer breakwater at Crescent City, California. In the spring of 1984, we repeated some of the Humboldt Bay surveys to document changes produced by winter waves. In the summer of 1984, we dove around the structures to see if we could improve our interpretation of the sonographs. The goals of these surveys were (1) to develop a general survey methodology that could be used to inspect other such structures along the California coast and (2) to test the methodology by ascertaining in situ the condition of the structures at the two sites.

## LOCATION AND DESCRIPTION

Humboldt Bay, the harbor for the city of Eureka and the largest bay on the northern California coast, is about 400 km (215 nmi) north of San Francisco. Crescent City, located on the south side of Point St. George, is about 120 km (65 nmi) north of Eureka. Figure 1 shows the location of the study area; figure 2 shows the jetties at the entrance to Humboldt Bay, and figure 3 shows the outer breakwater configuration at Crescent City. Both the jetties and the breakwater are rubble-mound structures with large, cast-armor units in selected places.

Stabilizing the entrance to Humboldt Bay commenced in 1881 and has continued sporadically to the present. Repairs have been so extensive that Hagwood (1981, p. 176) stated that the quantity of stone used to repair the Humboldt Bay jetties has been, in total, greater than that used for the original structures. At present, Humboldt Bay has parallel jetties that are 610 m (2,000 ft) apart; each jetty is over 2,000 m (6,560 ft) long. Repeated dredging maintains a navigation channel, 152 m (500 ft) wide by 13 m (43 ft) deep, near the south jetty.

Because of strong storm waves in the area, both jetties have experienced repeated damage and repair. Because traditional designs were unable to protect the jetty heads, in 1971 both were widened and

armored with 38- and 39-t (42- and 43-ton) dolosse. This was the first use of these units in the United States (Hagwood, 1981, p. 348). At present, the heads of both jetties have settled, and in one place the inside flank of the south jetty has separated from the cap.

Figure 1: Location of the study sites at Crescent City and Eureka, northwestern California.

The outer breakwater at Crescent City is knee-shaped, extending southeast from the shore for about 1,128 m (3,700 ft) and then turning east for about 305 m (1,000 ft). Construction of the initial breakwater was finished in 1930. That first section extended 914 m (1,000 ft) southeast from the shore toward Round Rock. Later, engineers decided to extend the breakwater to Round Rock, forming a breakwater about 1,740 m (5,700 ft) long. That plan proved to be unfeasible, and the easterly arm was added instead, leaving a submerged rocky reef extending to the southeast.

Model studies at the Waterways Experiment Station, Vicksburg, Mississippi led, in 1956, to the placement of 23-t (25-ton) tetrapods on the easterly arm, the first use of these units in the western hemisphere (Hagwood, 1981, p. 341). Because of further storm damage, 38-t (42-ton) dolosse were added to protect the corner in 1974.

#### Equipment and Procedures

Although this survey was the first of its kind on the west coast, the various instruments have been used separately in similar

Figure 2: Entrance to Humboldt Bay at Eureka, California.

Figure 3: Harbor at Crescent City, California.

Figure 4: Plan view (left) of the jetties at Humboldt Bay, California showing the location of cross sections plotted on the right.

situations. Bathymetric surveys are commonly conducted around coastal structures. Patterson and Pope (1983) used side scan sonar to inspect structures in quiet waters; Mazel (1984) described how to use side scan sonar to inspect vertical surfaces; and surface-towed seismic transducers are often used to study surficial sand bodies.

Equipment used during this study included precision depth recorders, 100- and 500-kHz side-scan sonars, and a surface-towed 3.5-kHz subbottom profiler. The instruments were deployed from the (43 ft) R/V David Johnston or from a small (21 ft) boat. Instruments were chosen to fulfill specific objectives: the precision depth recorders were used to survey the bottom in the vicinity of the structures and to determine structure slopes; the side-scan sonar provided images of the toes of the structures and of surficial features on the adjacent sandy bottom; and the subbottom profiler determined the depth to bedrock and type of near-surface internal structure.

During the summer of 1984, scuba divers swam along the toes of, and occasionally onto, the three structures, and their direct observations were used to clarify the sonographs.

## RESULTS

The 1983 and 1984 geophysical surveys and the 1984 scuba dives produced accurate data on the toes of the three structures, detailed bathymetric maps and slope profiles, and a rough picture of the subsurface. These surveys failed to produce detailed information on the distribution of armor on the structures or the location of buried armor. Sub-bottom techniques capable of accurately locating objects as large as the armor units failed to do so because of adverse conditions.

### Humboldt Bay

Water depth varies considerably and systematically throughout the inlet and adjacent nearshore zone, as shown in figure 4. Whereas water is deep on the southwest side of both jetties, only along the south jetty is the water deep adjacent to the inlet-side (inside) flank. Figure 5, a plot of additional profiles run perpendicular to the south jetty, shows the disparity in depth between its outside and inside flanks. Near the head of the south jetty, the water is deeper on the south (outside) flank; however, landward from the back of the head, the water is deeper on the inside.

The seismic profiles showed that the shallow subsurface is sandy. Transects in the bay that crossed the center lines of both jetties show subsurface faulting that would lie under the south jetty when extended (fig. 6). However, over 20 m (66 ft) of unfaulted sediment overlies the faults. Waves distorted the offshore records to the extent that subbottom features could not be discerned. Attempts to locate buried armor were not successful.

The sonographs delineate the toes of the jetties and large subaqueous dunes in shallow parts of the inlet; slope changes and individual armor upon the jetties were identified. The location of the

Figure 5: Profiles along the south jetty at Humboldt Bay, California. Zero on the abscissa is at the centerline of the jetty. Station numbers represent distances in hundreds of feet, with the largest value being at the jetty head.

Figure 6: Location and trend of subsurface faults inshore of the south jetty at Humboldt Bay, California.

jetty toes, as calculated from the sonographs, are shown in figure 4.

The scuba dives, although conducted when water visibility was poor, led to the discovery that the jetty toes have different makeups. As shown on figure 7, the toe of the south jetty varies from large rock, to dolosse, to large rock with extensive sand that forms ramps up the flank, whereas the toe of the north jetty varies from large rock, to dolosse, to large areas covered with gravel and small rock.

#### Crescent City

Surveys at Crescent City covered the area between the outer breakwater and Round Rock to the south and Steamboat Rock to the west and the area adjacent to the inside of the arm (see fig. 3). Outside the Crescent City breakwater, the bottom is irregular because of extensive bedrock outcrops, is gently sloping, and is punctuated by rocky pinnacles that occasionally reach the sea surface. Depths along the outside of the shore-attached breakwater are as much as 9 m (30 ft) at the corner of the breakwater, maintaining that depth along the east-trending arm. The bottom shallows over the rocky reef, which nearly reaches the surface in places. One notable difference from the Humboldt Bay bathymetry data is the absence of depressions along the breakwater toe.

The sonographs showed extensive bedrock outcrops. On many records, such as the one shown in figure 8, it was hard to separate the breakwater toe from the naturally outcropping material. Figure 9 shows the location of the toe of the breakwater and of features thought to be outcrops rather than the breakwater itself. At one site just west of the corner of the breakwater, divers noted that the bulge is actually bedrock and that the toe is straight.

Seismic profiling confirmed that bedrock lies at or near the surface throughout the region. Typically, sand is restricted to depressions, forming patches less than 2 m (6 ft) thick. The only areas where sand completely covers the bedrock are east of the breakwater head and along the inside of the arm.

#### DISCUSSION

At Humboldt Bay, the bottom is sandy, and depth varies with location such that the greatest depths occur between the entrance channel and the south jetty and adjacent to the south sides of both jetty heads. The flanks of the south jetty slope as much as 42°, and the adjacent bottom drops off from the channel to the jetty without forming a channel wall (fig. 5). Continuing that profile to the ocean side of the jetty revealed highly unequal water depths on the two sides of the jetty--the outside being much shallower. That discrepancy is typical except at the head where, it reverses so that the deep scour appears on the outside. For interpretative purposes we divided the sea floor around and between the jetties into five parts: (1) the areas southwest of both heads, (2) elsewhere along the outside of the jetties, (3) the inside of the south jetty, (4) the entrance channel, and (5) elsewhere in the inlet.

Figure 7: Location of armor types and sand ramps along the jetties at Humboldt Bay, California.

Figure 9: Location of the toe of the outer breakwater at Crescent City, California, as interpreted from sonographs. Also shown are bedrock outcrops near the breakwater.

Figure 8: Sonographs of the bottom adjacent to the corner of the outer breakwater at Crescent City, California. Strong reflectors are bedrock outcrops. A 500-kHz sonograph is to the left, and a 100-kHz sonograph to the right.

Southwest of both heads, storm waves produce large, year-round, scour holes along the heads that are slightly deeper in the winter. Perhaps tidal flows or shelf currents contribute to the extensive erosion in this area. Overlaying the bathymetry on the construction drawings shows that the jetty toes have been extensively undermined in this area (Doug Pirie, oral commun., 1984).

Farther onshore, the waves have not created large depressions along the outsides of the jetties. Instead, the bathymetric data show a shallowing shoreward trend. Going from north to south there is about a 610-m (2,000-ft) shoreward offset of the shoreline.

Along the inside of the south jetty, strong tidal currents appear to have eroded the bottom, creating a continuous depression. Here, the divers found sand that formed ramps from the floor up the flank. The location and orientation of these sand ramps--abutting the east side of large armor and whose axes are tilted slightly shoreward-- suggest either flood-tide control or control by the distribution of armor. The entrance channel is periodically dredged to 13 m (43 ft). Its proximity to the inside of the south jetty may contribute to the extreme scour along that stretch of the toe.

Waves and tides interact to control the rest of the inlet. The traces of old groins, which were built to inhibit erosion along the north jetty (Chuck Orvis, oral commun., 1984), on both summer and winter sonographs suggest that tidal flows limit the depositional depth of the wave-driven sand in that area. Large bedforms in the central part of the inlet also suggest strong wave and tidal currents.

At the Crescent City study area bedrock dominates. Because the breakwater sits on bedrock, scour at the toe is minimal. Divers found, in places where sand or gravel abutted the breakwater, that the slope is gentle up to approximately 1 m (3 ft) of the armor and then steep down to the base of the armor; wave activity probably causes this pattern. Tidal currents appear to be relatively unimportant around the breakwater. Outside, waves attack the breakwater; inside, the water is often quiescent.

Wave action reduced the quality of the various records. Records collected on the (rare) calm days showed much more detail; furthermore, records could be collected over the structures only on such days. Most of the records, however, were affected by wave activity to the extent that details were missing. Each of the aspects of the study-- bathymetry, seismic profiling, side scanning, and diving--could have contributed more information under better conditions.

Wave activity affected the bathymetric surveys by introducing large offsets to the bottom traces and by preventing us from surveying over the steep slopes of the structures. To a great extent, wave noise can be visually removed from the bathymetric records, but fine detail is lost. However, not being able to survey over the structures made it difficult to accurately locate the toes of the structures.

Side scan sonar helped in determining toe location when working

over the structure was not possible. However, if, as in the case of the south jetty at Humboldt Bay, the bottom depth was much different at the toe than at the point where the side scan fish was being towed, the distance measured from the sonograph would not be the horizontal distance from the ship's track to the toe. To obtain that distance a correction had to be made that depended on the depth at the toe, which necessitated knowing the location of the toe. Nevertheless, the error in toe location could be satisfactorily minimized by towing the fish near the bottom and knowing the approximate depth of the toe.

Patterson and Pope (1983) showed that side scan sonar can be used to recognize individual armor units and perhaps to recognize slope changes and missing armor. However, such detailed work requires ideal conditions, which, in many areas, occur only a few days per year. Those who plan surveys must, therefore, decide on whether or not it is economically feasible to wait for the right conditions. Although during this study wave conditions precluded our identifying individual armor or slope changes, variations in armor size between areas showed on the sonographs. Divers found that the groins along the north jetty at Humboldt Bay contain small rock, whereas the rest of that jetty has large rock or dolosse at the toe. Figure 10 shows how these differences appear on a sonograph.

Although the 500-kHz side scan sonar produced records with much more detail on them than did the 100-kHz sonar, both provided enough detail to determine toe location in most cases. However, the 500-kHz unit should be used when searching for small features.

Boat speed must be considered when looking for small features. If, for example, one wants to identify the sand ramps, which sit in 2- to 3-m (6- to 10-ft) gaps between large armor, boat speeds must be less than 1 m/s (2 kt). Otherwise, that section of the sonograph will be too narrow, making it impossible to resolve the feature.

Seismic profiling requires calm conditions to obtain interpretable records. This is especially true of a surface-towed unit. Again, detail is lost during wavy conditions. We attempted to find buried armor, which would show up on the record as point-source parabolas, but saw none. Although there may not have been any to find, excessive motion of the sled would have masked their presence.

Diving also requires calm conditions, both to improve visibility and to permit swimming around the structure. We were able to follow the toe, but unable to see far enough to assess large-scale irregularities.

#### CONCLUSIONS AND RECOMMENDATIONS

1. At Humboldt Bay extensive scour has taken place on the south sides of the heads of both jetties and along the south jetty between the inside flank and the entrance channel.
2. On all three structures, large rock is the predominant material found along the toes. At Crescent City, there are a few dolosse at the corner and tetrapods along much of the easterly extension. At

Figure 10: Sonograph of a groin along the inside of the north jetty at Humboldt Bay, California. The patterns on the sonograph indicate that the size of the material composing the groin and adjacent toe is smaller than the size of the material farther shoreward (A).

Humboldt Bay, there are dolosse on the bottom around both heads and smaller rock in a few places, primarily around the groins.

3. At Humboldt Bay, the subsurface is sandy; faulting extends under the south jetty but does not break the surface. At Crescent City, bedrock is present at or near the bottom throughout the study area.

The surveys showed that some techniques have general applicability and that others are more specialized. Also, they showed the extent to which such surveys depend on calm seas. On the basis of our work around these structures, we make the following recommendations:

1. Bathymetric surveys are fundamental to conducting condition surveys on coastal structures. They can be used under more severe conditions than the other techniques, and most wave noise can be filtered from the records.
2. Side scan sonar is an important adjunct to bathymetry in determining the location of the toe of the structure and the position of bottom features. It also can be used to look for features on the structures, but only when seas are calm.
3. Seismic profiling is useful when large-scale features are to be resolved. More work with different devices, however, must be done before it will be known if seismic techniques can locate buried armor.
4. Diving is a useful tool when visibility and wave climate permit. It can provide information on small features that often cannot be resolved with the geophysical tools.

#### ACKNOWLEDGMENTS

This study was sponsored by the Los Angeles District, U.S. Army, Corps of Engineers. We thank the many people from the U.S. Geological Survey, the Corps of Engineers, and the Humboldt Bay Coast Guard Station who helped us during the study. Chuck Orvis of the Los Angeles District and the staff of the Eureka office of the Corps of Engineers were especially helpful. Beth Laband and George Tait improved this manuscript with their reviews.

## CHAPTER ONE HUNDRED SEVENTY EIGHT

### Reef Type Breakwaters

John P. Ahrens, Aff. M. ASCE\*

#### Introduction

Reef type breakwaters refers to a low-crested rubble mound breakwater without the traditional multilayer cross section. This type of breakwater is little more than a homogenous pile of stones with individual stone weights sufficient to resist wave attack.

In recent years a number of low-crested breakwaters has been built or considered for use at a variety of locations. Most of these structures are intended to protect a beach or reduce the cost of beach maintenance. Other applications include protecting the water intakes for power plants, the entrance channel for small boat harbors, and providing an alternative to revetment for stabilizing an eroding shore line. In situations where only partial attenuation of the waves on the leeside of the structure is required, or possibly even advantageous, a low-crested rubble mound breakwater is a logical selection. Since the cost of a rubble mound increases rapidly with the height of the crest, the economic advantage of a low-crested structure over a traditional breakwater that is infrequently overtopped is obvious. Because the reef type breakwater represents the ultimate in design simplicity it could be the optimum structure for many situations. Unfortunately, the performance of low-crested rubble mound structures, and particularly a reef type breakwater, is not well documented or understood.

#### Background and Objectives

A number of papers have noted that the armor on the landside slope of a low-crested breakwater is more likely to be displaced by heavy overtopping than the armor on the seaward face, Lording and Scott (1971), Raichlen (1972), and Lillevang (1977). Raichlen discusses the characteristics of the overtopping over the crest and the inherent complexity of the problem. Walker, et al. (1975) give a carefully reasoned discussion of the many factors influencing the stability of heavily overtopped rubble mound breakwaters. Walker, et al. also show a figure which suggests what armor weight might be required for stability on the beachside of a low-crested breakwater. Unfortunately, the data scatter shown in the figure undermines confidence in the suggested armor weights.

In Australia the breakwater at Rosslyn Bay was damaged severely during cyclone "David" in 1976, Bremner, et al. (1980). The crest height of the structure was reduced as much as four meters but still functioned effectively as a submerged breakwater for over two years until it was

\*Oceanographer, Coastal Engineering Research Center, U. S. Army Engineer Waterways Experiment Station, P. O. Box 631, Vicksburg, MS 39180

repaired. Based on the surprisingly good performance of the damaged Rosslyn Bay breakwater and the findings from model tests, a low-crested design was chosen for the breakwater at Townsville Harbor, Australia. This breakwater is unusual because it was built entirely of stone in the 3- to 5-ton range, Bremner et al. Reef breakwaters, as described in this paper, are very similar to the Townsville breakwater except a wider gradation of stone was used in the model breakwater tests discussed herein.

Seelig (1979) conducted an extensive series of model tests to determine the wave transmission and reflection characteristics of low-crested breakwaters, including submerged structures. From these tests Seelig concluded that the component of transmission due to wave overtopping was very strongly dependent on the relative freeboard, i.e. the freeboard divided by the incident significant wave height. Recent work by Allsop (1983) with multilayered, low-crested breakwaters showed that the wave transmission was strongly dependent on a dimensionless freeboard parameter which included the zero-crossing period of the irregular wave conditions. Allsop did not find much wave period dependency in his evaluation of breakwater stability but indicates that since the wave transmission (which is largely due to overtopping) is dependent on the period, then possibly the stability of the backface would also be a function of wave period.

A study currently being conducted at the Coastal Engineering Research Center (CERC) is intended to document the performance of low-crested breakwaters. This paper discusses laboratory model tests of reef type breakwaters and provides information on their stability to wave attack and the wave transmission and reflection characteristics of the structures.

#### Techniques Used

To date 205 two-dimensional laboratory tests of reef breakwaters have been completed. These tests were conducted in a 61-centimeter-wide channel within CERC's 1.2- by 4.6- by 42.7-meter wave tank (see Figure 1 for a plan view of the tank and test setup).

All tests were conducted with irregular waves. The spectra used have wave periods of peak energy density,  $T_p$ , ranging from about 1.45 to 3.60 seconds. The signals to control the wave blade were stored on magnetic tape and were transferred to the wave generator through a data acquisition computer system (DAS). For this study there were four files on the tape which would produce a distinct spectrum for each file. Table 1 gives the nominal period of peak energy density for each file.

<u>Tape File</u>	<u>Approximate <math>T_p</math> (sec)</u>
1	1.45
2	2.25
3	2.86
4	3.60

Table 1. Period of peak energy density for each file.

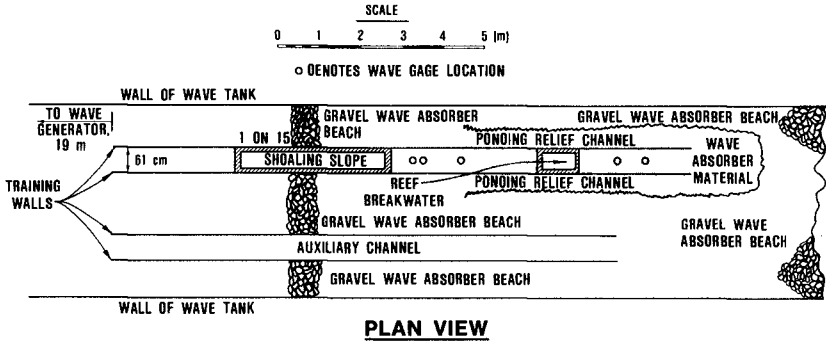

Figure 1. Plan view of wave tank and test setup.

Figure 2. Cross sectional view of the initial and damaged breakwater profile.

If there were no attenuation of the signal to the wave generator the files used were intended to produce a saturated spectrum at all frequencies above the frequency of peak energy density for the water depth at the wave blade. For frequencies lower than that of the peak, the energy density falls off rapidly. This procedure produced a spectrum of the Kitaigorodshii type as described by Vincent (1981). The amplitude of the signal to the wave generator could be attenuated by a 10-turn potentiometer in a voltage divider network which allowed control of the wave heights generated. In addition, the waves were generated in a water depth 25 centimeters greater than at the breakwater and shoaled to the water depth of the structure over a 1 on 15 slope (see Figure 1). This setup ensures that very severe conditions can be developed at the structure site. Incident zero-moment wave heights ranged from about 1 to 18 centimeters.

Three parallel wire resistance-type wave gages were used in front of the breakwater to resolve the incident and reflected wave spectrum using the method of Goda and Suzuki (1976). Two wave gages were behind the structure to measure the transmitted wave height. The location of the gages is shown in Figure 1. During data collection the gages were sampled at a rate of 16 times per second for 256 seconds by the same DAS which controlled the wave generator motion.

Two distinct types of model tests were conducted during this study. They will be referred to as "stability" tests and "previous damage" tests. For a stability test the following test sequence was used:

1. Rebuild the breakwater from the previously damaged condition.
2. Survey the breakwater to document its initial condition.
3. Calibrate the wave gages.
4. Select the wave file and signal attenuation setting.
5. Start the wave generator and run waves.
6. Collect wave data (several or more times).
7. Stop the wave generator.
8. Survey the breakwater to document its final condition.

The duration of wave action lasted from 1-1/2 hours for a test using the File 1 spectrum to 3-1/2 hours for a File 4 spectrum. Generally, the technicians observing the tests thought that most of the stone movement occurred during the first 10 or 15 minutes of wave generation, so the final survey is regarded as an equilibrium profile for the structure. In rebuilding the breakwater the technicians rarely touched the stone but merely pushed it around by foot until the shape conformed to the desired initial profile. This procedure was a conscious effort to avoid overly careful placement of the stone. Outlines of the desired initial profile were fixed to the walls of the testing channel and a moveable template was used to ensure that the initial profile was reasonably close to the desired profile. Initial configuration of the breakwater for a stability test is a narrow, trapezoidal shape with the seaward and landward slopes of 1 on 1-1/2 (see Figure 2). Figure 2 also shows a typical profile after moderately severe wave attack during a stability test. Wave transmission and reflection also were measured during a stability test.

Tests referred to as previous damage were conducted to answer the question of how the breakwater would perform for typical wave conditions after it had been damaged by very severe wave conditions. For previous damage tests there was very little readjustment of the damage profile from test to test since the breakwater is not rebuilt at the end of a test. There really was no stability information obtained from these tests and the duration of wave action is only half an hour, but wave transmission and reflection were measured. Previous damage tests had the following sequence of events:

1. Final survey of the breakwater for the last test which becomes the initial survey for this test.
2. Calibrate wave gages.
3. Select the wave file and signal attenuation setting.
4. Start generator and run waves for half an hour.
5. Collect wave data (two or three times).
6. Stop the wave generator.
7. Survey breakwater as noted above in Step 1.

All 205 of the completed tests of this study logically can be divided into 10 subsets or test series. Because of the test plan stability test series have odd numbers and previous damage test series have even numbers. Table 2 gives the basic information about each subset.

<u>Subset No.</u>	<u>No. of Tests</u>	<u>Water Depth (cm)</u>	<u>Crest Height as Built (cm)</u>	<u>Median Stone Weight (gr).</u>	<u>Area of Breakwater Cross Section (cm<sup>2</sup>)</u>

Table 2. Basic data for each subset.

Two different sizes of stone were used during this study. For subsets 1 through 6 an angular quartzite with a median weight of 17 grams was used and for subsets 7 through 10 a blocky to angular diorite was used. Table 3 summarizes the information about the stone used in this study.

<u>Characteristic</u>	<u>Quartzite</u>	<u>Stone Type Diorite</u>
Median weight (gr)	17.0	71.0
Density	2.63	2.83
$W_{98}/W_2$	3.9	10

Table 3. Stone and gradation characteristics.

Table 4 provides a summary of the definitions for variables used in this study.

Symbol, Definition (units)

$H_S$	, incident zero-moment wave height (cm)
$H_T$	, zero-moment transmitted wave height (cm)
$H_c$	, zero-moment wave height at transmitted gage locations with no breakwater in channel (cm)
$T_p$	, wave period of peak energy density of spectrum (sec)
$d_s$	, water depth at breakwater (cm)
$L_p$	, Airy wave length calculated using $T_p$ and $d_s$ (cm)
$W_{50}$	, median stone weight, subscript indicates percent of total weight of gradation contributed by stones of lesser weight (gr)
$w_r$	, density of stone
$w_w$	, density of water, tests conducted in fresh water $w_w = 1.0$
$h_c$	, crest height of breakwater as built (cm)
$h_c$	, crest height of breakwater after wave attack (cm)
$A_t$	, cross sectional area of breakwater (cm <sup>2</sup> )
$A_D$	, area of damage to breakwater (cm <sup>2</sup> )
$K_R$	, reflection coefficient of breakwater as defined and calculated by method of Goda and Suzuki (1976)

Results

Stability. To prevent confusion it should be mentioned that the stability will be quantified by the damage or lack of damage during a test. For reef breakwaters, stability logically can be viewed from two perspectives. One perspective is volumetric damage. This type of damage is related to the number of stones displaced from their original location and possibly includes where the stones were deposited. Information regarding volumetric damage is important when considering maintenance requirements for the structure. The second aspect of stability is the reduction in the crest height of the breakwater due to wave action. Since the performance of a reef breakwater will be judged largely by its wave transmission characteristics, this aspect of stability is quite important because wave transmission is very sensitive to the crest height

of the structure relative to the water depth. Two dimensionless variables are used to define these two aspects of the stability of the breakwater; they are the relative crest height,  $h_c/d_s$ , and the dimensionless damage,  $D'$ , which is defined as

$$D' = \frac{A_d}{(w_{50}/w_r)^{2/3}}$$

The relative crest height is the ratio of the equilibrium or stable crest height to the water depth at the site for the given wave conditions and  $D'$  is a measure of the number of stones removed from the damaged area. Experience indicates that damage to a rubble mound breakwater will be strongly dependent on Hudson's stability number  $N_s$ , Hudson (1959). The stability number is defined for irregular waves as

$$N_s = \frac{H_s}{(w_{50}/w_r)^{1/3} \left( \frac{w_r}{w_w} - 1 \right)}$$

In Figures 3a and 3b  $h_c/d_s$  and  $D'$  are plotted versus  $N_s$  for data of subset 1. These data trends generally are what would be expected: as the severity of wave attack increases, i.e. increasing  $N_s$ , the volume of stone displaced increases at an ever-increasing rate and the height of the breakwater decreases gradually. On the whole, the stability number does a fairly good job of explaining the damage to the structure but careful inspection of the data points in Figures 3a and 3b suggests that there is a wave period effect. The effect indicated is that wave spectra with large  $T_p$ 's do more damage than spectra with small  $T_p$ 's, other factors being equal. This finding is consistent with the findings of Gravesen, et al. (1980) who have conducted an extensive study of the stability of rubble mound breakwaters to irregular wave attack. The breakwaters studies by Gravesen, et al. are considerably different from reef breakwaters in that they are high multilayered structures with large concrete caps designed so the structure is rarely overtopped. Gravesen's, et al. work suggested that a modified stability number which took into account the period of peak energy density of the spectrum might describe damage to the breakwaters better than the traditional stability number. Following Gravesen, et al. the spectral stability number,  $N_s^*$  is defined

$$N_s^* = \frac{(H_s^2 L_p)^{1/3}}{(w_{50}/w_r)^{1/3} \left( \frac{w_r}{w_w} - 1 \right)} \quad \text{Eq. 1}$$

When the data shown in Figures 3a and 3b are replotted versus  $N_s^*$  in Figures 4a and 4b there is a considerable reduction in the data scatter. When the other stability data subsets are compared as in Figures 3 and 4 it is found that using  $N_s^*$  reduces the scatter in all subsets, eg. see Figure 5 which shows the data for Subset 5.

Figure 3. Damage response of breakwater as a function of stability number for data subset 1.

Figure 4. Damage response of breakwater as a function of the spectral stability number for data subset 1.

(a)

(b)

(c)

(d)

Figure 5. Damage response of breakwater for data subset 5.

Although the reason is not entirely clear, it appears that  $H_s^2 L_p$  is a better measure of wave severity than  $H_s^3$ , at least as far as reef breakwaters are concerned. Part of the reason may be due to relating damage to the zero-moment wave height rather than a larger wave in the height distribution. It is convenient to relate damage to the zero-moment wave height because of the statistical stability of the parameter and because of its relation to the area under the spectrum; however, it is commonly observed that the larger waves in the distribution move most of the stone. In addition, for a given water depth, the maximum stable wave height increases with period; therefore, for a fixed water depth and zero-moment wave height it would be the file with the longer period of peak energy density which would have the larger waves striking the breakwater. Another factor which might cause longer waves to be more damaging could be called the runup factor. Generally, on rough porous slopes, longer period waves have higher runup than shorter waves if other conditions are equal (see Figure 12 in Seelig 1980). A longer period and higher runup mean a greater return flow which can cause damage on a high structure and a greater volume and celerity of overtopping flow to cause damage on a low-crested breakwater.

Somewhat surprisingly, the classic picture of a large wave curling over and breaking on the structure was rarely observed during this study. Possibly because of the porous nature of the breakwater, waves appeared to be partly absorbed into the structure before they could break on it. Usually it was the drag forces caused by heavy overtopping flow which moved most of the stones rather than wave impact.

Since the relative height of the breakwater was so strongly dependent on  $N_s^*$  for all the stability subsets it is instructive to look at all five trends together in one Figure. Figure 6 shows these trends which indicate that there is little or no degradation of the breakwater for  $N_s^* \leq 6$ , but for the higher structures there is quite noticeable degradation for  $N_s^* \geq 8$ . Figure 6 also shows that the damage rate is reduced after the crest has been battered down to about the still water level by wave attack. Once the structure is submerged the overlying water provides considerable protection from further damage. This tendency has been observed in the field for a number of damaged breakwaters, Wiegell (1982).

#### Wave Transmission

For these tests the wave transmission coefficient  $K_T$  is defined as:

$$K_T = \frac{H_t}{H_c}$$

Although this is not the most commonly used definition of  $K_T$  it has some advantages over the traditional definition which is given by the ratio of  $H_T$  to  $H_s$ . The definition given above can be stated as

Figure 6. Damage trends as a function of the spectral stability number for data subsets 1, 3, 5, 7, and 9.

Figure 7. Wave transmission as a function of the relative freeboard.

the ratio of the transmitted wave height to the wave height which would be observed at the same location without the breakwater in the channel. This definition eliminates wave energy losses occurring between the incident and transmitted gages in the absence of a breakwater in the testing channel. These losses were observed to be considerable for the most severe wave conditions during calibration of the channel. In effect  $K_T$  measures the attenuation of wave energy due strictly to the presence of the breakwater and eliminates additional energy losses due to natural wave breaking processes occurring between the incident and transmitted wave gages. Because of this definition  $K_T$  should be somewhat conservative.

In an extensive study of wave transmission, Seelig (1979) concluded that the relative freeboard  $F/H_s$  was the most important variable in explaining the transmission characteristics of submerged and overtopped breakwaters, where  $F = h_c - d_s$ . Figure 7 shows a trend curve for  $K_T$  as a function of  $F/H_s$  based on results from this study. The curve shown in Figure 7 is schematic in nature because it tries to follow the trend of the data from all 10 subsets. There are some small inconsistencies introduced by using this approach because the larger structures will attenuate the waves better than the smaller structures for the same relative freeboard, i.e. the broader the crest of the breakwater, the greater the reduction in the transmitted wave height. Another problem is that for relatively high breakwaters transmission is no longer dominated by wave overtopping but by energy transmission through the structure which is a function of, among other things, wave steepness,  $H_s/L_p$ . It is this changing role in the dependence of  $K_T$  on  $H_s$  which causes the paradoxical trend in the data which is suggested by the dashed curve in Figure 7. The transition in modes of transmission occurs at approximately  $F/H = 1.5$  for reef breakwaters. In Figure 7 the dashed curve is not intended to suggest that for a fixed incident height the transmitted height will increase if the freeboard is increased but rather that with a fixed freeboard the transmission coefficient will increase if the incident wave height is reduced. Despite its limitations Figure 7 provides a reasonably good idea about the performance of reef breakwaters over a wide range of conditions. The problem is a typical one: the phenomena of interest is not a function of one variable over the entire range of interest.

Analysis of the wave transmission data is continuing. It appears that  $F/H_s$  and  $H_s/L_p$  provide a reasonably good way to parameterize wave transmission due to overtopping and through the breakwater, respectively. However, the work of Allsop (1983) suggests that there should be some influence of wave period in the portion of wave transmission due to overtopping.

#### Wave Reflection and Energy Dissipation

Wave reflection from the breakwater is more strongly dependent on wave period or wave length than is the wave transmission. Reflection, however, also is strongly dependent on  $F/H_s$  which provides an opportunity to plot wave reflection data along with wave transmission data.

A figure showing both wave reflection and transmission can be used to estimate the amount of wave energy dissipated by the structure. Generally, the more wave energy dissipated the more effectively the breakwater is functioning since both reflection and high levels of transmission are undesirable. The following equation represents the energy balance in the vicinity of the reef breakwater.

$$K_R^2 + K_R^2 + \text{dissipation} = 1.0 \quad \text{Eq. 2}$$

where  $K_R$  is the energy-weighted reflection coefficient given by Goda and Suzuki (1976) as

$$K_R = \sqrt{E_R/E_I}$$

where  $E_R$  and  $E_I$  are the reflected and incident wave energy, respectively, and "dissipation" is the fractional part of the wave energy remaining after the transmitted and reflected energy are subtracted from the total incident wave energy. Since the water depth is the same on both sides of the breakwater and the period of peak energy density is usually about the same on both sides of the breakwater, Equation 2 should be approximately correct. Figure 8 shows the results of using Equation 2 for the data collected during this study. In Figure 8 energy is plotted versus the relative freeboard with the transmitted energy to be read against the scale on the left side of the figure and the reflected energy to be read against the scale on the right side of the figure. Wave energy dissipated by the structure is the energy remaining in the central part of the figure after the reflected and transmitted energy are subtracted from the total incident wave energy. Figure 8 is schematic in nature because there are variables affecting reflection and transmission which cannot be taken into account by the figure, but it illustrates in a reasonably accurate way the most important function of the breakwater, i.e. to dissipate wave energy.

#### Conclusions

The severity of irregular wave attack is measured better by the parameter  $H_s^2 L_p$  than it is using  $H_s^3$ , at least for reef breakwaters.

If a stability number similar to Hudson's (1959) is defined using  $H_s^2 L_p$ , a variable is formed which is a very useful measure of the cause of damage to the breakwater for irregular wave conditions. This variable is referred to as the spectral stability number,  $N_s^*$ , and is defined by Equation 1. All of the test series used to evaluate stability indicate there is a threshold for stone movement around  $N_s^* = 7$ . When  $N_s^* \leq 6$  there is little or no stone movement and when  $N_s^* \geq 8$  there is noticeable stone movement and damage to the breakwater.

Wave transmission is caused by wave overtopping and transmission through the breakwater which for a given structure are primarily functions of  $(h_c - d_s)/H_s$  and  $H_s/L_p$ , respectively.

Wave reflection from the breakwater was measured during these tests. By subtracting the reflected and transmitted energy from the total incident energy an estimate of the wave energy dissipation by the breakwater as a function of  $(h_c - d_s)/H_s$  was obtained (see Figure 8).

## CHAPTER ONE HUNDRED SEVENTY NINE

### RIGID BODY MOTION OF A FLOATING BREAKWATER

Robert W. Miller<sup>1</sup> and Derald R. Christensen<sup>2</sup>

#### ABSTRACT

Predictions of the dynamic response of a floating breakwater obtained from a frequency domain analysis are compared with full-scale field measurements. Those parameters prominently affecting accurate response predictions are identified and discussed.

#### I Introduction

##### A) Overview

While concrete pontoon floating breakwaters have been successfully used under certain conditions to provide wave attenuation, their design has been primarily based upon empirical considerations. It has only been in the last decade that both the analytical tools and the field data have reached a state of refinement and sophistication which enables the reliable construction and calibration of breakwater response models.

This paper presents a simplified mathematical model of breakwater motion response. The model uses a frequency-domain approach to predict the harmonic responses of a breakwater to short-crested seas for five degrees-of-freedom of rigid-body motion. Rigid-body accelerations for three degrees of freedom as predicted by the model were compared with the corresponding full-scale field measurements. An attempt has been made to identify those parameters which most heavily affect the ability of the model to produce accurate results.

The funding for both the field-measurements and model development was provided by the United States Army Corps of Engineers as part of the West Point Prototype Breakwater Test Project. This project and its scope are more fully described in "Ship-Wake Attenuation Tests Of A Prototype Floating Breakwater" (1984) by Nece and Skjelbreia.

#### II Field Data

The project site and layout of the instruments of interest to this report are depicted in Figure 1. The two pontoons pictured were rigidly bolted together during the period under discussion. The project site was chosen to maximize exposure to wave attack. Measured

Coordinate Definitions

Global:  $x, y, z$   
 Equilibrium:  $x, y, z$   
 Body:  $x_b, y_b, z_b$

Relative Motion

$\eta_1$  = surge       $\eta_4$  = roll  
 $\eta_2$  = sway       $\eta_5$  = pitch  
 $\eta_3$  = heave       $\eta_6$  = yaw

quantities which were used in this study were incident wave height, breakwater accelerations, and wind direction. Timeseries of all measured quantities contained 2048 samples (4 samples per second for 8 1/2 minutes).

Incident wave measurements were made at a location 150 feet from the breakwater and located such that wave diffraction or reflection due to the breakwater itself was minimal. Timeseries of incident wave heights were converted into autospectral estimates by means of Fast Fourier Transform techniques. These estimates were used as inputs into the analytical model. Servo-accelerometers measuring sway, heave, and roll were located approximately at the center of mass of each pontoon. Timeseries of these quantities were also transformed and the resulting spectral estimates used for comparison with the model output.

Measurements of wind direction were used to estimate the principal angle of wave attack. This angle was assumed to be coincident with the mean wind direction. The extent to which this assumption is valid is very likely dependent upon the length of time the wind has been blowing in approximately the same direction.

### III Description of Model

The analytical techniques employed in breakwater motion prediction are essentially those of ship motion or seakeeping theory as described in St. Denis, 1953; Ochi, 1974; Salveson, 1970. Strip theory is used to estimate the hydrodynamic properties of the body and linear second order differential equations of motion are solved at each discrete frequency of interest. Motion response is therefore confined to the frequency of the excitation with harmonics and second-order effects neglected by the model.

This methodology has been applied to barges (Hutchison, 1977) and breakwaters (Hutchison, 1982; Adee, 1976), but, to the knowledge of the authors, never in a directional sea with the benefit of extensive full-scale data. As pointed out by Hutchison, (1976), barges (and therefore concrete pontoon breakwaters) should be excellent shapes for such an analysis. Many of the problems which have troubled ship motion predictions such as forward speed corrections, bilge keels etc. are absent in breakwaters. Discontinuities in the submerged perimeter are localized in the ends which should provide a suitable situation for strip theory. However, successful treatment of nonlinear phenomenon such as square-law damping or the load-displacement relationships of mooring lines may present additional problems.

#### B) Coordinates

The coordinate systems used in this analysis are depicted in Figures 2-4. Global coordinates X,Y,Z remain stationary with respect to a fixed point on the earth. The origin of the equilibrium coordinate system is located at the mean still water level in the vertical direction and at the mean position of the center of mass in the horizontal plane. In traditional seakeeping analysis, the

equilibrium frame frequently translates or rotates at a constant rate with respect to the global frame. For a moored breakwater, the distinction between the two frames would only become apparent as a result of long-term changes in mean position of the body due to tide, current, or wind. This distinction, therefore, serves no further purpose in the present analysis.

The body coordinate system ( $x_b, y_b, z_b$ ) remains fixed in the breakwater itself and is the frame of reference implicitly held by the accelerometers attached to the breakwater.

### C) Equations of Motion

The basic equation of motion for the six-degree-of-freedom rigid body response is:

$$\sum_{j=1}^6 (I_{ij} + A_{ij}(\omega)) \ddot{\eta}_j + B_{ij}(\omega) \dot{\eta}_j + (C_{ij} + K_{ij}) \eta_j = F_i e^{i\omega t};$$

for  $i = 1$  to  $6$  3.1

where

I	is the inertia coefficients matrix,
A	is the added mass coefficients matrix,
B	is the hydrodynamic damping coefficients matrix
C	is the hydrostatic restoration coefficients matrix,
K	is the linearized mooring force restoration matrix,
F	is a complex amplitude vector consisting of 6 wave excitation forces,
$\omega$	is the angular frequency of the incident wave,
$\eta_j$	is a complex vector describing the amplitude and phase of the motion in the $j$ th direction in the equilibrium frame,
$e^{i\omega t}$	is a unit vector rotating with angular frequency $\omega$ ,
	and the dots indicate differentiation with respect to time.

The use of the term "coefficients" is in contrast to "variable" and is not intended to imply non-dimensionality.

The values of the hydrodynamic mass and damping terms as well as the wave excitation forces were determined by the NSRDC Ship Motion and Sea Loads Computer Program (Meyers, 1975), which has exhibited success in the accurate prediction of the motion of destroyer hulls (Salveson, 1970).

Linearized mooring force restoration stiffnesses were obtained from Program BRKMOOR (Adee, 1976) which uses a finite-element approach to establish the equilibrium position of the breakwater. Restoring constants are then determined by perturbing the breakwater from its equilibrium position and calculating the change in mooring tension that

results.

D) Modeling of Square-Law Roll-Damping

The hydrodynamic damping terms presented in the previous section produce damping forces which are linearly proportional to the velocity of the motion. It has been found (Salveson, 1970; Ochi, 1976) in the case of ships that such neglect of higher order (e.g. damping proportional to the square or cube of the velocity) produces satisfactory response prediction except in the case of roll motion. If significant wave energy is present near the roll natural frequency, then the predicted roll response will be much too great. In the case of the West Point floating breakwater, it was also found necessary to include an accounting of square-law roll damping in the analytical model in order to avoid overprediction.

While space limitations preclude a detailed treatment in this report, a thorough development of the following equations may be found in (Schmitke, 1978) for the interested reader. Since a floating breakwater has no mean forward velocity, the only sources of square-law roll damping considered were those due to eddy-making and those due to hull-friction. The approach employed was to calculate the amount of work done by the aforementioned nonlinear damping forces during a complete roll cycle. An equivalent linear roll damping coefficient,  $B^*44$  was then defined which dissipates the same amount of energy during the cycle. Since the amplitude of the roll motion must be known to calculate the energy dissipation, the procedure involved is iterative, requiring repetitive solution of the equations of motion until the calculated and assumed roll amplitudes are in sufficiently close agreement.

Equation 3.1 described above is solved repeatedly at each discrete angle of wave attack and frequency of interest. If the excitation force used is that which would be caused by a wave of unit amplitude incident upon the structure, the solution results in a complex vector termed the frequency response operator or FRO. This quantity is also referred to in the literature as the transfer function. The FRO provides a linear transformation between the amplitude and phase of the wave and that of the motion response of the breakwater. For a particular frequency and angle of wave attack this relationship is:

$$S_{\eta}(\omega, \theta) = H_{\eta}(\omega, \theta) S_{\xi}(\omega, \theta) H_{\eta}^*(\omega, \theta) \quad 3.2$$

where  $S_{\eta}(\omega, \theta)$  is the response autospectrum for a given frequency and angle

$S_{\xi}(\omega, \theta)$  is the incident wave height autospectrum for that frequency and angle

and  $H_{\eta}(\omega, \theta)$  is the FRO for the frequency  $\omega$  and angle  $\theta$  and the superscript \* denotes the complex conjugate

Since a random short-crested sea-state may be represented at the summation of monochromatic waves of different frequencies and direction (St. Denis, 1953), it is possible, by means of linear superposition, to

predict the response to a variety of sea states given a complete set of appropriate FROs. This is done using the following form of equation 3.2 given in discrete form:

$$S_{\eta}(\omega) = \xi [H_{\eta}(\omega, \theta) S_{\xi}(\omega, \theta) H_{\eta}^*(\omega, \theta)] \quad 3.2a$$

Since directional spectra for the project site were not known, it was assumed that

$$\begin{aligned} S_{\xi}(\omega, \theta) &= S_{\xi}(\omega) \Psi(\theta) & 3.3 \\ \int_{-\pi}^{\pi} \Psi(\theta) d\theta &= 1.0 & 3.4 \end{aligned}$$

The form of  $\Psi(\theta)$  employed was

$$\begin{aligned} \Psi(\theta) &= K \cos^n(\theta - \theta_0), \quad -\pi/2 \leq \theta \leq \pi/2 & 3.5 \\ \Psi(\theta) &= 0 \quad \text{otherwise} \end{aligned}$$

where  $\Psi(\theta)$  is referred to as the spreading function  
 $\theta_0$  is the principal or mean angle of wave attack  
 and  $K$  is a constant chosen to satisfy equation 3.4

#### F) Operator Transformations

As mentioned previously, solution of the equations of motion in the form in which they have been presented results in displacement frequency response operators about the origin of the x y z coordinate frame. To enable direct comparison of predicted with measured results these operators must i) relate to accelerations, not displacements ii) be valid at the physical location of the instruments and iii) be written in the body rather than equilibrium coordinate system. These transformations will be briefly outlined.

##### i) Acceleration FRO

since  $H_{\eta}(\omega, \theta)$  is assumed to be of the form

$$H_{\eta}(\omega, \theta) = /H_{\eta}(\theta) / e^{i\omega t} \quad 3.6$$

it follows that

$$H_{\eta}''(\omega, \theta) = -\omega^2 /H_{\eta}(\theta) / e^{i\omega t} \quad 3.7$$

$H_{\eta}''(\omega, \theta)$  is referred to as the Acceleration FRO.

##### ii) Spatial Transformation

In general if  $\{A\}$  and  $\{R\}$  are translational and rotational vectors respectively then

$$\{A(x, y, z)\} = \{A_0(x_0, y_0, z_0)\} + \{R_0\} X \{r\} \quad 3.8$$

where the subscript '0' denotes the original (untransformed) location,  $r$  is the position vector from  $(x_0, y_0, z_0)$  to  $(x, y, z)$  and 'X'

denotes the vector cross-product.

iii) Transformation to Body Coordinates

Acceleration in the body coordinate system is defined by the following relation:

$$\{\ddot{A}_b\} = [T] \{A\} \quad 3.9$$

where the subscript 'b' denotes the body coordinate system and [T] is the transformation vector for a sequence of rotation of the Euler angles  $\eta_6, \eta_5, \eta_4$ . For small angles,

$$[T] = \begin{bmatrix} 1 & \eta_6 & \eta_5 \\ \eta_6 & 1 & \eta_4 \\ \eta_5 & \eta_4 & 1 \end{bmatrix}$$

It is to be noted that vectors of rotational quantities are invariant to the foregoing two transformations.

IV Analysis and Discussion

General Method

Many of the parameters required as input into the analytical model just described are not known with certainty. Since one of the purposes of this work was to establish estimates of these values which yielded acceptable response predictions, a consistent method was desired for varying the input parameters. Because much of the processing was done on relatively slow microcomputers, it was necessary to allow flexibility in the application of this method to insure that a reasonable amount of data was examined.

Unknown quantities which appeared to have the largest influence upon the shape and magnitude of the predicted results include the value of the exponent in the cosine-power spreading function, the mooring stiffnesses, the value of the effective bilge radius of the breakwater cross-section, and the reciprocal wave steepness,  $1/WS$  which is defined as the wave length divided by the wave height. The latter two quantities primarily influence roll while it is shown later that the mooring stiffness only significantly affect the sway response. The value of 'n' is therefore the only value of large uncertainty which has a substantial influence over the heave response.

Calibration of  $R_e$ , the bilge radius, was performed by selecting an input wave spectrum based upon measurement taken during a strong steady wind which blew for several hours directly to beam. A value of n was found which appeared to give good results for heave acceleration response. The values of  $R_e$  and the wave steepness were then varied until good results in roll were obtained. While the wave steepness could be expected to change with variations in the wave climate, the bilge radius is a property of the breakwater cross-section and should not change, although its proper value for a cross-section with flat

sides and sharp corners is not obvious. Therefore, after initial calibration, its value was not altered in subsequent runs.

#### Statistical Measures of Predictive Accuracy

It is appropriate to mention that the spectral density functions derived from measurements are estimates. The 95% confidence band ranges between 0.65 and 1.75 of the plotted ordinate. In most cases, differences between analytical model outputs and spectral estimates fall well within the 95% confidence band. For this reason, conclusions should be drawn based upon trends in the analysis which appear over several runs rather than upon one record only.

In order to present and discuss the results meaningfully for a large number of runs, it was desirable to develop some quantitative measures of closeness of the predicted and measured autospectral estimates. Two quantities were used for this purpose: the predicted variance normalized by the measured variance, henceforth referred to as the variance ratio, VR;

$$VR = \frac{\sigma^2 \text{ predicted}}{\sigma^2 \text{ measured}} \quad \text{where } \sigma^2 \text{ is the response variance} \quad 4.2$$

and the normalized squared error,  $E_n^2$  as defined by the following:

$$E_{n,4.2}^2 = \frac{\epsilon}{\omega} [ \{ (S_{\eta}^{\ddot{}}(\omega) \text{ measured} / \sigma^2 \text{ measured}) - (S_{\eta}^{\ddot{}} \text{ pred.}(\omega) / \sigma^2 \text{ pred.}) \}^2 ]$$

where the summation is over each of the discrete frequencies analyzed.

The variance ratio is intended as an indication of the closeness of the predicted to the measured response magnitudes with 1.0 expressing perfect agreement, numbers greater than 1.0 indicating over-prediction, and numbers less than 1.0 indicating underprediction of the acceleration response magnitude. This statistic, however, does not consider the closeness of the shapes of the curves under comparison, which may differ appreciably while enclosing the same area. When both spectra to be compared to one another are normalized so that each encloses a unit area, the extent to which  $E_n^2$  differs from zero is strictly a result of differences in general shape between the two curves. Identical curves, translated with respect to one another along the frequency axis, however, would have different values of  $E_n^2$ . The unidirectional wind duration, uwd, was defined as the number of hours that the mean wind direction remained within 20 degrees of the mean for the record under consideration.

#### Evaluation of Results

Table 1 summarizes the results obtained for all model runs made. Overall agreement is generally good except where the wind direction was not steady for several hours or when the significant wave height was low. No obvious overall trends were evident, except perhaps for the

Table 1 Summary Statistics for all Model Runs (1983)

sway and roll variance ratios to be low rather than high while in heave they tended to be high rather than low. It is encouraging that no degree of freedom experienced inordinately poorer results than the others suggesting a proper balance of terms in the equations of motion. Figure 5 through 7 show typical graphical results obtain for the three degrees of freedom examined.

#### Heave

In general, more consistent results over a wider range of conditions were obtained for heave than for the other two degrees of freedom, particularly on the records examined which had short wind duration and those with recent wind directional shifts. Even when magnitude discrepancies occurred in heave, the predicted maximum response was at the correct frequency. This is not surprising in view of the fewer uncertain input parameters in heave, the relatively small stiffness provided by mooring restraints in this mode, and the absence of significant higher order damping effects.

Heave acceleration variance ratios ranged approximately from 0.55 to 1.25. The mean variance ratio, averaged over all runs was 1.02 while the normalized squared error,  $E_n^2$  in heave averaged 22.8 over all runs. This value is lower than for the other two degrees of freedom, and if one outlier is discarded, it drops to 16.6.

#### Roll

The general level of agreement obtained in predicting roll motions is quite good. If only records with fairly constant wind directions for at least four hours are considered, then the ratio of predicted to measured variances ranges from 0.85 to 1.03 with a mean of 0.93. A glance at Table 1 shows that a slight tendency toward underprediction exists overall. If only records are considered during which the breakwater underwent wave attacks within ten degrees of beam, then the mean variance ratio improves to 0.98.

The estimated roll natural frequency is approximately 0.3 hertz which agrees well with both model output and measurements. In runs 6, 7, and 9 the measured peak roll response appears to be shifted slightly toward lower frequencies. Runs 6, 7, and 9 were all of short unidirectional wind duration and records 6 and 7 both exhibit low significant wave heights and relatively large angles of wave attack with respect to beam. Oblique wave attack angles tend to shift the forcing functions to lower frequencies but this should be correctly predicted by the analytical model. Since square law roll damping was only modeled in a narrow frequency range (0.289 to 0.32 hertz) it is difficult to explain a shift of the entire response by means of inaccurate estimation of square law damping parameters.

#### Sway

Sway is only marginally a harmonic response mode due to the absence of a hydrostatic restoring constant. The mooring restraints do provide

Figure 5. Measured and Predicted Heave Acceleration Autospectral Estimates for West Pontoon: Run 4.

Figure 6. Measured and Predicted Roll Acceleration Autospectral Estimates for West Pontoon: Run 4.

Figure 7. Measured and Predicted Sway Acceleration Autospectral Estimates for West Pontoon: Run 4.

a small restoring force but this does not produce much effect on the acceleration of the body except in the low frequency range. The sway response, however, is harmonic in character due to the periodic nature of the wave excitation force and coupling with other truly harmonic degrees of freedom such as roll. Prediction of sway motions can be difficult because other causes such as wind, tides, and currents can produce significant sways excitations. Long period or steady drift-type forces may have a large effect on mooring stiffnesses which could certainly influence the displacement response and can affect the acceleration response in the low frequency range (Oppenheim, 1980).

It is therefore quite encouraging that the sway variance ratios do not appear to be seriously worse than those of heave or roll. Predicted variance ratios ranged from about 0.5 to 1.1 with a mean of 0.75 over all runs indicating a tendency toward underestimation, particularly as the wind direction veered away from beam. If only records are considered with a mean wind direction within 25 degrees of beam and at least four hours unidirectional wind duration, then the mean variance ratio improves to 0.89. The sway mode was generally more sensitive to input parameters relating to the state of the wave field than either heave or, to a lesser extent, roll.

Although the variance ratios obtained for sway showed poorer agreement than in roll or heave, the mean sway normalized squared error,  $E_n^2$  averaged over all runs was 25.8. This is only slightly higher than for heave (24.5) and significantly lower than roll (40.5). Underestimation of response magnitudes accompanied by good agreement of shape could indicate an underestimation of the forcing functions in the frequency range of maximum wave energy. Such an underestimation would not severely affect the shape of the response curves if it were consistent over attack angles and frequencies of interest, but would cause a depression of the response magnitude.

While these results suggest that a reasonable estimate may be made of the time-varying transverse horizontal inertial force on the body, it should be remembered that some of the considerations mentioned previously would have to be adequately addressed to correctly estimate the lower-frequency forces on the body due to mooring, current etc.

#### Discussion of Important Parameters

##### Significant Wave Height

The quantitative measures of closeness, VR and  $E_n^2$  are displayed by significant wave height in figures 8 through 13. A distinction was made between the data records in which the unidirectional wind duration was four hours or greater than those in which it was not.

The accuracy of the heave response predictions shows no particular dependency on  $H_s$  while both roll and sway acceleration had noticeably poorer agreement at smaller significant wave heights. There may be a tendency for milder sea states to have a more complex directional character due to higher frequency components in the spectrum. Such

Figure 8. Variance Ratios in Heave Mode versus Significant Wave Height for All Runs.

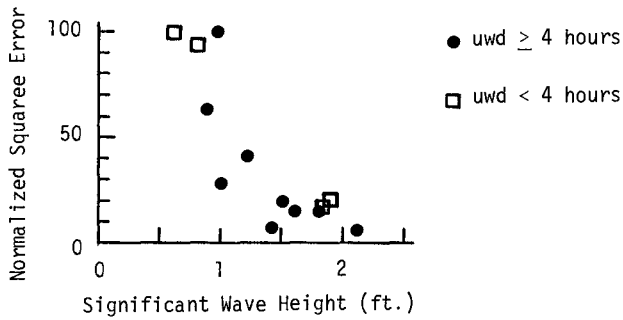

Figure 12. Normal Squared Error in Roll Mode versus Significant Wave Height for All Runs.

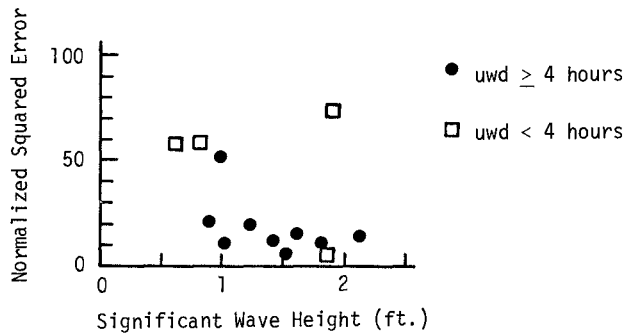

Figure 13. Normalized Squared Error in Sway Mode versus Significant Wave Height for All Runs.

seas would arise and decay faster and respond more quickly to wind shifts. This condition would affect roll and sway more than heave due to the greater sensitivity of these modes to the principal angle of attack. Some of the apparent decline in accuracy, however, is undoubtedly due to the fact that the records with the four smallest significant wave heights all have wind headings of about 25 degrees off beam, so it is unclear which parameter had the greatest effect in reducing agreement.

#### Wind Direction

Predictive accuracy, as quantified by VR and  $E_n^2$ , was less in the sway and roll modes as the wind direction moved off beam. The data examined only contained wind angles from 0 to 30 degrees off beam, but even this amount of obliqueness appeared to adversely influence the accuracy of the predictions. Since the purpose of a floating breakwater is to provide shelter from incident waves, the ability to accurately predict response to beam seas is of paramount importance, but a lessening of predictive accuracy with such small shifts of the wave attack off beam could indicate a problem with the model. Increments of 10 degrees were used to compute excitation forces, and smaller increments might have been more appropriate.

#### Directional Spreading Function

The directional characteristics of the limited-fetch short-crested seaway is a subject for which only a very limited amount of data is available. While various methods for modeling this phenomenon exist, the presence of only one node in this analysis made a long-crested superposition approach by far the most straightforward.

Opinions differ as to appropriate values of the exponent,  $n$ , in equation 3.5. Generally accepted values range between 2 and 10 for the Puget Sound Region (Langen, 1981).

Some of the values of  $n$  found to result in the best agreement between measured and predicted autospectra are higher than can be justified in the literature. Powers of 18 were used twice and on one occasion a unidirectional sea was found to provide the best agreement with the data. The best agreement with the response data was usually obtained when powers of 7 to 12 were employed. It is worthy of mention that values of  $n$  which gave the best agreement tended to increase with increasing unidirectional wind duration.

#### Mooring Forces

The procedure whereby mooring forces are modeled in a frequency domain analysis is a weakness of the method. It is well known that the forces exerted by a non-taut hanging cable are not a linear function of displacement. The question is not so much whether such forces respond linearly to displacements, but over what range of conditions is the error incurred by making such an assumption acceptable.

If second order forces are small and the mooring cables do not lose their hanging catenary shape, the magnitude of the mooring forces are small compared with other forces present such as inertial, wave excitation, and damping. Reasonable estimates of maximum dynamic transverse shear stresses in the major portions of the pontoons themselves could therefore be made despite the rough nature of the mooring force estimates provided by the method of analysis described in this report. Economical design of the mooring system itself, as well as local reinforcement detail in the pontoon near the points of attachment, however, might be better pursued with the aid of a supplementary low-frequency analysis such as described by Oppenheim (1981) or Standing (1981.)

### Conclusions

Reasonable agreement was found between acceleration response statistics obtained from a frequency domain model and those based upon measurements from a full-scale floating breakwater. Predicted response variances typically ranged from 0.5 to 1.3 of those obtained from field measurements. Within the limits of the data, predictive accuracy appeared to increase with increasing significant wave height.

The best results were obtained for the heave or vertical degree of freedom. Response magnitudes tended to be underpredicted in many cases in the sway or transverse mode and (to a lesser extent) in the roll of longitudinal rotation modes.

Predictive accuracy appears to be high enough to produce reasonable estimates of the internal forces in the breakwater itself. Caution should be exercised, however, in the sway mode in the low frequency range where slowly varying forces unaccountable by this model may be significant. While the method might therefore be appropriate as a tool in floating breakwater design, other more accurate (and costly) methods may be more appropriate in the prediction of mooring forces.

## CHAPTER ONE HUNDRED EIGHTY

### ASPHALT STABILIZATION OF RUBBLE SLOPES

E.J.Schmeltz, M.ASCE<sup>1</sup>, M.J.McCarthy, A.M.ASCE<sup>2</sup>, N.Lopez<sup>3</sup>

#### ABSTRACT

During the spring of 1982 a new container terminal was under construction at the Port of Haina, Dominican Republic. Changes in design conditions due to damages to the protective breakwaters at the port entrance required modifications to the design of slope protection under the pier. The stabilization of the rubble slope was, in fact, a stop gap measure in that repairs would be instituted on the breakwaters in the near future.

Due to a lack of suitable stone, the location of structural elements already in place and severe time constraints, an asphalt coating over relatively light weight rubble was selected to armor the slopes under the pier. The asphalt coating was prepared in a locally available batching plant and placed on-site using a crane equipped with a 4 cubic yard bucket. As a result of the use of the asphalt coating, construction delays were minimized and adequate slope protection was provided for the container pier without extensive design modifications.

The purpose of this paper is to discuss the advantages and disadvantages of the use of asphalt in the construction of shore protection facilities in the context of the site specific application at the Port of Haina.

#### INTRODUCTION

The Dominican Republic occupies the eastern portion of the island of Hispaniola in the Caribbean Sea. The Port of Haina is located on the southern coast of the Dominican Republic at the mouth of the Haina River, as shown in Figure 1. The Port is approximately 12 kilometers west of Santo Domingo, the capital city of the Dominican Republic.

The Port of Haina is a fully developed port complex with a wide spectrum of cargo handling capabilities. The complex includes a major sugar processing and loading facility, fertilizer and ferronickel loading wharf, Sealand container offloading facility, diesel fuel unloading area, container wharf under construction as described herein and a proposed coal offloading facility for a planned generating station.

3. Department of Public Works, Santo Domingo, Dominican Republic

Figure 1  
Location Plan

The harbor is protected against incoming waves by two breakwaters as shown in Figure 2. During the fall of 1979, the site was affected by two hurricanes, Frederick and David, which resulted in considerable damage to the breakwaters. 110 meters of the east breakwater and 65 meters of the west breakwater were essentially destroyed. Since that time, progressive deterioration of the structures has resulted in increased exposure of the south end of the container terminal which was under construction.

The design of the container terminal pier included a pile supported relieving platform constructed over a rock armored dike which surrounded fill material used for the container storage area, as shown in Figure 3. The armor layer consisted of stone with a median weight of 300 kilograms and an average specific gravity of 2.6. Based on Hudson's equation (Reference 1), using a design slope of 1:1.75, this stone was found to be stable for wave heights of up to 1.25 meters. At the time of this study, in April 1983, exposure of the site had increased to a point where the original one meter design wave height could be as high as 2.6 meters. Since this wave height was in excess of the stable wave height for the proposed stone armor layer, a study was initiated to determine alternative methods of temporary reinforcement.

Figure 2  
Site Plan

Figure 3  
Typical Section of Container Berth As Designed

It should be noted that at the time of this effort, a substantial amount of construction was completed on the container berth. Piles and pile caps were in place and the majority of the deck was completed. Figure 4 provides an aerial view of the facility around this time. Only the southern end of the structure was of concern since the deterioration of the breakwaters resulted in a high exposure level to southerly waves at this "head" section. A total of approximately 150 linear meters of the structure were involved.

Figure 4  
Container Facility Under Construction  
(View from the north)

Modifications to the original design of the section were not instituted earlier in the project because reconstruction of the breakwaters was anticipated. This reconstruction, which would have reduced the wave action to an acceptable level, was delayed for a variety of reasons beyond the scope of this discussion. Suffice it to say that the net result was a severe time constraint on design and construction of any possible alternative. Due to the inherent difficulties associated with the repair of the rubble dike under the relieving platform, completion of the head section was not judged to be prudent as discussed in the following paragraphs.

## ALTERNATIVES CONSIDERED

Various slope protection alternatives were considered in light of the expected 2.6 meter design waves, including:

- increase the primary armor stone size
- addition of artificial armor units to the slope
- placement of concrete filled mats
- construction of a wave skirt on the fender panels
- placement of asphalt grout or stone asphalt on the slope protection stone

The following paragraphs discuss these alternatives and present the rationale for the final selection of asphalt grout. The basic criteria utilized to assess the effectiveness of the alternatives were:

- constructibility
- cost
- engineering adequacy.

**Do Nothing:** The do nothing alternative implied construction of the dike slope protection as originally designed and acceptance of damages during periods with wave heights exceeding 1.25 meters at the structure. This alternative was deemed unacceptable due to the unknown period of time until the breakwaters were repaired and the consequences of a slope failure. In addition, after construction of the deck was completed, a major reconstruction effort would be required to make repairs to the rubble slope.

**Increased Stone Sizes:** Utilizing Hudson's equation for quarystone randomly placed in two layers, the required median stone size was found to be on the order of 2.3 metric tons for the design wave of 2.6 meters. Increasing the size of the rock used as the primary armor layer in this area to 2.3 metric tons was not an acceptable option since rock of the size and quality necessary is not locally available. As a consequence, material would have to be brought in from distant sources at high cost and would result in unacceptable delays in the completion of the facility. Discussions with the contractor on site confirmed this finding.

Additionally, the increased thickness of the required two layers and underlayers would necessitate removal of materials already placed in order to avoid intrusion on the berth area, and placement between piles would be, at best, difficult. As a result of the high anticipated costs, delayed construction and the encroachment problem, this alternative was ruled out.

**Concrete Filled Mats:** Concrete filled mats have been used in some shore protection applications and in numerous hydraulic structures. They are not, however, generally used in structures subject to large wave heights. Several questions were raised about the application of concrete filled mats to the project at the Port of Haina, including:

- the effects of the expected increase in wave runup due to the relatively smooth slopes
- the possibility of cracking the relatively thin mats during design wave events and disintegration of the slope
- lack of availability on short notice of the mats and equipment necessary for placement

Further, placement between existing piles and caps would be difficult. Consequently, this alternative was dropped from further consideration.

**Wave Skirt:** An indirect method of increasing the stability of the rock dike involved reducing the wave heights affecting the slope. Due to the relatively low deck elevation, a wave skirt placed below the fender face would function on the principle of stopping the wave energy in the upper part of the water column from reaching the rock dike under the structure. Energy during storm conditions would be decreased on the dike via reflection from the skirt and overtopping of the deck. Although technically feasible, this type of structure has not apparently been employed for this purpose. Additionally, structural connections would be difficult and might cause excessive loadings on the deck structure. It was felt that this option would require a significant amount of engineering, and further that construction might also be somewhat complicated causing further delays in the project. This option was not considered appropriate for further consideration.

**Asphalt Grout Or Stone Asphalt:** The final alternative consisted of the placement of an asphaltic compound in the interstices of the armor stone; or mixing armor stone with an asphaltic compound and placement on the structure. The asphalt then acts as a binder increasing the effective "weight" of the armor layer and therefore its stability. This type of approach has been employed successfully in both Holland (References 2 through 7) and the United States (References 2 , 5) on similar projects in the past. The material can be placed either as a grout or as a stone asphalt layer.

The use of asphalt had several distinct advantages for stabilization of rubble slopes, particularly from the standpoint of this project. First, the basic materials were available locally. Secondly, construction could be accomplished with standard construction equipment, e.g. cranes and buckets already at the site. Third, the basic cross section of the dike would be essentially unchanged so encroachment in the berth area would not pose a problem. Construction could presumably be accomplished before placement of the deck sections without significant delays in the contractor's work. The end result then would be stabilization of the structure at a relatively low cost to the owner.

Discussions with a specialty contractor involved in this type of construction revealed that the mixes utilized, although slightly different from routine pavement asphalt, could be manufactured in any asphalt plant in good working order. A limiting wave height on these structures of around 4.0 meters is normally assumed. This level was certainly within those anticipated at this location, and this alternative was selected for further analysis.

## HISTORICAL USES OF ASPHALT

A review of available literature (References 2 through 7) was conducted to develop a basis for the design of the asphalt grout for use at the Port of Haina. Based on this review, it was found that asphalt had been used in marine structures since the late 1920's, but it was not until the early 1930's that systematic applications began (Reference 3).

Some of the earliest uses of asphalt involved the construction or rehabilitation of groins, primarily along the coast of Holland. These structures utilized asphalt both as a grout over stones and in sand mixtures which could stand alone. Typical

mixes used in the asphalt grout included 70-72 percent sand, 10 percent filler and 18-20 percent asphalt (Reference 3).

Later uses of asphalt in marine structures along the coast of Holland included an asphalt and sand mixture for the Harlingen Harbor Breakwater. This structure, constructed in 1948, was subject to severe overtopping due to its low crest elevation. A second structure, the breakwater at Scheveningen, was grouted using an asphalt mix during this same year. Eight ton blocks on the Scheveningen Breakwater were successfully grouted during a repair project (Reference 3).

A number of additional examples of the use of asphalt and asphalt grout were found throughout the European Coastline (Reference 6). These included the asphalt grouting of 4 ton blocks forming the foundation of a vertical wall breakwater located in Marseilles, France. The blocks were located at a depth of approximately 12 meters (40 feet). A mix consisting of 60 percent fine sand, 20 percent limestone filler and 20 percent bitumen, 40-50 penetration was used. The asphalt was lowered in a bucket which was opened just above the rock surface. The initial temperature of the asphalt was 180 degrees C. Grouting of large concrete blocks was also accomplished at the River Adour northern breakwater also located in France. At this structure, 15 ton concrete blocks were grouted. Another example was the Pointe de Grave breakwater in France, where three to five ton stones were grouted using a mix consisting of 12 percent filler, 34 percent beach sand up to 6.0 mm, 34 percent dune sand up to 0.05 mm and 13 percent bitumen, 60-70 penetration.

At Porto Levante on the Po Delta in Italy, an asphalt grout consisting of 70 percent fine sea sand, 10 percent filler and 20 percent bitumen, 40-50 penetration, was placed on a breakwater at temperatures of 180 to 200 degrees C. Finally, a breakwater at Hirtshals Harbor in Denmark was grouted from 4.0 meters below the zero datum to 1.5 meters above. The mix used on this structure consisted of 72 percent sand, 10 percent limestone filler and 18 percent bitumen, 80-100 penetration.

In the United States, one of the earliest and most successful uses of asphalt grouting was during the rehabilitation of the Galveston, Texas jetty in 1935-1936 (References 2, 5). The armor on the south jetty at Galveston consisted of 6 to 10 ton stone, and the jetty cross section had deteriorated and become porous. After several mixes were tried, the jetty was grouted with a mix consisting of 70 percent Galveston beach sand, 12 percent Mississippi River loess (filler) and 18 percent asphalt cement, 30-40 penetration. The asphalt was placed at 204 degrees C (400 degrees F.).

## SELECTED DESIGN

The evaluation of the available literature on the use of asphalt in shore protection structures made one major factor eminently clear: very little published information exists on the design of such structures. The choice, however, was still desirable given the historical successes of the basic method, the rapid construction necessitated by project requirements, locally available materials and relatively low cost.

The basic design for this project consisted of placement of asphalt as a grout to fill the interstices of the existing primary armor. From the top of structure to a level 4.0 meters below the datum, the asphalt would be placed as a continuous cover. The lower level was selected since it is approximately 1.5 times the design wave height below the surface. Below - 4.0 meters, the material would be "pattern"

grouted to result in approximately 50% coverage. The purpose of the pattern grouting was to permit relief of pore pressures in the rock-fill. Penetration of the asphalt to a depth of 0.3 meters was judged to be adequate to bind the primary armor. The design section is shown in Figure 5.

Figure 5  
Revised Cross Section With Asphalt Grout

Critical to the successful placement of the asphalt was the determination of a reasonable mix for the material. Some valuable information was obtained from work by Mulders (Reference 8), however due to the lack of available detailed design information, selection of the mix was an iterative process.

The initial mix selected for use is shown in Table 1 along with several iterations leading to the final mix. The initial proportions were selected based on information in the literature from past uses. Prior to placement, however, the mix was modified because of the highly fluid nature of the original mix. It appeared that penetration into the rock might be too great therefore increasing the volume of asphalt necessary to complete the work.

The second mix, with 25% one half inch aggregate, retarded flow of the material in the interstitial spaces to a greater extent than desirable. The final mix shown in Table 1 resulted in a reasonable level of flow and good filling of the voids in the armor layer.

TABLE 1  
ASPHALT MIXES

	INITIAL MIX	2nd TRIAL	FINAL MIX
ASPHALT	15	12	12
SAND	70	52	58
FILLER	15	11	15
GRAVEL	—	25	15

- NOTES: 1. Asphalt penetration 60-70  
2. Asphalt mixes and temperatures were controlled to some extent by the capabilities of the existing plants

Placement temperatures ranged from a low of 99° C (210 °F) to a high of 215° C (410°F). Both the low and high ends of the temperature range were troublesome since low temperatures resulted in poor flow; high temperatures in a spongy mass in the water and excess steam formation. The majority of the material was placed at approximately 165° C (330° F) which resulted in good flow and reasonable under water placement. The asphalt was supplied from a plant approximately 10 kilometers from the site. Delivered to the site in 15 cubic meter batches by truck, the material was dumped into a rock bin (steel holding box) as shown in Figure 6.

The material was placed on the structure with a 4 cubic yard clamshell as shown in Figure 7. When placed above water workmen utilized shovels and rakes to move the asphalt as required, although on the slopes it flowed well. Below water, the clamshell was opened near the water surface and material was dropped in mass to the rock surface. The pattern was obtained by locating the bucket relative to the pile caps and horizontal members already in place.

Two hundred and sixty cubic meters of asphalt were delivered and placed on the structure. With an adequate supply, approximately 60 cubic meters were placed in a working day. A total of 1150 square meters of rock protection surface between elevation +1.3 and -4.0 meters were completely grouted; 1450 square meters from -4.0 to -10.8 meters were pattern grouted with approximately 50% coverage achieved. Figures 8 and 9 provide views of the above water section and near the water line, respectively.

Unfortunately, photographs below water are not available, however sections under-water were inspected by divers who reported both adequate penetration, coverage and a durable mass.

## SUMMARY AND CONCLUSIONS

Initial placement of the asphalt began on 26 April 1983 and was completed on 11 May 1983. As a result of the timely manner in which the redesign and construction of the armor layer was conducted, the contractor was able to maintain his work schedule and ultimately completed overall construction ahead of schedule.

Based on the experience gained on this project in the use of asphalt grout at the Port of Haina, the major advantages of the material included:

- the use of locally available materials
- a flexible finished structure
- minimized armor stone size
- relative ease of construction

The disadvantages of the asphalt grout included a lack of available design criteria, potentially increased runup and pore pressure buildup. One further aspect of the use of asphalt which may be of great concern in some areas is the environmental impact of placement in the water. Although no information could be found in the literature, several on site observations are worthy of note.

Placement of the material resulted in a substantial cloud of steam which was anticipated because of the high temperatures. Shortly after placement, a film of oil was visible on the water surface which dissipated relatively quickly. Fish normally seen around the structure returned within an hour or two of placement and seemed to be feeding on the asphalt surface. It is difficult to draw any firm conclusions from these observations, and environmental impacts of this method of slope stabilization should be considered where appropriate.

In conclusion, the placement of asphalt at the Port of Haina project has manifested itself as a technically and economically feasible method of increasing the stability of the stone armor layer to withstand wave attack. Inspection of the armor layer after slightly more than one year indicated that the asphalt grouted slope was stable and performing satisfactorily. Several periods of severe wave conditions occurred during this time, although it is unlikely that the design conditions were experienced.

## ACKNOWLEDGMENTS

The authors would like to express their appreciation to the Department of Public Works Executive Unit of the Port of Haina, Dominican Republic for their support in this project. We would also like to thank the on-site personnel of the contractor, Conde-Meisner, for their assistance and valuable suggestions during the construction of this work.

## CHAPTER ONE HUNDRED EIGHTY ONE

### REEF RUNWAY WAVE PROTECTIVE STRUCTURE, HONOLULU INTERNATIONAL AIRPORT, OAHU, HAWAII, STABILITY PERFORMANCE EVALUATION

Robert S. Chun\*, Edward K. Noda\*\*, Elaine E. Tamaye\*\*\*

#### Abstract

An inspection survey of the Reef Runway Wave Protective Structure at the Honolulu International Airport was accomplished in 1982 to assess the performance of the dolos and rock armored structure to date. The inspection showed the structure to be performing adequately considering that the design wave conditions were experienced.

#### Introduction

In 1972, the State of Hawaii began construction of an offshore runway at the Honolulu International Airport. This project, called the Reef Runway, was undertaken to alleviate aircraft noise and safety concerns over metropolitan Honolulu, provide more flexibility for aircraft takeoff and landings, and increase airfield capacity. The project encompasses dredged fill on 1,240 acres of offshore coral reef with a 16,100 foot-long wave protective structure, a 12,000 foot-long by 200 foot-wide runway, 1,350 feet of apron and clear zone bordering the runway, and taxiways and service roads which connect the runway to shore. The protective structure is of rubblemound construction and armored with 4 and 6 ton dolos concrete units along the deepwater sections. Figure 1 shows a General Plan view of the Reef Runway at the Honolulu International Airport. The project was the subject of environmental controversy, and was held up for approximately one year due to various court actions. Finally, the U.S. Supreme Court allowed the project to proceed after declining to hear appeals from environmental groups on the adequacy of the Environmental Impact Statement. In 1975, the Reef Runway protective structure was completed, and in 1977, the Reef Runway was dedicated and operational. The Reef Runway was named one of the Ten Outstanding Engineering achievements of 1977 by the National Society of Professional Engineers, and one of Outstanding Projects of 1977 by the American Society of Civil Engineers. The Federal Aviation Administration also elected the Reef Runway an Environmental Excellence Award.

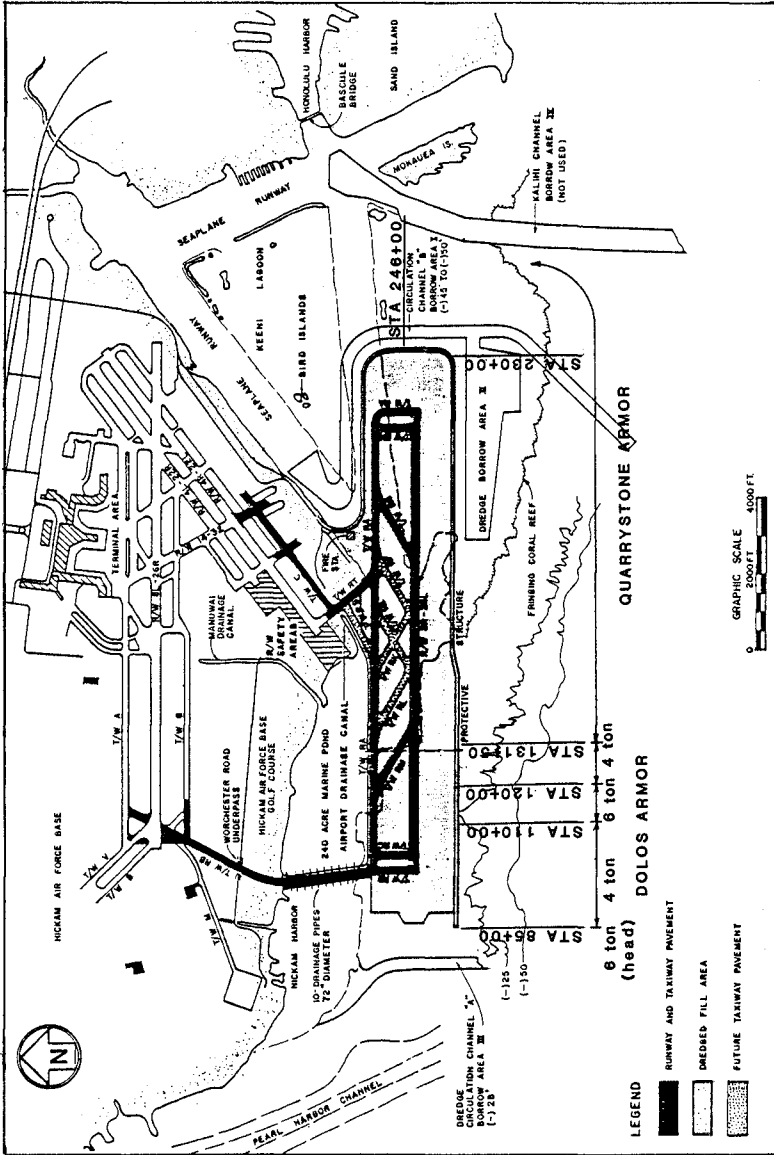

FIG. 1 GENERAL PLAN OF THE REEF RUNWAY AT HONOLULU INTERNATIONAL AIRPORT

In mid 1982, a detailed inspection of the Reef Runway protective structure was initiated by Edward K. Noda & Associates for the Reef Runway Managing Consultant at the request of the State of Hawaii. The survey was undertaken as a precautionary measure to assess the performance of the structure to date. In view of the controversy which has developed as to the viability of existing stability criteria for concrete armor units in rubblemound structures, stemming from the breakwater failure at Port Sines on the Atlantic coast of Portugal in 1978, the results of the survey were expected to serve as verification of the design criteria as well as to provide a baseline data set for future inspection and maintenance surveys. The inspection revealed no significant damages, and the protective structure was found to be performing as designed. The evaluation of the stability performance of the wave protective structure was two-fold. First, the physical condition of the structure was assessed to determine the percent damage to the armor units. Second, the wave conditions to which the structure has been subjected to date were evaluated to determine whether the design wave criteria were experienced. This paper summarizes the results of the inspection and stability performance evaluation of the Reef Runway protective structure.

### **Reef Runway Protective Structure Design**

The basic design criteria for the Reef Runway wave protective structure was developed by Tetra Tech of Pasadena, California, in 1972 for the Reef Runway Managing Consultant, the Ralph M. Parsons Company.

#### Oceanographic Design Criteria

Tetra Tech recommended a design stillwater elevation of +3.0 feet above Mean Sea Level (MSL) based on evaluation of the following factors:

- \*Set-up due to wind stress components
- \*Water level increase due to atmospheric pressure reduction associated with storm centers
- \*Wave set-up due to breaking waves
- \*Astronomical tide

It is interesting to note that the highest tide recorded to 1981 was 2.39 feet above MSL. The Mean Higher High Water (MHHW) level is 1.08 feet above MSL.

The design wave criteria was based on the maximum possible wave height,  $H_{max}$ , that could theoretically exist at the toe of the structure. For the deepwater dolos-armored section, the maximum wave height was given by:

$$H_{max} = (0.73 + 5.6 S)D \quad (1)$$

where:

S = the ocean bottom slope seaward of the toe  
 D = the total water depth at the toe

Thus, the design wave height varied as a function of the local bottom slope and water depth along the toe of the structure, and the highest computed  $H_{max}$  was 25.2 feet at Station 116+00. To determine the maximum wave height for the shallow water section fronted by fringing reef, S, in the above equation, was set to zero.

Tetra Tech also reviewed and evaluated previously measured and hindcasted storm events to verify that waves as large as  $H_{max}$  could physically be generated in the region, and concluded that 25 foot waves could be expected to occur once in ten years.

#### Armor Stability Criteria

Primary armor design for stability was evaluated using the Hudson equation:

$$W = \frac{w_r H^3}{K_D (S_r - 1)^3 \cot \phi} \quad (2)$$

where:

W = weight of individual armor units (lbs)  
 $w_r$  = unit weight of the armor unit (lbs/ft<sup>3</sup>)  
 H = design wave height at the structure (ft)  
 $S_r$  = specific gravity of the armor unit relative to seawater = ( $w_r/w_w$ )  
 $w_w$  = unit weight of seawater = 64 lbs/ft<sup>3</sup>  
 $\phi$  = angle of the structure face measured from horizontal  
 $K_D$  = stability coefficient (varies primarily as a function of the shape of the armor units, roughness of the armor units, and degree of interlocking obtained in placement)

The layer thickness of the primary armor units is given by:

$$t = n k_t (W/w_r)^{1/3} \quad (3)$$

where:

t = thickness of primary armor layer (ft)  
 n = the number of units comprising the armor layer thickness  
 $k_t$  = layer coefficient (varies as a function of the type of armor unit)

Finally, the density of units in the primary armor layer is given by:

$$N = n k_e (1 - P/100) (w_r/W)^{2/3} \quad (4)$$

where:

$N$  = the number of armor units per square feet of surface area

$P$  = the average porosity of the primary armor layer (%)

For the exposed deepwater section of the wave protective structure, various primary cover layer designs were assessed and designs completed for five alternative protection schemes. In the competitive bidding process, Hawaiian Dredging and Construction Company was the low bidder, and chose a design consisting of 4 and 6 ton dolos concrete armor units. It has been recognized that rubblemound structures can accept some level of damage and still remain stable. In view of this, and the acceptability of a degree of risk associated with the recurrences of significant storm events, the stability coefficient  $K_D$  was selected to yield an acceptable damage level of 4% and 2% for the 6 and 4 ton dolos trunk sections, respectively. Tests conducted by the USAE Waterways Experiment Station (Davidson & Markle, 1976) indicate that stability is affected only when random breakage exceeds 15% and cluster breakage exceeds 3 units. Table 1 summarizes the stability criteria adopted for the final design of the dolos covered sections.

Table 1. Stability Criteria for Dolos Armor  
(Sta 85+00 to 131+50)

	Breakwater Head	Trunk Sections	
	Sta 85-86	Sta 110-120	All other
Nominal weight of units	6 ton	6 ton	4 ton
Unit weight, $w_r$	147 lb/ft <sup>3</sup>	147 lb/ft <sup>3</sup>	147 lb/ft <sup>3</sup>
Design wave height, $H_{max}$	13.8 ft	25.2 ft	<18 ft*
Cot structure slope	2.25	1.5	1.5
Stability coefficient, $K_D$	6.8	64	32
Allowable damage	0%	4%	2%
Layer thickness, $t$	11.3 ft	11.3 ft	9.9 ft
Number of units thick, $n$	2	2	2
Layer coefficient, $k_e$	1.3	1.3	1.3
Density of armor units, $N$	.055/ft <sup>2</sup>	.055/ft <sup>2</sup>	.075/ft <sup>2</sup>
Porosity of armor layer, $P$	60%	60%	60%
Crest elevation above MSL	16 ft	20 ft	16-20 ft

\*While maximum wave heights were typically less than 18 feet, within a short reach maximum wave heights to 19.3 feet can be expected.

The armor layer extends down to the toe of the structure, where the maximum water depth is 27 feet below MSL at

Station 116+00. Figure 2 depicts typical cross sections for the protective structure. Figure 3 depicts the relative dolos dimensions and Table 2 lists the design dimensions for the 4 and 6 ton units, based on a unit weight of 147 lb/ft<sup>3</sup> for concrete.

Table 2. Design Dimensions for Individual Dolos Units

	Nominal Weight of Units	
	4 ton	6 ton
Volume = 0.16 C <sup>3</sup>	54.9 ft <sup>3</sup>	81.9 ft <sup>3</sup>
Overall dimension, C	7 ft	8 ft
Waist dimension, B = 0.32 C	2' 1''	2' 5''
Fluke dimension, A = 0.20 C	1' 5''	1' 7''
Fillet dimension, D = 0.057 C	5''	6''

#### Inspection and Damage Assessment

The inspection survey was performed during the period July 1982 through January 1983, and involved a visual, photographic and underwater reconnaissance of the entire Reef Runway protective structure. Although a major portion of the structure is fronted by shallow reef which facilitated the inspection, approximately 7,000 lineal feet is in deeper water sometimes exceeding 25 feet. Inspection of the underwater regions of the deepwater sections were hampered by poor visibility water conditions, resulting in three months of delay from September to December 1982 before conditions improved sufficiently to enable completion of the survey.

A total of 301 dolos armor units were damaged out of a total of 18,009 units originally placed, yielding an overall damage of 1.67% to the primary armor cover. An estimated 71 out of the 4,317 6-ton units placed and 230 out of 13,692 4-ton units placed were broken or displaced, yielding damages of 1.64% for the 6-ton and 1.68% for the 4-ton units. Table 3 provides a detailed damage assessment. The number of dolos placed per various reaches are estimated based on the total number of dolos known to have been placed and the percent of square footage covered within the given reach, assuming reasonably uniform density of placement for given dolos size.

Since the water depth at the toe varies considerably over short distances, the maximum design wave height and actual  $K_D$  vary within given reaches of a specified nominal dolos size. For the head section to Sta 86+00, the design  $K_D$  of 6.8 is slightly conservative over the actual  $K_D$  of 6.6; however, the actual damage is greater than the no-damage design criteria. For Sta 110+00 to 120+00 which also utilized 6 ton dolos, the design  $K_D$  of 6.4 is

6 ton Total		57	14	71					4,317		1.64%
4 ton Total		171	59	230					13,692		1.68%

similarly conservative over the actual range of  $K_D$ ; and in this reach the actual damage overall is well within the 4% design damage criteria. For the reaches with 4 ton dolos, the actual  $K_D$  sometimes exceeded the design  $K_D$  of 32; however, the actual damage overall was within the 2% design damage criteria.

For those reaches with 4 ton dolos, the actual  $K_D$  is as high as 40 in one area. However, test results (Zwamborn, 1980) indicate that for the design packing density, the  $K_D$  of 40 is still within the envelope of data for 2% damage. For a relative packing density of 0.075 units/ft<sup>2</sup>  $\times V^{-2/3} = 1.08$  for the 4 ton dolos, the test data indicate a minimum  $K_D$  of 16, mean  $K_D$  of 25.5, and maximum  $K_D$  of 41. The data indicates an optimum double-layer packing density of 0.9 to 1.0  $V^{-2/3}$ , with corresponding mean  $K_D$  of 32 to 28. The design packing densities of 0.055 units/ft<sup>2</sup>  $= 1.04 V^{-2/3}$  for the 6 ton dolos and 0.075 units/ft<sup>2</sup>  $= 1.08 V^{-2/3}$  for the 4 ton dolos would indicate less stability than optimum. In fact, Darling (1976) indicates that the required packing densities resulted in a three-layer cover, with a large percentage of the total 1.4% breakage during placing operations resulting from trying to fit the top layer of dolos.

In general, the damaged units were found scattered randomly throughout the structure, and the primary armor cover appeared to retain its original integrity. The broken dolos were intermixed with the unbroken units, and a few units were displaced from the structure. However, it was difficult to determine where the displaced units came from. Figures 4 and 5 show typical damages to the dolos.

During the period when the survey was delayed due to poor visibility water conditions, Hurricane Iwa struck the Hawaiian Islands. Both above water and underwater inspections indicated no evident additional damage as a result of the storm. Apparently, most of the damage to the dolos occurred prior to the wave attack from Hurricane Iwa.

### Wave Evaluation

In order to provide a credible assessment of the performance of the Reef Runway wave protective structure, an evaluation of the types and magnitudes of the largest waves to have attacked the structure following completion of construction in the fall of 1975 to the completion of the inspection survey in January 1983 was accomplished. Figure 6 depicts the general location of the project site within the Hawaiian Islands, and Figure 7 shows the site in relation to adjacent facilities along the south coast of Oahu. Three distinct wave types have attacked the structure during this period:

**FIG.4 TYPICAL DOLOS BREAKAGE (6-TON UNITS AT STA 119+25)**

**FIG.5 TYPICAL DOLOS BREAKAGE (4-TON UNITS AT STA 128+50)**

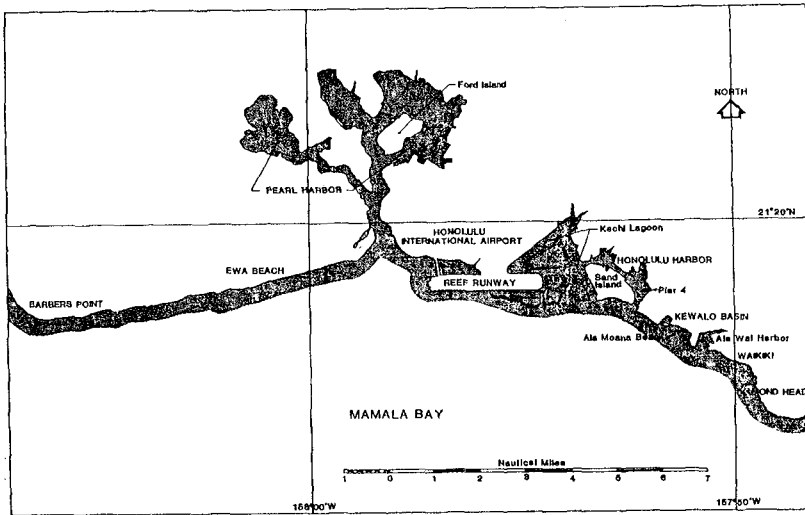

FIG.7 VICINITY MAP OF PROJECT SITE ON SOUTH SHORE OF OAHU

- \*Locally generated "Kona" storm waves
- \*Southerly swell generated by Southern Hemisphere storms
- \*Hurricane Iwa waves

#### Kona Storm waves and Southerly swell

Nov 24, 1975 storm: South and southeast winds generated estimated maximum surf of about 6 feet at Ala Moana. Although winds were not particularly strong at the Honolulu International Airport, estimated 25 to 30 mph winds generated waves large enough to wash a 118-foot fishing vessel aground at the entrance to Honolulu Harbor. A 41-foot Coast Guard rescue boat trying to help the fishing vessel ran aground nearby.

Feb 5-6, 1976 storm: This was a major storm which generated large southwest waves offshore the Reef Runway for about two days. Peak gust at Lihue Airport, Kauai, was 46 mph from the southwest. The average wind speed at Honolulu International Airport was 17.5 mph, with the fastest mile of 26 mph. Although the wind data at Honolulu Airport did not indicate exceptionally strong southwest winds, the waters southwest of the Reef Runway did experience strong Kona winds. Estimated surf was about 6 feet at Ala Moana.

Jan 8-10, 1980 storm: Up to that time, this storm caused the greatest monetary loss ever recorded in the State. Heavy rains, Kona winds, high waves, and two tornadoes accompanied the passage of two successive cold fronts. Wind gusts of 100 mph were recorded on Mt. Haleakala, Maui. Honolulu International Airport recorded gusts of 52 mph. The long duration of strong winds generated high waves which battered the south and west shores of all the islands. Estimated maximum surf was about 6 feet at Ala Moana, with surf to 15 feet reported in other areas. Bretschneider (1984) reports hindcast deepwater significant wave heights of 29 feet with significant period of 13.5 seconds.

Southerly swell: During the summer months, large swell from Southern Hemisphere storms frequently cause high surf conditions along the southern shores of the Hawaiian Islands. The following are occurrences of estimated high surf conditions:

- \*July 27-28, 1976: 8 feet
- \*July 29, 1976 : 7 to 9 feet, max 10-12 feet
- \*May 25, 1977 : 8 feet

#### Hurricane Iwa waves

On November 23, 1982, the most destructive storm in Hawaiian history, Hurricane Iwa, struck the Hawaiian

Islands. Hardest hit were the islands of Niihau, Kauai, and Oahu, where storm surge and waves inundated the southern coast of Kauai and the leeward and portions of the southeast coast of Oahu. Statewide storm-related damages exceeded \$310 million.

A hindcast analysis of the expected hurricane waves at the Reef Runway was accomplished utilizing the significant wave approach by Bretschneider (1970, 1972a, 1972b, 1976). The hurricane parameters used in the hindcast are as follows:

Central Pressure,  $P_c$  = 28.6 inches Hg (measured)  
Pressure depression,  $\Delta P$  = 1.32 inches Hg  
Radius of maximum wind,  $R$  = 20 nautical miles  
(estimated)  
Latitude,  $\phi$  = 22 degrees  
Average forward speed,  $V_F$  = 20 knots

Figure 8 shows the track of Hurricane Iwa, where the storm center passed within 110 to 120 nautical miles of the Reef Runway at its closest point of approach. The hindcast indicated maximum significant wave heights of 39.8 feet with wave period of 13.3 seconds, and expected significant wave heights offshore the Reef Runway of about 31 feet associated with sustained winds of 35 knots. Bretschneider (1984) suggests that the radius of maximum wind was probably as large as 50 nautical miles, with hindcast maximum significant wave heights of 41 to 43 feet and periods of 14.2 to 14.7 seconds. Based on his hindcast analysis, expected significant wave heights offshore the site were on the order of 35 feet.

No instrument measurements are available to confirm the hindcast wave heights. However, the US Navy reported that its guided missile destroyer USS Goldsborough was hit by a "30 foot" wave about 2 miles offshore the entrance to Pearl Harbor at 4:30 pm, on 23 November 1982, which killed a crew member on the forward deck and washed a second crew member overboard. While direct wave measurements are not available, wind speed measurements at the Honolulu International Airport confirm the hindcast 35 knot sustained wind speeds.

Measurements of the rise in water level elevation due to the passage of Hurricane Iwa are also available. Data from gage measurements in Kewalo Basin, approximately 3 miles from the Reef Runway, indicates that the difference between measured water levels and predicted tide levels was a maximum of 41 inches (3.4 feet) due to the storm. The design water level for the Reef Runway wave protective structure was 3.0 feet above MSL.

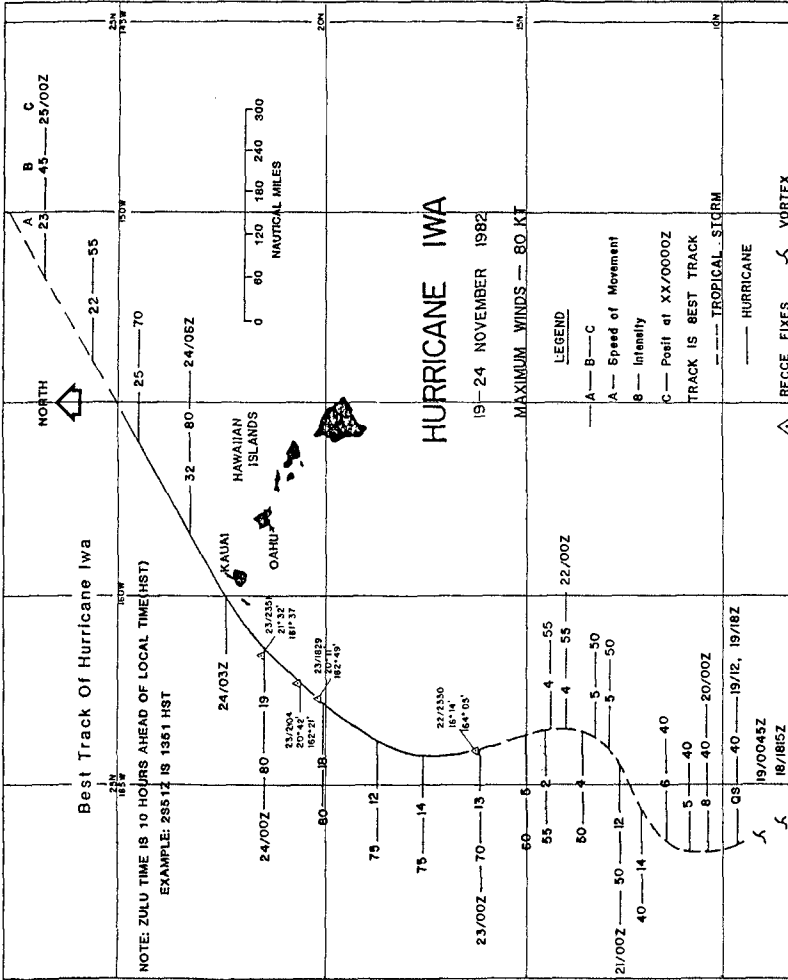

FIG. 8 TRACK OF HURRICANE IWA, NOVEMBER 1982

### Summary and Conclusions

A visual and photographic inspection of the wave protective structure for the Reef Runway, Honolulu International Airport, has been performed to assess the present physical state of the structure. The performance of the protective structure was assessed by reviewing the basic design criteria and design practices utilized for construction, and evaluation of the maximum waves which have attacked the structure.

A review of the design procedure for the wave protective structure performed in 1972 indicates that the design practice implemented for the Reef Runway protective structure is still consistent with present day techniques. Hindcasts of the wind-generated waves from Hurricane Iwa indicates that significant wave heights of up to 35 feet would be expected offshore the Reef Runway located approximately 110-120 nautical miles from the hurricane center. Comparison of these hurricane hindcast waves with the design maximum breaking waves along the exposed deepwater sections of the protective structure shows that Hurricane Iwa most probably generated maximum design wave conditions for the structure.

The design water level for the wave protective structure was 3.0 feet above MSL, and water level measurements at Kewalo Basin during Hurricane Iwa indicate a maximum measured rise of about 36 inches above MSL. When analysis is performed subtracting expected tidal fluctuations from measured water level, a maximum water level rise due only to Hurricane Iwa is calculated at 41 inches.

In general, the Reef Runway wave protective structure is in very good condition. The exposed deepwater section protected by 4 and 6 ton dolos concrete armor units has undergone the most severe wave attack and is the only major region where wave damage is evident. Underwater and above water visual inspection surveys were performed both prior to and after wave attack from Hurricane Iwa. These inspections indicate that no visually discernable damage to the dolos armored sections occurred due to Hurricane Iwa wave attack.

A numerical count of broken dolos by station locations was performed and the results show that 301 units were found broken, comprising about 71 each 6-ton units and 230 each 4-ton units. At the completion of construction in late 1975, 4,317 each 6-ton and 13,692 each 4-ton dolos units were installed yielding a percent damage of 1.64% for the 6-ton and 1.68% for the 4-ton units, with an overall damage percentage of 1.67% for all dolos installed.

The design criteria utilized a 2% damage level for the 4-ton dolos, a no-damage criteria for the 6-ton dolos at the

breakwater head, and a 4% damage level for the 6-ton dolos along the trunk section. Comparison of this design damage level versus the existing damage indicates that the structure is performing adequately following the design wave attack.

Underwater visual inspections show that the dolos protected deepwater sections remain integrally intact, and that broken dolos parts generally still remain imbedded in the structure cover layer. At Station 88+00 is the only area which was noted to have a small void region on the slope face with some broken dolos sighted 10-15 away from the structure toe.

Historically, scale-model experiments of dolos protected rubblemound structures indicate that the stability characteristics increase with small levels of damage. The reason is attributed to the condition that under wave attack, usually by relatively smaller waves than the design waves, units which were placed in an unstable position would either move and break or would be displaced off the structure, thereby resulting in a small percent damage. Those units not broken or displaced would nest and stabilize, thereby developing greater interlocking stability with a consequent capability to remain stable under the design wave attack. This condition is believed to have occurred for those sections of the Reef Runway protective structure utilizing dolos armor units. Following construction, wave attack from Kona storm waves and Southern Hemisphere generated swell, generally smaller than the design wave heights, served to increase stability by increasing the as-constructed interlocking capability of the random placed dolos units, with the inherent consequences of suffering a small level of damage. It is believed that the overall 1.67% dolos damage level noted during this survey occurred prior to wave attack from Hurricane Iwa. With an increased stability capability, the dolos armored structure was able to withstand wave attack from Hurricane Iwa with no increase in damage as compared to prior visual surveys.

## CHAPTER ONE HUNDRED EIGHTY TWO

### MARINE ROUGHENED CYLINDER WAVE FORCE COEFFICIENTS

John H. Nath, Fellow, ASCE\*

#### ABSTRACT

Steel cylinders were submerged on a platform in the South Pass region of the Gulf of Mexico for one year to accumulate biofouling for later laboratory testing to determine wave force transfer coefficients. They were positioned at -55, -140, and -190 feet below the still water surface. Laboratory tests comprised steady tow up to Reynolds number of  $7 \times 10^5$ , and periodic waves up to Reynolds number of  $1.6 \times 10^5$  and Keulegan-Carpenter number up to 25. The force transfer coefficients for the -55 cylinder were about equal to those for a sand roughened cylinder with relative cylinder roughness,  $\epsilon/D$ , of .03, where  $\epsilon$  is the height of the equivalent sand roughness size and  $D$  is the smooth cylinder diameter. The drag coefficient for very high Keulegan-Carpenter number, or steady tow, is about 1.0 if the effective cylinder diameter is taken into account, for the rougher cylinders.

#### INTRODUCTION

Most information about force transfer coefficients for cylinders in waves or in steady flow is based on smooth cylinders or cylinders uniformly roughened with glued-on sand. Biofouling, however, can be very irregular, have a much thicker accumulation, and protrude much further into the flow field from the cylinder surface than any sand coated cylinder ever tested.

In order to gather wave force information on cylinders roughened with real marine growths, three 8-5/8 inch diameter steel cylinders were positioned at -55, -140, and -190 feet below the still water surface at a platform positioned in the Gulf of Mexico near the mouth of the Mississippi River at the coordinates 89° 23' East and 28° 50' North. Three cylinders were positioned at each level so that they could be tested after 1, 2, and 3 years' of growth. This paper reports on the results obtained from the 1-year old cylinders.

---

\*Professor, Ocean Engineering Program, Dept. of Civil Engineering, Oregon State University, Corvallis, OR 97331.

## EQUIPMENT

The cylinders were constructed from 8-5/8 inch diameter steel pipes, 2 feet long. They were split longitudinally so they could be attached to a test beam for the laboratory tests in steady flow and waves (4,5,6), using countersunk, flush-headed machine screws. The test beam was about 10 feet long, mounted horizontally between 2 vertically suspended low-drag support members that were positioned close to the wave flume walls. The support members hung from a tow carriage. The Oregon State University (OSU) Wave Research Laboratory (WRL), the tow carriage, and the test beam are further described in (4,5,6).

The half cylinders were mounted to strain gage force dynamometers so that the total horizontal and vertical forces could be measured on the 2-foot long test section. They were carefully calibrated in all directions before and after each test with the test beam submerged. The calibration constants were linear and varied by less than 2% between the calibrations prior to the tests and those after the tests. The water surface fluctuation was measured directly above the beam. A current meter was positioned 2 cylinder diameters above the cylinder surface, but the measurements therefrom have not been used in the analysis because of the modification to the rotating flow from the presence of the cylinder.

Two dummy cylinders (each were split) were attached to the test beam to provide a continuous cylindrical surface. They were roughened artificially with glued-on sand, barnacles, corks and fuzzy material to provide a roughness about equal to that of the center test surface. The position of the test section relative to the water surface and wave flume floor is shown in Fig. 1. There was a space of less than 1/8 inch between the test section and the dummy section that did not influence the results, as proved in other testing (6).

Data were recorded digitally on a PDP-11 minicomputer. For reliability there were 2 channels for horizontal force, 2 for vertical force, 1 each for the horizontal and vertical current measurement and 1 for the water surface profile.

Photographs of the cylinders were made by personnel at the ocean platform prior to mounting them in shipping containers of sea water. They were shipped quickly by air freight to OSU, where they arrived with almost all of the organisms still alive. At OSU they were photographed, aerated, and removed from their mounting core prior to placement under water (fresh water) on the test beam. A photograph of the cylinder from -55 feet is shown in Fig. 2.

Fig. 1 Horizontal cylinder location in the wave flume.

Fig. 2 Cylinder from -55 feet, South Pass platform.

Most of the organisms stayed alive until placed in fresh water, whereupon the cylinders were immediately tested in steady state towing. They soon died in the fresh water, but they generally remained attached to the cylinder for the remainder of the testing. The test results showed that the death of the organisms caused no appreciable change in the force transfer coefficients.

#### TESTS

There have been earlier tests on smooth and sand roughened cylinders at OSU (5), some results of which will be repeated here for comparison with the marine roughened cylinders. The South Pass cylinders were first towed at speeds from 1 to 10 fps. Then the ends of the carriage test beam were guyed to the WRL walls for tests in periodic and random waves. (The tests in random waves are not reported on herein.) After the wave tests, the cylinders were again towed to see if there was a detectable change in the steady state drag coefficients due to a loss of biofouling from the fresh water and the vigorous action from waves. The cylinders were then dried and the soft (now crisp) organisms were brushed off. The cylinders were tested again in steady tow to see if there was a detectable change in the steady state drag coefficients due to the loss of the soft, flexible organisms. These 3 conditions of the organisms during the tests are termed "live", "after" and "dried" for this report.

The various cylinder roughnesses are given abbreviated designations in this report for ease in referring to them. These designations are summarized in Table 1.

Table 1. Cylinder designators.

Designation	Explanation
SMC	Smooth cylinder
SRC.02	Sand roughened cylinder with $\epsilon/D = .023$
SRC.03	Sand roughened cylinder with $\epsilon/D = .032$
SP1-55	South Pass cylinder, 1 year old, -55 ft,
SP1-140	South Pass cylinder, 1 year old, -140 ft,
SP1-190	South Pass cylinder, 1 year old, -190 ft,

## ANALYSIS

The steady state tow drag coefficient,  $C_{ds}$ , was calculated from

$$C_{ds} = \frac{F}{\frac{1}{2} DL\rho U^2 \delta} \quad (1)$$

where  $F$  is the average force on the test section,  $D$  is the smooth cylinder diameter,  $L$  is the test section length (2 feet),  $\rho$  is the water mass density,  $U$  is the steady tow speed (the carriage was timed over a measured distance), and  $\delta$  is the effective diameter coefficient ( $\delta \geq 1$ ). For very rough and irregular growths, and for significant, flexible biofouling, like heavy accumulations of kelp, it is sometimes difficult to define an effective diameter that can be universally accepted. Therefore, for much of the analysis for this work the coefficient,  $\delta$  was set equal to 1. Much of the data presented here were so calculated, but for some data  $\delta$  was computed from the circumferential measurements of the cylinders.

The force transfer coefficients were computed with least squares methods using a vector form of the Morison equation that is reviewed in more detail in (5,11). During a test, measurements were made for 4 wave periods, from which 3 complete crest-to-crest waves could be defined. Coefficients were calculated for each of the 3 waves and averaged. These average values are reported herein.

The Morison equation for the force per unit of length,  $\vec{F}$ , on a horizontal cylinder is then written as

$$\vec{F} = \frac{1}{2} C_d \delta D \rho \vec{q} |\vec{q}| + C_m \pi \frac{(\delta D)^2}{4} \rho \vec{\dot{q}} \quad (2)$$

where  $\vec{q}$  is the velocity vector and  $\vec{\dot{q}}$  is the acceleration vector. In the least squares analysis,  $C_d$  and  $C_m$  are assumed to be constant with time. If  $\delta$  is assumed to be 1, the increase in diameter due to biofouling is included in  $C_d$  and  $C_m$ . Where  $C_d$  and  $C_m$  are so computed, they can be corrected with appropriate manipulations with the  $\delta$  desired.

It is well known with respect to wave forces on cylinders that are small in diameter compared to the wave lengths that the averaged force transfer coefficients computed from least squares techniques are functions of the Keulegan-Carpenter number and the Reynolds number. They are defined, respectively, as

$$K = \frac{u_{\mu} T}{D\delta} \quad (3)$$

$$\text{and } R = \frac{u_{\mu} D\delta}{\nu} \quad (4)$$

where  $u_{\mu}$  is the maximum horizontal water speed at the cylinder $_{\mu}$  position,  $T$  is the wave period, and  $\nu$  is the kinematic viscosity.

More recently the particle orbit shape has been found to influence force transfer coefficients for vertical smooth cylinders. The orbit shape is usually quantified with the ratio

$$\Omega = \frac{u_{\mu}}{w_{\mu}} \quad (5)$$

where  $w_{\mu}$  is the maximum vertical velocity.

For a horizontal cylinder with the axis parallel to the wave crests the vortex shedding characteristics are influenced considerably by  $\Omega$ . Without the cylinder present the velocity vector rotates, at the position of the center of the cylinder, in a clockwise direction if the progressing wave is travelling from left to right. The vector changes in magnitude with time if the wave is not a linear, deep water wave. Otherwise, the magnitude remains constant and  $\Omega = 1$ .

For this work  $.4 < \Omega < 1.0$ , as detailed in ref. (5). However, the wave conditions were such that  $K$  and  $R$  could not be varied through the full range for each value of  $\Omega$ . Therefore, the lower values of  $\Omega$  are usually associated with the higher values of  $K$  and  $R$ .

Another way to consider the wave forces is through the maximum force coefficient,  $C_{\mu}$ , and the phase shift,  $\hat{\phi}$ . The first is defined as

$$C_{\mu} = \frac{F_{\mu}}{\frac{1}{2} DL\rho u_{\mu}^2 \delta} \quad (6)$$

and the phase shift is (please refer to Fig. 3)

$$\hat{\phi} = \frac{\phi_f}{\phi_a} \quad (7)$$

Fig. 3 The velocity vector,  $\vec{q}$ , drag force,  $\vec{F}_d$ , acceleration vector,  $\dot{\vec{q}}$ , inertia force,  $\vec{F}_m$ , "lift" force,  $\vec{F}_l$ , and the phase angles for a wave with the crest parallel to the axis of a submerged horizontal cylinder.

It can be shown (7) that as  $K$  gets very large,  $C_u \rightarrow C_{ds}$  in Eq. (6). Where  $\phi_f$  is the instantaneous phase shift (in space) between the velocity vector and the total force vector, and  $\phi_a$  is the phase shift between the velocity vector and the acceleration vector (which =  $90^\circ$  only for deep water small amplitude waves). Note that the "lift" force,  $\vec{F}_l$ , which is orthogonal to the velocity vector, is not included in Eq. (2), so the somewhat random influence from vortex shedding will appear as scatter in both  $C_d$  and  $C_m$ . However, Eq. (6) should not be influenced quite so much from such effects, so one would expect less scatter in the results for  $C_u$ . On the other hand,  $\hat{\phi}$  should be very sensitive to vortex shedding and one would expect considerable scatter in experimental values for  $\hat{\phi}$ .

There is as much information about the wave force in Eqs. (6) and (7) as in Eq. (2) if one considers  $\hat{\phi}$  to be a function of time. Actually,  $\hat{\phi}$  is evaluated when  $F$  is  $F_u$ . An advantage for Eqs. (6) and (7) is that they conceivably can be based on measurements only. There is no theory involved if  $\dot{\vec{q}}$  is measured in some way. In this paper  $\dot{\vec{q}}$  is based on the water surface profile and Dean's stream function wave theory. For vertical cylinders it is easier to base Eq. (6) on pure measurements. It also turned out that there was much less scatter in the  $C_u$  plots than for  $C_d$  and  $C_m$ . In this case there is more scatter in  $\hat{\phi}$  because of its sensitivity to vortex shedding. Another advantage to Eq. (6) is that  $u$  need not be measured right at the cylinder, but can be any distance away, at the same depth. But measurement of the water surface profile,  $\eta(t)$ , or theory, must be used to be able to evaluate  $\hat{\phi}$ . Herein the stream function theory is used.

Another advantage in considering Eq. (7) is in the

clear realization of whether the wave force is dominated by water acceleration or velocity effects. If  $\phi$  is 1.0, clearly the force is acceleration dependent. If it is 0.0 it is velocity (drag) dependent. Further discussion on this point can be seen in (7).

#### RESULTS

The SRC.03 could not be towed, so no  $C_{ds}$  values are presented for it. The results of circumferential measurement of the various cylinders are given in Table 2.

Table 2. Effective diameter coefficients for the various cylinders from circumferential measurements and sand sizes.

Designation	$\epsilon/D$	$\delta$
SMC	0	1.00
SRC.02	.023	1.046
SRC.03	.032	1.064
SP1-55	.037	1.074
SP1-140	small	1.00
SP1-190	0	1.00

The SP1-190 cylinder was so smooth that it was not tested. The SP1-140 only had a few very small anemones and a few other crusty organisms. The SP1-55 cylinder had a large number of acorn barnacles attached and one tintinnabulum balanus with average heights of 0.34 inches and a standard deviation of .23 inches. However, the average of several circumferential measurements yielded the results given in Table 2.

Steady tow test results for the SMC, SRC.02, SP1-140 and SP1-55 cylinders are shown in Figs. 4 through 7. There is some obvious scatter in Fig. 5, the true source of which is unknown. Some of it is probably due to small amplitude vibrations of the tow carriage, modifying the wake separation points to some degree. Figure 5 also indicates that the  $C_{ds}$  values may be influenced about 2.9% or less because of limited water space above the cylinder (surface effects). This magnitude of difference was later verified with additional testing. Figure 6 shows that the SP1-140 cylinder had a roughness between that of the SMC and the SRC.02. Figure 7 shows that the roughness of the SP1-55 cylinder did not change appreciably between the live, after, and dried conditions. In addition, its roughness appeared to be about equal to that for the SRC.02.

Fig. 4 Steady state tow  $C_{dS}$  for SMC.

Fig. 5 Steady state tow  $C_{dS}$  for SRC.02.

Fig. 6 Steady state tow  $C_{ds}$  for SPL-140.

Fig. 7 Steady state tow  $C_{ds}$  for SPL-55.

Figure 8 shows the results for  $C_d$  from periodic waves for the SMC, SRC.02 and SRC.03 cylinders for  $15 < K < 25$ . All results fall below those for the results from (8) for oscillatory flow ( $\Omega = 0$ ), for  $K = 20$ . The results for the SMC have a lot of scatter around  $R = 1.8 \times 10^5$ , the true source of which is not yet known.

Fig. 8 Drag coefficients in steady tow and wavs for:  
 - - - - - Sarpkaya (8),  $\epsilon/D = .02$ ,  $K = 20$ ; - - - - - Sarpkaya  
 (8), smooth,  $K = 20$ ; — — — — —  $C_{ds}$ , SRC.02; ······  $C_{ds}$ ,  
 smooth;  $\Delta$  SRC.03,  $15 < K < 25$ ;  $\square$  SRC.02,  $15 < K < 25$ ;  $\circ$   
 smooth,  $15 < K < 25$ .

Figure 9 shows the same results for the SP1-140 and SP1-55 cylinders. Figures 10 and 11 are the counterparts of 9 and 10, only for  $C_m$ . These results show very approximately that the SP1-55 cylinder has an equivalent  $\epsilon/D \approx .03$  and the SP1-140 is somewhere between the smooth condition and  $\epsilon/D \approx .02$ .

The data for the SRC.02, SRC.03, and the SP1-55 were also processed according to Eqs. 6 and 7 using the  $\delta$  values indicated in Table 2. The results are plotted in Figs. 12 and 13. Figure 12 fairly clearly shows how  $C_\mu$  increases with roughness in the range of  $4 < K < 15$ . In addition, the  $C_{ds}$  values for SP1-55 and the SRC.02 are plotted at high  $K$  in Fig. 12. In the range  $15 < K < 25$  the differences in  $C_\mu$  are less clear. The figure indicates that the experimental  $C_\mu$  values may well merge with the  $C_{ds}$  values at high  $K$  and that  $C_{ds} \approx 1.0$  for both  $\epsilon/D \approx .03$  and  $\epsilon/D \approx .02$  providing the proper  $\delta$  is used. This figure may have considerable importance because it implies the  $C_\mu$  values for the region of  $25 < K < 200$ , which includes the full scale values of  $K$  for ocean platforms.

Fig. 9 Drag coefficients in steady tow and waves for: ——— Sarpkaya (8),  $\epsilon/D = .02$ ,  $K = 20$ ; - - - Sarpkaya (8), smooth,  $K = 20$ ; - · -  $C_{ds}$ , SRC.02; —△—  $C_{ds}$ , SP1-55; —□—  $C_{ds}$ , SP1-140; △ SP1-55,  $15 < K < 25$ ; □ SP1-140,  $15 < K < 25$ .

Fig. 10 Inertia coefficients for: ——— Sarpkaya (8),  $\epsilon/D = .02$ ,  $K = 20$ ; - - - Sarpkaya (8), smooth,  $K = 20$ ;  $\Delta$  SRC.03,  $15 < K < 25$ ;  $\square$  SRC.02;  $15 < K < 25$ ;  $\circ$  smooth,  $15 < K < 25$ .

Fig. 11 Inertia coefficients in waves for: ——— Sarpkaya (8),  $\epsilon/D = .02$ ,  $K = 20$ ; - - - Sarpkaya (8), smooth,  $K = 20$ ;  $\Delta$  SP1-55,  $15 < K < 25$ ;  $\square$  SP1-140,  $15 < K < 25$ .

Fig. 12 Maximum force coefficient, horizontal cylinder in waves for: ● SPI-55; △ SRC.03; □ SRC.02; —□  $C_{ds}'$ , SRC.02; ●—  $C_{ds}'$ , SPI-55.

Fig. 13 Phase shift, horizontal cylinder in waves for: ● SPI-55; △ SRC.02; □ SRC.02.

The phase shift results are plotted in Fig. 13. Not surprisingly, scatter is more prevalent in the range  $6 < K < 20$ . It is clear that as  $K$  increases, the maximum force on the cylinder becomes more velocity (drag) dependent. What is not clear, surprisingly, is that the rougher cylinders are not more drag dependent in the range  $10 < K < 20$ . More data are required to determine relationships on a statistical basis for so much scatter. However, at  $K = 25$  the few data available indicate that the SP1-55 is more drag dominated than the SRC.02; furthermore,  $\phi$  is about the same for SP1-55 and the SRC.03. Perhaps the differences in roughness in this study do not have an important influence on the value of  $\phi$  because as  $K$  increases due to an increase in  $\epsilon/D$ ,  $\phi$  tends to increase because  $K$  becomes smaller ( $K = u_T/D\delta$ ); but, as the surface roughness increases, the flow should become more drag dependent, tending to make  $\phi$  decrease. These opposing trends tend to compensate.

#### CONCLUSIONS

Within the range of tests herein the soft fuzzy growths that covered the barnacle-type growths neither appreciably increased nor decreased the drag or inertia coefficients.

The effective roughness of the SP1-55 cylinder was about  $\epsilon/D \approx .03$  and the effective diameter coefficient was about  $\delta \approx 1.07$ .

For drag dominated flow and high  $K$  values, the maximum force coefficient should approach the value of  $C_{ds}$ . Furthermore, within these tests,  $C_{ds} \approx 1.0$  for all rough cylinders providing appropriate values of  $\delta$  are used, which can be determined from circumferential measurements.

#### ACKNOWLEDGEMENTS

The placement and retrieval of the cylinder was done by Chevron USA. Support for the tests and the transfer coefficient analysis was from the American Petroleum Institute. The  $C_u$  and  $\phi$  analysis support was provided partially by the OSU Sea Grant Program, Grant No. NA 81AA-D-00086, and partially by the National Science Foundation, Grant No. CEE-8310732. The author gratefully acknowledges the support from each of these organizations.

## CHAPTER ONE HUNDRED EIGHTY THREE

### TIME AND FREQUENCY LOADING ANALYSIS OF SUBMARINE PIPELINES

H. C. Alexander, P. L. Allen and J. L. Warner\*

#### ABSTRACT

Fatigue damage to marine pipelines subjected to wave forces is evaluated using time-domain and frequency-domain methods. Spectral techniques are applied to North Sea, Gulf of Mexico and offshore Atlantic Canada wave conditions. Time-domain analysis is applied to wave conditions in the Canadian North Atlantic Ocean.

The frequency-domain analysis is performed using spectral and probabilistic techniques suggested by L. Borgman (2). The pipeline dynamic characteristics are described by classical analytical descriptions. The time-domain analysis computes time histories of wave force loading on the submerged pipeline from actual wave records. The traditional Morison wave force equation is used to obtain the time history of the loading on the pipeline. Empirically determined wave spectra are shown not to produce as good a correlation with the deterministic results as the actual wave spectra.

Free spanning submarine pipelines subjected to cyclic surface wave loading accumulate strength reductions leading to failure from material fatigue. The Palmgren-Miner rule for the linear accumulation of fatigue damage is applied to evaluate the time to failure. The American Welding Society X-X stress accumulation curve is applied.

The results of the deterministic analysis were compared with those of the more efficient spectral analysis. It is shown that comparable results can be obtained from the spectral analysis provided the actual spectra of the water surface elevation is employed in the spectral analysis.

## NOMENCLATURE

$A_n$	amplitude of nth wave component
$a_i$	water particle acceleration in the ith time interval
$C_D$	drag force coefficient
$C_M$	inertia Force Coefficient
$C_1, C_2$	Morison wave force equation coefficients
$D_o$	outer diameter of steel linepipe
$D_{Con}$	outer diameter of concrete coating
$d$	water depth
$F$	wave force per unit length of pipe
$F_i$	wave force in the ith time interval
$F_M$	magnitude of the Mth Fourier force coefficient
$f$	wave frequency
$g$	gravitational acceleration
$H_s$	significant wave height
$L$	length of unsupported span of pipeline
$S_{nn}(f)$	spectral density of water surface elevation
$t_{Con}$	thickness of concrete jacket
$t_w$	wall thickness of steel pipeline
$U_{19.5}$	wind velocity at a height of 19.5 meters
$u_i$	water particle velocity at the ith time interval
$Z$	distance above the sea bed
$\alpha, \beta$	empirically derived constants that appear in the P-M formulation of the wave spectrum
$\eta$	water surface elevation
$\sigma_i$	bending stress in the ith time interval
$\rho_{con}$	density of concrete
$\rho_{fl}$	density of fluid
$\phi_n$	nth Fourier cosine series phase angle

## 1.0 INTRODUCTION

Extensive production of petroleum and natural gas now takes place in coastal waters with the move being to exploration, and in the near future, production in deep ocean waters. Studies show that the most efficient way of transporting the hydrocarbon products onshore is by submarine pipelines, where possible. Some structures offshore have been at a particular site for over 20 years. Engineers have recognized that these structures have undergone long-term cyclic loading and have developed methods of evaluating the accumulated damage caused by the cyclic wave loading. The analyses have been predominantly probabilistic in nature, and have been extended by Alexander (1) to evaluate the fatigue life of a free span of submarine pipeline.

An increasing amount of actual water surface elevation records for particular sites are becoming available. More accurate probabilistic analyses are now possible and as well deterministic (time-domain) analyses which involve no assumptions regarding wave spectra or the linearization of the drag term in the Morison (6) wave force equation, are also available.

The line pipe, Figure 1, used in the offshore industry is of circular cross-section, seamless, fabricated from steel and is generally jacketed in concrete to provide protection and insure negative buoyancy. Moybo (5) has shown that the concrete jacket does not appreciably alter the flexible stiffness of the submerged steel pipe. The scour of sediment and sand from around a pipeline laid on the ocean bottom, due to the action of both surface waves and bottom currents, can cause submarine pipelines to be exposed and suspended as shown in Figure 2. Herbich (3) and Strating (9) have documented many cases of submarine pipelines becoming free spanning. These free-spans of submarine pipelines have the potential to fail from fatigue due to surface-wave induced, generally low level, cyclic loads. Vortex induced loading also caused by surface-waves and bottom currents, which may also contribute to the fatigue damage, are not included in this analysis.

In order for a structure to suffer from fatigue damage it must undergo a displacement process. Anytime a structure is displaced in a cyclic manner the possibility of the displacement of the structure being dynamically amplified exists. This analysis involved an evaluation of the range of frequencies over which the hydrodynamic loading might dynamically amplify the response of the free-spanning submarine pipeline structure. The range of natural frequency for a typical pipe span length is shown in Figure 3. Where dynamic amplification was significantly small a more efficient quasi-static method was used to evaluate pipeline response.

Airy wave theory was employed to describe surface-wave induced water particle kinematics. This theory allowed water particle velocity and acceleration to be determined at the elevation of the free-spanning pipeline. An Airy wave description is shown in Figure 4.

## 2.0 WAVE RECORD AND FORCE ANALYSIS

An ocean engineer faced with the task of analysing the wave climate at a particular location can proceed in two different directions. The traditional method developed by Pierson and Moskowitz (8) was to relate wave amplitude as a function of wave frequency and with further analysis the spectral energy density  $S_{\eta}(f)$  as a function of the wave frequency as given by Equation 1<sup>n</sup>

$$S_{\eta}(f) = \alpha \frac{g^2}{[(2\pi)^4 f^5]} \exp [-\beta (g/2\pi U_{19.5} f)^4] \quad (1)$$

where  $\alpha$  and  $\beta$  are empirically derived coefficients, respectively equal to 0.0081 and 0.74 and valid for fully arisen sea conditions. Significant wave height,  $H_s$ , and significant wave period may be determined from the spectral density relationship. Fully arisen seas are rarely encountered in coastal waters off the coast of Atlantic Canada. The spectral density of the water surface elevation is not accurately represented by the P-M spectrum at these locations.

When time histories of water surface elevation are available for a particular location the ocean engineer can proceed with an alternate analysis. Of late, extensive libraries of time histories of water surface elevation, in the coastal waters of Atlantic Canada, are available from the Marine Environment Data Service (MEDS) of Fisheries and Oceans Canada. Such a record is shown in Figure 6, for station 144 near the Sable Island region of offshore Atlantic Canada. This record will be presented as an example analysis. The twenty minute records available are assumed to represent the sea conditions which exist over a three hour period. Assuming that the water surface elevation function  $\eta(t)$  repeats itself every twenty minutes a Fourier cosine series of the record may be written such that  $N$  equations describing the water surface elevation would be of the form

$$\eta_i = \sum_{n=1}^N A_n \cos(\pi i n/N + \phi_n) \quad (2)$$

where  $A_n$  is the amplitude of the  $n^{\text{th}}$  wave component and  $\phi_n$  is its corresponding phase angle. Similarly water particle velocity and acceleration,  $u_i$  and  $a_i$  can be written in discrete form. The Morrison equation can now be used in discrete form

$$F_i = C_1 u_i |u_i| + C_2 a_i \quad (3)$$

to obtain the response of the submarine pipeline to wave loading. Even efficient fast fourier transforms require significant computer time to analyze several twenty minute records each consisting of two thousand points.

A more efficient method when the actual wave records are available is to obtain the actual spectral density of the surface elevation. The actual spectral density for wave record station 144 is shown compared with other empirically derived spectra in Figure 5. Little correlation exists between the actual and the P-M and the modified P-M spectra. The Jonswap spectrum shows acceptable correlation but only when the necessary coefficients are determined from the actual spectrum. This cannot be done a priori. Clearly, actual wave spectra should be employed when determining the hydrodynamic loading.

The spectral density for the wave force can be evaluated by several methods. Firstly, the wave force can be assessed in the time-domain using equation 3. A high degree of confidence can be placed in this method. Secondly, Borgman's transformation can be used to obtain the spectral density of the wave force from the Fourier transformation of the discrete time series. This hybrid time-frequency-domain analysis and results appear to be acceptable. The third method employs the Borgman transformation from an empirically formulated energy spectrum. Since poor correlation exists between

the actual spectrum and the empirically formulated spectra only marginal confidence can be placed in this method.

Flow charts of the evaluation of the force spectral density for the time-domain analysis (method 1) and the frequency-domain analysis (method 2 and 3) follow:

### 3.0 FATIGUE ANALYSIS

Offshore structures which are subjected to cyclic hydrodynamic loading suffer a reduction in strength, which may eventually cause failure, through a process called fatigue. The fatigue life of structure may be determined by applying the Palmgren (7) and Miner (4) law of linear-accumulated damage. It states that fatigue failure will occur when

$$\sum_i \frac{m_i}{N_i} = 1 \quad (4)$$

where  $m_i$  is the actual number of occurrences of stress magnitude  $\sigma_i$  determined from the wave loading spectrum.  $N_i$  is the permissible number of occurrences of stress determined from S-N curves which relate the number of cycles to failure to a certain stress range. The American Welding Society S-N curve, ASW-X was used as the failure criteria. The fatigue damage sustained by a submarine pipeline was assessed for a year. The reciprocal of this value was taken as the fatigue life.

The relationship between the force spectral density and the stress spectral density is determined by considering the force spectral density as an input to the linear free-spanning submarine pipeline system. The displacement response and the stress response are directly related and expressed in the frequency-domain.

In the time-domain analysis the uniformly distributed wave load is replaced by a concentrated wave load applied at the center of the pipe span, which produces the same maximum bending stress. This concentrated load is used as the forcing term in the dynamic equation of the pipeline motion. An iterative procedure is included to solve for the relative velocity between the structure and the water particles. Once the structure displacement is determined, bending stresses are calculated from simple beam theory assuming that the suspended line-pipe has pinned-supports. The exact procedure required to determine the stress-history in the time-domain is complex and time consuming even on high-speed digital computer.

### 4.0 RESULTS

The following pipeline and environmental parameters were used in the fatigue analysis as applied to six 20 minute wave records from Station 144.

Pipe diameter ( $D_0$ )	600 mm (24 inches)
Pipe wall thickness ( $t_w$ )	13 mm (0.5 inches)
Concrete jacket thickness ( $t_{con}$ )	38 mm (1.5 inches)
Concrete density ( $\rho_{con}$ )	2400 kg/m <sup>3</sup> (150)

	$1b_m/ft^3$ )
Hydrocarbon density ( $\rho_{f1}$ )	800 $kg/m^3$ (50 $1b_m/ft^3$ )
Length of span (L)	40 m (131 ft)
Water depth (d)	20 m (66 ft)
Height of span above sea bed (Z)	2 m (6.5 ft)
Inertia coefficient ( $C_m$ )	2.5
Drag coefficient ( $C_D$ )	1.5

When the fatigue damage incurred during the twenty minute period was extrapolated to one year by assuming that the particular record persisted for the entire year the following fatigue life was determined for each record from the time-history analysis.

Wave record	1	2	3	4	5	6
$H_s$ (m)	2.0	2.15	2.59	2.44	2.16	3.19
Fatigue Life (years)	8187	5048	515	214	1284	14

The value for the fatigue life yielded in this manner is only representative of the actual fatigue life in so far as the particular sea state chosen is representative of the wave climate averaged over one year. However, if the twenty minute wave record were analyzed statistically then there appears the probability of encountering larger waves and thus higher stress ranges than actually detected during the twenty minute time-domain analysis. Fatigue life results for each record assuming a statistical analysis of the twenty minute wave record are now:

Wave record	1	2	3	4	5	6
$H_s$ (m)	2.0	2.15	2.59	2.44	2.16	3.19
Fatigue life (years)	2320	1690	1750	453	1150	18

The fatigue life predictions by the spectral method are presented for the actual wave spectrum, the P-M spectrum, the modified P-M spectrum and the JONSWAP spectrum.

Wave record	1	2	3	4	5	6
$H_s$ (m)	2.0	2.15	2.59	2.44	2.16	3.19
Fatigue life (years)						
Actual Spectrum	2085	1561	2300	670	1573	47
P-M	7868	3350	420	795	3175	45
Modified P-M	2130	1295	4598	578	1687	46
JONSWAP	1628	860	160	269	799	40

It is shown that a particular empirical formulation for wave spectrum performs acceptably in a spectral fatigue analysis when it acceptably matches the actual spectrum. Fatigue life predictions by the spectral method are comparable when actual wave spectrum is employed.

#### 5.0 CONCLUSIONS

Extensive wave record analysis would predict fatigue life by deterministic methods. This is expensive, often not possible and not necessary.

Segmented wave records provide sufficient data for an acceptably accurate fatigue life analysis by deterministic methods. This is still costly.

Spectral techniques, when applied using the actual wave spectrum are efficient and correlate reasonably well with the deterministic evaluation.

Submarine pipelines subjected to seas with significant wave heights less than 2.0 m (6.5 feet) need not be analyzed for fatigue failure.

Analysis of only six-twenty minute wave records predicts fatigue failure from 14 to 47 years. This is a matter of concern.

ir. A. Bernard \*\*\*\*

#### Abstract

The design scheme of the Zeebrugge Outer Harbour, Belgium, consists of two breakwaters protruding into the sea as far as 1,750 m beyond the existing môle or 3,000 m out from the coastline. The west outer breakwater is 4,280 m long, the east breakwater runs 4,030 m out from the sea-wall. The east outer harbour will accommodate terminals for liquid bulk products such as LNG. The west outer harbour will provide space to install two harbour basins to suit general cargo, hazardous cargo, container and ferry traffic.

In the paper emphasis is put on the use of sand in the design of the breakwaters, firstly as part of the foundation by replacing the little resistant top layers by dumped sand, and secondly as part of the core, by dumping sand above the original sea-bottom. In as far as proposed criteria were not fulfilled, the dumped sand had to be compacted. Two methods are discussed : compaction by vibrating needles and compaction using explosives.

#### 1. INTRODUCTION

The construction of the existing port of Zeebrugge has been a royal decision pronounced by H.M. King Leopold II in 1881. Almost a century later, in 1970, the Belgian Government decided to build a new inner harbour and finally in 1976 the decision was taken to the extension of the outer harbour. The outer harbour should provide a protection for the access channel to the new inner harbour. Moreover the outer harbour was necessary to accommodate the national LNG-terminal.

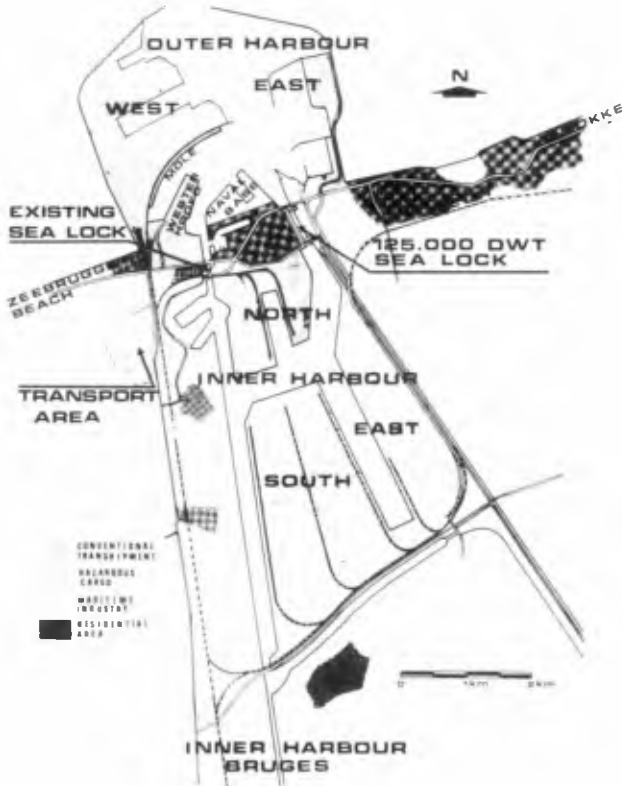

Fig. 1 : general layout of the Zeebrugge Port Extension Scheme

The masterplan finally adopted provides 3,370 ha sub-divided as follows (fig. 1) :

- outer harbour, including the existing port	1,165 ha
- inner harbour	1,705 ha
- port area of Bruges	450 ha
- transport area	50 ha.

The design scheme of the outer harbour consists mainly of two breakwaters protruding into the sea as far as 1,750 m beyond the existing môle.

The breakwaters are from the rubble-mound type. The west outer harbour breakwater is 4,280 m long. The east breakwater runs 4,030 m out from the sea-wall (fig. 2). The east outer harbour will accommodate terminals for liquid bulk products, such as LNG. A LNG-terminal is at present under construction and will be operational mid 1987. The west outer harbour will provide space to install two harbour basins to suit hazardous cargo, general cargo, container and ferry traffic.

## 2. DESIGN OF THE BREAKWATERS

The design of the breakwaters has been discussed in a paper on the Coastal Engineering Conference in Cape Town.

By developing the design the rubble-mound breakwater has been judged to be the best viable alternative taking into account costs, technical risks, construction problems and flexibility by changing environmental conditions.

An important economization in the design was the use of sand in the breakwater as soil replacement and as raised foundation.

Indeed, because the existing and future navigation channels to the harbour have to be deepened, some 30 million m<sup>3</sup> of relatively coarse sea-sand was available.

The quarry stone is won at distances of 100 km to 200 km off Zeebrugge and is rather expensive. So every possible substitution of quarry stone by sea-sand was an economical operation.

Technically the design with soil replacement has been assessed by evaluating the alternative of a breakwater built directly on the existing sea-bed, where the overall stability is given by equilibrium embankments at both sides.

## 3. ENVIRONMENTAL DESIGN CONDITIONS

### 3.1. Bottom depth

The bottom depth in the alignment of the outer harbour breakwaters ranges fairly between Z - 5.00 and Z - 7.00 (chart datum Z = mean low low water spring + 0.08).

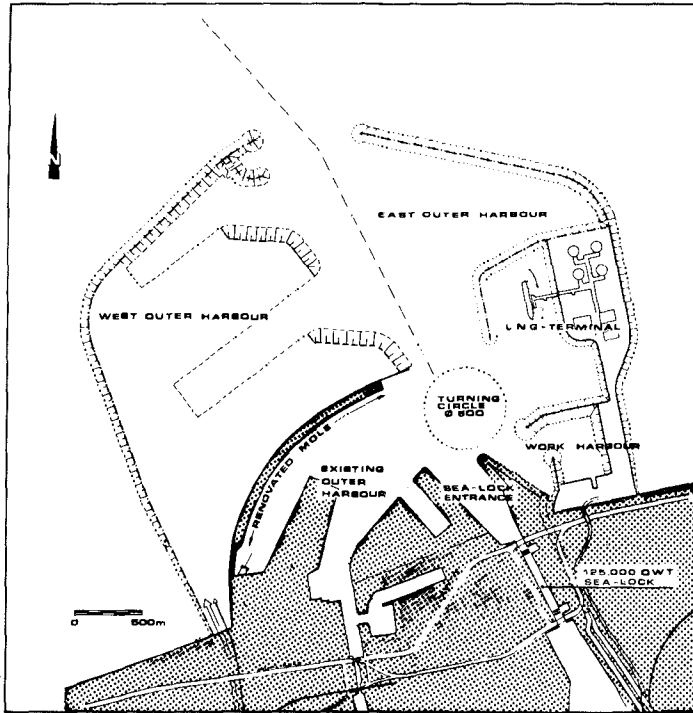

Fig. 2 : layout Masterplan Zeebrugge Outer Harbour

Fig. 3 : geological profile outer harbour breakwater alignment

### 3.2. Tidal conditions

The tide is semi-diurnal with levels ranging from amplitudes of 4.30 m at mean spring tide to 2.80 m at mean neap tide. The meteorological set-up is up to 2.45 m in the defined design period and probability of exceedance. The tidal currents at the final breakwater alignment will be (at surface) 1.2 m/s to 2.00 m/s at spring flood tide and 1.0 m/s to 1.6 m/s at spring ebb tide.

### 3.3. Soil conditions

The new outer harbour at Zeebrugge is located in the Scheldt Estuary which is characterized by a very heterogeneous soil composition of the top layers. In behalf of the construction of the new outer harbour a very extensive site investigation program consisting of continuous seismic profiling, CPT tests type M4 and borings with undisturbed sampling and laboratory tests is performed.

A geological profile along the axis of the breakwaters, resulting from the performed site investigation, is shown in fig. 3.

At the location of the new harbour the quaternary cover consists of loose sands and soft clays to a depth of about 4 to 6 m, underlain by a medium dense to dense sand layer. In the north eastern part of the new outer harbour the dense sand layer is not present and the top loose sands and soft clays are immediately resting on a stiff tertiary clay layer (Bartonian Clay).

The layer of soft clay and loose sand has cone resistances ranging between 0 and 1.5 MN/m<sup>2</sup>.

## 4. SAND USED AS PART OF THE BREAKWATER

### 4.1. As part of the foundation : soil replacement

Over large lengths of the breakwaters the bearing capacity of the surface layers was insufficient.

Only locally it was possible to construct the breakwaters directly on the natural soil layers on condition to provide a heavy toe construction.

Based on technical and economical considerations a soil replacement was decided over about 8 km of the breakwaters. The top loose sands and soft clays are dredged by large sea-going cutter suction dredgers and hopper suction dredgers and are replaced by relatively coarse sea-sand won in the existing and future navigation channels to the harbour. The mean diameter of the dumped sand is about 170 to 300  $\mu$ m. The cross-section of the dredged trench with a width of about 100 m is shown in fig. 4.

It is generally known that by the execution of a soil replacement by dredging and filling a trench, a transitional layer occurs at the bottom of the dredged trench. Special precautions had to be taken to

Fig. 4 : typical cross-section NW-NE breakwater

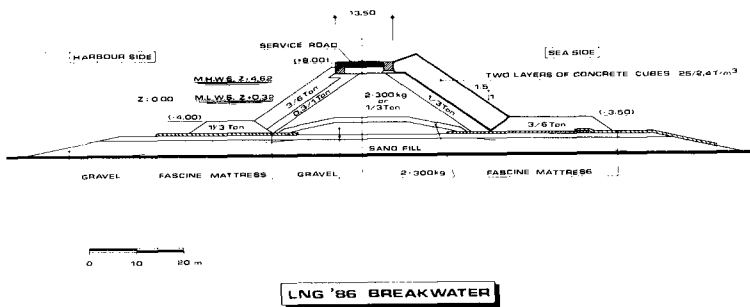

Fig. 5 : typical cross-section LNG '86-breakwater

Fig. 6 : results of 3 CPT tests performed in the dumped sand

minimize the extent and thickness of that layer. In addition to that phenomenon, at Zeebrugge a supplementary supply of mud in the dredged trench is caused by waves and strong tidal currents. In order to minimize the sedimentation of mud in the dredged trench, immediately after preparing a compartment with a length of about 150 to 250 m, the sand was dumped at a quick rate with hopper suction dredgers.

The sand dumping was done with advancing slope in order to push forward the eventual mud sediments in the direction of the open part of the trench, where the mud was sucked by the hopper dredger after completing its dumping activity (the so-called cleaning phase).

The theoretical bottom line of the trench could be reached very smoothly. The deviation in depth varied between 0 and 1.00 m. The trench slopes varied between 1:10 to 1:15 for hopper suction dredgers and between 1:4 to 1:6 for cutter suction dredgers. In the case of hopper suction dredgers, the transition layer consisting of silty mud at the bottom of the excavated trench was less pronounced.

In order to reduce the cost of the superstructure of the breakwaters, the sand was dumped as high as possible, on an average about 1 m above the original sea-bottom. This was only possible by using hopper suction dredgers with slidebottomdoors and split-hopper trailer dredgers. In order to limit the loss of dumped sand by the tide-run the sand was covered as soon as possible with about 1 m of unscreened sea-gravel.

The controlled dumping of the sand was executed without any mooring. High accuracy in positioning could be reached especially by using hoppers equipped with bow thrusts or propellers.

#### 4.2. As part of the core : raised foundation

In the zone of the LNG-breakwater, where the soft and loose top soil layers were dredged for the exploitation of the existing harbour, sand was dumped immediately on the sea-bed over a height of about 5 m in order to reduce the quantity of quarry stone of the breakwater. The sand was on both sides protected with gravel banks (fig. 5).

### 5. SOIL IMPROVEMENT

#### 5.1. Mechanical characteristics of the dumped sand

To control the quality of the soil replacement, CPT tests type M4 are performed at regular distances in the soil replacement areas. In fig. 6 the results of 3 CPT tests are given as an example. On each CPT diagram of fig. 6 the bottom of the dredged trench is indicated. Although precautions were taken to minimize the quantity of mud at the bottom of the trench before dumping the sand, it can be deduced from the results of the CPT tests that this could not be prevented completely. In each diagram of fig. 6, a thin layer with relatively small cone resistances can be distinguished at the bottom of the previously dredged trench, indicating the presence of a relatively thin layer of silty or clayey sand. In general however, from a depth of about 1 or

2m underneath the top of the dumped sand layer, the cone resistance in the dumped sand layer reaches values of about 6 to 10 MN/m<sup>2</sup>, or even more. The gradual increase of the cone resistance in the upper 1 to 4m of the dumped sand is to be attributed to the effect of depth.

The design criteria of the quality of the dumped sand were made bearing in mind that liquefaction of the dumped sand foundation of the breakwaters was not admitted.

Based on practical experience with natural soil layers and with hydraulic sand-fills on land, and considering CPT tests type M4 with measurements of the cone resistance every 20 cm, the following criteria were put forward for the evaluation of the quality of the dumped sand :

- underneath the critical depth in the CPT test, the mean cone resistance over any meter of depth must be higher than 5 MN/m<sup>2</sup> :  $q_{c,mean} > 5 \text{ MN/m}^2$  ;
- over any meter of depth, at most 2 values of the cone resistance may be smaller than 4 MN/m<sup>2</sup>.

Answering to the criteria was checked by one CPT test M4 per area of about 4000 m<sup>2</sup>.

Considering for instance the CPT test diagrams of fig. 6 :

- at the vertical of the CPT test ZW-GZ/D29 of fig 6.c the dumped sand layer has a thickness of 7.60 m. At the bottom of the backfilled trench only one relatively small value of the cone resistance is found indicating the presence of a thin clayey sand layer. Up to a depth of 2.00 m underneath the sea-bottom the cone resistance increases nearly linearly with depth and reaches values ranging between about 7 MN/m<sup>2</sup> and about 10 MN/m<sup>2</sup>. Only at a depth of 5.80 m one value of the cone resistance smaller than 4 MN/m<sup>2</sup> is measured. The above-mentioned evaluation criteria are thus fulfilled over the whole depth of the dumped sand layer.
- At the vertical of the CPT test NW-GZ/D40 of fig. 6.b the dumped sand layer has a thickness of 6.80 m. At the bottom of the backfilled trench a layer with relatively small cone resistance is found over a thickness of about 0.40 m. Apart from that layer only at a depth of 3.40 m one value of the cone resistance is smaller than 4 MN/m<sup>2</sup> and the evaluation criteria can be considered as fulfilled.
- At the vertical of the CPT test ZW-GZ/D19 of fig. 6.a the dumped sand layer has a thickness of 7.60 m. At the bottom of the backfilled trench a layer with relatively small cone resistances is found over a thickness of about 0.40 m. The evaluation criteria are fulfilled up to a depth of 3.80 m. From that depth and up to the bottom of the trench the criteria are not fulfilled. In as far as the criteria were not fulfilled, the dumped sand had to be compacted.

Handling the criterion for density control, compaction was only necessary over a length of about 25 % of the breakwaters where dumped sand has been used.

### 5.2. Deep compaction using vibrating needles

At Zeebrugge a compaction in depth based on vertical vibration is applied using a patented vibration probe constituted of three steel plates welded together with a cross-section of a three pronged star, hence the name "starprofile". The probe is hung in an electric or hydraulic vibrator block and is lowered into the dumped sand from a jack-up platform by means of a heavy crane. The energy of the vertically vibrating probe is transferred to the soil mainly through a series of ribs working as individual pounders (fig. 7). The vibrating probe is introduced in the ground to a depth of about 2m into the natural soil layers underneath the bottom of the filled trench.

Based on experience a vibration time of 15 minutes per "compaction prick" has been used. The distance between the compaction centres on a triangular pattern was determined depending on the results of the CPT tests performed before compaction, and on the cone resistance to be obtained in the dumped sand after compaction.

For the compaction of the dumped sand foundation layer of the northern breakwater of the Workharbour, compaction grids of one prick per 4 m<sup>2</sup>, one prick per 6 m<sup>2</sup> and one prick per 8 m<sup>2</sup> have been used. Fig. 8 shows the results of CPT tests performed before and after compaction, according to the different spacings of the compaction centres on a triangular pattern. The post-compaction tests were positioned in the centre of the treatment pattern remote from the compaction centres. Fig. 8.a gives the influence on the cone resistance in the dumped sand layer of one compaction prick per area of 8 m<sup>2</sup>. Fig. 8.b gives the influence of one prick per area of 6 m<sup>2</sup> and fig. 8.c of one prick per area of 4 m<sup>2</sup>. From fig. 8 it can be deduced that the influence of the compaction on the cone resistance in the dumped sand layer is higher the smaller the spacing of the compaction centres. It may be remarked that the transitional layer at the bottom of the previously dredged trench could not be eliminated completely by compaction, which is to be attributed to the clay content of that layer.

A diagrammatic picture of CPT tests performed before and after compaction is given in fig. 9. Before compaction, due to the influence of depth, the cone resistance in the dumped sand layer increases nearly linearly with depth from the sea-bottom up to a depth  $z_0$  where the cone resistance reaches a value  $q_{c,z_0}$ .

After compaction the cone resistance increases more rapidly with depth from the sea-bottom up to approximately the same depth  $z_0$ , but reaches a higher value  $q_{c,z_0}^n$  at that depth.

Fig. 7 : vertically vibrating probe

Fig. 9 : diagrammatic picture of CPT tests before and after compaction

Fig. 10 : comparison of predicted and measured cone resistance profile after compaction

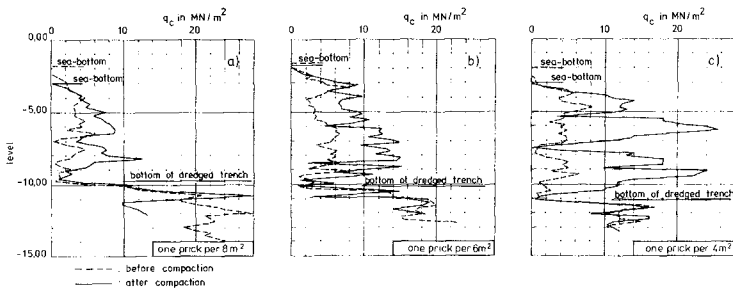

Fig. 8 : results of CPT tests before and after compaction

The ratio of the cone resistance at the depth  $z_0$  after and before compaction is given by

$$r = \frac{q_{c,z_0}^n}{q_{c,z_0}^v} > 1$$

From a systematic analysis of 14 pairs of CPT tests performed in a zone with a compaction grid of one prick per 6 m<sup>2</sup> a ratio  $r$  could be derived, ranging between 3.3 and 1.5, with a central value  $r_6 = 2.4$ . From 11 pairs of CPT tests performed in a zone with a compaction grid of one prick per 9 m<sup>2</sup> a ratio  $r$ , ranging between 2.7 and 1.2, with a central value  $r_9 = 1.7$  was deduced. From 16 pairs of CPT tests performed in a zone with a compaction grid of one prick per 12 m<sup>2</sup> a ratio  $r$ , ranging between 2.9 and 1.1, with a central value  $r_{12} = 1.5$  was obtained. The values of  $r_6$ ,  $r_9$  and  $r_{12}$  reflect the effectiveness of the different compaction grids. Having at disposal the results of CPT tests which doesn't fulfil the quality criteria, a rough estimation of the cone resistance profile after compaction can thus be made and thus a choice of the compaction grid.

In fig. 10 the schematic cone resistance profile ABC, predicted from the results of CPT test NW-GZ/D54 for a compaction grid of 1 prick per 9 m<sup>2</sup>, is compared with the results of CPT test NW-GZ/D5, performed after compaction. The prediction can be considered as fairly good.

### 5.3. Deep compaction using explosives

Although the deep compaction with the vibrating probe has given satisfactory results, a program was set up to examine the feasibility of in situ densification using explosives.

#### 5.3.1. Design of the blast program

-----

The impact of the explosive charge causes momentary liquefaction of loose saturated sands which subsequently adopt a more dense, stable structure under the weight of the overburden and increased drainage. Literature presents empirical relationships for single concentrated charges relating size of charge, depth of charge and spacing of blast holes based on extensive field and laboratory test data. However, no clear information is presented in the literature about size and depth of two concentrated charges placed at different depths in the same blast hole.

The depth of the lower charge was selected considering that the upper layer was liquefied by the upper charge and thus could be neglected when the lower charge was detonated; in this reasoning the lower charge was detonated within one to two seconds after the detonation of the upper charge.

The sequence of blasting was planned bearing in mind that successive blasts are more effective than a single heavy blast or different small blasts at the same moment. For the time interval between successive blasts at least 4 hours was chosen as suggested in literature.

### 5.3.2. Set-up of charges

-----

#### 5.3.2.1. Explosive

A high explosive "Blastogel" with a density of 1.4 kg/dm<sup>3</sup>, primarily composed of nitroglycerine (50-60 %) and containing no ammoniumnitrate (NH<sub>4</sub>NO<sub>3</sub>) was used. This explosive is initially waterresistant but decomposes under water in about one month. An eventually not detonated charge couldn't present a latent danger for the achieved breakwater. Blastogel has an equivalence factor of 1.0915 with regard to TNT. Blastogel was delivered in cylindrical blocks  $\varnothing$  85 mm of 5 kg mass.

#### 5.3.2.2. Firing system

As the electrical firing system and the use of detonating cord were excluded for underwater blasting, a non-electrical firing system NONEL was chosen, being waterresistant and presenting sufficient strength against water currents and accidental pull.

#### 5.3.2.3. Charges

The upper and lower charges of one vertical were prefabricated on the deck of the drilling platform. A scheme of the building up is given in fig. 11. The upper charge weights 4.5 kg, the lower charge 5.5 kg.

#### 5.3.2.4. Round

For sake of security each charge was fitted with two detonators NONEL with suitable delay. The four NONEL tubes of the upper and lower charge of one vertical were connected together above the waterlevel and bundled with the NONEL tubes of the charges placed in the other boreholes of the same blasting series. An electric detonator was then coupled to the bundle of NONEL tubes and was detonated from a blasting initiator placed on the deck of the drilling platform.

### 5.3.3. Blasting program

-----

The blasting program was carried out in the foundation layers at the extremity of the north western breakwater. The jack-up platform was equipped with three jetting rigs and the platform was moved in parallel lanes in order to minimize movements of the platform anchors.

The charge holes are jetted in parallel lines at distances of 7.5 m and the explosive charges are placed at depths of 4.5 m and 9.0 m below the sea-bottom. Blasting is executed in a triangular pattern, the charges at the corners of one triangle are detonated at least four hours after detonation of the charges of the adjacent triangle. The

Fig. 11 : prefabricated couple of charges

Fig. 12 : principle of arrangement

Fig. 13 : CPT tests D62 and D63

Fig. 14 : min. and max.  $q_c$  values of tests S10 to S13 after blasting with tests D62 and D63 before blasting

principle of the arrangement for the blasting is shown in fig. 12. In a first pass of the platform in a lane the charges of triangles  $i-1$ ,  $i$ ,  $i+1$ , ... are detonated consecutively ; the charges of triangles  $j-1$ ,  $j$ ,  $j+1$ , ... are detonated consecutively in a second pass of the platform in the same lane. After all charges of one lane were detonated, the platform was moved to the adjacent lane. In this way the same volume of soil was influenced by different blasts at different times.

A total surface area of about 14,000 m<sup>2</sup> was compacted over a period of fifteen days. Compaction was carried out over a thickness of layer of about 11 m using about 15.3 g of Blastogel per m<sup>3</sup> of soil. In the compacted area 242 borings with a total length of 2,180 m were carried out in waterdepths varying between 8 and 13 m, 2,300 kg of explosives were detonated.

The increase in density of the sand after blasting was evaluated by performing a number of CPT tests.

#### 5.3.4. Blast results

-----

Before starting the blast program, two CPT tests numbered D62 and D63, are performed (fig. 13).

After completion of the whole blasting program over an area of 13,612 m<sup>2</sup>, another 4 CPT tests numbered S10 to S13, were performed. In fig. 14 the maximum and minimum cone resistances of these tests are compared with the results of the two virgin tests D62 and D63. The results of the tests S10 to S13 confirmed the rather important increase of the cone resistances in the dumped sand layer. In the natural layer above the level of the lower charge, the minimum cone resistances in the tests S10 to S13 are of the same magnitude as the minimum cone resistances in the virgin tests D62 and D63 ; however, the maximum cone resistances after blasting are higher than in the tests before blasting. The thin clay lenses after blasting thus influence the minimum cone resistances as before blasting ; in the sand between the clay seams higher cone resistances are obtained after blasting.

## 6. CONCLUSIONS

- 6.1. The soil improvement technique by replacing in open sea the soft top layers by dumped sand was successfully developed.
- 6.2. Even by equal costs, the soil improvement profile still offers a more controlled construction and a foundation pad with a higher quality level. By using this profile less settlements may be expected.
- 6.3. Compaction of the dumped sand can be done as well by using a vertical vibrating probe as by using explosives.

## CHAPTER ONE HUNDRED EIGHTY FIVE

### A Review of Breakwater Development in Australia

D.N. Foster\* M.I.E. (AUST), M.A.S.C.E.

#### 1. Introduction

Prior to 1970 rubble mound breakwaters in Australia were armoured with rock or concrete rectangular prisms. Model testing was rarely undertaken. During storms some damage to the breakwaters was tolerated with repairs being undertaken as and when necessary. This procedure is still successfully used today. However since 1970 there has been a move towards designing breakwaters to minimise or eliminate maintenance and to optimise costs. This paper reviews some of the less conventional developments that have taken place over this period, with references to reports and papers for those who wish to obtain more detailed information on any of the projects.

#### 2. Sea-Wall Mascot Airport N.S.W.

The extension of Mascot airport into Botany Bay required that the perimeter be protected from wave attack. The design wave conditions were 4.6 m significant height with a depth limited upper wave height of 5.8 m in a water depth of 7.6 m. The designers were the Department of Housing and Construction. Model tests were undertaken at the Water Research Laboratory (Ref 9).

Interesting features related to the project are:

- i. Dry construction was specified. An initial bund of sand was pumped along the alignment of the seawall to above the reach of normal tides and waves. A trench was then cut through the sand bund and the seawall placed in the dry. The offshore sand was then pumped onto the reclamation area and the seawall completed to its design height. This technique worked extremely well with substantial cost savings.
- ii. Uniform placed Tribars were used as armour. The mass of the unit was 5 tonnes designed according to conventional practice. As it was known that the seawall would be constructed in the dry the benefits that might be achieved by pattern placement of the units was studied. The first pattern tested was the most dense possible (lowest porosity) with the legs of a Tribar abutting the webs of the adjacent units. Rather surprisingly (at that time), this section failed at wave heights very much less than the design wave as the legs of the Tribar could easily rotate about the webs and interlocking was lost. Model testing (Ref 9) showed that the most

\* Director, Water Research Laboratory, University of New South Wales, King Street, Manly Vale, N.S.W., 2093, Australia.

structurally stable pattern was one such that all the legs were in contact. This had the added advantage that it was the least dense (highest porosity) with a consequent cost saving in concrete and number of units to be placed. With this configuration Hudson damage coefficients in excess of 100 could be achieved. However, as failure tended to be catastrophic the pattern placement was used only as an added factor of safety and to reduce concrete and placement costs.

The seawall was constructed in 1970 and no maintenance has been required. However as a result of configuration dredging for port development (Ref 24), wave conditions at the site have been significantly reduced and the structure has not and will never be subjected to the design wave conditions. Some minor breakage of the legs of the Tribars have occurred as a result of settlement.

### 3. Seawall Banksmeadow N.S.W.

The development by the Maritime Services Board of Botany Bay as a major port for N.S.W. is described in Ref 23. An interesting feature was the use of configuration dredging to reduce wave action in the shipping lanes (Ref 24).

The development required the construction of a revetment/breakwater to provide protection to the harbour area. The design offshore wave conditions were a significant wave height of 7.8 m. Water depths at the toe of the structure varied between zero and 13.5 m and limited the height of the maximum wave. Model testing of the structure was undertaken by the Water Research Laboratory of the University of N.S.W. (Refs 6, 8, 16 and 17) and the Hydraulic Research Station Wallingford (Ref 19).

Features of interest are:

- i. The initial design was a copy of the Mascot seawall using pattern placed uniform Tribars of 2, 8 and 20 tonnes depending upon the water depth.
- ii. Construction methods were not specified and the contractor elected to undertake the work in the wet.
- iii. The pattern placement was extremely difficult to achieve as divers were required for the placement of each unit. As a consequence primary armour placement lagged behind the placement of the core and secondary armour.
- iv. Storms in May/June 1974 (Ref 10) caused major damage to the unprotected core and secondary armour. As a result the contractor was in considerable difficulty to meet his obligations and requested consideration be given to a re-design of the remainder of the breakwater using Dolosse.
- v. Model testing indicated Dolosse would be a suitable alternative armour. However, as a stockpile of Tribar units had already been

produced, a composite armour of Dolosse below water and pattern placed Tribars above water was tested and finally adopted.

- vi. Model testing indicated that in the composite design the junction between the Tribar and Dolosse units was a weak point and vulnerable to damage. It was initially thought that the best junction would be to anchor a leg of the Dolosse below the Tribar. However, this proved to be negative as movement of the Dolosse acted as a catapult to dislodge the Tribar. The best joint developed was simply a butt joint.

The prototype performance has been satisfactory. The structure has been subjected to near design wave conditions on two occasions. Some breakages of Dolosse units have occurred. A lot of this damage is towards the bed and is the result of settlement. There has been negligible damage of the Tribar armouring.

The composite armour used arose from the construction difficulties of pattern placing Tribars below water. Despite its adequate performance use of a composite section is not recommended as the junction between the units is a definite weak spot.

#### 4. Rock Breakwater Little Crassy Bay Tasmania

This rather unconventional breakwater arose from the availability of large quantities of waste rock overburden from a nearby sheelite mine. Five per cent of the rock was in the range 2 to 10 tonnes, with 95% being run of quarry less than 2 tonne.

Design wave conditions were estimated to be 10.5 m significant with a depth limited upper wave associated with a 18 m water depth.

The proposal was to push a core of run of the quarry material out to an adjacent offshore island which would act as a roundhead. The core would be allowed to pull down under wave action to form a beach on which would be placed selected 6 to 10 tonne armour rock as required. The purpose of this armour was to increase the stability of the breakwater and to reduce losses from littoral drift along the breakwater.

The initial crest width of the core was 60 m to allow for an adjustment of the face slope to 1 in 10.

The breakwater was designed by Maunsell and Partners, Consulting Engineers. Testing by the Water Research Laboratory (Ref 7) indicated that the proposal was feasible. Construction commenced in 1972 and was completed in 1974.

Construction and behaviour of the prototype is discussed in Ref 5. During construction the seaward face rapidly pulled down to a slope of 1 in 3.5. During storm action it can be expected that this will pull down to a flatter slope. Model tests indicated that the equilibrium slope of the core material (without armouring) would be between 1 in 7 and 1 in 10. However prototype experience indicates that the actual slopes may be somewhat steeper than that predicted by the model. Over

the 10 year period since its completion the breakwater has satisfactorily performed its design function.

#### 5. Rosslyn Bay Breakwater Queensland

Rosslyn Bay is a small fishing and recreational port in mid Queensland. Normal wave conditions are moderate; however, during cyclones (hurricanes, typhoons) the site is subject to design waves of significant height of 4.6 m superimposed on storm tide levels of 3 to 8.5 m on low water datum as compared to H.A.T. of 4.8 m. The high storm surge presents problems in the design of breakwaters in the lower latitudes which covers much of Australia's coastline as economics normally require a crest level subject to overtopping under extreme conditions.

The original breakwater was constructed in 1966 and suffered severe damage during Cyclone David in 1976 as a result of overtopping of the crest. A detailed account of this failure is given in Ref 14. Some notable features of the failure were:

- i. The failure was catastrophic taking place over a few hours.
- ii. After failure the structure continued to give substantial protection, significantly reducing damage to the harbour infrastructure and enabling the harbour to be used for its design function under the more common weather conditions that followed.
- iii. Model testing (Ref 11) was able to closely simulate the failure and the breakwater profile after failure.

Repairs to the breakwater were designed by Blain Bremner and Williams, Consulting Engineers. The repair made as much use of the failed breakwater as possible. The seaward face was flattened to 1 on 4 and the landward face to 1 on 2. Armour mass was increased to 5 tonne nominal and was carried over the crest and down the leeward face to allow for overtopping. The tests indicated that damage to the crest is a function of wave period and water levels as well as wave height and there was a critical combination of these variables which resulted in the highest damage. Further studies related to this aspect are given in Ref 13.

After the quarry was opened up the yield of 5 tonne rock was less than anticipated. For this reason the crest was actually armoured with 3.2 tonne modified cubes and the seaward and leeward face with a composite armour of 6 tonne rock and 3.2 tonne modified cubes which provided a dense interlocking combination which has proved very satisfactory.

Construction of the breakwater was completed in 1978 and has been subjected to several severe cyclonic storms with no significant damage.

#### 6. Breakwater and Seawall Townsville Queensland

To provide additional infrastructure to the port facilities at Townsville an area of land was to be reclaimed. The seaward face of the reclamation was to be protected against a significant wave height of

4.15 m superimposed on a storm tide level of 4.45 m corresponding to the 1 in 100 year event. The high value bulk and containerised cargoes required that the system be designed for zero overtopping.

Three alternatives were considered:

- i. A seawall along the face of the reclamation using conventional design practice.
- ii. A shore parallel offshore breakwater to provide protection to the reclamation area using conventional breakwater techniques.
- iii. A shore parallel submerged breakwater to provide protection to the reclamation area.

Economic analysis indicated that the third proposal offered cost savings of about 40 per cent over the other two. However, as all breakwater construction in Australia is undertaken using land based plant, there was difficulty in constructing such a breakwater in its final form. The failure of the Rossllyn Bay breakwater had indicated that damage to a breakwater of this type occurs in a controlled manner and that model testing could be used to simulate this damage. The concept was therefore to construct a mound of nominal 4T rock which would be allowed to reform as a submerged breakwater under the action of storm waves. The design was undertaken by Blaim Bremner and Williams, Consulting Engineers, and was model tested by the Water Research Laboratory. Details of the investigations are given in Refs 1 and 15 which demonstrated the feasibility of the proposal. Construction was undertaken in 1980. To date no significant cyclones have occurred at the site and the prototype performance can not as yet be evaluated.

#### 7. The Hanbar Unit

Many of the older breakwaters in N.S.W. have been armoured with rock or concrete rectangular prism dumped at their natural angle of repose. A commonly adopted size of the concrete units is 40 tonnes on the trunk and 60 tonnes on the head.

Along this section of coast extreme deep water significant wave heights are 8 to 10 m (May 1974, 9.5 m Ref 10; March 1978, 7.7 m with a maximum recorded wave of 16.4 m Ref 20). Under these conditions some damage to the breakwaters resulted requiring maintenance to be undertaken. Following damage to a number of breakwaters in the storms of May 1974, the N.S.W. Department of Public Works undertook an investigation into other forms of armour which might have a better performance. The restricted access, uneven slope and size of existing armour and the immediate need for patch repairs using readily available equipment, often in remote locations, suggested the need for a tippable unit. The unit finally adopted was a modification of British Transport Dock Board Tripod to simplify form work and to reduce construction costs. In Australia the unit is known as the "Hanbar". Prototype tests on both reinforced and un-reinforced units showed that when tipped on the Port Kembla breakwater they fell a distance of 7 m down the slope without breaking, and with only minor damage to the extremities. Consequently

all future units have been un-reinforced. Between 1975 and 1980, some 1,500 units have been used for repair of existing breakwaters.

Model tests by the Department of Public Works (Ref 21) indicate values of Hudson damage coefficient under depth limited breaking waves of approximately 7 for 0 to 5 per cent damage.

Since development of the Hanbar it has proved to be competitive with other units such as the Dolosse because of its relatively low construction cost, and has been used recently in seawalls at Port Kembla and Hay Point.

#### 8. Abbott Point Mole Queensland

Armouring of the mole at Abbott Point, Queensland, against a depth limited 4.3 m wave height was undertaken using the recently developed Seabee unit (Refs 2-4) at a cost significantly lower than other armour units. This unit is hexagonal in cross-section and is placed in an array. The length, mass and porosity of the unit can be varied to suit design and construction requirements. The unit was developed by Chris Brown, Consulting Engineer, and has been extensively tested by the Water Research Laboratory.

The mole was designed by MacDonald Wagner and Priddle, Consulting Engineers. The characteristics of the units adopted were Trunk (diameter 1800, length 900, porosity 36.5%, mass 2.9 tonne) and Head (diameter 1800, length 1200, porosity 36.5%, mass 3.9 tonne).

Model testing of the structure was undertaken by the Water Research Laboratory and considerable effort was made to determine the minimum acceptable standard of construction (i.e. surface condition of underlay, gaps between units, etc.). As a result of this work it was established that acceptable minimum standards of placement were 90% on the trunk and 80% on the roundhead of the theoretical maximum cover provided gaps greater than half a meter were filled with in situ concrete.

Construction was completed in 1982. The breakwater has been subjected to near design wave conditions and has performed to design expectations.

#### 9. Hay Point Tug Harbour Queensland

This breakwater is proposed to provide protection to a harbour for tugs used to berth bulk coal carriers at the Hay Point offshore coal loading terminal. At present these tugs have to operate out of MacKay some 20 km away. The design wave and storm tide conditions for the 1 in 100 year return period are 5 m significant height with a 7 second peak period superimposed on a storm tide level of 4.50 m. Offshore depth limits the maximum wave height at the structure to approximately 7 to 8 m.

The breakwater has been under consideration since 1977. The initial proposal was for a conventional breakwater armoured with a 6 to 8 tonne Dolosse (Ref 18). This proved to be too expensive and a modified design was undertaken of an overtopped structure using 12 tonne Dolosse

on a slope of 1.5:1 with a cap designed to be overtopped with cast in situ concrete blocks each of 400 tonnes in weight (Ref 22). However, the cost of the breakwater was still substantial and raised doubts of its economic viability. Further investigation of quarries in the region indicated the possibility of obtaining large quantities of rock ranging in size between 3 to 7 tonnes and a modified design was considered using a similar principal to that adopted at Little Grassy, Tasmania. The concept was to place a mound of sufficient size to allow storm waves to pull it down to a stable profile.

The breakwater was designed by Blain Bremner and Williams, Consulting Engineers, and was model tested at the Water Research Laboratory (Ref 12). Some of the interesting aspects of the tests were:

- i. Damage was much less than anticipated.
- ii. Whilst severe overtopping was expected this did not occur.
- iii. Provided the initial estimates of rock quantities from the quarry are proven, the cost will be approximately 30 per cent less than that of a conventional breakwater.

#### 10. Conclusions

Breakwater construction in Australia over the past 25 years has seen some developments which might be described as non-conventional. These have achieved improved performance and most importantly, cost savings. The paper summarises some of these developments. For further details the reader is referred to the references, most of which can be obtained on request from the Water Research Laboratory of The University of New South Wales.

## CHAPTER ONE HUNDRED EIGHTY SIX

### BREAKWATER ARMOR DISPLACEMENT THRESHOLDS: A POSSIBLE CORRELATION WITH CUMULATIVE WAVE ENERGY

Daniel L. Behnke, A.M. ASCE<sup>1</sup>  
Fredric Raichlen, F. ASCE<sup>2</sup>

#### Abstract

An extensive program of stability experiments in a highly detailed three-dimensional model has recently been completed to define a reconstruction technique for a damaged breakwater (Lillevang, Raichlen, Cox, and Behnke, 1984). Tests were conducted with both regular waves and irregular waves from various directions incident upon the breakwater. In comparison of the results of the regular wave tests to those of the irregular wave tests, a relation appeared to exist between breakwater damage and the accumulated energy to which the structure had been exposed. The energy delivered per wave is defined, as an approximation, as relating to the product of  $H^2$  and  $L$ , where  $H$  is the significant height of a train of irregular waves and  $L$  is the wave length at a selected depth, calculated according to small amplitude wave theory using a wave period corresponding to the peak energy of the spectrum. As applied in regular wave testing,  $H$  is the uniform wave height and  $L$  is that associated with the period of the simple wave train. The damage in the model due to regular waves and that caused by irregular waves has been related through the use of the cumulative wave energy contained in those waves which have an energy greater than a threshold value for the breakwater.

#### Introduction

To properly design a breakwater and its armor and to evaluate any damage that a structure has received, it is necessary to characterize the wave conditions in a meaningful way. Most often breakwater armor stability has been evaluated using hydraulic models exposed to regular waves. More recently irregular waves have been used in the laboratory to simulate the actual wave climate to which the breakwater would be exposed. Usually the irregular waves which are used for design purposes are characterized by an energy density spectrum. The spectrum may be described in general terms by using: a statistical measure of the wave height, the period of the maximum energy density of the spectrum, and a description of the shape of the spectrum. There are other

<sup>2</sup> Professor of Civil Engineering, W. M. Keck Laboratory of Hydraulics and Water Resources, California Institute of Technology, Pasadena, CA, U.S.A.

variables which may be important for a design, such as the wave direction, the storm duration, the stillwater level, and the wave groupiness. Each of these descriptors of the irregular wave train can change with time during a particular storm, and they can also occur in different combination over the lifetime of a structure. Therefore, the design wave conditions for a structure must be defined by a combination of wave characteristics which will be the most serious to the particular breakwater under consideration.

For breakwater armor experiments which are conducted with regular waves, the degree of damage of the breakwater is usually a function of the number of waves of a given wave height to which the breakwater is exposed. In other words, a group of waves of a given height and duration may slightly damage a structure whereas an increase in duration may destroy it. In most tests which are conducted, the experimental conditions include a range of wave periods and stillwater levels to more realistically account for changes in the prototype wave climate in addition to wave duration. The design wave height which is used in regular wave tests often is defined in terms of a statistical height related to the ocean waves such as the significant wave, i.e., the average of the highest one-third waves in a wave train, or some other higher wave average; the latter might be used to incorporate a higher degree of conservatism into the design. The shape of the armor pieces, their weight, and the seaward and landward slopes of the breakwater are chosen based on the model results so that under exposure to regular waves of a given height an acceptable amount of damage occurs. This may range from no movement of units to a significant displacement of armor units depending upon economics and the function of the structure.

In any event, the height of the regular waves which would be used in laboratory model tests generally is "numerically equal" to a statistically defined design wave height. (The term "numerically equal" is used to emphasize the difference between a wave height which characterizes a train of irregular waves and the height of waves in a periodic train). One has to be careful in this definition because, for example, a group of regular waves with height  $H$  has twice the energy of a group of irregular waves where heights follow a Rayleigh distribution with a significant wave height equal to  $H$ . In addition, it is recalled that the irregular wave train could include waves more than twice the height of the significant wave as well as waves which are much smaller. Therefore, a priori, it is not clear how the results of breakwater model tests with regular waves can be used to define the design where the actual breakwater will be exposed to a train of complex waves.

Many of the questions which have been raised could be avoided by the use of irregular waves in two-dimensional and three-dimensional models of coastal structures. This method of testing is becoming increasingly common and important since a variety of wave spectra can be used to simulate the design wave conditions at a site. The spectra can be varied throughout a test program to reproduce the growth and decay of waves from a storm, and the shape of a spectrum and the frequency of the maximum energy can be varied also to examine these effects on the

stability of the breakwater. A major difficulty with this technique is the number of experiments required to cover the possible combinations of wave heights, periods, and growth and decay characteristics which would be combined to give the worst conditions. In three-dimensional models additional experiments would be required to evaluate the effect of wave direction.

The resistance of breakwater armor to wave damage has been related to the wave height without regard for the wave period in the commonly used equations of Irribarren and Nogales (1953) and Hudson (1959). The basis for these equations has been described by Raichlen (1975) where the simplifications made in their developments are summarized. More recently experimental data have demonstrated the effect of wave period or wave length on armor stability. A summary paper published by the Permanent International Association of Navigation Congresses (1976) lists sixteen different formulae of which twelve use a term proportional to  $H^3$ , two use a term proportional to  $H^2L$ , and two use a term proportional to  $H^2T$ ; where  $H$  is the design wave height,  $L$  is the wave length, and  $T$  is the wave period. Thus, the importance of wave length has been incorporated in several design approaches.

In this paper the results of a limited series of experiments with a three-dimensional hydraulic model of a breakwater armored with Tribars will be used to suggest a possible correlation of the stability of the breakwater to a measure of the energy in groups of regular and irregular waves. If this is valid for a wider range of conditions than those tested, such a method may be able to resolve some of the problems of correlating the results of regular wave testing with those from irregular wave programs.

#### The Hydraulic Model

The hydraulic model from which these results were obtained was a three-dimensional model of the west and east breakwaters at the Diablo Canyon Nuclear Power Plant where an extremely complex offshore bathymetry was carefully reproduced in an undistorted model built to a scale of 1 foot in the model corresponding to 45 feet in the prototype. The breakwater is armored with a single layer of pattern place Tribars with weights of 21.6 tons (19.6 metric tons) and 36.8 tons (33.4 metric tons) and slopes of 1.5 horizontal to 1 vertical on the landward side of the trunk of the breakwater and 2.25 horizontal to 1 vertical on the seaward face of the trunk; the terminus cone has a slope of 3 horizontal to 1 vertical. The interested reader is referred to Lillevang, Raichlen, Cox and Behnke (1984) for the details of the breakwater cross-section, its construction, a complete description of the model, and the testing program. The model was needed for engineering design purposes because the west breakwater had been damaged by waves from a storm on January 28, 1981 and a reconstruction scheme was required so the structure could withstand future expected storm waves. The model was exposed to both regular waves and irregular waves representing the most severe storms in the past 85 years as determined by storm wave hindcasts and also from available buoy measurements. In addition, the directions of these waves were varied.

Since the model was not constructed for basic research on breakwater stability, the results presented herein are limited to a single unique breakwater design. However, as mentioned earlier, it is hoped that the concepts developed in this study may be useful evaluating other breakwater designs and testing programs.

#### Presentation and Discussion of Results

A series of regular wave experiments were conducted using the hydraulic model discussed by Lillevang et al. (1984) to examine the effect of the wave length on the stability of 36.8 ton (33.4 metric ton) Tribars which armored the terminus cone of the breakwater. The duration of the tests extended until damage began, with the initiation of damage for the structure defined as the removal of four contiguous Tribars from the armor blanket. This number was based on the observation that the removal of four adjacent Tribars generally led to rapid failure of the armored slope whereas the removal of less Tribars from an area did not appear to affect the armor stability.

The variation of the wave height necessary to initiate damage as a function of the number of waves to which the structure was exposed until that damage was observed is presented in Figure 1. It is apparent in Figure 1 that for a given wave height regular waves with larger wave periods are more damaging than those waves with the same wave height but smaller wave periods. In addition, for each wave period there is a threshold wave height below which no damage to the breakwater occurs regardless of the number of waves.

Considering the observed effect of wave period, or wave length, on the armor stability, the variation of the stability with the parameter  $H^2L$  was investigated. This parameter is of interest since it is proportional to the energy contained in a periodic wave with height  $H$  and wave length  $L$ . The data which were shown in Figure 1 are presented in Figure 2 in terms of the parameter  $H^2L$  as the ordinate with the number of waves to initiate damage as the abscissa. (The wave length has been calculated from small amplitude wave theory for a depth of about 75 feet (23 m) which represents the region just offshore of the west breakwater terminus.) The data appear to be less scattered when presented in this manner which indicates that the effect of wave length on Tribar stability may be related to the energy to which the structure is exposed. The solid curve shown in the figure was fitted to the data and the dashed curves represent a variation of plus or minus 10 percent from the solid curve. The data still exhibit scatter which may be due to the fact that each data point represents damage at a somewhat different location on the structure which is probably a function of the variation in the fitting of the Tribars in the armor layer. A similar correlation between stability and the energy,  $H^2L$ , has been shown for other breakwater armor types, including rubble mounds by Ahrens (1984) and Gravesen et al. (unpublished); these tests primarily used irregular waves.

Figure 1. Wave Height to Initiate Damage as a Function of Period and Number of Waves

Figure 2. Total Energy,  $H^2L$ , Versus Number of Waves to Initiate Damage

The energy parameter,  $H^2L$ , appears to account for the effect of wave length (wave period) and wave height on the stability of the breakwater armor. However, as such, it does not provide a direct means of comparison of the results of regular wave tests to those from irregular wave experiments where the structure is exposed to a simulated storm wave spectrum. In addition, this does not appear to provide a means for comparing the damage caused by waves from a storm composed of a small number of large waves to the damage due to the waves from a less intense storm with a larger number of small waves. A method is proposed herein to extend the concepts just presented to that situation.

In developing these relationships use will be made of the concept of a "zero damage wave height". This wave height, also denoted as the threshold wave height, was mentioned earlier and refers to the wave height below which no damage occurs for a given breakwater armor and geometry. As could be seen in Figure 2, the threshold also applies to the wave energy parameter,  $H^2L$ , i.e., there is a value of the wave energy parameter below which no damage occurs regardless of the number of waves to which the structure is exposed. This threshold value is denoted as  $(H^2L)_{TH}$ . The assumption is made in this development that the damage due to a single wave greater than this threshold value is proportional to the magnitude of  $H^2L$  for that wave. Furthermore, it is assumed that the total damage to a structure is a result of the cumulative effect of all waves which have a total energy which exceeds the threshold value. Therefore, for a train of  $N$  regular waves with height  $H$  this cumulative energy would be equal to  $NH^2L$ . Note that this implies that waves of different wave height and different wave periods can have the same potential for damage to the same structure.

Applying this concept to irregular waves, the cumulative magnitude of  $H^2L$  for all waves with "energy" greater than the threshold value,  $(H^2L)_{TH}$ , is dependent on the joint probability distribution of wave height and wave period. To simplify the analysis it is assumed that the frequency distribution of wave heights follows a Rayleigh distribution and that the wave length is independent of wave height. Hence, the cumulative "energy" can be written as:

$$\Sigma(H^2L)_{TH} = NL \int_{H_{TH}}^{\infty} H^2P(H)dH \quad (1)$$

where the representative wave length for the storm waves is taken as that defined by the period of the peak of the energy spectrum at the depth of interest, and the probability distribution of wave height is denoted as  $P(H)$ . As mentioned, the Rayleigh distribution is used as a representative probability distribution:

$$P(H) = 4.01 \frac{H}{H^2_{33\%}} \exp \left[ -2.01 \left( \frac{H}{H_{33\%}} \right)^2 \right] \quad (2)$$

Substituting Equation 2 into Equation 1 and performing the integration one obtains the following:

$$\Sigma(H^2L)_{TH} = \frac{1}{2} NLH^2_{33\%} [2.01 \left(\frac{H_{TH}}{H_{33\%}}\right)^2 + 1] \exp [-2.01 \left(\frac{H_{TH}}{H_{33\%}}\right)^2] \quad (3)$$

Equation 3 provides a measure of the cumulative total energy incident on a breakwater which is contained in those waves whose height is greater than the threshold height  $H_{TH}$ . It should be noted that the number of waves  $N$  used is based on the interval of time for which the particular significant wave height applies and the period of the peak of the energy spectrum. Thus, the assumption is made that the spectrum is a narrow band spectrum as is indicated by the use of the Rayleigh distribution.

A series of breakwater stability tests that were conducted in connection with the reconstruction efforts of the Diablo Canyon breakwater have been analyzed using the concept of the cumulative energy,  $\Sigma(H^2L)_{TH}$ . These tests were conducted with both regular and irregular waves so that there was an opportunity to compare stability for a particular structure with these different waves. For these experiments in the Diablo Canyon breakwater model, the breakwater was armored with 21.6 ton (19.6 metric ton) Tribars. The regular waves had a wave period of 16 seconds and the peak of the energy spectrum for the irregular waves was 16 seconds also. The geometry of the breakwater was identical in all experiments. To have a basis for comparison, the damage to the breakwater armor was defined in terms of the total number of Tribars displaced, since for a pattern placed armor consisting of a single layer the number of units which were displaced could be evaluated easily. Another criterion for comparison of the effect of regular and irregular waves is the displacement of the cap-blocks which form the crest of the breakwater (see Lillevang et al., 1984). The concrete cap-blocks consisted of individual cast in place concrete blocks, each approximately 30 feet (9.1 m) long, 21 feet (6.4 m) wide, and 7 feet (2.1 m) thick with a weight of about 300 tons (270 metric tons) In the prototype, a number of these cap-blocks were displaced in a storm which occurred in January 1981. In the model the displacement of the blocks was useful in comparing the results of regular and irregular wave tests.

The damage to the breakwater is shown in Figure 3 in terms of the number of dislodged Tribars as a function of the cumulative energy. For 16 second waves a threshold wave height of 17.5 feet (5.3 m) was determined from the experiments and this was used in Equation 3. It should be noted that the threshold wave height is less than that shown in Figure 2 because 36.8 ton (33.4 metric ton) Tribars had been used in the former case and the smaller 21.6 ton (19.6 metric ton) Tribars were used for these data. Two forms of testing were used for the periodic waves: either exposing the structure to bursts of 9 waves with a 16 second period or to a continuous train of these waves. There does not appear to be a significant difference in the results from these two different types of regular wave tests. The irregular and regular wave

tests are specifically denoted in Figure 3. It can be seen that the results of these two types of experiments are similar. An important fact related to the experiments is that a greater number of waves (and greater total cumulative wave energy) impacted the breakwater during the irregular wave tests. However, because only the energy in those waves greater than a threshold limit was summed, the damage potential for the irregular waves was accounted for in a way similar to that for the regular wave experiments.

In a similar manner the number of dislodged cap-blocks versus the cumulative energy is shown in Figure 4. The cap-blocks were cast for each separate experiment and were not reused in a subsequent experiment once they had been displaced. Generally there is considerably more scatter of the data in Figure 4 compared to Figure 3, although the irregular wave damage results agree well with the regular wave damage for Tests 1 and 4. There appears to be a much greater resistance of the cap-blocks to motion for Test 3 which was conducted using regular waves. It is believed that this was a result of the underside of the cap-blocks for these experiments being much rougher than in other tests, which resulted in a greater interlocking with the underlying intermediate stone layers and thus an increased resistance to sliding. This increased roughness was due to a different method of casting the cap-blocks for this particular test. Also shown in the figure is the best estimate of displacement of the prototype cap-blocks which occurred on January 28, 1981 (see Lillevang et al., 1984). The data shown are based on observations of the time of cap-block motion and estimates of storm wave conditions based on wave measurements from a National Oceanographic and Atmospheric Administration (NOAA) buoy located 18 miles from the site. It is postulated that the slower rate of damage of the prototype cap-blocks as compared to those in the model tests may be due to differences between the roughness of the underside of the blocks in the prototype and the model. Since there were no direct measurements possible of the actual prototype cap-block roughness, it cannot be determined whether this was accurately reproduced in the model. Of course, there are certainly other difference which could contribute to the differences. Not the least of these is the water surface time history used in the model, which had to be synthesized from a measured spectrum without wave phase information. The results shown in Figure 4 indicate that design conclusions for the rate of damage of the cap-blocks based on this model are probably conservative, leading to a factor of safety in the interpretation of the model results. Even though the rate of damage in the model was in some cases different, the mode of failure of the breakwater was accurately described by the model.

The relation of the breakwater armor displacement to cumulative wave energy has been developed based on limited data from experiments on this particular breakwater design. However, it appears that this approach has potential for providing a means of characterizing storm waves for breakwater design and model testing which could be much more generally applicable.

One question which occurred in this investigation related to storm events which took place after the model tests were completed. A series of storms occurred in the winter and spring of 1983 offshore of the west coast of the United States which caused significant damage along the California coast. Since the model tests were completed and there was not opportunity to expose the hydraulic model to a spectrum representing the waves from those storms, the question was raised as to what the effect of recent storms on the reconstructed breakwater could have been, compared to the results of the storm waves to which the breakwater model had been exposed during the extensive model testing program. The characteristics of the most serious irregular wave system the breakwater had been exposed to in the testing program was obtained from hindcasts of a storm which occurred in March 12 and 13, 1905. This storm was hindcast to have had a maximum significant wave height of about 31 feet (9.4 m) with the period of the peak of the spectrum of about 15 seconds. The storm of March 1983 had considerably larger wave periods which varied from about 13 seconds to 25 seconds and about the same maximum significant wave height. The wave data from this recent event were obtained from the NOAA buoy mentioned earlier, so that the variation of the period of the peak energy of the spectrum as the storm grew and subsided could be incorporated in computations. The proposed method was applied to this storm (and several others measured with the NOAA buoy) and compared to the hindcast 1905 storm waves. These results are shown in Figure 5 where the cumulative total energy has been plotted as a function of the elapsed time of the storm as the abscissa. The cumulated energy from the model experiments using the 1905 storm waves are shown along with that for the 1983 storm. It is seen that the storms to which the model was exposed had about the same total maximum cumulative energy as the recent (1983) storm waves, but the former occurred in a shorter elapsed time. The major reason for this is that the storm to which the model was exposed grew and decayed more rapidly than the 1983 storm did. Thus, if the concept of cumulative energy is correct, it would be expected that the effect of the 1983 storm on the breakwaters would not be more serious than the storms to which the model had been exposed in the testing program. Several other storms which are of lesser consequence are also shown in the figure.

As shown, the method of cumulative energy can be applied in assisting in the interpretation of hydraulic model results in light of prototype wave measurements. There are additional applications of this approach which can be mentioned.

The first might be the use of the term  $H^2_{33\%}L$  to characterize the peak intensity of a storm, instead of  $H_{33\%}$  as is commonly done. This would allow the effect of period on breakwater armor stability to be accounted for when selecting a design storm or storms for use in breakwater model testing. The second would be to characterize storms whose spectral characteristics vary throughout their duration into a single parameter,  $\Sigma H^2_{33\%}L$ , which accounts for variations in wave height, periods, and duration. Thus, a large number of storms could be evaluated as to their total potential for damage, instead of simply using the significant wave height associated with the peak of the

storm, for instance, in the development of storm return periods. A third application of the proposed method would be in breakwater model testing for design purposes. Instead of testing the breakwater design over a wide range of spectral characteristics and durations, regular wave tests could be used to determine  $(H^2L)_{TH}$ . The potential of damage due to any storm of given wave characteristics and duration could then be compared to results of damage due to a limited number of regular and irregular wave tests which would characterize the response of the breakwater design to  $\Sigma(H^2L)_{TH}$ . This could reduce the number of tests required, and allow a wider range of potential storms to be evaluated.

### Conclusions

A relationship between breakwater armor displacement and wave energy has been demonstrated for a single breakwater design. The armor consisted of both Tribar and crest cap-blocks. In addition, the damage in the model due to regular waves and that caused by irregular waves for the same structure has been related through the use of the cumulative total wave energy contained in those waves which have an energy greater than a threshold value for the breakwater. The threshold damage value is that magnitude of wave energy which will do no damage to the breakwater independent of the number of waves which impinge on the structure. For a given wave period, the threshold wave energy  $(H^2L)_{TH}$  can be related to a threshold wave height  $H_{TH}$  for which there is no damage to the breakwater. The application of experiments with irregular waves to situations which have not been tested is described in these results. It should be emphasized that these results were for a specific breakwater model, so that additional studies would be necessary to demonstrate the applicability of this approach to a wider range of breakwater armor types and breakwater geometries.

### Acknowledgments

The authors would like to express their appreciation to Mr. Omar J. Lillevang, the project engineer for the breakwater study. It was his initial comment regarding the possible importance of wave energy which led to the development described herein. The Pacific Gas and Electric Company is also acknowledged for their support of the project, as well as their permission to publish this paper.

#### ABSTRACT

Ten years after it was completed, and intact as originally built, West Breakwater at Diablo Canyon on the central coast of California was severely damaged during a wave storm in January 1981. The paper describes uncommonly detailed site investigations that followed and the development of a large three-dimensional hydraulic model for discovering the specific mechanism that precipitated the damage, and then for verification of the effectiveness of concepts for rebuilding the breakwater to resist greater storm events than had been used for the original design. Unique procedures for modelling contorted terrain, for producing reflection-corrected irregular wave systems, for eliminating abnormal waves at the start and at the end of test runs are discussed. The tested final concept for reconstruction is described and surveyed results of closely packed Tribar armoring, as reconstructed in 1983-84, are illustrated.

The authors conclude that investigations of problems involving wave attack on the termini of rubble mound breakwaters should always be undertaken with the aid of three-dimensional physical modelling unless owner and engineer are in a position knowingly to take large risks. Further, that physical modelling at suitably large scale is virtually mandated if the submerged terrain at a site is not regular.

#### INTRODUCTION

At dawn on January 28, 1981, the first five massive concrete blocks capping the seaward 150 feet of Diablo Canyon West Breakwater was observed to slide into the sea, in reaction to attack by a strong wave storm. Three of the other four sections, averaging 300 tons each, followed in quick succession and the fifth, now unsupported under much of its 600 square feet base at 13 feet above tidal datum, went in finally, about two months later.

The two breakwaters at Diablo Canyon Nuclear Power Plant were built in 1970-71 initially to provide sufficient wave shelter to enable

construction of intake pumping facilities for the first two generating units at the site. Each of four sea water circulation pumps in the intake structure would deliver approximately 900 cubic feet of cold sea water per second (25.5 cubic meters per second). The rotating parts of the pumping equipment, single impeller vertical turbines, and the rotors of their electric motors would provide sufficient flywheel effect that quick suction-side variations of water level of 5 feet would be acceptable. Consequently it was determined by the project owner that the breakwaters need not provide their full sheltering effect except at such future times that construction might again be undertaken; that it would be economically appropriate to restore deteriorated breakwaters periodically rather than incur the added costs of construction to resist extreme storms of infrequent occurrence. With parts of West Breakwater extending to depths as great as 70 feet on an unprotected coast, the breakwaters that were built were massive. As shown by Figure 1, West Breakwater's trunk slopes at 2.25:1 on the seaward side and is armored by Tribars weighing 21.5 tons each that abut on concrete crest blocks 7 feet thick by 21 feet wide. Their upper surfaces are 20 feet above datum. The sheltered side of the trunk slopes at 1.5:1 and is armored by 36.8 ton Tribars. The conical terminus slopes at 3:1 and was armored by the smaller Tribars. The profile, at 20 feet above Mean Lower Low water, was not high enough to prevent heavy overtopping and the designs were developed so as to survive such overtopping during the ordinary heavy storms of each winter. The original project was described in detail by the senior author in a paper published in 1977 (4).

The design engineer, on site during the latter hours of the damaging storm, identified for the owners three fundamental questions that needed to be answered:

1. What is the extent and significance of the damage done by the storm?
2. How was the damage done; what was the mechanism of the damage?
3. What could or should be done in a reconstruction effort?

It was pointed out and accepted, that until there were solidly based answers to the first two questions, the third one at that time could only be answered by speculation. That would be unworthy, and attention therefore was initially concentrated on the prerequisites. Instructions were issued, that the answers to all three questions be pursued.

#### SITE AND CONDITION SURVEYS

Towill, Incorporated, with long experience at surveys in the marine environment, was engaged to provide detailed maps of the damaged areas of West Breakwater and of the location and configuration of debris shoals from the damaged areas. They also were to identify, by serial numbers that had been cast into the concrete, and to locate precisely in three dimensions all Tribars that remained intact in their original positions. Towill in turn acquired the services of engineer

Figure 1  
ORIGINAL CROSS-SECTIONS, 1970-71  
(Ref. 4)

divers from Ames and Associates, Consulting Engineers, to assist in the Tribar inventory surveys. The center at the top of each leg of each Tribar was located horizontally by the intersection of lines of sight from two transits. The elevation of the top center of each leg was derived from vertical angles read from the transits, which had made their observations on a painted band on a pole held vertically by a swimmer at the water surface, while his partner, in diving gear and with cable communication with one of the transmitters, held the pole at the required point on each leg of each Tribar. On the seaward side, landward of the damage, only the toe Tribars and the Tribars above water were surveyed. Figure 2 is reduced from a part of the resultant "map inventory" of the intact Tribars. It was of great interest, that the map showed virtually no damage had occurred below the breakwater armor zone region at 15 to 20 feet below Mean Lower Low Water. The map also showed that the debris from the damaged areas above about -15 feet had not been carried into the entrance channel between East and West Breakwaters. It had all been dropped by the waves on the channelward slope of the West Breakwater's terminal cone.

When original construction of the breakwaters was under way in 1970 and 1971, and during the nearly ten years that passed before West Breakwater was damaged in January of 1981, there had been wave behavior that suggested the presence of bottom terrain features that the available hydrographic maps did not show or, if suggested by the maps, were not delineated with enough detail for adequately explaining how they affected the waves. Towill, Inc. was therefore also asked to map the ocean floor out to the 110 foot depth contour, designing their survey coverage appropriately to define contours at two-foot depth intervals, at a horizontal scale of 1"=20' (1:240) within 1,000 feet West of West Breakwater and similar radial distances from its terminus, and at 1"=100' (1:1200) the rest of the way to the limiting 110 foot depth contour. Obviously they could not resurvey the ocean floor where the breakwaters had already been built, and it was not deemed necessary to do new mapping of the intake basin, so the maps that finally were compiled were composites made up from the new and densely covered areas West and South of West Breakwater, and the earlier surveys which had been done in 1967 by the same firm. Figure 3 is a reduction of the composite map. It represents sea floor terrain over a width from East to West of one mile, or 1600 meters, and a width at its greatest of 0.7 miles, or 1100 meters. The sea floor is essentially free of sediments above elevation -70 feet and the details of its features are extremely contorted and abrupt in relief. A massive rock mound referred to as "The Wash Rock", just 350 feet West of West Breakwater, proved to be so steep that two-foot contours could not be drawn at its flanks as separately distinguishable lines, so there the contours are drawn only for each 10 feet.

#### THE STORM, IN DEEP WATERS

With the peak of the storm of January 28, 1981 occurring in the early morning hours, there were no qualified engineers on site at that time to note technical details of the wave attacks. Hindcasts from meteorological data were acquired therefore from marine meteorologist R. Rea Strange III. He described the deep water wave system offshore

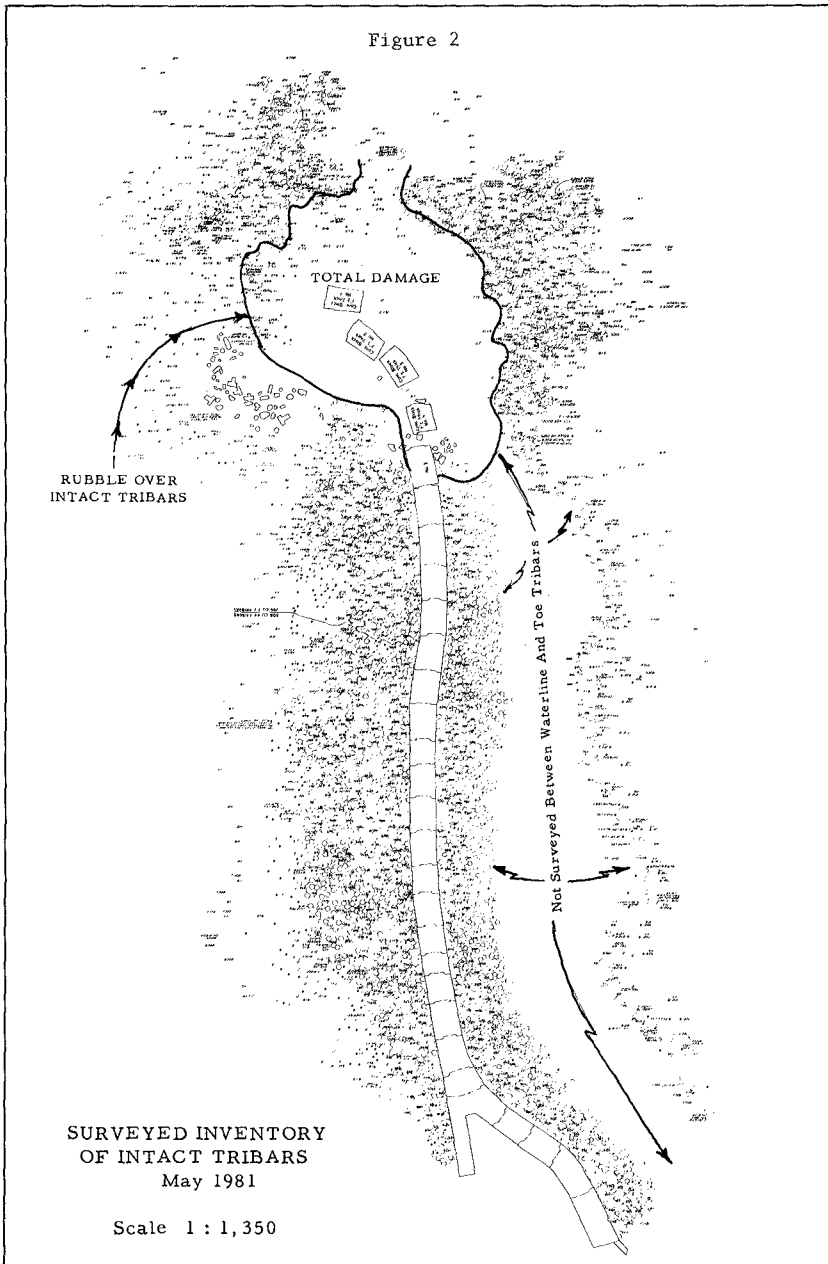

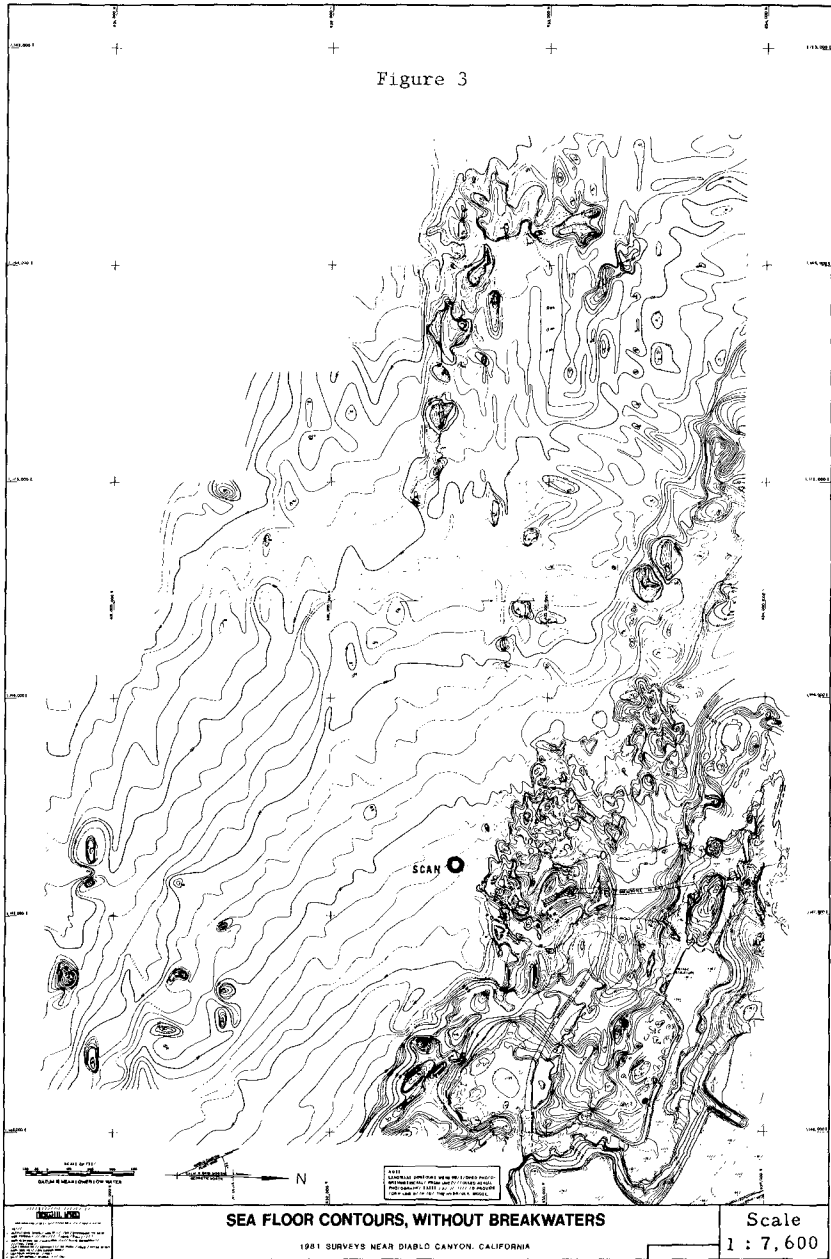

Figure 3

as being composed of seas that were being generated by a local storm, with winds from azimuth 225°, which for 12 hours had "significant" heights of 13.5 feet, and of swells from a storm 900 miles distant at azimuth 260°. The swells rose very abruptly after the seas had begun to drop. The maximum significant height of the combined swells and seas was 20.8 feet; the peak of the combined spectra was 17.5 seconds. The significant height of the swell component was 19.9 feet, of the seas, 6.1. The periods, respectively, were 17.5 and 8.5 seconds. About two weeks after submitting his hindcasts, Mr. Strange discovered the existence of a wave data buoy, anchored in deep water by the National Oceanic and Atmospheric Administration at a location only 18.6 nautical miles from Diablo Canyon Site. Apparently the buoy had recorded the waves on January 28, 1981, without any lapses. The investigators acquired duplicate magnetic tapes of the data transmitted by the NOAA buoy, number 46011, that had been recorded at its shore station in Mississippi. They were not raw data, so a factual water surface time profile could not be taken from the tape. Instead, the tape had spectral data which had been refined at the shore station from partially processed accelerometer records compiled by a microprocessor aboard the buoy. The raw data were processed aboard the buoy for each 20 minutes of record. They were sampled each two-thirds of a second. When the twenty minutes of partially processed data were transmitted to shore by radio satellite, records for the next 20 minutes were processed on the buoy, eradicating what had been there before.

Figure 4 shows the hourly variations of the NOAA buoy's spectral energy data, by separate frequency bands, through the two days of the storm. The presence and persistence of energy in the lower frequencies is worthy of note. Figure 5 breaks the energy data down to show the variations during the storm's strongest hours of the significant wave height ( $H_{33}$ ) as calculated from total energy, of the period at the peak of the spectral energy, of the deep water wave length for the peak energy component, and of the variation of  $H_{33}^2-L$ , a characterization of the energy per wave in the deep water condition.

The investigators had no basis for confirming in detail how well the accelerations of the NOAA buoy were interpreted to yield the energy data it preserved, so no conclusions could be reached as to the comparative qualities of the buoy's data and the hindcast data. If all else should be equal, there were advantages in the buoy recordings in their being available at 20-minute intervals instead of the 3 hours for hindcasts, and they did of course give clear indications of the time of rise and fall of the storm. They could not, however, provide any information as to the directions of the waves. The hindcasts did provide that information.

#### THE STORM, IN SHALLOW WATERS

The NOAA buoy was located in 133 fathoms depth. Thus, with normal criteria considered, its recordings were deep water data for all wave frequencies above 0.055 Hertz ( $T=18$  seconds). Hindcasts also yield deep water data, so it was necessary to determine the adjustments that should be made to the deep water storm descriptions in order to describe the waves at Diablo Canyon site that had damaged West

Breakwater. To enable making the appropriate adjustments, to deep water waves of any period from any azimuthal direction, a numerical model of the ocean floor was created and used with a refraction program elaborated by Dr. R.C.Y. Koh at California Institute of Technology from concepts developed by Professor Fredric Raichlen and published in 1970 (1). The model extends 15 miles from the coast out to the 206 fathoms depth contour and reaches from 35 miles downcoast from Diablo Canyon to 6 miles upcoast. Elevation data were entered at grid intervals of 250 feet between the coast and about the 40 fathoms curve. Between the 40 fathoms contour and 75 fathoms, data were entered for each 500 feet, and seaward from the 75 fathoms depth the elevations were stored for each 1,000 feet. Twenty thousand such points were input from manual takeoffs, using the new maps by Towill Inc. close in and several of the "smooth sheets" from the mid-1930s archives of the United States Coast and Geodetic Survey for the rest of the modelled area that would be used for wave refraction calculations. Seventeen thousand more elevations were computer interpolated between the input points and stored to define a "fine grid" of 250 feet mesh out to the 40 fathoms area and to define a coarse grid of 500 feet spacing for the rest of the model. Unused areas of a rectangular outline enclosing the above also had to be stored in the model, so pseudo elevations were used for such points. Thus the model consequently contained 109,000 data points. Figure 6 provides a locality map showing the Diablo Canyon Site between Point Buchon at the North and Point Arguello at the South, the NOAA buoy and the physical extent of the numerical model.

Fan diagrams were used, with a ray emanating from each 2.5 degrees of azimuth at an arbitrary point named SCAN at 75 feet depth, close to West Breakwater, to discover the deep water locations from which to propagate waves of selected deep water directions at various periods or frequencies that would bracket the coastal site. The location of SCAN is shown on Figure 3. With tabular as well as graphic output from the program to work from, representing calculations for over 500 wave refraction rays, a matrix was compiled that can be interpolated to give the refracted energy or height and the refracted azimuth at SCAN of waves of any deep water period up to 22 seconds with any deep water azimuth between 180 and 300 degrees.

With use of the numerical refraction model and accepting the hind-cast estimates of direction in deep water of the storm waves, the January 28, 1981 recordings by the NOAA buoy were transformed to represent shallow water waves at Diablo Canyon Site. Figure 7 shows both the deep water spectra and the spectra of the refracted waves at the 100 foot depth locality. The data for the 100 foot depth condition were used later for programming random wave generation in the physical hydraulic scale model that is described following.

#### THE HYDRAULIC MODEL

The extremely contorted submarine terrain that has previously been shown on Figure 3 was a major contributor to the assumptions that complex three-dimensional wave phenomena are present at Diablo Canyon Site that would be best reproduced by competent three-dimensional physical modelling. A new basin to hold such a model was built in Escondido,

Figure 6

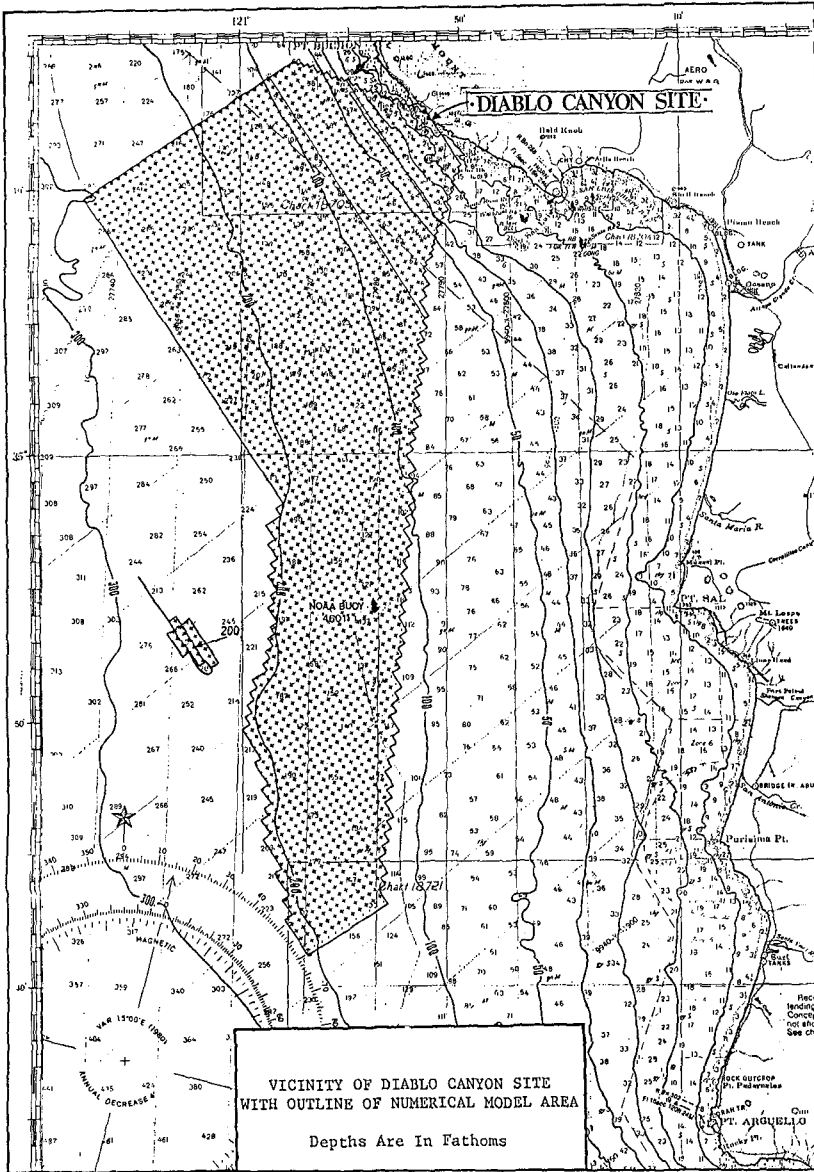

Figure 7

WAVE SPECTRA IN DEEP AND IN SHALLOW WATER  
FROM NOAA BUOY RECORDS ON JANUARY 28, 1981

California, alongside Offshore Technology Corporation's existing facilities. With a model scale of 1 to 45, the terrain above the 100 feet contour that is mapped on Figure 3 was fitted into the 80 feet by 120 feet basin. The basin's walls were at the edge of the Figure 3 map.

Several known techniques for molding the terrain accurately in the model were considered, but the great irregularity of the contours and the firm commitment to make the model as accurate a representation of the mapped features as possible, ruled those traditional methods out and a unique approach was developed. First, photographic enlargements of each 150' x 200' rectangular extent of the maps on sheets 40 by 54 inches in size were printed at 1:45 scale. Those sheets then were glued as a controlled mosaic on the floor of the model basin. Along every contour, typically at about eight-inch intervals, angle-iron clips were fastened to the floor with power-actuated stud drivers, the clips being so placed that their standing legs were tangent to the contour line. Galvanized steel strips, or "ribbons", were then bowed to follow each contour on the map and were spot welded to the angles after a surveyor had verified, by differential levelling, that the upper edges of each of the ribbons were positioned accurately to scale at the elevation defined by the contour. At single points representing peaks or hollows in the terrain, or at features where contours were too closely spaced or too tightly curved to leave room for the angles and ribbons, 10-inch galvanized spikes that are sold for eaves gutter fastening were driven to prescribed model elevations so they could be used like grade hubs. With the ribbons and spikes properly in place, sand was laid on the basin floor up to within 2 or 3 inches of the surfaces represented by the upper edges of the ribbons and the spikes, and then the remaining 2 or 3 inches were filled with sand-cement concrete and shaped to the contour controls by trowelling. Figure 8 shows the angles fastened along contours of the mosaic, steel ribbons temporarily

clamped to the angles, surveyors confirming the accuracy of the clamping and technicians with a portable spot welder fastening the ribbons permanently in place.

Four existing wave makers, each 11 feet long, were re-built to a modified configuration and a fifth was built to the new design, in which the moving blade's suspension was an articulated parallelogram support that caused the blade to remain aligned vertically throughout its stroke rather than swinging through a long radius arc from a single axis, like a door on edge. The re-built linkage is shown schematically by Figure 9. Screw jack castered wheels were included that could be

Figure 9

ARTICULATION OF WAVE BLADES

cranked down to make moving the modules relatively easy. Thus various alignments of the wave machines could be achieved for propagating waves across the model terrain toward the breakwaters. The five modules were aligned with a straight front and their blades were moved identically and simultaneously to produce continuous wave crests 55 feet long. Perpendicular to the 55 feet long blade at each end a wave guide fence that self-adjusted to profile features was extended toward the area under test, to control losses of wave energy laterally from the waves. Wherever reflections were seen that were caused by model boundaries but would not occur at the coastal site, open barred cages filled with lathe shavings of stainless steel were deployed to absorb the energy that otherwise would be reflected.

The wave blades were moved through the water by two-way hydraulic cylinders that tapped an open loop of a circulating oil supply at near constant pressure. Servo valves controlled the displacement time-history of the blade and these valves functioned in response to a voltage time-history that was constructed from spectra, either hindcast or measured, using the method proposed in 1970 by Goda (2). The variable voltage signals were recorded and played back during wave generation on conventional C-60 audio tape cassettes.

The testing program was devised to determine the effects on the model breakwaters of either uniform waves or of trains of random waves of equivalent energy. Except for the largest wave periods, where six or seven waves was the limit, the uniform waves were sent against the model breakwaters in bursts of nine and the machines then were stopped until the basin was suitably calm again. Then another burst of nine would continue the test. Two interesting techniques that had evolved in previous studies at California Institute of Technology were used with these uniform waves that were important improvements over traditional ones. First, instead of sinusoidal waves, which would not be a stable profile for gravity waves in depths as shallow as 100 feet, the variable voltage signals to the wave makers were programmed so that cnoidal wave profiles were produced within very short intervals of travel away from the blades of the wave machines, usually before those waves began to cross the modelled sea floor terrain. The other innovation eliminated a nuisance that historically has confused interpretations of model experiments. The first wave or two and the last one in a test run are almost always abnormal. Often the last wave has been compounded by reflections off of the blade and can be a high energy "rogue" that can do damage that the preceding train's series of prescribed waves had not been capable of doing. A simple concept was employed that essentially eliminated these first and last wave anomalies. No matter what phase of generating motion the blade might be in when a test run was completed, and a halt command was sent, sensing circuitry automatically delayed the effect of the halt instruction until the blade had completed its programmed traversal to its fully retracted position, and only then did it stop moving. At that phase of wave generation the blade's translatory velocity is zero; extraordinary waves do not result and start-up for following sets of waves is smooth and free of the lurching that is frequent when reactions to instantaneous demands of the system occur for motion.

Capacitance type probes were utilized to sense wave heights at various separate locations within the basin. The capacitance probes were essentially copper rods which had been insulated by continuous heat shrink tubing. As a probe becomes immersed in water, a change in capacitance is sensed between the copper rod core and the surrounding body of water. This change in capacitance is sensed by an electronic circuit which transforms it to a change in voltage which then is correlated with different degrees of immersion so that the change in water level due to the passing of the wave is sensed and related to wave height. As many as sixteen wave probes were deployed in the model basin at selected locations in different runs. They were mounted on tripod stands with adjustable legs that facilitated placement in various water depths and over the complex bottom topography. To relate the signal from a wave probe to the change in water level each probe was frequently calibrated by use of centrally controlled motors that drove them up and down in the water for known amounts of displacement. Information on the voltage reading of the probe and the displacement was supplied to a Tektronix 4052 computer which calculated the calibration value for each wave probe as a function of voltage and displacement. The results were highly linear and stable with time.

Measured wave heights were compiled by digital sampling, utilizing the Tektronix 4052 computer. Up to 16 channels of analog wave information were converted to digital form and were input to the computer. Once detected and processed by computer software, the information could then be permanently stored on floppy disk and also be presented in a hardcopy form for evaluation, through a graphics printer. The data were taken in unfiltered form and sampled at a rate of 10 Hertz. Lengths of test records were limited to the maximum number of samples that could be stored in the memory of the computer. A total of 128,000 samples could normally be stored using 12-bit format, limiting the maximum duration for compiling a record of a wave train to approximately 13 minutes of a test. With a slightly less accurate 8-bit format 256,000 samples could be stored, which made it possible to record as much as 26 minutes of testing.

Standard data that was output for both tests with regular waves and tests using irregular waves included wave time histories at each of the wave probes and basic statistical information on the waves that were measured including significant wave height and peak wave height. An example of a series of waves recorded during a test is shown by Figure 10, along with statistical information derived by the computer during the test. More sophisticated analyses that were also made from the probe records included presentation of actually measured wave spectra and the decomposition of the wave signals from two or more of the probes into incident and reflected wave components.

All relevant wave data were stored in computer compatible form for easy retrieval and analysis. Data were read to the Tektronix 4907 floppy disk memory unit, which transcribed the information onto 8 inch soft disks. The data were stored in an uncalibrated form with calibration factors stored in a separate header. The calibration factors were stored with each test run, rather than in one file only, to minimize or avoid any wrong calibration factors inadvertently being applied to

Figure 10

the raw data.

When test runs were made that used random waves the succession of wave bursts and intervening rests that were used for the uniform wave tests was not acceptable. The random wave sequences ran for tens of model minutes. With periods at peak energy of the random waves being 12 to 14 prototype seconds, which would be 1.8 to 2.1 seconds in the model, roughly 300 waves would be generated each ten minutes in the model. Such prolonged episodes provided considerable opportunity for wave reflections to build up between the model breakwaters and the wave machines. Routines were devised to adapt concepts to a three-dimensional wave basin that were described by Goda (3) for two-dimensional wave tests in flumes, for separating reflected wave components from the incident. The procedures involved comparing the histories of the water surfaces at two probes closely located one to the other along the direction of wave motion and near the wave machine, determining the separate incident and reflected spectra by harmonic analysis and computing adjusted signals to send to the servomechanisms to produce the effect of the desired net incident wave spectrum.

An office trailer placed alongside the test basin housed all central electronic gear and control stations, as well as computers,

plotters, printers and physical storage of records. Video recording terminals and monitors, with titling equipment and cameras, both video and film, standby equipment, etc., were housed in a smaller portable building alongside. Two-way speaker-microphone stations were installed to cover the whole model basin and in both portable buildings, so that all personnel could hear or contribute to voice communication.

Catwalks and booms, adjustable for height and rotatable from a mainmast to any location were cantilevered from the mast at the basin's edge. Fixed video and film cameras were mounted which could be activated remotely. All test runs included a recorded running commentary by the test engineers that later was transcribed. Parts of the commentary also were on the video cassettes that were recorded continuously during every test run. Parts of selected tests also were recorded on moving picture film exposed at 128 frames per second. When exposed at normal projection speeds, the moving images slowed to approach full-scale time of wave motion. That made more acute observation possible of fast acting events that had occurred in the model.

The model breakwaters were built over the molded sea floor terrain in close compliance with the original design. The core in the model breakwaters was made of coarse sand that was generally larger than the 1:45 linear model scaling of the prototype material would call for. That was deliberate, so viscous effects with smaller grain sizes would not distort the experimental results. The intermediate zone between the core and the Tribar armor layer, either B Stone or E Stone, was modelled to scale of volumes, i.e.  $1/45^3$ . The gradation called for the median stone's volume to be twice the volume of the minimum piece and the maximum stone to be twice the volume of the median. In either B or E Stone, the median size was 10 per cent of the volume of the Tribar armor piece. That gradation produces a voids volume approximating 45 per cent of gross volume occupied by the mixture. With nominal diameters of the scaled-down stones ranging between 2.1 and 3.3 centimeters for the smaller B Stone and between 2.5 and 3.9 centimeters for the E Stone it was determined that viscosity effects would be unimportant so it was scaled linearly. The model B and E Stone mixtures were made from crushed rock of appropriate specific weight. Proper shape and size distributions were obtained by hand selection and weighing each individual stone and classifying into two bins, using median size as the separation. Then equal weights of the two classifications were combined and mixed to produce a practical model gradation of the specified stone.

The model Tribars were cast under tightly controlled procedures in RTV molds, each of which was discarded after about 80 castings had been made from it. Thermal-setting resins were used to which industrial grade barium sulfate (barite) was added to obtain the correct specific gravity. Liquid catalyst was added to harden the pour before the finely divided weighting mineral could settle out of the honey consistency resin. Air that was entrained during the mixing of the parts was extracted from the catalyzed mixture under a vacuum bell jar before the mixture was poured into the molds. The heat of the catalyst is ineffective, however, where the mold and the resin interface, so external heat is necessary to harden the resin there. To provide the surface

heat the molds were first placed in controlled temperature ovens and then were removed just as the resin-barite-catalyst mixture was ready for pouring. Minimal flashing that resulted was removed from the castings after they were taken from the mold. After the hardened pouring chimney material had also been ground away each of the Tribars was weighed and one in ten was tested for specific gravity. No pieces were overweight and the specific gravity was almost without exception on target. None of the Tribars of 296 cubic feet size was as much as 3 per cent off on weight and the pieces of most accurate weight, ranging between 0 and 0.14% underweight, were code painted blue and were used in the model where surveys had shown removals by the January 28, 1981 wave storm. Those that were underweight by between 0.14 and 1.00% were painted green and were placed adjoining the historically damaged zones. The rest, sometimes painted black but mostly left in their unpainted milk chocolate brown color, were used elsewhere on West Breakwater beyond expected aggravated damage and on East Breakwater.

Figure 11 illustrates one of two possible geometric patterns for placing Tribars that represents the so-called 100 per cent pack. All pieces are in juxtaposition. In that configuration, one Tribar occupies  $5.008d^2$  units of area,  $d$  being the common diameter of each cylindrical leg or spoke in the Tribar. The theoretical perfect pack, at

Figure 11

## GEOMETRICAL ARRANGEMENT OF TRIBARS IN 100% PACK

100 per cent, cannot be achieved in actual construction but tight packing is an important objective for a Tribar armor zone. With close fitting, each Tribar is restrained by its abutting neighbors from tilting out of the "fabric" if it becomes unstable due to uneven support by the stones underneath and suffers displacing forces from the moving water. With the possibility under consideration that reconstruction specifications might require the builder to document achievement of a 90 per cent pack, the model breakwater armoring was placed to approximate 85 per cent, a consciously conservative modelling provision. Limits were also imposed on how much the legs of one Tribar could extend above or below those of an adjoining one, and as to how far the plane defined by the

ends of the three legs of any Tribar could tilt from the surface slopes defined by the design cross-sections.

A fast hardening and water resistant material named "Duracal" by one of several firms marketing it, and normally used for thin patches on deteriorated surfaces of concrete slabs, curbs or steps, was used for casting the model crest blocks. Barite was blended in to bring the material to appropriate density. The cap blocks were cast in place on the model breakwater, with a double layer of woven plastic screen cloth overlaid with a paper towel sheet being used to keep the simulated concrete from intruding the voids in the quarrrstones that support the crest block. In the prototype, chain link fencing mesh had been used, with asphaltic felt paper as an overlay, for this same purpose. After the blocks had hardened and their side forms had been taken away, each block was carefully lifted out, the mesh and paper towel membrane were removed, the tops were sanded smooth and the vent holes specified in the design were drilled. Each block was then put very carefully back in its original place. Each time that the breakwater was restored, in preparation for another test, new cap blocks were poured in place to replace the ones that the waves had removed during the preceding test. The displaced ones were not used again.

Figure 12 shows several of the features that have been discussed. The model's West Breakwater can be seen, ready for the first tests. The extreme relief characteristics of the terrain features are evident. Five of the wave recording probes on their tripods, with full-thread rods for adjustable legs, are aligned just West of West Breakwater, one of the profile-accommodating wave guide fences for containing the ends of waves is seen in the background, as is one of the crates containing stainless steel shavings for absorbing unwanted reflections at borders of the model. Figure 13 is a view from East of the Intake Structure of a test in progress. Water in the model basin is at extreme high tide stage +7.5 feet, while uniform waves 19 feet high and with 16 seconds period are attacking from a shallow water azimuth of 249 degrees. The catwalk for observations and camera station is also to be seen. Due to either a kind providence or Southern California weather this outdoor operation was at no time shut down because of wind conditions compromising testing conditions. On only one occasion was it necessary briefly to suspend progress due to rain. Much of the restructuring of the model breakwater extended into night shifts and on occasion test runs were made on the night shift.

#### THE MODEL CONFIRMED - THE DAMAGE MECHANISM IDENTIFIED

Five separate test runs were made that each confirmed the model's ability to reproduce the damage that was done to West Breakwater on January 28, 1981. The model was also consistent in that each of the tests produced the same damage. It was of considerable interest that essentially identical results were displayed by the three tests that were made with successive bursts of nine uniform height waves and that were made by the two continuous tests where the breakwaters were subjected to attack by random height waves. The wave series in the random heights tests carefully reproduced the energy characteristics at the 100 feet depth region of the model that had been derived from the

Figure 12

DETAIL OF THE MODEL

Figure 13

TESTING UNDER WAY

records made during the January 28, 1981 storm by the NOAA wave buoy. In all five of the test runs the wave machines were oriented to agree with azimuths that were derived by use of the numerical model for refraction, with input of Strange's hindcasts of deep water azimuths for that storm. Tide variations for January 28, 1981 at the site were not great through the hours of the storm's stronger phases, so no variation of water level was used during these five test runs, all being made with a tide stage in the model basin representing elevation +3.7 feet.

The damage sequence began with displacement by the waves of a Tribar on the edge of the armor pattern, at a specific point at the toe of the slope of the terminal cone. That specific location is where a blunt rocky ridge with its crest at elevation -15 feet was partly covered by the breakwater. Water rushing back down the conical surface of the breakwater's terminal cone, after passage of the preceding wave crest, proved to be capable of shifting the bottom row Tribar away from those upslope Tribars against which it had been tightly fitted during construction. After being moved downslope, away from the abutting support of the upslope Tribars the force of a following wave's uprush was sufficient to lift the shifted Tribar off of its base and then to tumble it across the breakwater's conical terminal surface toward deeper water on the sheltered quarter of the cone. Tribars that had been installed at the same -15 feet elevation either side of this localized high toe were not moved because they were in the middle of a pattern of Tribars and packed closely, so that freedom to move sufficiently to be tipped out was not available. The Tribars that shifted and then came out did so because of what was clearly an edge phenomenon. After the first Tribar was carried away its former immediate upslope neighbors became edge pieces and in succession they were loosened downslope by downrushing phases of the waves and then, newly without buttressing restraint from their former upslope neighbors, they were tilted out and carried over to a developing shoal of Tribar debris on the back slope. Every removal of a Tribar expanded the "unhemmed" edge of the pattern of remaining intact elements and the progress of damage increased rapidly as the perimeter of unsupported Tribars grew longer.

For some time the stripped off area's "downstream" boundary did not grow beyond the conical element of the terminus that paralleled the crests of the waves. That was the high point of the armoring crossed by the transiting waves. Beyond that "ridge line" there was no backrush of water after a wave's passage. The only forces by moving water that was felt by those Tribars tended to drive the edge pieces more firmly against their buttressing neighbors. In later tests that were carried on with long durations those edge Tribars did finally come loose, but due to a different cause. They tipped backward into the stripped off area after persisting high velocity forward wash of the waves eroded the stripped off area to a lowered profile. That eventually under-cut the quarrystone that had been supporting those Tribars, and they fell back and then were carried away forward to the debris shoal.

Once the rapid removal of the Tribar armor had grown to an area roughly elliptical in outline, with the major axis of the ellipse extending from the -15 feet initial point up to the near corner of the

end cap block (Cap Block No. 1), the rapid growth continued at its edge toward the breakwater's root. The other edge, along the "ridge line" of the cone as described above, did not grow very much at that phase. At the lower parts of the growing edge of the ellipse uprushing waves passed over Tribars whose upslope neighbors had already been carried away. Those lower Tribars were dislodged by the uprushing waves, transported upslope to come to rest momentarily against the crest block for a wave or two, rolling short distances up and down slope. They were then carried parallel with the breakwater's axis toward the breakwater's end and thence across the terminal cone for eventual deposition in the debris shoal. As the Tribars at the bottom parts of the ellipse came away, Tribars on the upper reaches of that edge lost support from below and were dislodged, and the cycle continued. The edge toward the breakwater's root of the stripped off area maintained its curved configuration as the damaged area grew.

Generally, there was no detectable rocking or movement of the crest block above the area currently being stripped of Tribars until right after all of the Tribars immediately below that block had been carried away. At about that time the full undiffused force of the uprushing waves was impacting against the 7 feet vertical extent of the block. The block could be seen to rock upward very slightly as each wave struck and was pivoted more or less on the opposite edge of its base. Simultaneously there was a violent diversion of energy downward and upward at the block face. The upward diversion was visibly evident by the splash from the wave. The downward diversion caused vertical downward jet just as the confining weight of the crest block on its foundation quarrrystones was momentarily relaxed through the upward rocking of the block. The large quarrrystones on which the cap normally was supported were quickly picked away in the split second that the block tended to rock upward. The progressive undercutting soon removed a third or more of the support and then the block slid toward the sea, badly tilted and no longer an effective element of the breakwater.

Figure 14, in three parts, shows in (a) and (c) the damage in the model after eight crest blocks had been dislodged after an extended run during the first model confirmation test. Part (b) is a reduced size excerpt from the map of the surveys of condition that were made at Diablo Canyon Site just after the storm of January 28, 1981. The curved and rising edge of the stripped away areas are seen in all three illustrations. Figure 15 is reproduced from the test records and shows outlines of the growing area of Triabar removals in the model that were sketched from vertical photographs at nine stages of the testing. The position of the dislodged crest blocks is not sketched, but as noted in Figure 15 Blocks 1 through 12 were dislodged in this test. It was continued well beyond the conditions that reproduced the historical damage, primarily to see if the storm in nature might have destroyed West Breakwater completely, had it persisted long enough.

Test 1, which Figure 15 summarizes, was made with regular waves that were delivered in bursts of nine. As shown by the Figure the test began with 54 waves that increased from 13 to 17 feet in prototype height and with a period in prototype time of 16 seconds. No damage resulted. Then, without changing the period, the wave height was

increased to 30 feet and shortly damage began to develop. Table A is a timing breakdown of the data in Figure 15. The center column shows the total number of large waves (greater than 17 feet) that had attacked the breakwater during Test 1 when each numbered area on Figure 15 was observed to have developed, and when each crest block was displaced.

The damage to the Tribar armor grew more and more slowly as the Tribar removals passed the general locality of Crest Block Number 5. By the time the seaward face of the breakwater was denuded as far back as the limit of Area 9, at Block Number 15, the rate of growth of the damage was hardly perceptible. Reasons for this were not rigorously investigated but are believed to be uniquely related to the site, with particular relationship to the path the waves moved over submerged terrain features toward the landward part of West Breakwater's alignment.

Test runs 2 and 3 duplicated Run Number 1. Runs 4 and 5 also tested the original configuration of the breakwaters but random waves were generated instead, in which the spectral energy equaled the energy at SCAN that was derived from the records made by the NOAA buoy during the actual storm of January 28, 1981. The synthesized trains of random height waves that were generated in the model differed however between Run Number 4 and Run Number 5 in one respect. The wave train of Test Number 5 was one of "high groupiness" and the one generated for Test Number 4 was of "low groupiness". The groupiness factor relates to the concept that the higher waves in a random set often are found together in the train. If the large amplitude waves occur together, that can be referred to as high groupiness, but if the high waves are dispersed more evenly it can be referred to as low groupiness.

There was no difference to be seen in any of the five tests as to how and exactly where the Tribar removals began, or in how the striping away of Tribars progressed. Neither were any differences apparent in the tests as to the sequence of events that led to displacement of each crest block. There were noticeable differences shown in the resistance to displacement by individual crest blocks and in exactly where they had come to rest when a test was completed. Those differences were known to relate to the impossibility of duplicating exactly the quarystone beddings on which the blocks were poured.

Those first five tests, with the breakwaters modelled as the prototype originally had been designed, and attacked in the model by waves that are believed to be closely comparable in energy with the historical wave event of January 27, 1981, produced essentially identical results in steps that were closely alike. The results they produced closely matched the conditions that site surveys showed immediately after the 1981 storm and in each test the damage began at exactly the same point.

#### HEMMING THE EDGE

The edge Tribars at the -15 feet locality of West Breakwater's terminal cone were given restraint against downslope displacement by the downrushing of waves by embedding their legs in simulated pumped-in-place concrete. Two rows of Tribars at that locality of the toe

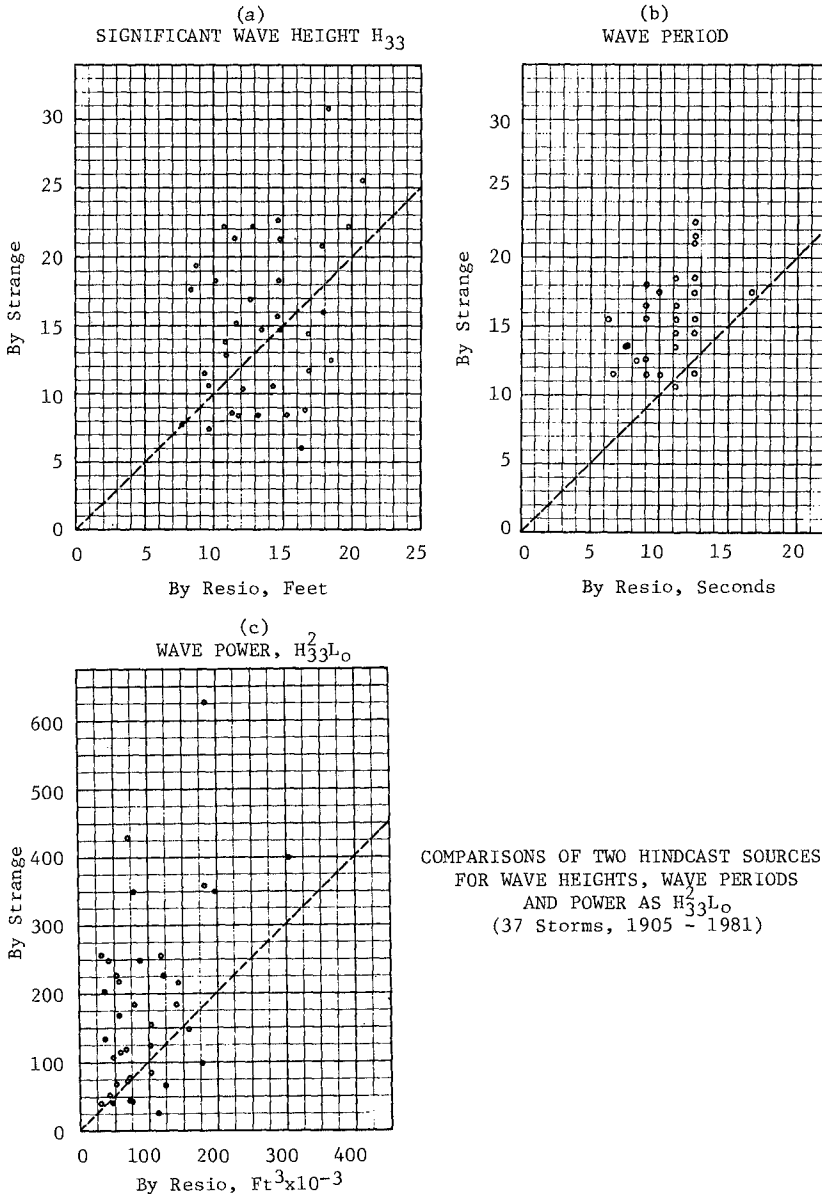

of the slope were embedded to a thickness equal to one-half the Tribars' height. This procedure was first used in 1975 to solve an edge restraint problem on the toe of East Breakwater's sheltered side and proved to be effective and was found in 1981 to be entirely intact (4, pgs 87-91). To be conservative, the embedment was continued along the toe of slope until it reached to the -30 feet contour on both sides of the -15 feet rock. The whole breakwater was again rebuilt, otherwise exactly according to the original design, and again tested with both uniform wave trains of up to 21 feet heights and random wave trains like those of January 28, 1981, in which the significant height of the wave train was 19 feet. The results at the embedded toe were good, the edge Tribars were successfully restrained from shifting.

#### UPGRADED RECONSTRUCTION GOALS

The weak link in West Breakwater's resistance to the original design goals had been found and was remedied by the pumped concrete "hem" at the high level toe of the terminal slope. However, with prolonged attack in the model by the January 28, 1981 peak wave train it was eventually able to remove a cluster of three or four Tribars on the far side of the terminus. Once such a cluster of Tribars had tediously been removed by prolonged attack, another analogy to the behavior of the ravellable fabrics was evident. Like a hole in the middle of some fabric meshes, the cluster of stripped away Tribars grew rapidly. It was obviously the edge effect again. With clusters of only 2 or possibly 3 Tribars removed by waves the perimeter Tribars around the cluster area appeared to be giving mutual restraint, each to the adjoining two, against being shifted by moving water. It was much as arch stones carry higher structural loads laterally and then down to a masonry building's foundation. But when the three or four Tribars were gone such arching action between peripheral remaining pieces diminished and the wave overwash shifted, then tipped, then rolled out and carried away the edge pieces in rapid succession. It was evident that the January 28, 1981 storm, which had at its peak an  $H_{3/3}^L$  value per wave of 350,000 at SCAN as contrasted with the original design's value of 205,400, would eventually have damaged West Breakwater if the "weak link" at the high edge of the terminus' toe had not existed at all.

The project owners needed to know the probable recurrence interval for the 1981 storm in order to have a decision basis for questions of upgrading vs. reproducing the original structure. Identical wave hindcast assignments were separately given to two qualified marine meteorologists, to identify all storms in the weather maps that had been compiled since the earliest days that had inferrable potential for severe attack in the inshore waters at Diablo Canyon Site. They collaborated only in searches of the records, beginning with those of 1899 and continuing through January of 1981, and reached a consensus on forty events. It was understood that either hindcaster was free to make further additions or deletions as he got deeper into his assignment. R. Rea Strange III compiled 47 hindcasts of his expanded list of storms and D. T. Resio submitted 41. The results from the two efforts were carefully compared and, as shown by Figure 16(a), their wave height hindcast data were fairly well centered on a 1:1 comparison line, though quite scattered. Figure 16(b) however shows consistent

Figure 16

COMPARISONS OF TWO HINDCAST SOURCES  
 FOR WAVE HEIGHTS, WAVE PERIODS  
 AND POWER AS  $H_{33}^2 L_0$   
 (37 Storms, 1905 - 1981)

disagreement between the peak frequencies of the spectra from the two hindcasters. In most storms the frequency according to Strange was lower than the values from Resio. Each hindcaster's data are also compared by using the wave periods to calculate wave lengths and thus to derive the  $H_{3/3}^2L$  characteristics at the peak of each storm. That comparison appears in Figure 16(c). With the typically larger wave periods thus affecting the comparison it was clear that use of Strange's hindcasts would be the more conservative choice. That the periods hindcast by Strange also compared satisfactorily with the periods found in the few buoy records of storms that had also been independently hindcast, confirmed the conclusion that Strange's results should be used in the present studies when wave storms that had not been recorded would be generated in the model basin.

The most severe storm in the hindcast report, between 1899 and 1981, occurred on March 13, 1905. According to Professor Leon E. Borgman, who analyzed the storms statistically for the principal investigator, that storm has a probable return frequency of 100 years at SCAN if the wave height is used for ranking, and of 80 years when the  $H_{3/3}^2L$  characteristic is used to rank the storms' strength. The respective values for the January 28, 1981 storm he found to be 13 and 18 years. The original design criteria would fall on Borgman's return frequency curves at 8 years for wave height and 8 years also for  $H_{3/3}^2L$ .

The project owner instructed that an upgraded design be developed for West Breakwater, to provide a level of resistance to storm attack that would provide undiminished shelter for the intake basin on a continuous basis. An important constraint on an upgraded West Breakwater design was however defined by the owner, namely that for environmental concerns a rebuilt breakwater had to fit within the cross-section, profile and planform limits of the original structure. With that limitation sharply in focus, the investigators tested to see how strong a storm an upgrade concept might be able to resist. After proving the effectiveness of embedding the toe Tribars at the high parts of the terminal cone, the West Breakwater model was rebuilt with 36.8 tons Tribars in the damaged area instead of the 21.5 tons pieces of the original design and of all of the preceding tests. The model was then subjected to several tests with the January 28, 1981 spectrum of irregular waves, and with regular waves whose height was built up from burst to burst until they were on the order of the highest 1 per cent of the waves in the corresponding irregular wave train, or even higher. Eventually in each test several Tribars did come out of the pattern on the back side of the terminal cone and then, as described before, the damage spread quickly. The embedment concept was then adapted to this type of damage evolution, by creating parallel "ribs" of embedded Tribars across the terminal cone. Gaps were left between parallel adjoining ribs so that air that might otherwise be trapped by uprushing waves in the voids of the quarrystone supporting the Tribars could vent harmlessly away. Like rows of stitching across a banner to limit tearing or unravelling of the fabric, the ribs minimized or eliminated the development of clustered Tribar removals. Consequently edge removals of intact Tribars did not grow after single Tribars might be carried away from the gaps between ribs.

Compressive strength of concrete in the prototype specifications was set at 4,500 pounds per square inch at 28 days. Scale strength for the 1:45 model would then be 100 pounds per square inch. A mixture was prepared for the model concrete that was composed of Plaster of Paris, sand, barite and water. It could easily be made to the correct density, had good pouring qualities and the correct scaled compressive strength. However, it was found after several test runs that extended immersion caused the material to become so weak that it could easily be crumbled by pinching it between finger and thumb. Its use was discontinued. Interestingly, however, the embedment functioned effectively in its saturated weak condition, restraining the model Tribars from movement by big waves. Although the embedment concrete undoubtedly should be strong, to achieve longevity of the embedment, the compressive loading on the mass of embedment concrete by Tribars that are being attacked by the waves is low. The function of the embedment is simply to provide a passive restraint against initial movement.

Instead of the Plaster of Paris mixture another material named "Modcrete" was used for both the toe embedment and the rib embedment of Tribars in all the remaining tests. It was developed for the work by personnel of ARCTEC, Incorporated, by adapting and altering that firm's model scaled ice compound, changing its strength and elastic properties by adjustment of proportions of its ingredients and weighting it with barite to achieve the correct specific weight.

A pattern of ribs evolved as the tests proceeded with the 1981 storm conditions. Those ribs stabilized the breakwater for that storm condition, but survival of higher attack levels was desired.

Table B shows the characteristics at the 100 feet depth locality of ten greatest storms at Diablo Canyon Site among the 47 that were selected and hindcast by Strange.

Table B

1/06/39	16.9	18.5	260°	248,000

The hindcasts were reviewed to identify the historical storms that had been most severe from each of four subdivisions of the whole sector from which any damaging waves had reached the site. Three of the four sub-sectors had storms among the ten most severe in the 81 years

covered by the hindcasts. In the remaining sub-sector, the most southerly one, the worst storm was that of January 25, 1914, It was ranked as the 17th strongest of the 47 in the 80 years of hindcasts. The events in March 1905, January 1914, February 1960 and January 1981 were selected for the four events that should be reproduced in continuing test series to discover whether or not additional measures for upgrading West Breakwater should be taken and, if so, to test such measures for effectiveness.

Table C presents the maximum wave conditions from each of the four sub-sectors of approach to which the model breakwaters were exposed. The sets of tests were not done in the order they appear in the table. Each set began with runs using small regular waves and then they were built up toward the maxima until substantial damage developed. At that point the run was halted. The damage was mapped by a surveyor, photos were taken and modifications of the rib patterns were decided upon. The breakwater was then rebuilt accordingly. The maximum heights of regular waves that were reached generally approximated or exceeded the 1 per cent wave height for the hindcast waves of the maximum historical storm for that sector of approach.

After the attacks by the maximum hindcast storm spectra from the four sub-sectors of approach had been made, and in each test the embedded ribs had been improved so that West Breakwater survived without progressive damage, the 1905 storm spectrum was generated from each of the four sectors at several tide stages for each direction. As indicated by the  $H^2L$  factors shown in the last column at the right of Table C, those tests using the 1905 spectrum substantially exceeded the attack levels of the historical storms in each of the other three sectors. Furthermore, the durations of the test runs from the 1905 storm in its own sector,  $233^\circ$ , at fixed tide levels rather than naturally transient levels, constituted attacks that were more drastic than the historical. Single Tribars at randomly scattered locations were removed by waves during some of the 1905 storm tests, two adjoining Tribars in one case, but none of those areas then grew larger during persistent continuing attack by these final extreme condition tests. In fact, these small opened areas shrank slightly, enough that a Tribar could not be reinserted in the remaining space.

Figure 17 shows the plan that was recommended for the restoration and upgrading of West Breakwater; Figure 18 presents the related cross-sections. During the final verification testing, when extreme storm conditions were imposed, some vulnerability of the Tribars was seen at two shallow toe features and at the emergent edge of the armoring where East Breakwater springs from a reef at its root. As shown on Figures 17 and 18 embedment of the toe at those locations was included in the recommended plan. The recommendations were adopted and the breakwater was reconstructed accordingly. Packing the Tribars to 90 per cent of the theoretically perfect pack was specified. As each Tribar was set in place the three coordinate values for the center at the top of each of the 3 legs of the piece were determined by instrument surveys and field computer, to determine if an acceptable placement had been achieved before the Tribar was released from the setting crane's tackle. No new work shift was started by the contractor until it had

been demonstrated to the Resident Engineer by computer analysis that the preceding shift's placing results had met or exceeded the packing requirement that was specified. Figure 19 is printed at greatly reduced scale from the map at 1"-20' (1:240). It shows a computer plot of the surveyed Tribars as built in the prototype in 1983-84.

#### CONCLUSION

The solution for upgrading the breakwater's resistance to storms that has been described is by no means conventional; that is mostly due to the constraint that had been laid down, that the original alignment, profile and cross-section limits had to enclose the upgraded structure. However, the unique character of the terrain effects at the site and the conventional influences of cost for larger structures in the sea might well have made this an appropriate solution even if the environmentally related limits had not been imposed.

The authors conclude that investigations of problems involving wave attack on the termini of rubble mound breakwaters should always be undertaken with the aid of three-dimensional physical modelling unless

owner and engineer are in a position knowingly to take large risks. Further, that physical modelling at suitably large scale is virtually mandated if the submerged terrain at a site is not regular.

## CHAPTER ONE HUNDRED EIGHTY EIGHT

### ANALYSIS OF UPRIGHT STRUCTURE FOR WAVE DISSIPATION USING INTEGRAL EQUATION

Kazuhiro Hagiwara

#### ABSTRACT

A theoretical analysis using an integral equation derived for the unknown horizontal velocity component in a pervious wall is proposed for estimating the reflection and transmission coefficients of upright structures for wave dissipation, and various factors related to wave and structural conditions having influences on the wave dissipating characteristics are investigated for a breakwater with pervious vertical walls at both seaward and landward sides.

In two-dimensional experiments, the theoretical results are in good agreement with experimental data with respect to reflection and transmission coefficients, and therefore, the wave dissipating characteristics of upright structures for wave dissipation can be explained by the integral equation method theory.

#### INTRODUCTION

Recently, the decline of water quality in harbors has become a serious problem in Japan. Therefore, upright breakwaters for wave dissipation such as those with pervious vertical walls at both seaward and landward sides have been constructed for the purposes of reducing reflected wave heights in the harbor, and facilitating exchange of water inside and outside of the harbor. With this type of breakwater, sea water in the protected area can be kept relatively clean to allow the water to pass through the breakwater, but calmness inside the harbor is liable to be disturbed. Consequently, the structural dimensions of this type of breakwater which is required to satisfy the contrasting demands for wave dissipation and water passage must be carefully examined.

A number of theoretical studies such as by Sawaragi and Iwata have been conducted regarding the problem of wave transmission through and reflection from upright structures for wave dissipation. However, equations for calculating the reflection and transmission coefficients are not easily derived.

In this paper, a theoretical method for estimating reflection and

transmission coefficients of an upright structure for wave dissipation based on an integral equation is proposed while examining various factors related to wave and structural conditions having influences on the dissipating characteristics. In addition, experimental data are utilized to substantiate this theory.

THEORY

Suppose a breakwater, as shown in Figure 1, with pervious vertical walls at both seaward and landward sides, the origin of the coordinate system being taken at the still water surface at the center of the reservoir space with the  $x$  axis horizontal and  $z$  axis vertical and pointing upward. The pervious parts of the front wall with thickness  $b_1$  at  $x = -l$  and of the rear wall with thickness  $b_2$  at  $x = l$  are  $-d_2 \leq z \leq -d_1$  and  $-d_4 \leq z \leq -d_3$ , respectively. Also, suppose that the influence of the discontinuity of water stream is within the limits of  $x_{-2} \leq x \leq x_{-1}$  at the front wall and  $x_1 \leq x \leq x_2$  at the rear wall, respectively, and is very small compared with the wave length. The water area is divided into three regions, (I), (II), and (III).

Assuming a small-amplitude wave in an incompressible perfect liquid in two dimensions with the velocity potential in each region  $\phi_s(x, z; t) = \phi_s(x, z)e^{i\sigma t}$  ( $s=1,2,3$ ), where  $\sigma$  is the incident wave of frequency, then, solutions for Laplace's equation which satisfy surface and boundary conditions are expressed as follows:

Figure 1 Definition sketch of breakwater with pervious vertical walls at both seaward and landward sides.

$$\begin{aligned} \phi_1(x, z) = & \{A \exp(-ik(x+l+b_1)) + B \exp(ik(x+l+b_1))\} \frac{\cosh k(z+h_1)}{\cosh kh_1} \\ & + \sum_{m=1}^{\infty} C_m \exp(k_m(x+l+b_1)) \frac{\cos k_m(z+h_1)}{\cos k_m h_1} \quad \dots (1) \end{aligned}$$

$$\begin{aligned} \phi_2(x, z) = & (D \frac{\cos k'x}{\cos k'l} + E \frac{\sin k'x}{\sin k'l}) \frac{\cosh k'(z+h_2)}{\cosh k'h_2} \\ & + \sum_{n=1}^{\infty} (F_n \frac{\cosh k_n'x}{\cosh k_n'l} + G_n \frac{\sinh k_n'x}{\sinh k_n'l}) \frac{\cos k_n'(z+h_2)}{\cos k_n'h_2} \quad \dots (2) \end{aligned}$$

$$\begin{aligned} \phi_3(x, z) = & I \exp(-ik''(x-l-b_2)) \frac{\cosh k''(z+h_3)}{\cosh k''h_3} \\ & + \sum_{s=1}^{\infty} J_s \exp(-k_s''(x-l-b_2)) \frac{\cos k_s''(z+h_3)}{\cos k_s''h_3} \quad \dots (3) \end{aligned}$$

where,  $A$  is the known complex constant which represents the incident wave.  $B$  and  $I$  are unknown complex constants representing reflected and transmitted waves, respectively. Also,  $D$ ,  $E$  and  $C_m$ ,  $F_n$ ,  $G_n$ ,  $J_s$  are unknown complex constants for standing and scattered waves, respectively. Further,  $k$ ,  $k_m$ ,  $k'$ ,  $k_n'$  and  $k''$ ,  $k_s''$  are eigenvalues determined by the following relations:

$$\sigma^2 = gk \tanh kh_1 = -gk_m \tan k_m h_1 \quad (m=1, 2, 3, \dots) \quad \dots (4)$$

$$\sigma^2 = gk' \tanh k'h_2 = -gk_n' \tan k_n' h_2 \quad (n=1, 2, 3, \dots) \quad \dots (5)$$

$$\sigma^2 = gk'' \tanh k''h_3 = -gk_s'' \tan k_s'' h_3 \quad (s=1, 2, 3, \dots) \quad \dots (6)$$

where,  $g$  is gravitational acceleration,

Let the horizontal velocity of the pervious part of the vertical wall be  $U_1(z)$  and  $U_2(z)$  at the front and rear walls, respectively. Then the principle of conservation of mass requires the following conditions;

$$U_1(z) = \frac{1}{\epsilon_1} \frac{\partial \phi_1}{\partial x} \Big|_{x_2 \approx -(l+b_1)} = \frac{1}{\epsilon_1} \frac{\partial \phi_2}{\partial x} \Big|_{x_1 \approx -l} \quad \dots (7)$$

$$U_2(z) = \frac{1}{\epsilon_2} \frac{\partial \phi_2}{\partial x} \Big|_{x_1 \approx l} = \frac{1}{\epsilon_2} \frac{\partial \phi_3}{\partial x} \Big|_{x_2 \approx l+b_2} \quad \dots (8)$$

where,  $\epsilon_1$  and  $\epsilon_2$  are opening ratios of the pervious parts of the front and rear walls, respectively. Substituting Eqs. (1), (2) and (3) into Eqs. (7) and (8), we have the following equations:

$$\begin{aligned} \epsilon_1 U_1(z) = & -i(A-B) \frac{k \cosh k(z+h_1)}{\cosh kh_1} + \sum_{m=1}^{\infty} C_m \frac{k_m \cos k_m(z+h_1)}{\cos k_m h_1} \quad \dots (9) \\ = & (D \tan k'l + E \cot k'l) \frac{k' \cosh k'(z+h_2)}{\cosh k'h_2} \end{aligned}$$

$$-\sum_{n=1}^{\infty} (F_n \tanh k_n' l - G_n \coth k_n' l) \frac{k_n' \cos k_n'(z+h_2)}{\cosh k_n' h_2} \dots, (10)$$

$$\begin{aligned} \epsilon_2 U_2(z) = & -(D \tan k' l - E \cot k' l) \frac{k' \cosh k'(z+h_2)}{\cosh k' h_2} \\ & + \sum_{n=1}^{\infty} (F_n \tanh k_n' l + G_n \coth k_n' l) \frac{k_n' \cos k_n'(z+h_2)}{\cosh k_n' h_2} \dots, (11) \end{aligned}$$

$$= -i I \frac{k'' \cosh k''(z+h_3)}{\cosh k'' h_3} - \sum_{s=1}^{\infty} J_s \frac{k_s'' \cos k_s''(z+h_3)}{\cosh k_s'' h_3} \dots, (12)$$

Considering the orthogonality of the function hyperbolic sine and sine, we multiply each term of Eq. (9) by  $\cosh k(z+h_1)$  and  $\cos k_m(z+h_1)$ , of Eqs. (10) and (11) by  $\cosh k'(z+h_2)$  and  $\cos k_n'(z+h_2)$ , and of Eq. (12) by  $\cosh k''(z+h_3)$  and  $\cos k_s''(z+h_3)$ . In consideration of  $U_1(z) = U_2(z) = 0$  except for  $-\bar{d}_2 \leq z \leq -\bar{d}_1$  and  $-\bar{d}_4 \leq z \leq -\bar{d}_3$ , integrating from  $z = -h_1$  to  $z = 0$ ,  $z = -h_2$  to  $z = 0$ , and  $z = -h_3$  to  $z = 0$  at each region with respect to  $z$ , we can write the unknown complex constants included in Eqs. (1), (2) and (3).

$$B = A - i \frac{1}{N_0} \int_{-\bar{d}_2}^{-\bar{d}_1} \epsilon_1 U_1(\xi) \cosh k(\xi+h_1) d\xi \dots (13)$$

$$C_m = \frac{1}{N_m} \int_{-\bar{d}_2}^{-\bar{d}_1} \epsilon_1 U_1(\xi) \cos k_m(\xi+h_1) d\xi \dots (14)$$

$$\begin{aligned} D = & \frac{1}{2 N_0' \tan k' l} \left[ \int_{-\bar{d}_2}^{-\bar{d}_1} \epsilon_1 U_1(\xi) \cosh k'(\xi+h_2) d\xi \right. \\ & \left. - \int_{-\bar{d}_4}^{-\bar{d}_3} \epsilon_2 U_2(\xi) \cosh k'(\xi+h_2) d\xi \right] \dots (15) \end{aligned}$$

$$\begin{aligned} E = & \frac{1}{2 N_0' \cot k' l} \left[ \int_{-\bar{d}_2}^{-\bar{d}_1} \epsilon_1 U_1(\xi) \cosh k'(\xi+h_2) d\xi \right. \\ & \left. + \int_{-\bar{d}_4}^{-\bar{d}_3} \epsilon_2 U_2(\xi) \cosh k'(\xi+h_2) d\xi \right] \dots (16) \end{aligned}$$

$$\begin{aligned} F_n = & \frac{1}{2 N_n' \tanh k_n' l} \left[ \int_{-\bar{d}_2}^{-\bar{d}_1} \epsilon_1 U_1(\xi) \cos k_n'(\xi+h_2) d\xi \right. \\ & \left. + \int_{-\bar{d}_4}^{-\bar{d}_3} \epsilon_2 U_2(\xi) \cos k_n'(\xi+h_2) d\xi \right] \dots (17) \end{aligned}$$

$$\begin{aligned} G_n = & \frac{1}{2 N_n' \coth k_n' l} \left[ \int_{-\bar{d}_2}^{-\bar{d}_1} \epsilon_1 U_1(\xi) \cos k_n'(\xi+h_2) d\xi \right. \\ & \left. + \int_{-\bar{d}_4}^{-\bar{d}_3} \epsilon_2 U_2(\xi) \cos k_n'(\xi+h_2) d\xi \right] \dots (18) \end{aligned}$$

$$I = i \frac{1}{N_0''} \int_{-\bar{d}_4}^{-\bar{d}_3} \epsilon_2 U_2(\xi) \cosh k''(\xi+h_3) d\xi \dots (19)$$

$$J_3 = -\frac{1}{N_3''} \int_{-d_4}^{-d_3} \epsilon_2 U_2(\xi) \cos k_S''(\xi+h_3) d\xi \quad \dots\dots(20)$$

where,

$$\left. \begin{aligned} N_0 &= \frac{\sinh 2 kh_1 + 2 kh_1}{4 \cosh kh_1}, & N_m &= \frac{\sin 2 kmh_1 + 2 kmh_1}{4 \cos kmh_1} \\ N_0' &= \frac{\sinh 2 k'h_2 + 2 k'h_2}{4 \cosh k'h_2}, & N_m' &= \frac{\sin 2 k_n'h_2 + 2 k_n'h_2}{4 \cos k_n'h_2} \\ N_0'' &= \frac{\sinh 2 k''h_3 + 2 k''h_3}{4 \cosh k''h_3}, & N_3'' &= \frac{\sin 2 k_S''h_3 + 2 k_S''h_3}{4 \cos k_S''h_3} \end{aligned} \right\} \dots\dots(21)$$

The principle of conservation of momentum at the pervious part of the front wall requires the following condition as shown by Mei et al.:

$$P_{x-2} = P_{x-1} + \rho \left( \frac{1}{2} C_1^* |U_1 e^{i\sigma t}| U_1 e^{i\sigma t} + L_1^* \frac{\partial}{\partial t} (U_1 e^{i\sigma t}) \right) \quad \dots\dots(22)$$

where,  $P$  is fluid pressure,  $\rho$  is fluid density,  $C^*$  is head loss coefficient, and  $L^*$  is apparent orifice length. From the condition in which the energy loss for one period in a linear system is equivalent to that in a non-linear system, the linear resistance coefficient  $f$  is given as follows:

$$f_1^* = \frac{4}{3\pi} C_1^* \bar{U}_1 \quad \dots\dots(23)$$

where,  $u_1 = \bar{U}_1 \sin \sigma t$ . Consequently, Eq. (22) is expressed by the velocity potential as follows:

$$\phi_2|_{x-1} - \phi_1|_{x-2} + \beta_1 \left. \frac{\partial \phi_2}{\partial x} \right|_{x-1} = 0 \quad \dots\dots(24)$$

$$\beta_1 = \frac{1}{\epsilon_1} \left( i \frac{f_1^*}{\sigma} - L_1^* \right) \quad \dots\dots(25)$$

In the same way, we obtain the relationships below with respect to the rear wall,

$$\phi_3|x_2 - \phi_2|x_1 + \beta_2 \left. \frac{\partial \phi_2}{\partial x} \right|_{x_1} = 0 \quad \dots\dots(26)$$

$$\left. \begin{aligned} \beta_2 &= \frac{1}{\epsilon_2} \left( i \frac{f_2^*}{\sigma} - L_2^* \right) \\ f_2^* &= \frac{4}{3\pi} C_2^* \bar{U}_2 \end{aligned} \right\} \dots\dots(27)$$

Substituting Eqs. (1) to (3) into Eqs. (24) and (26), we have the following relationships:

$$\{D(1 + \beta_1 k^t \tan k'l) - E(1 - \beta_1 k^t \cot k'l)\} \cdot \frac{\cosh k'(z+h_2)}{\cosh k'h_2}$$

$$\begin{aligned}
 & + \sum_{n=1}^{\infty} \{F_n(1 - \beta_1 k_n' \tanh k_n' l) - G_n(1 - \beta_1 k_n' \coth k_n' l)\} \\
 & \frac{\cos k_n'(z+h_2)}{\cos k_n'h_2} - (A+B) \frac{\cosh k(z+h_1)}{\cosh kh_1} - \sum_{m=1}^{\infty} C_m \frac{\cos k_m(z+h_1)}{\cos k_m h_1} = 0
 \end{aligned}
 \tag{28}$$

$$\begin{aligned}
 & \{D(1 + \beta_2 k' \tan k'l) + E(1 - \beta_2 k' \cot k'l)\} \cdot \frac{\cosh k'(z+h_2)}{\cosh k'h_2} \\
 & + \sum_{n=1}^{\infty} \{F_n(1 - \beta_2 k_n' \tanh k_n' l) + G_n(1 - \beta_2 k_n' \coth k_n' l)\} \\
 & \frac{\cos k_n'(z+h_2)}{\cos k_n'h_2} - \frac{\cosh k''(z+h_3)}{\cosh k''h_3} - \sum_{s=1}^{\infty} J_s \frac{\cos k_s''(z+h_3)}{\cos k_s''h_3} = 0
 \end{aligned}
 \tag{29}$$

Then, substituting Eqs. (13) to (20) into Eqs. (28) and (29) and making a rearrangement, we get, finally, the following results:

$$\epsilon_1 \int_{-d_2}^{-d_1} S_1(z, \xi) U_1(\xi) d\xi + \epsilon_2 \int_{-d_4}^{-d_3} S_2(z, \xi) U_2(\xi) d\xi = A\zeta(z) \dots \tag{30}$$

$$\epsilon_1 \int_{-d_2}^{-d_1} T_1(z, \xi) U_1(\xi) d\xi + \epsilon_2 \int_{-d_4}^{-d_3} T_2(z, \xi) U_2(\xi) d\xi = 0 \dots \tag{31}$$

where,

$$\zeta(z) = \frac{2 \cosh k(z+h_1)}{\cosh kh_1} \dots \tag{32}$$

$$\begin{aligned}
 S_1(z, \xi) = & \frac{\beta_1 k' + \cot 2k'l}{N_0' \cosh k'h_2} \cosh k'(z+h_2) \cosh k'(\xi+h_2) \\
 & + i \frac{1}{N_0' \cosh kh_1} \cosh k(z+h_1) \cosh k(\xi+h_1) \\
 & + \sum_{n=1}^{\infty} \frac{\beta_1 k_n' - \coth 2k_n'l}{N_n' \cos k_n'h_2} \cos k_n'(z+h_2) \cos k_n'(\xi+h_2) \\
 & - \sum_{m=1}^{\infty} \frac{1}{N_m \cos k_m h_1} \cos k_m(z+h_1) \cos k_m(\xi+h_1) \dots \tag{33}
 \end{aligned}$$

$$\begin{aligned}
 S_2(z, \xi) = & - \frac{1}{N_0' \sin 2k'l} \frac{1}{\cosh k'h_2} \cosh k'(z+h_2) \cosh k'(\xi+h_2) \\
 & + \sum_{n=1}^{\infty} \frac{1}{N_n' \sin 2k_n'l} \frac{1}{\cosh k_n'h_2} \cos k_n'(z+h_2) \cos k_n'(\xi+h_2) \dots \tag{34}
 \end{aligned}$$

$$T_1(z, \xi) = S_2(z, \xi) \dots \tag{35}$$

$$\begin{aligned}
 T_2(z, \xi) = & \frac{\beta_2 k'' + \cot 2k''l}{N_0'' \cosh k''h_3} \cosh k''(z+h_3) \cosh k''(\xi+h_3) \\
 & + i \frac{1}{N_0'' \cosh k''h_3} \cosh k''(z+h_3) \cosh k''(\xi+h_3)
 \end{aligned}$$

$$\begin{aligned}
 & + \sum_{n=1}^{\infty} \frac{\beta_2 k_n' - \coth 2k_n' l}{N_n' \cos k_n' h_2} \cos k_n'(z+h_2) \cos k_n'(\xi+h_2) \\
 & - \sum_{s=1}^{\infty} \frac{1}{N_s'' \cos k_s'' h_3} \cos k_s''(z+h_3) \cos k_s''(\xi+h_3) \dots\dots(36)
 \end{aligned}$$

Eqs. (30) and (31) are Fredholm's simultaneous integral equations of the first kind. The integral kernels  $S_1(z, \xi)$ ,  $S_2(z, \xi)$ ,  $T_1(z, \xi)$  and  $T_2(z, \xi)$  are known, while  $U_1(\xi)$  and  $U_2(\xi)$  are unknown functions. These functions cannot be determined analytically except for special problems, and so, they must be solved numerically in terms of approximate values. Then, using weight coefficient  $R_i^n$ , we discretize the integrals of Eqs. (30) and (31) as follows:

$$\left. \begin{aligned}
 \int_{-d_2}^{-d_1} S_1(z, \xi) U_1(\xi) d\xi &= \sum_{i=1}^n R_i^n S_1(z, \xi_i) U_1(\xi_i) (d_2 - d_1) \\
 \int_{-d_4}^{-d_3} S_2(z_1, \xi) U_2(\xi) d\xi &= \sum_{i=1}^n R_i^n S_2(z, \xi_i) U_2(\xi_i) (d_4 - d_3) \\
 \int_{-d_2}^{-d_1} T_1(z, \xi) U_1(\xi) d\xi &= \sum_{i=1}^n R_i^n T_1(z, \xi_i) U_1(\xi_i) (d_2 - d_1) \\
 \int_{-d_4}^{-d_3} T_2(z, \xi) U_2(\xi) d\xi &= \sum_{i=1}^n R_i^n T_2(z, \xi_i) U_2(\xi_i) (d_4 - d_3)
 \end{aligned} \right\} \dots\dots(37)$$

Now, with

$$\begin{aligned}
 f_j &= Af(z_j), \quad U_i^{(1)} = \epsilon_1 (d_2 - d_1) U_1(\xi_i) \\
 U_i^{(2)} &= \epsilon_2 (d_4 - d_3) U_2(\xi_i) \dots\dots(38) \\
 S_{ji}^{(1)} &= S_1(z_j, \xi_i), \quad S_{ji}^{(2)} = S_2(z_j, \xi_i) \\
 T_{ji}^{(1)} &= T_1(z_j, \xi_i), \quad T_{ji}^{(2)} = T_2(z_j, \xi_i)
 \end{aligned}$$

Eqs. (30) and (31) to be finally solved will be the following in terms of matrix expression:

$$\begin{bmatrix} R_1^n S_{11}^{(1)} & \dots & R_n^n S_{1n}^{(1)} & R_1^n S_{11}^{(2)} & \dots & R_n^n S_{1n}^{(2)} \\ \vdots & & \vdots & \vdots & & \vdots \\ R_1^n S_{n1}^{(1)} & \dots & R_n^n S_{nn}^{(1)} & R_1^n S_{n1}^{(2)} & \dots & R_n^n S_{nn}^{(2)} \\ R_1^n T_{11}^{(1)} & \dots & R_n^n T_{1n}^{(1)} & R_1^n T_{11}^{(2)} & \dots & R_n^n T_{1n}^{(2)} \\ \vdots & & \vdots & \vdots & & \vdots \\ R_1^n T_{n1}^{(1)} & \dots & R_n^n T_{nn}^{(1)} & R_1^n T_{n1}^{(2)} & \dots & R_n^n T_{nn}^{(2)} \end{bmatrix} \begin{bmatrix} U_1^{(1)} \\ \vdots \\ U_n^{(1)} \\ U_1^{(2)} \\ \vdots \\ U_n^{(2)} \end{bmatrix} = \begin{bmatrix} f_1 \\ \vdots \\ f_n \\ 0 \\ \vdots \\ 0 \end{bmatrix} \dots\dots(39)$$

For incident wave of  $\eta = (H_I/2) \cdot \cos(kx - \sigma t)$ , we have constant A in region (I) as follows:

$$A = i \frac{H_I}{2} \frac{g}{\sigma} \exp(ik(l+bt_1)) \quad \dots, (40)$$

The values of  $U_i(1)$  and  $U_i(2)$  were determined in this study using the Gauss-Moor method as shown by Hidaka. On obtaining the values, reflection coefficient  $K_R$  and transmission coefficient  $K_T$  can be calculated by Eqs. (13) and (19), respectively.

#### LABORATORY EXPERIMENTS

##### 1. Experimentation Equipment and Procedures

Tests were performed in a two-dimensional wave channel made of steel, 20.0 m long, 0.6 m wide, and 1.0 m deep. The breakwater model having two slotted walls of 2.6-cm thickness was made of vinyl chloride and the front wall was fixed at 14.0 m from the wave generator plate.

The depth of water was maintained constant at 50 cm in the experiments. For wave period of 1.2 sec and incident wave height of 2 cm, the opening ratios  $\epsilon_1$  and  $\epsilon_2$  of the front and rear walls, and the chamber width  $C_w (= 2L)$  were suitably varied.

Capacitance-type wave gages were used to measure wave height. Partial clapotis was measured on the front of the model using a mobile carriage equipped with the wave gages, the reflection coefficient being calculated by Healy's method. The transmitted wave height at a location one-fourth of a wave length back of the model was determined by average of five consecutive wave heights.

##### 2. $C^*$ and $L^*$ of Slotted Wall

The head loss coefficient  $C^*$  and the apparent orifice length  $L^*$  must be determined to calculate the reflection and transmission coefficients. For one slotted wall, Mei et al. gave  $C^*$  as a function of the discharge coefficient and the opening ratio of the wall, and indicated  $L^*$  by the geometric dimensions of the wall on the basis of acoustics. Kondo and Sato connected  $C^*$  and  $L^*$  of one perforated wall with drag coefficient  $C_D$  and inertia coefficient  $C_M$  of the wall, respectively, and gave  $C^*$  as a function of both opening ratio and Reynolds number. Also, they gave the non-dimensional parameter  $L^*/L$  ( $L$ : incident wave length) as a function of the Keulegan-Carpenter number. For a caisson with a slotted front wall, Tanimoto and Yoshimoto gave  $C^*$  as a function of the opening ratio of the wall, and also, the non-dimensional parameter of  $L^*$  and the wall thickness as a function of the ratio of chamber width to wave length of the chamber. They obtained an experimental formula of  $C^*$  and  $L^*$  by minimizing the square sum of the difference between the calculated and experimental values related to the reflection coefficient. In this paper,  $C^*$  and  $L^*$  are related to  $C_D$ ,  $C_M$  and the geometric dimensions of the slotted wall, respectively, on the basis of an approach similar to that of Kondo and Sato.

To consider the equilibrium of force on the pervious wall in unsteady flow, it can be expressed as "forces generating flow" = "inertia force of fluid" + "force acting on body." The force acting on the body

can then be expressed separating into drag force and inertia force as follows:

$$Fd = \rho V_f \frac{dq}{dt} + (\rho C_D A_S \frac{|q| \cdot q}{2} + \rho C_M V_S \frac{dq}{dt}) \quad \dots (41)$$

where,  $q$ : fluid velocity in the opening part of the pervious wall,  $V_f$ : volume of fluid,  $V_S$ : volume of the non-opening part of the pervious wall,  $A_S$ : projected area of the non-opening part of the pervious wall.

As the forces which generate flow are due to the pressure gradient between the front and back of the pervious wall, Eq. (41) may be re-written as follows:

$$-\frac{1}{\rho} \frac{\partial P}{\partial x} = C_D \left( \frac{A_S}{V_T} \right) \frac{|q|q}{2} + \left( \frac{V_f}{V_T} + C_M \frac{V_S}{V_T} \right) \frac{dq}{dt} \quad \dots (42)$$

Using the opening ratio  $\epsilon$  and the wall thickness  $\Delta x$ , Eq. (42) may be expressed as:

$$-\frac{1}{\rho} \frac{\partial P}{\partial x} = C_D \frac{1-\epsilon}{\Delta x} \frac{|q|q}{2} + \{ \epsilon + C_M(1-\epsilon) \} \frac{dq}{dt} \quad \dots (43)$$

Meanwhile, the equation of motion of flow in the vicinity of the pervious wall is expressed by Eq. (22) which can be rewritten as follows:

$$-\frac{1}{\rho} \frac{P}{x} = C^* \frac{1}{\Delta x} \frac{|q|q}{2} + L^* \frac{1}{\Delta x} \frac{\partial q}{\partial t} \quad \dots (44)$$

As Eqs. (43) and (44) are equivalent,  $C^*$  and  $L^*$  will be the following:

$$\left. \begin{aligned} C^* &= C_D(1-\epsilon) \\ L^* &= \epsilon \{ 1 + C_M(1-\epsilon) \} \Delta x \end{aligned} \right\} \quad \dots (45)$$

For the inertia coefficient, we use  $C_M = 2.19$  obtained from the potential theory for a square pillar. For the drag coefficient, the following is considered. From Hino and Yamasaki, the quantity of energy dissipation per period is expressed as shown below.

$$\delta = \int_0^T F(t)q(t)dt \quad \dots (46)$$

where, the force  $F(t)$  on the pervious wall and the velocity  $q(t)$  at the opening part of the pervious wall are hypothesized as follows:

$$\left. \begin{aligned} F(t) &= \frac{1}{2} C_D \rho (1-\epsilon) h |q(t)|q(t) \\ q(t) &= q_0 \sin \sigma t \end{aligned} \right\} \quad \dots (47)$$

Substituting Eq. (47) into Eq. (46), we have the following relationship:

$$\delta = \frac{2TC_D \cdot \rho(1-\epsilon)h q_0^3}{3\pi} \dots\dots(48)$$

With  $q_0$  as the average value of the  $Z$  direction at the time phase when  $q(t)$  in Eq. (47) is at the maximum,  $q_0$  is expressed as follows:

$$q_0 = \frac{1}{h} \int_{-h}^0 \frac{1}{\epsilon} \frac{\pi H I}{T} \frac{\cosh k(z+h)}{\sinh kh} dz \dots\dots(49)$$

Consequently, substituting Eq. (49) into Eq. (48),  $\delta$  will be as follows:

$$\delta = \frac{2\pi^2 H I^3 (1-\epsilon) \rho C_D h}{3T^2 \epsilon^3 (kh)^3} \dots\dots(50)$$

or

$$\frac{\delta}{W} = C_D \frac{1-\epsilon}{\epsilon^3} \frac{1}{(kh)^3} \dots\dots(51)$$

where,

$$W = \frac{2\pi^2 H I^3 h}{3g T^2} \dots\dots(52)$$

In this case,  $\delta/W$  indicates the non-dimensional quantity concerning energy dissipation at the pervious wall. We examine  $C_D$  by means of comparing the calculated results with the experimental ones.

The ratio of energy dissipation  $E_I$  for the incident wave is expressed by the reflection coefficient  $K_R$  and the transmission coefficient  $K_T$  as follows:

$$E_I = 1 - K_R^2 - K_T^2 \dots\dots(53)$$

Hence, the quantity of energy dissipation is obtained by multiplying  $E_I$  by the energy and period of the incident wave:

$$\delta = E_t(E \cdot C_g) i \cdot T = (1 - K_R^2 - K_T^2) \cdot \frac{1}{8} \rho g H i^2 \cdot C_g i \cdot T \dots\dots(54)$$

where,  $C_g i$  indicates the group velocity of the incident wave, and is expressed as follows:

$$\left. \begin{aligned} C_g i &= n \cdot C_i \\ n &= \frac{1}{2} \left[ 1 + \frac{2 kh}{\sinh 2 kh} \right] \end{aligned} \right\} \dots\dots(55)$$

where,  $C_i$  is wave velocity. Dividing Eq. (54) by  $W$ , the non-dimensional expression with  $C_D$  corresponding to Eq. (51) as the parameter is obtained.

Figure 2 presents comparisons of  $\delta/W$  between the calculated results by Eq. (51) and the measured ones for the single-slotted wall. These results indicate that the measured values can be approximated by the calculated curve for  $C_D = 2.05$ . Also, Urashima et al. found  $C_D =$

Figure 2 Experimental and theoretical  $\delta/W$ .

2.05 and  $C_M = 2.19$  could be approached when flow velocity was defined by the actual velocity in the slot, and consequently, in this paper,  $C_D = 2.05$  was adopted for both the front and rear walls.

3. Comparisons Between Experiment and Theory

Figure 3 shows comparisons of the reflection and transmission coefficients between experiments and theory for a breakwater having a single vertical slotted wall. The measured values are in good agreement with the theory.

Figures 4 and 5 show comparisons of the experimental and theoretical reflection and transmission coefficients for a breakwater having vertical slotted walls at both the seaward and landward sides. These figures indicate a tendency for theoretical values to be in agreement with measured values, though the latter are generally smaller than the calculated results in Figure 4.

This theory is then compared with the experimental results of other researchers, Figure 6 shows comparisons of the reflection and transmission coefficients from experiments by Kono and Tsukayama and from this theory for a submerged breakwater. As for Figure 7, it shows a comparison of the transmission coefficient from experiments by Kato and Jouman and this theory for double rigid thin barriers. The theoretical results for each type of breakwater are in good agreement with

Figure 3 Breakwater with single vertical slotted wall.

Figure 4 Breakwater with double vertical slotted walls. Plots of  $K_R$ ,  $K_T$  versus  $CW/L$ .

Figure 5 Breakwater with double vertical slotted walls. Plots of  $K_R$ ,  $K_T$  versus  $\epsilon_1$ .

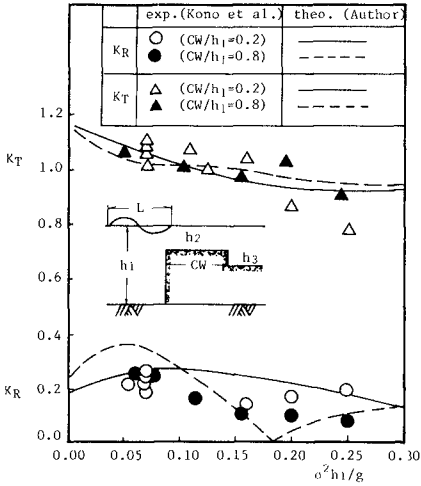

Figure 6 Submerged breakwater.

Figure 7 Double rigid thin barriers.

measured results of other researchers. Consequently, it has been found that the wave dissipating characteristics of the upright structures can be explained well by the integral equation method theory.

VARIOUS FACTORS HAVING INFLUENCES ON REFLECTION AND TRANSMISSION COEFFICIENTS

Suppose a prototype breakwater with pervious vertical walls at both seaward and landward sides and examine various factors having influences on the reflection and transmission coefficients, numerically.

Figure 8 shows the relationships between the reflection and

Figure 8  $K_R$ ,  $K_T$  and  $C_W/L$ .

Figure 9  $K_R$ ,  $K_T$  and  $\epsilon$ .

transmission coefficients  $K_R$ ,  $K_T$  and the relative chamber width  $C_W/L$  under the conditions of  $\epsilon_1 = 0.25$ ,  $\epsilon_2 = 0.1$  and  $H_I/L = 0.02$ . The reflection coefficient is a minimum at  $C_{W0}/L$  making the wave energy dissipation maximum. The value of  $C_{W0}/L$  changes by the period  $T$ , that is, the relative water depth  $h_1/L$ , and becomes large for the smaller values of  $h_1/L$ . The transmission coefficient does not change as much as the reflection coefficient for the relative chamber width and the period.

Figure 9 shows the relationships between the reflection and transmission coefficients and the opening ratios for the front and rear pervious walls under the conditions of  $H_I = 1.0$  m,  $T = 6.0$  sec, and  $C_W/L = 0.2$ .

Figure 10  $K_R$ ,  $K_T$  and  $h_2/h_1$ .

Figure 11  $K_R$ ,  $K_T$  and depth of pervious wall.

The value of  $\epsilon_1$  taking the minimum value of  $K_R$  is small as  $\epsilon_2$  decreases, but the minimum value of  $K_R$  is small as  $\epsilon_2$  increases.  $K_T$  increases as the values of both  $\epsilon_1$  and  $\epsilon_2$  become larger and larger. Consequently, the opening ratios of the front and rear pervious walls having influences on  $K_R$  and  $K_T$  are important, so it is possible to make the values of both  $K_R$  and  $K_T$  small by choosing the opening ratios appropriately.

The relationships between the reflection and transmission coefficients and the water depth in the chamber under the conditions of  $\epsilon_1 = 0.25$ ,  $\epsilon_2 = 0.1$ , and  $C_W/L = 0.25$  are shown in Figure 10. As the values of relative water depth  $h_2/h_1$  become larger and larger,  $K_R$  decreases and  $K_T$  increases, that is, as the water depth in the chamber becomes deeper than one-half of the water depth in front of the breakwater,  $K_R$  decreases suddenly depending on the period, although some amount of waves is let through to the back.

Figure 11 shows the relationships between the reflection and transmission coefficients and depth of the pervious wall under the conditions of  $H_I = 1.0$  m,  $T = 6.0$  sec,  $\epsilon_1 = 0.25$ ,  $\epsilon_2 = 0.1$ , and  $C_W/L = 0.2$ . As the depth of the rear pervious wall becomes greater,  $K_R$  decreases slightly although  $K_T$  increases gradually. Also, the depth of the front pervious wall has a great influence on  $K_R$  more than on  $K_T$ .

#### CONCLUSIONS

- (1) An analytical solution of reflection and transmission coefficients has been derived for an upright breakwater with pervious walls at both seaward and landward sides based upon an integral equation.
- (2) The head loss coefficient and apparent orifice length in the present theory have been related to the drag and inertia coefficients in the wave force equation and the geometric dimensions of the slotted wall, respectively.
- (3) The theoretical results of each type of upright breakwater have been compared with the experimental results of the author and other researchers, and as a result, it has been found that the wave dissipating characteristics of the upright structure with the pervious wall can be explained well by the present theory.
- (4) For the purpose of making both the values of the reflection and transmission coefficients small, it is important to determine the relative chamber width and the opening ratio of the pervious wall appropriately.

#### ABSTRACT

Southern California was subjected to a series of severe winter storms in 1983 that caused record damages to the coast. In the aftermath of the storms, emergency repairs were made and new designs were developed that responded to the severe conditions. These designs were often considerably more conservative than those previously undertaken. Agencies, owners, and engineers were compelled to use both higher design criteria and longer recurrence intervals to account for the wave characteristics and water levels that caused damages along the coast. This paper briefly discusses the unusual circumstances of the storm conditions and the associated damages. The primary purpose of the paper is to present new data that incorporates the effects of the 1983 winter storms to estimate the change in perception of what the wave climate and design criteria may be in this highly developed coastline. The results indicate that the design wave height for a given recurrence interval has increased approximately 26 percent, the wave periods are longer than previously used, and the severe storms tend to coincide with the extreme water levels. The engineer should consider the impacts of the 1983 winter storms in future designs. Despite the record damages, many structures survived. Merely using the highest water elevations and most severe waves of record may not be the most prudent design criteria. The concept of project life and economics must be employed to develop a design.

## INTRODUCTION

A series of intense storms during the winter of 1983 caused extensive damages to the Southern California coast. Several piers, breakwaters, revetments, homes and beaches were damaged due to a combination of unusually high waves with long periods from an unusual direction of approach coincident with high water elevations. In the aftermath of the storms, public outcry was for more stringent design criteria. Newspapers across the state quoted expert opinion that the wave conditions and water elevations experienced in 1983 were only the beginning of a long-term trend of severe weather for the state and the 1983 storms should be used as the new design storms. The addition of new storm waves and water levels plus the increase of design recurrence intervals may result in an unwarranted compounded increase in design criteria.

## RECENT COASTAL DAMAGES

The winter of 1983 was characterized by several extreme extratropical storm events that occurred during high water levels. The storm events were among the strongest of recorded history; the water levels were the highest of recorded history. The severity of the storm events and the high water levels have been associated with the El Nino-Southern Oscillation (ENSO) as described by Seymour, Strange, Cayan and Nathan (11). These storms were estimated by the U.S. Army Corps of Engineers and the State of California (14) to have caused in excess of \$116 million to coastal structures. Figure 1 shows a summary of the piers that were damaged and Figure 2 is a summary of the breakwaters and jetties that were damaged. Over 70 percent of the damages occurred in Southern California. Several beaches lost considerable quantities of sand and there was conjecture that these beaches would never return because the sand was carried too far offshore to return under normal wave conditions. Many coastal streets, utilities, homes and restaurants were flooded by overtopping waves and high water levels. An oil island located off Seal Beach was completely destroyed. Many of the destroyed structures had survived for 80 years with only minor repairs. Other structures were in need of repair prior to the storms. The primary factors in the damaged structures appear to be the extreme high water level and the high waves with unusually long wave periods approaching from a westerly direction.

Two examples of damages were the San Pedro Breakwater and the San Clemente Pier. The San Pedro Breakwater that protects Los Angeles Harbor was built in the early 1900's. Overtopping waves caused a 400-foot (122 meters) long gap after 80 years of service. A post-storm survey by the U.S. Army Corps of Engineers (13) indicated that there were 166 repair areas to the breakwater and that 87 percent of the failures were on the backslope. Walker, et al. (15) explains the failure mechanism due to excessive water levels and wave heights in relation to the crest elevation. Another mode of failure was the possibility that the stone size was not sufficient for the storm event. The breakwater was repaired by the U.S. Army Corps of Engineers in a manner similar to the original construction.

Figure 1. Pier Damage

Figure 2. Breakwater and Jetty Damage

The San Clemente Pier was a wooden pile structure that lost approximately 500 feet of the seaward end. Figure 3 shows the existing pier elevation and depth-controlled breakers. Two wave crest elevations are given. The one labeled "prior to 1983" represents the depth-controlled breaker on a 6.0-foot (1.8 meters) mean lower low water elevation that was used as the original design criterion. The wave crest elevation labeled "1983" represents the depth-controlled breaker on a recorded 7.5-foot (2.3 meters) mean lower low water elevation that was measured in San Diego Harbor during one of the events in 1983 that damaged the pier. In this case, damage was attributed to the combination of the wave crest exceeding the pier deck, scour at the sea bed, excessive wave-induced forces on deteriorated piles, and broken pile debris impacting on other piles. Arbitrarily raising design criteria in one aspect may not solve all of the problems. The damage can be readily described using normal water elevations without the need to resort to wave setup and other factors that could raise the water level by 2.0 to 3.0 feet (0.6 to 0.9 meters).

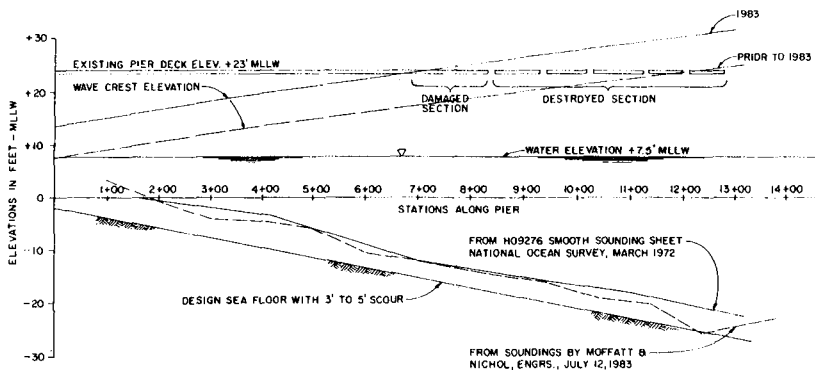

Figure 3. San Clemente Pier

#### EFFECTS OF 1982-1983 WINTER

The ENSO of 1982-1983 was exceptionally strong and had several effects that lead scientists and engineers to suspect that there may be a correlation between high water levels and storm events. When strong ENSOs occur, the water levels are increased, the extratropical cyclones approach from more westerly directions and are closer to the coast, wave heights are higher and periods are greater [see Seymour, et al. (11)]. Shoreline segments that are typically sheltered by the offshore islands and refraction effects from northwesterly waves were more directly exposed to the westerly waves.

### Water Elevations

Prior to 1983, water levels were based primarily on the recordings of nearby harbors such as the gages at Los Angeles and San Diego. These gages incorporated the effects of astronomical tides, ENSO anomalies and some components of storm surge such as the barometric effect. Designers would often add a foot to some water level to account for storm surge and wave setup.

Table 1 is a summary of design water elevations taken from design documents<sup>1</sup> over the last 40 years for typical shore protection structures. Design water elevations were typically lower than the highest of record. The rationale for this was that the probability of the design wave occurring at the same time as the highest water elevation is small. Design water elevations for shore protection structures have increased from mean higher high water [5.4 feet (1.6 meters) above mean lower low water] in the 1940's and 1950's to 10.0 feet (3.0 meters) above mean lower low water in 1984. Design reports showed an increase of 2.0 to 4.0 feet (0.6 to 1.2 meters) following the 1983 winter storms.

TABLE 1

#### Design Water Elevations

1940's - 50's: 5.4 to 6.0 feet (1.6 to 1.8 meters) above MLLW  
1960's - 70's: 6.0 to 7.0 feet (1.8 to 2.1 meters) above MLLW  
1980's: 7.0 to 7.5 feet (2.1 to 2.3 meters) above MLLW  
After 1983 storms: 8.0 to 10.0 feet (2.4 to 3.0 meters) above MLLW

In Southern California, the highest tides of the year usually occur in January; the same month which extratropical storms frequently occur. Record-high water elevations of 7.96 feet (2.43 meters) above mean lower low water and 8.35 feet (2.55 meters) above mean lower low water were recorded on January 27, 1983 at Los Angeles and San Diego, respectively. At the same time, deepwater significant wave heights up to 27.0 feet (8.2 meters) were recorded offshore. The previous record-high water elevations occurred on November 30, 1982. The recorded elevations were 8.09 feet (2.47 meters) above mean lower low water at San Diego and 7.76 feet (2.37 meters) above mean lower low water at Los Angeles.

Recorded annual extreme high water elevations obtained from the National Ocean Service for the San Diego Bay and Los Angeles Outer Harbor reference tide stations were statistically analyzed using the Gumbel (also termed Fisher-Tippett I) distribution. The "tide year" was defined as September to the following August such that the winter season is included within the year. Water elevation records from the San Diego station are available from 1926; Los Angeles water elevation records are available from 1923.

---

<sup>1</sup>The principal source is U.S. Army Corps of Engineers, Los Angeles District, General Design Memorandums.

Figure 4 is a plot of the annual extreme high water elevations versus recurrence intervals for the San Diego and Los Angeles stations, respectively. For each station, the dashed line is a plot of the annual extremes prior to the 1982-1983 record-high water elevation; the solid line is a plot of the annual extremes which have incorporated the record-high water elevation into the data set.

Comparing annual extreme high water elevations at the Los Angeles tide station before and after the 1982-1983 record-high water elevations show that an 8.0-foot (2.4 meters) mean lower low water elevation prior to 1982-1983 has a recurrence interval of approximately 130 years. When the record-high water elevation is added to the data set, the recurrence interval for an 8.0-foot (2.4 meters) water elevation is now approximately 80 years. A 10.0-foot (3.0 meters) mean lower low water elevation with the 1982-1983 water elevation included in the data set has a recurrence interval greater than 500 years. A similar trend is shown for the San Diego Harbor station.

#### Wave Characteristics

Selection of design wave characteristics for coastal structures in Southern California is either based on published hindcasted wave data for a station in deep water or on a hindcast for a specific site. The published data sources typically used in Southern California are hindcasted wave data from the most severe storms occurring between 1900 and 1957 by Marine Advisers (5), from 3-year hindcasts by Marine Advisers (6) and by National Marine Consultants (9), or from once-daily wave computations from 1951 to 1974 by Meteorology International Incorporated (7). Measured wave data which was available during these periods formed short records or records with notable gaps during high wave episodes. Design waves were therefore obtained strictly through hindcast techniques, which differed considerably as a result of a number of factors. First, and most important, is the lack of good meteorological data from ships at sea prior to the mid-1940's. Compounding the problem is the fact that wave forecast techniques differ appreciably among themselves and all utilize empirical wave data collected in the Atlantic, not the Pacific. The same forecast techniques can produce different results when used independently by meteorologists whose experience in the field may differ.

The Marine Advisers (6) and National Marine Consultants (9) wave hindcasts were presented as monthly and annual averages and do not include specific storm wave characteristics. The Marine Advisers (5) and Meteorology International Incorporated (7) do include extreme storm wave characteristics over periods of 58 and 24 years, respectively. The Marine Advisers hindcasts have been used extensively but the Meteorology International Incorporated hindcasts have been judged to be deficient [see Cross (12) and Strange (12)]. For example, only four storms producing combined wave heights of 16 feet (5 meters) or more in twenty-four years were noted. Two of these were not during the storm season, and none of the well-documented high wave episodes are reflected in the statistics. Results of this hindcast have been studied in detail with the conclusion that there are major problems with the methods employed. Therefore, no further

Figure 4. Water Elevation vs. Recurrence Interval

Figure 5. Wave Height Distribution, 1900-1957

Figure 6. Wave Height Distribution, 1900-1983

consideration is given to the Meteorology International Incorporated wave hindcasted data for purposes of this paper.

The Marine Advisers (5) hindcast study was prepared for the U.S. Army Corps of Engineers to evaluate characteristics of severest probable waves as a basis for design of small-craft harbor protective structures at Oceanside and Dana Point. This study has subsequently been used to determine design waves for other marinas, seawalls, and offshore oil platforms from San Diego County to Los Angeles County. Weather maps, newspapers, and ship observations from 1900 to 1957 were examined. Fifteen storms were selected based on reports for their general severity or coastal damage. Two of the fifteen selected storms gave lower wave heights than anticipated and were thus excluded. Table 2 is a list of the hindcasted results in an exposed deepwater location for the remaining 13 storms.

Following the 1983 storms, the Marine Advisers severe storm hindcasted wave data set was updated with wave hindcasts prepared by Pacific Weather Analysis (10) for severe storms occurring between 1958 and 1983 in Southern California in deep water outside the offshore islands. Table 3 is a summary of the maximum wave characteristics hindcasted for each of the storms by Pacific Weather Analysis.

Direct comparison of Tables 2 and 3 is not statistically valid. The wave hindcasts were prepared using different procedures, different quantities of synoptic data, different time periods, and varying degrees of experience which have calibrated wave hindcasts with

<sup>a</sup>tropical storm

Source: Pacific Weather Analysis (10)

recent wave measurements. The proper procedure would be to update all storms of record using similar hindcast procedures. Such an effort was not possible for the purposes of this paper. It was assumed that the methodologies of the two hindcasts are similar enough to permit a reasonable estimate of wave height distribution over the entire period of record.

The extreme wave statistics presented in Tables 2 and 3 have waves from two meteorological sources: extratropical storms and tropical storms. The most frequent and severe waves are due to the extratropical storms. However, the largest hindcasted wave event of record was the 1939 tropical storm that made landfall in Southern California. The three maximum tropical storm swells in Table 3 are included for comparison with the 1939 event. The 1939 tropical storm is usually treated as a rare event and is not included as a design condition for most structures. However, the consequences of damages in the event that another tropical storm similar to the 1939 storm occurs should be considered in design of structures.

The distribution of wave heights without the tropical storms which were used prior to 1983 and after 1983 are compared. Rather than select one probability distribution a priori, five different distributions as described by Isaacson and MacKenzie (4) are fitted to the wave data using a least squares fit; the best-fit curve is then selected among the log-normal, Gumbel, Fretchet, Weibull lower-bound, and Weibull upper-bound distributions. The selected distribution for both data sets is the Weibull lower-bound.

The deepwater wave height distribution for Southern California using the Marine Advisers data set without the 1939 tropical storm is shown in Figure 5. The 100-year recurrence interval wave height is 6.6 meters (21.7 feet). Figure 6 shows the effect of including the severe waves of 1983 and the addition of hindcasts from 1958 to 1983 without the tropical storms. The 100-year recurrence interval wave height is now 8.3 meters (27.2 feet). The additional data increased the 100-year recurrence interval wave height in deep water outside the offshore islands by 25.8 percent.

Measured and hindcasted wave data indicated that peak energy periods were much longer than previously considered. The measured data were from NOAA buoys recently installed in deep water off the coast of California. Prior to the recent storms, typical design waves had periods of 10 to 14 seconds. Some previously used hindcasted data sets indicated that waves of 14 seconds or more existed only as low forerunners. The buoy data on the other hand as shown in Table 4, indicate that rarely is there a high wave episode with peak energy periods below 14 seconds. The peak wave energy periods for the 1983 winter storms ranged from 14 to 25 seconds and these were associated with the peak wave heights.

Another characteristic of the 1983 storms was the direction of wave approach. The storm waves approached from a more westerly direction than normal; 280 degrees in the 1982-1983 winter as opposed to a long term average of 290 degrees. Areas typically sheltered by offshore islands or by refraction effects, such as the Los Angeles Harbor were directly exposed to storm waves as shown in Figure 7. The pre-frontal winds also generated local seas from the south that were higher than normal, and in some cases arrived simultaneously with the westerly swell.

## DISCUSSION

The recent storm events of 1983 have dramatically changed the concept of design criteria. Not only have the individual parameters of wave height, wave period, and water level changed, but also the simultaneous occurrence has been revealed as more likely. The extreme storm events of 1983 would have been classified as having wave heights with over 100-year recurrence intervals prior to their occurrence. The storm waves are now considered to have recurrence intervals on the order of 40 years. These individual storm waves must be brought to shore past the offshore islands and refracted across locally complex bathymetry to nearshore sites. Recurrence intervals are therefore likely to show wide variation from site to site. For instance, design calculations for the San Clemente Pier indicate that the recurrence interval for wave heights hindcasted during the March 1983 storm which would be directly exposed to the site is 100 to 150 years.. [see Moffatt & Nichol, Engineers (8)]. A blanket acceptance

of this storm and the exceptional water levels for all coastal sites and problems may lead to unrealistic design requirements. The engineer needs to analyze the data at the particular site including the particular design circumstances such as safety aspects, economic consequences of the design parameters being exceeded, and the particular experience with similar structures. These data should be discussed with the client to evaluate the risk levels involved; it should be recognized that rare and unusual events can and do occur.

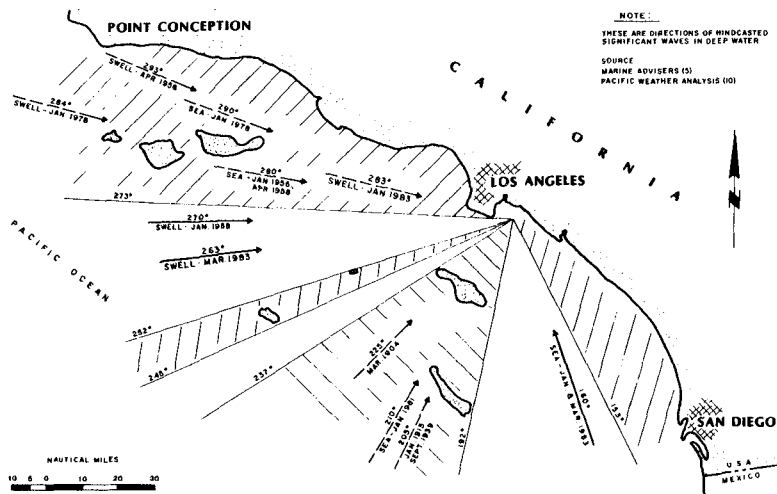

Figure 7. Wave Exposure

The extreme high water levels measured in 1983 coincident with the severe storm waves have caused coastal flooding that has not occurred in the past. This has prompted designers to look for justification for higher design water levels. Review of some of the recent design reports by the authors indicate a compounding of water levels has occurred. For instance, the record-high water level measurements include astronomical tide, barometric tide, sea level rises, and ENSO effects. Addition of 1.0 or 2.0 feet (0.3 to 0.6 meters) to account for these effects appears to be a duplication of the effects. Review of Figure 4 indicates that the 100-year recurrence interval water elevation should be on the order of 8.0 feet (2.4 meters) above mean lower low water at Los Angeles Harbor and about 8.3 feet (2.5 meters) above mean lower low water at San Diego Harbor.

Care should also be exercised in application of the wave setup term. Wave setup varies as a function of the breaking wave characteristics and relative position in the surf zone. For instance, the breaker point has a set down and setup is a maximum at the beach. Large waves persistently breaking offshore may induce a setup on the beach which raises the water level near the shoreline, but not at the seaward end of a pier.

## CONCLUSIONS

The following specific conclusions regarding the relation of the 1983 winter storms to previously used criteria which has been used in design of many coastal projects in Southern California are presented. These conclusions are presented to document the relative importance of the recent storms and to discuss their potential impact on future design policies. No attempt is made herein to establish a specific design criteria.

1. The deepwater wave height for a 20-year recurrence interval and a 50-year recurrence interval has increased from 16.5 and 19.5 feet (5.0 and 6.0 meters) to 21.5 and 25.0 feet (6.5 and 7.6 meters), respectively.
2. The wave period associated with an extratropical storm has increased from a range of 10 to 14 seconds to 14 to 25 seconds.
3. Severe storms usually approach from a more westerly direction during ENSO events.
4. The simultaneous occurrence of an extreme water level and extreme wave event must be considered as dependent events to a greater degree than has been customary.
5. The 1982-1983 winter had three of the top five extreme wave events in deep water over the past 80 years.
6. The coastal damages which occurred were due to a combination of factors including extreme water level, extreme wave height, extreme wave period, direction of approach which exposed segments of shoreline that are traditionally protected by the offshore islands, and to the aged condition of some of the pile structures.
7. Employing all of the considerations cited above may lead to a significant increase in design criteria which could lead to some very conservative and expensive designs.

## RECOMMENDATIONS

It is recommended that designers of coastal structures consider the effects of the 1983 winter storms in their new designs, but that the increase in water level and wave characteristics be evaluated in terms of how neighboring structures performed during the storms and the economical and safety consequences of the design being exceeded by larger waves. It may be very difficult for the engineer to use a 100-year design storm and water level criteria based on the new data set and current design procedures with non-linear waves compared to a 20-year design storm and water level using statistics developed in 1960 and linear wave theories. For instance, most of the breakwaters on the Southern California coast were built using previous criteria. The local rock quarries can supply up to about 12 to 16 ton armor stone and these structures have functioned reasonably well over their project life. If strict application of the data set with the 1983

storms included, quarry stone would be considered impractical and more expensive precast concrete armor units would be required. Then the engineering design must more seriously consider the economics of repairs to the stone structures and the risk of damages. While these optimization design procedures are documented by Bruun (1) and the Delft University of Technology (3), they are rarely explicitly applied in Southern California because local traditional methods have been satisfactory until 1983.

## CHAPTER ONE HUNDRED NINETY

### A SIMULATION METHOD FOR SMALL CRAFT HARBOUR MODELS

by

Dov Sergiu Rosen<sup>1</sup>, M.ASCE and Eliezer Kit<sup>2</sup>

#### ABSTRACT

A simulation method is presented to improve small craft harbour design by studying the behaviour of moored vessels in small craft harbours, using physical modelling in medium size wave basins, available at most laboratories. Instead of carrying the study in an agitation model with moored vessel models and built in a large wave basin at a large geometric scale, it is performed in two consecutive models of different scales, in a medium size basin. Transfer functions of vessel movements and mooring and fender forces are determined in the first model, for representative types of vessels moored alternately at a solitary berth, under simulated inside harbour conditions and for various sea states and directions. Near berth wave spectra are obtained in the second (agitation) model for sea states covering the local climate. Integration of the wave spectra with the transfer functions leads to response spectra of vessel movements and forces. Finally, maximum movements and forces are determined from the response spectra and are used together with limiting criteria and the long term wave statistics to choose the optimum configuration of: harbour layout, types of berth structures and mooring and fendering systems.

#### INTRODUCTION

The design of small craft harbours has usually been based on agitation models in which only waves were measured inside and in the surroundings of the simulated breakwaters' layout of a small craft harbour model, for various incident wave heights, periods and directions. The types of wave disturbance studied were short wave disturbance induced by gravity waves (periods 3-30 sec) and seiche disturbance induced by infragravity waves (periods 30-180 sec). The wave disturbance data required in the agitation model have been used to determine the optimum layout and the optimum types of structures of the designed small craft harbour, on the basis of empirical rules regarding allowable wave heights and current strength. Such rules, specifying only the maximum allowable wave height near a harbour berth were presented by Dunham and Finn (4), Le Mehaute (7), Mercer et al. (8). It was clear that such criteria could be used only as general guidance for small craft harbour design but that they were not sufficient for an optimum design

<sup>2</sup> Senior Researcher, Ph.D., CAMERI-Coastal and Marine Engineering Research Institute, Technion City, Haifa 32000, Israel.

including harbour layout, inner harbour configuration, type of berth structure for each berth and mooring and fendering systems. Therefore, it is not surprising that the importance of simulating moored vessel behaviour in the model for reliable design of large commercial harbours has been recognized many years ago Vasco Costa(13), and nowadays has become the usual modelling procedure. Although the same importance was attributed to simulating moored vessels for the design of small craft harbours, its application was performed only in few small craft harbour studies, e.g. Isaacson and Mercer (5). Most of the model studies of small craft harbours however, continued to be carried out in agitation models lacking the presence of moored vessel models, Stickland (12). The lack of moored vessels in the simulated models seems to be due to the difficulty to fulfill simultaneously the two following requirements:

- a) The harbour model should cover the area of the harbour and its surroundings. Hence, it has to be built at a relatively small geometric scale (1:80 - 1:125) in order to fit into a medium size wave basin (available at most laboratories).
- b) The models of small vessels (sailboats, lighters, trawlers, patrol boats, etc.) have to be made at relatively large geometric scales (1:20 - 1:50). Since such vessels are light and have small displacements (compared to commercial ships) this requirement is necessary in order to allow the correct simulation of loading conditions (displacement, mass distributions) and natural periods of oscillation(roll,pitch) as well as accurate measurements of vessel movements and of forces in the mooring lines and into the berth fenders.

Obviously, these requirements could be fulfilled only when a large size wave basin was available. Even then, vessel models were usually not used, due to the much increased costs for building the model and carrying out the study of the small craft harbour at a large scale relatively to the expenses of a model built at a small geometric scale (about 4:1).

This paper presents a simulation method which includes the study of moored small craft vessels, but which allows to carry out the model study in a medium size basin and at competitive costs performance, relatively to those of an agitation model without vessel models. (Costs about 1.5 - 2 times more than those of an agitation model). Furthermore, using this simulation method, the simultaneous fulfillment of the above requirements a) and b) is no longer necessary. This method was applied at CAMERI for the design study of a relatively large fishing harbour.

#### DESCRIPTION OF THE MODEL SIMULATION METHOD

##### General Concept

Two basic concepts stay behind the present simulation method. The first one, known as the Froude-Kriloff hypothesis (see Korvin-Kroukovsky (6)) states that the effect of a vessel located in a wave field on that wave field can be considered negligible. Consequently, the measurements of the wave field in an agitation model are expected to provide all the necessary information required to forecast the behaviour of a vessel

in that wave field, if the transfer functions relating the input waves with the response behaviour of the vessel are known.

The second concept, known as the Froude hypothesis on linear superposition, states that the resulting amplitudes of movements of a vessel located in an irregular wave field can be determined by linear superposition of the separate contributions of regular waves of corresponding wave energy at each frequency band to that existing in the irregular field at that frequency band.

On the basis of these two concepts, the simulation procedure assumes that the results which would be obtained from a physical model with moored vessel models built at a large geometric scale (say 1:30-1:50), may also be sufficiently accurately determined in the case of a small craft harbour built in shallow water, by dividing the study into two separate physical models and by combining analytically the results of these two studies.

The first model would be a "moored seakeeping model study" in which the transfer functions of vessel movements and mooring and fender forces are determined for various wave conditions, while the second model would be an "agitation model" in which near-berth wave spectra are measured and logged for various harbour configurations and for various representative sea states covering the wave climate at the site of the proposed small craft harbour. The application of the measured wave spectra on the transfer functions determined, would provide response spectra of moored vessel movements and mooring and fender forces, from which maximum movements and forces can be determined. The combination of the results obtained for various types of vessels, and for various types of harbour configurations due to various sea states, with the limiting criteria of vessel movements, mooring and fender forces and harbour entrance wave heights and with the statistics of the long term wave climate, would allow the choice of the optimum configuration of breakwaters layout, berth structures and mooring and fendering systems and would ensure the optimum operability and safety of the small craft harbour design.

Since each of the above mentioned models can be carried out separately, each of them can be performed at its optimum geometric scale. Each one would usually fit in a medium size wave basin and they may be carried out in two consecutive testing stages.

The general simulation procedure is schematically presented in Figure 1.

#### Moored Seakeeping Model Study

In order to obtain the transfer functions of the vessel movements and of the mooring and fender forces for relevant vessels representing the fleet determined to be serviced by the proposed fishing harbour, a moored seakeeping model study was carried out. The model was built in a wave tank of limited overall dimensions (24x 26m), at a geometric scale of 1:50, large enough for the simulation of the vessels considered. Two types of vessels were chosen for the study, namely a trawler of 800 DWT and a tuna boat of 400 DWT. Each of the vessel models was calibrated for two loading conditions, one of ballast at departure, the other of laden at arrival.

The vessel models were alternately moored at a solitary berth in a number of alternative mooring and fendering systems of varying stiffness,

	FREQUENCY DOMAIN	TIME DOMAIN
Stage 2 - Agitation model study	Incident wave energy spectrum (outside harbour) 	+  +  • • • = 
	Transfer function of the waves energy at a certain harbour berth 	Response (height of regular waves near berth) = Incident wave height (outside harbour)
	Response wave energy spectrum at a certain harbour berth 	For regular waves by calculation +  +  • • • =  For irregular waves directly 
Stage 1 - Moored seakeeping model study	Transfer function (of movement or of a force) 	Response amplitude (of movement or force) = Wave height near berth
Stage 3 - Integration of the results of stage 1 and stage 2	Response spectrum (of movement or force when a vessel is moored at the certain berth) 	+  +  • • • = 

Fig. 1. Schematic description of the procedure to obtain response spectra of vessel movements and forces in mooring lines and in fenders by linear superposition.

while the berth structure was alternately changed to represent three types of berth structure; an open structure on piles, an impervious wave reflecting sheet pile structure and an impervious but wave absorbing rubble slope beneath a piles supported structure. The models of mooring lines and fenders were made in such a way as to correctly represent the nonlinear load deflection curves of the mooring lines and the nonlinear load compression curves of the fender units. For the model of a mooring line the correct load deflection was achieved by attaching one of the ends of a stiff thread representing the mooring line to two linear springs located on the vessel model and the other end to a force transducer located on the berth. Of the two springs only one worked at the beginning while after a certain loading was achieved both springs worked together (see Fig. 2).

For the model of a fender unit the non linear load compression curve was obtained also with the aid of two linear springs located one inside the other and working in a similar way as the springs of a mooring line model (see Fig. 3).

Vessel movements were measured with the aid of rotational potentiometers, forces were measured by means of linear displacement voltage transducers and waves were measured by resistance type wave gauges, (see Fig. 7). Unidirectional incident waves of regular and irregular type were separately generated in transient water depth. The incident waves were adequately shoaled by sloping bottom and then were propagated over a constant water depth section on which the solitary berth was located. The water depth at that section corresponded to the designed water depth inside the proposed harbour. In this way the direct excitation of near-berth shoaled waves on the moored vessel model was obtained for various conditions tested.

The measured movements, forces and wave data were statistically analyzed in real time and logged on magnetic media by a minicomputer system which controlled also the wave generation.

The tests with regular waves covered the wave periods range corresponding to gravity and infragravity waves (3-30 sec and 30-60 sec). The tests with irregular waves were performed to study the additional effects of drift forces (induced by wave groups) on the moored vessels, because these forces are not obtained with regular waves. For both wave types a few wave heights (calibrated in the absence of vessels) were tested with various configurations. The wave heights range was from 0.2 m to 0.8 m (prototype). Care was taken to remove parasitic components of the waves generated. Under these circumstances, the response amplitude operators (RAO), i.e. the transfer functions of the vessel movements and forces were determined for three angles of wave incidence considered relevant in this study ( $0^\circ$ ,  $30^\circ$ ,  $60^\circ$ ) relative to the vessel longitudinal axis.

#### Agitation Model Study

After the moored seakeeping model study was finished, an agitation model in fix bed was built in the same wave tank at a geometric scale of 1:100. The model covered the harbour and its surroundings in order to allow the correct simulation of boundary conditions. Various sea states, covering the local climate at the site of the proposed harbour were generated using unidirectional irregular waves (in situ recorded) for various configurations (i.e. for various layouts

Fig. 2. Schematic modelling of load-elongation characteristics of a mooring line.

Fig. 3. Schematic description of a fender model.

of the protecting breakwaters, for various inner harbour layouts of the berths and for various types of berth structure). The wave data measured at the various harbour berths as well as these measured at the harbour entrance and at various locations in the surroundings of the harbour were statistically processed in real time and were logged on magnetic media by a minicomputer system. Off line spectral processing of the logged wave data yielded the response wave spectra of the harbour at every berth as induced by the various incident deep water sea states. These response wave spectra of the harbour to the external wave excitation became the input wave spectra which would be applied on vessels moored at the harbour berths. The wave spectra measured for various wave conditions at a majority of harbour berths showed wave energy concentration in two frequency ranges: one with less energy in the high frequency range, the other with equal or more energy in the low frequency range.

It is estimated that the concentration of wave energy in the low frequency range is related to the interaction between the wave groups with the harbour geometry.

Examples of incident wave spectra in deep water and in shallow water and for the corresponding inside harbour wave spectra, are shown for four sea states in Fig. 4, 5 and 6.

Since the wave field inside the harbour is composed of incident waves entering the harbour and of reflected waves from the harbour structures, the directional spectrum of the waves at any harbour berth would be important for the correct determination of the response spectra of the vessel movements and forces.

However, for the present model directional spectra could not be measured and consequently some simplifications have been adopted. Firstly, it was realized that the direction of wave incidence inside the harbour at a berth is almost independent of the direction of incidence of the waves outside harbour. Secondly, the general wave pattern in the harbour could be determined visually by photography. From the analysis of pictures, it was observed that the waves approaching any berth of the harbour have mainly a two dimensional nature (as can be seen in Fig. 8). Furthermore, the variance spectrum of the waves measured at each berth included already possible reflected waves. On the basis of these remarks it was possible to proceed further with the determination of the response spectra of the vessel movements and forces, considering the waves approaching any berth to behave like unidirectional waves.

#### Determination of Response Spectra of Vessel Movements and Forces

Assuming the Froude hypothesis mentioned before to be true under the excitation of relatively small waves (below 1 m significant height), the behaviour of the oscillating system composed by a vessel and its moorings and fenders may be considered linear. Consequently, one may obtain in such a case the response spectra of the various movements and forces according to the following formula:

$$(1) \quad S_R(f) = T^2(f) \cdot S_W(f).$$

where:  $f$  - frequency;  $S_R(f)$  - response variance spectrum of a movement or force;  $S_W(f)$  - wave energy (variance) spectrum measured at a certain berth for a certain sea state and harbour layout;  $T(f)$  - transfer

Fig. 4. Incident deep water wave spectra for four peak periods generated and measured in agitation model.

Fig. 5. Shallow water wave spectra in front of harbour entrance measured in agitation model.

Fig. 7. Instrumentation set-up used in moored seakeeping model study.

Fig. 8. Wave incidence pattern observed in agitation model.

function of a movement or of a mooring or fender force.

A problem arose in the evaluation of the response spectrum regarding the choice of the correct transfer function, among the three transfer functions obtained for the three directions of wave incidence.

The logical procedure would be to determine the optimum orientation of the harbour berths on the basis of the values of the response amplitude operators (RAO) of the transfer functions of the predominant vessel movements. However, in the present study the berth orientations were predetermined by the designers on the basis of backland constraints. In view of these conditions it was decided to use for every movement or force of a vessel, only one transfer function, possessing the largest RAO values among those obtained for the three wave directions in the moored seakeeping model. Care was taken not to use the function obtained for a wave direction which was unreasonable in view of the wave pattern observed by photography. Still, the transfer functions obtained in this way lacked the contribution of the additional effects induced inside the harbour by the wave groups. Nevertheless, these effects could be discarded in the case of a small craft harbour because of the following two reasons:

- a) The effect of drift forces induced by wave groups inside the harbour was in general small because the wave energy of the short waves was small too.
- b) The spectral energies of the long waves induced in the harbour at the various berths were in general of the same order of magnitude or greater than the spectral energies of the short waves (see Fig.6 ). Therefore, the direct effect of the long waves was in general much larger than the one induced by the drift forces.

However, if the spectral energy would be larger than that in the low frequency range, the contribution of the drift forces becomes important and can not be neglected. In such a case, it would be necessary to determine transfer functions on the basis of irregular waves to add the contribution of the second order drift forces, but this was not the case in

Consequently, in the case of a small craft harbour located in shallow water the proposed simulation method was applicable and the response spectra were estimated to lead to slightly conservative results. An example of a response spectrum is shown in Fig. 9 for surge movement.

#### Evaluation of Maximum Movements and Forces

From the response spectra, maximum vessel movements and mooring and fender forces occurring in various sea states and layouts were determined by the following procedure: Firstly, for each response spectrum obtained, the spectral variance  $\sigma_R^2$  and the zero crossing wave period  $T_z$  of the response were evaluated using the formulas:

$$(2) \quad \sigma_R^2 = \int_0^{\infty} S_R(f) df$$

and

$$(3) \quad T_z \approx T_{m_0,2} = \sqrt{m_0/m_2}$$

Fig. 9. Example of computer plot of computed response spectrum for surge movement (trawler vessel, full)

where  $T_{m_{0,2}}$  is the spectral estimate of the zero crossing period and  $m_0$  and  $m_2$  are the zeroth and second spectral moments of the response. Secondly, assuming a quasi-stationary sea state to prevail for a time period  $t$ , the average number of reversals ( $N$ ) of a movement or force, was obtained from

$$(4) \quad N = t/T_z$$

Finally, assuming the movements and the forces during a quasi-stationary sea state to be Rayleigh distributed the maximum value of the response  $R_{max}$  was determined from the formula (Ochi (9)):

$$(5) \quad R_{max} = \sigma_R \left( \frac{1}{2} \ln N \right)^{1/2}$$

Though the assumption of Rayleigh distribution for mooring and fender forces is not quite true due to their non linear characteristics, it was estimated that this assumption led to conservative values.

A problem arose regarding the determination of maximum values for the many cases of two peaked response spectra. To solve this, it was decided to divide the response spectrum into two separate response spectra, one covering the high frequency range and the other covering the low frequency range and treat them as individual spectra, following the procedure outlined above. The maximum value of the response spectrum was obtained in this case by the summation of the individual maximum values obtained from the two divisions of the response spectrum.

## HARBOUR OPTIMIZATION

### Limiting Criteria

In order to determine limiting criteria regarding maximum allowable values of vessel movements and mooring and fender forces for safe operation at the harbour berths, a literature survey and discussions with a number of skippers and marina operators were carried out. Limiting values regarding mooring and fender forces were presented by mooring lines manufacturers (Samson Ocean Systems(10), British Ropes (2)) and by PIANC (9), while limiting values of vessel movements are presented by Bruun (3). The discussions conducted led to the conclusion that beside the forces in moorings and fenders, the safety of mooring and loading or unloading operations is affected more by crew behaviour on vessel than by the amplitudes of vessel movements, though the latter are usually assumed to determine the crew behaviour. However, as shown by various studies of human behaviour during aircraft flight or seakeeping (e.g. Arwas and Rolnick (1)), the main factor in influencing human behaviour is the acceleration of the body and not the body velocity of movement.

After studying the information collected, the following criteria have been established as safety limit criteria.

- maximum linear acceleration : 0.4 m/sec<sup>2</sup>
- maximum angular acceleration : 2.0 deg/sec<sup>2</sup>
- maximum peak to peak roll : 6.0 degrees
- maximum force in a mooring : 20% of breaking load
- maximum force in a fender : 60% of ultimate load

Here the movement limitation for roll was needed to prevent

entanglement of vessel masts while mooring side by side.

In order to determine maximum accelerations, response spectra of the accelerations corresponding to the six vessel movements were evaluated. The method described previously on response spectra was used, by applying the following formula:

$$(6) \quad S_a(f) = (2\pi f)^4 \cdot T^2(f) \cdot S_w(f)$$

where:  $S_a(f)$  - acceleration response variance spectrum. Maximum accelerations were obtained assuming again the values to follow the Rayleigh distribution.

#### Determination of Yearly Average Operability

The maximum values obtained were combined with the wave statistics and the above criteria, yielding average yearly operabilities at every berth for the various layouts. From these results, the optimum harbour configuration was chosen.

#### CONCLUSIONS

A relatively inexpensive simulation method has been derived for the study of small craft harbours. This is estimated to allow sufficiently reliable determination of optimum harbour layout (breakwaters, quays) and optimum type of structure for each berth, in respect to safe operational conditions for the vessels serviced by the small craft harbour, using small to medium size wave basins which are available at most laboratories. In order to further increase its reliability a model study has been initiated at CAMERI, to compare this method with the results of direct measurements of vessel behaviour in a harbour model.

## CHAPTER ONE HUNDRED NINETY ONE

### Hydrodynamic Forces on a Circular Cylinder due to Combined Wave and Current Loading

Yuichi Iwagaki\* and Toshiyuki Asano\*\*

#### ABSTRACT

The hydrodynamic force acting on a circular cylinder in a wave-current co-existing field and its generating mechanism are discussed. This study focuses on the asymmetries of both the water particle movement and the resultant vortex property with respect to the cylinder, which produce inherent characteristics in the hydrodynamic forces in the wave-current co-existing field.

First of all, the vortex property around a circular cylinder in the wave-adverse current co-existing field has been examined by flow visualization tests. It has been found that the vortex property depends on the flow characteristics around the trough phase when the wave-current composite velocity becomes maximum and can be represented with a newly proposed  $K.C.$  number for the co-existing field.

Secondly, the characteristics of the in-line force has been made clear by evaluating the drag coefficient and the mass coefficient in the expanded Morison's equation for the co-existing field. These coefficients can be well arranged by  $(K.C.)^{\frac{1}{2}}$ , which is one of the newly proposed  $K.C.$  numbers, and their characteristics coincide with the existing results in the wave only field. The in-line hydrodynamic force in the co-existing field can be explained sufficiently by considering the vortex property in the same manner as clarified in the wave only field.

Thirdly, the characteristics of the transverse force (lift force) are discussed in connection with the vortex properties. It has also been found that the fluctuating frequency of the lift force is synchronized with the loading wave frequency.

#### 1. Introduction

Evaluation of wave forces acting on a circular cylinder is one of the most important subjects in coastal and ocean engineering. Recently, Sarpkaya and Isaacson<sup>1)</sup> systematically assembled and organized comprehensive research efforts in this field, and they pointed out several problems which remain unsolved. The study on hydrodynamic forces

\* Professor, Dept. of Civil Eng., Kyoto University, M. of ASCE

\*\* Research Associate, Dept. of Civil Eng., Kyoto University  
Yoshida-honmachi, Sakyo-ku, Kyoto 606 Japan

in wave-current co-existing fields is one of such problems. However, researches on this subject are scarce and as yet there is not a sufficient understanding.

A quasi wave-current co-existing field can be easily obtained either by oscillating a cylinder in the in-line direction in a uniform flow, or by moving it at a constant speed in a harmonically oscillating flow. Verley and Moe<sup>1,2)</sup> examined the drag and the mass coefficients by using the former field, while Horikawa et al.<sup>2)</sup> treated them in the latter field. However, the existing studies have not sufficiently discussed the hydrodynamic forces based on the vortex properties around a cylinder.

As an essential difference of the generation mechanism of the hydrodynamic forces in the wave-current co-existing field from that in the wave-only field, this study focuses on the asymmetry of a water particle movement with respect to a cylinder.

In the wave-only field, the water particle moves almost symmetrically in both phases of wave crest and wave trough, while in the co-existing field it does asymmetrically due to a superimposed current. Consequently, the properties of the vortex formation, development and shedding become different from the wave-only field, and they produce inherent characteristics in the hydrodynamic forces.

From the above mentioned viewpoint, in this study first of all, flow visualization tests are performed in wave and adverse current co-existing fields to examine the vortex properties.

Secondly, the characteristics of the in-line force are made clear through the experimental data of the drag and the mass coefficients in the expanded Morison's equation to the co-existing field. Moreover, the generation mechanism of the in-line force associated with the vortex properties is discussed in detail.

Thirdly, the characteristics of the lift force are examined in regard to both the lift coefficients and the fluctuating frequencies. Further, "synchronization" between the lift force fluctuation and the loading wave frequency in the co-existing field is examined.

## 2. Vortex properties around a circular cylinder in co-existing fields

### (1) Flow visualization test

Experiments were carried out in a wave tank, 27m long, 0.5m wide and 0.7m high, in which a circulating flow can be generated by a power pump. The water depth was kept constant 30cm. The vertical circular cylinders used in this test were 30 mm and 60mm in diameter.

Test runs were conducted under conditions that the wave frequency  $f$  was 0.5Hz, the wave heights  $H$  were 1.1~3.9cm, the currents were in the opposite direction to the wave propagation and their velocities varied 0~13.9 cm/sec. The flow visualization around the cylinder was performed with aluminum powder, and photographs of fluid motion at the water surface were taken with a motor-drive camera at the speed of 3 frames per second.

## (2) Experimental results and discussion

To clarify the effect of the current on the vortex properties, the experiments were carried out under the condition that the wave height and period are almost constant, and only the current velocity is varied.

Fig.1 shows the results of experiments when the surface  $K.C.$  numbers  $K.C._s$  calculated from the water particle velocity of only the wave component, are approximately equal to 3 and only the current velocity is varied.

$K.C._s$  is defined as follows:

$$K.C._s = u_{ms} T / D \quad (1)$$

in which,  $u_{ms}$  is the velocity amplitude of wave component at the still water level,  $T$  the wave period and  $D$  the diameter of a cylinder.  $u_{ms}$  was calculated from the small amplitude wave theory. The subscript 's' denotes the value at the water surface.

$(K.C._s)_\dagger$  and  $(K.C._s)_\ddagger$  in Fig.1 are introduced as new  $K.C.$  numbers in the co-existing field. Their definition will be described later. In these numbers, the water particle velocity is represented by a composite velocity of the wave and current components at the trough phase. The direction of the wave propagation in Fig.1 is from left to right, and that of current is from right to left.

Fig.1(a), which is the case of the wave-only field, shows that a pair of symmetric vortices are generated and they are not shed from the cylinder. Fig.1(b) shows the case when a current of 6.3 cm/sec in velocity is superimposed on the waves. In this figure, it is observed that a pair of symmetric vortices are generated at the phase III, when the composite velocity becomes large, and they develop, decay and vanish as the phase proceeds. Fig.1(c) is the case when a faster current than in the case of (b) is superimposed, so that the movement of the water particles is uni-directional throughout all phases. It is observed that one vortex is generated in one wave period at one side, and in the following wave period one vortex is generated at the other side. As the current velocity still increases, a pair of asymmetric vortices are generated as shown in Fig.1(d).

From Fig.1 and other visualization tests, the following vortex properties were made clear.

The vortices which are generated at the trough phase when the composite velocity becomes maximum dominate the vortex pattern all over the wave phases. The relation between the vortex pattern and  $(K.C._s)_\dagger$  or  $(K.C._s)_\ddagger$  coincides with that of existing results in the wave-only field.<sup>9), 10)</sup> It cannot be decided here which  $K.C.$  number best represents the vortex properties in the co-existing field, since the number of the experimental data is not sufficiently large. However, concerning the coefficients of the hydrodynamic force,  $(K.C._s)_\ddagger$  was found to be the better parameter to describe them than  $(K.C._s)_\dagger$ .

Meanwhile, the flow properties during the crest phase are so affected by the still existing vortices generated during the trough phase that the vortex properties cannot be explained by the

Fig.1 Changes of vortex pattern due to currents

Photo.1 An example of visual observations  
 (this photograph corresponds to Fig.1(c),  $t/T=4/6$ )

characteristics of the water particle movement.

The vortex properties clarified here are considered to control not only the characteristics of the in-line force but also those of the lift force.

### 3. Characteristics of in-line force acting on a circular cylinder

#### (1) Experimental procedure

The experimental apparatus was almost same as that used in the flow visualization test. Two vertically supported circular cylinders having  $D=30\text{mm}$  and  $60\text{mm}$  diameters are mainly used in this experiment. Test runs using a cylinder of  $20\text{mm}$  in diameter were added in order to obtain large  $K.C.$  numbers.

The experiments were conducted under the conditions of the wave frequencies  $f=0.5\sim 1.6\text{Hz}$  and the wave heights  $H=0\sim 21.0\text{cm/sec}$ . The currents were opposite direction to the wave propagation and their velocities varied  $U=0\sim 27.1\text{cm/sec}$ . The total number of the test runs was 80 for the wave only field, and 104 for the co-existing field. The water depth was kept constant  $40\text{cm}$ . The hydrodynamic forces were detected as moments by two strain gauges.

#### (2) Procedure of analysis

The hydrodynamic forces acting on a cylinder are represented by the following Morison's equation taking into account the effect of currents:

$$dF(z) = \frac{\rho}{2} C_D (u(z) + U(z)) |u(z) + U(z)| Dz + \frac{\rho\pi}{4} C_M D^2 \frac{\partial u(z)}{\partial t} dz \quad (2)$$

in which,  $dF$  is the horizontal hydrodynamic force acting on a segment  $dz$ ,  $\rho$  the density of fluid and  $C_D$  and  $C_M$  the drag and the mass coefficients respectively.

The wave component in the water particle velocity  $u(z)$  was assumed to be expressed by the small amplitude wave theory. The current velocity  $U(z)$  was assumed to be uniform in depth.

In this study two estimation methods of  $C_D$  and  $C_M$  were used. The first one is that either  $C_D$  or  $C_M$  is calculated at the specific phase when the inertia force or the drag force becomes zero respectively. Although this method is simple for calculation, it has some defects. That is to say, the reliability for the calculated value decreases significantly under such a wave and current composing condition that the water particle velocity or acceleration becomes small. Furthermore, for the case when the current velocity is larger than the amplitude velocity of the wave component,  $C_M$  cannot be calculated since the composite velocity never becomes zero throughout the wave phases.

Therefore, this method is applicable only for estimating  $C_D$  at the trough phase when the composite velocity becomes maximum.  $C_D$  estimated by the above mentioned method is expressed as  $(C_D)_{tr}$ , in which the subscript 'tr' means the value at the trough phase.

The second method estimating  $C_D$  and  $C_M$  is that proposed by Reid.<sup>5)</sup> By this method, water particle velocity  $u$  and acceleration  $\dot{u}$  are calculated from the water surface deviation  $\eta$  by using a numerical filter, and  $C_D$  and  $C_M$  are estimated from the measured hydrodynamic force by using the least squares method. The frequency response functions on  $\eta \sim u$  and  $\eta \sim \dot{u}$  with consideration of a current should be used.

The hydrodynamic force coefficients estimated by the above method are denoted as  $(C_D)_{b.f.}$  and  $(C_M)_{b.f.}$ , in which the subscript 'b.f.' means the best fit value.

### (3) Predominant parameters for expressing hydrodynamic force coefficients

Existing studies have treated the  $K.C.$  number and the Reynolds number as the predominant parameters expressing the hydrodynamic force coefficients in the wave only field. However, in the range of the Reynolds number in this experiment was between  $2 \cdot 10^3 \sim 2 \cdot 10^4$  where Sarpkaya<sup>6)</sup> reported that the changes of  $C_D$  and  $C_M$  with the Reynolds number are not so much. Accordingly, this study focuses on only the  $K.C.$  number as the predominant parameter for the force coefficients.

In the present study, two definitions are proposed as new  $K.C.$  numbers in the co-existing field. As shown in Chapter 2, the vortex properties around a cylinder throughout the phases are dominated by the water particle motion around the trough phase when the composite velocity becomes maximum.

As the first  $K.C.$  number, considering the composite velocity at the trough phase, the following parameter is introduced:

$$(K.C.)_1^* = (u_m + |U|)T/D \quad (3)$$

The physical meaning of the  $K.C.$  number can be considered as the ratio of the moving distance of a water particle in the one side direction of the cylinder  $s$  to the cylinder diameter  $D$ .

$$K.C. = \pi s/D \quad (4)$$

The second  $K.C.$  number is defined by the following equation expanding the above mentioned idea to the co-existing field.

For  $U \leq u_m$

$$(K.C.)_2^* = 2\pi \int_{t^*}^{T/2} |U + u_m \cos \sigma t| dt/D \quad (5)$$

in which,  $t^*$  denotes the time when the composite velocity becomes zero;

$$t^* = \cos^{-1}(-U/u_m)/\sigma \quad (6)$$

For  $U > u_m$

$$(K.C.)_2^* = \pi UT/D \quad (7)$$

As an expression for the component ratio of the wave and the current, the following parameter is introduced:

$$C_{asym} = u_m / (u_m + |U|) \tag{8}$$

This ratio becomes 1 at the limit of wave-only and tends to 0 as the current component becomes large compared with the wave component. Since this parameter represents the degree of asymmetry of the flow with respect to the center of a cylinder, the subscript of 'asym' denotes the abbreviation of asymmetry. In Eqs.(3), (5), (6) and (8), the velocity amplitude of the wave component  $u_m$  is defined as the root mean square value in the range from the water surface to the bottom.

Next, the ratio of the drag force to the inertia force is discussed. The maximum values of the drag and inertia forces throughout the wave phases,  $dF_{D,max}^r$  and  $dF_{M,max}^r$  are expressed by,

$$dF_{D,max}^r = (1/2) \rho C_D D (u_m + |U|)^2 dz \tag{9}$$

$$dF_{M,max}^r = (1/2) \rho \pi^2 C_M D^2 (u_m/T) dz \tag{10}$$

Accordingly, the ratio of both forces is calculated as follows:

$$\frac{dF_{D,max}^r}{dF_{M,max}^r} = \frac{C_D}{C_M} \left( \frac{u_m T}{D} \right) / \pi^2 \left( \frac{u_m}{u_m + |U|} \right)^2 = \frac{C_D}{C_M} (K.C.) / (\pi^2 C_{asym}^2) \tag{11}$$

The condition that the drag force is just equal to the inertia force is examined by using Eq.(11) under the assumption that  $C_D=1$  and  $C_M=2$ , independently of  $K.C.$  and  $C_{asym}$ . The result is shown in Fig.2, in which the predominant region of the drag or the inertia force is illustrated.

Fig.2 Predominant region of either drag or inertia force

(4) Experimental results and discussions

At first, preliminary experiments in the wave-only field were carried out. It is confirmed that the results coincide well with the existing ones in the wave-only field.

Next, the results obtained in the co-existing field are discussed. Fig.3 shows the relation between  $(C_D)_{tr}$  calculated at the wave trough phase and the  $K.C.$  number. It is observed that the characteristics of  $(C_D)_{tr}$  are not made clear by the  $K.C.$  number only, but they become evident after classifying the data into several ranges of  $C_{asym}$ . Also

Fig.3 Drag coefficient  $(C_D)_{tr}$  at trough phase versus K.C. number (co-existing field)

Fig.4 Drag coefficient  $(C_D)_{tr}$  at trough phase versus  $(K.C.)_1^*$  (co-existing field)

Fig.5 Drag coefficient  $(C_D)_{tr}$  at trough phase versus  $(K.C.)_2^*$  (co-existing field)

Fig.6 Mass coefficient  $(C_M)_{b.f.}$  fitting best with measured forces throughout wave phases versus  $(K.C.)^*_2$  (co-existing field)

Fig.7 Drag coefficient  $(C_D)_{b.f.}$  fitting best with measured forces throughout wave phases versus  $(K.C.)^*_2$  (co-existing field)

Fig.8 Ratio of lift force frequency  $f_L$  to loading wave frequency  $f_W$  versus  $K.C.$  (wave only field)

the peaks of the averaged curves shift in the direction of an increase in the  $K.C.$  number as  $Casym$  increases.

The results arranged by  $(K.C.)_1^*$  and  $(K.C.)_2^*$ , proposed as the new parameters in the co-existing field, are shown in Figs.4 and 5, respectively. In comparing both plots, the degree of scattering in Fig.5 using  $(K.C.)_2^*$  is less than that in Fig.4 using  $(K.C.)_1^*$ . In addition to this, from the view point of the physical meaning of the  $K.C.$  number, it is concluded that  $(K.C.)_2^*$  is a more appropriate parameter than  $(K.C.)_1^*$ .

The results of  $(C_D)_{b.f.}$  and  $(C_M)_{b.f.}$ , which are obtained by the least squares method in order to best fit the calculated values with the measured one, are discussed. Since  $(K.C.)_2^*$  is found to be the most suitable parameter as mentioned above, the data of  $(C_D)_{b.f.}$  and  $(C_M)_{b.f.}$  are also arranged by it. The results are shown in Figs.6 and 7 respectively.

Comparing Fig.5 with Fig.6, not much difference of the  $C_D$  values by the estimating methods is found. Furthermore, it is also made clear that the characteristics of the hydrodynamic force coefficients in the co-existing field show a good agreement with those in the wave-only field.

The reason why  $C_D$  and  $C_M$  are expressed well by  $(K.C.)_2^*$ , which represents the flow property around the trough phase, is considered that this flow property dominates the whole one throughout the wave phases. These characteristics of  $C_D$  and  $C_M$  can be explained by the established physical views in the wave only field<sup>4)</sup>.

Furthermore, several examinations on  $C_D$  and  $C_M$ , such as an effect of convective acceleration on them, were carried out and they were reported at the previous paper<sup>4)</sup>.

#### 4. Characteristics of lift force acting on a circular cylinder

##### (1) Experimental procedure

The experimental apparatus was almost same as that used in the flow visualization test and the in-line force measurements. Lift forces were measured by using two vertically supported cylinder of which diameters were 30mm and 60mm.

The experiments were conducted under the conditions of the wave frequency  $f=0.5\sim 0.8\text{Hz}$  and the velocities of adverse currents  $U=0\sim 25\text{cm/sec}$ . The water depth  $h$  was kept constant 40cm; however, several test runs were added under the condition of the water depth  $h$  reduced to 30cm to make current velocity large.

##### (2) Synchronization between lift force fluctuating frequency and loading wave frequency

Generation mechanism of lift force can be explained by vortex shedding around a cylinder. Accordingly, the vortex shedding frequency  $f_V$  generally coincides with the lift force fluctuating frequency  $f_L$ .

For a steady current, the relation between the current velocity  $U$  and the lift force fluctuating frequency  $f_C$  due to the current, which is

called here as Strouhal frequency, are described by Strouhal number  $S_t$ .

$$S_t = f_c D / U \quad (12)$$

The value of  $S_t$  is nearly constant at 0.2 in wide ranges of Reynolds number; therefore, the value of  $f_c$  increases continuously as the current velocity increases.

For the wave only field, however, it has been pointed out that  $f_L$  varies stepwisely with increasing in  $K.C.$ . Fig.8 shows the experimental results on the relation of  $f_L/f_W$  and  $K.C.$ . This result shows that even if the water particle velocity increases so far as the  $K.C.$  number does not exceed a certain value,  $f_L$  still remains constant. Namely, it is considered that the lift force fluctuation is strongly controlled by the loading wave frequency. This phenomenon is named here "synchronization".

The wave current co-existing field is considered as a transitional field connecting between the current only field and the wave only field; therefore, it is interesting to examine which property of currents or waves dominates in the co-existing field.

### (3) Experimental results on lift force fluctuation

Fig.9 shows some examples on the relation between lift force fluctuations and water surface deviations. Fig.9(a) is a result in the wave-only field, and shows that the frequency of the lift force is twice that of the wave. Fig.9(b) shows a result in the wave-current co-existing field. It is found in other many cases that  $f_L/f_W$  takes half odd numbers such as 0.5, 1.5, 2.5, ..., and this is considered to be an inherent property in the co-existing field.

Thus, in this study, the term of "synchronization" is used extensively for the case that  $2 \cdot f_L/f_W$  becomes an integer in addition to the case that  $f_L/f_W$  is an integer.

Fig.9(c) is a result of a relatively strong current and small waves combined loading. The figure shows that there is no obvious relation between the lift force fluctuations and the water surface deviations, and the value of  $f_L$  coincides with the Strouhal frequency  $f_c$  estimated from Eq.(12); therefore, it can be decided that the synchronization exists no longer in this case.

However, it is rather difficult to distinguish the case that  $f_L$  coincides with the Strouhal frequency  $f_c$  from the case that synchronization occurs, because when the value of  $f_L/f_W$  becomes larger than around 3, the lift force becomes irregular.

The experimental results on  $f_L/f_W$  are plotted in Fig.10. As the current velocity becomes large relative to the wave component, the value of  $f_L/f_W$  becomes large and finally  $f_L$  reaches to  $f_c$ . The data that  $f_L=f_c$  are plotted as a sign of "x" in the figure. In such cases that decision whether  $f_L$  is a multiple of  $f_W$  or equal to  $f_c$  is difficult, both signs are plotted in the figure.

It is noticeable in Fig.10 that  $2 \cdot f_L/f_W$  remains an integer even when the current velocity becomes large compared with the wave component

Fig.9 Records of lift force fluctuations and water surface deviations

Fig.10 Comparisons of experimental results with calculated ones on a ratio of lift force frequency  $f_L$  to loading wave frequency  $f_w$

Fig.11 Schematic illustration of a model on  $f_L/f_w$

of water particle velocity.

It can be concluded that the lift force frequency or the vortex shedding frequency is strongly dominated by the loading wave frequency in the wave-current co-existing field.

This phenomenon is similar to the well known "synchronization" for a steady current field<sup>8)</sup>: When a cylinder is oscillated in a steady current, the forced oscillation locks the vortex-shedding frequency and controls the shedding process. Recently, a similar phenomenon is reported on aerodynamic responses on a bridge that a turbulent fluctuation of wind is possible to control the vortex-shedding<sup>9)</sup>.

#### (4) A model for predicting $f_L/f_W$

In this section, a simple model for predicting the experimental results on  $f_L/f_W$  is proposed.

Concerning an approximate estimation on the fluctuating frequency of lift force  $f_L$ , it is sufficient to consider only both properties of vortex shedding and mean flow velocity variation. It is not necessary to consider vortex generation, decay and movement.

Here, therefore, the lift force variations are approximated with the following Kutta-Joukowski type equation:

$$F_L = -\rho V \Gamma \quad (13)$$

in which  $\Gamma$  is a circulation around a cylinder.

Sawamoto and Kikuchi<sup>10)</sup> proposed a model to estimate lift forces in wave only field under the following assumptions: In a steady flow, a pair of vortices are shed from a cylinder when the moving distance of a water particle  $s$  exceeds 5 times the cylinder diameter  $D$ , which is easily obtained from the relationship of Eq.(12). They applied this idea extensively to the wave only fields, and estimated the number of shedding vortices during a wave period. Furthermore, they considered the variation of the circulation around a circular cylinder in the following way: Whenever a vortex sheds from a cylinder, the same magnitude and opposite sign circulation is added according to Kelvin's circulation theory.

Here, this study applied Sawamotos' idea to the wave-current coexisting field. Fig.11 shows schematically the variation of the circulation around a cylinder, the water particle velocity and the estimated lift force fluctuation.

In the wave only field, a water particle moves symmetrically with respect to the cylinder so far as non-linearity is ignored; therefore, equal number of vortices are shed from up-stream and down-stream sides of the cylinder. The number of shedding vortices while a water particle moves in one direction is presented by "n", then the total number of shedding vortices during a wave period is equal to  $2n$ . Consequently, the circulation  $\Gamma$  changes its sign  $2n$  times during a wave period. Meanwhile, the main stream velocity  $U+u_m \cos \omega t$  changes its sign 2 times during a wave period. Accordingly,  $f_L/f_W$  is given as

$$f_L/f_W = n + 1 \quad (14)$$

In the wave-current co-existing field, water particles move asymmetrically due to a superimposed current, so that the number of vortices from each side of the cylinder becomes different.

At first, we consider a case that current velocity  $U$  is smaller than the amplitude velocity of the wave component  $u_m$ . The numbers of shedding vortices from both sides of the cylinder are denoted as  $n_1$  and  $n_2$ . Since the circulation  $\Gamma$  changes its sign  $n_1 + n_2$  times and the main stream velocity does 2 times, the value of  $f_L/f_W$  for this case is calculated as follows:

For  $|U| \leq u_m$

$$f_L/f_W = (n_1 + n_2 + 2)/2 \quad (15)$$

Next, for another case of  $|U| \leq u_m$ , a water particle moves in the uni-direction throughout a wave period.  $\Gamma$  changes its sign  $n$  times, in which  $n$  denotes the number of shedding vortices during a wave period, while  $U + u_m \cos \omega t$  never changes its sign. Consequently, the following equation is obtained:

For  $|U| > u_m$

$$f_L/f_W = n/2 \quad (16)$$

It is easily confirmed from Eqs.(15) and (16) that  $f_L/f_W$  is possible to take a value of half odd number. The numbers of  $n_1$ ,  $n_2$ ,  $n$  are calculated based on the assumption that one vortex is shed when the moving distance  $s$  exceeds 2.5 times the cylinder diameter  $D$ . For example,  $n_1$  in Eq.(15) is calculated by following equation:

$$\begin{aligned} n_1 &= \left\{ 2 * \int_0^{t^*} (U + u_m \cos \omega t) dt / (2.5D) \right\} \\ &= \left\{ \frac{2}{5} \cdot \frac{K.C.}{\pi} \left( \sin \omega t^* + 2\pi \frac{U}{u_m} \frac{t^*}{T} \right) \right\} \end{aligned} \quad (17)$$

in which,  $\{ \}$  shows the maximum integer not to exceed the inside value of the bracket.  $t^*$  denotes the time when the wave-current component velocity becomes zero as shown in Eq.(6). If two parameters of  $K.C.$  (Eq.(1)) and  $C_{asym}$  (Eq.(8)) are given, all the values of  $n_1$ ,  $n_2$  and  $n$  can be calculated and then  $f_L/f_W$  also can be estimated from these values.

The results on  $f_L/f_W$  estimated by this model are shown in Fig.10 with the experimental results, where the boundaries on the values of  $f_L/f_W$  are drawn by dotted curves. The reason why the calculated  $f_L/f_W$  values vary at  $C_{asym}=0.5$  is that the model estimates them using the different equations between for  $|U| > u_m$  and for  $|U| \leq u_m$ .

From the comparison of calculated results with experimental ones, it is found that this simple model predicts satisfactorily well the experimental results including the property that  $f_L/f_W$  has a value of half odd number.

#### (5) Lift force coefficient in wave-current co-existing fields

In this section, the lift force coefficient and the predominant

parameters are discussed. The lift coefficient  $C_L$  in the co-existing field are defined as the following equation:

$$C_L = F_L / \{0.5\rho D(u_m + |U|)^2\} \quad (18)$$

in which,  $F_L$  is the individual peak value of the lift force fluctuation. Since lift forces generally do not show regular fluctuations even if regular forces load on a cylinder, it is necessary to use statistic representatives on  $C_L$ .

Here three representatives are used, such as, the mean, the one-third and the one-tenth largest lift coefficients which are denoted as  $\overline{C_L}$ ,  $C_{L1/3}$ , and  $C_{L1/10}$ , respectively.

In the wave only field, it has already been pointed out that  $C_L$  becomes the maximum when  $K.C.$  is around 10~12. Fig.12 shows the experimental results on the one-tenth largest lift force coefficient performed by the authors and Sawaragi-Nakamura<sup>9)</sup>.

Fig.13 shows the results on the mean lift coefficient  $\overline{C_L}$  in the wave-current co-existing field against  $K.C.$ . Since the parameter  $K.C.$  does not consider the current component, there appears much scatter.

Next, the same results are arranged by the newly proposed  $K.C.$  number in the co-existing field  $(K.C.)_{\frac{1}{2}}$  which is defined by Eqs. (5) and (7). The results are shown in Fig.14 and similar results on the one-third and the one-tenth largest lift coefficients  $C_{L1/3}$  and  $C_{L1/10}$  are shown in Figs.15 and 16 respectively.

It is found from these figures that the lift force co-efficients are well arranged by  $(K.C.)_{\frac{1}{2}}$  and take their maximum around  $(K.C.)_{\frac{1}{2}} = 10 \sim 12$ . This fact coincides with the property obtained in the wave only field as shown in Fig.12. The property that  $C_L$  takes the maximum around  $(K.C.)_{\frac{1}{2}} = 10 \sim 12$  is explained by the vortex property obtained in Chapter 2; that is, asymmetric vortices are generated in the flow condition when  $(K.C.)_{\frac{1}{2}} = 10 \sim 12$ .

It is concluded that  $(K.C.)_{\frac{1}{2}}$  which expresses the vortex property in the wave current co-existing field can represent the property of the lift force coefficient as well as the in-line force coefficients.

## 5. Conclusions

The vortex properties around a circular cylinder depend on the flow properties around the phase when the wave-current composite velocity is maximum.

The force coefficients for both in-line and transverse forces are arranged well by  $(K.C.)_{\frac{1}{2}}$  which is proposed as a new  $K.C.$  number in the wave-current co-existing field. The relations between these coefficients and  $(K.C.)_{\frac{1}{2}}$  are in good agreement with the results on the relations between the coefficients and  $K.C.$  established in the wave only field.

Furthermore, on the lift force frequency the following inherent properties in the co-existing field are obtained: the ratio of its

Fig.12 One-tenth largest lift coefficient  $C_{L1/10}$  versus K.C. (wave only field)

Fig.13 Mean lift force coefficient  $\overline{C_L}$  versus K.C.

Fig.15 One-third largest lift coefficient  $C_{L1/3}$  versus  $(K.C.)^{1/2}$

Fig.14 Mean lift coefficient  $\overline{C_L}$  versus  $(K.C.)^{1/2}$

Fig.16 One-tenth largest lift coefficient  $C_{L1/10}$  versus  $(K.C.)^{1/2}$

frequency to the loading wave frequency is possible to take a half odd numbers, and the both fluctuations synchronize each other.

## CHAPTER ONE HUNDRED NINETY TWO

### WAVE POWER EXTRACTION AT COASTAL STRUCTURE BY MEANS OF MOVING BODY IN THE CHAMBER

Hideo KONDO<sup>1</sup>, M.ASCE, Tomiji WATABE<sup>2</sup> and Kenji YANO<sup>3</sup>

#### Abstract

A series of study on wave power extractors which may utilize a part of the coastal structures has been performed by the group of faculties of Muroran Institute of Technology since 1978. Three kinds of extractor belonging to the so-called fixed type had been developed and studied in the laboratory. They are the air chamber with flap, the wave turbine system and the pendolor system. The last two systems have been subsequently studied at the field test plant constructed at Port Muroran. The study shows that the pendolor system brings an excellent power conversion efficiency.

#### 1 INTRODUCTION

Numerous apparatus have been proposed for the purpose of extracting usable energy from sea waves. However, none of them except the Masuda air buoy as navigational markers are in practice because of the economical difficulty to cope with oil. These extractors are classified roughly into two types, namely, the floating and the fixed ones. Table 1 presents a further classification of the two types of extractors from the viewpoint of dynamic property and direction of body or water, etc.

Much effort had been devoted to develop the floating type extractors just after the 1973 oil crisis. Generally speaking, they require large floating bodies with durable mooring equipments, which raises the cost of energy to be produced. The idea of so-called fixed coastal type has a longer history than the floating one but less attention had been paid for it in the 70's. The drawback of the floating type made a few groups reexamine the merit of fixed type.

Coastal defensive structures, namely, breakwaters, dykes, and revetments have been so designed as to reflect and/or to dissipate the incoming waves. If we could extract a considerable amount of the incident wave energy at these structures without spoiling their essential functions, the cost of energy must be remarkably decreased from that by the conventional apparatus. With this line of thought, the group of civil, mechanical and electric engi-

neering faculties of the institute headed by the senior author had tried to find the fixed type extractors which can be set within coastal structures and be easily operated , since 1978. The three extractors developed are the resonant fixed type ones and are those underlined in Table 1.

2 AIR CHAMBER WITH FLAP

The first extractor studied consists of an air chamber with the oscillating flap hinged at the top, which pushes and draws the air confined in the chamber to rotate the turbine on it while the incoming waves swing the flap, as shown in Fig. 1. The chamber may be surrounded with the curving backwall, the partision walls and the coping in which the air duct locates. The cofiguration of backwall looks like those of common seawalls and of dykes.

The experiment in a 24 meter long, 0.6 meter wide and 1 meter deep wave channel with regular waves, showed 20 to 50 % of the incident wave power was converted to the air pressure power, as shown in Fig. 2. The conversion efficiency  $\eta_a$  of the vertical axis in the figure is that defined as

$$\eta_a = \frac{\bar{w}_a}{B \cdot \bar{w}_i} \times 100 \quad (1)$$

where  $\bar{w}_i$  is the incident wave power per unit crest width and is given by the following equation for the regular waves.

$$\bar{w}_i = \bar{E} \cdot C_g = \frac{1}{8} \rho g H^2 C_g \quad (2)$$

where  $C_g$  is the group velocity of the incident wave.  $\bar{w}_a$  is the average air pressure power absorbed by the system of length  $B$  and is estimated as

$$\bar{w}_a = \frac{1}{T} \int p \cdot dV \quad (3)$$

where  $T$  is the wave period,  $p$  is the air pressure and  $V$  denotes the volume of air in chamber.

The effect of the opening ratio of air duct  $e$  is not clear. There are two apparent peaks of the efficiency, for  $T/T_N = 1.5$  and 2.1.  $T_N$  is the natural period of the pendular.

Because of the efficiency of model air turbine being low, torque of air turbine remains about 2 % of the regular incident wave power. This figure, of course, will be much improved by employing a more efficient air turbine.

FIG.2 CONVERSION EFFICIENCY FROM  
WAVE TO AIR

### 3 WAVE TURBINE SYSTEM

The next system has a three-vane Savonius turbine rotating around the vertical axis fixed in the rectangular water chamber formed in the reinforced concrete caisson without the seaward wall as seen in Fig. 3. The plane form of the turbine is asymmetric in order to rotate it in the same direction in spite of the reciprocating wave force acting on it. The guide plates are attached to the partition walls and aim to concentrate the flow near the turbine and eventually to increase the torque of it. A standing wave occurs in the chamber. Thus the highest conversion efficiency is expected where the distance between the axis and the backwall is about the one quarter of the wave length in the chamber. That means the axis lies near the node of the standing wave. For the cases of relatively larger wave length, the caisson may be installed on a solid or a rubble base mound to decrease the depth of chamber, in which case the wave length becomes short so

FIG. 3 SKETCH OF WAVE TURBINE SYSTEM AND WATER PARTICLE MOTION AROUND IT

that the caisson width can be decreased for the given wave period and for the original depth  $h_1$ .

The experiment was performed for the power extraction, wave reflection and wave force characteristics of the system in the same channel described in the section 2. The details of the result had been reported by KONDO et al. (1980, 1981). The average power extracted by the turbine  $\bar{w}_t$  was evaluated by

$$\bar{w}_t = \tau \bar{\dot{\theta}} \quad (4)$$

where  $\tau$  is the load torque and  $\dot{\theta}$  is the angular velocity of turbine. The conversion efficiency  $\eta_t$  from incident wave power to torque of turbine of length is defined as

$$\eta_t = \frac{\bar{w}_t}{B \cdot \bar{w}_i} \times 100 (\%) \quad (5)$$

The actual efficiency of mechanical conversion for the system with  $h_1 \neq h_2$  in which a part of incident wave power is reflected, should be defined as

$$\eta_e = \frac{\bar{w}_t}{B \cdot \bar{w}_i'} \times 100 (\%) \quad (6)$$

where  $\bar{w}_i'$  is the transmitted wave power into the chamber per unit crest width without the system.  $\eta_e$  should be  $\eta_t$  for the case  $h_1 = h_2$ . The efficiency  $\eta_e$  takes the maximum for the relative distance of axis from backwall  $D/L$  around 0.25 as expected, which can be seen in Fig. 4. The guide plates are much effective to increase the extracted power as shown in the figure. However,  $\eta_e$  remains 20 % at most. The theoretical values of  $\eta_e$  shown with solid and broken lines in the figure were those of calculated with the approach presented in the Appendix.

The reflection coefficient of the structure as a whole is almost less than 0.4 and is comparable to that of common rubble mound breakwaters. Fig. 5 presents the critical wave height to slide the caisson with the system, from which the horizontal wave force against the structure as a whole is estimated to be 50 % or less of that on the imperious upright breakwaters.

#### 4 PENDULOR SYSTEM

The last system has an oscillating pendulor around the horizontal axis perpendicular to it, and transmits the power of pendulor to that of oil pressure through the reciprocating cylinder connected to the pendulor at the top, as illustrated in Fig. 6.

The experiment had been performed on the horizontal bottom in a 18.5 meter long, 0.4 meter wide and 1 meter deep wave channel at the initial stage and later in the 24 meter channel stated in the section 2. The average power extracted to the oil pressure was determined in the experiment by

$$\bar{w}_p = \frac{1}{T} \int F_C r_C \dot{\theta} dt \quad (7)$$

where  $r_C$  is the distance between the neutral position of pendular and the center of cylinder, and  $\dot{\theta}$  is the angular velocity of pendulor.  $F_C$  is the reaction force of cylinder.

FIG. 5 CRITICAL INCIDENT WAVE HEIGHT FOR SLIDING OF CAISSON

FIG. 4 CONVERSION EFFICIENCY FROM THE TRANSMITTED WAVE POWER INTO THE CHAMBER TO THE TORQUE

FIG. 6 SKETCH OF THE PENDULOR SYSTEM

FIG. 7 CONVERSION EFFICIENCY FROM WAVE TO OIL PRESSURE VERSUS RELATIVE DISTANCE OF THE PENDULOR AXIS FROM BACKWALL

der and is evaluated as

$$F_C = F_O + \beta (r_C \dot{\theta})^2 \quad (8)$$

where  $F_O$  is the frictional force of cylinder and  $\beta$  is the load coefficient due to the orifice restrictor. Then the conversion efficiency of the system with length  $B$  is

$$\eta_p = \frac{\bar{W}_p}{B \cdot \bar{W}_i} \times 100 \quad (\%) \quad (9)$$

The system also brings the maximal of  $\eta_p$  where the neutral position of pendular coincides the location of node of the standing waves formed in the chamber, as clearly seen in Fig. 7. The maximum value of  $\eta_p$  was 80 % in the experiment . The two dimensional analysis for the small amplitude wave had been derived by Asano (1980), outline of which will be introduced in the paper by Ando et al. (1984). Fig. 8 presents the result of comparison of theoretical efficiency with experimental one. The theory successfully predicts the experimental data or the cases of relatively lighter load condition and of shorter wave period, as shown in Fig. 8.

5 FIELD EXPERIMENT

In order to investigating feasibility of the last two systems at the sea, a series of the field test has been carried out employing a test caisson. It is 6.1 meter long,

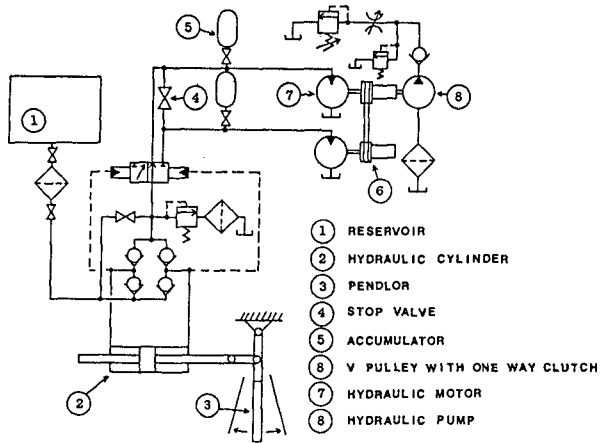

FIG.10 THE OIL PRESSURE CIRCUIT OF TEST PLANT

FIG.11 EXAMPLE OF THE DATA MEASURED AT TEST PLANT

7 meter high and 8 meter wide, and had been constructed seaward of the south breakwater of Port Muroran in the spring of 1980 ( see Fig.9 and Photo.1 and 2 ). As seen from Photo. 1, the caisson has two chambers to be able to install two kinds of systems. Since the port faces to a bay on the Pacific south west coast of Hokkaido Island, the waves of  $H_{1/3} \geq 1.0$  meter is approximately 12 % and appear mostly in winter.

The power extracted by the wave turbine system at the caisson transmits via a flywheel to the 2 kW D.C. generator. The extracted power measured in front of the generator was in the range of 3 to 8 % of the incident wave power, and much fluctuated. The incident wave power of the sea waves was estimated with the following equation to the Bretschneider-Mitsuyasu spectrum, provided that the waves belong to those of deep water.

$$\bar{w}_i = \int_0^{\infty} S(f) \cdot C_G \cdot df = 0.44 \cdot H_{1/3}^2 \cdot T_{1/3} \quad (kW/m) \quad (10)$$

where  $S(f)$  is the frequency spectrum, and  $H_{1/3}$  and  $T_{1/3}$  are the significant wave height and period, respectively. About 60 % of the torque power was converted to the electric power. The wave data used were of 2 km offshore.

The pendulum system which had been installed in the another chamber of caisson in 1983 is of 2.5 ton of weight and the length from the rotational axis to the lower end is 7.1 meter, as shown in Fig. 9. The plate to receive wave force at the lower part of it is 2 meter wide and 3.5 meter high ( see Fig.9 and Photo.3 ). The secondary conversion block consists of the oil circuit which outputs the oil pressure with employing an oil pump instead of a generator which is illustrated in Fig. 10. The circuit can be used in the three ways, namely, the smoothing, the nonlinear and the linear ones, respectively. Fig. 11 presents an example of the measured data of the pendulum system. The

FIG.12 CONVERSION EFFICIENCY VERSUS WAVE FREQUENCY OF THE FIELD TEST

FIG.13 WAVE SPECTRUM SEAWARD OF THE CAISSON

FIG.14 TIME HISTORY OF EXTRACTED OIL PRESSURE POWER

FIG.15 THE SPECTRUM OF THE EXTRACTED POWER

circuit I (smoothing) gave higher efficiency than the circuit II (nonlinear) did as shown in Fig. 12. The pendulum system with the smoothing circuit could convert about 35 % of the incident wave power to the oil pressure power. This figure seems to be a remarkably higher value as the data in real sea.

Figs. 13, 14 and 15 give examples of the wave spectrum from the datum measured 5 meter apart from the caisson with the ultrasonic wave gage set over the water surface, the time history of extracted power, and the spectrum of extracted power, respectively. The extracted power is much smoothed with the aid of the smoothing circuit.

## 6 CONCLUDING REMARKS

The cost of electricity to be produced by the pendulum system in prototype commercial plant is estimated to be approximately 26 Yen/kWh or 11 US cents/kWh at the price of the year of 1982 in Japan, provided the average incident wave power  $\bar{w}_i = 25$  kW/m and the overall efficiency 20% (Ref. 5)). This figure can be reduced to about 60 % of that for the cases of construction cost of caisson being exempted, which may occur when it serves also as any breakwater, dyke or revetment. The pendulum system seems to be one of the most prospective wave power extractors, though there remains several engineering problems to be solved before the commercial use.

A small pilot plant of the pendulum system has been operated at Mashike Town, in the Japan Sea coast of Hokkaido, the details of which will be reported by Ando, et al. (1984).

## ACKNOWLEDGEMENTS

The authors are much appreciative for the co-operation of those who had been or are presently the members of the group for wave power utilization study at the institute, Professors K. Orikasa, S. Ozaki, K. Okuda, T. Matsuda and Y. Dote. Thanks must go to the some forty former graduate and undergraduate students of the institute, who had participated with the study during the period 1976 - 83.

We also wishes to express our appreciation to Drs. A. Ando and M. Takagi, Mr. M. Kuroi, and the late Mr. S. Asano of Hitachi Zosen Corporation who have studied the pendulum system jointly with us and had made the plant of Mashike.

Major part of the present study has been supported by Science Research Fund of the Ministry of Education.

## APPENDIX - The Simplified Analysis of the Power Extraction for the Wave Turbine System

The dynamic equation for the wave turbine of vertical axis set in the chamber as illustrated in Fig. 3 can be expressed as

$$(I + I_a) \ddot{\theta} + N_w \dot{\theta} + k\theta = \tau_w - \tau \quad (11)$$

where  $I$  is moment of inertia of the turbine,  $I_a$  added moment of inertia,  $N_w$  damping coefficient due to radiation

waves generated by the turbine,  $k$  restoring coefficient of the turbine,  $\tau_w$  wave exciting torque on the turbine,  $\tau$  torque of load,  $\theta$  rotational angle of the turbine. The dot denotes the time derivative.

The torque  $\tau_w$  on the turbine such as shown in Fig. 3 is approximated as

$$\tau_w = \rho C_t U_2^2 R_0^2 h_2 / 2 \quad (12)$$

where  $\rho$  is the density of fluid and  $C_t$  coefficient of torque on the turbine.

The horizontal water particle velocity  $u_2$  is expressed as

$$u_2 = U_2 \cos(\sigma t - \delta) \quad (13)$$

Then, the time average of  $\tau_w$  in Eq.11 is given by

$$\bar{\tau}_w = \rho R_0^2 h_2 U_2^2 C_t / 4 \quad (14)$$

The load torque  $\tau$  may be expressed as

$$\tau = N_t \dot{\theta} + \tau_{t0}$$

where  $N_t$  and  $\tau_{t0}$  are the coefficients related to load resistance. Since the coefficient  $k$  may be relatively small for the system, Eq.11 becomes

$$\ddot{\theta} + p\dot{\theta} = r \cos 2(\sigma t - \delta) + s \quad (15)$$

wh

$$p = \frac{N_t + N_t}{I + I_a}, \quad r = \frac{\bar{\tau}_w}{I + I_a}, \quad s = \frac{\bar{\tau}_w - \tau_{t0}}{I + I_a}$$

The solution of Eq.15 is given as follows.

$$\theta = \frac{r}{2\sigma\sqrt{4\sigma^2 + p^2}} \cdot \sin[2(\sigma t - \delta) + \gamma] + \frac{q}{p}t + Ce^{-pt} \quad (16)$$

where  $\gamma = \tan^{-1}(\frac{2\sigma}{p})$

After calculating  $\theta$ , the power extracted by the turbine is obtained with Eq.4 in section 3.  $U_2$  of Eq.4 may be approximated with wave deformation theory for the stepwise previous structure by Kondo (1983).

## CHAPTER ONE HUNDRED NINETY THREE

### FULL-SCALE WAVE FORCES ON PILES IN SHALLOW WATER

by

Uwe Sparboom <sup>+</sup>

Nico Efthimiou <sup>++</sup>

Andreas Voigt <sup>++</sup>

#### ABSTRACT

This paper presents some results of simultaneous full-scale wave kinematic and local force measurements (field and laboratory) on a slender, vertical cylindrical pile (test-section) under shallow water conditions. The usual application of Morison's equation is taken under critical consideration due to the real flow regime near the surf zone. The data were analyzed in the time domain as well as in the amplitude and frequency domain. Two estimation methods for force coefficients were tested and compared.

#### INTRODUCTION

Pile-supported substructures are often needed for various coastal engineering structures. There are still many difficulties in the design of cylindrical slender structures in shallow water regions which are characterized by surf zones with an important dissipation of energy, especially under storm surge conditions. A decisive advance in determining reliable force coefficients is to measure the water particle kinematics synchronously with the surface elevations (waves) and wave pressures or wave forces in the field (Dean (/2/)). Results of field-measurements and added two-dimensional full-scale laboratory investigations with the same test-pile used in the field enable to describe the mechanism of wave-structure interactions more sufficiently. The real wave attack in the experiments reported in this paper occurred at supercritical Reynolds number conditions.

### FIELD MEASUREMENTS

In order to obtain field-data at high Reynolds numbers the measuring facilities were installed in the nearshore area of the Eastfrisian Island Norderney on the German North Sea Coast. Detailed informations can be found in Sparboom (/8/). In Fig.1 the configuration of the measuring devices which were used for this paper is drawn up schematically. Wave pressures were measured at a test-section in 16 points at even spaces on the circumference of the pile (diameter 0.7 m). In a distance of about 5.0 m from the pile the surface elevations and the velocities of the water particle motions (two components in a vertical plane and two components in a horizontal plane) were measured synchronously. It should be noted here, that the test-section of the pile is structurally combined with a calibrated two-component strain gauge unit measuring the total wave forces acting on the test-section. These force signals were used to control the forces obtained by integrating the pressures which were measured synchronously by 16 single transducers. Representative samples of field data were recorded in some winter-seasons under different storm surge conditions at high tide water levels. Simultaneous records of wave kinematics and wave forces can be seen exemplarily in Fig.2. It could be assumed that the wave kinematics (horizontal velocities and accelerations, surface elevations) were always unaffected by the pile. The direction nearly normal to the shore was defined as mean inline direction (X-axis), because it coincided with the mean direction of the incoming waves. The direction nearly parallel to the shore was similarly defined as mean transverse direction (Y-axis).

### LABORATORY FULL-SCALE TESTS

With the end of the winter-season 1982/83 the research program was changed to systematic full-scale tests in the new Large Wave Channel (Grüne and Führböter, (/4/); Führböter, (/3/)). The part of the test-pile in the field which contains the test-section was recovered and used for first laboratory investigations with respect to regularly generated waves (periods from 5.0 to 8.0 seconds, wave heights from 1.0 to 2.0 meters). The configuration of the installed sensors and transducers is given in Fig.3. Regarding the configuration in Fig.1 care was taken to realize the laboratory full-scale tests under equal conditions as used in the field. An example for simultaneous records of the first tests in the Large Wave Channel is plotted in Fig.4. The measured values of the horizontal transverse velocity components were very small. Therefore they were neglected for further calculations.

### WAVE FORCE ANALYSIS IN THE TIME DOMAIN

The mostly used approach in the course of estimating the loading of vertical cylindrical structures is as follows: For a given set of wave height  $H$  and wave period  $T$  the wave kinematics  $u$  and  $\dot{u}$  are calculated theoretically; with a suitably chosen pair of coefficients  $C_d$  and  $C_m$  and application of Morison's equation maximum wave forces are estimated. This method contains uncertainties arising from the validity or not of wave theories proposed for the actual sea state, particularly in the nearshore zone. With measured kinematics only the uncertainty in determining  $C_d$  and  $C_m$  remains. This problem will be subject of this paper.

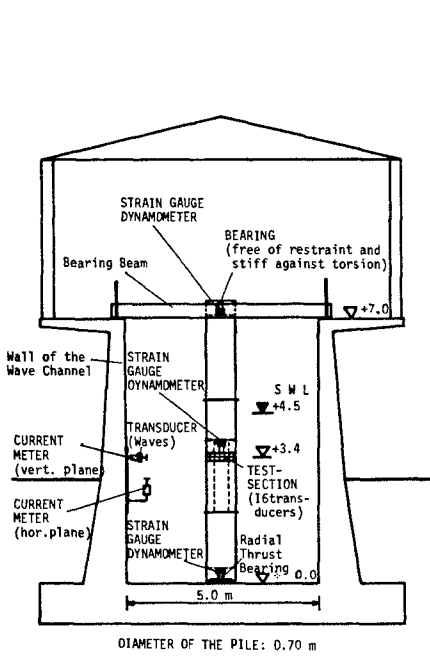

Fig. 3:  
Full-Scale Configuration  
in the Laboratory

Fig. 4:  
Simultaneous Laboratory  
Records of Wave Kinematics  
and Wave Forces in the  
Test-Section Level

Utilizing the first simultaneous field data it was found that the values of the force coefficients plotted against Reynolds and Keulegan-Carpenter numbers displayed high scatter (Sparboom (/8/)). The main reasons for the large amount of scatter are as follows:

- three-dimensional effects; large variability of wave kinematics direction
- interactions of wave kinematics and test-structure (test-section) due to vortex shedding
- superposed long-periodic oscillations; presence of trend values
- wave deformation near the breaker zone.

Fig.5 gives an example for the time-dependent development of simultaneously measured horizontal velocity and wave force vectors (single step equal to 0.192 seconds). The plotted traces represent a record of about 40 seconds.

Fig. 5: Measured Vector Traces of Horizontal Velocity and Test-Section Wave Forces

In order to check the reliability of Morison's equation under shallow water conditions a statistically based method was applied to determine force coefficients. With reference to Pearcey and Bishop (/6/) the mean square method was utilized and computed.

A definition sketch for the apparatus used in full-scale investigations of wave-loading can be seen in Fig.6.

Fig. 6: Definition Sketch of Test-Section Wave-Loading

A complete analysis for the loading of cylindrical piles from the hydrodynamic considerations is beyond the scope of this paper. It is, however, instructive to recall some of the basic assumptions associated with the derivation of Morison's equation. This formula depends on the linear superposition of wave force terms as a result of water particle motions (velocity and acceleration or drag and inertia portions). One classical approach to the derivation of Morison's equation starts with the fluid power equilibrium (Lighthill (/5/)). The inertial term in Morison's equation is derived by equating the time rate of work done by the inertial force on a Newtonian fluid to the time rate of change of the fluid kinetic energy due to irrotational flow, under the assumptions of flow field uniformity (no convective accelerations) and existence of a potential function. Similarly, the drag term is derived by equating the power by drag forces to the sum of the time rate of change of kinetic energy in the wake (rotational flow) plus the power dissipation in the wake due to viscous effects. Again, uniformity of flow is assumed; additionally, this term is derived by assuming that the velocity is constant or very slowly varying. Taking into consideration the contribution to the pressure gradient due to the interaction between velocity and vorticity an additional lift force term may be derived. In this case the following assumptions are made: The vorticity is uniformly distributed; the vorticity is proportional to the velocity.

The wave force acting on a vertical, smooth slender cylinder in the horizontal plane then becomes

$$\vec{F} = \vec{F}_{\text{drag}} + \vec{F}_{\text{inertia}} + \vec{F}_{\text{lift}} + \vec{F}_w \quad (1)$$

with  $\vec{F}_w$  = Waterline Force.

The first three terms are usually determined by integrating with respect to  $z$  the force per unit length of the submerged portion of the cylinder given in cartesian coordinates by

$$\begin{pmatrix} f_x \\ f_y \end{pmatrix} = \frac{1}{2} C_d \rho D \sqrt{(u_x - \dot{x})^2 + (u_y - \dot{y})^2} \begin{pmatrix} u_x - \dot{x} \\ u_y - \dot{y} \end{pmatrix} \quad (2a)$$

$$+ \rho \frac{\pi D^2}{4} \begin{bmatrix} 1 + C_{xx} & 1 + C_{xy} \\ 1 + C_{yx} & 1 + C_{yy} \end{bmatrix} \begin{pmatrix} \dot{u}_x \\ \dot{u}_y \end{pmatrix} - \begin{bmatrix} C_{xx} & C_{xy} \\ C_{yx} & C_{yy} \end{bmatrix} \begin{pmatrix} \ddot{x} \\ \ddot{y} \end{pmatrix} \quad (2b)$$

$$\pm \frac{1}{2} C_l \rho D \sqrt{(u_x - \dot{x})^2 + (u_y - \dot{y})^2} \begin{pmatrix} u_y - \dot{y} \\ u_x - \dot{x} \end{pmatrix} \quad (2c)$$

- $f_x, f_y$  = wave force per unit length  
 $\rho$  = water density  
 $D$  = diameter of the vertical cylindrical pile  
 $C_d$  = drag coefficient  
 $C_{xx}, C_{yy}$  = added mass coefficients  
 $C_l$  = lift coefficient  
 $u_x, u_y$  = horizontal orbital velocity  
 $\dot{u}_x, \dot{u}_y$  = temporal derivatives of  $u_x$  and  $u_y$   
 $\dot{x}, \dot{y}$  = horizontal displacement velocity  
 $\ddot{x}, \ddot{y}$  = horizontal displacement acceleration

The reducing assumptions that pile movements are of very small value and therefore ineffective regarding force generation, and that the potential field is axial-symmetric, i.e.  $1 + C_{xx} = 1 + C_{yy} = C_m$  (inertia coefficient), yield

$$\begin{pmatrix} f_x \\ f_y \end{pmatrix} = \frac{1}{2} D \rho C_d |\vec{u}| \begin{pmatrix} u_x \\ u_y \end{pmatrix} + \frac{\pi}{4} \rho D^2 C_m \begin{pmatrix} \dot{u}_x \\ \dot{u}_y \end{pmatrix} \pm \frac{1}{2} \rho D C_l |\vec{u}| \begin{pmatrix} u_y \\ u_x \end{pmatrix} \quad (3)$$

with  $|\vec{u}| = \sqrt{u_x^2 + u_y^2}$ .

Due to the complex vorticity mechanism the sign of the lift term cannot be defined theoretically. The inline force in X-direction becomes

$$f_x = \frac{1}{2} \rho D C_d u_x |\vec{u}| + \frac{\pi}{4} \rho D^2 C_m \dot{u}_x \pm \frac{1}{2} \rho D C_l u_y |\vec{u}|. \quad (4)$$

Neglecting the lift term we get

$$f_x = \frac{1}{2} \rho D C_d u_x |\vec{u}| + \frac{\pi}{4} \rho D^2 C_m \dot{u}_x. \quad (5)$$

For the two-dimensional case in the wave channel  $u_y$  in equation (3) disappears so that equation (5) gives the well-known Morison's equation

$$f_x = \frac{1}{2} \rho D C_d u_x |u_x| + \frac{\pi}{4} \rho D^2 C_m \dot{u}_x \quad (6)$$

For determining Morison coefficients from time-averaged field measurements the mean square method was applied (/6/). Equation (5) goes over in

$$\overline{f_x^2} = A^2 \overline{u_x^2 |u_x|^2} + B^2 \overline{\dot{u}_x^2} + 2 A B \overline{u_x \dot{u}_x |u_x|} \quad (7)$$

The bars indicate mean values of the squares of the measured quantities ( $f_x$ ,  $u_x$ ,  $|u_x|$ ,  $\dot{u}_x$ ) integrated over a chosen interval. Assuming linear independence between  $u_x |u_x|$  and  $\dot{u}_x$  the cross product can be neglected. The solution of a pair of linear equations for consecutive intervals gives the unknown coefficients A and B and also the Morison coefficients

$$C_d = \frac{A}{\frac{1}{2} \rho D} \quad , \quad C_m = \frac{B}{\frac{\pi}{4} \rho D^2} \quad .$$

It should be noted here, that the solution of the linear system of equations (7) will be valid if the flow is stationary and if the parameters are time-invariant.

Mean squared equation (6) becomes

$$\overline{f_x^2} = A^2 \overline{u_x^4} + B^2 \overline{\dot{u}_x^2} + 2 A B \overline{u_x \dot{u}_x |u_x|} \quad (8)$$

The mean squares corresponding to equation (4) lead to a more complicated formula

$$\overline{f_x^2} = A^2 \overline{u_x^2 |u_x|^2} + B^2 \overline{\dot{u}_x^2} + C^2 \overline{u_y^2 |u_x|^2} + 2 A C \overline{u_x u_y |u_x|^2} + 2 B C \overline{\dot{u}_x u_y |u_x|} + 2 A B \overline{u_x \dot{u}_x |u_x|} \quad (9)$$

Due to linear independence the last term can be neglected again. Because there are nonvanishing cross terms in (9), there exists no linear solution. Instead of solving equation (9) the square of the error E which is defined as the difference between the right and left hand side of equation (9) is minimized:

$$\frac{1}{2} \sum_{i=1}^N E_i^2 \quad (A, B, C) \xrightarrow{!} \text{Min} \quad (10)$$

N = number of averaged intervals

The unknown coefficients for the feedback to equation (4) are

$$C_d = \frac{A}{\frac{1}{2} \rho D} \quad , \quad C_m = \frac{B}{\frac{\pi}{4} \rho D^2} \quad , \quad C_l = \frac{C}{\frac{1}{2} \rho D} \quad .$$

The minimization is performed by an iterative gradient technique. The essentially same method can be used to minimize the two-parametric equations (7) and (8). Two independent solutions for the parameters from the same time-averaged record can therefore be obtained and compared.

## ANALYSIS IN THE AMPLITUDE AND FREQUENCY DOMAIN

Measured field data and wave channel data were analyzed using similar procedures (except for minor differences in their smoothing requirements detailed later on). The analysis was performed in the frequency domain and in the amplitude domain.

At the first stage, data were checked for stationarity. To this purpose, the original record was partitioned in equal time intervals (about 30 sec) for each of which a sample mean was calculated. Next, the number of runs about the mean value calculated for the entire record was counted and compared to the values for the run distribution. The hypothesis of stationarity was rejected at the  $\alpha = 0.05$  level of significance because the number of runs counted was considerably lower than the lower bound of the acceptance region (this was especially true for the surface elevation record, less so far the horizontal orbital velocity). This implies that there is a non-negligible contribution to the surface elevation with a period at least one order of magnitude longer than the wave periods. This phenomenon may be attributed to surf beat due to wave groupiness.

Now, letting  $z(t)$  be the nonstationary surface elevation,  $\eta(t)$  a random process with a stationary mean value of zero, and  $G(t)$  a very slow process (henceforth called the trend of  $z(t)$ ) compared to  $\eta(t)$ , we may write

$$z(t) = G(t) + \eta(t) \quad (11)$$

It can then be shown (Bendat and Piersol (/1/)) that the expected value of  $z(t)$  is  $G(t)$ . The mean square value of  $z(t)$  is

$$E [(G + \eta)^2] = E [G^2] + E [\eta^2] + 2 E [G \cdot \eta] \quad (12)$$

where the last term turns out to be of negligible magnitude compared to the other two, implying that  $G(t)$  and  $\eta(t)$  are linearly independent; for, in this case,  $E [G \cdot \eta] = E [G] \cdot E [\eta]$  and  $E [\eta]$  is zero by definition. Equation (12) shows that the mean square value of the surface elevation would be overestimated by the amount  $E [G^2]$  if the trend portion is not removed. It is by precisely this amount that the spectral density function would also be overestimated (specifically, in the lower frequency range). In fact, the trend would nullify the estimation of low frequency spectral content. It is for these reasons that it was decided to remove the trend. An appropriate estimate for  $G(t)$  is given by short time averaging as follows:

$$\hat{G}(t) = \frac{1}{2T} \int_{t-T}^{t+T} z(\tau) d\tau \quad (13)$$

It was found that a satisfactory trade-off between bias error and random error for  $G(t)$  could be achieved for  $2T = 47$  sec. For a digitized  $z(t)$  with sampling rate  $t$ , this operation is equivalent to the application of a finite-impulse-response digital filter with transfer function

$$H(\omega \Delta t) = \frac{\sin(\omega T)}{\sin \frac{\omega \Delta t}{2}} \cdot \frac{\Delta t}{2T} \quad (14)$$

The transfer function being real-valued, there is no phase distortion associated with the filtering operation. Additionally, if the same

linear operation is performed on two different records (e.g. surface elevation and horizontal orbital velocity), then the transfer function and associated coherence remain unchanged. This prompted us to use the trend filter on all processed signals. Data analysis in the frequency domain concentrated on the estimation of power spectral density functions  $\hat{S}_{ii}(f)$ , gain functions  $|\hat{H}_{ij}(f)|$  and coherence functions  $\hat{\gamma}_{ij}(f)$ . Preliminary tests showed that there are no significant contributions above 0.6 Hz. The estimates obtained were therefore plotted up to that frequency (some up to 0.5 Hz), not up to the Nyquist frequency, this being 2.6 Hz for field measurements and 20 Hz for wave channel measurements. Since records of various length were used (15 to 20 min for the field), it was decided to keep the number of degrees of freedom for the spectral estimates practically constant at  $n = 40$ . This means the normalised standard error

$$\epsilon_r = \left(\frac{1}{2} \cdot n\right)^{-\frac{1}{2}} = 0.22$$

The reasons leading to the choice for  $n$  are:

- a smaller number of degrees of freedom would appreciably increase the random error in the spectral estimates. For instance,  $n = 22$  would give  $\epsilon_r = 0.3$ .
- a larger number of degrees of freedom would not lead to a corresponding reduction of random error. For example, to achieve  $\epsilon_r = 0.1$ , we would require  $n = 200$  (five times more degrees of freedom). Such a disproportionate increase in the number of degrees of freedom would require increasing the resolution bandwidth (and thus increasing the bias error) or increasing the record length (and thereby violating the stationary assumption).

Frequency smoothing need not be performed on regular wave data obtained under laboratory conditions.

Standard FFT procedures are used to obtain all estimates from the time records. For the power spectral density estimate  $\hat{S}_{\dot{u}\dot{u}}$  of the horizontal acceleration  $\partial u / \partial t$  for field data, however, use of the well-known identity

$$\mathcal{F}\left[\frac{\partial u}{\partial t}\right] = j\omega \mathcal{F}[u]$$

where  $\mathcal{F}[\ ]$  is the Fourier Transform and  $j = \sqrt{-1}$  was made,

RESULTS AND CONCLUSIONS

The application of the mean square method in two-dimensional case (equ. (8) for regular waves in the laboratory) seems to be quite satisfactory. The mean parameters  $C_d$  and  $C_m$  corresponding to various time-averaged intervals were plotted in Fig. 7 for the linear solution and for the minimization of the squared error.  $C_m$  is almost independent from the length of intervals. The values for  $C_d$  differ significantly between the estimation methods used and display considerable scatter.

Feeding back a suitable pair of force coefficients ( $C_d = 1.0$ ;  $C_m = 1.5$ ; Dean's reliability ratio  $r = 0.8$  to  $1.8$ ) to equation (6) and operating with measured kinematics, the force was obtained in comparison to the real measured force (Fig.8). A quite good agreement of measured and calculated force plots can be observed. The goodness of mean square based estimations was also verified by the gain and coherence functions

Fig. 7: Calculated Force Coefficients from Laboratory

Fig. 8: Time History of Measured and Calculated Test-Section Wave Forces

between measured and calculated forces (Fig.9). The gain function shows that a proportional relation exists in the range of high coherence; the value of  $|H_{xy}|$  is nearly unity. Utilizing mean square method in field data processing equations (7) and (9) were computed. Fig.10 displays results for two- and three-parametrical cases. It should be noted, that the lift term in equation (9) is superposed in inline direction because the present velocity in transverse direction generates this lift force, theoretically. Again, the coefficient  $C_m$  is nearly independent from the length of intervals and from the estimation methods. Values of  $C_d$  are somewhat smaller in the three-parametrical case. Feeding back suitable pairs of estimated force coefficients to equation (5) with the simultaneously measured kinema-

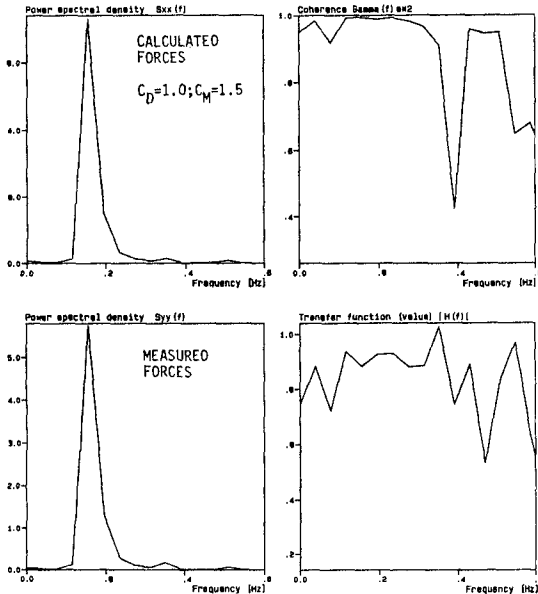

Fig. 9: Frequency Characteristics of Measured and Calculated Forces-Laboratory (Regular Waves)

Fig.10: Calculated Force Coefficients from Field Data

tics, time records of calculated forces were obtained. These time records matched poorly with the measured force. Inclusion of the lift term in equation (4) didn't give any better fit. These comparisons indicate that Morison's equation may be deemed adequate in predicting the inline force for simple flow structures (harmonic unidirectional waves and no current) as encountered under laboratory conditions; this is not the case for complex flow regimes as found in the nearshore area, in particular predicting maximum forces. This should not be surprising, since the assumptions associated with the derivation of Morison's equation are valid to a much higher degree for laboratory conditions than in the real irregular sea.

On the other hand it can be noted that the power (zero order moment) of the calculated force spectrum ( $C_d = 0.8$ ;  $C_m = 1.4$ ;  $r = 1.2$  to  $2.0$ ) has nearly the same value as that of the measured force (Fig.11). For lower frequencies the calculated forces are somewhat overestimated and in the range of higher frequencies they are underestimated. The amount of total energy within a 16 minute record is fairly good represented by recalculations with Morison's equation using measured kinematics and mean square estimated coefficients. This was expected, because Morison's equation is derived from power equilibrium considerations. Due to rapid changes in the flow (Sarpkaya (/7/)) inline force components at higher frequencies than those considered by Morison's equation occurred in the field. The interaction between transverse and inline forces, further influenced by nearshore currents, might be responsible for the higher frequency contributions to the inline force spectrum.

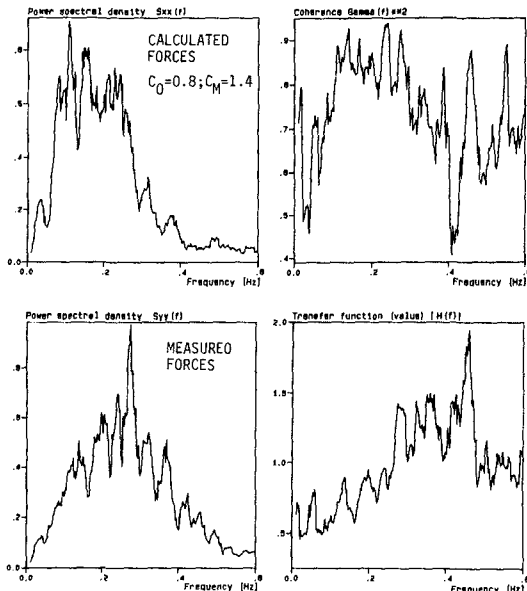

Fig.11: Frequency Characteristics of Measured and Calculated Forces-Field (Irregular Sea State)

Frequency analysis of field data, performed as described in the previous section, resulted in power spectra for the surface elevation, measured wave kinematics and measured forces, resolved in quasi-inline and quasi-transverse directions. Representative plots for several processed tests are given in Fig.12. Contrary to reported data obtained from deepwater offshore structures (Pearcey and Bishop (/6/)), it can be readily ascertained that the quasi-transverse force spectrum has a comparable amount of spectral content to the quasi-inline force spectrum. This prompted some additional investigations regarding the directionality of force calculating the force spectra for several pertinent directions. Fig.13 illustrates the directionality of force power spectra associated with a cylindrical nearshore pile (test-section) under the influence of storm surge conditions. At first, it may seem surprising that the spectral content (which is best summarised by the  $m_0$  parameter) is maximum about  $45^\circ$  from the mean incident wave direction, falling off gradually from this maximum to both sides and reaching a minimum at  $-45^\circ$  from the mean wave direction; the ratio of the maximum to the minimum value being 1.6 to 1.0. If, however, we consider the slowly varying velocity component established by the trend removal procedure, then the disparity between mean wave direction and "mean force direction" may be accounted for. This gradually varying current  $V$  (magnitude 0.4 m/s to 0.7 m/s), moving obliquely against wave propagation direction, conspires with the wave-induced velocities to produce an asymmetric flow pattern. An idealized model derived for this flow situation suggests that the clockwise-directed vortex is consistently reenforced to the detriment of the anti-clockwise vortex. This should result in a force component in "mean force direction". The observed effect due to complex interactions in the surf zone might explain reported failures of nearshore structures which often demonstrated material fatigue nearly transverse to the mean incident wave direction. In conclusion, only two-dimensional full-scale laboratory investigations with respect to lift force interactions will not suffice to determine the magnitude of these forces as measured nearshore at storm surge conditions.

## CHAPTER ONE HUNDRED NINETY FOUR

### THE WAVE PRESSING PLATE FOR PROTECTING COOLING WATERWAYS OF COASTAL POWER PLANTS

by

S. C. Chow<sup>1</sup>      Frederick L.W. Tang<sup>2</sup>  
H. H. Hwung<sup>3</sup>

#### ABSTRACT

A horizontal plate laid on water surface to reduce the wave motion is proved to be effective theoretically and verified by model tests done at Tainan Hydraulics Laboratory. This principle has been put into practice on the northern coast of Taiwan for protecting a nuclear power plant cooling water intake against intruding waves.

The design and construction of wave prevention works of such type are described succinctly in the paper. Also the effect of wave diminishing has been affirmed by measuring the respective waves heights outside and inside of the wave pressing plate.

#### INTRODUCTION

Almost all of the nuclear and fossil power plants in Taiwan are constructed on coast of the island with cooling water intakes and outlets facing open sea. For many years the traditional layout of breakwaters has normally been used to protect these cooling waterway structures against typhoon and monsoon waves and the sheltering effect of breakwaters is efficient. However, as these waterways are not intended for navigation, the traditional layout of breakwaters may be unnecessary and too expensive. An attractive alternative is presented herein.

1. Vice President, Taiwan Power Company, Retired since August 1, 1984 and presently Senior Adviser of Sinotech Engineering Consultants, Inc. R.O.C.
2. Dr. Eng. Professor, National Cheng Kung University, Taiwan, R.O.C.
3. Dr. Eng. Associate Professor and Director of Tainan Hydraulics Laboratory, National Cheng Kung University, Taiwan, R.O.C.

Basis of this paper originates from the idea described by J. J. Stoker in his book "Water Waves" that a horizontal plate placed on water surface is able to reduce the waves transmitting under it. Following that idea, the authors thought that some practical arrangements could be developed to keep off the waves intruding into the cooling water intake basin of coastal power plants without resorting to the building of conventional breakwaters. When the second nuclear power plant located on the northern coast of Taiwan was planned in 1974, the authors started to investigate the feasibility of applying such type of wave prevention system. Then elaborate model tests were carried out and verified that such an idea is feasible. Furthermore, the construction cost will be much less in comparison with building breakwaters, approximately in the ratio of one to three. An estimated saving of US\$ 10 million can be achieved for Taipower Fourth Nuclear Project by adopting the wave pressing plate intake system constructed on rock against an intake system of traditional breakwaters constructed on beach.

#### THEORETICAL CONSIDERATION

Now, if we consider a horizontal plate located on water surface as shown in Fig-1

Fig - 1

From this figure, the wave motion can be divided into three regions, (I) an incidental wave region, (II) the wave motion being pressed by a horizontal plate and (III) a transmitting wave region. Since the wave motion is an inviscid, incompressible, irrotational flow and the water depth of such water way is small enough to assume the incidental wave as a long wave, the potential function of

wave motion can be written as

$$\Phi = \left. \begin{aligned} & \frac{A \cosh [k_0 (z+d)]}{\cosh (k_0 d)} \exp [i (k_0 x + \omega t)] \\ & + \frac{B \cosh [k_0 (z+d)]}{\cosh (k_0 d)} \exp [i (k_0 x - \omega t)] \\ & + \sum_{n=1}^{\infty} \frac{C_n \cos (k_n' (z+d))}{\cos (k_n' d)} \exp (k_n' x + i \omega t) \\ & + \sum_{n=1}^{\infty} \frac{D_n \cos [k_n' (z+d)]}{\cos (k_n' d)} \exp (k_n' x - i \omega t) \end{aligned} \right\} \quad (1)$$

Here, A, B, C<sub>n</sub>, D<sub>n</sub> are the arbitrary constants of integration. And the potential function will be satisfied with Laplace's equation.

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \quad (2)$$

Then applying the method of separation of variables and the boundary conditions of the above wave motion, we can obtain the potential functions in regions (I)(II)(III) respectively as follows:

$$\Phi_1 = A \exp [i (k_0 x + \omega t)] + B \exp [-i (k_0 x - \omega t)] \quad (3)$$

$$\Phi_2 = (C + D x) \exp (i \omega t) \quad (4)$$

$$\Phi_3 = E \exp [i (k_0 x + \omega t)] \quad (5)$$

And A, B, C, D, E will be solved from the continuous conditions of wave motion at the boundary of the horizontal plate, we got

$$\left. \begin{aligned} B &= \frac{i \lambda \pi \exp (2 i \lambda \pi)}{1 + i \lambda \pi} A \\ C &= A \exp (i \lambda \pi) \\ D &= \frac{i \lambda \pi \exp (i \lambda \pi)}{\ell (1 + i \lambda \pi)} A \\ E &= \frac{\exp (2 i \lambda \pi)}{1 + i \lambda \pi} A \end{aligned} \right\} \quad (6)$$

and the coefficient of wave reflection  $K_r$  and transmission  $K_t$  will be worked out respectively

$$\left. \begin{aligned} K_r &= \left| \frac{B}{A} \right| = \frac{\lambda \pi}{\sqrt{1 + (\lambda \pi)^2}} \\ K_t &= \left| \frac{E}{A} \right| = \frac{1}{\sqrt{1 + (\lambda \pi)^2}} \end{aligned} \right\} \quad (7)$$

where  $\lambda$  is the ratio of the horizontal plate length  $2\ell$  to wave length  $L$ , and  $A$ ,  $B$ ,  $E$  represent the amplitudes of incidental wave, reflecting wave and transmitting wave respectively. Equation (7) shows that the wave height behind the horizontal plate will be reduced effectively as the plate is made long enough.

#### HYDRAULIC MODEL TESTS

Before we commenced the hydraulic model tests for the cooling water intake of the nuclear power plant, various calculations had to be performed to estimate the water elevations of tide, storm surge, tsunami and intensity of waves due to lack of available field records except meteorological and tidal data in the vicinity of the plant site.

From the numerical calculations, the highest surge deviation caused by typhoons was determined to be 1.20m. Then based on the past records of submarine earthquakes from 1904 to 1963 in the north-east of Taiwan Island, the largest wave height and period of tsunami were calculated to be 10 meters and 49 minutes by Wilson's formula, and the height of run-up to be about 8 meters by Iida's empirical data which is close to the recorded value of 7.5 meter experienced at Keelung Harbor in 1918.

Furthermore, waves of typhoons were also calculated by numerical method. Four real typhoons passing through the northern coast of Taiwan were picked out, and in addition, three model typhoons advancing from east to west were also assumed into the computer program. The routes of these typhoons are shown in Fig-2, and the calculated result of the maximum wave height is 7.86 meters and the period is 8.78 seconds in NNE direction.

Finally, the numerical calculations of wave reflection in shallow water region in front of the second nuclear power plant were also performed.

Based on the above mentioned calculations, we proceeded with three dimensional physical model tests to measure wave features and to verify whether the general intake

layout of the second nuclear power plant was proper or not. Fifty-one test runs of experiments had been carried out and the best layout was determined.

Fig - 2

Time interval between points: 6 hrs.

Afterwards, according to the best intake layout, the detailed experiments on the arrangement of wave dissipation structures were performed in a wave channel with circulation water system to simulate the coexistent situation of waves being acting on various structures and water being sucked through the intake basin. The scale of the model was decided to be 1:36, and wave features, water elevations and intake cooling water discharge were incorporated in this model. After a number of testing runs, we found that it was very important to determine the elevation of the horizontal plate located across the cooling water entrance and the tetrapod blocks installed in front of intake basin.

Experimental results indicated that with the horizontal plate, 18 meters in length, placed on the elevation of

+1.70 m and the tetrapod blocks raised to elevation +3.50m, the cooling water pumping system was able to suck cooling water through intake basin satisfactorily, because in most test runs, water surface fluctuations in front of the pump house were less than 40 cm. Such intake arrangement, though relatively complicate, will be more economical. And the flow patterns in the basin were observed incidentally. Eddies were recognized on both left and right portions of the basin, and flow velocity across the entrance was found to be smaller than 90 cm/sec. As a refinement splitter walls were added just downstream of the entrance, so that the flow would be more regulated to reduce the eddies. The plan view and side view of intake system of the second nuclear power plant were shown in Fig-3.

Fig - 3

After obtaining the test results of physical model, the authors set the vital design guides of the wave protection works for intake system of the second nuclear power plant: (1) a horizontal plate of 18 meters in length be placed on the waterway connecting lead channel with intake basin, (2) elevation of the horizontal plate be set at +1.70m and (3) tetrapod blocks be raised to elevation +3.5 m in front of the intake entrance. Moreover, two straight

piles of tetrapod blocks, one on each side, have been built to elevation +7.0 m for reducing wave overtopping in case of extraordinary high tide caused by typhoon.

Incidentally the lead channel arrangement also contribute to wave dissipation. Two parallel channels about 150 meters long and 50 meters apart are tied together by a cross channel to form a U-loop in front of the intake. Flow to the horizontal wave pressing plate is taken from the central portion of the cross channel so that waves rushing in along the parallel channels will have to make a right angle turn to enter into the tie channel in opposite directions. The opposing flows cause waves to die down considerably as can be seen from Photo-1.

#### CONSTRUCTION RESULTS

The construction works were completed in 1980 as shown in the following photos. Photo-1 is a birds-eye view of the intake system of the second nuclear power plant. Photo-2 is a rear view of intake structures taken from the pump house. Photo-3 is a front view of the horizontal pressing plate and entrance taken from lead channel and Photo-4 is a side view of the horizontal pressing plate with two splitter walls extending into the intake basin.

PHOTO - 1

PHOTO — 2

PHOTO — 3

PHOTO - 4

After operation of the second nuclear power plant, waves at an offshore point of 15 m deep below the low water level and water surface fluctuation in the intake basin have been measured constantly. Several typhoons attacked the coast and from records of the intake basin we found only five times when the maximum wave height exceeded 0.5m, but all the significant wave heights measured in those two years were below 0.3m. Fig-4 shows the wave records measured from 7th to 17th, August, 1982; the solid line record wave height at an offshore point of 15m deep below the low water level and dashed line recorded wave height in intake basin respectively. It is seen that the wave heights are greatly reduced while waves pass through under the wave pressing plate of the intake structure. The intake structure design has therefore been proven to be completely successful.

Fig-4 wave comparison of outside and inside of the horizontal pressing plate

CONCLUSION

According to the experience obtained from the model tests and the construction works in prototype, it would be worthwhile to introduce to the technical community the effectiveness of the wave pressing plate in protecting the cooling waterways and the potential saving in construction costs due to adoption of the wave pressing design. However, the application is limited to rocky coast for cooling water intake. Where sandy beach is near the rocky intake, the designer should be alert to sedimentation problem since during sustained rough weather more and more fine sand particles would be in suspension and move with the cooling water flow.

The wave pressing plate idea is also applicable to cooling water discharge on beach in a reversed direction of water flow. One typical example is the cooling water discharge at Hsinta Fossil Power Plant where two 500 MW units are in operation and two 550 MW units are under construction.

## CHAPTER ONE HUNDRED NINETY FIVE

### Wave Forces and Impacts on a Circular and Square Caisson

J.W. van der Meer\* and E. Benassai\*\*

#### Abstract

The existing breakwater at Civitavecchia Harbour, Italy, will be extended with a part of caissons. In order to investigate wave forces for this caisson, the Ministero dei Lavori Pubblici commissioned the Delft Hydraulics Laboratory to perform a model investigation on the proposed extension. In the first part of the study quasi-static wave forces on the entire caisson were measured by means of a force measuring frame. In the second part wave impacts were recorded by pressure cells at 22 positions of the caisson.

The investigation contained two main items which are discussed in this paper:

- Comparison of quasi-static wave forces with maximum forces by wave impacts.
- Comparison of forces and impacts for a circular caisson with those measured for a square caisson.

#### Introduction

The stability of a caisson against wave attack can be described by external parameters (loads) and internal parameters (strength). External parameters are for example, wave height, wave period, foreshore and structure geometry. Internal parameters are dimensions, mass and mass distribution of the caisson and the friction coefficient between the bottom of the caisson and the foundation. If the loads are known for a given external geometry of the caisson, the mass and dimensions required for stability can be calculated. These calculations are simple when quasi-static wave forces are assumed, i.e. forces which vary with the wave period. They can be found in most handbooks. The measuring of the loads and the calculations on stability become more complicated, when also wave impacts have to be considered. For stability calculations which include the time-dependent dynamic forces one is referred to [1].

In this paper an investigation is described on wave forces on a caisson subject to both quasi-static wave forces and wave impacts. Both a caisson with a circular and a rectangular cross-section was examined.

\* Delft Hydraulics Laboratory, P.O. Box 177, 2600 MH Delft, The Netherlands

\*\* Professor of Maritime Constructions at Hydraulics and Hydraulic Engineering, Naples, Italy

The main dimensions of the caisson are shown in Fig. 1. Both caissons consisted of a base plate with dimensions of  $20 \times 22 \text{ m}^2$  and a curved crest wall with the top elevation 8.5 m above Mean Sea Level (M.S.L.). The cylindrical caisson had a diameter of 19 m, for a square caisson the dimensions were  $19 \times 20 \text{ m}$ . The caissons were founded on a berm 18.5 m below M.S.L. The water depth in front of the caisson was approximately 30 m.

The design conditions were established at a significant wave height of 8.0 m and an average wave period of 10.5 s. The linear scale factor used for the investigation was 38. All tests were conducted in a 1.0 m wide, 1.2 m deep and 50.0 m long wave flume with the test section installed about 45 m from the random wave generator. This wave generator is capable of performing both translatory and rotational motions by means of a hydraulic actuator, programmed by a closed loop servo-system. The command signal of this loop is obtained from a punched tape, representing a random signal with a predetermined wave energy density spectrum.

#### Quasi-Static Wave Forces

Sliding and overturning are the failure mechanisms for an entire caisson. This means that only the total horizontal and vertical wave force and the total overturning moment on the caisson are of interest for stability calculations. One is not interested in the distribution of the wave pressures on the caisson. In this case the wave forces can simply be measured by a caisson attached to a force metering frame.

Tests on quasi-static wave forces were performed on one caisson in the middle of the flume with on each side another half caisson. The middle caisson was suspended above the floor of the flume by rigid metal plates attached to the inner section of the Laboratories force metering frame, see Fig. 2. The inner section of the metering frame was supported by a rigidly mounted external frame section through five suspensions with strain gauges, two in the horizontal and three in the vertical planes. A clearance of approximately 3 mm was left around the front and sides of the middle caisson to ensure complete freedom of movement during the force measuring tests. A pressure cell in front of the caisson measured the variation in water level.

Typical signal recordings of the five gauges and the pressure cell are shown in Fig. 3. Impact forces will cause resonance of the suspended caisson at its natural frequency. Second-order low-pass electrical filters of 5 Hz were installed in the force metering recording circuits to eliminate this effect. This means, however, that only the quasi-static forces and no wave impacts were present in the measured signals.

The signals of the strain gauges were recorded by a HP 1000 computer with a sampling frequency of 25 Hz. The time histories of the total horizontal force ( $F_h$ ), the total vertical force ( $F_v$ ) and the total overturning moment ( $M_A$ ) were calculated from the signals of the strain gauges, using the equations given in Fig. 2. The maximum force and moment for each wave crest were calculated from these time histories and with these data exceedance curves were calculated. Fig. 4

FIGURE 1. DIMENSIONS OF THE CAISSON

vertical force :  $F_v = F_{v1} + F_{v2} + F_{v3}$   
 horizontal force :  $F_h = F_{h1} + F_{h2}$   
 moment :  $M_A = F_{v1} \cdot a - (F_{v2} + F_{v3}) \cdot b + (F_{h1} \cdot F_{h2}) \cdot c$

 total horizontal force  $F_h = F_{h1} + F_{h2}$

FIGURE 3. TYPICAL RECORDINGS OF THE FORCE MEASURING FRAME

FIGURE 4. EXCEEDANCE CURVE FOR THE TOTAL HORIZONTAL FORCE

gives the exceedance curve for the horizontal force, both for a circular and a square caisson.

Although a small difference exists for the two exceedance curves, the maximum horizontal force is the same for a circular and a square caisson. This maximum horizontal force amounted to 47 MN, full scale value. It can be concluded that the shape of the caisson has hardly any influence on the quasi-static horizontal wave forces.

#### Wave Impacts

Wave impacts can cause very high local pressures, exceeding the hydrostatic pressures by a factor 10-50. The parts of a structure where impacts occur should be designed for these high pressures. For this reason wave impacts were measured on the caisson.

The front side of one caisson with on each side another half caisson was constructed of 10 mm thick steel, see Fig. 5. The rear side was strengthened by steel diaphragms to ensure a rigid model construction. The caissons were founded on a rigid steel base, the berm in front of the caisson was constructed of concrete. Six or seven pressure cells were applied for each test to measure wave impacts simultaneously along a vertical or horizontal axis. A front view of the positions of the pressure cells is given in Fig. 6. In this way impacts were measured at 22 positions of the caisson. Tests 1..4 refer to the circular caisson. In test 5 the square caisson was investigated. To maintain a constant water level the overtopped water at the rear side of the caisson was pumped back to the sea side.

For the tests 0.8 cm diameter DRUCK PDCR 10 miniature pressure transducers were used, each having operating pressure of 100 kPa with 400% overpressure capability. The pressure cells were mounted on a brass plate. The transducer calibrations supplied by the manufacturer were confirmed by static pressure tests. The natural frequency in air was 28,000 Hz and mounted on the caisson and in water approximately 10,000-15,000 Hz. Outputs from the pressure transducers were fed into a RACAL magnetic tape recorder for off-line processing. Seven data channels were available for the RACAL tape recorder. For a recording speed of 15 inch/s (0.38 m/s) the recorder had a 100% frequency response up to 4000 Hz and up to 5000 Hz for an accuracy of 70%. The ten highest impacts, determined from a Honeywell oscillographic visicorder (model 1858) were recorded on a second RACAL tape recorder with a time expansion of 16 times. These analog signals were used, again with a time expansion of 16 times, for sampling by means of a HP1000 computer with a sampling frequency of 100 Hz. Therefore the sampling frequency of the original pressure outputs was  $16 \times 16 \times 100 = 25,600$  Hz. The overall frequency of the measuring system was about 4,000 Hz.

Digital processing of data give a fast method to combine all pressure signals into a total force by multiplying with different factors, representing the respective working area. Two impacts, plotted at different time scales, are shown in Fig. 7.

For each test and for each pressure cell the ten highest impacts were plotted. The schematization and the location of these impacts on

FIGURE 5. TEST SET - UP FOR WAVE IMPACT STUDY

FIGURE 6. FRONT VIEW OF CAISSON WITH POSITIONS OF PRESSURE CELLS

Fig a. impact due to wave tongue

Fig b. impact due to enclosed air pocket

FIGURE 7. IMPACTS AT DIFFERENT TIME SCALE

the caisson are shown in Fig. 8. All local impacts could be described by four diagrams, two with the shape of one or two triangles and two with the shape of a damped oscillation. Fig. 8 shows also the moment just before the impacts occurs. The wave front rises along the vertical wall and a wave tongue falls on the upper part of the crest wall, whilst an air pocket is formed for the lower section of the crest wall. At the upper part high impacts occur under the wave tongue with impact type 1 or 2. At the lower part of the crest wall, oscillation of the air pocket was observed. Pressures are less high and the rising time longer (type 3). This oscillation generates pressure waves which travel through the water and give impact pressures at the pressure cells below M.S.L. (type 4) with a fast damping. Impact types 1 and 2 have been found for breaking waves on a slope and type 3 was found by Ramkema [2].

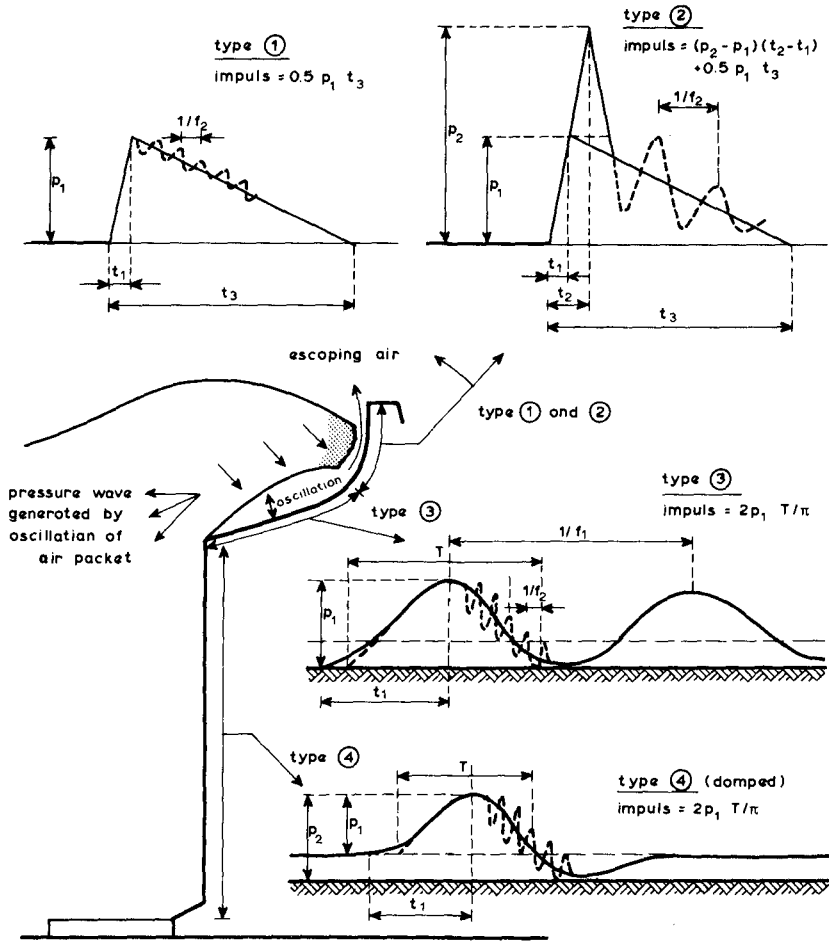

Every impact is completely described by the pressure  $p_1$  and  $p_2$ , the rising times  $t_1$  and  $t_2$ , the impact duration  $t_3$ , the duration  $T$  of the first half oscillation (type 3), the frequency of this oscillation  $f_1$  and the frequency  $f_2$  of oscillations during the decrease of the pressure. The impulse of the impact can be calculated with the above mentioned characteristics and formulae are given in Fig. 8. The impact by the wave tongue (type 2) gives the highest pressures, up to  $44.5 \text{ kN/m}^2$ , model value. The frequency of the oscillation of the air pocket is within the range of  $33 < f_1 < 80 \text{ Hz}$ . Oscillation of little air bubbles was observed with frequencies in the range of  $200 < f_2 < 2000 \text{ Hz}$ .

#### Comparison Wave Impacts for Circular and Square Caisson

For each test six or seven impacts were recorded simultaneously, see Fig. 6. The sum of the signals was calculated, taking into account the area corresponding to each cell, the direction of the resultant force and the scale of the model. No correct scaling laws are available for all types of impacts observed for the tests. Maybe the model law given by Ramkema [2] may be applied for impact types 3 and 4, the higher impacts types 1 and 2 are not scaled correctly with this law. The common relationship (Froude) is  $n_p = n_l$  and  $n_t = \sqrt{n_l}$ . As this relationship gives the most conservative results it was used for all impacts. The scale factor for the pressure was  $n_p = 38$  and for the time  $n_t = 6.16$ . The time history of the total force per meter width for test 1 (circular caisson) and test 5 (square caisson) is shown in Fig. 9 for the highest impact. From this figure the following conclusions can be derived for the maximum horizontal force per meter width:

The maximum horizontal force for the circular and square caisson are almost the same and amounted to  $4.4 \text{ MN/m}$  and  $5.0 \text{ MN/m}$  respectively. The impulse, however, was 1.8 times larger for the square caisson ( $i = 0.188 \text{ MNs/m}$  and  $i = 0.347 \text{ MNs/m}$  for the circular and square caisson, respectively).

For the circular caisson the impacts on 22 pressure cells were measured. Combination of these signals obtained from tests 1..4 gives the total horizontal signal for the circular caisson. The total horizontal force per meter width for test 5 (see Fig. 9) multiplied by 20 m gives the total horizontal force for the square caisson. The time history of the horizontal force for the circular caisson and for the

$t_1, t_2$  = rising time  
 $t_3$  = impact duration  
 $p_1, p_2$  = maximum pressures  
 $\Delta t_f$  = phase lag between maximum of two pressure cells

$f_2$  = frequency of air bubble oscillation in the wave front  
 $f_1$  = frequency of air packet enclosed by overlapping wave  
 $T$  = duration of half a sine

FIGURE 8. SCHEMATIZATION OF WAVE IMPACTS AND CORRESPONDING LOCATION

FIGURE 9. TIME HISTORY OF THE MAXIMUM HORIZONTAL IMPACT FORCE FOR TESTS 1 AND 5

FIGURE 10. TIME HISTORY OF THE MAXIMUM TOTAL HORIZONTAL IMPACT FORCE FOR THE ENTIRE CAISSON

square caisson are shown in Fig. 10 for the highest impact. From this figure the following conclusions can be derived for the total maximum horizontal impact force for the entire caisson:

- The maximum horizontal forces for the square caisson are 1.5 times higher than for the circular caisson. The average maximum horizontal force was  $F_h = 65.8$  MN for the circular caisson and  $F_h = 100.0$  MN for the square caisson.
- The impulse is also about 1.5 times higher for the square caisson. The impulse for the circular caisson was  $i = 3.8$  MNs and for the square caisson  $i = 6.4$  MNs.
- Rising time and duration of the impacts are almost the same for the circular and square caisson. The rising time is about  $t_1 = 0.07$  sec and the total duration of the impact  $t_3 = 0.17$  sec.

#### Comparison Quasi-Static Wave Forces and Wave Impacts

The maximum quasi-static force was established at 47 MN for both the circular and square caisson. This value is also given in Fig. 10. Scaling impact forces according to the Froude number, as was done in Figs. 9 and 10, gives maximum impact forces which are 2 times higher for the square caisson and 1.3 times higher for the circular caisson than the maximum quasi-static force.

The model law for iso-thermal compression, described by Ramkema [2] can be used for impact types 3 and 4. Although this law is not correct for impact types 1 and 2 it will be used in order to calculate a lower boundary for the impact force. In this case the maximum impact for the square caisson was used, where even the highest located impacts could be described by impact type 3, see Fig. 11. Results are given in Fig. 12 for the impact pressures and in Fig. 13 for the total maximum impact force for the caisson. The force signal of Fig. 10 (Froude scaling) has been added to Fig. 13.

Scaling according to the model law for iso-thermal compression shows much lower impacts than for scaling to the Froude number. The maximum horizontal force is about 40 MN for the compression model, whilst a force of 100 MN was calculated according to the Froude number. The actual maximum force in nature will be within this range and probably close to 50 MN, as impact types 1 and 2 are only present on a small part of the caisson.

#### Main Conclusions

- 1 Horizontal quasi-static wave forces on a circular and square caisson are almost the same.
- 2 All local impacts could be described by four diagrams, two with the shape of one or two triangles and two with the shape of a damped oscillation, see Fig. 8. The triangular types are caused by the impact of the wave tongue and can be compared with a wave breaking on a slope. The damped oscillation is caused by the compression of an enclosed air pocket as found by Ramkema [2]. The impact by the wave tongue gives the highest pressures, (up to  $44.5$  kN/m<sup>2</sup>). The frequency of the oscillation of the air pocket is within the range

FIGURE 11. MAXIMUM IMPACT PRESSURES FOR THE SQUARE CAISSON

FIGURE 12. PRESSURES OF TEST 5 SCALED ACCORDING TO THE COMPRESSION MODEL

of  $33 < f_1 < 80$  Hz. Oscillation of little air bubbles was observed with frequencies in the range of  $200 < f_2 < 2000$  Hz.

- 3 Total impact forces for a square caisson are 1.5 times higher than for a circular caisson, whilst also the impulse is about 1.5 times higher. Rising time and duration are almost the same for the circular and square caisson, see Fig. 10.
- 4 Scaling impact pressures according to the Froude number gives maximum impact forces which are 2 times higher for the square caisson and 1.3 times higher for the circular caisson than the maximum quasi-static force. Scaling according the model law for iso-thermal compression (Ramkema [2]) shows impact forces with the same values as the maximum quasi-static wave force.

## CHAPTER ONE HUNDRED NINETY SIX

### ATTENUATION OF WAVE INDUCED OSCILLATION IN PORTS BY IMPROVING THE CONDITIONS AT THE HARBOR ENTRANCE

M. Kubo<sup>1</sup>, S. Aoki<sup>2</sup> and J.J. Avitia Segura<sup>3</sup>

#### ABSTRACT

The authors developed the numerical method to calculate the wave height distribution around a pair of breakwaters with arbitrary shape of the edge. The effect of the resonators equipped in the breakwaters on the diffracted wave height is simulated by using this method. Simulated results show that the resonators have remarkable effect to reduce wave heights in a harbor. However, in the experiments, resonators are not so effective as predicted by the theory.

#### I. INTRODUCTION

A harbor should be a protected zone of water, able to bring safety for ships to permit the activities of traffic of merchandises and persons at all time. However, in harbors suffering from storm waves, cargo handlings are often interrupted and sometimes mooring lines are broken by large ship motions.

In order to protect a harbor from waves, a lot of money have been spent in constructing breakwaters. No matter how effective breakwater may be, waves pass through the breakwater gap inevitably. Once waves enter the harbor, it is difficult to absorb these energy in the harbor surrounded with vertical walls, and sometimes harbor resonance is induced when the wave period is close to the natural period of the harbor.

So the development of a new method to trap the wave energy before the waves enter the harbor is desired. As a new method to trap the wave energy, a resonator was introduced by Valembos in 1953 and defined as a wave absorber which can trap the wave energy by taking advantage of the resonance phenomenon. After that, some researchers investigated the wave resonators built in a channel and showed that they were sufficiently effective. (for example, W. James (1968,1970))

In this paper, we deal with diffraction problem by the breakwaters equipped with a resonator. The mathematical model is proposed to predict the diffracted wave height distribution for arbitrary shape of entrance and for any angle of the wave incidence. By using this

-

  2. Research Associate, Osaka Univ., Osaka, Japan
  3. Planeacion y Proyectos S.C., Mexico

model, wave transformation around the wave resonators is simulated. The calculated wave height are discussed by comparing with the experimental results.

## II. THEORY AND NUMERICAL PROCEDURE

In this section, first, the theoretical analysis to predict the diffracted wave height distribution for arbitrary shape of entrance is developed by modifying Lee's method (1970) which is widely used to calculate the wave height distribution in a harbor. Then, the numerical procedure to simulate diffracted waves are shown. Finally, the procedure is verified by comparing with the analytical solutions.

### (A) Theory

Let us take  $z$  axis upward from the still water level and assume that the fluid is invicid and the motion is irrotational. The equation of continuity for an incompressible fluid is expressed by the Laplace equation by using the velocity potential  $\Phi(x, y, z, t)$ :

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \quad (1)$$

For a sinusoidal wave with frequency  $\omega$ ,  $\Phi$  which satisfies the boundary condition at  $z=-h$ ,  $\partial\Phi/\partial z = 0$  is expressed as

$$\Phi(x, y, z, t) = A \frac{\cosh k(h+z)}{\cosh kh} f(x, y) e^{-i\omega t} \quad (2)$$

where  $A$  : constant,  
 $h$  : constant water depth,  
 $k$  : wave number,  
 $i = \sqrt{-1}$ ,

and  $f(x, y)$  is the wave function which satisfies the Helmholtz equation:

$$\frac{\partial^2 f(x, y)}{\partial x^2} + \frac{\partial^2 f(x, y)}{\partial y^2} + k^2 f(x, y) = 0 \quad (3)$$

The velocity potential of the fluid motion is determined by solving Eq. (3) under boundary conditions.

Fig. 1 shows a pair of straight breakwaters with arbitrary shape of edges and a coordinate system. To solve Eq.(3) in the domain of interest shown in Fig.1, we divide it into three regions. I is the open sea region, II is the entrance region and III is the harbor region.

The velocity potential in each region is described as  $\Phi_I$ ,  $\Phi_{II}$  and  $\Phi_{III}$ .  $\Phi_I$  can be divided into two terms  $\Phi_{I0}$  and  $\Phi_{I1}$  and described as follows:

$$\Phi_I = \Phi_{I0} + \Phi_{I1} = A \frac{\cosh k(h+z)}{\cosh kh} (f_0 + f_1) e^{-i\omega t} \quad (4)$$

where suffix 0 represents the composite waves of the incident and reflected waves when the boundary  $C_1$  is closed, and suffix 1 indicates the quantities concerning with the correction term due to the scattering waves from the region II.

Fig.1 The domain of interest and the coordinate

If the incident wave profile  $\zeta_I$  is given by the following equation:

$$\zeta_I = \zeta_0 \exp \{ -i (k_x x \cos \omega + k_y y \sin \omega + \omega t) \}, \tag{5}$$

the surface profile of the composite waves  $\zeta_I + \zeta_R$  becomes

$$\zeta_I + \zeta_R = 2 \zeta_0 \cos(k_y y \sin \omega) e^{-i k_x x \cos \omega} \cdot e^{-i \omega t} \tag{6}$$

where  $\zeta_0$  is the amplitude of the incident waves and  $\omega$  is the angle of the wave incidence defined in Fig.1. Another description of the surface profile is given by the dynamic condition on the free surface.

$$\zeta_I + \zeta_R = -\frac{1}{g} \left( \frac{\partial \Phi_{I0}}{\partial t} \right)_{z=0} = \frac{i \omega}{g} A f_0 e^{-i \omega t} \tag{7}$$

Comparing Eq.(6) and Eq.(7) and taking  $A = \frac{g \zeta_0}{i \omega}$ ,  $\Phi_I$  is expressed by

$$\Phi_I = \frac{g \zeta_0}{i \omega} \frac{\cosh k(h+z)}{\cosh k h} (f_0 + f_1) e^{-i \omega t} \tag{8}$$

where

$$f_0 = z \cos(k_y y \sin \omega) e^{-i k_x x \cos \omega} \tag{9}$$

Similarly the velocity potentials in region II and III can be expressed as

$$\Phi_{II} = \frac{g\zeta_0}{\lambda\sigma} \cdot \frac{\cosh kR(R+z)}{\cosh kR} f_2 e^{-i\omega t} \quad (10)$$

$$\Phi_{III} = \frac{g\zeta_0}{\lambda\sigma} \cdot \frac{\cosh kR(R+z)}{\cosh kR} f_3 e^{-i\omega t} \quad (11)$$

Taking the normal vector  $n$  of each region outward, the conditions of continuity of pressure and velocity between each region are described as follows:

on  $C_1$

$$f_0 + f_1 = f_2 \quad (12)$$

$$\frac{\partial f_1}{\partial n} = -\frac{\partial f_2}{\partial n} \quad (\because \frac{\partial f_0}{\partial n} = 0) \quad (13)$$

on  $C'_1$

$$\frac{\partial f_1}{\partial n} = 0 \quad (\because \frac{\partial f_0}{\partial n} = 0) \quad (14)$$

on  $C_2, C_4$

$$\frac{\partial f_2}{\partial n} = 0 \quad (15)$$

on  $C_3$

$$f_2 = f_3 \quad (16)$$

$$\frac{\partial f_2}{\partial n} = -\frac{\partial f_3}{\partial n} \quad (17)$$

on  $C'_3$

$$\frac{\partial f_3}{\partial n} = 0 \quad (18)$$

Furthermore the radiation condition must be considered:

$$f_i \rightarrow 0, \quad f_3 \rightarrow 0 \quad ; \quad \text{when } \sqrt{x^2+y^2} \rightarrow \infty \quad (19)$$

While, the wave function  $f_i$  ( $i=1,2,3$ ) at any position inside each region can be expressed in terms of  $f_i$  and  $\frac{\partial f_i}{\partial n}$  at the boundary of each region by applying Weber's solution of Helmholtz equation and Eq.(19).

$$f_1 = -\frac{\lambda}{4} \int_{C_1+C'_1} \left\{ f_1 \frac{\partial}{\partial n} H_0^{(1)}(kR) - H_0^{(1)}(kR) \frac{\partial f_1}{\partial n} \right\} ds \quad (20)$$

$$f_2 = -\frac{\lambda}{4} \int_{C_1+C_2+C_3+C_4} \left\{ f_2 \frac{\partial}{\partial n} H_0^{(1)}(kR) - H_0^{(1)}(kR) \frac{\partial f_2}{\partial n} \right\} ds \quad (21)$$

$$f_3 = -\frac{\lambda}{4} \int_{C_3+C'_3} \left\{ f_3 \frac{\partial}{\partial n} H_0^{(1)}(kR) - H_0^{(1)}(kR) \frac{\partial f_3}{\partial n} \right\} ds \quad (22)$$

,where  $H_0^{(1)}(kr)$  is the zeroth order Hankel function of the first kind and  $r$  is the distance between the point inside the region and that on the boundary. Similarly,  $f_i$  on the boundary is expressed in terms of  $f_i$  and  $\partial f_i / \partial n$  on the boundary as follows:

$$f_1(\text{on } C_1, C_1') = -\frac{i}{2} \int_{C_1+C_1'} \left\{ f_1 \frac{\partial}{\partial n} H_0^{(1)}(kr) - H_0^{(1)}(kr) \frac{\partial f_1}{\partial n} \right\} ds$$

$$= -\frac{i}{2} \int_{C_1} H_0^{(1)}(kr) \frac{\partial f_1}{\partial n} ds \tag{23}$$

$$(\because \partial f_1 / \partial n = 0 \text{ on } C_1 \text{ and } \frac{\partial}{\partial n} H_0^{(1)}(kr) = 0 \text{ on } C_1 \text{ and } C_1')$$

$$f_2(\text{on } C_1, C_2, C_3, C_4) = -\frac{i}{2} \int_{C_1+C_2+C_3+C_4} \left\{ f_2 \frac{\partial}{\partial n} H_0^{(1)}(kr) - H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} \right\} ds \tag{24}$$

$$f_3(\text{on } C_3, C_3') = -\frac{i}{2} \int_{C_3+C_3'} \left\{ f_3 \frac{\partial}{\partial n} H_0^{(1)}(kr) - H_0^{(1)}(kr) \frac{\partial f_3}{\partial n} \right\} ds$$

$$= -\frac{i}{2} \int_{C_3} H_0^{(1)}(kr) \frac{\partial f_3}{\partial n} ds \tag{25}$$

Using Eqs. (12), (13) and (23),

$$f_2 = f_0 - \frac{i}{2} \int_{C_1} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \quad (\text{on } C_1) \tag{26}$$

Eqs. (15) and (24) give the relation

$$f_2 = -\frac{i}{2} \int_{C_1+C_2+C_3+C_4} f_2 \frac{\partial}{\partial n} H_0^{(1)}(kr) ds + \frac{i}{2} \int_{C_1+C_3} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \tag{27}$$

(on  $C_1+C_2+C_3+C_4$ )

and Eqs. (16), (17) and (25) lead to the equation

$$f_2 = -\frac{i}{2} \int_{C_3} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \quad (\text{on } C_3) \tag{28}$$

The wave function  $f_2$  and  $\partial f_2 / \partial n$  are determined by solving Eqs. (26), (27) and (28). While, Eqs. (20) and (22) can be rewritten as follows, by using Eqs. (12), (13), (16) and (17):

$$f_1 = -\frac{i}{4} \int_{C_1} \left\{ f_2 \frac{\partial}{\partial n} H_0^{(1)}(kr) + H_0^{(1)}(kr) \frac{\partial f_1}{\partial n} \right\} ds$$

$$- \frac{i}{4} \int_{C_1'} f_1 \frac{\partial}{\partial n} H_0^{(1)}(kr) ds \tag{29}$$

$$f_3 = -\frac{i}{4} \int_{C_3} \left\{ f_2 \frac{\partial}{\partial n} H_0^{(1)}(kr) + H_0^{(1)}(kr) \frac{\partial f_3}{\partial n} \right\} ds$$

$$- \frac{i}{4} \int_{C_3'} f_3 \frac{\partial}{\partial n} H_0^{(1)}(kr) ds \tag{30}$$

In these equations,  $f_1$  on  $C'_1$  and  $f_3$  on  $C'_3$  are given by substituting Eqs. (13) and (17) into Eqs. (23) and (25):

$$f_1 = -\frac{\lambda}{2} \int_{C_1} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \quad (\text{on } C'_1) \tag{31}$$

$$f_3 = -\frac{\lambda}{2} \int_{C_3} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \quad (\text{on } C'_3) \tag{32}$$

Consequently,  $f_1$  and  $f_3$  inside each region are expressed in terms of  $f_2$  and  $\frac{\partial f_2}{\partial n}$  on the boundary as follows:

$$f_1 = -\frac{\lambda}{4} \int_{C_1} \left\{ f_2 \frac{\partial}{\partial n} H_0^{(1)}(kr) + H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} \right\} ds - \frac{\lambda}{4} \int_{C'_1} \left\{ -\frac{\lambda}{2} \int_{C_1} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \right\} \frac{\partial}{\partial n} H_0^{(1)}(kr) ds \tag{33}$$

$$f_3 = -\frac{\lambda}{4} \int_{C_3} \left\{ f_2 \frac{\partial}{\partial n} H_0^{(1)}(kr) + H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} \right\} ds - \frac{\lambda}{4} \int_{C'_3} \left\{ -\frac{\lambda}{2} \int_{C_3} H_0^{(1)}(kr) \frac{\partial f_2}{\partial n} ds \right\} \frac{\partial}{\partial n} H_0^{(1)}(kr) ds \tag{34}$$

Finally, the variations of the free surface in each region are given as follows:

$$\zeta_1 = -\frac{1}{g} \left( \frac{\partial \Phi_I}{\partial t} \right)_{z=0} = \zeta_0 (\zeta_0 + f_1) e^{-\lambda \alpha t} \tag{35}$$

$$\zeta_2 = -\frac{1}{g} \left( \frac{\partial \Phi_{II}}{\partial t} \right)_{z=0} = \zeta_0 f_2 e^{-\lambda \alpha t} \tag{36}$$

$$\zeta_3 = -\frac{1}{g} \left( \frac{\partial \Phi_{III}}{\partial t} \right)_{z=0} = \zeta_0 f_3 e^{-\lambda \alpha t} \tag{37}$$

Therefore, the diffraction coefficient  $K_d$  is determined by

$$K_d = \left| \frac{\zeta_3}{\zeta_2} \right| = \left| \frac{\zeta_0 f_3 e^{-\lambda \alpha t}}{\zeta_0 e^{-\lambda(kx \cos \omega + ky \sin \omega)} e^{-\lambda \alpha t}} \right| = |f_3| \tag{38}$$

(C) Numerical Procedure

In order to solve Eqs. (26), (27) and (28) numerically, we divided the boundaries into some segments as shown in Fig.2, and then these equations are described in discrete form at each segment as follows:

$$f_2(\lambda) = f_0(\lambda) - \frac{\lambda}{2} R \sum_{j=1}^{N_1} H_0^{(1)}(kR_j) \bar{f}_2(j) \Delta S_j \quad (\lambda=1, N_1) \tag{39}$$

$$f_2(\lambda) = \frac{i}{2} R \sum_{j=1}^{N_1+N_2+N_3+N_4} f_2(j) H_1^{(1)}(Rr_{\lambda j}) \Delta s_j - \frac{i}{2} R \sum_{j=1}^{N_1+N_3} H_0^{(1)}(Rr_{\lambda j}) \bar{f}_2(j) \Delta s_j \quad (\lambda=1, N_1+N_2+N_3+N_4) \quad (40)$$

$$f_2(\lambda) = -\frac{i}{2} R \sum_{j=1}^{N_3} H_0^{(1)}(Rr_{\lambda j}) \bar{f}_2(j) \Delta s_j \quad (\lambda=1, N_3) \quad (41)$$

where  $\bar{f}_2(j) = \frac{1}{R} \frac{\partial f_2(j)}{\partial n}$ ,  $H_0^{(1)}(Rr_{\lambda j})$  is the first order Hankel function of the first kind,  $i$  and  $j$  are the calculation points on the boundary.

Fig.2 Segmentation of boundaries

The number of unknowns  $f_2$  and  $\bar{f}_2$  is  $2N_1+N_2+2N_3+N_4$  and the number of equations is the same. So,  $f_2$  and  $\bar{f}_2$  on the boundaries  $C_1, C_2, C_3$  and  $C_4$  are given by solving Eqs. (39), (40) and (41).

Eqs. (33) and (34) are also rewritten as follows:

$$f_1(x, y) = -\frac{i}{4} R \sum_{j=1}^{N_1} \{ f_2(j) H_1^{(1)}(Rr_{xj}) + H_0^{(1)}(Rr_{xj}) \bar{f}_2 \} \Delta s_j - \frac{i}{4} R \sum_{j=1}^{2N_1} \left\{ -\frac{i}{2} R \sum_{\ell=1}^{N_1} H_0^{(1)}(Rr_{j\ell}) \bar{f}_2(\ell) \Delta s_\ell \right\} H_1^{(1)}(Rr_{xj}) \Delta s_j \quad (42)$$

$$f_3(x, y) = -\frac{i}{4} R \sum_{j=1}^{N_3} \{ f_2(j) H_1^{(1)}(Rr_{xj}) + H_0^{(1)}(Rr_{xj}) \bar{f}_2 \} \Delta s_j - \frac{i}{4} R \sum_{j=1}^{2N_3} \left\{ -\frac{i}{2} R \sum_{\ell=1}^{N_3} H_0^{(1)}(Rr_{j\ell}) \bar{f}_2(\ell) \Delta s_\ell \right\} H_1^{(1)}(Rr_{xj}) \Delta s_j \quad (43)$$

Although the number of segments  $N_1$  and  $N_3$  must be infinite, we put them finite because the influence of the point far away from the region II is very small. Here, the length of  $C_1$  and  $C_3$  is taken 10 times of wave length.

## (c) Verification of numerical solution

Here, the validity of the numerical method and the stability of the solution are discussed. Fig.3 shows a pair of breakwaters with square edge. For this type of breakwaters, some analytical solutions of diffraction were obtained. However, there is the limitation in these solutions that the width of a breakwater is infinitely small. So, the numerical solutions used in this study are compared with the analytical solutions proposed by Takayama (1981) for the case of small width of a breakwater.

Fig.3 A pair of straight breakwaters with square edges

Figs. 4 (a) to (d) show the diffraction coefficient  $K_d$  at the point of  $Y/L=0.1, 0.5$  and  $1.0$  for the case of  $b/L=0.01, B/L=0.5$  and  $\omega = 90^\circ, 150^\circ$  and  $165^\circ$ . In these cases, the maximum length of a segment  $D_{max} \leq L/10$  ( $L$ : wave length), namely, each boundary is divided into small segments whose length is smaller than  $L/10$ .

As can be seen from these figures, the solutions of the proposed numerical method (shown by the broken lines) are a little smaller than the exact solutions shown by the solid lines. These small differences are not improved by shortening the length of a segment. It is not clear whether these differences come from the influence of the width of a breakwater or from the numerical error. However, the results of our numerical method sufficiently agree with the analytical solutions.

Next we calculated the wave height distribution for rectangular resonators shown in Fig.5. Fig.6 shows the diffraction coefficient  $K_d$  with wave resonators at the point of  $X/B=0.0$  and  $Y/B=1.33$  and the amplification factor  $\zeta_A/\zeta_I$  for the case of  $L/B=0.5, B_R/B=0.08$  and  $b_R/B=0.03$ . The solid lines represent the case where the maximum length of a segment  $D_{max}$  is smaller than  $L/20$  and the broken lines represent the case of  $D_{max} \leq L/50$ .

It is noted that the difference between two curves is remarkable especially near the resonant point in the resonator. It is also found that it is impossible to stabilize the numerical solution even in the case of  $D_{max} \leq L/100$  when the resonance takes place. The reason for this instability is supposed that the value of a calculation point does not correspond to the value on a segment owing to the marked variation of  $f_z$  and  $\partial^2 \zeta / \partial n^2$  in the resonators. So it is difficult to obtain stable solutions (especially in the state of resonance) even if

Fig.4 Diffraction coefficients  $K_d$

(a)  $\omega = 90^\circ$ ,  $B/L = 0.5$ ,  $b/L = 0.01$ ,  $D_{max}/L = 0.08$

(b)  $\omega = 90^\circ$ ,  $B/L = 1.0$ ,  $b/L = 0.01$ ,  $D_{max}/L = 0.09$

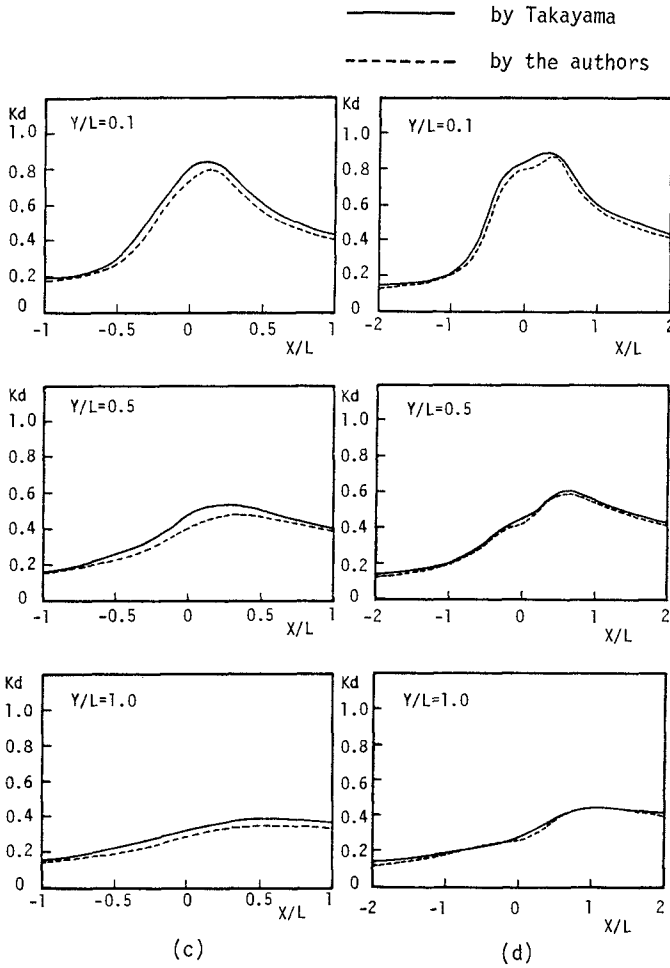

Fig.4 Diffraction coefficients  $K_d$

(c)  $\omega = 150^\circ$ ,  $B/L = 0.5$ ,  $b/L = 0.01$ ,  $D_{max}/L = 0.08$

(d)  $\omega = 165^\circ$ ,  $B/L = 1.0$ ,  $b/L = 0.01$ ,  $D_{max}/L = 0.09$

the length of the segment is considerably small. However, judging from the results shown in Fig.6, it is reasonable to consider that our numerical method is applicable to discuss the variation of diffraction coefficients qualitatively because the variation of  $K_d$  with varying  $L/B$  calculated from different  $D_{max}$  are similar.

Fig.6-(b) Amplification factor  $\zeta_A/\zeta_I$  at the point of (A)

III. THEORETICAL DEFINITION AND EFFECTS OF A WAVE RESONATOR

As shown in Fig.6, the diffraction coefficients in the case with resonators are strongly dependent on the wave length (i.e. wave period) and indicate a remarkable decrease at the point where the resonance occurs in the resonators ( $L/B = 2.2$ ). In this section, the function of a wave resonator that diminishes the diffracted wave height is investigated theoretically.

Firstly, let us divide  $f_1$  and  $f_3$  in Eqs.(8) and (11) into two components respectively:

$$f_1 = f_{10} + f_{1R} \tag{44}$$

$$f_3 = f_{30} + f_{3R} \tag{45}$$

where  $f_{10}$  and  $f_{30}$  are the wave function in the case without resonator and  $f_{1R}$  and  $f_{3R}$  represent the influence of resonators on  $f_1$  and  $f_3$  and are called here after the wave functions of radiated waves from resonators.  $f_{1R}$  and  $f_{3R}$  are obtained by calculating  $f_1$ ,  $f_3$ ,  $f_{10}$  and  $f_{30}$ .

Fig.7 and Fig.8 illustrate the wave height distribution in region I and III when  $\omega=90^\circ$ . Fig.(a) in each figures shows the wave height distribution around breakwaters without resonators, Fig.(b) represents the radiated waves from resonators obtained by using Eqs.(44) and (45) and Fig.(c) shows the wave height distribution in the case with resonators. The wave height distribution in Fig.(c) can be regarded as the composite waves of the diffracted waves in Fig.(a) and the radiated waves in Fig.(b). The numerals in these figures indicate the ratio of the wave height to the incident wave height  $H/H_1$ .

The geometric profile and dimensions of the resonator in Figs. 7 and 8 corresponds to that in Fig.6. Fig.7 shows the wave height distributions in the case of  $L/B=2.5$ . In this case, the amplification factor at the point A in the resonator  $\zeta_A/\zeta_1$  is small as shown in Fig.6 (b). Fig.8 shows the wave height distribution in the case of  $L/B=2.2$  and it is found from Fig.6 (b) that the resonance occurs in the resonators.

In the case of Fig.7, the radiated wave height is relatively small. Therefore the difference of the wave height distribution in Fig.(c) is similar to that in Fig.(a). On the other hand, in the case of Fig.8, the composite wave height in the harbor region becomes very small, and at the same time, the radiated wave height shown in Fig.8(b) is much larger than Fig.7-(b). The distribution of the radiated waves in the harbor (Fig.8-(b)) is similar to that of diffracted waves without resonators shown in Fig.8-(a).

So it is clear that the effectiveness of resonators comes from the phase interaction between diffracted waves in the case without resonator and the radiated waves from resonators. However, it must be paid attention to the fact that the wave heights in the open sea region becomes larger than those in the case without resonator. (See Fig.8-(c))

Fig.9 and Fig.10 show the wave height distribution in the case where resonance takes place when the entrance width  $B$  is larger than the wave length  $L$ . These figures demonstrate that each resonator located at the edge of breakwater has a tendency to function independently as the ratio  $L/B$  becomes small. The wave height distribution is much different from that shown in Fig.8 and the resonators is not so effective to reduce the diffracted wave height.

## IV. EXPERIMENTAL VERIFICATION

Judging from the numerical calculation, resonators are very effective to diminish the diffracted wave height and are expected to reduce harbor oscillation. In order to verify these results, model tests were carried out in a wave basin of 15m x 5m and 0.6m deep shown in Fig.11.

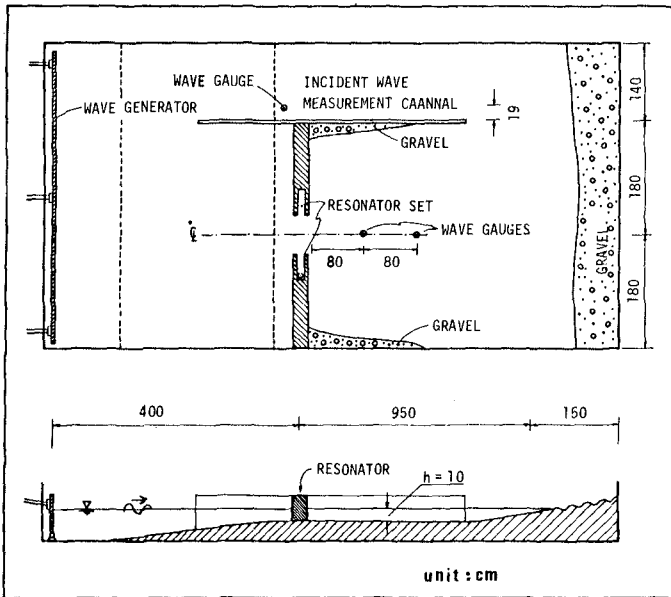

Fig.11 Wave basin

In the wave basin, an over floor made of wood was constructed in order to generate waves of about 2cm height at the depth of 10cm. A flap type wave generator located at one end of the basin was used. At the other end, a gravel sloped beach was equipped as a wave absorber. A lateral wave channel to measure the incident waves during the experiments was also prepared.

Three types of resonators (Case-A, Case-B and Case-C) shown in Fig. 12 (a), (b) and (c) were tested. The results obtained in these cases are shown in Fig.13, 14 and 15 by comparing with theoretical results. The theoretical results in the case C was calculated by using Lee's method.

Fig. 12 Experimental cases

Fig. 14 Diffraction coefficient (Case-B)

Fig. 13 Diffraction coefficient (Case-A)

Fig. 15 Amplification factor at  $P_1$  (Case-C)

In all these cases, the abscissas represent the ratio of the wave length to the width of the harbor entrance  $L/B$ . The ordinates in Figs. 13 and 14 are the diffraction coefficient  $K_d$  at the point of 80cm away from the breakwaters in the harbor region. The ordinate in Fig.15 shows the amplification factor at the point  $P_1$  in Fig.15. The dotted lines represent the calculated response in the case without resonator and the open circles are the experimental results. The solid lines are the calculated response in the case with resonators and closed circles show the experimental results.

The calculated results indicate an apparent decrease of wave height when a resonance takes place in the resonator, but such a decrease can not be seen in all experiments as shown in Figs. 13 to 15. It is also found that the agreement between experimental results and theoretical ones is not good even in the case without resonator. The cause of this is assumed that the transversal oscillation in the wave basin exists. Of course, in the case where the resonator was equipped, this transversal oscillation also affected the experimental results. However, this is not the main reason why the experimental results do not show a significant decrease.

As mentioned above, only when the resonance occurs in the resonators the resonators become effective to reduce the diffracted wave height. So the response in the resonator was investigated based on the experimental results obtained in Case-A. Fig. 16 shows the amplification factor  $H/H_x$  at the point (A) in the resonator shown in Fig.5. Clearly, the resonance in the experiments is not as remarkable as that in the calculated results and the measured peak of the response appears at the different position from the calculated response. This is probably due to the energy dissipation at the resonator mouth.

Fig.16 Amplification factor at (A) in the resonator (Case-A)

Consequently, it must be concluded that the wave resonators treated here are not so effective as predicted by the theory, and the reason is considered that sufficient resonance to reduce the diffracted wave height does not occur in the resonator.

#### V. CONCLUSIONS

In this paper, the effect of wave resonators on wave diffraction by breakwaters was investigated theoretically and experimentally. The numerical method developed here shows that resonators equipped at the edge of a breakwater are very effective to reduce diffracted wave heights when resonance occurs in resonators. This effect comes from the phase interaction between the diffracted waves in the case without resonator and the radiated waves from resonators.

The effectiveness of resonators predicted by the numerical simulation was not verified by experiments. The main reason of this is supposed to be the energy dissipation at the resonator mouth which prevents from occurring the sufficient resonance in the resonator.

## CHAPTER ONE HUNDRED NINETY SEVEN

### DYNAMIC ANALYSIS OF PILE STRUCTURES TO PERIODIC WAVES

Hajime Ishida  
Associate Professor, Department of Civil Engineering,  
Kanazawa University, Kanazawa, Japan

and

Yoshinori Konda  
Staff, Aichi Prefectural Government, Nagoya, Japan

#### ABSTRACT

This paper has dealt with the dynamic response of offshore structures to the ocean waves. In order to establish the calculation scheme for offshore structures, the methods of transfer matrices and of structural-property matrices have been introduced and applied to the analysis of dynamic response of pile structures. The validity of these calculation methods have been verified by the experiments in the laboratory.

#### INTRODUCTION

The need for drilling oil from the sea bed has induced the progress of ocean structures until now, and much more structures should be constructed to extract the new sources and energies from the oceans in the future. Then, more precise design of structures should be demanded with considering the dynamic behaviours from the viewpoint of reliability and economical efficiency.

The purpose of this paper is to advance the calculation scheme of dynamic analysis of offshore structures and to clarify the characteristics of the dynamic response to waves. The structural forms treated in this paper are as follows: (1) a vertical small diameter pile, (2) a platform supported by four small diameter piles and (3) a vertical large diameter pile. These three structures are analysed with modeling as a multi-degrees-of freedom system by using the methods of transfer matrices and of structural-property matrices.

The method of transfer matrices is suitable for the analysis of harmonic vibrations, and this method has already been applied to the vibrational analysis of offshore structures by Gaither and Billington.<sup>1)</sup> However, only the monochromatic concentrating forces were used as the

external forces and no calculations have been performed by using the wave forces in their study. Then, in this paper, the authors advance their study and indicate the calculation method for the ocean waves. In the case of a small diameter pile, not only the small amplitude wave theory but also the Stokes wave theory are applied to the Morison's formula to explain the resonant characteristics. In the case of a large diameter pile, MacCamy-Fuchs' diffraction theory<sup>2)</sup> is used as the equation of wave force in stead of Morison's formula.

The method of structural-property matrices<sup>3)</sup> is convenient for calculating the transient response with including the initial conditions or the random vibrations induced by irregular waves. In this paper, this calculation method and the results of some model calculations are shown mainly in the case of periodic waves.

In order to discuss the validity of these calculation methods and to find the characteristics of real vibrations, the laboratory experiments are conducted in the wave tanks by using the model structures mentioned above.

METHOD OF TRANSFER MATRICES

EVALUATION OF TRANSFER MATRICES<sup>1)</sup>

The coordinate system is shown in Fig.1. The share force in the direction of the z-axis and the corresponding displacement are denoted by  $V_z$  and  $w$  respectively. The bending moment around the y-axis and the corresponding slope are denoted by  $M_y$  and  $\psi$  respectively. Henceforth,  $V_z$ ,  $M_y$ ,  $w$  and  $\psi$  are used as the complex amplitudes. The amplitudes are generated by eliminating from their real quantities the time part oscillating with an angular frequency  $\Omega$ ,  $exp(j\Omega t)$ , in which  $t$  is the time and  $j=\sqrt{-1}$ .

The vertical column vector constructed by their real and imaginary parts is called the state vector and is denoted by  $\{z\}$  as follows:

$$\{z\} = \underbrace{\{-w, \psi, M_y, V_z\}}_{\text{Real}} \underbrace{| -w, \psi, M_y, V_z | 1 \}_{1}}_{\text{Imaginary Unit}}^T \cdot (1)$$

To apply the method of transfer matrices, the continuous member is idealized as a discrete series of masses and beams as shown in Fig.2. The external forces are considered to act upon the masses.

Using the compatibility and equilibrium conditions at the beam  $i$ , the relationship between the state vector of the upper side of the mass  $i-1$  denoted by  $\{z\}_{i-1}^U$ , and that of lower side of the mass  $i$  denoted by  $\{z\}_i^L$ , can be described by the matrix equation

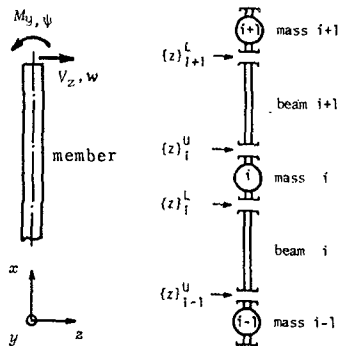

Fig.1 Coordinate system<sup>4)</sup>.

Fig.2 Mass-beam system<sup>4)</sup>.

$$\{z\}_i^L = [F]_i \{z\}_{i-1}^U, \dots \dots \dots (2)$$

in which  $[F]_i$  is called the field transfer matrix and given by

$$[F]_i = \left[ \begin{array}{ccc|ccc} 1 & L & \frac{L^3}{2EI(1+\epsilon^2)} & \frac{L^3}{6EI(1+\epsilon^2)} & 0 & 0 & \frac{\epsilon L^2}{2EI(1+\epsilon^2)} & \frac{\epsilon L^2}{6EI(1+\epsilon^2)} & 0 \\ 0 & 1 & \frac{L}{EI(1+\epsilon^2)} & \frac{L^2}{2EI(1+\epsilon^2)} & 0 & 0 & \frac{\epsilon L}{EI(1+\epsilon^2)} & \frac{\epsilon L^2}{2EI(1+\epsilon^2)} & 0 \\ 0 & 0 & 1 & L & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & \frac{-\epsilon L^2}{2EI(1+\epsilon^2)} & \frac{-\epsilon L^2}{6EI(1+\epsilon^2)} & 1 & L & \frac{L^2}{2EI(1+\epsilon^2)} & \frac{L^3}{6EI(1+\epsilon^2)} & 0 \\ 0 & 0 & \frac{-\epsilon L}{EI(1+\epsilon^2)} & \frac{-\epsilon L^2}{2EI(1+\epsilon^2)} & 0 & 1 & \frac{L}{EI(1+\epsilon^2)} & \frac{L^2}{2EI(1+\epsilon^2)} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & L & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{array} \right]_i \dots \dots \dots (3)$$

In Eq.(3),  $E$  is the elastic modulus,  $A$  is the cross-sectional area,  $I$  is the second moment of inertia about the  $y$ -axis,  $L$  is the beam length between the two masses, and  $\epsilon$  is a constant number driven by considering the structural damping to the beam. The range of values is commonly indicated as  $\epsilon=0 \sim 0.015$ .

By applying the same conditions to the mass  $i$ , the relationship between the state vectors  $\{z\}_i^U$  and  $\{z\}_i^L$  is obtained as follows:

$$\{z\}_i^U = [P]_i \{z\}_i^L, \dots \dots \dots (4)$$

in which  $[P]_i$  is the point transfer matrix and given by

$$[P]_i = \left[ \begin{array}{ccc|ccc} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & I_y \Omega^2 & 1 & 0 & c_z \Omega & -f_z \\ m \Omega^2 & 0 & 0 & c_z \Omega & 0 & -f_z \\ \hline 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & -c_\psi \Omega & 0 & 0 & I_y \Omega^2 & 1 \\ -c_\psi \Omega & 0 & 0 & m \Omega^2 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 1 \end{array} \right]_i \dots \dots \dots (5)$$

In Eq.(5),  $m$  is the mass,  $I_y$  is the mass moment of inertia about the  $y$ -axis, and  $c_z$  and  $c_\psi$  are the coefficients of viscous damping in the direction of the  $z$ -axis and around the  $y$ -axis respectively.  $f_z$  and  $f_\psi$  are amplitudes of the external forces in the direction of the  $z$ -axis and the external moment around the  $y$ -axis respectively.

Fig.3 shows the pile idealized as the mass-beam system. Transferring the state

Fig.3 Idealized pile as mass-beam system<sup>4)</sup>.

vector  $\{z\}$  from the fixed base at A to the free end at B by using Eqs. (2) and (4), the following equation which gives the relationship between the state vector at the location A denoted by  $\{z\}_A$  and that of the location B denoted by  $\{z\}_B$  is obtained:

$$\{z\}_B = [F]_7 [P]_6 [F]_6 \dots [P]_1 [F]_1 \{z\}_A = [U]_{BA} \{z\}_A \dots \dots \dots (6)$$

The boundary conditions for this case are given as follows:

for the location A :  $w = 0, \psi = 0, \dots \dots \dots (7)$   
 for the location B :  $V_z = 0, M_y = 0.$

Substituting Eq.(7) to Eq.(6),  $M_y$  and  $V_z$  at the location A, and  $w$  and  $\psi$  at the location B can be obtained, that is  $\{z\}_A$  and  $\{z\}_B$  can be determined so as to satisfy the boundary conditions. The state vector of each location, therefore, can be calculated by using Eqs.(2),(4) and the state vector  $\{z\}_A$ .

EXTERNAL FORCE TERMS DUE TO WAVES

In the following, the coordinate system is taken as shown in Fig.4.  $\xi$  denotes the displacement of pile in the direction of the x-axis.  $u$  and  $\dot{u}$  denote respectively the water particle velocity and its acceleration in the direction of the x-axis.

Applying Morison's formula and using the relative velocities to express the wave forces on the pile in the direction of the x-axis, the equation about the transverse vibration of pile is expressed as follows:

$$\rho A \xi_{tt} + c_1 \xi_t + EI \xi_{zzzz} = \frac{1}{2} C_D \rho_w D (u - \xi_t) |u - \xi_t| + (C_M - 1) \rho_w A (\dot{u} - \xi_{tt}) + \rho_w A \dot{u} \dots \dots (8)$$

Fig.4 Coordinate system of wave field.

in which,  $\rho$  and  $\rho_w$  are the densities of pile and water respectively,  $c_1$  is the damping coefficient,  $D$  is the diameter of pile, and  $C_D$  and  $C_M$  are the drag and inertia coefficients respectively. The lower indices of  $\xi$ ,  $t$  and  $z$ , indicate the differentiation  $\xi$  with respect to  $t$  and  $z$  respectively.

Eq.(8) is nonlinear with respect to  $\xi$ , however, if the assumption that  $u \gg \xi$  is made, the Eq.(8) becomes linear as follows:

$$(\rho A + K \rho_w A) \xi_{tt} + (c_1 + 2C_D' |u|) \xi_t + EI \xi_{zzzz} = C_D' u |u| + C_M' \dot{u} \dots \dots \dots (9)$$

in which,  $C_D' = C_D \rho_w D / 2$ ,  $C_M' = C_M \rho_w A$ ,  $K = C_M - 1$ , and  $K$  is called the added mass coefficient.

By using the small amplitude wave theory, the water level variation  $\eta$ , the water particle velocity  $u$  and its acceleration  $\dot{u}$  at the location  $x=0$  are described as follows:

$$\eta = a \cos \sigma t, \dots\dots\dots(10)$$

$$u = a\sigma (\cosh kz / \sinh kh) \cos \sigma t, \dots\dots\dots(11)$$

$$\dot{u} = -a\sigma^2 (\cosh kz / \sinh kh) \sin \sigma t, \dots\dots\dots(12)$$

Substituting Eqs.(11) and (12) into Eq.(9), and integrating Eq.(9) along the divided length  $\Delta z_i = z_i - z_{i-1}$  shown in Fig.5,  $m_i$  and  $C_{z_i}$  included in  $[P]_i$  of Eq.(5) can be obtained as follows:

$$m_i = (\rho A + K\rho_w A) \Delta z_i, \dots\dots\dots(13)$$

$$c_{z_i} = c_1 \Delta z_i + 2C'_D a\sigma \{ (\sinh kz_i - \sinh kz_{i-1}) / (k \sinh kh) \} | \cos \sigma t |, \dots\dots\dots(14)$$

Fig.5 Range of the integration.

The wave forces acting on the mass  $i$  can be expressed as follows:

$$f_i(t) = X_i \cos \sigma t | \cos \sigma t | + Y_i \sin \sigma t, \dots\dots\dots(15)$$

in which,

$$X_i = C'_D (a^2 g k / \sinh 2kh) \{ (\sinh 2kz_i - \sinh 2kz_{i-1}) / 2k + \Delta z_i \}, \dots\dots\dots(16)$$

$$Y_i = -C'_M (ag / \cosh kh) (\sinh kz_i - \sinh kz_{i-1}), \dots\dots\dots(17)$$

If we expand the part  $\cos \sigma t | \cos \sigma t |$  in Eq.(15) into the Fourier series and take up to the third term, the Eq.(15) yields

$$f_i(t) = \frac{8}{3\pi} X_i \cos \sigma t + \frac{8}{15\pi} X_i \cos 3\sigma t - \frac{8}{105\pi} X_i \cos 5\sigma t + Y_i \sin \sigma t, \dots\dots\dots(18)$$

It can be recognized that the four terms  $(8/3\pi)X_i$ ,  $(8/15\pi)X_i$ ,  $(8/105\pi)X_i$  and  $Y_i$  are generated as the amplitudes of external forces  $f_{z_i}$  included in  $[P]_i$  of Eq.(5), and that  $\Omega_i$  in this case becomes  $\Omega$ ,  $3\Omega$ ,  $5\Omega$  and  $\Omega$  corresponding to each amplitude. Therefore, in order to obtain the actual state vector including the time part, each  $\{z\}$  must be calculated by using each  $f_{z_i}$  and  $\Omega_i$ . Then each  $\{z\} \exp(j\Omega t)$  must be calculated, and the real part or imaginary part of  $\{z\} \exp(j\Omega t)$  must be chosen whether the phase of the terms of external force is  $\cos$  or  $\sin$  respectively. Finally, these must be composed.

In the actual calculations,  $f_\psi$ ,  $I_y \Omega^2$  and  $C_\psi \Omega$  included in Eq.(5) are all neglected because they are ascertained as not greatly effecting the values of state vectors by performing some model calculations. Moreover,  $c_1$  in  $C_{z_i}$  of Eq.(14) is also neglected because of being small compared with  $2C'_D |u|$ .

RESONANCE OF PILE DUE TO SMALL AMPLITUDE WAVE

In order to explain some characteristics of the vibrations of a vertical circular cylinder, some calculations have been performed by using the method indicated above. The calculating conditions are determined by considering the scale of the experiments.

The water depth  $h$  is 40cm. The diameter of the cylinder  $D$  is 3cm, the length 60cm, the specific density 1.12, and the elastic modulus  $E$  500Kg/cm<sup>2</sup>. It is inappropriate to always give the drag and inertia coefficients  $C_D$  and  $C_M$  definite values, therefore they should be changed according to the various cases. Practically, however, it is difficult to choose appropriate values in each case because these values cannot be determined only by the Reynolds number and Keulegan-Carpenters' number<sup>9)</sup> In this paper, therefore,  $C_M=2.0$  and  $C_D=1.0$  were ventured to be used as the design criteria<sup>6)</sup> in all cases. Moreover, the added mass coefficient  $K$  is fixed to 1.0 and structural damping is neglected as  $c=0$ . The cylinder is idealized by 6 masses and 7 beams as shown in Fig.3. The lengths of the beams are 5cm at the locations of the fixed bottom and top, and 10cm at the other locations.

Fig.6 shows the characteristics of resonance, taking the horizontal axis as wave period  $T$  and the vertical axis as maximum values of the displacement at the top point in the direction of wave propagation. The dotted lines in this figure indicate that the waves exceed their breaking limit  $H/L=0.14$ .

It can be seen from this figure that the resonance occurs at  $T=0.44$ sec and 1.32sec ( $=3 \times 0.44$ sec) because of the first and fourth terms having the angular frequency  $\sigma$ , and the second term having  $3\sigma$  in the right hand side of Eq.(18), respectively. However, as the wave height increases, the resonant effects at  $T=2.20$ sec ( $=5 \times 0.44$ sec) become more indistinguishable at the displacement of the positive side (not of the negative side) because of the negative sign of the third term having the angular frequency  $5\sigma$  of Eq.(18).

Generally speaking, the resonance of pile structures appears at the wave periods of odd number intervals' natural period in the case where the small amplitude wave theory is used.

Fig.6 Characteristics of resonance due to small amplitude waves<sup>4)</sup>.

Fig.7 shows the time variations of the displacement at the top point during a cycle of waves by successively changing the wave periods.  $t/T=0$  and  $\pm 0.5$  express the phases of the wave crests and troughs coming to the position of the cylinder respectively. The displacements are divided by their maximum value in each case to standardize them. In all cases, the ratio of the maximum inertia forces to the maximum drag forces are 2:1, and therefore, the high frequency components of the drag forces are not so large. However, it can be seen from this figure that high frequency vibrations appear in the time variations of displacement in the cases  $T=1.30\text{sec}$  or  $1.35\text{sec}$  and  $2.20\text{sec}$  because of resonant effects.

#### RESONANCE OF PILE DUE TO STOKES WAVE

An experiment concerning vibrations of a circular cylinder has been performed at the Department of Civil Engineering of Kanazawa University. The experimental apparatus is shown in Fig.8. The dimension of the wave tank used in this experiment was 50cm wide, 60cm high and 14m long. A wave generator of the plunging type was installed at the end of this wave tank. A circular cylinder of which end the plate spring was attached was vertically installed 4.5m apart from this wave generator. The diameter of this cylinder  $D$  was 3cm, the length 60cm, the specific gravity 1.60, and the elastic modulus of the plate spring  $E$  400Kg/cm<sup>2</sup>. The dynamic displacements of this cylinder were measured at its top part, at which a copper plate was attached, by using the electromagnetic displacement meter of the non-contact type. The water depth  $h$  was 40cm.

Fig.7 Time variations of the displacement at the top point of cylinder<sup>4)</sup>.

Fig.8 Experimental apparatus in the case of a pile.

In this experiment, the resonance appears by the waves of which period is integer times natural period of the cylinder. This phenomenon cannot be explained by using the small amplitude wave theory but the Stokes wave theory. This reason is that the inertia force contains the frequency terms of  $\sin\omega t, \sin 2\omega t, \sin 3\omega t, \sin 4\omega t, \dots$  and the drag force produces the frequency terms  $\cos\omega t, \cos 2\omega t, \cos 3\omega t, \cos 4\omega t, \dots$  when the Stokes wave theory is applied to the Morison's formula.

Fig.9 shows the comparison between the experimental data and the calculated values by using the small amplitude wave theory and the Stokes wave theory. In this figure, it is recognized that the calculated values by using the Stokes wave theory agree roughly well with the experimental ones near the resonant point  $T=0.71$ sec which is two times the natural period of cylinder  $T=0.354$ sec.

Fig.9 Characteristics of resonance in the case of small diameter cylinder due to Stokes wave.

DYNAMIC RESPONSE OF PLATFORM

In the case of a platform, the axial force  $N$  and its displacement  $u$  shown in Fig.10 should be introduced. Therefore, the state vector is denoted as follows:

$$\{z\} = \underbrace{\{u, -w, \psi, M_y, V_z, N\}}_{\text{Real}} \underbrace{|u, -w, \psi, M_y, V_z, N|}_{\text{Imaginary}} \underbrace{1}_{\text{Unit}} \}^T \dots \dots (19)$$

The portion of the corner idealized as mass-beam system is shown in Fig.11, in which the corner transfer matrix  $[C]$  is newly introduced to change the direction of the neutral axis at the corner. The corner transfer matrix is indicated by Eq.(20) in the case that the neutral axis turns 270 degrees clockwise. The point transfer matrix and the field transfer matrix are indicated by Eqs.(21) and (22) respectively. The state vectors can be determined by multiplying these matrices in the same manner as the vertical pile<sup>1)</sup>.

Fig.10 Coordinate system.

The experiment has been carried out to the platform shown in Photo. 1. Four vertical piles supporting the aluminum plate are made of rubber, and their diameter is 3cm, the elastic modulus  $600\text{Kg/cm}^2$ . Idealizing this platform as mass-beam system as shown in Fig.12, the analyses have been performed by using the small amplitude wave theory to simplify the calculations.

One of the model calculations about resonance is shown in Fig.13, in which the horizontal axis is the wave period  $T$ , and the vertical one is the maximum value of the displacement at the corner point B. The wave steepness is kept  $H/L=0.1$ , and the added mass coefficient  $K$  is changed 0, 1 and 2. From this figure, it can be seen that the resonant wave period decreases as  $K$  decreases from 2 to 0, and the value of the displacement becomes minimum at the wave period  $T=0.54\text{sec}$ . The minimum point of the displacement appears when the wave length becomes about two times distance between piles because the directions of wave forces acting on the piles become opposite with each other.

Photo.1 Model of platform.

Fig.12 Idealized platform as mass-beam system.

Fig.13 Characteristics of resonance of the platform.

Fig.14 shows the comparison of the time variations of the displacement at the point B between the experimental values and the calculated ones. From this figure, it is recognized that the calculated values shown by chain lines agree well with the experimental ones shown by solid lines.

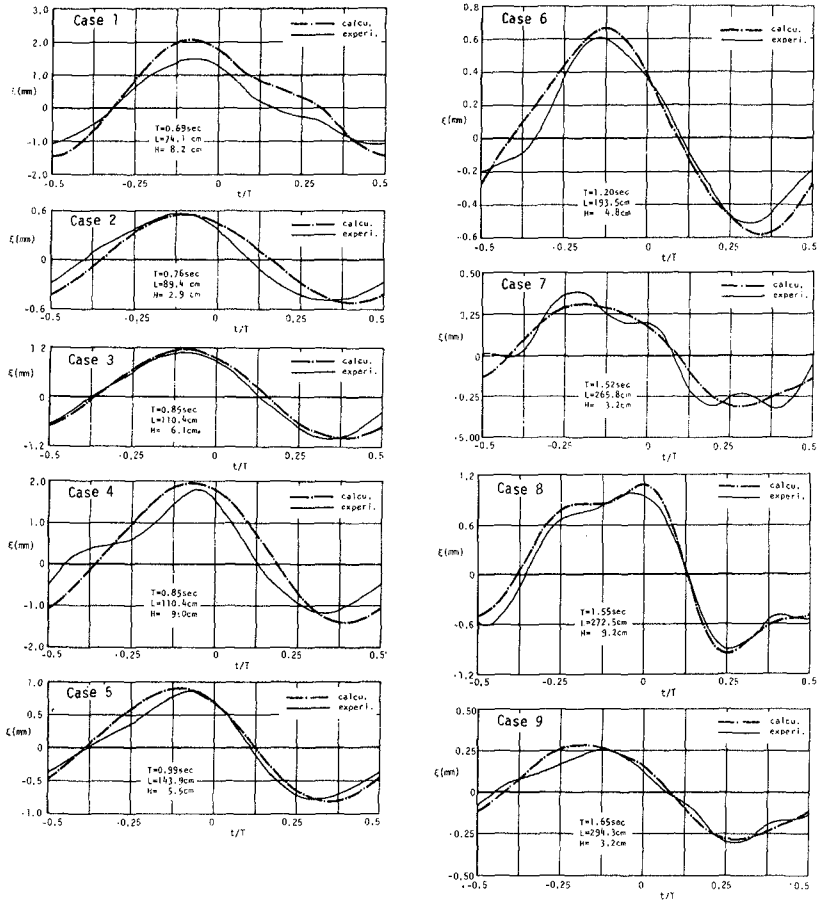

Fig.14 Comparison of the time variations of displacement between the experimental values and the calculated.

DYNAMIC RESPONSE OF LARGE DIAMETER PILE

In the case of a large diameter pile, MacCamy-Fuchs' diffraction theory can be applied to the equation of wave forces instead of Morison's formula in its calculations. On the occasion of this experiment, the circular cylinder shown in Fig.15 has been used. The diameter of this cylinder is 40cm and the experimental apparatus is shown in Photo.2. The dimension of the wave tank is 6.7m long, 4.3m wide and 55cm deep. The water depth was kept 35cm, and the displacement was measured by using the contact type displacement meter. The natural period of this cylinder is 0.56sec in the still water.

Fig.16 shows the characteristic of resonance of this cylinder with comparing the experimental values with the calculated ones. From this figure it is recognized that the solid line calculated by using  $K=0$  is closer to the experimental values than the broken line calculated by using  $K=1$ . This fact may indicate that the added mass coefficient  $K$  decreases from 1.0 with according to the increase in magnitude of the displacement.

Photo.2 Experimental apparatus.

Fig.15 Large diameter pile.

Fig.16 Characteristics of resonance.

METHOD OF STRUCTURAL-PROPERTY MATRICES

EVALUATION OF STRUCTURAL-PROPERTY MATRICES

The method of transfer matrices has been proved most effective for the analysis of harmonic vibrations. On the other hand, the method of structural property matrices is available for the non-harmonic vibrations. In this approach, the structure is assumed to be divided into a system of discrete elements which are interconnected only at a finite number of nodal point. The properties of the complete structure are then found by evaluating the properties of the individual finite elements and superposing them appropriately<sup>3</sup>.

Fig.17 shows the beam element of number i, in which the displacements and rotations at node i and i-1 are denoted by  $\xi_i, \xi_{i-1}$  and  $\theta_i, \theta_{i-1}$  respectively. The deflected shape of the element  $\xi(x)$  can be expressed in terms of its nodal rotations and displacements as follows:

$$\xi(x) = \psi_1(x)\xi_{i-1} + \psi_2(x)\xi_i + \psi_3(x)\theta_{i-1} + \psi_4(x)\theta_i, \dots (23)$$

in which,  $\psi_n(x)$  (n=1,2,3,4) are the deflections developed in the element subjected to the unit nodal displacements which can be expressed as follows:

for $\xi_{i-1}=1$ ;	$\psi_1(x) = 1 - 3(x/l)^2 + 2(x/l)^3$	} .....	(24)
for $\xi_i = 1$ ;	$\psi_2(x) = 3(x/l)^2 - 2(x/l)^3$		
for $\theta_{i-1}=1$ ;	$\psi_3(x) = x(1 - x/l)^2$		
for $\theta_i = 1$ ;	$\psi_4(x) = (x^2/l)(x/l - 1)$		

Here, the displacement vector of i-th beam is defined in terms of its nodal rotations and displacements as follows:

$$u_i = (\xi_{i-1}, \theta_{i-1}, \xi_i, \theta_i)^T \dots (25)$$

The external forces and moments applied to a beam element are assumed to act only upon its nodes as shown in Fig.17. The force vector of j-th beam is defined in terms of these forces and moments as follows:

$$F_j = (P_{i-1}^j, M_{i-1}^j, P_i^j, M_i^j)^T \dots (26)$$

When the force vector  $F_j$  acts upon the i-th element, the equation of motion about the i-th element is given as follows:

Fig.17 Notation of forces and displacements at beam element.

$$[M]_i \ddot{u}_i + [C]_i \dot{u}_i + [K]_i u_i = F_i, \dots\dots\dots(27)$$

in which,  $[K]_i$ ,  $[M]_i$  and  $[C]_i$  are called the stiffness matrix, the mass matrix and the damping matrix respectively. By applying the principle of virtual work to the element, these matrices can be evaluated as shown in Eqs.(28), (29) and (30) respectively, in which,  $\psi_n'' = d^2\psi_n/dx^2$ ,  $\bar{m}$  and  $\bar{c}$  is the mass and the damping coefficient per unit length which can be calculated from Eqs.(13) and (14) respectively. Moreover, the force vectors can be evaluated by using the Morison's formula, and however, the moments may be neglected when their magnitudes are small.

Evaluating the equations of motion for the individual finite elements and superposing them, the equation of motion for the complete structure can be obtained. The time variations of the displacement vectors can be calculated from this equation.

$$[K]_i = \left[ EI \int_0^l \psi_j'' \psi_k'' dx \right]_i = \left( \frac{2EI}{l^3} \right) \begin{bmatrix} 6 & 3l & -6 & 3l \\ & 2l^2 & -3l & l^2 \\ \text{Sym.} & & 6 & -3l \\ & & & 2l^2 \end{bmatrix}_i, \dots\dots\dots(28)$$

$$[M]_i = \left[ \bar{m} \int_0^l \psi_j \psi_k dx \right]_i = (\bar{m}l)_i \begin{bmatrix} \frac{13}{35} & \frac{11}{210}l & \frac{9}{70} & -\frac{13}{420}l \\ & \frac{1}{105}l^2 & \frac{13}{420}l & -\frac{1}{140}l^2 \\ \text{Sym.} & & \frac{13}{35} & -\frac{11}{210}l \\ & & & \frac{1}{105}l^2 \end{bmatrix}_i, \dots\dots\dots(29)$$

$$[C]_i = \left[ \bar{c} \int_0^l \psi_j \psi_k dx \right]_i = \left( \frac{\bar{c}}{\bar{m}} \right)_i [M]_i, \dots\dots\dots(30)$$

TIME VARIATION OF PILE DISPLACEMENT

Some experiments and calculations have been performed for the small diameter cylinder, of which end the plate spring is attached. The length of this cylinder is 60cm and the diameter is 4cm. The flexural rigidity of the plate spring  $EI$  is  $1.93 \times 10^5$  Kg.cm<sup>2</sup>. The natural period of the cylinder was changed appropriately by arranging the length of plate spring. In the experiment, the water depth was always kept 40cm. In the calculations, this cylinder is divided into seven elements as shown in Fig.18. The Newmark's  $\beta$  method has been applied to calculate the time variations of the displacement vector with selecting  $\beta=0.25$ .

Fig.18 Division of pile into elements.

Fig.19 shows the time variations of the displacement at the cylinder top, in which the dotted lines and solid lines indicate the experimental values and the calculated ones respectively. In Fig.19(a), the displacements become larger to a certain magnitude as the time proceeds, because the wave period  $T=0.84\text{sec}$  is close to the natural period  $0.80\text{sec}$ . In Fig.19(b), the displacements are beating, because the wave period  $T=0.92\text{sec}$  is slightly different from the natural period. In Fig.19(c), the calculated values agree well with the experimental.

Fig.20 is one of the examples applied to the case of hyperbolic waves, in which the upper figure shows the water level variation  $\eta$  and the lower one is the displacement  $\xi$  calculated from  $\eta$ . In the displacement, the natural vibrations are generated by the high frequency component waves included in the wave crests.

(a)  $T=0.84\text{sec}$ ,  $H=1.9\text{cm}$ ,  $\xi_{\text{max}}=4.85\text{cm}$ .

(b)  $T=0.92\text{sec}$ ,  $H=4.1\text{cm}$ ,  $\xi_{\text{max}}=4.91\text{cm}$ .

(c)  $T=1.18\text{sec}$ ,  $H=4.6\text{cm}$ ,  $\xi_{\text{max}}=1.98\text{cm}$ .

Fig.19 Time variations of displacement of small diameter pile.  
(Solid line: Calculated. Dotted line: Experiment)

Fig.20 Time variations of hyperbolic waves and the displacement of small diameter pile.

In the case of irregular waves,  $\xi$  can be calculated only from  $\eta$  by using the linear filters<sup>2)</sup>. Fig.21 is one of the examples of irregular waves, in which, the calculated values of the displacement shown by solid line agree well with the experimental ones shown by dotted line.

## CONCLUSIONS

The harmonic vibrations of structures can be calculated by the method of transfer matrices. On the other hand, in order to calculate the transient response with considering initial conditions or the random vibrations induced by irregular waves, the method of structural-property matrices should be used. In these calculations, the added mass coefficient should be given an appropriate value in the range from 0 to 1 in accordance with the magnitude of a displacement, and also the damping coefficient should be determined with considering the interaction effect between structures and waves.

The resonance of a small diameter pile occurs at the wave periods of integer times natural period, which has been confirmed by the experiments and the calculations. The time variations of the displacement of structures can be calculated correctly by using the matrix methods shown in this paper.

## ACKNOWLEDGEMENT

The authors wish to express their gratitudes to Mr. H.Sawaki, Mr. H.Masuya and Mr. T.Hosogai (who were postgraduate students at that time) for their assistances through this investigation.

## CHAPTER ONE HUNDRED NINETY EIGHT

### EVOLUTION OF INTERFACIAL WAVES ALONG AN UNSTEADY SALT WEDGE

by

Wataru Nakano\* and Isao Yakuwa\*\*

#### ABSTRACT

Field measurements of the receding salt wedge were made at the mouth of the Ishikari River in October 1981. The gradually growing interfacial waves and the diffusion pattern of salinity are visualized by the Ultrasonic Method. The evolution mechanisms of waves are analysed in detail by calculating the power spectra of wave records. It is pointed out that the wave breaking, the wave-eddy interaction and the nonlinearity of waves are factors dominating the evolution. The nonlinear property of interfacial waves is studied further by watertank experiments.

#### INTRODUCTION

Because a salt wedge influences the flow structure and water quality in the estuary, many studies about it have been carried out by various research methods. The theoretical study and laboratory experiment have found out the importance of internal waves in the dynamics of the stratified shear flow[8]. The results of field observations, however, shows that in the steady state of the salt wedge the interfacial waves are not the factor controlling the diffusion process because the amplitudes of interfacial waves are small under this condition. Do the interfacial waves, on the other hand, play an important role in the unsteady salt wedge? Regrettably, there is not enough observational research of the unsteady salt wedge. So we planned to observe the interfacial waves along the unsteady salt wedge in the Ishikari River.

The Ishikari River, which has a length of 262 km, flows through the Ishikari Plain and pours into the Japan Sea (Fig. 1). The normal discharge of this river is about  $300 \text{ m}^3/\text{sec}$ . Because the critical discharge  $Q_c$  for the intrusion of the salt wedge into the river mouth is about  $600 \text{ m}^3/\text{sec}$  [3], the salt wedge steadily lies in the water course to a point about 8 km upstream from the river mouth under the usual river flow.

Fig.2 Location map

Fig.1 The Ishikari River and the route of the Typhoon 8124

From October 22 to October 23, 1981, a severe 960-millibar typhoon (the Typhoon 8124) hit and passed through the Japanese Islands as shown in Fig.1. Because of the heavy rain brought about by this typhoon in the drainage basin of the Ishikari River, the river discharge increased from 300 to 2,250 m<sup>3</sup>/sec beyond the critical value  $Q_c$ . On these two days, we had a chance to observe the interfacial gravity waves propagating along the interface of the unsteady salt wedge. The purpose of this paper is to report the observational results and to make clear the evolution mechanisms of the interfacial waves along an unsteady salt wedge.

### FIELD OBSERVATION

The estuary of the Ishikari River is drawn in Fig.2. The observation was conducted on a pier which locates 3.5 km upstream from the river mouth. As shown in Fig.3, the displacement of interface was measured with two echo-sounder transducers, No.1 and No.2. No.1 was settled facing downwards slightly under the water surface, whereas, No.2 was settled facing upwards on the riverbed to record the both of the water level and the displacement of interface.

Fig.3 Pier station and two echo-sounder transducers

Fig.4 Hydraulic conditions. (a)History of river discharge  $Q$  and tidal level. (b)History of the level of surface  $H$  and interface  $H'$ .

The hydraulic conditions during the observation are summarized in Fig.4. Fig.4(a) shows the history of the river discharge and the tidal level. The latter has been observed at Otaru Port which locates about 30 km west from the river mouth. Fig.4(b) shows the history of the surface level  $H$  and the interface level  $H'$  measured at the station. After a weak tidal motion, the interface level  $H'$  begins to lower rapidly at 9:00 on October 23 according to the increase of river discharge. The echo-sounder measurement was performed from 11:00 to 15:00 on October 22 and from 8:00 to 13:00 on October 23. The six series of wave records were sampled at short time intervals numbered from D1 to D6 in Fig.4(b). Because we had to use the clearer image to analyse the data accurately, the data D1, D2 and D3 are sampled from the chart of echo-sounder No.1, and the data D4, D5 and D6 are sampled from that of No.2.

The charts D1, D2 and D3 in Fig.5(a) were recorded on October 22. At these stages the river charged almost steady discharge of  $350 m^3/sec$  that was fairly smaller than the critical value  $Q_c$  of  $600 m^3/sec$ . The depth at the observation point was about 11 m. The river bed cannot be seen in these figures. The chart D1 shows that several waves of small amplitude are intermittently propagating along the interface lying at 3.5 m depth. The wave height and the wave period are about 30 cm and 18 sec respectively. In the stage of D2, the waves are going through more frequently, and in the stage of D3, the wave height attains to 50 cm and the waves become short-crested. It

will also be noted that the wave breaking and the destruction of interface are taking place.

On October 23, the river discharge abruptly increased beyond the critical discharge  $Q_c$ . The recorded charts are shown in Fig.5(b). D4 shows the large scale random and modulated waves, which are propagating along the interface lying at 6 m depth and are causing violent wave breaking. It may be seen that the interfacial waves are playing an important role in salinity diffusion. The wave height is about 80 cm and the wave period is obtained as about 21 sec. The waves shown in D5 have longer period of 30 sec and waves are propagating more periodically. After 85 minutes, in the stage shown in D6, the waves recur to the modulated state and the wave period lengthens up to 40 sec and the wave height attains to 2 m.

### SPECTRAL ANALYSIS

To make clear the evolution mechanism of interfacial waves, we calculated the power spectra of recorded waves, which are shown in Fig.6. Each spectrum was calculated by FFT method with 512 data sampled from the recorder charts shown in Fig.5(a) and (b). In each figure the spectrum is drawn with a solid line. Further, the spectrum of preceding step is drawn with a broken line for a convenience of comparison.

Fig.5(a) Echo-sounding images recorded on Oct. 22.

Fig.5(b) Echo-sounding images recorded on Oct. 23.

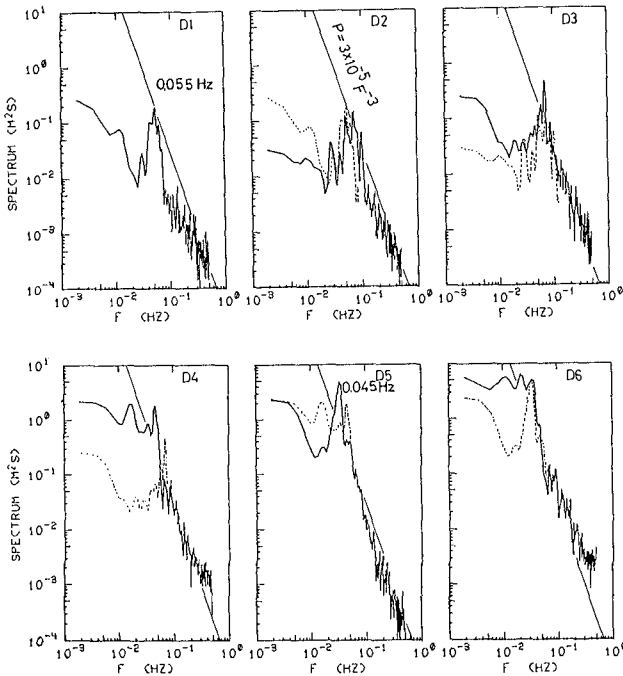

Fig.6 Power spectra of interfacial waves (solid lines). The broken line in each figure represents the spectrum of the preceding step.

Corresponding to the mean wave period of 18 sec shown in the chart of Fig.5(a), the spectrum of D1 has a distinct spectral peak at 0.055 Hz. In this stage, the power spectra in higher frequency range decreases with frequency  $f$  more dully than  $f^{-3}$ . After this stage the spectrum approaches a saturated spectral form in high frequency range which decreases with  $f$  as  $f^{-3}$  as shown in D2 and D3. Spectral form of this type has been observed in the spectra of ocean internal waves [2] and theoretical explanation of this spectral form has been proposed by Phillips[6]. Phillips[6] derived the  $f^{-3}$ -spectrum by assuming the local breakdown of internal waves caused by shear stress in wave motion. Therefore, the growth of spectrum from D1 to D3 indicates that the local breakdown process of the interfacial waves is beginning at this stage. The local breakdown process must be the mechanism controlling the earlier stage of evolution.

Though the  $f^{-3}$ -spectrum in high frequency range is maintained also in the later stage, another feature is noted in D4, D5 and D6 of

Fig.6. The spectrum of D4 has one small peak and two larger peaks. The small one grows the narrow dominant peak in D5. After this stage, the lower side components of this peak grow the new maximum peak in D6. This result indicates that in these stages the waves go through a modulation-demodulation cycle and the frequency of dominant components shifts to the lower frequency side. These phenomena are explained in the following section.

### TWO MECHANISMS OF EVOLUTION

The process of modulation-demodulation and frequency downshift of interfacial waves can be interpreted by assuming two different mechanisms:

The first mechanism is an interaction between the interfacial waves and turbulent eddies in the upper layer. The upper figure of Fig.7 is same as the chart D5 of Fig.5(a). The diffusion patterns of salinity in the upper layer indicates the existence of large scale turbulent eddies in this layer. It seems that these eddies have a mean vertical scale comparable to the thickness of the upper layer and have a mean period comparable to that of the interfacial waves. These eddies will cause the pressure disturbance along the interface. This pressure disturbance will supply its energy to the interfacial waves of the same horizontal scale as that of eddies as shown in Fig.8(a). By the way, the scales of the eddies are restricted under the thickness of the upper layer, which increases with discharge. It follows that the length and period of interfacial waves increase as the discharge increases. Further, if the horizontal scales of waves and eddies are mismatched, the wavetrain will modulated as shown in Fig.8(b). The cycle of matching and mismatching of two scales will lead the waves to the process of modulation-demodulation.

The second mechanism is based on the nonlinearity of interfacial waves. Both of the modulation-demodulation cycle and the downshift of frequency were observed by Lake et al.[5] in the laboratory experiment of finite amplitude surface waves. The former phenomenon was explained by the nonlinear Schrödinger equation for complex amplitude  $A(x,t)$ :

$$i\left(\frac{\partial A}{\partial t} + \frac{d\omega}{dk} \frac{\partial A}{\partial x}\right) + \mu \frac{\partial^2 A}{\partial x^2} + \nu |A|^2 A = 0, \quad (1)$$

where  $k$  and  $\omega$  are carrier wave number and carrier frequency respectively, and  $\mu$  and  $\nu$  are coefficients characteristic of the system. The displacement  $\eta(x,t)$  is related to  $A(x,t)$  by

$$\eta(x,t) = A(x,t)\exp[i(kx-\omega t)] + c.c. \quad (2)$$

The nonlinear modulational instability described by the equation(1) is summarised as follows: The nonlinear plane wave shown in Fig.9(a) is unstable to small disturbances in the form of a pair of side-band modes; at initial stage the modulational disturbances grow

Fig.7 Large scale turbulent eddies in the upper layer.

Fig.8 Eddy-wave interaction

exponentially with time; the long-time evolution is completely recursive and the side-band modes are symmetric throughout the evolution as shown in Fig.9(c)-(e). In the experiments performed by Lake et al.[5], however, the side-band components grew asymmetrically as shown in Fig.9(f)-(h) and the downshift of wave frequency was observed.

At present stage, the data is not sufficient to conclude this problem. In the following chapter, the nonlinear instability of interfacial waves is investigated by laboratory experiment.

EXPERIMENT

The apparatus used is depicted in Fig.10. The experiments were performed in the 25cmx50cmx600 cm watertank in which a two-layer density stratification had been formed by fresh water (specific gravity of 1.004) and salt water (specific gravity of 1.061). The thickness of fresh water layer was 20.5 cm and that of salt water layer was 19.5 cm. Modulated waves were generated by a wave maker at one end of the tank and absorbed by a wave absorbing beach at the opposite end. The evolution of waves was measured with seven infrared type wave amplitude gauges located at the stations 0.5m, 1m, 2m, 3m, 4m, 5m, and 5.4 m downstream of the wave maker. The wave gauges are similar to that imploved by Koop et al.[4]. The data measured at all stations were recorded on the chart of multi-pen recorder and the data

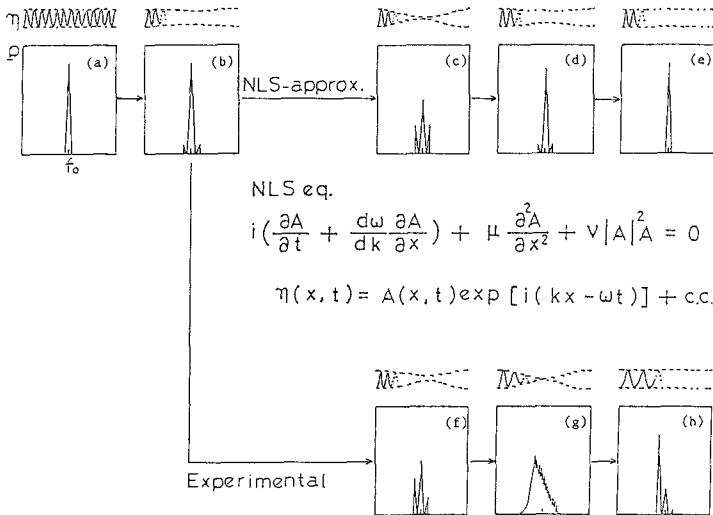

Fig.9 Nonlinear modulational instability of surface waves. Theoretical prediction based on the nonlinear Schrödinger equation and the experimental result of Lake et al.[5].

measured at stations 0.5m, 1m, 2m and 3m were recorded also in a 4-ch FM data-recorder to calculate power spectra of interfacial waves.

It is well known that wave train is unstable to modulational disturbance if the coefficients of the nonlinear Schrödinger equation(1)  $\mu$  and  $\nu$  satisfy the inequality:

$$\mu\nu > 0 \quad (3)$$

Tanaka[7] derived formulae which express the coefficients characteristic of interfacial waves as functions of the wave number, the density of two fluids and the thickness of each layer. Since the wave length is 31 cm in our experiments, the coefficients are calculated as  $\mu=8.5 \text{ cm}^2\text{sec}^{-1}$  and  $\nu=0.049 \text{ sec}^{-1}\text{cm}^{-2}$  by Tanaka's formulae[7]. Because  $\mu\nu=0.42 \text{ sec}^{-2}>0$ , the modulational instability can be expected under this condition. The growth of modulational disturbance, however, depended on the strength of initial modulation given by the wave generator because the viscosity dumped the power of small amplitude disturbance. For example, the waves which had not been modulated at the wave generator were never modulated throughout the propagation even when it satisfied the instability condition (3).

When the waves had been initially modulated, modulation-demodulation cycles were found, as shown in Fig.11. Initially modulated waves have large modulation amplitude at the station of 0.5 m, and become almost unmodulated state at 1.0 m. At the station of 2.0 m, strong modulation appears for the second time, and at 3.0 m the modulation becomes relatively weak. After these stages, waves are separated into many wave pulses. This figure resembles that measured by Lake et al.[5].

To examine whether the recurrence observed in the experiment is a nonlinear phenomenon or not, we calculated power spectra of the data measured at the stations 0.5 m, 1.0 m, 2.0 m and 3.0 m. The calculated spectra are shown in Fig.12. In Fig.12(a) the spectrum has one large peak at frequency 0.36 Hz and two smaller side-band peaks at frequencies  $0.36 \pm 0.039$  Hz. These side-band components are severely modulating the carrier waves in this stage, but they decrease in the stage of Fig.12(b) showing that the modulation are weakened. In the following stages shown in Figs.11(c) and (d), the lower side-band components increase a little as shown in Fig.12(d), whereas the fundamental components and higher side-band components decrease, in consequence, it may be regarded that the lower side-band components are growing in relative sense. This mutual exchange of spectral power between different modes indicates that the modulation-demodulation process observed in the experiment is the nonlinear process in essence.

### CONCLUSIONS

Based on the results of the field measurement of an unsteady salt wedge, it is concluded that:

1. When the river discharge increases beyond a critical value, the salt wedge recedes and interfacial waves of considerable amplitude appear along the interface of fresh and salt water.
2. These interfacial waves grow through following two stages:

In the earlier stage, the interfacial waves of small amplitude grow and become short-crested. The growth of waves in this stage is controlled by the mechanism of local breakdown discovered by Phillips[6].

In the later stage the violent wave breaking begins and the interfacial waves become an important factor of salinity diffusion.

3. The process of modulation-demodulation and frequency downshift observed in the later stage may be interpreted by either or both of the following mechanisms: (a) Interaction between interfacial waves and turbulent eddies in the fresh water layer, (b) Nonlinear modulation mechanism in large amplitude interfacial waves. But at present stage, the data are not sufficient to conclude.
4. In laboratory scale, the nonlinear modulational instability takes place also in interfacial waves if the initial modulation is sufficiently strong.

## CHAPTER ONE HUNDRED NINETY NINE

### MODELING ESTUARIAL COHESIVE SEDIMENT TRANSPORT

By E. J. Hayter,<sup>1</sup> A.M. ASCE and A. J. Mehta,<sup>2</sup> M. ASCE

#### ABSTRACT

Cohesive sediment related problems in estuaries include shoaling in navigable waterways and water pollution. A two-dimensional, depth-averaged, finite element cohesive sediment transport model, CSTM-H, has been developed and may be used to assist in predicting the fate of sorbed pollutants and the frequency and quantity of dredging required to maintain navigable depths. Algorithms which describe the transport processes of redispersion, resuspension, dispersive transport, settling, deposition, bed formation and bed consolidation are incorporated in CSTM-H.

The Galerkin weighted residual method is used to solve the advection-dispersion equation with appropriate source/sink terms at each time step for the nodal suspended sediment concentrations. The model yields stable and converging solutions. Verification was carried out against a series of erosion-deposition experiments in the laboratory using kaolinite and a natural mud as sediment. A model application under prototype conditions is described.

#### INTRODUCTION

Fine, cohesive sediments in estuaries are comprised largely of terrigenous clay-sized particles. The remainder may include fine silts, biogenic detritus, organic matter, waste materials and sometimes small quantities of very fine sand. The electrical surface repulsive forces which act on each elementary clay particle are several orders of magnitude larger than the gravitational force. As a result, the physico-chemical properties of fine sediments are controlled mostly by the surface forces.

In water with a very low salinity (less than about one part per thousand, ppt) the elementary particles are usually found in a dispersed state. A slight increase in the salinity (up to 2-3 ppt) is sufficient to repress the repulsive surface forces between the particles, with the result that the particles coagulate to form units known as flocs. Each floc may consist of thousands of elementary particles. Coagulation depends upon inter-particle collision and cohesion resulting from collision. The three principle mechanisms of inter-particle collision in suspension are Brownian motion, internal fluid shearing and differential sedimentation. Cohesion of particles

<sup>1</sup>Asst. Prof., Dept. of Civil Engrg., Clemson Univ., Clemson, SC 29631.

<sup>2</sup>Assoc. Prof., Coastal and Oceanographic Engrg. Dept., Univ. of Florida, Gainesville, Fla. 32611.

is caused by the presence of net attractive surface forces. The latter condition is caused by the increased concentration of dissolved ions, which serves to depress the double layer around each particle and allow the attractive forces to predominate.

Flocs have a tendency to build up or combine under favorable fluid shearing rates to form larger units known as aggregates. The transport of aggregates in estuaries is affected by the hydrodynamic conditions and by the chemical composition of the suspending fluid. Most estuaries contain abundant quantities of cohesive sediments which usually occur in the coagulated form in various orders or degrees of aggregation. The orders of aggregation classify aggregates according to their density and shear strength. Therefore, an understanding of the transport properties of these sediments requires a knowledge of the manner in which the aggregates are transported in estuarial waters.

Fine sediment related problems in estuaries include sedimentation and water pollution. Under low flow velocities, sometimes coupled with turbulent conditions which favor the formation of large aggregates, fine sediments have a tendency to deposit in dredged cuts and navigation channels, in harbors and marinas, and behind pilings placed in water (9). In addition, the mixing zone between upland fresh water and sea water in estuaries is a favorable site for bottom sediment accumulation. Inasmuch as estuaries are often used as transportation routes, it is desirable to be able to accurately estimate the amount of dredging required to maintain navigable depths in these water bodies, and also to predict the effect of new estuarial development projects such as the construction of a port facility or dredging of additional navigation channels.

A significant portion of the pollution load in water is quite often transported sorbed to cohesive sediments rather than in the non-sorbed state (16). Thus, the importance of considering the movement of cohesive sediments in predicting the fate of pollutants (e.g. pesticides, radioisotopes, and toxic elements such as lead, mercury, cadmium and nickel) cannot be over emphasized. The properties of cohesive sediments, and in particular clays, which cause the sorption of pollutants are the large surface area to volume ratio, the net negative electrical charges on their surfaces and their cation exchange capacity.

#### TRANSPORT MODEL

Prediction of the fate of sorbed pollutants or the annual dredging requirements of a harbor can be accomplished by modeling the movement of cohesive sediments. This requires mathematical descriptions of the various physical processes which govern cohesive sediment transport under turbulent flow. Algorithms which represent the processes of redispersion, resuspension, dispersive transport, settling, deposition, bed formation and consolidation have been developed and incorporated in a two-dimensional transport model which solves the depth-averaged advection-dispersion equation (Eq. 1) using the finite element method.

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} = \frac{\partial}{\partial x} (D_{xx} \frac{\partial C}{\partial x} + D_{xy} \frac{\partial C}{\partial y}) + \frac{\partial}{\partial y} (D_{yx} \frac{\partial C}{\partial x} + D_{yy} \frac{\partial C}{\partial y}) + S \quad (1)$$

where  $C$  = depth-averaged suspension concentration,  $u, v$  = local depth-averaged water velocity components in the  $x$  and  $y$  directions,  $D_{ij}$  = effective sediment dispersivity tensor, and  $S$  = source/sink term which accounts for the rate of sediment addition (source) due to erosion and the rate of sediment removal (sink) due to deposition. The resulting transport model, CSTM-H, is capable of predicting the horizontal and temporal variations of the depth-averaged suspended sediment concentrations and bed surface elevations in an estuary, coastal waterway or river. Previous models are not as comprehensive as they use mathematical descriptions (or algorithms) of the considered transport processes that are based on limited studies conducted prior to the early 1970's. In this study field evidence and the considerable amount of experimental research that has been conducted on cohesive sediment transport mechanics since that time have been used to develop new algorithms. A description of the algorithms is given below.

Surficial layers of estuarial beds, typically composed of flow-deposited cohesive sediment aggregates, are stratified with respect to bed shear strength and density, and occur in three different states: stationary suspensions, partially consolidated (or consolidating) beds and settled (fully consolidated) beds. Stationary suspensions, which may be regarded as extremely under-consolidated soil, develop whenever the settling rate of concentrated mobile suspensions exceeds the rate of self-weight consolidation. They tend to have a very high water content and low shear strength and are redispersed, or mass eroded, when subjected to an excess bed shear stress, i.e. when the bed shear stress is greater than the mechanical shear strength of the bed surface. That portion of the suspension that is not redispersed undergoes: 1) consolidation, due to overburden resulting from the weight of the overlying sediment which crushes the aggregate network below, and 2) thixotropic effects, i.e. slow rearrangement of deposited aggregates attributed to internal energy and unbalanced internal stresses, both of which alter the order of aggregation of the sub-surface bed layers. This results in a vertical stratification of the bed with respect to density and shear strength, with both properties typically increasing with depth (11). Differential settling caused by sorting processes is another cause of stratified bed formation.

Partially consolidated deposits have a somewhat lower water content and higher shear strength, and are eroded aggregate by aggregate when subjected to an excess shear stress. Settled beds possess a much lower water content, a much higher shear strength and as well are resuspended aggregate by aggregate when subjected to an excess shear, unless the excess shear stress is very large in which case large chunks of material may detach from the bed and be entrained. Both stationary suspensions and partially consolidated beds undergo consolidation, with the bed density and shear strength increasing with time of consolidation. In settled beds, the shear strength and density profiles exhibit relatively uniform properties over depth.

To facilitate the modeling of changes in the bed surface elevation due to erosion, deposition and consolidation, the bed is treated in the following manner: 1) it is discretized into layers and 2) bed properties, i.e. density and shear strength, are assumed to be spatially (in the x-y plane) invariant within each element, but not so from element to element, in order to account for inter-element spatial variances in shoaling and/or scouring patterns. These two factors are explained below.

The bed in each element is considered to be composed of two sections: 1) the original, settled bed that is present at the start of modeling and 2) new deposits located on top of the original bed, that result from deposition during model simulation. Each of these two sections is divided into a number of layers in order to specify the actual shear strength and bulk density profiles in the model. The new deposit section is subdivided into two sub-sections, the top referred to as unconsolidated new deposit (UND) layers and the bottom as partially consolidated new deposit (PCND) layers (Fig. 1). The number of layers indicated in Fig. 1 for each of the three bed sections are not fixed, as each section can be assigned any number of layers. Within each layer the bed shear strength and density are assumed to vary in a linear manner with depth. Previous models have used a constant bed shear strength and density for each layer, and only a single layer for the partially consolidated bed section. Therefore, the stratified nature of partially consolidated beds is not represented in these models.

Fig. 1 Bed Schematization Used in Bed Formation Algorithm (4).

Stationary suspensions are represented as being the top section of the layered bed model, even though they do not constitute a true bed, in order to account for the subsequent redispersion and/or consolidation of these suspensions. However, the time-varying thickness of the bed in each element is equal to the sum of only the NLAYT (number of PCND layers) PCND layers and the MLAYO settled bed layers.

The bed formation algorithm uses the following procedure to form the new deposit bed layer(s). The dry sediment mass per unit bed area per element,  $M_D$ , read in as an initial condition if a new deposit is initially present on top of the settled bed in any element, or deposited during the modeling (as determined by the deposition algorithm) is used in conjunction with the assumed linear bed density profiles in the UND and PCND layers to iteratively solve for the thickness of bed formed by  $M_D$  for each element where  $M_D > 0$ . The bed structure (i.e. bed shear strength and density profiles) of the existing bed is adjusted to account for the added sediment mass. During periods of deposition, first the UND layers are filled and then the PCND layers. The bottom PCND layer can never fill up; therefore, continuing deposition is accounted for by increasing the thickness of this layer, while the thicknesses of the overlying UND and PCND layers remain the same. This particular filling sequence was used in order to account for the consolidation of the sediment bed due to overburden during the bed formation phase by virtue of the increasing bed shear strength and density values with depth. Previous models use the assumed constant bed density value in each layer to solve explicitly for the bed thickness formed by  $M_D$ .

The erosion algorithm simulates the erosion of saturated, flow-deposited cohesive sediment beds on an element by element basis in the following manner. Redispersion of stationary suspensions (i.e. the UND layers) is represented by instantly reentraining the thickness of the bed above the level at which the bed shear stress,  $\tau_b$ , is equal to the bed shear strength,  $\tau_c$ . The mass of sediment that is redispersed per time-step is determined from the linearly varying  $\tau_c$  and dry sediment bed density,  $\rho$ , profiles in each stationary suspension layer. The average resuspension rate,  $\epsilon$ , of partially consolidated bed layers over one time-step,  $\Delta t$ , is given by the following empirical law that is analogous to the rate expression which results from a heuristic interpretation of the rate process theory of chemical reactions (11):

$$\epsilon = \epsilon_{0i} \exp\left\{\alpha_i \left(\frac{\tau_b - \tau_c}{\tau_c}\right)\right\} \quad (2)$$

where  $\epsilon_{0i}$  and  $\alpha_i$  are empirical coefficients for the  $i$ -th PCND layer. In Eq. 2,  $\tau_c$  is taken to vary linearly with  $z_b$ , the depth below the sediment-fluid interface, in the discretized manner explained previously. The rate expression given by Eq. 2 for PCND layers indicates that the resuspension rate varies exponentially with the excess bed shear stress,  $\tau_b - \tau_c$ . The average resuspension rate of settled bed layers is given by an empirical expression that is proportional to the first term of a Taylor series expansion of Eq. 2, and thus is linearly proportional to the excess shear stress (8). The proportionality coefficient is termed the erodibility constant,  $M_i$ , where the subscript  $i$  represents the value of  $M$  for the  $i$ -th settled bed layer

below the new deposit bed sections. The dry sediment mass and bed thickness of PCND or settled bed layers eroded per time-step are determined with the appropriate rate expression as functions of the time-varying  $\tau_c$  and  $\rho$  profiles using an iteration routine. New layer thicknesses and  $\tau_c$  and  $\rho$  profiles are then determined.

The effect of salinity,  $S$ , on the bed shear strength and hence on the erosion rate of that bed, as determined from laboratory resuspension tests is incorporated into the erosion algorithm. The bed shear strength of a natural mud was found to nearly double in value, in a linear manner, between  $S \approx 0$  and 2 ppt, and thereafter (for  $S > 2$  ppt) was found to remain practically constant (5). Consequently, the rate of erosion is predicted to decrease with increasing salinity up to 2 ppt, where it becomes essentially invariant with respect to salinity. The mud used in these tests was from Lake Francis, Nebraska, and consisted of particles 50% of which were finer than  $2\mu\text{m}$ , with montmorillonite, illite, kaolinite and quartz being the predominant minerals. It had a cation exchange capacity (CEC) of 100 milliequivalents/100 grams. This high CEC value indicates a higher percentage of montmorillonite than the other two clay minerals.

In the erosion algorithm, redispersion and resuspension are simulated to occur in unsteady flows only during temporally accelerating flows, i.e.  $\tau_b(t+\Delta t) > \tau_b(t)$ . Thus, even though  $\tau_b(t+\Delta t)$  and/or  $\tau_b(t)$  may be greater than  $\tau_c(z_b=0)$ , no erosion will be predicted if  $\tau_b(t+\Delta t) < \tau_b(t)$ . This stipulation for the occurrence of erosion, and an analogous one for deposition, is based on an interpretation of typically observed Eulerian concentration-time records in estuaries. Laboratory evidence further suggests that under accelerating flows, erosion occurs without redeposition of the eroded sediment, and that during decelerating flows, sediment deposits without reentrainment of the deposits (10,11,16). During periods of steady flows, erosion or deposition may occur, but never simultaneously.

The dispersive transport terms in Eq. 1 account for the transport of sediment by processes other than advective transport. Some of these processes include the effects of transverse and vertical velocity variations in bounded shear flows and turbulent diffusion. Thus, the effective sediment dispersion coefficients in Eq. 1 must include the effect of all processes whose scale is less than the grid size of the model or what has been averaged over time and space.

In modeling dispersion of a nonconservative constituent, e.g. sediment, it is essential to determine which of the four primary dispersion mechanisms - baroclinic circulation, shear-flow dispersion, bathymetry induced dispersion and wind-induced circulations - are important in the water body being modeled. Because of well-known problems in identifying, describing and modeling the combined effects of the various dispersion mechanisms, the dispersion algorithm in CSTM-H includes only shear flow dispersion. Following the analysis of Holley (6), it is assumed that the dispersion in wide, vertically well mixed estuaries is associated primarily with the vertical shear. The limitations of this assumption, which determine the applicability of such a dispersion algorithm, are consistent with those associated with a two-dimensional, depth-averaged model.

The shear flow dispersion algorithm uses the Reynolds analogy between mass and momentum transfer, which was verified by Jobson and Sayre (7) for sediment particles less than about 100  $\mu\text{m}$  in diameter, and calculates the four components of the two-dimensional sediment dispersivity tensor (Eq. 3) using the following formulation derived by Fischer (3) for bounded shear flows:

$$D_{ij} = 0.04 u_i u_j d^2 I_{ij} / \bar{E} \quad i, j = 1, 2 \quad (3)$$

in which  $u_i$  = local depth-averaged velocity in the  $x_i$ -direction,  $\bar{E}$  = depth-averaged diffusion coefficient in the  $z$  (vertical) direction, and  $I_{ij}$  is a dimensionless triple integral which expresses correlation between the rate of cross-stream mixing and the slope of the vertical velocity profile. Fischer (3) recommended that a value of 0.10 be used for  $I_{ij}$  since 1) in most investigations the vertical velocity profiles,  $u(z)$  and  $v(z)$ , and the vertical turbulent diffusion coefficient,  $E_z$ , are not known with a high degree of accuracy, and 2) the value of  $I_{ij}$  is fairly insensitive to the shape of the vertical velocity profile. The value of  $\bar{E}$  is given by  $0.067 u_* d$ , in which  $u_*$  = friction velocity. This expression for  $\bar{E}$  results from integrating the expression for  $E_z$  obtained by Elder (2) for shear flow down an infinitely wide inclined plane over  $d$ . Values of  $D_{ij}$  are calculated at each time step using the specified nodal values of  $u$ ,  $v$ ,  $u_*$  and  $d$ .

The deposition algorithm integrates the concepts proposed by various investigators (9,10) and represents a unified model of this process. The rate of deposition is given by

$$\frac{dC}{dt} = \frac{W'_s C}{d} \quad (4)$$

where  $W'_s$  = apparent sediment settling velocity. Laboratory experiments have shown that  $W'_s$  is a function of the bed shear stress, suspension concentration,  $C$ , and salinity,  $S$ . Figure 2 shows various ranges in which  $W'_s$  is defined. Deposition is predicted to occur only in decelerating flows, i.e.  $\tau_b(t + \Delta t) < \tau_b(t)$ , when  $\tau_b$  is less than the maximum shear stress at which deposition can occur,  $\tau_{b\text{max}}$ . In Ranges IA and IIA the sediment aggregates settle independently without much mutual interference, and therefore  $W'_s$  is independent of  $C$ . In Range IB, which corresponds to concentrations between approximately  $C_1 = 0.1 - 0.7$  gram/liter (g/l) and  $C_2 = 10-15$  g/l,  $W'_s$  increases with increasing concentration due to accompanying increase in inter-aggregate collisions, and therefore increased mutual interference. In Range IC (for  $C > C_2$ ),  $W'_s$  decreases with increasing concentration. At such high concentrations the sediment suspension, often referred to as fluid mud or mud cake, hinders the upward flux of water expelled by consolidation of the lower suspension (9). This type of settling is referred to as hindered settling. In Range IIB,  $W'_s$  increases with increasing suspension concentration and is obtained from a log-normal relationship (10). Expressions for  $W'_s$  as a function of  $C$ ,  $\tau_b$  and  $S$  for the five settling domains are given by Hayter (4).

Fig. 2 Apparent Settling Velocity Description in Domains Defined by Suspended Sediment Concentration and Bed Shear Stress.  $\tau_{bmin}^*$ ,  $\tau_{bmax}^*$ ,  $\tau_{bc}^*$  and  $\tau_b^*$  are characteristic values of  $\tau_{bm}^*$  (4).

The deposition rates of the Lake Francis mud were found to have a slight dependence on salinity. A power relationship between  $W_s$  and  $S$  of the form  $W_s \propto S^n$ , with  $n = 0.13$ , was determined from analysis of deposition tests conducted at salinities ranging from 0 to 35 ppt and under bed shear stresses varying from 0.0 to 0.30  $N/m^2$  (5).

The amount of sediment deposited onto the bed per time-step is determined on an element-by-element basis by integrating Eq. 4 over  $\Delta t$ , and the thickness and structure (i.e. density and shear strength profiles) of the bed are adjusted accordingly by the previously described bed formation algorithm. When deposition is not occurring (i.e. after bed formation) the bed is simulated to undergo consolidation, which is the result of soil mass volume reduction accompanied by outflow of water from the soil pores (primary consolidation), and plastic deformation of the bed (i.e. soil aggregates) under overburden forces (secondary consolidation).

The consolidation algorithm accounts for the consolidation of a stationary suspension and partially consolidated bed by increasing the bed density and bed shear strength and decreasing the bed thickness with time. Consolidation is considered to begin after the bed formation process is complete, at which time the bed thickness will be maximum. Laboratory experiments have revealed that after a consolidation time,  $T_{dc}$ , of a certain magnitude,  $T_{dc1}$ , stationary suspensions undergo resuspension (as opposed to redispersion with  $T_{dc} < T_{dc1}$ ) when subjected to an excess shear stress (4). Accordingly, the dry sediment mass in a stationary suspension for which  $T_{dc} = T_{dc1}$  ( $T_{dc1}$  was determined to be equal to three hours in a laboratory test using kaolinite) is incorporated into the partially consolidated bed, and therefore will undergo resuspension when subjected to an excess bed shear.

The following normalized relationship was found between the depth-averaged dry sediment density  $\bar{\rho}$  and  $T_{dc}$  and is used in the consolidation algorithm to determine  $\bar{\rho}$  (4).

$$\frac{\bar{\rho}}{\bar{\rho}_{\infty}} = 1 - \alpha \exp(-\lambda T_{dc}) \quad (5)$$

where  $T_{dc}^1 = T_{dc}/T_{dc\infty}$ ,  $\bar{\rho}_{\infty}$  = final (i.e. fully consolidated) mean bed density at consolidation time  $T_{dc\infty}$ . Least squares analysis gave  $\alpha = 0.845$ ,  $\lambda = 6.58$ . Owen (14) found  $\bar{\rho}_{\infty}$  to vary linearly with the initial suspension concentration.

The dry sediment density profile,  $\rho(z_b)$ , found by Owen (15) and Thorn and Parsons (17) for four natural muds with  $T_{dc} \geq 48$  hours can be expressed as

$$\frac{\rho(z_b)}{\bar{\rho}} = \beta \left(\frac{H-z_b}{z_b}\right)^{\delta} \quad (6)$$

where  $z_b$  = depth below the bed surface and  $H$  = bed thickness. Both  $\beta$  and  $\delta$  were found to be constants for  $T_{dc} > 48$  hours (4). Using  $\bar{\rho}$  determined by Eq. 5, the density profile  $\rho(z_b)$  is determined from Eq. 6.

Due to the limited available information on bed shear strength profiles in cohesive sediment beds, the increase of the shear strength,  $\tau_c$ , of a bed with  $T_{dc}$  is accounted for in the algorithm through use of a power law relationship between  $\rho$  and  $\tau_c$  (14,17)

$$\tau_c = \zeta \rho^{\xi} \quad (7)$$

with  $\zeta = 6.85 \times 10^{-6}$  and  $\xi = 2.44$  for Avonmouth mud (14).

The variation of  $\rho(z_b)$  and  $\tau_c(z_b)$  with  $T_{dc}$  is determined using the empirically determined relationships given by Eqs. 5-7. The thickness of the bed is reduced to account for the expulsion of pore water during consolidation, and to insure that sediment mass in the bed is conserved. The new deposit bed section (composed of stationary suspension and partially consolidated bed) of the layered bed is further divided into a finite number of strata in order to account for repeated periods of deposition, as typically occur in estuaries due to the oscillatory tidal flow. The top stratum may be composed of a stationary suspension and partially consolidated bed, whereas the buried strata are composed of just partially consolidated sections. The degree of consolidation of a particular stratum is accounted for by using a separate consolidation time for each stratum.

The finite element solution routine developed by Ariathurai (1) was modified to include the two cross product dispersion coefficients,  $D_{xy}$  and  $D_{yx}$ . The Galerkin weighted residual method is used to solve the advection-dispersion equation (Eq. 1) for the nodal depth-averaged suspended sediment concentrations, and a Crank-Nicholson type finite difference formulation is used to solve the temporal problem, i.e. advance the spatial solution in time. The model yields stable and converging solutions. The accuracy of the solution is affected when

the Peclet number becomes too large (greater than  $10^2$ ) or too small (less than  $10^{-3}$ ).

#### MODEL SYNOPSISIS

A synopsis of the operations performed by CSTM-H during each time-step and the data required is given below.

The average bed shear stress induced by the turbulent flow velocity of the suspending fluid is calculated for each element. Then the amount of sediment, if any, that is deposited onto or resuspended from the bed in each element during the current time-step is determined using the deposition and erosion algorithms, respectively. The dispersion algorithm then calculates the values of the four components of the two-dimensional sediment dispersivity tensor. Using these values and the prescribed velocity field and concentration boundary conditions, Eq. 1 is solved for the depth-averaged suspended sediment concentration at each node for the next time-step. The new bed elevation in each element is determined by adding or subtracting the thickness of sediment deposited onto or resuspended from, respectively, the bed profile that existed during the previous time-step. Lastly, the consolidation algorithm calculates for each element the increase in bed density and shear strength and the decrease in bed thickness due to consolidation during the previous time-step.

The following four types of data are required: 1) finite element grid of the system to be modeled, 2) two-dimensional depth-averaged velocity and salinity fields, 3) concentration initial and boundary conditions and 4) properties of the cohesive sediments which characterize their erosion, deposition, bed formation and consolidation.

#### VERIFICATION

Model verification was carried out against four erosion-deposition experiments, three of which were performed in an 18m long, 0.61 m wide recirculating flume and the fourth in an 0.76 m mean radius rotating annular flume. The bed shear stress history for one of the three experiments performed in the recirculating flume using kaolinite in tap water was the following: bed shear stress  $\tau_b = 0.06$  N/m<sup>2</sup> for two hours, then increased to 0.12 N/m<sup>2</sup> for the third and fourth hours, and finally decreased to 0.03 N/m<sup>2</sup> for the final five hours. In this nine hour experiment the bed was prepared by mixing the sediment-water suspension at a shear stress of approximately 0.5 N/m<sup>2</sup> for four hours, after which the flow was reduced to a shear stress of approximately 0.025 N/m<sup>2</sup> for eight hours. The flow in the flume was then completely stopped and the flow deposited bed was allowed to undergo consolidation for 3 hours. Figure 3 shows both the measured and predicted depth-averaged suspension concentration-time record. Satisfactory agreement between measurement and prediction is seen for this experiment, and a similar degree of agreement was obtained for the other two experiments.

The experiment in the rotating flume was conducted using the Lake Francis mud in water with 10 ppt sodium chloride concentration. The

Fig. 3 Measured and Predicted Suspension Concentration for Experiment in Recirculating Flume (4).

Fig. 4 Velocity - Time Record and the Measured and Predicted Suspension Concentrations for Experiment in Rotating Flume (4).

sediment-water mixture was mixed at a shear stress of  $1.7 \text{ N/m}^2$  for 24 hours, after which the flume was stopped and the sediment allowed to deposit and undergo consolidation for 40 hours. A micro-computer driven flow control system was used to generate semi-diurnal, constant water depth (30 cm) tidal flow shown in Fig. 4. Also shown in this figure are the measured and predicted suspension concentration-time records. Except for the short time-lags between predicted and measured concentrations at the times of maximum and minimum velocities, satisfactory agreement was again achieved. The empirical parameters which characterize erosion, deposition and consolidation of the sediment used in each experiment were determined in laboratory tests. An important conclusion from the verification process is that laboratory measured, transport-related parameters can be successfully used for model simulation.

#### APPLICATION

The utility of the model was shown by simulation of sedimentation in Camachee Cove Yacht Harbor, located adjacent to the Intercoastal Waterway in St. Augustine, Florida. An aerial view of the basin is shown in Fig. 5. The semi-rectangular shaped basin has approximate dimensions of 300 m in length and 100 m in width, and the entrance channel is 60 m wide. The mean depth of the basin is approximately 3 m. The hydrographic and sediment data required to model both the predominantly tide-induced circulation and fine sediment transport in the basin were collected by the Coastal Engineering Laboratory of the University of Florida. The hydrodynamic modeling was performed using the two-dimensional (depth-averaged) finite element flow model RMA2 (13). Results from flow modeling as well as the required sediment data measured during the field study were used in modeling sediment transport in the basin. The results are shown in Fig. 6, which shows contours of the predicted amount (thickness) of sediment deposition in centimeters per year. The observed shoaling pattern is not unexpected, as the greatest amount of sediment deposition would occur near the entrance because of the extremely small flow velocities (maximum  $\sim 10^{-2} \text{ m/sec}$ ) in that vicinity and throughout the basin as well. A mean shoaling rate of 15.1 cm/year was predicted, which is reasonably close to the measured 14.6 cm/year (12). The latter value was obtained by comparing bathymetric surveys conducted in March, 1980 and September, 1982.

#### SUMMARY AND CONCLUSIONS

Previous fine, cohesive sediment transport models have used transport algorithms based on limited studies conducted prior to the early 1970's. Utilization of contemporary laboratory experimental and field evidence to develop algorithms which describe erosion, dispersion, settling, deposition and bed consolidation has resulted in a model with predictive capability. The following is a summary of improvements over previous models: 1) The model includes the cross product dispersion coefficients in the two-dimensional advection-dispersion equation; 2) includes a dispersion and bed consolidation algorithm; 3) calculates the erosion rate of partially consolidated beds as an exponential function of the excess bed shear stress; 4)

Fig. 5 Aerial View of Camachee Cove Yacht Basin (4).

Fig. 6 Predicted Sedimentation Contours for Camachee Cove Yacht Basin, in cm/year (12).

represents the stratified nature of consolidating sediment beds by assuming a linear intra-layer bed density and shear strength variation (instead of constant values) in the layered bed model in determining the mass of sediment eroded or thickness of bed formed by deposition of a given sediment mass; 5) accounts for flow acceleration in determining occurrence of erosion or deposition under a given bed shear stress; 6) predicts that deposition occurs in decelerating flows when  $\tau_b < \tau_{bmax}$ , whereas previous models predict deposition only when  $\tau_b < \tau_{bmin}$  in either accelerating or decelerating flows. Thus, deposition is predicted to occur in the previous models during only a small percentage (e.g. 20% for kaolinite in tap water) of the shear stress range in which deposition has been observed to occur in laboratory steady flow experiments. 7) The model accounts for the effect of salinity on the rates of erosion and deposition of fine sediments. This feature of the model is particularly important in upstream estuarial reaches as well as in downstream regions when high runoff due to storms reduces the salinity.

A two-dimensional, depth-averaged model such as CSTM-H can strictly be applied only to well-mixed estuaries, harbors and basins where the horizontal dimensions of the water body are at least one order of magnitude greater than the vertical dimension. Applications to partially mixed water bodies or especially to highly stratified water bodies should be made when only extremely rough estimates of some sedimentary process, e.g. shoaling rate, are required.

A significant conclusion from this study was that laboratory measured transport-related parameters can satisfactorily reproduce the concentration-time history in laboratory erosion-deposition experiments and a mean sedimentation rate in the prototype, given settling velocity values derived from field measurements in the latter case.

#### ACKNOWLEDGMENT

The work was performed while the first author was a graduate student at the University of Florida. Support by the Water Resources Division of the U.S. Geological Survey under their thesis support program is gratefully acknowledged. Simulation of sedimentation in Camachee Cove Yacht Harbor was carried out with the help of support from Florida Sea Grant College, NOAA, through project R/C-6.

## CHAPTER TWO HUNDRED

WATERQUANTITY AND -QUALITY RESEARCH FOR THE RHINE MEUSE ESTUARY

BY  
A. Roelfzema<sup>1)</sup>, M. Karelse<sup>2)</sup>, A.J. Struijk<sup>3)</sup> and M. Adriaanse<sup>4)</sup>

### ABSTRACT

In commission of the Dutch Government (Ministry of Public Works), the Delft Hydraulics Laboratory carries out a long term research programme on the water quantity and water quality of the Rhine-Meuse estuary. The researchprogramme has to provide the necessary hydraulic data as input for a management decision-making process. The programme is based on an "integrated approach philosophy" with respect to the various subjects to be studied and the research tools to be used (data from nature, hydraulic model, mathematical models and fundamental research). The paper presents the essentials and backgrounds of the research programme and discusses some first results.

### 1. INTRODUCTION

Estuaries play an important role in life and economy. Many important cities have developed on their shores where navigation meets the inland transport systems and man has tried to interfere with estuarine systems in various ways. Hydraulically speaking estuaries are far from simple (e.g. Fischer et al, 1979). The tide penetrates, causing the water to rise and fall and to flow in and out with the regularity of its astronomical cause. Seasonal flows of fresh water from the river(s) traverse the estuaries and mix with the waters of the sea. The heavier sea water tries to intrude along the bottom, which is counteracted by internal friction and mixing with the fresh water.

Estuarine waters are far from pure. Salt penetrates from the sea, but also the "fresh" river flows carry a "natural" load of millions of tons of dissolved matter. Moreover, estuaries are often polluted by a diversity of wastes and heat from cities, industries and agriculture. Especially the suspended fine sediments absorb large quantities of chemical substances, thus contributing to the transportation and deposition of pollutants in the system.

Estuarine management tries to obtain an optimum balance between the different, often conflicting, interests. Essential for the management decision making process on estuarine system is the input of water quantity and water quality parameters, see figure 1.1. These parameters must be estimated by hydraulic research.

3) Senior-engineer, Ministry of Public Works (Rijkswaterstaat)

4) Research engineer, Ministry of Public Works (Rijkswaterstaat)

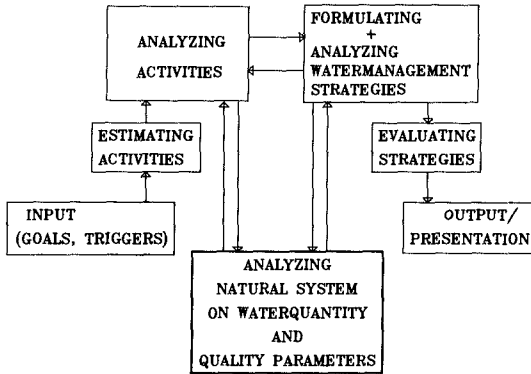

Fig.1.1 PROCESS WATERMANAGEMENT ANALYSIS

The Rhine-Meuse estuary is situated in the south-western part of the Netherlands and covers a densely populated area. The estuary system consists of various branches, forming a network with the Rotterdam harbours in the northern part and large tidal areas in the southern part, see figure 1.2. At the upstream side the system is bounded by three fresh-water river branches, the downstream salt tidal boundary consists of a free and a regulated outflow into the North sea.

Salinity intrusion is of the partly mixed and layered type (Van der Heijden, de Jong, Kuijper, Roelfzema, 1984) and regularly reaches upstream of Rotterdam. The Rijkswaterstaat (Dutch Government, Ministry of Public Works) is responsible for the management of the Rhine Meuse estuary. The water quantity and -quality problems that play a role are safety against inundation, maintenance of infrastructural works, water supply for industrial, agriculture and public use, discharging and flushing the system and the accessibility for navigation. These management aspects show interferences and conflicting interests. The management aspects have been translated into a number of subjects on which hydraulic research is carried out. These interrelated subjects, are :

- flood and flood control
- morphological stability of the system (sedimentation and erosion)
- distribution and discharge of (fresh) water
- salinity intrusion (intake locations of fresh water)
- siltation (dredging of harbours and ecological impacts)
- dispersion of heat and waste
- discharge of ice

Guidelines for the management and therefore also for the research on these subjects are, amongst others, the economy (e.g. with respect to the dredging) and laws and legal statements with respect to the distribution of fresh water, pollution of surface water and to salinity intrusion.

## 2. THE RESEARCH PROGRAMME

Relevant for the set up of the research programme are the complexity of the physical processes in the estuary system, the variety of water quantity and -quality problems to be studied and the required accuracies of the answers to be given. The physical processes and the variety of problems have a common basis: the inhomogeneous tidal flows in the system (= affected by the density differences between sea and rivers). These inhomogeneous tidal flows are primary determining the physics in the system.

Understanding these flow phenomena under various hydraulic and geometrical circumstances is therefore essential for analyzing and interpreting research results on the different problems, separately and with their interference, see figure 2.1. A systematic investigation on these various conditions, in this way, forms the core of the long term research programme. Within this systematic investigation the main objectives are to solve practical problems on water quantity and/or quality and to provide data based on which optimum water management strategies can be developed. Additional objectives are the development of mathematical models and the development of techniques for research and interpretation.

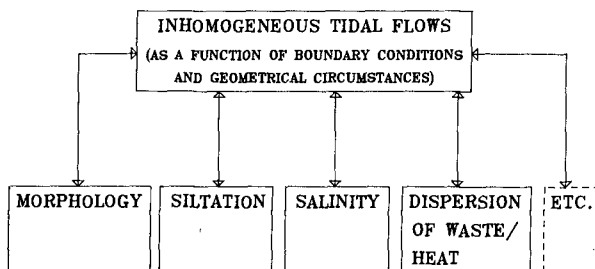

Fig.2.1 PHYSICAL RELATIONS

The systematic investigation on various hydraulic and geometrical circumstances includes seven groups of similar subjects. The groups are a result of an analysis of the physics of nature and of the water quantity and -quality problems. The question has been to estimate the ranges of the hydraulic and geometrical conditions, regarding the present situation of the estuary system and the possible changes due to nature or due to man-made measures. The resulting groups are:

- boundary conditions (tides, including meteorological effects on mean sea levels, and riverdischarges)
- closing or opening harbours or branches
- withdrawals and changing the discharges between riverbranches
- deepening or raising bottom levels of branches
- resistance and mixing of branches
- dispersion of heat and waste, and
- small scale measures like groynes, bars (to be removed), bottomgroynes (to be build), cut-off bends, etc.

For these groups the relevant parameters have to be investigated in a systematic way for a wide, but realistic, range including the direct practical problems. Because of the necessity of an unambiguous comparison of research results the total programme is carried out under standardized boundary conditions. Depending on the accents to be laid, different combinations of boundary conditions, resulting from the first group, can be used (neap tide/spring tide time series, change of the mean sea level due to meteorological effects and the discharge of the fresh water river inflows).

In the research programme, as described above, emphasis is laid on (the changes in) the inhomogeneous tidal flows as a common basis for analyses and interpretations. This "integrated approach philosophy" is employed also with respect to the research tools. For each specific problem an adequate set of research tools is used; the hydraulic scale model of the Rhine-Meuse estuary, various mathematical models, measurements in nature and, for general support, fundamental studies. The set-up serves two objects: the solving of the water quantity and water quality problems and the development of mathematical models, gradually making the hydraulic scale model redundant.

With respect to the solving of the practical problems, up to now the hydraulic model is the core of the programme. Field data, and mathematical models are mainly used as a guide for the measurements in the hydraulic model, by providing in a systematic way tendencies and (rough) indications. Subsequently a restricted selection of tests in the hydraulic model gives the detailed information with the required accuracies for the practical use. For example: changes in salinity distributions near intake points have to be obtained with an inaccuracy in the order of 100 mg Cl/1. On the other hand the hydraulic model provides input for mathematical models. For example detailed measurements of the inhomogeneous tidal flows serve as input for calculations on siltation or water quality processes, see figure 2.2.

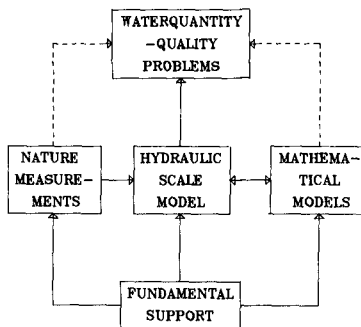

Fig. 2.2 OPERATIONAL USE RESEARCH TOOLS

With respect to the development of mathematical models one has to distinguish several phases. The actual development takes place in the fundamental framework, including estimation of numerical scheme, treatment of boundaries, research on and the description of turbulent

processes on momentum and mass etc. The hydraulic scale model is used to verify the models under systematically varied circumstances with respect to geometry and boundary conditions.

Finally a relatively restricted verification (or validation) on field data proceeds the operational use of the mathematical models. This set-up implies an interactive development process between the various research tools, see figure 2.3.

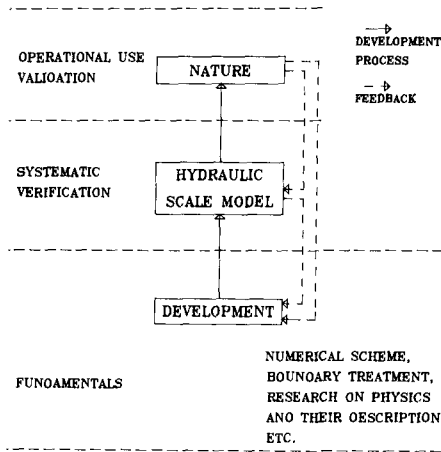

Fig. 2.3 DEVELOPMENT MATHEMATICAL MODELS

### 3. FACILITIES

In this chapter, a brief description will be given of the facilities "field measurements", hydraulic scale model, mathematical models and fundamental support.

#### 3.1- Field measurements

The measurements can be divided into two types: continuous measurements of waterlevels and salinities and "special purpose" measurements. The former includes estimation on fixed locations all over the estuary system of some 40 waterlevels and of some 10 salinities. The measurements are mainly meant for long term system control.

The latter may include calibration measurements with, in addition to the permanent measurements, extensive measurements with boats of flows and salinity distributions (Van der Heijden, Kuijper, de Jong, Roelfzema, 1984), verification measurements and measurements on specific locations and on phenomena such as exchange processes between harbour and river, dispersion processes, streampattern on junctions, etc.

All the field measurements are performed by the Ministry of Public Works.

### 3.2- Hydraulic scale model

The hydraulic scale model of the Rhine-Meuse estuary, simulating tidal flows and salinities, is operational since summer 1982, see figure 3.1. The model covers the area of figure 1.2 and is the rebuilt and extended version of the earlier Rotterdam Waterweg hydraulic model (Van Rees, Van der Kuur, Stroband; 1972), (Breusers, Van Os; 1980). Its scale factors are therefore the same: 1 : 64 for the vertical and 1 : 640 for the horizontal scale. The model has been calibrated and verified with extensive field data showing a good simulation of the dominant physical processes, viz, tidal flows, changes of the mean sea level due to meteorological effects, river discharges, vertical gravitational circulations and vertical turbulent diffusion (Van der Heijden, Kuijper, de Jong, Roelfzema, 1984). The area where salinity intrusion occurs has been modelled, in plan view, similar to nature. The sea area and the

Fig. 3.1 HYDRAULIC SCALE MODEL

upstream parts of the model are mainly meant to provide the correct boundary conditions. Measurements include waterlevels, velocities, discharges and temperatures and conductivities which are combined to densities. The discharges are measured on 14 locations near the junctions of branches in the network by means of acoustic instruments. Using the doppler-principle and by integrating the signals over their cross-sections, these instruments present continuously cross-sectional discharges. For the measurements of conductivities, besides of the conventional "one-point" probes, the Delft Hydraulics Laboratory developed bar-type conductivity probes. Every bar includes conductivity probes, which makes it possible to present the conductivities in 12 positions in the vertical. In the model more than 20 of these conductivity bars are operated. Combined with temperatures, these bars allow continuous measurements of the vertical salinity distribution under tidal time series.

### 3.3- Mathematical models

It is the intention to replace the hydraulic model by a set of mathematical models as soon as possible. The main reasons for this are the relatively high cost of exploitation of the hydraulic model and the necessity to have facilities to study, beside the water motion and salt distribution, the transport of sediment (especially mudtransport), the transport of cooling water and the waterquality. The set of mathematical models will be a system consisting of a base model that simulates the water motion and salt distribution and several transport models coupled to the base model for the computation of sediment transport, cooling water transport or water quality.

#### - Choice of the base model

For the selection of the most adequate model with predictive properties for the Rhine-Meuse estuary it is necessary to have insight into the physical mechanisms that are dominating in the problems under study. Important for the choice is the geometry of the area and the stratification of the estuary. In this respect the Rhine-Meuse estuary can be divided into 4 areas:

- the homogeneous network of tidal rivers which are relatively narrow (width/depth ratio  $B/H < 100$ ). Generally a one dimensional (1D) basemodel is sufficient in this area
- the wide homogeneous southern part of the estuary. A twodimensional depth averaged (2Dh) model gives generally sufficient information
- the inhomogeneous, narrow ( $B/H < 100$ ) tidal area Rotterdamse Waterweg, New- and Old Meuse in which a stratified salinity distribution is present (see figure 3.2) while gravitational circulation and exchange phenomena are important. So the phenomena in the vertical plane through the axes of the river are important and at least a twodimensionally laterally averaged (2Dv) branched model is necessary.

#### STRATIFICATION RWW + N.MAAS

Fig. 3.2

- the stratified, wide sea-area at the mouth of the Rhine-Meuse estuary. Beside the two horizontal dimensions along the coast a stratified situation is often present because of river discharge from the estuary and so the vertical dimension is important too: a 3D model will be needed.

For the choice of the base model other important factors are the availability (now and in the future) and the cost of development and operational use. A 1D model for the whole estuary, called ZWENDL, is available, which has been calibrated for the water motion. A 2Dv model for the salt intrusion part of the estuary, called DISTRO, has been build, which was developed from a tidal flume version [Perrels and Karelse, 1981], see figure 3.3

COMPARISON OF MEASURED AND COMPUTED INFLUENCE OF THE HARBOUR ON THE LONGITUDINAL DENSITY DISTRIBUTION AT L.W.S. AND AT H.W.S.

Fig. 3.3 2-Dv MODEL

These considerations have resulted in the choice for a base model consisting of a combination of a 3D, a 2Dv (DISTRO) and a 1D (ZWENDL) model which are coupled with each other, see figure 3.4. A two-layer model will serve as an alternative for the 2Dv model and as a special purpose model for the simulation of silt transport processes in the inhomogeneous part of the estuary.

With respect to the modelling of sediment transport, cooling water transport and water quality for each area the type of modelling still has to be chosen (the choice is limited by the choice of the base model).

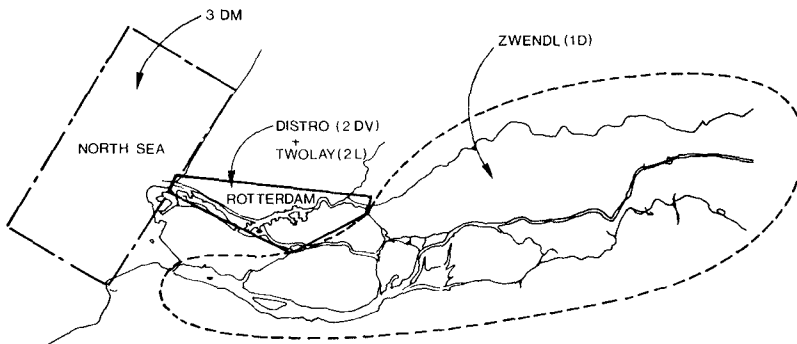

Fig. 3.4 BASE MODEL

The coupling of these models to the base model will present numerical problems. At this moment the 2Dh (preceeding the 3D development)/1D coupling is under research. Another important problem using 3 types of models and comparing computational results with each other and with measured results from prototype or hydraulic model is to get a unification of

- . geometry schematization
- . initial- and boundary conditions
- . in- and output and the databases
- . presentation of results
- . way of calibration and interpretation

Activities on these aspects are carried out.

As mentioned before the 1D model ZWENDL is an operational model with respect to the water motion for the whole Rhine-Meuse estuary.

#### Description ZWENDL

The one-dimensional model "ZWENDL" covers the tidal part of the rivers. The sea boundary is situated near Hook of Holland. Longitudinal dispersion is modelled as a gradient type transport. At first a "Thatcher Harleman"-like approach was followed for the dispersion coefficient and the sea boundary conditions for salt.

The results of the calibration and verification of ZWENDL with this formulation for the tidal motion and salinity distribution in the Rhine-Meuse estuary were unsatisfactory. So the study is going continued to obtain best formulation for the dispersion relation as function of location, time and circumstances and the best formulation of the sea boundary for salt as function of time and conditions.

LD models for sediment transport and waterquality in estuaries are available, they have to be coupled to ZWENDL.

#### Description "DISTRO"

The two-dimensional vertical model DISTRO covers the salt influenced part of the rivers (see fig. 3.4).

The vertical diffusion is modelled with a mixing length approach. The reduction of vertical diffusion due to density differences is modelled as a first approach with damping functions to represent the effect of stratification. A  $K-\epsilon$  modelling is in study. The horizontal dispersion is modelled as a gradient type transport. The sea boundary condition is similar with the one-dimensional (Thatcher-Harleman-like) approach but now for each layer in the vertical [Perrels, Karelse, 1981].

Besides DISTRO a 2 Dv cooling watermodel and water quantity model is available and a silt transport model will be developed in the near future.

The development of a 3D model for the sea part of the estuary is still in a begin stage of development

### 3.4- Fundamental support

A basic part of the set of research facilities is formed by the fundamental support. Also in commission of the Dutch Ministry of Public Works the Delft Hydraulics Laboratory carries out a long term research programme on inhomogeneous flows and silt transport processes. The programme includes research on turbulent mixing in stratified flows and on the transport mechanisms of silt and silt layers under inhomogeneous circumstances. Based on these studies, theoretical as well as experimental, also the mathematical models for the Rhine-Meuse estuary are developed and improved. For this fundamental research, the Delft Hydraulics Laboratory will again have the possession of a tidal silt/salinity flume (of 130 m length), to replace the flume that was destroyed by a fire in 1979.

## 4. RESULTS/DISCUSSION

In the research programme, systematic studies have been carried out on the effect of boundary conditions (tides, including wind effects and river discharges) and on the effect of changes in the tidal area (building or closing harbours). Tests, carried out under cyclic and under time series conditions of several weeks show the importance of the interaction of harbours with the tidal boundary conditions. Wind effects generating elevations of the mean sea level introduce complex effects on the salinities, see figures 4.1 up to 4.2). The mixing influence of harbours on the salinity distribution appeared to be significant. Closing all the harbours, implying decreased tidal filling- and emptying

Fig. 4.1 VERTICAL TIDES AT TWO LOCATIONS, WITH- AND WITHOUT ELEVATION OF MEAN SEALEVEL

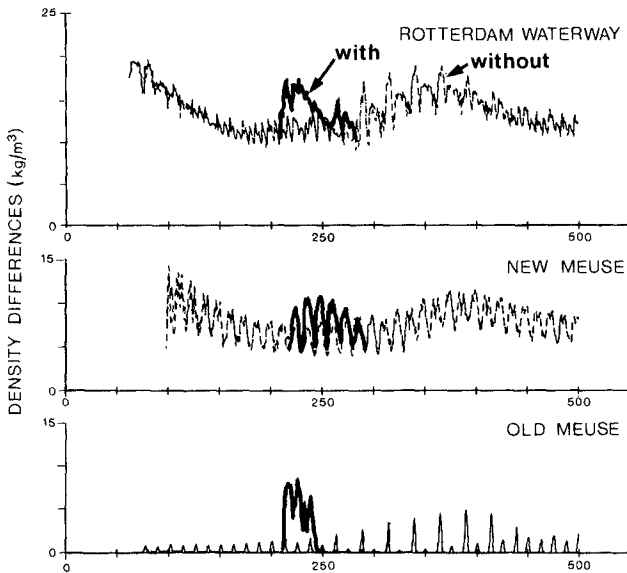

Fig. 4.2 TIME SERIES SALINITIES

volumes results in a smaller salinity intrusion on the one hand. On the other hand closing the harbours results in smaller tidal amplitudes causing less vertical mixing and therefore resulting in a larger salinity intrusion. For the Rhine-Meuse estuary, closing all the harbours results in an increase of vertical stratification and thereby an increase of salinity intrusion, figure 4.3). The same tendencies result from closing single harbours on the Nieuwe Maas, (see also: Abraham, De Jong, Van Kruiningen, 1984).

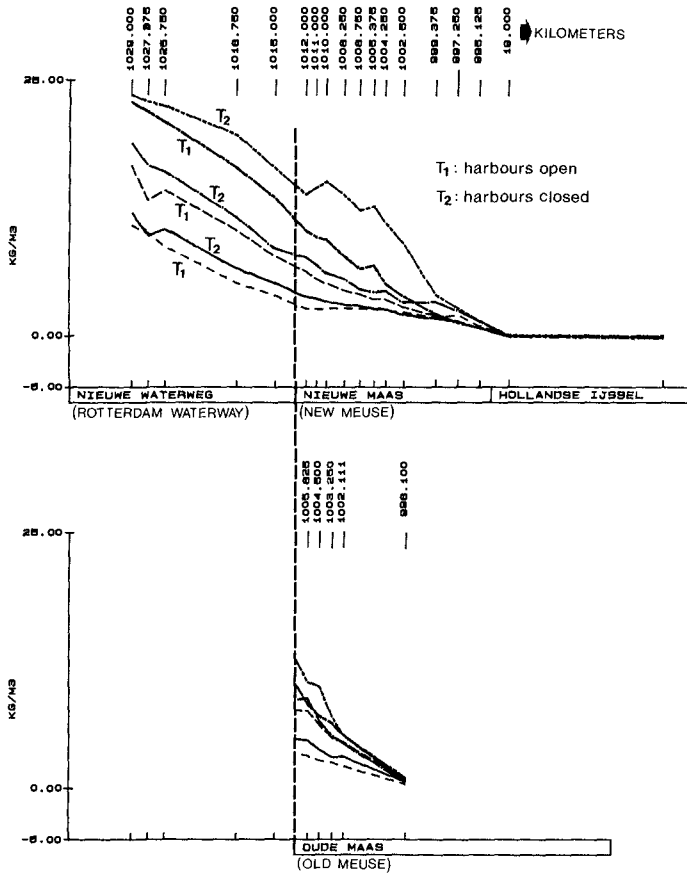

Fig. 4.3 ISOHALINES AT HWS

These experiences are relevant for the mathematical modelling, especially with respect to the length of the time series to be simulated and the density of data to be acquired. On the short run the experiences are used for the improvement of the inhomogeneous 1-D dispersion description and for the further verification of the 2-Dv model. Tests in the hydraulic scale model provide velocity- and salinity distributions on the base of which, in an inverse way, one-dimensional dispersion coefficients are estimated. Analyses of these coefficients may lead to an improved dispersion formulation.

A first test of the 2-Dv model with damping functions to represent the effect of stratification, resulted in a systematic difference between the model and nature; the model generates too much mixing. Besides of the implementation of the more sophisticated  $K-\epsilon$  modelling, the schematization has to be refined resulting in the lay-out of fig. 4.4. Subsequently a systematic research on the sensitivity for numerical, geometrical and hydraulic parameters has to be carried out (gridsize, boundaries, harbours, junctions, roughness, longitudinal viscosity and dispersion and stratification).

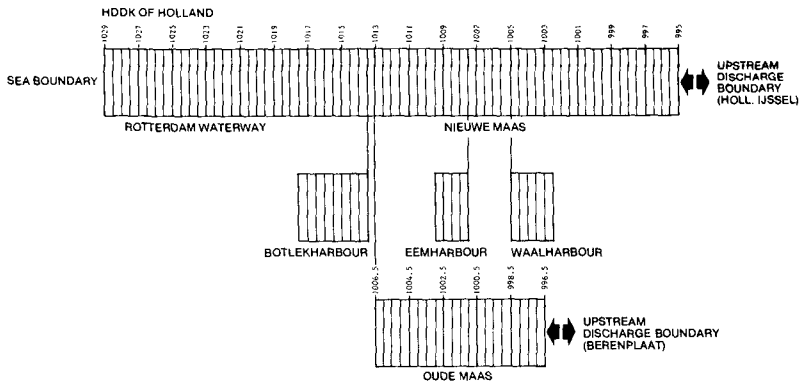

Fig. 4.4 SCHEMATIZATION OF SALT INTRUSION PART OF RHINE MEUSE ESTUARY  
IN DISTRO MODELLING  $\Delta X = 500$  m

In this integrated approach as described above, the results of the research programme provide information for the practical management of the estuary system. For example on the effect on the inhomogeneous tidal flows due to the eventual closing of smaller Rotterdam harbours, or on the impact of exchange phenomena between harbours and rivers on local siltation processes.

## CHAPTER TWO HUNDRED ONE

### SEDIMENTATION PATTERNS IN A TIDAL INLET SYSTEM MORICHES INLET, NEW YORK

Michael J. Vogel and Timothy W. Kana  
RPI Coastal Science and Engineering, Inc.  
Columbia, South Carolina

#### ABSTRACT

A detailed study of the historical development of Moriches Inlet, Long Island (New York), was completed to determine the morphodynamic interaction of tidally influenced processes and the effects of man-made alterations on the inlet channel and affiliated flood and ebb-tidal deltas. The south shore of Long Island in the vicinity of Moriches Inlet is a microtidal, wave-dominated (mixed-energy) environment. Characteristic of this setting, the inlet bisects a low-lying barrier island backed by an open bay and has a prominent flood-tidal delta.

In this study, bathymetric charts of the inlet, bay, and barrier nearshore zones were contoured for analysis. Using a polar planimeter, the areas between isobaths from mean high water to the bottom surface were measured. This information was used to determine the volumetric distribution of sediment and water in the system. In addition, harmonic analysis was applied on digitized bay-tide records to ascertain the relationships of the semidiurnal overtide constituents. From the results, mean rise/fall duration differences, related to the conservation of mass, were calculated.

The results of the quantitative spatial analysis indicate that Moriches Inlet was flood-dominant from breach in 1931 until closure in 1951. After reopening in 1953, the inlet became ebb-dominant as a result of inlet stabilization and extensive dredge-and-spoil operations in the inlet and bay. Good correlations exist between net sedimentation in the inlet with (1) bay-surface area change, (2) water storage capabilities of the flood-tidal delta, and (3) the cross-sectional area of the inlet. The relationship among these variables suggests that there is a system-wide response to the change in the hydrodynamics caused by man-made alterations, resulting in ebb dominance.

#### INTRODUCTION

Research in coastal processes and geomorphology has recognized the relationship between the scope and distribution of morphologic features and the hydrodynamic regime of the environment. The interaction of the morphology with tidal and wave energy, or the morphodynamics of a system, involves continual change toward an equilibrium condition. Through detailed examination of an environment, process/

response models have been developed to help understand this interaction.

This study focuses on the morphodynamics controlling the tidally influenced sedimentation patterns in a tidal inlet/bay system at Moriches Inlet, Long Island (New York). Through modifications of the inlet and bay configurations, the hydrodynamic adjustment resulted in a reversal in tidal dominance. In order to quantify this reversal and to identify the controlling factors of tidal dominance in the system, an historical analysis of the evolution of the inlet and associated depositional bodies was completed. Detailed bathymetric charts of the entire inlet system that document the morphological changes, supplemented with bay-tidal records, comprise the data base for this study.

### INLET DYNAMICS

The dynamics of flow in an inlet/bay system can be described by two governing principles: (1) the equation of motion (or conservation of momentum) and (2) the continuity equation (or conservation of mass). Assuming that the velocity in the inlet is constant (i.e., local acceleration is neglected) and that the tidal wave is much longer than the inlet length, the one-dimensional equation of motion can be integrated to yield:

$$g(h_o - h_b) = L \frac{du}{dt} + \frac{1}{2}(1 + \frac{2r}{h})ul \quad (1)$$

where  $g$  is the acceleration of gravity,  $h_o$  is the ocean water-surface elevation,  $h_b$  is the bay water-surface elevation,  $L$  is the entrance length,  $u$  is the average inlet velocity,  $h$  is the water depth in the inlet, and  $r$  is the square law friction coefficient defined as:

$$r = \sigma/\gamma u^2$$

where  $\sigma$  is the bottom shear stress and  $\gamma$  is the density of water. This equation represents the difference in bay and ocean water levels as proportional to the flow velocity squared, through a channel of a given geometry based on its length, depth, and the effects of inertia.

The equation of continuity can be stated as:

$$UA_c + Q = A_b [dh_b/dt] \quad (2)$$

where  $A$  is the cross-sectional area of the inlet,  $A_b$  is the bay surface area, and  $Q$  is discharge from river flow or sources other than the inlet. This equation relates the velocity to (1) the rate of change of the bay water level and (2) the ratio of the bay surface area over the inlet cross-sectional area. As  $A_c$  and  $A_b$  vary over a tidal cycle, the peak ebb and flood velocities, as well as their duration will differ.

### STUDY AREA

Moriches Inlet is located on Fire Island, off the south shore of Long Island, New York (Fig. 1). One of five inlets on the south shore, Moriches Inlet connects Moriches Bay and the Atlantic Ocean. The inlet is 80 miles (mi), by water, east of The Battery (New York

FIGURE 1. Location map of Long Island, New York, and Moriches Inlet on the south shore.

City) and is 52 mi west of Montauk Point. The inlet separates Great South Beach (Fire Island) on the west and Cupsogue Spit, or Pike's Beach (eastern end of Westhampton Beach), on the east.

Moriches Bay is 12.8 mi long, including the adjacent Narrow Bay. The width of the bay varies from 0.75 mi to 2.5 mi, whereas Narrow Bay, which connects Moriches Bay to Great South Bay to the west, has widths of 1,000 to 4,000 feet (ft). The total water surface area of the combined bay is approximately 20 square miles (mi<sup>2</sup>). Moriches Bay also connects with Shinnecock Bay to the east through Quantuck and Quogue Canals. The largest streams which drain into Moriches Bay are the Forge River and Seatuck Creek; a total of 60 mi<sup>2</sup> of land area drain into the bay.

The astronomic tides at Moriches Inlet are semidiurnal with a mean range of 2.9 ft. The mean spring and neap tidal ranges are 3.5 ft and 2.1 ft, respectively. Visual observations of the nearshore wave climate were compiled by the Coastal Engineering Research Center from June 1970 to May 1973. The average breaker height, based on these observations, was 2.25 ft, and the average breaker period was 7.9 seconds.

#### GEOMORPHIC/HYDRAULIC HISTORY

The geomorphic and hydraulic history of Moriches Inlet and Bay from 1931 to 1967 can be described by two phases: (1) an initial post-breach period during which the inlet system was relatively natural and eventually shoaled closed, and (2) a period beginning after the inlet was stabilized and artificially reopened--characterized by human manipulation of the inlet and bay. The apparent contrast in sedimentation patterns between these two periods provided the basis for this study on tidal inlet dominance.

##### 1931-1951

The modern Moriches Inlet was breached on 4 March 1931 by a severe extratropical storm. A July 1931 survey shows an initial configuration of the inlet 800 ft wide and 1,500 ft long with channel depths up to 18 ft. A prominent flood-tidal delta with an intertidal perimeter existed landward of the inlet. A line of breakers indicated on the sheet suggest that an ebb-tidal delta had formed also. The bay tidal range was measured at 0.4 ft.

From the breach in 1931 to 1940, the inlet migrated westward a distance of 3,500 ft from its original breach position. During this time, the inlet/bay system was a sediment trap, as net sedimentation continued on both the ebb- and flood-tidal deltas. The morphology and the hydraulics of the inlet adjusted to the tidal flow demonstrated by a small increase in the bay tidal range as well as an increase in the inlet length and width. These processes were probably enhanced by the impact of storms in 1934, 1938, and 1940.

In 1947, a jetty was constructed on the west side of the inlet in an attempt to stop its westward migration. The construction was

performed in conjunction with channel dredging to the west of the inlet. The combined effects of this artificial manipulation of the inlet caused increased shoaling. The updrift barrier, Cupsogue Spit, laterally accreted westward and narrowed the inlet throat and length. A highly detailed survey taken in 1949 reveals a developed ebb-tidal delta and a large flood-tidal delta, mostly supratidal. By July 1951, the inlet closed naturally.

Hydrographic measurements taken by current-float observations during the 1949 survey show that peak ebb and flood velocities were nearly equal at 5.2 and 5.3 ft/sec, respectively. The bay high tide followed peak flood flow by 24 minutes, while peak ebb flow trailed low water by 1.5 minutes. The close phase relationship of the vertical tidal curve and current velocities denotes a progressive tidal wave condition at the inlet.

#### 1952-1967

In 1952, jetty construction was initiated to reopen and stabilize Moriches Inlet in response to local interests. An eastern jetty was built approximately 800 ft from the western jetty. In 1953, when construction was completed across the barrier island, dredging began to reestablish the inlet. On 6 November 1953, before channel completion, an extratropical storm impacted the area and breached the new opening.

For the remainder of the study period, the geomorphic and hydraulic history of the inlet was dominated by dredge/spoil operations (Table 1). During this time, 2 million yd<sup>3</sup> of sediment were dredged from the inlet and bay, with much of the spoils placed on the flood-tidal delta. As a result of the excavation projects and natural scouring, the hydraulic radius of the inlet increased, accompanied by an increase in the bay tidal range from 0.6 ft in 1955 to 1.5 ft in 1967.

The changes in the inlet delta morphology and tidal current regime indicate that the sedimentation patterns changed. A marked decrease in size of the flood-tidal delta simultaneous with an increase in size of the ebb-tidal delta suggest bay flushing had begun. Current velocity measurements taken in 1955-56 and in 1967 confirm that the inlet was hydraulically ebb-dominant. In November 1955 through May 1956, inlet velocities were measured at 5.2 ft/sec during flood and 6.5 ft/sec during ebb. In 1967, current velocity measurements taken mid-channel at an intermediate depth gave peak flood velocities at 2.4 ft/sec while peak ebb velocities were recorded at 4.3 ft/sec.

#### METHODOLOGY

The primary data base for analysis is a time-series of bathymetric surveys of Moriches Inlet and Bay, including coverage of the inlet, adjacent barrier islands, ebb-tidal delta, flood-tidal delta, and the surrounding bay. A spatial analysis was undertaken on each chart in an attempt to distinguish the morphological components of the system and their changes through time. The objective is that this type of

analysis should yield time-averaged results of net sediment transport within the surveyed areas.

TABLE 1. Moriches Inlet improvement projects based on published and unpublished records of the New York District (U.S. Army Corps of Engineers) and Suffolk County Department of Public Works.

Date	Project	Agency
1933	Dredge: 600 ft x 35 ft x 6 ft channel = 4,600 yd <sup>3</sup>	Local Interests
1935	Dredge: 3,360 yd <sup>3</sup>	Suffolk County
1947	Construction: West jetty	Suffolk County
	Dredge: Northwest Channel	
1952	Construction: Jetties spaced 800 ft	New York State
	East jetty (846 ft long)	
	West jetty (1,461 ft long)	
1953	Dredge: 747,310 inlet cut	Suffolk County
1954	Construction: Jetties extended	Suffolk County
	Spoil: Close Northwest Channel	New York State
1958	Dredge: 365,715 yd <sup>3</sup> - Northwest Channel (200 ft x 10 ft channel)	Suffolk County
1962	Dredge: 1,014,834 yd <sup>3</sup> - dredge inlet	Suffolk County
	Spoil: Close Northwest Channel	
1966	Dredge: 677,850 yd <sup>3</sup> - Northwest Channel (1,300 ft wide x 12 ft deep)	Suffolk County

In addition to documenting the changes of the inlet/bay system, critical parameters were examined in order to develop a process/response relationship for ebb-tidal dominance. One of the more significant factors influencing tidal dominance is the change in bay surface area over a tidal period (Oliviera, 1970; King, 1974; Seelig and Sorensen, 1978; FitzGerald and Nummedal, 1983). None of the surveys available to this study, however, covered the entire bay. As a result, the soundings were confined to the flood-tidal delta in the immediate inlet vicinity.

The selection of surveys with adequate coverage of the features aforementioned produced five working maps—a composite of 1932 and 1933 surveys, 1940, 1949, 1955, and 1967. A control grid of the study area was also constructed. The size of the grid was dictated by the survey of minimum areal coverage (Fig. 2). The establishment and utilization of this grid allow quantitative comparisons of the inlet/bay system to be made.

A survey of Moriches Bay and Fire Island from 1891, when no inlet existed, provided a baseline for comparison of the development of the flood-tidal delta. At that time, maximum depths in the bay were 8 ft. However, no available bathymetry of the nearshore zone exists which could serve as a baseline for ebb-delta growth. Soundings were

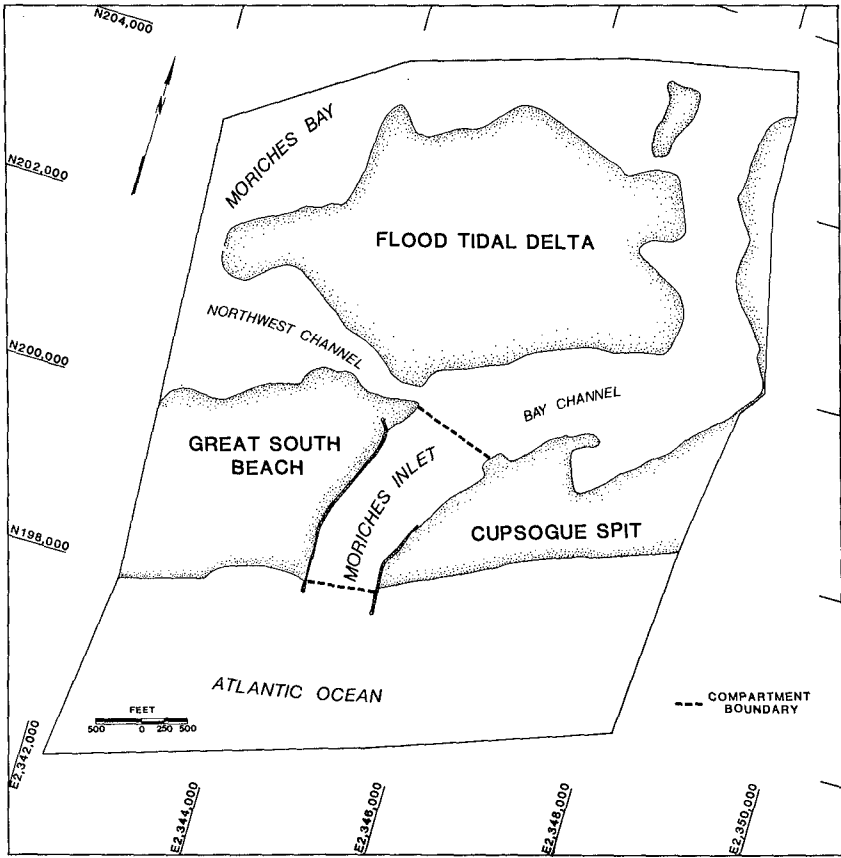

FIGURE 2. Control grid dimensions and compartment locations. MSL shoreline shown based on USACE 1955 survey.

taken, though, in 1951 when the inlet had naturally closed. Using the technique developed by Dean and Walton (1975), a hypothetical shoreline was created based on these soundings in which contour lines parallel the coast. The idealized bathymetry was then used in conjunction with the 1891 bay for analysis. For reference, the control grid was superimposed on the site of the stabilized inlet.

For the purposes of this study, the Moriches Inlet and Bay system was divided into three compartments within the control grid:

- 1) The bay, which represents the area landward of the bay shoreline.
- 2) The inlet proper.
- 3) The ocean or nearshore zone—that area oceanward of the inlet including subtidal segments of the barrier islands.

These subdivisions allow independent analysis of the inlet and the ebb- and flood-tidal deltas (Fig. 2).

The areal distribution of the geomorphic features on the individual charts was measured using a digital compensating polar planimeter. Areas enclosed between isobaths within the control grid were obtained to the nearest 1,000 ft<sup>2</sup>. The area measured for each interval supplied the data for volumetric analysis.

The areas measured at each isobath by planimetry were multiplied by the contour interval to produce a volumetric "slice" of water. The sum of all slices is a close measure of the total amount of water in that compartment. In this way, the amount of sediment deposited in the ebb and flood deltas of each survey can be directly compared.

## HARMONIC ANALYSIS

In the absence of complete velocity measurements, vertical tide records taken at the U.S. Coast Guard Station in Moriches Bay were obtained. Four 29-day continuous records were selected which roughly corresponded with the bathymetric surveys or significant events from 1944, 1955, 1966, and 1967. Based on the equation of continuity (2) and following the work of Boon and Byrne (1981), the tidal signatures of the bay can be related to the dynamics of the tidal flow through the system.

Harmonic analysis used on filtered, digitized bay-tidal curves supplied the amplitude and phase relationships of the principal tidal constituents. In a semidiurnal system, the constituents which can sufficiently represent the bay tidal curves are the  $M_2$  [the principal lunar semidiurnal constituent with a period of 12.42 hours (hr)],  $M_4$  (6.21-hr period), and  $M_6$  (4.14-hr period) harmonics (Shureman, 1958). These overtides have speeds (frequencies) which are exact multiples of the elementary constituent. Therefore, the combination of the overtides can represent the distortion of the mean bay tidal curve, and rise/fall durations can be observed.

## RESULTS

## VOLUMETRIC RESULTS

The results of the volume calculations are presented in Table 2. These are calculations of the water volume for each compartment referenced to MSL. This datum plane is considered constant through the study period.

TABLE 2. Compartment and total water volumes. Reference datum is mean sea level. Unit of measure is  $\times 10^3$  ft<sup>3</sup>.

Survey Date	Inlet Compartment Volume	Bay Compartment Volume	Ocean Compartment Volume	Total Volume
Hypothetical	0	146,168	198,106	344,274
1932-1933	4,782	127,900	186,334	319,016
1940	22,784	27,546	131,116	181,446
1949	1,710	56,136	202,462	260,308
1955	14,590	61,964	195,466	272,020
1967	17,134	128,568	124,640	270,342

The raw volumes are not adjusted for any dredge and spoil quantities listed in Table 1. While these quantities alter the results to some degree, the exact location of the dredging projects and the distribution of spoils are not known. Therefore, it is difficult to calculate the amount of sediment which has truly been removed from the control area.

The water volumes for the bay and ocean compartment both show an increase in sedimentation from the time of the breach until 1949, or approximately the time of the inlet closure. The 1940 survey results show that period as the 'richest' in sediment. From 1955 to 1967 (or extrapolating back to the reopening in 1953), the bay and ocean compartments show a complementary trend. As the bay compartment exported sediment as indicated by the increase in water volume, the sedimentation in the ocean compartment increased. These results are clear evidence that Moriches Inlet became ebb-dominated after reopening.

The totals shown in Table 2 also signify that the inlet system was stable after jetty construction, measured by the total sediment flux. The total water volume varied by only  $10 \times 10^6$  ft<sup>3</sup> from 1949 to 1967. As expected, sediment volume was lowest in the pre-breach and 1932-1933 composites due to the relative immaturity of the inlet/bay system.

## INLET MEASUREMENTS

Inlet dimensions, parameters in the governing equations of the dynamics of tidal flow (Equations 1 and 2), were measured from the base maps. With a known inlet volume previously identified, the mean cross-sectional area can be calculated using the inlet length. Table 3 lists inlet lengths, widths, and cross-sectional areas at MSL.

TABLE 3. Moriches Inlet dimensions.

Date	Inlet Length (ft)	Width (ft)	Mean Cross-sectional Area (ft <sup>2</sup> ) (MSL datum)
1932-1933	520	1,420	9,196
1940	3,108	2,442	7,331
1949	652	337	2,623
1955	2,100	800	6,948
1967	1,384	800	12,380

Moriches Inlet reached its greatest cross-sectional area of 12,380 ft<sup>2</sup> in 1967 from scouring and dredging. In the 1932-1933 composite, the inlet had a large hydraulic radius, producing a relatively high mean cross-sectional area of 9,196 ft<sup>2</sup>. The inlet was most constricted in 1949 with a mean area of 2,623 ft<sup>2</sup>. After construction of the jet-ties (1952), inlet size increased again to 6,948 ft<sup>2</sup> by 1955.

## INTERTIDAL AREA

The change in bay area over a tidal cycle is an important quantity affecting net sediment transport (Equation 2). According to King (1974), a large area change produces net offshore transport. In Moriches Inlet, the amount of intertidal area change within the control grid is a function of a combination of factors. These factors include the size of the flood-tidal delta, the slopes of the flood-tidal delta margins, and perhaps most significant, the varying tidal range in the bay.

Table 4 lists the intertidal area changes in both the bay and inlet compartments as determined by measurement and hypsometric analysis. The inlet compartment, which was included to account for the water storage of the 1940 survey, had a significant amount of intertidal area within the long waterway. The tabulated totals for each survey show a correlation with the magnitude of the tide range at that time. In 1967, when the bay tidal range was 1.5 ft, the corresponding intertidal area was  $9,638 \times 10^3$  ft<sup>2</sup>, while in 1932-1933 when the tidal range was only 0.4 ft, the intertidal area was also the lowest at  $1,132 \times 10^3$  ft<sup>2</sup>. The data from 1940, 1949, and 1955 (when the tidal range was

nearly constant) show that the smaller-scale variations in intertidal area were the result of the flood-tidal delta morphology.

TABLE 4. Intertidal areas of the bay and inlet compartments. Unit of measure =  $\times 10^3$  ft<sup>2</sup>. (1) MHW to MSL area from measured results. (2) MSL to MLW area from hypsometric function.

Date	Inlet <sup>1</sup>	Inlet <sup>2</sup>	Bay <sup>1</sup>	Bay <sup>2</sup>	Total
1932-1933	34	46	648	404	1,132
1940	440	701	2,055	1,347	4,543
1949	12	14	2,865	1,992	4,883
1955	14	16	3,812	1,986	5,828
1967	0	4	6,260	3,374	9,638

#### HARMONIC ANALYSIS

In contrast to the work of Boon and Byrne (1981), the results from the harmonic analysis of the bay tidal records show no mean rise/fall duration differences. Mean sinusoidal curves produced from the amplitudes and phase angles of the  $M_2$ ,  $M_4$ , and  $M_6$  constituents for each digitized record were constructed. In the resultant curve of each tide record, the rise duration equals the fall duration within the resolution of the five-minute increment used in calculation.

The type and degree of distortion in the combined tidal signature are primarily a function of the phase angle relationship among the overtides. The distortion, however, only appears significant when the ratio of the  $M_4$  and  $M_2$  amplitudes are greater than 0.1. Table 5 illustrates that while the phase angles of the overtides do change, the  $M_4/M_2$  amplitude ratios never exceed 0.04. The effect, then, of the  $M_4$  and  $M_6$  overtides on the principal semidiurnal component are so small that any distortion created is minimal.

The hydrographic data from Moriches Inlet show a small phase lag between bay tidal elevations and channel velocities, indicating a progressive tidal wave condition in the inlet/bay system. Under these circumstances, it appears that, without distortion of the bay tidal elevations, there are still ebb- and flood-velocity differences evidenced by the hydrographic measurements as well as changes in the sizes of the ebb- and flood-tidal deltas. Therefore, other morphodynamic factors such as the frictional effects of a change in bay surface area or channel dimensions must be influencing the direction of net sediment transport.

TABLE 5. Moriches Bay overtide constituents phase angle (degrees) and amplitude (ft).

	$M_2$	$M_4$	$M_6$	$M_4/M_2$ Ratio
1944				0.03786
Amplitude	0.1215	0.0046	0.0040

Phase	61.66	12.39	254.71	

## DISCUSSION

The morphodynamics of an estuarine environment are fundamentally dependent upon wave and tidal energy, and sediment input. In Moriches Inlet and Bay, modulations in tidal range and available sediment appear to be closely related to the variation in morphology and tidal dominance. These changes are primarily the result of man-made modifications through stabilization and dredging of the inlet/bay system.

Relating these factors to the study, it has been demonstrated that the tidal energy in Moriches Inlet has changed over the course of this study. No available data covering the entire study period exist, but it is assumed that wave energy has been relatively constant. Long-shore transport rates, storm deposition, jetty trapping, and inlet bypassing--all affect the sediment flux to the inlet/bay system which has been further altered by dredge and spoil operations.

To account for changes in sediment input, the measured volumes were normalized by creating percentiles of the sum of total water volume in the control grid and (1) the inlet and bay total and (2) the ocean compartment. In this way, any decrease or increase of sediment that would affect the system as a whole is taken into consideration.

Figure 3 is a graph showing the distribution of water volume in the control grid for each survey. Incorporated in this figure are pertinent dredge volumes which alter the relative percentage. This correction is based on an assumption that dredged sediment within the control grid is removed from the subtidal system. A decrease in the percent of water in a compartment indicates an increase in sedimentation. Comparing the proportions of volume with a semihypothetical pre-inlet condition, the volume of sediment in the bay and inlet compartments increased to 1949. This trend reversed between 1949 and

FIGURE 4. Correlation between percent water volume (indicating net sedimentation) and intertidal area of bay and inlet compartments. Note favorable correlation from 1949 to 1967.

FIGURE 3. Relative percentage of water volume within the control grid. Movement to the left represents flood dominance; movement to the right represents ebb dominance.

1967 when the majority of sedimentation took place in the ocean compartment or ebb-tidal delta. Figure 3 can be interpreted by describing the inlet/bay system as flood-dominant from breach to closure in 1951 and as ebb-dominant from the reopening of the inlet in 1953 to 1967.

The net sedimentation in the bay during flood dominance is due to a combination of factors. Modelers (Oliviera, 1970; King, 1974; Seelig and Sorensen, 1978) have shown that net bayward transport is possible when there is negligible change in the bay-surface area over a tidal period. Flood currents carrying a bedload of sand can lose competence upon entering the static, deeper bay from the confined flow of the inlet, analogous to the formation of a river delta. Other possibilities for bay sedimentation processes include storm and wash-over deposits, or increase in the flood-tidal delta volumes attributable to spoil operations.

In order to determine the extent of tidal influence on net sedimentation patterns, the principal factors relating to tidal dominance were examined in relation to the volumetric distributions of Figure 3. As mentioned, the variation in intertidal area is considered a dominant factor for bay flushing. Figure 4 shows the relationship of the change in area between MHW and MLW within the control grid plotted against the volumetric percentage of the ocean compartment.

Of the five survey dates, there is a favorable correlation in 1949, 1955, and 1967. The lack of association between the variables of the earlier surveys is due possibly to (1) the lower precision of the 1940 survey and, therefore, more significant error and (2) a lack of equilibration of the immature system in 1932-1933. However, both these surveys were taken within two years after the impact of major storms on the area. This suggests that the morphology in 1932-1933 and 1940 was shaped more by the occurrence of storms than by tidal flow.

In Figure 5, the intertidal water volumes in the bay and inlet are presented with the same volumetric distributions. The volume of water was obtained by multiplying the intertidal areas by the tidal range. This calculation emphasizes the change in area due to increased tidal range rather than the size and shape of the ebb-tidal delta. The correlation in this graph implies that the water-storage capacity of the flood-tidal delta or the degree of flow through the intertidal areas is also closely related to tidal dominance and not just to the change in area over a tidal period. The greater flow would have higher frictional distortions which indirectly determine the magnitude and direction of tidal dominance.

The tidal range for a given bay-surface area, or more directly the tidal prism, is related to the cross-sectional area of the inlet, according to the work of O'Brien (1931, 1969) and Jarrett (1976). The cross-sectional area and its variation is also an indication of inlet stability (O'Brien and Dean, 1972) and the degree of inlet channelization. Since net transport is sensitive to inlet depth and channel dimensions (King, 1974), the mean cross-sectional areas from Table 3 were plotted against the volumetric distribution as in Figures 4 and 5. From the graph in Figure 6, the cross-sectional area correlated well with the

FIGURE 6. Good correlation between percent water volume and inlet cross-sectional area. The control of channel dimensions reflects ebb dominance.

FIGURE 5. Correlation between water volume and interstitial water volume in the bay and inlet compartments. Note the improved correlation from previous figure, suggesting the importance of the bay-tidal range.

percentage of water volume in the bay and inlet compartments. Both variables decreased to a minimum in 1949 and subsequently increased to 1967.

It is worth noting that the changes in mean cross-sectional area qualitatively correspond with the amount of channelization in the flood-tidal delta, as indicated by the hypsometric analysis and bathymetric charts. One can conclude from Figure 6 that as the degree of flow through the inlet increased with the tidal prism, this flow became more confined by the flood-tidal delta complex. The system response was an increase in effective channelization (i.e., more efficient flow) and ebb-dominant, net-sediment transport.

By examining the process/response relationships of the inlet/bay system, one can construct an interpretational history of the evolution of Moriches Inlet and Bay. The natural setting of Fire Island is a typically long, low-lying, microtidal barrier island backed by a broad open bay. Through the impact of storms, the barrier has been breached frequently, creating temporary inlets with deltas forming from the excess available sediment. With minimum tidal flow and perpetual longshore transport of sediment, Moriches Inlet migrated west-erly with gradual inlet shoaling. As the inlet laterally migrated, it successfully receded from the flood-tidal delta complex, leaving the easternmost portions inactive. With the migration, the inlet faced a portion of the open bay, which enabled further sedimentation through bay trapping.

This natural process was interrupted initially by the construction of the western downdrift jetty. By preventing continued migration, sediment from longshore transport accelerated the rate of shoaling in the inlet throat, resulting finally in inlet closure.

When Moriches Inlet was reopened, the twin jetties were emplaced at an 800-ft spacing, much narrower than any inlet width that had been maintained naturally. The jetties also prevented the inlet from migrating away from the flood-tidal delta in addition to trapping sand from longshore transport. The effect was to initiate scouring through the inlet and contiguous flood-tidal delta. The system responded with an increase in channelized flow, increase in the tidal range, and the initiation of bay flushing and net oceanward sediment transport.

The subsequent dredging and spoil operations in the inlet and bay enhanced this response by increasing the scale of channelized flow through the inlet and bay, the inlet cross-sectional area, the bay-tidal range, and the change in bay surface area. By 1967, Moriches Inlet had become ebb-dominant as a result of these man-made alterations to the system.

## CONCLUSIONS

An historical spatial analysis of the Moriches Inlet and Bay system revealed that:

- 1) Moriches Inlet experienced a reversal in net sedimentation from flood-dominant during 1931-1951 to ebb-dominant during 1953-1967.
- 2) This reversal was initiated by modifications of the system by dredging and inlet stabilization. The modifications enhanced system-wide variations indicated by changes in:
  - a) Intertidal bay surface area.
  - b) Inlet cross-sectional area.
  - c) Tidal range.
  - d) Channelized tidal flow.These factors control the direction and magnitude of tidal dominance.
- 3) Harmonic analysis of Moriches Bay tidal records for 29-day periods in 1944, 1955, 1966, and 1967 indicate that no rise/fall duration differences exist in the mean tidal curve to account for dominant tidal flow.

## CHAPTER TWO HUNDRED TWO

### NUMERICAL MODELING OF SHORELINE EVOLUTION AROUND THE RIVER MOUTH

MING-CHUNG LIN\* and JYH-CHERNG WANG\*\*

#### 1.0 INTRODUCTION

The river sediments transport into coastal water together with wave-induced longshore sediment transport make shoreline evolution much complicated. Fig.1 shows typical feature of shoreline shape around a river mouth. Recently there are some investigators treated this problem (Grijm, 1964, Bakker & Edelman, 1964; Komar, 1973; Tsuchiya & Yasuda, 1978), and had developed some mathematical or numerical models. This paper proposes a numerical model for predicting long-term shoreline evolution around a river mouth by incorporation certain river parameters into the Willis beach evolution model (1978). The proposed model is at first applied to four ideal cases to investigate its general characteristics and adaptability, and reasonable results are found. In our results the accretion on updrift side is faster than downdrift side under the oblique incident wave condition and the width of the river mouth increase steadily. These results are different from other approaches that the shoreline shape is always nearly symmetrical with respect to the centerline of the river mouth. Finally, as an field case application of the model, a numerical simulation of shoreline changes around the Cho-shui River mouth is performed and compared with field data.

#### 2.0 FORMULATION OF THE MODEL

##### 2.1 Assumptions

In order to make the problem tractable, we make some basic assumptions:

- (1) A year is divided into some periods, and in each period the wave characteristics such as height  $H_0$ , period  $T_0$  and length  $L_0$  are const..
- (2) Wave will break at the place where water depth is equal to  $1.25 H_0$ .
- (3) The energy of breaking wave will not exceed five times of offshore wave. The exuding energy, if any, will be distributed to the elements of each side.
- (4) The upper swash limit of waves equal to mean high water level plus one breaking wave height; the critical water depth of sediment movement is twice breaking waves height below the mean low water level.
- (5) The sand transport by wind, tidal current and the artificial effect will leave out of consideration.
- (6) The wave-induced alongshore discharge and the river-induced alongshore discharge can be a linear accumulation.

\*Professor, Dept. of Naval Architecture, National Taiwan University, Taipei, Taiwan, 107, R.O.C.

\*\*Senior Coastal Engineer, China Engineering Consultants, Inc., Taipei, Taiwan, R.O.C.

- (7) A year is divided into some periods, and the discharge, and the sediment concentration of the river in a period are constant.

## 2.2 Shoreline Evolution Equations

In the proposed model we consider two regions. One is coastal region away from river mouth, in which no river discharge and sediment directly flow into the elements. The other is river mouth region.

### (1) Coastal region

As Willis (1978), the sand transport zone is schematized as a triangle prism bounded by the instantaneous mean water level, the flat sloping bed and a depth equal to twice the average breaking wave height (Fig. 2). The alongshore discharge and sediment flow into the element equal to  $Q_x \Delta t$  and  $C_n Q_x \Delta t$  respectively. The amount of flowing out are

$$\left[ Q_x + \frac{\partial Q_x}{\partial x} \Delta x \right] \Delta t + Q_{nw} \Delta t$$

$$\left[ C_n + \frac{\partial C_n}{\partial x} \Delta x \right] \left[ Q_x + \frac{\partial Q_x}{\partial x} \Delta x \right] \Delta t + C_{nw} Q_n \Delta t$$

According to the continuity of discharge we will get

$$Q_{nw} = - \frac{\partial Q_x}{\partial x} \Delta x \quad (1)$$

by applying the continuity to sediment transport within the element, it yields

$$\begin{aligned} & \left[ C_n + \frac{\partial C_n}{\partial x} \Delta x \right] \left[ Q_x + \frac{\partial Q_x}{\partial x} \Delta x \right] \Delta t + C_{nw} Q_{nw} \Delta t \\ & = C_n Q_x \Delta t - (D2-F) \Delta Y \Delta x \end{aligned} \quad (2)$$

here the sediment transport is expressed as the product of flow discharge and sediment concentration.

Substituting Eq.(1) into Eq.(2) then yields

$$(D2-F) \frac{\Delta Y}{\Delta t} + (C_n - C_{nw}) \frac{\partial Q_x}{\partial x} + Q_x \frac{\partial C_n}{\partial x} + \frac{\partial C_n}{\partial x} \frac{\partial Q_x}{\partial x} \Delta x = 0 \quad (3)$$

where

(D2-F) = vertical distance from the upper swash limit of waves to the critical water depth of sediment movement

$Q_x$  = alongshore discharge which is equal to  $Q_L + Q_{W_x}$ ;  $Q_L$

denotes the river-induced alongshore discharge,  $QW_x$   
denotes the wave-induced alongshore discharge.

$Q_n$  = onshore-offshore discharge.

$C_n$  = alongshore sediment concentration.

$C_{n\omega}$  = onshore-offshore sediment concentration

The shoreline change  $\Delta y$  of coastal region can be calculated by Eq. (3). The form of this equation (3) is the same as that of Willis. But we must point out that herein  $Q_x$  is different from that of the Willis equation.

## (2) River mouth region

In this region river discharge  $QR_n$  and river sediment  $C_{nR}$   $QR_n$  are taken into account in the elements. By the continuity equation of discharge we can get

$$Q_{n\omega} = - \frac{\partial Q_x}{\partial x} \Delta x + QR_n \quad (4)$$

By the sediment continuity equation we get

$$Q_x C_n \Delta t + QR_n C_{nR} \Delta t - \left[ Q_x + \frac{\partial Q_x}{\partial x} \Delta x \right] \left[ C_n + \frac{\partial C_n}{\partial x} \Delta x \right] \Delta t - C_{n\omega} Q_{n\omega} \Delta t = (D2-F) \Delta Y \Delta x \quad (5)$$

From Eq.(4) and Eq.(5) it yields readily

$$(D2-F) \frac{\Delta Y}{\Delta x} + (C_n - C_{n\omega}) \frac{\partial Q_x}{\partial x} + Q_x \frac{\partial C_n}{\partial x} + \frac{\partial C_n}{\partial x} \frac{\partial Q_x}{\partial x} \Delta x + (C_{n\omega} - C_{nR}) \frac{QR_n}{\Delta x} = 0 \quad (6)$$

The shoreline change  $\Delta y$  of river mouth region then can be computed by Eq.(7). For solving Eq.(3) and Eq.(6) the evaluations of  $QL_n$ ,  $QW_x$ ,  $C_n$  and  $C_{n\omega}$  are needed in advance.

## 2.3 The River-induced Alongshore Discharge

We here model the flow at river mouth by a turbulent plane jet flow. Fig. 3 shows the elements schemed and the flow distribution. For the center element 1, the river discharge flowing in is  $QR_1$  and the jet discharge flowing out is  $QO_1$ . By applying continuity equation, we get alongshore current discharge induced by river at element 1

$$QL_1 = KR \frac{QR_1 - QO_1}{2} \quad (7)$$

where KR is a modification factor. When performing numerical calculation afterward, we take it to be 1.0. Similarly, the river-induced alongshore current discharge in the element n can be expressed as

$$QL_n = KR (QR_n - QO_n) + QL_{n-1} \tag{8}$$

If  $|x|$  is larger than  $b_0$ , the  $QR_n$  is equal to zero. If the  $|x|$  is larger than the boundary of the jet velocity distribution, we assume the alongshore discharge will be decreased in the manner of the form:

$$QL_{n+m} = QL_n / (1+m)^2 \tag{9}$$

Where  $QO_n$  can be obtained by integrating the velocity distribution of a turbulent plane jet flow. In the present study, the velocity distribution in turbulent plane jet interacting with obliquely incident wave developed by Hwang & Chen (1981) is used. Fig. 4 shows the coordinate system they used. Hwang and Chen assumed that the velocity distribution be a Gaussian distribution for a wave period average.

$$\frac{\bar{u}(x,y)}{[\bar{u}(0,y)]_{\max}} = \exp\left(-\frac{x^2}{2C_1 y^2}\right) \tag{10}$$

in which  $C_1$  is a velocity distribution coefficient. By momentum conservation concept, it reads

$$[u(0,y)]_{\max} = \left\{ \frac{2 b_0}{1+0.5\alpha^2(y,\theta)\sqrt{\pi} C_1 y} \right\}^{0.5} u_0 \tag{11}$$

where

$$\alpha(y,\theta) = \frac{\frac{\bar{u}_w^2}{u_0^2} - \sqrt{\pi} C_1 \frac{y}{b_0} \cos^2\theta}{2 - \frac{\bar{u}_w^2}{u_0^2} - \sqrt{\pi} C_1 \frac{y}{b_0} \cos^2\theta} \tag{12}$$

$$\bar{u}_w^2 = \frac{\pi H^2}{2T^2} \coth^2\left(\frac{2\pi h}{L}\right) \tag{13}$$

Where h denotes water depth.

The width of velocity distribution is expressed as

$$\frac{b(y,\theta)}{b_0} = \sqrt{\frac{\pi}{2}} C_1 \frac{y}{b_0} + \frac{\varepsilon(y,\theta)}{b_0 \alpha(y,\theta)} \tag{14}$$

Where

$$\varepsilon(y,\theta) = \frac{\pi H}{L} \coth\left(\frac{2\pi d}{L}\right) \sqrt{\pi} C_1 y \cos^2\theta \tag{15}$$

Here  $H$ ,  $L$ ,  $d$  denote the wave height, wave length, and water depth respectively. From Eq.(11) - Eq.(16)  $\bar{u}(x,y)$  can be calculated and then  $QO_n$  can be obtained.

In the present study, when numerical calculation is performed, wave refraction is calculated by the Brampton model (1977), wave-induced long-shore current and discharge by the Willis (1978a) work and sediment concentration by the Willis (1978b) formula.

### 3.0 NUMERICAL FORMULATION

#### 3.1 Difference Form of Shoreline Evolution Equation

Fig. 5 shows the differential element layout, in which  $y_n$  is the distance from baseline to the middle of the upper swash limit and the critical water depth of sediment movement. We set

$$y_{n-\frac{1}{2}} = \frac{1}{2} (y_{n-1} + y_n) \quad (16)$$

And the angle between shoreline and baseline  $A_S$  at gride  $n$  is

$$A_S(n,t) = \tan^{-1} \left[ \frac{y(n+\frac{1}{2},t) - y(n-\frac{1}{2},t)}{\Delta x} \right] \quad (17)$$

The angle between shoreline and wave crest line  $A_{br}$  then can be got by  $A_S$ . Now let

$$DQ = Q_x(n+1,t) - Q_x(n,t)$$

$$DC = C_n(n+1,t) - C_n(n,t)$$

$$Q_{ave} = \frac{1}{2} [Q_x(n+1,t) + Q_x(n,t)]$$

$$QR_{ave} = \frac{1}{2} [QR(n+1,t) + QR(n,t)]$$

$$DNC = \frac{1}{2} [C_n(n+1,t) + C_n(n,t) - C_{n\omega}(n+1,t) - C_{n\omega}(n,t)]$$

$$DNR = \frac{1}{2} [C_{n\omega}(n+1,t) + C_{n\omega}(n,t) - C_{nr}(n+1,t) - C_{nr}(n,t)]$$

then, from Eq.(3), difference equation for coastal region is

$$DY = \frac{\Delta t}{(D2-F)\Delta x} [DQ \times DNC + Q_{ave} \times DC + DC \times DQ] \quad (18)$$

and the difference form of Eq.(6) in river mouth region is

$$DY = \frac{\Delta t}{(D2-F)\Delta x} [DQ \times DNC + Q_{ave} \times DC + DC \times DQ + DNR \times QR_{ave}] \quad (19)$$

### 3.2 Input Data

The proposed model needs the following input data

- (1) The height, direction, period and length of incident wave in each calculated period, and the duration of each period in a year.
- (2) The location, discharge, sediment concentration and width of river in each period, and the duration of each period in a year.
- (3) The kinematic viscosity and density of sea water.
- (4) Density, porosity,  $D_{50}$  of sand, and the relative roughness.
- (5) Mean high water level and mean low water level.
- (6) The initial water depth chart.
- (7) The other special data, such as no-erosible region or coastal structure.

## 4.0 NUMERICAL RESULTS OF FOUR IDEAL CASES

### 4.1 Input Data of Four Ideal Cases

For investigating the general characteristics and adaptability of the proposed model, we run four ideal cases. The same part of input data are as follows:

- (1) beach slope 0.01
- (2) Kinematic viscosity of fluid  $1.3 \times 10^{-6} \text{ m}^2/\text{S}$
- (3) Density of sea water  $1020 \text{ kg/m}^3$
- (4) Density of sand  $2650 \text{ kg/m}^3$
- (5) Porosity of sand 0.35
- (6) Central grain diameter 0.0002 m.
- (7) Width of river mouth 1.2 Km
- (8) Relative roughness of sand 0.0007m
- (9) River flow velocity at mouth 0.6 m/S
- (10) Incident wave height 2 m

Table 1 shows the other input data for each case.

Table 1 Input data for four ideal cases

	The depth of river (m)	River Discharge (cms)	River sediment concentration	Wave incident angle (°)
Case A	1.5	1080	0.0004	45
B	1.0	720	0.0006	45
C	1.0	720	0.0004	45
0	1.0	720	0.0004	30

#### 4.2 The Features of the Present Model

The numerical results are shown in Fig.6. From these results, some important features can be described as follows.

- (1) In all cases the accretion on updrift side is faster than downdrift side under the assumed oblique incident wave condition.
- (2) In all cases the width of the river mouth increase steadily and the center lines are always refracted to the direction of nearshore current.
- (3) Fig. 6a shows the results of case A and B, which indicate that when the total sediment transport of river is constant, an increase in river discharge will decrease the accretion of downdrift side.
- (4) Fig. 6b shows the results of case B and C, which indicate that when river discharge is equal, the accretion of each drift side is in proportion to sediment concentration.
- (5) Fig. 6c shows the results of case A and C, which indicate that if sediment concentration is equal, the accretion of updrift side increases with river discharge increase, but in downdrift side is just opposite.
- (6) Fig. 6d shows the results of case C and D, which indicate that if all input data of the river is the same, the accretion of updrift side increases with wave-induced nearshore current velocity increase, but in downdrift side is just opposite.

### 5.0 FIELD CASE APPLICATION OF THE MODEL

#### 5.1 Introduction

Cho-Shui River, located in the mid-west Taiwan, is the biggest one in Taiwan. The annual total discharge is about  $4.65 \times 10^9$  m<sup>3</sup>/year. The total sediment load is about  $4 \times 10^7$  m<sup>3</sup>/year, among which  $1 \times 10^7$  m<sup>3</sup>/year of sediment load being deposited on the river bed and the left  $3 \times 10^7$  m<sup>3</sup>/year sediment load flowing into the coastal water and settled down the river mouth. Due to the river flow and incident wave, the shoreline evolution is severe and complicated. Fig. 7 shows the change of the shoreline around the Cho-Shui river between 1903 and 1972. Before 1911 the Cho-Shui river use the channel of the old Cho-Shui river, but after a work of channel regulation done in 1911, the mouth of the Cho-Shui river was changed to the present location. The change get a severe erosion of the shoreline around the Old Cho-Shui river mouth and a great accretion around the Present Cho-Shui river mouth.

#### 5.2 Description of Input Data

- (1) The variation of the discharge and the sediment concentration of the Cho-Shui river is very large. Table 2 shows the various data of discharge in a year at the Silo station. It is quite difficult to choose the amount of discharge in each period

Table 2. Discharge of Cho-Shui River (Unit: Cms)

Month Item	1	2	3	4	5	6	7	8	9	10	11	12
Monthly average	6.91	6.61	17.39	30.05	122.30	412.43	170.77	317.36	194.70	91.26	30.86	18.77
Max. monthly average	31.28	51.40	108.07	195.98	364.22	1,058.03	569.90	878.68	480.32	269.26	226.10	70.38

Average discharge	Max. annual average		Min. annual average		Max. day average			Min. day average				
122.95	208.34		36.23		6,610.00			0.09				

Table 3. Input data combination

Item Time step	Duration (month)	Wave direction	Wave height (m)	Waver period (s)	Discharge (cms)	Sediment concentration	Sediment load (m <sup>3</sup> /month)
1	8.3	NE	1.63	5.50	2,100	0.0006	3.26x10 <sup>6</sup>
2	3.7	SW	0.70	5.00	500	0.0006	7.78x10 <sup>5</sup>

for use. It is also not easy for selecting correctly the sediment concentration by its large variation from 40 ppm to 3500 ppm. For deciding feasonably the discharge and the sediment concentration of the river, we had made a several tests for several combinations. Considering the fact that the proposed model is more suitable for large discharge, we finally suggest taking a discharge larger than the real discharge in each period. This discharge combining with the sediment concentration, which is little than the real average concentration, make sure the total sediment load equal to the real total load. The combination we take is shown in table 3.

- (2) According to the report of Taichung Harbour Bureau (1973), we decide the incident wave height and period in monsoon and summer season as shown in table 3.
- (3) For the initial water depth chart we used the sea chart No.234 of Japanese Navy Waterway survey department in 1903. Fig.8 shows the water depth in the scope we decided. This scope includes the old Cho-Shui River in order to understand the effect of the Cho-Shui river channel regulation in 1911.
- (4) The other input data we used just as follow:

kinematic viscosity of sea water	$1.3 \times 10^{-6} \text{ m}^2/\text{s}$
density of sea water	$1020 \text{ kg}/\text{m}^3$
density of sand	$2650 \text{ kg}/\text{m}^3$
width of river mouth	2.1 km
central grain diameter	0.0002 m
sand relative roughness	0.0007 m
porosity of sand	0.35

### 5.3 The Result of The Numerical Simulation

Fig. 9 shows the simulated result. The centerline of the Cho-Shui river is at the grid 27.5 in x-axis. The result is not good enough because we had not considered the artificial effect just like oyster and other water fowls growth. In the following some discussions about the result is described for three regions.

- (1) The region 1 is from grid 40 to grid 55, being just at the south side of the old Cho-Shui river mouth. Either the sea chart or our simulation result show this region had a quickly accretion from 1903 to 1972. But the accretion velocity of the sea chart is large than the simulation one. For understanding the reason we investigated the shoreline of this region and found that there were many oyster growth fields there. These oyster growth fields had made a large deposition of the longshore sediment load beyond the nature quantity. It seems that the existence of this artificial oyster fields make the deviation of numerical result.
- (2) The region 2 from grid 20 to grid 40 is just at the Cho-Shui river

mouth. Either the field or numerical result showed this region also had a quickly accretion from 1903 to 1972, and a delta had been grown. The location of the delta in our simulation result is at the north side of the field one, but the accretion velocity was almost equal, and the area of accretion in region 1 and region 2 in simulation is almost equal to that of the field result. Consequently this unagreement between numerical and field result might be due to the over deposition in region 1.

- (3) In the region 3 from grid 10 to gride 20, which is at the south side of the Cho-Shui river mouth, there are no artificial oyster growth and other coastal structures. The simulation result agree the field data very well.

From the fact metioned above, if there are no artificial effects, the present model would be able to give a reasonable agreement.

## 6.0 CONCLUSIONS

According to the results described above, we get some conclusions:

- (1) The proposed model assumes that the river flow in the coast around the river mouth is a turbulent plane jet. So the model is more suitable for the rivers with large discharge and velocity.
- (2) The other approachs either mathematical solutions or numerical simulations always lead to unreasonable results that the shoreline shape is nearly symmetrical with respect to the centerline of river mouth even if oblique wave approachs, and that under constant river sediment supply the shape of shoreline at the river mouth maintains no change even though the river discharge or sediment concentration is changed. The proposed model, in contrast, can give more reasonable results with more general conditions.
- (3) The proposed model can be used readily for field cases to predict the shoreline evolution around the river mouth.

## CHAPTER TWO HUNDRED THREE

### SEDIMENTATION PROCESSES ALONG THE EAST FRIESIAN ISLANDS, WEST GERMANY

Duncan M. FitzGerald<sup>1</sup>

Shea Penland<sup>2</sup>

Dag Nummedal<sup>3</sup>

#### ABSTRACT

The East Friesian Islands are located on a high energy shoreline. The average deepwater significant wave height exceeds 1.0 m and the spring tidal range varies from 2.7 to 2.9 m. A large easterly net longshore transport rate has caused eastward growth of the barrier islands. Reclamation of tidal flats has significantly reduced the backbarrier area and has resulted in a decrease in the ratio of inlet width to barrier island length from 42% to 16% during the past 300 years.

The headwaters of the major channel dissecting the tidal flats erode in an eastward direction in response to tidal and wave driven currents, wave suspension, and eastward barrier island elongation. Consequently, the drainage systems of most of the inlets are highly asymmetric with 70-80% of the tidal prism coming from the east. This pattern results in a hooked main channel. The location of the channel at the inlet throat is controlled by the westward ebb flow in the main channel, the inertia of ebb flow in the tributary creeks, eastward longshore sediment transport, and the regional stratigraphy.

The position and orientation of the main ebb channel controls the symmetry of the ebb-tidal delta about the inlet shoreline. This, in turn, affects the location of swash bar attachment to the beach and overall trends of erosion and deposition along the downdrift barrier.

#### INTRODUCTION

The East Friesian Islands are a barrier chain that has

  2. Coastal Geology Program, Louisiana Geological Survey, Baton Rouge, LA 70893
  3. Department of Geology, Louisiana State University, Baton Rouge, LA 70803

undergone a great amount of change during the past 300 years. These changes are the result of natural processes and man's influences. It is the objective of this paper to report the historical changes that have occurred to these barriers and to show that these changes can be explained in terms of the regional stratigraphy and the sedimentation processes active in this area.

This paper represents a summary of several papers published by the authors dealing with the morphodynamics of the East Friesian Islands. These works include a discussion of sediment transport patterns at Norderneyer Seegat (Nummedal and Penland, 1981), control of barrier island morphology by inlet sediment bypassing processes (FitzGerald et al, 1984A), and the correlation that exists between inlet narrowing and backbarrier filling (FitzGerald et al, 1984B).

#### PHYSICAL ENVIRONMENT

The East Friesian Islands consist of six barriers and five tidal inlets, spanning a 90 km stretch of shoreline along the West German North Sea coast (Fig. 1). The barriers are separated from the mainland by a 4-12 km wide tidal flat and creek system. The tidal flats are comprised of medium-fine sand near the inlets fining to muds toward the drainage divides (Fig. 2).

The winds in this area blow out of the westerly quadrant during the entire year with an average velocity of 8-15 kt (Luck, 1976A). This produces a net eastward long-

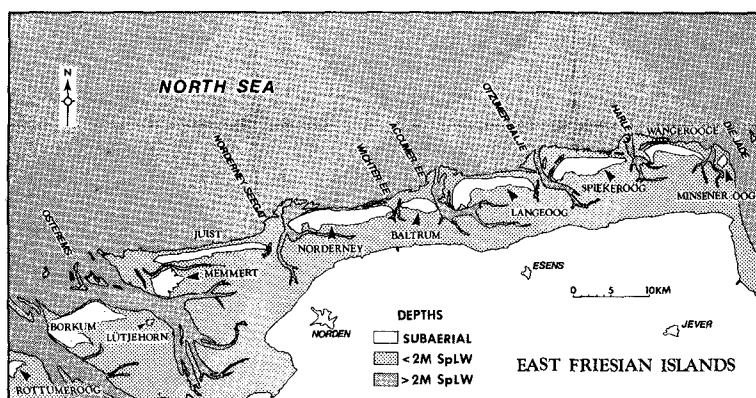

Figure 1. Location map of the East Friesian Islands.

Figure 2. Aerial photograph of Baltrum and Langeoog looking east. Note the coastal structures on the western ends of the islands.

shore power component of  $4.44 \times 10^3 \text{ W-m}^{-1}$  (azimuth= $101^\circ$ ) (Fig. 3) (Nummedal and Penland, 1981). It has been estimated, using morphological data, that a minimum of  $2.7 \times 10^5 \text{ m}^3$  of sand is transported to east yearly (FitzGerald et al, 1984A).

The tides in the North Sea are semi-diurnal and propagate in an easterly direction along the coast. The tidal lag between the islands of Juist and Wangerooge is approximately one hour. Spring tidal range varies from 2.5 m at the mouth of Osterems to 2.9 m at Die Jade.

#### HISTORICAL ANALYSIS

Historical changes of the East Friesian Islands were determined from sequential maps compiled by Homeier and Luck (1969). One of the overlays that were constructed from these maps is shown in Figure 4. During the 310 year period of record the Island of Norderney prograded 12 km to the east. Note, however, that the eastward growth of Norderney was accommodated not only through inlet migration but also by the narrowing of Wichter Ee. This same trait is apparent at Accumer Ee and repeated along the rest of the barrier island chain.

During the past 310 years an abundant sediment supply has led to an 80% increase in aerial extent of the barrier islands (Fig. 4). Of this increase, 45% was due to land reclamation along the backsides of the barrier (Fig. 2), while the rest of the growth (35%) was caused by natural

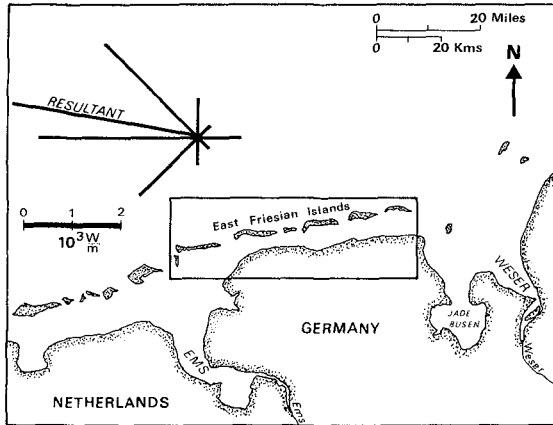

Figure 3. Deep-water wave power distributions for the Bremerhaven data square as determined from the Summary of Synoptic Meteorologic Observations. The northwesterly resultant component of wave energy produces a large easterly longshore transport rate (from Nummedal and Penland, 1981).

processes including spit accretion and beach progradation. During this same time span empoldering was also occurring along the mainland shoreline (Fig. 4). Since 1650 the backbarrier drainage area has been reduced by 30%. As discussed by FitzGerald et al (1984B), the decrease in bay area has caused a reduction in the inlet tidal prisms. This, in turn, has resulted in smaller equilibrium inlet cross sectional areas (O'Brien, 1931, 1969). One reflection of this has been a continued decrease in total inlet width from 20.4 km in 1650 to 9.4 in 1960. One other consequence of the smaller tidal prisms has been a decrease in the size of the ebb-tidal deltas (Walton and Adams, 1976; FitzGerald et al, 1984B).

#### BACKBARRIER PROCESSES

From the historical analysis it is known that most of the East Friesian barrier islands and some of the tidal inlets have migrated in an easterly direction. Therefore, it would be expected that if the backbarrier channels had remained relatively static then through time they would have become hook-shaped and oriented toward the west. However, just the opposite pattern has developed. As seen in Figure 5, the channels are indeed hook-shaped, but they are oriented west, not east. The reason for this is that

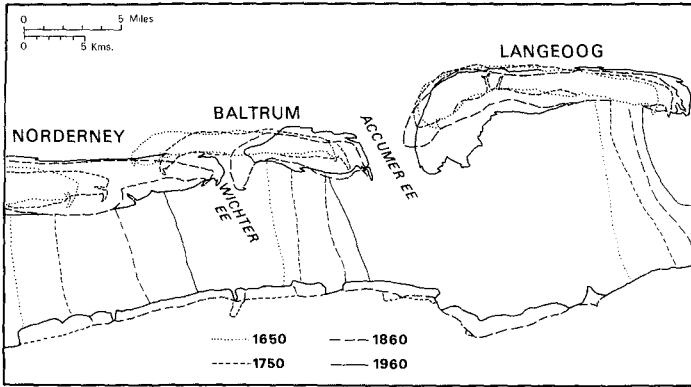

Figure 4. Historical changes for a portion of the East Friesian barrier island chain. Constructed from maps produced by Homeier and Luck (1969).

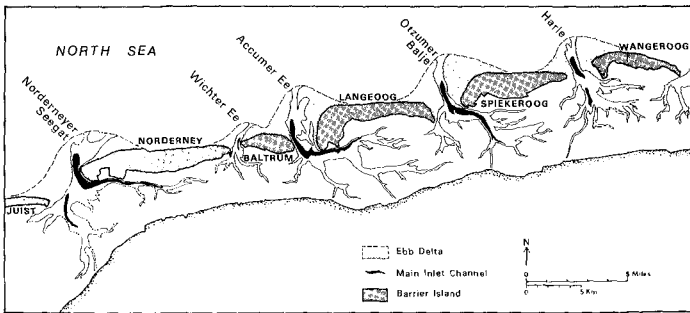

Figure 5. Positions of the main ebb channels and configurations of the ebb-tidal deltas.

through time the drainage divides have also migrated in an easterly direction, keeping pace with the growth of the barrier islands (Fig. 4). The easterly extension of the backbarrier channel systems is a product of headward erosion with a net transport fine-grained material to the east across the drainage divides.

The processes affecting sedimentation in the back-barrier include tidal current 1) time asymmetry and 2) velocity asymmetry. Time asymmetry, as first put forth

by Van Straaten and Kuenen (1957), Postma (1961, 1967), Groen (1967), Reineck (1967) and others, refers to the condition when maximum current velocities do not take place at mid-tide but rather occur early or late in the tidal cycle. This condition was used by the above workers to develop the concepts of scour and settling lags to explain the net landward movement of fine-grained sediment on Dutch and German tidal flats. Velocity asymmetry occurs when the maximum current velocities are unequal during the flood and ebb cycles. In the East Friesian Island backbarrier flood tidal currents predominate. This velocity asymmetry is attributed primarily to: 1) a steepening of the tidal wave and 2) wind effects.

Redfield (1978) has shown that as the tidal wave propagates across a wide shallow shelf it steepens in a manner similar to a wind generated wave along a beach. This steepening produces a shorter period in the rise of the tide than its fall. In the main inlet channels of the East Friesian Islands this difference in tidal duration amounts to approximately one half hour. Because the water has a shorter time to enter the inlet than to exit the currents must move more swiftly, hence, the stronger flood tidal currents.

As mentioned earlier, the winds along this portion of the North Sea blow out of the westerly quadrant during the entire year. This direction coincides with the longest fetch length of the backbarrier region (E-W). Consequently, superimposed on the tidal regime is an easterly movement of water driven by wind stresses. Winds of 15-30 kph are capable of producing current velocities of 10-20 cm/sec. The effect of the winds on the backbarrier water circulation, if tidal currents were symmetrical, would be to cause stronger flood currents in the eastern portion of the inlet drainage and to increase ebb flow in the western part of the drainage system.

Current velocities recorded by Koch and Luck (1974) behind the island of Juist show the effects of the factors that have been discussed above (Fig. 6). Stations #7 and 8 on the western side of the drainage divide have stronger flood than ebb tidal currents. On the opposite side of the divide stations #9 and 10 are clearly dominated by ebb currents.

Thus it is proposed that the easterly migration of the drainage divides is the result of net sediment transport to the east. This is caused primarily by wind-generated currents augmenting and retarding the tidal currents.

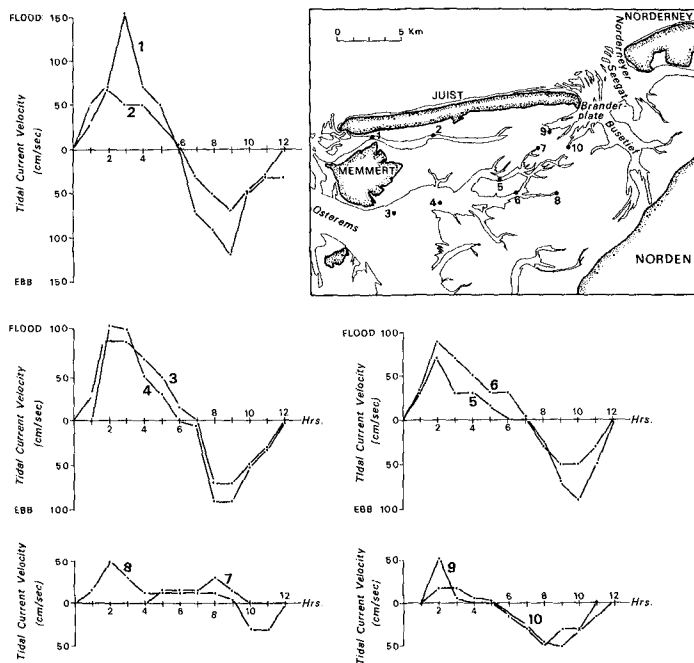

Figure 6. Velocity curves in the tidal channels behind the island of Juist. Note the flood dominance of stations #7 and 8 and the ebb dominance of stations #9 and 10. Velocity data from Koch and Luck (1974).

TIDAL INLETS

Morphology

Tidal inlets along the East Frisian Islands are classified in Hayes' (1979) and Nummedal and Fischer's (1978) mixed energy (tide-dominated) coastal setting. They are fronted by well developed ebb-tidal deltas and have main ebb channels that are dominated by ebb-tidal currents. Inlet throat geometry exhibits a large degree of variability along the island chain. Most often, the channels are highly asymmetric with their thalwegs abutting the updrift or downdrift shoreline (Fig. 5). The factors that control channel morphology include: 1) easterly longshore sediment transport, 2) stratigraphy of the area, 3) backbarrier tidal channel distribution and 4) stabilization projects. Changes in tidal inlet morphology

have been discussed by Luck (1976B).

The strong easterly longshore transport system would seem to dictate that all the Friesian inlets should have channel thalwegs along their eastern downdrift sides. However, this is not the case (Fig. 5). As Sindowski's (1973) stratigraphic study of the barriers has revealed, several of the inlets have scoured into semi-indurated marine clays or glacial tills. The resistance of these sediments to erosion has served to naturally stabilize these inlets and control their geometry. For example, the thalweg at Accumer Ee is anchored along the western side of the inlet, having eroded into glacial tills. While the position of inlet thalweg was stabilizing at Accumer Ee, the back-barrier tidal channels continued to erode in an easterly direction. In this hook-shaped configuration the ebb-tidal flow in the main backbarrier channel is directed toward the western side of the inlet. This further stabilizes the thalweg along the updrift inlet shoreline.

At Nordeneyer Seegat the deepest portion of the inlet channel abuts the island of Norderney (Fig. 5) and has eroded laterally into compacted glacial sediments (Sindowski, 1973). The downdrift location of the channel thalweg is a product of the position and orientation of Buse Tief (a tributary creek with a northwesterly orientation) and the downdrift offset inlet shoreline configuration which affords greater exposure of the inlet channel to the dominant westerly wave energy.

It should be mentioned that during the past 100-150 years many of the inlets have been stabilized with groins and seawalls of various constructions (Fig. 2). A jetty has also been built at Harle Inlet.

#### Inlet Processes

Tidal inlet hydraulics and sediment transport patterns have been studied in detail at Nordeneyer Seegat by Nummedal and Penland (1981) and at Harle Inlet by Hanisch (1981). The data base for these investigations consisted of historical information, grain size data, box cores, bedform measurements, velocity profiles and tracer experiments. Although in each of the studies different sediment transport processes were deemed most important similar sediment transport trends were envisioned. Nummedal and Penland's (1981) sediment transport model for Nordeneyer Seegat is shown in Figure 7. The bedform data at Wichter Ee (Fig. 8) corroborate these general sand transport patterns.

Sand bypasses tidal inlets along the East Friesian Islands by a combination of wave and tidal processes in a manner first described by Brunn and Gerritsen (1959).

Figure 7. Sediment transport patterns at Norderney Seegat (from Nummedal and Penland, 1981).

One of the end products of inlet sediment bypassing process is the attachment of large bar complexes to the downdrift beach. Sand is transported to the inlets by wave action from the west. Once in the vicinity of the ebb-tidal delta sand is moved toward the inlet through marginal flood channels by flood tidal currents and wave-generated currents. Most of the sand that is delivered to the main ebb channel is transported in a net seaward direction by dominant ebb tidal flow. This sand is deposited along an arcuate series of bars (reef bow) that comprise the outer portion of the ebb-tidal delta. These bars migrate in an easterly fashion along the periphery of the delta (Fig. 9) (Homeier and Kramer, 1957). Aerial views of the ebb-tidal delta bars at Norderney Seegat and Wichter Ee are shown in Figure 10.

Sand from the ebb-tidal delta is ultimately added to the downdrift beach through the landward migration of large swash bars, which may be more than 1 km in length. Bar complexes in the process of welding to the shoreline of Baltrum are illustrated in Figure 11. It should be emphasized that as much as half of the volume of sand that bypasses the inlet is moved onshore by wave action

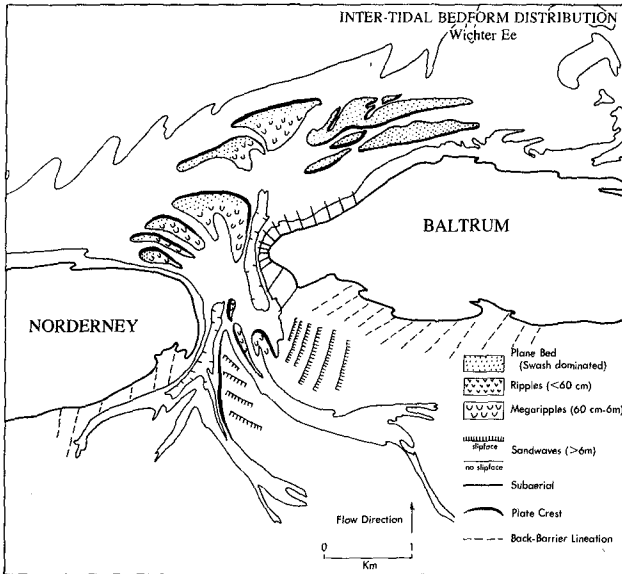

Figure 8. Bedford distribution map for Wichter Ee.

independent of the bar complexes.

#### BARRIER ISLAND PROCESSES

Erosional-depositional trends along the East Friesian Islands are discussed in detail by Luck (1975 and 1976B). These trends correlate well with the location where bars weld to the beach and the local longshore transport patterns. If the bars move onshore some distance down-drift of the inlet shoreline then the updrift end of the barrier is likely to be erosional. Conversely, the site where the bars weld to the beach and the shoreline down-drift of this location are normally accretionary (Luck, 1975).

FitzGerald et al (1984) have also shown that the shape of the East Friesian barriers is tied closely to the bar welding process (Fig. 12). If the bars move onshore close to the inlet mouth then a drumstick barrier develops, as would be predicted by Hayes and Kana (1976). However, when the bar complexes attach to the beach some distance away from the inlet a humpbacked or down-drift bulbous barrier is formed (FitzGerald et al, 1984A).

Figure 9. Aerial photographs of A. Norderneyer Seegat and B. Wichter Ee.

The position along the downdrift barrier island shoreline where the bar complexes weld to the beach is a product of the size and symmetry of the ebb-tidal delta. These factors control the amount of overlap of the ebb-tidal delta and therefore the distance from the inlet that the sediment bypassing process is completed. The size of inlet is a function of the backbarrier drainage area. The symmetry of the ebb delta is controlled by the position of the main ebb channel at the inlet throat. The influence of these various factors is demonstrated in Figure 5. Note that the large size of Norderneyer Seegat coupled with the downdrift location of the main channel at the inlet throat have produced a highly asymmetric ebb-tidal delta that

Figure 10. Pathways of bar movement at Wichter Ee and Accumer Ee (from Homeier and Kramer, 1957).

Figure 11. View of swash bars welding to the beach along Baltrum.

greatly overlaps the downdrift beach (5.0 km). This explains the humpbacked development of the island of Norderney. Contrastingly, the western position of the main ebb channel at Accumer Ee has resulted in a symmetrically-shaped delta. Bar welding along Langeoog occurs close to the inlet and thus Langeoog has a drumstick shape.

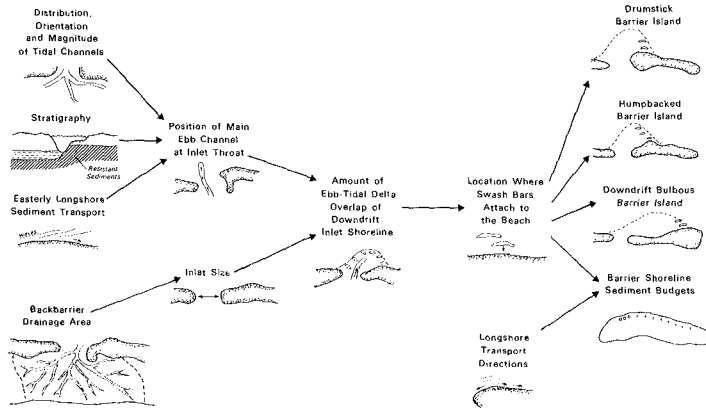

Figure 12. Model of the morphological development of East Friesian barrier islands.

SUMMARY

- 1) The East Friesian Islands have undergone dramatic changes since 1650. An abundant sediment supply has resulted in a 35% increase in aerial extent of the barrier islands. Coincident with this growth was a 30% decrease in backbarrier drainage area due to land reclamation efforts. This decrease in bay size has caused a reduction in the tidal prisms and smaller equilibrium tidal inlet cross sectional areas.
- 2) The strong westerly wind regime of this region produces a dominant easterly longshore transport direction. This easterly transport of sediment has caused an eastward extension of the barrier islands. Some of this eastward growth has occurred through an easterly migration of the tidal inlets. However, most of the growth has been accommodated by a narrowing of the inlets.
- 3) There has been a long-term eastward migration of the backbarrier drainage systems caused by the dominant westerly winds. Wind driven currents augment and retard the tidal currents resulting in a net easterly transport of sediment and headward erosion of the tidal

creeks. This has produced hook-shaped backbarrier channels. The position of the main channel at the inlet throat and the degree of hook-shape of the backbarrier channels are controlled by the stratigraphy of the region. Norderneyer Seegat and Accumer Ee have scoured into resistance sediments and thus have stabilized. At these locations there has been little inlet migration and their main channels are highly hooked. Conversely, Harle Inlet has had a history of easterly migration prior to jetty construction and its main channel is fairly straight.

- 4) Sediment bypasses the inlets in the form of landward migrating swash bars. Sand is also bypassed independent of the bars along the periphery of the delta. The location where the bars weld to the beach is controlled by the overlap of the ebb-tidal delta which, in turn, is a function of inlet size and position of the main ebb channel at the inlet throat. The site where swash bars move onshore coincides with the bulbous portion of the barriers. This accretionary process is responsible for barriers of various shape.

## CHAPTER TWO HUNDRED FOUR

### Lateral Distributions of Water, Salt and Sediment Transport in a Partly Mixed Estuary

R.J. Uncles, R.C.A. Elliott and S.A. Weston\*

The transverse structure of the residual transport of water, salt and suspended sediment in the upper reaches of the Tamar Estuary is investigated. Data were obtained at three cross-sections for spring and neap tides. The transport for each variable is analyzed in terms of the governing physical processes.

#### Introduction

The objectives of this paper are to investigate transverse variations in the transport of water, salt and suspended sediment in the upper reaches of the Tamar Estuary, which is a partly mixed estuary in the southwest of England (Figure 1). Tides are semi-diurnal, with mean neap and spring ranges of 2.2 and 4.7 m, respectively.

Observations of the transverse structure of currents and salinity have been made for some other estuaries, generally with a view to investigating dispersion processes (4,6,7,8,10,11). In this work we present data on the transverse variations in the advective, tidal pumping and vertical shear components of the salt and sediment transport.

#### Observations

Three sections (1, 2 and 3 in Figure 1) were worked for spring and neap tidal cycles. Velocity, temperature, salinity and suspended sediment were profiled at either four or five positions over each section. Some of these stations dried out near low water. Measurements were made at half-hourly intervals from a seatruck anchored in the centre of a section, and at approximately three-quarter-hourly to hourly intervals at the remaining stations. Transverse topography at the experimental sections is shown in Figure 2. Positions of the high and low water lines for the spring and neap tide surveys are drawn, together with the station positions. The mean, axial, depth averaged current speeds in the deepest parts of the sections were roughly  $0.4 - 0.5 \text{ m s}^{-1}$  during spring tides, and less than half this at neap tides.

Table 1 shows background data for sections 1 to 3. Up-estuary flows are negative. The estimated residual flow due to diurnal inequality over each observed tidal cycle is given, together with the sum of flows due to run-off and inequality,  $Q$ .

None of the sections were vertically well mixed for salinity, and

Figure 2. Transverse topography at sections 1 to 3, showing station positions and depths (m) below the high water springs line.

TABLE 1: Background data for sections 1-3, springs (S) and neaps (N). Residual flows due to daily-averaged run-off, diurnal inequality and their sum, Q, are shown (negative up-estuary).

Section	Date	Tidal Range (m)	Run-off ( $\text{m}^3 \text{ s}^{-1}$ )	Inequality ( $\text{m}^3 \text{ s}^{-1}$ )	Q ( $\text{m}^3 \text{ s}^{-1}$ )
1(N)	18/5/82	2.3	3.7	-0.5	3.2
2(N)	19/3/82	1.6	41.8	-1.8	40.0
3(N)	18/2/82	1.8	21.3	3.8	25.1
1(S)	25/5/82	4.9	3.6	0.0	3.6
2(S)	27/4/82	4.6	5.9	0.0	5.9
3(S)	26/2/82	4.9	25.9	14.3	40.2

section 2 (Neaps) was strongly stratified, owing to high run-off (see Table 1). Consequently, at section 2 (Neaps) the residual (tidally averaged) current was directed down-estuary throughout the column. The residual currents at sections 1 and 3 (Neaps) showed classical gravitational circulation. At spring tides, the stronger residual tidal wave (Stokes) transport generated compensating down-estuary residual currents which greatly reduced the gravitational circulation at all sections.

Concentrations of suspended sediment were much higher during spring tides, and increased towards the bed. Therefore, local resuspension of sediment was important. During neap tides, concentrations were typical of those associated with freshwater and marine inputs, although the slight increase in suspended sediment with depth at section 1 (Neaps) showed that a small amount of local resuspension occurred.

#### Calculation of Transport

If  $\bar{Q}$  is the volume transport of water per unit width,  $\bar{Q} = H\bar{U}$ , where H is total depth, U velocity and the overbar denotes a depth average, then the residual transport is given by:

$$\langle \bar{Q} \rangle = \langle H\bar{U} \rangle = Q_E + Q_S = Q_L$$

in which the diamond bracket denotes a tidal average, and where:

$$Q_E = \langle H \langle \bar{U} \rangle \rangle \quad (1)$$

$$Q_S = \langle \hat{H}\hat{U} \rangle \quad (2)$$

with  $\hat{U} = \bar{U} - \langle \bar{U} \rangle$  and  $\hat{H} = H - \langle H \rangle$

$$\text{and } Q_L = Q_E + Q_S \quad (3)$$

Therefore,  $Q_E$  is the Eulerian residual transport per unit width,  $Q_L$  is the residual transport of water per unit width, and  $Q_S$  is the residual transport associated with the tidal wave (equivalent to the Stokes transport for one-dimensional flows (12)). On intertidal areas,  $Q_E$  is also defined from equation (1), except that the substitution  $\bar{U} = 0$  is made during times when a station is not submerged;  $Q_S$  is then defined from equation (3) rather than from equation (2).

The residual, depth averaged rate of transport of salt per unit width is (in ppt  $m^2 s^{-1}$ ):

$$F = F_L + F_{TP} + F_V \quad (4)$$

where  $F_L$  is due to the residual flow of water,  $Q_L$ , and  $F_{TP}$  and  $F_V$  are due to tidal pumping and vertical shear, respectively (5, 9, 13). If  $S$  denotes the instantaneous salinity and  $\hat{S} = S - \langle S \rangle$ , then:

$$F = \langle \overline{HUS} \rangle \quad (5)$$

$$F_L = Q_L \langle \bar{S} \rangle \quad (6)$$

$$F_{TP} = \langle \overline{QS} \rangle \quad (7)$$

$$\text{and } F_V = \langle \overline{HU'S'} \rangle \quad (8)$$

where  $S' = S - \bar{S}$  and  $U' = U - \bar{U}$ . Fluxes are taken to be zero in these tidal averages when a station is not submerged on the intertidal areas.

The residual, depth averaged rate of transport of sediment per unit width is (in ppm  $m^2 s^{-1}$ , where ppm = parts per million by weight of water):

$$G = G_L + G_{TP} + G_V \quad (9)$$

Subscripts have the same meaning as those for the salt transport (equation (4)). If  $P$  denotes the instantaneous suspended sediment concentration, and  $\hat{P} = P - \langle P \rangle$ , then:

$$G = \langle \overline{HUP} \rangle \quad (10)$$

$$G_L = Q_L \langle \bar{P} \rangle \quad (11)$$

$$G_{TP} = \langle \overline{QP} \rangle \quad (12)$$

$$\text{and } G_V = \langle \overline{HU'P'} \rangle \quad (13)$$

where  $P' = P - \bar{P}$ .

Results

The cross-sectionally averaged currents, salinity and suspended sediment load over a tidal cycle are shown in Figure 3. An overbar is used to denote a cross-sectional average, rather than a depth average, in this figure. The cross-sectional area is denoted by A. Cross-sectional values were deduced by interpolating observed data onto a rectangular grid of points covering each section. The interpolation program has been widely used for such problems ( 2, 3 ). The program was also used to extrapolate data from the outer stations on each section (Figure 2) to the banks. Extrapolation is least accurate for the velocity, owing to its large spatial variations. Because of this, a condition of zero velocity was applied at the bed over the region of extrapolation, and on the banks, so that the problem reverted to one of interpolation.

Typical maximum current speeds were of order  $1 \text{ m s}^{-1}$  during spring tides. Speeds were less than half of this during neap tides. Currents

Figure 3. Tidal cycles of sectionally-averaged velocity (—), sediment load (---) and salinity (●-●-●).

were much more distorted during spring tides. At sections 1 and 2 the flood currents exceeded the ebb currents and were of shorter duration.

This tidal asymmetry is typical of estuarine flows in shallow water (14,1). At the seaward section (section 3) the tidal asymmetry was very small and the down-estuary-directed Eulerian residual current was sufficiently strong to generate an ebb-dominated flow.

Asymmetry in the tidal currents affected the suspended sediment load during spring tides. At sections 1 and 2 the enhanced flood currents produced more resuspension and a higher suspended sediment load than during the ebb tides (Figure 3). At section 3 the suspended load maximized during the ebb tide. Sediment loads during spring tides were very much higher than during neap tides. There is some indication that slight resuspension of sediment occurred during maximum flood currents at section 1 (Neaps).

Cross-sectionally averaged salinity is shown in Figure 3. Near the head, at sections 1 and 2, the salinity was zero near low water as the fresh water-brackish water interface swept through the section. Salinity was very low throughout the tidal cycle at section 2 (Neaps) owing to the high freshwater run-off (Table 1).

#### Water Transport

Transverse distributions of the residual rates of transport of water per unit width of estuary are shown in Figure 4. Data are given for neap

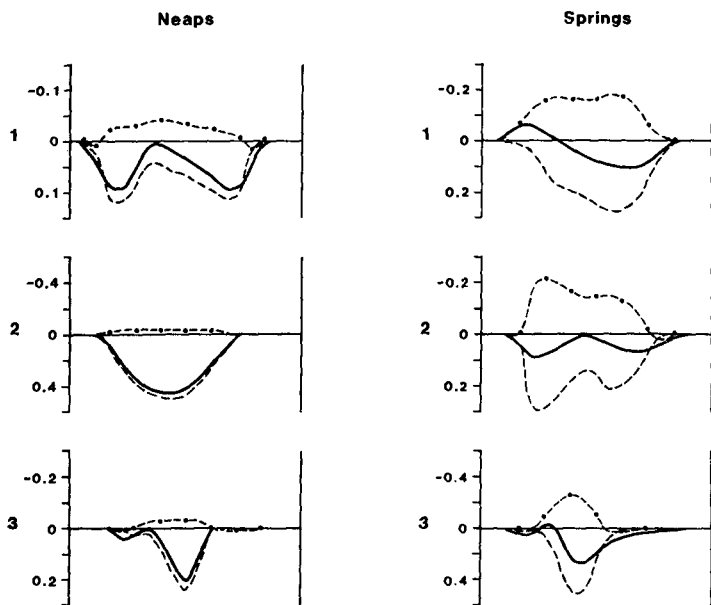

Figure 4. Lateral profiles of residual water transport per unit width ( $m^2s^{-1}$ ). Stokes (-.-), Eulerian (- - -), Total (—).

and spring tides at sections 1 to 3. The tidal wave (Stokes) transport  $Q_S$  was directed up-estuary over the deeper parts of each cross-section, and was small and directed down-estuary over the intertidal areas. This transport was much higher during spring than neap tides. The Eulerian transport  $Q_E$  was always directed down-estuary, and was driven by surface slopes generated by the overall up-estuary tidal wave transport, as well as those due to freshwater inputs to the estuary, density effects and non-linear tidal effects. At section 2 (Neaps) the Eulerian transport had a simple river-like form, with fastest speeds in the deeper, central part of the section. Physical conditions were governed by the high run-off at that time.

Transverse distributions of the total residual rates of water transport per unit width  $Q_T$  were similar to those for the Eulerian transport at neap tides, owing to the smaller tidal wave (Stokes) transport. The distributions at sections 1 and 3 (Neaps) and 2 and 3 (Springs) showed a systematic pattern of circulation. Transport in the central, deeper part of the section was small, whereas over the shallower subtidal and intertidal areas the transport was stronger and directed down-estuary. This pattern consisted of three components: a run-off induced residual flow which was directed down-estuary everywhere; a density-driven component which was down-estuary in the shallow subtidal and intertidal areas, and up-estuary in the deeper, central parts of a section; and a tidally-induced component, which acted to enforce the density-driven flow. The density-driven and tidally-induced flows opposed the river-like circulation in the centre of the sections, leading to small transport there. The opposite occurred in the shallow areas.

#### Salt Transport

Transverse distributions of the residual rate of salt transport per unit width ( $\text{ppt m}^2 \text{ s}^{-1}$ ) are given for sections 1 to 3 in Figure 5. Rates of transport due to vertical shear ( $F_V$  in equation (8)), tidal pumping ( $F_{TP}$  in equation (7)) and advection ( $F_L$  in equation (6)) are shown.

Transport due to vertical shear was always directed up-estuary, and was largest in the deeper, central parts of a section. Here, the vertical variations in both currents and salinity were largest, and pronounced gravitational circulations occurred. Transport due to tidal pumping was directed up-estuary in the deeper parts of a section, but sometimes reversed direction in the shallow areas. With the exception of section 1 (Neaps), this down-estuary transport due to tidal pumping was extremely small, and is thought to be due to the reduced phases of the tidal currents (a response to the increased frictional drag in these areas) relative to those in the deeper regions.

The advective transport of salt due to the residual flow of water had a very similar pattern to the residual flow of water (compare Figures 4 and 5). This is because of the relative insignificance of transverse variations in salinity when compared with sectionally-averaged values. Thus, the advective transport of salt tended to be small in the deeper parts of a section, and large and directed down-estuary in the shallower areas. Rates of transport due to vertical shear and tidal pumping were large and directed up-estuary in the deeper part of a section. Therefore,

the residual transport was directed up-estuary in the central, deeper part of a section, and directed down-estuary in the shallow regions.

Figure 5. Lateral profiles of residual salt transport per unit width ( $\text{ppt m}^2 \text{s}^{-1}$ ). Advection (—), Pumping (- - -), Shear (-.-).

#### Sediment Transport

Transverse distributions of the residual sediment transport per unit width ( $\text{ppm m}^2 \text{s}^{-1}$ ) are given for sections 1 to 3 in Figure 6. Rates of transport due to vertical shear ( $G_v$  in equation (13)) were negligible and are not plotted. This is because of the low and fairly uniform concentrations of suspended sediment during neap tides; marine and freshwater concentrations were comparable (5-10 ppm). During spring tides the much higher concentrations were generated by local resuspension at maximum flood and ebb currents, and temporal correlations of the vertical shear transport were small.

The advective transport of suspended sediment due to the residual flow of water had a very similar pattern to the residual flow of water (compare Figures 4 and 6). Transport during spring tides was between one and two orders of magnitude larger than during neap tides.

Tidal pumping of sediment was directed up-estuary at section 1, and was considerably larger during the spring tide. The residual, up-estuary transport due to tidal pumping was a consequence of enhanced re-suspension of sediment, and associated up-estuary transport during peak flood currents (see also Figure 3). Flood currents also exceeded ebb currents at section 2 (Springs), and up-estuary tidal pumping occurred in the shallow areas. However, weak down-estuary pumping occurred in the deeper part of the section. This was possibly due to the absence of easily erodible bed sediment in the deepest part of the section. Tidal pumping of non-locally suspended sediment acted in the opposite way to that for salt (salinity increased down-estuary, whereas suspended sediment concentrations decreased), and so pumped sediment out of the estuary. Asymmetry between flood and ebb currents was small at section 3 (Springs). Here, the associated up-estuary pumping in the shallow areas was weak, and the down-estuary pumping in the deeper part of the section was large.

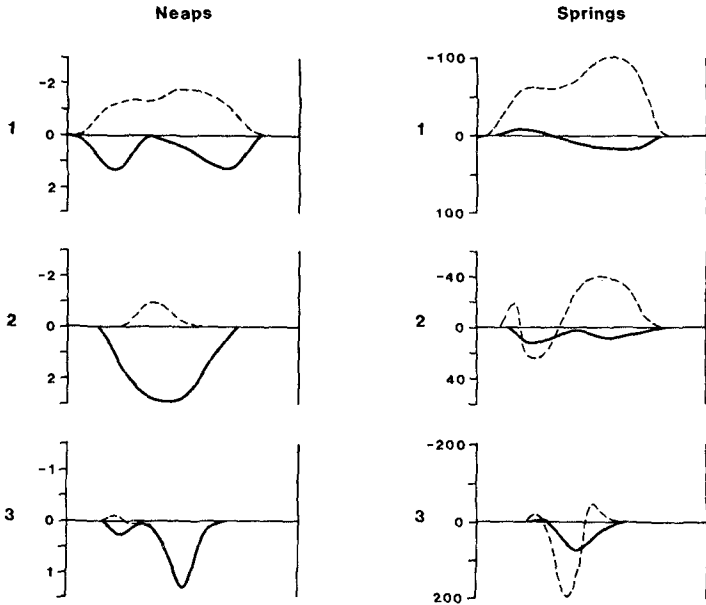

Figure 6. Lateral profiles of residual sediment transport per unit width ( $\text{ppm m s}^{-2}$ ). Advection (—), Pumping (---).

#### Conclusions

Spring tidal currents showed a strong asymmetry in the upper reaches of the estuary with flood currents exceeding ebb currents. Maximum current speeds were more than twice those at neap tides. Suspended sediment concentrations at spring tides were between one and two orders of magnitude higher than those at neap tides, owing to strong local resuspension of

sediment in the faster tidal currents.

The residual, tidal wave (Stokes) transport of water was much higher during spring tides. The transport was directed up-estuary in the deeper parts of a section, but could reverse direction in the shallow intertidal areas. The Eulerian residual transport was always directed down-estuary. The total residual rate of transport tended to be directed down-estuary over the shallow and intertidal areas, whereas in the deeper parts of a section it tended to be smaller, and could be directed up or down-estuary.

Tidal pumping of salt was directed up-estuary in the deepest part of a section, whereas it was small and could be directed down-estuary in shallow and intertidal areas. This was possibly due to reduced phases of the tidal currents (slack water occurring earlier) in the shallow areas. Vertical shear transport of salt was always directed up-estuary, and was largest in the deeper regions where vertical stratification was more pronounced and gravitational circulation was present. Residual salt transport due to local advection by the residual flow of water closely followed the pattern of residual water flow, owing to the relative insignificance of cross-estuary variations in salinity. The total residual transport of salt was directed up-estuary in the deeper parts of a section, and down-estuary in the shallower regions.

Tidal pumping dominated the suspended sediment transport during spring tides. Pumping was directed up-estuary over the whole section near the head. This was because of the much stronger flood currents (and associated erosion stresses) and the existence of a plentiful supply of bed sediment for erosion and resuspension. The asymmetry in the tidal currents was weaker further down-estuary. Tidal pumping was directed down-estuary in the deeper part of a section. This is thought to be due to the absence of easily erodible bed sediment in the deep channel. In absence of local resuspension, the tidal pumping of sediment acted in the opposite way to the tidal pumping of salt (salinity decreased up-estuary whereas suspended sediment concentrations increased). Fine sediment was present in the shallow and intertidal areas further down-estuary, and the tidal pumping there was weak but directed up-estuary.

Vertical shear transport of sediment was very much smaller than that due to pumping and advection. Pumping dominated advection at spring tides, whereas the reverse was true at neap tides. Transport was much smaller at neap tides, but weak resuspension and tidal pumping occurred near the head.

## CHAPTER TWO HUNDRED FIVE

### STABILITY PARAMETERS OF WESTERN SCHELDT ESTUARY

by

H. de Jong<sup>1</sup> and F. Gerritsen<sup>2</sup>

#### 1. INTRODUCTION

The Western Scheldt is a major estuary in the Southern part of The Netherlands and the Northern part of Belgium. It is an important navigational route connecting the city of Antwerp with the North Sea. At the entrance Vlissingen is a major Dutch port. (Figure 1)

Figure 1: Western Scheldt Estuary

During recent years much dredging work has been carried out by the Belgian Government (16 million m<sup>3</sup> in 1977) to remove shoals and improve channel alignments in the estuary, in view of increasing vessel drafts and traffic density to the port of Antwerp (Belgium).

It is of great importance to predict the effects of future dredging operations, carried out in the outer shoals and in major navigation channels on tidal regime (tides and currents) and on morphological changes in other parts of the estuary.

<sup>1</sup> Researcher, Rijkswaterstaat, Vlissingen, The Netherlands

<sup>2</sup> Professor and Chairman, Dept. of Ocean Engineering, Univ. of Hawaii Honolulu, HI

Calculations based on detailed hydrographic surveys have indicated that where the estuary used to be subject to sedimentation, the situation may now have changed to one of dominant erosion.

## 2. MORPHOLOGICAL STABILITY OF TIDAL CHANNELS

### The stability equation

The morphological stability of tidal channels has two major components:

- (a) location stability
- (b) cross-sectional stability

The location stability has to do with the meandering of channels, where the channel migrates gradually within the physical boundaries of the estuary. The nature of this process is strongly affected by the type of estuary, by the nature of bottom conditions (presence of silt layers) and by the type of coastal protection works (if present) along the estuary's boundaries.

Migration of tidal channels in the outer part of the estuary is often a cyclic process with a period of a number of years which is governed by the external boundary conditions related to tide, waves and littoral drift. The process of cyclic changes can be arrested or slowed down by high capacity dredging operations.

The development and migration of tidal channels in an estuary is connected with the system of flood and ebb channels in an estuary. Flood channels are characterized by dominating flood flow; they have a shoal at their inner end. In ebb channels the ebb flow dominates and a shoal is usually present at their seaward ends. Tidal channels are neutral when flood and ebb flow are of equal magnitude.

Cross-sectional stability relates to the variability of the cross-sectional area of tidal channel and to its dependency on tidal flow characteristics.

Tidal inlets are often characterized by a gorge, in which the tidal flow is well organized and where channel migration does not play a major role.

In this paper we will particularly be concerned about the cross-sectional stability of tidal channels whereby we will examine the total channel, as well as the individual flood or ebb channels, if they can be clearly identified.

The cross-sectional stability of a tidal channel is in general governed by the equation:

$$\frac{\partial Q_s}{\partial x} = 0 \quad (1)$$

if  $Q_s$  represents the sediment transport rate ( $m^3/sec$ ) and  $x$  the mean direction of the flow through a channel.

For (1) to be valid it is necessary that the mean sediment concentration over the channel cross-section does not vary with time.

For channels subject to tidal flow the stability equation must be intergrated over time and gives the condition ( $T$  = tidal period):

$$\frac{\partial}{\partial x} \int_0^T Q_s dt = 0 \quad (2)$$

under the assumption that the transport process repeats itself in equal manner during subsequent tidal cycles.

In case a strong difference exists between neap tide and spring tide cycles the integration is to be performed over a series of cycles to cover a sequency which repeats itself:

$$\frac{\partial}{\partial x} \int_0^t Q_s dt = 0 \quad (3)$$

where  $t \gg T$ .

Unfortunately the detailed knowledge about the sediment transport process is not adequate enough at the present time to use equation (3) with confidence to predict changes in bottom configuration.

#### Solutions to the stability problem

For many years the relation between the cross-section of a tidal channel and the tidal flow characteristics has been recognized.

A classical paper is that of M.P. O'Brien (9) who arrived at an empirical relationship between cross-sectional area and tidal prism for inlets on the U.S. West Coast. The tidal prism was calculated as the product of tidal storage area and tidal range. For the latter the difference between MHHW and MLLW was assumed.

The relation obtained was purely empirical because no consideration was given to relevant physical parameters such as:

- grain size
- littoral drift transport in relation to tidal transport,
- river discharge
- relative depth of channel (Chézy)
- presence of jetties
- presence of shoals, etc.

Because of the complexity of the problem it may be expected that certain empirical relationships would not be universally valid for other situations.

In more recent papers O'Brien and several other authors recognized this problem and certain modifications of the relationship were proposed.

In 1960 and in subsequent years Bruun and Gerritsen (3) attempted to evaluate the effect of various physical parameters on the empirical stability equations. They introduced the concept of stability shear stress  $\tau_s$  and found that this parameter was a useful parameter to define inlet stability. The variability of  $\tau_s$  with a number of physical parameters affecting inlet stability was thereby investigated. A comprehensive analysis is presented by Bruun (4).

A satisfactory solution to the stability equation (3) can only be obtained if the process of sediment transport through the channels can be accurately described by a sediment transport formula.

At present existing knowledge does allow the description and calculation of tides and currents in an estuary in a satisfactory manner. Work of fundamental importance was done by Dronkers (6) for one-dimensional flow and by Leendertse (8) for two-dimensional tidal problems. However the state of the art regarding the description of the sediment transport phenomenon in an estuary is not accurate enough to predict erosion and sedimentation rates according to equation (3).

The Kalinske and Morra formulation has been used in combination with a one-dimensional tidal model to predict morphological changes in the form of erosion and sedimentation rates for the Western Scheldt. The one-dimensional tidal model does not adequately distinguish between transport through channels and over shoals. Results of this approach can at best be qualitative.

The problem is magnified in the outer estuary where a formulation is required describing the sediment transport as a function of waves and currents combined. Such a formulation was proposed by Bijker (2).

Until a sufficiently accurate formulation for the sediment transport processes has been found an interim solution may be utilized, in which a mathematical model for flow is utilized to calculate the changes in water levels and currents, and where the changes in bottom configuration are predicted from empirical relationships between flow parameters and channel dimensions. For this, however, it is necessary that these empirical relationships, which have a statistical nature, are sufficiently accurate to use them as a predictive tool. The method to be applied is an iterative scheme: the changes in tide conditions are predicted using the numerical tidal hydraulics model; then channel profiles are adjusted based on the empirical relationship between tide parameters and channel dimensions. The process is repeated until stability conditions are fulfilled. It is the purpose of this paper to investigate a number of empirical relationships for the whole of the Western Scheldt, whereby the channel cross-section is related to a variety of tidal parameters such as velocity, tidal discharge, tidal prism, bottom shear stress, Chézy coefficient, etc.

The assumption is made that certain empirical relationships are not only valid for the entrance area but are applicable to the inner tidal channels as well.

It is furthermore assumed and verified that river discharge is negligible compared to tidal discharge and that density differences have no appreciable effect on the sediment transport equation.

The usefulness of various relationships will be evaluated from the calculated values of correlation coefficients obtained from the regression analysis.

In the study the cross-sectional area is treated as the independent variable, plotted on the horizontal axis of the regression diagrams.

Flow parameters are then considered as a function of the cross-sectional area.

Furthermore it must be noted that all tidal characteristics refer to mean tidal conditions, unless otherwise stated.

### 3. METHOD OF INVESTIGATION

#### Data used for analysis

The data have been obtained from extensive field measurements carried out by the Hydraulic Advisory section of the Rijkswaterstaat at Vlissingen over a number of years.

The basis is the set of velocity measurements, simultaneously carried out in different stations, at depths ranging from a little below the surface to a short distance above the bottom. Most of the measurements were carried out with the Ott current meter, and included current directions. The measurements were always done twice on successive days. Velocity measurements were integrated to flow values and flow values to tidal volumes. All flow data were reduced to mean tide conditions valid for the year in which the measurements were carried out. For this reduction the tidal range of the nearest tidal station was used as a reference. The reduction was done in a linear fashion, which has been shown to be an adequate procedure. Simultaneous measurements were usually carried out in 5-7 stations in one profile in cross-sections numbered 1-11 in Figure 1. Simultaneous measurements were carried out in a reference station. The vertical tide was measured (continuously) at 5 fixed tidal stations along the estuary. A discussion on the tidal regime for the Western Scheldt is presented by Daamen (5). The bottom of the Western Scheldt consists of fine alluvial sands, diameter  $d_{50} = 40-450\mu$ . For the profiles 12 and 13, situated in the outer part of the estuary (see Figure 1) insufficient velocity measurements were available to form a reliable base for the calculation of tidal flow and tidal prism. Therefore these values were calculated from the flow values for Profile 11, using the continuity equation. The possible error in the flow data is estimated at  $\pm 10\%$ .

The cross-sectional area was used in two different ways in the analysis of regression relationships:

- (1) the area  $A_c$  measured between bottom and the standard reference level N.A.P. (approximately equal to Mean Sea level)
- (2) the area  $A_c^1$  measured between the bottom and the water level at the time the flow (Q) has its maximum value ( $Q_{max}$ )

Reference is made to Figure 2. For the ebb situation  $A_c$  and  $A_c^1$  are not much different. For the flood, however, there is a considerable difference between  $A_c$  and  $A_c^1$ .

Figure 2: Tide and Flow Characteristics

### Method of Analysis

The following hydraulic and morphological parameters were included in the analysis:

$\bar{v}$ : mean velocity over tidal period ( $\text{m sec}^{-1}$ )

$v_{\text{max}}$ : maximum velocity  $\frac{Q_{\text{max}}}{A}$  ( $\text{m sec}^{-1}$ )

$Q_{\text{max}}$ : maximum tidal flow through cross-section ( $\text{m}^3/\text{sec}$ )

$\Omega_{\text{flood}}$ : tidal volume ( $\int Q dt$ ) during flood ( $\text{m}^3$ )

$\Omega_{\text{ebb}}$ : tidal volume during ebb ( $\text{m}^3$ )

$A_C$ : cross-sectional area below NAP ( $\sim$ MSL) ( $\text{m}^2$ )

$A'_C$ : cross sectional area below level at which  $Q_{\text{max}}$  occurs ( $\text{m}^2$ )

$\tau_s$ : stability shear stress ( $\text{N}/\text{m}^2$ )

$C$ : Chézy coefficient ( $\text{m}^{1/2} \text{sec}^{-1}$ )

A regression analysis between morphological and hydraulic parameters has been carried out for various cross-sections (Fig. 1). The statistical significance of the relationship tested is expressed by the value of the calculated correlation coefficient.

In the regression analysis the cross-section is used as the independent parameter, and is plotted horizontally in various graphs.

In Bruun and Gerritsen (3) the stability shear stress was used as a parameter of tidal inlet cross-sectional stability. It was defined as the mean bottom shear stress along a cross-sectional profile at maximum flow conditions during spring tide.

The use of springtide was selected because bedforming flow conditions occur during that phase of the tide. To some degree this corresponds with the calculation of the tidal prism in O'Brien (9) where for the U.S. West Coast the difference between MHHW and MLLW is used as basis for the calculations.

In this study all data have been referenced to mean tide conditions; regarding the stability shear stress values with reference to both mean tide and springtide were calculated.

The general formulation of the mean shear stress in a channel cross-section may be given by:

$$\tau = \rho g R S \quad (4)$$

where R is the hydraulic radius of the channel and S the slope of the energy gradient line.

Using the Chézy expression for the average channel velocity v:

$$v = C \sqrt{RS} \quad (5)$$

The mean shear stress can be expressed in terms of v:

$$\tau = \rho g \frac{v^2}{C^2} \quad (6)$$

and since  $v = \frac{Q}{A}$ , also in terms of Q:

$$\tau = \rho g \frac{Q^2}{C^2 A^2} \quad (7)$$

From equation (7) the stability shear stress is defined by:

$$\tau_s = \rho g \frac{Q_{\max}^2}{C^2 A^2} \quad (8)$$

where  $Q_{\max}$  is the maximum tidal flow during springtide for either ebb or flood conditions.

From equation (8) the cross-sectional area A can be expressed in terms of stability shear stress by the equation:

$$A = \frac{Q_{\max}}{C \sqrt{\tau_s / \rho g}} \quad (9)$$

In a correlation diagram between  $\frac{Q_{\max}}{C \sqrt{\tau_s / \rho g}}$  and A a line under  $45^\circ$  will be obtained if proper values for C and  $\tau_s$  are introduced.

For the cross-section value in equation (9) both the quantities  $A_c$  and  $A_c^2$  have been utilized in the regression analysis.

Stability shear stress for a combined effect of current and wave conditions.

In the outer part of the estuary the sediment transport by tidal currents is affected by waves.

As a first attempt to evaluate the effect of wave action on the stability shear stress parameter the formula developed by Bijker (2) was used to describe the bedload transport as a function of waves and currents. It is realized that the bottom sediment in this area is comparatively fine and therefore transport in suspension dominates. The use of the Bijker formula may still be valid because of the relationship between bedload transport and transport in suspension.

The Bijker formula can be written in the form:

$$Q_b = BD \frac{v}{C} \sqrt{\frac{\tau_c}{\rho}} e^{-\frac{0.27 \Delta D \rho g}{\mu \tau_c \left\{ 1 + \frac{1}{2} \left( \xi \frac{u_0}{v} \right)^2 \right\}}} \quad (10)$$

where  $Q_b$  = bedload transport

$B$  = dimensionless coefficient

$C$  = Chézy coefficient

$\tau_c$  = bottom shear stress from currents only

$v$  = mean velocity over profile

$u_0$  = maximum orbital velocity near the bottom induced by waves

$\Delta$  = relative sediment density =  $\frac{\rho_s - \rho}{\rho}$

$\rho$  = density of sea water

$\rho_s$  = density of sediment

$g$  = acceleration of gravity

$\mu$  = ripple coefficient

$\xi$  = factor to increase shear stress in a combination of current and waves

An equivalent shear stress  $\tau'$  is now defined in such a manner that transport by currents and waves and shear stress  $\tau'_s$  is equal to the transport without waves and shear stress  $\tau_s$ .

This gives the relationship:

$$\tau_s e^{-\frac{0.27 \Delta D \rho g}{\mu \tau_s}} = \tau'_s e^{-\frac{0.27 \Delta D \rho g}{\mu \tau'_s \left\{ 1 + \frac{1}{2} \left( \xi \frac{u_0}{v} \right)^2 \right\}}} \quad (11)$$

The values of  $\tau_s^i$  can be calculated using the above relationship and can be used in stability relationships for the outer estuary (profiles 12, 13, Figure 1). The value of  $u_0$  is related to wave height, wave period and depth.

4. RESULTS OF INVESTIGATIONS

Mean tidal velocity ( $\bar{v}$ )

In past studies (v.d. Kreeke and Haring, (7)), the mean tidal velocity has been used as a reference velocity for stability. Its value is defined by:

$$\bar{v} = \frac{\Omega_{flood} + \Omega_{ebb}}{AT}$$

where  $\Omega_{flood}$ ,  $\Omega_{ebb}$  are respectively the flood and ebb volumes of a tidal cycle, also called tidal prism.

Figure 3 shows the value of this velocity along the axis of the estuary, as well as the cross-sectional areas at the same locations.

Figure 3: Variation in cross-sectional area and tidal velocity,  $\bar{v}$ , along longitudinal axis of the estuary.

The geometry of the estuary shows profiles at stations 7 and 11 to be smaller than would be expected from the general trend due to restrictions in the natural width at these locations. The graph for the mean tidal velocities show bumps in these locations (7,11) accordingly.

The general trend is a fairly constant value of 0.55 m/sec for  $\bar{v}$  for the upper 30 km and a decrease in value for the outer portion of the estuary (profiles 12, 13) to 0.45 m/sec.

#### Maximum tidal velocities ( $V_{max}$ )

The trend in maximum velocities is shown in Figure 4. Maximum flood velocities are considerably higher than maximum ebb velocities and show greater modulations. Part of this is due to the width restrictions in profiles 7 and 11. In profile 7 the maximum flood velocity (averaged over profile) is 1.25 m/sec.

Seaward of profile 11 maximum velocities also decrease significantly in seaward direction.

Figure 4: Variation in cross-sectional area and maximum tidal velocity,  $V_{max}$ , along longitudinal axis of the estuary.

#### Maximum flow ( $Q_{max}$ )

In earlier studies (Bruun and Gerritsen, (3)), it was found that  $Q_{max}$  was a useful parameter to characterize a stable channel. This was confirmed in this study.

It appears from the analysis that the use of  $A_C$  gives a slightly better result than that of  $A_C^i$  (contrary to expectations).

Figure 5 gives the regression using the  $A_C^i$  for flood and ebb.

Figure 5: Regression  $Q_{max}$  versus  $A_c^1$   
(A) Flood; (B) Ebb.

The dotted line is for  $Q_{max} = A_c^1$  (in metric units). Flood flows are somewhat higher and ebb flows somewhat lower than this dotted line relationship.

This corresponds to higher maximum flood currents compared to the maximum ebb current as shown in Figure 4. The profiles 12 and 13 do fit the general relationship for flood but they do not fit the relationship for ebb.

The sinusoidal maximum flow ( $\hat{Q}$ )

Another useful parameter for regression analysis is the sinusoidal maximum flow,  $\hat{Q}$ , defined by

$$\hat{Q} = \frac{\pi(\Omega_{\text{flood}} + \Omega_{\text{ebb}})}{2T}$$

The correlation  $\hat{Q}$  versus  $A_C$ , has a correlation coefficient of 0.990, for profiles 1-11.

Van de Kreeke and Haring (7) found for the relation between  $\hat{Q}$  and  $A_C$  (for inlet portion only):

$$A_C = 1.117 \hat{Q}$$

This study gives (for profiles 1-11 only)

$$A_C = 1.08 \hat{Q}$$

with profiles 12 and 13 deviating from this relationship.

Tidal prism ( $\Omega$ )

The correlation between tidal prism and cross-sectional area  $A_C$  is shown in Figure 6 for flood and ebb.

The solid lines represent the average regression for profiles 1-11. The difference between the lines for  $\Omega_{\text{flood}}$  and for  $\Omega_{\text{ebb}}$  is very small.

Again the profiles 12 and 13 do not fit the average relationship for the profiles 1-11. The deviations are almost equal for flood and for ebb.

Stability shear stress ( $\tau_s$ )

In order to satisfy the identity expressed in equation (9) a certain value for the stability shear stress must be selected. Again it was found that the behavior of profiles 12 and 13 differed from the other profiles (1-11). The values of the stability shear stress which had to be introduced to obtain a satisfactory identity are presented in table 1. Values are given for mean tide as well as for spring tide.

Figure 6: Regression  $\Omega$  versus  $A_c^1$   
(A) Flood; (B) Ebb.

Figure 7: Regression  $\frac{Q_{max}}{C \sqrt{\tau_s} \rho g}$  versus  $A_c^1$   
(A) Flood; (B) Ebb.

Table 1. Values of stability shear stress, profiles 1-11 (N/m<sup>2</sup>)

Tide	Average $\tau_s$ (1-11)	$\tau_s$ (ebb)		$\tau_s$ (flood) (1-11)
		(1-5)	(6-11)	
Mean tide	3.90	4.00	4.90	3.30
Spring tide	5.00	5.00	6.50	4.30

For the calculation of the required values of  $\tau_s$ , values for the Chézy coefficient must be introduced. Based on earlier studies in the Western Scheldt (Beyl (1)), the following relationships were used to calculate C:

$$\text{flood: } C = 56.9 v^{0.48} \text{ m}^{1/2}/\text{sec.}$$

$$\text{ebb: } C = 42.9 v^{0.28} \text{ m}^{1/2}/\text{sec.}$$

The results of the regression analysis (based on  $A_C^1$ ) are shown in Figure 7, indicating good agreement for profiles 1-11. In section 3 it was proposed to adjust the stability shear stress in areas where currents and waves affect the sediment transport. A method to calculate a representative shear stress, based on the Bijker formula, was suggested.

Introducing the modified stability shear stress  $\tau_s^1$  as proposed in section 3, corrections for the profiles 12 and 13 can be made. These are shown as 12<sup>a</sup> and 13<sup>a</sup> in Figures 7A and B. Regarding Figure 7A which describes flood conditions, the corrections for profiles 12 and 13 to points 12<sup>a</sup> and 13<sup>a</sup> bring the latter very well in agreement with the other profiles. For the ebb, (Figure 7B) there is considerable improvement but the fitting of 12<sup>a</sup> and 13<sup>a</sup> into the general curve is not quite satisfactory. A possible reason for the difference between flood and ebb may lie in the way the Chézy coefficients were calculated. The C-values used in the calculations may deviate from the actual C-values for those profiles.

Overall, however, the method suggested seems to be promising to bring all data of the entire estuary into one regression relationship.

#### Flood and ebb channels

For various flow parameters correlations have been determined for a number of well defined flood and ebb channels.

In general correlation coefficients of the same order of magnitude were found.

## 5. CONCLUSIONS

The study of the stability relationships for the Western Scheldt Estuary has led to the following conclusions:

- (1) The correlation coefficient ( $\gamma$ ) for the regression between various flow parameters and the cross-sectional area, for profiles 1-11, decreases in the following order:

1. $\frac{Q_{\max}}{C \sqrt{\tau_s / \rho g}}$	versus $A_C^1$ :	$\gamma_{\text{flood}} = 0.994$
		$\gamma_{\text{ebb}} = 0.995$
2. $\Omega$	versus $A_C$ :	$\gamma_{\text{flood}} = 0.988$
		$\gamma_{\text{ebb}} = 0.991$
3. $Q_{\max}$	versus $A_C$ :	$\gamma_{\text{flood}} = 0.978$
		$\gamma_{\text{ebb}} = 0.985$

- (2) For the separate tidal channels the same sequence is found for the flood channels. For the ebb channels the sequence is 1-3-2.
- (3) Profiles 12 and 13 generally deviate from the regression relationships established for profiles 1-11. Exceptions are the relationships  $Q_{\max}$  versus  $A_C$  and  $Q_{\max}$  versus  $A_C^1$  for flood.
- (4) Profiles 12 and 13 also fit in the relationship  $\frac{Q_{\max}}{C \sqrt{\tau_s / \rho g}}$  versus  $A_C^1$ , for flood if  $\tau_s$  is adjusted to  $\tau_s^1$  accounting for wave action.
- (5) The values for  $\tau_s$  found for the Western Scheldt corresponds very well with the values established by Bruun and Gerritsen (3).
- (6) The established relationships have correlation coefficients between 0.95 and 0.99. It appears that these relationships may be utilized in one-dimensional tidal models for the calculation of changes in profiles as a result of changes in external boundary conditions such as in dredging operations.

## CHAPTER TWO HUNDRED SIX

### EFFLUENT DISPERSAL IN EUROPEAN COASTAL WATERS

D. PRANDLE

Institute of Oceanographic Sciences, Bidston Observatory,  
Merseyside, L43 7RA, U.K.

#### ABSTRACT

The mixing of dissolved material discharged from the Windscale nuclear re-processing plant is examined. The first phase involves a numerical modelling study of large-scale long-term mixing over the entire Continental Shelf. The second phase involves a similar modelling study of near-source mixing processes over a region some 100 km square immediately adjacent to the discharge position. In this latter phase, reproduction of instantaneous peak concentrations is required.

The first phase of this simulation has been successfully completed while the second phase is presently being considered. Ironically, it is shown that this second phase poses far more difficult modelling problems and hence the accuracy of simulation attained in the first phase may not be reproduced. The contrasts in these two modelling approaches are examined and their varying complexities explained.

#### 1. INTRODUCTION

The long-term residual circulation of the waters over the European Continental Shelf is of interest for studies such as : the dispersal of pollutants, the dynamics of marine biology and marine chemistry, sediment transport etc. Several numerical models have been formulated to simulate both the tidal and wind-driven dynamics, these models have provided estimates of residual circulation. Some of these estimates are in reasonable agreement as might be expected from the basic similarity in the models. Confidence in such models must be established by verification against actual observed data. However, a preponderance of small-scale variability allied to inadequate instrumental accuracy obstructs direct measurement of the residual circulation.

Since 1963 various substances have been discharged at monitored rates by pipeline into these coastal waters from the nuclear re-processing plant at Windscale (see figure 1). A number of these substances are non-existent in natural form and their introduction is almost exclusively from Windscale. Thus by modelling the mixing processes of such substances and comparing, through time, observed and calculated distributions the validity of the calculated residual circulation can be established. In the present study, Caesium 137 ( $^{137}\text{Cs}$ ) was adopted as a suitable trace material since it remains almost entirely in dilution and with a half-life of 30.1y retains sufficient mass over the time scale of interest.

Regular monitoring of the spread of  $^{137}\text{Cs}$  has revealed a net transport northwards out of the Irish Sea, then proceeding in a confined coastal zone around the Scottish Coast into the North Sea. Much of the material then flows in an anti-clockwise gyre southwards along the English coast, eastwards along the Continental coast and finally, some 5 years after the discharge, the material flows northwards along the Norwegian Coast.

The spread of  $^{137}\text{Cs}$  may be conveniently partitioned into two phases. The first phase concerns movement over a region approximately 1500 km square embracing the entire Continental Shelf region while the second phase covers movement over a region some 100 km square immediately adjacent to the discharge point. In the first case, the aim was to reproduce mean concentrations averaged over large spatial areas and long time periods while in the second case maximum instantaneous peak concentrations are of concern. (Chatwin and Allen (1985) emphasise the important difference in such requirements). The large scale simulation has been successfully completed (Prandle 1984). Here we summarise the approach used in this simulation and thence outline the related difficulties associated with the near-source simulation.

Perhaps unexpectedly, the near-source problem is shown to be more complex, as a simple illustration of this finding we now examine the relative values of advection and dispersion in mixing processes. The time scale,  $t_A$ , for a pollutant to travel a distance  $L$  when transported by an advective velocity  $U$  is simply  $L/U$ . The time scale,  $t_D$ , for a pollutant to spread over a region  $L$  squared by dispersive processes is  $L^2/K$  where  $K$  is the horizontal dispersion coefficient. Thus a rough comparison of the relative effectiveness of these two processes is given by the Peclet Number,  $Pe$  where

$$Pe = \frac{t_A}{t_D} = \frac{L/U}{L^2/K} = \frac{K}{LU} \quad (1)$$

For values of  $Pe \ll 1$  advection predominates whereas for  $Pe \gg 1$  dispersion predominates. In the present region residual velocities

are of the order of  $1 \text{ cm s}^{-1}$  and  $K \approx 10 \text{ cm}^2 \text{ s}^{-1}$ , hence for distance greater than 100 km from the source advection predominates whereas for distances less than 1 km dispersion predominates. Thus we immediately see that the near-source problem is likely to be more complex since both mixing processes are equally important.

Figure 1.  
Extent of the numerical model of the European Continental Shelf.

## 2. HYDRODYNAMIC MODEL OF THE CONTINENTAL SHELF

The boundaries of the numerical model extend over the complete region shown in figure 1. The location of these open-boundaries in deep oceanic waters beyond the Shelf Edge allowed two important assumptions to be introduced into the prescription of external boundary conditions.

- (i) Variations in mean sea level or any attendant residual flow in the ocean can be neglected since numerical simulations show that the Shelf is effectively isolated from such residual forcing terms.
- (ii) The concentration of  $^{137}\text{Cs}$  was set to zero, reflecting the near-infinite sink capacity of the deep ocean.

Figure 2.

Residual tidal flow, streamlines in  $10^4 \text{ m}^3 \text{ s}^{-1}$ .

Tidal forcing, emanating from the North Atlantic, is the major energy source driving the Shelf Seas. Moreover, within this tidal forcing, the single lunar semi-diurnal constituent  $M_2$  predominates to an extent that in most locations the amplitude of  $M_2$  is greater than the sum of all other constituent amplitudes. These two characteristics permit the following assumptions to be made in the large-scale long-term simulation.

- (i) the net tidal residual may be approximated by the  $M_2$  residual
- (ii) the equations of motion for wind-driven and density-driven flows may be linearised using coefficients derived simply from the  $M_2$  tide.

Figure 3.  
Response to a westerly wind (mean stress of  $0.529 \text{ dyn cm}^{-2}$ ),  
streamlines in  $10^4 \text{ m}^3 \text{ s}^{-1}$ .

In consequence of (i) and (ii), the net residual motion at any time can be reasonably approximated by linear superposition. Thus, first we computed the (linear) response to (a) a westerly wind stress of unit magnitude and (b) a southerly wind stress of unit magnitude. Then for any specific period we simply add to the tidal residual the results from (a) multiplied by the relevant westerly wind stress and likewise for (b).

Limitation of computer capacity (even using a Cray machine) dictated the use of a vertically-averaged numerical model. Some allowance for density-driven residuals was made by including longitudinal density gradients. However, in general these were shown to be small except for certain localised regions and hence this forcing term was neglected in subsequent simulations.

Figure 4.

Response to a southerly wind (mean stress of  $0.435 \text{ dyn cm}^{-2}$ ),  
streamlines in  $10^4 \text{ m}^3 \text{ s}^{-1}$ .

Figure 2 shows the  $M_2$  tidal residual flow, figures 3 and 4 the residual flows corresponding to the long-term mean wind stress from the west and south respectively. In obtaining these results it is important to recognise the reliance on earlier work namely :

- (i) oceanic tidal measurements made by Cartwright et al. (1980)
- (ii) modelling of North Atlantic tides by Flather, IOS Bidston - to be published
- (iii) evaluation of appropriate long-term wind stress data (Thompson et al. 1983)

Figure 5.

Net residual flow (tide + winds), streamlines in  $10^4 \text{ m}^3 \text{ s}^{-1}$ .

Early confidence in the results shown in figures 2 to 4 was established by comparison with (a) related modelling studies and (b) indirect observational data. With residual currents of typically 1 or 2  $\text{cm s}^{-1}$  superimposed on to tidal currents often exceeding  $100 \text{ cm s}^{-1}$  it is difficult to obtain reliable observational data using existing current meters. However, the validity of the net residual flow pattern (figure 5) was finally established by comparing the computed mean sea level variations (which coincide with the residual flow distributions) with the observed variations in m.s.l. deduced by Rossiter (1967). The close agreement illustrated in figure 6 provided the necessary confidence in the hydrodynamic model to proceed to the development of a mixing model.

Figure 6.

Mean sea level variation (tide + winds) in cm,  $\bullet$  observed value from Rossiter (1967).

### 3. MIXING MODEL OF THE CONTINENTAL SHELF

Tides represent a well-ordered spectrally narrow phenomenon and thus their propagation is more amenable to numerical simulation than mixing processes which occur over a much wider spectral range and involve random processes.

#### 3.1 Numerical dispersion

A low-order difference scheme was used, this scheme introduces additional numerical dispersion such that the dispersion coefficient  $K$  is increased by  $\delta K$  given by (Roache 1976)

$$\delta K = \frac{1}{2} (u \Delta x - u^2 \Delta t) \quad (2)$$

Since stability requires  $\Delta x / \Delta t > u$ , in most cases  $\delta K \rightarrow \frac{1}{2} u \Delta x$ . The model grid size  $\Delta x = 35$  km and hence to keep  $\delta K < K$  ( $\approx 5 \times 10^6 \text{ cm}^2 \text{ s}^{-1}$ ) required  $U < 3 \text{ cm s}^{-1}$ . Thus to avoid excessive numerical dispersion it was necessary to drive the mixing model using only the residual flow field. Dispersion due to oscillatory tidal motions was introduced by defining the dispersion coefficients  $K_x$  and  $K_y$  in terms of the  $M_2$  tidal current amplitudes  $\hat{U}$  and  $\hat{V}$  (along orthogonal  $x$  and  $y$  axes respectively) as follows :

$$K_x = 1000 \hat{U} (\hat{U}^2 + \hat{V}^2)^{1/2} \quad \text{and} \quad K_y = 1000 \hat{V} (\hat{U}^2 + \hat{V}^2)^{1/2} \quad (\text{cm}^2 \text{ s}^{-1}) \quad (3)$$

The inclusion of only residual motions yielded the advantage of enabling a time step of  $\Delta t = 12\text{h}$  (from  $\Delta t < \Delta x / u$ ) to be used in the mixing model, whereas simulation of oscillatory tidal motion would require  $\Delta t \approx 0.5\text{h}$ .

#### 3.2 Model evaluation

Discharges of  $^{137}\text{Cs}$  from Windscale started in 1963 with the major discharges occurring in the decade 1970 to 1980. Discharges from other sources may be neglected in comparison with Windscale. Using wind stress data from this period from Thompson (1983). Figure 7 indicates observed and computed concentrations over the Shelf for May 1983 and August 1979. In view of the many simplifications and approximations inherent in the modelling approach, the level of agreement shown was judged to be highly satisfactory.

Sensitivity tests were carried out setting (i)  $K_x = K_y = 0$  and (ii) increasing both  $K_x$  and  $K_y$  by a factor of 5. The computed concentrations showed significant changes in both cases thus indicating that the level of agreement illustrated in figure 7 was a consequence of accurate specification of  $K_x$  and  $K_y$ . Similar sensitivity tests were carried out setting wind stress values to zero, these tests indicated that good reproduction of  $^{137}\text{Cs}$  distributions also depended on accurate specification of the wind-induced advective transport. Thus it was shown that correct simulation of the spread of  $^{137}\text{Cs}$  depends on accurate reproduction of both advection and dispersion.

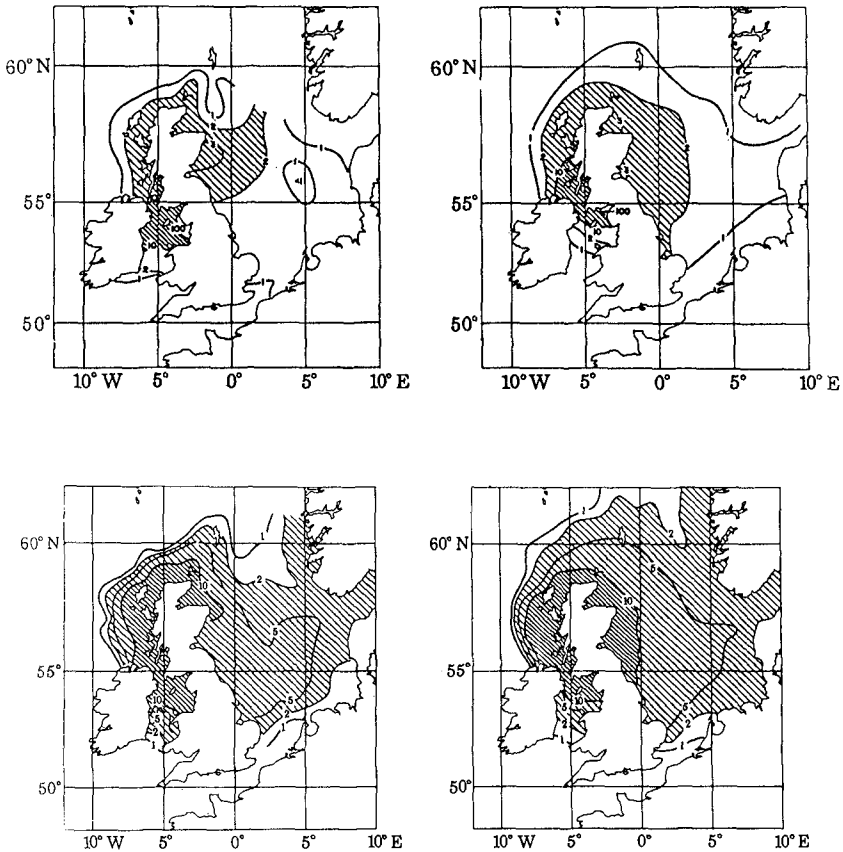

Figure 7.

Observed (left) against computed (right) levels of  $^{137}\text{Cs}$  ( $\mu\text{Ci l}^{-1}$ ) in May 1973 (top) and August 1979 (bottom)

Figure 8.

'Turn-over-times' for model grid-boxes in days, (grid size 20' lat. x 30' long.)

## 4. MIXING TIME SCALES OF THE CONTINENTAL SHELF

Having validated both the hydrodynamic and mixing models it is useful to calculate pertinent time-scales associated with water quality studies.

Figure 8 shows,  $T_f$ , the 'turn-over-time', or 'flushing time' associated with each grid box of the model. The value  $T_f$  corresponds to the time taken for the concentration within a grid box to be reduced by a factor  $1/e \approx 0.37$  when all surrounding boxes have an initial zero concentration. The actual values of  $T_f$  are a function of grid size, however the variation in values is of interest. In particular, when areas of large  $T_f$  (sluggish circulation) lie close to areas of small  $T_f$  (vigorous circulation) we might expect to see the formation of thermal fronts at certain seasons.

Figure 9 shows the 'age',  $T_a$  of material released from Windscale where  $T_a$  represents the average travel time between discharge and arrival at any location. In simple terms, the distribution of  $T_a$  is shown to be a combination of radial dispersion from the source modified by the advective transport paths shown earlier.

Figure 9. Age (in years) of material discharged from Windscale.

## 5. SIMULATION OF NEAR-SOURCE MIXING

The interest in localised instantaneous peak concentrations in this region precludes the approach used in the earlier study whereby wind-driven residual flows and tidal residuals were superposed. The requirement to simulate hour by hour motions dictates that real-time surge-tide and tide-tide non-linear interactions must be incorporated (Prandle and Wolf 1978).

In the hydrodynamic section of the model the above requirements mean that boundary conditions must be supplied from an external model dynamically meshed with the 100 km square region of immediate interest. Similarly the specification of concentrations along the boundary of this inner region must involve some real-time simulation of the external region. In both cases, the extent of the meshed external region will be governed by the duration of events to be simulated. For the hydrodynamic model, the speed of propagation of surface gravity waves means that far-distant boundaries are necessary to avoid spurious reflections. However, for the mixing model, lower mass-propagation speeds allow for closer location of external boundaries.

The success of the earlier study suggested that, in most regions, vertical mixing was sufficiently intense to render the problem effectively two-dimensional. Moreover, careful examination of the wind and tidally-driven residual streamlines reveals a close similarity which may be explained by the existence over large areas of a near-geostrophic balance which produces topographic steering of flow along depth contours. Thus, what appears initially to be a three-dimensional mixing problem is effectively reduced to a one-dimensional problem. To a large extent, one-dimensional mixing problems enjoy a self-correcting mechanism whereby an excess of wind-driven advection for one month may be effectively counter-balanced by a corresponding reduction in the next. Unfortunately, the near-source mixing problem is fully three-dimensional with complications including density fronts.

One advantage in the smaller model concerns numerical dispersion. Thus from (2) with a grid size of 1 km and tidal currents less than 50 cm/s, the level of numerical dispersion may be sufficiently contained to allow simulation of tidal oscillatory motions, such simulation is clearly required. If numerical dispersion is found to be troublesome some corrective scheme would have to be employed (see for example Zalesak 1979, Smolarkiewicz 1984).

## 6. SUMMARY AND CONCLUSIONS

The success of the large-scale long-term simulation of mixing over the Continental Shelf can be attributed to the following :

- (i) Siting of open-sea boundaries beyond the Shelf edge thereby providing suitable boundary conditions for both the hydrodynamic and mixing models.
- (ii) Predominance of the  $M_2$  tidal constituent, obviating the necessity to consider other tidal constituents and permitting wind-driven residual flow to be linearly superposed.
- (iii) Availability of excellent field data including oceanic and coastal tide gauges and comprehensive surveys of  $^{137}\text{Cs}$  distributions.
- (iv) Strong vertical mixing combined with a near-geostrophic balance for residual flows effectively reduce a 3 dimensional problem to a one-dimensional problem with flow confined to fixed streamlines. Under these conditions a degree of self-correction exists in relation to temporal variations in the advective motions.

The second phase of this study involves a near-source simulation with particular interest in maximum instantaneous concentrations. This study is directly analogous to typical coastal engineering problems involving dispersion from power stations or sewage treatment plants. Unfortunately, none of the above factors apply to this second phase and hence, ironically, a more complex modelling approach is required and the accuracy of simulation is likely to be reduced.

The work described in this paper was funded by the Natural Environment Research Council and by the Ministry of Agriculture, Fisheries and Food.

## CHAPTER TWO HUNDRED SEVEN

### Mathematical Modelling of Water-quality for long time periods

P Huizinga\*

#### ABSTRACT

This paper presents a one-dimensional dynamic water-quality model suitable for long-term application to estuaries. The computation techniques used in the model are very simple, but very good results have been obtained both for theoretical test cases and from applications to estuaries when compared with prototype measurements.

#### 1. INTRODUCTION

To investigate water-quality problems in several narrow tidal estuaries in South Africa a mathematical model was required which could be applied easily and economically for long-period investigations. The model presented in this paper has certain features similar to that described by Orlob (1972) and in applying the model in combination with a one-dimensional explicit hydrodynamic model, very good results were obtained.

A brief description is given of the method employed. Some test results are shown of simulations in theoretical channels. The paper includes calibration and verification results of an application to the Knysna estuary, which is located 500 km east of Cape Town on the south coast of South Africa, as well as results of investigations of the effect of changes in fresh-water inflow on the salinity distributions in this estuary.

#### 2. THE COMPUTATIONAL METHOD

##### 2.1 General

One-dimensional advection and dispersion is described by the formula (see list of symbols):

$$\frac{\partial(\text{Vol}.C)}{\partial t} = \frac{\partial(Ax.K.\frac{\partial C}{\partial x})}{\partial x}.dx - \frac{\partial(Ax.u.C)}{\partial x}.dx \quad (2-1)$$

Extra terms can be included for other phenomena such as breakdown and growth or lateral inflows of contaminants.

Computational schemes are often designed for a simplified version of this equation in which constant velocity, depth and cross-sectional area are assumed:

\* National Research Institute for Oceanology, Stellenbosch, Republic of South Africa.

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} = K \frac{\partial^2 C}{\partial x^2} \quad (2-2)$$

Mathematical models based on this formula can give very good results if applied to channels and rivers with almost constant flow and cross-sectional area. They should not be applied to estuaries with complex topography and under tidal influence.

The computational method on which this model is based is similar in certain respects to that described by Orlob (1972). In principle it is based on a finite difference approximation of the equation 2-1. It consists of two stages per timestep, first, the total advective and diffusive transport between nodes are computed, in other words the right-hand side of formula 2-1 is computed. Then, knowing the change in volume in a node and also the in- and outflow volumes and concentrations, the new concentration for each node can be computed. Special routines are used to handle side branches with splitting points and positions where pollutants are released.

## 2.2 Advective Transport Computation

The advective transport through a cross-section during a time-step can be computed directly from the flow through that cross-section for that timestep multiplied by the average concentration. For section M-1 or between nodes N-1 and N on Figure 1 this transport is:

$$ATR_{M-1} = Q_{M-1} \cdot C_{M-1} \cdot \Delta t \quad (2-3)$$

Figure 1.

Similarly for section M:

$$ATR_M = Q_M \cdot C_M \cdot \Delta t \quad (2-4)$$

If there are no side branches at nodes N-1, N or N+1 a linear interpolation together with a slight correction due to the velocity U can be made to determine C<sub>M</sub>.

$$C_M = C_N + (C_{N+1} - C_N) \cdot (0,5 \cdot dx_M - 0,5 \cdot U_N \cdot \Delta t) / dx_M \quad (2-5)$$

and

$$C_{M-1} = C_{N-1} + (C_N - C_{N-1}) \cdot (0,5 \cdot dx_{M-1} - 0,5 \cdot U_{M-1} \cdot \Delta t) / dx_{M-1} \quad (2-6)$$

At release positions and at splitting points sudden changes of concentrations can occur. For those situations other interpolation routines are used to estimate concentrations through cross-sections ( $C_M$ ). If  $C_{N+1}$  is a splitting point and  $C_N$  not, then  $C_M$  is determined by linear extrapolation from  $C_{N-1}$  and  $C_N$ . If this would cause negative values for  $C_M$ , then  $C_M$  is set equal to zero. If  $C_N$  and  $C_{N+1}$  are splitting points and the flow is to the right then  $C_M$  is taken to be equal to  $C_N$ .

### 2.3 Dispersive Transport Computation (Figure 1)

Dispersion in estuaries has been extensively described by many authors (see for example, Fisher, 1979), but no predictive formula exists that can be generally applied to determine the dispersion coefficient ( $K$ ) For a number of tests described in this report the coefficient was determined as suggested by Leendertse (1970). This consists of a constant part and a part dependent on velocity, depth and Chezy-coefficient.

$$K = \frac{Df/U \cdot R}{C_F} + D_w \quad (2-7)$$

In the salinity tests for the Knysna estuary the dispersion coefficient was determined from the salinity distribution in the estuary and the inflow of fresh water.

$$K = \frac{(\partial S / \partial x)}{(U_n) \cdot S} \quad (2-8)$$

$U_n$  is the net downstream velocity caused by the freshwater discharge.

The dispersive transport through a cross-section (Figure 1) during a timestep ( $\Delta t$ ) is computed by:

$$DTR_{M-1} = -K_{M-1} \cdot (C_N - C_{N-1}) \cdot \Delta t \cdot A_{M-1} / dx_{M-1} \quad (2-9)$$

and

$$DTR_M = K_M (C_{N+1} - C_N) \cdot \Delta t \cdot A_M / dx_M \quad (2-10)$$

### 2.4 Computation of Concentrations

After having computed the transports through all the cross-sections and also knowing the changes in volumes for all the nodes, the next step is to compute the new concentrations at all the nodal points.  $CTR_N$ , the total transport through all the sections leading to nodal point N, is then used to compute the new concentration at node N.

$$C_N^1 = (C_N \cdot \text{Vol}_N + \text{CTR}_N) / \text{Vol}_N^1 \quad (2-11)$$

If N is also an outfall release position, the extra transport towards N due to this outflow is also included in  $\text{CTR}_N$ .

## 2.5 Stability and Accuracy

The water quality model is connected to an explicit one-dimensional hydrodynamic model (CSIR, 1976) and is operated at the same schematization and timestep. This set-up implies certain disadvantages but model simulations have shown that it is a practical combination.

For stability reasons the timestep of the hydrodynamic computation is limited due to the Courant criterion.

$$\Delta t < \frac{\Delta x}{\sqrt{gR}} \quad (2-12)$$

For advective transport only a similar criterion is valid for the water quality computation.

$$\Delta t < \frac{\Delta x}{u} \quad (2-13)$$

The celerity of the long wave ( $\sqrt{gR}$ ) is normally an order of magnitude faster than the water velocity. Therefore, if both models are operated on the same timestep, the Courant criterion for the hydrodynamic model determines the timestep of the computation.

Normally the water level variation with time and distance is gradual, but, variations of concentrations can be sudden which means that the section lengths in the water quality model must be small.

Therefore, in this model combination, the section length is selected first, based on the topography and on the accuracy wanted from the water quality computation, and then the timestep is set, based on the Courant criterion for the hydrodynamic computation.

## 2.6 Adaptation to Topography

The model has facilities to adapt cross-sectional areas, hydraulic radii, surface areas and volumes for increasing and decreasing of water levels, which makes it particularly suitable for applications to tidal estuaries.

# 3. RESULTS IN THEORETICAL CHANNELS

## 3.1 General

A few model tests were done for theoretical channels with rectangular cross-sections to test the quality of the computation techniques.

3.2 Channel with Rectangular Cross-section

Figure 2.

Figure 3.

The results of tests on numerical dispersion in a straight channel are shown in Figures 2 and 3. The channel has a depth of 2 m and a length of 15 400 m. It is open on the left-hand side where a water level variation with an amplitude of 1 m and a period of 12,5 hours was applied, and it is closed off on the right-hand side. The initial distribution of a conservative pollutant is indicated by I.D. and the computed concentrations at high and low water are marked by H.W. and L.W. The graphs at high and low water are plotted at intervals of 25 hours. In the first test (Figure 2) only advective transport was taken into account and in the second test (Figure 3) dispersive transport was computed as well, with a dispersion coefficient of  $6,0 \text{ m}^2/\text{s}$ . The very small deformation of the graphs on Figure 2 shows that the numerical dispersion is very small compared to the dispersion in the second test (Figure 3).

3.3 Channel with Branching

Figure 4.

Figure 5.

Figure 6.

The test described under 3.2 was repeated for a channel in which a portion of the channel was split up into several branches as shown in Figure 4. Figure 5 shows the results from a computation with only advective transport; for those in Figure 6 dispersive transport was also taken into account. The numerical dispersion (Figure 5) is slightly more than in the previous test (Figure 2) but still very small when compared with the simulation in which dispersive transport was included (Figure 6).

3.4 Channel with Constriction

Figure 7.

Figure 8.

Figure 9.

The same test (3.2) as repeated for a channel with a constriction in it (Figure 7). Again the numerical dispersion with only advective transport (Figure 8) is very small compared to the model test in which dispersive transport was also taken into account (Figure 9).

4. APPLICATION TO KNYSNA ESTUARY

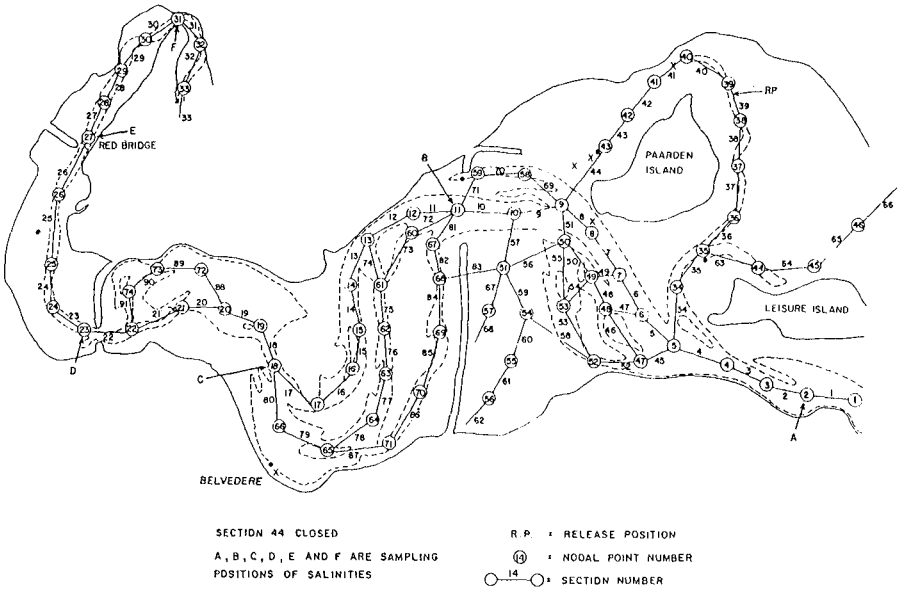

Figure 10.

4.1 General

The Knysna estuary on the south coast of South Africa has a complicated channel system, with extensive flood plains in the downstream area (Figure 10). At the upstream end fresh water from the Knysna river enters the estuary causing gradients in salinity concentrations along

the estuary. Increasing demands for fresh water have led to investigations of the feasibility of extracting water from the Knysna river upstream of the estuary. The problem is to determine the effect this could have on the salinity distributions and variations and on the ecology of the estuary. Salinity concentrations were measured on a certain day, then the river flow was monitored and after a period of about seven days the salinities were measured again. An estimation was made for the dispersion coefficients in the estuary. With these data available, model simulations were done. The starting conditions were the salinity distributions of the beginning of a period. At the open sea boundary a recorded tidal variation was used and at the upstream end the recorded river flow was used for boundary conditions. The salinities computed with the model after the period were then compared with the measured salinities of the corresponding time. A reassessment was then made of the dispersion coefficients and the model simulation was repeated. After a few tests good agreement was achieved between model results and prototype data and the model was considered to be calibrated. Verification runs were done for other periods with equally good results. A number of model tests were then done under different flow conditions for investigating salinity distributions under these circumstances.

#### 4.2 Calibration Tests

In Figure 11A the start condition is shown, which was measured at low water on 18 January 1984 and which was used for the calibration runs. The period covered by the tests was from 18 till 25 January 1984. The river flow was constant at  $0,8 \text{ m}^3/\text{s}$  and at the open sea boundary the water level variation was recorded. A first estimation of the dispersion coefficient ( $K$ ) was made using formula 2.8. In the first calibration test  $K = 45 \text{ m}^2/\text{s}$  was used for all the sections. The model results are compared on Figure 11B for 25 January 1984. The model results are slightly higher compared to the field data in the upstream region (Sections 23 to 33) of the estuary.

A second calibration test was done in which  $K = 45$  for all sections except  $K = 35$  for Sections 23 to 26 and  $K = 25$  for Sections 27 to 32. The model results are now slightly too low at the upstream region of the estuary indicating that the adaptation was a little too drastic (Figure 11C).

A third calibration test was therefore done in which  $K = 45$  for all sections except  $K = 40$  for Sections 23 to 26 and  $K = 35$  for Sections 27 to 32. Figure 11D shows that excellent agreement between model results and field data was achieved. In all further tests these dispersion coefficients were used.

#### 4.3 Verification Tests

The first verification test was done for the period 10 to 17 March 1984. The flow was variable from  $1,82 \text{ m}^3/\text{s}$  on 10/03/1984 to  $2,90 \text{ m}^3/\text{s}$  on 13/03/1984 to  $1,15 \text{ m}^3/\text{s}$  on 17/03/1984. The agreement between model results and prototype data was still good for 17/03/1984, although the river flow data was probably not very accurate (Figure 12B).

A. Simulation 1

B. SALINITIES AT SPRINGTIDE AND RIVER FLOW OF 0.5 m<sup>3</sup>/s

C. SALINITIES AT SPRINGTIDE AND RIVER FLOW OF 0.3 m<sup>3</sup>/s

Figure 14

A second verification test was done for the period 16 to 23 April 1984. The flow data used was  $0,85 \text{ m}^3/\text{s}$  for 16 to 19/04/1984,  $0,70 \text{ m}^3/\text{s}$  for 20 and 21 April 1984 and  $0,60 \text{ m}^3/\text{s}$  for 22 and 23 April 1984. The results again show good agreement between model and prototype results (Figure 12D).

#### 4.4 River Flood Test

On Figure 13 the effects of a minor river flood on the salinities in the estuary is shown. The shape of the hydrograph with a maximum flow of  $40 \text{ m}^3/\text{s}$  is shown on each graph.

At the upstream end of the estuary, positions E and F (see also Figure 10), the salinities drop down to zero but later return to their normal values. The graphs for positions A, B, C and D all show the effects of this flood, with the strongest influence upstream in the estuary and the weakest effect near the estuary mouth. On all the graphs the effect of the spring-neap-spring tidal variation is also visible.

#### 4.5 Tests under different constant-flow conditions (1,0, 0,5 and $0,3 \text{ m}^3/\text{s}$ )

The start condition in all these tests was the salinity distributions as measured at low water on 18 January 1984. The results are shown as graphs of distributions in the main channel of the estuary in Figure 14.

For Sections 1 to 22 all the graphs show little difference between high and low water, but considerably bigger differences for Sections 23 to 33, in the narrow upper channel of the estuary. It can also be seen that the influence of the fresh water inflow is considerable at the upper end of the estuary, but small in the downstream part (Sections 1 to 22).

#### 4.6 Details of Computation

The Knysna model tests were done at a timestep of 30 seconds to fulfil the Courant criterion for the hydrodynamic computation (formula 2-12). As stated before (Section 2.5) the hydrodynamic and water quality computations were done at the same timestep. The operation of the Knysna model on the CDC-cyber 750 computer could be done at a cost of about \$10 a day (prototype time).

### 5. CONCLUSIONS

The model presented is one-dimensional and is also 100 per cent conservative. Simulations with test models of simple geometrical structure show that the numerical dispersion is very small. This numerical dispersion increases slightly at models with irregular topography and networks, but for the test cases described here this dispersion was always very small.

As shown by its application to the Knysna estuary, the model is easily applicable to suitable estuaries, which means estuaries that are

vertically well-mixed and in which two-dimensional horizontal current patterns are negligible.

The calibration and verification runs for the Knysna estuary in particular show the reliability of the model and the subsequent tests for different flow conditions show the potential of the model as a tool for investigations of the influences of these conditions on salinities and these results can be used for further ecological studies.

The model could be developed further to simulate chemical and biological processes, but it would probably be better to use the other existing models, like the Dynamic Estuary Model (DEM) from the Environmental Protection Agency (EPA) in the USA. As mentioned before, the model presented here has similar features to this DEM.

Finally, the present combination of the hydro-dynamical with the water-quality model computations has the disadvantage that the model has to be operated on a small section length (100 to 500 m) and time-step (30 to 60 seconds). It was possible though to carry out the tests at relatively low cost. The Knysna model for example, was operated at about \$10 per day or \$300 per month. This shows that the model can be a practical tool for many investigations at reasonable cost.

#### LIST OF SYMBOLS

ATR	=	advective transport
$A_x, A_N$	=	cross-sectional area at x or N ( $m^2$ )
C	=	concentration ( $kg/m^3$ )
$C_N$	=	concentration of position N ( $kg/m^3$ )
$C_f$	=	Chezy coefficient ( $m^{1/2}/s$ )
CTR	=	sum of all advective and diffusive transport to and from a nodal position
Df	=	constant used which is actually $Df = Df^1 \cdot \sqrt{2g}$ in formula for diffusion coefficient (2-7)
DTR	=	diffusive transport
DW	=	diffusion coefficient ( $m^2/s$ )
$dx_N, dx_M$	=	nodal length at N, section length at M (m)
K	=	dispersion coefficient ( $m^2/s$ )
<u>M</u>	=	identification of section number (also as subscript)
N	=	identification of nodal number (also as subscript)
Q, $Q_M$	=	flow through cross-section (M) ( $m^3/s$ )
R	=	hydraulic radius (m)
S	=	salinity concentration (mg/l)
t	=	time (s)
$\Delta t$	=	timestep of computation (s)
$u_M$	=	mean velocity (m/s)

$u_N$  = net downstream velocity due to fresh water discharge  
Vol = volume ( $m^3$ )  
 $x$  = distance (m)  
<sup>1</sup> = all variables marked like this are on a new time level

## CHAPTER TWO HUNDRED FOUR

### THE EXCHANGE OF WATER IN FJORDS: A SIMPLE MODEL OF TWO-LAYER ADVECTIVE REACHES SEPARATED BY MIXING ZONES

E.D. Cokelet<sup>1</sup>  
R.J. Stewart<sup>2</sup>  
C.C. Ebbesmeyer<sup>3</sup>

We propose a model for the two-layer, mean transport within a branched, recirculating fjord system. The recirculation is parameterized in terms of efflux/reflux coefficients at distinct mixing zones. The mass fluxes and efflux/reflux coefficients are determined from long-term salinity and current meter observations. The model provides a way to predict the mean concentrations of pollutants introduced within the system. An application to Puget Sound shows that different discharge sites markedly affect the concentrations landward of the sites themselves.

#### 1. Introduction

The task of predicting the long-term build-up of pollutants within estuaries is becoming more important with increasing urban and industrial pressure and environmental awareness. Historical data sets are often available on only the density of the seawater via temperature and salinity observations. Modern time-dependent computational models have the potential for being up to the task, but they are expensive to run over simulation periods of several years. We have developed a model for the steady-state circulation within a fjord system based upon the principal of conservation of mass.

In a classical fjord the long-term mean circulation pattern is two-layered with runoff-laden brackish water flowing seaward at the surface and entraining salt water from the slow, landward-flowing lower layer. In such a system a soluble, conservative pollutant added to the upper layer would simply be carried out to sea as if on a conveyor belt. Unfortunately many actual fjords are more complex than this. They consist of a sequence of deep, stratified reaches separated by shallower sills formed by past glaciers. Sometimes one fjord arm may branch into two or more arms at a junction. Mixing

Contribution No. 750 from PMEL

between the layers often occurs at these sills and junctions due to enhanced tidal currents. This intermixing complicates the "conveyor-belt" view of pollutant flushing.

2. Simple Junctions

Our premise is that many fjord systems can be thought of as made of two different components, reaches and mixing zones. In a two-layered reach the mean motion is purely horizontal advection. The two layers communicate only at mixing zones at the ends of each reach. These zones are complex regions where turbulent transport by tidal currents or shorter-period features often dominate the slow mean circulation, but it is not necessary to consider in detail the flows there. The net effect of the mixing zones is expressible solely in terms of the properties of the layers entering and leaving them.

Figure 1. Two reaches meeting at a simple junction mixing zone.

A model for two reaches meeting at a simple junction is shown in Figure 1. The steady mass flux,  $Q_i$ , in any reach layer can be expressed in terms of the salinity,  $S_i$ , and runoff,  $R$ , by Knudsen's Hydrographic Theorem (ref. 3), i.e.,

$$Q_1 = \frac{S_2}{S_1 - S_2} R, \quad Q_2 = \frac{S_1}{S_1 - S_2} R. \quad (1)$$

$S_i$  is the flux-weighted salinity which must be determined from hydrographic and current observations. It is defined by

$$S_i = \frac{1}{Q_i} \int_{A_i} \bar{\rho} \bar{S} \bar{u} \cdot \mathbf{n} \, dA \quad (2)$$

with

$$Q_i = \int_{A_i} \bar{\rho} \bar{u} \cdot \mathbf{n} \, dA. \quad (3)$$

Each integral is evaluated over the cross-sectional area,  $A_i$ , of layer  $i$  with a downstream unit normal  $\mathbf{n}$ . The long-time-mean density, salinity and velocity are  $\bar{\rho}$ ,  $\bar{S}$  and  $\bar{\mathbf{u}}$ , respectively. These equations come from volume integrals of the steady continuity and salinity equations. Molecular diffusivity of salt is neglected as well as mean, turbulent salt transport within the reaches. Furthermore it is assumed that only salinity contributes to the density, hence temperature effects are neglected. Further details can be found in reference 1.

The flow in any layer is apportioned into two parts when it enters a mixing zone. A fraction,  $\alpha_{34}$ , of the landward reach's outflow (layer 4) mixes downward and refluxes into that reach's lower layer 3. The remaining fraction,  $\alpha_{24}$ , effluxes into layer 2. Likewise a fraction,  $\alpha_{21}$ , of layer 1's inflow refluxes seaward in layer 2, and the remainder,  $\alpha_{31}$ , effluxes landward. Conservation of water and salt lead to the following matrix equation for the efflux/reflux coefficients,  $\alpha_{ij}$ :

$$\begin{bmatrix} Q_1 & Q_4 & 0 & 0 \\ S_1 Q_1 & S_4 Q_4 & 0 & 0 \\ 0 & 0 & Q_1 & Q_4 \\ 0 & 0 & S_1 Q_1 & S_4 Q_4 \end{bmatrix} \begin{bmatrix} \alpha_{21} \\ \alpha_{24} \\ \alpha_{31} \\ \alpha_{34} \end{bmatrix} = \begin{bmatrix} Q_2 \\ S_2 Q_2 \\ Q_3 \\ S_3 Q_3 \end{bmatrix} . \quad (4)$$

With the aid of Knudsen's relations the solution becomes

$$\begin{aligned} \alpha_{21} &= \frac{S_1 S_2 - S_4}{S_2 S_1 - S_4} & \alpha_{24} &= \frac{S_1 S_3 - S_4}{S_3 S_1 - S_4} \\ \alpha_{31} &= \frac{S_4 S_1 - S_2}{S_2 S_1 - S_4} & \alpha_{34} &= \frac{S_4 S_1 - S_3}{S_3 S_1 - S_4} . \end{aligned} \quad (5)$$

Hence the flux-weighted salinities lead directly to the efflux/reflux coefficients.

The sum of all coefficients emanating from a layer, i.e. with constant second subscript, must be unity. The  $\alpha_{ij}$  lie between zero and one. For instance, the reflux coefficient in the inner reach,  $\alpha_{34}$ , is zero when the two lower-layer salinities are equal,  $S_1 = S_3$ . It approaches unity and complete recirculation as  $S_3$  approaches  $S_4$  — a limit which can never be reached unless the runoff is negligible.

### 3. N-Tuple Junctions

An N-tuple junction is a mixing zone in which N reaches meet. Figure 2 shows a schematic of one reach branching into two more at a triple junction. The layers are drawn side-by-side for convenience, but usually they are superposed.

Figure 2. Schematic diagram of three reaches meeting at a triple junction. Only three of the nine efflux/reflux coefficients are shown for clarity.

In general  $N$  tracers (fresh water and salt being two) are needed to determine completely the  $N$  efflux/reflux coefficients at an  $N$ -tuple junction. The problem may be formulated in terms of a matrix equation similar to (4). The tracer concentrations must be independent of one another for a solution to exist. If through local knowledge or an independent set of measurements,  $N(N-2)$  efflux/reflux coefficients can be specified, then water and salt conservation are sufficient to determine the system.

An  $N$ -tuple junction with  $M$  rivers directly entering the mixing zone is treated the same as an  $(N+M)$ -tuple junction. The efflux/reflux matrix formulation also applies to a sequence of reaches and mixing zones.

#### 4. Pollutant Fluxes

Suppose a conservative pollutant is continuously injected at a mass rate  $p_i$  by a perfect diffuser at the upstream end of each layer of a simple junction fjord system as in Figure 1. Mass conservation

of the pollutant with concentration  $C_i$  in each layer leads to the following equation:

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ -\alpha_{21} & 1 & 0 & -\alpha_{24} \\ -\alpha_{31} & 0 & 1 & -\alpha_{34} \\ 0 & 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} C_1 Q_1 \\ C_2 Q_2 \\ C_3 Q_3 \\ C_4 Q_4 \end{bmatrix} = \begin{bmatrix} P_1 \\ P_2 \\ P_3 \\ P_4 \end{bmatrix} \quad (6)$$

Here we have assumed that the pollutant mass input rate is negligible compared to the layer fluxes,  $Q_i$ . Inverting yields the steady state concentrations as a function of the efflux/reflux coefficients, mass fluxes, and inputs, i.e.

$$\begin{bmatrix} C_1 \\ C_2 \\ C_3 \\ C_4 \end{bmatrix} = \begin{bmatrix} \frac{1}{Q_1} & 0 & 0 & 0 \\ \frac{1}{Q_2} & \frac{1}{Q_2} & \frac{1}{Q_2} & \frac{1}{Q_2} \\ \frac{\alpha_{31}}{\alpha_{24} Q_3} & 0 & \frac{1}{\alpha_{24} Q_3} & \frac{\alpha_{34}}{\alpha_{24} Q_3} \\ \frac{\alpha_{31}}{\alpha_{24} Q_4} & 0 & \frac{1}{\alpha_{24} Q_4} & \frac{1}{\alpha_{24} Q_4} \end{bmatrix} \begin{bmatrix} P_1 \\ P_2 \\ P_3 \\ P_4 \end{bmatrix} \quad (7)$$

The coefficient  $\alpha_{24}$  plays a crucial role since the concentrations within the landward reach vary as its reciprocal. Hence a small value corresponding to large refluxing will lead to high pollutant concentrations. Equations (6) and (7) can be generalized to more complex fjord geometries, an example of which is given below.

##### 5. The Puget Sound Refluxing Model

The theory outlined above and given more completely in reference 4 has been applied to Puget Sound to provide the first quantitative examination of the long-term behavior of conservative pollutants in the entire system. Figure 3 shows a map of the region which consists of a series of deep, glacially carved channels with typical depths of 60 m to 200 m. Sills due to glacial hanging valleys or terminal moraines separate the various reaches. The main basin off Seattle is about 200 m deep along its axis with a sill at Admiralty Inlet to the north which shoals to 60 m. Near Tacoma the main basin shoals at the Narrows whose sill depth is approximately 40 m. There two sill zones have strong tidal currents (1.5-2.5 m/sec) with vigorous mixing.

Figure 4 shows a schematic of the model with the Puget Sound system divided into 9 two-layer reaches. Usually each seaward flowing layer lies above a landward flowing one, but layers 7 and 8 are an exception. Current meter observations indicate that the mean flow is juxtaposed with a surface-to-bottom mean circulation flowing clockwise around Vashon Island due to tidal rectification. No modifications to the theory are necessary for this case.

Mixing zones occur either at sills, river mouths or multiple junctions. Five mixing zones are simple junctions with rivers entering directly. The indeterminacy associated with each is dispensed with by assuming that all of the buoyant, freshwater river flow leaves the zone via the outflowing surface layer; hence none enters the outflowing bottom layer. The remaining efflux/reflux coefficients for each of the five mixing zones are then uniquely determined from water and salt conservation.

At the head of layer 18 a "leak" through Deception Pass allows salt water and some river water from the second largest river in the system, the Skagit River, to flow directly into layer 4. This is accounted for by making three assumptions based upon limited local observations (ref. 2):

1. 60% of the Skagit River flow exits directly into layer 4, i.e.  $\beta_{4,18} = 0.6$ ,
2. the mean volume flux through Deception Pass is  $1125 \text{ m}^3/\text{sec}$ , and
3. no layer-3 water flows over the shallow, ten-meter-deep sill in the Pass, i.e.  $\alpha_{18,3} = 0$ .

Here  $\beta_{ij}$  represents the efflux coefficient to layer  $i$  from river  $j$  which enters at the head of surface layer  $j$ .

One Puget Sound mixing zone, Admiralty Inlet, is a quadruple junction with a river ( $R_4$ ) entering directly. Water and salt conservation give 8 equations for 20 efflux/reflux coefficients. A variety of possible assumptions have been tried to close the system. The one considered here is that the three surface layers and the river flowing into the mixing zone combine to form an intermediate salinity water. Then this mixes in varying proportions with the inflowing bottom water of layer 3 to supply bottom layers 5, 13 and 17. This leads to the following 12 independent equations which close the system:

$$\begin{aligned}
 \alpha_{4,6} &= \alpha_{4,14} = \alpha_{4,18} = \beta_{4,4} \\
 \alpha_{5,6} &= \alpha_{5,14} = \alpha_{5,18} = \beta_{5,4} \\
 \alpha_{13,6} &= \alpha_{13,14} = \alpha_{13,18} = \beta_{13,4} \\
 \alpha_{17,6} &= \alpha_{17,14} = \alpha_{17,18} = \beta_{17,4}.
 \end{aligned}
 \tag{8}$$

We are interested in the mean circulation over time scales of about one year. The mass fluxes and efflux/reflux coefficients depend critically upon the observed salinity and current distributions through the flux-weighted salinities. Even though Puget Sound has been studied extensively for over 50 years only during one year, December 1953 to November 1954, do sufficient salinity profiles exist at monthly intervals for each reach in the model. Current meter data does not exist for this time but is available sporadically, being principally concentrated in the 1970's with a varying degree of spatial coverage. Thus we use a synthesized data set consisting of 1953-54 runoff and salinity data and available current observations. The technique of combining this data to provide rational estimates of the flux-weighted salinities is beyond the scope of this paper but is presented in reference 4.

Typically the flux-weighted annual mean salinities in the system are about 30‰. Landward of layers 5 and 6 the total runoff is about 400 m<sup>3</sup>/sec which, combined with a bottom-to-surface salinity difference of about 1‰, gives a net volume flux from Knudsen's relations (1) of approximately 12,000 m<sup>3</sup>/sec. Column 2 of Table 1 shows the calculated volume fluxes for each layer. Fluxes in layers 1 and 2, the Strait of Juan de Fuca, are large due to the large runoff from river 2 (the Fraser River) of over 5000 m<sup>3</sup>/sec. The flux values are somewhat dependent upon how the salinity and current meter data are analyzed as explained in reference 4.

Table 1. Predicted Volume Fluxes and Pollutant Concentrations, C<sub>i</sub>, in Puget Sound.

Layer i	Volume Flux (10 <sup>3</sup> m <sup>3</sup> /sec)	C <sub>i</sub> due to Layer-6 Input (µg/kg)	C <sub>i</sub> due to Layer-7 Input (µg/kg)
1	116	0	0
2	123	8	8
3	40	21	21
4	42	44	44
5	13	66	66
6	14	137	137
7	19	65	141
8	19	64	139
9	14	64	139
10	14	63	137
11	4.3	64	138
12	4.4	63	136
13	6.3	60	60
14	6.5	58	58
15	2.2	60	60
16	2.4	56	56
17	2.1	79	79
18	1.6	67	67

The model in Figure 4 has 54 efflux/reflux coefficients of which 12 are specified by the assumptions of the previous paragraphs. The remaining 42 are determined uniquely from the flux-weighted salinities via mass conservation and equations (8).

#### 6. Puget Sound Pollutant Concentrations Due To Alternative Sources

One way to utilize the model is to contrast the difference between discharging a conservative pollutant at two different input sites. The simple example of equation (7) shows that given the pollutant input rates,  $p_i$ , we can calculate their steady-state concentrations,  $C_i$ , and this holds true for the complex model of Figure 4.

Let us suppose that we wish to discharge 1 kg/sec of an arbitrary, conservative pollutant through a perfect diffuser (such that it mixes into its discharge layer completely) at the head of either layer 6 or layer 7. Columns 3 and 4 of Table 1 show the predicted concentrations due to the discharge sites. Pollutants introduced at either site are broadcast throughout the system owing to recirculation. They appear at the landwardmost reaches of all of the fjord arms.

In layers 1-6 and 13-18, mean concentrations do not depend upon the location of the discharge. This is because these layers are seaward of the seawardmost discharge site. As with conservative pollutants discharged into a river, the downstream concentration cannot be altered by simply relocating discharge sites already upstream of the observation point.

Reach layers 7-12, landward of the discharge sites, have equilibrium concentrations which depend significantly upon the sites. This is in stark contrast to the "conveyor-belt" view of fjord flushing in which no landward layer could receive pollutants. Layer-7 discharge leads to about twice the layer-6 discharge concentrations due to the fact that layer 7 flows landward coupled with the effluxing/refluxing at various mixing zones.

#### 7. Summary

We have developed a theory for recirculation within a fjord system composed of a sequence of advective reaches separated by mixing zones. Long-term salinity and current observations lead to the efflux/reflux coefficients which relate directly to conservative pollutant concentrations. An application to Puget Sound has shown one potential use for the model, that of predicting steady-state pollutant concentrations as a function of various discharge sites. Investigations are underway to compare the Puget Sound Refluxing Model predictions with observations of various trace metals, especially dissolved copper. Also work is in progress to determine the residence time of such a system.

## CHAPTER TWO HUNDRED FIVE

### SEWAGE DISPOSAL IN SHALLOW COASTAL WATERS

by

Hans H. Dette

#### Abstract

The disposal of sewage effluent into coastal waters for dilution and final disposal requires an effective mixing of sewage with the seawater in order to achieve the necessary or demanded reduction of bacterial population. Most of the design parameters originate from work done on ocean outfalls. RAWN et al. (1960) developed curves from field data for the determination of initial dilution in a waste issuing from a horizontal port. ABRAHAM (1963) extended these curves to show that the dilution is a function of the depth of discharge port, the diameter of the discharge orifice  $D$  and the FROUDE number  $F$ .

The question, to which extent this calculation method is also valid for outfalls in shallow water regions, is still open. In connection with the actual design of a diffuser in shallow coastal water the method of ABRAHAM was applied together with a new method derived by BERGEN (1980) which is based upon experiments which were carried out in the Leichtweiss-Institute at semi-technical scale. After the diffuser had been taken into operation by means of in-situ measurements the demanded dilution could be checked and herewith also the reliability of the applied design method for practical use.

#### Experimental investigations on concentration ratio

For a comprehensive application, especially in case of discharges at low jet velocities (FROUDE number  $F < 1$ ), the calculation method of ABRAHAM (1963) is insufficient. Therefore investigations were carried out in order to extend ABRAHAM'S work into a wider range of validity (Table 1).

The experiments were carried out in a water tank with a depth of 3.5 m. For the measurement of instantaneous concentrations along the axis of freshwater upwelling in seawater the conductivity method was selected. For this purpose a grid of horizontal and vertical tungsten wires was installed in the tank so that disturbances on the dispersion in the tank were reduced to a minimum (Fig. 1).

It was the aim of the investigation to describe approximately by means of a 1st order theory diffusion processes. All derivations are related to an axially symmetrical and vertical buoyant jet originating from the discharge of a lighter fluid into a heavier one at still water.

Chief Engineer, Leichtweiss-Institute, Technical University of  
Braunschweig, Fed. Rep. of Germany M. A.S.C.E.

Table 1: Parameter variations in the experiments of the Leichtweiss-Institute and of ABRAHAM

Parameter	Range of variations			
	LEICHTWEISS-INSTITUTE		ABRAHAM	
	from	to	from	to
FROUDE number	0.0001	11.7	1	95
REYNOLDS' number	$0.15 \cdot 10^3$	$45 \cdot 10^3$	$1.8 \cdot 10^3$	$8.7 \cdot 10^3$
outlet velocity	0.0014 m/s	0.45 m/s	0.1 m/s	0.68 m/s
concentration ratio $c_m/c_o$	0.76	0.001	0.67	0.085
dilution	1 : 1.3	1 : 1000	1 : 1.5	1 : 12

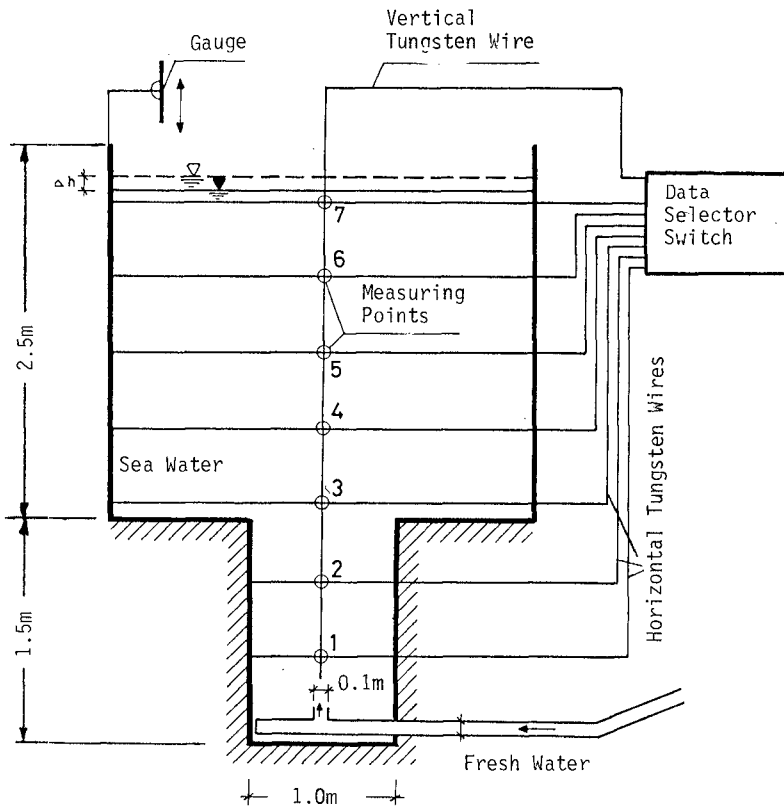

Fig. 1: View of the test facility for measuring concentrations along the axis of jet

In case of low outlet velocities the distribution profile of concentration is not so distinct as in case of high velocities; besides the mean upwelling velocity in the axis of jet is much higher than in cross direction. As for design purpose mostly maximal data are needed an uniform distribution of concentration  $c$  and velocity  $v$  is assumed in the cross-section of the jet. It follows that the concentration at any point of the cross-section is equal that along the axis.

Table 2 shows as example the results of one test series. For different outlet velocities ranging from very low ( $v = 0.0014$  m/s) up to velocities of 0.45 m/s the connected FROUDE and REYNOLDS' numbers are listed together with the measured concentration ratios at different levels  $\frac{x}{D}$ .

Table 2: Test results of concentration ratio measurements (BERGEN, 1980)

TEST SERIES II $\Delta\rho_o / \rho_o = 0.02192$

57		23,5				0.0321
58		28,5				0.0046
59		33,5				0.0173

In Fig. 2 these data are plotted through which for each test linear curves were drawn for further use.

A qualitative analysis of the test results revealed that at low jet velocities (e.g.  $v_o = 0.0015$  m/s. Curve A in Fig. 3 a relatively high initial dilution  $v_o$  is obtained in the direct vicinity of the outlet,

Fig. 2: Correction curves for measured concentration ratios (BERGEN, 1980)

here demonstrated by the lowest point of curve A (at  $x/D = 3.5$ , with  $x$  = vertical distance from outlet and  $D$  = diameter of outlet pipe = 0.10 m in the tests). In the course of further upwelling the dilution further increases by a factor between 4 to 6 (at  $x/D = 35$ ).

At higher jet velocities (e.g.  $v_0 = 0.2315$  m/s, which is more than two orders of magnitude higher than the previous example, curve B (in Fig. 3) the initial dilution is considerably lower but increases by a factor between 20 and 50 (at  $x/D = 35$ ). These results are in agreement with the statement of ABRAHAM (1959) that for Froude numbers  $\rightarrow 0$  (low velocity) the mean concentration  $c_m$  decreases faster than for Froude numbers  $\rightarrow \infty$ .

Fig. 3: Test results of dilution distribution at low (curve A) and at higher (curve B) jet velocities

Computation method for the determination of the concentration ratio

Based upon the already mentioned assumptions and approximations BERGEN (1980) derived an equation for the computation of concentration ratio by means of experimental data.

The following linear approach

$$\frac{c_m}{c_o} = \left[ \frac{x}{D} \right]^{-1} \left[ B_1 \cdot \left[ \frac{x}{D} \right]^2 + B_2 \right]^{-1/2}$$

was abandoned in favour of a nonlinear approach in which a hyperbolic cross-sectional shape of the jet is assumed (Fig. 4)

After certain transformations BERGEN (1980) obtained the following equation:

$$\frac{c_m}{c_o} = 2 \left[ \frac{b-3}{2} \right] \sqrt{\frac{Fr}{b}} \cdot D \left[ \frac{5-b}{2} - \frac{2}{5} \right] \cdot \left[ \frac{x}{D} \right]^{-\frac{2}{5}}$$

Fig. 4: Hyperbolic cross-sectional shape of jet (schematic)

By introducing three coefficients which are functions of two known parameters (Froude number  $F$  and outlet diameter  $D$ ) and only one unknown (parameter  $b$ )

$$B_3 = 2 \left[ \frac{b-3}{2} \right] \cdot \sqrt{\frac{Fr}{b}} \quad (B_3 = f(b, Fr))$$

$$B_4 = D \left[ \frac{5-b}{2} - \frac{2}{b} \right] \quad (B_4 = f(b, D))$$

$$B_5 = \frac{2}{b} \quad (B_5 = f(b))$$

the above equation can be written

$$\frac{c_m}{c_0} = B_3 \cdot B_4 \cdot \left[ \frac{x}{D} \right]^{-B_5}$$

For the determinations of the three coefficients the iteration method was applied so far until the computed concentration ratio was equal the measured one

$$\frac{c_m}{c_0} (\text{theory}) \cong \frac{c_m}{c_0} (\text{experiment})$$

Table 3 shows as example the computed coefficients obtained by iteration for the measured concentration ratio  $c_m/c_o$  (experiment). The scattering of the value b can be explained by the fact that in the equation no distinction is made between the direct vicinity of jet release and the further distant where upwelling is more defined.

Table 3: Computation of coefficients  $B_3$ ,  $B_4$  and  $B_5$  and parameter b by iteration for measured concentration ratio (BERGEN, 1980)

With respect to a parameter b which is independent of the distance x from outlet a parameter  $B_e$  is introduced as follows:

$$B_e = \frac{\sum_{i=1}^n b_i}{n}$$

with n = number of data from one test

By assuming  $b \equiv B_e$  then only the parameter b has to be replaced in the derived equation.

If a satisfactory relation between parameter  $B_e$  and a given experimental or design parameter can be found the derived equation can be applied for actual design.

Fig. 5 shows for the parameter  $Be$  related to the REYNOLDS' number  $Re$  a relative good agreement so that this graph can be used as key curve for design purpose.

Fig. 5: Key curve for the calculation of concentration ratio (BERGEN, 1980)  
Application of the computation method for design

As could be shown in the preceding chapter the single design parameters on concentration ratio depend from each other so that the optimal values have to be found by iteration. In order to facilitate the computation of the concentration ratio number according to BERGEN'S equation for engineering purpose three diagrams (II, III, IV) in relation to diagram I as the key curve (Fig. 5) were developed (Fig. 6).

Actual design of a multiport diffuser in shallow coastal water

The sewage of the city of Kiel for many years was released through a single point outlet into the Baltic Sea. The distance from the shoreline was 250 m (Fig. 7).

Due to bacterial population above the allowed boundary values and odour nuisance the recreational beaches adjacent to the point of release had to be restricted for public use. In order to re-establish bathing water quality it was demanded to extend the outlet up to 1.500 m distant from the shoreline in order to prevent further shore pollution. By extensive field measurements (DETTE, 1984) it was concluded that a multiport

Fig. 6: Application diagrams for the computation of the concentration ratio  $c_m/c_0$  (BERGEN, 1980)

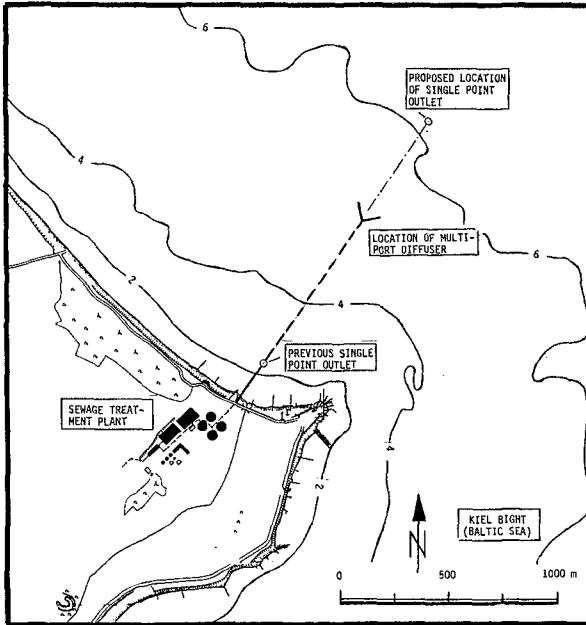

Fig. 7: Sewage release in shallow coastal water

y-shaped diffuser should be built at a distance of 1.000 m from the shoreline (Fig. 7).

As design criteria for the diffuser it was demanded that a dilution of 1 to 10 should be obtained at the water surface above the diffusers. With respect to the optimization of porthole diameter and number of portholes for a given sewage discharge of  $Q = 0.7 \text{ m}^3/\text{s}$  in one arm of the y-shaped diffuser the calculation methods of ABRAHAM (1959) and that of BERGEN (1980) were applied.

The results are plotted in Fig. 8.

In order to obtain an uniform outflow from all portholes variable distances between the single portholes were calculated and suggested for execution (Fig. 9). Details of the diffuser system are shown in Fig. 10. For the 1000 m long submarine pipeline of DN 1500 mm (diameter) tubes of 6 m length were welded together on land to lengths of 50 m which were afterwards brought into the water and transported as floating elements to their final position. For the underwater connection of the sections special couplings (type: Straub Flex) were used.

Fig. 8: Computation of porthole numbers in relation to outlet diameter according to ABRAHAM (1959) and BERGEN (1980)

#### Control measurements on initial dilution

After the new diffuser had been taken into operation control measurements were carried out in the direct vicinity of the diffuser in order to know to which extent the number of coliforms has been reduced in comparison to those values sampled at the plant itself. The reduction in the number of coliforms can be regarded in shallow water as direct indicator of the obtained dilution. Fig. 11 shows the locations where samples have been taken from the water surface. In Table 4 the results are listed. With respect to the number of total coliforms a mean reduction to approx. 3 percent is obtained directly above the diffuser in comparison to a demanded reduction to 10 percent. At a distance of 10 m from the diffuser already a further reduction of one order of magnitude is reached (0.3 percent).

It is therefore concluded that the applied calculation method on concentration ratio and the layout of the diffuser fulfilled the targets so that a general application for sewage release in shallow water can be recommended.

Table 4: In-Situ measurements of coliforms in the vicinity of the diffuser carried out by Institute of Marine Microbiology at University of Kiel

## CHAPTER TWO HUNDRED TEN

### LARGE DIAMETER POLYETHYLENE SUBMARINE OUTFALLS

L. A. Jackson \*

#### 1.0 INTRODUCTION

This paper presents the state of the art that has now evolved in Australia and shows the trend towards using high density polyethylene pipes for submarine conditions and the varying techniques and materials utilised.

Prior to 1981 High Density Polyethylene (H.D.P.E.) was not produced in Australia in diameters larger than 630mm and even in the available sizes submarine outfalls were in the main constructed of mild steel or concrete pipes.

In 1980 the Gold Coast City Council called tenders for the supply and installation of a 1500 metre, 1 metre diameter, outfall across the Southport Broadwater which is an active tidal estuary area. The proposed route crossed a main navigation channel and required trenching up to 8 metres into sand and sandstone. After consideration of the special requirements and high tender prices for conventional materials, Council constructed a temporary 400mm diameter H.D.P.E. outfall while the design of the permanent outfall was re-evaluated. The outfall was eventually constructed by day labour utilising a 1 metre diameter H.D.P.E. at a cost saving of approximately \$1.5 million over the lowest tender price utilising steel pipes.

Manufacturing facilities were imported into Australia for this job and now other large diameter submarine H.D.P.E. outfalls have been constructed in Australia and this material is now gaining acceptance.

\* Special Projects Engineer, Gold Coast City Council, Bundall Road, Surfers Paradise, Gold Coast, Queensland, Australia, 4217.

## 2.0 MATERIAL AND DESIGN CONSIDERATIONS

H.D.P.E. is a flexible material and as such the design and installation techniques vary considerably from conventional pipe materials.

The properties are summarised as below:-

Density	- 0.96
Min. Bending Radius	- 33 x Pipe O.D.
Flow Characteristics	- $C(20^{\circ}) \approx 155$ (max.)
Tensile Strength	- 24 MPa
Impact Strength	- 18 mj/mm <sup>2</sup>
Flexural Strength	- 32 MPa
Hardness	- 63
Co-efficient of	
Linear Expansion	- $2 \times 10^{-4}/^{\circ}\text{C}$
Thermal Conductivity	- 0.37 K. Cal/M.L. <sup>^{\circ}\text{C}</sup>
Crystalline Melting	
Point	- 130 <sup>^{\circ}\text{C}</sup>
Chemical Resistance	- Not affected except by strong oxidising agents.

Thus in general H.D.P.E. is a material which has good flow characteristics, chemical resistance and is flexible but due to its low S.G. requires weighting to provide negative buoyancy. The minimum S.G. of the pipeline weighted system will depend on the wave, current and backfill material characteristics. Experience has shown that as the pipe is flexible, then unless the final weight is adequate and the weight spacing is not excessive, floatation can occur during backfilling.

Due to the flexibility and buoyancy of H.D.P.E. pipe, various construction techniques can be utilised as listed:-

- (a) Fabricate the entire length, float into position and sink.
- (b) Progressively fabricate on, and lay off, a barge.
- (c) Progressively fabricate and bottom pull into place.
- (d) Progressively fabricate and flange join each length above or below water.

The pipe may either be laid in place on the seabed or in a prepared trench, or, due to its flexibility, jetted into the seabed material or undercut and lowered by dredging alongside the sunken pipeline.

Because of its light weight, flexibility, and ease of welding, H.D.P.E. can be assembled and laid without expensive specialised equipment and with a minimum of construction personnel. Overheads are therefore low and the cost of stand downs during adverse weather conditions is minimal.

### 3.0 CASE HISTORIES

Three case histories of major H.D.P.E. pipelines which have been constructed recently in Australia follow. Each job involved construction problems associated with the site conditions but the total job budget could not accommodate the use of large expensive specialised equipment. Different techniques were evolved for each job to suit the conditions and each was able to be carried out using readily available equipment and labour at a cost less than on comparable pipelines of alternate materials. The location of each job is shown in Fig. 1.

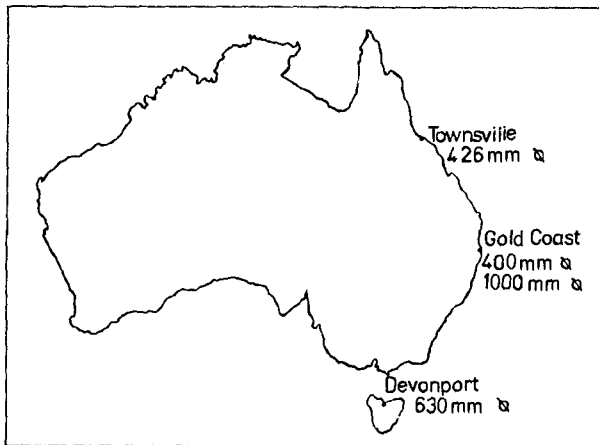

FIG. 1

(a) Gold Coast, Queensland (1982) (ref. Jackson, 1983 (2))

Location: Southport Broadwater (Nerang River Estuary)

Use: The pipeline serves as a submarine outfall to dispose of effluent from the recently constructed Coombabah carousel type sewerage treatment plant (50,000 e.p. capacity). Tenders for the pipeline construction were originally called but due to excessive costs the lowest tender utilising concrete lined mild steel was not accepted. Due to these delays it was necessary to provide a temporary outfall which

was constructed by Council's day labour force utilising 400 mm H.O.P.E. at a cost of \$200,000.

Site Description: The route traversed the wide estuary located at the mouth of the Nerang River and crossed two major navigation channels, which could not be closed, and the active sand bars of the internal delta. In the sand bar area up to 7m of sand and 1.5m of sandstone needed to be removed by dredging. The high tidal velocities made work difficult and caused rapid siltation/scour of the trench.

Length: 1450 m

Oiameter: 1000 mm (nom.) O.D.

Wall Thickness: 43.5 mm to 50.9 mm

Pressure Rating: 45 m

Average Flow: 1800 l/s

S.G.: 1.26 (too low!)

Costs: Total = \$2.5 million

Pipe Materials = \$730,000 of MSCL	\$745,645
Concrete	\$538,013
F.R.P.	\$731,612

Contractor: Day Labour (Gold Coast City Council)

Consultant: Camp Scott & Furphy

#### Fabrication:

- (1) 12 m plain ended pipes were butt fusion welded on land into lengths approximately 200 m long and progressively winched over steel rollers into a shallow holding area as each length added.
- (2) Each fabricated length hydrostatically tested and refloated.
- (3) Concrete weights were then attached to the floating length using a catamaran barge with lifting gantry.

#### Installation:

- (1) Oredge trench progressively.
- (2) Tow fabricated length and sink into position as trench prepared (end left afloat for dry attachment of next length).
- (3) Level and backfill each length as laid.
- (4) Attach next length above water using catamaran barge as trench prepared and then sink.
- (5) Place prefabricated flexible concrete scour mattresses under channels.

(b) Townsville, Qld (ref Bryne & Reidel, 1983 (1))

Location: Cleveland Bay between Townsville and Magnetic Island (Fig 2).

Use: In order to provide water to the growing population on Magnetic Island, a new water supply pipe was required.

The material was not specified, but H.D.P.E. was nominated by the successful tenderer.

Site Description: The route traversed Cleveland Bay which is up to 5m deep with waves of 2.0m maximum and currents up to 1.5 km/hr. The bottom material varied from coral to soft mud in the intertidal zone.

Diameter:	426mm O.D.
Length:	5610m
Working Pressure (max):	0.7 MPa
Minimum Flow	155 l/sec
Burial 1.5m in the surf zone	
Water Temperature:	26 <sup>0</sup> ± 8 <sup>0</sup> C
Design Waves: Height	4 metres
Period	8.5 seconds
S.G.:	1.5
Wall Thickness:	40mm
Cost:	\$1.8 million (\$321/m)
Contractor:	Construct Pty Ltd
Consultant:	Reidel & Byrne Consulting Engineers Pty Ltd

## Fabrication:

- (1) 17m plain ended pipes butt fusion welded into 400m lengths on beach.
- (2) Concrete weights attached prior to launching by lifting and dragging.

## Installation:

- (1) Excavate trench progressively in reef, surf and intertidal zones using amphibious excavator.
- (2) Lift pipe into water and tow with additional floats into place and sink completely into 1.5m (max) deep trench.
- (3) Flange joint next pipe under water when next 400m of trench prepared.
- (4) Bury seabed sections of pipeline using the diving operated jetting machine.

Jointing: Epoxy coated steel flanges and galvanised bolts (all cathodically protected).

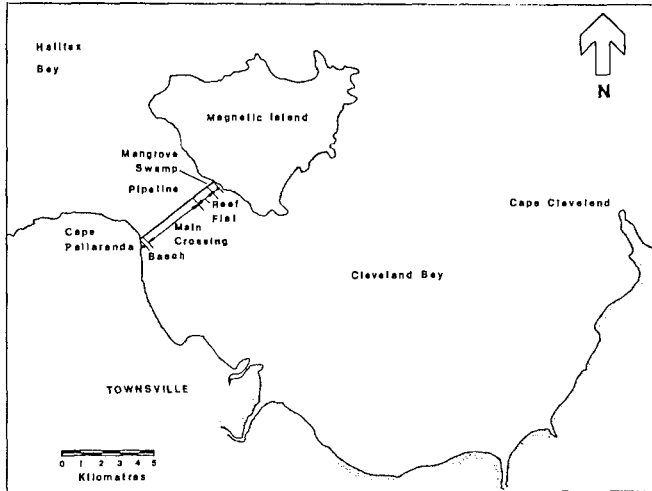

FIG. 4

(c) Devonport, Tasmania (1982)

Location: Mersey River

Use: The main carries raw sewage to the new East Devonport Plant.

Site Description: The main crosses the deep Mersey River which carries a high volume of commercial marine traffic which includes the Melbourne to Tasmania Ferry. In order to prevent excessive disruption the river could not be closed for more than 12 hours at any one time. Due to the site conditions, the need to be corrosive resistant both internally and externally and the need to be laid quickly at a reasonable cost, the Council selected H.D.P.E. over steel and concrete.

Length:	288m
Diameter:	630 mm
Wall Thickness:	30 mm
S.G.:	1.3
Costs:	\$250,000 (\$868/m)
Construction:	Day Labour (Devonport City Council)
Consultant:	(Reidel & Bryne Consulting Engineers Pty Ltd)

## Installation:

- (1) Dredge 2m deep trench
- (2) Fabricate one 288m length from 12m plain ended pipes using butt fusion welds on a nearby beach (4 days)
- (3) The lower half of the 54 concrete weights were laid out on the beach along side the pipe and the pipe lifted onto the weights using a fleet of front end loaders. The top sections of the weights were then bolted on top. The operation was completed in 8 hours.
- (4) The weighted pipe was then towed into the water over greased timber skids at high tide.
- (5) Using a tug and several small work boats the pipe was towed into position and sunk into the trench by flooding with town water in 3 hours.

FIG. 5

#### 4.0 OVERVIEW

The three cases cited all involved difficult conditions but as illustrated by utilising the inherent flexibility of H.D.P.E., construction techniques such as prefabrication and above water flange joining were utilised to enable these projects to be carried out economically without the need for specialised equipment or labour. Due to the nature of the pipe, detailed design of the weighting system, scour protection and corrosion protection/minimisation of joint materials are necessary.

## CHAPTER TWO HUNDRED ELEVEN

### OPTIMIZING DUMPING SITES NEAR DREDGED CHANNELS

Dipl.-Ing. Ulrich Kögel           \*  
Dipl.-Ing. Friedrich Ohlmeyer   \*\*

#### ABSTRACT

To maintain the depth of the deepwater channel of the Elbe-Waterway extensive dredging has to be done permanently. Dumping should be optimized, choosing sites near the dredging area but with a small risk of recirculation of the dumped material. In order to estimate this risk field measurements with current meters and radioactive tracer tests in field and model were carried out.

#### 1.0 INTRODUCTION

The deepwater channel of the river Elbe from Hamburg to the North Sea has been deepened to an average depth of 13,5 m below chart datum. The mean tidal range is about 3 m.

The channel has to be kept free by constant dredging. A volume of 8 to  $10 \cdot 10^6 \text{ m}^3$  fine and medium sand has to be dredged annually from the North Sea up to Hamburg. The dredged volume has increased the last three years nearly up to twice the amount before. This caused the Board of Waterway in Cuxhaven to look for the most economical way of dredging. The dredged material could be dumped near the dredging

---

Research engineer,	Hydraulics Research Station of the Federal Institute of Waterways 2000 Hamburg, Wedeler Landstr. 157

fig. 1 geographical location

sites as very deep areas are situated on both sides of the deepwater channel. But this method is only acceptable if there is no recirculation of dumped material into the deepwater channel within a short time. One of the main dredging sites with a dredging volume up to  $2.8 \cdot 10^6 \text{ m}^3$  p.a. is the training wall area near Cuxhaven (Fig. 1). This area has been researched to find out the reasons of accretion, especially as two dumping sites had been opened up on both sides of the dredging area. Recognizing a constant depth at the two dumping sites a flux of the dumped material is evident.

The dumping sites were checked for their suitability. For this, measurements in field using current meters and several investigations with radioactive tracers in a hydraulic model and in field were carried out with the aim to get informations of direction of the sediment transport. The influence of wave pressure and direction was neglected, because the wave height is very small in comparison with the water depth.

## 2.0 PRELIMINARY SURVEY

The sounding maps (fig. 2) of this area gives a picture of the sites of accretion and of the depth situation below mean spring low water. By investigations it was found that the highest inflow was from the south. Most dredging had to be done there. A comparison between the dredged and the dumped volume in this area of the year 1983 shows, that the dredged volume was up to 2,4 times the amount of the volume dumped in the vicinity. Therefore the dumping of the material on both sides of the deepwater channel cannot be the only reason of the increased sedimentation.

## 3.0 INVESTIGATION OF THE DUMPING SITE I

### 3.1 MEASUREMENTS WITH CURRENT METERS

At first field measurements with recording current meters were carried out. The aim of this investigations was determine the direction of sediment transport and also to estimate the amount of accretion

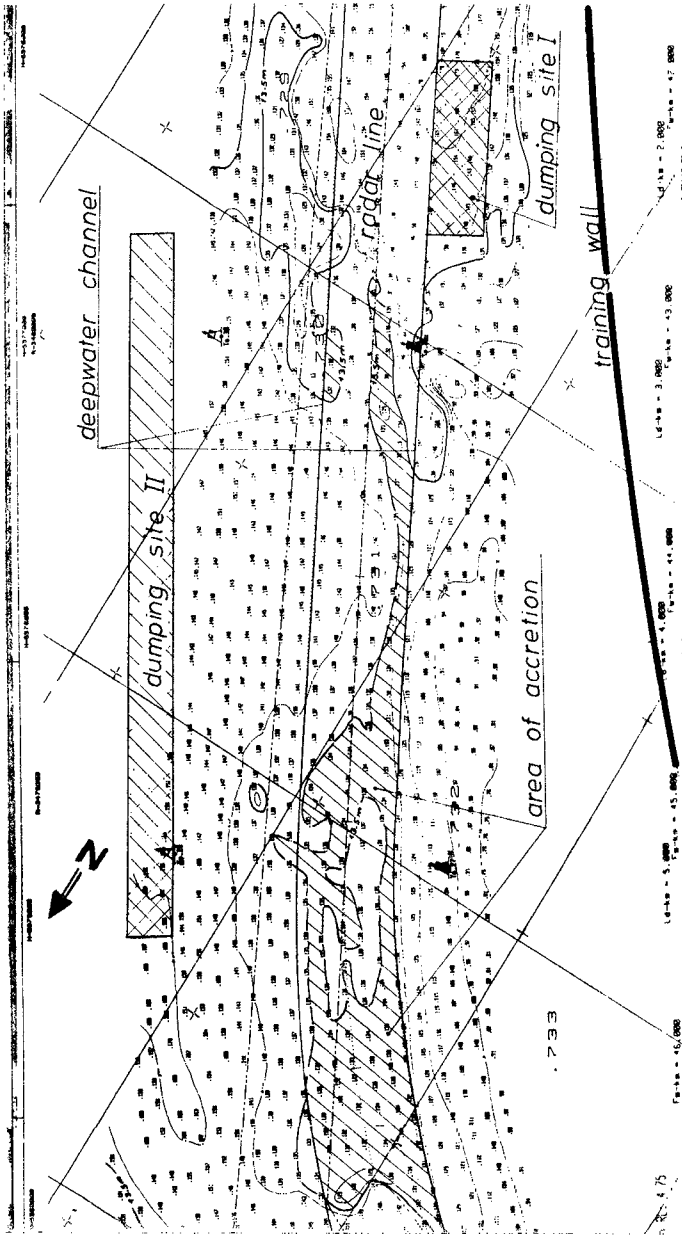

fig. 2 Sounding map with dumping and dredging areas

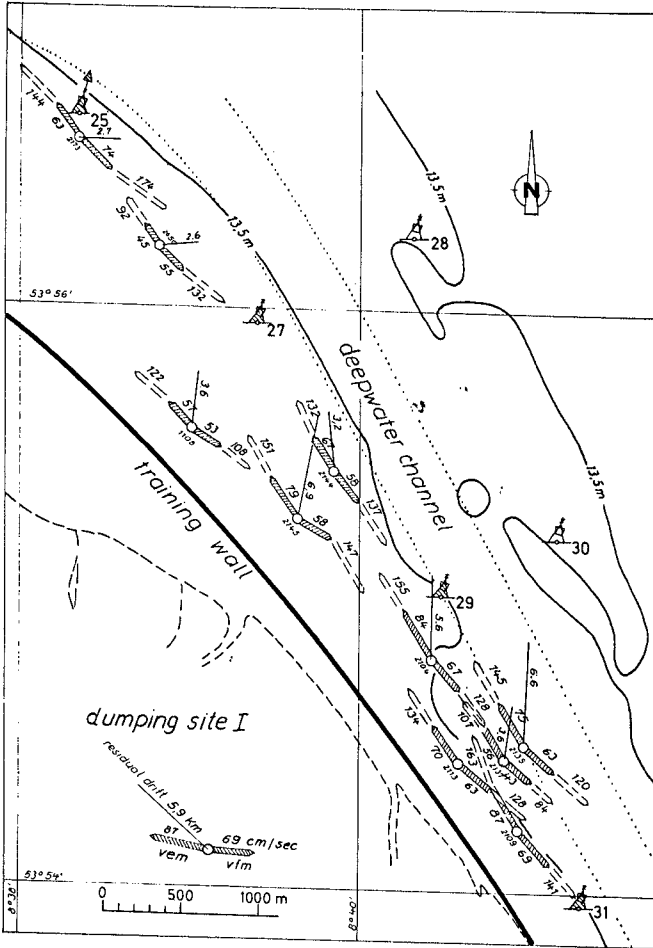

fig. 3 Bed current measurements in field, I

dependant on conditions of ebb- and flood current. The velocity and direction of current are recorded with current meters, moored 0,5 m above the bed. The currents measured at that level are regarded as relevant for sediment transport in this case. The results are stored on magnetic tapes. Mostly the measurements were carried out continuously. The 14 days measurements took into account the effect of the mean, the spring and the neap tides. The data showed, that up to 1000 m downstream from buoy 29 the ebb current dominates, but from buoy 27 onwards the mean ebb and flood velocities are equal. Downstream from buoy 27 the mean flood velocity prevails (fig. 3).

The ebb- and flood-current in this area reaches 45 - 87 cm/s. The highest rate 84 - 174 cm/s. There is a residual drift of 2.6 - 6.9 km/tide towards downstream or upstream and towards the deepwater channel depending on the dominating ebb or flood current. The residual drift is calculated from the vectoral additions of the ebb and flood current data measured in 5 minutes intervals.

All measurements were evaluated by means of tapereader, desk-top computer and plotter. A good overall picture of the expected sediment transport can be obtained by consulting the current velocity rose, which shows the current velocity and directions (fig. 4). The direction of ebb- and flood currents oscillates in an angle-scope of 25 degrees. The ebb current dominates in this case, ebb and flood direction diametrically opposed to each other. The residual drift vector calculated of it, shows the direc-

Strömungsgeschwindigkeits- und -richtungsverteilung

fig. 4 current velocity rose

tion of the mean ebb current from which one can deduce that the sediment is transported in this case in the direction of ebb current. The measurements of the individual measuring points were compared with the results of neighbouring points. By this the following overall result was reached:

Because of the prevailing ebb current upstream from buoy 27 and the prevailing flood current downstream from this buoy and the respective residual drifts towards the deepwater channel, sediment transport must be expected from the south into the deepwater channel up- and downstream from buoy 27.

The direction of the residual drift indicates, that the greater part of the dumped material from dumping site I moves back into the deepwater channel between buoy 27 and 29. This assumption is confirmed by comparing the grain sizes of the material ( $d_{50} = 0.16$  mm) dumped in dumping site I and being dredged on the southern sides of the dredging area between buoy 27 and 29.

### 3.2 MEASUREMENTS WITH RADIOACTIVE TRACERS IN MODEL

The results of the field measurements were confirmed by investigations in a hydraulic model with movable bed using a radioactive tracer. This model of the Elbe estuary is managed by the Bundesanstalt für Wasserbau in Hamburg. The model scales are 1 : 800 horizontal and 1 : 100 vertical. The hydrodynamic time-scale is non Froudeian; one tidal period of semi-diurnal type lasts 13.03 min. The bed material consists of polystyrene grains with  $d_m = 2.0$  mm and a density of  $1.035$  g/cm<sup>3</sup>. The theory is referred to Vollmers/Giese, (2) and aims in a natural simulation of dune structures.

The  $\gamma$ -radiating isotope Br 82 with a half-life of 36 hours was used to label 25 g of the polystyrene-grains, which were put into the model at high water

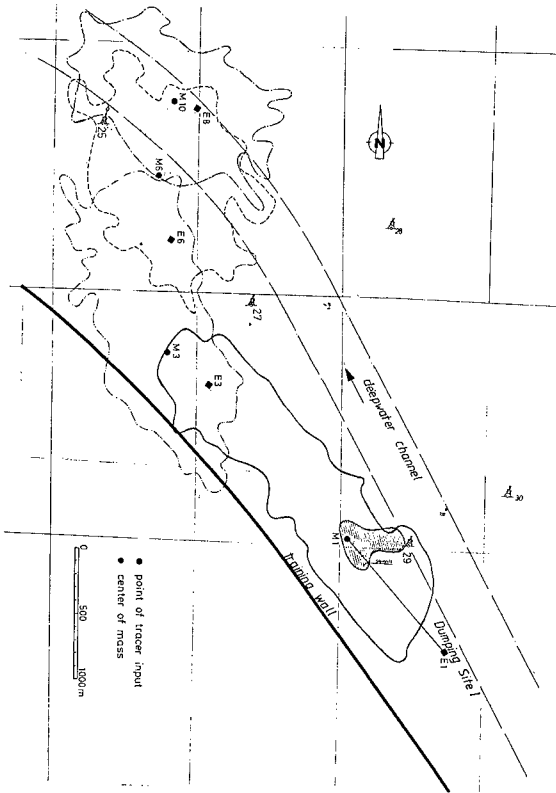

fig. 5 Radioactive tracer spreading in model, 1

slack. After a run of 150 tides in model the tracer has spread over an area of several square meters due to current and turbulence activities. The spreading area was scanned in a grid of 10 to 15 cm using a radiation detector and a scintillation counter. Detailed informations about this subject were given by Rohde, (1).

Between training wall and navigation channel 4 investigations were carried out in the model. (fig. 5). The spreading figures of the tracer-only the lines of the weakest radiation with 20 impulses per minute are depicted - can be interpreted in two ways. The one is to consider the direction of the longer main axis of the figures and the other is to draw the vectors from the input points to the centers of mass.

The results are in good conformance with the current measurements in field. The dominating ebb-current moves the material from dumping site I first parallel to the training wall. 2000 m downstream from the point of tracer input it sweeps round towards the deepwater channel and causes here a considerable accretion.

### 3.3 CONCLUSION

The results of the investigations led to the conclusion the recirculation -rate between dumping site and dredging area to be very high. Therefore the dumping activities at point I were stopped.

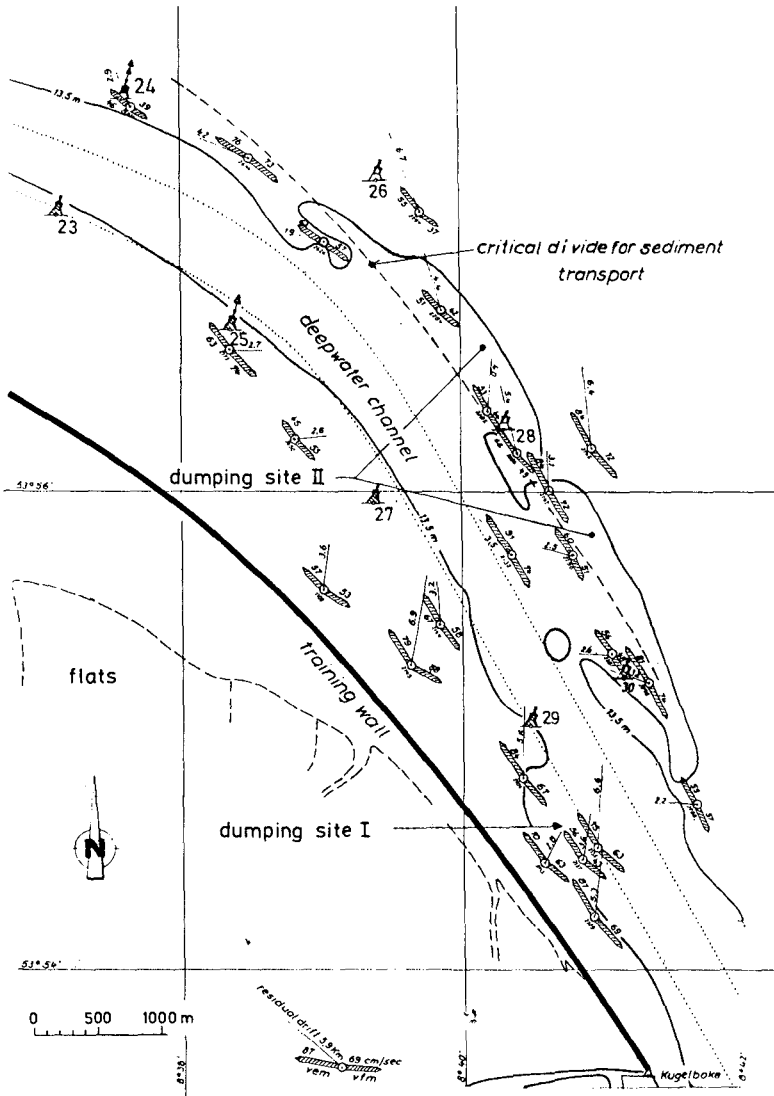

fig. 6 Bed current measurements in field, II

#### 4.0 INVESTIGATION OF THE DUMPING SITE II

The dumping site II was investigated by current measurements in the field and radioactive tracers experiments in model and the field.

#### 4.1 MEASUREMENTS WITH CURRENTS METERS

The results of the current measurements can be assumed as following (Fig. 6):

1. The mean and maximum ebb current velocities are higher than the corresponding flood velocities.
2. The residual drifts are clearly directed downstream, but one is directed to the north and the other towards the deepwater channel. The residual drift vectors are directed on the one hand to the north and on the other hand towards the deepwater channel separated by a dividing line.
3. In all cases the ebb current dominates and a dominating ebb-transport can be suggested.

#### 4.2 TRACER TESTS IN MODEL

This general tendency obtained with current meters is confirmed by research with radioactive tracers in the model. The tracer dumped in the middle of dumping site II spreads out to buoy 28 in a very soft angle towards the deepwater channel, from there it moves more steeply towards the deepwater channel and reaches it at buoy 25. The paths of the mass-centers are shown in fig. 7. A general tendency of decreasing vector lengths can be recognized.

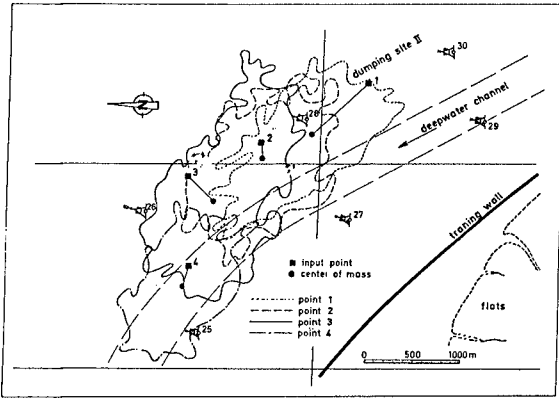

fig. 7 Radioactive tracer spreading in model, II

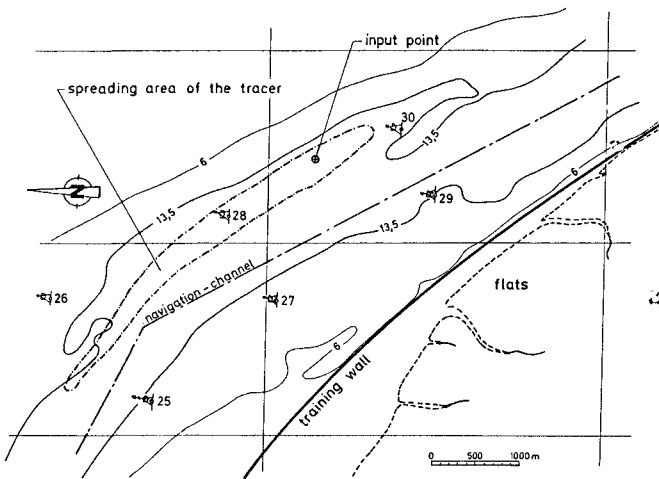

fig. 8 Radioactive tracer spreading in field

#### 4.3 MEASUREMENTS WITH RADIOACTIVE TRACERS IN NATURE

For better estimation of the suitability of the dumping site an additional investigation with radioactive sand was carried out in the field.

To prepare the tracer 10 kg fine to medium sand with a  $d_{50} = 0.26$  mm was taken from the river bottom and with the help of waterglass labelled with scandium (half-life 84 days). A heavy sledge with a scintillation detector was used to measure the radiation. The sledge was pulled over the river bed by a towing boat. The radioactivity was recorded by a scintillation counter. Hifix digital navigation system was employed for the location. More details about the tracer experiment are published by Rohde, (1).

The radioactive sand was introduced into the center of dumping site II. The area in which radioactive material could be found is shown on Fig. 8. In the first stages the tracer spread from the point of input downstream in a small plume, almost parallel to the axis of the deepwater channel. From buoy 28 on, the material moved towards the northern side of the waterway. The spreading of the tracer in lateral direction did not extend more than 300 m. It was possible to keep track of the tracer for about 3500 m downstream from the input point only. The tracer was suggested to be transported into the deepwater channel and passing on its northern side.

#### 4.4 CONCLUSION

These results of the different measurements led to the following procedure of dumping: The dumping site is restricted to an area downstream from buoy 28 and very close to the 13.5 m -line. It is supposed the transported sediment will not affect the deep-water channel essentially.

#### 5.0 RÉSUMÉ

Current measurements in field, radioactive tracer test in the field and in a model with movable bed are good tools in optimizing dredging and dumping procedure. These three methods have to complete each other as long as there is no better understanding of the complex physical process of sediment transport in tidal areas.

## CHAPTER TWO HUNDRED TWELVE

### A New Nuclear Density Gauge to Measure Directly High Turbidities in Muddy Areas

A. Caillot, G. Meyer, D. Chambellan, J.C. Tanguy\*

#### Foreword

A better knowledge of the characteristics of muddy areas, in access fairways and port basins, and of the behaviour of ships during their crossing, presents the double interest of enhancing the navigation possibilities, through a more precise adjustment of the ship draught to the status of the bottoms, and permitting a more rational organization of the maintenance dredging campaigns. Considerable savings will be obtained through the development of such knowledges for harbours management.

These improvements imply the use of measuring equipments which must be handy, sturdy, reliable and which give accurate measurements.

The JTD3 gauge presented by the Radioisotopes Applications Service of the French Atomic Energy Commission is an important step in the development of such measuring equipments. It is now in running order, and commercially available, after thorough test campaigns, undertaken during many months in different french harbours.

New developments are already engaged, namely through the design of a turbidity gauge able to make dynamic measurements.

P. Monadier  
Head Central Technical Service  
Harbours and Maritime Navigation Directorate  
French Sea Ministry

#### I - Introduction

The depth necessary for sailing includes the free space between the keel and the bed of the channel, called keelclearance (Fig. 1a). However in muddy areas, it is quite possible for ships to sail through non consolidated silt (Fig. 1b) without reducing the safety.

The usual method to determine the water depth is based on the traditional hydrographic survey. But the upper trace recorded by echosounder appears as the bottom of the channel. In these conditions it is very difficult to say exactly where the nautical depth is, and the maintenance dredging takes two aspects:

- when, where to dredge and to which depth ?
- how to control dredging works cost ?

In assessing the nautical as well as the dredging aspects, an important factor is the density of the silt/water mixture. For this purpose, a nuclear scattering gauge, called SAPRA JTD3, has been developed to measure directly in the mud layer, vertical density (or concentration) profiles versus depth.

II - Principle and Description of the Scattering Gauge

II.1 - Principle

Fig. 2 - Scheme of the SAPRA JTD3 probe.

Gamma rays emitted in all directions by a very small cesium 137 sealed source (500  $\mu$ Ci or 18.5 MBq - Energy 661 keV - half life 30.18 years), are scattered through the sediment (Fig. 2).

The detector is shielded from direct gamma rays emitted by the source by the mean of a conical shaped tungsten plug set between the detector and the source housing (Fig. 3). The source to detector spacing is nominally 5 cm.

Gamma rays emitted by the source interact with the electrons of matter through two main ways: Compton effect and photoelectric absorption. Figure 4 shows the relative importance of those interactions versus gamma energy and atomic number Z.

Fig. 4 - Relative importance of the different interaction effects between X or  $\gamma$  rays with matter.

The probability of occurrence of Compton effect is proportional to the ratio  $Z/A$  of an atom ( $A$  atomic mass of the element). This ratio is nearly the same for all the element, except hydrogen. That means that the diffusion effect is nearly independent of the chemical constitution of the sediment one wants to measure the concentration. But the probability of occurrence of photoelectric effect is proportional to the ratio  $Z^5/A$  of an atom. So this absorption effect will increase with the presence of mineral element of higher mean atomic number than classical  $SiO_2$ ,  $CaO$ ,  $Al_2O_3$ ,  $K_2O$ ... and so on.

As the two effects occur in competition in the same media, one must be careful to calibrate the probe in a media of chemical composition, more precisely mean atomic number not too different from the material which will be measured in situ.

#### 11.2 - Description

The probe device consists in a stainless steel pencil-shaped tube (Fig. 3). Length: 1000 mm, diameter: 55 mm, weight about 20 kg. Due to its shape, this gauge penetrates easily into the mud layer up to a density of 1.3 (about  $500 \text{ gl}^{-1}$ ). It is connected with an electronic data acquisition system through a four conductors steel cable (diameter 4.6 mm - tensile strength 1200 daN) stored on an electric winch.

This gauge can be connected (Fig. 5) to a small computer (APPLE 11) which controls the winch and calculates the sediment concentration profile.

The submersion depth is determined by a pressure sensor up to a maximum depth of 100 m. Winch and data processing equipment are powered by a gasoline or oil fired generator providing an AC 220 V supply.

Fig. 5 - Photograph of the SA70-JD3 gauge showing the probe, the winch, the computer and the printer.

### II.3 - Safety

The radioactive source is certified as "material under special form" ISO CE 65 535 in agreement with international standards.

Maximum dose equivalent rate in contact with the gauge close to the source is less than 10 mrem/h when the probe is out of its transport shielding. In these conditions the handling of the probe requires minimum radiation safety.

### III - Measurements in Practice

#### III.1 - Calibration

The calibration will be done in large barrels (called infinite medium size ones). The probe hanging in medias ranging from water (fresh or salt water) up to mud suspension in the range density from 1 to 1.5.

Reference measurements  $N_W$  is taken in water. Table I and Fig. 6 give typical results.

Table I - Calibration of the gauge

Concentrations G in g/l	0	195	262	306	359	413	484	542	629
Densities $\rho$	1	1,12	1,16	1,18	1,21	1,25	1,29	1,32	1,37
$R = \frac{N_e}{N_W}$	1	1,037	1,040	1,054	1,063	1,074	1,083	1,094	1,113

A least square fit (first order) gives the following calibration relation:

$$\frac{N}{N_W} = 0.700 + (0.301 \pm 0.01) \rho$$

Such coefficients must be entered in the computer by the operator.

#### III.2 - Field Measurements

Operational density measurements using SAPRA JTD3 gauges have been performed in harbours and channels like ZEEBRUGE (Belgium), SINGAPORE, LOIRE esturay, ROGHEFORT (France),...etc.

Fig. 6 - Calibration of the gauge.

The motor boat is neither morred nor anchored. The lowering speed of the probe is fixed between 0 to 30 cm/s (the usual lowering speed is 5 to 10 cm/s). Every second a measurement is realised, however the accuracy increases as the counting time increases too (typically this counting time is 5 seconds).

Typical concentration profiles are given on Fig. 7.

### III.3 - Performances

The instrument has a measurement range densities of 1.020 to 1.350 (about 30 to 580 g/l).

Fig. 7 - Typical density profiles in Rochefort harbour.

The accuracy is about  $\pm 0.010$  with a confidence level 95%.

The volume "seen" by the gauge is a horizontal cylinder (diameter: 60 cm - height: 15 cm).

Ten to fifteen vertical profiles per hour are recorded if the water current is lower than 2 m/s.

## IV - Conclusion

In muddy areas, such as access channels and harbours, where repeatable in situ measurements of the density in sediment layers are necessary, the SAPRA JTD3 gauge and the echosounder are complementary tools. This nuclear gauge's use permits to get an optimization of the dredging schedules.

## CHAPTER TWO HUNDRED THIRTEEN

### CALIBRATION AND ADJUSTMENT PROCEDURES FOR THE RHINE-MEUSE ESTUARY SCALE MODEL

H.N.C.M. van der Heijden<sup>1)2)</sup><sup>BY</sup>, P. de Jong<sup>1)</sup>, C. Kuijper<sup>1)</sup>,  
and A. Roelfzema<sup>3)</sup>

#### ABSTRACT

At the Delft Hydraulics Laboratory the hydraulic model of the Rhine-Meuse estuary has been rebuilt and extended after being destroyed by fire in 1979. The new model has been operational since the summer of 1982 for water quantity and water quality research. The present paper deals with the calibration and adjustment procedures for this hydraulic model. Successively the (physical) backgrounds for the calibration process, the techniques used for provision of boundary conditions and the procedures for adjusting flows and salinity distribution are discussed. Finally, the results of calibration and verification and the experiences gained on the employed techniques will be analysed.

#### 1. INTRODUCTION

The new hydraulic scale model is, in commission of Rijkswaterstaat (Ministry of Public Works), employed as one of the research tools in the framework of a long term research programme on water quantity- and water quality problems of the Rhine-Meuse estuary (Roelfzema, Karelse, Struijk, Adriaanse, 1984). See fig. 1.1 and 1.2. The model has, for practical reasons the same scales as those of the earlier model, i.e. the vertical scale factor is 64 and the horizontal scale factor is 640. Reviews of the earlier model are given by Van Rees, van der Kuur, Stroband (1972) and by Breusers and Van Os (1981).

Hydraulic modelling of the complicated inhomogeneous flows of the Rhine-Meuse estuary implies that the various physical mechanisms are simulated in an integrated way. A basic requirement for such a simulation is knowledge of these physical mechanisms. Based on this knowledge the appropriate scale laws and scale factors have to be estimated (or, in this case reanalysed) and the most adequate type of additional roughness - and mixing elements has to be chosen, section 2.

Section 3 and 4 deal with the time variant boundaries of the rivers and sea, section 5 describes the adjustment of the "roughness" of the river system. To adjust the flows of the complex network a procedure based on a least squares method, with a general applicability for the convergence of the calibration processes has been developed.

Adjusting the salinity distribution was achieved with more conventional methods. The actual calibration process is discussed in section 6, while in section 7 the results of calibration and verification are analysed and some concluding remarks are made.

HYDRAULIC SCALE MODEL

## 2. BACKGROUNDS HYDRAULIC MODELLING

Characteristic for the geometry of the Rhine-Meuse estuary is its network system, consisting of a number of rivers with almost rectangular cross-sections. Only in the upstream parts of the system there are branches with flow and storage areas. In the northern part the Rotterdam harbours are found while in the southern part large, flat storage areas are present, forming about the half of the total tidal area of the estuary system.

The system is bounded at the upstream part by three river inflows, with a total discharge ranging from about  $600 \text{ m}^3/\text{s}$  up to about  $8500 \text{ m}^3/\text{s}$ . The downstream part is bounded by a free and a regulated outflow into the North Sea. The water levels show a dominant semi-diurnal tidal variation of about 2,20 m and 1.50 m at springtide and neaptide respectively.

The density difference between the sea and the fresh river inflow is about  $25 \text{ kg/m}^3$ .

The resulting inhomogeneous tidal flows show tidal influences to more than 100 km upstream from the mouth of the Rotterdam Waterway and salinity intrusion ranging from 30 up to 50 km.

Analyses of the physics of the system has been made possible by various

measurements carried out in the last few decades. Applying the internal estuarine number  $E_d$  according to Thatcher and Harleman (1972), the estuary system appears to be a partly mixed or layered type with normal values between 2,5 and 0,5. Amongst other approaches as dimensional analyses and decomposition methods, these measurements show that the dominant mechanisms are the vertical tidal effects, including the meteorological influences on the mean sea level, the river discharges, the vertical gravitational circulations due to density differences between sea and rivers and between rivers and harbours and the vertical turbulent diffusion. Of minor importance or negligible are horizontal circulations, lateral effects, longitudinal and lateral turbulent diffusion and wind effects on mixing. Applying the Froude-law, a basic condition for the modelling of gravitational and inertial forces has been satisfied, and thus for the modelling the dominating mechanisms of tides, river discharges and gravitational circulations.

The vertical scale factor of 64, taken over from the former model, allows in general a sufficiently high Reynolds number to simulate the overall structure of turbulence. A resulting representative Reynolds number is of the order of  $10^4$ . In this way the large scale turbulent eddies are reproduced correctly, satisfying a necessary modelling condition.

While the vertical scale factor had to be determined by principal considerations, the horizontal scale factor in general is determined on practical considerations of costs/economics. The horizontal scale factor of 640, also taken over from the former model, meets a reasonable optimum between the practical considerations and the experiences gained on distorted, inhomogeneous tidal models, (van Rees, et al 1972).

With these scale factors, the model (fig. 1.2) includes the research part of the estuary system along with a part of the North Sea and the fresh water rivers. These rivers have the correct scale for all hydraulic relevant parameters (length, depth, cross-sectional area etc.), but they have been bent to limit the total area of the building. In the Rhine-Meuse estuary the bottom influence on turbulent shear stress and on mixing are strongly dominating the side wall influences. The additional bottom roughness- and mixing elements, necessary because of the distorted scales, effectuates that in the model bottom influences are also dominating. To find the most adequate type of elements, analyses and flume tests have been carried out.

Premises for these activities were that the bottom elements have to be as small as possible to minimize local disturbances. Also they have to provide the model with non-directional resistance. Furthermore the elements have to facilitate flows near the model bottom in order to allow (analyses of) sediment transport processes, they have to allow occasional cleaning of the model and they have to be removed and to be replaced easily in order to facilitate the calibration process. Several types of elements have been investigated (viz. blocks, plates, bars, etc.), finally resulting in the choice for cross-shaped elements, fixed with a short bar on the modelbottom, fig. 2.1.

Fig. 2.1  
CROSS-SHAPED  
ELEMENTS

With respect to the geometry to be modelled it is very hard to estimate the actual differences between a model of concrete and a prototype under water. However, experience from past models has shown that no systematic differences could be found if every possible precaution was taken to make the model as accurate as possible. The results of new economic techniques involving concrete blocks of model, cast on polystyrene moulds were carefully compared to the more labour intensive ways of manually modelling a river. Although the result does not look as natural, no systematic differences could be found.

### 3. THE RIVER BOUNDARIES

From a research point of view only the central part of the model is of interest. The upstream river branches and the downstream model sea serve as generators of non-reflective boundary conditions for the area of interest.

The three upstream river branches begin in the model at places where the tide is negligible or that coincide with weirs. It is necessary to prescribe discharges at the river boundaries which may vary smoothly in time. In general these discharges are derived from water levels by means of a rating curve.

Tests in mathematical models showed that accuracy of the flow control should be so good that the mean over one minute should deviate less than 0.2% of the prescribed value within the whole range from 1.8 l/s (600 m<sup>3</sup>/s) to 26 l/s (8500 m<sup>3</sup>/s). This could be accomplished by using a constant head water tank and a system with several flow meters and valves, that switches slowly and automatically from one valve and flowmeter to the next.

### 4. THE SEAWARD BOUNDARY.

The conditions in the river mouth are described by the time variant water level and by the density, which is a function of time and depth. This water level and density are not directly controlled but are generated by the real flow field in the model sea. As there is hardly any stratification in the prototype at the position of the boundaries in

the sea, these boundaries have been constructed in the model as actively mixed sections (each of four meters length) where the total flow is accurately controlled (fig. 4.1). The layout is the same as in the old model (see Van Rees et al.), but all boundaries are now flow controlled. The electronics and the real time software are comparable to that of the old model (see Adriaanse et al.), but have been updated (completely digital) and highly integrated.

The problem with the control of these boundaries is that usually when prototype measurements on the river take place, the measurements in the sea are very limited in number. The procedures described in this section make the generation of reliable boundary conditions for such periods possible by using the measurements of other periods. The time series used to control these boundaries are derived from measurements as follows:

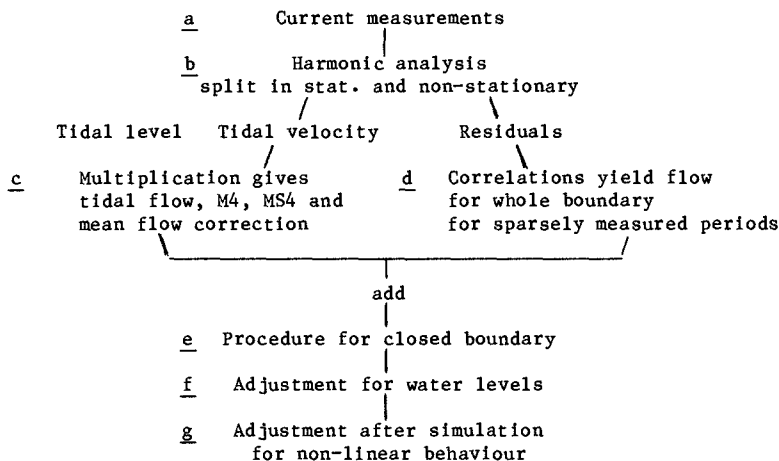

Fig. 4.1

- a. The currents at sea were measured at about 8 points during various periods of about one month. (fig. 4.1). Several measurements were simultaneous, others were not.
- b. According to good practise in time series analysis, the non-stationary part of the signal was separated from the stationary (this is the part for which the expectation does not change with

- time). Harmonic analysis was used to compute the tidal part and the stationary residual was assumed to consist of meteorological effect and noise.
- c. The tidal flow through each of the sections was then computed as the product of the velocity component perpendicular to the boundary and the time variant cross sectional area. This product yielded relevant higher harmonics (M4 and MS4) and gave a large correction to the mean flow. Gaps were filled in using correlations from short (13 hours) manual measurements made at many points on the boundaries.
  - d. For the meteo part of the flow no relevant correlations were found between the residuals of water levels and currents. Correlations between the residuals of simultaneous current meters at different positions were found to be significant for longer period variations (over 12 hours). In this way the residuals of current measurements at one position gave information about the flow through each of the model sections during the periods to be simulated.
  - e. As the flow pattern at sea is mainly parallel to the coast the north-western boundary of the model is a closed boundary (for economic reasons). Therefore procedures were developed in the old model to add the flow through this boundary to specific sections of the other boundaries (mainly the northern section of the north-east boundary). Afterwards these procedures were checked by studying the behaviour of the fresh water wedge in the prototype and the model sea.
  - f. The basic time series of the flow will not necessarily result in the correct water level in the model. Therefore cross-spectral analysis (of initial simulations) between the total volume of water in the model and the water level at the mouth of the river was used to compute a transfer function. It shows very clearly a resonance period of about 70 s. This function was measured for periods of 1125 s (= 25 hours prototype) to 56 s and extended to 28 s to give a smooth damped time representation used for convolution. Applying this function to the desired water level at the mouth of the river gives the desired total volume of water in the model. Comparing this with the basic flow of the model sections gives a correction to the flow into the model. This correction was then distributed over all model sections in proportion to their cross sectional area. The correction is small and will not affect the flow pattern in the model sea.
  - g. Then the period is simulated in the model. As the cross-spectral analysis uses linear relations there will be some differences between the desired and realized water levels. The same response function as used in paragraph f is then used to make another extremely small update for the flow sections to compensate for the non-linearities. A slow back-coupling from water levels to the flow sections is used to facilitate starting up and to compensate for drift in flow meters or intentional changes in river discharges.

##### 5. ADJUSTING ROUGHNESS

The damping of the tide wave, penetrating into the system from sea is caused by loss of momentum due to turbulent momentum exchange between the flow and the geometry. Though the loss of momentum on a river is often described with a "roughness-constant" (e.g. Chezy, Manning) it is clear that the hydraulic conditions are of primary importance in determining the turbulent structure of the flow. Since, in practice, it

is not possible to measure the momentum-exchange directly in prototype or model, calibrating the flow in a distorted model implies the adjustment of the correct amount of roughness-elements in order to achieve a proper reproduction of the flow. In that case loss of momentum on a river is correctly scaled, as can be derived from the momentum equation.

Apart from the problem how to direct the adjustment of the roughness in a new and complicated model one of the first problems seems to be the enormous amount of information it generates and how to control this. Changing the roughness in one branch might cause the water to take another route and although there would certainly be a human damping factor in the procedures a tedious trial and error procedure would not be welcomed. This section describes how the dataset was reduced to give overall picture of the model as compared to the prototype. It shows how this set was then used to interactively give information about the changes in roughness to be made. For this purpose it was necessary to estimate the effect of changes in roughness from the behaviour of a mathematical model. This behaviour also gives a broad idea of the situation that will emerge after these changes have been implemented. It was shown for a non-dendritic system (a system with islands) that the adjustment should be done on water levels and discharges simultaneously if the circumference of the islands is small with respect to the tidal wavelength. This problem was solved by using acoustic open channel flow meters at several points in the model that gave the total instantaneous flow in one reading instead of one position in a cross section (see Botma, 1978 and Roelfzema et al., 1984).

In the following sections the procedures used will be described in detail. Section 5.1 shows the principle of least squares as used for the optimisation and in section 5.2 the solution procedure is described. Section 5.3 gives an idea of how the procedures were implemented.

### 5.1 Least squares for optimisation

The purpose of the adjustment may be formulated as getting the best possible reproduction of the water levels and discharges in the model. "Best" was then defined to be the situation with the smallest sum  $F$  of the standard deviations of the difference between the time function  $f$  of model ( $m$ ) and prototype ( $n$  for nature).

$$F = \sum_p \frac{1}{s_p^2 T} \int_T (f_n - f_m)^2 dt \quad (1)$$

where  $p$  is the number of measured locations,  $T$  is the measured period and  $s_p$  is a weight function, that is taken to be the inaccuracy of the measurement at the point  $p$  in prototype and model combined.  $s_p$  makes  $F$  dimensionless and creates the possibility of incorporating water levels and discharges in one object function. Furthermore it was decided to compute  $F$  only for the mean and for the most relevant tidal components ( $M_2$ ,  $S_2$ ,  $M_4$ ,  $MS_4$ ,  $O_1$ ) or their fourier equivalents as far as they may be computed from the measured period. Each such component is called a characteristic. This leads to an enormous data reduction. Actually the calibration aimed at a correct reproduction of these characteristics, giving an overall good reproduction and discarding minor deviations.

Using Parseval's theorem  $F$  may now be written as

$$F = \sum_p \frac{1}{s_p^2} \left\{ (\Delta A_o)^2 + \frac{1}{2} \sum_j ((\Delta a_j)^2 + (\Delta b_j)^2) \right\} \quad (2)$$

where  $\Delta A_0$  is the difference in the mean value and  $j$  is the counter for the relevant fourier component,  $\Delta a_j$  and  $\Delta b_j$  are computed from the amplitude  $A_j$  and the phase  $\phi_j$  as follows:

$$A_j \cos(\omega_j t - \phi_j) = a_j \cos \omega_j t + b_j \sin \omega_j t \quad (3)$$

$$\Delta a_j = a_{j,n} - a_{j,m} \quad (4)$$

$$\Delta b_j = b_{j,n} - b_{j,m}$$

It is clear that  $F$  is a function of the roughness  $R_k$  in all the river branches  $k$  as the amplitudes  $a_{j,m}$  and  $b_{j,m}$  depend on  $R_k$ .  $F$  is also a function of the boundary conditions of the model; if, for example, a discharge was measured on a river branch which was different from the discharge at the boundary (both measures with the same accuracy) then one might take the discharge for the model to be somewhere in between, resulting in a lower  $F$  over the two points. By distinguishing between the boundary conditions and the measured values at the boundaries of the model one eliminates the overweight usually present there. So in the following one should not only think of roughness when  $R$  is used but also of several characteristic features of the boundary conditions that may be adjusted during the process of calibration. Six boundary conditions were used (three discharges, mean sea level and the amplitude and phase of the semidiurnal tide) and 19 sections of river branches where the roughness may be changed.

Could one be more explicit about the relation between  $F$  and  $R_k$ ? In the study phase for the adjustment an analytical harmonic model was build which behaved astonishing well. From such a model (as fully described by Dronkers (1964)) the following assumptions were derived:

1. For the roughness parameter  $R_k$  the formula  $R = g/C^2$  may be used where  $g$  is the acceleration of gravity and  $C$  is Chezy's  $C$ .
2. A change in  $R_k$  will give a change in the mean components  $A_0$ , proportional to the change in  $R_k$ . Actually this only applies to the tidal region but for small changes in  $R_k$  it may also be used for the upstream branches of the model where the quadratic nature of the resistance becomes significant.
3. A change in  $R$  will give a change in the amplitude  $A_j$  in proportion to the change in  $R$  and the value of  $A_j$ .
4. A change in  $R_k$  will give a change in phase that is proportional to this change.

In formula:

$$\begin{aligned} A_0^{\text{new}} &= A_0^{\text{old}} + \alpha_1 \Delta R_1 + \alpha_2 \Delta R_2 \dots \\ \ln(A_j^{\text{new}}) &= \ln(A_j^{\text{old}}) + \Delta R_1 \ln(1+\beta_1) + \Delta R_2 \ln(1+\beta_2) \dots \quad (5) \\ \phi_j^{\text{new}} &= \phi_j^{\text{old}} + \Delta R_1 \omega \gamma_2 + \Delta R_2 \omega \gamma_2 \dots \end{aligned}$$

As stated the  $\alpha$ ,  $\beta$  and  $\gamma$ 's are constants and valid in a very wide range of circumstances. This is a linear mathematical model of the estuary. To make  $F$  an explicit function of the change in roughness one would like to have equations in the form of

$$\begin{aligned} A_0^{\text{new}} &= A_0^{\text{old}} + \alpha_1 \Delta R_1 + \alpha_2 \Delta R_2 \dots \\ a_j^{\text{new}} &= a_j^{\text{old}} + \delta_1 \Delta R_1 + \delta_2 \Delta R_2 \dots \quad (6) \end{aligned}$$

$$b_j^{new} = b_j^{old} + \epsilon_1 \Delta R_1 + \epsilon_2 \Delta R_2 \dots$$

It can be shown that

$$\delta_i \approx a_m \beta_i - b_m \sin \omega \gamma_i \tag{7}$$

$$\epsilon_i \approx b_m \beta_i + a_m \sin \omega \gamma_i$$

The substitution of the actual  $a_m$  and  $b_m$  is the reason why (6) is valid in a much smaller range of circumstances. But (6) may now be substituted into (2) making F an explicit quadratic function of all  $R_k$ . To find the minimum of F the normal least squares is followed:

$$\frac{\delta F}{\delta R_k} = 0 \text{ for each } K \tag{8}$$

which results in (9) if we do not include the weighting factor  $1/s_p$  and use the notation of the first equation of (6) uniformly for the other two equations of (6) (numbering the  $\alpha$ 's with one more index i which runs continuously through all equations).

$$\begin{bmatrix} B & B & B & B \\ \sum_{i=1} \alpha_{i1}^2 & \sum_{i=1} \alpha_{i1}\alpha_{i2} & \sum_{i=1} \alpha_{i1}\alpha_{i3} \dots & \sum_{i=1} \alpha_{i1}\alpha_{iK} \\ B & B & B & B \\ \sum_{i=1} \alpha_{i2}\alpha_{i1} & \sum_{i=1} \alpha_{i2}^2 & \sum_{i=1} \alpha_{i2}\alpha_{i3} \dots & \sum_{i=1} \alpha_{i2}\alpha_{iK} \\ \dots & \dots & \dots & \dots \\ B & B & B & B \\ \sum_{i=1} \alpha_{iK}\alpha_{i1} & \sum_{i=1} \alpha_{iK}\alpha_{i2} & \sum_{i=1} \alpha_{iK}\alpha_{i3} \dots & \sum_{i=1} \alpha_{iK}^2 \end{bmatrix} \begin{bmatrix} \Delta R_1 \\ \Delta R_2 \\ \dots \\ \Delta R_K \end{bmatrix} = \begin{bmatrix} B \\ \sum_{i=1} \alpha_{i1} \Delta A_i \\ B \\ \sum_{i=1} \alpha_{i2} \Delta A_i \\ \dots \\ B \\ \sum_{i=1} \alpha_{iK} \Delta A_i \end{bmatrix} \tag{9}$$

where K is the total number of  $R_k$  and B is the total number of characteristics of all points.

The linear mathematical model (the  $\alpha$ 's) is obtained from successive simulations in a mathematical model, changing one roughness parameter ( $g/C^2$ ) or boundary condition at a time. As the coefficients  $\alpha$ ,  $\beta$ ,  $\gamma$  are valid for every period and are not very sensitive for the period used in simulation they are determined by simulating periods of 25 hours. The mathematical model does not need to be very sophisticated or to have a fine grid, small inaccuracies in the linear mathematical model (the  $\alpha$ 's) will only result in a somewhat slower optimisation. In the study phase  $\alpha$ 's from an analytical harmonic model were used quite successfully to adjust a finite difference model. Although differences in the roughness effects between the hydraulic model and the mathematical model may exist, obtaining the  $\alpha$ 's from the hydraulic model would be a tedious job. Solving (9) now gives a set of changes of the roughness  $\Delta R$ 's that will result in a lower F.

5.2 Options

It would not be very satisfactory if one were only to get a set of changes to be made to all the roughness parameters and all the boundary conditions together; one would like to see if the mean water levels and discharges relate to the same changes as the semidiurnal water levels and discharges do and so on. One might like to exclude certain  $R_k$ 's; for example the boundary conditions should not yet be changed after the first simulation. One might like to get a more regional impression of the changes to be made in several branches combined, or the change to be

made in all deep and narrow branches to see whether there are systematic deviations from the expected roughness. And most of all one would like to have an impression of the accuracy and the effect of the changes to be made.

This section gives some indications how this may be accomplished within the scope of least squares procedures.

It will be clear that equation (9) may be computed for each characteristic as defined in section (5.1). The building of the matrices should then be done by summation not from 1 to B but over specified subsets. The sum may be a weighted sum, stressing one characteristic over the others. The same applies to the function F that may be related to each of the characteristics. The equation (9) to be used then consists of the sum of several or all of the subsets. After the simulation, when all the characteristics from the model have been calculated the matrix (9) and the value of F is computed for each of the characteristics and put in a file. Thus in this way, it is possible to solve (9) once for a set that includes the mean water levels and the mean discharges and then for a set that includes the semidiurnals or both.

Before starting to solve the set of equations one might like to exclude certain  $R_k$ 's by omitting the corresponding rows and columns from the matrices and lower the dimension. The solution will then never indicate a change in this  $R_k$ .

Another important operation to be done on equation (9) is the combination of several  $R_k$ 's. This may be done by adding the corresponding elements of the rows and columns to one new row and column and lower the dimension accordingly. The resulting change in  $R_k$  should then be used for all the members of the combination; in this way one may get an indication of a trend, for example that the initial roughness of all the deep and narrow river branches has been overestimated.

It is outside the scope of this paper to describe how the matrix (9) may be inverted but it is good to notice the following: F is a quadratic function of all the  $R_k$ 's and (9) may be written as:

$$\begin{bmatrix} \frac{\partial^2 F}{\partial R_1^2} & \frac{\partial^2 F}{\partial R_1 \partial R_2} & \dots & \frac{\partial^2 F}{\partial R_1 \partial R_K} \\ \ddots & \ddots & \dots & \ddots \\ \frac{\partial^2 F}{\partial R_1 \partial R_K} & \frac{\partial^2 F}{\partial R_K \partial R_2} & \dots & \frac{\partial^2 F}{\partial R_K^2} \end{bmatrix} \begin{bmatrix} \Delta R_1 \\ \dots \\ \Delta R_K \end{bmatrix} = \begin{bmatrix} \frac{\partial F}{\partial R_1} \\ \dots \\ \frac{\partial F}{\partial R_K} \end{bmatrix} \quad (10)$$

so with a Taylor series expansion (9) gives a complete description of F as a function of all  $R_k$ 's (as far as (6) is valid). The procedures used for inverting the set of equations compute the change of F simultaneously with the step by step inversion. If it is now assumed that F has a normal distribution then one can give a simple statistical indication of the importance of a certain change in  $R_k$ , based on the decrease of F, the resulting F and the number of measured locations and  $R_k$ 's involved. A good description of these statistics may be found in Himmelblau (1970). The actual inversion procedure may be found in Efronson (1959). It does not give the solution of the whole set (9) at once, but it selects first the  $R_k$  that is most effective (that gives the greatest decrease of F). It then computes how big the change in  $R_k$  should be if this were the only change to be made; it computes the

resulting  $F$  and gives an indication of the accuracy of the change in  $R_k$ . In the next step it takes one more  $R_k$ , computes the desired change in each of them, the change in  $F$ , the accuracy of each of the individual changes and so on. The procedure may go as far as producing a completely inverted matrix (9) but obviously was stopped at the point where  $F$  does not decrease significantly any more.

Substitution of the indicated changes into the equations (5) or (6) then gives the values to be expected at the individual measured locations. Comparing these values with the values from prototype and from the previous simulation in the model gives then a very detailed view of the progress of the calibration.

### 5.3 Implementation

A series of programs was written for the DEC BASIC compiler. After a simulation these calculated the characteristics of the model, the matrices (9) and the  $F$ 's for each of the characteristics summed over all water levels or over the discharges. Then an interactive program was run that combines a selected set of characteristics, deletes and combines  $R$ 's and solves the equations step by step, printing information about the accuracies, the resulting  $F$  and so on. In each step the  $F$  that is related to each of the individual characteristics may be computed from a Taylor series using (10) giving information about the improvement of other characteristics. After this terminal session an even better idea of what may be expected may be obtained by substitution of the intended changes into (5) and plotting the expected characteristics together with the last simulation and the prototype (compare fig. 7.2-7.4). After this the change in roughness (which is still in  $g/C^2$ ) is converted to a change in the number of roughness elements.

## 6. CALIBRATION AND VERIFICATION

For the calibration and verification of the model an extensive measurement campaign has been carried out by Rijkswaterstaat (Ministry of Public Works) in 1979. Four periods of three days in May and September were used for the measurement of flows and salinity distribution, with 35 boats simultaneously. These periods included the weekends when nautical activities on the river are less. In this way detailed information about the vertical velocity- and salinity profiles was obtained. From the velocity profiles discharges were derived in the main branches of the estuary. During the whole period of May and September 1979 waterlevels all over the system and salinities at some locations were measured continuously, thereby providing data about springtide-neap tide-springtide time series. Finally some automatically monitoring instruments were used for measurements at sea. Considerations with respect to salinity intrusion, meteorological influences (wind), possible withdrawals and the integral quality of the measurements resulted in the choice of September for calibration of the model (relatively low river discharges) and of May for the verification. Within September the first period of three days with the 13 hours discharge- and salinity vertical measurements was selected for the adjustment process (wind influences being almost negligible in this period). In order to verify the model on hydraulic conditions with extreme low river discharges, which are especially of interest from a research point of view, use was made of available prototype data of August 1976. For that period only time series of waterlevels and a restricted number of salinity recordings are available. Essential for the above described

prototype data is the possibility to adjust the model on large scale phenomena under time series conditions, thereby allowing an assessment of the time-fluctuating dominant phenomena of the tide, mean sea level, river discharge and gravitational circulation. Within these time series the consistency of the detailed reproduction of the vertical velocity and salinity profiles can be considered, giving also insight into the simulation of the vertical turbulent diffusion process.

The actual calibration and verification was then carried out as follows. Based on experiences with one-dimensional models and on a reanalysis of the characteristics of the network system, the hydraulic model was provided with an initial amount of additional roughness.

Subsequently the flows of the September time series were adjusted in a first approximation by means of the procedures as described in chapter 5. By doing so, also the density distribution will be simulated in a global sense as it is primarily determined by the advective transport processes. Then the next phase is the final adjustment by optimizing in an alternating way flows (of the September timeseries) and density distribution, based on the first period with detailed information about the vertical salinity profiles. This optimisation completes the calibration resulting in a mix of various additional roughness- and mixing elements. Based on this model lay-out the verification was performed on the timeseries and vertical salinity profiles of May 1979 and on the timeseries of August 1976.

## 7. RESULTS/DISCUSSION

The provision of boundary conditions was straight forward. Updates could easily and quickly be made. The water levels in the mouth of the river are accurately reproduced from prototype data (see fig. 7.1).

Fig. 7.1

The flow field at sea in front of the river mouth is rather satisfactory, according to comparisons of floats from model and prototype and according to the behaviour of the fresh water wedge at sea.

For optimisation of the salt boundary conditions at the mouth of the Rotterdam Waterway a calibration on tidal flows and on salinity distribution (thin fresh layer due to the river outflow) appeared to be necessary. For this reason additional field measurements in the sea near

the mouth of the Rotterdam Waterway have been carried out in order to verify the model on these data, which may lead to a combined (flows and salinities) improvement of the downstream boundary provision. In this respect it is relevant that the accuracy of the prediction of tidal currents may be considerable less than the accuracy of the prediction of water levels (Godin, 1983).

The adjustment procedures for the waterflows gave very good results. For the complicated network system the final accuracy of the reproduction of the vertical and horizontal tides was met in a few steps. It is very well possible to adjust the roughness in several branches at a time without losing control. The linear mathematical model may be derived from a simpler model than the model that has to be adjusted. The procedures aided in stopping the process of calibration at the point when the result of going on would have been negligible. In this way, this part of the calibration process was accelerated manifold with respect to conventional methods. Based on these experiences, the principles of this optimisation technique will be used also for the development (calibration/optimisation) of mathematical models for the Rhine-Meuse estuary network system (Roelfzema, et al., 1984).

The final result of the calibration and verification shows a fairly good agreement with the prototypedata. Flow characteristics of the vertical tides generally are reproduced within inaccuracies of about 1%, horizontal tides within about 5 to 10%. With this respect figures 7.2 up to 7.4 show some illustrations of the reproduction quality of the mean waterlevels, the semidiurnal amplitude of the vertical tide and its phase as mean values over a neap tide/spring tide/neap tide time series, while figures 7.5 and 7.6 show the reproduction of waterlevels and discharges as functions of time.

Instantaneous inaccuracies of the densities generally vary between 1 to 10%. Tidal mean values show considerable lower inaccuracies. It is important to remark that, in spite of instantaneous differences between model and prototype, the long term tendencies, in general are reproduced fairly, thereby showing the capability of the model to reproduce the overall, dominant characteristics of nature, see figures 7.7 and 7.8.

A remark has to be made with respect to the verification quality of the second period in September 1979. In this period with a combination of neap tide and strong gradients in the mean waterlevels the model probably generates insufficient turbulent diffusion, resulting in larger differences between the vertical salinity distribution of model and prototype, see figure 7.9. For smooth parts of some river branches an opposite effect appeared in the contribution of the additional roughness— an mixing elements in their contribution to the resistance on the one hand and to the mixing on the other. These parts required less resistance and more mixing so an optimum had to be found.

This evidence and the result according to figure 7.9 emphasize the importance of studies on the quantitative knowledge about the vertical diffusion process and requires fundamental research work in a tidal salinity flume on the turbulent exchange processes on mass and momentum and their modelling (physical and mathematical).

## CHAPTER TWO HUNDRED FOURTEEN

### COMPARISON OF TURBULENT LATERAL MIXING MODELS

William G. McDougal and Robert T. Hudspeth<sup>1</sup>

#### ABSTRACT

A variety of different lateral mixing models have been employed in the equation of motion for determining wave-induced longshore currents. The equation of motion is cast into a general form which enables a comparison of the various models. Analytic solutions for longshore currents are developed for seven different mixing models. A nonplanar beach profile is employed because it has been found to be representative of many beaches and it allows for a distinction between offshore and depth scaling of eddies. The seven different mixing models include models which vary monotonically with horizontal distance offshore and models which change form at the breaker line. Numerical results indicate that the longshore current profile is rather insensitive to the form of the mixing model for nonplanar beach profiles.

#### INTRODUCTION

Horizontal mixing due to turbulence has a significant influence on the longshore current profile. The equation of motion describing the longshore velocity is not forced seaward of the breaker line if energy flux is conserved. In the absence of lateral turbulent mixing, a discontinuity is developed in the longshore current at the breaker line for simple periodic waves. This physically unrealistic solution is improved by the inclusion of lateral turbulent mixing. The lateral diffusion of momentum flux couples the solutions across the breaker line and eliminates the velocity discontinuity.

There is a general consensus that lateral mixing should be included in the equation of motion. However, there is little agreement on the exact mathematical form of the mixing term and several different models may be found in the literature.

One of the earliest models is that of Inman, et al. (1971) in which an empirical relationship was determined from field studies of dye dispersion. Two physical discussions were presented to justify the model, a mixing length approach and a friction velocity based on the radiation stresses. For a given wave and beach, the model predicted a constant eddy viscosity. Bowen (1969) had assumed a constant eddy viscosity for estimating longshore currents and provided an estimate of the eddy viscosity based on laboratory measurements. Thornton (1970)

---

proposed a model based on the product of the water particle velocity and excursion length to develop a mean Reynolds stress due to wave motion. The magnitude of the eddy viscosity increased out to the breaker line, but decreased seaward of the breaker line. Longuet-Higgins (1970b) suggested that the scaling for the eddies is proportional to the horizontal distance offshore and the shallow water wave celerity. This eddy viscosity increases monotonically with distance offshore. Jones (1975) developed an eddy viscosity by analogy with mass transport and Fickian flux. The model provided reasonable estimates for laboratory data, but was in very poor agreement with the field measurements of Inman, et al. (1971). Kraus and Sasaki (1979) following Madsen, et al. (1978) used a model which was proportional to the maximum wave orbital velocity at the bottom. Battjes (1975) provided an energy dissipation derivation that led to an eddy viscosity similar to the Longuet-Higgins model for planar beaches. However, this similarity was only for planar beaches because the Battjes model was slope-dependent. This model has been extended by Battjes (1983) to include the diffusive transport of turbulence and a solution for the model was presented by Visser (1984).

In order to evaluate the effects of these various mathematical models for mixing, a general expression for the equation of motion is developed which allows examination of the different mixing models. Analytical solutions for longshore current on a nonplanar beach profile are developed for a variety of mixing models. Numerical results indicate that the longshore current profile is rather insensitive to the choice of any of these individual lateral mixing models. This insensitivity has also been noted by several other investigators. Wu (personal communication) employing a two-dimensional nonlinear numerical model observed little change in the longshore current profile for very different eddy viscosity models. Kraus, et al. (1980) examined a variety of mixing models and again noted a lack of sensitivity. The method employed to compare different mixing models in this paper is similar to the technique used by Kraus, et al. (1980).

#### EQUATION OF MOTION

The time- and depth-averaged longshore equation of motion for the nonplanar beach profile shown in Fig. 1 is given by [Longuet-Higgins (1970b)]

$$-\frac{d}{dx} S_{xy} + \tau_{by} + \frac{d}{dx} (\mu_e d \frac{d}{dx} v) = 0 \quad (1)$$

in which  $S_{xy}$  is the onshore-longshore component of radiation stress;  $\tau_{by}$  is the bottom stress;  $\mu_e$  is an eddy viscosity;  $d$  is the total depth (still-water-depth plus the wave-induced setup); and  $v$  is the longshore current. Implicit in this equation are the assumptions of steady state; of no longshore gradients, of slowly varying depth, of no surface stresses, of small viscous transport of momentum with respect to the turbulent transport, and of an eddy viscosity model. The eddy viscosity model may be represented by a general expression that will permit comparisons between various mathematical models that have been used to represent the turbulent stress.

Figure 1. Definition Sketch

The divergence of the radiation stress is given by

$$\frac{d}{dx} S_{xy} = \begin{cases} -\frac{5}{16} \rho g \kappa^2 d \sqrt{d/d_B} \sin \theta_B \frac{d}{dx} d & ; x < x_B \\ 0 & ; x > x_B \end{cases} \quad (2a)$$

$$(2b)$$

in which  $\rho$  is the density of water;  $g$  is the acceleration due to gravity;  $\kappa$  is a breaker index;  $\theta$  is the wave angle; and the subscript B denotes the value at the breaker line. It is assumed that wave energy flux is conserved seaward of the breaker line, that wave angles are small, that shallow-water wave conditions exist shoreward of the breaker line, and that the breaking wave height is proportional to the local water depth ( $H = \kappa d$ ).

The bottom shear stress may be approximated using linear, shallow water wave theory and small-angle relationships [cf. Liu and Dalrymple (1978)]

$$\tau_{by} = -\frac{C_f}{\pi} \kappa \rho \sqrt{gd} v \quad (3)$$

in which  $C_f$  is an empirically determined friction coefficient of order 0.01 and  $\pi$  is a numerical constant.

Longuet-Higgins (1970b) assumed that the eddy viscosity coefficient is proportional to a velocity scale and a length scale was taken to be a linear function of the horizontal distance offshore. This particular choice for horizontal scale of the turbulent eddies is limited by the shoreline boundary inside the surf zone. However, for a planar beach this scaling gives the same offshore dependency as eddies which are limited by the depth. Therefore, it is of interest to examine a non-planar, concave-up beach profile where these two types of eddy scaling may be treated differently. An eddy viscosity model similar to that used by Longuet-Higgins (1970b) will be adopted, but the length scale of the eddies will be considered to be an arbitrary exponential function of the horizontal distance offshore. The following general expression allows comparison with other turbulence models by varying the exponent to represent the scale of the eddy size; i.e.,

$$\mu_e = N\rho (gd)^{1/2} \frac{x^p}{x_B^{p-1}} \quad (4)$$

where  $N$  is a numerical constant and  $p$  is a shape factor for scaling the eddy size.

Introducing (2), (3), and (4) into (1) gives

$$\frac{N\pi}{C_f \kappa} x_B^{1-p} \frac{d}{dx} (x^p d^{3/2} \frac{d}{dx} v) - d^{1/2} v = \begin{cases} -\frac{5}{16} \frac{\pi}{C_f} g^{1/2} \kappa \frac{\sin \theta_B}{d_B^{1/2}} d^{3/2} \frac{d}{dx} d & ; x < x_B \\ 0 & ; x > x_B \end{cases} \quad (5a)$$

$$(5b)$$

Nondimensionalizing all length scales by the horizontal surf zone width,  $x_B$ , and the velocity scales by the no-mixing planar beach velocity at the breaker line,  $v_{BL}$ , given by Longuet-Higgins (1970a), the dimensionless longshore equation of motion (denoted by upper case letters) becomes

$$\frac{N\pi}{C_f \kappa} \frac{d}{dX} (X^p D^{3/2} \frac{dV}{dX}) - D^{1/2} V = \begin{cases} -\Delta D^{3/2} \frac{dD}{dX} & ; X < 1 \\ 0 & ; X > 1 \end{cases} \quad (6a)$$

$$(6b)$$

in which

$$X = x/x_b \quad (6c)$$

$$V = v/v_{BL} \quad (6d)$$

$$\Delta = \left(\frac{x_B}{d_B}\right)^2 \quad (6e)$$

$$v_{BL} = \frac{5}{16} \frac{\pi \kappa}{C_f} s v \sin \theta_B \sqrt{gd} \quad (6f)$$

and  $s$  is the planar beach slope including setup.

The boundary conditions which are to be imposed to determine the integration constants require that the velocities be bounded at both the shoreline ( $X = 0$ ) and offshore ( $X \sim \infty$ ) and that both the magnitude of and the gradient of velocity be continuous at the breaker line ( $X = 1$ ).

## BEACH PROFILE

Equations (6) are expressed in terms of an arbitrary total water depth,  $D(X)$ . However, this depth profile must increase monotonically with horizontal distance offshore. This restriction is due to the breaker index which relies on the so-called spilling breaker assumption in which the breaking wave height is considered to be proportional to the local water depth. This assumption is frequently employed in analytical longshore current models and is obviously a weak assumption. However, it is not the intent of this paper to improve on breaking wave models, but rather to cast the equation of motion into a somewhat standard form and to then examine the influence of various mathematical expressions for the lateral mixing models on the longshore current profile.

The monotonically increasing depth profile is required to avoid wave heights which increase over inshore troughs. An arbitrary, but monotonic, depth profile is given by

$$D = B X^q \quad (7)$$

in which  $q$  is an arbitrary shape factor that need not be an integer and  $B$  is analogous to slope. Equation (7) allows the equation of motion to be expressed in terms of a general depth profile according to

$$P \frac{d}{dX} \left[ X^{(3/2 + q + p)} \frac{d}{dX} v \right] - X^{1/2 + q} v = \begin{cases} -q X^{5/2 + q - 1} & ; X < 1 \quad (8a) \\ 0 & ; X > 1 \quad (8b) \end{cases}$$

in which  $P$  is a mixing strength parameter defined by

$$P = \frac{N\pi}{C_f \kappa} B \quad (8c)$$

Equations (8) are general and may be applied to a variety of beach profiles which increase monotonically in depth offshore. For  $p=q=1$ , (8) reduce to the planar beach equation of Longuet-Higgins (1970b). For  $p=1$ ,  $q=1/2$  (8) reduce to the Bruun profile evaluated by McDougal and Hudspeth (1983a). Rather complex beach profiles may be modeled piecewise using (8) along with appropriate matching of boundary conditions at the ends of each piecewise segment. This approach was employed by McDougal and Hudspeth (1984a) to model a composite beach having a non-planar, concave-up beach profile in the offshore segment with a planar beach face on the nearshore segment.

Natural beaches tend to be concave-up rather than planar. A beach profile in which the still-water-depth is proportional to the horizontal

distance offshore raised to the 2/3 power has been deduced from physical arguments by Bruun (1954), Dean (1977), and Bowen (1978). In an examination of a total of 502 beach profiles along the Atlantic and Gulf coasts of the United States, Dean (1977) estimated a relationship between the coefficient of proportionality and the grain size. The 2/3 power profile has also been observed along the Danish coast by Bruun (1954).

McDougal and Hudspeth (1983) determined the setup/setdown on this 2/3 type beach profile and found the total depth (still-water-depth plus wave-induced setup) to be well approximated by a total water depth profile that is proportional to the horizontal distance offshore raised to the 1/2 power. This 1/2 power total depth profile will be employed in this study. This profile enables a distinction between the length scale associated with the offshore distance and local depth length scale in the eddy viscosity.

#### EDDY VISCOSITY MODELS

Analytical solutions are developed for seven different eddy viscosity models for the 1/2 power beach profile. Accordingly,  $q = 1/2$  in (8) for all values of  $p$  used below. The relevant parameters for comparing the models are summarized in Table 1. Solutions to (8) have been given by Hildebrand (1976). Longshore current profiles are plotted for each model in Figures 2 and 3 for mixing strengths of 0.1 and 1.0, respectively.

Linear Scale:  $p = 1$

The eddy viscosity model employed by Longuet-Higgins (1970b) assumed that the velocity and length scales were proportional to the shallow-water wave celerity and the horizontal distance offshore. This corresponds to a value of  $p=1$  in (8). Solutions to the equation of motion satisfying the boundary conditions are given in McDougal and Hudspeth (1984b).

Depth Scale:  $p = 1/2$

Battjes (1975) has suggested that a more appropriate length scale for eddies is the depth rather than the horizontal distance offshore. For an eddy length scale proportional to the depth this yields  $p = 1/2$  for a nonplanar,  $X^{1/2}$  concave-up profile.

Maximum Scale:  $p = 3/2$

It may be shown by the method of Frobenius (Hildebrand, 1976) that the maximum value  $p$  may obtain is 3/2.

Constant Scale:  $p = -1/4$

Bowen (1969) assumed and Inman, et al. (1970) observed that the eddy viscosity was a constant independent of the horizontal distance offshore. For an  $X^{1/2}$  beach profile, a constant eddy viscosity given by (4) requires that  $p = -1/4$ .

Table 1. Summary of Mixing Models for Nonplanar Beaches (q=1/2)

Model	p	Mixing Strength (P)
Linear Scale	1	$\frac{N\pi}{C_f \kappa} B$
Depth Scale	1/2	$\frac{N\pi}{C_f \kappa} B$
Maximum Scale	3/2	$\frac{N\pi}{C_f \kappa} B$
Constant Scale	-1/4	$\frac{N\pi}{C_f \kappa} B$
Wave Kinematic Scale	1/4 ; X < 1 -7/4 ; X > 1	$\frac{\pi \kappa}{8 C_f} \frac{B^2}{\omega} \left(\frac{g}{d}\right)^{1/2}$
Modified Linear Scale	1 ; X < 1 1/2 ; X > 1	$\frac{N\pi}{C_f \kappa} \beta$
Energy Dissipation Scale	1/3 ; X < 1 (4r <sub>2</sub> +3)/12 ; X > 1	$\frac{N\pi}{C_f} \left(\frac{5}{32} \kappa^2 B^7\right)^{1/3}$

Figure 2. Comparison of Longshore Current Profiles (P = 0.1, q = 0.5)

Figure 3. Comparison of Longshore Current Profiles ( $P = 1.0, q = 0.5$ )

Figure 4. Comparison of Actual and Approximate Velocity Scales for the Energy Dissipation Model

Thornton Model Scale:  $p = 1/4, -7/4$

Thornton (1970) proposed a model which relates the eddy viscosity to the absolute value of the time-averaged product between the water particle excursion due to the wave motion,  $l'$ , and the water particle velocity fluctuation due to the waves,  $u'$ . This model is given by

$$\mu_e = \rho \langle |u' l'| \rangle \quad (9)$$

where  $\langle \cdot \rangle$  is the temporal averaging operator over the wave period.

Evoking the both small wave angle assumption and linear wave theory at the bottom, (9) may be written as

$$\mu_e = \frac{\rho \omega H^2}{8 \sinh^2 kd} \quad (10)$$

in which  $k$  is the wave number and  $\omega$  is the radian wave frequency. Inside the breaker line shallow water assumptions are made and the eddy viscosity is given by

$$\mu_e = \rho g \frac{\kappa^2}{8\omega} d \quad (11)$$

Substitution of this eddy viscosity into (1) instead of using (4) results in a different mixing strength parameter,  $P_T$ , given by

$$P_T = \frac{\pi \kappa B^2}{8 C_f \omega} \left( \frac{g}{d_B} \right)^{1/2} \quad (12)$$

and the resulting equation of motion is equivalent to  $p = 1/4$ .

Seaward of the breaker line the wave-induced turbulence is much less. The eddy viscosity model proposed by Thornton (1970) changes form at the breaker line. The waves are no longer breaking and the shallow water assumption is inappropriate. In this relatively deeper region, the eddy viscosity decays approximately hyperbolically with increasing distance from shore. Assuming deep water conditions, using the concave beach profile and requiring  $\mu_e$  to be continuous at the breaker line, the offshore eddy viscosity is approximately given by

$$\mu_e = \rho g \frac{\kappa^2}{4\omega} d_B \left( \frac{d}{d_B} \right)^{3/2} \quad (13)$$

The mixing strength parameter is the same as for  $X < 1$  given by (16) and the resulting equation of motion is equivalent to  $p = -7/4$ .

Modified Linear Scale:  $p = 1, 1/2$

Kraus and Sasaki (1979) developed a model which is applicable in the offshore employing results from Madsen, et al. (1978). Requiring continuity of the eddy viscosity at the breaker line, this model may be approximated as

$$\mu_e = \begin{cases} N\rho \times \sqrt{gd} & ; X < X_B & (14a) \\ N\rho \times \sqrt{gd} \frac{d_B}{d} & ; X > X_B & (14b) \end{cases}$$

which is the same as the Longuet-Higgins model shoreward of the breaker line. The modification in the offshore region reduces the rate at which the eddy viscosity increases, but it still increases monotonically. The resulting mixing strength parameter is given by (8c) and the equation of motion corresponds to  $p = 1$  for  $X < 1$  and  $p = 1/2$  for  $X > 1$ .

Energy Dissipation Scale:  $p = 1/3, (4r_2 + 3)/12$

Battjes (1975) estimated the horizontal turbulent momentum exchange from an examination of the turbulent energy dissipation. The model turns out to be similar in form to an eddy viscosity model, but this assumption was not made a priori. However, this similarity was only for planar beaches because the model was slope-dependent. This model was not applicable seaward of the breaker line. Citing results from dye studies in the surf zone, Battjes (1975) observed that the turbulence is primarily contained within the surf zone, but that there must be some production of turbulence seaward of the breakers to avoid a velocity discontinuity at the breaker line. By including the diffusive transport of the turbulent momentum, Battjes (1983) extended the range of application of the turbulence model to include the entire nearshore region. A solution to the equation proposed by Battjes (1983) for the balance of turbulent energy was presented by Visser (1984).

$$\mu_e = M \rho \kappa d q \tag{15a}$$

in which

$$q = \begin{cases} [A_1 x^{r_1} + \frac{5}{16} \kappa^2 g^{3/2} d^{3/2} \frac{d}{dx} d]^{1/3} & ; x < x_p & (15b) \\ [A_2(x-a)^{r_2}]^{1/3} & ; x > x_p & (15c) \end{cases}$$

and  $M$  is an empirical coefficient of order 1;  $r_1$ ,  $r_2$ , and  $a$  are wave field parameters; and  $A_1$  and  $A_2$  are integration constants which can be

determined by requiring continuity of  $q$  and the gradient of  $q$  at the plunge point,  $x_p$ . The production of turbulence begins at the location of actual breaking,  $x_p$ , not the location of the initiation of breaking,  $x_{B1}$  and this effect was included in the Visser solution. However, this effect was not included in any of the other models. To allow direct comparison of the models it will be assumed that  $x_p = x_B$ .

When the nonplanar beach profile is employed in Eqs. (15) and the wave field parameters are evaluated, the resulting forms for the eddy viscosity are not compatible with Eq. (4). Therefore, the following approximations are used

$$q = \begin{cases} \psi x^{1/12} = \psi x_B^{1/12} X^{1/12} & ; X < 1 & (16a) \\ \psi x_B^{1/12} \left(\frac{x}{x_B}\right)^{1/3} r_2 = \psi x_B^{1/12} X^{1/3} r_2 & ; X > 1 & (16b) \end{cases}$$

where

$$\psi = \left(\frac{5}{32} \kappa^2 g^{3/2} \beta^{5/2}\right)^{1/3} \quad (16c)$$

These approximations are compared with the full equation for a nonplanar profile and with  $x_p = x_B$  in Figure 4. Upon substitution into the equation of motion, a different mixing strength parameter,  $P_B$ , results.

$$P_B = \frac{M\pi}{c_f} \left(\frac{5\kappa^2}{16} B^7\right)^{1/3} \quad (17)$$

The resulting eddy scale of (4) requires that  $p = 1/3$  and  $p = (4r_2+3)/12$  for  $x < 1$  and  $x > 1$ , respectively. The solution is sensitive to the breaking wave height. Larger wave heights yield velocity profiles which appear to have lower lateral turbulent mixing strengths. The numerical results shown in Figures 2 and 3 are for small wave height conditions.

#### DISCUSSION

Solutions to the longshore equation of motion have been developed for seven different lateral mixing models on a nonplanar beach profile which are summarized in Table 1. Longshore velocity profiles obtained for these solutions are shown in Figures 2 and 3 for each mixing model for mixing strengths of  $P = 0.1$  and  $P = 1.0$ , respectively. There are relatively small differences between these velocity profiles, and these differences decrease as the mixing strength decreases due to the obvious requirement that all of the models must converge for  $P = 0$ .

The differences between the equations listed in Table 1 for the mixing strength parameters defined by Battjes and by Thornton compared to the other four models appear to be significant. However, the dif-

ferences in the numerical values for the longshore current computed by each of these models are rather small and most of the models have similar dependencies on the various parameters. Each of the models exhibit similar dependencies on mixing for nonplanar beaches in that steeper slopes yield greater mixing strengths. Increasing the bottom roughness results in decreasing the strength of lateral mixing in each model. All of the models listed in Table 1, except the wave kinematic and the energy dissipation, are inversely related to the breaker index. This implies that if the spilling wave longshore current models are applied to plunging or surging breakers the mixing should be reduced. The wave kinematic model is linearly dependent on the wave period such that longer waves will be more mixed than shorter waves. The energy dissipation model is also a function of the wave conditions with larger wave heights being less mixed.

These numerical results demonstrate that the longshore current profile is only weakly dependent on the analytical form of the lateral mixing model employed. This observation suggests that any reasonable analytical model for the lateral turbulent mixing may be selected for a particular application based solely on its computational efficiencies. However, the kinematic and energy dissipation models provide more physically realistic estimates of mixing. The velocity profiles are obviously sensitive to the strength of mixing. Komar (1975) suggests that values for the mixing strength should generally be less than 0.4.

## CHAPTER TWO HUNDRED FIFTEEN

### Surges and Waves Generated by Ships in a Constricted Channel

John B. Herbich\* and Robert E. Schiller, Jr.\*\*

#### Introduction

A study of surges and waves was initiated because of serious bank erosion along the Sabine-Neches Waterway, located in East Texas. The Waterway provides ship access from the Gulf of Mexico to Port Arthur and Beaumont. The design water depth in the ship channel is 12.12 m (40 ft). The 1978 tonnage of ships using the waterway was 69,740,900 tons (1). The highway on the east bank of the Waterway between Port Arthur and Mesquite Pt. leading to Louisiana had to be relocated several times because of bank erosion. The erosion was thought to be principally caused by ship traffic generating surges and waves.

The main purpose of the study was to:

1. evaluate the magnitude of surges and waves generated by ships using the Waterway,
2. evaluate bank erosion potential, and
3. evaluate and recommend the most economical structural measures to prevent further bank erosion.

The results of this first part of the study are reported in this paper.

#### Literature Review

The literature on waves and surges created by ships in dredged navigational channels is rather limited, but occurrences of such phenomena have been observed in many countries. The most severe problem occurs in an artificial channel dredged in a shallow inlet or a tidal estuary. Large ships passing through such a confined deep channel cause a significant initial drop in water level and a resulting surge as the ships proceed along the channel. The waves generated by such ships are relatively small as compared with the magnitude of the generated surge. Small, high-speed vessels generate only insignificant surges, but may create relatively high waves.

Lee and Bowers (5) conducted tests for the Panama Canal and made extensive drawdown measurements for a wide range of channel depths,

\*\*Professor, Civil and Ocean Engineering, Texas A&M University, College Station, TX, USA.

widths, and ship speeds. Helm and Woltinger (4) stated that the speed of the return flow (surge) provides an indication of the magnitude of the soil erosion problem.

Gelencser (3) confirmed the occurrence of drawdown created by ships in the St. Lawrence Seaway.

Dand and White (2) reported on the studies conducted in the Suez Canal and indicated that one of the disadvantages of a horizontal berm at the western side of the Canal is the generation of surge waves. A dimensionless plot of the vessels Froude Number, as a function of the blockage ratio, was developed to indicate the possibility of creating a drawdown at the berm.

Balanin, et al. (1) and Van de Kaa (8) also addressed the problem of the drawdown that occurs with ship's passage. Maynard (7) conducted field studies on the Sacramento River Deep Water Ship Channel concerning riprap protection in navigation channels.

#### Generation of Surges and Waves

In an artificially-dredged channel, in otherwise shallow water, a large ship displaces a large volume of water which must then follow in the opposite direction to the ship's movement along both sides of the ship (Figure 1). This causes a surge which moves perpendicularly to the bank at a high velocity, thus causing bank erosion (Figure 2). Surges as high as 3.3 m (10 ft) have been observed during the passage of large vessels moving at a relatively high speed. In addition, bow and stern waves are generated by the vessels, but these are of small magnitude as compared with generated surges. Small work boats and tugs generate only insignificant surges but generate waves which may be of the order of 1 to 1.2 m (3 to 4 ft) when travelling at high speed.

Figure 1. Dredged Ship Channel

Figure 2. Waves and Surges Generated by a Ship in a Constricted Channel

### Field Measurements

Field measurements of ship's speed, draft, generated waves and surges were taken with a video tape recorder, movie camera and pressure transducers installed at several locations along the banks of the Waterway. Pressure transducers were installed in about 2.1 to 2.4 m (7 to 8 ft) of water and connected to a recorder on land.

Transducers, approximately 6.4 cm (2.5 inches) diameter at the base and 18.5 cm (7.25 inches) long, were constructed of stainless steel. The transducers were connected to an electronic recorder which traced the water level as a function of time. Since the recorders were powered by batteries, they were only turned on when a vessel passed through the Waterway.

A typical recorded surge trace by a deep-draft vessel is shown in Figure 4 and a typical recorded wave trace is shown in Figure 5. A sample surge trace as a function of time is shown in Figure 5 for a 4.7 m (15.5 ft) draft vessel moving at 9.77 knots. It will be noted that surging continued for several minutes (the recorder was turned off after 5 minutes.). In some cases, surging was observed for 20 minutes or more.

### Data Analysis

#### Surge height for a range of ship drafts

The surge height as a function of Froude Number for a range of ship drafts is shown in Figures 6 and 7. The surge height is shown in

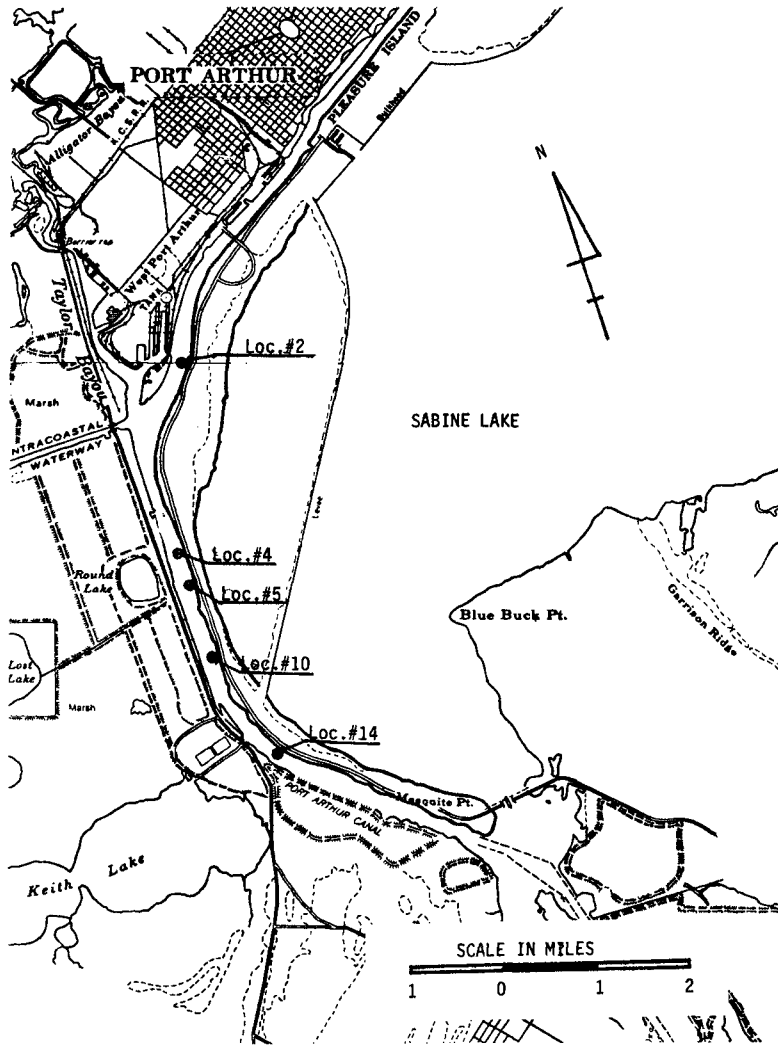

Figure 3. Sabine-Neches Waterway between Port Arthur and Mesquite Pt. (Texas)

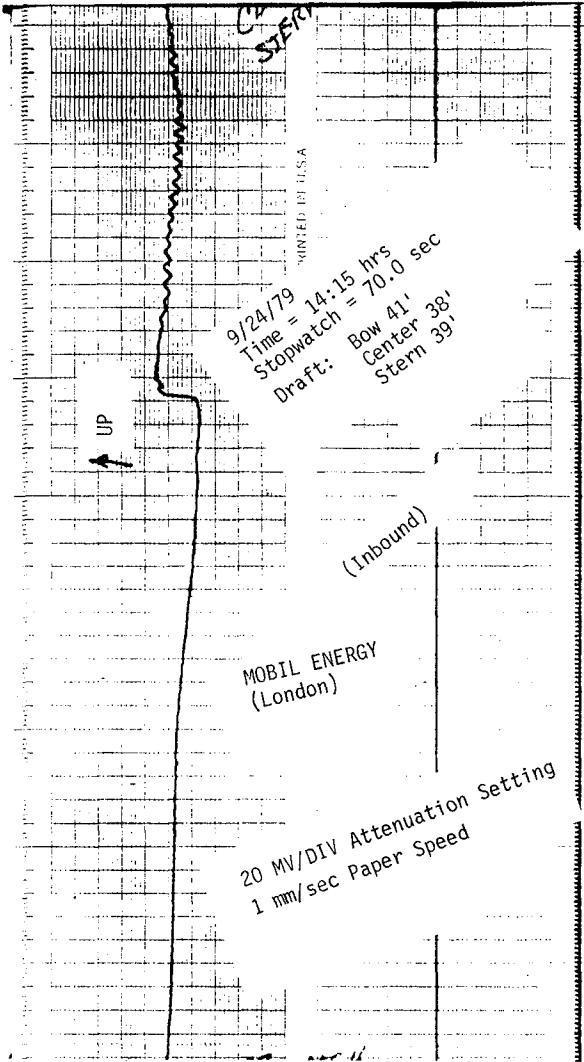

Figure 4. Typical Recorder Trace of Surge Due to Passage of a Ship

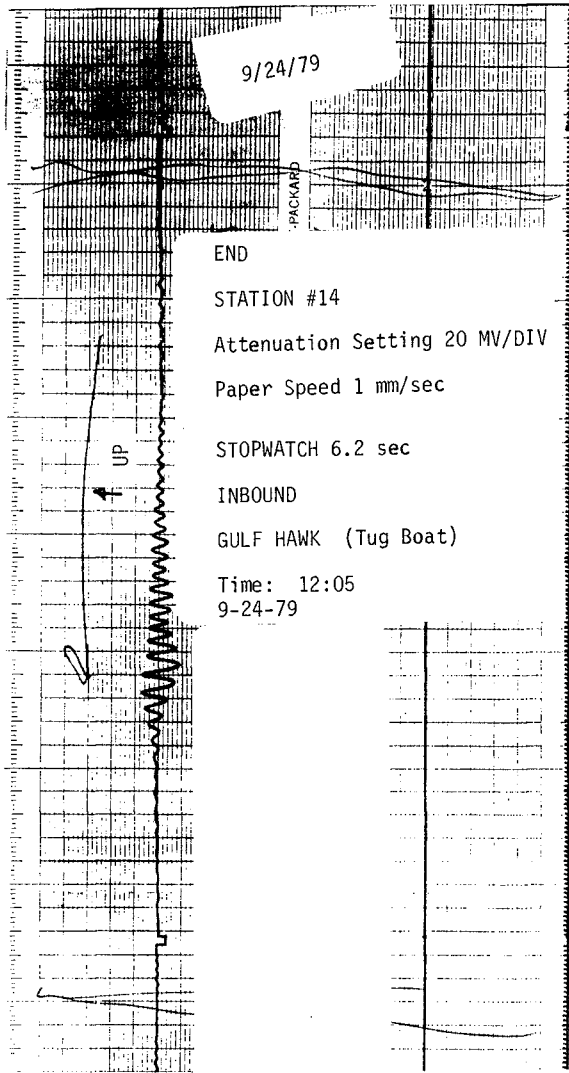

Figure 5. Typical Recorder Trace of Waves from Wake Due to Passage of a Tug Boat

Figure 6. Surge Height Vs. Froude Number at Location #2 for Inbound Ships (Equal Draft)

Figure 7. Surge Height Vs. Froude Number at Location #2 for Outbound Ships (Equal Draft)

feet (1 ft = 0.3048 m) and the Froude number is defined as

$$\frac{V}{\sqrt{gD}}$$

where

V = vessel's speed,  
g = acceleration due to gravity, and  
D = vessel's draft.

The vessel's draft is also shown in feet.

Figure 6 represents the data for inbound ships at location No. 2 (see Figure 3 for actual location) and Figure 7 shows similar information for outbound ships. The lines are drawn for ships of equal draft ranges. It is quite clear from the figures that the surge height is a function of the Froude Number and the ship's draft. The surge height increases rapidly with the Froude Number.

#### **Surge height for a range of ship speeds**

The surge height as a function of Froude Number for a range of ship speeds is shown in Figures 8 and 9 for outbound ships.

#### **Surge height for a range of ship drafts and observed ship speeds**

Figure 10 presents the surge height measurements for outbound ships at location No. 2 as a function of ship's speed, and Figure 11 presents the surge height measurements for inbound ships at location No. 14.

#### **Surge height/length of ship (B.P.) for a range of ship drafts**

Figures 12 through 14 present the surge height data in a dimensionless form (surge height/length of ship between perpendiculars) as a function of Froude Number for two locations, No. 2 and No. 14. Figures 12 and 13 are for location No. 2 for inbound and outbound ships respectively and Figure 14 is for location No. 14.

#### **Occurrences of surge heights**

Figure 15 presents the number of surge height occurrences measured at location No. 2, and Figure 16 shows the number of occurrences of ship-generated wave heights measured at location No. 14. Figure 15 presents the data for deep-draft vessels and Figure 16 is for small vessels moving at low speeds.

Figure 15. Number of Occurrence Vs. Surge Height at Location #2

Figure 16. Number of Occurrence Vs. Wave Height at Location #14

### Conclusions

1. Considerable surges and waves generated by ships were observed in the Sabine-Neches Waterway. Such surges and waves are the principal cause of bank erosion along the Waterway.
2. The surge height generated by large vessels in a dredged channel, in an otherwise shallow estuary or inlet, is a function of ship's draft and ship's speed. In general, the greater the ship's draft and ship's speed, the greater the generated surge and drawdown.
3. The waves generated by small vessels are principally a function of ship's speed.
4. The surge height generated by large vessels is considerably higher than the waves generated by such vessels.
5. The wave heights generated by small vessels are very large in comparison with surges generated by such vessels. In fact, the surges generated by small vessels can be considered insignificant.

**Acknowledgment**

The study was sponsored by the Texas State Department of Highways and Public Transportation in cooperation with the Texas Transportation Institute. The cooperation of Mr. Franklin C. Young and Mr. William A. Potter, III is gratefully acknowledged. Mr. K. Kim and T.Y. Lee, graduate students in ocean engineering, assisted in data collection and analysis. Mr. A. R. Toussaint, an undergraduate student in Ocean Engineering, did most of the pressure transducer installations.

## CHAPTER TWO HUNDRED SIXTEEN

### DEVELOPMENT OF SHIP WAVE DESIGN INFORMATION

Robert M. Sorensen, F. ASCE\*  
J. Richard Weggel, F. ASCE\*\*

#### ABSTRACT

During the last three decades several field and laboratory investigations have been conducted in which the waves generated by a wide variety of vessels have been measured. There is a need to synthesize the data published from these studies and to develop general ship wave prediction methods for designers. To complete this task some additional ship wave data must be collected. This paper initiates the effort to develop these prediction methods. A summary and critique of available data are given. Then, the appropriate portion of these data is employed to develop a ship wave height predictor model that gives the maximum ship wave height as a function of ship speed and displacement, water depth, and distance from the sailing line. This is an interim model that is quite applicable but can be improved pending additional data. Finally, planned future efforts to further develop design wave prediction methods are discussed.

#### INTRODUCTION

The design of various waterway features such as bank erosion control structures and marina protective works, as well as the establishment of allowable ship speeds in navigable waterways, require a knowledge of the characteristics of the waves generated by the ship traffic using the waterway. The characteristics of the ship waves (wave heights, periods, crest orientations) depend on the ship speed and direction, the water depth, the ship hull form and draft, and the distance from the sailing line.

During the later 19th Century, Kelvin developed the first ship wave theory and Froude conducted towing tank experiments to measure ship wave resistance. However, only during the last twenty-five years has there been a serious effort to conduct field and laboratory measurements of the characteristics of ship-generated waves. Data has been collected in towing tanks and in restricted and open waterways, for deep and shallow water wave conditions generated by a variety of vessels. Typically, for a given test run, reported data consists of the height of the highest wave in a wave record generated by the passing ship and its associated half period, for the particular speed and distance from the sailing line.

Available experimental data covers a wide range of ship types and speeds and waterway conditions; however, certain data deficiencies do

---

\* Professor of Civil Engineering, Lehigh University, Bethlehem, PA 18015  
\*\*Associate Professor of Civil Engineering, Drexel University,  
Philadelphia, PA 19104

exit. Specifically, there is insufficient data for large ship draft to water depth ratios. Also, hull forms for the vessels studied are inadequately defined.

The data that are available (plus additional data to be collected) need to be synthesized and analysed to develop a coherent procedure for predicting ship wave heights and periods for given ships, ship speeds, water depths and distances from the sailing line.

Also, design analyses often require more information on ship wave characteristics than the maximum wave height and associated half-period. Of more value, for example, would be a representative wave height similar to the significant wave height from a wind wave record and the typical distribution of wave heights in a ship wave record for given conditions.

With these deficiencies in view, the authors have initiated a study to improve ship wave design information and procedures. This paper presents initial results of the study.

#### SHIP-GENERATED WAVE CHARACTERISTICS

A brief summary of ship wave characteristics is presented here; see Sorensen (1973) for more details.

As water flows past the bow of a ship, a pressure gradient develops and waves are generated. The pressure gradient and resulting height of generated waves depend on the relative water velocity (i.e. ship speed), the bow shape, the ship draft, and the clearance below the keel (i.e. ship draft to water depth ratio). The resulting pattern of wave crests generated by the bow of a ship moving in deep water (Figure 1) consists of a symmetrical set of diverging waves that move obliquely out from the sailing line and a single group of transverse waves that move in the direction of the sailing line. The transverse and diverging waves meet to form cusps located along lines  $19^{\circ}28'$  out from the sailing line. If the ship speed is increased, this pattern retains the same geometric shape but grows in size as the wave lengths increase. A similar pattern of waves typically with lower wave heights is generated at the ship's stern.

At increasing distances from the bow, diffraction increases the wave crest length and decreases the wave amplitude. Havelock (1908, 1914) demonstrated analytically that the wave heights at the cusp points decrease at a rate inversely proportional to the cube root of the distance from the bow while the transverse wave heights along the sailing line decrease at a rate inversely proportional to the square root of the distance from the bow. Thus, at greater distances from the ship, the diverging waves become more prominent than the transverse waves.

Figure 2 show a typical water surface-time history measured at a point during the passage of a ship. Most published data on ship waves present the maximum wave height,  $H_m$ , and the associated half-period,  $T/2$ , from such a record.

The transverse waves have a celerity equal to the speed of the ship. Thus, using linear wave theory, their length and period can be calculated for a given ship speed and water depth. The diverging waves have a celerity that is less than the ship speed and equal to  $V \cos \theta$ , where  $V$  is the ship speed and  $\theta$ , defined in Figure 1, is approximately  $55^{\circ}$ . Thus, the diverging wave length and period can also be calculated (see Sorensen, 1967).

Figure 2 Water Surface Time History at Point For Waves From Mariner Model Ship (Das 1969).

Figure 1 Deep Water Wave Crest Pattern Generated by Ship's Bow

Figure 3 Variation of  $H^*$  with  $x^*$  for Various Values of  $d^*$ . Froude Number = 0.28.

When the water depth is less than about one half the length of the ship waves, the waves "feel" bottom and their characteristics and crest pattern are significantly modified. This "shallow water" condition occurs for depth Froude numbers,  $F$ , in excess of approximately 0.6 (Sorensen, 1966), where  $F = V/\sqrt{gd}$ , and  $d$  equals the water depth.

In shallow water, as  $F$  increases from 0.6 to 1.0 the cusp locus angle increases from  $19^{\circ}28'$  to  $90^{\circ}$ . The leading transverse and diverging wave heights are accentuated at the expense of the following waves. At  $F = 1.0$ ,  $V = \sqrt{gd}$  and the transverse and diverging waves combine to form a single wave having a crest line perpendicular to the sailing line. Thus, as would be expected,  $H_m$  and  $T/2$  increase at an increasing rate through this range of Froude numbers. Ships rarely operate at speeds exceeding a Froude number of unity (see Schofield, 1974) so the wave pattern and characteristics in this region will not be considered here.

For a given vessel shape and speed, water depth, and distance from the sailing line, there is a significant increase in  $H_m$  as the ship draft increases (see Johnson, 1958). On the other hand, light vessels that increase their speed may plane before reaching a Froude number of unity and once planing commences there is essentially no increase in wave height with increasing ship speed.

#### EXPERIMENTAL DATA

Several laboratory and field investigations of ship-generated waves have been conducted during the last twenty-five years. Table 1 summarizes the test conditions and data collected from published investigations.

Typically, in each investigation the water surface time history was measured at one or a few points (distances from the sailing line) as the ship passes. Few of the actual time history records have been published; most authors just present data on  $H_m$  and  $T/2$  as a function of ship speed and distance from the sailing line. Some authors have published an average period,  $\bar{T}$ , equal to the number of waves divided into the duration of the "wave packet". Wave records with a strong contribution from both diverging and transverse waves would have a bimodal distribution of wave periods so an "average" period could be misleading.

Zabawa and Ostrom (1980) also present ship wave energy density data (for each test run) based on the root mean square wave height for the waves in a given record. Similarly, Ofuya (1970) presents data on the total energy in a ship wave record based on the root mean square wave height and the period of  $H_m$ . Das (1969) presents energy spectra for eight of his test runs.

Usually, experiments were conducted with whatever model or prototype vessels were available and most experiments, particularly in the field, were conducted with a small ship-draft to water-depth ratio ( $D/d$ ). Consequently, the data do not cover waves generated by a uniform range of hull forms and in almost all cases  $D/d$  is less than 0.5. Also, for most data sets, the ship hull geometry was very inadequately defined or reported, making it difficult or impossible to quantify the hull form geometry with respect to its wave generating capability. For some data sources, block coefficients (displaced volume/length x beam x draft) could be defined. For others, the

Bhowmik et al. 1982	P	0.10-0.65	59 barge tows of opportunity	0.06-0.3 (approx.)	varied	Hm versus Vs, x; river currents with/against tow; blockage ratio: 14.7-226.9.
Maynord and Oswalt, 1984	M	0.3-0.62	Barge tows	0.90-0.64	varied	Hm versus Vs, x at channel bank; blockage ratio: 4.6-16.4.

block coefficient could at best be estimated, or only a verbal description of the hull form could be obtained.

#### INTERIM MODEL TO PREDICT SHIP-GENERATED WAVE HEIGHTS

An interim model has been developed to predict ship-generated wave heights at a given location when a ship's speed and displacement, water depth, and distance from the sailing line are known. Obviously, the heights of ship-generated waves depend on hull characteristics other than just the ship's displacement; for example, factors such as the beam to length ratio, beam to draft ratio, and the ratio of the displaced volume to the product of the beam, draft and length (block coefficient) affect wave heights. The model presently considers only the ship's displacement but work is underway to improve the model by considering other relevant hull-shape parameters. Some progress in this direction is presented here.

The data used for developing the interim model was the field data presented by Sorensen (1967) and includes wave height data from seven different ships having displacements ranging from 3 to 18,800 tons, lengths ranging from 23 to 504 feet and drafts ranging from 1.7 feet to 28 feet.

The important variables considered in the interim model to describe the ship-wave generation problem and their dimensions are:

- H = ship-generated wave height, (L)
- d = water depth, (L)
- x = distance from the sailing line to the point where the wave height is measured, (L)
- V = ship speed, (L/T), and
- $\Psi$  = volume of water displaced by the ship, (L<sup>3</sup>)

In addition, the length, beam, and draft of the ship are important although they are not initially considered in the interim model. Their influence will be discussed later.

Dimensional analysis of the above variables yields four dimensionless variables. The form for each of the dimensionless variables selected for the present analysis was largely dictated by the available data; that is, the dimensionless parameters were selected so that the functional relationship between two variables could be investigated while the remaining variables were held constant or nearly constant. One set of dimensionless variables meeting this criterion is:

$$\frac{V}{\sqrt{gd}} = \text{Froude number}$$

$$\frac{H}{(\Psi)^{1/3}} = \text{dimensionless wave height (dependent variable),}$$

$$\frac{x}{(\Psi)^{1/3}} = \text{dimensionless distance from sailing line,}$$

$$\frac{d}{(\Psi)^{1/3}} = \text{dimensionless depth.}$$

where the term,  $\Psi^{1/3}$ , is a characteristic length dimension of the ship.

In the interim model, all of the ship's characteristics are embodied in this parameter which may be physically interpreted as the length of the side of a cube having the same displacement as the ship. If the length, beam, and draft of a ship are also considered, at least three additional dimensionless variables must be added to the above. For example, they could be defined,

$$\frac{L}{(\Psi)^{1/3}} = \text{dimensionless length}$$

$$\frac{B}{(\Psi)^{1/3}} = \text{dimensionless beam}$$

$$\frac{D}{(\Psi)^{1/3}} = \text{dimensionless draft}$$

Other parameters have been used to describe hull forms including the block coefficient, or a parameter suggested by Brebner et al. (1966) defined as the square root of the maximum cross-sectional area of the hull divided by the distance from the bow to the cross-section of maximum area.

#### EMPIRICAL RELATIONSHIPS

Letting  $F$ ,  $H^*$ ,  $x^*$ , and  $d^*$  be the Froude number, dimensionless wave height, dimensionless distance from the sailing line, and dimensionless water depth, respectively, empirical relationships were established among these variables. Havelock (1908) found that the wave height decreases as the one-third power of the distance from the sailing line; hence, the dimensionless wave height,  $H^*$ , was assumed to decrease exponentially with distance from the sailing line. Figures 3, 4 and 5 show the decrease of  $H^*$  with  $x^*$  for three different values of the Froude number. Each figure also shows how  $H^*$  varies with the dimensionless depth,  $d^*$ . In general form, the assumed variation is given by,

$$H^* = \alpha x^{*n} \quad (1)$$

where the exponent  $n$  and coefficient  $\alpha$  are functions of the remaining dimensionless variables. Actually, both  $n$  and  $\alpha$  were found to be functions of the Froude number and the dimensionless water depth  $d^*$ . As shown in Figure 6  $n$  could be expressed as,

$$n = \beta d^{*\delta} \quad (2)$$

$$\text{where} \quad \beta = -0.225 F^{-0.699} \quad 0.2 \leq F \leq 0.55 \quad (3)$$

$$\beta = -0.342 \quad 0.55 \leq F \leq 0.8$$

$$\text{and,} \quad \delta = -0.118 F^{-0.356} \quad 0.2 \leq F \leq 0.55 \quad (4)$$

$$\delta = -0.146 \quad 0.55 \leq F \leq 0.8$$

as shown in Figure 7. Note that the lower and upper bounds for the definitions of  $\beta$  and  $\delta$  are assumed to be 0.2 and 0.8 respectively since the interim model should not be used much beyond the range of the data from which it was derived.

Figure 4 Variation of  $H^*$  with  $x^*$  for Various Values of  $d^*$ . Froude Number = 0.48.

Figure 5 Variation of  $H^*$  with  $x^*$  for Various Values of  $d^*$ . Froude Number = 0.67.

Figure 6 Exponent  $n$  as a Function of  $d^*$  and  $F$ .

Figure 7 Coefficients  $\beta$  and  $\delta$  as Functions of Froude Number.

Figure 8 shows the variation of  $\alpha$  with  $d^*$  for three values of  $F$ . An empirical expression for  $\alpha$  is given by,

$$\log \alpha = a + b \log (d^*) + c (\log^2 (d^*)) \quad (5)$$

As shown in Figures 9 and 10, empirical expressions for the coefficients are given by,

$$a = -0.6/F \quad (6)$$

$$b = 0.75 F^{-1.125} \quad (7)$$

and 
$$c = 2.6531 F^{-1.95} \quad (8)$$

Equations 1 through 8 permit calculation of ship-generated wave heights at a location given the ship's displacement and speed, the distance between the location and the ship's sailing line, and the water depth. A comparison between the wave heights predicted by equations 1 through 8 and the original data used to develop the empirical relationships is given in Figure 11. The predicted wave heights are plotted against the measured wave heights used to develop the model. While there is some scatter, the equations do a fair job of predicting the data considering that the ship's characteristics have been embodied into a single parameter, the cube root of the displaced volume,  $\Psi$ .

The interim model was subsequently checked against three other data sets for several ships with known hull forms. Figure 12 compares values of  $H^*$  calculated using the interim model with the data obtained by Sorensen (1967) for five geometrically similar box-like models. (For clarity, only data from three of Sorensen's models are shown in the figure. All of Sorensen's data follow the same trend.) The models were basically rectangular boxes with pointed bows, each having the same shape but at a different scale. Their lengths varied from 1.5 feet to 4.0 feet. Figure 12 shows that the waves generated by the box hulls exceed those predicted by the interim model; however, measured and calculated values of  $H^*$  vary linearly suggesting a correction equation given by,

$$H^*_{\text{meas}} = 2.427 H^*_{\text{calc}} - 0.0728 \quad (9)$$

The interim model was also evaluated against the laboratory data obtained by Das (1969) for two ships with distinctly different hull forms, a "Cruiser" hull with a relatively broad beam and a "Mariner" tanker hull with a more streamlined form. A comparison of measured values of  $H^*$  with values of  $H^*$  predicted by the interim model for the "Cruiser" model is shown in Figure 13. Generally, the "Cruiser" data also suggest a linear correction to bring measured and calculated values together. For the "Cruiser" data the correction equation is given by,

$$H^*_{\text{meas}} = 3.158 H^*_{\text{calc}} - 0.1105 \quad (10)$$

The "Cruiser" data also suggest that the hull is more efficient for generating waves than the interim model predicts.

Several data points in Figure 13 are given by Das as being "Cruiser" data in the tables appended to his report. The points, however, are not consistent with the majority of the "Cruiser" data and are suspected of having been obtained from the "Mariner" tanker model.

The "Mariner" data is shown in Figure 14. Again the deviation of

Figure 9 Coefficients  $a$  and  $b$  as Functions of Froude Number.

Figure 10 Coefficient  $c$  as a Function of Froude Number.

Figure 11 Comparison Between Measured and Calculated Values of  $H^*$  for Data Used to Develop Model.

Figure 12 Comparison Between Measured and Calculated Values of  $H^*$  for Sorensen's (1967) Model Data.

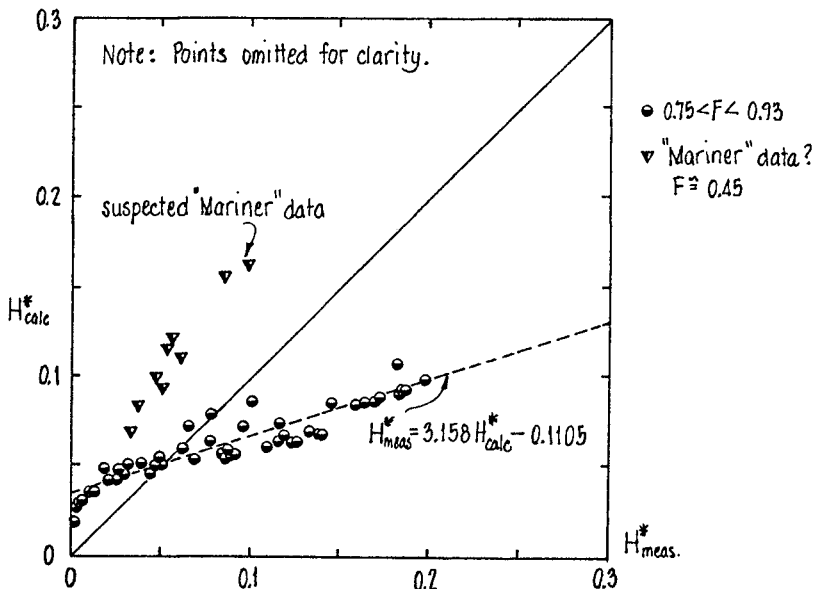

Figure 13 Comparison Between Measured and Calculated Values of  $H^*$  for Das' (1969) "Cruiser" Data.

Figure 14 Comparison Between Measured and Calculated Values of  $H^*$  for Das's (1969) "Mariner" Data.

Figure 15 Comparison Between Measured and Calculated Values of  $H^*$ . Linear Corrections to Sorensen's and Das's Data.

the data from the interim model can be adjusted through a linear correction, in this case given by,

$$H^*_{\text{meas}} = 0.835 H^*_{\text{calc}} - 0.0225 \quad (11)$$

A number of data points in Figure 14 are not consistent with the remainder of the "Mariner" data. These points are suspected of being "Cruiser" data instead of "Mariner" data. The "Mariner" data shows that this more streamlined tanker hull is not as efficient in generating waves than is the "Cruiser" hull or Sorensen's box hulls. Generally, the coefficient of  $H^*$  in equations 9 through 11 is a measure of how efficiently the hull generates waves. The larger the coefficient, the greater the hull's efficiency in generating waves. In fact, the two coefficients in the correction equations should be related to hull characteristics such as the block coefficient or Brebner's parameter. For example, Brebner's parameter (the ratio of the square root of the ship's maximum cross-sectional area to the distance from the bow to the cross-section of maximum area) is believed to be larger for the "Cruiser" hull and for Sorensen's box model hulls than for the more streamlined "Mariner" hull. Unfortunately, the information to calculate Brebner's parameter for the "Cruiser" and "Mariner" hulls is not available. Investigators usually report basic hull dimensions such as length, beam, and draft but rarely report relevant cross-section dimensions that would allow this parameter to be determined.

The interim model was also evaluated against the barge-tow data obtained on the Illinois River by Bhowmik et al. (1982), but without success.

#### FUTURE WORK

Future work will initially be directed toward obtaining available wave data from various ships for which hull shape is reported in sufficient detail to calculate the relevant hull parameters. These data will be used to refine the interim model to account for hull shape in determining ship-generated wave heights. Specifically, the coefficients of the linear correction equations (equations 9 through 11) will be empirically related to the various dimensionless parameters describing the hull. Since data appears to be available for only a limited number of hulls, additional wave data from hulls with known configuration will need to be collected. Also, data are needed for a wider range of ship-draft to water-depth ratios.

The preceding analysis provides only a method for estimating  $H_{\text{max}}$  which may or may not be the relevant parameter to predict the effects of ship-generated waves on structures or shorelines. Information on the energy contained within the wave packet and its distribution with frequency might, in fact, be more relevant; hence, spectral descriptions of ship generated waves need to be investigated.

## CHAPTER TWO HUNDRED SEVENTEEN

### The Effect of Wave Direction on Ship Motions in a Harbour Entrance Channel - Model Study Approach

A C van Wyk\* and J A Zwamborn\*

#### ABSTRACT

Basic knowledge of a ship's vertical motions in waves of different angles of approach is an essential requirement in the formulation of allowance criteria on which to base harbour accessibility under extreme wave conditions.

A comprehensive series of scale model tests are being undertaken to establish minimum underkeel clearance for given channel depths and sea states using two models representing typical 150 000 and 270 000 dwt bulk carriers.

#### 1. INTRODUCTION

The increasing demand for harbour utilization by deeper-draught ships has necessitated a more critical look at harbour accessibility in terms of accepted safety criteria. Based on experience gained at Richards Bay, South Africa's major coal export port (Campbell and Zwamborn, 1977 and 1984; see also figure 1), it was realized that sufficient knowledge of the effect of wave direction on the motions of bulk carriers in limited depths of water is a primary requirement.

Figure 1. Aerial view of Richards Bay harbour entrance

\* Maritime Structures Division, National Research Institute for Oceanology, CSIR, Stellenbosch, RSA.

Details of field measurements of ship motions in the approaches to South Africa's major export ports were given by Zwamborn and Van Wyk (1981) and Van Wyk (1982). The measurements have confirmed the excessive vertical motions of large coal carriers induced by quartering to near-beam swells in the approach channel to Richards Bay harbour. These swells, up to 3 m in height and with periods ranging between 12 and 17 s, have resulted in maximum draught increases of up to twice the significant wave height (Figure 2).

Figure 2. Maximum vertical ship motions at Richards Bay harbour

To assist in the optimum operation of Richards Bay harbour and to determine minimum dredging requirements in the entrance channel for ships up to 250 000 dwt, an extensive programme of research was undertaken, including both physical and mathematical modelling techniques and further prototype measurements.

A start was made with this programme of research during the second half of 1982 with the acquisition of a computer program, based on the 3-D source technique, to calculate ship motions, preparations for the development of suitable scale model ships and laboratory equipment, and the construction of a test basin equipped with irregular wave generators.

The establishment of these facilities, including the wave generators, took almost two years, so that the basic testing only started just before the conference. The present paper, therefore, includes a brief description of the main objectives of the model studies, the required facilities and equipment and their calibration, the approach adopted for the model studies and some initial results.

## 2. STUDY OBJECTIVES

The main objective of this study is to determine **vertical ship motions** as function of wave direction. This implies determination of a ship's behaviour, firstly, as a result of her own inherent properties, and, secondly, as a result of the prevailing environmental conditions.

The ship's inherent properties are the principal dimensions, hull shape (as well as appendages), the loading condition, the speed of advance and the manoeuvrability characteristics. The environment comprises the channel dimensions (including the depth of water), the wave conditions, and possibly currents and wind.

The main objective is being met by conducting a series of basic tests, using scale model ships, assisted by the use of the mathematical model.

## 3. TEST FACILITIES AND EQUIPMENT

Two 1-in-100 scale model ships, representing 150 000 and 270 000 dwt bulk carriers, were built for the basic model tests. The hulls were accurately scaled-down from line drawings of existing prototype vessels and were made of glass fibre (Figure 3).

Figure 3. Mould for construction of glass fibre model hull

Figure 4. Distribution of lead weights for proper loading

The required model loading was obtained by proper distribution of lead weights during inclining experiments in air and in water (Figure 4). Provision was made for both a 'short' and long' period natural roll at full load.

The models are self-propelled and self-steered with true-to-scale speed and rudder response (Figure 5).

Figure 5. Model propulsion unit

The basic tests are conducted in a  $23 \times 28 \text{ m}^2$  flat-bottomed basin, with a maximum depth of 0,35 m, equipped with a bank of SEASIM programmable irregular wavemakers (Figure 6).

Figure 6. Model test basin with Seasim irregular wavemakers

During testing, the model is run along a straight course, at different angles to the waves, covering a distance of about 20 m (2 km prototype). Measurement of the resistance between four electrodes attached to the model's hull/keel (Figure 7) and galvanised steel plates fixed to the basin floor allows continuous recording of the underkeel clearance (UKC) at the ships quarters and shoulders.

Figure 7. Electrodes attached to model's keel for UKC measurement

Simultaneously with the UKC measurements, the following are recorded: the waves encountered (using a wave probe on the ship's bow) and the rudder deflections and propeller rpm's.

At present, both model control and data transmission are done via a light-weight ship/shore cable but this will soon be replaced by a remote-controlled radio telemetry system, which will also include an autopilot system with feedback to shore.

The ship's horizontal excursions are monitored by two remote-controlled overhead cameras which can be triggered as fast as every 0,2 s (Figure 8). This, together with the feedback from the ship, gives information on the course-keeping ability of the model during tests.

Figure 8. Overhead camera to record model's horizontal excursions

Data handling and analysis are catered for by a shore-based data acquisition system, featuring 16 channel A-to-D conversion and an H.P. mini-computer with on-site graphics terminal (Figure 9).

The ship's vertical response will also be calculated using the mathematical model with the ship's hull simulated by a representative number of panels and with the loading conditions in accordance with those of the scale models. This model makes possible a frequency domain solution of the coupled equations of motion. The resulting response amplitude operators (RAO) can also be combined with a wave spectrum to obtain short-term statistical averages of the vessel's motions.

Figure 9. Data acquisition system in the control room

4. APPROACH OF MODEL STUDIES

The studies are conducted in two successive stages, namely Stage I, calibration (Figure 10) and Stage II, the actual model tests (Figure 11).

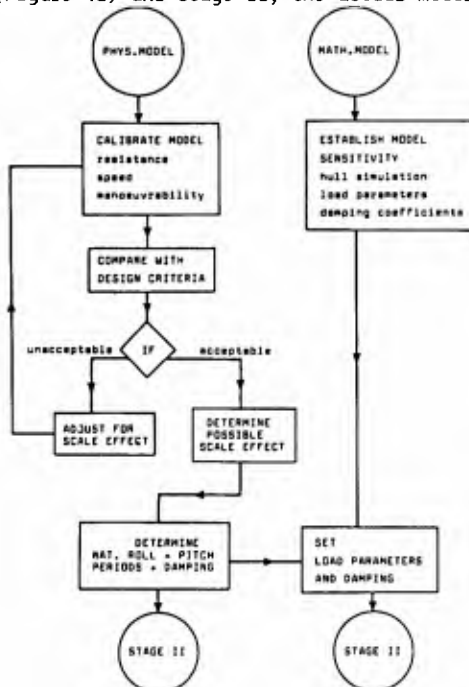

Figure 10. Approach of model studies - stage I

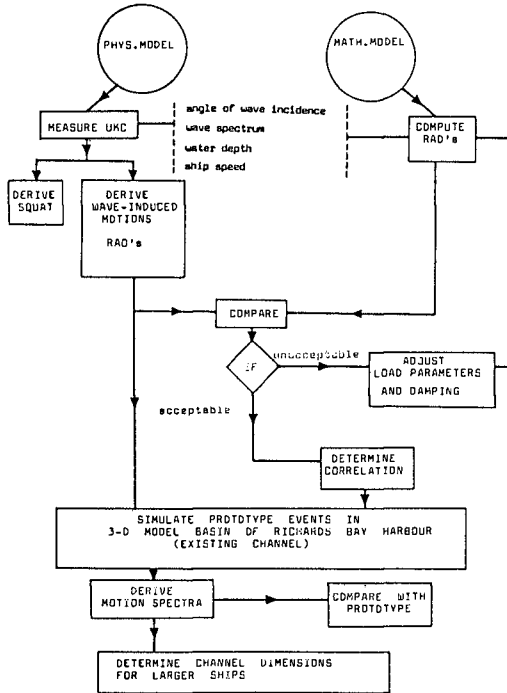

Figure 11. Approach of model studies - stage II

**Stage I** comprises the basic setting-up procedures and the calibration of the two model ships with respect to resistance in water, speed of advance and manoeuvrability. The natural periods of oscillation in roll and pitch as well as the damping coefficients as functions of water depth were also established for various load conditions.

Stage I also includes a series of sensitivity runs with the mathematical model. The experimentally derived natural periods and viscous damping coefficients will be used as input for the mathematical model runs of Stage II.

**Stage II** involves a series of model tests concentrated on the two ship sizes selected. The RAO's for the wave-induced vertical motions will be determined for the two ship sizes as function of angle of wave incidence, wave height and period, water depth and ship speed. The physical model test results will then be compared to predicted RAO's obtained from the mathematical model.

5. RESULTS OF MODEL CALIBRATION TESTS

At the time of the conference, most of the Stage I tests were completed with respect to the smaller model ship and the Stage II tests had just started.

The results of the towing resistance and model speed tests for the 150 000 dwt model ship are shown in Figure 12.

Figure 12. Model towing resistance and speed

The model's towing resistance for a depth-over-draught ratio of  $d/T = 1,9$  was found to agree reasonably closely to the predicted value for deep water. The model speeds for  $d/T = 1,9$  are about 10 per cent less than the calculated deep water values. Since  $d/T > 2$  is usually accepted to represent deep water conditions it means that the model's resistance is, perhaps, only slightly too high.

A significant reduction in speed, for the same propulsion force, is evident in shallower water. This reduction is also shown clearly by the relationship between propeller rpm and model speed (Figure 12).

Figure 13. Results of turning circle test

A typical result of a turning circle test is shown in Figure 13. The diameter of the turning circle, the position of the point of maximum advance (transfer) and the tactical diameter are all in agreement with prototype data, obtained under similar conditions.

The effect of  $d/T$  on the model roll period and the damping coefficient is shown in Figure 14. The tests were done under full load conditions but with two different load distributions, resulting in 'deep' water roll periods of 1,26 and 1,66 s respectively.

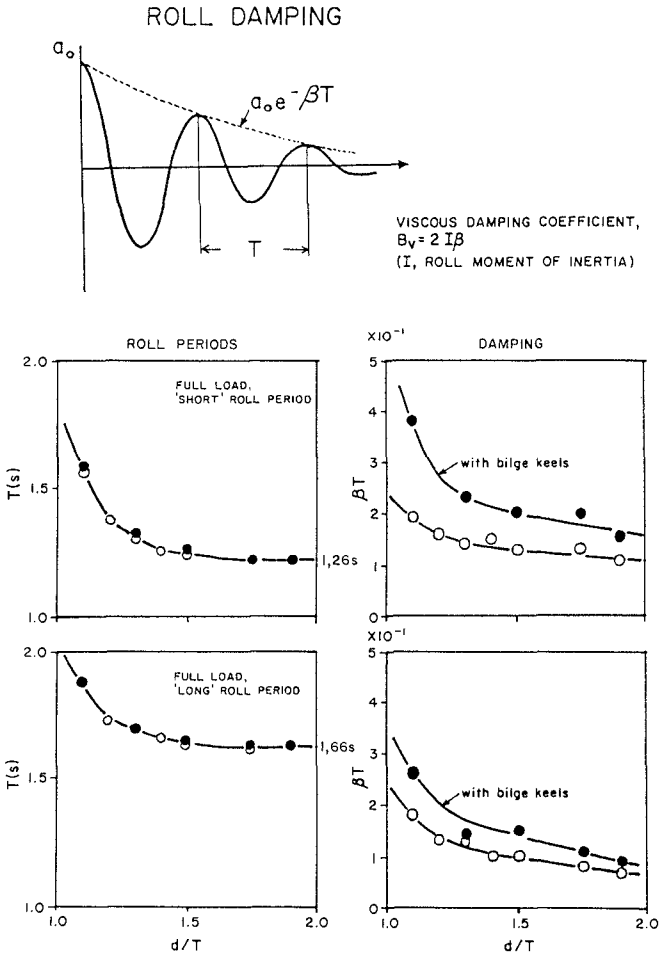

Figure 14. Roll periods and damping for various depth-over-draught ratios

The results show significantly longer roll periods for smaller under-keel clearance, particularly for the 'short' roll period case. A similar trend is visible for the damping coefficients which are much greater in shallower water.

As could be expected, the roll periods are not affected by the presence of bilge keels but the damping coefficients increase considerably (by 30 to 100 per cent) with the presence of bilge keels on the model ship.

#### 6. PRELIMINARY RESULTS OF ACTUAL MODEL TESTS

All the scale-model tests are conducted in unidirectional waves of various spectral shape. Angles of wave incidence will be varied in steps of  $15^\circ$  in the regions where the ship's response is very sensitive to wave direction and in steps of  $30^\circ$  for the remainder of the directions (Figure 15).

Figure 15. Model test run with  $90^\circ$  wave approach

Most of the tests are done with waves which have a spectral shape based on actual recorded wave spectra. Figure 16 shows 128 normalised spectra, recorded at Richards Bay. These cover conditions with  $H_{m0} = 1$  to  $= 5$  m and  $T_p = 11$  to  $17$  s, which are the most relevant conditions with regard to ship motions. The spectra are seen to be remarkably similar with quite a narrow variation, and the mean spectral shape was considered representative for conditions at Richards Bay. This spectrum was therefore used for most of the tests although tests with different spectral shapes are also done to check on sensitivity.

Figure 16. Normalized Richards Bay wave spectra

Sample amplitude response functions for the starboard and port shoulders of the 150 000 dwt model ship for beam waves are shown in Figure 17. These results are based on a model run of 20 m length. The amplitude response (RAO) was determined by dividing the response spectra by the wave input spectrum. Maximum response is seen to occur at about 13 s which is the ship's natural roll period for a depth-overdraught ratio of 1,3. A peak response (mainly roll because of beam waves) of 5 m/m was found for both shoulders.

Some preliminary results of the mathematical model are shown in Figure 18. This figure clearly shows the influence of wave direction on the ship's roll response.

Figure 17. Sample amplitude response functions, 90° wave approach

Figure 18. Mathematical model roll response for different wave directions

## 7. CONCLUDING REMARKS

The results of these studies will be applied to formulate allowance criteria on which to base optimum harbour usage under all wave conditions. This will serve to update and improve the present operational manual being used at Richards Bay harbour (Campbell and Zwamborn, 1984 and Zwamborn and Cox, 1982).

On completion of the basic tests, a series of tests are planned in a 1-in-100 scale model of the Richards Bay harbour entrance channel. These tests will involve simulation of prototype events/conditions to compare the 150 000 dwt model behaviour to field measurements as well as tests using the 270 000 dwt model to determine channel dimensions (dredging requirements) for possible future extensions.

## ACKNOWLEDGEMENT

The work described in this paper is carried out by the CSIR under contract for the South African Transport Services. Their permission to publish this paper is acknowledged with thanks.

## CHAPTER TWO HUNDRED EIGHTEEN

SHIP WAVES IN SHALLOW WATER AND THEIR EFFECTS ON MOORED SMALL VESSEL

by

Katsuhiko Kurata\* and Kazuki Oda\*\*, M.ASCE

### ABSTRACT

The characteristics of ship-generated waves in shallow water and the motions of moored small vessel induced by the ship waves were investigated in a wide range of water-depth and ship-length Froude Numbers.

The maximum heights and periods of ship waves were obtained as functions of Froude Number. The relationships between maximum angular and translatory displacements of moored vessel and the maximum ship waves were determined.

### INTRODUCTION

The waves resulting from passages of ships have relatively large heights compared with their lengths, and hence the surface slopes of ship-generated waves are steep so as to cause large motions of small vessels moored at the structures adjacent to waterways such as wharves, quays and piers.

Since the pioneer's work by W.Froude, many experimental and theoretical studies about ship waves have been performed primarily in the fields of naval architecture and partly in coastal and harbor engineering. (1)-(3), (11), (13)-(15) The first theoretical treatment about ship waves was the application of the solution for the problem of "Waves generated by a point impulse moving with a constant speed on water surface", which gives the similar wave pattern to the actual one. (3), (13) Applying the thin ship theory and/or the slender body theory to the problems about flows around ships, the more strict solutions for the water surface undulations around ships can be obtained using the point source distributions or the Green's functions to satisfy the adequate boundary and radiation conditions under such assumptions that the beam and/or draft of ship are negligibly small compared with its length. (7), (18) More improved theories have been developed taking the effects of the curvature and thickness of ship-hull shape on the flow around the ship into account. (9), (19) Most of those studies in naval architecture, however, were conducted from the standpoint as to how the waves affected the resistances of ships. While, from the standpoint of coastal and harbor engineering, the significance of ship wave influences on the bank erosions of canals, the safety navigations and moorings of small vessels have been emphasized. (6), (10), (15), (17) In a harbor, a canal and a navigation channel the ship wave generated by a small tug boat has

a significant influence on moored vessel rather than a large ship, because the small boat passes nearer the moored vessel with faster speed than the large ship. However, there are little quantitative data available on ship wave influences on moored vessel.

According to the results of model and field tests, the hydraulic model tests are efficient for investigating the ship waves because they yield the results similar to the prototypes.(16)

In the present paper, (1)the characteristics of ship waves generated by a large ferry boat and a small tug boat in relatively shallow water and (2)the motions of moored small cargo ship induced by the ship waves will be discussed.

#### MODEL TESTS

The model tests were carried out based on the Froude law of similarity at the Hydraulic Engineering Laboratory of Osaka City University, Osaka, Japan. The model scale was 1/60.

#### SHIP WAVES

Models of a car ferry boat and a tug boat were towed at various speeds in water of various uniform depths. A basin was approximately 40 m long and about 6 m wide.

The straight guide-rail was placed above the basin. The model ship was attached fore by short string to a carriage on the rail connected with a taut line which passed over pulleys at both ends of rail and was driven by an electric motor.(See Figs.1 and 2) The speed of ship was accurately computed from the time interval between marks made on charts during each advancing every 2 meters of ship.

The ship waves were measured by capacitance-type wave gages at five positions along a perpendicular to the sailing line as shown in Fig.3, and they were recorded on charts by using a multi-pens recorder.

The dimensions of towed ships, the ship speeds,  $V$ , and the water depths of basin,  $h$ , for the tests were listed on Table 1.

MOTIONS OF MOORED VESSEL

Model of small cargo ship was moored at a wharf in a usual manner with fenders and mooring lines. The model fender was made by rubber-sheet with 3.3 mm thickness, 9 mm length and 9 mm height. Its characteristic curve was similar to that of prototype as shown in Fig.4(a). Although the characteristic curve of mooring line in model, which was rubber-string with 0.9 mm square section, was different from that in prototype as seen in Fig.4(b), the slopes of tangents of those curves were almost the same each other in the test range so that the mooring line in model and prototype were considered to have the similar load-elongation relationships. Then, the rubber-string used in the tests was supposed to be suitable for the model of mooring line.

As the incident ship waves to the moored vessel were assumed the waves measured by a servo-type wave gage at a symmetrical position of the center of gravity of moored vessel, *C.G.*, in a state of rest with respect to the sailing line. (See Figs. 5 and 6)

The motions of moored vessel induced by the ship waves were measured by a ship-motion meter using potentiometers shown in Fig.7. Angular displacements around *C.G.* (rolling, pitching and yawing) and translatory displacements of *C.G.* (surging, swaying and heaving) were obtained from the measurements of current-variations through potentiometers installed at *C.G.* and at the upper carriage of the meter, which were linearly proportional to the vessel motions. (See Fig.8)

The ship waves and motions of vessel as shown in Fig.9 were recorded on magnetic-tapes by using a multi-channels data-recorder.

The dimensions of moored vessel and towed ship, the speeds of towed ship, *V*, the water depths at navigation channel, *h*, and at the wharf and natural periods of moored vessel motions were listed on Table 2.

## RESULTS AND DISCUSSIONS

## DEFINITIONS

The maximum wave height,  $H_{max}$ , and the maximum wave period,  $T_{max}$ , in ship wave train were defined as Fig.10.(3) The maximum wave height is the vertical distance of the maximum crest above the following trough, and the maximum wave period is twice as long as the related time interval.

Maximum angular and translatory displacements of moored vessel were defined like the maximum wave height.

MAXIMUM WAVE PERIOD

The diverging waves are predominant in the ship waves, which originate from the hump of water surface at the bow and the hollow at the stern advancing with together the ship. Then, the characteristic period  $T_0 = 2\pi V/g$  ( $g$ :acceleration of gravity) was introduced to represent the inherent period of waves generated by the ship going with the speed of  $V$ . The values of  $T_{max}/T_0$  indicate which the ship waves with period  $T_{max}$  are "deep water waves" or "shallow water waves", because  $T_0$  corresponds to the period of deep water wave with the phase velocity of  $V$ . The ratios of  $T_{max}$  to  $T_0$  were obtained as shown in Fig.11. Circles and triangles in Fig.11 denote the mean values of  $T_{max}/T_0$  for the cases of tug boat and ferry boat at each water-depth Froude Number,  $Fr = V/\sqrt{gh}$ , respectively. A hatched region means the results from field tests by Sorensen. (12)

In a region of  $Fr < 0.8$ , the mean values are approximately 0.8 to 0.9 for the tug boat and 0.6 to 0.8 for the ferry boat, and hence the ship waves are considered as the deep water waves. While, due to the definition of  $T_0$ , when  $Fr > 0.56$  the ship waves are expected as the shallow water waves. The discrepancy between the test and the theory may be due to the fact that the apparent propagation direction of ship waves is oblique to the sailing line so that the apparent propagation velocity is less than  $V$ . From Fig.11 it is clear that the model test results agree reasonably well with the field test results, and hence there are little scale effects on the test results found.

When  $0.8 < Fr < 1.0$ , the mean values are almost constant to be 0.9 to 1.0 for the tug boat and around 1.2 for the ferry boat. In this range the ship waves may have the characteristics of the shallow water waves.

The region of  $Fr > 1.0$  is called as the super-critical region where no waves have the greater phase velocity than the ship speed, because  $\sqrt{gh}$  corresponds to the maximum wave velocity which can exist in water of depth  $h$ . In this region only the diverging waves were observed and no transverse waves were seen. The mean values of  $T_{max}/T_0$  take the peak values at  $Fr \sim 1.0$  and decrease to become almost constant with  $Fr$ .

Fig.11 Ratios of  $T_{max}$  to  $T_0$

From the results in Fig.11, the ratio of  $T_{max}$  to  $T_0$  is supposed to relate only to Froude Number. Here, we let

$$T_{max}/T_0 = C \quad (1)$$

where  $C$  is a coefficient dependent upon  $Fr$ . Then

$$T_{max} = C \cdot 2\pi V/g \quad (2)$$

At a field far from a vertical cylinder in a steady free surface flow with a uniform current velocity,  $V$ , and a uniform depth,  $h$ , a wave number,  $k$ , of water surface undulation is approximately given as follows.(5)

$$\tanh kh/kh = A \cdot Fr^2 \quad (3)$$

$$Fr = V/\sqrt{gh} < 1.0$$

where  $A$  is a constant equal to 3/4 or 1/2.

The period of progressive wave,  $T$ , which has the same wave number as  $k$  obtained by Eq.(3), is yielded by using the small amplitude wave theory as Eq.(4).

$$T = (\sqrt{A}/\tanh kh) \cdot 2\pi V/g \quad (4)$$

If we put

$$T_{max} = T \quad (5)$$

then

$$C = \sqrt{A}/\tanh kh \quad (6)$$

The comparisons of the maximum wave periods  $T_{max}$  with the calculated periods  $T$  by Eqs.(3) and (4) are shown in Fig.12 for the cases of  $Fr < 1.0$ . The calculated values of  $T$  agree well with the values of  $T_{max}$ . The calculated values of  $\sqrt{A}/\tanh kh$  were approximately 0.9 to 1.0 for the tug boat and 0.7 for the ferry boat under the test conditions. Those values are in a good agreement with the values of  $C = T_{max}/T_0$  shown in Fig.11. From the comparisons of  $T_{max}$  with  $T$ , namely  $C$  with  $\sqrt{A}/\tanh kh$ , it may be concluded that (1) the wave period at the field far from the origin of waves have no reference to the draft and shape of the object producing the waves, (2) the maximum wave period can be theoretically estimated by using Eqs.(3) and (4) when the water-depth Froude Number is once determined. However, the difficulties still remain to decide precisely the value of the constant  $A$  for the specified ship-hull shape.

### MAXIMUM WAVE HEIGHT

The ship wave height is closely related to wave-making resistance of ship which varies with ship-length Froude Number,  $F_L = V/\sqrt{gLs}$  ( $Ls$  : ship length). (8) The maximum wave height is inversely proportional to a cubic root of a distance from the sailing line,  $x$ . (2), (4) Considering the facts above mentioned, the non-dimensional maximum wave height  $(H_{max}/B)(x/L)^{1/3}$  was introduced to be investigated their changes with  $F_L$ .  $B$  is a ship beam and  $L$  a wave length for the period  $T_{max}$  and the water depth  $h$ .

As shown in Fig.13, the non-dimensional maximum wave height for both the ferry and tug boats increase with  $F_L$  until critical value. At  $F_L \sim 0.5$  they attain the peak values. When  $F_L > 0.5$ , those values decrease with  $F_L$ . The changes of non-dimensional maximum wave heights with  $F_L$  seem similar to those of wave-making resistance coefficients as expected. Although the data show some scattering, it is clear that the non-dimensional maximum wave heights depend mainly upon the ship-length Froude Number but slightly upon the ratio of water depth to ship draft and the water-depth Froude Number.

### MOTIONS OF MOORED VESSEL

As shown in Fig.14, the ship waves are so small that the motions of moored vessel induced by them are also small in a region of  $Fr < 0.7$  to 0.8.

In a range of  $0.7 < Fr < 1.0$ , the wave height increases rapidly with  $Fr$ . The exciting force on the moored vessel might be considered proportional to  $H_{max}^2$ . As a sequence, the rolling and swaying motions of vessel rapidly increase with  $Fr$ . The cusp line, namely the apparent crest line, of ship waves approaches perpendicular to the bow-stern line of moored vessel, hence the pitching and surging motions become large. The ship waves with large height and long length go into the gap between the moored vessel and the wharf, and the phase lag between the exciting forces on the bow and the stern of the vessel cause the large yawing motion of vessel.

In the super-critical region of  $Fr > 1.0$ , the motions of moored vessel increase with  $Fr$  as well as the maximum wave period, although the maximum wave height decrease to become almost constant.

Thus, the motions of moored vessel seem to depend upon the wave heights, wave length and wave direction. The heaving motion, however, may be considered dependent upon the vertical motion of the water surface (wave height). The maximum heaving motion seems to have almost the same amplitude as the maximum wave in a range of  $0.6 < Fr < 1.4$  without regard to the wave conditions and the mooring conditions as presented in Fig.15.

FOURIER TRANSFORMS

For analyzing the transient phenomena such as the ship waves and the moored vessel motions induced by them shown in Fig.9, the Fourier transform is generally used.

According to the results by the Fourier transforms of the incident ship waves and the motions of moored vessel, the motion of vessel resonate to have a large amplitude at the natural period in each mode as shown in Fig.16. At the period when the maximum amplitude of ship wave component occurs, the amplitude of motion of vessel is also large. From the results by the Fourier transforms, the response factors of moored vessel to the waves might be obtained. The moored vessel motion to the arbitrary incident waves may be predicted by using those factors.

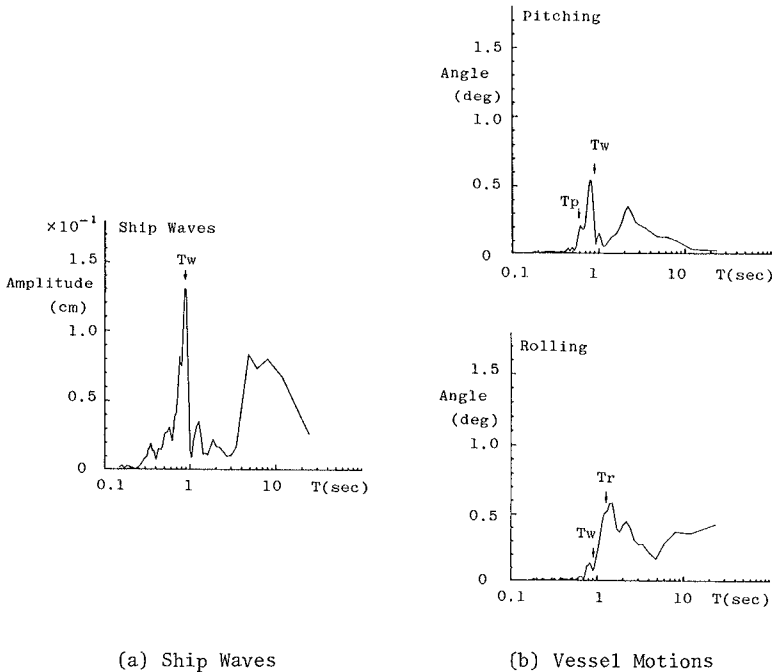

Fig.16 Fourier Amplitudes of Ship Waves and Vessel Motions

### CONCLUSIONS

The maximum height and the maximum period of ship wave and the motions of moored vessel induced by the ship waves were investigated in a wide range of the water-depth and ship-length Froude Numbers.

The maximum wave period is related to the water-depth Froude Number and can be estimated theoretically when its value is once specified.

The non-dimensional maximum wave height depends upon the ship-length Froude Number. The wave length refers to the wave period, which is decided by the water-depth Froude Number. Then, the maximum wave height is considered as a function of the ship-length and water-depth Froude Numbers.

The relationships between the maximum angular and translatory displacements of moored vessel and the maximum ship waves were obtained. The maximum displacements of vessel are related to wave height, wave period and wave direction.

The responses of moored vessel to the ship waves were investigated by using the Fourier transforms. The vessel motion responses are large at the natural period and at the period when the maximum amplitude of component wave occurs.

The influences of the passing ships, with the speeds of 10 knots or less (usually  $Fr < 0.5 \sim 0.6$ ) through fareways or navigation channels, are considered not to be significant on the small cargo ships moored at the wharves.

### ACKNOWLEDGEMENTS

The authors thank to Mr.T.Kimura, a technical staff, Mr.S.Hirai and Mr.A.Kitaura, post-graduate students, Mr.Y.Kouzaki and Mr.K.Matsui, under-graduate students of Dept. of Civil Eng., Osaka City University, for their help with conducting the tests.
