We here ought to mention that the entire implementation was done on an IBM 3081 using double precision floating point numbers, which corresponds to approximately 16 floating point digits.

Solution No. II has a maximum error in  $A/A_1$  of -0.0981 (corresponding to 4.14%) at  $r/r_a = 1$  and  $\theta = 0^\circ$  (i.e. same point Q as for solution No. I). If we compare with Houston (1981), Figs. 7 and 9, which has a similar comparison but for another period ( $T = 120$  sec.), it is seen that the largest error is found on the 'illuminated' side of the island (around point P in Fig. 3). From this we can draw the conclusion that the location of the largest error is very much dependent on the wave period. For the 28 results in Table I the mean error for  $A/A_1$  is 0.0223, or relative mean error 1.63% (which is about three times larger values than what was found for solution No. I). The rightmost column informs us that also for this solution (No. II) the sum of the errors along  $r/r_a = 1$  equals approximately the sum of the errors along the other three semi-circles  $r/r_a = 2, 3,$  and  $9$ . Note that for all considered 28 points the signs of the errors in solutions No. I and II are the same, and the magnitude is roughly a factor three larger in case II than in case I.

The maximum error on the phases in solution No. II is  $-5.28^\circ$  and it is found in the same point as the maximum phase error in solution No. I. The mean error in  $\varphi$  in solution No. II is  $1.55^\circ$  for the 28 results presented. Again this mean error is approximately about three times larger than the corresponding mean error for solution No. I. A calculation similar to case No. II with the same finite element grid but  $n_{\max}$  increased from 11 to 20 was performed. Over the shoal there was no change in the solution for the five digits shown in Table I. However, for  $r/r_a = 9$  minor changes in the errors were noticed, but these modifications were so small that the mean errors in  $A/A_i$  and  $\varphi$  given above did not change. Again, this is in agreement with Skovgaard and Jonsson (1981), where it was shown that for  $r/r_a = 9$ ,  $n_{\max} = 11$  is just about too small to yield five digits of accuracy.

A contour plot of the  $A/A_i$  solution in model No. I is shown in Fig. 5. A three-dimensional plot of an instantaneous surface elevation around the island is shown in Fig. 6.

Figure 5. Contours for the relative amplitude around the Homma island,  $T = 480$  sec. The interval between  $A/A_i$ -curves is 0.25.

Figure 6. Relative surface elevation around the Homma island,  $T = 480$  sec.

Finally, we stress that in this section we have investigated a rather difficult bottom geometry giving rise to combined shoaling, refraction, and diffraction in an infinite ocean model.

#### 4. An Example of Absorption and Superposition: Rectangular Harbour

In this section we will demonstrate the effect of energy absorption along boundaries, the effect of obliquely incident waves, and finally the effect of superposition of incident waves of different angles and amplitudes. The presentation will be restricted to the simple harbour geometry shown in Fig. 7, left.

In Section 3 we considered an example of an infinite ocean (Fig. 1). Here we consider an example of a semi-infinite ocean (Fig. 2). The layout of the finite element grid and the location of the boundary  $\partial A$  between the finite element area  $A$  and the outer region  $R$  is given in Fig. 7, right. In Fig. 8 an enlarged sketch of the finite element grid around the tip of one of the breakwaters is shown.

Figure 7. Left: Sketch of harbour geometry. Constant water depth in- and outside the harbour. Right: Sketch of finite element grid and boundary  $\partial A$  between finite element area A and semi-infinite ocean R.

Figure 8. Detail of finite element grid around breakwater.

Figure 9. The coefficient matrix  $\{K\}$  and its three submatrices  $\{K_1\}$ ,  $\{K_2\}$ , and  $\{K_3\}$ .

The total number of nodal points in the finite element grid is 5,445 and the total number of elements is 10,556. Along the left and right boundaries inside the harbour there are 83 element sides, i.e. the short and long sides are 6.26 m and 9.02 m respectively. Along the innermost boundary of the harbour there are 60 element sides, i.e. the short and long sides are 6.50 m and 9.02 m respectively. In all the following figures a representative short wave period of  $T = 9$  sec. has been used corresponding to a wave length in the entire area (constant water depth in the whole area for simplicity) of  $L = 95.57$  m. This corresponds to a ratio of maximum side length in the elements to wave length of  $9.02/95.57 = 0.0944$  or minimum 10.6 element sides per wave length. This resolution is representative of what a practical engineer would use. Referring to the previous section one would expect a relative mean error in  $A/A_i$  and  $\phi$  of

the magnitude 1-2% and  $1^{\circ}$ - $2^{\circ}$  respectively. All figures were first calculated using  $n_{max} = 20$ . Hereafter all calculations were repeated with  $n_{max} = 24$  (i.e. an increase of 4). No change could be detected in any figure.

The nodal points were numbered starting at the left-hand corner and going right on the innermost boundary of the harbour, i.e. the numbering was done along lines parallel to the x-axis (see Fig. 7, left). This principle has been used in the entire grid, also in the minor part of area A outside the entrance of the harbour. This was done to minimize the bandwidth in the coefficient matrix  $\{K_1\}$ , which is by far the largest of the coefficient matrix  $\{K\}$ , see Fig. 9.

The submatrix  $\{K_1\}$  is stored in packed form giving it the dimensions: the number of nodal points (5,445) times the largest difference in nodal point numbers found in any element plus 1 (here  $62 + 1 = 63$ ), i.e.  $5,445 \times 63 = 343,035$  complex numbers. The quadratic submatrix  $\{K_2\}$  has the side length equal to the number of expansion coefficients, i.e.  $n_{max} + 1 (= 21)$ , i.e.  $21 \times 21 = 441$  complex numbers in the full matrix.

The submatrix  $\{K_3\}$  has the dimensions of the largest difference in nodal point numbers of the nodes on  $\partial A$  (here equal to 283) times  $n_{max} + 1 (= 21)$ , i.e.  $283 \times 21 = 5943$  complex numbers.

The programming was done using the IBM OS PL/I Optimizing Compiler, release 4.0, see IBM (1981a) and IBM (1981b). All the programming was done in double precision, which with our machines is approximately 16 digits (8 bytes per real number and 16 bytes per complex number). The program was compiled and executed with VM/CMS on an IBM 3033 and with MVS/TSO on an IBM 3081 (16 M bytes of core memory on each machine). The CPU-times given below are from executions on the IBM 3081, which is a dual-processor machine. In the timings only one processor was used.

After testing, all debugging facilities were removed from the code and all programs were recompiled with the REORDER and OPTIMIZE(TIME) options. In the execution of this relatively modest harbour the whole code could reside in core memory during execution. For one single period (no superposition) the execution time was approximately 140 CPU-seconds (i.e.  $2\frac{2}{3}$  min.) and the memory size 6 M bytes. Houston (1981) reported for a model of the same size (10,560 elements) an execution time of less than 1 min. on a CRAY-1. He used single precision in his FORTRAN program, which is approximately 15 floating point digits on a CRAY-1. When the CRAY-1 vector-computer is being used as a scalar computer, it is approximately 4-5 times as fast as a single processor of the scalar IBM 3081 computer. So we can conclude that our implementation is at least twice as fast as Houston's implementation. Note that the two implementations use approximately the same number of digits in the floating point calculations, viz. 16 and 15.

In Paper I, Figs. 3 and 4, an example of contours of relative amplitude and three-dimensional surface elevation at a specific time has been given in the case of normal incidence (in Fig. 7, left,  $\theta^i = 270^{\circ}$ ) and all boundaries being fully reflecting. To further illustrate these two figures we here show the relative wave amplitudes in three cross-sections parallel to the y-axis (see Fig. 7) in Fig. 10 and three cross-sections parallel to the x-axis in Fig. 11.

The first example is rather academic due to all boundaries being fully reflecting. In the following examples partial reflection is included in accordance with the  $\alpha$ -values in Fig. 7, left. To be very precise, the  $\alpha$ -value of 0.5 was used along the inner side of the breakwaters, around

Figure 10. Relative wave amplitudes  $A/A_i$  for  $T = 9$  sec. in three cross-sections:  $x = -195$  m,  $0$  m,  $+195$  m. All boundaries are fully reflecting, i.e.  $\alpha = 0$  everywhere.  $\theta^i = 270^\circ$ .

Figure 11. Relative wave amplitudes  $A/A_i$  for  $T = 9$  sec. in three cross-sections:  $y = -532.53$  m,  $-269.40$  m,  $-12.53$  m. All boundaries are fully reflecting, i.e.  $\alpha = 0$  everywhere.  $\theta^i = 270^\circ$ .

the tip of the breakwaters, and on that part of the outer side of the breakwaters that is inside area A.

In Figs. 12, 13, and 14 the results are shown for  $\theta^i = 270^\circ$  with the absorbing boundary conditions.

Figure 12. Harbour, contours of relative amplitudes  $A/A_i$ .  $T = 9$  sec.,  $\theta^i = 270^\circ$ . Partial absorption as defined in Fig. 7, left.

Figure 15. Same as Fig. 12, except that  $\theta^i = 247.5^\circ$ .

Figure 13. Same as Fig. 10, except for partial absorption as defined in Fig. 7, left.

Figure 14. Same as Fig. 11, except for partial absorption as defined in Fig. 7, left.

In Figs. 15, 16, 17, 18, and 19 the results are shown for  $\theta^i = 247.5^\circ$  with absorbing boundary conditions.

Figure 16. Same as Fig. 13, except that  $\theta^i = 247.5^\circ$ .

Figure 17. Same as Fig. 14, except that  $\theta^i = 247.5^\circ$ .

In Figs. 18 and 19 the results are shown for superposition of three different angles of incidence ( $\theta^i = 225.0^\circ, 247.5^\circ, \text{ and } 270.0^\circ$ ) with  $A/A_i = 1/\sqrt{6}, \sqrt{2}/3, 1/\sqrt{6}$  respectively (i.e.  $A/A_i \approx 0.41, 0.82, \text{ and } 0.41$ ). Note that  $\Sigma(A/A_i)^2 = 1$  for the three incident wave systems.

Figure 18. Harbour, contours of relative amplitudes  $A/A_i$ . Superposition of three incident wave systems,  $\theta^i = 225.0^\circ$ ,  $247.5^\circ$ , and  $270.0^\circ$ .  $T = 9$  sec. Partial absorption as defined in Fig. 7, left.

Figure 19. Harbour, relative surface elevation at a specific time corresponding to the example in Fig. 18.

#### 5. Discussion and Conclusion for the Harbour Example

The first set of figures (Figs. 10, 11 and Figs. 12, 13, and 14) demonstrated in detail the effect of full reflection vs. partial absorption.

The next set of figures (Figs. 12, 13, and 14 and Figs. 15, 16, and 17) demonstrated in detail the effect of normal incidence vs. oblique incidence (same partial absorption in both cases).

The final set of figures (Figs. 15, 16, and 17 and Figs. 18 and 19) demonstrated in detail the effect of one direction of incidence with all the wave energy vs. the same amount of energy spread over three directions of incidence. The dominant direction in the superposed wave fields is the same as in Figs. 15, 16, and 17.

We notice that in the cases with normal wave incidence ( $\theta^i = 270^\circ$ ) there is full symmetry, which is illustrated by Figs. 10-14.

The conclusions which can be drawn from all the sets of figures are not surprising: partial absorption diminishes the wave amplitudes drastically; the distribution of the same total wave energy among several directions has some diminishing effect on the wave amplitudes.

The execution time for calculating the wave field for a single period was earlier given to be  $2\frac{1}{3}$  min. The code is still a research code, and if, in the future, consulting engineers are going to superpose many directions and many periods for each lay-out of the harbour geometry a more optimized code has to be developed.

A more promising alternative to decrease the execution time would be to develop and implement the model on a vector-processor like CRAY-X-MP, CYBER 205, NEC SX-2, FUJITSU VP-200, or HITACHI S-810. The first three machines are strictly FORTRAN-machines, but the last two have IBM-compatible sets of machine instructions and should therefore be able to run IBM PL/I, which has vector operations built into the language itself.

## CHAPTER SEVENTY FIVE

### CURRENT DEPTH REFRACTION OF REGULAR WAVES

Ivar G. Jonsson<sup>1</sup> and John B. Christoffersen<sup>2</sup>

#### ABSTRACT

The complete set of equations for the refraction of small surface gravity waves on large-scale currents over a gradually varying sea bed is derived and presented. Wave lengths, direction of propagation and wave heights are all determined along the so-called wave rays as solutions to ordinary, first-order differential equations.

Dissipation due to bed friction in the combined current wave motion is included. The ray tracing method is used in an example. A method for the calculation of current depth refraction of weakly non-linear waves is proposed.

#### 1. INTRODUCTION

When water waves propagate over an area with a variable water depth and current velocity, the ensuing gradients together with the current wave interaction can cause drastical changes in the direction, length and height of the waves, see e.g. Mallory (1974). In this transformation of the waves, diffraction effects are often negligible, and the phenomenon is termed current depth refraction.

This phenomenon is a significant physical process in many coastal and offshore areas, for instance near river mouths and tidal inlets, in the surf zone along a beach, and where wind waves meet major ocean currents. The refraction is of great importance for erosion and deposition in coastal areas, forces on offshore structures, and ship navigation.

Current depth refraction is a complex problem of wave propagation in an inhomogeneous, anisotropic, dispersive, dissipative and moving medium. Attempts to solve the general case have therefore been scarce. Noda et al. (1974) are probably the first to try this. They employed a global finite difference scheme for solving the governing partial differential equations and experienced so many difficulties that they advocated a search for a method which made integration along characteristic curves possible. Later Iwagaki et al. (1977) tried such an approach, but since they mixed different kinds of characteristic curves and furthermore did not introduce wave action conservation, they did

not really succeed in creating a practical model.

For wave height calculations on a current field the so-called wave action is important. Independently of each other this concept was found by Bretherton and Garrett (1968) for a rather general class of waves and by Hayes (1968) for acoustic waves. Jonsson et al. (1970) introduced the similar concept for water waves on a current, see their eq. (5.6).

Peregrine (1976), Phillips (1977), Jonsson (1978a), Peregrine and Jonsson (1983), and Peregrine et al. (1983) have given detailed reviews of waves on currents.

While today efficient and accurate models exist for the calculation of pure depth refraction, see e.g. Skovgaard et al. (1975), a similar model for the calculation of current and depth refraction does not exist. It is the main purpose of this paper to introduce the complete mathematical framework for such a model, which also takes bed friction and dissipation into account. It will be shown that the existence of a phase function, combined with a dispersion relation and a wave action conservation equation (which will be shown to be just a manipulated energy principle), lead to ordinary (first-order) differential equations along so-called wave rays for all wave quantities.

Small, regular waves are assumed; however, also non-linear waves are briefly dealt with.

Also an example of the practical use of a current depth refraction model will be presented. It is based exclusively on ray theory.

## 2. ASSUMPTIONS AND BASIC CONCEPTS

In most of this study small (and regular) progressive gravity waves are considered. Fluxes of mass, momentum and energy are integrated over depth and averaged over absolute period  $T_a$ , in that order. The problem is therefore formulated in two horizontal dimensions  $x_i, i = 1, 2$ .

A pure wave motion is defined as one with no net drift; thus the average - over-depth current velocity  $U_1$  is a zeroth order quantity. For a further discussion of this subject, see Jonsson (1978b), p. 228, and Jonsson and Wang (1980), pp. 157-158. The current velocity is assumed constant over depth.

Bed shear and accompanying dissipation is included. However, shear stresses in vertical sections are neglected. The bed slope is assumed small, so that the horizontal bed expressions are valid locally, i.e.  $|\nabla h| \ll kh$ , where  $\nabla$  is the horizontal gradient operator ( $\partial/\partial x_1, \partial/\partial x_2$ ), and  $k$  is the magnitude of the wave number vector  $k_i$ , so that  $k = 2\pi/L$ ,  $L$  being wave length. Furthermore, only large-scale currents in space and time are considered, i.e.  $|\nabla U| \ll kU$  and  $|\partial U/\partial t| \ll \omega_a U$ , where  $U$  is current speed,  $t$  is time, and  $\omega_a = 2\pi/T_a$  is the absolute angular frequency.

The study is within the framework of geometrical optics, i.e. wave fronts of small curvature are assumed thus excluding diffractive effects.

Two frames of reference are introduced. One is a coordinate system fixed in space; this is the absolute frame of reference, in which is used subscript 'a'. The other is a Galilean transformation of the first where the transformation velocity is the current velocity. Observations in this moving system are termed 'relative', and subscript 'r' is used here.

Referring to Fig. 1 the following relation exists between absolute and relative phase velocities

$$c_a = c_r + U \cos(\delta - \alpha) \quad (1)$$

Fig. 1 - Horizontal sketch for characteristic curves, angles and velocities.

where angles  $\delta$  and  $\alpha$  are explained in the figure. (Note that by definition  $c_a$  is at right angles to the wave front, and that the vector  $U_i + (\hat{c}_r)_i$  has no physical meaning). Multiplying (1) by wave number  $k$  yields the Doppler relation

$$\omega_a = \omega_r + k_i U_i \tag{2}$$

in which the tensor summation notation is used, i.e.  $k_i U_i = k_1 U_1 + k_2 U_2 = kU \cos(\delta - \alpha)$ . The relative angular frequency is  $\omega_r = 2\pi/T_r$ ,  $T_r$  being relative period. The dispersion relation is

$$\omega_r^2 = g k \tanh kh \tag{3}$$

with  $g$  being gravity acceleration. Relative phase speed is found from  $c_r = \omega_r/k$ . Note that while  $\omega_a = \omega_a(h, k_i, U_i)$  we have  $\omega_r = \omega_r(h, k)$ .

In Fig. 1 three sets of curves are distinguished, streamlines, wave orthogonals and wave rays. The new concept is the wave ray, which goes in the direction of the absolute group velocity

$$(c_{ga})_i = c_{ga} (\cos\mu, \sin\mu) \tag{4}$$

The wave ray is not a unique concept. In the general (i.e. non-steady) case one must distinguish between *ray paths*, analogous to particle paths in conventional hydrodynamics, and *ray lines*, analogous to streamlines. In steady flow these curves are identical. The term wave ray will in the general case normally be used for the ray path, and in steady flow for ray line. The differential equation for the wave ray is

$$\frac{dx_i}{dt} = (c_{ga})_i \quad i = 1, 2 \quad (5)$$

in which in general  $(c_{ga})_i$  is a function of  $x_i$  and  $t$ .

In Fig. 2 ray paths and ray lines are illustrated together with the concepts of ray tube element and ray tube, which will be introduced in connection with the wave height calculation.

Fig. 2 - Horizontal sketch showing ray path, ray line, ray tube element and ray tube.

From (2) we find the relation between the absolute group velocity and the relative ditto  $(c_{gr})_i$

$$(c_{ga})_i \equiv \frac{\partial \omega_a}{\partial k_i} = \frac{\partial \omega_r}{\partial k_i} + U_i = (c_{gr})_i + U_i \quad (6)$$

which is illustrated in Fig. 1. The relative group velocity goes in the direction of the wave orthogonal and is given by

$$(c_{gr})_i = c_{gr} (\cos \alpha, \sin \alpha) \quad (7)$$

with the relative group speed

$$c_{gr} = \frac{1}{2} c_r (1 + G) \quad (8) \quad G = \frac{2kh}{\sinh 2kh} \quad (9)$$

Also the relative phase velocity goes in the orthogonal direction:

$$(c_r)_i = c_r (\cos \alpha, \sin \alpha) \quad (10)$$

The time derivative 'seen' by an observer moving along a wave ray with speed  $c_{ga}$  is

$$\frac{d}{dt} = \frac{\partial}{\partial t} + (c_{ga})_i \frac{\partial}{\partial x_i} = \frac{\partial}{\partial t} + c_{ga} \frac{D}{Dr} \quad (11)$$

where 'r' is the length along the ray. This operator ( $d/dt$ ) turns out to be extremely important.

### 3. PROBLEM FORMULATION

In an environment with waves and currents the coastal and ocean engineer is primarily interested in the effect of the fluid flow on structures, the sea bed and vessels. To achieve this goal one must know the wave length ( $L$ ), direction of propagation ( $\alpha$ ), wave height ( $H$ ), as well as the mean water level ( $b$ ) and the current vector ( $U_i$ ), all as functions of space and time ( $x_i, t$ ). This enables a calculation of the total water particle velocities and pressures and thus the forces.

The length and time scales for the waves are most often very much smaller than the corresponding scales for the current. Because of these contrasting scales it is natural to solve the wave field and the current field in two separate steps; this so-called two-level approach was suggested by Skovgaard and Jonsson (1976). Another good reason for this approach is that only at the current level one has to deal with partial differential equations. At the wave level, it turns out that only ordinary differential equations have to be solved. This is done by integration from initial (i.e. one point) boundary conditions along the wave rays. There is naturally, a coupling between the two levels (through bed shear and radiation stress), and an iterative procedure will in principle be necessary.

The known quantities in a water area will be the 'geometrical depth'  $D(x_i)$  (see Fig. 3) describing the bathymetry, and the Nikuradse roughness  $k_{N_i}(x_i)$  of the bed. Also certain lateral boundary conditions must be specified for the current field; for the waves, input data must be specified where the waves 'enter' the calculation area. Details of calculation for the current field will not be presented here; reference is made to Christoffersen (1982).

Fig. 3 - Vertical sketch. Definitions of geometrical depth  $D$ , mean surface elevation  $b$ , and mean water depth  $h$ .

In refraction calculations one normally assumes a steady state. In this paper, however, we shall present the general non-steady formulae, since the derivation of these is not more complicated than the steady ones. The steady state is hereafter considered as a special case.

#### 4. THE KINEMATICS

The basic assumption of ray theory (kinematic wave theory) is that changes in wave characteristics are so slow that locally plane waves can be assumed, see Hayes (1970). This means that *locally* we can introduce a phase function

$$\theta = \omega_a t - k_i x_i + \theta_0 \quad (13)$$

By differentiation of (13) we obtain

$$\frac{\partial \theta}{\partial t} = \omega_a \quad (14) \quad \frac{\partial \theta}{\partial x_i} = -k_i \quad (15)$$

These two quantities are then allowed to vary on a larger scale, and by further differentiation we find the so-called consistency relations

$$\frac{\partial k_i}{\partial t} + \frac{\partial \omega_a}{\partial x_i} = 0 \quad (16) \quad \frac{\partial k_i}{\partial x_j} = \frac{\partial k_j}{\partial x_i} \quad (17)$$

Equation (16) expresses conservation of waves, and (17) that the wave number vector is irrotational. On this basis it becomes possible to find the wave number vector, and thus the wave length and propagation direction, since  $L = 2\pi(k_1^2 + k_2^2)^{-1/2}$  and  $\tan \alpha = k_2/k_1$ . (A further consequence of the assumption of locally plane waves is the Doppler relation (3)).

Using the operator (11) on  $k_i$ , and for  $\partial k_i/\partial t$  inserting (16) yields

$$\frac{dk_i}{dt} = -\frac{\partial \omega_a}{\partial x_i} + (c_{ga})_j \frac{\partial k_i}{\partial x_j} \quad (18)$$

Since  $\omega_a = \omega_a(h, k_j, U_j)$  one obtains

$$\frac{\partial \omega_a}{\partial x_i} = \frac{\partial \omega_a}{\partial h} \frac{\partial h}{\partial x_i} + \frac{\partial \omega_a}{\partial k_j} \frac{\partial k_j}{\partial x_i} + \frac{\partial \omega_a}{\partial U_j} \frac{\partial U_j}{\partial x_i} \quad (19)$$

Using (2) to give  $\partial \omega_a/\partial h = \partial \omega_r/\partial h$  and  $\partial \omega_a/\partial U_j = k_j$ , further introducing (17) and (6), (18) and (19) finally yield

$$\frac{dk_i}{dt} = -\frac{\omega_r G}{2h} \frac{\partial h}{\partial x_i} - k_j \frac{\partial U_j}{\partial x_i} \quad (20)$$

Here it is used that  $\partial \omega_r/\partial h = \omega_r G/2h$ , see Christoffersen and Jonsson (1980). Since  $d/dt$  is given by (11), the important result is achieved that through (20) the rate of change of the wave number vector is found along a ray.

In conclusion, the ray path  $x_i$  and the wave number vector  $k_i$  along this path, are determined by the 4 ordinary, first-order differential

equations (5) and (20), with proper initial conditions.

The absolute angular frequency can be determined either from the algebraic Doppler relation (2) or from (Christoffersen, 1982)

$$\frac{d\omega_a}{dt} = \frac{\omega_r G}{2h} \frac{\partial h}{\partial t} + k_j \frac{\partial U_j}{\partial t} \tag{21}$$

It appears that for a steady medium,  $\omega_a$  remains constant for a 'ray tube element', see Fig. 2.

Similarly, an equation for  $d\omega_r/dt$  along a wave ray can be found, see Christoffersen (1982), chapter 4. The relative angular frequency can also be found from the algebraic expression (3).

In the next chapter it will be found that the evolution of the so-called ray tube element (Fig. 2) must be known in order to calculate the wave height along a ray. Since this is a kinematic problem, it will be dealt with in the present chapter.

A ray tube element is a differential concept, to be visualized as an infinitesimally short 'tube' made up of neighbouring rays. Its area being  $dA$ , the 'Jacobian'  $J$  is introduced as

$$J = \frac{dA}{dA_{st}} = \frac{De}{De_{st}} \frac{c_{ga}}{c_{ga,st}} \tag{22}$$

since  $dA = De Dr$  (Fig. 2), and  $Dr = c_{ga} dt$ . In (22) suffix 'st' stands for 'start' or initial value.

Knowledge of how a ray tube element changes as it moves is found in Aris (1962), pp. 83-84. The so-called Euler expansion formula simply states that

$$\frac{1}{J} \frac{dJ}{dt} = \frac{\partial (c_{ga})_i}{\partial x_i} \tag{23}$$

Using (6) and (2) to evaluate the right hand side of (23) (the divergence of  $(c_{ga})_i$ ) it is found that

$$\frac{1}{J} \frac{dJ}{dt} = \frac{\partial^2 \omega_r}{\partial k_i \partial k_j} \frac{\partial k_j}{\partial x_i} + \frac{\partial^2 \omega_r}{\partial k_i \partial h} \frac{\partial h}{\partial x_i} + \frac{\partial U_i}{\partial x_i} \tag{24}$$

The second order derivatives in (24) are

$$\frac{\partial^2 \omega_r}{\partial k_i \partial h} = \frac{\partial^2 \omega_r}{\partial k \partial h} \frac{k_i}{k} \tag{25}$$

$$\frac{\partial^2 \omega_r}{\partial k_i \partial k_j} = \left( \frac{\partial^2 \omega_r}{\partial k^2} - \frac{1}{k} \frac{\partial \omega_r}{\partial k} \right) \frac{k_i k_j}{k^2} + \frac{1}{k} \frac{\partial \omega_r}{\partial k} \delta_{ij} \tag{26}$$

where  $\delta_{ij}$  is the Kronecker delta.

The evaluation of  $\partial k_j / \partial x_i$  in (24) is quite tricky. Playing around with the consistency relations and the Doppler relation finally yields the 'derived ray equation' (Hayes, 1970).

$$\begin{aligned} \frac{d}{dt} \left( \frac{\partial k_j}{\partial x_i} \right) = & - \frac{\partial k_k}{\partial x_i} \left[ \frac{\partial^2 \omega_r}{\partial k_k \partial k_\ell} \frac{\partial k_\ell}{\partial x_j} + \frac{\partial^2 \omega_r}{\partial k_k \partial h} \frac{\partial h}{\partial x_j} + \frac{\partial U_k}{\partial x_j} \right] - k_k \frac{\partial^2 U_k}{\partial x_i \partial x_j} \\ & - \frac{\partial k_k}{\partial x_j} \left[ \frac{\partial^2 \omega_r}{\partial k_k \partial h} \frac{\partial h}{\partial x_i} + \frac{\partial U_k}{\partial x_i} \right] - \frac{\partial^2 \omega_r}{\partial h^2} \frac{\partial h}{\partial x_i} \frac{\partial h}{\partial x_j} - \frac{\partial \omega_r}{\partial h} \frac{\partial^2 h}{\partial x_i \partial x_j} \end{aligned} \quad (27)$$

in which  $\partial \omega_r / \partial h = \omega_r G / 2h$ . This equation contains three ordinary differential equations, determining the symmetrical tensor  $\partial k_j / \partial k_i$  along rays. For details see Christoffersen (1982), and Jonsson and Christoffersen (1982).

## 5. THE DYNAMICS

The mass conservation equation is simply

$$\frac{\partial}{\partial t} (\rho h) + \frac{\partial}{\partial x_i} (\rho h U_i) = 0 \quad (28)$$

The momentum conservation equations (Phillips, 1977, eq. 3.6.11), with the mean bed shear stress  $(\tau_b)_i$  added, read

$$\frac{\partial}{\partial t} (\rho h U_i) + \frac{\partial}{\partial x_j} (\rho h U_i U_j + S_{ij}) + \rho g h \frac{\partial b}{\partial x_i} + (\tau_b)_i = 0 \quad (29)$$

Standard sign convention is adopted for shear, i.e. the shear stress acting on the *bed* is taken positive in the positive  $x_i$ -direction. Phillips' bed shear stress appears with the opposite sign (his p. 65).

The energy conservation equation (Phillips, 1977, eq. 3.6.18) with the total dissipation per unit area  $E_d$  added reads

$$\begin{aligned} \frac{\partial}{\partial t} \left( \frac{1}{2} \rho h U_j^2 + E + \frac{1}{2} \rho g (b^2 - D^2) \right) \\ + \frac{\partial}{\partial x_i} \left( \frac{1}{2} \rho h U_i U_j^2 + \rho g h U_i b + E (c_{ga})_i + S_{ij} U_j \right) + E_d = 0 \end{aligned} \quad (30)$$

Note that there is some ambiguity in Phillips' definition of dissipation, see Christoffersen and Jonsson (1980). In the above equations  $S_{ij}$  is the radiation stress tensor given by

$$S_{ij} = \delta_{ij} S_p + \frac{k_i k_j}{k^2} S_m \quad (31)$$

where  $S_p$  and  $S_m$  are the pressure and momentum parts of the radiation stress given by

$$S_p = \frac{1}{2} E G \quad (32) \quad S_m = \frac{1}{2} E (1 + G) \quad (33)$$

Here  $E$  as usual is the wave energy density,  $1/8 \rho g H^2$ .

Christoffersen and Jonsson (1980) derived the wave action equation for a dissipative steady medium. The wave action equation for a general unsteady dissipative medium is here derived in a simpler and more straightforward way.

Eliminating first the mean surface height  $b$  by multiplying (29) by  $U_i$  and subtracting the result from (30) yields

$$\frac{\partial E}{\partial t} + \frac{\partial}{\partial x_i} \left( E (c_{ga})_i \right) + S_{ij} \frac{\partial U_j}{\partial x_i} + E_d - (\tau_b)_i U_i = 0 \tag{34}$$

Dividing by  $\omega_r$  and using also (11) gives

$$\begin{aligned} \frac{\partial}{\partial t} \left( \frac{E}{\omega_r} \right) + \frac{\partial}{\partial x_i} \left( \frac{E}{\omega_r} (c_{ga})_i \right) + \frac{E_d - (\tau_b)_i U_i}{\omega_r} \\ + \frac{1}{\omega_r} \left( \frac{E}{\omega_r} \frac{d\omega_r}{dt} + S_{ij} \frac{\partial U_j}{\partial x_i} \right) = 0 \end{aligned} \tag{35}$$

Here, the variation of  $\omega_r$  along a ray can be expressed in terms of the radiation stress tensor as (Christoffersen, 1982)

$$\frac{E}{\omega_r} \frac{d\omega_r}{dt} = - S_{ij} \frac{\partial U_j}{\partial x_i} \tag{36}$$

Inserting (36) in (35), the last term vanishes, and the new general wave action equation emerges as

$$\frac{\partial \mathcal{A}}{\partial t} + \frac{\partial}{\partial x_i} \left( \mathcal{A} (c_{ga})_i \right) + E_w = 0 \tag{37}$$

in which wave action  $\mathcal{A}$  and 'wave action dissipation'  $E_w$  are by definition

$$\mathcal{A} = \frac{E}{\omega_r} \tag{38} \quad E_w = \frac{E_d - (\tau_b)_i U_i}{\omega_r} \tag{39}$$

Note that all terms in (37) vanish for a vanishing wave motion. Thus the energy equation (30) for the total flow has been transformed into a neat energy equation for the wave motion. This can be further simplified, though. Introducing (23) in (37) yields

$$\frac{d}{dt} (\mathcal{A} J) + E_w J = 0 \tag{40}$$

This means that wave action  $\mathcal{A}$  - and thus wave height  $H$  - can be calculated along a wave ray by solving the ordinary differential equation (40). By introducing (22), an alternative version of (40) appears as

$$\frac{d}{dt} (\mathcal{B} De) + E_w c_{ga} De = 0 \tag{41}$$

with wave action flux  $\mathcal{B} \equiv \mathcal{A} c_{ga}$ .

### 6. WAVE HEIGHT CALCULATION

The wave height equation is most easily found by looking at the steady case. With  $\partial/\partial t = 0$  we find from (11) and (41),  $D(\mathcal{B}De)/Dr + E_w De = 0$ , where 'r' is distance along the ray, and 'e' is distance at right angles to this (Fig. 2). It thus appears that wave action propagates between neighbouring rays and is dissipated through wave action dissipation. The wave action flux through the ray tube is  $\mathcal{B}_{st} De_{st}$  at one end ('st' stands for start), and  $\mathcal{B} De$  at an arbitrary

point (Fig. 2). Taking the square root of the ratio between these two quantities yields the wave height equation

$$\frac{H}{H_{st}} = \sqrt{\frac{\omega_r}{\omega_{r,st}}} \sqrt{\frac{c_{ga,st}}{c_{ga}}} \sqrt{\frac{De_{st}}{De}} \sqrt{\frac{\mathcal{A}_J}{\mathcal{A}_{st,Jst}}} \quad (42)$$

$$= K_C \times K_S \times K_{ra} \times K_f$$

in which  $K_C$  is the 'Doppler coefficient',  $K_S$  the 'shoaling coefficient',  $K_{ra}$  the 'refraction coefficient', and  $K_f$  the 'friction coefficient'. It can be shown that (42) also is valid in the non-steady case, see e.g. Jonsson (1982). The three first coefficients are determined by the kinematics of the current-wave field, and it is immediately seen from (22) that  $J = (K_S K_{ra})^{-2}$ , i.e.

$$\frac{H}{H_{st}} = K_C J^{-1/2} K_f \quad (43)$$

By dividing (40) with  $\mathcal{A}_{st} J_{st}$  ( $J_{st} \equiv 1$ ) and introducing the expression for  $K_f$  in (42), we find for the friction coefficient

$$\frac{d}{dt} (K_f^2) = - \frac{E_w}{\mathcal{A}_{st}} J \quad (44)$$

i.e. yet another ODE to be solved along the rays.

There remains the calculation of  $E_w$  in (44). From (39) it appears that this calls for the determination of bed shear  $(\tau_b)_i$  and dissipation  $E_d$ . In Christoffersen and Jonsson (1984) a detailed calculation procedure is presented for the calculation of these quantities. The method is based on two-layer models for the current-wave boundary layer, one for 'small roughnesses' and one for 'large roughnesses'. In general the following approximate result was obtained:  $E_d = (\tau_b)_i U_i + \langle (\tau_{wb})_i (u_{wb})_i \rangle$ , whereby from (39) we find  $E_w = \langle (\tau_{wb})_i (u_{wb})_i \rangle / \omega_r$ . Here  $(\tau_{wb})_i$  is the wave part of the bed shear stress and  $(u_{wb})_i$  the wave particle velocity just outside the wave boundary layer at the bed.

## 7. SUMMARY OF RESULTS

The procedure for the calculation of the wave field ( $k_i, H$ ) is hereafter. The wave ray - along which all other quantities can be calculated - and the wave number vector are determined by the four differential equations (5) and (20) with proper initial conditions, assuming water depths and current velocity known. Note that operator  $d/dt$  is given by (11).

The wave height is then determined by (43). Doppler coefficient  $K_C$  is found from its definition in (42), and the Jacobian  $J$  by the four differential equations (24) and (27). Finally  $K_f$  is found from (44).

The above procedure is generally valid. In practise a steady situation is often assumed, and simpler equations emerge, see Christoffersen (1982), and Jonsson and Christoffersen (1982). A discussion of the possible calculation of the current field, and of the interaction between the waves and the currents through radiation stress and bed shear is given in the former reference.

8. EXAMPLE

To illustrate the effect of currents on waves, we look at conditions outside an inlet with a 'jet' ebb flow as shown in Fig. 4.

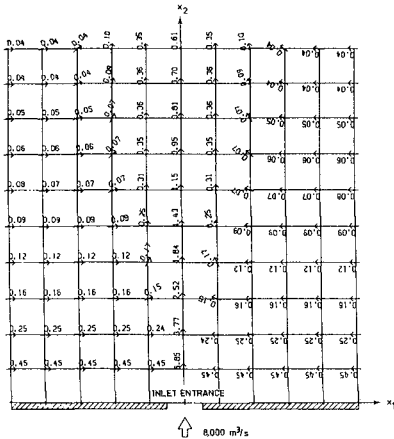

Fig. 4. Horizontal plan. Ebb current velocities (m/s) outside inlet. Arrows indicate current direction and numbers are current speed. The current is symmetrical about the  $x_2$ -axis. Grid spacing is 200 m, and water depth is  $h = 10\text{ m} + 0.02 x_2$  ( $x_2 > 0$ ), i.e. bed slope 1:50. The inlet entrance is 200 m wide, with water depth  $h_0 = 10\text{ m}$ . Discharge through inlet is  $Q = 8,000\text{ m}^3/\text{s}$ , giving an average-over-width current velocity  $U_0 = 4\text{ m/s}$ .

Fig. 5. Horizontal plan. Wave rays (...) on ebb current in Fig. 4. Arrows indicate orthogonal direction, and numbers are wave heights (m) (no dissipation). The thirteen computed rays start at  $x_2 = 5,000\text{ m}$  ( $h = 110\text{ m}$ ). The corresponding  $x_1$ -values vary from  $x_1 = -3,600\text{ m}$  to  $x_1 = -1,200\text{ m}$ , with 200 m spacing. The angle of incidence is here  $30^\circ$ . Initial wave height is  $H_{st} = 1\text{ m}$ , and absolute wave period is  $T_a = 8\text{ s}$ .

With angle of incidence  $30^\circ$  far from the inlet, the computed orthogonal directions and wave heights (no dissipation) are presented along the rays in Fig. 5. The fact that wave rays and orthogonals do not coincide (when currents are present), is most clearly seen near the inlet entrance, where current velocities are large. The most striking - and perhaps unexpected - result of our calculations as presented in Fig. 5, is the marked reduction in wave height in the central part of the ebb current. The reason for this is that the oblique incidence of the waves on the opposing current in ques-

tion, in this area generates a sharp reduction in refraction coefficient. This is a result of the obvious increase in ray spacing here.

9. NON-LINEAR WAVES

In Shen and Keller (1973) and Shen (1975) (considering non-linear wave propagation in shallow water without a current) it was found that the kinematics to a first approximation was governed by linear theory, i.e.  $\omega_r = k \sqrt{gh}$ , which is the shallow water version of (3). This meant that non-linearity only played a role in the calculation of the dynamics, which was governed by a Korteweg-DeVries equation. This equation is known to have cnoidal wave solutions, see Svendsen and Hansen (1978) where the energy flux has been calculated for cnoidal waves.

Fig. 6 - Shoaling curves. Full lines: Cokelet's theory. Dashed lines: Svendsen and Brink-Kjær (1972). (From Sakai and Battjes, 1980) Dots: Present study. Values of  $H_0/L_0$  are shown.

Further Ryrie and Peregrine (1982), considering refraction of numerically exact finite-amplitude waves, found that linear wave theory normally proved quite accurate for predicting the wave directions. These observations really indicate that a first simple extension to include weakly non-linear waves, could be to keep the linear-wave kinematics unaltered, and only take non-linearity into account in the wave action equation (40). This means that one just replaces the linear wave energy density in (38) with the non-linear wave energy density  $E = B(m) \rho g H^2$  where

$$B(m) = \frac{1}{3m^2} \left[ \frac{E}{K} (2 + 2m_1 - 3 \frac{E}{K}) - m_1 \right] \tag{45}$$

see e.g. Sarpkaya and Isaacson (1981), p. 185.

Here  $m_1 = 1-m$ , and further  $K(m)$  and  $E(m)$  are the complete elliptic integrals of the first and second kind, respectively. The parameter  $m$  is determined from  $HL^2/h^3 = (16/3) m K^2$ .

Because of  $B(m)$  ( $= 1/8$  for linear waves), a fifth factor  $K_n = \sqrt{B_{st}/B}$  is introduced in (42), to account for non-linearity.

To illustrate the applicability of this new and simple approach, we show in Fig. 6 the results of shoaling without a current.

In the figure, the Sakai and Battjes (1980) results for shoaling of finite amplitude waves (using Cokelet's theory) have been compared with our model, and with the results of Svendsen and Brink-Kjær (1972), showing that our model yields encouraging results for the wave heights, also giving a smooth transition from deep to shallow water. The smaller the steepness, the better the agreement with the Cokelet theory.

The proposed extension does not only give improved results, (as compared with linear theory), but it is also easy to implement in a refraction program capable of treating arbitrary bathymetries and current fields.

## 10. CONCLUSIONS

The assumption of *locally* plane waves, combined with a dispersion relation and wave action conservation, have led to the complete set of equations for current and depth refraction of regular water waves. These are ordinary, first-order differential equations for all wave quantities, when formulated along the so-called wave rays. Bed friction and accompanying dissipation is included. The ray equations form the basis of a computer program, which is applied to a case of refraction on an ebb current outside an inlet. A method to incorporate non-linear waves in the system is proposed.

Dr. Ove Skovgaard, Laboratory of Applied Mathematical Physics, is acknowledged for his unfaltering interest and good advice on the computational problems.

## CHAPTER SEVENTY SIX

### A Numerical Model For Refraction Of Linear And Cnoidal Waves

John R. Headland<sup>1</sup>, A.M. ASCE  
Hsiao-Ling Chu<sup>2</sup>, M. ASCE

#### Abstract

A numerical model for refraction of linear and cnoidal waves over an arbitrary bottom is presented. The model, which is based on the ray theory of refraction (11), utilizes linear theory in deep and intermediate water and cnoidal theory in shallow water. The model permits one to determine nearshore wave properties using a nonlinear wave theory. Nearshore wave properties such as wave height, celerity, and wave angle determined using the linear-cnoidal refraction model may vary considerably from those determined using a linear refraction model. In general, cnoidal waves refract less, travel faster, and shoal higher than linear waves. This result can have a considerable effect on coastal engineering design, particularly in the areas of coastal structure design and longshore transport computations.

#### Introduction

Linear theory is generally used for wave shoaling and refraction computations despite its well-documented inability to accurately predict shallow water wave characteristics (6). Several investigators (6, 8, 14) have used nonlinear theories to analyze wave refraction over straight and parallel bottom contours but have not extended the work to an arbitrary bottom. Crowley et. al. (5) have developed a nonlinear refraction model for an arbitrary bottom utilizing vocoidal wave theory. This paper presents a numerical model for wave refraction over an arbitrary bottom which incorporates linear theory in deep and intermediate water but uses cnoidal theory in shallow water.

The numerical model presented herein is based on the ray theory of refraction. Ray theory suffers from several shortcomings, especially the inability to provide realistic solutions in areas of strong convergence and caustics. A variety of refraction-diffraction models have been developed in recent years (1, 2, 12) to overcome problems associated with ray theory. These models may utilize either linear (2, 12) or nonlinear theory (1). Refraction-diffraction models are clearly an improvement over ray theory, but use of these models requires substantial computer time even for a

<sup>2</sup>Professor of Civil Engineering, California State University, Long Beach, California 90840.

relatively small geographical area (2). Ray models are therefore indispensable at the present state-of-the-art and are often used as input to a refraction-diffraction model or to a physical model. Ray models were recently used on two major coastal engineering projects (9, 10).

The objective of this paper is to present the governing equations for wave refraction, present the linear and cnoidal equations used in them, and discuss their numerical solution. Application of the model to straight and parallel bottom contours and an idealized shoal are presented and discussed. Differences in nearshore wave characteristics based on cnoidal versus linear wave refraction are emphasized.

Wave Refraction Equations

Figure 1 illustrates the nomenclature and coordinate system for the wave refraction problem. The wave ray (orthogonal) travels with celerity,  $c$ , makes an angle,  $A$ , with the  $x$ -axis, and its position at a given time,  $t$ , is defined by the coordinates,  $x$ , and  $y$ . The wave ray separation factor,  $\beta$ , which is related to the refraction coefficient by  $K = \sqrt{1/\beta}$ , is also defined in Figure 1. The governing equations for wave refraction used in the model are those presented by Skovgaard et. al. (13) with time,  $t$ , as the independent variable. Wave ray paths are governed by the following equations:

Fig. 1 Wave refraction nomenclature .

$$\dot{x} = c \cos A \quad (1)$$

$$\dot{y} = c \sin A \quad (2)$$

$$\dot{A} = \frac{dc}{dh} (h_x \sin A - h_y \cos A) \quad (3)$$

Where the subscripts on  $h$  denote a partial derivative (i.e.,  $h_x = \partial h / \partial x$ ) wave separation is determined using the following equation:

$$\ddot{\beta} + p_t \dot{\beta} + q_t \beta = 0 \quad (4)$$

where

$$p_t = -2 \frac{dc}{dh} (h_x \cos A + h_y \sin A) \quad (5)$$

$$q_t = c \frac{dc}{dh} (h_{xx} \sin^2 A - h_{xy} 2 \sin A \cos A + h_{yy} \cos^2 A) + c \frac{d^2c}{dh^2} (h_x \sin A - h_y \cos A)^2 \quad (6)$$

Equations 1 through 6 are valid for both linear and cnoidal theories (14). These equations require determination of the wave speed,  $c$ , and its first and second derivatives with water depth (i.e.,  $dc/dh$ ,  $d^2c/dh^2$ ) according to a particular wave theory. This is done readily for linear theory because one can uncouple the wave speed and wave height computations. On the other hand, the cnoidal wave speed depends on wave height and thus the wave separation factor,  $\beta$ . This complicates evaluation of the wave speed derivatives with depth because other variables such as wave height also vary with depth.

### Linear Theory

Linear theory is used when the relative depth  $d/L > .10$  or when the Ursell parameter,  $U = HL^2/h^3 < 15$ , (15,16). Equations for the linear wave celerity,  $c$ , and its derivatives with depth are as follows, (13):

$$c = \frac{gT}{2\pi} \tanh kh \quad (7)$$

$$\frac{dc}{dh} = \frac{c}{h} \frac{G}{1+G} \quad (8)$$

$$\frac{d^2c}{dh^2} = -\frac{dc}{dh} \frac{2g}{c^2 (1+G)^2} \quad (9)$$

$$G = \frac{2kh}{\sinh 2kh} \tag{10}$$

where T = wave period, h = water depth, k = wave number = 2π/L, and L = wave length. Wave heights in the linear region are computed as follows:

$$H = H_0 K_R K_S \tag{11}$$

where H = local wave height, H<sub>0</sub> = the deepwater wave height, K<sub>R</sub> = the refraction coefficient, and K<sub>S</sub> = the shoaling coefficient. The shoaling coefficient according to linear theory is as follows:

$$K_S = \sqrt{\frac{1}{\tanh(kh) (1 + G)}} \tag{12}$$

Cnoidal Theory

Cnoidal theory is used when the relative depth, d/L<sub>0</sub> <.10 and/or the Ursell parameter, U > 15. The cnoidal equations used are those reported by Svendsen and Brink-Kjaer (15). These equations represent first-order cnoidal theory.

$$c^2 = gh (1 + \frac{H}{h} A_C) \tag{13}$$

$$U = \frac{16}{3} m K^2 = \frac{HL^2}{h^3} \tag{14}$$

$$E_f = \rho g H^2 c B_C \tag{15}$$

where  $A_C = \frac{2}{m} - 1 - \frac{3E}{mK} \tag{16}$

$$B_C = \frac{1}{m^2} \left[ \frac{1}{3} (3m^2 - 5m + 2 (4m-2) \frac{E}{K}) - (1 - m - \frac{E}{K})^2 \right] \tag{17}$$

Where m = elliptic parameter, ρ = mass density of water, K = complete elliptic integral of the first kind, E = complete elliptic integral of the second kind, and E<sub>f</sub> = the wave energy flux. Wave speed derivatives dc/dh and d<sup>2</sup>c/dh<sup>2</sup> are determined by adjusting Equations 13 through 15 for refraction and combining them to give the following:

$$\lambda = c^2 - gh - gA_c E_{f0}^{1/2} B_c^{-1/2} c^{-1/2} \beta^{-1/2} = 0 \quad (18)$$

$$\begin{aligned} \Omega = E_{f0}^{-1/2} B_c^{-1/2} c^{3/2} \beta^{-1/2} - \frac{16}{3} K^2 \frac{h^3}{T^2} \\ + \frac{16}{3} m' \frac{K^2 h^3}{T^2} = 0 \end{aligned} \quad (19)$$

where  $m'$  = the complementary elliptic parameter ( $1 - m$ ) and  $E_{f0}$  is the reference value of energy flux. The first derivative of the wavespeed with depth,  $dc/dh$ , is determined by applying the chain rule to equations 18 and 19:

$$\lambda_h + \lambda_c \frac{dc}{dh} + \lambda_{m'} \frac{dm'}{dh} + \lambda_\beta \frac{d\beta}{dh} = 0 \quad (20)$$

$$\Omega_h + \Omega_c \frac{dc}{dh} + \Omega_{m'} \frac{dm'}{dh} + \Omega_\beta \frac{d\beta}{dh} = 0 \quad (21)$$

$$\text{where} \quad \frac{d\beta}{dh} = \frac{1}{c} \frac{d\beta}{dt} (h_x \cos A + h_y \sin A)^{-1} \quad (22)$$

The subscripts on  $\lambda$  and  $\Omega$  denote a partial derivative e.g.,  $\partial\lambda_h = \partial\lambda / \partial h$ . Equations 20 through 22 are solved simultaneously for  $dc/dh$ ,  $dm'/dh$  and  $d\beta/dh$ . The second derivative of wave celerity with depth,  $d^2c/dh^2$ , is determined by applying the chain rule to equations 20 and 21 to give:

$$\begin{aligned} \lambda_{hh} + 2 \lambda_{hc} \frac{dc}{dh} + \lambda_{hm'} \frac{dm'}{dh} + \lambda_{h\beta} \frac{d\beta}{dh} + \\ 2\lambda_{m'c} \frac{dc}{dh} \frac{dm'}{dh} + 2\lambda_{\beta m'} \frac{d\beta}{dh} \frac{dm'}{dh} + 2\lambda_{\beta c} \frac{dc}{dh} \frac{d\beta}{dh} \\ + \lambda_{cc} \left(\frac{dc}{dh}\right)^2 + \lambda_c \frac{d^2c}{dh^2} + \lambda_{m'm'} \left(\frac{dm'}{dh}\right) + \lambda_{m'} \frac{d^2m'}{dh^2} \\ + \lambda_{\beta\beta} \left(\frac{d\beta}{dh}\right)^2 + \lambda_\beta \frac{d^2\beta}{dh^2} = 0 \end{aligned} \quad (23)$$

$$\begin{aligned}
 &\Omega_{hh} + 2\Omega_{hc} \frac{dc}{dh} + \Omega_{hm'} \frac{dm'}{dh} + \Omega_{h\beta} \frac{d\beta}{dh} + \\
 &2\Omega_{m'c} \frac{dc}{dh} \frac{dm'}{dh} + 2\Omega_{\beta m'} \frac{dm'}{dh} \frac{d\beta}{dh} + 2\Omega_{\beta c} \frac{dc}{dh} \frac{d\beta}{dh} \\
 &+ \Omega_{cc} \left(\frac{dc}{dh}\right)^2 + \Omega_c \frac{d^2c}{dh^2} + \Omega_{m'm'} \left(\frac{dm'}{dh}\right)^2 + \Omega_{m'} \frac{d^2m'}{dh^2} \\
 &+ \Omega_{\beta\beta} \left(\frac{d\beta}{dh}\right)^2 + \Omega_{\beta} \frac{d^2\beta}{dh^2} = 0
 \end{aligned} \tag{24}$$

where

$$\frac{d^2\beta}{dh^2} = \frac{d^2\beta}{ds^2} \left(\frac{d^2h}{ds^2}\right)^{-1} \tag{25}$$

$$\begin{aligned}
 \frac{d^2\beta}{ds^2} &= \frac{1}{c^2} \frac{dc}{dh} (h_x \cos A + h_y \sin A) \frac{d\beta}{dt} - \frac{dc}{dh} \\
 &\frac{1}{c} (h_{xx} \sin^2 A + h_{xy} 2 \sin A \cos A + h_{yy} \cos^2 A) -
 \end{aligned} \tag{26}$$

$$\begin{aligned}
 &\frac{d^2c}{dh^2} \frac{1}{c} (h_x \sin A - h_y \cos A)^2 \beta \\
 \frac{d^2h}{ds^2} &= -\sin A \frac{dA}{ds} h_x + \cos A (\cos A h_{xx} + \sin A h_{xy}) \\
 &+ \cos A \frac{dA}{ds} h_y + \sin A (\cos A h_{xy} + \sin A h_{yy})
 \end{aligned} \tag{27}$$

$$\frac{dA}{ds} = \frac{1}{c} \frac{dc}{dh} (\sin A h_x - \cos A h_y) \tag{28}$$

Equations 23 through 28 are solved simultaneously for  $d^2c/dh^2$ .

Numerical Solution of the Linear and Cnoidal Equations

The linear dispersion equation (Eq. 7) is solved by the Newton-Raphson method. The cnoidal wave equations (Eq. 13 through 15) are combined to form the cnoidal shoaling equation (15):

$$M f_1 (U) + N f_2 (U) = 1 \tag{29}$$

where  $f_1 (U) = -B_c^{-2/3} U^{-1/3} A_c \tag{30}$

$$f_2 (U) = B_c^{2/3} U^{4/3} \tag{31}$$

$$M = (H_r B_r L_r)^{2/3} / h^2 \tag{32}$$

$$N = M^{-1} h/gT^2 \tag{33}$$

The reference values of  $H_r$ ,  $L_r$  and  $B_r$  may be given in deep water according to linear theory or in shallow according to cnoidal theory; the choice depends on where refraction computations are started. Eq. 29. is solved numerically using the Newton-Raphson Method. However, several precautions are necessary to ensure a proper solution. The Newton-Raphson procedure is formulated in terms of the complementary elliptic parameter,  $m'$ , instead of the elliptic parameter,  $m$ . This is necessary because, as the elliptic parameter,  $m$ , approaches 1 (i.e.,  $m'$  approaches zero), the numerical computations cannot be computed with accuracy.

The elliptic functions E and K are evaluated using the Arithmetic/Geometric Mean (AGM) scale presented in (7). The following AGM scale is used to evaluate the elliptic functions:

$$\begin{array}{lll}
 a_0 = 1 & b_0 = \sqrt{m'} & c_0 = \sqrt{1 - m'} \\
 \\
 a_1 = \frac{1}{2} (a_0 + b_0) & b_1 = \sqrt{a_0 b_0} & c_1 = \frac{1}{2} (a_0 - b_0) \\
 \text{---} & \text{---} & \text{---} \\
 \text{---} & \text{---} & \text{---} \\
 \text{---} & \text{---} & \text{---} \\
 \\
 a_N = \frac{1}{2} (a_{N-1} + b_{N-1}) & b_N = \sqrt{a_{N-1} b_{N-1}} & c_N = \frac{1}{2} (a_{N-1} - b_{N-1})
 \end{array} \tag{34}$$

The coefficients  $a_n$ ,  $b_n$ , and  $c_n$  are computed using nine steps ( $N=9$ ) which give accurate estimates (i.e.  $c_9 < 10^{-6}$ ). From the AGM scale, E and K are computed as follows:

$$K = \pi/2a_N \tag{35}$$

$$E = K(1 - \frac{1}{2} (c_0 + 2c_1 + 2^2 c_2^2 + \text{---} + 2^N c_N^2)) \tag{36}$$

A second difficulty encountered in solving the cnoidal shoaling equation by the Newton-Raphson Method is that the equation has two roots (14, 15). Skovgaard and Petersen (14) conclude that the correct root corresponds to the smallest value of  $m'$  or the highest value of  $m$ . The Newton-Raphson interaction is started at a sufficiently low value of  $m'$  (i.e.,  $m' = 1 \times 10^{-37}$ ) to assure convergence to the correct root. Iterations are continued until the value of  $m'$  is determined within an accuracy of  $1 \times 10^{-6}$ .

The cnoidal shoaling equation describes the variation of a wave of given energy flux and wave period in the cnoidal region. Originally, Svendsen and Brink-Kjaer (15) solved the cnoidal shoaling equation assuming a continuity in energy flux between linear and cnoidal theories at the matching point of  $h/L_0 = 0.10$ . However, this results in a discontinuity in wave height. Svendsen and Buhr-Hansen (16) compared the shoaling characteristics of laboratory waves to shoaling predicted by cnoidal theory and found that cnoidal theory predicted shoaling more accurately if wave height instead of wave energy is matched at  $h/L_0 = 0.10$ . This presents some difficulties for wave refraction computations because there are discontinuities at the linear-cnoidal interface not only in wave height and/or wave energy, but also in wave celerity, separation, and other variables. This problem is of secondary importance for practical applications.

Numerical Solution of the Refraction Equations

The governing equations for wave refraction (i.e. 1 through 6) are solved as an initial value problem in a manner similar to Skovgaard et. al. (13). Equation 4 for the wave separation is rewritten as two first order differential equations and the governing equations are solved as a system of ordinary differential equations:

$$\dot{Z} = \dot{\beta} \tag{37}$$

$$\dot{Z} = -p_t Z - q_t \beta \tag{38}$$

with the following initial conditions:

$$\begin{aligned} x &= x_0 \\ y &= y_0 \\ A &= A_0 \\ \beta &= \beta_0 \\ Z &= Z_0 \end{aligned} \tag{39}$$

The integration is carried out using a combination of the Runge-Kutta-Gill and Adams-Moulton methods for initial value problems.

### Evaluation of Water Depth and Water Depth Derivatives

Water depth values are stored in a bathymetry grid. The partial derivatives of water depth are computed using central difference finite difference formulas. Values of water depth (and/or its derivatives) at a point which is not on a grid point are interpolated using the following formula (4):

$$f_{i+p, j+q} = (1-p)(1-q)f_{i,j} + p(1-q)f_{i+1,j} \\ + (1-p)qf_{i,j+1} + pqf_{i+1,j+1} \quad (40)$$

where  $i$  and  $j$  denote the  $x$  and  $y$  grid point respectively, and  $p$  and  $q$  define the  $x$  and  $y$  position within a grid space and  $f$  denotes the water depth and/or one of its derivatives.

### Verification for Straight and Parallel Contours

Calculations were performed for straight and parallel bottom contours. The results were compared to analytical solutions based on Snell's Law. Snell's Law is expressed by the following:

$$\text{Ray Paths: } \frac{\sin \alpha}{c} = \text{constant} \quad (41)$$

$$\text{Ray Separation: } \beta = \frac{\cos \alpha}{\cos \alpha_0} \quad (42)$$

In the above equations  $\alpha$  = the wave ray angle with the shore normal. The bathymetry grid for the verification runs was arranged so that  $\alpha = A$  (the wave ray angle with the positive  $x$ -axis).

Problems in matching linear and cnoidal theories preclude complete verification of the model for straight and parallel contours. For this reason, the model was verified for the linear and cnoidal ranges separately. Accuracy of the linear portion of the model was similar to that reported by (4) and (13) for both Eq. 41 and Eq. 42. Typically, linear refraction computations deviated from Snell's Law results only about 1 part in 10,000 per time step for a variety of conditions.

The numerical model was tested in the cnoidal region for straight and parallel contours by using initial conditions appropriate for cnoidal theory. To avoid erroneous results accurate initial conditions must be specified; these values include:

$$x, y, A, Z, \beta \\ \text{and } c, dc/dh, d^2c/dh^2, B_c, L, h, U, H, A_c$$

The initial values for  $\beta$ , and  $Z$  are given by the following according to (13):

$$\beta = \frac{\cos \alpha}{\cos \alpha_{st}} \tag{43}$$

$$Z = \frac{\sin \alpha}{\cos \alpha_{st}} (-h_x \sin A + h_y \cos A) \frac{dc}{dh} \tag{44}$$

where  $A = \alpha$  for the test cases, and  $st$  denotes the starting value.

Figure 2 shows the bathymetry grid, initial conditions, and wave rays for both cnoidal and linear theory for one of the test runs. In general, computational accuracy is less for cnoidal theory than linear theory. Typically, the results deviate from the Snell's Law results about 5 parts in 1000 per time step. This error stems from a variety of factors such as grid size, time step, and initial wave conditions, but primarily results from round-off error in the computation of the elliptic functions and more importantly in computation of the derivatives of the elliptic functions. Effort is presently underway to improve the accuracy of these computations. In the meantime, the verification results show the numerical scheme to be adequate for engineering applications. Uncertainties in incident wave conditions, bathymetry, and subjectivity associated in bathymetric smoothing, overshadow the small round-off error present in the model.

Fig. 2 shows that the cnoidal wave rays refract less than the linear rays, (i.e. the wave ray separation is less and the nearshore wave angle is higher for the cnoidal rays). Not evident from Fig. 2 is the fact that the cnoidal rays shoal significantly higher than the linear rays. These results are summarized in Table 1 which compares the cnoidal and linear wave rays at an equal nearshore depth. The above findings are consistent with those of Skovgaard and Petersen (14) who investigated cnoidal wave refraction over straight and parallel contours. A direct comparison to Skovgaard and Petersen (14) is not possible because computations performed for this paper were started in the cnoidal region whereas the results of Skovgaard and Petersen were related to deepwater values.

Table 1. Typical Results for Straight and Parallel Contours  
Wave Characteristics at  $h = 2.5$  feet (0.76 meters)

Results For An Idealized Shoal

Refraction of cnoidal waves over an arbitrary bottom is illustrated by applying the model to an idealized shoal, similar to that used by Walker (17). The idealized shoal and bathymetry grid is shown in Fig. 3. Fig. 3 also shows the initial conditions and wave rays for a series of linear and cnoidal rays. Qualitatively, the refraction pattern for the cnoidal rays differs significantly from the linear rays as the cnoidal rays converge less over the shoal. The results are analogous to those for straight and parallel contours. Table 2 provides a comparison of linear and cnoidal results for ray number 4 at nearly equal depths. Table 2 indicates that the linear rays bend more and converge more than the cnoidal rays (i.e. higher wave angle and higher refraction coefficient). Table 2 also indicates that, despite the higher refraction coefficient for linear theory, the resulting wave height is higher for the cnoidal ray. This suggests that wave shoaling, rather than refraction, dominates the wave height growth. In summary, the cnoidal rays travel faster, propagate further, refract less, and shoal higher than linear rays.

Table 2. Typical Results For An Arbitrary Bottom

Wave Characteristics for Ray No. 4

Theory	A degrees	$\beta$	h feet (meters)	$K_s$	$K_R$	C feet per second (meters per sec.)	H, feet (meters)
Linear	8.28	0.9406	1.90 (.579)	1.42	1.031	7.75 (2.36)	1.41 (.43)
Cnoidal	3.65	0.9673	2.04 (.622)	1.85	1.017	10.38 (3.16)	1.74 (.53)

Summary

A numerical model for the refraction of linear and cnoidal waves is presented. The numerical model provides an engineering solution to the refraction of cnoidal waves. The model shows that cnoidal waves refract less and shoal higher than linear waves. Problems associated with matching linear and cnoidal theories require further research but the present model can be used until such research is available. The numerical approach is a general procedure which provides framework for incorporation of other nonlinear theories, such as third order Stokes waves in deep and intermediate water. Present effort is directed towards improving the numerical accuracy of the elliptic function and elliptic function derivatives.

The results shown in Fig. 3 for an idealized shoal are indicative of the differences between cnoidal and linear refraction for prototype applications. Clearly, nearshore waveheights based on cnoidal theory will vary considerably from those based on linear theory. This could have a considerable impact on coastal structures located in an area of divergence subjected to nonbreaking or near breaking waves. Higher nearshore wave heights and more importantly wave angles would have an impact on longshore transport calculations.

## CHAPTER SEVENTY SEVEN

### EFFECTS OF OPPOSING CURRENT ON WAVE TRANSFORMATION

#### ON SLOPING SEA BED

by

Shigeki Sakai\* and Hiroshi Saeki\*\*

#### ABSTRACT

The transformation and the breaking of waves affected by an opposing current on the sloping sea bed were discussed. It was found that the characteristics of wave transformation before breaking point can be determined by the deep water wave steepness and the dimensionless unit width discharge. Concerning the wave decaying due to breaking, the characteristics of the change in the wave height depend only on the slope of the sea bed.

Fourth order solutions of Stokes wave on a uniform current were calculated based on the first and second definition of the wave celerity, respectively. The theoretical solutions for wave transformation by the energy flux method were presented. Comparisons between the theoretical solutions and the experimental results gave the criteria of the applicability of our solutions corresponding to the dimensionless unit width discharge. In the calculation of energy flux, it was pointed out that the change in the mean level of the free surface should be taken into account. It was made clear that the change in the mean level of the free surface can be evaluated by Bernoulli's equation, and the energy flux in which the change in the mean level of the free surface was taken into account was proposed.

The criteria of breaking corresponding to the dimensionless unit width discharge were clarified, experimentally.

#### 1. INTRODUCTION

The river mouth blocking is a very serious problem for coastal engineers. The goal of the study is to clarify how the sand is piled up at the river mouth by waves and currents. And for the first step to this problem, the transformation and breaking of waves affected by an opposing current on the sloping sea bed were investigated.

\* Instructor, Department of Civil Engineering, Iwate University, Morioka, Japan

\*\* Professor, Department of Civil Engineering, Hokkaido University, Sapporo, Japan

Various studies about the wave transformation without an opposing current have been presented by many researchers, and it has been clear that the characteristics of wave transformation can be determined by the slope of the sea bed and the deep water wave steepness. But no systematical experiment for the transformation of waves affected by an opposing current has been carried out.

Concerning the theoretical approach to this problem, Longuet-Higgins and Stewart(1960) and Jonsson, Skovgaard and Wang(1970) presented the attractive papers, and their treatments were the second order of approximation.

With respect to the wave breaking affected by an opposing current, Yu(1952) presented the paper about the breaking due to a current in deep water, and Iwagaki, Asano et al(1980) showed the characteristics of breaking due to a current in shallow water. Authors(1981) proposed relationships between the breaker indexes and the characteristics of wave in deep water, however an equation for criteria of breaking affected by an opposing current on the sloping sea bed has not been obtained.

In this paper, the characteristics of wave transformation was described throughout a number of experiments. Fourth order solutions of Stokes wave on a uniform current were calculated. The theoretical solutions for wave transformation by applying the energy flux method to our solutions were presented, and were compared with the experimental results to examine an applicability of our solutions. And criteria of breaking were clarified by experiments. In the calculation of the energy flux, it was pointed out that a change in a mean level of a free surface should be taken into account.

2. EXPERIMENTAL RESULTS

2-1. Experimental Equipment and Procedure

Our experiments were conducted with the general setup as shown in Fig.1. This wave channel had a length of 26m, a width of 36cm and a depth of 1m. A pump and a flap-type wave generator were located at one

Fig.1 General setup

end of the channel. The water which was transported by the pump was received by an upper tank and the discharge was controlled in this tank by a valve. The turbulence of falling water into a lower tank was dissipated by screens in the lower tank, and the water flowed onto a sea bed as an opposing current. The slopes of the sea bed were 1/15, 1/30 and 1/50.

The water level was determined so that the hydraulic jump would not appear and the water surface on the sea bed would not be disturbed. In the experiments for wave transformation, wave profiles were measured by six wave gauges at intervals of 50cm. In the experiments for wave breaking, five wave gauges were placed at every 15cm intervals in order to measure accurately the breaking points and the wave height and wave celerity at those points. The wave period  $T$ , the wave height in deep water  $H_0$  and the unit width discharge  $q$  were varied as in Table 1.

Table 1

$T$	: 0.85 ~ 2.76	( s )
$H_0$	: 1.1 ~ 28.3	( cm )
$q$	: 100.0 ~ 790.0	( $\text{cm}^3/\text{s}/\text{cm}$ )

2-2. Wave Transformation before Breaking

It has been clear that the characteristics of wave transformation without an opposing current are determined by the slope of the sea bed  $S$  and the deep water wave steepness  $H_0/L_0$ . But when waves are affected by an opposing current, the characteristics will depend on the unit width discharge of current  $q$ . Figure 2 shows the effects of  $q$  on the shoaling coefficients. The horizontal axis gives the dimensionless water depth  $h^*$ ,  $h^*$  is  $h$  divided by  $gT^2$ , where  $h$  is a water depth,  $g$  is

Fig.2 Effects of the unit width discharge on the shoaling coefficients

the gravity acceleration and  $T$  is a wave period. The vertical axis indicates the shoaling coefficients. In this figure, there are four kinds of data, and all of them have the same  $S$ , the same  $T$  and the almost same  $H_0/L_0$ . From this figure it is shown that a wave with a larger  $q$  has larger shoaling coefficients, in other words, the characteristics of wave transformation vary with  $q$ . Figure 3 is a comparison of the shoaling coefficients of waves which have a different  $T$ , but have the same  $S$ , the same  $q$  and the almost same  $H_0/L_0$ . This comparison gives the fact that a wave with a shorter  $T$  has larger shoaling coefficients. Consequently, it can be concluded that the effects of an opposing current on wave transformation depend not only on the unit width discharge but also on the wave period.

When a dimensionless unit width discharge as a parameter which indicates the effects of an opposing current on wave transformation is introduced as follows;

$$q^* = q / g^2 T^3 \quad \text{----- (2-1)}$$

we can arrange the data using this parameter as shown in Fig.4, and it is verified that the shoaling coefficients of waves which have the same  $S$ , the same  $H_0/L_0$  and the same  $q^*$  are identical to each other, and that waves with a larger  $H_0/L_0$  and a larger  $q^*$  have larger shoaling coefficients before breaking points.

Concerning the change of the wave length, Fig.5 shows that the change of a ratio of wave length to wave length in deep water  $L/L_0$  can be also determined by  $S$ ,  $H_0/L_0$  and  $q^*$ , and that waves with a larger  $H_0/L_0$  and a larger  $q^*$  have smaller  $L/L_0$ . Therefore, it is clear that the characteristics of wave transformation before breaking point are determined by the slope of the sea bed, the deep water wave steepness and the dimensionless unit width discharge.

Fig.3 Effects of the wave period on the shoaling coefficients

Fig.4 Effects of the dimensionless unit width discharge and the deep water wave steepness on the shoaling coefficients

Fig.5 Effects of the dimensionless unit width discharge and the deep water wave steepness on the change of wave length

Next, the effects of the slope are examined. Figure 6 gives a comparison of the shoaling coefficients on three kinds of the slope, and all of them have the almost same  $H_0/L_0$  and the same  $q^*$ . Though the breaking depth and the breaking wave height depend on  $S$ , the shoaling coefficients before breaking points are similar to each other. Then it is found that the effects of the slope on the wave transformation before breaking points can be ignored, when the slope is between 1/15 and 1/50.

Fig.6 A comparison of the shoaling coefficients on different kinds of the slope

2-3.Wave Decaying due to Breaking

With respect to wave decaying due to the breaking, it has been clear that the changes of wave height without an opposing current depend only on the slope of the sea bed  $S$ . Though our experiments show that a ratio of wave height to water depth at the breaking point has a small influence on the change of wave height, it can be regarded as a whole that the change of wave height with an opposing current depends only on  $S$ . In Fig.7, the broken lines indicate the results without an opposing current which were presented by Saeki and Sasaki(1974), and the solid lines give our results. The decaying of wave height with an opposing current is larger than a wave without an opposing current on all kinds of the slope. And the decaying of wave height becomes milder as the slope becomes steeper. The characteristics of decaying on  $S=1/50$  is different from the other, by reason that waves on  $S=1/50$  were reformed after progressing a certain distance, and decayed by the second breaking again. This phenomenon is peculiar to waves on the mild slope.

Fig.7 Effects of the current and the slope on the decaying due to the breaking

Fig.8 Coordinates system

It is remarkable that the slope is a most important parameter for wave decaying due to the breaking even when waves are affected by an opposing current, while the most important parameters for wave transformation before breaking are the deep water wave steepness and the dimensionless unit width discharge.

3. THEORETICAL APPROACH

3-1. Fourth Order Solutions of Stokes Wave on a Uniform Current

It has been pointed out that the solutions of wave theory vary with the definition of the wave celerity, by some researchers. First and second definition of the wave celerity are defined as Eqns. (3-1) and (3-2), respectively.

$$C = \int_0^L (C + u) dx / \int_0^L dx \quad \text{----- (3-1)}$$

$$C = \int_0^L \int_{-h}^{\zeta} (C + u) dz dx / \int_0^L \int_{-h}^{\zeta} dz dx \quad \text{----- (3-2)}$$

where C is a wave celerity, u is a horizontal velocity, L is a wave length, h is a water depth and zeta is a wave profile.

In the coordinates system as shown in Fig.8, Laplace's equation and the boundary conditions are expressed as follows:

$$\nabla^2 \phi = 0 \quad \text{----- (3-3)}$$

$$\phi_t + gz + \frac{1}{2} (\nabla \phi)^2 = B \quad z = \zeta \quad \text{----- (3-4)}$$

$$\phi_z - \phi_x \zeta_x - \zeta_t = 0 \quad z = \zeta \quad \text{----- (3-5)}$$

$$\phi_z = 0 \quad z = -h \quad \text{----- (3-6)}$$

where phi is a velocity potential and g is the gravity acceleration.

According to the perturbation method of the fourth order of approximation,  $\phi$ ,  $\zeta$ ,  $B$ ,  $C$  are assumed as follows:

$$\begin{aligned} \phi = & U \cdot x + (C - U) \{ \lambda^2 A_{02} + \lambda^4 A_{04} \} \cdot x \\ & + \frac{(C - U)}{k} \{ (\lambda A_{11} + \lambda^3 A_{13}) \cosh k(h+z) \sin \theta \\ & + (\lambda^2 A_{22} + \lambda^4 A_{24}) \cosh 2k(h+z) \sin 2\theta \\ & + \lambda^3 A_{33} \cosh 3k(h+z) \sin 3\theta \\ & + \lambda^4 A_{44} \cosh 4k(h+z) \sin 4\theta \} \end{aligned} \quad \text{----- (3-7)}$$

$$\begin{aligned} \zeta = & \frac{1}{k} \{ \lambda f_{11} \cos \theta + (\lambda^2 f_{22} + \lambda^4 f_{24}) \cos 2\theta \\ & + \lambda^3 f_{33} \cos 3\theta + \lambda^4 f_{44} \cos 4\theta \} \end{aligned} \quad \text{----- (3-8)}$$

$$B = B_0 + \lambda^2 B_2 + \lambda^4 B_4 \quad \text{----- (3-9)}$$

$$\{ C - U \}^2 = \{ C_0 - U \}^2 \{ 1 + \lambda^2 C_2 \} \quad \text{---- (3-10)}$$

where  $U$  is a velocity of steady uniform current,  $k=2\pi/L$ ,  $L$  is a wave length,  $\theta=k(x-Ct)$  and  $\lambda$  is an expansion parameter. After Eqns.(3-7), (3-8), (3-9) and (3-10) are substituted into Eqns.(3-3), (3-4), (3-5) and (3-6), the coefficients in  $\phi$ ,  $\zeta$ ,  $B$ ,  $C$  are finally calculated as:

$$\begin{aligned} A_{11} &= \frac{1}{s^*} \quad , \quad A_{13} = -\frac{1}{8} \frac{C^*2}{s^{*5}} \{ 5C^*2 + 1 \} - \frac{A_{02}}{s^*} \\ A_{22} &= \frac{3}{8} \frac{1}{s^{*4}} \\ A_{24} &= \frac{1}{768} \frac{1}{s^{*10}} \{ 192C^*8 - 424C^*6 - 312C^*4 + 480C^*2 - 17 \} - \frac{3}{8} \frac{A_{02}}{s^{*4}} \\ A_{33} &= -\frac{1}{64} \frac{1}{s^{*7}} \{ 4C^*2 - 13 \} \\ A_{44} &= \frac{1}{1536} \frac{1}{s^{*10}} (6C^*2 - 1) \{ 80C^*6 - 816C^*4 + 1338C^*2 - 197 \} \end{aligned} \quad \text{---- (3-11)}$$

$$\begin{aligned} f_{11} &= 1 \quad , \quad f_{22} = \frac{1}{4} \frac{C^*}{s^{*3}} \{ 2C^*2 + 1 \} \\ f_{24} &= \frac{1}{384} \frac{1}{s^{*9}} \{ 272C^*9 - 504C^*7 - 192C^*5 + 322C^*3 + 21C^* \} \\ f_{33} &= \frac{3}{64} \frac{1}{s^{*6}} \{ 8C^*6 + 1 \} \\ f_{44} &= \frac{1}{384} \frac{1}{s^{*9}} (6C^*2 - 1) \{ 768C^*11 - 448C^*9 - 48C^*7 + 48C^*5 \\ & \quad + 106C^*3 - 21C^* \} \end{aligned} \quad \text{---- (3-12)}$$

$$\begin{aligned} B_0 &= \frac{U^2}{2} \quad , \quad B_2 = \frac{g}{4k} \frac{1}{s^* C^*} + U \{ C_0 - U \} A_{02} \\ B_4 &= -\frac{g}{64} \frac{1}{k} \frac{1}{s^{*7} C^*} \{ 4C^*6 + 16C^*4 - 38C^*2 + 9 \} \\ & \quad + \frac{1}{16} U \{ C_0 - U \} \frac{1}{s^{*4}} \{ 8C^*4 - 8C^*2 + 9 \} A_{02} \\ & \quad + \frac{1}{2} \{ C_0^2 - U^2 \} A_{02}^2 + U \{ C_0 - U \} A_{04} \end{aligned} \quad \text{---- (3-13)}$$

$$\begin{aligned} \{ C_0 - U \}^2 &= \frac{g}{k} \tanh kh \\ C_2 &= \frac{1}{8} \frac{1}{s^{*4}} \{ 8c^{*4} - 8c^{*2} + 9 \} + 2 A_{02} \end{aligned} \quad \text{---- (3-14)}$$

where  $c^* = \cosh kh$ ,  $s^* = \sinh kh$ .

And a relationship between  $\lambda$  and a wave steepness is as follows:

$$\frac{H}{L} = \frac{1}{\pi} \left\{ \lambda + \frac{3}{64} \lambda^3 \frac{1}{s^{*6}} ( 8c^{*6} + 1 ) \right\} \quad \text{---- (3-15)}$$

Applying the first definition of the wave celerity expressed by Eqn. (3-1), the coefficients  $A_{02}$  and  $A_{04}$  become as:

$$A_{02} = A_{04} = 0 \quad \text{---- (3-16)}$$

The coefficients based on the second definition are calculated as:

$$\begin{aligned} A_{02} &= - \frac{1}{2} \frac{c^*}{kh s^*} \\ A_{04} &= \frac{1}{32} \frac{c^*}{kh s^{*7}} \{ 4c^{*6} - 20c^{*4} + 16c^{*2} - 9 \} - A_{02}^2 \end{aligned} \quad \text{---- (3-17)}$$

### 3-2. Change in Mean Level of Free Surface

In order to calculate a wave transformation by using our solutions of Stokes wave on a uniform current, the energy flux method is applied.

As regard with the energy flux of a wave on a uniform current, Eqn. (3-18) which was presented by Longuet-Higgins and Stewart (1960) is well known.

$$R_x = ECg + EU + SxU + \frac{1}{2} \rho h U'^3 \quad \text{---- (3-18)}$$

This equation was derived from the following equation.

$$R_x = \int_{-h}^{\zeta} \left\{ p + \frac{1}{2} \rho u^2 + \rho g z \right\} u dz \quad \text{---- (3-19)}$$

where  $u = U + u'$ ,  $U$  is a velocity of a steady uniform current,  $u'$  is a horizontal velocity of wave motion,  $u^2 = u'^2 + v^2$ ,  $v$  is a vertical velocity,  $p$  is a pressure and  $\rho$  is a density of fluid. In their derivation, a mean level of a free surface was set on an origin of Z-axis, then a potential energy  $gz$  was measured from the mean level of the free surface. When energy fluxes expressed by Eqn. (3-18) are compared at various water depth and current, and if the mean level of the free surface change depending on the water depth and the current, the change in the mean level of the free surface results in the change of the basis of the potential energy. Therefore Eqn. (3-18) can not be applied directly to calculate the transformation of wave progressing over varying depth.

Jonsson, Skovgaard and Wang (1970) introduced a conception named "mean energy level", from which the potential energy was measured. They took the change in the mean level of the free surface into account, and indicated that the conservation of the energy flux of wave on a non-uniform current should be expressed as follows:

$$\frac{d}{dx} \left\{ \left( 1 + \frac{U}{C} \right) ( U + Cg ) E \right\} = 0 \quad \text{---- (3-20)}$$

This equation is effective for the second order of approximation.

In order to apply fourth order solutions of Stokes wave on a uniform current to calculate the wave transformation on non-uniform current with varying depth, some more consideration about the change in the mean level of the free surface is needed. For this purpose, we use Bernoulli's equation as:

$$\phi_t + \frac{p}{\rho} + gz + \frac{1}{2} (\nabla\phi)^2 = c(t) \quad \text{---- (3-21)}$$

In the derivation of our solutions, the mean level of the free surface was set on the origin of the Z-axis, and the potential energy was measured from this origin of the Z-axis, in other words from the mean level of the free surface. When this coordinate is named Z'-axis, Bernoulli's equation with respect to such coordinates system is expressed as follows:

$$\phi'_t + \frac{p'}{\rho} + gz' + \frac{1}{2} (\nabla\phi')^2 = B' \quad \text{---- (3-22)}$$

B' has a value particular to the basis of the potential energy besides a water depth, a wave height and a wave length. Now, we define that the origin of Z-axis and the basis of the potential energy are set on the mean level of the free surface in deep water, and that Δh is a difference between the origin of Z-axis and the Z'-axis which was used for the derivation of wave solutions in an arbitrary water depth, as shown in Fig.9. When Z'-axis is transformed like Eqn.(3-23), Eqn.(3-22) becomes as follows:

$$z = z' - \Delta h \quad \text{---- (3-23)}$$

$$\begin{aligned} \phi_t + \frac{p}{\rho} + gz + \frac{1}{2} (\nabla\phi)^2 = c(t) = B' \text{ deep} \\ = B' - g\Delta h \quad \text{---- (3-24)} \end{aligned}$$

Because Bernoulli's equation is satisfied over all region of water depth, and B' in deep water calculated by Stokes wave theory vanishes, a relationship between B' and Δh is verified as:

$$\Delta h = B'/g \quad \text{---- (3-25)}$$

Therefore it becomes clear that B'/g calculated with respect to the Z'-axis is identical to the change in the mean level of the free surface. Using Eqn.(3-24) and (3-23), the energy flux can be calculated as:

$$W = -\rho \int_{-h}^{\zeta} \phi_t \cdot \phi_x dz = -\rho \int_{-h}^{\zeta'} \phi'_t \cdot \phi'_x dz' \quad \text{---- (3-26)}$$

Fig.9 Coordinates systems and Δh

Thus, we can obtain the energy flux in which the change in the mean level of the free surface is taken into account, by using the velocity potential  $\phi'$  described with respect to  $Z'$ -axis.

If Airy wave theory is applied to Eqn.(3-26), the energy flux is identical to that in Eqn.(3-20) by Jonsson, Skovgaard and Wang. And if the second order theory is used for Eqn.(3-25), the change in the mean level of the free surface is identical to the wave set-down due to radiation stress given by Longuet-Higgins and Stewart(1964). And our treatment about the change in the mean level of the free surface is more general.

Substituting our fourth order solutions into Eqn.(3-26), the energy flux  $W$  are finally calculated as

First definition;

$$W = \rho \frac{C}{k} \{ U \cdot (C-U) \cdot Q_{11} + (C-U)^2 \cdot Q_{12} \} \quad \text{---- (3-27)}$$

where

$$Q_{11} = \lambda^2 \frac{1}{s^{*2}} \left\{ \frac{1}{2} s^* c^* + \frac{\lambda^2}{32} \frac{c^*}{s^{*5}} (-4c^{*6} + 20c^{*4} - 16c^{*2} + 9) \right\}$$

$$Q_{12} = \lambda^2 \frac{1}{s^{*2}} \left[ \frac{1}{4} (s^* c^* + kh) + \frac{\lambda^2}{8} \left\{ \frac{1}{8s^{*6}} (s^* c^* + kh) \cdot \right. \right.$$

$$\left. \left. (-20c^{*6} + 16c^{*4} + 4c^{*2} + 9) \right. \right.$$

$$\left. \left. + \frac{c^*}{4s^{*3}} (16c^{*4} + 2c^{*2} + 9) \right\} \right]$$

Second definition;

$$W = \rho \frac{C}{k} \{ U \cdot (C-U) \cdot kh \cdot Q_{21} + (C-U)^2 \cdot Q_{22} \} \quad \text{---- (3-28)}$$

$$Q_{21} = \lambda^2 \left[ \frac{1}{2} \frac{c^*}{kh s^*} - \lambda^2 \left\{ \frac{C-U}{U} \frac{1}{4} \frac{c^{*2}}{(kh)^2 s^{*2}} \right. \right.$$

$$\left. \left. + \frac{1}{32} \frac{c^*}{kh s^{*7}} (4c^{*6} - 20c^{*4} + 16c^{*2} - 9) \right. \right.$$

$$\left. \left. - \frac{1}{4} \frac{c^{*2}}{(kh)^2 s^{*2}} \right\} \right]$$

$$Q_{22} = \lambda^2 \frac{1}{s^{*2}} \left[ \frac{1}{4} (s^* c^* + kh) + \frac{\lambda^2}{8} \left\{ \frac{c^{*3}}{2s^{*3}} (2c^{*2} + 1) \right. \right.$$

$$\left. \left. + 3 s^* c^* + \frac{3}{s^{*3}} (2c^{*2} - 1) \right. \right.$$

$$\left. \left. + \left( 2 \frac{c^*}{s^*} \frac{1}{kh} - \frac{c^{*2}}{2s^{*4}} (5c^{*2} + 1) \right) (s^* c^* + kh) \right. \right.$$

$$\left. \left. + \frac{9}{8} \frac{1}{s^{*6}} ((2c^{*2} - 1) s^* c^* + kh) \right\} \right]$$

### 3-3. Applicability of Solutions

In order to examine an applicability of the theoretical solutions of wave transformation calculated by our solutions, the theoretical solutions are compared with the experimental results. Figure 10 is an example of the comparison between the experimental results and the theoretical solution based on the first definition of the wave celerity. The theoretical solution illustrated as a solid line agrees with the

experimental results from deep water to the breaking points. Thus, the solution can be regarded as a fairly good approximation. In some cases, the theoretical solutions have larger values than the experimental results in the region of shallow water, and the difference becomes larger as the dimensionless water depth  $h^*$  becomes smaller. And it seems that the extent of  $h^*$  in which the theoretical solution is applicable depend on a parameter  $H_0/gT^2$ , which means the deep water wave steepness, and the dimensionless unit width discharge  $q^*$ .

We took points where the experimental result intercepts with a range of  $\pm 5\%$  of the theoretical solution, and defined criteria of the applicability. Figures 11 and 12 show relationships between a ratio of water depth to wave length  $h/L$  and a ratio of wave height to wave length  $H/L$  at the criteria of the applicability of the solutions based on the first and second definition of the wave celerity, respectively. In these figures, the results for all kinds of the slopes are included, and classified by  $q^*$ . The average lines corresponding to a similar  $q^*$  can be drawn as shown as the solid lines in Fig.11 and 12.

The effects of  $H_0/gT^2$  on the criteria were examined, and the effects could be ignored compared with the effects of  $q^*$ .

Then, it was found that the criteria of the applicability of the theoretical solutions depend on  $q^*$ , and the extent of the applicability based on the first definition of the wave celerity is wider than the extent based on the second definition with larger  $q^*$ .

Fig.10 A comparison between experimental results and a theoretical solution based on the first definition of the wave celerity

Fig.11 Criteria of the applicability of solutions based on the first definition of the wave celerity

Fig.12 Criteria of the applicability of solutions based on the second definition of the wave celerity

Next, the applicability of the theoretical solutions for the change of wave length is examined. Figure 13 is a comparison between the experimental results and the theoretical solutions. L, S-1 and S-2 indicate the solution by Airy wave theory, our solution of Stokes wave theory based on the first definition of the wave celerity and our solution based on the second definition, respectively. Figure 13 shows that L and S-2 are good approximations for the experimental results in deep water, and S-1 and S-2 are good in shallow water. Therefore it is concluded that S-2 is a best approximation, as a whole, for the change of the wave length on an opposing current.

Fig.13 A comparison between experimental results and theoretical solutions for changes of wave length

4. CRITERIA OF BREAKING

In order to clarify the criteria of breaking on an opposing current, relationships between a ratio of wave height to wave length  $(H/L)_b$  and a ratio of water depth to wave length  $(h/L)_b$  at breaking points are shown in Fig.14. The experimental results are classified by the dimensionless unit width discharge  $q^*$ . S-1 and S-2 indicate theoretical criteria of breaking calculated by applying Rankine-Stokes' breaking condition to our fourth order solutions. The theoretical criteria give larger values than the experimental results. This disagreement can be explained by the fact that the theoretical breaking depth is shallower and the theoretical breaking wave height is larger than the experimental results, even when the theoretical wave transformation before breaking point agrees with the experimental results, as shown in Fig.10.

The theoretical criteria shows a relationship like as :

$$\left(\frac{H}{L}\right)_b = \alpha \tanh\left(\frac{2\pi h}{L}\right)_b \quad \text{---- (4-1)}$$

Iwagaki, Asano, Yamanaka and Nagai presented that Miche's equation which is expressed as Eqn.(4-2) was a relatively good approximation for wave breaking due to the current on a flat bed.

$$\left(\frac{H}{L}\right)_b = 0.142 \tanh\left(\frac{2\pi h}{L}\right)_b \quad \text{----- (4-2)}$$

While Miche's equation agrees with our results for no current and smaller  $q^*$ , this equation shows an upper limit of the experimental results, and in particular this can not approximate experimental results for larger  $q^*$ .

Experimental results show that one average line can be drawn as a whole, but the difference of the relationship due to  $q^*$  can be recognized. We assumed that Eqn.(4-1) expresses criteria of breaking affected by an opposing current on a sloping sea bed, and we obtained the proportional coefficient  $\alpha$  corresponding to  $q^*$  as shown in Fig.15. When  $q^*$  is small,  $\alpha$  is similar to Miche's coefficient, and as  $q^*$  becomes larger,  $\alpha$  becomes smaller than Miche's coefficient and approaches a certain value gradually.

By the experimental results and the theoretical approaches, the criteria of the applicability of our solutions on an opposing current and the criteria of wave breaking corresponding to each  $q^*$  are found in Fig.16.

Fig.14 Relationships between a ratio of wave height to wave length and a ratio of water depth to wave length at breaking point

Fig.15 Relationships between  $\alpha$  and  $q^*$

Fig.16 Criteria of the applicability of theoretical solutions and criteria of the breaking, corresponding to  $q^*$

5. CONCLUSIONS

The transformation and breaking of waves affected by an opposing current on a sloping sea bed were discussed, experimentally and theoretically. Main conclusions in this paper are as follows:

- (1) The characteristics of wave transformation before breaking points can be determined by  $H_0/gT^2$  and  $q^*$ . Waves with larger  $H_0/gT^2$  and larger  $q^*$  have larger  $H/H_0$  and smaller  $L/L_0$ .

- (2) Wave decaying due to breaking depends only on the slope of the sea bed. Wave height decaying with an opposing current is larger than the decaying without an opposing current for all kinds of the slope, and it becomes milder as the slope becomes steeper.
- (3) The solutions of Stokes wave on a uniform current were calculated based on the first and second definition of the wave celerity, respectively.
- (4) It was clarified that the change in the mean level of the free surface due to the variation of the water depth and the current can be evaluated by Bernoulli's equation, and the energy flux in which the change in the mean level of the free surface are taken into account was presented.
- (5) Comparisons between the theoretical solutions for wave transformation and the experimental results yielded the criteria of applicability of our solutions, corresponding to each  $q^*$ .
- (6) The criteria of wave breaking corresponding to  $q^*$  were proposed, experimentally.

## CHAPTER SEVENTY EIGHT

### Measurements of Mass Transport over a Rough Bed

by J.F.A. Sleath\*

Measurements have been made with a laser doppler anemometer of the time-mean velocity of the fluid close to the bed in a wave flume. Both a rough bed, consisting of gravel of median diameter 11 mm, and a smooth bed were investigated. With the rough bed the time-mean velocity at a given height was found to be strongly dependent on position relative to prominent roughness elements. At one point the time-mean drift at a given height might be in the direction of wave propagation while, at another, in the opposite direction. Significant variation in time-mean drift with horizontal position was observed at all values of Reynolds number tested. The effect of bed roughness on the average value of the time-mean velocity at a given height was found to be most marked at low Reynolds numbers: the maximum near bed value with this gravel bed was about 3 times that for a smooth bed at the lowest Reynolds numbers tested. At the highest Reynolds numbers there was no clear difference between the rough and smooth bed values even though the boundary layer over the rough bed was fully turbulent whereas that over the smooth bed was laminar. However, at these high Reynolds numbers both the rough and the smooth beds showed a reduction in drift velocity below that predicted by Longuet-Higgins (9) because of the increased importance of higher harmonics in the flow.

#### INTRODUCTION

It is well known that water waves induce a steady drift of fluid particles in addition to an oscillatory motion. Although this steady drift, which is usually referred to as the 'mass transport' velocity, is weak compared with the oscillatory component of velocity it has a significant effect on the dispersion of pollutants in the sea. It is also important in any study of the transport of sediment, particularly in the onshore-offshore direction.

Despite its engineering importance, rather little is known about the mass transport velocity under the sort of conditions encountered on site. Longuet-Higgins (9) has obtained a theoretical solution for the mass transport produced by waves over a smooth bed in laminar flow. Laboratory tests (e.g. ref. 2) show that for smooth beds and constant depth there is good agreement between theory and experiment in the boundary layer at the bed provided allowance is made for higher harmonics under more extreme wave conditions (see refs. 4, 11). However, most beds on site are far from smooth and the flow is usually turbulent. Longuet-Higgins (10) suggested that the mass transport velocity just outside the boundary layer would be the same in turbulent flow as for laminar flow. On the other hand, Johns (5) calculated that the maximum

\* Lecturer, Cambridge University Engineering Department, Trumpington Street, Cambridge, England

value of the time-mean component of the Eulerian velocity in a turbulent boundary layer was less than half that for laminar flow.

It might seem that all that would be required to settle this question would be a few well-chosen experiments. The problem is that the observation of dye traces or neutrally buoyant beads, which is the method traditionally used for laminar flows, is not reliable in turbulent flows. When the flow is turbulent dye traces are rapidly diffused and neutrally buoyant beads are hurled from one fluid layer to another so that their final displacement is the result of velocities at many different heights. Some rough bed measurements were made by Brebner et al (1) using dye traces and neutrally buoyant beads. These suggested that the mass transport velocity was increased by bed roughness when the flow was laminar but decreased when the flow was turbulent. However, for the reasons outlined above there is clearly a need to confirm and extend these tests using some other measuring technique. In addition, since Brebner et al's tests could not extend far into the turbulent regime, there is a need for tests with significantly higher levels of turbulence.

The objectives of the present work were thus to make new measurements of the drift velocity, using a different method from that of Brebner et al, and to study flows in which the boundary layer really was fully turbulent.

#### EXPERIMENTAL APPARATUS AND LAYOUT

The experiments were carried out in the 17.5 m wave flume of the Cambridge University Engineering Department. This wave flume is 0.58 m wide internally, has a flap type wave generator at one end and a pebble beach at a slope of 1:20 at the other. The test section is of constant depth and approximately 9 m long.

The test conditions are shown in Table 1. In this Table  $T$  is period,  $H$  is wave height,  $d$  is mean water depth,  $\theta$  is water temperature,  $k$  is wave number and  $a$  is the theoretical value of the orbital amplitude of the fluid just outside the boundary layer at the bed. Both  $k$  and  $a$  have been calculated from first-order small-amplitude wave theory. For the larger wave heights and smaller values of  $kd$  this small-amplitude theory is not a good approximation and consequently the quoted values should be treated with caution. In no test did wave breaking occur in the test section.

Most of the tests were carried out with a single layer of gravel of median diameter 11.0 mm and  $\phi$ -standard deviation 0.14 spread uniformly over the bed for a distance of 8 m near the middle of the flume. However, for purposes of comparison, a number of tests were carried out with a smooth bed. This consisted of a sheet of plate glass of length 3 m backed up at each end by steel sheets, each of length 2 m, with a gloss paint finish.

The fluid velocities were measured with a laser doppler anemometer mounted on a milling machine base so that it could be traversed vertically and horizontally. The anemometer consisted of a 5 mW Helium Neon laser with DISA optics and frequency shifter and either a Cambridge

Table 1. Test conditions

Consultants or a DISA frequency tracker. Apart from the different frequency shifter the system and mode of operation were the same as that described by Du Toit & Sleath (3). Most of the measurements were made with the Cambridge Consultants tracker but occasionally the DISA tracker was used as a check. Analogue output from the frequency tracker was stored on an FM instrumentation tape recorder and subsequently re-played via an analogue-to-digital converter into a computer for analysis. With the aid of a phase marker, recorded at the same time as the anemometer output, the computer calculated the mean velocity over 60 wave cycles. The velocity harmonics for the mean cycle obtained by superimposing the 60 individual cycles and the root-mean-square fluctuation in velocity from the mean cycle were also calculated. Each channel from the tape recorder was sampled 400 times per wave cycle.

Calibration of this equipment was carried out in two ways. First of all, the frequency trackers were checked at intervals during the test programme by feeding sinusoidal signals of known frequency from a signal generator into the input terminal and measuring the output with a digital voltmeter. This provided a check on the frequency/voltage conversion factor quoted by the manufacturers and also on the stability and linearity of these instruments. Secondly, with still water in the wave flume but sufficient seeding particles in the measuring volume to provide a reasonable signal, the output from the trackers was recorded with a variety of known voltage offsets provided by a variable voltage source. These recordings were then analysed by the computer in the normal way. This allowed the conversion factor between tracker voltage and computer output to be determined as well as the zero corresponding to no flow. This second calibration was also repeated at intervals throughout the test programme.

Measurements were also made of the wave reflection from the beach and of the three-dimensionality of flow in the flume. In none of the tests did the reflected wave height exceed 3% of the incident wave height. Significant three-dimensionality of the time-mean drift was observed very close to the walls of the flume and also in the body of the flow near the water surface. However, in the immediate vicinity of the bed three-dimensionality was negligible for the smooth bed over most of the width of the flume. For the rough bed, any variation across the flume in the vicinity of the bed was insignificant compared with the much larger perturbations caused by the individual roughness elements.

The normal test procedure was for the still water level to be measured, the laser switched on and then the wave generator started up at the required stroke and frequency. After approximately one hour the water temperature was recorded, the wave period was measured with a stopwatch, and the wave height with hook and pointer gauges which were removed from the water as soon as the measurement had been made. Next the required velocity measurements were made. Finally, wave height, period and water temperature were measured again and the wave generator and laser were switched off. All electronic equipment other than the laser was left running continuously day and night. Normally only one test was carried out each day in order to ensure that no residual drifts remained from previous tests. Seeding of the flow was provided by adding small quantities of milk as required.

## TEST RESULTS AND DISCUSSION

Fig. 1 shows a comparison between the amplitude of the measured and theoretical velocities  $U_{\infty}$  just outside the boundary layer at the bed. In addition to the tests listed in Table 1, Fig. 1 also includes results for a number of preliminary tests in which drift velocity was not measured. The quantity  $(U_{\infty})_{\text{meas}}$  is the amplitude of the fundamental component of velocity obtained by Fourier analysis of the velocity record and the 'theoretical' velocity  $(U_{\infty})_{\text{theor}}$  is that calculated from first-order small-amplitude wave theory for the given test conditions. On the whole, the agreement between theory and experiment is quite good. The main reason for discrepancy is that, as pointed out above, many of the waves are not well represented by small-amplitude theory.

Bed roughness also introduces uncertainties into any comparison between theory and experiment. With very coarse roughness, as in the present case, the boundary layer is no longer negligibly thin compared with the depth of water. Thus a velocity measured outside the boundary layer is too far from the bed to be equal to the theoretical bed velocity whereas, closer to the bed boundary layer and bed geometry effects may be significant.

The effect of bed geometry is particularly important for the drift velocity. Fig. 2 shows an example of the way in which the time-mean velocity varies with distance across the flume at various heights above the grain crests. According to Kamphuis (7), the Nikuradse roughness length  $k_s$  is equal to  $2D_{90}$ . In the present case that would give a roughness length of 24.5 mm. This is comparable with the lateral distance between peaks in the drift velocity shown in Fig. 2. In fact, it was observed that the time-mean velocity in the direction of wave propagation was strongest in the troughs between roughness elements and decreased as the measuring point approached a protruding grain. This is not surprising since it is well known that individual roughness elements on the bed set up their own re-circulating drift currents which can significantly alter the mean drift produced by wave action.

If the perturbation in drift velocity is associated with individual roughness elements it should decay at large distances from the bed like  $\exp(-2\pi y/k_s)$  with  $k_s = 25.4$  mm in the present case. Fig. 3 shows the way in which the perturbation  $\bar{u}'$  varies with height at three positions (A,B,C) across the wave flume in two different tests. In each case the amplitude of the perturbation at height  $y$  has been normalised in terms of its value at the level of the grain crests ( $y = 0$ ). The experimental points in Fig. 3 do seem to be tending towards the predicted curve at large values of  $y$ .

Another example of the way in which the perturbation in velocity decays with height is shown in Fig. 4. In this Figure,  $x$  is the horizontal distance from the centreline of the flume. It is clear that only a small shift in horizontal position can produce a dramatic change in the measured time-mean velocity  $\bar{u}$ .

In many situations it is the mean drift velocity, averaged across the wave flume, which is of most interest. Fig. 5 shows how the

Fig. 1 Comparison of measured and theoretical values of the velocity amplitude just outside the boundary layer

Fig. 3 Variation of perturbation in drift velocity with height for Tests 25 and 28

Fig. 4 Variation of the time-mean velocity  $\bar{u}$  with height  $y$  at three positions across the flume (Test no. 13)

spatial-mean value of  $\bar{u}$  at the level of the grain crests varies with the ratio of fluid orbital amplitude  $a$  to grain size  $D$  for the rough bed. In each case the spatial-mean value of  $\bar{u}$  at the level of the grain crests was also the maximum measured value of this mean drift in the direction of wave propagation, which is why it is denoted by  $\bar{u}_{\max}$  in Fig. 5 (and also in Table 1). It is possible that the mean velocity in the troughs between crests might be even higher but even with the laser tilted at an angle to the horizontal detailed measurements could not be made much below the mean crest level so it was not possible to investigate this point. Also shown in Fig. 5 are the smooth bed results, for which  $D$  should be interpreted as a numerical constant equal to 11.0 mm. For the smooth beds it was, of course, possible to determine the actual maximum value of  $\bar{u}$  in the direction of wave propagation.

At first sight the results shown in Fig. 5 are somewhat confusing. This is because the drift velocity is affected both by the bed roughness and by wave harmonics. Collins (2) found that for a smooth bed the mass transport velocity was reduced from Longuet-Higgins' theoretical value when wave conditions became severe. Sleath (11) and Isaacson (4) have shown that this reduction is due to the effect of higher harmonics on the solution (Longuet-Higgins' theory is only a first approximation). Thus, in assessing the effect of bed roughness it is necessary to compare the rough bed results with those for the smooth bed under similar conditions. When this is done, we see that for values of  $a/D$  less than about 1.5 bottom roughness increases  $\bar{u}_{\max}$  whereas at large values of  $a/D$  there is little difference between the results for rough and smooth beds.

A possible reason for the increase in the mean drift velocity at low values of  $a/D$  is the effect of wave asymmetry on the formation of vortices by individual roughness elements on the bed. If vortices were formed more vigorously during one half cycle than during the other some change in the mean drift might be expected. The reduced effect at high  $a/D$  may be attributed to less clearly defined vortex formation with increasing turbulence and the relatively smaller influence of wave asymmetry when well away from the conditions at which vortices only just form. The parameter  $a/D$  is proportional to the Keulegan Carpenter number  $Kc$ . It is well known that force coefficients for isolated bodies in oscillatory flow are strongly dependent on  $Kc$  at low values of this parameter but relatively independent at high  $Kc$ . This behaviour is usually attributed to the effect of vortex formation.

Fig. 5 shows results for two quite different values of  $kd$ . This is because the existing equipment did not allow a very wide range of  $a/D$  to be covered at a single value of  $kd$ . Low values of  $a/D$  were inaccessible at  $kd \approx 0.7$  because the waves became too small for meaningful measurements whereas at  $kd \approx 1.7$  wave breaking prevented the investigation of large  $a/D$ . It should be borne in mind that the effect of wave harmonics on  $\bar{u}_{\max}/(U_{\infty}^2 k/\omega)$  is different for different values of  $kd$  and consequently the two sets of points do not necessarily follow the same curve when plotted against  $a/D$ . However, in both cases the smooth bed results should tend to  $\bar{u}_{\max}/(U_{\infty}^2 k/\omega) = 0.87$  in the limit as  $a/D$  tends to zero. Fig. 5 shows that this is the case, at least for the  $kd \approx 1.7$  results.

Fig. 5 Variation of the maximum value of the mean drift velocity with  $a/D$ . (For the smooth bed tests take  $D = 11.0$  mm)

Fig. 6 Comparison of the maximum drift velocity measured for rough beds in the limit as  $a/D \rightarrow 0$  with that for smooth beds under similar wave conditions

Various criteria for transition to turbulence over rough beds have been put forward. For example, Kajiura (1968) suggested that the process of transition to turbulence begins when  $U_{\infty} D/\nu$  exceeds 104 and that the flow is fully turbulent when  $U_{\infty} D/\nu$  exceeds 1000. For the present bed roughness and wave conditions this would mean that fully developed turbulence occurred with the rough bed for  $a/D > 1.3$  when  $kd \doteq 1.7$  and  $a/D > 2.4$  when  $kd \doteq 0.7$ . The first signs of turbulence would be apparent with the rough bed for  $a/D > 0.13$  when  $kd \doteq 1.7$  and  $a/D > 0.25$  when  $kd \doteq 0.7$ . Although it is possible to argue about the exact limits for transition to turbulence it is clear that at the larger values of  $a/D$  in Fig. 5 the boundary layer over the rough bed would certainly be fully turbulent. In fact, observations with dye traces showed significant dispersion in all of the rough bed tests.

As mentioned above, the fluctuation in velocity from the average cycle obtained by superimposing the 60 recorded cycles was also calculated. The variation in the root-mean-square value of this fluctuation was qualitatively similar to that described by Kemp & Simons (8). However, background noise was too great for more detailed study.

#### COMPARISON WITH OTHER RESULTS

As far as the writer is aware, the only published measurements of the effect of bed roughness on the mass transport velocity are those of Brebner et al (1). At low values of  $a/D$  they also observed that bed roughness tended to increase the maximum forward drift near the bed. Fig. 6 shows the ratio of the maximum drift velocity measured for the rough bed in the limit as  $a/D \rightarrow 0$  to that for a smooth bed under the same wave conditions. It should be emphasised that since Brebner et al's tests were carried out with dye and neutrally buoyant beads they refer to the Lagrangian velocity whereas the present measurements were of the Eulerian velocity. Consequently the results are not directly comparable even though the appropriate expression was used for the smooth bed velocity in each case. Nevertheless it is clear that the present results are not inconsistent with those of Brebner et al in the limit as  $a/D \rightarrow 0$ . In Fig. 6,  $\beta$  is equal to  $(\omega/2\nu)^{1/2}$ . Thus  $\beta D$  is a measure of the ratio of bed roughness size to viscous boundary layer thickness.

At high values of  $a/D$  Brebner et al observed the mass transport velocity over their rough beds to be less than that given by Longuet-Higgins' (9) theory. However, Collins (2) also observed a similar reduction with smooth beds in the same wave flume under equivalent conditions. Once again, these results are not inconsistent with what was observed in the present tests.

Finally, it is of interest to compare the present findings with the predictions of Longuet-Higgins (10) and Johns (5) for turbulent boundary layers. In each case the theory assumes a fully turbulent boundary layer so that the comparison ought to be with the test results at large  $a/D$ . Under these conditions the present measurements show no clear difference between the spatial-mean values for the rough bed tests, for which the boundary layer was fully turbulent, and those for the smooth bed, for which the flow was laminar. The test results would thus seem to support Longuet-Higgins' suggestion that turbulence does not affect the value of the drift velocity at the outer edge of the boundary layer.

However, because of the experimental scatter and because the drift velocity at large  $a/D$  is relatively weak (because of the effect of higher harmonics) Johns' prediction of a reduction in drift due to turbulence cannot be totally excluded.

#### CONCLUSIONS

The laser doppler anemometer measurements of the drift velocity in a wave flume with rough and smooth beds show the following results:

(1) over a rough bed the time-mean velocity at a given height is critically dependent on position relative to prominent roughness elements on the surface of the bed. At one point the mean drift may be in the direction of wave propagation while, at another, in the opposite direction. These perturbations were found to be significant close to the bed for all values of  $a/D$  tested. They do, however, decrease with height above the bed.

(2) If the time-mean drift at a given height is averaged across the wave flume it is found that bed roughness produces a significant increase in the maximum drift velocity near the bed at small values of  $a/D$ . At large values of  $a/D$  there was no clear difference between the maximum mean drift velocities above rough and smooth beds even though the boundary layer was fully turbulent for the rough bed and laminar for the smooth bed.

## CHAPTER SEVENTY NINE

### NEAR BOTTOM VELOCITIES IN WAVES WITH A CURRENT; ANALYTICAL AND NUMERICAL COMPUTATIONS

W.G.M. van Kesteren<sup>1)</sup> <sup>by</sup> and W.T. Bakker<sup>2)</sup>

#### ABSTRACT

In this paper, starting from the Prandtl hypothesis a three-dimensional numerical bottom boundary layer model has been developed, which allows to calculate bottom friction by a combination of waves and currents. The model has been compared with two-dimensional analytical computations which gave similar results. The bottom friction values found are comparable to the ones, found by Lundgren (1972), however in the most relevant cases somewhat less. Furthermore in the two-dimensional case the model has been compared with measurements of Bakker and Van Doorn (1978). With respect to the oscillatory motion, still some minor deviations occur between theory and measurements, due to deficiencies of the Prandtl theory.

#### 1 Introduction

Investigation of the bottom boundary layer is primary of importance because it reveals the stirring mechanism of the sand in the surf zone. This is one of the most important factors, determining the sand transport in the surf zone and therefore coastal erosion and sedimentation.

Furthermore, the boundary layer determines the bottom friction and therefore the velocity of, for instance, the longshore current and the wave energy loss.

From the present paper may be expected:

- . insight in the internal flow field, when waves and currents make an angle with each other;
- . insight in the turbulent viscosity;
- . a formula for bottom friction for waves and currents, making an angle with each other.

For this, the old, well-known Prandtl mixing-length theory is used.

From the data, presented by Bakker and Van Doorn (1978) it appears, that this theory overestimates the turbulent viscosity in the higher layers somewhat. Figure 1 shows a characteristic set of velocity profiles as measured by Van Doorn and as presented according to the Prandtl hypothesis. The general picture tallies, but the overshoot in reality is somewhat larger than theory predicts.

2 Instantaneous velocity field

Assuming uniform flow in horizontal direction and the Prandtl/Von Karman hypothesis for the shear stress in Appendix A an equation is developed for the intrusion of the shear stress into the fluid:

$$\frac{\partial \tau}{\partial t} = \underline{\underline{S}} v_t \frac{\partial \tau}{\partial z^2} \quad (1) \quad \text{wherein: } v_t = \kappa z \sqrt{|\underline{\underline{I}}|/\rho} \quad (2)$$

Here  $\tau$  stands for the shear stress with components  $(\tau_x, \tau_y)$ ,  $x$  and  $z$  are the horizontal and vertical coordinate respectively,  $t$  = the time,  $\rho$  = the specific density,  $v_t$  the turbulent viscosity,  $\kappa$  = the Von Karman constant, and  $\underline{\underline{S}}$  a second-order tensor, specified in Eq. (A9).

Eq. (1) is analogous to the famous diffusivity equation, where the viscosity  $\nu$  replaces the turbulent viscosity, and in which  $\underline{\underline{S}}$  can be omitted. Tensor  $\underline{\underline{S}}$  accounts for the difference in direction between  $\partial \tau / \partial t$  and  $\partial^2 \tau / \partial z^2$ .

Furthermore, in appendix A an equation (A11), similar to (1) for the defect velocity  $\underline{u}_d$  has been derived; the defect velocity is the difference  $\underline{u} - \underline{U}$  between the velocity  $\underline{U}$  far from the bottom and the local velocity  $\underline{u}$  in the boundary layer (Fig. A1). This equation (A11) is solved numerically. Figure 1 gives a solution for the two-dimensional case, compared with data of Bakker and Van Doorn (1978). It shows, that the Prandtl hypothesis overestimates the turbulent viscosity in the higher layers somewhat. The general picture tallies, but the overshoot in reality is somewhat more than the theory predicts. Figure 2 shows the standard deviation (theory compared with measurements) as function of the height above the bottom. The figure demonstrates, that the present model is more accurate than the one, presented in 1978 (Bakker and Van Doorn), mainly because the upper boundary can be fulfilled without approximation.

(N.B. scale of the horizontal coordinate perpendicular to orbital motion has been exaggerated, the same holds for Figure 3c to 3f).  
Figure 3b Time averaged velocity profile ( $\bar{u}$ ) and amplitude of orbital motion ( $\bar{v}$ ).

(N.B. scale for  $\bar{v}$  differs from  $\bar{u}$ ).

Figure 3c to 3f Momentaneous velocity profiles.

Figure 3 shows the solution in a three-dimensional case.

In Figure 3a the direction of the current far from the bottom is equal to the direction of the pressure gradient. The direction of the orbital motion is given by the points 1, 2 etc., representing the point of the current vector far from the bottom at successive times,  $1/4$  wave period apart. Figure 3c to 3f show these velocity profiles for 4 successive times. All the vectors are in a horizontal plane; the direction changes when going from upward to downward. In Figure 3b the resulting profile for the mean velocity and the amplitude of the first harmonic are shown. From this figure it appears that the direction of the mean velocity near the bottom differs considerable from the direction of the mean velocity outside the boundary layer, which asymptotically approaches the direction of the mean pressure gradient, or, which is the same, the mean shear stress. This effect should be taken into account in cases with for instance sandtransport near the bottom. The kink in the mean velocity profile will be treated in the next chapter.

Similar to the viscous boundary layer a unique relation can be expected in the turbulent case between horizontal velocity just outside the boundary layer and the shear stress acting on the bottom. However when the Prandtl hypothesis is used for determining the turbulent shear stresses in terms of the local velocity field it appears from analytical considerations (Appendix B) and numerical computations that only a unique relation can be obtained when the shear stress velocity  $p_b$  is used instead of the shear stress near the bottom  $\tau_b$ . The shear stress velocity  $p$  in the three dimensional case is defined as:

$$\underline{\tau} = \rho \underline{p} |\underline{p}| \quad (5)$$

The shear stress velocity can be expressed in terms of the local velocity field according to the Prandtl hypothesis (see Appendix B):

$$p = \kappa z \frac{\partial u}{\partial z} \quad (6)$$

The relation (5) has been treated more elaborate in Appendix B in order to make analytical computations of the instantaneous velocity field by linearizing Eq. (1) (see Appendix B) and of the time-averaged velocity field (see next chapter).

The amplitude of the first harmonic of the shear stress velocity  $\hat{p}_b$  at the bottom is related to the amplitude of the first harmonic of the oscillation  $\hat{U}$  far from the bottom. For moderate currents<sup>1)</sup> (time-averaged shear stress  $\bar{\tau}$  smaller than  $0.01 \rho \hat{U}^2$ ) there exists a unique relation between  $\hat{p}_b/\hat{U}$  and the ratio strouhalength  $a$  ( $= \hat{U}T/2\pi$  where  $T$  is the wave period) over bottom roughness  $r$ , which is shown in Figure 4 and can be approximated by:

$$\frac{\hat{p}_b}{\hat{U}} = \exp \left[ \sum_{n=0}^3 k_n \{\ln(a/r)\}^n \right] \quad (7)$$

wherein:  $k_0 = -1.092$ ;  $k_1 = -.3364$ ;  $k_2 = +.01876$ ;  $k_3 = -4.621 \cdot 10^{-4}$   
Using  $\hat{p}_b$  as basis for mathematical modeling, Figure 5 represents a dimensionless plot of the amplitude and phase of the first harmonic of the defect velocity  $\hat{u}_d^*$  ( $= \hat{u}_d/\hat{p}_b$ ) as function of the dimensionless

1) For larger currents is referred to Appendix B.

Figure 4 Relation between  $\hat{p}_b/\hat{U}$  and  $a/r$

Figure 5 Dimensionless amplitude and phase of the defect velocity

height  $z^*$  above the bottom; here the height  $z$  above the bottom has been made dimensionless with a characteristic height  $Z$ , which refers to the intrusion depth of the instantaneous shear stresses i.e. the boundary layer thickness coherent with the oscillatory motion. Based on analytical considerations (see Appendix B)  $Z$  is expressed as:

$$Z = \kappa \hat{p}_b T \quad (8)$$

In Figure 5 curves are given for waves and current codirectional and perpendicular to each other and for several values of mean shear stress over amplitude of the first harmonic of the bottom shear stress ( $\bar{\tau}/\hat{\tau}_b$ ). The increasing numbers at the lines refer to these rates and give an increasing effect of current with respect to the oscillation. Here  $\bar{\tau}$  denotes the time-averaged shear stress and  $\hat{\tau}_b$  the amplitude of the first harmonic of the shear stress at the bottom. Increasing the mean shear stress results (after an initial small decrease) in an increase of the amplitude of the defect-velocity; for moderate currents

( $\bar{\tau} < 0.01 \rho \hat{U}^2$ ) the effect of magnitude and direction of the mean shear stress is small. The phase is more sensible for mean current changes. The dash-dot-lines in Figure 5 are the results of analytical computations, which are treated in Appendix B. For clearness' sake only the case without current is shown.

The dots in Figure 5 representing measurements of Bakker and Van Doorn show, that although the amplitude is rather well produced, the phase of the calculated oscillatory motion still has discrepancies with respect to measurements, due to deficiencies of the Prandtl model.

### 3 Time-averaged velocity field

Consider the time-averaged velocity field. The equation of motion reads (see also Appendix A and B):

$$\frac{\partial u}{\partial t} = - \frac{1}{\rho} \text{grad } P + \frac{1}{\rho} \frac{\partial \tau}{\partial z} \quad (9)$$

wherein: grad P = horizontal pressure gradient

Averaging over the wave period, the acceleration term cancels out. For a flow with confined depth  $h$ , the shear stress increases linearly with the depth. Furthermore, the mixing length  $l$  should be:

$$l = \kappa z \sqrt{(1-z/h)} \tag{10}$$

From Eq. (9) and (10), for stationary flow a logarithmic velocity distribution would result. However, this distribution would be found also from the assumptions made in this paper: a mixing length  $\kappa z$  and a uniform shear stress over the depth.

The period mean velocity field can be derived from the internal shear stress velocity  $p$ , and a given mean shear stress by using Eq. (5) and (6) time averaged.

If, for simplicity in the two-dimensional case, only the mean  $\bar{p}$  and first harmonic  $\hat{p}$  of the shear stress velocity are considered, the shear stress according to Eq. (5) equals ( $\omega$  being the angular velocity):

$$\tau = \rho(\bar{p} + \hat{p} \sin \omega t) |\bar{p} + \hat{p} \sin \omega t| \tag{11}$$

Hence  $\bar{\tau}$  is larger than  $\rho \bar{p}^2$ .

Figure 6 Computation mean velocity schematically

The nearer to the bottom, the larger the fluctuations of the shear stress and therefore, the larger the contribution of these fluctuations to the total shear stress. Thus the hatched part in Figure 6a shows the contribution of the mean shear stress velocity to the shear stress and the blank part the contribution of the variable part. One may schematize this picture to Figure 6b. The same figure is depicted in Figure 6c, however now the time-averaged shear stress velocity  $\bar{p}$  is plotted on the horizontal axis instead of the mean shear stress  $\bar{\tau}$ .

The time averaged velocity can be found from integration the time-averaged Eq. (6) over the depth:

$$\bar{u} = \int_{z_0}^z \frac{\bar{p}}{\kappa z} dz \quad \text{wherein: } z_0 = r/33 \tag{12}$$

Thus integrating Figure 6c over the depth, on logarithmic paper a broken line will come to being. This is shown schematically in Figure 6d. The gradient on the upper part is the same as one would have had without the effect of waves, but with the same pressure gradient (i.e.  $\bar{\tau}$ ).

In fact, the lower part of the line in Figure 6d is not too important. One might extend the upper part in downward direction, thus finding an increase of the apparent roughness with a factor  $\alpha$ . Lundgren (1972) presents this feature in the following way:

$$\bar{u}(z) = \sqrt{\bar{\tau}/\rho} \left( \frac{1}{\kappa} \ln \frac{z}{z_0} - A \right) \tag{13} \text{ wherein: } A = \frac{1}{\kappa} \ln \alpha \tag{14}$$

In Eq. (13),  $\bar{\tau}$  can be found from the waterlevel gradient <sup>1)</sup>. This parameter A implies a reduction of the velocity u with A times the shear stress velocity (see Fig. 6d). The same is found for the depth-averaged velocity, as A does not depend on the level z. For example: if the mean velocity is 1 m/s, corresponding with a shear stress velocity of 4 cm/s, a value A of 1 corresponds with a velocity reduction of 4 cm/s.

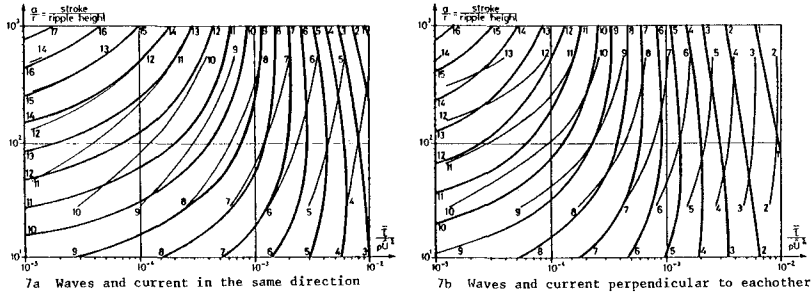

Figure 7 Comparison A-values according to Lundgren (1972) and analytical theory

In Figure 7 the values of A are plotted as function of  $\bar{\tau}/(\rho \hat{U}^2)$  and a/r. Figure 7a shows the case, that waves and currents are codirectional, Figure 7b that waves and currents are perpendicular to each other. The thin lines refer to Lundgren (1972), the thick lines to the present theory. Differences in A between both theories are not more than 2 in the relevant area.

When waves and current are perpendicular to each other, the variations of p during the wave period are less than when waves and current are in the same direction. Thus  $\rho \hat{p}^2$  will differ less from  $\bar{\tau}$  (Fig. 6a) and therefore in the first case the factor A will be smaller (Fig. 7).

If one wants to implement the friction factors in a mathematical model, the use of graphs is inconvenient. For this goal the following formula for A may be useful:

$$A = \frac{1}{\kappa} (K_1 - K_2 \ln z_0^* + K_3 z_0^*) \tag{15}$$

where  $K_1$ ,  $K_2$  and  $K_3$  are given functions (see (C7)) of the ratio  $\bar{\tau}/(\rho \hat{p}_b^2)$ ; the ratio  $\hat{p}_b/\hat{U}$  is found from Eq. (7). The constants  $K_1$ ,  $K_2$  and  $K_3$  also depend on the angle  $\alpha_{wc}$  between waves and currents (appendix C). Furthermore, A is a function of the dimensionless  $z_0^*$  given in Eq.(C8) where  $z_0$  (equal to  $r/33$ ) has been made dimensionless with the reference height Z (see Eq. (8)). Analytical calculations concerning A and the constants  $K_1$ ,  $K_2$  and  $K_3$  are given in Appendix C.

1) In the case of breaking waves from the onshore gradient of the "shear stress" component of the radiation stress.

• From Bakker et al (1978) (test V20RA: mean velocity averaged over the height was  $20 \text{ cm.s}^{-1}$ ; amplitude first harmonic just outside boundary layer was  $24.3 \text{ cm.s}^{-1}$ )  
 --- numerical computation  
 ——— analytical computation  
 inset: numerical computation:  
 waves // current (—)  
 waves  $\perp$  current (---)

Figure 8 Mean velocity; theory compared with experiment of Bakker and Van Doorn (1978)

Figure 8 shows the velocity profile as result of measurements (Bakker and Van Doorn, 1978) and computations in a two-dimensional case. The inset shows the same velocity profile again, in combination with the case that waves and current are perpendicular to each other. One observes, that the apparent roughness in the case with waves and current perpendicular to each other is smaller than for parallel wave- and current direction; for this extend the upper part of the lines in the inset in downward direction. N.B. When using Eq. (13) for cases with combined waves and currents, it should be kept in mind, that the non-linear transport of water in the area above the wave trough falls outside the scope of this paper. This transport can be considerable.

4 Coastal engineering history

Very schematically, the history of science about the combination of waves and currents is the following (see Fig. 9). In the past one did not realize oneself, that waves additional to current effect this current (Fig. 9a). In 1967 for a given discharge Bijker pointed out the increase of shear stress by waves (Fig. 9b). This inversely includes the reduction of current by waves, given a mean water level gradient. In present time we realize ourselves, that waves change the vertical velocity distribution and therefore, that the reduction in discharge is not as drastically as Bijker predicts (Fig. 9c).

Figure 9 History of computation of mean velocity

5 Notation

$\lambda$	stroklength ( $=\lambda T/2\pi$ )	(m)
A	factor determining the influence of waves on the time-averaged velocity-profile according to Lundgren (Eq.(13))	(-)
A, B	complex constants in hypergeometric functions (Eq.(B16))	(-)
a,b,c,d	constants in approximation K(z) (Eq.(B12) and (B13))	(-)
C <sub>1,2,3,4</sub>	complex integration constants in Eq. (B16) to (B18)	(-)
E	complete elliptic integral of the second kind	(-)
k <sub>i=0,1...</sub>	coefficient of power-series-expansions	(-)
ker <sub>i</sub> , kei <sub>i</sub>	Kelvin functions of order i	(-)
ber <sub>i</sub> , bei <sub>i</sub>		(-)
K	complete elliptic integral of the first kind	(-)
K <sub>1,2,3</sub>	coefficients in Eq. (15) for A - value of Lundgren	(-)
K(z)	coefficient in differential equation analytical theory (Eq. (B4) and (B5))	(m <sup>2</sup> s <sup>-1</sup> )
l	turbulent mixing length (Eq.(10))	(m)
m, n	constants in approximation influence $\alpha_{wc}$ on A-value Lundgren (Eq.(C2))	(-)
N <sub>0</sub> , $\phi_0$	modulus and phase of zero order Kelvin' functions	(-)
p	internal shear stress velocity	(ms <sup>-1</sup> )
P	internal fluid pressure	(Pa)
r	Nikuradse roughness	(m)
S	second order tensor (Eq.(A9))	(-)
T	wave period	(s)
t	time	(s)
u	horizontal velocity	(ms <sup>-1</sup> )
U	horizontal velocity far from the bottom and boundary condition for the velocity field	(ms <sup>-1</sup> )
u <sub>d</sub>	defect-velocity ( $=u-U$ ; see also Fig. A1)	(ms <sup>-1</sup> )
x, y	horizontal coordinates	(m)
z	vertical coordinate	(m)
z <sub>0</sub>	height above the bottom where the horizontal velocity is zero ( $=r/33$ )	(m)
Z	reference height for the boundary layer thickness coherent with the oscillatory motion (Eq.(8))	(m)
$\alpha$	factor determining the increase of apparent bottom roughness (Eq.(14))	(-)
$\alpha_{wc}$	angle between wave-propagation and current far from bottom	(deg)
$\beta_{wc}$	tangent modulus in approximation of p*	(-)
$\gamma$	Euler's constant	(-)
$\delta$	direction of first derivative of horizontal velocity	(deg)
$\zeta$	argument in analytical solution (Eq.(B16))	(-)
$\theta$	phase of u <sub>d</sub> (Eq.(B19))	(rad)
$\kappa$	Von Karman's constant	(-)
$\Lambda$	sum of digamma functions (Eq.(B16))	(-)
$\nu$	kinematic viscosity	(m <sup>2</sup> s <sup>-1</sup> )
$\nu_t$	turbulent viscosity	(m <sup>2</sup> s <sup>-1</sup> )
$\xi$	factor for influence $\alpha_{wc}$ in analytical theory (Eq.(B11))	(-)
$\rho$	specific density	(kgm <sup>-3</sup> )
$\tau$	internal shear stress	(Pa)
$\phi$	phase of p (Eq.(B2))	(rad)
$\chi_{1,2}$	hypergeometric functions (Eq.(B16))	(-)
$\psi$	digamma function	(-)
$\omega$	angular velocity (2 $\pi$ /T)	(s <sup>-1</sup> )

Other symbols added to a variable x:

$\vec{x}$	vector
$\bar{x}^*$	dimensionless value
$\bar{x}$	time-averaged value
$\tilde{x}$	amplitude first harmonic
$\hat{x}$	first harmonic
$x_b$	value at the bottom

Appendix A: Numerical computations

Assumptions:

a. Only horizontal velocities, uniform in horizontal direction, are considered i.e. pressure gradient grad P uniform in vertical direction

b. The shear stress  $\tau$  can be found from the Prandtl hypothesis:

$$\tau = \rho v_t \frac{\partial u}{\partial z} \quad (A1)$$

$$v_t = \kappa^2 z^2 \left| \frac{\partial u}{\partial z} \right| \quad (A2)$$

wherein:  $\left| \frac{\partial u}{\partial z} \right| = \sqrt{\left( \frac{\partial u_x}{\partial z} \right)^2 + \left( \frac{\partial u_y}{\partial z} \right)^2}$  (A3)

c. The time averaged shear stress  $\bar{\tau}$  is uniform in vertical direction (cf ch.3).

Derivation of Eq. (1) and numerical solution:

According to assumption a the equation of motion reads:

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \text{grad } P + \frac{1}{\rho} \frac{\partial \tau}{\partial z} \quad (A4)$$

Define  $\underline{U}$  and  $\underline{u}_d$  in the following way:

$$\frac{\partial \underline{U}}{\partial t} = -\frac{1}{\rho} \text{grad } P \quad (A5)$$

$$\underline{u}_d = \underline{u} - \underline{U} \quad (A6)$$

Figure A.1 Definition defect-velocity.

The velocity  $\underline{U}$  (only a function of  $t$ , cf. assumption a) denotes the velocity at a depth, to be chosen arbitrary, however far enough above the bottom to attenuate the periodical changes of  $\tau$ . This can be seen from Eq. (A4) by taking the 2nd term on the right handside equal to zero (assumption c). The velocity  $\underline{u}_d$  denotes the defect-velocity (see Fig. A1).

Substitution of Eq. (A5) and (A6) into (A4) yields:

$$\frac{\partial \underline{u}_d}{\partial t} = \frac{1}{\rho} \frac{\partial \tau}{\partial z} \quad (A7)$$

Write  $\tau$  as  $(\tau_x, \tau_y)$ , and  $\underline{u}$  as  $(u_x, u_y)$ , then differentiation of  $\tau_x$  to  $t$  gives, using Eq. (A1) to (A3):

$$\begin{aligned} \frac{\partial \tau_x}{\partial t} &= \rho \left\{ \frac{\partial v_t}{\partial t} \frac{\partial u_x}{\partial z} + v_t \frac{\partial^2 u_x}{\partial t \partial z} \right\} \\ &= \rho v_t \left\{ (1 + \cos^2 \delta) \frac{\partial^2 u_x}{\partial z \partial t} + \sin \delta \cos \delta \frac{\partial^2 u_y}{\partial z \partial t} \right\} \end{aligned}$$

wherein:  $\cos \delta = \frac{\partial u_x}{\partial z} / \left| \frac{\partial u}{\partial z} \right|$  and  $\sin \delta = \frac{\partial u_y}{\partial z} / \left| \frac{\partial u}{\partial z} \right|$

Computation of  $\partial \tau_y / \partial t$  in a similar way yields:

$$\frac{\partial \tau}{\partial t} = \rho v_t \underline{S} \cong \frac{\partial^2 u}{\partial z \partial t} \tag{A8}$$

wherein: 
$$\underline{S} = \begin{vmatrix} 1 + \cos^2 \delta & \cos \delta \sin \delta \\ \cos \delta \sin \delta & 1 + \sin^2 \delta \end{vmatrix} \tag{A9}$$

Differentiation of Eq. (A7) to z, multiplication with  $v_t \underline{S}$  and substitution of Eq. (A8) results in Eq. (1), because  $\partial u / \partial z$  equals  $\partial u_d / \partial z$ .

With a similar derivation as the one for  $\partial \tau / \partial t$  one finds:

$$\frac{\partial \tau}{\partial z} = \frac{\rho}{\kappa z} v_t \underline{S} \cong \frac{\partial}{\partial z} \left\{ \kappa z \frac{\partial u}{\partial z} \right\} \tag{A10}$$

Substitution of Eq. (A2) into (A10) and Eq.(A10) into (A7) yields an equation for the defect-velocity:

$$\frac{\partial u_d}{\partial t} = \kappa z \frac{\partial u_d}{\partial z} \cdot \underline{S} \cong \frac{\partial}{\partial z} \left\{ \kappa z \frac{\partial u_d}{\partial z} \right\} \tag{A11}$$

Eq. (A11) has been solved numerically using a finite difference method based on the Crank-Nicholson implicate integration scheme with the boundary conditions:

- $\frac{u_d}{z} = 0$  at the upper end
- $\frac{u_d}{z} = -U$  near the bottom at a height  $z_0$  which is proportional to the dimension of the bottom roughness  $r$  ( $z_0 = r/33$ )
- $\underline{U} =$  imposed velocity at the upper boundary

Appendix B: Analytical computations

In this appendix only relations will be derived, on one hand for parallel direction of oscillation and current (i.e.  $\alpha_{wc} = 0^\circ$ ) and on the other hand for oscillation and current perpendicular to each other (i.e.  $\alpha_{wc} = 90^\circ$ ).

Differentiation of the equation of motion (A4) to z using assumption a, multiplication with  $\kappa z$  and substitution of (6) gives:

$$\frac{\partial p}{\partial t} = \frac{1}{\rho} \kappa z \frac{\partial^2 \tau}{\partial z^2} \tag{B1}$$

When only the first harmonics are taken into account for the linearized approximation the shear stress  $\tau$  and shear stress velocity  $p$  can be written as:

$$\begin{aligned} p &= \bar{p} + \tilde{p}; & \tilde{p} &= \hat{p} \sin(\omega t + \phi) \\ \tau &= \bar{\tau} + \tilde{\tau}; & \tilde{\tau} &= \hat{\tau} \sin(\omega t + \phi) \end{aligned} \tag{B2}$$

wherein:  $\phi =$  phase of  $\tilde{p}$  and equals in an approximation upto the first harmonic the phase of  $\tilde{\tau}$

Because  $\tilde{p}$  and  $\tilde{\tau}$  are in phase, derivation to  $t$  yields in the case of  $\alpha_{wc} = 0^\circ$  and  $90^\circ$ :

$$\frac{\partial \tilde{p}}{\partial t} = \tilde{\tau} \cdot \frac{\partial \tilde{\tau}}{\partial t} \tag{B3}$$

wherein:  $\hat{p}, \hat{\tau}$  the modulus of  $\tilde{p}$  and  $\tilde{\tau}$

Evidently Eq. (B3) is only relevant in the plane of oscillation. Only considering this plane in the following, the vector-sign (underlining) may be skipped.

After substitution of (B3) into (B1) and using assumption c an equation, similar to (1) is found<sup>1)</sup>:

$$\frac{\partial \tilde{\tau}}{\partial t} = K \frac{\partial \tilde{\tau}}{\partial z} \tag{B4} \quad \text{wherein: } K = \kappa z \frac{\hat{\tau}/\rho}{\hat{p}}$$

For  $\alpha_{wc} = 0^\circ$  from Eq. (5) and (B2) can be derived:

$$\frac{\hat{\tau}}{\rho \hat{p}^2} = \frac{4}{\pi} \frac{\bar{p}}{\hat{p}} \arcsin \frac{\bar{p}}{\hat{p}} + \frac{4}{3\pi} \left( 2 + \frac{\bar{p}^2}{\hat{p}^2} \right) \sqrt{1 - \frac{\bar{p}^2}{\hat{p}^2}} \quad \text{for } \bar{p} < \hat{p}$$

$$\frac{\hat{\tau}}{\rho \hat{p}^2} = 2 \frac{\bar{p}}{\hat{p}} \quad \text{for } \bar{p} > \hat{p} \tag{B6}$$

$$\frac{\bar{\tau}}{\rho \bar{p}^2} = \frac{2}{\pi} \left( \frac{1}{2} + \frac{\bar{p}^2}{\hat{p}^2} \right) \arcsin \frac{\bar{p}}{\hat{p}} + \frac{3}{\pi} \frac{\bar{p}}{\hat{p}} \sqrt{1 - \frac{\bar{p}^2}{\hat{p}^2}} \quad \text{for } \bar{p} < \hat{p}$$

$$\frac{\bar{\tau}}{\rho \bar{p}^2} = \frac{1}{2} + \frac{\bar{p}^2}{\hat{p}^2} \quad \text{for } \bar{p} > \hat{p} \tag{B7}$$

These keep their validity in dimensionless shape, wherein  $\bar{p}, \hat{p}, \bar{\tau}$  and  $\hat{\tau}$  are made dimensionless with the value of  $\beta$  at the bottom (i.e.  $\hat{p}_b$  for  $\bar{p}$  and  $\hat{p}$ , and  $\rho \hat{p}_b^2$  for  $\bar{\tau}$  and  $\hat{\tau}$ ). In the following these dimensionless values are denoted with an asterisk.

- 1) Eq. (B4) is quite similar to (1). Generally it should be kept in mind, that Eq. (B4) is a linearized equation, where (1) has general validity, and therefore the coefficient K is not equal to  $v_t^2$ . However for parallel oscillation and current  $\delta$  equals 0,  $v_t$  and therefore in the plane of oscillation Eq. (1) and (A9) yields:

$$\frac{\partial \tau}{\partial t} = 2 v_t \frac{\partial \tau}{\partial z} \quad \text{wherein: } v_t = \kappa^2 z^2 \left| \frac{\partial u}{\partial z} \right|$$

For large  $z$  the value of  $|\partial u/\partial z|$  approaches  $\bar{p}/\kappa z$ , and therefore  $2v_t + 2\kappa z \bar{p}$ . As  $\hat{\tau}/\rho$  will be  $2 \bar{p}\hat{p}$  for large value of  $z$  (see Eq. (B6)), the value of K according to Eq. (B5) equals  $2 v_t$ . This demonstrates the similarity between Eq. (1) and (B4) in this case.

- 2) Even, generally, the time-independent K is not equal to the time-averaged  $\sum v_t$ .

In Figure B1 is displayed a dimensionless  $K^* = K/(\kappa^2 \hat{p}_b^2 T)$  versus a dimensionless height  $z^* = z/(\kappa \hat{p}_b T)$ . Furthermore the value of  $K^*$  depends on  $\bar{\tau}/\hat{\tau}_b$ . For the relation  $\hat{p}^* = \hat{p}/\hat{p}_b$  an exponential decay is assumed (Bakker, 1973):

$$\hat{p}^* = e^{-(3\pi^3/16) z^*} \tag{B8}$$

The rate of decay according to Eq. (B8) is coherent with the choice of the reference height  $Z$ , defined as  $Z = \kappa \hat{p}_b T$ . A relation between  $\bar{\tau}^*/\hat{\tau}_b^*$  and  $\hat{p}^*$  follows from division of (B7) by (B6). Given the value of  $\bar{\tau}^*/\hat{\tau}_b^*$  using Eq. (B8) the value of  $\hat{p}^*$  can be found. From (B7) results  $\bar{\tau}^*$ . For a certain level  $z^*$ , the value of  $\hat{p}^*$  follows from Eq. (B8). As  $\bar{\tau}^*$  remains constant in the vertical sense, the value of  $\bar{\tau}^*/\hat{p}^{*2}$  is known. Substitution of this value in Eq. (B7) yields a value of  $\bar{p}^*/\hat{p}^*$ , which further can be substituted in Eq. (B6) yielding  $\tau^*/\hat{p}^{*2}$  and therefore  $K^* (= z^* \hat{\tau}^*/\hat{p}^*)$ . For  $\alpha_{wc} = 90^\circ$  a similar approach can be chosen. Instead of Eq. (B6) and (B7) is found:

$$\frac{\hat{\tau}}{\rho \hat{p}^2} = \frac{4}{3\pi} \sqrt{1 + \frac{\bar{p}^2}{\hat{p}^2}} \left[ (2 + \frac{\bar{p}^2}{\hat{p}^2}) E \left\{ \frac{1}{1 + \frac{\bar{p}^2}{\hat{p}^2}} \right\} - \frac{\bar{p}^2}{\hat{p}^2} K \left\{ \frac{1}{1 + \frac{\bar{p}^2}{\hat{p}^2}} \right\} \right] \text{ for } \bar{p}/\hat{p} > 0 \tag{B9}$$

$$\frac{\bar{\tau}}{\rho \hat{p}^2} = \frac{2}{\pi} \frac{\bar{p}}{\hat{p}} \sqrt{1 + \frac{\bar{p}^2}{\hat{p}^2}} E \left\{ \frac{1}{1 + \frac{\bar{p}^2}{\hat{p}^2}} \right\} \text{ for } \bar{p}/\hat{p} > 0 \tag{B10}$$

wherein:  $K \{ \} =$  complete elliptic integral of the first kind  
 $E \{ \} =$  complete elliptic integral of the second kind

For the analytical computations of the time-dependent velocity field the coefficient  $K^*$  is approximated in 3 sections (see Fig. B1): Above the intersection of the straight line and the curve valid for waves only, the straight line is assumed i.e.:

$$\text{upper part: } K^* = \xi \cdot z^* \sqrt{\bar{\tau}^*} \tag{B11}$$

wherein:  $\xi = 2$  for  $\alpha_{wc} = 0^\circ$  ;  
 $\xi = 1$  for  $\alpha_{wc} = 90^\circ$

Eq. (B11) follows from substitution of Eq. (B6) ( $\alpha_{wc} = 0^\circ$ ) or Eq. (B9) ( $\alpha_{wc} = 90^\circ$ ) into Eq. (B5) for the limiting case of  $\bar{p}/\hat{p} \rightarrow 0$  and  $\bar{p} \rightarrow \sqrt{\bar{\tau}/\rho}$ . Below the intersection of the straight line and the curve for waves only, the curve is assumed, which is approximated by:

$$\text{middle part: } K^* = ae^{-bz^*} \quad ; \quad a = 0.111 \quad b = 3.267 \tag{B12}$$

$$\text{lower part: } K^* = cz^* - dz^{*2} \quad ; \quad c = 0.849 \quad d = 2.817 \tag{B13}$$

The intersection of lower and middle part is situated at  $z^* = 0.186$ . The influence of the current on the time-dependent solution is restricted to the upper part where Eq. (B11) is valid. As long as the straight line in Figure B1 intersects the curve I + II for waves only, the influence of the current on the time-dependent velocity field is negligible near the bottom. This can also be seen from nu-

Figure B.1 Coefficient  $K^*$  as function of  $z^*$   $C_1, C_2, C_3$  en  $C_4$ :  
(analytically and approximation)

lower part: the solution consists of hypergeometric functions, which in the following already are expressed in power-series-expansions

$$\hat{u}_{dc}^* = \frac{d}{kc} [C_1 \{ 1 + \chi_1(\zeta) \} + \frac{\hat{\tau}_b^*}{d} \{ 1 + \ln \zeta + \chi_2(\zeta) \}] \quad (B16)$$

wherein:  $c, d$  are given in Eq. (B13)

$$\chi_1(\zeta) = \sum_{n=1}^{\infty} \frac{(A+1)_n (B+1)_n}{(n+1)! n!} \cdot n \cdot \zeta^{n-1}$$

$$\chi_2(\zeta) = \sum_{n=1}^{\infty} \frac{(A+1)_n (B+1)_n}{(n+1)! n!} \cdot n \cdot \zeta^{n-1} \Lambda(n)$$

$$(A+1)_n = (A+1) (A+2) \dots (A+n)$$

$$\Lambda(n) = \psi(A+1+n) - \psi(A+1) + \psi(B+1+n) - \psi(B+1) - \psi(n+2) + \psi(2) - \psi(n+1) + \psi(1)$$

$$\psi(m) = \text{digamma function} = -\gamma + \sum_{n=1}^{m-1} \frac{1}{n}$$

1) Mind that (exact) the same solution is found for waves and current codirectional and perpendicular to each other, if in the last case the time-averaged shear stress is four times as large as in the first case (because then part III is the same; see Eq. (B11)).

merical computations in Figure 5.1) The intersection disappears for large currents, when the slope of the straight line exceeds the tangent of the basic curve at the origin (Fig. B1) i.e.:

$$\xi \sqrt{\frac{a}{\tau}} > \frac{8}{3\pi} \quad (B14)$$

With above given approximations for  $K^*$ , Eq. (B4) can be solved analytically with the boundary conditions:

$$z = 0: \underline{\tau} = \frac{\bar{\tau}}{\tau} + \frac{\hat{\tau}_b}{\tau} \sin \omega t \quad (B15)$$

$$z \rightarrow \infty: \underline{\tau} \rightarrow \bar{\tau}$$

When the time dependent shear stress  $\bar{\tau}$  is found, with Eq. (A7) the time-dependent defect velocity  $\hat{u}_d$  can be computed. The analytical solutions for the amplitude and phase of the first harmonic of  $u_d$  (in complex form; suffix  $c$  denotes 'complex') are determined apart from complex integration constants

$$\begin{aligned} \gamma &= .57722 \text{ (Euler's constant)} \\ A, B &= \text{complex constants restricted by} \\ & \quad A + B = -1; A \cdot B = 2\pi i/d \\ & \quad \text{(as } d = 2.817: A = 0.617 - 0.999 i \\ & \quad \quad \quad \quad \quad \quad \quad \quad B = -1.617 + 0.999 i) \\ \zeta &= \frac{d}{c} \cdot z^* \end{aligned}$$

middle part: the solution consists of Kelvin functions:

$$\hat{u}_{dc}^* = \frac{b \zeta}{\kappa} [C_2 \{ \ker_1(\zeta) + i \cdot \text{kei}_1(\zeta) \} + C_3 \{ \text{ber}_1(\zeta) + i \cdot \text{bei}_1(\zeta) \}] \quad (B17)$$

wherein:  $\zeta = 2\pi \sqrt{\frac{2}{\pi a}} e^{\frac{1}{2}bz^*}$

$\ker_1(\zeta)$ ,  $\text{kei}_1(\zeta)$ ,  $\text{ber}_1(\zeta)$  and  $\text{bei}_1(\zeta)$  are Kelvin functions  
upper part:

$$\hat{u}_{dc}^* = C_4 [ \ker_0(\zeta) + \text{kei}_0(\zeta) + i \{ \text{kei}_0(\zeta) - \ker_0(\zeta) \} ] \quad (B18)$$

wherein:  $\zeta = 2 \sqrt{\frac{2\pi z^*}{\xi \sqrt{\tau^*}}}$

For large currents, when only the upper part can be applied, Eq. (B18) becomes:

$$\hat{u}_d^* = \frac{2\hat{\tau}_b^*}{\xi \sqrt{\tau^*}} \cdot \frac{1}{\kappa} N_0(\zeta) \quad ; \quad \theta = \phi_0(\zeta) \quad (B19)$$

wherein:  $N_0(\zeta) = \sqrt{\ker_0^2(\zeta) + \text{kei}_0^2(\zeta)}$   
 $\phi_0^0(\zeta) = \arctan \{ \text{kei}_0(\zeta) / \ker_0(\zeta) \}$   
 $\phi^0 = \text{phase of } \hat{u}_d^0 \text{ defined by } \hat{u}_d = \hat{u}_d \sin(\omega t + \theta)$

For clearness' sake only the analytical solution for the case of waves only is presented in Figure 5. The analytical solution then consists only of the combination of Eq. (B16) and (B17).

From Eq. (B19) a simple relation can be derived between the ratio  $\hat{\tau}_b / (\rho \hat{U}^2)$  and the ratio stroklength over bottomroughness  $a/r$ . Replace in Eq. (B19) the dimension operator  $\hat{p}_b$  (denoted by a asterisk) by  $\hat{U}$ , and consider Eq. (B19) at a level  $z = z_0$ , where  $\hat{u}_d = \hat{U}$ . The result is:

$$\frac{\hat{\tau}_b}{\rho \hat{U}^2} = \frac{\kappa \xi}{2} \sqrt{\frac{\tau}{\rho \hat{U}^2}} N_0^{-1}(\zeta) \quad (B20)$$

wherein:  $\zeta = \frac{2}{\sqrt{33 \kappa \xi a/r \sqrt{\tau/\rho \hat{U}^2}}}$

This equation is only valid when Eq. (B14) can be applied. Practically Eq. (B19) and (B20) differ only slightly from the numerical solution in the range of  $a/r > 1$  and  $\tau/(\rho \hat{U}^2) >> 0.1$ .

Appendix C: Analytical calculation of Lundgren's A-value

In this appendix the analytical solution for the time-averaged velocity field will be treated. With Eq. (12) this field can be found from the time-averaged shear stress velocity. The last can be found from the definition of the shear stress velocity by Eq. (5) in the following way<sup>1)</sup>

As described in Appendix B, the ratio  $\bar{p}^*/\hat{p}^{*2}$ ) can be found as function of the dimensionless height  $z^*$  above the bottom using Eq. (B7) when  $\alpha_{WC} = 0^\circ$  and Eq.(B10) when  $\alpha_{WC} = 90^\circ$ . From Eq. (B8) the dimensionless  $\bar{p}^*$  can be derived. For various values of  $\bar{\tau}/\hat{\tau}_b$  those curves are plotted in Figure C1, in the case of  $\alpha_{WC} = 0^\circ$ .

Fig. C.1 Profile for  $\bar{p}^*$  and  $\hat{p}^*$  (anal. and approx.)

For integrating over the depth according to Eq. (12) the curves for  $\bar{p}$  are approximated by a vertical and an oblique line (see Fig. C1). The vertical line corresponds with the value of  $\bar{p}^* = \sqrt{\bar{\tau}^*}$ , the oblique line connects the bottom point  $\bar{p}^* = \bar{p}_b^*$  with the point, where  $\bar{p}^* = \hat{p}^*$ :

$$\bar{p}^* = \bar{p}_b^* + \beta z^* \tag{C1}$$

This approximation can only be applied, when  $\bar{p}_b^* < 1$ . As will be shown later this restriction covers the cases where the influence of waves on a current becomes significant. As the dash-dot line in Figure C1 denotes  $\hat{p}^*$  (given by Eq. (B8)), the intersection point of the drawn line and the dash-dot line is also a point of the oblique line.

From Eq. (B7) and (B10) it shows, that in the intersection points, ( $z^* = z_s^*$ ), where  $\bar{p}^* = \hat{p}^*$  the value of  $\bar{\tau}^*/\hat{p}^{*2}$  equals 1.5, when  $\alpha_{WC} = 0^\circ$  and  $2\sqrt{2}/\pi E\{\frac{1}{2}\} = 1.216$  when  $\alpha_{WC} = 90^\circ$ . Generally it can be derived that:

$$\hat{p}^* = \sqrt{\frac{\bar{\tau}^*}{1 + (m + n \cos^2 \alpha_{WC})^2}} \tag{C2}$$

wherein:  $m^2 = \frac{2\sqrt{2}}{\pi} E\{\frac{1}{2}\} - 1 \approx 0.216$

$$n = \frac{1}{2}\sqrt{2} - m$$

$E\{\}$  = complete elliptic integral of the second kind.

Using Eq. (B8) for  $\hat{p}^*$  from Eq. (C1) the height of the intersection level  $z_s^* = z_s^*$  is found:

$$z_s^* = -\frac{8}{3\pi} \ln \left\{ \frac{\bar{\tau}^*}{1 + (m + n \cos^2 \alpha_{WC})^2} \right\} \tag{C3}$$

1) In an approximation, up to the first harmonic.

2) The asterisks have the same meaning as in Appendix B.

Then from Eq. (C1)  $\beta$  can be derived:

$$\beta = (\hat{p}^* - \bar{p}_b^*) / z_k^* \tag{C4}$$

The level  $z_k^*$ , where the vertical line and the oblique line intersect equals:

$$z_k^* = (\sqrt{\bar{\tau}^*} - \bar{p}_b^*) / \beta \tag{C5}$$

From integration, according to Eq. (12), the velocity  $\bar{u}_k^*$  at the level  $z_k^*$  can be found. For  $z^* > z_k^*$  a logarithmic velocity profile is found (Fig. 6d) i.e. a straight line on logarithmic paper through the point  $(z_k^*, \bar{u}_k^*)$  under the inclination  $\arctan(\kappa / \sqrt{\bar{\tau}^*} / \rho)$ . Extension of this line, in downward direction yields the level  $\alpha z_0^*$  where  $\alpha$  is the magnification of the apparent bottom roughness (Fig. 6d):

$$\ln \alpha = (1 - \frac{\bar{p}_b^*}{\sqrt{\bar{\tau}^*}}) \ln \frac{z_k^*}{z_0^*} - \frac{\beta}{\sqrt{\bar{\tau}^*}} (z_k^* - z_0^*) \tag{C6}$$

Using Eq. (14) this gives the A-value of Lundgren according to Eq. (15) wherein:

$$K_1 = K_2 \ln z_k^* - K_3 z_k^* ; K_2 = 1 - \frac{\bar{p}_b^*}{\sqrt{\bar{\tau}^*}} ; K_3 = \frac{\beta}{\sqrt{\bar{\tau}^*}}$$

( $\beta$  and  $z_k^*$  according to Eq. (C4) and (C5))  
 The coefficient  $K_1$ ,  $K_2$  and  $K_3$  can be written as function of  $\bar{\tau} / (\rho \hat{p}_b^2)$  and  $\alpha_{wc}$ . These functions are approximated with power-series-expansions for the cases  $\alpha_{wc} = 0^\circ$  and  $\alpha_{wc} = 90^\circ$ :

$$K_i = \sum_{n=0}^4 k_{in} \{ \ln(\frac{\bar{\tau}}{\rho \hat{p}_b^2}) \}^n \quad (i = 1, 2, 3) \tag{C7}$$

The coefficients  $k_{in}$  are listed in the table below.

	$\alpha_{wc} = 0^\circ$					$\alpha_{wc} = 90^\circ$				
	$k_0$	$k_1$	$k_2$	$k_3$	$k_4$	$k_0$	$k_1$	$k_2$	$k_3$	$k_4$
$K_1$	-0.914	.623	.159	.0110	-	-0.3921	.2264	-.1325	-.00410	-.002850
$K_2$	.284	-.285	-.0416	-.00214	-	.1120	-.0858	.0737	.0175	.001092
$K_3$	2.654	-.511	-.408	-.0761	-.00464	1.3845	.1398	.3302	.0883	.006240

The values of the coefficients for  $0^\circ < \alpha_{wc} < 90^\circ$  can be approximated by linear interpolation.

Eq. (C7) and (15) relate A to  $\bar{\tau} / (\rho \hat{p}_b^2)$  and  $z_0^*$ ; this relationship can be easily converted to the presentation according to Lundgren (Fig. 7). Here  $\bar{\tau} / (\rho \hat{U}^2)$  replaces  $\bar{\tau} / (\rho \hat{p}_b^2)$ . Evidently these dimensionless variables can be converted to each other with the aid of the ratio  $\hat{p}_b / \hat{U}$ , given in Eq. (7) as function of the ratio  $a/r$ . Furthermore in Lundgren's presentation the variable  $a/r$  replaces  $z_0^*$ ; these variables are related in the following way (using Eq. (8)):

$$z_0^* = \frac{z_0}{\kappa \hat{p}_b T} = \frac{1}{66 \kappa \pi} \frac{\hat{U}}{\hat{p}_b} \frac{1}{a/r} \tag{C8}$$

## CHAPTER EIGHTY

### FIELD AND LABORATORY VERIFICATION OF THE WAVE PROPAGATION MODEL CREDIZ

M.W. Diggemans<sup>1)</sup>, M.J.F. Stive<sup>1)</sup>, A.J. Kuik<sup>2)</sup>, A.C. Radder<sup>3)</sup> and N. Booij<sup>4)</sup>

#### ABSTRACT

Both the effects of refraction and diffraction may be efficiently modeled in wave propagation models by introduction of the parabolic approximation. The performance of the model CREDIZ, which is based on this parabolic approximation, was investigated in three verification studies. Two of these studies concern laboratory situations, i.e. one having a simple geometry and one having a more complicated geometry. The third study concerns a field situation, i.e. a shoal dominated area in an estuary mouth. It is found that despite the schematization to monochromatic, nearly linear wave propagation, the model CREDIZ performs remarkably well for engineering purposes.

#### 1.0 INTRODUCTION

For the prediction of wave behaviour in coastal regions numerical wave propagation models are common engineering practise nowadays. The majority of the models are based on linear wave propagation. The physical processes usually accounted for are: shoaling, refraction and diffraction. The various approximations can be derived from the now well-known mild slope equation in which refraction and diffraction effects are both modeled. Because of the elliptic nature of this equation the numerical solution is quite involved. Neglecting the diffraction altogether in the mild slope equation results in the wave ray (geometric optics) approximation. An intermediate case is obtained by neglecting the diffraction only in the main wave propagation direction and maintaining it in the transverse direction, which results in the so-called parabolic approximation.

A wave propagation model, frequently used in the current Dutch advisory practice, is CREDIZ. This numerical model is based on the parabolic approximation and determines the combined effect on a monochromatic wave field of arbitrary bottom topographies and current patterns, including energy dissipation effects due to wave breaking and bottom friction (Radder, 1979, Booij, 1981). To assess the accuracy of CREDIZ, two verification studies in laboratory wave basins have been carried out. Recently, a field study in a coastal region in the SW part of the

3) Rijkswaterstaat, Department of Data Processing, Rijswijk, the Netherlands

4) Delft University of Technology, Delft, the Netherlands.

Netherlands, offshore the Haringvliet sluices, was conducted. Results of these verification studies are reported here.

2.0 MATHEMATICAL FORMULATION OF CREDIZ

Without sources and sinks, the mild slope equation, including currents reads

$$\nabla \cdot (cc_g \nabla \phi) + 2i\omega \vec{U} \cdot \nabla \phi - (\omega_r^2 - \omega^2 - k^2 cc_g) \phi = 0, \tag{1}$$

where terms with  $\nabla \cdot \vec{U}$  and  $\vec{U}^2$  are neglected.  $\vec{U}$  is the (steady) current velocity,  $\nabla$  is the horizontal gradient operator,  $\phi(x_1, x_2)$  is the complex wave potential function,  $k$  is the wave number,  $\omega$  is the absolute angular frequency and  $\omega_r$  is the relative angular frequency. The absolute and the relative frequency are related by

$$\omega = \omega_r + \vec{k} \cdot \vec{U}, \tag{2}$$

where  $\omega_r$  fulfils the linear dispersion relation

$$\omega_r = [gk \tanh kh]^{\frac{1}{2}} \tag{3}$$

with  $g$  being the gravity acceleration and  $h$  the local depth.

In the parabolic approximation the assumption is made that the waves propagate mainly into a specific direction  $s$ . Introducing the coordinate  $n$ , which is orthogonal to  $s$ , an operator  $M$  can be defined by

$$M\phi = (\omega^2 - \omega_r^2) \phi + \frac{\partial}{\partial n} (\beta \frac{\partial \phi}{\partial n}) + 2i\omega U_n \frac{\partial \phi}{\partial n} \tag{4}$$

where  $\beta = cc_g$  and  $U_n$  is the current component in the direction  $n$ . The parabolic approximation to (1) is then given by

$$\left( \frac{i\omega U_s}{\beta} + \frac{\partial}{\partial s} \right) [\sqrt{\beta k} \phi + \frac{p_1}{k\sqrt{\beta k}} M\phi] - ik\sqrt{\beta k} \phi - i \frac{p_2}{\sqrt{\beta k}} M\phi = 0, \tag{5}$$

where the coefficients  $p_1$  and  $p_2$  result from the approximation of pseudo operators by differential operators and are related by

$$p_2 = p_1 + 1/2, \quad 0 \leq p_1 \leq 1/2 \text{ (optimal, } p_1 = 1/4). \tag{6}$$

Because of the intended use in coastal areas, wave dissipation is also modeled in CREDIZ, i.e. both dissipation due to bottom friction and dissipation due to wave breaking are accounted for. Introduction of dissipative terms leads to the addition of the following expression to the left-hand side of (5)

$$\left( \frac{i\omega U_s}{\beta} + \frac{\partial}{\partial s} \right) p_1 \frac{i\omega W}{k\sqrt{\beta k}} \phi + p_2 \frac{\omega W}{\sqrt{\beta k}} \phi. \tag{7}$$

where  $W = W_b + W_f$ , and  $W_b$  and  $W_f$  are the contributions due to wave breaking and bottom friction respectively. For the dissipation due to bottom friction is used

$$W_f = \frac{s_o^2}{2g} \left( \frac{8}{3\pi} f_w s_o H + 2f_s \dot{U} \right), \quad s_o = \omega_r / \sinh(kd). \quad (8)$$

where  $f_w$  and  $f_s$  are coefficients for the wave-induced and the wave-current induced parts of the shear stress. Standard values are  $f_w = 0.01$  and  $f_s = 0.005$ . The dissipation due to wave breaking is modeled according to the model of Battjes and Janssen (1978) (see also Battjes and Stive (1984) in these proceedings).

The influence of the wave amplitude  $a$  on the propagation velocity is taken into account in an approximate way, following Walker (1976): for the depth  $h$  in the dispersion relation (3) is taken

$$h = d + p_v * a,$$

where  $d$  is the actual mean water depth and  $p_v$  is an adjustable parameter, with a standard value of 1. It is noted that in the limit for shallow water the wave celerity of a solitary wave from the KdV equation results for  $p_v = 1$ . In the deep water limit the linear expression for  $c$  is recovered.

The solution of (5) requires the availability of initial and boundary conditions. The initial values can be derived from the incoming wave field, which may be (weakly) non-uniform with regard to amplitude and direction. For the lateral boundaries, one has to deal with the presence of open boundaries on which the wave field is generally not known. A simple boundary condition is

$$\cos\chi \frac{\partial\phi}{\partial s} + \sin\chi \frac{\partial\phi}{\partial n} = ik\phi,$$

which ensures the absorption of waves with local wave number  $k$  approaching under an angle  $\chi$  exactly, and waves in other directions are absorbed partially. A zone along the lateral boundaries in which the results are less accurate is indicated in the sketch.

### 3.0 VERIFICATIONS

#### 3.1 Laboratory

In the laboratory both a simple and a realistic bottom topography were used; both periodic and random, unidirectional waves without currents were applied. In the simple situation, consisting of a parabolic shoal on a sloping bottom, small amplitude waves were applied to study the purely linear part of CREDIZ only: results are given by Berkhoff et al. (1982). Here we report results of a computation in which amplitude effects are taken into account. The more realistic situation pertained to a coastal topography at the NW coast of Spain. In this case also finite-amplitude waves were applied resulting in breaking waves in the model.

The shoal situation.

The simple laboratory situation consisted of a parabolic shoal (elliptic in the plane) placed on a 1/50 shoaling bottom, see Figs. 1 and 2. The measurements were conducted in a wave basin of 30 by 35 m in extent and a 20 by 20 m measuring areas was taken in which a measuring grid of at least .5 by .5 m was taken: locally this grid was reduced to .25 by .25 m. The comparison of the computed and measured wave field is specifically carried out along five sections tranverse to and three sections in the wave propagation distance, see Fig. 1. A comparison of the iso-amplitude contours for the situation of regular waves (incoming wave amplitude 2.32 cm and wave period T = 1 s) is given in Fig. 3. Here purely linear wave propagation in the computation is considered, see also Berkhoff et al. (1982) from which this case is taken. The iso-amplitude contours show a satisfactory agreement, but locally, in the convergence zone, some deviations in lateral extent of the convergence region can be noticed. This is mainly due to the linear nature of the computation, as confirmed by Kirby and Dalrymple (1984) who took non-linearity into account. Because CREDIZ also allows the incorporation of an amplitude effect on the wave propagation characteristics by choosing  $p_v \neq 0$ , we recomputed the shoal situation at the end of September 1984, taking  $p_v = 1$ . The iso-amplitude contours for this situation are shown in Fig. 4, giving indeed a better correspondance with the measurements behind the shoal. The difference between the two computations ( $p_v = 0$  versus  $p_v = 1$ ) can be most clearly seen by considering sections 5 and 6. The results are given in Fig. 5 for both  $p_v = 0$  and  $p_v = 1$ . For both sections 5 and 6 a much better correspondance with the measurements is obtained for the  $p_v = 1$  case compared to the  $p_v = 0$  case, although even in the purely linear situation a satisfactory correspondance is obtained. For both situations the rms deviations  $\epsilon_{rms}$  and the bias b are defined by

$$b = n^{-1} \Sigma (a_c - a_m) / [n^{-1} \Sigma a_m]$$

$$\epsilon_{rms} = [n^{-1} \Sigma (a_c - a_m)^2]^{1/2} / [n^{-1} \Sigma a_m]$$

We have for section 5 and 6 separately and for all sections together the following results (taken from Dingemans and Radder, 1984)

section	$p_v = 1$		$p_v = 0$	
	b	$\epsilon_{rms}$	b	$\epsilon_{rms}$
5	0.9	10.6	2.5	35.8
6	-1.2	10.8	10.2	36.7
all	3.0	10.2	3.0	22.5

Table 1 Bias b and rms deviation  $\epsilon_{rms}$  in %

The realistic laboratory situation.

The realistic bottom geometry concerns a coastal region near San Ciprian (NW Spain), built in a wave basin for other purposes, see Fig. 6. The region of interest is also shown in the Figure. Notice the cape just seawards from the proposed breakwater alignment. The measuring grid is

shown in Fig. 7. Of the several tests in which the significant wave period, wave height, etc. were varied, the cases of run 6 with very high initial wave height and run 3 with moderate initial wave height are discussed here; in both tests random waves were applied. For the other cases reference is made to Stive and Dingemans (1983). The iso-wave height lines for both the measurement and the computation of run 6 are shown in Fig. 8, together with contour lines of the normalized difference (in %). The comparison is done point by point. The rms deviation is 16% with a bias of 9%. Along the breakwater the comparison is shown in Fig. 10. It is seen that the computed wave heights are essentially higher than the measured ones, but the trend is nearly the same. For this case much wave breaking occurred in the model experiment. For run 3 the results are shown in Figures 9 and 11; the rms deviation is 10.8% and the bias is 5.3%. Both computations for runs 3 and 6 were carried out with  $p_v = 1$  and  $\gamma = 0.8$ , while no bottom friction effects were taken into account. For run 3 wave breaking is of no importance, but for run 6 it is (breaking waves were observed in the physical model). Estimating  $\gamma$  with the formula given by Battjes and Stive (1984) yields for run 3  $\gamma = 0.70$  and for run 6  $\gamma = 0.83$ ; therefore the deviation along the breakwater alignment for run 6 (Fig. 10) cannot be explained by differences in wave breaking characteristics (the value for  $\gamma$  used is lower than the optimal one and with the latter the deviation would become larger). It seems that the computed results are somewhat smeared out in CREDIZ; this is presumably due to an overemphasis of the diffraction effect. This can also be observed from Figs. 12 and 13 in which scatter plots of the results are given. The variation in computed wave heights is less than it is in the measured ones. From the other cases studied in Stive and Dingemans (1983) it was found that the correspondance of CREDIZ is closer in the random wave tests than it is in the periodic wave tests, which is fortunate because CREDIZ is meant to be applied in the field. The present measurements applied random wave without directional spreading so that it may be expected that the correspondance between computations with the monochromatic model CREDIZ and measurements becomes even more close in situations in which tests are conducted with a two-dimensional spectrum.

### 3.2 Field

For the field measurements a region offshore the Haringvlietsluices was chosen. The area is characterized by a shallow shoal which falls partly dry during low tide, a region with nearly straight isobaths offshore the shoal, and a complicated bottom geometry inshore of the shoal, see Fig. 14. A measurement campaign was especially set up in order to assess the applicability of CREDIZ in realistic field situations. At the start of the project the results of the shoal experiment (see Berkhoff et al. (1982)) were available and therefore the main attention was directed to those aspects not yet studied, i.e. the dissipation processes and the effect of non-linearity on the wave celerity. Six waverider buoys were placed more or less around the Hinderplaat; the one available directional buoy (a WAVEC buoy) was especially used to obtain good initial conditions for the computations. Furthermore, two wave staffs were present in the region. Further offshore also wave information was available from the platform LEG and the waverider EURO-3. The measurement campaign was conducted in Fall 1982 and lasted 13 weeks of which during the first 8 weeks the directional buoy was available.

The method of comparison in this case of a relatively small number of point measurements is done as follows. From the file of measurements, given in the form of wave parameters, measurements under specific conditions were selected. Several wave registrations meeting these conditions are usually found, sometimes several weeks apart. A computation is performed for the averaged boundary condition, usually provided by the WAVEC. The comparison is based on the averaged wave parameters at each sensor location. Another method concerns a hindcast in which single measurements are used. Computed wave heights are averaged afterwards over some spatial region because the wave measurement at a sensor location is taken to be characteristic for some region of space; here a region of 250 by 250 m is used.

One measurement condition was called "the ideal condition" because of the fact that a wave condition was selected for which the mathematical model may be expected to give reasonable results. The selection criteria consisted of: 1) registrations of good quality, 2) not too low water levels (water levels between 1.25 and 1.60 m with respect to chart datum (NAP)), 3) not too low waves ( $H_{mo} > .50$  m), 4) waves from the North-West (principal wave direction between  $300^\circ$  and  $330^\circ$ ), being the direction which is nearly perpendicular to the isobaths offshore the Hinderplaat, 5) not too much directional spreading, and 6) old waves, giving swell-type of waves. Five wave registrations were found to comply with these criteria, two on September 22 and three on October 16. Since not all sensors were sampled simultaneously, a time window was applied in order to obtain approximately simultaneous wave registrations at the various sensors. As time window was taken  $t - 25 \text{ min} \leq t_o \leq t + 35 \text{ min}$ , where  $t_o$  is the start time of the wave registration at either the WAVEC or at the staff Ha-1, which were samples starting at each whole hour (the WAVEC for one half hour duration and Ha-1, as were all other sensors, for 20 minutes).

The mean values of  $H_s (=H_{mo})$ ,  $T_p$ , the principal wave direction  $\theta$  and the water level, WST, at the WAVEC are  $\langle H_s \rangle = 133 \text{ cm}$ ,  $\langle T_p \rangle = 7.02 \text{ s}$ ,  $\langle \theta \rangle = 321.4^\circ$  and  $\langle \text{WST} \rangle = 143 \text{ cm}$ ; the standard deviations are  $s(H_s) = 11.0 \text{ cm}$ ,  $s(T_p) = 0.2 \text{ s}$ ,  $s(\theta) = 3.2^\circ$  and  $s(\text{WST}) = 11.5 \text{ cm}$ . The results of computation T26, with parameters  $p_v = 1$ ,  $\gamma = 0.70$ ,  $f_w = 0.005$  are compared with the measurements in the Table below.

sensor	measurement		computation	
	$\langle H_s \rangle$	$s(H_s)$	$\langle H \rangle$	$s(H)$
WR1	133.7	8.4	130.0	5.4

Table 2 Comparison of ideal condition with CREDIZ computation T26.  
Wave heights in cm

A quite satisfactory correspondance is obtained at all sensor locations, except at location E-75, close to the sluices. At E-75 a relatively large discrepancy is found; the principal reason is that the location is far behind the breaker zone (visible in Fig. 15 for the iso-amplitude contours) and the characteristic wave period T differs much before and behind a strong dissipation zone. The relative error is defined by  $\delta = (\langle H \rangle - \tilde{H}_s) / \tilde{H}_s$ . Taken over all sensors we have  $\langle \delta \rangle = 7.4\%$ , where as for E-75 alone we have  $\delta = -42\%$ ; without E-75 one has  $\langle \delta \rangle = 3.0\%$  and  $s(\delta) = 2.1\%$ .

#### The hindcast.

The period of 14 and 15 October 1982 was selected for the hindcast; wind and water level time histories are shown in Fig. 16. In the hindcast period a rather constant wind direction from North-Westerly directions is present. An example of a wave spectrum of the directional buoy is shown in Fig. 17 and a nearly simultaneous spectrum of WR4 (behind the Hinderplaat) is given in Fig. 18. The results of the hindcast is shown in Figs. 19-21 in which the crosses denote the computed wave heights and the points the ones measure ( $H_{mo}$ ). A scatter plot of all pairs computed and measured wave heights is given in Fig. 22. Especially E-75 is seen to give unsatisfactory results, and for low water levels, also WR4. In terms of the bias and the rms deviation the results as given in the following Tables are obtained. The bias b and the rms deviation  $\epsilon_{rms}$  are defined by

$$b = n^{-1} \Sigma (\langle H \rangle - \tilde{H}_s) / [n^{-1} \Sigma \tilde{H}_s]$$

$$\epsilon_{rms} = [n^{-1} \Sigma (\langle H \rangle - \tilde{H}_s)^2]^{1/2} / [n^{-1} \Sigma \tilde{H}_s]$$

time	17:00	20:00	22:00	23:00	02:00	04:00
WST	-10	20	85	170	150	45
all sensors	29.6	37.2	18.9	8.6	16.0	22.3
not E-75	21.3	27.6	13.9	7.9	9.5	22.7
not E-75, WR4	8.2	12.5	8.9	8.5	7.3	13.5

Tabel 5 Overall error  $\langle \delta \rangle$  in %

Because of the before mentioned fact that CREDIZ is not suited to predict the wave height at E-75, the station far behind the dissipation zone, with reasonable accuracy and because for low water levels the predicted wave height at WR4, just behind the Hinderplaat is not accurate, the figures for the case that both E-75 and WR4 are excluded have most significance. Notice that the shallowest part of the Hinderplaat is only 10 cm below chart datum and that the bottom soundings at the Hinderplaat are relatively less accurate than elsewhere in the region. It thus follows from the hindcast that wave heights are predicted with an accuracy of at least 15%.

#### 4.0 CONCLUSION

Despite the schematization to monochromatic waves and nearly linear wave propagation the model CREDIZ performs remarkably well for engineering purposes in a variety of conditions in coastal areas, as indicated by both the laboratory and the field verification studies. The findings may be stated as follows.

- For those situations in which the (random) wave field can be characterized by a single frequency and a single wave height measure, CREDIZ gives quite accurate results for the wave height in coastal areas, typically better than 15% deviation. For regions far behind a dissipation zone the results are less accurate, but then the wave field can hardly be characterized by a single frequency.
- From the laboratory studies it followed that the computed wave height field is smoother than the measured one for periodic waves. CREDIZ is more suited for application to random wave fields for not too broad spectra.
- The field comparisons are carried out without accounting for current due to lack of simultaneous current measurements. Currents are typically less than 1 m/s maximum.
- Better results may be obtained by choosing input parameters such as  $\gamma$  for the breaking process and the friction coefficient more carefully than was done here. As an example serves the ideal condition for which deviations of less than 5% were obtained after a short sensitivity study.

#### ACKNOWLEDGEMENT

The performance and analysis of the field experiments has been carried out by the Advisory Branch Hellevoetsluis of Rijkswaterstaat, under the direction of Mr. W.R. Abels. For the numerical computations we were assisted by Mr. P. v.d. Bosch of Delft Hydraulics Laboratory and Mr. G.M. Visser of the Delta Department of Rijkswaterstaat.

## CHAPTER EIGHTY ONE

### CONFORMAL MAPPING SOLUTION OF A WAVE FIELD ON THE ARBITRARILY SHAPED SEA BOTTOM

by

#### ABSTRACT

A new wave equation has been derived for the full nonlinear dispersive waves propagating over an arbitrarily shaped sea bed. The method of the derivation of the equation uses a conformal mapping technique by which the original domain can be transformed onto a domain with a uniform depth to make the basic equation easily integrable vertically. By taking an inverse Fourier transform, the velocity potential obtained by the integration can be expressed in the form which can construct the exact wave equation from the water surface boundary conditions. An algorithm for the numerical integration of the equation is presented with some examples of the solution.

#### 1. INTRODUCTION

Nearshore wave deformation is characterized mainly by the effects of nonlinearity and dispersivity of waves, and non-uniformity of bottom topography. So far there have been many studies on the wave deformation by using the well known KdV equation or Boussinesq equation ( e.g., Peregrine, (1967), Madsen and Mei(1969) ). Although these equations have been modified to include the bottom effect by Kakutani(1972), Shuto(1974), Peregrine (1967) and others, their applicability is limited to slowly varying bottom topography. Furthermore, these wave equations can describe only weak nonlinearity and dispersivity of waves.

The present study derives a new wave equation which may be applied to full nonlinear-dispersive waves propagating over a sea bottom with an arbitrary topography. The method of the derivation of the equation uses a conformal mapping technique by which the original domain can be transformed onto a uniform depth region. The mapping does not change the form of the basic equation, i.e., Laplace's equation on a velocity potential, and simplifies bottom boundary condition so that the basic equation becomes easily integrable. The velocity potential function obtained by the integration includes all components of a time-varying wave number spectrum. Further, the velocity potential function so obtained may be expressed as a function with a convolutional integral by an inverse Fourier transform technique. Hence, the water surface boundary conditions can yield the exact wave equation by using the representation of the velocity potential at the water

surface. An algorithm of the numerical integration of the equation is presented with some examples of the solution. In the appendixes, some descriptions on an analytical method to obtain an approximate solution by using a WKB perturbation technique are presented with a method to estimate wave reflection coefficients.

2. FORMULATION OF EQUATIONS

2.1 Basic Equation and Boundary Conditions in a Mapped Space

Physical plane denoted by  $z = x+iy$  may be transformed conformally onto a  $\zeta$ -plane by an analytical complex function,

$$\zeta = f(z). \tag{1}$$

The function  $f$  can be chosen as that which transforms the domain  $D$  with an arbitrarily shaped bottom topography in the  $z$ -plane onto the domain  $D'$  with a uniform depth  $\beta_0$  in the  $\zeta$ -plane as shown in Fig.1. If we denote  $\zeta$ -plane as  $\zeta = \alpha+i\beta$ , Eq.(1) can be written as

$$\begin{aligned} \alpha &= \phi_1(x,y), \\ \beta &= \phi_2(x,y), \end{aligned} \tag{2}$$

or inversely,

$$\begin{aligned} x &= \psi_1(\alpha,\beta), \\ y &= \psi_2(\alpha,\beta). \end{aligned} \tag{3}$$

The function  $f$  defines the curvilinear coordinates system  $(\alpha,\beta)$  in the original domain. From another point of view, it can be said that the function  $f$  is just a complex velocity potential function so that the constant  $\alpha$  and  $\beta$  lines correspond to equi-potential lines and stream lines, respectively. Therefore, we can utilize the usual potential flow theory to construct the function  $f$  in which one of the stream lines forms the bottom boundary and another stream line coincides with the still water surface. For example, the region over a uniformly sloping beach can be transformed into a constant depth region by the complex function

$$\zeta = \ln z. \tag{4}$$

This is a velocity potential function for the flow due to a point source with a unit strength located at the intersection of bottom line and the still water surface (Fig.2). For the more general case of the bottom topography, we can use a numerical method proposed by, e.g., Chenin and Schwartz (1982).

Fig.1 Conformal mapping of wave field

Fig. 2 Orthogonal curvilinear grid system for uniformly sloping beach

The basic equation and the boundary conditions in the z-plane may be written as follows.

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0, \tag{5}$$

$$\frac{\partial \Phi}{\partial y} = - \frac{\partial \Phi}{\partial x} \cdot \frac{\partial h}{\partial x}, \quad y = -h(x) \tag{6}$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial \Phi}{\partial x} \cdot \frac{\partial \eta}{\partial x} - \frac{\partial \Phi}{\partial y} = 0, \quad y = \eta(x, t) \tag{7}$$

$$\frac{\partial \Phi}{\partial t} + \frac{1}{2} \cdot \left[ \left( \frac{\partial \Phi}{\partial x} \right)^2 + \left( \frac{\partial \Phi}{\partial y} \right)^2 \right] + g\eta = 0, \quad y = \eta(x, t) \tag{8}$$

where  $\Phi$  is a velocity potential,  $h$  is a water depth,  $\eta$  is a water surface elevation, and  $g$  is the gravitational acceleration.

In the  $\zeta$ -plane, the boundary conditions become

$$\frac{\partial \Phi}{\partial \beta} = 0, \quad \beta = -\beta_0 \tag{9}$$

$$\frac{\partial \tilde{\eta}}{\partial t} + s^2 \cdot \left[ \frac{\partial \Phi}{\partial \alpha} \cdot \frac{\partial \tilde{\eta}}{\partial \alpha} - \frac{\partial \Phi}{\partial \beta} \right] = 0, \quad \beta = \tilde{\eta}(\alpha, t) \tag{10}$$

$$\frac{\partial \Phi}{\partial t} + \frac{s^2}{2} \cdot \left[ \left( \frac{\partial \Phi}{\partial \alpha} \right)^2 + \left( \frac{\partial \Phi}{\partial \beta} \right)^2 \right] + g \cdot \psi_2(\alpha, \tilde{\eta}) = 0, \quad \beta = \tilde{\eta}(\alpha, t) \tag{11}$$

where  $s$  is a scale factor related with the mapping defined as

$$s = \left| \frac{d\zeta}{dz} \right|. \tag{12}$$

In the water surface boundary conditions (10) and (11), the scale factor  $s$  is coupled with the nonlinear terms. Hence it can be said that the scale factor  $s$  directly affects the nonlinearity of waves. Further, the scale factor  $s$  represents nonuniformity of the gravity as will be shown later.

In contrast with the boundary conditions, the basic equation remains its form unchanged through the mapping by the nature of the conformal transform, i.e.,

$$\frac{\partial^2 \Phi}{\partial \alpha^2} + \frac{\partial^2 \Phi}{\partial \beta^2} = 0. \tag{13}$$

Therefore, the basic equation can be easily integrable vertically on the  $\zeta$ -plane with the simplified bottom boundary condition (9).

2.2 General Solution of the Basic Equation

The Fourier transform of Eq.(13) with regard to  $\alpha$  becomes

$$\frac{\partial^2 \bar{\Phi}}{\partial \beta^2} + k^2 \bar{\Phi} = 0, \tag{14}$$

where  $\bar{\Phi}$  is the Fourier transform of  $\Phi$  with respect to  $\alpha$  defined as

$$\bar{\Phi}(k, \beta, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \Phi(\alpha, \beta, t) \cdot e^{-ik\alpha} \cdot d\alpha. \tag{15}$$

Eq.(14) can be integrated with the bottom boundary condition

$$\frac{\partial \bar{\Phi}}{\partial \beta} = 0,$$

to yield

$$\bar{\Phi}(k, \beta, t) = A(k, t) \cdot \frac{\cosh k(\beta + \beta_0)}{\cosh k\beta_0}. \tag{16}$$

Therefore,  $\Phi$  is represented by the inverse Fourier transform of  $\bar{\Phi}$

$$\Phi(\alpha, \beta, t) = \int_{-\infty}^{\infty} A(k, t) \cdot \frac{\cosh k(\beta + \beta_0)}{\cosh k\beta_0} \cdot e^{ik\alpha} \cdot dk, \tag{17}$$

where  $A(k, t)$  is a time varying wave number spectrum to be determined by the water surface boundary conditions, Eqs.(10) and (11).

From Eq.(17),  $\Phi_\alpha$ ,  $\Phi_\beta$  and  $\Phi_t$  can be represented as

$$\frac{\partial \Phi}{\partial \alpha} = i \int_{-\infty}^{\infty} k \cdot A(k,t) \cdot \frac{\cosh k(\beta + \beta_0)}{\cosh k\beta_0} \cdot e^{ik\alpha} \cdot dk, \tag{18}$$

$$\frac{\partial \Phi}{\partial \beta} = \int_{-\infty}^{\infty} k \cdot A(k,t) \cdot \frac{\sinh k(\beta + \beta_0)}{\cosh k\beta_0} \cdot e^{ik\alpha} \cdot dk, \tag{19}$$

$$\frac{\partial \Phi}{\partial t} = \int_{-\infty}^{\infty} \frac{\partial}{\partial t} A(k,t) \cdot \frac{\cosh k(\beta + \beta_0)}{\cosh k\beta_0} \cdot e^{ik\alpha} \cdot dk. \tag{20}$$

To execute the inverse Fourier transform of the right hand side of the above equations, we may introduce a new variable  $\chi(\alpha,t)$  defined as

$$\chi(\alpha,t) = \int_{-\infty}^{\infty} A(k,t) \cdot e^{ik\alpha} \cdot dk, \tag{21}$$

and use the following inverse Fourier transform formula ( e.g., Erdélyi, 1954 ),

$$F^{-1} \left[ \frac{\cosh k(\beta + \beta_0)}{\cosh k\beta_0} \right] = - \frac{2\pi}{\beta_0} \left\{ \frac{\sin(\frac{\pi\beta}{2\beta_0}) \cdot \cosh(\frac{\pi\alpha}{2\beta_0})}{\cosh(\frac{\pi\alpha}{\beta_0}) - \cos(\frac{\pi\beta}{\beta_0})} \right\} \equiv K_1(\alpha,\beta), \tag{22}$$

(  $-\beta_0 \leq \beta < 0$  )

$$F^{-1} \left[ \frac{\sinh k(\beta + \beta_0)}{\cosh k\beta_0} \right] = i \cdot \frac{2\pi}{\beta_0} \left\{ \frac{\cos(\frac{\pi\beta}{2\beta_0}) \cdot \sinh(\frac{\pi\alpha}{2\beta_0})}{\cosh(\frac{\pi\alpha}{\beta_0}) - \cos(\frac{\pi\beta}{\beta_0})} \right\} \equiv i \cdot K_2(\alpha,\beta), \tag{23}$$

(  $-\beta_0 \leq \beta < 0$  )

where  $F^{-1}[\cdot]$  is the operator to take inverse Fourier transform. From the above equations and the convolution formula (24) on the inverse Fourier transform,

$$F^{-1}[\bar{f}_1(k) \cdot \bar{f}_2(k)] = \frac{1}{2\pi} \int_{-\infty}^{\infty} f_1(\xi) \cdot f_2(\alpha - \xi) \cdot d\xi. \tag{24}$$

we can express the velocity potential  $\Phi(\alpha,\beta,t)$  and its partial derivatives with respects to  $\alpha$ ,  $\beta$  and  $t$  as follows.

$$\Phi(\alpha,\beta,t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} K_1(\xi,\beta) \cdot \chi(\alpha - \xi,t) \cdot d\xi, \tag{25}$$

$$\frac{\partial \Phi}{\partial \alpha} = \frac{1}{2\pi} \int_{-\infty}^{\infty} K_1(\xi,\beta) \cdot \frac{\partial}{\partial \alpha} \chi(\alpha - \xi,t) \cdot d\xi, \tag{26}$$

$$\frac{\partial \Phi}{\partial \beta} = \frac{1}{2\pi} \int_{-\infty}^{\infty} K_2(\xi,\beta) \cdot \frac{\partial}{\partial \alpha} \chi(\alpha - \xi,t) \cdot d\xi, \tag{27}$$

$$\frac{\partial \Phi}{\partial t} = \frac{1}{2\pi} \int_{-\infty}^{\infty} K_1(\xi,\beta) \cdot \frac{\partial}{\partial t} \chi(\alpha - \xi,t) \cdot d\xi. \tag{28}$$

Hence the water particle velocity in the  $\zeta$ -plane can be calculated through these equations by prescribing the value of  $\chi$ . However it should be noted that the region in which the above equations are valid is  $-\beta_0 \leq \beta < 0$ .

2.3 Derivation of Linear Full Dispersive Wave Equation

For linear waves, the water surface boundary condition on  $\Phi$  becomes

$$\frac{\partial^2 \Phi}{\partial t^2} + g \cdot s_0(\alpha) \cdot \frac{\partial \Phi}{\partial \beta} = 0, \quad \beta = 0. \tag{29}$$

where  $s_0(\alpha)$  is the scale factor at  $\beta = 0$ . In the above equation, the gravitational acceleration  $g$  is coupled with the scale factor  $s_0(\alpha)$ . Hence, it can be said that, for the linear waves, the mapping replaces the effect of the water depth variation in the  $z$ -plane with that of non-uniformity of the gravity in the  $\zeta$ -plane.

The limit values of  $\Phi_\beta$  and  $\Phi_t$  represented as Eqs.(26) and (27) when  $\beta \rightarrow -0$  are

$$\lim_{\beta \rightarrow -0} \frac{\partial \Phi}{\partial \beta} = \frac{1}{2\beta_0} \int_{-\infty}^{\infty} K(\xi) \frac{\partial}{\partial \alpha} \chi(\alpha - \xi, t) d\xi,$$

$$\lim_{\beta \rightarrow -0} \frac{\partial \Phi}{\partial t} = \frac{\partial}{\partial t} \chi(\alpha, t),$$

where  $K(\xi)$  is a kernel function defined as

$$K(\xi) = \operatorname{cosech}\left(\frac{\pi}{2\beta_0} \xi\right). \tag{30}$$

Substituting these equations into Eq.(29) and using the relation  $\chi_t = g \cdot \eta$ , we can obtain the following linear wave equation to describe evolution of water surface elevation  $\eta$ .

$$\frac{\partial^2}{\partial t^2} \eta(\alpha, t) + \frac{g}{2\beta_0} \cdot s_0(\alpha) \cdot \int_{-\infty}^{\infty} K(\xi) \frac{\partial}{\partial \alpha} \eta(\alpha - \xi, t) d\xi = 0. \tag{31}$$

In the second term of the above equation, the non-uniformity of the gravity expressed as  $g \cdot s_0(\alpha)$  represents the effect of bottom topography in the original  $z$ -plane and the convolutional integral includes the effect of wave dispersivity. For long waves, Eq.(31) becomes

$$\frac{\partial^2}{\partial t^2} \eta(\alpha, t) - g \cdot s_0(\alpha) \cdot \beta_0 \cdot \frac{\partial^2}{\partial \alpha^2} \eta(\alpha, t) = 0. \tag{32}$$

2.4 Derivation of Full Nonlinear-Dispersive Wave Equation

Nonlinear wave equation may be derived by the almost same manner as the case of linear waves. In this case, however, Eqs.(26) to (28) on  $\Phi_\alpha$ ,  $\Phi_\beta$  and  $\Phi_t$  are not applicable in the region of  $\beta \geq 0$  as already mentioned. This limitation is originated from the formula (22) and (23) on the kernel functions  $K_1$  and  $K_2$ . Therefore, alternative methods must be developed to evaluate the value of those kernel functions at the water surface boundary.

The one method is to reevaluate  $K_1$  and  $K_2$  by replacing the denominator of Eq.(16) with  $\cosh k(a_0 + \beta_0)$  where  $a_0$  is a parameter chosen as  $a_0 > \tilde{\eta}_{\max}$ . The other method is to take Taylor expansion of the functions to be transformed in Eqs.(22) and (23) around  $\beta = 0$ . The results by the latter method become as follows.

$$K_1(\alpha, \beta) = 2\pi \sum_{n=0}^{\infty} (-1)^n \frac{\beta^{2n}}{(2n)!} \cdot \delta^{(2n)}(\alpha) + \frac{\pi}{\beta_0} \int_{-\infty}^{\infty} K(\xi) \cdot \sum_{n=0}^{\infty} (-1)^n \frac{\beta^{2n+1}}{(2n+1)!} \cdot \delta^{(2n+1)}(\alpha - \xi) d\xi, \tag{33}$$

$$K_2(\alpha, \beta) = \frac{\pi}{\beta_0} \int_{-\infty}^{\infty} K(\xi) \cdot \sum_{n=0}^{\infty} (-1)^n \frac{\beta^{2n}}{(2n)!} \cdot \delta^{(2n)}(\alpha - \xi) d\xi - 2\pi \sum_{n=0}^{\infty} (-1)^n \frac{\beta^{2n+1}}{(2n+1)!} \cdot \delta^{(2n+1)}(\alpha), \tag{34}$$

where  $\delta^{(n)}(\alpha)$  is the n-th derivative of Dirac's delta function. From Eqs. (33) and (34),  $\Phi_\alpha$ ,  $\Phi_\beta$  and  $\Phi_t$  can be expressed as

$$\frac{\partial \Phi}{\partial \alpha} = \chi^{(1)}(\alpha, t) + \frac{\beta}{2\beta_0} \int_{-\infty}^{\infty} K(\xi) \cdot \chi^{(2)}(\alpha - \xi, t) d\xi + \dots, \tag{35}$$

$$\frac{\partial \Phi}{\partial \beta} = \frac{1}{2\beta_0} \int_{-\infty}^{\infty} K(\xi) \cdot \chi^{(1)}(\alpha - \xi, t) d\xi - \beta \cdot \chi^{(2)}(\alpha, t) + \dots, \tag{36}$$

$$\frac{\partial \Phi}{\partial t} = \frac{\partial}{\partial t} \chi(\alpha, t) + \frac{\beta}{2\beta_0} \int_{-\infty}^{\infty} K(\xi) \cdot \frac{\partial}{\partial t} \chi^{(1)}(\alpha - \xi, t) d\xi + \dots, \tag{37}$$

where the superscripts (n) for  $\chi$  indicate the n-th order partial derivative with respect to  $\alpha$ .

Substitution of Eqs.(35) to (37) into the surface boundary conditions (10) and (11) leads to the following integro-differential equations on  $\tilde{\eta}$  and  $\chi$ .

$$\frac{\partial \tilde{\eta}}{\partial t} + \frac{1}{2\pi} \cdot s^2(\alpha, \tilde{\eta}) \cdot \left[ \int_{-\infty}^{\infty} K_1(\xi, \tilde{\eta}) \frac{\partial}{\partial \alpha} \chi(\alpha - \xi, t) d\xi \cdot \frac{\partial \tilde{\eta}}{\partial \alpha} - \int_{-\infty}^{\infty} K_2(\xi, \tilde{\eta}) \frac{\partial}{\partial \alpha} \chi(\alpha - \xi, t) d\xi \right] = 0, \tag{38}$$

$$\int_{-\infty}^{\infty} K_1(\xi, \tilde{\eta}) \frac{\partial}{\partial t} \chi(\alpha - \xi, t) d\xi + \frac{1}{4\pi} \cdot s^2(\alpha, \tilde{\eta}) \cdot \left[ \left\{ \int_{-\infty}^{\infty} K_1(\xi, \tilde{\eta}) \frac{\partial}{\partial \alpha} \chi(\alpha - \xi, t) d\xi \right\}^2 + \left\{ \int_{-\infty}^{\infty} K_2(\xi, \tilde{\eta}) \frac{\partial}{\partial \alpha} \chi(\alpha - \xi, t) d\xi \right\}^2 \right] + 2\pi g \cdot \psi_2(\alpha, \tilde{\eta}) = 0. \tag{39}$$

Since the equations are derived without any assumptions and constraints, they constitute a set of exact wave equations on  $\tilde{\eta}$  and  $\chi$ . Therefore they can essentially express arbitrary degree of nonlinearity, dispersivity and the effect of non-uniformity of the water depth.

Fenton & Rienecker (1980) proposed a numerical method for the accurate solution of nonlinear equations for water waves over a horizontal bed. The method uses the finite Fourier series approximation on the velocity potential  $\phi$  and predicts the evolution of water surface elevation  $\eta$  with that of the Fourier coefficients. On the contrary, the wave equations (38) and (39) include all components of the continuous wave number spectrum  $A(k, t)$ , and they can describe directly the evolution of  $\tilde{\eta}$  and  $\chi$  in the physical space.

### 3. NUMERICAL SOLUTION OF WAVE EQUATIONS

#### 3.1 Algorithm of the Numerical Integration of the Equations

The kernel function  $K(\xi)$  included in the linear wave equation (31) and the nonlinear wave equations (38) and (39) has a singularity at  $\xi = 0$  such as

$$\lim_{\xi \rightarrow \pm 0} K(\xi) = \pm \infty.$$

To avoid this singularity the following procedure has been developed.

If the interval of integration of a convolutional integral  $I(\alpha, t)$  for  $K(\alpha)$  and a continuous function  $f(\alpha, t)$  is divided into the three parts as

$$\begin{aligned} I(\alpha, t) &= \int_{-\infty}^{\infty} K(\xi) \cdot f(\alpha - \xi, t) d\xi \\ &= \left( \int_{-\infty}^{-\Delta\xi} + \int_{-\Delta\xi}^{\Delta\xi} + \int_{\Delta\xi}^{\infty} \right) \cdot K(\xi) \cdot f(\alpha - \xi, t) d\xi \\ &= I_1 + I_2 + I_3, \end{aligned} \tag{40}$$

then the singularity is included in the second integral  $I_2$ . Substitution of the Taylor expansion of  $f(\alpha - \xi, t)$  around  $\xi = 0$  into the second integral  $I_2$  leads to

$$I_2(\alpha, t) = \sum_{n=0}^{\infty} \int_{-\Delta\xi}^{\Delta\xi} (-1)^n \frac{\xi^n}{n!} \operatorname{cosech}\left(\frac{\pi}{2\beta_0}\xi\right) d\xi \cdot \frac{\partial^n}{\partial \alpha^n} f(\alpha, t).$$

When  $n$  is an even number, the value of the integral becomes zero in the sense of Cauchy principal value because the kernel function  $K(\xi)$  is an odd function. Thus, if  $\Delta\xi$  is taken to be enough small to neglect the higher order terms,  $I_2(\alpha, t)$  can be evaluated by

$$\begin{aligned} I_2(\alpha, t) &\cong - \int_{-\Delta\xi}^{\Delta\xi} \xi \cdot \operatorname{cosech}\left(\frac{\pi}{2\beta_0}\xi\right) d\xi \cdot \frac{\partial}{\partial \alpha} f(\alpha, t) \\ &= -2 \cdot \left(\frac{2\beta_0}{\pi}\right)^2 \cdot \operatorname{Shi}^* \left(\frac{\pi}{2\beta_0}\Delta\xi\right) \cdot \frac{\partial}{\partial \alpha} f(\alpha, t), \end{aligned} \quad (41)$$

where

$$\begin{aligned} \operatorname{Shi}^*(x) &= \int_0^x \frac{\xi}{\sinh \xi} d\xi = \sum_{k=0}^{\infty} \frac{(2-2^{2k})B_{2k}}{(1+2k)(2k)!} x^{1+2k} \\ &= x - \frac{x^3}{3 \cdot 3!} + \frac{7x^5}{15 \cdot 5!} - \frac{31x^7}{21 \cdot 7!} + \frac{127x^9}{15 \cdot 9!} - \dots, \end{aligned} \quad (42)$$

(  $|x| < \pi$  )

and  $B_n$  is Bernoulli numbers.

Using the above procedure, we can obtain an alternative representation of the linear wave equation.

$$\begin{aligned} \frac{\partial^2}{\partial t^2} \eta(\alpha, t) &= -\frac{g}{2\beta_0} s_0(\alpha) \int_{-\infty}^{-\Delta\xi} K(\xi) \frac{\partial}{\partial \alpha} \eta(\alpha - \xi, t) d\xi \\ &\quad + \left(\frac{2}{\pi}\right)^2 \beta_0 g \cdot s_0(\alpha) \cdot \operatorname{Shi}^* \left(\frac{\pi}{2\beta_0}\Delta\xi\right) \cdot \frac{\partial^2}{\partial \alpha^2} \eta(\alpha, t) \\ &\quad - \frac{g}{2\beta_0} s_0(\alpha) \cdot \int_{\Delta\xi}^{\infty} K(\xi) \frac{\partial}{\partial \alpha} \eta(\alpha - \xi, t) d\xi. \end{aligned} \quad (43)$$

Since the above equation has no singularity, it may be easily solved by a usual finite difference scheme.

For the nonlinear wave equation, the almost same procedure as the linear case can be used except that the nonlinear wave equation includes higher order derivatives of the unknown variable  $\chi$ .

3.2 Examples of Numerical Solutions

(1) Linear waves

As an example of the numerical solution for the linear wave equation (43), a calculation has been made for waves propagating over a stepped sea bed with a slope of arbitrary inclination as shown in Fig.3. The scale factor  $s_0(\alpha)$  for this case becomes

$$s_0(\alpha) = \frac{\beta_0}{h} e^{\theta 1/(2\beta_0)} \cdot \left[ \cosh\left(\frac{\pi 1}{2\beta_0}\right) - \tanh\left(\frac{\pi \alpha}{2\beta_0}\right) \cdot \sinh\left(\frac{\pi 1}{2\beta_0}\right) \right]^{-\theta/\pi}, \quad (44)$$

where

$$1 = \frac{\beta_0}{\theta} \cdot \ln\left(\frac{h}{b}\right). \quad (45)$$

The above equation may be obtained by using the Poisson-Schwartz's integral formula. The solid lines in Fig.3 represent the constant  $\alpha$  and  $\beta$  lines. The initial conditions for the integration adopted here are

$$\eta(\alpha, 0) = a \cdot \exp\left[-(\alpha - \alpha_0)^2 / (2\beta_0)^2\right], \quad (46)$$

with  $a = 1.5m, \quad \beta_0 (= h) = 10m,$

and

$$\frac{\partial}{\partial t} \eta(\alpha, 0) = 0.$$

The inclination of the slope  $\theta$  and the water depth ratio  $b/h$  are chosen as the value of  $45^\circ$  and  $1/4$ , respectively. The upper figure in Fig.3 shows the scale factor  $s_0$  as a function of  $x$ . From the meaning of the scale factor as previously mentioned, we can say that, in the  $\zeta$ -plane, the gravitational acceleration for the shallower region is four times as great as that for the large depth region.

The result of the computation is shown in Fig.4 where the full lines represent the solution for the linear full-dispersive wave equation (31), while the broken lines show the solution for the linear long wave equation (32). The full-dispersive wave solution shows that, in contrast with the non-dispersive wave solution, the longer waves propagate faster than the shorter waves. This is a direct manifestation of the wave dispersivity. The figure also shows that the right going waves divide into reflected waves and transmitted waves on the slope.

(2) Nonlinear waves

Nonlinear wave solution has been obtained for the same stepped bottom topography as the above. For the reason of simplicity, only the first terms in the power series of Eqs.(35) to (37) are taken for the calculation here. The initial condition for  $\tilde{\eta}$  is chosen as the same as Eq.(46) but with  $a = 2.0 m$ . The initial condition for  $\chi$  is taken as  $\chi(\alpha, 0) = 0$  which means that there is no fluid motion at the initial stage.

Fig.3 Orthogonal curvilinear grid system and scale factor  $s_0(x)$  for a stepped bottom profile.

Fig.4 Linear wave evolution over a stepped sea bed.

Fig.5 Nonlinear wave evolution over a stepped sea bed.

Fig.6 Nonlinear wave evolution over a uniformly sloping beach.  
 (  $\tan\beta_0 = 1/30$  )

Figure 5 shows the result of the computation and indicates that the dispersion and reflection of waves take place as in the case of linear waves. The figure also reveals that the right going waves steepen their front face as they propagate over the slope and give rise to fission into the several solitons on the step. This phenomena of solitons has been already reported by Madsen and Mei (1969) and is considered to be due to the combined effects of nonlinearity and dispersivity of waves and bottom topography. Figure 6 shows another example for waves on a uniformly sloping beach for which the mapping function  $f$  is defined as Eq.(4).

From these examples, it may be concluded that the wave equation derived in the present study is effective to describe the wave evolution under the combined effects of nonlinearity and dispersivity of waves and nonuniformity of the water depth.

APPENDIX A. WKB Solution for Progressive Waves over a Gradually Varing Bottom

If the bottom variation is gradual, the use of the conformal mapping technique becomes not so essential and an approximate solution can be obtained by a usual WKB method ( e.g., Chu and Mei, 1970 ). However, for the problems such as sediment transport, conformal mapping solutions gives more usefull estimation of bottom velocity field compared with other methods because the conformal mapping solution satisfies exactly the bottom boundary condition.

This appendix describes an approximate method to obtain an analytical conformal mapping solution. The method uses a WKB perturbation technique developed by Hamanaka and Kato (1982).

Introducing a small parameter  $\delta$  which characterizes the horizontal scale of the bottom variation, we can normalize the variables as

$$\begin{aligned} (\alpha', \beta') &= (\delta\alpha, \beta) \cdot \frac{\omega^2}{g}, & t' &= \omega t, \\ (\tilde{\eta}', \beta'_0) &= (\tilde{\eta}, \beta_0) \cdot \frac{\omega^2}{g}, & \Phi' &= \Phi \cdot \frac{\omega^3}{g^2}. \end{aligned} \tag{A-1}$$

For convenience the primes will be dropped from here on. From this normalization the linearized governing equations become

$$\delta^2 \frac{\partial^2 \Phi}{\partial \alpha^2} + \frac{\partial^2 \Phi}{\partial \beta^2} = 0, \tag{A-2}$$

$$\frac{\partial \tilde{\eta}}{\partial t} - s_0^2(\alpha) \cdot \frac{\partial \Phi}{\partial \beta} = 0, \quad \beta = 0 \tag{A-3}$$

$$\tilde{\eta} + s_0(\alpha) \cdot \frac{\partial \Phi}{\partial t} = 0, \quad \beta = 0 \tag{A-4}$$

$$\frac{\partial \Phi}{\partial \beta} = 0, \quad \beta = -\beta_0. \tag{A-5}$$

In the next step, let us introduce a local wave number  $k$  and transform the independent variables as

$$(\alpha, \beta, t) \rightarrow (\alpha, \beta, \xi), \quad \xi = \delta^{-1} \int k d\alpha - t. \tag{A-6}$$

Then Eqs.(A-2) to (A-5) become

$$k^2 \frac{\partial^2 \Phi}{\partial \xi^2} + \frac{\partial^2 \Phi}{\partial \beta^2} = -\delta^2 \frac{\partial^2 \Phi}{\partial \alpha^2} - \delta \left( \frac{\partial k}{\partial \alpha} \cdot \frac{\partial \Phi}{\partial \xi} + 2k \cdot \frac{\partial^2 \Phi}{\partial \alpha \cdot \partial \xi} \right) \tag{A-7}$$

$$s_0^2(\alpha) \cdot \frac{\partial \Phi}{\partial \beta} + \frac{\partial \tilde{\eta}}{\partial \xi} = 0, \quad \beta = 0 \tag{A-8}$$

$$\tilde{\eta} - s_0(\alpha) \cdot \frac{\partial \Phi}{\partial \xi} = 0, \quad \beta = 0 \tag{A-9}$$

$$\frac{\partial \Phi}{\partial \beta} = 0, \quad \beta = -\beta_0. \tag{A-10}$$

The unknown variables  $\Phi$ ,  $\tilde{\eta}$ , and  $k$  may be expanded by  $\delta$  as

$$\begin{aligned} \Phi &= \Phi_0 + \delta\Phi_1 + \delta^2\Phi_2 + \dots, \\ \tilde{\eta} &= \tilde{\eta}_0 + \delta\tilde{\eta}_1 + \delta^2\tilde{\eta}_2 + \dots, \\ k &= k_0 + \delta k_1 + \delta^2 k_2 + \dots. \end{aligned} \tag{A-11}$$

Substituting (A-11) into Eqs. (A-7) to (A-10) and separating the orders we obtain a set of systematically solvable equations. The solutions can be summarized as follows.

At  $O(\delta^0)$ :

$$\begin{aligned} \Phi_0 &= a \cdot \cosh k_0 (\beta + \beta_0) \cdot \sin \xi, \\ \tilde{\eta}_0 &= a \cdot s_0(\alpha) \cdot \cosh k_0 \beta_0 \cdot \cos \xi, \\ s_0(\alpha) \cdot k_0 \cdot \tanh k_0 \beta_0 &= 0. \end{aligned} \tag{A-12}$$

At  $O(\delta^1)$ :

$$\begin{aligned} \Phi_1 &= - \left\{ \frac{1}{2} a (\beta + \beta_0) \frac{\partial k_0}{\partial \alpha} \cosh k_0 (\beta + \beta_0) + \frac{\partial a}{\partial \alpha} (\beta + \beta_0) \sinh k_0 (\beta + \beta_0) \right\} \cdot \cos \xi, \\ \tilde{\eta}_1 &= s_0(\alpha) \cdot \left\{ \frac{1}{2} a \beta_0 \frac{\partial k_0}{\partial \alpha} \cosh k_0 \beta_0 + \frac{\partial a}{\partial \alpha} \beta_0 \sinh k_0 \beta_0 \right\} \cdot \sin \xi, \\ k_1 &= 0. \end{aligned} \tag{A-13}$$

⋮

For nonlinear waves, the solution can be obtained by the almost same manner as the above by introducing another small parameter  $\epsilon$  which characterizes nonlinearity of waves and by representing the unknown variables in the form of double perturbation with respect to  $\delta$  and  $\epsilon$ .

APPENDIX B. Reflection Coefficients for Linear Steady Waves

For the case of the steady waves with angular frequency  $\omega$ , the linear wave equation (31) becomes

$$\hat{\eta}(\alpha) = \frac{g}{2\beta_0\omega^2} \cdot s_0(\alpha) \cdot \int_{-\infty}^{\infty} K(\xi) \cdot \frac{d}{d\alpha} \hat{\eta}(\alpha - \xi) d\xi, \tag{B-1}$$

where  $\hat{\eta}(\alpha)$  is an amplitude of the water surface fluctuation and defined as

$$\eta(\alpha, t) = \hat{\eta}(\alpha) \cdot e^{i(\omega t - \pi/2)}. \tag{B-2}$$

Although Eq.(B-1) can be used to calculate reflection coefficients for linear steady waves, a simpler and more direct method can be developed with an approximation on  $\Phi$ . At first, the assumption is made on the velocity function  $\Phi$  such as

Fig. B1

Fig. B2

$$\Phi = F(\alpha) \cdot \frac{\cosh\{k(\alpha)(\beta + \beta_0)\}}{\cosh\{k(\alpha)\beta_0\}} \cdot e^{i\omega t}, \quad (\text{B-3})$$

which satisfies the bottom boundary condition (9). This equation is valid for the case of  $\Phi_{\alpha\alpha} \ll \Phi_{\beta\beta}$ . In particular Eq.(B-3) becomes exact for long waves.  $k(\alpha)$  in the above equation must hold the following relation from the surface boundary condition (29) on  $\Phi$ .

$$\omega^2 = g \cdot s_0(\alpha) \cdot k(\alpha) \cdot \tanh\{k(\alpha)\beta_0\}. \quad (\text{B-4})$$

From the linearized boundary condition and Laplace's equation on  $\Phi$ , Eq. (B-3) yields the following differential equation on  $\hat{\eta}(\alpha)$ .

$$\frac{d^2}{d\alpha^2} \hat{\eta}(\alpha) + k^2(\alpha) \cdot \hat{\eta}(\alpha) = 0. \quad (\text{B-5})$$

The reflection coefficient  $|r(\alpha)|$  for the wave field expressed by the above equation can be calculated from the following Riccati's equation derived by the invariant imbedding method (Bellman and Kalaba, 1959).

$$\frac{d}{d\alpha} r(\alpha) = -2ik(\alpha) \cdot r(\alpha) - \frac{k'(\alpha)}{2k(\alpha)} \cdot \{1 - r^2(\alpha)\}. \quad (\text{B-6})$$

The reflection coefficient to be obtained is the value of  $|r(\alpha)|$  at  $\alpha = -\infty$ . Therefore, it is more convenient to change the independent variable from  $\alpha$  to  $\xi$  by the function  $\xi = \tanh \alpha$ . From this transform, the domain of the independent variable becomes  $[-1 < \xi < 1]$ .

The reflection coefficient can be obtained by a numerical integration using a usual integration scheme such as Runge-Kutta-Gill method. The integration is to be performed backward from  $\xi = 1$  to  $\xi = -1$  under the initial condition,  $r = 0$  at  $\xi = 1$ .

As an example, the calculation was carried out for the stepped bottom shown in Fig.3. Figure B1 shows the results for the case of  $\theta = \pi/2$ . In this special case, the reflection coefficient can be also estimated accurately by, e.g., Ijima's method (1971) in which the velocity potential is found by matching conditions at the junction of sea bed. The full lines in the figure indicate the result by the present method, while the broken lines show the result by the Ijima's method. It is shown that, for the case of  $\omega^2 h/g = 0.5$  corresponding to shallow water waves, the result by the present method shows fairly good agreement with the Ijima's result, and even for the case of  $\omega^2 h/g = 2.0$  corresponding to almost deep water waves, the present method gives still good results.

The effect of the inclination of the slope has been investigated by the present method. The results are shown in Figs. B2 (a) and (b). From these figures, it is found that the effect of the inclination on the reflection coefficients is more significant for the case of the large value of  $\omega^2 h/g$ . This is considered to be due to the difference of the ratio of the horizontal scale of the slope to the wave length.

## CHAPTER EIGHTY TWO

### A FINITE ELEMENT METHOD FOR STORM SURGE AND TIDAL COMPUTATION

by

Y.COEFFE (1), S.DAL SECCO (2), P.ESPOSITO (3), and B.LATTEUX (4)

#### Abstract

The paper reports the current progress in developing a finite element method for the shallow water equations. Some recent developments as the implementation of a semi implicit scheme or the use of an incident wave condition are described. Different realistic applications are presented concerning tidal and storm surge simulations.

#### Introduction

Long waves in coastal areas, when water depth is small compared to the wave length, can be numerically simulated by the resolution of the shallow water equations. The use of a finite element method is then specially well fitted when the shape of the domain to deal with is rather complex, as it often occurs in the field of maritime hydraulics, or when some areas of particular interest require a finer description (entrance of a harbour, for example).

Such a model has been developed, using a special procedure to reduce the storage requirement by deriving from the basic equations separate problems on each of the scalar variables. The implementation of a semi-implicit scheme makes it possible to avoid wave damping when simulating wave propagation on broad areas with a limited number of nodes in a wave length. Finally the possible use of an incident wave condition, the consideration of the atmospheric forcing terms, as well as the use of spherical coordinates, qualify the model to examine the generation and propagation of storm surges.

Equations and general description of the method

The shallow water equations are the following (\*):

$$\frac{\partial z}{\partial t} + \text{div } \bar{Q} = 0 \quad (1)$$

$$\frac{\partial Q_i}{\partial t} + \text{div} (Q_i \bar{u}) + gh \frac{\partial z}{\partial x_i} - K \Delta Q_i = F_i \quad (i = 1, 2) \quad (2)$$

where

$$\left\{ \begin{array}{l} g = \text{acceleration due to gravity} \\ h = \text{depth of water} \\ K = \text{dispersion coefficient} \\ \bar{Q} \left\{ \begin{array}{l} Q_1 = \text{flow rate per unit length} \\ Q_2 \end{array} \right. \\ \bar{u} \left\{ \begin{array}{l} u_1 = \text{velocity field} \\ u_2 \end{array} \right. \\ z = \text{free surface elevation} \\ \bar{F} \left\{ \begin{array}{l} F_1 = \text{forces (Coriolis, bottom} \\ F_2 \text{ friction, wind, atmospheric} \\ \text{pressure gradient)}. \end{array} \right. \end{array} \right.$$

Fractional step algorithm for the convection terms

Taking a simple first order time discretisation of equations (1) and (2) between two time steps  $t^n$  and  $t^{n+1}$ , the discretised unknown fields  $\bar{Q}^n$ ,  $z^n$ ,  $\bar{u}^n$  and  $\bar{Q}^{n+1}$ ,  $z^{n+1}$ ,  $\bar{u}^{n+1}$  are introduced.

Then, using an auxiliary unknown field  $\bar{Q}^*$ , equations (1) and (2) can be decomposed into a pure convection system and the remainder.

$$\begin{aligned} \text{* convection step : } & \frac{\partial Q_i}{\partial t} + \text{div} (Q_i \bar{u}^n) = 0 \quad (i=1,2) \quad (3) \\ & \text{this step gives } \bar{Q}^* \end{aligned}$$

\* diffusion and propagation step :

$$\left\{ \begin{array}{l} \frac{\partial z}{\partial t} + \text{div } \bar{Q} = 0 \\ \frac{\partial Q_i}{\partial t} - K \Delta Q_i + gh \frac{\partial z}{\partial x_i} = F_i \quad (i=1,2) \end{array} \right. \quad (4)$$

with initial conditions  $z^n$ ,  $\bar{Q}^*$  at  $t^n$ .

The convection step is solved using characteristics method.

---

(\*) These equations are written in cartesian coordinates, but spherical coordinates can also be used in the model.

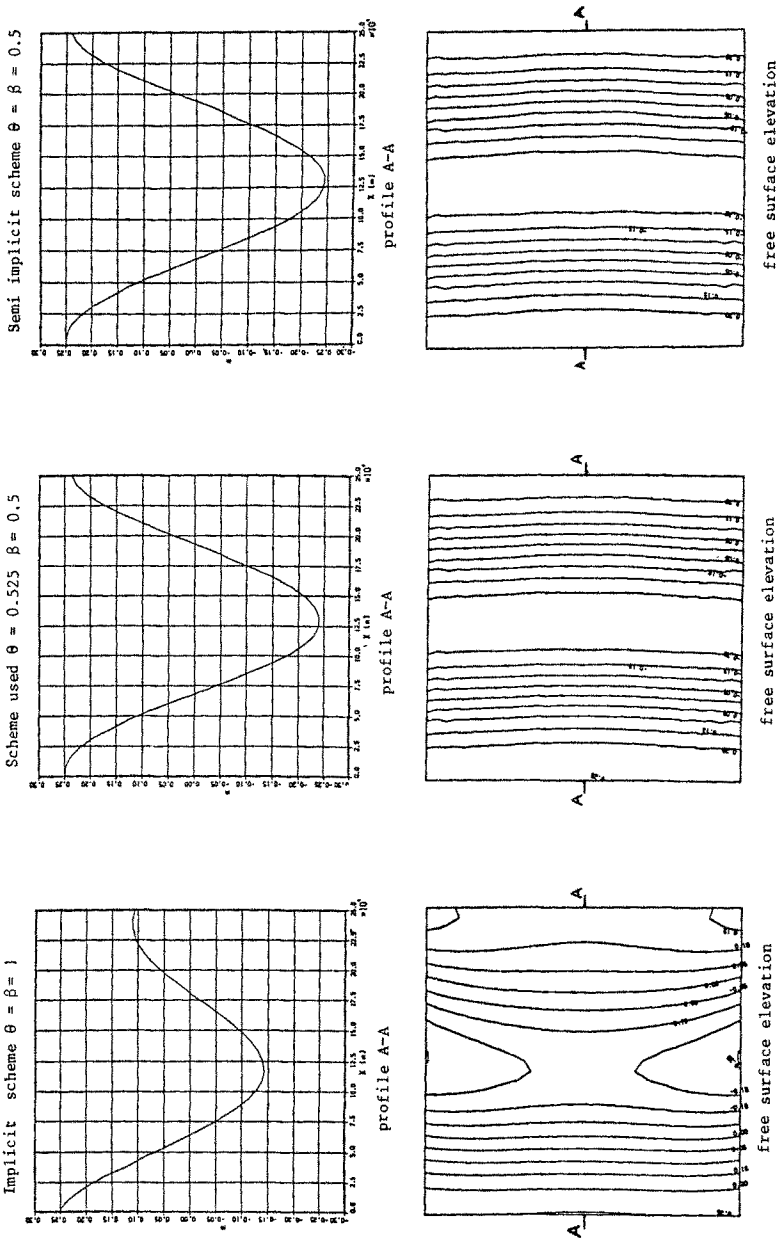

FIGURE 1 : Influence of semi-implication. A plane wave moves from left to right in a square vessel with 17 nodes per wave length.

The main advantages of this method are :

- unconditional stability
- no non-symmetric system to assemble and solve at each time step
- good accuracy (reduced numerical diffusion) when using quadratic shape functions (at least).

The main drawback of classical characteristic method is probably the fact that conservativity is not ensured by the scheme. But a new approach using a weak formulation of equations (3) can be used in order to achieve conservativity [2]. However the results presented in this paper are rather good as for conservativity.

#### Diffusion-Propagation step

A semi-implicit discretisation has been chosen for system (4) because it has been shown that pure implicit schemes have poor propagation characteristics when used on a coarse mesh (figure 1 and [4]).

The non linear term  $g h \text{grad} z$  is first splitted up into two terms :

$$g h_m \text{grad}(z) + g(h - h_m) \text{grad}(z)$$

$h_m$  being a reference depth of water dependant on the location of the point but independent of the time.

Then introducing 
$$\left\{ \begin{array}{l} C = \sqrt{gh_m} : \text{celerity of waves} \\ \alpha = \frac{1}{\Delta t} \\ \theta, \beta \in [0.5, 1] \text{ two coefficients} \end{array} \right.$$

the following discretisation :

$$\left\{ \begin{array}{l} \frac{\partial z}{\partial x_i} = \beta \frac{\partial z^{n+1}}{\partial x_i} + (1 - \beta) \frac{\partial z^n}{\partial x_i} \end{array} \right. \quad (5)$$

$$\left\{ \begin{array}{l} \frac{\partial Q_j}{\partial x_i} = \theta \frac{\partial Q_j^{n+1}}{\partial x_i} + (1 - \theta) \frac{\partial Q_j^n}{\partial x_i} \end{array} \right. \quad (6)$$

leads to the system to be solved :

$$\left\{ \begin{array}{l} \alpha^2 z^{n+1} - K\theta\alpha\Delta z^{n+1} - \theta \text{div}(C^2 \beta \text{grad} z^{n+1}) = W \end{array} \right. \quad (7)$$

$$\left\{ \begin{array}{l} \alpha \bar{Q}^{n+1} - K\theta\Delta \bar{Q}^{n+1} + C^2 \beta \text{grad} \bar{Q}^{n+1} = \bar{T} \end{array} \right. \quad (8)$$

where equation (7) comes from  $\alpha(1) + \theta \text{div}(4)$  and  $(W, \bar{T})$  are known at each time step.

It must be noticed that equation (7) can be solved easily if  $z^{n+1}$  is given on the boundary. Then,  $\bar{Q}$  can be computed from equation (8) where the term  $C^2 \beta \text{grad } z^{n+1}$  is now a known function and can be rejected into the right hand side.

The problem then amounts to the determination of the trace of  $z$  on the boundary. The procedure used for this purpose is an extension of the technique proposed by Glowinski-Pironneau [3] for the Stokes problem. It is described in detail in [1] and [8].

#### Finite Element Discretisation

All the numerical results presented in this paper have been carried out using a quadratic triangular mesh for the flow rate  $\bar{Q}$  and for the surface elevation  $z$ . The elliptic problems of equations (7) and (8) lead to the resolution of 3 symmetric definite matrix problems (one for  $z$  and one for each component of the flow rate). At each time step the boundary conditions for  $z$  is computed through the resolution of 3 problems (similar to the 3 previous one) and the resolution of a boundary problem (the size of its definite matrix being the number of boundary points).

This technique is advantageous on the point of view of computational efficiency. Two "domain" matrices have to be stored, one for the variable  $z$ , another for each component of  $\bar{Q}$  (it is the same matrix for the two components). They are symmetric and sparse and small enough to be processed by an in-core solver such as an incomplete Choleski preconditioned conjugate gradient. In addition, the matrix of the boundary operator has to be factorized and stored.

#### Boundary conditions

On the coast a simple prescribed flux condition can be prescribed :  $\bar{Q} = \bar{0}$ .

On the open boundaries, a specified flux condition (both components) could be too reflexive. In order to specify a wave rather than a flow rate and above all to let waves generated inside leave the domain easily, an incident wave boundary condition may be used. Such a condition, described in details in LABADIE and LATTEUX [8], is written in the following way :

$$\left\{ \begin{array}{l} - C^2 z + K \frac{\partial \bar{Q}}{\partial n} \cdot \bar{n} + c \bar{Q} \cdot \bar{n} = (\bar{n} \cdot \bar{u} - 1) c^2 \psi \quad (9) \\ K \frac{\partial \bar{Q}}{\partial n} \cdot \bar{\tau} + c \bar{Q} \cdot \bar{\tau} = (\bar{\tau} \cdot \bar{u}) c^2 \psi \quad (10) \end{array} \right.$$

Where  $\bar{n}$  and  $\bar{\tau}$  denote boundary exterior normal and tangent vectors,  $\bar{u}$  is a unit vector indicating the direction of the wave to specify and  $\psi$  is a scalar function of space and time describing the incident wave entering the domain through the open boundary ( $z$  and  $\bar{Q}$  must be discretised by equations (5) and (6)). The conditions (9) and (10) allow any wave normal to the boundary to leave the domain

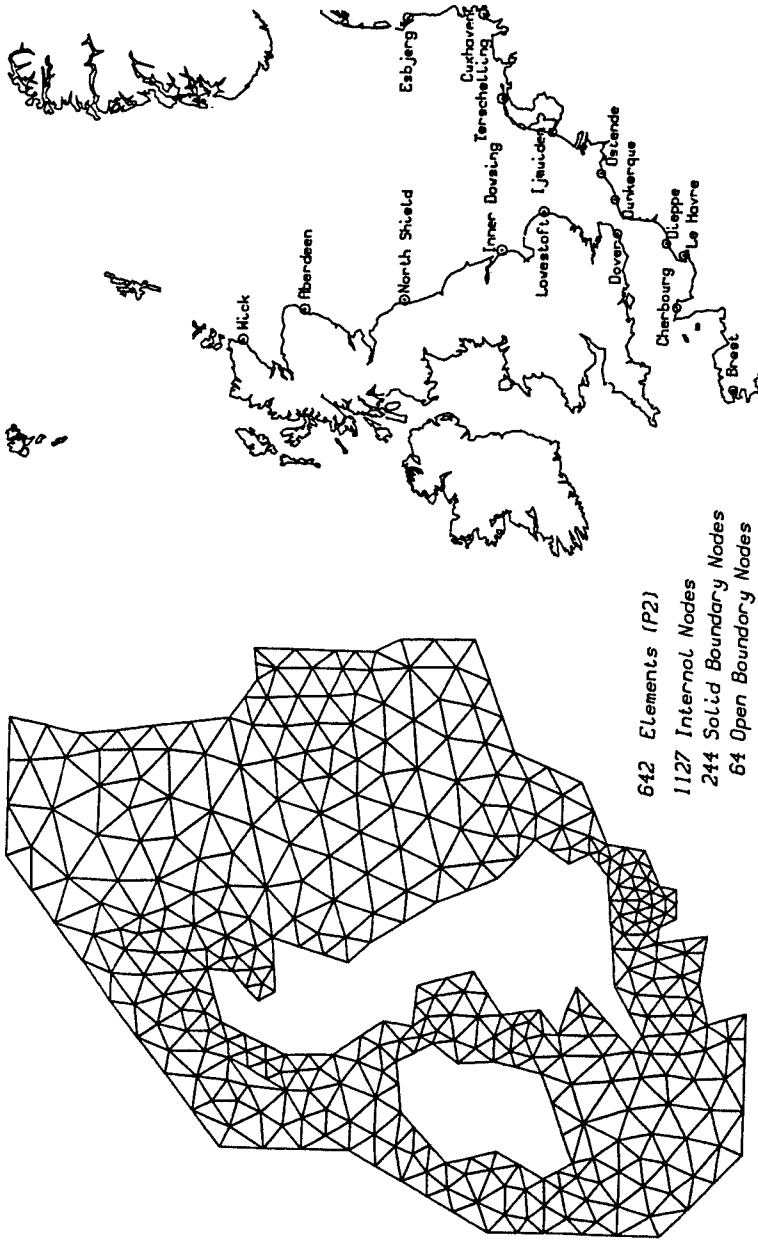

Figure 2 : Finite Element Mesh of the North-West European continental shelf and position of ports

without any reflexion. In the simple study of storm surges described further,  $\psi$  can be chosen as follows :

$$\psi = \psi_0 = \frac{P - P_0}{\rho g}$$

with  $P$  : atmospheric pressure  
 $P_0$  : reference atmospheric pressure : 1013 mb

This expression denotes simple static equilibrium at the edge of the continental shelf. But, as we shall see further, taking  $\psi = 0$  seems to give better results. Other terms may be added in order to take into account tidal forcing.

#### Numerical results

A previous paper [6] reported a first realistic computation concerning the tidal flow pattern in the vicinity of the new outer harbour of Dunkirk.

The present one gives the results of simulation of storm surges on the North-West European Continental Shelf and of tide in the English Channel.

#### The November 1973 storm surge

A series of storm surge computation models of the North-West European Continental Shelf has been developed since 1969 at the I.O.S. (Institute of Oceanographic Sciences, BIDSTON, UK) using finite difference discretisations and a review of this work is given by HEAPS [7]. As a test for an extended prediction covering a period of 44 days, FLATHER [5] computed the surges from 4 november to 18 december 1973 by means of an improved model including tidal influence. Using our model on the spherical coordinate mesh of figure 2 and taking meteorological data from a tape furnished by JONSMOD (JOINT NORTH SEA MODELLING GROUP) we computed the surge of 19 and 20 november.

Figure 3 presents an exemple of surface elevation and currents just before the very high surge of 19 november 13 h TU. It is an instant when the currents reach their maxima. Although the meteorological data have different origins, the results of this computation and previous results from FLATHER [5] are very similar. The comparison between measurements, FLATHER's results and this finite element computation is done by means of the plots of figure 4a and 4b. In order to simulate the surge of 19-20 november, the computation was started 3 days before (16/11/73 at 3 h).

It can be shown that the behaviour of the finite element model is rather good in general and that the two peaks of 16 and 19 November are very well reproduced, although interaction with the tide was not considered in this simulation.

Figure 4 a: STORM SURGES AT CONTINENTAL PORTS

Figure 4b : STORM SURGES AT BRITISH PORTS

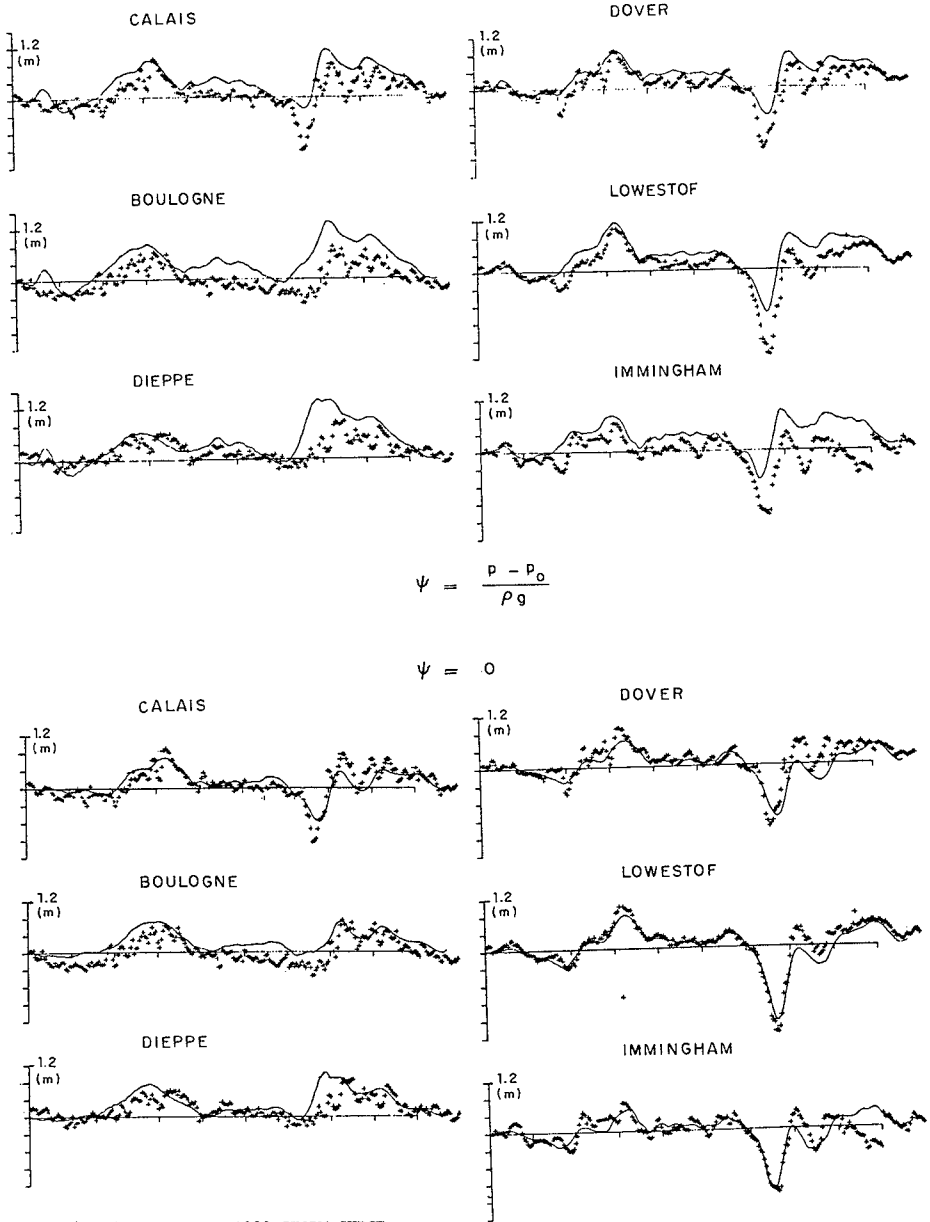

Fig. 5 : DECEMBER 1982 STORM SURGE

#### The December 1982 storm surge

The November 1973 storm surge was mostly what we should call a North Sea storm surge. Indeed, the depression moved approximately East-South-East from somewhere between Iceland and the Faroes, subsequently crossing southern Scandinavia, and was therefore located far away from the English Channel.

The December 1982 storm surge was different because two large depressions successively joined the English Channel while crossing the North Sea. Our first results obtained using the "incident wave condition" and taking  $\Psi = (P-P_0)/\rho g$  showed overestimations of water levels in almost every port. Taking  $\Psi = 0$ , i.e. without generating external waves, but only letting internal waves leave the domain, the results obtained were much better (see figure 5). The reason is that taking  $\Psi = (P-P_0)/\rho g$ , an important external wave normal to the boundary is generated and that was probably not the case in the reality.

Two other storm surges similar to the previous one were simulated and the incident wave condition with  $\Psi = 0$  always gave better results than with  $\Psi = (P-P_0)/\rho g$ . Our conclusion is that the hydrostatic approximation doesn't reproduce correctly an external surge. In particular the effects of the wind are omitted in the expression of  $\Psi$ . Some investigation has to be made on the subject. However the good agreement between observed and computed elevations is very encouraging since we can improve our model using tidal influence, better meteorological data, optimised mesh...

#### Tidal simulation in the English Channel

The tidal phenomenon in the English Channel can be considered as an interesting case for the application of the model on a large domain : tide and currents are rather well known, and the high tide ranges, small depths and strong currents provide a good test for the treatment of the non-linearities of the equations (propagation and friction terms).

The domain extends westwards till to the edge of the continental shelf, and covers on the north-east a small part of the North Sea.

Computation has just begun, under simple conditions : flow discharge prescribed on the boundaries, corresponding to a mean spring tide, and totally implicit numerical scheme. Besides, the advection step is not considered here.

The mesh is rather coarse for this first trial on the English Channel (fig. 6) : there are 220 triangular elements, and 521 nodes of discretization for the quadratic approximation. This rough discretization allows a very fast computation : the whole tide is simulated within less than 10 minutes C.P.U. on a CRAY 1 computer.

Fig.6- Finite element grid of the English Channel

Fig.7- Computed tidal currents at HW. at BREST

b) Measured co - tidal lines

a) Computed co-tidal lines

Fig.8 \_Comparison between computed and measured tide ranges in the English Channel (Mean Spring Tide)

Fig. 7 displays the tidal current pattern at High Water (Brest). Fig. 8 exhibits the comparison between computed and measured tide range over the English Channel. The main features of the complex tidal pattern in this region, as the significant difference between english and french coast, due to the rotation of the Earth, and the wave amplification in the Gulf of Saint-Malo, are qualitatively well reproduced. However a damping of the computed tidal wave is obvious, coming from the use of an implicit scheme : with only 40 nodes in a wave length, the tide range has generally been weakened by 10 to 20 %.

Further computations performed with a semi-implicit scheme, and possibly with a finer mesh, will probably strongly improve these results.

#### Conclusion

A finite element method has been developed to solve the shallow water equations, and has proved to be particularly well fitted for the simulation of hydrodynamics in complex shaped domains, whatever their size, with reasonable in core memory requirements.

It is the feeling of the authors that, thanks to the advantages of a grid of finite element type (large elements far away, small elements near the region of interest) which decreases the number of required unknowns, the cost of such a model becomes comparable to the one of a classical finite difference model.

The use of a semi-implicit scheme enables the model to avoid wave damping even with a coarse discretization of a wave length ; the implementation of an incident wave condition and the consideration of the atmospheric forcing terms make it quite convenient for the study of the generation and propagation of storm surges on broad areas, just as the North-West European Continental Shelf ; first results concerning the simulation of a measured storm surge has turned to be very satisfactory.

Next steps will concern the tuning of the model on other observed storm surges, the examination of tide-storm surge interaction and, thanks to a better model of turbulence, a better modelling of 2 D boundary layers developped near obstacles and of associated boundary conditions.

## CHAPTER EIGHTY THREE

### ADDED EVIDENCE ON NEW SCALE LAW FOR COASTAL MODELS

Robert Hallermeier\*

#### Abstract

*Further positive results on appropriate scaling of movable-bed models support an analytical expression developed in 1983. That development examined a simple parameter for a profile view of nearshore sedimentation, making a distinction between small and large situations by the incorporated threshold of sand motion. The resulting scale laws proved fairly consistent with various empirical results, including those by E. Noda and P. Vellinga.*

*The focus here is on full utilization of 25 available tests of profile development in large wave tanks. Seven published small tests are found to be notably accurate as unintended models of various large tests, giving support to the new scale law. Also, the occurrence of shore erosion or accretion in all large tests is seen to be in accordance with the basic sedimentation parameter.*

#### INTRODUCTION

Two distinct approaches to predictive capability for nearshore changes are mathematical and physical modeling. In mathematical models, the appropriate level of detail seems a fundamental quandary: relatively simple treatments using some overall conditions offer intuitive appeal but have not yet managed impressive results in correlating measured beach changes (Seymour and King, 1982), while intricate computer models are still subject to fundamental questions about advisable numerical techniques and adequately detailed physics (McDowell and O'Connor, 1982). It is well known that prediction of average sand transport rates by waves is subject to large uncertainties, and this places limits on the present potential of mathematical models.

On the other hand, physical models are subject to criticism because of known differences in sand-bed processes in large prototype and small laboratory situations. However, scale effects do not preclude accurate reproduction of natural nearshore changes, if important transport mechanics are clearly enough identified that the model's design permits it to function as a meaningful physical analog for the prototype. Identification of dominant

\*Visiting Coastal Scientist, Cyril Galvin, Coastal Engineer, Box 623, Springfield, Virginia 22150, U.S.A.

transport mechanisms is a central topic of the present research on physical modeling (and conclusions might also be pertinent to adequate mathematical models).

This paper is the last in a series of three concerning laboratory models for sandy nearshore regions dominated by wave action. All considerations have been based on distinct thresholds in wave-sand interactions, with quantitative deductions about accurate modeling compared to empirical evidence. The first paper (Hallermeier, 1984) examined two types of wave-cut features occurring outside the breakers, and concluded that practical models should omit the extensive region of moderate bed agitation and be confined mainly to the surf zone. The second paper (Hallermeier, 1985) developed a new analytical viewpoint for accurate profile modeling, and showed it to be supported by many published empirical results and by a new test program. This paper presents additional evidence on the validity of the new design guidance for physical surf-zone models.

Examining literature on coastal models from the past 15 years, actual treatments seem to separate into categories somewhat different from the three given by Keulegan (1966). Customary approaches to design guidance for physical models with sand and waves might be classified according to three types of basis, here called formal, empirical and parametric. The first type considers basic principles for replicating flows in terms of conserving force ratios (Froude, Reynolds, Archimedes, etc., numbers) between model and prototype. This formal approach is exemplified by modeling guidance presented by Yalin (1971) and Kamphuis (1975, 1982). A judgment on relative importance of various processes must enter such developments if they provide practical guidance about compromises always necessary between the contradictory formal requirements for physical modeling.

The empirical approach to model design recommendations proceeds solely from correlation of actual successes and failures, as in guidance by Noda (1972) and Vellinga (1982). Although disguised by usual expressions of results in generalized form, such conclusions strictly pertain only to prototype and model conditions actually investigated.

Fundamental limitations of formal and empirical routes has led to model design guidance based on preserving some parameter(s) judged most crucial to coastal processes. One example is research examining the sediment excursion ratio  $H/wT$ , where  $H$  is wave height,  $w$  is sediment fall velocity, and  $T$  is wave period (Dean, 1973). However, investigations to date (Noda, 1978; Vellinga, 1978; Gourlay, 1980; Sayao and Guimaraes, 1984; Hallermeier, 1985) have indicated that preserving  $H/wT$  between model and prototype is neither sufficient nor necessary to reproduce nearshore profiles.

The development pursued here is based on a different parameter meant to indicate sand movement in the surf zone: sand mobility is measured in terms of the threshold of sand motion rather than the fall velocity. To some extent, this corresponds to considering the stage of bedload or total sand transport rather than suspended sand movement alone.

#### NEW VIEWPOINT OF NEARSHORE SEDIMENTATION

The new parameter treating sedimentation on nearshore profiles is defined by characteristic flow velocities:

$$\psi = (V_h/U_o)/V_v \quad (1)$$

where  $V$  is peak wave-induced velocity,  $U_o$  is the threshold (horizontal) velocity for sediment motion, and subscripts  $h$  and  $v$  indicate horizontal and vertical components. The postulate is that planar similarity between model and prototype exists when identical values of  $\psi$  occur. Development of model design guidance proceeds (Hallermeier, 1985) by noting that these peak velocities share a common time scale, the wave period  $T$ , so their ratio can be given by the ratio of characteristic length scales  $L_h/L_v$ . The other step is to invoke convenient asymptotic expressions (Hallermeier, 1980) for sand motion thresholds in small and large situations, i.e., with laminar shearing of the boundary layer (for relatively high frequency waves) versus with a thoroughly mixed boundary layer (for lower frequency waves).

Preservation of  $\psi$  in an overall sense between small model and large prototype requires a scale ratio of

$$N_v/N_h = 0.0494 (T_m)^{0.5} (s_m)^{0.75} (gD_m)^{0.25} (s_p D_p)^{-0.5} \quad (2)$$

$N$  indicates (fairly large) length scale between the two situations; subscripts  $p$  and  $m$  refer to prototype and model;  $D$  is sediment grain diameter;  $s$  is relative immersed sediment density in the fluid; and  $g$  is acceleration due to gravity. Besides Eq. (2), customary Froude scaling of waves requires time scale between prototype and model to be

$$N_t = (N_v)^{0.5} \quad (3)$$

giving a dynamic and a kinematic requirement for accuracy.

Perhaps the most encouraging evidence regarding the proposed scaling law in Eq. (2) is its quantitative similarity to the empirically-based conclusion by Vellinga (1982). That result was expressed using the scale between sediment fall velocities, and omitted any independent effect of wave period as in Eq. (2), but values for appropriate model distortion  $\Delta = (N_h/N_v)$  by the two approaches show generally fair agreement in common open-coast conditions with quartz sands. Thus, Eq. (2) is supported by

many of the Vellinga test results on dune erosion by extreme storm events on The Netherlands coast. The present relationship also appears to help correct the weakness noted by Vellinga (1982) in his recommended modeling law.

Another persuasive item of general evidence is that the present approach can nearly recover an empirical scaling law given by Noda (1972). In his laboratory investigations, all tests were evidently small in an absolute sense so the identical (laminar) asymptotic expression for sand motion is applicable to each. In that case, preservation of between two situations requires

$$\frac{N_h}{N_v} = \left[ \frac{D_p T_p^2 S_p^3}{D_m T_m^2 S_m^3} \right]^{0.25} = (N_D N_V)^{0.25} (N_S)^{0.75} \text{ (small replicas; 4)}$$

using Eq. (3) and introducing the scales of sand diameter and immersed density between the two cases. Noda's results were given as two independent equations yielding

$$N_h/N_v = (N_v)^{0.25} (N_D)^{0.127} (N_S)^{-0.151} \quad (\text{E. Noda; 5})$$

or, if  $N_S$  is eliminated because the major empirical emphasis was on  $N_S = 1$  with quartz sediment in both situations,

$$N_h/N_v = (N_v)^{0.205} (N_D)^{0.209} \quad (\text{E. Noda; 6})$$

There is a striking similarity between Eqs. (6) and (4) for the case of  $N_S = 1$ , so the present viewpoint seems to point out the mistaken nature of the scaling law deduced by Noda (1972): that it pertains to appropriate design giving profile replication between a pair of small situations, and not to the design of an accurate model for a large prototype.

The opposite case of replication consists of two large profiles. Then sand motion is governed by the same equation in each situation, that for a thoroughly mixed boundary layer. This yields for the preservation of  $\psi$

$$N_h/N_v = (N_D N_S)^{0.5} \quad (\text{large replicas; 7})$$

a form quite different from Eqs. (2) or (4).

From the present viewpoint, scale relations are not continuous. Distinction between models and either small or large replicas seems necessary for consistent treatment of scaled profile development. The idea that models and replicas are fundamentally different concepts has never received proper emphasis, but some evidence is apparent in a recent empirical analysis by Ito and Tsuchiya (1984).

The present approach and results on accurate scaling are entirely consistent internally, including an objective

classification of "small" and "large" situations in terms of sand motion initiation. An intermediate range of transitional situations must be expected, but "small" has an upper size bound related to cessation of laminar boundary flow while "large" has a lower size bound related to onset of thoroughly-mixed flow in the boundary layer (Sleath, 1974, 1984). These size bounds are sensibly consistent with usual laboratory models being small and natural coastal situations of engineering interest being truly large.

#### **MODELS OF LARGE-SCALE PROFILE CHANGES**

New test results reported in Hallermeier (1985) gave some support for present guidance on accurate models, and clearly contradicted preservation of  $H/wT$  as a scaling law. Positive evidence consisted of only a few accurate models from a program of about 50 tests, each aiming to reproduce some profile developed in a large wave tank at the Beach Erosion Board, U.S. Army Corps of Engineers (Saville, 1957). Successful models were in fair accord with Eq. (2), whereas unsuccessful tests were usually not;  $H/wT$  had about the same value in most pairs of situations.

Reproduction of profile development from an initially plane sand slope provides a stringent test of modeling guidance: success indicates that the spatial pattern of net transport through corresponding times was identical on model and prototype profiles. Successful models do not imply that nearshore transport processes have been reproduced, but do demonstrate that net effects have been accurately scaled in a sensitive situation. Besides scale effects, possible laboratory effects on test results should be considered: for example, there are start-up effects in mechanical wave generation (Madsen, 1970) and the artificial borders to the sand bed can affect transport processes, as when a bulkhead eventually becomes exposed to waves. Some care was taken in the test program described by Hallermeier (1985) to reproduce steady wave durations in meaningful situations, but undesirable laboratory complications must be present in an additional data base on models assembled here.

The following results pertain to unintended models of the 25 available tests in large wave tanks, so timing of wave stops and fully consistent scales are quite unlikely. The large-scale data base includes 15 BEB tests mentioned above, and 10 recent tests at CRIEPI, Japan. Full documentation of the two BEB test series has never been published, but original test data are available at the Waterways Experiment Station (WESCR), Vicksburg, Mississippi. A brief report by Kajima, et al. (1982) on CRIEPI tests does not provide full details such as stopping times or intermediate profiles. Together the 25 large tests of profiles developed by steady wave action include  $H$  between 0.5 and

1.8 m,  $T$  between 3 and 16 sec, three initial slopes, and four fine to medium quartz sands; a wide range of conditions is represented but coverage is not intensive.

Potential unintended models for these 25 prototypes can be sought in over 50 reports documenting profile development in small situations. For the present search, attention was limited to 20 accessible recent reports, which include about 150 profile development tests. The search for unintended models began by requiring a good match between a small and large test in deep-water wave steepness ( $H_o/L_o$ ) as required by Eq. (3). Then fairly consistent scaling in wave height, water depth, wave period, and duration of profile development was sought. In this way, seven model/prototype pairs listed in Table 1 were located; model slope distortion relative to the prototype is in each case fairly consistent with the requirement of Eq. (2). (Besides space limitations here, full comparison of all small and large profiles is not provided because the present partial search aimed only at extending the scant data base of successful models, and definitive contradiction of present modeling guidance would be doubtful, in that laboratory effects are unknown.)

Table 2 provides a summary of profile features arising in model/prototype pairs. There is a distinct similarity in nearshore profile development for each case, with matches tending to be more quantitative than qualitative in pairs of situations with more consistent overall scaling. Given the startling variety of profile developments which can occur on an initial plane slope, in terms of number, location, and dimensions of major features, these seven cases distinctly provide support for Eq. (2) as a scale law.

To give a quantitative indication of Eq. (2) guidance, Figure 1 presents a nomogram constructed by standard means (Levin, 1946). Taking the prototype to be  $s_p = 1.6$  (quartz in saltwater), remaining parameters are arranged by like exponents into three ratios:  $D_p/T_p$ ,  $N_v/D_m$ , and  $N_h/N_v$ . The dual central axis of Figure 1 shows necessary distortion for either quartz or coal in water as model materials.

Figure 1 also indicates some of the range of validation provided by models newly described here or in Hallermeier (1985). Conditions for all 9 models shown by dashed lines include quartz sand. This display of various cases supporting Eq. (2) may be deceptive in exaggerating the range of model conditions: individual values of five parameters rather than three ratios actually gives the empirical basis for the new scaling law. However, this indicated basis excludes other published model tests whose support for Eq. (2) was discussed previously (Hallermeier, 1985).

Figure 1. Nomogram for sedimentation similitude with either quartz or coal as model material, based on Eqs. 2 and 3, along with presumption that prototype has  $s_p = 1.6$  [quartz in saltwater]. Support for this scale law, related here or in Hallermeier (1985), is indicated by dashed lines showing approximate conditions for quartz models of large tank tests.

The overall range of verification with radically different prototype situations provides extensive corroboration for the new parametric viewpoint of sedimentation.

#### SOME BASIC EFFECTS IN LARGE PROFILE CHANGES

Situations in large tests of profile development have been idealized, but the present viewpoint indicates scale effects are absent so recorded changes should be exactly pertinent to net onshore/offshore sand transport in large field waves. Results in large tests can be directly applicable to several cases of engineering interest. One example is immediate adjustment of a beach fill which might be placed as a direct berm extension into the usual surf zone. Another example is erosion of a simple accreted beach profile by relatively steady storm waves.

The latter case can be illustrated using results of a BEB test along with the well-documented (Gable, 1981) storm event which occurred during a Nearshore Sediment Transport Study experiment at Santa Barbara, California. Quartz sand of 0.227 mm diameter and foreshore slope about 1 on 15 at Leadbetter Beach matched the first series of large tank tests, so Eq. (7) shows a relationship is possible between field and laboratory events. Representative wave conditions may be approximated as  $H = 1.25$  m and  $T = 14$  sec for the 5-day California storm during February 1980; near this is laboratory test number 7 with steady waves of  $H = 1.6$  m and  $T = 16$  sec. This yields a match in wave steepness, so the tank test can be an undistorted replica of the Leadbetter Beach event, at about 30% linear magnification. Such a viewpoint is seen to be consistent with recorded shore effects (Figure 2) which include fairly steady shoreline retreat totaling 40 m over the 5-day storm.

In the laboratory, waves ultimately exposed a concrete wall behind the sand slope so only the first 20 hours of testing should be considered; in that time, the still-water shoreline retreated 10 m (Caldwell, 1959). Mean-sea-level shoreline at Leadbetter Beach retreated 9 m during the first storm day, exactly consistent with laboratory effects being at the stated magnification. Agreement of recorded shore changes persists into finer details: in each case the foreshore steepened with lesser retreat at higher elevations up to the berm crest; also, behind the berm crest there was slight sand deposition. These effects indicate marked similarity of shore hydraulics and net sand transport in the two cases. However, the laboratory situation was in fact much simpler: nearly two-dimensional with no alongshore transport and with steady waves and no tide on a plane slope.

Still, this example reveals a fundamental congruence of large-tank profile development to natural effects, and encourages classification of basic results from large lab-

Figure 2. Similar shore changes recorded in large tank test and during storm at Leadbetter Beach, California.

oratory tests. The occurrence of shore erosion or accretion at large scale will be examined in terms of two published treatments and the present viewpoint.

The two treatments of profile modification considered here are those by Dean (1973), who introduced sediment fall velocity as a crucial parameter, and Sunamura and Horikawa (1974), who developed a more detailed parametric model for net sand transport. Dean (1973) reported a successful break of storm/eroded vs. normal/accreted profiles for 184 (mainly small) tests by a linear relationship between  $H_o/L_o$  and  $w/gT$  (parameters combined in  $H/wT$ ). Sunamura and Horikawa (1974) distinguished shore erosion or accretion in terms of a linear relationship between  $H_o/L_o$  and a semi-empirical parameter including  $D$ ,  $L_o$ , and initial slope; their main data base was about 75 long-term small tests but the same functional result was judged pertinent to shore changes in 23 large situations. (In each treatment results indicated marked change between small and large situations in the numerical coefficient of the relationship, and those changes can be shown to be roughly consistent with Eqs. (4) and (7) for usual conditions; however, the present viewpoint indicates a different correlating parameter should arise for changes in small and large situations.)

For the 25 available tests in large wave tanks, Figures 2a and 2b display types of shore change (above still water line) in terms of those two relationships. Conditions in terms of those parameters provide a useful demarcation of test results, although the originally proposed relationships ( $45^\circ$  lines in this format) cannot be retained. The dashed lines shown provide a clear break between shore erosion and accretion, with only one outlier in Figure 2a and none in Figure 2b. Close examination reveals the break in Figure 2b to be somewhat more clear, with better ordering of marked erosion through neutral development to marked accretion. This verifies the importance of initial slope  $M$ .

The third panel of Figure 2 evaluates the usefulness of sedimentation similitude considerations in attempting such a demarcation of conditions for shore erosion or accretion. The Appendix develops from Eq. (1) the abscissa

$$\psi' = \pi(8sD)^{0.5}/(TM'g^{0.5}) \quad (8)$$

where  $M'$  denotes initial slope divided by 1 on 15, slope for a majority of the tests. Results in Figure 2c upon close inspection show a somewhat clearer break of actual effects than is obtained in the other panels. The major difference in the third plot is that the Eq. (8) parameter has a stronger dependence on initial slope (derived from the requirements for sedimentation similitude in large-scale replications). Empirical results of Sunamura and

SHORE CHANGES IN 25 LARGE WAVE-TANK TESTS WITH PLANE SLOPES

 $\circ$  CRIEPI } Doubled Symbol Indicates Marked Change

Figure 3. Three classifications with erosion at left and accretion at right of dash lines: a. Dean (1973); b. Sunamura and Horikawa (1974); c. new sedimentation parameter.

Horikawa (1974) indicating a relatively weak slope dependence were primarily from small-scale profile developments, where the independent effects of slope and wave steepness, when combined into the surf-similarity parameter, apparently tend to cancel (Hallermeier, 1984).

Although only large-scale data have been considered, these findings definitely support the new viewpoint of nearshore sedimentation and thus of appropriate model design. Note that preceding examinations do not exhaust the usefulness of available large tests. The few situations exhibiting little profile development or a switch in shoreline movement seem worth special study. Also, inshore and offshore profile changes remain of basic interest, even though profile forms developed in large tanks may be somewhat unnatural due to the steep initial slopes, i.e., the marked distortion of natural surf zones.

#### CONCLUDING REMARKS

Evidence presented above and in Hallermeier (1985) is favorable rather than definitive regarding the accuracy of the proposed scaling law for coastal models. The approach yielding Eq. (2) has been shown to explain various previously reported empirical results including fairly successful movable-bed models. However, the new modeling relation has not yet been subjected to a stringent test program designed to define its usefulness and limitations.

Several unverified aspects of the guidance in Eq. (2) should be mentioned. If a model is to use prototype sediment for convenience and accuracy in size distribution, and to be undistorted for accurate wave patterns near structures, the new scale law provides no free choices: one value of  $N_v$  will be appropriate. Whether or not distortion of a chosen magnitude can be successfully imposed on a sand model remains unanswered. Also largely unknown is the usefulness of Eq. (2) with lightweight model sediments and in design of three-dimensional models. Finally, with prototype wave period figuring in basic model design (because of the sand motion process in the laboratory), a representative period must be determined.

One way to evaluate present guidance further would be review of the designs for three-dimensional models documented to have been either accurate or erroneous. Preliminary examination of some successful models reveals that it is possible to find designs basically agreeing (Fried, 1976) or disagreeing (Noda, 1966) with Eq. (2). However, detailed consideration of prototype sites with regard to littoral drift, dominant structures, etc., would be required for firm assessments. Also needing consideration are different procedures and informal approaches to the "modeling art" arising in various laboratories.

To summarize available evidence, Eq. (1) gives a direct and rational viewpoint of nearshore sand movements on the profile. Horizontal flow velocity divided by the threshold velocity for sand motion is a primary indicator of transport stage, and  $\psi$  seems a more fundamental sedimentation indicator than a parameter with sediment settling velocity can be. Also, settling velocity for common sands depends on fluid viscosity, so its absence for present guidance prevents an awkward requirement to control water temperature in laboratory models. Although limited, empirical results give clear support to the new viewpoint of modeling.

#### APPENDIX - DERIVATION OF EQUATION (8)

The fundamental definition of Eq. (1) is invoked along with linear wave theory at mid-depth in shallow water and the threshold for sand motion in large situations, giving

$$V_h = 0.5 H (g/d)^{0.5} \quad (A1)$$

$$V_v = 0.5 \pi H/T \quad (A2)$$

$$U_o = (8sgD)^{0.5} \quad (A3)$$

$$\psi = T/\pi(8sdD)^{0.5} \quad (A4)$$

where  $d$  is nearshore water depth. To measure profile changes by a meaningful dimensionless form, the last expression is multiplied by wave celerity  $c = (gd)^{0.5}$ , propagation rate of mobilizing impulses. For comparable dependences with other sedimentation parameters used in Figure 3, the present measure must be inverted.

Adjustment is needed for effect of varying initial slope since Eq. (7) indicates large tests are related by

$$N_h/N_v = (N_M)^{-1} = (N_D N_S)^{0.5} \quad (A5)$$

where  $M$  is bed slope. This indicates the functional trade-off, e.g., between a steeper slope and a finer, less dense sediment, with respect to replicating some standard large situation. Choosing test conditions with the most common slope ( $M = 1/15$ ) to remain unadjusted, a parameter for profile changes based on Eq. (1) may thus be written as

$$\psi' = \pi(8sD)^{0.5}/(TM'g^{0.5}) \quad (A6)$$

where  $M' = (15M)$ . This is the form provided in Eq. (8).

#### ACKNOWLEDGEMENTS

This research began at "CERC North", Fort Belvoir, Virginia, in the summer of 1983, and thanks are due those responsible for that unique research environment. I appreciate support provided by Cyril Galvin, Coastal Engineer, for attendance at the Houston Conference and final preparation of this paper.

## CHAPTER EIGHTY FOUR

### Onshore-Offshore Sediment Transport Numerical Model

A. Swain<sup>1</sup> and J. R. Houston<sup>2</sup>, A. M. ASCE

#### Abstract

A numerical model is presented for calculating beach profile development due to offshore sediment transport and tested with laboratory and field data. The model allows variable wave conditions, water level fluctuations due to tide and storm surge, arbitrary bathymetry, and arbitrary sediment size. The agreement between calculated and measured beach profile erosion is good.

#### Introduction

The interactions of waves and currents with beaches are not well understood. The complexities of the phenomena do not allow useful closed-form solutions. On the other hand, hydraulic models designed to simulate these phenomena are subject to fundamental limitations of laboratory test and scale effects. Various numerical models have been developed (e.g. 1,2) to describe beach profile development due to wave attack. Although some of these models provide reasonable qualitative results, none have been shown to produce good quantitative predictions. This paper describes a numerical model based upon concepts developed by Swart (3), to calculate beach profile development. The model was tested by comparison with laboratory experiments and field data. The response of beach profiles during a period of extreme tides and storm surge also was investigated and results are presented.

#### Governing Equations

The numerical model developed in this study uses the governing equations obtained by Swart (3). Swart (4) conducted model studies and used regression analysis to obtain equations governing development of beach profiles (4). The readers may refer to references 3 and 4 for details.

The beach profile development during a time step was calculated according to the following equation from Swart (3) (See Fig. 1):

$$h_{ti} = h_{1i} \exp(-X_b t) + \delta_{Ai} (1 - \exp(-X_b t)) \quad (1)$$

<sup>1</sup>Research Hydraulic Engineer, Research Division, Coastal Engineering Research Center, U. S. Army Engineer Waterways Experiment Station, P. O. Box 631, Vicksburg, MS 39180-0631

<sup>2</sup>Chief, Research Division, Coastal Engineering Research Center, U. S. Army Engineer Waterways Experiment Station, P. O. Box 631, Vicksburg, MS 39180-0631

in which  $h_{ti}$  = depth of profile measured from the water level (MSL + Tide) at time  $t$  and at location  $i$  on the profile;  $h_{li}$  = depth of initial profile measured from the water level (MSL + Tide) at time  $t=0$  and at location  $i$  on the profile;  $\delta_{Ai}$  = depth of the equilibrium profile measured from the same reference at location  $i$ ; and  $X_b$  is a time factor (rate coefficient) (5).

Method of Calculation

The method of calculation is as follows: first an initial profile ( $h_{li}$ ) is selected. Then, from the known wave characteristics (height, period, and angle), sediment size, and time-varying tide,  $h_o$ ,  $X_b$ , and  $\delta_{Ai}$  are calculated according to the method of Swart. Equation 1 is then solved to calculate  $h_{ti}$  during the first time step. At the beginning

Figure 1. Definition Sketch of Various Numerical Parameters

of the second time step, a new set of wave and tide conditions is input. Equation 2 is then used to calculate the new position of the developed profile with respect to the new datum (MSL + Tide),

$$h_{li} = h_{ti} - RELV \tag{2}$$

in which

$$RELV = (h_o + Tide)_t - (h_o + Tide)_{t+\Delta t} \tag{3}$$

where  $h_o$  = elevation from the MSL to the upper boundary of developed profile, and  $\Delta t$  is the time step. A one-hour time step was used throughout the entire study. It should be noted that the elevation  $h_o$  corresponds to the most shoreward location that waves reach on the beach.

In the numerical model this location varied with time, because the tide datum and wave climate varied. Figure 1 presents a definition sketch showing the various parameters involved in Eqs. 1, 2, and 3. The governing equations (3) for  $X_b$ ,  $h_o$ , and  $\delta_{Ai}$  were calculated and Equation 1 was then numerically solved. The above procedure was repeated during each time step, until the desired number of iterations for the final beach profile development was attained.

#### Model Testing

The accuracy of the numerical model was tested by comparison of calculations with laboratory experiments and with prototype measurements. Figure 2 shows a comparison of the beach profile measured in hydraulic model tests by Eagleson et al. (6), and calculations of the profile response numerical model. The parameters used in the numerical model calculations were identical to those of the laboratory tests (initial profile, wave height, wave period, diameter of testing material, and length of time of the test). Figure 2 shows that the major features of the measured profile were reproduced by the numerical model. Additional comparisons of hydraulic scale model tests with the results of the numerical model are given in Swain and Houston (5).

Figure 2. COMPARISON BETWEEN EXPERIMENTAL (EAGLESON, 1963, TEST 3) AND CALCULATED ONSHORE-OFFSHORE PROFILES

Figure 3 presents a comparison between numerical model calculations and measured profile change in the prototype. The field data include a 16-21 February 1980 storm off the west coast of the United States, at Leadbetter Beach, Santa Barbara, California. The Nearshore Sediment Transport Study (NSTS) documented daily profile measurements in addition to complete directional spectral wave data during the storm (7). This was a large storm that produced approximately 40 m (122 ft) of shoreline erosion. The inputs to the numerical model were sand grain size, initial profile, and hourly values of significant wave height, period, direction, and tide level. Figure 3 shows good agreement between measured profiles and the numerical calculations over the 5-day period of the storm. An important result found in the numerical calculations was that tidal fluctuations were a first-order effect in the mechanism of offshore sediment

transport (8). The sensitivity of the numerical model to other important parameters is discussed by Swain (9).

Figure 3. COMPARISON OF CALCULATED AND MEASURED BEACH PROFILES  
LEADBETTER BEACH, CALIFORNIA, 1980, NEARSHORE SEDIMENT TRANSPORT STUDY

An additional comparison between measured profile modification during the Currituck Sand-Bypass Study (10), and the profile response numerical model calculations was made. This study involved placement of 26,750 cu m (34988 cu yd) of sediment on the coast near New River Inlet, North Carolina, using the split-hull dredge CURRITUCK. A profile was chosen through the center of the dump to avoid "end effects." Wave characteristics were obtained during the study using the Littoral Environment Observation (LEO) technique. The mean diameter of the disposal

Figure 4. COMPARISON OF CALCULATED AND MEASURED SHORE-NORMAL PROFILE  
NEW RIVER INLET, NORTH CAROLINA  
(DREDGED DISPOSAL SAND MOVEMENT)

material was 0.23 mm. Figure 4 shows the initial profile measured after the dump was completed, and measured and calculated profiles after 36 days. The numerical calculations predicted that there would be little modification in the profile over the time period except for some erosion of the break point bar and filling of the adjacent trough. The measured profile confirms the numerical prediction. Figure 4 shows the calculated and measured profiles differ at most by a few tenths of a meter in elevation. This difference is within the level of accuracy of the profile measurements.

As a final test for the model, beach erosion caused by the 1962 Ash Wednesday storm along the Outer Bank Barrier Islands of North Carolina on the east coast of the United States was simulated. This study area includes the vicinity of the Oregon Inlet which is presently the only inlet along the Outer Banks between Cape Hatteras and Chesapeake Bay. Bodie and Pea Islands border the north and south sides of the Oregon Inlet respectively. Figure 5 presents a portion of the barrier islands system. Wave characteristics were obtained from the U. S. Army Engineer Waterways Experiment Station (WES) Wave Information Study (11). Tide and surge elevations were obtained from the WES Implicit Flooding Model, a tidal circulation and storm surge model (12). Wave conditions were available at three-hour intervals for a period of 4 days. However,

Figure 5. **AERIAL PHOTOGRAPH OF OREGON  
INLET BEFORE AND AFTER THE  
1962 ASH WEDNESDAY STORM**

tidal and surge elevations were generated at intervals of one hour for the same number of days. Thus the tide and surge level was updated each time step and the wave conditions updated every third time step. Figure 6 shows a comparison of the calculated and the measured shore-normal erosion along Bodie Island. Measurements show that beach erosion varied from a few hundred feet along much of the island to approximately 1500 ft near the north spit. The north spit was a low-lying area that was

inundated during the storm. The numerical calculations predict a similar trend. Figure 7 presents a similar plot along the Pea Island. It is seen that the calculated erosion agrees well with the measurements.

Figure 6. COMPARISON OF CALCULATED AND MEASURED SHORE-NORMAL EROSION OREGON INLET, NORTH CAROLINA (BODIE ISLAND, 1962 ASH WEDNESDAY STORM)

Figure 7. COMPARISON OF CALCULATED AND MEASURED SHORE-NORMAL EROSION OREGON INLET, NORTH CAROLINA (PEA ISLAND, 1962 ASH WEDNESDAY STORM)

However, the comparison is not a rigorous test of the model since there was a constraint that stopped further erosion. The storm produced large waves over such long duration that erosion continued until stopped by the large sand supply of the high dunes. The north spit did not have high dunes and the erosion distance shown in Fig. 6 is the width of the barrier island since the spit was completely eroded.

#### Conclusions

A time-dependent numerical model to predict beach profile erosion was developed. The accuracy of the model was tested with laboratory experiments and with prototype measurements. It was found that the beach response model can accurately predict profile response to waves and fluctuating water levels.

## CHAPTER EIGHTY FIVE

### MEASUREMENTS OF BEDLOAD TRANSPORT IN THE NEARSHORE ZONE USING RADIOISOTOPIC SAND TRACERS.

by

Georges Drapeau and Bernard Long\*

#### ABSTRACT

A field study was conducted on the North Coast of the Gulf of St. Lawrence in Eastern Canada to evaluate sediment transport processes in a coastal area that would be affected by the modification of river regimes for hydropower production. Radioactive tracers were used to evaluate the mobility of coastal sediments. Three injections were carried out using Neodymium 147 (half-life 11.1 days), at 450, 550 and 2200 m. from the shoreline at depths from 3 to 10 m. The high sensitivity of the detection system allowed to monitor the study area for 44 days. The tagged sediments responded to waves and tidal currents and were sensitive to minor changes. Comparison of the patterns of evolution of the three injections permitted to evaluate the relative mobility of bottom sediments as a function of water depth and distance from shore. Bedload transport rates were calculated but they are related to specific events such as storms within the Gulf of St. Lawrence more than to steady state conditions.

#### INTRODUCTION

Among the long term hydropower developments on the North Shore of the Gulf of St. Lawrence, one project would divert part of the Saint-Jean River into the Romaine River (Figure 1). This modification of the Saint-Jean River drainage basin would decrease the sediment supply to the coastal zone and aggravate coastal erosion. Coastal erosion in this area is enhanced by the directional wave attack from the South West while the coast is protected from eastern fetches by a series of coastal islands (Figures 1 and 2). A research program was initiated to evaluate sediment transport processes in the coastal area that would be most affected by the modification and regulation of river regimes. Radioactive tracers were used to define

---

\* Professors, INRS-Océanologie, Université du Québec, Rimouski, Qc, Canada G5L 3A1.

the mobility of coastal sediments and contribute to the study of sediment transport processes in that portion of the coastal zone of the Gulf of St. Lawrence.

Figure 1. Location map of the study area.

Figure 2. Regional map of the study area. This map in conjunction with figure 1 outlines that the study site is exposed to waves from SW and W and is protected from storms from other directions by Anticosti Island and a series of coastal islands. Longue Pointe is lined up with the western extremities of Anticosti Island and the coastal archipelago and it demarcates westward an erosional coastline and eastward an accretional coastline.

This paper describes the results obtained with radioactive tracers with some emphasis on the theory and methodology used, because they differ from other radioactive tracer experiments carried out in North America, namely those of Duane and his colleagues on the coast of California (Duane and James, 1980) and Lavelle and his colleagues on the New York continental shelf (Lavelle et al., 1978).

The study area is located 5 km East of the St. Jean River on the North Coast of the Gulf of St. Lawrence (Figure 2). This region is characterized by the fact that the coastline is erosional westward from Longue Pointe and accretional eastward from that point, because of the directional wave approach along that coast. The main fetch for that area is from the South-West as shown on figure 1. Figure 2 outlines with more detail that the study area is exposed to fetches from the South-West and that the window of wave propagation is quite narrow because of the protection offered by Anticosti Island and a series of coastal islands. West of Longue Pointe the present shoreline cuts through shorelines formed at higher sea levels from 1660 BP to present (Long et Drapeau, 1983). The shoreline is accretional East of Longue Pointe because of the protection offered by the coastal islands.

The study area is subjected to the combined action of waves and tidal currents. The tide is semi-diurnal and ranges between 1.7 and 2.9 m. Four Aanderaa current meters were deployed during the survey and measured reversing tidal currents of 24 to 50 cm/s during flood tides and 15 to 28 cm/s during neap tides. Long term records are not available to define yearly wave climates. During the fall of 1982, waves occasionally reached a height of 1.5 m and periods of 5 to 6 seconds in response to winds blowing from the South-West.

The nearshore zone in the study area is characterized by a shallow platform that reaches a depth of 10 m, 2.3 km offshore (figure 4). The surficial sediments are composed of well sorted 0.2 to 0.4 mm sand. Sources for these sediments are on one hand the material eroded from the coastline and on the other hand the input from the North Shore rivers (Cataliotti-Valdina et Long, 1983). Nearshore sand bars are developed on the shallow inshore platform. These bars are aligned parallel to the shoreline although they are discontinuous. Karakiewicz et al. (1983) relate the formation of this sand bar system to progressive gravity waves in the presence of tides.

#### BEDLOAD TRANSPORT EQUATION

The bedload transport rate  $Q$  is based on the mean velocity  $V_m$  of the mobile bedload layer of width  $L$ , usually taken as unit width, and the thickness of the mobile layer  $E$ . This volume rate is multiplied by the density  $\rho$  of the sediment to determine the transport in terms of mass per unit time for a unit width.

$$Q = \rho V_m L E$$

The unknowns are then  $V_m$  and  $E$ .  $V_m$  is determined by measuring the movement of the centroid of the tracer cloud as it is done currently with radioactive as well as luminescent tracers.

The estimation of the thickness of the mobile sediment layer is more problematic. The approach used for this study was developed by Sauzay (1967) at the Université de Toulouse and used extensively in France, particularly by the Centre d'Études Nucléaires de Saclay (Tola, 1982).

Sauzay based his analysis on the principle that if the total amount of radioactive material used for injection is measured precisely and if the detections that follow the tracer injection account for all the tracer used, then a relationship exists between the amount of tracer used  $A$ , the total count of detected radiation  $N$  and the thickness of burial of the tracer  $E$  (Figure 3).

Figure 3. Schematic of the concept of count rate balance. «A» is the amount of tracer energy. «N» is the amount of tracer detected and «E» is the thickness of the tracer in the mobile sediment layer.

The probe is calibrated to conform to the penetrating power law for a point source:

$$f(z) = f_0 e^{-\alpha z} \tag{1}$$

where  $f_0$  and  $\alpha$  are calibration constants.

As the sand tracer is not a point source and is rather scattered within the sediment from the seafloor (depth = 0) to a maximum depth  $E$ , equation 1 is integrated.

$$f(z) = \int_0^E f_0 e^{-\alpha z} dz \tag{2}$$

The count rate recorded by the probe is also a function of the tracer concentration with depth  $C(z)$  and should also be part of the integration process.

$$f(z) = \int_0^E f e^{-\alpha z} C(z) dz \quad (3)$$

We analyse first a hypothetical case where the concentration of the tracer is uniform for the whole depth  $E$ , then

$$C(z) = C_m \quad (4)$$

The radiation count rate  $N$  is then easily determined by integrating equation 3 for the interval 0 to  $E$ .

$$N = C_m f_0 \frac{1}{\alpha} \left[ 1 - e^{-\alpha E} \right] \quad (5)$$

The initial amount of radioactivity injected  $A$  being known as well as its half-life, the remaining activity at the time of a given survey  $A(t)$  can be determined. The hypothetical uniform tracer concentration per unit  $C_m$  used in the preceding equation can be expressed as:

$$C_m = \frac{A(t)}{E} \quad (6)$$

and by substitution of equation 6 in equation 5 we obtain:

$$N = \frac{A(t)}{E} f_0 \frac{1}{\alpha} \left[ 1 - e^{-\alpha E} \right] \quad (7)$$

Remains to be reconsidered the initial hypothesis of constant tracer concentration with depth. The distribution of radioactive tracer within the mobile sediment layer can take different configurations. Sauzay (1967) has analysed different tracer distributions as a function of depth and he has integrated these data to obtain what is termed the equivalent concentration  $C_c$ .

$$C_c = \int_0^E C(z) dz \quad (8)$$

The approach taken by Sauzay is to introduce the coefficient:

$$\beta = \frac{C_c}{C_m} \quad (9)$$

The maximum depth  $E$  is then obtained implicitly by solving the equation

$$N = \beta \frac{A(t)}{E} f_0 \frac{1}{\alpha} \left[ 1 - e^{-\alpha E} \right] \quad (10)$$

Experience has shown (Tola, 1982) that a parabolic tracer distribution is the most realistic and the use of a constant value of 1.15 for  $\beta$  has produced consistent results.

## FIELD DEPLOYMENTS

The radioactive element used for that series of experiments on the North Shore of the Gulf of St. Lawrence is Neodymium 147 whose half-life is 11.1 days. The radioactive tracer used is made of specially prepared glass containing neodymium. This glass was radioactivated at the Centre d'Études Nucléaires de Saclay. For the purpose of this experiment, the granulometry of the glass was chosen between 0.2 and 0.4 mm to coincide with that of the natural sediment.

The radioactive tracers were injected at three locations in the study area (see Figure 4). Two injections were deployed nearshore, one on each side of a sand bar located 450 m offshore at a depth of 3 m. The third injection was located at the edge of the flat platform, 2.2 km offshore. Five hundred grams of glass radioactivated at the level of 2.9, 2.2 and 1.7 Curies were spread on the seafloor surface at each location.

Figure 4. Seafloor profile of the study area. The location of the three injection points is indicated by black triangles. The characteristics of the tracer are summarized on the figure.

The detection equipment used was developed at the Centre d'Études Nucléaires de Saclay. It is composed of a NaI scintillation probe which is connected to two parallel systems of detectors, counters and plotters, one system working on a linear scale and the other on a logarithmic scale. This combination permits to follow with the same precision the response of the tracer at low as well as high levels of radioactivity.

The scintillation probe used is miniature as compared with the RIST probe (Duane, 1970; Lavelle et al., 1978). It is contained within a waterproof stainless steel cylinder 5.3 cm in diameter by 36 cm long that weighs only 2 kg. The probe is mounted on a sled that maintains the center of the probe at a constant height of 5 cm above the seafloor (Figure 5).

Figure 5. Drawing of the scintillation probe mounted on a sled that maintains the probe at a constant height of 5 cm above seafloor (after Anguenot, Caillot et Courtois, 1968).

It is essential that each survey completely covers the radioactive cloud as schematized on figure 3. As explained previously, the evaluation of the thickness  $E$  of the mobile sediment layer is based on the assumption that each survey detects all the tracer initially injected. The survey lines are oriented perpendicular to the direction of sediment transport and are prolonged to ascertain that the limits of the survey extend well beyond the radioactive cloud.

Radiation count rates are integrated for each transect and totalled for the whole survey. Calculations are based on a towing velocity of 1 m/sec because the probes are calibrated for radiation count rates in counts per second with reference to radioactive material uniformly covering one square meter. Sauzay (1967) has shown that towing the detection system at a constant velocity of 1 m/sec produces the same results as if count rates per second were measured at fixed grid locations. It was possible during the surveys in the Gulf of St. Lawrence to maintain a survey velocity of 1 m/sec and to correct for departures using a Trisponder system for positioning.

## RESULTS

Contours of the radiation levels and locations of the centroid of the labelled zones are shown on figure 6. The contours of radiation levels outline how the initial 500 gram release of radioactive glass mixes with the indigenous sediment and spreads on the seafloor. The lowest contour is 50 counts/sec above background and the other contours are for 150, 500, 1500, 5000, 15 000, and 50 000 counts/sec. In the case of these experiments on the North Coast of the Gulf of St. Lawrence, all three injections show that the highest tracer concentration has moved and that the tracers have spread during the 44 days that the experiment lasted.

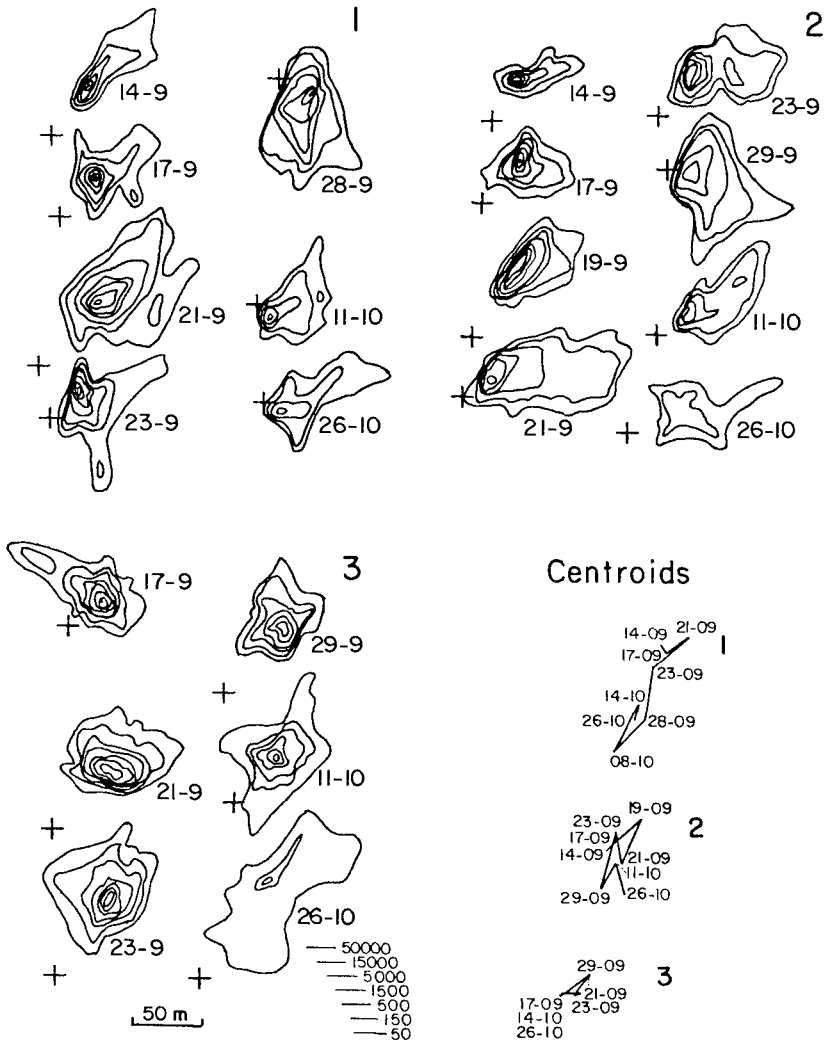

Figure 6. Evolution of tracer patterns for the three experimental sites. Each site is identified by a bold figure and each survey is identified by date-month. A cross is drawn as a fixed reference for each site to evaluate the movement of the tracer cloud. The outer countour is always 50 counts/sec and the others are 150, 500, 1500, 5000, 15000, and 50000 counts/sec. The movement of the centroids is shown in the lower right portion of the figure.

The movement of the centroid of the tagged sediments is used to calculate the mean velocity of the mobile sediment layer. It is apparent on figure 6 that the movement of the centroid, although alike, does not coincide with the highest tracer concentration.

Experiment number one was the closest to the seashore, that is 350 m from the high tide line in a slight depression on the shore side of the first sand bar (Figure 4). The first survey on September 14, two days after injection, shows that the tagged sediments have spread towards the North-East. As the sea was calm during these two days, the spreading pattern of the tagged sediments outlines the influence of the ebbing tidal currents that prevailed during and immediately following the injection of the tracer on the seafloor. The survey on 17 September outlines the influence that 0.5 m waves had on the labelled sediments. Tidal currents reached 41 cm/sec for a period of two hours between 14/9 and 17/9. The survey on 21/9 shows the result of a 30 hour storm that produced 5 to 6 second waves that reached 1 m heights. The following surveys show the evolution with time of the tagged sediments, but it should be kept in mind that the contours of radiation levels are not compensated for radioactive decay and by 26 October only 6.5 percent of the initial radioactivity was left.

The second injection site was located between the first and the second sand bar, 600 metres from the shoreline. The first survey on September 14 outlines essentially the same characteristics as for the first site that the tracer two days after injection has spread towards the North-East but is still concentrated within a 40 by 70 meters area. Comparison of surveys 19/9 and 21/9, before and after the storm mentioned previously, indicates that the movement of sediments on the seafloor has been somewhat more intense at that second location. Tidal currents were stronger: flood currents reached 20 cm/sec and ebb currents of 52 cm/sec were measured during the storm. After that storm, the tagged sediments at that location evolved in a similar manner as those of the inshore location.

The third experiment took place beyond the sand bars, 2.2 km offshore at a depth of 10 meters. The distance offshore and the greater water depth explain that the tracer was less mobile at that location. The elongation of the radioactive cloud towards the North-West is a response to flood tidal currents of 37 cm/sec. The survey 21/9, when compared with those of experiments 1 and 2 for the same date, indicates that the disturbance of the seafloor by storm waves was less intense at that third location because of the greater water depth. Tidal currents reached 41 cm/sec during the storm that preceded that survey. The comparatively large area covered by the 50 counts/sec outside contour on 26/10 could be explained by the fact that the radioactive tracers were less dispersed at that location further offshore and could yield a uniform signal above 50 counts/sec after 44 days.

The movement of the centroid of each radioactive cloud is also shown on figure 6. As explained previously, the movement of the centroid is not identical to that of the highest tracer concentration. The figure 6 outlines the relative mobility of each cloud of radioactive sediments. Sediments from experimental site 1 were closest to

shore and also the most mobile. By contrast, the centroid of the tagged sediment from experimental site 3, 2.2 km offshore, only moved back and forth a distance of some 25 m.

## DISCUSSION

Bedload sediment transport rates have to be identified with the time scale of interest, be it that of waves, tides or seasonal storms. For instance, direct methods that measure grain-to-grain movement respond to all modes of excitation of the seabed and particularly to the oscillatory movement of waves. The experiments with radioactive tracers on the North Shore of the Gulf of St. Lawrence responded to tidal and storm events and they outlined that the net movement of sediments after 44 days is of comparable amplitude to the movements linked to tides and storms. Ideally, the rate of movement of the radioactive tracers would reach an asymptotic value as the tracer becomes more homogeneously integrated to the seabed. This asymptotic value would be representative of the yearly rate of transport. This «steady-state» was not reached during these experiments with Neodymium 147 on the North Shore of the Gulf of St. Lawrence: a longer half-life tracer would be needed.

Bedload sediment transport rates were calculated however for the main storm on September 20th. The centroid of the tagged sediments moved a distance of 36 m during a period of 48 hrs, that is  $V_m = 0.75$  m/hr. Using the algorithm described above, the thickness of the mobile layer was determined as  $E = 2.95$  cm for the 19/9 survey before the storm and  $E = 13.06$  cm for the 21/9 survey after the storm. A mean value of 5 cm was used for the bedload calculations. These data yielded a bedload transport rate of 60 kg/m/hr in the direction 163 degrees from North. These results are compared with calculations based on the bedload sediment transport model developed by Vincent, Young and Swift (1982). Nearbed current velocities were obtained from Aaderaa current meters fixed upsidedown on the seafloor to measure currents 50 cm above bottom. Records from these current meters are reproduced on figure 7 and they show a very good signature from the tidal currents, but they also indicate that Savonius-type current meters are not suitable to monitor wave-dominated conditions. To obviate the problem of not having current measurements during the storm itself, current data for September 19th were used because the records show that tidal currents are not varying much from one day to the next one (see Figure 7). Calculations for different wave conditions, that is wave periods of 5 seconds and wave heights of 0.5, 0.7, 0.9, and 1.0 meter are shown on figure 7. The transport model predicts 58.3 kg/m/hr for 1 m waves which corresponds to the waves conditions that prevailed in the study area on September 20th.

The good agreement between the tracer experiment and the calculated sediment transport rate has its merits but it could be anticipated. The model developed by Vincent, Young and Swift (1982) is based on linear wave theory which implies that even the highest waves would not produce the slightest net residual transport component. In the study area, on the North Shore of the Gulf of St. Lawrence, tidal

Figure 7. Experimental site 2. A time series of a portion of current meter deployment is shown on the upper left. The V(North) and U(East) components outline the semidiurnal tidal currents. A progressive current vector diagram for the diurnal tide of 19 September, delineated by dotted lines on the time series, is drawn in the center of the figure. A sediment transport progressive vector diagram appears on the right side of the figure. This diagram reproduces the progressive vector for sediment transport resulting from the combined effect of the tidal currents and 1 m high waves. Resulting transport vectors for 0.5, 0.7 and 0.9 m waves are also shown on the same diagram. A vector representing the transport rate measured with radioactive tracers (60 kg/m/hr) is also drawn at the extreme right for comparison. The results of transport calculations for different combinations of wave heights with the tidal current are tabulated on the lower left side of the figure.

currents are important and the application of a linear wave theory model reflects this phenomenon. The good agreement between the field measurements and the calculations is also interesting because the model is used at the limits of applicability. On one hand the model developed by Vincent and his colleagues uses bottom friction concepts developed by Grant and Madsen (1978) for waves in the presence of weak currents; in the present study the tidal currents are comparable to the nearbed wave orbital velocities. On the other hand the water depth versus wave height is also a limiting factor in this study that uses a linear wave theory. The latter problem is presently investigated by Boczar-Karakiewicz (1981). For many sediment tracer studies in the nearshore zone a non-linear wave model combined with nearbed

currents of comparable amplitude to the bottom wave orbital velocities would provide a more realistic representation of the environmental conditions.

The rate of sediment transport (60 kg/m/hr) determined with radioactive tracers for the moderate storm conditions of September 20th are of the same order of magnitude as results obtained in other areas. Lavelle and colleagues (1978) used radioactive sediment tracers on the Long Island inner shelf and obtained sediment flux estimates of 61.2 kg/m/hr (0.17 gm/cm/sec) for winter storm conditions. The approach taken by Lavelle and colleagues to determine the sediment flux is basically different from that of the present study however, as they assumed that the points of highest tracer concentration were stationary and used an advection-diffusion equation to obtain flux estimates of the tagged sediments. Vincent, Young and Swift (1982) used their model to calculate bedload transport at a 10 m water depth 1 km from the Long Island coastline where they estimated bedload transport peaks of 316 kg/m/hr (3160 gm/cm/hr).

#### SUMMARY AND CONCLUSIONS

To summarize, this study shows that radioisotopic sand tracers were used successfully in the nearshore environment of the North Coast of the Gulf of St. Lawrence. The main conclusions drawn from these experiments are:

1. The compactness and lightweight of the scintillation probe and support equipment facilitated the logistics. It was then possible to improve the precision of the surveys using a highly maneuverable small fishing boat.
2. Radioisotopic sand tracers are very effective because they can be surveyed accurately without disturbing the sediment with which they intermix. The labelled sediments were sensitive to waves and tidal currents. It was possible to relate the evolution of the radioactive cloud patterns to specific events such as peak tidal currents and storm generated waves.
3. The use of three tracer injections permitted to evaluate the relative mobility of the seabed. Ideally, the rate of movement of the radioactive tracers would reach an asymptotic value as the tracer becomes more integrated with seabed. These experiments with Nd 147 did not last long enough to reach that steady state.
4. Estimates of sediment transport rates of 60 kg/m/hr during a storm compare with other radioisotopic sand tracer measurements particularly on the Long Island Shelf. Comparison of storm transport rates using tracers also shows a very good coherence with a linear wave analytical model.

#### ACKNOWLEDGMENTS

This research was supported by grants from the National Sciences and Engineering Council of Canada, the Ministère de l'Éducation du Québec and Hydro-Québec. The authors would like to express their thanks to Dr. A. Caillot for his collaboration to the radioactive

tracers study, to Dr. R.A. Young for his assistance with the transport model and to Mr. M. Gagnon for processing the current meter data.

## CHAPTER EIGHTY SIX

### SAND TRANSPORT BY WIND ON A WET SAND SURFACE

Shintaro Hotta<sup>1</sup>, Susumu Kubota<sup>2</sup>

Sadakazu Katori<sup>3</sup> and Kiyoshi Horikawa<sup>4</sup>

#### ABSTRACT

Using those results which were judged to be reasonable among various experiments, an equation predicting the threshold shear velocity on a wet sand surface was obtained. Then, based on a literature survey, results from fundamental experiments, and information obtained from a series of field observation carried out by the authors, a hypothesis to explain the blown sand phenomena on a wet sand surface was developed. Experiments with a well-sorted sand having a median diameter of 0.3 mm showed that the prediction was valid if the water content of the sand layer was less than 8 %.

#### I INTRODUCTION

One of the important problems in coastal engineering in recent years has been the unraveling of the processes of beach change. Extensive studies have been carried out on this topic throughout the world. Most research has been concerned with the study of waves on beaches and the resultant beach change due to wave action. However, on beaches where a strong seasonal wind blows, the sand transport by wind will be an important factor affecting beach change. In such a case, the transport by wind should be included in the sand budget on beaches. Therefore, we undertook comprehensive field investigations and laboratory studies to establish calculation methods for the transport of sand by wind on beaches (Horikawa, Hotta and Kubota, 1982; Kubota, Horikawa and Hotta, 1982; Horikawa, Hotta, Kubota and Katori, 1983; Horikawa, Hotta, Kubota and Katori, 1984).

At the first stage of this study, the troublesome fact was encountered that sand transport by wind on beaches often occurs during seasons when the sand surface is wet with rain or snow, e.g., beaches on the Japan Sea Coast in winter. Few studies of blown sand on a wet sand surface have been carried out, in contrast to the considerable number of studies of blown sand on a dry plane sand surface.

In order to fully evaluate the contribution of transport by wind in the sand budget, the problem of blown sand on a wet sand surface should not be neglected. As a first step in grappling with this problem, a literature survey was made and the present state of knowledge was summarized. To fill in various information gaps, two simple fundamental experiments were performed for 1) the threshold shear velocity of sand with high water content and 2) the sand transport rate by wind on a wet sand surface. These results are described in Horikawa, Hotta and Kubota (1982). The purpose of the present paper is to describe the work performed subsequent to the above work.

## II DISCUSSION OF SELECTED PREVIOUS WORKS

For convenience in later discussion, we will first give a brief summary of the present state of blown sand on a wet sand surface, based on our previous work (Horikawa et al., 1982). That is:

1. A considerable amount of laboratory and field data exists on the threshold wind speed or threshold shear velocity of sand grains on a wet sand surface. However, the definition of the critical condition at which grains begin to move, the elevation from the sand surface at which the wind speed as an external force was measured, and the sand characteristics varied among the experiments. Therefore it is difficult to quantitatively compare the relationships obtained.

Figure 1 shows the experimental results of threshold wind speed obtained by various workers. Generally speaking, with a water content up to 10% the threshold wind speed increases linearly with an increase in the water content of the sand surface. Also, the larger the median diameter of the sand the higher the threshold wind speed will be.

Theoretical and empirically-based equations for the threshold wind speed or the threshold shear velocity have been proposed by Belly (1962), Kawata and Tsuchiya (1976), and Nakashima and Suematsu (1976). They are:

$$u_{*c} = A \sqrt{\frac{\rho_s - \rho_a}{\rho_a}} g d (1.8 + 0.8 \log_{10} w) \quad (\text{Belly}) \quad (1)$$

$$\begin{aligned} \tau_{*c} &= \frac{u_{*c}^2}{((\rho_s/\rho_a) - 1) g d} \\ &= A^2 \left\{ \frac{\sin(\varphi - \theta)}{\cos \varphi} \right\} \left\{ 1 + \frac{2\sqrt{3}}{5} \sqrt{\alpha_1} \alpha_2 \sqrt{n_0} \frac{\sin 2\varphi}{\sin(\varphi - \theta)} T_k \right\} \end{aligned}$$

$$T_k = \sqrt{\frac{\rho_s}{\rho_w}} \frac{T \sqrt{w} \cos \xi}{(\rho_s - \rho_a) g d^2} \quad (\text{Kawata \& Tsuchiya}) \quad (2)$$

$$u_{15f} = \sqrt{\frac{B'}{A'}} \sqrt{g \cdot d \cdot \frac{\rho_s}{\rho_a}}$$

$$A' = -2.0 \times 10^{-7} + 22.0 \times 10^{-7} \exp(0.39w)$$

$$B' = 1.0 \times 10^{-5} \exp(-0.34w) \quad (\text{Nakashima \& Suematsu}) \quad (3)$$

where  $u_{*cw}$  is the threshold shear velocity on a wet sand surface,  $\rho_s$ ,  $\rho_a$  and  $\rho_w$  are the densities of sand, air and water,  $A$  is a constant with an approximate value 0.1,  $g$  is the acceleration of gravity,  $d$  is the grain diameter and  $w$  is the water content which is defined by the ratio of water weight contained in sand and dry sand weight. The quantity  $\varphi$  is the friction angle of a sand grain at rest,  $\theta$  is the average angle of the sand surface slope,  $T$  is the surface tension,  $n_0$  is the number of contact points of a grain in the sand layer,  $\sqrt{\alpha_1}$  and  $\alpha_2$  are constants,  $\xi$  is the angle of contact between sand grain and water,  $u_{15}$  and  $u_{15f}$ , are the wind speed and the threshold wind speed at a height of 15 cm, and  $A'$  and  $B'$  are constants.

The curves for Eqs. 1, 2, and 3 are drawn in Fig. 2 for comparison. Figure 2 will be explained a later. Otherwise, the threshold shear velocity on a dry sand surface is given by

$$u_* = A \sqrt{\frac{\rho_s - \rho_a}{\rho_a} g d} \quad (\text{Bagnold, 1954}) \quad (4)$$

2. The sand transport rate by wind on a wet sand surface is as yet an unsolved problem. The empirical coefficient value obtained various worker on a wet sand surface is small compared with the case of a dry sand surface, if the Bagnold formula is assumed. Also, there is no evidence that the Bagnold formula is applicable. The mechanism of sand movement on a wet sand surface has not been theoretically formulated and developed. However, equations empirically obtained for predicting the sand transport rate by wind on a wet sand surface have been presented by Iwagaki (1950), and Nakashima and Suematsu (1976):

$$q = 0.3 (u_{100} - 6) \quad (\text{Iwagaki}) \quad (5)$$

$$q' = A' \frac{\rho_s}{g} u_{15}^2 (u_{15} - u_{15f}) \quad (\text{Nakashima \& Suematsu}) \quad (6)$$

where  $q$  and  $q'$  are the transport rate and  $u_{100}$  is the wind speed at a height of 1 m. Here  $q$  is given in  $\text{tf/m/day}$  and  $u_{100}$  in  $\text{m/s}$ . The coefficient  $A'$  is given in Eq. 3.

The above is a brief summary. Now, Eqs. 1, 2, 3, 5 and 6 are discussed and examined in more detail.

First, we shall examine Eq. 1, due to Belly. It is questionable as to whether we may discuss this equation on the same level as the other equations, because the way of moistening the sand layer was different than in the other experiments. In his experiment, the air was saturated and the sand layer was moistened by absorption from the air. Therefore, there was no evaporation to the air and the layer under the surface was

Fig. 1 Relationship between threshold wind speed and water content. (Redrawn by writers from data of original papers)

Fig. 2 Comparison of threshold shear velocities.

presumably dry. In all other experiments under discussion, the sand layer was moistened by directly spraying on water. Therefore, evaporation from the surface probably occurred to some degree. Putting this problem aside, we shall examine Eq. 1. We can see that the threshold shear velocity for a wet sand surface is given by adding an amount of increase due to the water to the threshold shear velocity for a dry sand surface. The curves given by Eq. 1 for the grain diameters of 0.2, 0.3 and 0.5 mm are drawn in Fig. 2. This equation is of the same type as Eq. 2. The amount due to the water is proportional to  $\log_{10} w$ . Therefore, the rate of increase of the shear velocity is large until 1% of the water content is reached. At a water content higher than 1%, the rate becomes gentler. This behavior does not agree with other experimental results.

Next, Eq. 2, obtained theoretically by Kawata and Tsuchiya (1976), is examined. Converting the shear stress to the shear velocity, and considering the condition of  $\varphi = 45^\circ$  and  $\theta = 0^\circ$  for simplicity, Eq. 2 becomes

$$u_{*cw} = A \sqrt{\frac{\rho_s - \rho_a}{\rho_a} gd} \sqrt{1 + D} \quad (7)$$

$$D = \frac{2\sqrt{6}}{5} \sqrt{\alpha_1 \alpha_2} \sqrt{n_0} \sqrt{\frac{\rho_s}{\rho_w}} \frac{T\sqrt{w} \cos \xi}{(\rho_s - \rho_a)gd}$$

The amount of increase due to the water,  $D$ , is directly proportional to the square root of the water content and is inversely proportional to the sand grain diameter. This means that  $D$  increases rapidly to unity and the rate of increase of  $D$  becomes small when the water content is greater than unity. In addition,  $D$  will be greater for smaller grain sizes. Therefore, this formulation predicts that for a given water content the threshold shear velocity of small grains is greater than that of large grains.

These characteristics of Eq. 7 are completely contrary to the experimental facts, i.e., the threshold shear velocity increases linearly with increases in the water content of the sand surface; it also increases with the median diameter of the sand, and the threshold shear velocity increases suddenly at a certain water content of the sand surface.

Now we will move to a discussion of Eqs. 3 and 6. The definition of the threshold condition by Nakashima and Suematsu as expressed in Eqs. 3 and 6 was quite reasonable if their experiments were carried out correctly. Their results were given as a function of the wind speed at the height of 15  $\mu$ m. To compare to the other equations and experimental results, the threshold wind speed in Eq. 3 was converted to the threshold shear velocity using a method proposed by Horikawa and Shen (1960). The results expressed in terms of the shear velocity are drawn in Fig. 2. The results are limited to less than 4% in the water content. The applicability of the constants  $A'$  and  $B'$  to other grain diameters has not been examined yet. In addition, the sand transport rate given by Eq. 6 becomes rather small if we accept this result. Equation 6 cannot explain the experimental results of Nishikawa, Tanaka

and Ikeda (1975) nor the results of the our observation carried out on January 1983, described Horikawa et al. (1984), namely that the sand transport rate on a wet sand surface is comparable to that on a dry sand surface when the wind speed is sufficiently high. Sand will be blown off when evaporation rate is high enough even though the sand layer has high water content. Equation 6 cannot explain this phenomenon. Thus Eqs. 3 and 6 are not applicable to calculation of the sand volume on a wet sand surface.

Finally, Eq. 5, due to Iwagaki (1950), is examined. Equation 5 was obtained from a field measurement of sand transport. In the process of determination of the empirical Eq. 5, the threshold wind speed of 6 m/s at a height of 1 m was assumed. But the threshold wind speed of 6 m/s is too small for a wet sand surface. Due to experimental limitations, Eq. 5 cannot be applied for wind speeds over 12 m/s. In addition, the same argument as for Eq. 6 pertains to Eq. 5. Therefore, Eq. 5 cannot be used for practical applications.

The conclusion of this discussion is that, at present, there are no appropriate general formulas for the threshold shear velocity and the sand transport rate by wind on a wet sand surface.

### III FORMATION OF THRESHOLD SHEAR VELOCITY

In the next section, a mechanism of blown sand on a wet sand surface is proposed according to laboratory results and field observation. The threshold shear velocity for a wet sand surface is required. Therefore, using the experimental results of Tanaka, Sano and Kakinuma (1954), the threshold shear velocity will be formulated.

As described in Section II, it was concluded that Eqs. 1, 2 and 3, which express the threshold shear velocity or the threshold wind speed on a wet sand surface, could not be applied under general conditions. This was due to the fact that there were considerable differences in the threshold shear velocity, or the threshold wind speed, obtained in previous experiments, because the criteria defining the threshold condition and the experimental method differed from one another. Therefore, the above experiments offer no way to reliably estimate the threshold shear velocity on a wet sand surface. To extend our results to include blown sand on a wet sand surface, it is necessary to formulate an expression for the threshold shear velocity.

Among the several experiments previously conducted, the authors judged that the experiment performed by Tanaka, Sano and Kakinuma (1954) was conducted under the most suitable conditions and that the results obtained were reliable. Therefore, using the experimental results of Tanaka et al., a formulation of the threshold shear velocity on a wet sand surface is attempted in this section.

Figure 2 will again be considered. As previously described, Eqs. 1, 2 and 3 are also drawn in this figure. A portion of the results of Tanaka et al. for the grain sizes under consideration are also drawn. The results of Tanaka et al. for the critical condition were expressed in terms of the wind speed at a height of 7 cm. The data in Fig. 2 were converted from wind speed to shear velocity using a logarithmic law for

the vertical wind speed distribution and the empirical formula for the roughness length by Zingg (1952), as proposed by Horikawa and Shen (1960).

In Fig. 2, for the water content of 0 % (which means the threshold shear velocity on a dry sand surface), the shear velocity is about 8 cm/s for 0.2 mm, 25 cm/s for 0.5 mm and 35 cm/s for sand 0.8 mm in diameter. Furthermore, for the water content of 0.5 %, the threshold shear velocity becomes 12 cm/s for 0.2 mm, 30 cm/s for 0.5 mm and 40 cm/s for 0.8 mm in diameter. The threshold shear velocity calculated from Eq. 4 on a dry sand surface is 22 cm/s for 0.2 mm, 32 cm/s for 0.5 mm and 41 cm/s for sand 0.8 mm in diameter. The values for the water content of 0 % given by the experiment of Tanaka et al. are smaller than the calculated values from Eq. 4.

However, the values for the water content of 0.5 % roughly agree with those values calculated by Eq. 4, except for the 0.2 mm-diameter sand. The water content is seldom zero percent and normally the water content is about 0.2 to 0.6 % when we measure sand under natural conditions (air dry condition). An experimental error of about 0.2 to 0.6 % in the measurement of the water content may exist, but it is reasonable to believe that sand absorbs water from the atmosphere as assumed by Belly (1962). In the experiments previously conducted to determine the threshold shear velocity on a dry sand surface, we may consider that the sand had in fact absorbed moisture from the air and the sand had about a 0.2 to 0.6 % water content. Therefore, we may accept the threshold shear velocity at around 0.5 % of water content in the experiment by Tanaka et al. as equivalent to that on a natural dry sand surface. Furthermore, we find another remarkable fact in the experiments, namely, that the gradient of the threshold shear velocity with respect to the water content is almost constant, 7.5 (cm/s)/%, for water contents lower than about 8 %, independent of the sand grain size.

From the above considerations and experimental results, an equation expressing the threshold shear velocity must have the properties (1) at 0.0% water content, the threshold shear velocity must correspond to that of a dry sand surface and (2) the gradient should be 7.5 (cm/s)/% for water content lower than 8 %, independent of the grain size. Therefore, the threshold shear velocity on a wet sand surface is taken to be given by

$$u_{*cw} = A \sqrt{\frac{\rho_s - \rho_a}{\rho_a} g d} + 7.5w \quad \begin{array}{l} 0.0 < w < 8.0 (\%), \\ 0.2 \text{ mm} < d < 0.8 \text{ mm} \end{array} \quad (8)$$

where  $w$  is the water content (%).

It is a matter of course that Eq. 8 will be replaced by a new equation in the future according to the results of further well-controlled experiments and theoretical considerations.

Finally, we shall consider why the experimental results of Tanaka et al. showed a linear increase in the threshold shear velocity with increase in the water content irrespective of the grain diameter. In the model developed before, the sand grain was assumed to be spherical. Now we consider real sand. The diameter of a sand grain will be defined

by the longest diagonal line as schematically shown in Fig. 3. The angles of the edges on the surface will be distributed depending on the history of how the sand grain was produced and on how it weathered. In the sand layer, it might be the case that certain sand grains in contact with each other will have sharp edges as for S in Fig. 3(a). It is natural to consider that as a contact configuration of adjoining grains, a sharp edge of a certain grain will touch the flat part of an adjacent grain as shown by A, B and C in Fig. 3(a). If so, the following model to explain the experimental results by Tanaka et al. might be valid (see Fig. 3(b)).

We assume that the representative angle of a sand grain edge is independent of the grain diameter. Then, at low water content (lower than about 8%), the condition of adhering water is independent of the grain diameter. Therefore, an increase in additional cohesive resistance force due to adherence of water at the contact point will be independent of the sand grain size, and a constant increase as given by Eq. 8 results. The above model helps us to understand the experimental results of Tanaka et al.

Fig. 3 Schematic diagram of the contact condition of sand grains.

#### IV SUMMARY OF INFORMATION AND DEVELOPMENT OF A HYPOTHESIS FOR BLOWN SAND ON A WET SAND SURFACE

From the literature survey, and from the fundamental experiments and field observations conducted in our work, much information concerning blown sand on a wet sand surface was obtained. The following gives a summary of the more important results:

- (1) The blown sand transport rate observed on a natural beach where a wet sand surface was exposed was almost the same as that measured on a dry sand surface (Kawata, 1950).
- (2) The water content of the blown sand caught by a trap and generated on a wet sand surface which contained about 9 % water content in the upper 10 cm of the surface was about 2.5 %. The empirical coefficient ranged from 0.065 to 0.116 if the Bagnold formula is assumed (Iwagaki, 1950).

- (3) The coefficient of the Bagnold formula was 0.25 on an open beach section and 0.0025 at a location behind a dune if the Bagnold formula is applicable (Aramaki, 1969).
- (4) With elapsed time, the sand transport rate decreased when the wind blew on a wet sand surface. The sand transport rate per 5 min with 0.5 % and 4.2 % water content on the surface was about 1/10 and 1/1000 of that on a dry surface (Nakashima, Sue and Nagasawa, 1973).
- (5) The sand transport rate observed on a wet sand surface with 6 % water content was almost the same as that on a dry sand surface when the wind speed at a height of 1 m was 15.8 m/s, even though it rained, (Nishikawa, Tanaka and Ikeda, 1975).
- (6) Within a few hours after rain stopped, the sand surface reached the air-dry condition when a strong wind blew (Nishikawa et al., 1975).
- (7) The sand transport rate suddenly increased when the water content of the surface sand became lower than 0.3 % and the rate of increase was proportional to the wind speed (Nishikawa et al., 1975).
- (8) There was a certain water content for which the sand transport rate suddenly decreased under a constant wind speed (Nakashima and Suematsu, 1976).

The above results were obtained from previous studies. From the our experimental study in a laboratory wind tunnel and a series of the field observations, we list:

- (9) When a constant wind speed (shear velocity of 42 cm/s) blew on the saturated sand surface,
  - (a) The blown sand on the surface with water content greater than 11 % was negligible, independent of the evaporation rate.
  - (b) The sand transport with a range of water content between 11 % and 6 % was a strong function of the evaporation rate, which was mainly controlled by the air conditions.
  - (c) The sand transport rate was high when the water content of the surface was below 6 %.
- (10) As soon as a rain stopped, blown sand was violently generated under recorded 10 minute-average wind speeds of about 15 m/s at a height of 5 m.
- (11) Within about 18 hr after a rain stopped, the sand volume accumulated in a trench was almost the same as that blown off a dry sand surface.
- (12) The sand volume blown off from a wet sand surface of about 3 or 4 % water content was the same as that trapped by a trench from a dry sand surface when the wind was strong, but the former was about

80 % of the latter when the wind was rather weak.

- (13) The blown sand dislodged from a wet sand surface with about 3 or 4 % of water content which moved downstream reached an equilibrium condition within about 10 m from the boundary where the sand was able to dislodge and the sand surface appeared to be dry. The water content of the flying sand grains was also lower than 1 %.

The above is the main information collected. By linking these fragments together, we become aware of three important matters with relation to the sand blown on a wet sand surface. That is,

- (1) The generation of blown sand on a wet sand surface will be strongly affected by the evaporation rate.
- (2) Concerning the water content, the sand transport rate on a wet sand surface is comparable to that on a dry sand surface when the water content of the surface is small. However, the transport rate decreases suddenly when the water content reaches a certain value.
- (3) Concerning the wind speed, the sand transport rate on a wet sand surface is low when wind speed is low. However, the transport rate becomes comparable to that on a dry sand surface when the wind speed is high even if the sand layer has water content of a few percent.

To explain the above phenomena for the blown sand on a wet sand surface, the following mechanism will be considered. When the sand layer is moist, the threshold shear velocity increases and should be given by an appropriate function of water content in the sand layer. The blown sand on a wet sand surface will then be generated under the same conditions as on a dry sand surface when the shear velocity exceeds the threshold shear velocity. However, even at a condition lower than the threshold shear velocity, sand will be blown when the evaporation rate, controlled by weather conditions, is high, since with a high evaporation rate the sand surface will rapidly dry and the threshold shear velocity of grains on the surface will become lower than that of the underlying sand layer. In this case, the transport rate at a given position depends on the evaporation rate.

The above can be expressed by modifying the Kawamura formula. Thus we write,

$$q = K \frac{\rho_a}{g} (u_* + u_{*cw})^2 (u_* - u_{*cw}) \quad (9)$$

$$u_{*cw} = A \sqrt{\frac{\rho_s - \rho_a}{\rho_a} g d} + 7.5 w I_w$$

$$0.0 < w < 8.0 (\%), 0.2 \text{ mm} < d < 0.8 \text{ mm} \quad (10)$$

where  $u_{*cw}$  is the threshold shear velocity on a wet sand surface and an appropriate function of the water content, and  $I_w$  is an appropriate function of the evaporation rate. The coefficient  $I_w$  has the value 1.0 when the shear velocity exceeds the threshold shear velocity on a wet sand surface and takes a value ranging from 0.0 to 1.0 depending on the

evaporation rate when the shear velocity is higher than the threshold shear velocity on a dry surface but lower than that on a wet surface. This condition is schematically described in Fig. 4. For example, the transport  $q_{w_s}$  in a case when  $I_w$  becomes meaningful is calculated by substituting  $u'_{*cw}$  into Eq. 9 and  $u'_{*cw}$  is an apparent threshold shear velocity given by Eq. 10 taking a value of  $I_w$  between 0.0 and 1.0 depending on the evaporation rate. It is considered that  $I_w$  is a coefficient which converts the drying speed of the wet sand surface by evaporation and a lowering of  $u_{*cw}$ , e.g., to  $u'_{*cw}$ . The coefficient  $I_w$  will be discussed further in Section VI.

The next task is to examine the sand transport rate on a wet sand surface when the shear velocity exceeds the threshold shear velocity on a wet surface.

Fig. 4 Schematic explanation of the point at which the coefficient  $I_w$  becomes important.

## V EXPERIMENT FOR THE SAND TRANSPORT RATE ON A WET SAND SURFACE UNDER HIGH SHEAR VELOCITY

### 5.1 Purpose

A hypothesis for the blown sand on a wet sand surface was given in Section IV. To examine this hypothesis, an experiment on a wet sand surface under high shear velocity was carried out. The results are described here.

### 5.2 Facilities (Wind tunnel and Anemometers)

Experiments were carried out using a blowoff type wind tunnel which was specially designed for studying blown sand at the Central Research Institute of Electric Power Industry. The wind tunnel has a test section 110 cm high, 100 cm wide and 20 m long. The bottom is tapered with a gradient of 1/10 at both ends and the cross section of the tunnel

is 100 x 100 cm on which sand can be placed to a thickness of 10 cm. A side wall of glass allows visual observation of the tunnel interior. The wind speed is variable from 3 to 30 m/s, controlled by the frequency of the rotary fan. A sand collecting chamber lies on the end opposite the blower.

For the wind speed measurement, a hot-film anemometer array consisting of four probes and one ultrasonic anemometer was used. The vertical distribution of the wind speed was measured at a location 16 m from the upstream end of the test section in the tunnel. The elevations at which the wind speed measurements were usually made were 5, 10, 20, 30 and 40 cm above the sand surface. These elevations were sometimes changed when some of the anemometers malfunctioned.

The output of the wind speed was recorded on a pen chart recorder with six channels, because a constant wind speed was applied. The wind speed was directly read from the chart. The shear velocity was calculated from the vertical distribution of the wind speed by Eq. 11.

$$u_* = (u_{10} - u_1)/5.75 \quad (11)$$

The sand used in the experiment was taken from Yonezu Beach, the site of our field investigations. The sand was well sorted with a median diameter of 0.3 mm and a uniformity coefficient of approximately 1.7.

### 5.3 Procedure

Sand was spread over the test section of the 20-m long tunnel. The sand surface was carefully flattened and water was gently applied without disturbing the surface until about one-third of the sand layer from the surface was wet. Then, in a period ranging from 10 to 25 days, the sand layer was left to dry until it reached a certain specified water content. The experiment was carried out when the overall sand layer achieved the suitable water content. On the sand surface, partially dried and dried portions of the surface appeared here and there in the tunnel. In this case, a preliminary burst of strong wind at the beginning of the experiment was applied and the dried sand layer on the surface was blown off. Then the experiment was executed.

For measuring the water content of the sand surface, 5-mm samples of sand were scraped from the surface. Immediately after scraping, the samples were weighed and dried and the water content was calculated. Four samples were scraped, two from the upstream side of the tunnel and two from the downstream side. Sampling was done before and after a run and an average value of the eight samples was employed for defining the water content of that run.

The most difficult procedure of the experiment was to achieve a certain specified water content over the sand bed. The tunnel is constructed out of doors. One side of the tunnel is directly exposed to the outside. The sand bed is strongly affected by the weather, such as the sunlight through the glass wall, the local wind flow passing the mouth and end opening of the tunnel, and shading of the tunnel roof by trees. In order to prepare a sand bed of constant water content, many

attempts by trial and error had to be made. In the end, we could not succeed in establishing a reliable method of making a sand bed of constant water content. However, the experiment runs were carried out only under conditions of constant water content of the sand bed.

#### 5.4 Experiment results and discussion

Figure 5 shows an example of the vertical distribution of the wind speed obtained on a wet sand surface for a constant water content of the sand bed. Figure 5 shows that the logarithmic law for the vertical distribution of wind speed was satisfied on the wet sand surface when blown sand was generated. The focal point is given by  $z' = 0.5$  cm and  $u' = 300$  cm/s and this value is of the same order as that for a dry sand surface. The difference is judged to be within experimental error.

Figure 6 shows the sand transport rate on a wet sand surface. Data for which the average water contents of the bed at the upstream side and downstream side of the tunnel before and after a run differed by more than  $\pm 1.0\%$  were not plotted in Fig. 6.

Fig. 5 Example of the vertical distribution of wind speed on a wet sand surface.

The experimental results shown in Fig. 6 for the sand transport rate agree fairly well with Eq. 9 for the values  $K = 1.0$  and  $I_w = 1.0$  when Eq. 10 is substituted into Eq. 9, although the data at high water content were limited. The shortage of data in the high water content range is due to the difficulty in preparing a bed of constant water content. A considerable scatter in the data is recognized in the low shear velocity region. This may be depend not only on experiment error and unsuitability of Eqs. 8 or 10, but also on the rate of evaporation.

Fig. 6 Sand transport rate under high shear velocity on a wet sand surface.

We conclude that sand will be blown off of a wet sand surface as well as off a dry sand surface when the shear velocity exceeds the threshold shear velocity under a certain water content of the sand surface, although the upper limit of the water content could not be determined from the present experiments.

#### VI FURTHER CONSIDERATION ON THE FACTOR $I_w$ AND THE THRESHOLD SHEAR VELOCITY ON A WET SAND SURFACE

The coefficient  $I_w$  will become meaningful when the shear velocity falls below the threshold shear velocity on a wet sand surface but is higher than that on a dry sand surface.

Considering  $I_w$  further,  $I_w$  is related to the sand transport rate from the upstream area and the water content of the sand surface, i.e., the threshold shear velocity. As described in Section IV, the sand dislodged from a wet sand surface rapidly loses its adhering water when blown downstream and the transporting sand volume increases (the sand transport rate becomes larger with downstream distance from the generation area). At a certain location under consideration, this transported sand volume from the upstream must be added to that which will be generated at that location by the evaporation rate. Thus the distance from the boundary from which the blown sand will be generated to the particular location enters into the determination of  $I_w$ . Furthermore, the sand blown off the downstream affects the water content, i.e., the threshold shear velocity on a wet sand surface. Eventually  $I_w$  and the water content on the wet sand surface become

interconnected. However, the relationship between  $I_w$  and the water content of the sand surface cannot be determined analytically because they are related to each other in a complicated way. Therefore, we have to search for approximate expressions for  $I_w$  and the water content of the surface after a rainfall.

## VII CONCLUSIONS AND SUGGESTIONS FOR FUTURE STUDIES

The important conclusions obtained from this study for the calculation of the sand transport on a wet sand surface are:

1. The threshold wind speed and the threshold shear velocity obtained in previous experiments differed considerably due to differences in experimental methods and the definition of the critical condition. It was difficult to decide which of the results were valid. No acceptable equations could be found for the prediction of the threshold shear velocity on a wet sand surface.

However, using those experimental results which were judged to be reasonable among the various experiments, an empirical equation predicting the threshold shear velocity was obtained (Eq. 8).

2. The sand transport rate will be given by Eqs. 9 and 10.

This equation should be applicable for water contents lower than 8 % on a wet sand surface.

3. The blown sand dislodged from a wet sand surface of 3 or 4 % water content rapidly lost its adhering water. Within about 10 m from the boundary where the sand was generated, the dislodged sand achieved the air-dry condition and the sand transport rate reached equilibrium.

Therefore, no experiment on sand transport may be made on a wet sand surface if there is a distance greater than 10 m at the upstream from the position for which the blown sand would be calculated, and if the water content of the same surface is lower than 4 %.

4. Whether it is raining or not, effective blown sand will be generated if the water content of the sand surface is relatively low or if the wind is strong.

5. In the field, the sand surface may rapidly achieve the air-dry condition due to a high evaporation rate, percolation to the underground and dried sand blown from upstream. In addition, after a rain stops, the sand volume trapped in a trench trap within 18 hr was comparable to the volume trapped corresponding to a dry sand surface.

Therefore, special consideration to rainfall may not be necessary for beaches such as Yonezu Beach where a series of field observation was carried out by the authors, and where blown sand is usually generated under fine weather and only occasionally under rain.

The above are the main conclusions obtained from this study concerning the topic of blown sand on a wet surface. Many other characteristics of blown sand on a wet sand surface were revealed, but

they were not deemed suitable for a quantitative discussion. An intensive effort should be made to investigate the characteristics of blown sand on a wet sand surface.

In particular, the following subjects should be studied.

1. How deep is the sand layer wetted by a rainfall? What relationships are there between the water content, amount of rainfall, median grain diameter and the sand diameter distribution?
2. What processes are involved in the drying of the sand surface? What are the roles of air temperature, humidity, wind speed and solar radiation? Is it possible to predict the water content of the surface at a given time after a rainfall?
3. What is the functional form of  $I_w$  ?
4. Is it possible to improve the equation for the threshold shear velocity, Eq. 8?

To solve the above problems, systematic field observations and well-controlled laboratory experiments are needed. In particular, it is recommended to perform field observations on a rainy beach such as a beach facing to the Japan Sea in winter. For the above studies, the development of new electronic instruments for the rapid measurement of the water content in the sand layer, for the continuous measurement of the blown sand rate, and for the exact measurement of the threshold wind speed are necessary.

#### ACKNOWLEDGMENTS

The support of The Central Research Institute of Electric Power Industry over the course of this work is greatly appreciated. We are also indebted Dr. N.C. Kraus for critically reading and refining the English manuscript, and also for supervising the typing, performed by Miss T. Kohno.

## CHAPTER EIGHTY SEVEN

### TRANSPORT OF NILE SAND ALONG THE SOUTHEASTERN MEDITERRANEAN COAST

Zev Carmel\*, Douglas L. Inman\*\* and Abraham Golik\*

#### ABSTRACT

The potential for longshore sediment transport (LST) is estimated from a three-year set of directional wave data measured off Haifa, Israel. The resulting annual cycle of LST, together with an analysis of the wave and shore characteristics, suggests a wave-induced sediment transport mechanism with a uni-directional annual transport that gradually decreases along the transport path from the source (Nile delta) to the sink (Haifa Bay). Existing estimates of the rates of transport of Nile sediment are in good agreement with this result.

#### Introduction

Mineralogical studies of coastal sediments from Alexandria eastward to the Sinai and Israel show that the Nile River has been the source of sediment for beaches and coastal dunes as far north as Akko, a shoreline length of about 700 km (Shukri, 1950; Emery and Neev, 1960; Shukri and Philip, 1960; Nachmias, 1969).

This suggests the coastline from the Nile delta through Akko (Fig. 1) to be a classical "littoral cell," i.e., a complete sedimentary compartment that includes the sediments' sources, transport paths and sinks (e.g. Inman and Brush, 1973). The Nile littoral cell thus begins with the Nile River as the original source of fine quartzitic sand whose path leads along the coasts of Sinai and Israel. The cell terminates near Akko, in the Haifa Bay sink (Emery and Neev, 1960; Nir, 1973; Inman et al., 1976; Goldsmith and Golik, 1980; Nir, 1982a). Since the construction of the High Aswan Dam, the Nile no longer brings sediment to the coast, and erosion of the Nile delta now constitutes the sediment source for the Nile littoral cell (Inman et al., 1976; Inman, 1984).

At source, the Nile material may be carried eastward by either the prevailing westerly waves, or the counterclockwise Mediterranean gyre, or both (Inman et al., 1976). Here, the large angle of wave attack (westerly waves on an east-west beach), coupled with the existence of rather high waves (Lowe and Inman, 1983), suggests a very high rate of wave-induced transport. Also, the existence of eastward currents outside of the breaker zone (Manohar et al., 1974; Inman, 1984) indicates the existence of a steady current (the east Mediterranean gyre). This current may also be instrumental in the eastward transport of the Nile material.

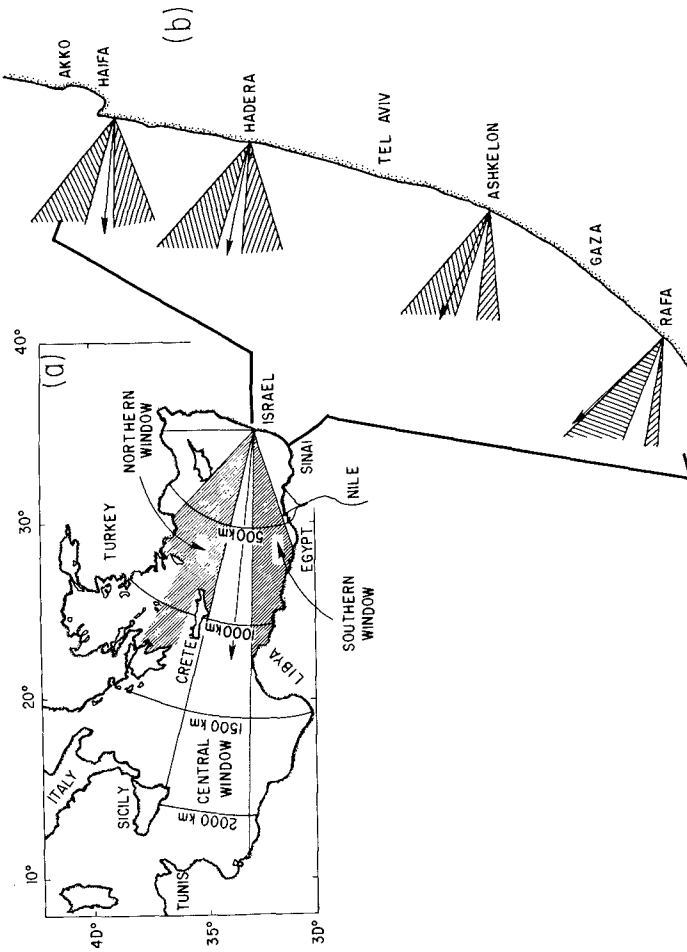

Figure 1. A general map (a) and detailed map (b) of the Eastern Mediterranean region showing the three windows for approach of deep-water waves. The detailed map shows the central window (open), the northern and southern windows (hachured)

Farther east, toward the Sinai and especially along the Israeli coast, the rate of wave-induced transport must obviously be reduced due to the change in shore orientation vis-a-vis the approach directions of deep-water waves (Fig. 1a). It is unclear whether a wave-induced transport ("longshore sediment transport" or LST) or a current-induced transport ("shelf transport") is the main mechanism for moving the Nile sand along the cell.

In this paper we consider the mechanism of sediment transport along the Nile cell, making use of some recent results from a directional wave measuring system off Haifa.

#### Previous Studies of Sediment Transport Along the Israeli Coast

The study of Emery and Neev (1960) is a pioneer work, and classical paper. The observed presence of quartzitic sand with a distinctive suite of heavy minerals, and the gradual decrease in sand size, led these authors to conclude that the beach sands of Israel are derived mainly from the Nile River. This sand is transported, they claim, by both the wave-induced longshore current and by the fringe of the offshore Mediterranean circulation current. During a three-day survey Emery and Neev measured the wave-induced current and found that it is northward directed and decreases in size as one moves along the coast from Sinai through Bat Yam (south of Tel Aviv), but reverses direction and gradually increases north of this nodal point.

Using some theoretical arguments on the beach orientation relative to an assumed dominant direction of wave approach, and the above experiment as an example, Emery and Neev generalize the above findings into the following conclusion. A supposed change in the net LST direction occurs near Tel Aviv, hence a significant amount of current-induced transport must be present to account for the abundance of Nile sediments north of Tel Aviv.

Although the Emery-Neev study deserves much credit for many of its pioneer findings, we feel that it errs in the above general conclusion. In particular, the three-day survey - conducted in the summer - is probably indicative of the summer LST trend, but certainly not of the winter and net annual trends (see later).

Using wave refraction diagrams for various combinations of wave period and direction, Goldsmith and Golik (1980) proposed a slightly different pattern for the LST along the Israeli coastline. According to their study the gross LST is equal or very close to the net transport and is directed eastward along the Sinai coast as far east as Rafa. From Rafa to Haifa sand is transported both northward and southward according to wave direction. Generally, the northward component is larger than the southward in the southern part of the coast, decreases as one goes northward along the coast, and is smaller than the southward component in the northern part of Israel. Again, as with the Emery-Neev study, Goldsmith-Golik invoke a nodal point of zero net-LST in the center of Israel and, consequently, require a large amount of current-induced transport.

Like the preceding Emery-Neev study, the Goldsmith-Golik study lacks adequate ground-truth wave data for proper evaluation. With the recent deployment of directional wave systems off the Israeli coast, we are now in a better position to understand the mechanism and rates of sediment transport along this coast.

#### An LST cycle at Haifa

A directional wave station at Haifa, Israel, provides long-term measurements of both wave energy and direction. It offers an opportunity for estimating the direction and rate of sediment transport within the eastern portion of the Nile littoral cell. Moreover, conclusions can be drawn regarding the sediment transport along the cell.

The following results are based on three years of twice daily wave measurements. Details on the measuring system, procedures, and analysis techniques are given in Carmel et al., 1984a,b.

The monthly-average significant wave height is shown in Fig. 2a. It indicates a bi-modal climate, with a primary (winter) cycle whose monthly average wave height peaks around December-January at about 1.1m, and a secondary (summer) cycle that peaks around July-August at about 0.8m. Further investigations reveal that the winter peak is caused by westerlies (eastward-moving low fronts) which move over southern Europe or northern Africa and generate big storm waves over the eastern Mediterranean (Carmel et al., 1984a). On the other hand, the summer peak consists of rather steady waves which are generated over the eastern basin of the Mediterranean by the seasonal trough of low pressure (Carmel, 1984).

The directional wave data may be used for estimating the potential for longshore sediment transport. This is done through the use of equation (1) (e.g., Inman and Bagnold, 1963; Komar and Inman, 1970; Inman et al., 1976):

$$Q_1 = \frac{K}{(\rho_s - \rho) g N_0} (E C_n \cos \theta \sin \theta)_b \quad (1)$$

where  $Q_1$  is the volume sediment transport rate,  $K = 0.77$  is a dimensionless constant (Komar and Inman, 1970),  $\rho_s = 2.65$  and  $\rho = 1 \text{ gm/cm}^3$  are the densities of the quartzitic grains and water, respectively,  $N_0 = 0.6$  is the "at rest" volume concentration of grains,  $E$  is the wave energy density,  $C_n$  is the group velocity,  $\theta$  is the angle between the wave crest and the beach, and the subscript  $b$  indicates the breaker point.

We use the bi-monthly accumulative wave data to estimate the bi-monthly LST rates from equation (1). The resulting net average LST rates are shown in Figure 2b. The net monthly transport shows an annual cycle with a northward peak of  $75 \times 10^3 \text{ m}^3/\text{month}$  in mid-winter and a southward steady rate of approximately  $-25 \times 10^3 \text{ m}^3/\text{month}$  in summer. Thus, the high winter waves generate a large northbound transport, while the smaller summer waves cause a smaller flow of sediments in the opposite direction. The net annual transport rate is  $110 \pm 100 \times 10^6 \text{ m}^3/\text{yr}$ .

Figure 2. The monthly average significant wave height at Haifa (a); the bi-monthly average sediment transport rates at Haifa, computed from the directional wave data (b).

Projections on the Longshore Transport Rates along the Nile Cell

The winter westerlies and the summer seasonal trough are the dominant meteorological phenomena to govern the wind and wave generation in the Eastern Mediterranean. One thus expects the wave climate along the entire Nile littoral cell to be highly correlative and basically similar.

The deep water waves arrive at Haifa from three windows of deep water wave approach (Fig. 1a). While the stormy winter waves arrive solely from the central and southern windows (Carmel et al., 1984a), the summer waves arrive only from the central and northern windows (Carmel, 1984).

Now, compare for instance the localities of Haifa, Hadera, Ashkelon and Rafa, arbitrarily picked along the Israeli coast (Fig. 1b). The beach normal is denoted by arrows, the wave approach windows, determined as in Fig. 1a by the protruding headlands of Egypt, Libya, Crete and Turkey, are shown by the open and hatched sectors. It is clear from Fig. 1b that the net transport must remain northbound and gradually increase with the southward distance from Haifa. This is a result of the gradual change in beach orientation.

The above presents a consistent picture, where the sediment transport is wave-induced, and the net annual transport is unidirectional and gradually diminishing along the sediment path, thus allowing for the buildup and maintenance of the abundant Nile-sand beaches and coastal sand dunes.

#### Estimates of LST at various locations along the Nile cell

Inman et al. (1976) use a 10-year data set of marine wave observations to compute the LST rate at various locations along the Nile delta. Because of the wide angle of wave attack, this method is considered reliable here. The computed results are "higher" than  $860 \times 10^3 \text{ m}^3/\text{yr}$  for the net (eastward) transport at the Rosetta and Damietta promontories. Only the main wave component was considered here. Quelenec and Manohar (1977), taking all wave components into account, indeed obtained higher rates;  $0-1.5 \times 10^6 \text{ m}^3/\text{yr}$  in between the two promontories, up to  $3 \times 10^6 \text{ m}^3/\text{yr}$  immediately on their eastern sides.

Inman et al. (1970; 1976) also estimate from the entrapment of sand at the entrances of the Bardawil Lagoon, that the net LST rate is about  $500 \times 10^3 \text{ m}^3/\text{yr}$  and eastward at this location in Sinai.

The huge breakwater of the Ashdod harbour in southern Israel has yielded diversified estimates of the LST rate there. Dornhelm (1972) studied the annual bathymetric maps and concluded that the breakwater has interrupted some 80% of the northward sand transport, yielding a rather low estimate of  $50,000 \text{ m}^3/\text{yr}$  northbound net transport. On the other hand, Finkelstein (1981), reanalyzing the same maps, found a large offshore sand accumulation and thereby arrived at a rather large estimate of  $560,000 \text{ m}^3/\text{yr}$  northbound net transport.

An excellent survey of the various estimates of LST along the Israeli coast is given by Nir (1982b), from which the following paragraph is quoted:

"On the basis of theoretical studies Migniot (1974), Sauzay et al. (1974) and Manoujian and Migniot (1975) show that the annual resultant sediment transport is always directed to the north and  $\text{m}^3$  reaches about  $400,000 \text{ m}^3$  at Gaza,  $215,000 \text{ m}^3$  at Ashdod,  $100-150,000 \text{ m}^3$  at Hadera and only  $80,000 \text{ m}^3$  at Atlit."

Figure 3. Existing estimates of the net annual LST rate (solid arrows) along the Nile littoral cell.

A summary of the above estimates, including that given by us for Haifa ( $110 \times 10^3 \text{ m}^3/\text{yr}$ ), is given by the direction and length of the solid arrows in Figure 3.

Several features are evident in Figure 3:

1. All estimates yield a counter-clockwise direction for the net transport, i.e., unidirectional along the way from source to sink.
2. Big discrepancies occur between the three estimates made at Ashdod, probably a result of the complicated path and entrapment of sediments around the harbour's breakwater. We take the average of these three estimates ( $275 \times 10^3 \text{ m}^3/\text{yr}$ ) to represent the true transport rate at this locality.
3. The LST estimates begin with a maximum at the Nile source ( $860 \times 10^3 \text{ m}^3/\text{yr}$ ), are gradually diminishing along the sediment pathway, and reach a final low near the Haifa sink ( $80\text{--}110 \times 10^3 \text{ m}^3/\text{yr}$  at Atlit and Haifa, respectively).

Hence, all existing estimates are in good agreement with our result on a wave-induced sediment transport, with a unidirectional and gradually decreasing rate from source to sink.

## CHAPTER EIGHTY EIGHT

### FLUCTUATIONS IN LITTORAL DRIFT

Richard Silvester<sup>(1)</sup>

#### ABSTRACT

The long assumed uniform movement of sand along the coast produced by wave action can be disputed when the interaction of storm sequences and swell is considered. Storm waves form a protective bar, which essentially puts material back into circulation for the oblique swell to work upon. The resulting longshore transport is swift whilst the bar exists but decreases to negligible proportions once it is denuded and the normal swell-built beach profile recurs. This impulsive drift has many implications for engineers and geomorphologists and to researchers attempting to predict annual rates of transport.

#### WAVE CLIMATE

In oceans a distinction can be made between storm waves and swell. The former are in the fetch, where winds are still generating them or maintaining a fully arisen sea. Swell is the term for waves that are dispersing across the sea outside the fetch. Since the energy concentrated in the relatively small storm zone is now spread over vast areas downwind of generation the wave heights must necessarily decrease (Silvester 1974). The characteristics of these two systems are specific in their influence on a mobile bed at the shoreline.

Storm waves are multi-directional from their mode of generation and due to the many fetches encompassed by a cyclone as it passes near or across the coast. They are continually breaking as the shorter waves steepen on the crests of longer waves, to pour down their front faces and so aid their growth. (Longuet-Higgins and Stewart 1960). Their optimum steepness implies that all waves contain much water above the SWL. Another characteristic of distinct importance is their short duration as on any coast a storm lasts for a few days only, with few repetitions annually.

Swell at any point in the dispersal area consists of waves propagating within a small fan of directions, encompassed by orthogonals to the side boundaries of the fetch. Thus swell waves arrive on a coast from persistent directions, certainly within the same quadrant, from the storm zones which are repetitive from month to month and year to year. In so spreading they take longer to arrive at a given shoreline, as recorded by Snodgrass et al (1966). On most western margins of continents swell arrives continually from the constant generation zones between 40° and 60° latitudes where cyclones travel from west to east. On eastern margins swell is more variable in direction throughout the year.

---

1. Department of Civil Eng., University of W.A. Nedlands, W.Aust.

Storm waves are variable in time until the fully arisen state is achieved and then vary at different points along the fetch. Swell, on the other hand, varies with distance from fetch and also continually with time. As components of the storm spectrum pass any point so the height and period change. The long low waves arrive first, followed by the high medium band of the spectral peak, after which the low period end of the spectrum arrives. It is therefore difficult for researchers to choose some mean wave condition for correlation with sediment transport over an annual period.

### SHORELINE PROCESSES

If there is a sedimentation problem on a section of coast it is due to longshore transport which results in either siltation or erosion, or generally both. It is axiomatic that the persistent swell waves, which effect this movement, are arriving obliquely to the coast, in order that there is a longshore component of energy on breaking.

In crossing the continental shelf these waves are refracted and steepened as they travel into shallower water. The water particles at the bed oscillate and hence disturb the bed but they also suffer a net movement in the direction of wave motion, known as mass-transport. This varies throughout the water column, as seen in Figure 1, with the depth ratio, but for long period swell it is maximum at the bed. (Longuet-Higgins 1953). It may take weeks for this distribution to diffuse from the bed and sea surface for any wave train but is **immediately**

Fig 1. Mass transport due to waves, where  $X$  is net movement per wave period  $T$  for height  $H$ , and  $g$  is accelerative due to gravity assuming a flat bed and laminar boundary layer.

available at the bed. Thus a sweeping motion is exerted on the sedimentary particles towards the shore, and along it, beyond the breaker zone.

When these swell waves are steepened to an unstable steepness they break and then proceed as a bore towards the beach, thus forming the surf zone. Much sediment is suspended by the bore which then carries it up the face of the beach, as seen in Figure 2. The water carried in this uprush percolates through the berm down to a water table at about mean sea level. This is possible whilst there is a reasonable time between each wave, which is the case for swell.

This percolation reduces the volume of downwash so causing the sand carried up to be stranded on the beach, which results in accretion. Such build-up continues so long as there is sufficient material offshore to be fed to the breaking waves. Freshly deposited sand is loose which aids percolation. After persistent swashing by waves the beach face becomes well compacted.

When storm waves arrive to this swell-built profile a crest breaks almost every second, resulting in large volumes of water running up the beach face. This saturates the beach, as seen in Figure 2,

Fig 2. Beach processes for swell and storm conditions.

causing the water table to become almost coincident with the face. The downrush equals the uprush which drags sand down the slope, forming a larger than normal hydraulic jump at the toe. This occurs in the zone where ground water is rising almost vertically in returning to the sea. This sets up a liquefaction or "quick-sand" condition which results in swift erosion and consequent collapsing of the beach face. This creates a near vertical face against which waves reflect. It is little wonder that the beach is eroded metres in a matter of minutes.

The mass of water thrown onto the beach must return to the sea, in this case laden with sand. This runs as a density current hugging the bed, aided by the strong shoreward current at the surface due to the

storm wind shear force. As deeper water is reached the velocity is reduced, so causing the sediment load to be dropped. A mound is formed some distance offshore which grows during the storm until the depth over it is sufficiently small for incoming waves to break over it. (See Figure 3). This breaking is also assisted by the seaward current from excess water returning to the sea. At this stage the major erosion ceases.

Fig 3. Offshore bar profiles during formation showing sediment sorting.

The first storm of the winter season exerts the greatest influence on the beach when the recession can be accepted as the maximum for the year. Only two situations can cause greater erosion. If a second storm is accompanied by a higher water level, due to a storm surge, or spring tide height, the bar must be elevated to break the waves. Also, if a subsequent storm is of longer duration the attenuated waves reaching the receded new vertical beach face can remove further material which fills the swale between bar and beach with the aid of the circulating current, as seen in Figure 3. An almost horizontal platform could result (Silvester 1979).

This natural sequence of forming a protective bar by storm waves is beautiful to behold. If it did not occur the previously accreted shoreline might be spread evenly over the seabed. It is a mechanism man cannot hope to emulate due to the large volume of material involved. Suggestions that a permanent bar be constructed by rubble-mounds is to no avail since the oblique swell waves would reflect from this submerged structure and scour the bed adjacent to it, so causing costly remedial measures. (Silvester 1977).

#### RETURN OF BAR

Part of this exciting phenomenon of coastal defense is the dismantling of the bar when it is no longer required. This is accomplished by the swell following the storm, either immediately or perhaps some weeks later. These break over the bar causing excessive suspension of sand which is redeposited on the beach. The berm is rebuilt up to the uprush of the waves. This is small initially as waves are well attenuated in traversing the bar and the wide surf zone. As the bar is lowered and the surf zone decreases in width so the run-up increases and hence the height of the berm. This is why the back berm can be lower than the seaward edge and shallow pools exist on it. The present discussion omits any influence of tides, which will have

little effect until they exceed 2 m range.

The seaward slope of the offshore bar could be steeper than the swell built beach as it results from deposition by a seaward current and opposing mass-transport of waves. As swell waves traverse this face their ratio of breaking to deep-water wave height increases, which must result in a stronger littoral current, which is dependent on the square of the breaking wave height. This current is therefore magnified concurrently with enlarged suspension and so results in a great pulse of drift alongshore. This is aided by the larger surf zone width since the total transport is the summation of rates across this normal to the beach, even extending beyond the breaker line. (Andersen and Fredsøe 1983). As sand is pushed shorewards the surf zone becomes very flat.

This excessive littoral drift exists whilst the bar is being returned to the beach, which may take two to three weeks with reasonable swell input. Japanese engineers have concluded that 90% of this transport can take place over two weeks and 10% over the remainder of the year. As can be imagined, the rate is optimum directly after the storm but reduces as the bar recedes and the normal parabolic profile is approached. This is due to the diminishing effect of the bar slope on the waves and the decreasing width of the surf zone. The suggested distribution over time is depicted in Figure 4, which requires

Fig 4. Suggested variation in littoral drift as bar material is replaced on beach.

verification from field measurements. To measure these peaks in drift it would be necessary to monitor accretion in sand spits or against some structures at daily intervals over the two or three weeks until the bar had disappeared, which would require profiling of the bar to ascertain its state.

### FLUCTUATIONS IN LITTORAL DRIFT

The importance of this phenomenon of pulses in longshore transport warrants a little more discussion of the reasons for it. As stated earlier the seaward slope of the bar could be steeper than the bed approaching the swell built profile where the surf zone exists. Whilst this mound could be spread widely by the storm waves and outgoing current during the storm the swell waves could quickly steepen it by their mass-transport in these shoaling conditions. It may be inferred that water entering the valley between bar and beach will inhibit this steepening, but this seaward flow is generally accomplished by rip currents forming at weak spots in the bar. It is well known that these dangerous currents occur just after storms, and hence flow is minimal over most of the bar.

The ratio of breaker height to deep-water height ( $H_b/H_0$ ) varies with deep-water wave steepness, but for any value of this ratio varies with the bed slope as in Figure 5 (Goda 1970). The ratio of crest height to deep-water wave height is decreased tending to make surging rather than plunging breakers. Another trend is for the wave front to become steeper (Adeyemo 1968) with increasing slope, again improving the ability to generate a littoral current through greater mass-transport. There is also the possibility of refraction lagging that from a mildly sloped bed thus increasing the angle at breaking, but this phenomenon has not been reported to the author's knowledge.

Once the waves have broken at the apex of the bar they then traverse obliquely either a swale or even two or three such depressions before arriving at the beach. As noted already these valleys may be filled with sediment if the storm duration is long. In any case they could well be smoothed out by the transport of sediment from the peaks before material is finally replaced on the beach. The resultant bed within the surf zone therefore could be very mildly sloped. This causes the broken waves to reduce more slowly in height as they proceed to the beach face. This again creates better conditions for a strong littoral current.

Another factor to be taken into consideration is the partial reflection of the swell waves from this relatively steep slope of the bar. Battjes (1974) has shown that when the surf similarity parameter  $[ = \tan\alpha / \sqrt{H_b/L_0} ]$  has a value of 2.3 it "corresponds to a regime about half way between complete reflection and complete breaking." These reflected waves, which must necessarily be angled to the bar, interact with the incident waves to establish a short-crested system (Silvester 1974) whose orbital motions are conducive to sediment suspension with a large mass-transport alongshore. This action will cause an excessive drift on the face of the bar beyond the breaker line, which could exceed values estimated from the littoral current expanding from the surf zone.

To show the possibility of this parameter being of this order consider a storm system with a wind speed ( $U_{19.5}$ ) of 30 knots in which case the component with most energy has a period of 10 seconds (Silvester 1974). The steepest bed slope as the swell arrives could be 1:6. If

Fig 5. Parameters of breaking waves as presented by Goda (1970).

these waves arrive from a distant fetch their deep water height is of the order of 0.5 m, which near breaking could be doubled to 1.0 metre. Substitution in the above parameter gives a value of 2.07. If 12 seconds were used it becomes 2.5, so that the critical value of 2.3 could readily occur.

Andersen and Fredsøe (1983) have computed littoral drift along a barred beach and compared it to that on an equivalent uniformly sloped profile. Figure 6 is taken from this reference where it is seen that the three bars in (a) cause local increases in  $H/h$  as in (b), from which values of  $q$  have been derived as in (c). The distribution of transport for the equivalent uniform slope is dotted in (c). Areas under these curves give the total rate of transport, which are essentially the same for barred and uniformly sloping beaches. An

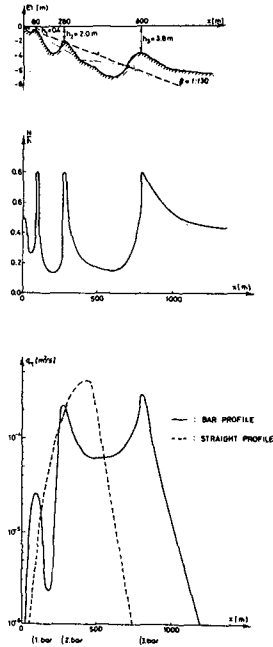

Fig 6. (a) Measured coast profile at the Danish west coast.  
 (b) Variation in wave height towards the coast.  
 (c) Computed sediment transport at the coast depicted in (a).  
 Taken from Andersen and Fredsøe (1983).

alternative progression is illustrated in Figure 7, where the swales are filled by bars seaward of them. This could result in two uniform slopes as shown in (a) which could result in the H/h curve as in (b). The  $q_T$  curve in (c) is based upon relationships indicated in Figure 6, which could result in greater overall transport. Taking in all the inaccuracies of these suppositions there is indicated the propensity for excessive drift whilst sand is being transported back to the beach.

Verification in models should be carried out on the littoral current generated on a barred beach, a uniform slope and the parabolic shape produced by swell waves. Realistic profiles could be formed in a fixed bed to confirm whether littoral current velocities differ greatly in distribution and overall discharge.

**SORTING OF SEDIMENT**

Another process worthy of consideration is the sorting that takes place of sand during the formation and ultimate replacement of Nature's protective bar. When the density current, at the initiation of erosion, slows down the first sand particles to be dropped are coarse, followed seawards by the median and fine components. As seen in Figure 3, the bar will comprise coarse sand at its landward base, median material in the middle, whilst the top and seaward face consist of the smallest grains.

Fig 8. Values of k (Dean et al 1982) versus number of storms during periodic assessment of littoral drift.

Fig 7. Modified transport distribution for a saturated bar with equivalent uniformly sloped beach from Fig 6.

When the swell commences to return the bar to the beach it is the finer material that is acted upon first. This is the stage when breakers are greatest, turbulence is optimum and the current is maximum. This small diameter sand is suspended more readily so that it is moved well downcoast from its original position by the time it is deposited on the back of the berm. Thus distribution aids the sorting in the next bar that is formed.

The median sand will be replaced somewhere in the centre of the berm with less longshore displacement. By the time the coarse material is shifted a short distance back to the outer berm the swell built profile almost exists with its reduced longshore transport capacity. Thus the coarse grains move very little downcoast. This is why measurements of fineness along the coast are taken as indicative of drift direction.

#### LITTORAL DRIFT CALCULATIONS

It is salutary to look at what variables are included in formulae for longshore drift and compare the assumptions with the conditions discussed above. It is normal to correlate volumes of accretion taken over a year with some average swell condition for the same period. As noted already, swell waves vary in height and period from hour to hour and hence the selection of some meaningful average, including direction of approach, is in the realms of fantasy.

As seen above the fluctuations in littoral drift are severe, the bulk of this transport taking place two or three weeks after each storm. If three storms occur during a year instead of one the drift can be trippled. No account appears to be taken of these events even though measured accretions vary tremendously for little apparent reason. Take, for example, the data gathered by Dean et al (1982) at Santa Barbara which recorded the filling of a dredged hole over a period of 380 days. Eight surveys were analysed which resulted in data as listed in Table I. The longshore wave energy was computed two different ways giving P and S. These were then divided into the immersed transport rate to give correlation constants K and  $K_*$ . The ratio of these was computed and listed to illustrate the sensitivity of the mode of deriving this input energy. They give factors varying from 1.78 to 2.94.

But accepting perhaps the usual constant K it is seen that this ranges from 0.32 to 1.63. The authors commented: "However the smallest value which exhibits the greatest deviation from the norm is associated with the fourth intersurvey period which is characterized by a very small value of I. If this one point is not included, the ratio of the largest to the smallest of the remaining K values is less than two, which appears reasonable for this type of measurement." (author's underlining). No mention is made in the article of storm sequences during these surveys but the extra high storm waves would have been included in the energy calculation without reference to the changing directions of these locally generated waves. But averaging of such coefficients, which in this case was 1.23, as distinct from the previously accepted value of 0.77 (U.S. Army Coastal Eng. Res.

Centre 1977) reduces confidence in such formulae.

Inspection of the U.S. Navy Marine Climate Atlas (1977) for the North Pacific Ocean shows the average number of storms for each month for the 10° square adjacent to the California coast near Santa Barbara. These were interpolated for the survey periods in Table I as used by Dean et al (1982) and this is graphed against K as in Figure 8. In spite of the scatter a relationship is indicated of K increasing with the number of storms. It would have been preferable to use the actual number of storms during the 1970-80 period of drift measurement but this was not possible from the wave data available. However, it would appear that this variable should be included in any future assessments of littoral drift.

**Table I** Field results from Santa Barbara (Dean et al 1982)

No. of days	Total Vol Change(m) <sup>3</sup> Rate I(N/S)	Immersed wt Transport Rate I(N/S)	Component Wave Energy Flux at breaking P (N/S)	K=I/P	Component of mmtm S(N/m)	K <sub>*</sub> =I/S (m/s)	K <sub>*</sub> /K
48	32,820	85.3	52.2	1.63	27.8	3.06	1.90
51	65,070	159.1	101.4	1.57	45.4	3.50	2.13
35	82,810	295.0	352.4	0.84	119.5	2.47	2.94
53	10,290	24.2	76.6	0.32	37.9	0.64	2.0
82	22,220	33.8	31.7	1.07	17.6	1.91	1.78
57	38,760	84.8	63.8	1.33	32.6	2.60	1.95
54	35,640	84.6	64.4	1.31	34.2	2.47	1.89

Another example is given of variations in computed drift, model verification, and actual measurements in a sand trap. (Pratte et al 1982). Two previous estimates were 120,000 and 205,000 m<sup>3</sup>/yr. whilst the model suggested 30,000 m<sup>3</sup>/yr. The actual accumulation to date of publication averaged 110,000 m<sup>3</sup>/yr., indicating the need for "a permanent dredging plant." Even though waves from the most severe annual storms were used in the model it is doubtful that a proper bar profile would have formed in the model. These large discrepancies point to some missing link in the chain of events, which is herein suggested as the impulsive movement after each storm. It is stated in this reference that "it took approximately 12 hours to fill in the entrance during storms", which could be taken to mean just after such sequences.

If it is accepted that the bulk of transport occurs during the removal of the bar the greatest concern is the difference in profile used in computations (a uniform slope) from the changing bed structure of this active period. Another important aspect is the assumption of uniform sand size. As noted above the fine sediment on the bar is moved first when turbulence and longshore current is optimum. As the swell-built

profile is approached it is the coarse material being returned a short distance to and along the shore.

#### GEOMORPHOLOGICAL CONSEQUENCES

The author has wondered for many years why sand spits are formed across deep embayments of the coast or why lagoons are enclosed parallel to the shoreline. Why, for example, should such indentations not be silted up completely by the slow uniform supply from littoral drift? The reason now seems to be available, of pulsational supply of sediment by waves that can only deposit it at the tip of the spit. In essence, too much material is fed for them to handle.

At the extremity of a spit, as seen in Figure 9, the waves refract sharply and lose their longshore transporting capacity. Deposition results at this point so that the spit is enlarged parallel to the shoaled wave crests. Sudden spit formation after storms has been observed by many but not monitored scientifically with simultaneous profiling of the disappearing bar associated with it. Such daily records over 2 to 3 weeks would require a large team of workers on stand-by, to go into action immediately after a storm event.

A model verification could be made by having a beach end abruptly as seen in Figure 10. Initially oblique monochromatic waves could break on a profile comprising a bar. Once this has been returned to the beach the bar could be reformed with the aid of wire templates shaped as a mound. A spit should emerge from this condition and could then be compared to the form of accretion when a swell profile is maintained along the upcoast beach. The templates should be extended as the spit elongates.

In natural conditions there could be periods of the year with little drift, in which case the tip of the spit could be rounded off, as indicated in Figure 10. But after the next storm and another pulse the spit will suddenly enlarge and the process continued. Aerial photographs of newly formed spits should exhibit such variations in width, with perhaps semi-circular beaches on the leeward side.

These spits, or barrier beaches as they are termed, occur the world over and vary greatly in magnitude. If conditions permit the shoreline can accrete extensively in front of an initially narrow spit. In this context it should be remembered that sediment transport in past geologic ages could have been much greater than today, because many rivers are now harnessed for water supply or to prevent flooding, thus diminishing the supply of material to the coast. Such barrier beaches will not form unless there is significant oblique swell energy for transport plus a good supply of sediment from rivers debouching upcoast. In some cases spits have formed from either side of an indentation due to swell energy arriving from two quadrants during different seasons of the year. This must be accompanied by storm cycles for impulsive drift to occur, which is a basic requirement for spit formation.

Fig 9. Accretion at the end of a spit during a pulse of littoral drift.

Fig 10. Spit construction at the extremity of a beach with pulsative drift.

Examples of barrier beaches are illustrated in Figure 11, being respectively from the Australian and Atlantic coasts. (Melville 1984). It can be seen that they run for tens of kilometres. These features are ubiquitous and very important commercially. Because of changed supply conditions many of these areas are now being eroded as Nature sculpts them to balance the existing wave climate (Converse 1982). Kaufman and Pilkey (1971) blame solely mans' actions on these adverse developments, but his influence is very modest and local compared to natural trends in longshore sediment distribution.

#### ENGINEERING IMPLICATIONS

Coastal engineers' for some decades have been trying to analyse why littoral drift and concomitant shoreline changes occur so continually and so swiftly. They certainly do not fit into the concept of a nice uniform process. This view of "A river of sand" has distracted research into this mammoth transporting mechanism resulting from severe meteorological fluctuations experienced over millions of years.

These spectacular changes are not only due to the processes described above but also result from other natural and man-made influences. Fluctuating sediment input from rivers, the predominant supply of material to the coast, can effect long-term fluctuations. Concentration of storm wave energy on specific lengths of shoreline can produce larger than normal bars and hence humps of sand traverse

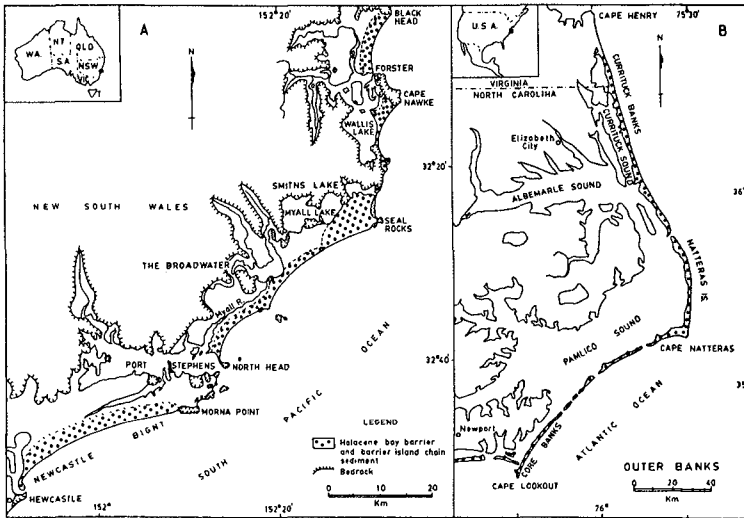

Fig 11. Barrier beaches formed on A: the NSW coast of Australia and B: the east coast of the USA (From Melville 1984).

the coast. Whilst the construction of breakwaters and groin fields can provide a transient interruption to longshore drift a much greater influence is exerted by channels dredged across the continental shelf to a port. This can cause cessation of sediment movement across this line as effectively as if a structure were built along the length of the channel. Material deposited in this trench is dredged and deposited well out to sea. Thus the offshore region downcoast is scoured. The bed is deepened and the profile to the beach steepened which then demands more sand for construction of the protective bar. Some of this will remain offshore to make up the deficiency there and hence the beach recedes. The rate of filling of the channel will vary with distance from shore but will fluctuate more near the surf zone, with peaks just after each storm. This knowledge should help in the surveying and planning of remedial dredging. The formation of shoals and even spits at river and harbour mouths will also be swift after a storm sequence. This affects navigation through these areas and hence recognition of the times of peak supply and perhaps verification of rates during these critical periods can assist by-passing operations. The action of weir-type jetties to accumulate drift for later disposal downcoast could be put in jeopardy by sudden silting of the structure to the outer full height segment.

The engineers' role should be to observe Nature on this precious margin of land and sea, accept these prodigious forces but not try to work against them. Nature achieves an admirable result in protecting the shorelines by her construction of the offshore bar. In this she can be helped by providing the volume of material required for this task. It is possible that this placement of material back into circulation need not be accompanied by longshore movement, if headlands are installed for Nature to sculpture bays of equilibrium shape. (Silvester and Ho 1972). In this case the persistent swell arrives normal to the beach around the complete periphery of the bay and hence places the bar material back from whence it came ready for the next storm.

### CONCLUSIONS

1. Storm waves and swell have denuding and accreting effects respectively on beaches, the former placing beach material in the sea for the latter to transport.
2. The action of storm waves in constructing an offshore bar is Nature's way of protecting the coastlines, which should be used and aided by man.
3. Whilst swell waves return the bar to the beach, over a very short period, the excessive littoral current and suspension of material causes a pulse of littoral drift far greater than on the swell built profile.
4. The reasons for this optimum drift are the increase in breaker height, enlargement of surf zone width, maintenance of broken wave height in this zone, perhaps greater obliquity of breakers, and partial wave reflection on the seaward face of the bar.
5. Sediment sorting during bar formation causes fine particles to be moved more readily alongshore than median sizes, with coarse material being least affected.
6. Formulae for littoral drift vary drastically in their predictions due to their non-recognition of the part played by storm sequences, as instanced in many reports.
7. Impulsive littoral drift can explain why sand spits have formed naturally across deep indentations of the coast to form barrier beaches.
8. Besides the transient peaks of drift from bar formation other longer term influences can vary sediment supply on any coast, the understanding of which should aid the coastal engineer in planning by-passing measures and coping with siltation.
9. Littoral drift can be minimised by headland control which entails sculpturing of equilibrium shaped bays between them, around which the persistent swell arrives normally and hence lacks a longshore component to generate a littoral current.

## CHAPTER EIGHTY NINE

### FLOW RESISTANCE DUE TO INTENSE BEDLOAD TRANSPORT

Daniel M. Hanes \*

#### Introduction

When water flows over a stationary bed the fluid motion is retarded by both skin the friction and local pressure gradient forces related to the roughness of the bed. If the bed itself is composed of discreet movable grains, the boundary is less clearly defined and the dynamics poorly understood (see Gust and Southard, 1983). Owen (1964) proposed that saltating grains (grains which lift off the bed, move through the fluid, and fall back to the bed without colliding with other grains) have the effect of increasing the frictional resistance of the bottom.

At higher flow stages, Hanes and Bowen (1984) have suggested a model for bedload transport which is based upon the dynamics of collisional grain flows following Bagnold (1954, 1956). In such a collision dominated flow, it appears that the resistance of the bed to the overlying flow can be less than the resistance of a fixed bed to the same overlying flow. This result is consistent with the dynamics of rapid granular-fluid flows, as will be discussed below.

#### Drag relation for rapid granular-fluid flows

In a collision dominated granular-fluid flow the relation between the shear stress and the flow parameters for rectilinear shear flow is given by Bagnold (1954) as:

$$U_*^2 = C \frac{\rho_s}{\rho} (\lambda D)^2 (dU/dz)^2 \quad (1)$$

where  $U_* = (\tau/\rho)^{1/2}$ ,  $D$  is the grain diameter,  $\rho$  is the fluid density,  $\rho_s$  is the grain density, and  $\lambda$  is the linear concentration.  $\lambda$  is related to the volume concentration  $N$  by:

$$\lambda = [(N_*/N)^{1/3} - 1]^{-1}, \quad (2)$$

---

\*Assistant Professor, Division of Applied Marine Physics, Rosenstiel School of Marine and Atmospheric Science, University of Miami, 4600 Rickenbacker Causeway, Miami, Florida 33149

where  $N_*$  is the maximum possible concentration of the granular material. The relation (1) has been experimentally verified with differing materials and apparatus by Bagnold (1954), Savage and Sayed (1984), and Hanes and Inman (1984a).

Equation (1) appears similar in form to the analagous relation for a wall bounded turbulent shear flow as given by:

$$u_*^2 = (\kappa z)^2 (du/dz)^2 \quad (3)$$

where  $\kappa$  is von Kármán's coefficient and is approximately 0.4. We can define "resistance coefficients" for equations 1 and 3 as:

$$\epsilon_g = C \frac{\rho_s}{\rho} D^2 \lambda^2 \quad (4a)$$

$$\epsilon_t = \kappa^2 z^2 \quad (4b)$$

where the subscript g refers to granular-fluid and the subscript t refers to turbulent clear fluid. The ratio of these two terms is given by:

$$\epsilon_g / \epsilon_t = \frac{C \rho_s D^2 \lambda^2}{\rho \kappa^2 z^2} \quad (5)$$

Equation 5 represents the ratio of the stress in a granular-fluid layer of thickness  $z$  to the stress in a wall bounded turbulent shear flow at a distance  $z$  away from the wall, where both flows have the same shear rate at  $z$ . Using values of  $C = 0.013$  (Bagnold, 1954),  $\rho_s = 2.65\rho$ , and  $\kappa = 0.4$ , equation 5 is shown in Figure 1 for differing values of  $\lambda$ . The natural limits on  $\lambda$  are 1 and 20. For  $\lambda < 1$  the concentration is too low to apply a collisional model, and for  $\lambda > 20$  the grains are so tightly packed the granular assembly takes on solid behavior. A typical value for  $\lambda$  is 5, corresponding to a volume concentration  $N$  of approximately 0.38. Clearly if  $z$  is greater than only a few grains diameters, the stress for the granular-fluid less than the stress for the turbulent fluid.

#### Observational evidence

There have been very few observations of flow resistance under conditions of intense bedload transport. The most comprehensive data set is Williams (1970). Williams varied the flume width and discharge independently. He was therefore able to evaluate and correct for side wall friction in estimating the bottom stress.

Williams data for flat bed conditions are shown in Figure 2, where  $(u_* / \bar{u})^2$ , representing a quadratic drag coefficient, has been plotted

Figure 1: The ratio of granular-fluid flow resistance to clear turbulent fluid flow resistance indicates the granular-fluid has lower resistance for flows thicker than a few grain diameters over the range of possible concentrations.

Figure 2: Drag coefficients from Williams (1970) data indicates lower flow resistance under high transport conditions. All data displayed are from flat bed experiments.

against nondimensional bedload transport. The lower flow regime occurs near the threshold for sediment motion, while the upper flow regime occurs at high flow stage after ripples disappear. The drag coefficients for the lower flow regime are clearly higher than those for the intense bedload upper flow regime. There appears to be a trend toward decreased resistance with increasing bedload transport.

#### Discussion

The largest uncertainty in this presentation is proof of the existence of the granular-fluid layer during intense bedload transport. If such a layer exists, it is not difficult to conceptualize the system as two fluid layers, where the lower (granular-fluid) layer is less viscous than the upper (turbulent fluid) layer.

Observations of intense bedload are inherently difficult to make. Horikawa et. al.(1982) used photographic and electro-resistance wires to measure sediment concentration near the bed under large oscillatory flows. They found a thin layer (10 to 20 grain diameters thick) of highly concentrated grains undergoing rapid shear. These observations are strongly supportive of a thin granular-fluid layer.

Other evidence comes from the laboratory shear cell experiments of Hanes and Inman (1984b), who suggest a dynamic Coulomb yield criterion applies at the boundary between the stationary bed and the moving grains. Unless there is a downward normal stress to counteract the shear stress, stationary grains will be mobilized into the flow. As argued by Bagnold (1956), the normal stress must arise from the immersed weight of the grains in the granular-fluid layer.

The applicability of these concepts to situations involving waves is unclear. During the peak phase of velocity the stress may be high enough to cause a granular-fluid layer. Because the motion is oscillatory, though, the system must pass through a stage of zero shear stress at which time there would not be a granular-fluid layer. The flow resistance and energy dissipation related to the mobilization and formation of the granular-fluid layer are unknown. It is therefore uncertain whether the net energy dissipation under large waves on a movable bed will be greater or less than the energy dissipation resulting from the interaction of same waves with a fixed bed.

#### Conclusions

The effects of intense bedload transport are shown to decrease the resistance of the bed to the overlying fluid. This is because the grain-to-grain collisions dominate the dynamics in the granular-fluid layer, which acts somewhat like a boundary layer of less viscous fluid. The adaptation and extrapolation of Owens (1964) saltation model to

intense bedload transport conditions will result in an overestimation of the drag coefficient.

## CHAPTER NINETY

### A Laboratory Experiment of Beach Cusps

Arata Kaneko\*

Beach cusps with a longshore spacing of 20 to 150 cm have been built by the continuous action of incident waves on a steep laboratory beach. In the formation stage of beach cusps, all bed materials on the beach moved shoreward. The backwash vortex, which was found first by Matsunaga and Honji (16,18) on a laboratory beach, gave a good explanation of the shoreward movement of bed materials. Beach cusps formed when the value of a dimensionless parameter  $H_b^2 L_b / h_b^2 L$ , which controls swash motion on a steep beach, became larger than 1.12;  $H_b$  is the height of the breaking wave,  $L_b$  its wavelength,  $h_b$  the water depth at the breaking point and  $L$  the horizontal distance from the shoreline for still water level to the breaking point. The observational spacing of beach cusps formed regularly were in quite good agreement with half a wavelength of the zero-mode subharmonic edge wave generated on a sloping flat beach. As a result of this study, the contribution of edge waves on cusp formation becomes more undoubted.

#### Introduction

Beach cusps have been known as a prominent sedimentary feature on beaches with a quasi-uniform longshore spacing less than several tens meter. Since the first extensive field observation of Shepard (20), many works have been attempted to clarify the dynamics of beach cusps. Although there is still some controversy as to the cause of beach cusps (12), it seems natural to relate their formation to edge waves which generate on a beach and have a longshore periodicity. Also recent field observations provide evidence that shows the close correlation between beach cusps and edge waves (5,6,8,11,19).

In this study, beach cusps are observed in detail through each stage of formation on a steep laboratory beach. Vortices generated on the beach by swash motion are visualized and the vortex-induced mass transport flows are related to cusp formation. The criterion controlling cusp formation and the role of edge waves in the formation are also examined.

 (a) motor; (b) wave generator;  
 (c) model beach; (d) projector;  
 (e) camera.

### Experiments

Experiments were carried out using a wave tank 300 cm long, 150 cm wide and 30 cm deep, equipped with a beach floor 200 cm long (Fig.1). The side walls of the tank were made of transparent plastic to enable observation of bed features and flows on the beach floor. Incident waves on the model beach were formed by oscillating a wave-paddle-type generator with a motor-crank system. The beach slope ( $s$ ) and the period of incident waves ( $T_1$ ) were adjustable in the range of 0.081–0.141 and 0.5–2.4 s, respectively. Glass beads of mean diameter ( $D$ ) 0.028 cm and density ( $\rho_s$ )  $2.43 \text{ g cm}^{-3}$  were used as an erodible bed material instead of natural sands. In the experiment of cusp formation, the beach floor was initially covered with a thin bed of glass beads. The surface of the floor was also painted black to view clearly the movement of glass beads against the dark background. The direction of mass transport flow close to the bed could be estimated by following the movement of glass beads on the beach. Flow visualization was made by tracing the paths of polystyrene beads of  $D=0.15 \text{ cm}$  and  $\rho_s=1.04 \text{ g cm}^{-3}$ , which were suspended in water from the bed by the action of breaking waves. The bed surface and a vertical slice of the flow field were illuminated with a 1-kw light projector and photographed by a 35-mm camera from the positions shown in Fig.1.

### Formation of Cusps

When surface waves climb on a steep beach, the wave steepness increases continuously with the growth of the wave-height and the sharpened water surfaces break down rapidly at a short distance from the shore. We shall define the breaking point as the position where the

height of waves climbing on a beach becomes maximum and the plunging point as the position where the forward face of breaking waves impinges on the water surface ahead. For convenience, we shall use the terms offshore and nearshore zone, respectively, for the seaward and the shoreward sides of a breaking point. The nearshore zone is further divided into breaker and swash zones at a plunging point. It should be noted that no surf zone exists on a steep beach. In all photographs presented later, the right-hand direction indicates shoreward.

Figure 2 shows the formation process of typical beach cusps formed at the condition of  $s=0.081$ ,  $T_1=1.15$  s,  $H_b=3.5$  cm and  $h_b=4.0$  cm, where  $H_b$  is the height of breaking waves and  $h_b$  the water depth at a breaking point. Photographs were taken obliquely over a side wall of the tank after the wave generator was stopped temporarily at each stage of cusp formation. Figure 2a shows the initial feature of the glass-bead bed with 0.2 cm thick over the nearshore zone of 49 cm wide. A dotted line indicates the shoreline for still water level, and a bar at top right is 10 cm. After breaking waves begin to attack the beach, all glass beads gradually move shoreward forming a sedimentary zone parallel to the shore just at the seaward side of the plunging point (Fig.2b). As a result, the amounts of glass beads piled up on the beach face increases continuously. The sedimentary zone begins to diminish with decrease of offshore glass beads, and the ridge of glass beads on the beach face becomes cut by a series of narrow channels equi-spaced in the longshore direction. Finally a clear ridge-channel system, as seen in Fig.2c, forms. The run-up length of water becomes maximum at the central point of the ridges and minimum at the channels. Therefore, water running up on the ridges turns back along the channels, forming strong rip currents. The geometry of the ridge-channel system and the pattern of water circulation are sketched in Fig.3. The same bed and

Figure 3. Sketch of the ridge-channel system. The bed profiles of sections A-A' and B-B' are presented at the lower and the left parts, respectively.

Figure 2. Formation process of typical beach cusps.  
 $t$  denotes the elapsed time from the start of the experiment.

flow features have often been observed in wave tanks (17,21). In the field, Sallenger (19) observed that a similar ridge-channel system generated in flood-tide changes to ordinary beach cusps after the mouth of the channels was eroded widely on ebb-tide. It will, therefore, be reasonable to call such a ridge-channel system the beach cusp. Kaneko (9) showed through a numerical experiment that horizontal circulation systems are induced by the nonlinear effect of swash motion due to edge waves. This circulation may also play a role in the initiation of beach cusps.

#### Flows on a Steep Beach

Figure 4 shows the anticlockwise-rotating vortex induced near a plunging point immediately after breaking waves forming beach cusps impinged on the forward water surface just beneath a horizontal scale of 4 cm. The experimental condition was at  $s=0.081$ ,  $T_i=1.68$  s,  $H_b=3.7$  cm and  $h_b=3.9$  cm. The vertical slice at a distance of 10 cm from a side wall was illuminated by a light projector and photographed through the side wall. This vortex, called the backwash vortex, was first found by Matsunaga and Honji (16) to form on a highly steep beach in a wave tank. The backwash from water running up on a beach face is responsible for the vortex formation. The backwash vortex is also known to make up a step-like bed profile, composed of a steep seaward face and a nearly horizontal top and called the backwash step (16). Taking into account flow fields induced by the backwash vortex, we can sketch the overall pattern of mass transport flow forming beach cusps and a backwash step, as in Fig.5. The piling-up of bed materials on the beach face, as seen in Fig.2, can also be well explained by the vortex-induced mass transport flow. The wave-induced mass transport flow of Longuet-Higgins (13) may play a role in the shoreward transport of offshore sands.

Figure 4. Flows beneath the breaking wave forming beach cusps.

Figure 5. Sketch of mass transport flow forming beach cusps and a backwash step.

Figure 6 shows the flow field near a plunging point photographed immediately after breaking waves forming a longshore bar impinged on the forward water surface just beneath a horizontal scale of 4 cm. The method of photography and light projection was the same as in Fig.4. The experimental condition was at  $s=0.081$ ,  $T_i=0.62$  s,  $H_b=3.3$  cm and  $h_b=4.3$  cm. Notice that  $T_i$  is remarkably reduced in comparison with that for Fig.4. Under such a condition, the period of breaking waves became shorter than that of swash motion. As a result, weak swash motion and prominent wave set-up took place. Flows near the plunging point construct a pair of vortices, a clockwise, shoreward vortex and an anticlockwise, seaward one. The paired vortex may be induced by that the wave-induced mass transport flow of Longuet-Higgins (13) and the undertow due to wave set-up proposed by Longuet-Higgins(15) meet near the plunging point. The longshore bar was observed to form on the bed between these vortices (10). We can also sketch the overall pattern of mass transport flow forming a longshore bar, as in Fig.7.

Figure 6. Flows beneath the breaking wave forming a longshore bar.

Figure 7. Sketch of mass transport flow forming a longshore bar.

Criterion for Cusps

In the present experiment, beach cusps developed from a thin glass-bead bed on a beach floor. Because of the small amount of glass beads used, the resulting bed deformation could not grow sufficiently to change the initial conditions of incident waves, the height of breaking waves and the breaking point. Under such a situation, the formation region of beach cusps may be determined by the wave conditions on a rigid plane beach.

As mentioned in the previous section, the backwash vortex generated by strong swash motion is responsible for the movement of bed materials to form beach cusps. We shall analyse the swash motion on a steep beach, making use of the terminology as sketched in fig.8. Let  $L_r$  and  $L$  denote the run-up length and the horizontal distance from a shoreline for still water level to a breaking point, respectively.

Figure 8. Sketch of the swash motion on a steep beach.

When we simulate a breaking wave by a progressive long wave with wave-height  $H_b$  and wavelength  $L_b$ , its energy over a wavelength may be estimated as proportional to  $\rho g H_b^2 L_b$ , where  $L_b = T_i \sqrt{g h_b}$ . We also simulate swash motion by a standing wave with maximum wave-height  $2L_r s$  at a shoreline for still water level and estimate its energy over a nearshore zone as proportional to  $\rho g (L_r s)^2 L$ . Since a part of energy of the breaking wave is transferred to the swash motion, both the energies may be correlated as follows:

$$\rho g H_b^2 L_b \propto \rho g (L_r s)^2 L \tag{1}$$

Rearranging eq.1 and using  $h_b = sL$ , we can obtain the following relation:

$$\frac{L_r}{L} \propto \left( \frac{H_b^2 L_b}{h_b^2 L} \right)^{1/2} \tag{2}$$

The observational values of  $L_r/L$  are plotted in Fig.9 against those of  $H_b^2 L_b / h_b^2 L$ . In Fig.9, the line for eq.2

$$\frac{L_r}{L} = 0.35 \left( \frac{H_b^2 L_b}{h_b^2 L} \right)^{1/2} \tag{3}$$

best fitting into the plotted data is also drawn. The dimensionless parameter  $H_b^2 L_b / h_b^2 L$  controlling swash motion on a steep beach is called the swash parameter here. Some deviation of the plotted data from eq.3 seems due to that the energy transferred to nearshore mass transport flow and wave set-up are neglected in this analysis. The deviation at the region of large  $H_b^2 L_b / h_b^2 L$  may also be influenced by the excitation of edge waves. The swash parameter can be rewritten as:

Figure 9. Run-up length.

$$\frac{H_b^2 L_b}{h_b^2 L} = \left( \frac{H_b}{s^2 g T_1^2} \right)^{-1/2} \left( \frac{H_b}{h_b} \right)^{5/2} \tag{4}$$

The values of  $H_b/h_b$  for the present experiment are plotted in Fig.10 against those of  $(H_b/s^2 g T_1^2)^{1/2}$ . Most of the plotted data are grouped by the critical line

$$\frac{H_b^2 L_b}{h_b^2 L} = 1.12 \tag{5}$$

or

$$\left( \frac{H_b}{h_b} \right)^{5/2} = 1.12 \left( \frac{H_b}{s^2 g T_1^2} \right)^{1/2} \tag{5}'$$

into two regions of the beach cusp and the longshore bar, where the dimensionless parameter  $(H_b/s^2 g T_1^2)^{1/2}$  has been called the surf similarity parameter by Battjes (2). According to Battjes' study, the generation regions for surging, plunging and spilling breakers are, respectively,  $(H_b/s^2 g T_1^2)^{1/2} < 0.2$ ,  $0.2 < (H_b/s^2 g T_1^2)^{1/2} < 1.0$  and  $1.0 < (H_b/s^2 g T_1^2)^{1/2}$ . It should be noted that the beach cusp is transferred to the longshore bar at a nearly central part of the generation region for plunging breakers.

Figure 10. Formation region of cusps.

## Edge waves

According to Ursell's theory (24), the wavelength of edge waves ( $L_e$ ) can be expressed as:

$$L_e = gT_e^2 \sin \{(2n+1)s\} / 2\pi \quad (6)$$

where  $T_e$  and  $n$  are the period and the offshore modal number of the edge wave, respectively. Edge waves on a beach may be classified into two types of subharmonic and synchronous depending on whether the period of edge waves is twice or the same as that of incident waves. Guza and Davis (4) predicted theoretically that the zero-mode ( $n=0$ ) subharmonic edge wave can most easily be excited by incident waves. Huntley and Bowen (7) and Guza and Bowen (6) also found that in the power spectra of nearshore currents, the zero-mode subharmonic edge wave takes place on real beaches. When the longshore undulation of small amplitude due to edge waves is superimposed on the uniform swash motion due to incident waves, the compound swash motion is known to have the longshore spacing of half a wavelength of subharmonic edge waves or a wavelength of synchronous ones (3,10). Equating the spacing of swash motion and beach cusps and using eq.6 and  $T_i$  instead of  $T_e$ , we can express the calculated spacing of cusps ( $L_{cal}$ ) as:

$$L_{cal} = L_e/2 = gT_i^2(\sin s)/\pi \quad (7)$$

for the zero-mode subharmonic edge wave and:

$$L_{cal} = L_e = gT_i^2(\sin s)/2\pi \quad (8)$$

for the zero-mode synchronous edge wave.

Other examples of beach cusps formed regularly are showed in Figs.11a to e. In all the figures, a bar at top right is 10 cm.

(a)

(b)

Figure 11. Five examples of beach cusps formed regularly.

Similarly to Fig.2, these beach cusps are composed of ridge-channel systems. Using the width of the wave tank ( $B$ ) and the total number of the ridges ( $N$ ), we can obtain the observational spacing of cusps ( $L_{\text{Obs}}$ ) as:

$$L_{\text{Obs}} = \frac{B}{N - 1} \quad (9)$$

The numerical data of these beach cusps are presented in Table 1. The value of  $L_{\text{Obs}}$  is in quite good agreement with that of  $L_{\text{Cal}}$  based on subharmonic edge waves. It seems that beach cusps become regular when the resonance condition of zero-mode subharmonic edge waves is satisfied with good accuracy. If edge waves occur on a beach, it will be expectable to find them in the longshore undulation of swash motion.

Table 1. Numerical data of beach cusps formed regularly.

Fig.11	s	T <sub>i</sub> (s)	H <sub>b</sub> (cm)	h <sub>b</sub> (cm)	$\frac{H_b^2 L_b}{h_b^2 L}$	L <sub>cal</sub> (cm)	L <sub>obs</sub> (cm)
a	0.081	2.38	3.4	3.1	4.08	143	150
b	0.081	1.72	3.1	3.1	2.42	74	75
c	0.141	0.98	4.2	3.2	4.30	42	38
d	0.107	0.98	3.4	2.9	2.85	32	30
e	0.107	0.76	3.5	3.1	2.20	19	21

Such a property of swash motion was visible only in the experiment for Figs.11a and b with the large cusp spacings. In other cases, edge waves excited may be too weak to be found in swash motion. The values of L<sub>obs</sub> for the laboratory experiments of Ann (1), Tamai (22) and the author, and the field observations of Longuet-Higgins and Parkin (14), Komar (11), Sallenger (19), Guza and Bowen (6) and Takeda and Sunamura (23) are plotted in Fig.12 against that of  $gT_i^2(\sin s)/\pi$ . The value of L<sub>cal</sub> for subharmonic and synchronous edge waves are also drawn with solid and dotted lines, respectively. Although all the laboratory data and most of the field data have a best fit with the solid line, there are some data of Longuet-Higgins and Parkin, Komar and Sallenger which show a scatter around the dotted line. The critical condition, at which synchronous edge waves are transferred to subharmonic ones, may exist.

Figure 12. Spacing of cusps.

## Conclusions

Main results obtained in the present study are summarized as follows:

- (1) Beach cusps develop at the beach face when all bed materials on a beach move shoreward, forming a backwash step along the plunging point.
- (2) When all bed materials on a beach assemble near the plunging point, beach cusps can not develop and instead a longshore bar forms along this point.
- (3) Vortices induced beneath the breaking waves by the action of swash motion or wave set-up control the movement of bed materials at the swash zone.
- (4) The transition from the beach cusp to the longshore bar takes place at  $H_b^2 L_b / h_p^2 L = 1.12$ . This dimensionless parameter controlling swash motion on a steep beach is called the swash parameter.
- (5) The observational spacing of beach cusps obtained in the laboratory experiment agrees well with half a wavelength of the zero-mode subharmonic edge wave. A relatively large scatter of the field data may be explained consistently by considering the existence of beach cusps generated by the zero-mode synchronous edge wave.

## CHAPTER NINETY ONE

### CALCULATION OF THE RATE OF NET ON-OFFSHORE SEDIMENT TRANSPORT ON THE BASIS OF FLUX CONCEPT

Ichiro Deguchi

Assistant Professor, Department of Civil Engineering  
Osaka University, Osaka, Japan

and

Toru Sawaragi

Professor, Department of Civil Engineering  
Osaka University, Osaka, Japan

#### Abstract

Time and spatial variations of sediment concentration of both bed load and suspended load in the process of two-dimensional beach deformation were investigated experimentally. At the same time, the relation between the velocities of water-particle and sediment migration was analyzed theoretically. By using those results, a net rate of on-offshore sediment transport in the process of two-dimensional model beach deformation  $\bar{q}_f$  was calculated on the basis of sediment flux. It is found that  $\bar{q}_f$  coincides fairly well with the net rate of on-offshore sediment transport calculated from the change of water depth.

#### 1. Introduction

The rate of sediment transport has been formulated in various ways and a variety of formulas have been proposed. Some of them deal with only bed load (Einstein(1972), Madsen et al.(1976)) and others are formulated by assuming that the most of sediment is transported in suspension (Bakker(1974), Nielsen et al.(1978), Kana et al.(1977)).

Generally, sediment is brought into suspension from the bed load layer by wave action and the bed load layer plays a role as a boundary condition for the suspended load. Therefore, bed load can exist but suspended load can not exist by itself. On the basis of this fact, some formulas to estimate the rate of suspended sediment transport are proposed by relating bed load to suspended load (Bijker(1971), Walton(1979)).

However, in most of the previous studies, the time averaged rate of sediment transport over one or one-half wave cycle is directly dealt with and only in a few studies (Bakker(1974), Nielsen et al.(1978)), phase variations of the rate of sediment transport are taken into account.

Further, bed load and suspended load differ in the speed of migration and sediment concentration each other. In a two-dimensional beach

deformation process, it is also said that the directions of sediment transport in bed load and suspended load do not always coincide. Consequently, two different expressions have been prepared to estimate the rates of bed load and suspended load.

The rate of sediment transport  $q(t)$  is universally expressed by using the sediment flux as a function of the phase as follow:

$$q(t) = \int_{-(h+\delta)}^{\eta(t)} C(z,t) U_s(z,t) dz \quad (1)$$

where  $C(z,t)$  is the volumetric concentration of sediment,  $U_s(z,t)$  is the velocity vector of sediment migration,  $\eta(t)$  is the surface elevation,  $h$  is the water depth defined as the distance from the still water level to the upper bed load layer and  $\delta$  is the thickness of the bed load layer. So,  $h+\delta$  is the depth where no sediment movement takes place.  $z$ -axis is taken upward from the still water level as shown in Fig.1.

Fig.1 Definition sketch

The aim of this study is to estimate the on-offshore sediment transport rate including both bed load and suspended load according to Eq.(1) systematically. To calculate  $q(t)$  from Eq.(1), it is necessary to estimate time and spatial variations of sediment concentration of both bed load and suspended load as well as the migration speed of sediment.

The authors, first, investigated the characteristics of bed load and suspended load concentration by measuring them in two-dimensional model beach experiments. Then, the relation between water-particle velocity and speed of sediment migration was investigated by analyzing the motion of sediment particle at various sediment concentration. Finally, the net rate of on-offshore sediment transport was calculated on the basis of Eq.(1) by using the measured sediment concentration and analyzed speed of sediment. The results are discussed by comparing with the on-offshore sediment transport rate calculated from the change of water depth.

2. Characteristics of time and spatial variation of sediment concentration

2.1 Previous works

A lot of studies on the suspended sediment have been conducted. Their objectives are to determine the vertical profile of time averaged suspended sediment concentration by applying an one-dimensional diffusion theory, that is, to determine the so-called height of reference level, concentration at the reference level and a diffusion coefficient  $\epsilon_z$ . Some attempts have been made to simulate the phase variation of suspended sediment concentration by assuming the constant  $\epsilon_z$  and the phase dependent concentration at the reference level (Bakker(1974), Nielsen et al. (1978)).

As for the concentration of bed load, only the experimental results measured by Horikawa et al.(1982) are reported. However, at present, it is impossible to quantitatively estimate the time variation of sediment concentration of both bed load and suspended load.

2.2. Measurement of sediment concentration of both bed load and suspended load

A resistance type sediment concentration measuring system devised by Horikawa et al.(1982)(see Fig.2) was used to measure sediment concentration of bed load and suspended load.

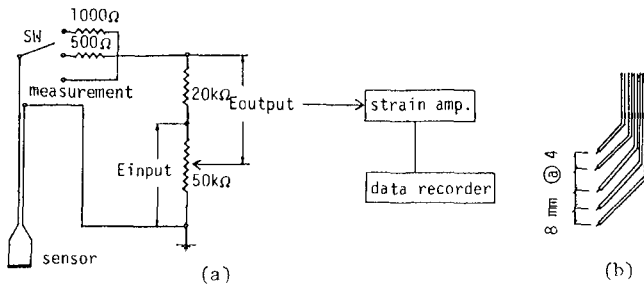

Fig.2 Resistance type sediment concentration measuring system

This system, first, measures the difference of electric resistance between clear water and sediment laden water and then transfers it to the concentration by using a calibration curve. The sensor was made of two enamel coated wires of 5cm long and 0.3mm diameter. Five sensors fixed vertically at a distance of 8mm were used to measure sediment concentration at five different levels simultaneously as shown in Fig.2(b).

Sediment concentration  $C(z,t)$  was measured in four different types of beach deformation processes as shown in Table 1 together with the experimental conditions. In Table 1,  $H_0$  is the deep water wave height,  $T$  is the wave period,  $i$  is the initial beach slope and  $d$  is the mean grain size of the bed material. Concentration measuring points covered whole littoral zone and were distributed vertically from the bed load layer and suspended load region.

Table 1  
Two-dimensional model beach experiments  
and their experimental conditions

	$H_0$ (cm)	T (s)	i	d (cm)	deformation types
Case 1	11	1.20	1/10	0.02	erosion type
Case 2	11	1.28	1/20	0.02	transition type
Case 3	18	1.28	1/20	0.05	transition type
Case 4	12	1.28	1/20	0.05	acretion type

From measured sediment concentration  $C(z,t)$ , time averaged concentration  $\bar{C}(z)$  and phase averaged concentration  $C_p(z,t)$  over 60 waves were calculated. Beach profiles and wave heights were also measured at definite time intervals.

### 2.3. Time variations of sediment concentration

Fig.3 shows examples of measured sediment concentration  $C(z,t)$  in the erosion type beach deformation. In Fig.3(a), measured beach profiles and 6 concentration measuring points (s-1 to s-6) are shown. Fig.3(b) is a result measured at s-4 (inside wave breaking point) and Fig.3(c) is a result obtained at a ripple crest (s-2) in the offshore region. Fig.(i) in each figure shows the surface elevation, Fig.(ii) indicates the concentration in the bed load layer ( $z \approx 0$ ) and Figs.(iii) and (iv) are the suspended sediment concentration at different heights ( $z \approx 0$ ) where  $z^*$  is measured upward from the bottom surface.

It can be seen from these figures that the concentration in the bed load layer in both the surfzone (Fig.3(b)(ii)) and the offshore region (Fig.3(c)(ii)) decreases when a wave crest passes and this indicates that at this phase, an intense sediment transport takes place in the bed load layer. Suspended sediment concentration near the bottom in the surfzone (fig.3(b)(iii)) increases corresponding to the decrease of concentration in the bed load layer and has one peak during one wave cycle. However, in the upper region (Fig.3(b)(iv)), concentration of suspended sediment no longer shows any correspondence with the surface elevation. While in the offshore region (Figs.3(c)(iii) and (iv)), concentration of suspended sediment has two apparent peaks during one wave cycle and this coincides with the results measured by Nakato et al.(1977) and others on a horizontal bottom with bed formations.

On the other hand, as can be seen from Figs.3(c)(iii) and (iv), the maximum concentration of suspended sediment appears almost at the same time without phase lag regardless of the height from the bottom. This indicates that the diffusion of suspended sediment takes place not only in the vertical direction but also in the horizontal direction. Therefore, one-dimensional diffusion theory can not apply to estimate the time variation of suspended sediment concentration. The authors analyzed time variations of suspended sediment concentration by assuming that suspended sediment diffuses from an instantaneous point source according to Ornstein-Uhlenbeck process with constant  $\epsilon_z$  (Soong(1973)). It is found that the procedure gives a good prediction of the time variation of suspended sediment concentration provided that the water-particle velocity due to waves is known.

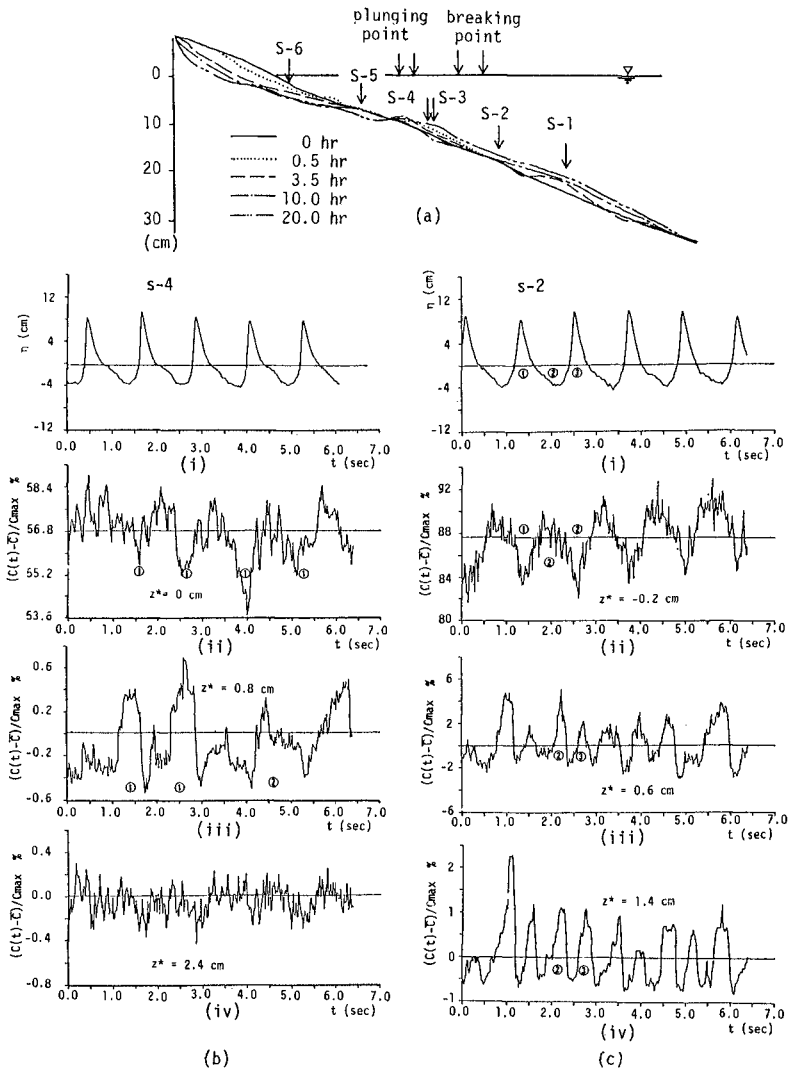

Fig.3 Time variation of sediment concentration  
(erosion type beach deformation)

#### 2.4. Vertical distribution of time-averaged sediment concentration

For reference, some examples of vertical distributions of time-averaged concentration of sediment  $\bar{C}(z^*)$  measured in the erosion type beach deformation process are shown in Fig.4.

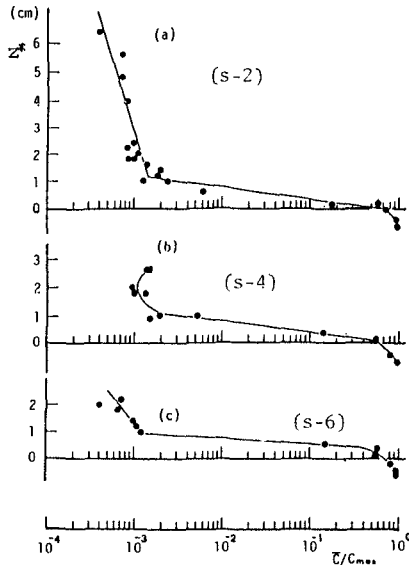

Fig.4 Vertical distribution of time averaged sediment concentration (erosion type beach deformation)

Fig.4(a) is the result obtained in the offshore region s-2 (corresponding to Fig.3(c)) showing that  $\log \bar{C}$  is proportional to  $z^*$ . Fig.4(b) is the result measured near the wave breaking point s-4 (corresponding to Fig.3(b)) and shows that  $\log \bar{C}$  is not directly proportional to  $z^*$ , that is, the concentration near the water surface is larger than that in the middle of water depth. This kind of  $\bar{C}$ -distribution have also been measured by Kana et al. (1977) in the field under plunging wave breaking.  $\bar{C}$ -distribution in Fig.4(c) was measured in the nearshore zone s-6 where the strong turbulence brought by plunging waves already attenuated. In this region,  $\log \bar{C}$  again becomes proportional to  $z^*$ .

From these figures together with the results measured in the other beach deformation processes, it is found that for the vertical distribution of time averaged suspended sediment concentration, one-dimensional diffusion theory with constant  $\epsilon_z$  is applied in appearance except for the region near the wave breaking point.

3. Relation between the migration speed of sediment and water-particle velocity

The motion of the particle suspended in a fluid is usually analyzed by Lagrangian method (Hinze(1959)). Namely, the linearized equation which subjects the motion of the particle in a fluid is expressed by

$$\frac{dU_s}{dt} + BU_s = BU_f + A\frac{dU_f}{dt} + C \tag{2}$$

$$A=3\rho/(2\rho_s+\rho), B=36\mu/((2\rho_s+\rho)d^2), C=(0,0,-2(\rho_s-\rho)g/(2\rho_s+\rho))$$

where  $\rho$  and  $\rho_s$  are the densities of fluid and particle,  $d$  is the diameter of particle,  $\mu$  is the fluid viscosity,  $g$  is the gravitational acceleration and  $U_s$  and  $U_f$  are the velocities of suspended particle and water particle. When the fluid motion is purely oscillatory in the direction of x-axis,ie,  $U_f=(\widehat{U}_{f0}\exp(-i\sigma t),0,0)$ , the solution which satisfies an initial condition at  $t=0,U_s=0$  becomes

$$U_s = \widehat{U}_{f0}G^{1/2} (\cos(\sigma t+\theta) - \exp(-Bt)\cos\theta) \tag{3}$$

$$G=(A^2\sigma^2+B^2)/(\sigma^2+B^2), \theta = \tan^{-1}((B\sigma(1-A))/(A\sigma^2+B^2))$$

where  $\sigma=2\pi/T$ .

Figs.5 and 6 show the amplitude ratio of water-particle velocity and the velocity of suspended particle  $\widehat{U}_s/\widehat{U}_{f0}$  and the phase shift  $\theta$  as a function of the diameter of particle  $d$ .

Fig.5 Relation between  $\widehat{U}_s/\widehat{U}_{f0}$  and  $d$

Fig.6 Relation between  $\theta$  and  $d$

From these figures, it is found that  $\widehat{U}_s/\widehat{U}_{f0} \approx 1$  and  $\theta \approx 0$  for the particle which is usually seen in suspension in the laboratory experiments( $d \leq 0.5mm$ ). So, the velocity of suspended sediment  $U_s$  is approximated by water-particle velocity  $U_f$ .

The same procedure can apply to the motion of a projected particle on the bottom (Eagleson et al.(1958)). However, the motion of bed load in a region where an intense sediment transport in high concentration takes place can not be analyzed by this method. Therefore, the authors analyzed the motion of bed load sediment in such regions by solving a boundary layer equation in the Eulerian system of coordinates shown in Fig.7 under the following assumptions:

- 1) the bed load layer is a Newtonian fluid with a hypothetical viscosity  $\mu_s$ ,
- 2) the flow on the bottom is a laminar, for simplicity,
- 3) the bottom sediment layer is moved by the boundary shear and the pressure in the bottom sediment layer.

Fig.7 Definition sketch of the coordinates.

According to Bagnold(1956), the first assumption is true when the concentration of the bottom sediment  $C_b$  is less than 0.53. Then, the equation of motion for  $z^* = \infty$  (main flow),  $z^* \geq 0$  (flow within the boundary layer) and  $z^* \leq 0$  (sediment motion in the bed load layer) are expressed as follows:

$$\begin{aligned} \frac{\partial U_{fo}}{\partial t} &= -\frac{1}{\rho} \left( \frac{\partial p}{\partial x} \right) & z^* = \infty \\ \frac{\partial U_f}{\partial t} &= -\frac{1}{\rho} \left( \frac{\partial p}{\partial x} \right) + \frac{\mu}{\rho} \left( \frac{\partial^2 U_f}{\partial z^{*2}} \right) & z^* \geq 0 \\ \frac{\partial U_{sb}}{\partial t} &= -\frac{1}{\rho'_s} \left( \frac{\partial p_s}{\partial x} \right) + \frac{\mu_s}{\rho'_s} \left( \frac{\partial^2 U_{sb}}{\partial z^{*2}} \right) & z^* \leq 0 \end{aligned} \tag{4}$$

where  $\rho'_s = (1-C_b) + \rho_s C_b$  is the density of the bottom sediment layer,  $p$  and  $p_s$  are the pressures in water and the bottom sediment layer and  $U_{sb}$  is the velocity of the bottom sediment layer.

For the pressure  $p_s$  in the bottom sediment layer, the following expression proposed by Sleath(1978) is used:

$$\begin{aligned} P_s &= P_0 \frac{\cosh(k(\kappa x / \kappa z) (z^* + \delta b'))}{\cosh(k(\kappa x / \kappa z) \delta b')} \exp(i(kx - \sigma t)) \\ P_0 &= \rho g H / (2 \cosh kh) \end{aligned} \tag{5}$$

where  $k$  is the wave number,  $\kappa_x$  and  $\kappa_z$  are the coefficients of permeability of the bottom sediment layer in  $x$  and  $z$  directions,  $\delta_b'$  is the thickness of the bottom sediment layer and  $H$  is the wave height at the water depth  $h$ .

For  $\mu_s$  in Eq.(4), the authors use the following relation proposed by Eilers(1941):

$$\mu_s/\mu = (1 + (2.5C_b/2(1 - 1.35C_b)))^2 \tag{6}$$

It is said that this relation remains valid for the wide range of  $C_b$ .

Boundary conditions are given as follows:

$$\begin{aligned} \text{at } z^* = \infty \quad U_f &= U_{f0} = \widehat{U}_{f0} \exp(i(kx - \sigma t)) \\ \text{at } z^* = 0 \quad U_f &= U_{sb} \\ &\text{and} \\ \mu(\partial U_f / \partial z^*) &= \mu_s(\partial U_{sb} / \partial z^*) \\ \text{at } z^* = -\delta_b \quad U_{sb} &= 0 \end{aligned} \tag{7}$$

$\delta_b$  in Eq.(7) is the thickness of the bed load layer and is determined as the largest integer  $\delta_b/d$ , i.e, the number of the bed load layer which satisfies the following inequality:

$$\mu_s(\partial U_{sb} / \partial z^*) \geq d(\rho_s - \rho)gC_b \tan\phi (\delta_b/d) \tag{8}$$

where  $\phi$  is the angle of repose of the bed material in water.

In the calculation, at first,  $\delta_b$  was assumed to be  $\delta_b'$  as a first approximation and the calculations were repeated until the boundary condition Eq.(7) and Eq.(8) were satisfied.

Fig.8 shows an example of calculated vertical distribution of  $U_{sb}$  as a function of the phase. The calculated conditions are also shown in the figure. The vertical distribution of the water-particle velocity obtained from an ordinarily laminar boundary layer equation under the boundary condition that at  $z^*=0$ ,  $U_f=0$ , that is,

$$\begin{aligned} U_f &= \widehat{U}_{f0}(\cos \sigma t - \exp(-\beta z^*) \cos(\sigma t - \beta z^*)) \\ \beta &= \sqrt{\sigma/2\nu} \end{aligned} \tag{9}$$

is also shown in the figure by dotted lines where  $\nu = \mu/\rho$ .

By comparing these two vertical profiles, it is found that the effect of the moving boundary remains in a so-called boundary layer ( $z^* = \sqrt{\nu T/\pi} \approx 0.2\text{mm}$ ). Further, the thickness of the bed load layer is also found to change within one wave cycle and it becomes only 1mm, in other words, only 3 layers move as a bed load at the maximum in the case shown in Fig.8.

Fig.9 shows the relation between the amplitude ratio  $\widehat{U}_{sb}/\widehat{U}_{f0}$  at the bottom surface ( $z^*=0$ ) and sediment concentration  $C_b$ . As can be seen from this figure,  $\widehat{U}_{sb}/\widehat{U}_{f0}$  decreases with increasing  $C_b$  and with decreasing Reynolds' number  $Re (= \widehat{U}_{f0}^2 T/\nu)$ . However, in the region where  $Re$  is larger than  $25 \times 10^4$ , the increase of  $\widehat{U}_{sb}/\widehat{U}_{f0}$  with increasing  $Re$  becomes less significant.

Fig.8 Vertical distribution of  $U_{sb}/\widehat{U}_{fo}$  and  $U_f/\widehat{U}_{fo}$

Fig.9 Relation between  $\widehat{U}_{sb}/\widehat{U}_{fo}$  and  $C_b$

An experimental result measured by Horikawa et al.(1982) under the sheet flow condition caused by the oscillatory flow is also shown in the figure. Although this value can not be directly compared with the calculated values, calculated results are judged to give a little larger value of  $\widehat{U}_{sb}/\widehat{U}_{fo}$  than the measured one when compared at the same  $Re$  and  $C_b$ .

However, the procedure to relate  $\widehat{U}_{sb}/\widehat{U}_{fo}$  to  $C_b$  mentioned above is little bit complicated to use in Eq.(1). Therefore, the authors tried to simplify this process. Bagnold(1956) derived the following relation between the drag coefficient  $f'$  of the sediment laden flow and sediment concentration  $C_b$ :

$$f'/f \propto (1 - C_b)^{-m} \quad , \quad m = 3 \text{ to } 4 \tag{10}$$

where  $f$  is the drag coefficient in the clear water defined by

$$f = \tau / (\rho U_f^2 / 2) \tag{11}$$

and  $\tau$  is the drag force acting on a particle and  $U_f$  is the velocity of the unidirectional flow. By using this relation, the ratio of the velocity of the particle in flow  $U_s$  and  $U_f$  can be expressed in term of only  $C_b$  as follow:

$$U_s/U_f = (1 - C_b)^{m/2} \tag{12}$$

However, in general, no sediment movement takes place when all particles in the bed layer are in static contact.  $C_b$  in the bed layer in this state corresponds to  $C_b=C_{max}=0.74$  for uniform spheres perfectly piled. Therefore, it seems reasonable to replace  $C_b$  in Eq.(12) with  $C_b/C_{max}$  as

$$U_s/U_f = (1 - C_b/C_{max})^{m/2} \tag{13}$$

Assuming that this relation holds in the case of sediment movement by waves,  $U_s/U_f$  calculated from Eq.(13) are also shown in Fig.9 for  $m=3$  and 4 by dotting lines. By comparing these with the results obtained from Eqs.(4) to (8), it is found that  $m$  in Eq.(13) depends on  $Re$  and  $m=3$  and 4 correspond to  $Re=16 \times 10^4$  and  $4 \times 10^4$  in the region where  $C_b$  is larger than 0.4. Therefore, in the calculation of Eq.(1), Eq.(13) is used as an approximation of Eqs.(4) to (8).

4. Calculation of the net rate of on-offshore sediment transport

4.1. Vertical distribution of the net sediment flux

In this section, the net rate of on-offshore sediment transport in four kinds of beach deformation processes(see Table 1) are calculated by using Eq.(1). In advance of the calculation of Eq.(1), the time averaged rate of local on-offshore sediment flux  $\overline{q}_f(z^*)$  defined by

$$\overline{q}_f(z^*) = \overline{U_s(z^*,t) C(z^*,t)} \tag{14}$$

was calculated. In this equation,  $U_s(z,t)$  was estimated from Eq.(13) in which  $U_{fo}(z^*,t)$  was calculated by using a linear wave theory,ie,

$$U_{fo} = \sqrt{g(h+\overline{\eta})} \frac{\eta(t) - \overline{\eta}}{h+\overline{\eta}} \tag{15}$$

where  $\overline{\eta}$  is the time averaged surface elevation and  $m$  in Eq.(13) was determined to be 4 for simplicity, although  $Re$  in the experiment ranged between  $10^4$  and  $5 \times 10^4$ . Because Eqs.(4) to (8) seems to overestimate  $U_{sb}/U_{fo}$ .

For  $C(z, t)$ ,  $\bar{C} + C_p$  calculated from the measured sediment concentration in the two-dimensional model beach experiments mentioned in § 2 within 3hrs. after waves began to incident.

Fig.10 shows some examples of the vertical distributions of  $\bar{q}_f(z)$  in the process of erosion type beach deformation. Concentration measuring points are again shown in Fig.10(a) together with beach profiles. As can be seen from Figs.10(b) and (c), in the offshore region, net bed load flux is in the direction of wave propagation (onshore direction) and net flux of suspended sediment is in the offshore direction. This means that the net rate of on-offshore sediment transport in these region is brought about by the difference of two large quantities, i.e. bed load in the onshore direction and suspended load in the opposite direction. While, in the surf zone shown in Figs.10(d), (e) and (f), both bed load and suspended load are in the offshore direction and suspended load apparently surpasses bed load.

Fig.11 shows the vertical distribution of  $\bar{q}_f(z)$  in the process of accretion type beach deformation. Beach profiles and concentration measuring points are shown in Fig.11(a). Being different from the case shown in Fig.10, there is no significant offshore suspended sediment transport throughout: the littoral zone and the maximum sediment flux appears on the bottom surface or in the bottom sediment layer. This means that in the process of accretion type beach deformation, onshore bed load transport is apparently surpasses offshore suspended sediment transport.

In the transition type beach deformations, it is found that there exist two regions, one is the region where onshore bed load transport surpasses and the other is the region where offshore suspended sediment transport surpasses.

As reported by the authors previously (Sawaragi et al. (1980)), whether bed load surpasses suspended load or not at an arbitrary point on a beach can be determined by the ratio of shear velocity  $U^*$  and settling velocity of sediment in still water  $w_0$ . That is, in the region where  $U^*/w_0$  is smaller than 1, onshore bed load transport surpasses offshore suspended load and in the region where  $U^*/w_0$  is larger than 1, suspended load becomes dominant. In which,  $U^*$  is defined by  $\sqrt{fUf_0^2/2}$  and  $f$  is estimated from Jonsson's formula (Jonsson (1980)) assuming that the roughness height is equal to the sediment diameter  $d$ . This criterion is reconfirmed by the present experiments.

#### 4.2 Calculation of the net rate of on-offshore sediment transport

Figs.12 and 13 show the comparisons of the net rate of on-offshore sediment transport  $\bar{q}_f$  obtained by integrating  $\bar{q}_f(z)$  shown in Figs.10 and 11 vertically with  $\bar{q}_h$  calculated from the measured change of water depth. In the integration,  $\bar{q}_f(z)$  was approximated by the dotted lines drawn in the figures.

As can be seen from these figures,  $\bar{q}_f$  calculated from the measured sediment concentration agrees with  $\bar{q}_h$  calculated from the change of water depth. Judging from these, the proposed procedure to calculate the net rate of on-offshore sediment transport provides a good estimate if only the time and spatial variations of sediment concentration and

Fig.10 Vertical distribution of sediment flux  
(erosion type beach deformation)

Fig.11 Vertical distribution of sediment flux (accretion type beach deformation)

water-particle velocity are known.

Fig.12 On-offshore sediment transport rate (erosion type beach deformation)

Fig.13 On-offshore sediment transport rate (accretion type beach deformation)

4.2. Attenuation of the net rate of on-offshore sediment transport

It is well known that the net rate of on-offshore sediment transport in the two-dimensional model beach deformation process decreases exponentially with increasing wave running time (Sawaragi et al. (1980)). There seems to exist three mechanisms of this decay of net on-offshore sediment transport. One is the decay of an agitational force of the fluid acting on the bottom sediment as a result of the interaction between the beach deformation and wave deformation. In this case, time averaged sediment concentration decreases with increasing wave running time inevitably. However, time averaged concentration did not change its magnitude and vertical profile in our experiments.

Another two mechanisms are as follows:

- 1) net onshore sediment transport by bed load decreases owing to the change of local bottom profile and consequently, the net offshore sediment transport in suspension decreases with increasing wave running time,
- 2) net rate of onshore bed load transport and net rate of offshore suspended sediment transport become the same, that is, the closed loop is attained between bed load and suspended load.

Fig.14 shows the comparison of  $q_{f0.5-1.5}$  with  $q_{f20-21}$  which are calculated from the measured sediment concentration during 0.5 and 1.5hrs. and during 20 and 21hrs. after waves began to incident in the process of erosion type beach deformation.

At point s-6 in the surf zone shown in Fig.(d), the decrease of net on-offshore sediment transport seems to be brought about by the latter mechanism mentioned above in 2) and at another points, net on-offshore sediment transport rates appear to decay by the former mechanism mentioned above in 1).

However, further detailed investigations about the time and spatial variations of sediment concentration are required to quantitatively estimate the decay of the net rate of on-offshore sediment transport.

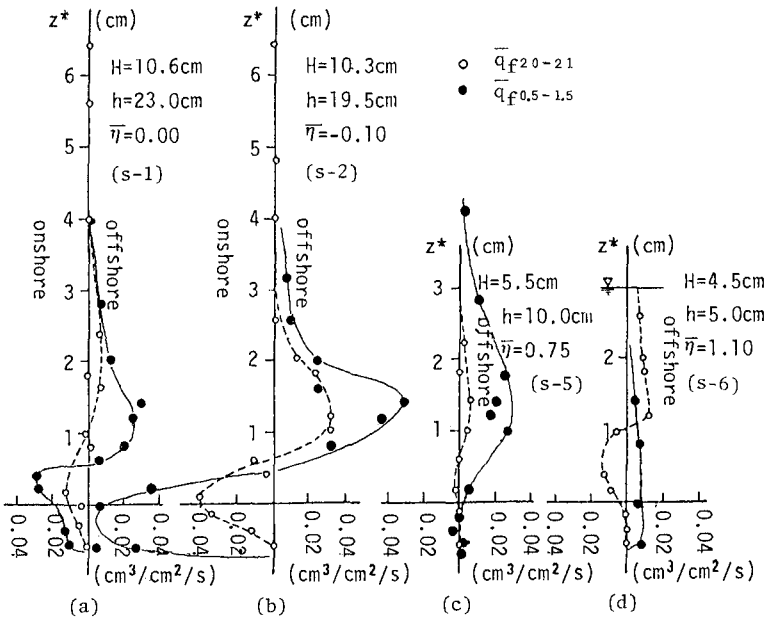

Fig.14 Decay of net on-offshore sediment transport (erosion type beach deformation)

## Concluding remarks

The net rate of on-offshore sediment transport was calculated on the basis of sediment flux by using the measured sediment concentration in two-dimensional model beach experiments and analyzed relation between water-particle velocity and the speed of sediment migration. The results coincide fairly well with the net rate of on-offshore sediment transport calculated from the change of water depth.

In that, interesting, though unverified at present, results about the velocity of the bed load layer and the thickness of the bed load layer are obtained. Some possible mechanisms which attenuate the net rate of on-offshore sediment transport are also pointed out.

The authors are proceeding further investigations about the water-particle velocity in the surfzone and the detailed mechanism of sediment movement to quantitatively predict the time and spatial variation of sediment concentration.

## CHAPTER NINETY TWO

### EXPERIMENTAL VERIFICATION OF SIMILARITY CRITERIA FOR EQUILIBRIUM BEACH PROFILES

Otávio S.F.J.Sayão<sup>1</sup>, M.ASCE and José Carlos Guimarães<sup>2</sup>

#### ABSTRACT

This paper presents an attempt towards the determination of the geometric distortion for beach mobile bed models. At first, a derivation of a scaling law for modelling equilibrium beach profiles is given, based on Valembois' (1961) work. Further, an experimental verification of some criteria presented in literature for the reproduction of beach profiles in coastal mobile bed models (e.g. Noda, 1971; Yalin, 1971 and Vellinga, 1982) is carried out, leading to a comparison with the criterion developed herewith.

Model experiments were undertaken in a two-dimensional wave flume with regular waves in an attempt to verify the validity of the four similarity criteria for the reproduction of beach profiles.

For fine sand as model material, the experimental results proved valid the modified criterion based on Valembois (1961), among all criteria used. The use of this similarity criterion showed that the beach profiles were correctly reproduced in the model.

The use of cellulose acetate as model material did not give good results, and none of the similarity criteria used were verified. The use of this lightweight material should be avoided for modelling beach processes.

Further testing with finer sand is recommended to analyse the influence of the dimensionless fall time parameter (Dean, 1973) and to confirm its use for the prediction of equilibrium beach profiles.

#### INTRODUCTION

Wave sediment transport in the nearshore zone is an important factor in the achievement of engineering solutions

to beach erosion problems. The determination of sediment transport rates along the shore and on-offshore is a subject of continuing research efforts all over the world. Usually, these studies are developed with the aid of Coastal mobile bed models. Of particular interest is the study of beach profiles, its formation due to wave action and its equilibrium form.

A beach profile is shaped depending on the interaction of the waves and the beach material. It has been reported in literature that the beach reaches an 'equilibrium profile', defined as a beach profile which maintains its geometrical form in time, see for instance, Eagleson et al (1963), Wiegél (1964), Nayak (1970), and Swart (1974).

A coastal mobile bed model is necessarily distorted. The actual value of this distortion is imposed by the model grain size, i.e. cannot be freely chosen. Bijker (1967) stated that the mobile bed model distortion should be equal to the ratio between the equilibrium beach slopes in the model and prototype. This was later endorsed by Fan and Le Méhauté (1969) and Kamphuis (1975).

Hence, it is common practice in littoral transport model investigations to select the model distortion by conducting preliminary flume tests to determine the equilibrium beach slope of different sand grain sizes under the action of the scaled down waves.

#### SCALE DEFINITIONS

For the rectangular coordinate system, the general model scale  $n$  is given by the vertical scale value

$$n = n_z \quad (1)$$

where the scale  $n$  is defined as the ratio of prototype value over the model value.

In an undistorted small scale hydraulic model all geometric scales are the same. In a geometrically distorted model, the two horizontal scales  $n_x$  and  $n_y$  are identical but differ from the vertical scale  $n_z$ . The geometric model distortion  $N$  may thus be defined as

$$N = \frac{n_x}{n_z} = \frac{n_y}{n_z} \quad (2)$$

A beach slope  $m$  may be defined by the ratio between a characteristic depth at the surf zone and a horizontal distance perpendicular to the beach. If, for instance, the depth of water at the breaking point  $d_b$  is taken as a characteristic depth, then the beach slope becomes

$$m = \frac{d_b}{\lambda_b} \quad (3)$$

where  $\lambda_b$  is the breaker distance, measured horizontally between the breaking point and the shoreline.

The model distortion may be written according to its definition as

$$N = \frac{m_m}{m_p} \quad (4)$$

where  $m_m$  is the model equilibrium beach slope and  $m_p$  is the prototype beach profile. The scale of the beach profile is then given as

$$n_m = \frac{m_p}{m_m} = N^{-1} \quad (5)$$

or

$$\left(\frac{d_b}{\lambda_b}\right)_m = N \left(\frac{d_b}{\lambda_b}\right)_p \quad (6)$$

As  $N > 1$  by definition, then it is clear that the beach profile in the model is steeper than the prototype one, i.e. exaggerated by a factor equal to the model distortion.

#### REVIEW OF PREVIOUS SCALING LAWS

Scaling laws for modelling equilibrium beach profiles have been previously proposed in literature. A review of some published similarity criteria is presented herewith.

Valembois (1961)

Both Valembois (1961) and Goddet and Jaffry (1960) have put forward similarity criteria that include in their expression a distortion of the wave height, which is not reasonable for modelling beach processes. Their work have been discussed in detail in Paul (1972) and Kamphuis (1975).

Valembois (1961) also presented a theoretical derivation of the geometric distortion for beach models based on the mechanism of bed material suspension by wave breaking. For the correct reproduction of equilibrium beach profiles, he stated that similarity of the following ratio is required:

$$\frac{\text{fall velocity/depth}}{\text{mass transport velocity/horizontal distance}} \quad (7)$$

This concept for similarity of Eq.(7) was further developed by Guimarães (1983) and will be discussed in a later chapter.

Noda (1971)

With the work of Fan and Le Méhauté (1969) as a basis,

Noda (1971) has conducted wave flume beach experiments, to find scaling laws on beach profile formation by breaking waves. Sand and several lightweight material were used as model material. Based on the experimental results, Noda (1971) proposed the following similarity criteria

$$n_D \cdot n_{(\gamma_s/\gamma)}^{1.46} = n_z^{0.55} \quad (8)$$

and

$$n_x = n_z^{1.32} n_{(\gamma_s/\gamma)}^{-0.35} \quad (9)$$

where  $n_D$  is the scale of the sediment grain size,  $n_{(\gamma_s/\gamma)}$  is the scale of the relative submerged unit weight of sediment, where

$$\gamma_s = (\rho_s - \rho) g \quad (10)$$

is the underwater unit weight of sediment.

Yalin (1971)

Based on dimensional analysis for sediment transport under the combined influence of short waves, long waves and unidirectional flow, Yalin (1971) developed expressions for nine dimensionless variables controlling bed phenomena for such flow regimes. These may be regarded as criteria for similarity. He also illustrates that similarity of only two out of the nine dimensionless variables proposed can be maintained for practical model design.

For the same fluid in model and prototype and considering unidirectional flow experimental data, Yalin (1971) proposed the following relationship

$$n_x = n_z^{3/2} \quad (11)$$

which may be written as

$$N = n_z^{1/2} \quad (12)$$

and agrees with the regime theory recommendation. Eq.(12) may also be found in Le Méhauté (1970), which derived it in a different manner, when studying similarity of sediment motion for littoral transport models, for sand models with prototype material only. Yalin (1971) suggests that Eq.(12) holds for tidal flow models rather than beach models.

Vellinga (1978, 1982)

Beach and dune erosion during storm surges have been

studied by Vellinga (1978; 1982) based on two-dimensional model experiments. Only fine sand of different grain sizes was used as model material. He considered the importance of the dimensionless fall time parameter  $P$  (Dean, 1973) for the reproduction of beach profiles, where

$$P = \frac{H}{wT} \quad (13)$$

and  $w$  is the fall velocity of the sand grains;  $H$  is the wave height and  $T$  is the wave period.

Vellinga (1978; 1982) proposed the following scaling relationships

$$\frac{n_x}{n_z} = \left( \frac{n_z}{n_w^2} \right)^\alpha \quad (14)$$

and

$$n_t = n_z^{1/2} \quad (15)$$

where the wave conditions were scaled down according to the Froude condition

$$n_H = n_T^2 = n_z \quad (16)$$

$n_w$  is the scale of the fall velocity of the sand grains  $n_H$  is the wave height scale,  $n_T$  is the wave period scale and  $n_t$  is the time scale for hydrodynamical and morphological process.

The empirical coefficient  $\alpha$  was found earlier (Vellinga, 1978) to vary with sand grain size, ranging from 0.5 to 0.3 with  $\alpha = 0.5$  recommended for very fine sand of  $D_{50}$  of the order of 0.1 mm. In a re-analysis of the data, Vellinga (1982) concluded that it should be taken as constant and equal to  $\alpha = 0.28$ . Hence, Eq.(14) becomes

$$\frac{n_x}{n_z} = \left( \frac{n_z}{n_w^2} \right)^{0.28} \quad (17)$$

Vellinga (1982) has compared his scaling law with data from three-dimensional model tests, from large-scale two-dimensional tests with irregular waves up to significant wave heights of 2 m, and from field experiments, and Eq.(17) was favorably verified. Also, a computer model for the prediction of dune erosion was developed, see Vellinga (1983).

#### DERIVATION OF A SIMILARITY CRITERION

The derivation of a scaling law for modelling equilibrium beach profiles is based on Valembois' (1961) work which was

further developed by Guimarães (1983).

Valembois' (1961) expression, see Eq.(7), must be made equal in prototype and model. This requirement becomes

$$\frac{w_p/d_p}{U_p/\lambda_p} = \frac{w_m/d_m}{U_m/\lambda_m} \quad (18)$$

which leads to

$$\frac{d_p}{d_m} \cdot \frac{U_p}{U_m} = \frac{w_p}{w_m} \cdot \frac{\lambda_p}{\lambda_m} \quad (19)$$

yielding in terms of model scales (prototype value/model value) the following relation

$$n_z = \frac{n_w}{n_U} \cdot n_x \quad (20)$$

where  $n_z = n_d$  is the vertical scale and  $n_x = n_\lambda$  is the horizontal scale of the model. Also,  $n_w$  is the scale of the fall velocity of the grains and the scale of the mass transport velocity is  $n_U = U_p/U_m$ .

On the other hand, similarity of the Froude number in model and prototype gives

$$\frac{v_p}{v_m} = \left(\frac{d_p}{d_m}\right)^{1/2} \quad (21)$$

or

$$n_v = n_z^{1/2} \quad (22)$$

in which the scale of the horizontal velocity is  $N_v = v_p/v_m$ .

Considering  $n_U = n_v$ , substitution of Eq.(22) into Eq.(20) gives the following scaling law

$$n_z = (n_w \cdot n_x)^{2/3} \quad (23)$$

Valembois' similarity concept has been transformed into a similarity criterion, i.e. a scaling relationship, see Eq.(23). For a given prototype situation where the bed material is known and considering given the model material and the horizontal scale, which may be determined according to the prototype geometry and laboratory dimensions, the scaling law of Eq.(23) would permit to determine the correct vertical scale

of the model and thus the model distortion. For the particular situation where prototype sand is used in the model, Eq.(23) reduces to Eq.(11).

Le Méhauté (1970) proposed a kinematic similarity condition for both fluvial and coastal modelling

$$\frac{n_x}{n_z} = \frac{n_u}{n_w} \quad (24)$$

where  $n_u$  is the scale of the horizontal orbital velocity. Vellinga (1978) showed that Eq.(24) may be written as

$$\frac{n_x}{n_z} = \left( \frac{n_z}{n_w Z} \right)^{0.5} \quad (25)$$

and this expression for the model distortion, which is the same as Eq.(14) with  $\alpha = 0.5$ , gave good results for his experimental data with finer sands.

It may be seen that Eq.(23) and Eq.(25) are the same but where derived differently. Vellinga (1978) calls  $\alpha = 0.5$  the 'theoretical' value and in later work he proposes the use of  $\alpha = 0.28$  and Eq.(17) for a distortion relationship.

Another different derivation of the same Eq.(23) may be found in Hughes (1983) where the modelling law was proposed based on distortion of the morphological time scale, deviating from the Froude similarity criteria by a factor of  $N$ .

The physical significance of Eq.(23) may be reasoned as follows. Let  $t_s$  be the fall time of the sediment grain, in still water, from the water surface to the bed. Thus  $t_s = d/w$  and the scale of the fall time of the grains is

$$n_{t_s} = \frac{n_d}{n_w} = \frac{n_z}{n_w} \quad (26)$$

Let  $t$  be the time for wave propagation. Hence, in shallow water  $t = \lambda/C_{gr} = \lambda/C$  where  $C_{gr}$  is the celerity of the wave group and  $C$  is the wave celerity. The Froudian time scale for wave propagation is thus

$$n_t = \frac{n_\lambda}{n_C} = \frac{n_x}{n_z^{1/2}} \quad (27)$$

If Valembois' (1961) similarity concept is written as follows

$$\frac{n_w/n_d}{n_U/n_\lambda} = 1 \quad (28)$$

then, considering  $n_U = n_V$ , substitution of Eqs.(22), (26)

and (27) into Eq.(28) gives

$$n_t = n_{t_s} \quad (29)$$

which means that the scale of the fall time of the sediment grain in still water must be equal to the Froudian time scale for wave propagation, or in other words, the fall time of the sediment grains in the model must be reduced in the same proportion as the breaking wave propagation time.

#### EXPERIMENTAL PROCEDURE AND RESULTS

The proposed scaling law of Eq.(23) may be experimentally verified if model tests designed according to it give a good reproduction (in the model) of the prototype beach profiles. By good reproduction of the prototype profiles it is meant that the scale of the beach profiles should be given by Eq. (4) or Eq.(5), i.e, the model distortion is obtained when dividing model beach profile by prototype beach profile.

It is considered in this paper that the coastal mobile bed model is distorted, even though some researchers have proposed to develop model studies in geometrically undistorted coastal models based on the concept of equality of the dimensionless fall time parameter in model and prototype (Dalrymple and Thompson, 1976; Vellinga, 1982; Kamphuis, 1983) or of a similar parameter (Hallermeier, 1984).

Two-dimensional model tests were performed in a wave flume at INPH/PORTOBRÁS, Instituto de Pesquisas Hidroviárias, Empresa de Portos do Brasil S.A., Rio de Janeiro. Detailed information on the experimental equipment and procedure may be found in Guimarães (1983).

#### Sediment Characteristics

Two model bed materials were readily available for testing, fine sand, mined from Cabo Frio dunes, Rio de Janeiro, and cellulose acetate, a lightweight material commonly used for modelling in INPH/PORTOBRÁS.

Model beaches were formed with the two different bed materials (fine sand or cellulose acetate) and were submitted to different monochromatic wave climate. Model tests were run maintaining constant the horizontal scale, and for several vertical scales. The simulated prototype beach profile is composed of fine sand grains and is located in Sergipe State, northeast of Brazil, see Figure 1.

Two sand samples were collected in the field and analysed in the laboratory with the purpose of obtaining the necessary information on the prototype bed material. Table 1 gives the sediment characteristics for both model and prototype materials and Figure 2 gives the grain size distribution curves.

The prototype average beach slope was defined based on 12 shore-normal profiles spaced at 500m intervals, covering both the beaches north and south of the Sergipe river inlet, see Figure 1. For an appraisal of the beach profiles evolution, nautical charts of the region were used with surveys from 1970, 1976 and 1979. The average beach slope obtained was approximately 1/400. This value was considered constant and was used as the prototype equilibrium beach slope, i. e.  $m_p \approx 1/400 = 0.25\%$ .

#### Horizontal Scale Definition

The definition of the horizontal scale was based on the design of a three-dimensional mobile bed model of Sergipe river inlet, presently (1984) underway at INPH/PORTOBRÁS. This model study is related to future port expansions inside the Sergipe river, the inlet behaviour and the sedimentation of the access channel to be dredged through the offshore bar. It was considered that a 200m wide channel in the prototype should be reproduced with a model width of 0.40m, to permit measurements of the small scale parameters with the available equipment at INPH. These dimensions lead to a horizontal scale of  $n_x = n_y = 500$ .

#### Fall Velocity Scales Selection

The fall velocity of the sediment grains was obtained through laboratory measurements. A 2m long glass tube with 3cm diameter was used to measure the fall time of several small sized sediment samples, considering the grain size distribution curves. For each diameter the fall time was recorded 6 times and an average value was found, see Table 2. The distribution curves for the fall velocity were then found (percent finer versus fall velocity curves) for the different materials, see Figure 3, based on the measured data as a function of grain diameter and also on the grain size distribution curves.

Using Figure 3 it was possible to find the scales for the fall velocity of the sediment grains, calculating an average ratio for each given constant value of percent finer as follows

$$\frac{w_1}{w_{1m}} = \frac{w_2}{w_{2m}} = \dots = \frac{w_i}{w_{im}} = \text{constant} = n_w \quad (30)$$

For the model with sand material, the fall velocity scale was found to be  $n_w = 0.671$ . For lightweight material in the model,  $n_w = 1.449$ . These values are also shown in Table 3. It is interesting to note that these values include the effect of the grain size distribution curves and different scale factors would be obtained if median diameter values for the fall velocity would be used.

### Vertical Scales Selection

In order to define the vertical scales to run the model tests, a preliminar calculation was made for the similarity criteria of Noda (1971), Eq.(9), Yalin (1971), Eq.(11), Vellinga (1982), Eq.(17) and modified Valembois, Eq.(23). The results are presented in Table 3.

Based on the variation of vertical scales results shown in Table 3, the tests programme was defined with  $n_z = 40, 50, 75$  and 100 for sand models and with  $n_z = 50, 75$  and 100 for lightweight material. These would provide the experimental verification of the similarity criteria if good reproduction of beach profiles are obtained in the model.

### Wave Flume Tests and Results

A total of 69 tests were performed in the two-dimensional wave flume of INPH/PORTOBRÁS, of which 42 with sand in the model and 27 with cellulose acetate in the model.

The wave flume is 45.5m long and 0.80m wide at the test section. Initial water depth in the model was 1.05m and the mean sea level was adjusted in the flume according to each vertical scale. A glass window 6.0m long permitted observation of the beach profile development. Regular waves were generated by a flap-type wave paddle, 1.5m wide and 2.0m high. Waves were recorded by a resistance type wave probe located in the flume at a depth corresponding to  $\sim 20$ m in the prototype. A one-channel Watanabe recorder gave a permanent recording of the measured wave heights on chart paper. Wave periods were recorded with a digital stop-watch.

The prototype wave climate was reproduced in the model based on measurements presented and analysed in Motta (1965) and Bandeira (1972) Tables 4 and 5 show wave and sea level parameters for both model and prototype, according to the several vertical scales used.

Prior to the start of each test the beach profile was planed and compacted to a uniform slope, calculated with Eq.(4), which would reproduce in scale the prototype beach profile (see Table 5). At the beginning of each test an exaggerated model wave height was produced in the flume for some minutes, in order to form ripples everywhere on the sloping model beach ensuring that a turbulent boundary layer was formed in the model, as suggested by Motta (1967).

During each test the beach profile would develop itself with the continuous action of the regular waves. Equilibrium was reached after 30 hours of testing for sand as the model material. The lightweight model beaches would reach an equilibrium profile after 5 hours of continuous testing. These model times for profile development are in accordance with the ones reported by Paul (1972), which were 24 hours for sand and 6 hours for bakelite beach profiles.

The monitoring of the equilibrium beach profiles in the flume was

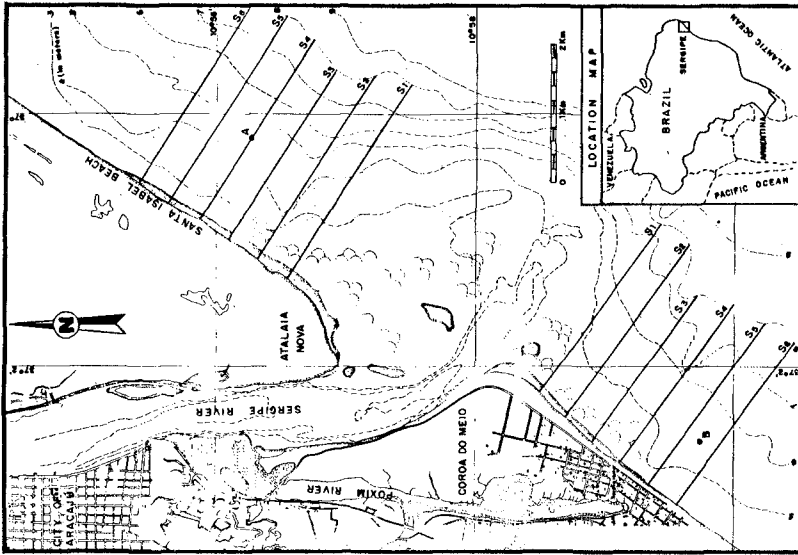

FIGURE 1 - LOCATION OF PROTOTYPE BEACH IN SERGIPE STATE, BRAZIL

FIGURE 2 - GRAIN SIZE DISTRIBUTION CURVES

FIGURE 3 - FALL VELOCITY DISTRIBUTION CURVES

done visually after 20 hours of model testing for sand and 3 hours for cellulose acetate. Every beach profile was traced on the window of the flume and whenever no considerable changes would be detected with the continuation of the tests, the profile was then considered to be in equilibrium and the test stopped. An example of the model profile development is shown in Figure 4.

At the end of each test the flume was drained, as slowly as possible, and the beach profile coordinates were recorded through the glass window. Up to 58 depth measurements were taken every 10cm along the profile seawards from the berm crest of the beach. The model beach

profile slope was defined as the best fit straight line through the experimental data.

The experimental results obtained during the tests are shown in Tables 6 and 7.

#### DISCUSSION

The model experiments were designed in accordance to the calculated vertical scales, see Tables 3 and 5. Given the values of  $n_z$  and knowing the prototype beach slope  $m_p$  for the selected horizontal scale  $n_x = 500$ , it is possible to calculate the beach slope to be expected to form in the model  $m'_m$ , using Eqs. (2) and (4) as follows

$$m'_m = m_p \cdot N = m_p \cdot \frac{n_x}{n_z} \quad (31)$$

From simple comparison of the values for  $m_p$  and  $m'_m$  (see Tables 6 and 7) it can be verified if the prototype beach profile  $m_p$  was well reproduced in the model.

#### Results with Lightweight Material

As it can be seen from Table 6, the use of cellulose acetate as model material did not give good results, and none of the similarity criteria used was verified.

For  $n_z = 50$  the results were very different than the calculated value. For  $n_z = 75$  the results did not depart so much from the calculated beach slope when the model wave height was small. This was due to the fact that not much sediment was moved by such small model waves and the measured profile would retain the influence of the initial beach slope. The same tendency was seen for the  $n_z = 100$  test results, as shown in Figure 5.

#### Results for the Sand Model

For fine sand as model material the experimental results for beach slope agreed well with the profile calculated values when the vertical scale tested was  $n_z = 50$ , see tests numbers 10 to 18 in Table 7. This vertical scale value ( $n_z = 50$ ) is approximately the same than the one calculated with Eq. (23), see Table 3.

Hence these experimental results proved valid the similarity criterion based on the work by Valembois (1961). The use of this scaling law Eq. (23) showed that the beach slopes were correctly reproduced in the model.

For  $n_z = 40$  the beach slope results presented in Table 7 (tests no. 1 to no. 9) did not depart much from the calculated value.

For  $n_z = 50$  and high waves in the model (tests no. 19 to no. 24) the measured beach slope values shown a deviation from the calculated one. This may be explained by the fact that the prototype beach profile was kept constant throughout the analysis and its value was taken from nautical charts which are based on calm weather site surveys, during the summer months.

FIGURE 4. Model Profile Development

When using Eqs. (9) and (17), the predicted values for the vertical scale are  $n_z = 100$  and  $n_z = 108$  respectively (see Table 3). For  $n_z = 75$  and  $n_z = 100$  the measured values for beach slope did not agree with the calculated values, see Table 7, tests no. 25 to no. 42. This seems to indicate that both Eqs. (9) and (17) do not give valid predictions for beach profiles when they are used as scaling laws.

If Eq. (11) is used, the predicted value for the vertical scale ( $n_z = 63$ ) falls between the tested values of  $n_z = 50$  and  $n_z = 75$  and it may be noticed that Eq. (23) is an improved version of Eq. (11) because it takes into account the influence of the fall velocity scale.

## Influence of the Fall Time Parameter

Sayão and Kamphuis (1983) have shown that the dimensionless fall time parameter (see Eq. 13) gives an indication of whether or not a shoreline is receding or progressing, being  $P \approx 1$  a critical value as shown in the Shore Protection Manual (US Army Corps of Engineers, 1977). For  $P > 1$  recession of the shoreline occurs, while for  $P < 1$  progression results.

Table 8 shows the values of the dimensionless fall time parameter for the tests where sand was used as model material. The scale of  $P$  is by definition given as

$$n_p = \frac{n_H}{n_w n_T} = \frac{n_z^{1/2}}{n_w} \quad (32)$$

and if Eq. (23) is used

$$n_p = \frac{n_x}{n_z} = N \quad (33)$$

and from Table 8, it is found that for tests with  $n_z = 50$  the values of  $n_p$  are approximately the same as the model distortion values.

It may be seen also from Table 8 that all  $P$ -values in the model are smaller than the critical value, whereas all prototype  $P$ -values are greater than the critical value. This indicates that there is a progressing beach in the model and a receding one in the prototype which will cause similarity problems if coastal sediment transport and coastal erosion are under investigation.

For almost all measurements of beach slope in the model it was noticed that the resulting type was a berm (summer) profile and the shoreline was progressing, as can be seen for example in Figure 4.

As the prototype values for the dimensionless fall time parameter are  $P > 1$ , the site beach should be a receding one. Bandeira (1972) has  $P$  calculated littoral drift along the Sergipe shoreline to be of the order of 800,000 cubic meters / year, with a southward direction. Hence, if the beach profiles are far enough south from the mouth of Sergipe river they would be expected to show a receding trend. No further conclusions could be made due to lack of measured prototype beach profiles.

## CONCLUSIONS AND RECOMMENDATIONS

The use of lightweight material cellulose acetate did not give good reproduction of beach profiles in the model, hence this material should not be used for modelling beach processes.

For fine sand as model material the experimental results proved valid the similarity criterion based on Valembois (1961), see Eq.(23), among all criteria used. The use of Eq. (23) showed that the beach profiles were correctly reproduced in the model, as far as beach slope is concerned.

The use of Eq.(23) means in fact that Vallinga (1982) coefficient is  $\alpha = 0.5$ , which also agrees with the theoretical value proposed by Le Méhauté (1970).

To design a model investigation of beach processes, where the fine sand grain size distribution curve to be used in the model is known, the vertical scale may be calculated with the aid of Eq.(23) and the scale of the fall velocity of the sand grains should be measured in the laboratory. It is to be noted the discrepancy between measured and calculated values of  $w$  (see Table 2).

To improve the data base of the present experiments further testing with finer sand (say  $D_{50} \approx 0.1\text{mm}$ ) would be required, so that the dimensionless fall time parameter in the model would be greater than the critical value. For further empirical research it is recommended that P-values for both model and prototype could be maintained in the same region, i.e., above or below the critical value. That may be sufficient, rather than preserving full similarity for the dimensionless fall time parameter between model and prototype as suggested by other researchers. Also, it would give more flexibility for model material selection.

## CHAPTER NINETY THREE

### Stability of Multiple Inlets

Jacobus van de Kreeke\*

#### Abstract

A computational framework is presented to evaluate the stability of two inlets connecting the same bay to the ocean. It is assumed that both inlets are scoured in alluvial material. The main ingredients in the stability analysis are the closure surface and the equilibrium stress surface. The closure surface of an inlet is defined as the relation between the tidal maximum of the bottom stress and the cross-sectional areas of both inlets. The equilibrium stress surface of an inlet is the relation between the tidal maximum of the bottom stress and the cross-sectional area of that inlet at the time the inlet is in equilibrium with its hydraulic environment. The method is applied to Pass Cavallo and the entrance to the Matagorda Shipping channel further referred to as Matagorda Inlet. Both inlets connect Matagorda bay to the Gulf of Mexico.

#### Introduction

Over a period of decades, many inlets exhibit a change in morphology. These changes are often caused by a gradual increase in length resulting from the deposition of sediment at the ocean-and bay side of the inlet. This in turn leads to a gradual decrease in conveyance and cross-sectional area. Superimposed on this trend are sudden changes in inlet dimensions associated with storms, changes in bay surface area (diking) and the opening or closure of companion inlets. The inlet will respond to these sudden changes by either closing or returning to the old or a new equilibrium morphology. The time for the inlet to adapt depends on whether the inlet is in a shoaling or scouring mode. When in a shoaling mode, the response time depends on the supply of sediment, i.e. the littoral drift, and could vary from weeks to years. On the contrary when in a scouring mode the response time will be short, i.e. less than a few weeks.

If as a result of a sudden change in inlet dimensions or hydraulic conditions the inlet tends to close, the inlet is said to be unstable. If instead the inlet returns to the original or a new equilibrium morphology, the inlet is said to be stable. The

---

\* Professor, Division of Ocean Engineering, RSMAS, University of Miami, 4600 Rickenbacker Causeway, Miami, Florida 33149

extent to which the inlet dimensions or the hydraulic environment can be altered before the inlet tends to close determines the degree of stability of the inlet.

In general stability analysis of inlets deal with the response of an inlet to 1) sudden changes in its dimensions resulting from storms, 2) a reduction in bay surface area and 3) the opening of a companion inlet, either by dredging or extreme events. In this paper, emphasis is on the response of an inlet to the opening of a companion inlet.

The stability analysis as presented in this paper basically deals with the conveyance of an inlet. Therefore the analysis does not yield a definite answer with regard to the navigability of the inlet. For this, more detailed information on cross-sectional areas and depths along the entire channel axis is needed.

Inlet Hydraulics; Closure Curve and-Surface

In analysing the stability, inlets are schematised to prismatic channels. The channel has a cross-sectional area A, (usually taken equal to the cross-sectional area of the gorge), a hydraulic radius R, a length L and a friction coefficient F. The sum of exit and entrance losses are represented by a coefficient m. A coefficient  $\mu$  is introduced to account for contraction of the flow. In terms of the foregoing parameters the cross-sectionally averaged velocity, u in the inlet follows from

$$u = \pm K' \sqrt{2g|\eta_o - \eta_b|} \tag{1}$$

$$\text{with } K' = \mu \sqrt{\frac{R}{mR + 2FL}}$$

In Eq. (1)  $\eta_o$  is the ocean tide and  $\eta_b$  is the bay tide. For a given head difference  $|\eta_o - \eta_b|$ , inlets with the same K' factor have the same current speed.

The bottom shear stress,  $\tau$ , in the inlet is related to the cross-sectionally averaged velocity by

$$\tau = \rho F u |u| \tag{2}$$

in which  $\rho$  is the density of water. In this paper, the friction factor F is related to the hydraulic radius and bottom roughness k by the Colebrook-White expression

$$F = g \left[ 18 \log \frac{12R}{k} \right]^{-2} \tag{3}$$

When considering a relatively short and deep bay connected to the ocean by more than one inlet the condition of continuity may be expressed as

$$\sum Q_i = A_b \frac{d\eta_b}{dt} \tag{4}$$

in which Q is the rate of flow in the inlet,  $A_b$  is the bay surface area and the summation is over the number of inlets.

For a given ocean tide, bay surface area and shape of the cross-section and using Eqs. (1)-(4) it can be shown that for a single inlet bay system the tidal maximum of the bottom shear stress  $\hat{\tau}$ , is a strong function of A and a weak function of L, k and m.

$$\hat{\tau} = \hat{\tau}(A; L, k, m) \tag{5}$$

Here it is assumed that the hydraulic radius R is uniquely determined by the cross-sectional area A. The general shape of the closure curve  $\hat{\tau} = \hat{\tau}(A)$  is indicated in Fig. 1. For small values of A,  $\hat{\tau} \propto A$  and for large values of A,  $\hat{\tau} \propto A^{-2}$ .

Fig. 1 Closure curve and equilibrium stress curve

For a two inlet bay system

$$\hat{\tau}_I = \hat{\tau}_I[A_I, A_{II}; L_I, F_I, m_I, L_{II}, F_{II}, m_{II}] \tag{6}$$

$$\hat{\tau}_{II} = \hat{\tau}_{II}[A_I, A_{II}; L_I, F_I, m_I, L_{II}, F_{II}, m_{II}] \tag{7}$$

The subscripts I and II refer to the respective inlets. The general shape of the closure surface  $\hat{\tau}_{II} = \hat{\tau}_{II}(A_I, A_{II})$  is indicated in Fig. 2.

In practice, difficulties in calculating the closure curves and closure surfaces might be encountered because of the uncertainties in the values of the inlet lengths, the bottom roughness and the energy loss coefficients.

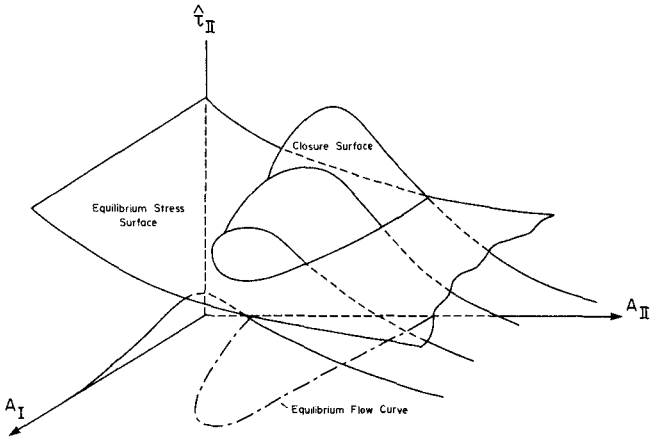

Fig. 2 Closure surface and equilibrium stress surface

The Equilibrium Bottom Shear Stress; Equilibrium Shear Stress Curve and - Surface.

It is postulated that inlets in alluvial material will adjust their dimensions until a bottom shear stress  $\hat{\tau}_{eq}$  is reached, Bruun [1978]. In general  $\hat{\tau}_{eq}$ , referred to as the equilibrium shear stress, will be a function of the littoral drift, wave climate and the dimensions of the inlet cross-section.

In principle for a given coast, and assuming that the littoral drift and wave climate are relatively uniform, the relation between equilibrium shear stress and inlet dimensions can be derived from the tidal prism-cross-sectional area relationships given by among others O'Brien [1969] and Jarrett [1976]. Unfortunately the correlation functions used to derive these relationships lack a physical basis and especially for the region of interest, i.e. the Gulf of Mexico coast, show considerable scatter. Therefore in the application to Pass Cavallo and Matagorda Inlet rather than making use of the tidal prism-area relationships, the value of  $\hat{\tau}_{eq}$  will be determined from the observation that in 1959 Pass Cavallo and in 1971-1972 Matagorda Inlet was in equilibrium with the hydraulic environment.

In a qualitative sense the shape of the equilibrium shear stress curve (pertaining to a one-inlet bay system) and the equilibrium shear stress surface (pertaining to a two-inlet bay system) are presented in respectively Figs. 1 and 2.

### Stability of a Single-Inlet Bay System

Referring to Fig. 1, a condition for the existence of an equilibrium flow area is that the closure curve and equilibrium stress curve intersect. The cross-sectional area  $A_1$ , represents an unstable inlet. The cross-sectional area  $A_2$  pertains to a stable equilibrium flow area. The equilibrium interval of  $A_2$  extends from the value of  $A_1$  to infinity, Escoffier [1940].

### Stability of a Two-Inlet Bay System

To delineate the stability of a two inlet-bay system, for each of the inlets the intersection of its closure surface and equilibrium stress surface is projected in the  $A_I, A_{II}$  plane; see Fig. 3. These curves are referred to as equilibrium flow curves. The equilibrium flow curve for inlet I is the loci of the set of values  $(A_I, A_{II})$  for which  $\tau_I = \tau_{eqI}$  and similarly for inlet II. The enhanced part of the equilibrium flow curves represent stable equilibrium flow areas. Therefore a condition for the simultaneous existence of stable equilibrium flow areas for both inlets is that the enhanced parts of the equilibrium flow curves intersect. In that case the cross-hatched area represents the equilibrium interval. If the actual values of the inlet cross-sections  $(A_I, A_{II})$  are outside the equilibrium interval, one or both inlets will close. For details on the stability of a two-inlet bay system, see van de Kreeke [1985].

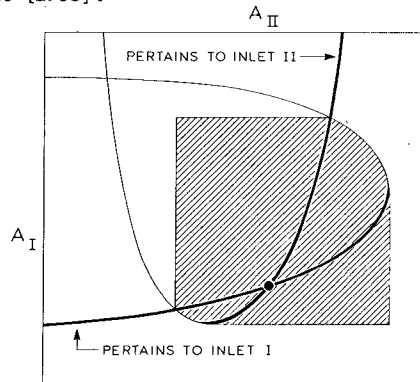

Fig. 3 Equilibrium flow curves for Inlets I and II

### Application to Pass Cavallo and Matagorda Inlet, Texas

The data used in this section is derived from Ward [1982], [1983] and Bruun, [1983]. Until 1963 Pass Cavallo was the only inlet connecting Matagorda Bay and the Gulf of Mexico. A second inlet was added in 1963; this inlet constitutes the entrance to the Matagorda shipping channel. For the location of the inlets and a plan view of the bay, see Fig. 4.

Fig. 4 Matagorda Bay and inlets

Matagorda Bay is a shallow bay with an average depth of 3 m. The Bay surface area is  $1100 \text{ km}^2$ . As a result of the shallow depth and the relatively large horizontal dimensions, the time it takes for the tidal wave to traverse the Bay is on the order of a few hours. Consequently in a strict sense Eq.(4) does not apply and to properly calculate the closure curve and closure surfaces, the propagation of the tide in the bay would have to be accounted for. Because this goes beyond the scope of this study, an approximate solution is sought in which the bay surface area is allowed to fluctuate uniformly. To arrive at realistic current speeds and tidal prisms a reduced bay surface area of  $350 \text{ km}^2$  is introduced.

Tides off Matagorda Bay are mixed. Maximum current speeds occur during spring tide conditions at which diurnal tides are prevalent. The spring tidal range is approximately 1 m.

During a 1959 hydrographic survey the following pertinent inlet characteristics were observed,  $A = 8000 \text{ m}^2$ ,  $R = 4 \text{ m}$ ,  $L = 2350 \text{ m}$ . An average value of the friction coefficient derived from observed velocity profiles is  $F = 5 \cdot 10^{-3}$ . Taking  $\mu = 1$  and  $m = 1$ , it follows that for Pass Cavallo in 1959,  $K' = 0.4$ . Using the approximate solution presented by Keulegan [1951], Eqs. (1) and (4) with  $A_b = 350 \text{ km}^2$  yield  $\hat{u} = 0.94 \text{ m/sec}$  and a tidal prism equal to  $2.5 \cdot 10^8 \text{ m}^3$ . This is close to the observed values of respectively approximately 1 m/sec and  $2.5 \cdot 10^8 \text{ m}^3$ . Furthermore it follows from Eq.(3),  $k = 0.17 \text{ m}$ .

During the years preceding the 1959 survey the geomorphology of Pass Cavallo changed little and it seems reasonable to assume that at the time of the survey the inlet was in equilibrium with the hydraulic environment. It then follows from Eq. (2) with  $F = 5 \cdot 10^{-3}$  and  $u = 0.94$  m/sec that  $\tau_{eq} = 4.4$  N/m<sup>2</sup>. This value is in the middle of the range of equilibrium shear stress values, 3.5-5.5 N/m<sup>2</sup>, suggested by Bruun [1978].

Making use of Eqs. (1)-(4) and the data listed in Table I, the closure curve for Pass Cavallo, Eq. (5), was calculated. The result is presented in Fig. 5. The relation between R and A used in the calculations, see Fig. 6, was established by assuming the inlet to have a parabolic shape and a constant width to maximum depth ratio equal to the value of 333 observed in the 1959 survey.

Table I

Values of pertinent parameter used in calculating the closure curve for Pass Cavallo prior to the opening of Matagorda Inlet.

L = 2350 m	2H = 1 m	$A_b = 3.5 \cdot 10^8$ m <sup>2</sup>
k = 0.17 m	T = 86,400 sec	
m = 1		
R = R(A) see Fig. 6	$A_c = 8000$ m <sup>2</sup> (from previous page)	

Fig. 5 Closure curve and equilibrium stress curves for Pass Cavallo prior to the opening of Matagorda Inlet

Two models are used for the equilibrium stress curves. In the first model the equilibrium shear stress is assumed constant and equal to the value observed in 1959 i.e.  $\tau_{eq} = 4.4$  N/m<sup>2</sup>. In the second model the current speed,  $u$ , is assumed constant and equal to 0.94 m/sec. The equilibrium shear stress follows from Eq. (2) with  $F$  given by Eq. (3). Equilibrium shear stress curves resulting from the two models are presented in Fig. 5. Note that in the second model  $\hat{\tau}_{eq}$  varies with  $A$ .

Fig. 6 Relation between hydraulic radius and cross-sectional area for Pass Cavallo and Matagorda Inlet

It follows from the closure curves and equilibrium shear stress curves presented in Fig. 5 that for both equilibrium shear stress models Pass Cavallo is stable. However the degree of stability especially when using the second shear stress model is at best marginal.

In 1963 a second inlet, Matagorda Inlet, was added. The sides of this inlet are protected by rubble and therefore in the stability calculations the width of the inlet is assumed constant and equal to the present width of 300 m. Furthermore a parabolic cross-section is assumed. The resulting relation between R and A for Matagorda Inlet is presented in Fig. 6. Other values of pertinent parameters used in calculating the closure surfaces of Pass Cavallo and Matagorda Inlet, i.e. Eqs. (6) and (7), are presented in Table II.

From observations it follows that after the opening of Matagorda Inlet, Pass Cavallo entered a shoaling mode, whereas Matagorda Inlet continued to scour. Surveys carried out in 1971-1972 yielded  $A_I = 7,500 \text{ m}^2$  and  $A_{II} = 3,600 \text{ m}^2$ . Using the data in Table II, it follows from Eqs. (1) and (4) that in 1971-1972  $\hat{u}_I = 0.75 \text{ m/sec}$  and  $\hat{u}_{II} = 1.2 \text{ m/sec}$ . These values agree with the observation that compared to the 1959 survey, current speeds in Pass Cavallo in 1971-1972 had considerably decreased and were well over 1 m/sec in Matagorda Inlet. The calculated values of

the maximum bottom shear stresses are  $\hat{\tau}_I = 2.8 \text{ N/m}^2$  and  $\hat{\tau}_{II} = 5 \text{ N/m}^2$ . Because of the relatively rapid response to scouring it may be assumed that during the 1971-1972 survey Matagorda Inlet was in equilibrium with its hydraulic environment and therefore  $\hat{\tau}_{eqII} = \hat{\tau}_{II} = 5 \text{ N/m}^2$ . This value is still within the range of equilibrium shear stress values suggested by Bruun [1978]. The values of the K' factor pertaining to the 1971-1972 conditions are  $K_I' = 0.38$  and  $K_{II}' = 0.65$ .

Table II

Values of pertinent parameters used in calculating the closure surfaces for Pass Cavallo and Matagorda Inlet

Pass Cavallo (I)	Matagorda Inlet (II)
L = 2350 m	L = 2150 m
k = 0.17 m	k = 0.17 m
m = 1	m = 1.5
R = R(A) see Fig. 6	R = R(A) see Fig. 6
2H = 1 m	$A_b = 3.5 \cdot 10^8 \text{ m}^2$
T = 86,400 sec	

The two models used to construct the equilibrium shear stress surface for Pass Cavallo are the same as before. The equilibrium shear stress model for Matagorda Inlet corresponding to Model I of Pass Cavallo is  $\hat{\tau}_{eqII} = 5 \text{ N/m}^2$ . The slightly higher value of the equilibrium shear stress for Matagorda Inlet is in agreement with the observation that jettied inlets require a somewhat larger tidal prism and thus larger bottom shear stress to maintain a certain cross-sectional area than unjettied inlets, Jarrett [1976]. The equilibrium shear stress model for Matagorda Inlet corresponding to model II of Pass Cavallo is  $\hat{\tau}_{eqI} = \rho F (1.2)^2$ .

The equilibrium flow curves (i.e. the projection of the intersection of the closure surfaces and equilibrium shear stress surfaces) using model I are presented in Fig. 7. Similarly for Model II the equilibrium flow curves are presented in Fig. 8. In these figures, the subscript I refers to Pass Cavallo and the subscript II refers to the Matagorda Inlet.

Because the enhanced parts of the equilibrium flow curves do not intersect, a combination  $(A_I, A_{II})$  for which both inlets are in equilibrium with the flow conditions does not exist. In 1971-1972, the cross-sectional area for Pass Cavallo and Matagorda Inlet were respectively  $A_I = 7,500 \text{ m}^2$  and  $A_{II} = 3,600 \text{ m}^2$ . Obviously, at that time, Pass Cavallo was in a shoaling mode. Since then the cross-sectional area of Pass Cavallo has gradually decreased leading Matagorda Inlet into a scouring mode. It is expected that this trend will continue. Because of the relatively fast response of an inlet to scouring the values of  $(A_I, A_{II})$  are expected to closely follow the enhanced part of the equilibrium flow curve for Matagorda Inlet.

In the absence of tropical storms and hurricanes, Pass Cavallo will ultimately close and the cross-sectional area of Matagorda Inlet will take on a value between 8,000 and 9,000 m<sup>2</sup>.

Fig. 7 Equilibrium flow curves for Pass Cavallo and Matagorda Inlet using equilibrium shear stress Model I.

Fig. 8 Equilibrium flow curves for Pass Cavallo and Matagorda Inlet using equilibrium shear stress Model II

Concluding Remarks

In applying the stability analysis, problems as to how to define the length of the inlet, how to estimate values of energy loss coefficients and bottom roughness and what to assume for the shape of the inlet will be encountered. In addition, if the inlet is in a shoaling or scouring mode, the question as to how the shape, the energy loss coefficients and the friction coefficient will change need to be addressed. Because the answers to many of these questions are not known, the proper evaluation of inlet stability requires calculating closure curves (surfaces) and equilibrium stress curves (surfaces) for a large range of inlet dimensions, energy loss coefficients, friction coefficients,

shapes of cross-sectional areas and closure scenarios.

Because of time and financial constraints the number of calculations in this study had to be limited. Also, the simplifying assumption of a uniformly fluctuating bay level is not justified. Therefore the final conclusion with regard to Pass Cavallo should be interpreted cautiously. However so far, all calculations point at a closure of the inlet barring the occurrence of tropical storms and hurricanes.

## CHAPTER NINETY FOUR

### Sediment Dynamics Field Experiment: Sunday's River

D H Swart\*

#### ABSTRACT

A field exercise was performed on a high-energy beach east of the Sunday's River in Algoa Bay on the east coast of the Republic of South Africa in the latter half of April 1983. Recorded data include nearly continuous wave data at 7 stations within the breaker zone with simultaneous waverider recordings in a water depth of 10 m, suspended sediment data gathered by means of 'bamboo' poles and instantaneous bottle samplers, daily topographical measurements of the beach and inshore area, data on rip current intensity and spacing for a 10 km coastal strip, more than 3 000 bottom sediment sample analyses and visual observations of wave height and longshore current velocity at hourly intervals through the recording period. Analysis of the data has been completed and interpretation and correlation of various measured phenomena are underway. A second exercise was performed in August 1984, when the emphasis was on nearshore circulation patterns.

#### 1. INTRODUCTION

The Departments of Botany and Zoology of the University of Port Elizabeth (UPE), South Africa, are studying the surf zone energetics in the Sunday's River mouth area. Surf diatom blooms occur very frequently in this area. One of the aspects which specifically needs attention is the physical mechanism which maintains these surf diatom blooms. Clarification of this aspect will help in establishing an energy balance for this area. The Sediment Dynamics Division (SDD) of the National Research Institute for Oceanology (NRIO) was approached to co-operate in the study. As a result two intensive field experiments were undertaken, one in April 1983 and the other in August 1984.

The exercise described here were undertaken jointly by the NRIO and the UPE, with the NRIO concentrating on physical aspects and the UPE on biological aspects. McLachlan and Bate (1984) have reported on certain aspects of the UPE work. The co-operation and support of the UPE were essential for the success of these field exercises. Although only one author is mentioned for this paper, the whole Sediment Dynamics Division co-operated in all aspects of the study.

#### 2. OBJECTIVES

The data gathered during these two field exercises serve a multiple purpose:

\* Head, Sediment Dynamics Division, National Research Institute for Oceanology, CSIR, Republic of South Africa.

- (1) It aids research on coastal sediment dynamics being undertaken by the SDD, in particular various aspects of breaking wave characteristics, nearshore wave dynamics and interaction between waves and currents on the one hand and nearshore suspended sediment motion on the other hand;
- (2) it will provide a physical description of the area to serve as a basis for the biological research carried out by UPE; and
- (3) it will allow the calibration of a 2D finite-element mathematical flow model for the nearshore region, which can then be used to generate a set of possible flow conditions for various wave conditions and nearshore topographies. These can then be used to compute energy budgets for the biota in the nearshore region.

The collaboration with the UPE determined the site for the exercise, as the UPE has for the last ten years been studying various aspects of the biota at the Sunday's River site. Figure 1 shows the position of Port Elizabeth on the South African coastline, whereas Figure 2 shows that the site is situated in a south-facing crenulate-shaped bay with its control point at Cape Recife in the west. The surf zone is of an intermediate type between dissipative and reflective and is characterized by rapidly changing bars, channels and rip currents which are in sympathy with the incident wave climate. The breaker zone slope is relatively mild at 1 in 60 but the seaward face of the bars is frequently as steep as 1 in 10 (see, for example, Figure 3, which was measured by lead line from a helicopter in August 1984). The dominant wave direction according to VOS data is the sector  $225^{\circ}$  to  $255^{\circ}$ . The median incident deepsea wave height in the area is about 3 m.

The Sediment Dynamics Division of the NRIO intends to start instrumenting a measuring site closer to its base at Stellenbosch. It is intended to establish a permanent measuring site at Yzerfontein, 80 km north of Cape Town on the west coast of South Africa (see Figure 1). The field exercise performed at the Sunday's River therefore also have an important secondary aim, namely, to aid in the development of equipment which can withstand the hostile surf on a high-energy coastline. At all times the emphasis was on low-cost experiments.

### 3. EXPERIMENTAL DESIGN

A measuring grid with three onshore-offshore measuring lines 50 m apart was set out and measuring devices were attached to measuring stands.

Fig 1: LOCALITY MAP

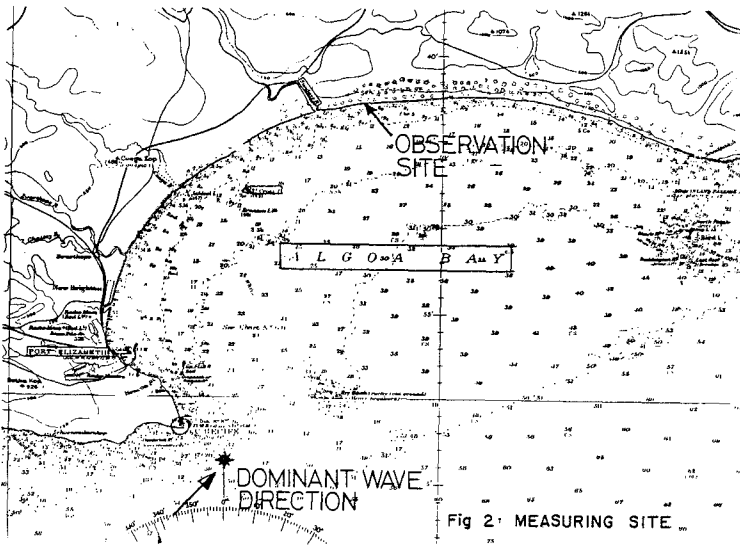

Fig 2: MEASURING SITE

SIZE OF GRID = 400m x 400m

Fig 3: SEA BED TOPOGRAPHY SUNDAY'S MEASURING SITE AUGUST 1984

The following aspects of the experimental set-up are particularly noteworthy:

- A measuring stand was designed after numerous trials. It has a base of 3 m x 3 m and a height of 4 m, and proved to be extremely stable in the surf zone (see Figures 4 and 5). It was placed loosely on the sandy bed and after settling some 5 to 10 cm did not move again, even though no formal anchoring was employed. It is thought that the open piped structure of the base was the reason for its stability. Various instruments were attached to the measuring stands.
- A 15 cm diameter segmented PVC "bamboo tube" with a length of 1,4 m (14 segments of 10 cm each) was designed as a sand trap in such a way that it could be easily attached to and removed from the measuring stand (Figure 6) and could be cleaned of its sand load as soon as possible (Figure 7). One half of the tube was continuous and the front half consisted of 10 cm wide semi-circular lids coinciding with the segments. The pairs of holes which allowed the sand to enter the segments were staggered by 90° at adjacent segments. Alternate pairs thus had the same orientation. Holes of 10 mm diameter were mostly used for 1 hour deployments. During longer deployments (up to 10 hours) holes of 5 mm diameter were used. To allow the transformation of the mass of sand caught in each segment to sediment concentrations, the bamboo tube was calibrated in the laboratory against known sediment concentrations.

Figure 4. Central line of measuring stand

Figure 5.  
Measuring stand  
in surf, note  
wave staff

Figure 6. Replacing bamboo sampler at measuring stand

Figure 7. Cleaning of bamboo sampler

- A 3,5 m long resistance wave height probe was designed and built by the Electronics Systems Division of the NRIO for the determination of water level fluctuations. Results were relayed from each measuring stand to shore by cable where it was recorded at 0,5 s intervals on digital dataloggers. Synchronous data were obtained from 7 wave probes. Data capture was continuous but analysis of the data was performed in 1024s blocks.
4. PRELIMINARY RESULTS

The analysis of the raw data obtained in both experiments has just been completed and the interpretation of the analysed data has commenced. A brief summary of the methods employed and some preliminary results are given below.

During the 1983 Exercise (PE83) the following observations were made:

**Incident waves:** Waves were measured continuously for a week by wave-rider in 10 m water depth directly opposite the measuring site. The measuring interval was 0,5 s. The significant wave height varied between 0,7 m and 1,4 m during this period, while the peak wave period always exceeded 10 s. Observations were also made with a graded telescope mounted on a 15 m high tower which was placed on top of the 10 m high primary dune. In the past this instrument, the so-called clinometer, was used extensively in South African waters for the estimation of wave height, period and direction. It has practically fallen into disuse because the results are observer-dependent.

**Surf zone waves:** Continuous, synchronous wave recordings were made for 4 days at up to 7 locations. More than 700 usable records, each with a length of 1024s, were obtained at these surf zone stations in water depths between 0,7 m and 2 m. Visual estimates of wave height and period at each stand were also made hourly. Wave directions in the surf zone were determined hourly by radar. Extremely consistent results were obtained. The dominant wave direction during the exercise was consistently just west of the normal to the beach.

The surf zone water elevations were analysed in two ways: by normal Fourier techniques as well as by the higher-order Vocoidal Fourier analysis developed by Swart and Fleming (1980) and Swart (1982). In the higher-order analysis vocoidal component waves are extracted instead of sinusoidal waves as in a normal Fourier analysis.

The results indicate that the representative height calculated from the higher-order analysis is always higher than for the customary first-order analysis (see Figure 8). This is in accordance with the earlier theoretical findings (Swart, 1982). Use of the first-order analysis leads to an underestimation of the representative wave height in shallow water. A similar conclusion is found to apply to the peak wave period, which again confirms an earlier theoretical conclusion (Swart, 1982). The wave records show the presence of energy of appreciably low frequency energy, with a peak period which is normally in the range 30 s to 100 s. The rms height in the low-frequency range ( $f < 0,038 \text{ s}^{-1}$ ) is typically about 0,1 to 0,2 m, which can be as high as 25 per cent of the rms height in the gravity wave range ( $f < 0,038 \text{ s}^{-1}$ ).

Fig. 8: TYPICAL LINEAR AND VOCOIDAL FOURIER ANALYSIS FOR SURF ZONE WAVES: 28 APRIL 1983; STAFF 4

Cross-sectional analyses are being done to differentiate between edge waves which essentially propagate alongshore and bound waves which essentially travel on-offshore. Figure 9 shows the coherency squared obtained by comparing the surface elevations at the outer (5) and central (3) wave staff in the central measuring line (staff 5 and 3 were 40 m apart) during both high and low tide. The coherency is more significant during high tide when the wave propagation is less affected by the irregularities in the topography. Figure 10 shows the accompanying phase diagram. The results indicate that bound waves in the low frequency band are more prevalent at high tide whereas edge waves are most prevalent at low tide. Analysis is still underway but this conclusion seems to be substantiated by the other analyses.

**Topography:** The nearshore topography from the upper beach to about 1 m below low tide level was determined daily over a distance of 500 m to each side of the central measuring line.

**Current patterns:** Longshore current velocities at the various measuring stands and nearshore current patterns were determined regularly by means of drogues and Rhodamine B dye. During the whole exercise an oblique rip current was situated across the central measuring line in a south-easterly direction. Mean current velocities of up to 5 m/s were measured in this reasonably confined (~ 20 m wide) rip current which pulsed with a period of 1 to 2 minutes and which was always stronger during low-tide.

In future exercises currents will be measured with ducted propellers and overall current patterns will again be determined by using dye.

**Aerial photographs:** A 10 km coastal strip to the east of the Sunday's River, with the measuring site situated about 2 km from the western end of the strip, was flown regularly during the week. Two overpasses were made each day during low tide and another two during high tide. On Friday, 29 April 1983 a total of 20 overpasses were made at roughly 15 minute intervals. The aerial photographs were combined into a mosaic for each overpass, which was then used to study the occurrence of rip currents. These currents were clearly visible on the photographs, while the extent of the surf circulation patterns could also be clearly discerned. The results show that the median surf cell width during the exercise varied between 250 m and 350 m, depending on the state of the tide and the incident wave conditions. The maximum width of the surf circulation cells, measured relative to the mean water line, was about 650 m.

**Sediment in suspension:** More than 100 sets of suspended sediment data were gathered during the week with the aid of bamboo poles and a further 20 sets of instantaneous suspended sediment data by means of sampling bottles. Figure 11 shows a typical correlation between the bottle sampler results and the bamboo sampler results. The 'bamboo' poles were usually removed after a deployment of one hour. Analysis of the sand weight caught in each 10 cm segment above the bed indicates that a sediment concentration based on any one of the following three assumptions would yield a goodness of fit to the data of nearly equal quality, namely a vertical diffusion coefficient which varies linearly or quadratically with distance above the bed or which is constant over the

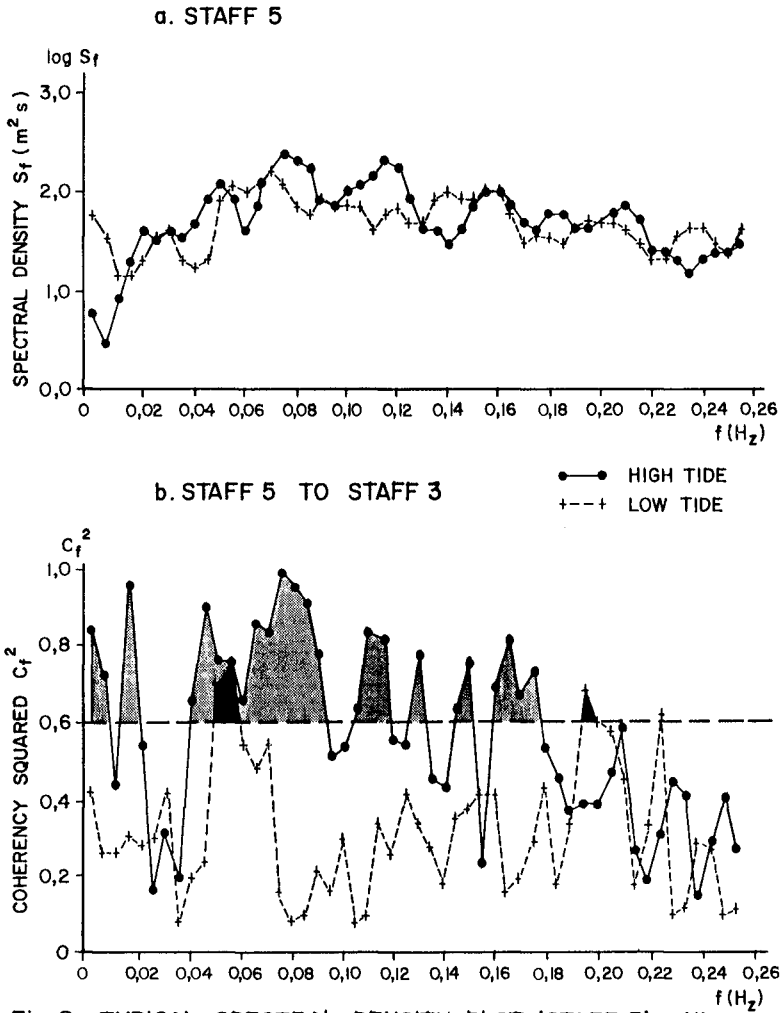

Fig. 9 TYPICAL SPECTRAL DENSITY PLOT (STAFF 3) AND COHERENCY (STAFF 5 TO STAFF 3)

Fig. 11 TYPICAL CORRELATION BOTTLE SAMPLER / BAMBOO SAMPLER

Fig. 12 VARIATION IN MAX. SEDIMENT CATCH

Fig. 13 TYPICAL VARIATION OF GRAIN SIZE WITH DISTANCE ABOVE BED

water column. This is in accordance with earlier findings by Swart (1976) and others, for example, Das (1972). The highest average concentration measured over a one-hour period in the first 10 cm above the bed was 27,1 g/l.

The variation in the maximum sediment load trapped in any segment (in all but a few cases this occurred in the bottom segment) is shown in Figure 12, which shows that the maximum load was 140 g/10 cm segment/hr, whereas the median load was 22 g/10 cm segment/hr. The data were also analysed for grain size variation with distance above the bed. Exponential decay of grain size was found (see Figure 13).

The magnitude of the total suspended load was found to be related strongly and uniquely to the relative position within the surf zone. A peak exists about halfway through the surf zone. It is intended to measure sediment concentration by optical or acoustical backscatter methods in future exercises, in parallel with the samplers employed to date.

**Bottom samples:** More than 3 000 bottom sediment samples were gathered on a regular grid in the measuring area as part of an investigation into the statistical distribution of bed material. The results indicate that longshore variations in grain size over a distance of 100 m are insignificant when compared to the onshore-offshore variations, which indicate a peak at the significant breaker line in both median grain size and the standard deviation of all measurements at a certain distance offshore. The standard deviation peaks at 10 per cent of the median grain size. The results give a preliminary indication about a representative sampling strategy to determine bed material characteristics.

In total 18 NRIO staff members and between 10 and 20 casual helpers participated in this exercise. The total running and capital expenditure was about US\$30 000.

The 1984 Exercise (PE84) was geared to the simultaneous recording of nearshore topography and current patterns.

The following techniques were used:

**Topography:** Conventional survey techniques were employed for daily surveys of 1 km coastal strip in the same manner as discussed for PE83. In addition, two surveys were made by lead line from a helicopter in a 0,4 km x 0,4 km area (see Figure 3). The lead line had a marker attached to it which was triangulated in from shore stations. Survey accuracies are estimated at about 10 cm. The technique supplied topographical information in the central surf zone under relatively high wave conditions (incident significant wave height between 1,5 m and 3 m) when other techniques currently employed in South Africa such as echo-sounding from a skiboat could not be used.

**Currents:** Current patterns were determined on three occasions from the observation of dye distribution after surf zone releases. Extremely complex current patterns were observed, with strong rip currents being concentrated in the channels shown in Figure 3.

**Aerial photographs:** Aerial strips were again done four times daily as in PE83. Data analysis is still underway.

During this 1984 exercise, the staff involvement on the NRIO side was 5, with support from 1 to 2 casual helpers at times. The emphasis in this exercise was more on biological responses than was the case during PE83. The total running and capital expenditure for NRIO was about US\$7 000.

## 5. SUMMARY

The following is a summary of the main conclusions from the two exercises and the results obtained to date.

(1) Extremely useful simultaneous, synchronous recordings at up to 7 wave staffs in the breaker zone and at a waverider in 10 m water depth were obtained. Interpretation of the data is shedding new light on the relative importance of edge waves and bound waves on high-energy intermediate beaches. In the barred beaches observed during the exercises edge waves predominated at low tide and bound waves at high tide.

(2) "Calibrated" data on sediment in suspension in the surf zone and good quantitative data on sediment sorting in the vertical under surf zone conditions were obtained.

(3) The bottom topography and flow patterns in a rough, wide surf zone were determined from a helicopter and by aerial photographs.

It is concluded that it is possible to run a prototype field exercise relatively inexpensively and still obtain very useful simultaneous wind, wave, current and sediment data.

The programme will be extended in the near future to include measured onshore-offshore and longshore current velocity components. A second site for future field exercises is being considered. It is situated in the centre of a 30 km long, flat crenulate bay about 80 km north of Cape Town.

## CHAPTER NINETY FIVE

### SCALE-MODEL RELATIONSHIP OF BEACH PROFILE

by

Masahiro Ito<sup>1</sup> and Yoshito Tsuchiya<sup>2</sup>

#### 1. ABSTRACT

This paper presents a scale-model relationship for the similarity between large and small scale-models in two-dimensional equilibrium beach profiles. Taking large scale-models using large scale equipment as prototypes, the experimental scale of a medium-sized model was gradually varied keeping the grain size ratio of model to prototype constant. A similarity-comparison between large and small scale beach profiles is made by considering the degree of experimental errors. Judgement results are graphically shown, and a scale-model relationship is proposed. It is found that the scale-model relationship proposed agrees with the ones derived from the empirical formulae expressing the properties of beach profiles. Additionally, the applicability of this scale-model relationship to the reproduction test of natural beaches is examined.

#### 2. INTRODUCTION

The similitude on the beach changes has often been studied experimentally and theoretically by several investigators. As an experimental method, the similitude of two-dimensional beach change was earlier studied using a regular wave flume in the Beach Erosion Board (presently, Coastal Engineering Research Center, US Army) in 1947. Saville (1957) and Iwagaki & Noda (1961) pointed out the scale effect as the reason that the beach profile in the model is not always in agreement with the prototype, when the wave height, wave length and grain-size scale of model are scaled down geometrically by the Froude law for the prototype. Noda (1972)

- 
- 1 Associate Professor, Department of Civil Engineering, Meijo University, Tempaku-ku, Nagoya, Japan.
  - 2 Professor, Disaster Prevention Research Institute, Kyoto University, Uji, Kyoto, Japan.

discussed how the scale-distortion among vertical and horizontal scales, sand grain-size and specific gravity of beach material of the model has an effect on the similitude relationship. Similitudes proposed with these methods are significant only within the specialized experimental conditions, and not clearly confirmed by the verification test on a natural beach.

This paper presents a scale-model relationship for the two-dimensional equilibrium beach profiles. The scale-model relationship proposed is examined by its applicability to the verification test on the natural beach at Ogata in Niigata, Japan.

### 3. EXPERIMENTAL ERROR IN REPRODUCTION TEST

If a laboratory experiment on beach processes is performed several time under initially the same conditions, in general, the properties of beach profiles and breaking waves vary considerably as seen in Fig. 1, in which position and height of  $\downarrow$ -symbol show breaking point and relative wave height, respectively. They happen independently of with wave duration time  $t$ . It is considered that the scatter of properties depends on (i) systematic error, (ii) accidental error and (iii) mistakes. In this study the scatter of data, namely experimental error, is investigated, using the mean error  $\epsilon'$  defined as

$$\epsilon' \Delta x = \frac{1}{n} \sum_{i=1}^n |x_i - \bar{x}| \quad (1)$$

where  $\epsilon \Delta x$  is the experimental error of shoreline change relating to beach profiles and waves,  $n$  the number of replications,  $x_i$  the measured value at the  $n$ -th, and  $\bar{x}$  the mean value.

The relationship between the experimental error of shoreline change evaluated with Eq. (1) and the wave steepness in deep water  $H_0/L_0$  is shown in Fig. 2 including the other data. In this figure, a parameter  $H_0/sd$  usually describing a measure of the scale effect in beach profile is shown. In the parameter,  $H_0$  is the wave steepness in deep water,  $s$  the specific gravity of beach sediment in water, and  $d$  the grain size. From Fig. 2 it is recognized that the parameter does not effect the experimental error of shoreline change. Since the values plotted in Fig. 2 scatter considerably, the solid line is drawn to envelop the highest values plotted. The solid line, namely the dimensionless experimental error of shoreline change  $\epsilon \Delta X_{s1}/L_0$ , is expressed as

$$\epsilon \Delta X_{s1}/L_0 = \pm 5.7 (H_0/L_0)^{1.2} \quad (2)$$

Also, the dimensionless experimental errors of position of berm crest  $\epsilon' \Delta B_x/L_0$  and breaking point  $\epsilon' \Delta X_b/L_0$  derived in the same manner are shown in Fig. 2 with broken and dotted lines, respectively.

Fig. 1 Experimental error of repeating runs at the wave operation time of 24 hours in Run No. 3M-28 in Table 1.

Fig. 2 Experimental errors of shoreline change berm crest position and breaking point .

#### 4. CRITERION OF SIMILARITY

To ensure the similarity of beach processes between the prototype (i. e., large-scale model) and the model (i. e., small-scale model), phenomena such as beach profile, breaking waves and sediment transport by waves have to be similar in both cases. The comparison of the similarity between the two must be judged while considering the experimental error proposed. By the degree of agreement between the two, therefore, the following three criteria are employed:

a) Similitude : The difference in the beach processes, such as changes in shoreline and breaking point, is less than twice the experimental error. The judgement in this case is designated by circles.

b) Dissimilitude : Beach profiles to be compared are substantially different in type such as "bar type" and "step type", and the difference in the beach processes is more than four times the experimental error. This is designated by dark squares.

c) Quasi-similitude : This case is an intermediate situation between a) and b), and designated by triangles.

#### 5. EXPERIMENTS

We performed a number of laboratory experiments in order to determine the scale-model relationship of two-dimensional beach change under the following conditions :

(1) The vertical and horizontal length scales, such as beach profile and water depth in the wave tank, are to be the same (i. e., undistorted), and both scales are to be subject to the Froude law.

(2) Wave characteristics such as wave height  $H$  and wave period  $T$  are determined by the Froude law. The wave generator operated until beach profiles reach equilibrium.

(3) The beach sediment of the small-scale models is sand or silica-sand with the same specific gravity as the sand used in the large-scale models. The grain size of the beach sediment in the model, i. e. the grain-size scale, is to be chosen independently of the experimental scales above-mentioned (1) and (2).

A large-scale model was carried out using a large-size two-dimensional wave flume of 78m long, 1m wide and 1.2m deep, and waves were generated for 60 hours on an initially even-sloping beach. We took the equilibrium beach profile and its experimental conditions to be the prototype. Additionally, those of the prototype-size experiment performed by Saville were also taken to be the prototype.

For comparison, experiments with small-scale models were carried out using the medium-sized wave flume of 28m long, 0.5m wide, and 1m deep. The grain size of the sand or silica-sand used in the model beach sediment was chosen independently of the experimental scale. The experimental scale was gradually varied keeping the grain size ratio of model to prototype constant. The initial beach slope of the model was identical to the prototype. Table 1 is an example of experimental conditions, in which  $d_{50}$  is

the medium size of the beach sediment,  $H_0$  the wave height in deep water,  $L_0$  the wave length in deep water,  $h$  the water depth in the wave tank,  $g$  the acceleration of gravity,  $\nu$  the kinematic viscosity of water and  $t$  the duration time in total. The grain size distribution of the beach sediment used in the prototype and the model is shown in Fig. 3. Median sizes of the beach sediment were used 0.15, 0.30, 0.42, 1.62mm in the model and 0.22, 0.94mm in the prototype, respectively.

Table 1 An example of experimental conditions for prototype and model.

6. EXPERIMENTAL RESULTS AND ANALYSIS

Fig. 4 (a) shows the properties of beach profiles and breaking waves which resulted from the experiment, and expresses similarity-comparisons between the prototype (Run No. 3 in Table 1) and the models (for example, Run No. 3M-30 ~ 3M-25). In this figure, P, S and SP indicate breaker types, such as plunging breaker surging breaker and spilling breaker. The comparison shown in Fig. 4 (a) was made gradually varying the experimental scale  $S=1/n$  [ $= \lambda_{H_0} = (H_0)_m / (H_0)_p = 1/1.82 \sim 1/6.7$ ], keeping the grain-size scale of the model to prototype,  $\lambda_d$  [ $= (d)_m / (d)_p = 0.45$ ] constant. Also, the comparison between the prototype by Saville's experimental result (Run No. T-22) and the models (Run No. T-27 ~ T-29) is also shown in Fig. 4 (b). The degree of experimental error in the experiments is recognized from check run of the Run No. T-28. The judgement of the similarity-comparison between the prototypes and models was made using the criteria a), b) and c) defined already, and the judgement results are shown on the left side of the figure, respectively. Only prototypes in which the ratio of grain size to wave height satisfied the condition that  $(d)_p / (H_0)_p \leq 0.01$  are used for comparison with the models. The results judged are arranged in Fig. 5 of which ranges of

experimental conditions of prototype cover  $H_o/L_o = 0.007 \sim 0.025$ ,  $d/H_o < 0.01$ , and  $i_o = 1/10 \sim 1/30$ , giving the inverse ratio of grain-size scale  $1/\lambda_d [(d)_p / (d)_n]$  the ordinate and the inverse ratio of experimental scale  $1/\lambda_{H_o} (1/S = n)$  the abscissa, respectively. Fig. 5 also includes the results which satisfy the range of the initial beach slope ranging  $1/10$  to  $1/30$  and of the deep water wave steepness ranging  $0.007$  to  $0.025$  among the experimental data from previously investigators.

It is possible to classify the data shown in Fig. 5 into three zones such as "Similitude", "Quasi-similitude" and "Dissimilitude". In Fig. 6, results in the case where  $H_o/L_o = 0.031 \sim 0.042$ , which are similarly classified, are superimposed on those of Fig. 5. In Fig. 6, ranges of experimental conditions of prototype cover  $d/H_o < 0.01$  and  $i_o = 1/10 \sim 1/30$ . A common similitude zone extends over both ranges  $1/\lambda_d > 1$  and  $1/\lambda_d < 1$  of the grain-size scale. The central position of the common similitude zone is shown with a dot-dashed line. The scale-model relationship indicated by the dot-dashed line within the range  $1/\lambda_d > 1$  is expressed by

$$\frac{1}{\lambda_d} = 1.7 \left(\frac{1}{H_o}\right)^b \tag{3}$$

which is transformed to

$$\frac{(d)_n}{(d)_p} = \left(\frac{1}{1.7}\right)^a \left(\frac{1}{n}\right)^b \tag{4}$$

where  $(d)_n / (d)_p$  is the grain-size scale,  $1/n$  the experimental scale, and the values of  $a$  and  $b$  are indicated in Table 2. From Fig. 6, it is seen that the scale-model relationship of Eqs. (3) and (4) shifts slightly from the Froude law stating that  $1/\lambda_d = 1/\lambda_{H_o}$  which is drawn by a dotted line.

Table 2 Values of  $a$  and  $b$  in Eqs. (3) and (4)

Experimental scale / Exponent	$1 > \frac{1}{n} > \frac{1}{2.2}$	$\frac{1}{2.2} > \frac{1}{n}$
a	0	1
b	0.83	0.2

Fig. 6 Similitude of beach profile within range of  $H_0/L_0=0.007 \sim 0.042$ .

## 7. COMPARISON

Let us compare the scale-model relationship indicated in Fig. 6 or Eqs. (3) and (4) with those derived by other investigators. Previous studies of the beach processes are summarized in column No. ③ in Table 3. In table 3,  $d_n$  is the mean diameter of beach sediment,  $w$  the fall velocity of the sediment,  $L_o$  the deep water wave length,  $i_o = \tan \beta$  the initial beach slope,  $l$  the typical length,  $\lambda_x$  the horizontal scale,  $\lambda_y$  the vertical scale,  $\sigma$  the density of beach sediment,  $\rho$  the water density and other notations were explained already. Now, arranging the relationship of column No. ③ using the definition,

$$\lambda \text{ parameter} = \frac{\text{model parameter}}{\text{prototype parameter}} \quad (5)$$

scale-model relationships as shown in column No. ④ are obtained. When the experimental conditions are restricted by the conditions (1), (2) and (3) described in 5, we may make the assumptions that  $\lambda_x = \lambda L_o = \lambda_y = \lambda H_o$ ,  $\lambda i_o = \lambda \tan \beta = 1$ ,  $\lambda t = 1$  and  $\lambda_s = 1$  as well as the water temperature and acceleration of gravity are the same between model and prototype,  $\lambda_v = 1$  and  $\lambda_g = 1$ , respectively.

Substituting these similitude conditions into the scale-model relationships of column No. ④, the relationships of column No. ⑤ are finally derived. Using the same coordinate ( $1/\lambda_d$ ,  $1/\lambda_{H_o}$ ) as Fig. 6, it is possible to describe relationships of column No. ⑤. Similitudes of Nos. A, B and C shown in Fig. 7 (a). The scale-model relationship of Nos. D, E and F is expressed using only the fall velocity of beach sediment  $w$ . Now, we consider the scale-model relationship between the fall velocity and the grain size of material. There are theoretical formula of Stokes, and empirical ones of Allen, Kármán and Newton for the fall velocity of sediment as reported by Tsurumi (1932). The applicable ranges of the four formulae depend on the Reynolds number  $Re = wd/\nu$ . Using the restricted conditions of this study,  $\lambda_s = 1$ ,  $\lambda_v = 1$  and  $\lambda_g = 1$ , the relationships of  $\lambda_w$  and  $\lambda_d$  are eventually obtained as,

Stokes' formula (In this formula, when  $s=1.65$ ,  $\rho=1.0\text{g/cm}^3$  (water density) and  $Re < 4.5$  are given, the applicable sediment size to the formula is  $d < 0.15\text{mm}$ .)

$$\lambda_w = \lambda_d^2 \lambda_s^{-1} \lambda_v \lambda_g^2 = \lambda_d^2 \quad (5)$$

Allen's formula (similarly,  $Re=4.5 \sim 300$ ;  $d=0.15 \sim 1.1\text{mm}$ )

$$\lambda_w = \lambda_d^{2/3} \lambda_s^{-1/3} \lambda_v^{2/3} \lambda_g = \lambda_d \quad (6)$$

Kármán's formula (similarly,  $Re=300 \sim 3200$ ,  $d=1.1 \sim 5.8\text{mm}$ )

$$\lambda_w = \lambda_d^{2/3} \lambda_s^{5/9} \lambda_v^{-1/9} \lambda_g^{5/9} = \lambda_d^{2/3} \quad (7)$$

Newton's formula (similarly,  $Re=3200 \sim 10000$ ,  $d > 5.8\text{mm}$ )

$$\lambda_w = \lambda_d^{1/2} \lambda_s^{1/2} \lambda_g^{1/2} = \lambda_d^{1/2} \quad (8)$$

In Table 3 all the relationship of No. D, E and F in column No. ⑤ can be expressed in Fig. 7 (b) taking the Reynolds number of the prototype as a parameter. Since the scale-model relationship in Fig. 6 is comparable with those shown in Fig. 7, it can be seen that the scale-model relationship proposed in this study agrees well with those derived from the relationships which express the properties of beach processes using the fall velocity of beach sediment.

**Table 3 List of similitudes derived from characteristics of beach profile.**

Fig. 7 Comparisons of scale-model relationship proposed with those in column No. ⑤ in Table 3.

**Fig. 8** Verification of proposed scale-model relationship by reproduction of natural beaches in scale models.

## 8. VERIFICATION TEST

To verify the scale-model relationship proposed in this study, experiments with a two-dimensional beach model of the Ogata coast in Niigata were carried out. On this coast, the predominant waves strike the shore orthogonally. Therefore, it may be considered that the coast has a two-dimensional property. The experimental conditions of the verification test were set with an experimental scale of  $S=1/50$  and a grain-size scale of  $\lambda_d \approx 1/3.2$  using the scale-model relationship. The properties of waves in the model reproduced the significant waves off Ogata, and the temporal wave change was chosen according to the Froude time scale. It was found that the verification test well reproduced the beach change at the coast. The grain-size scale and the experimental scale used in the verification test agree well with the similitude zone shown in Fig. 8. This figure, as a comparison, also includes other results of two-dimensional wave flume experiments by the first authors (1982) and Sizuoka prefecture (1973), and of the three-dimensional wave basin by Ozaki (1962) and by Tanaka-Osanai (1973). Consequently, it is concluded that the model can reproduce very well beach changes when the experimental conditions are set so as to be contained within the similitude zone proposed.

## 9. CONCLUSIONS

The main conclusions are summarized as;

- 1) The experimental errors of the shoreline change, berm crest position and breaking point in the two-dimensional beach processes are shown as a function of wave steepness in deep water. The tendencies of the three experimental errors on it are similar.
- 2) The three criteria for classifying the degree of similarity between prototype and model are defined from the degree of experimental error.
- 3) The similarity-comparison between prototype and model is made with reference to the similarity criteria. The scale-model relationship of beach changes is proposed from the Fig. 6 showing the result of similarity-comparison.
- 4) The scale-model relationship proposed agrees well with the one derived from the relationship expressing the properties of beach changes using the fall velocity of beach sediment.
- 5) It is found that the proposed scale-model relationship is applicable to reproduce changes in natural beaches in laboratory experiments.

## 10. ACKNOWLEDGMENTS

This study was supported by the Research Grant of Meijo University. The authors would like to express their gratitude to the personnel at the Research Section of Coastal Disaster, Disaster Prevention Research Institute, Kyoto University, and the students in the first author's laboratory, for their assistance during the study.

## CHAPTER NINETY SIX

### FORMATION OF TOMBOLO AT THE WEST COAST OF IWO-JIMA

By

Toshiyuki SHIGEMURA\*

Jouji TAKASUGI\*\*

and

Yoshihiro KOMIYA\*\*\*

#### Abstract

This paper intends to clarify why and how such a huge tombolo having a surface area of 1,700,000 m<sup>2</sup> has been formed at the west coast of Iwo-jima for relatively short period of 33 years after 1945.

Analyses are performed on various data obtained through literature survey and field measurements to determine the growth rate of tombolo and variation rate of shore and sea floor surrounding the island. Model tests are also made on the formation of tombolo.

The followings are the conclusions derived through the analyses:

- (1). Source of the sediments is the one produced at the northern part of island where sea floor has been lifting at a rate exceeding 30 cm per year.
- (2). Waves with dominant direction of N to NE which appear in fall and winter erode the northern coast and currents induced by these waves carry these sediments southward along both coasts of the island.
- (3). Waves with dominant direction of S to SE which appear in summer and their induced currents carry the sediments northward along both coasts of the island.

#### 1. Introduction

Iwo-jima is a small volcanic island located in the Pacific ocean at a location which is approximately 1250 km southward from Tokyo (24°45'N to 24°49'N in latitude and 141°17'E to 141°21'E in longitude). This island is situated at the southern tip of Izu-Ogasawara volcanic arc.

Figure 1 shows the present topography of Iwo-jima. Surface area and length of shoreline of the island are 23.2 km<sup>2</sup> and 24.3 km, respectively. Geologically, the island consists of the following three parts:

- (1). Motoyama area which is a broad dome or a truncated strato-volcano situating at the northern half of the island.
- (2). Suribachi-yama which is a pyroclastic cone locating at the southern tip of the island.

\* M.ASCE, Professor, Civil Engineering Dept., National Defense Academy  
1-10-20 Hashirimizu, Yokosuka, Kanagawa, Japan

\*\* Lt.s.g., Engineering Dept., Japan Maritime Self Defense Force

\*\*\* 1st Lt., 101 Topographic Battalion, Japan Ground Self Defense Force

(3). Chidoriga-hara area which is a gentle slope locating between Motoyama area and Suribachi-yama, formed by the fill of loose volcanic ashes and fine cinders<sup>1,5</sup>).

This island is relatively flat except for Suribachi-yama and most surface is covered by considerably thick vegetation. There are no rivers in this island, and a few cliffs eroded seriously by waves are found at northern coast. Judging from these features, it seems unnatural to anticipate that sediments are either produced in the island or transported from elsewhere in the vicinity of the island. Nevertheless, Iwo-jima is surrounded by relatively wide sandy beach except for northern part of the island. Further, the shoreline keeps advancing toward seaward year by year.

One of the remarkable characteristics of Iwo-jima is the continuous upheaval of island. This fact can be substantiated by the existence of numerous treads of marine terraces which are found all over the island. Especially for the past few decades, this island has kept lifting at the rate exceeding 30 cm per year at the northern part although upheaval rate at the southern part is smaller considerably<sup>6,10</sup>). This remarkable upheaval seems to have caused the continuous advancement of shoreline toward seaward.

Advancement of the shoreline has been quite remarkable especially at the west coast of Iwo-jima. Nautical chart published by US Navy in 1945 indicates that a group of rocks named kama-iwa was situated approximately 1 km off the west coast of Iwo-jima and the isthmus between kama-iwa and west coast used to be a navigable channel whose maximum depth was 36 m at that time. This channel got narrower and narrower since 1945, and in June 1968 when the island was returned to Japan, kama-iwa has finally touched with the tip of west coast to form a huge tombolo there.

This paper intends to clarify the following questions as quantitatively as possible by analyzing maps, charts and aerial photos of Iwo-jima which are available at the present stage and by performing both field surveys and model tests:

- (1). Where and how were the abundant sediments produced in this island ?
- (2). Why and how was the tombolo formed at the present location ?
- (3). Is the present topography of the island stable in future ?

## 2. Collection of Basic Data

### 2-1. Collection of data through literature survey

#### (1). Topographic data of Iwo-jima

To check the variation of both surface and bottom topographies, maps

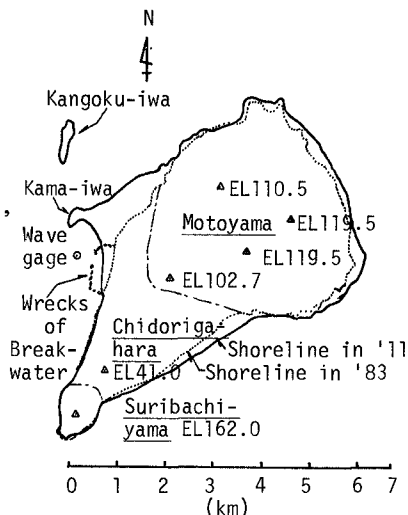

Fig.1. Topography of Iwo-jima.

and charts published and photos taken so far of Iwo-jima were all collected. Table 1 summarizes these collected materials.

Table 1. Source of data used for the analysis of topographic features of Iwo-jima.

No	Source of data	Office of publication	Year	Scale
1	Topographic map	Land Survey Dept., Japanese Imperial Army(Iwo To, No.12)	1911	1/50000
2	Chart	Hydrographic Dept., Japanese Imperial Navy (Iwo To, No.220-3003)	1934	1/30000
3	Chart	Hydrographic Office, US Navy (IO JIMA,DMA97BHA97562)	1945	1/20000
4	Map & Chart	US Army (IWO-JIMA,ST632II NW)	1952	1/25000
5	Topographic map	Geographical Survey Inst., Japan (Iwo To, NG-54-17-12-3)	1968	1/25000
6	Topographic map	National Research Center for Disaster Prevention,Japan (Volcanic Phenomena of Iwo-jima)	1972	1/10000
7	Chart	Hydrographic Dept., Japan Maritime Safety Agency (Chart of the surrounding Sea of Iwo jima)	1981	1/50000
8	Topographic map	Geographic Survey Inst., Japan (Iwo To, NG-54-17-12-1-3-4)	1982	1/50000
9	Aerial photo	Japan Maritime Self-Defense Force	1983	

Each of these materials was enlarged into the pictures with scale of 1/10000. Positions of the shoreline in each picture was determined at every increment of 5 mm or 5 m in real scale by tracing the shoreline with a device or an A-D convertor which converts the position of tracer into digital figures and punches them on data cards automatically. Depth data was determined in the following way, based on the enlarged pictures of the charts published by US Navy in 1945 and of the one published by the Hydrographic Department of Japan Maritime Safety Agency(JMSA) in 1981;

- (a). Provide a common area of 1.4 m in the direction from west to east, be 1 m in the direction from north to south on both enlarged pictures so that the island could be contained in the common area.
- (b). Divide the common area into 3500 square subsections each of which has the area of 2 cm by 2 cm.
- (c). Determine the depth at each corner of the subsections based on the depth data available in their vicinity.

#### (2). Meteorological data in Iwo-jima

Since 1968, a contingent troop of Japan Maritime Self Defense Force (JMSDF) has stationed in Iwo-jima and has been taking meteorological data every 3 hour. The data recorded during the period from 1968 to 1977 will be used for the analysis of meteorological features in Iwo-jima.

#### (3). Upheaval data in Iwo-jima

Kaizuka et al<sup>7)</sup> have pointed out in their paper that Iwo-jima is a top portion of a strato-volcano rising roughly 1500 m to 2000 m above the seabed on which foot of volcano is expanding about 40 km in diameter.

Ouyagi and Kumagai<sup>9)</sup> made <sup>14</sup>C dating test of carbonized wood pieces and corals sampled at various elevation of Iwo-jima and derived the following conclusions:

(a). Geological history of the island might be in the order of 3000 years at most.

(b). Average upheaval rate in the past would be 19 cm per year in Motoyama area and 3 cm per year in Suribachi-yama.

Tsuji et al<sup>10)</sup> compared the elevations of several points shown in the topographic map published by US Army in 1952 with the ones of the corresponding points which they got through their levelling performed in 1968. As a result, they found that outer edge of Motoyama area has upheaved roughly 9 m although Suribachi-yama has upheaved less than 2 m for the past 16 years after 1952.

Kosaka et al<sup>8)</sup> collected old maps and charts of Iwo-jima published after 1911. They also performed levelling at Iwo-jima four times in the period from 1968 to 1978. By analyzing these data, they found that mean upheaval rate in Motoyama area reached roughly 30 cm per year after 1952 although it was 11 cm per year before 1952.

## 2-2. Collection of data through field surveys

### (1). Wave data at Iwo-jima

Wave data has never been measured in Iwo-jima until lately.

On July 7, 1981, the authors installed a supersonic type wave meter about 450 m off the shoreline of west coast where the depth was roughly 12 m. Figure 2 shows the bottom topography in the vicinity of installation point. Bottom slope around there was roughly 1/40.

A mound made of 5 m steel pile with a diameter of 20 cm was driven 3.5 m in depth into the seabed. The sensor was mounted on the top of the mound and was connected to a penoscillograph in an observatory which was built on the shore, through a marine cable whose diameter is 39 mm. This wave meter can record only the fluctuation of water surface at the measuring point. Thus, information of the wave direction can not be obtained from the record. Due to the limitation of recording paper, the recorder was set so that wave data could be recorded for 10 minutes every two hour.

Unfortunately, cable was cut and washed away on August 19, 1981 when

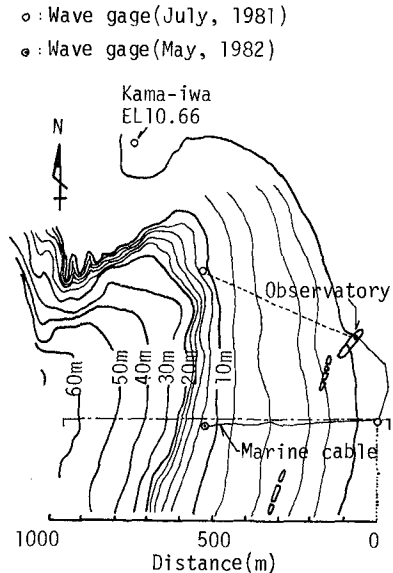

Fig.2. Installation point of wave meter

typhoon #15 hit the island. The record taken just before the incident indicated that the maximum height of the swells was roughly 10 m.

The same wave meter was installed again on May 10, 1982 at the location which is about 500 m south from the former position where the depth is also roughly 12 m (see fig.2). This meter survived for 19 months after the installation although it was also washed away on November 7, 1983 while typhoon #17 was hitting the island. For these 19 months, the recorder had kept recording wave data for 10 minutes every 2 hour. These data was processed by the A-D convertor mentioned previously at a sampling interval of 0.5 second and was punched on data cards automatically.

#### (2). Upheaval data on the backshore of Iwo-jima

Previous works have revealed that upheaval in Iwo-jima is dominant in Motoyama area and that it becomes greater and greater as it goes from the central portion to the shore of the island where the engineers are most interested in. Thus, it was planned to get more reliable upheaval data along the whole backshore of the island. Levelling have been performed three time for 19 months after August 1982, by using 50 measuring stations placed at almost equi-interval on the whole backshore of the island.

#### (3). Physical properties of sands along the shoreline of Iwo-jima

In order to see if the physical properties of sands around the shoreline will vary both seasonally and regionally, sands were sampled on June 1983 and on February 1984 at 50 locations along the shoreline where the lines each of which contain one of the 50 stations intersect perpendicularly to the shoreline. Both sieve analysis and specific gravity test were performed on all of these sands to determine their physical properties.

### 3. Analysis of Collected Data

#### (1). Meteorological features in Iwo-jima

JMSDF made an intensive statistical analysis on the meteorological data recorded in Iwo-jima for the past 10 years after 1968<sup>2)</sup>. Through these analyses together with the author's analysis, the following features were revealed on the meteorological characteristics in Iwo-jima:

##### (i). Temperature in Iwo-jima

(a). Mean monthly temperature is approximately 27°C through summer and fall although it is about 19°C in winter. From spring to summer, temperature rises from 19°C to 27°C almost linearly.

(b). Daily variation of temperature is less than 5°C through the year.

##### (ii). Rainfall in Iwo-jima

(a). Monthly rainfall exceeds 100 mm during the period from May to December although it is less than 70 mm in the rest of the months.

(b). Rainy days count approximately 145 days per year and yearly rainfall is roughly 1300 mm.

##### (iii). Winds in Iwo-jima

Figures 3 shows seasonal wind roses in Iwo-jima. In these roses, rigid lines indicate mean frequency of occurrence in each direction

which was determined from whole data of winds, and do the dotted lines the one determined through the data of winds whose velocities are greater than 10 m/s. From these wind roses, the following features were found on the wind characteristics in Iwo-jima:

(a). East winds are dominant in spring, summer and fall although north winds are dominant in winter. After east winds, south winds are dominant in spring and summer.

(b). West winds are quite few through the year.

(c). Only 3.5 % of total winds are the high winds whose velocities exceed 10 m/s.

(d). Dominant direction of high winds ranges from SE to SSE during summer although it ranges from NNW to NE in fall and winter. High winds also blow from the direction ranging from W to N in winter.

(iv). Typhoons in Iwo-jima

Figure 4 shows the yearly cumulative number of typhoons generated at the north Pacific after 1945<sup>3)</sup>. In this figure, rigid lines indicates cumulative number of whole typhoons generated at the north Pacific and do the dotted and chain lines the ones which hit Iwo-jima, respectively.

From this figure, the following facts were found on the typhoons in Iwo-jima:

(a). 20 to 40 typhoons are generated each year at the north Pacific.

(b). At least one fifth of them hit Iwo-jima every year.

(c). Typhoons with central pressure less than 960 mb possibly hit Iwo-jima at least once a year.

(2). Wave characteristics in Iwo-jima

Each of the 10 minutes records of wave data recorded for 19 months after May, 1982 was processed at a sampling interval of 0.5 second by an A-D convertor to yield 1200 data

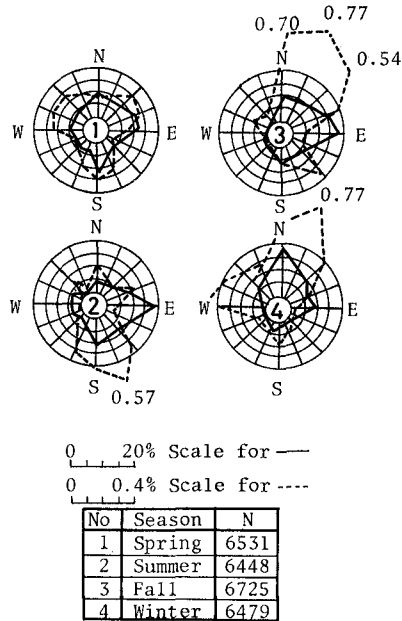

Fig.3. Seasonal wind roses in Iwo-jima.

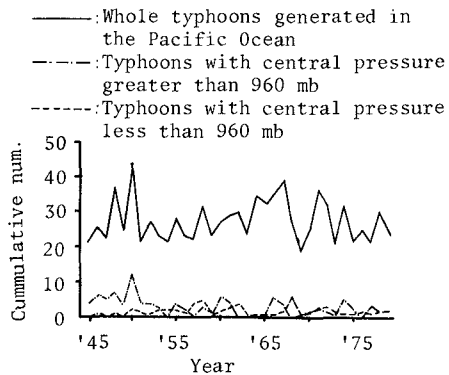

Fig. 4. Typhoon statistics in the north Pacific and Iwo-jima.

from it. These processed data were analyzed by means of the zero up crossing method to determine the heights and periods of waves.

Figure 5 shows an example of the analytical results. Huge peak appeared around the righthand edge are the swells which hit Iwo-jima when typhoon #10 with central pressure of 940 mb passed about 350 km off the west coast of Iwo-jima on July 31, 1982.

The maximum height and its significant period of the swells determined from the record taken at 8 AM of July 31 were 9.2 m and 19.0 seconds, respectively.

Table 2 summarizes seasonal distribution rate of significant waves whose height and period are in the given ranges of magnitude.

Table 2. Seasonal distribution rate of significant height and period of waves in Iwo-jima.

	$H_{1/3}$ (m)				$T_{1/3}$ (s)			
	0-1	1-2	2-3	<3	6	6-8	8-10	<10
Spring	62	36	1	1	29	51	16	4
Summer	70	20	4	6	21	42	21	16
Fall	73	14	7	6	8	43	27	22
Winter	59	35	6	0	31	49	16	4

From this table, it can be seen that dominant waves in Iwo-jima are those whose significant heights are less than 1 m and whose significant periods are less than 8 seconds except for the waves appearing in summer and winter.

Table 3. Values of  $H_{max}$  and  $T_{1/3}$  of the waves recorded while typhoons were hitting Iwo-jima.

No	Date	Time	$H_{max}$	$T_{1/3}$	Pres.	Location	$V_{max}$	$\theta$
#4	May 23, '82	0200	8.4 m	18.5 s	980 mb	NNW 150 km	27.5m/s	ENE
#5	Jun 26, '82	1000	5.4 m	11.1 s	975 mb	NW 250 km	32.5m/s	N
#10	Jul 31, '82	0800	9.2 m	19.0 s	940 mb	WNW 350 km	50.0m/s	NNW
#13	Aug 24, '82	2100	Lack of data		940 mb	W 850 km	45.0m/s	NNW
#15	Aug 30, '82	0900	Lack of data		945 mb	W 300 km	45.0m/s	NW
#18	Sep 11, '82	1000	5.3 m	12.0 s	965 mb	WNW 600 km	35.0m/s	NW
#19	Sep 19, '82	0000	5.2 m	8.3 s	940 mb	WSW1400 km	45.0m/s	WNW
#21	Oct 7, '82	1600	9.8 m	11.5 s	920 mb	WSW 600 km	50.0m/s	NNW
#5	Aug 13, '83	0600	9.8 m	13.3 s	915 mb	WSW1040 km	55.5m/s	NNE
#13	Oct 11, '83	1000	1.8 m	8.1 s	980 mb	NNW1050 km	25.3m/s	ENE
#17	Nov 2, '83	0200	Lack of data		985 mb	NNE1030 km	30.0m/s	NNW

Table 3 summarizes the values of the maximum height and the corresponding significant period of waves recorded for 19 months after May,

Fig. 5. Variation of significant height and period of waves in July, 1982.

1982 at the west coast of Iwo-jima while typhoons were hitting the island. In this table, location means the direction of and distance to the typhoon measured from the location of wave meter, does  $V_{max}$  the maximum velocity of the wind at the center of typhoon, and does  $\theta$  the advancing direction of the typhoon.

From this table, it can be noticed that swells whose maximum height is roughly 10 m and whose significant period is greater than 12 seconds will approach to the west coast of Iwo-jima when typhoons whose central pressure is less than 940 mb pass within a circle with semi-diameter of 400 km in which Iwo-jima is situated at its center.

Correlation analysis was performed among the characteristic values of the highest waves of each class. Table 4 summarizes correlation coefficients found among these characteristic values.

Table 4. Correlation coefficients among the characteristic values of waves.

	$H_{max}$	$H_{1/10}$	$H_{1/3}$	$H_{mn}$	$T_{max}$	$T_{1/10}$	$T_{1/3}$	$T_{mn}$	$T_{max}^2$	$T_{1/10}^2$	$T_{1/3}^2$	$T_{mn}^2$
$H_{max}$	1.00	0.98	0.97	0.95	0.44	0.52	0.54	0.56	0.31	0.48	0.54	0.61
$H_{1/10}$	0.98	1.00	1.00	0.98	0.47	0.55	0.58	0.59	0.33	0.51	0.58	0.64
$H_{1/3}$	0.97	1.00	1.00	0.99	0.46	0.55	0.57	0.59	0.32	0.51	0.58	0.64
$H_{mn}$	0.95	0.98	0.99	1.00	0.43	0.51	0.53	0.55	0.48	0.49	0.54	0.61

This table indicates that there exists quite high correlation among the wave heights of each class and among the wave periods of each class, respectively although correlation between height and period is quite low.

Table 5 summarizes results of the regression analysis performed among the wave height of the highest waves of each class. In this table,  $a_T$  means the regression coefficient determined through the data in Iwo-jima and does R the correlation coefficient, and does  $a_R$  the regression coefficient predicted through Rayleigh distribution.

These results clearly indicate that distribution of wave height agree quite satisfactorily with Rayleigh distribution.

As mentioned previously, no information was obtained from the records of waves on their directions. However, visually observed data is available on the direction of seas and swells.

Figure 6 shows the seasonal distribution of seas and swells in each direction which were determined on the basis of visually observed data by ships at the area in north Pacific in which Iwo-jima is included <sup>4)</sup>. In these figures, rigid lines indicate the distribution rate of seas and swells determined through the whole data observed in the period from 1973 to 1979. Comparison of figure 6 with figure 3 clearly indicates that distribution pattern of seas and swells are quite similar to those of the wind roses which were made based on the wind data measured at Iwo-jima.

(3). Physical properties of sands sampled along the shoreline of Iwo-jima

To see whether the physical properties of sands near the shoreline

Table 5. Results of the regression analysis performed among heights of the maximum waves of each class.

	$a_T$	R	$a_R$
$H_{max}/H_{1/10}$	1.21	0.98	---
$H_{max}/H_{1/3}$	1.51	0.97	---
$H_{max}/H_{mn}$	2.31	0.95	---
$H_{1/10}/H_{1/3}$	1.25	0.97	1.27
$H_{1/10}/H_{mn}$	1.94	0.98	2.03
$H_{1/3}/H_{mn}$	1.55	0.99	1.60

vary regionally and seasonally, sieve analysis and specific gravity test were performed on the sands sampled in June 1983 and in February 1984, respectively at 50 locations along the whole shoreline of Iwo-jima.

Figure 7 shows the distribution of median diameter ( $D_{50}$ ) and specific gravity ( $G_s$ ) of sands sampled along the shoreline of four coasts (see figure 9). In this figure, abscissa indicates the distance measured southward along the shoreline on each coast from its northern end.

From these figures, the following features were found on the physical properties of sands along the shoreline of Iwo-jima:

- (a). Sands sampled in both N-E and N-W coasts have fairly constant values of  $D_{50}$  ranging from 0.3 mm to 0.7 mm through the year.
- (b). Sands in both S-E and S-W coasts have larger values of  $D_{50}$  through the year in comparison to those in N-E and N-W coasts. Especially, sands sampled at S-W coast in June 1983 have the value of  $D_{50}$  which is greater than 5.0 mm.
- (c). Sands sampled in June 1983 at each coast have the values of  $D_{50}$  which tend to become greater slightly along the shoreline as it goes southward.
- (d). Specific gravity of sands is fairly constant through the year ranging from 2.3 to 2.8 except for that of the sands sampled at N-E coast. However, sands sampled in June 1983 at N-E coast have the values of  $G_s$  which are greater than 3.0.
- (e). Distinct tendency is not found in both regional and seasonal variation of the value of  $G_s$ .

Judging from these findings together with wind

Fig. 6. Distribution of seas and swells in north Pacific near Iwo-jima. (a) Distribution of  $D_{50}$  (b) Distribution of  $G_s$

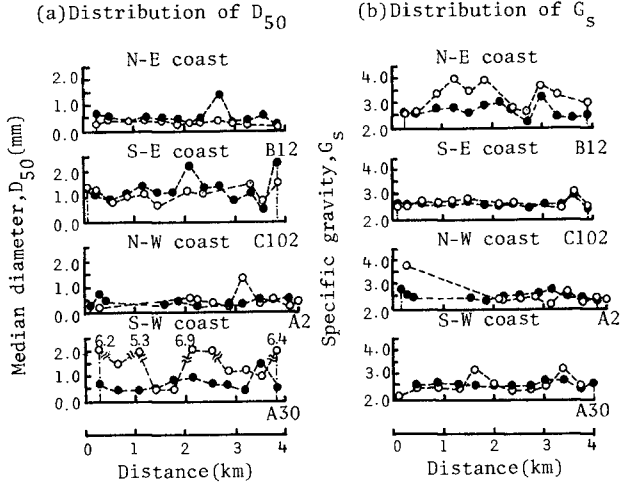

Fig. 7. Variation of median diameter and specific gravity of sands sampled along the shoreline of Iwo-jima.

and wave characteristics in Iwo-jima, it can be anticipated that littoral currents may flow southward in winter but northward in summer along both coasts of the island.

#### (4). Upheaval phenomena in Iwo-jima

Figure 8(a) shows the iso-upheaval lines in Iwo-jima which were presented by Tsuji et al in 1969. These lines were determined by comparing the elevations of several points shown in the map published by US Army in 1952 with the ones of the corresponding points which were obtained by Tsuji et al through their levelling performed in 1968.

Figure 8(b) on the other hand, shows the mean upheaval rate and cumulative upheaved height of Iwo-jima which were presented by Kosaka et al in 1979. They determined these values by comparing the elevations of several points in Motoyama area shown in older maps and charts published after 1911, and by analyzing their own data of the levelling which they performed four times in the period from 1968 to 1978.

These findings indicate the following facts on the upheaval phenomena in Iwo-jima:

- (a). Upheaval rate is not constant over the island but varies remarkably from place to place.
- (b). Upheaval rate in Motoyama area is roughly 30 cm per year recently and cumulative upheaved height has reached roughly 12 m since 1945.

The authors have also performed levellings on the backshore of Iwo-jima in August 1982, June 1983 and February 1984, respectively by using 50 measuring stations which have been placed along the whole backshore of the island. A bench mark was placed at the foot of Suribachi-yama where upheaval might be smallest in this island.

Figure 9 shows the relative values of upheaval height in each station which were determined on the basis of the elevation of each station measured in August 1982. From this figure, the following facts were revealed:

- (a). Stations in N-E coasts had sunk at the rate of roughly 25 cm to 30 cm per year for the first 10 months although they began to upheave at the rate of 30 cm per year after June 1983.
- (b). Northern stations in N-W coast began to upheave at a remarkable rate of roughly 1.5 m per year after June 1983 although southern stations near Kamaiwa area sank at the rate of 15 cm per year in the same period.
- (c). Stations placed in S-E coast kept upheaving at the rate of roughly 35 cm to 40 cm per year after August 1982.

These findings indicate that Iwo-jima keeps upheaving at present in an order of 30 cm to 40 cm per year as a whole although upheaving does not occur at a constant rate over the island but fluctuates from place

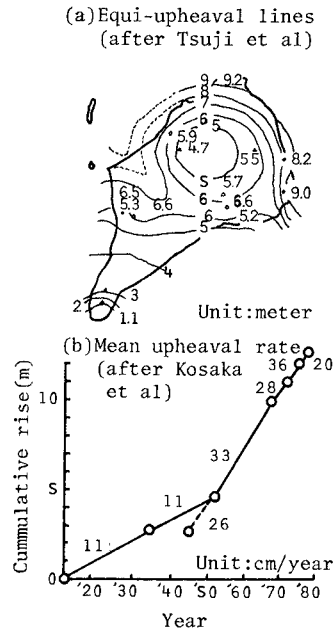

Fig.8. Upheaval phenomena in Iwo-jima.

not occur at a constant rate over the island but fluctuates from place to place and from time to time.

(5). Variation of the shore in Iwo-jima

Figure 10 shows the shorelines of Iwo-jima in 1911, 1952 and 1983, respectively. It can be clearly seen from this figure that shoreline of the island has kept advancing seaward since 1911. Further, it can be noticed that advancement of shoreline is quite remarkable at the west coast of Iwo-jima.

To see the variation of shore more quantitatively, length of the shoreline and shore area were calculated by using the processed data of the shorelines in each year which was stated previously.

Figure 11 shows the variation of both length of the shoreline and shore area which were the relative values determined by comparing those values with the their corresponding values in 1911.

From this figure, the following facts were revealed:

(a). Shoreline in the west coast was elongated continuously until 1972 at mean rate of 60 m per year although it began to be shorten at mean rate of 120m per year after 1972. Shoreline in the east coast, on the other hand has been repeating elongation and shortening since 1911 until present.

(b). Shoreline in the northern tip of the island kept advancing seaward until 1968 at mean rate of 6 m per year although it began to retreat landward at mean rate of 16 m per year after 1968.

(c). Shore area in the west coast kept increasing at mean rate of 3200 m<sup>2</sup> per year until 1972 although it began to decrease at mean rate of 39000 m<sup>2</sup> per year after 1972.

(d). Shore area in the east coast kept decreasing at mean rate of 35000 m<sup>2</sup> per year until 1934 although it has kept increasing at mean rate of 46000 m<sup>2</sup> per year after 1934.

(e). Shore area in northern tip of the island kept increasing until 1968 at mean rate of 5200 m<sup>2</sup> per year although it began to decrease at mean

Fig. 9. Upheaval phenomena on the backshore of Iwo-jima.

Fig. 9. Upheaval phenomena in the backshore of Iwo-jima.

rate of 18000 m<sup>2</sup> per year after 1968.

(f). Shore area in the whole coast has kept increasing after 1911 until 1968. Increasing was drastic especially after 1952 until 1968. In this period, mean rate of increasing reached 141000 m<sup>2</sup> per year. After 1968 however, shore area in this island has kept almost constant value until present.

Similarly, volumetric variation occurred on the sea floor was also calculated by using depth data in 1945 and 1981, respectively. Here, calculation was made within the zone surrounding the shoreline in 1945 with width of 1 km extended seaward.

Figure 12 shows the result of calculation. In this figure, abscissa indicates the distance measured from the northern edge of the considering area, and do the ordinate either eroded or the deposited volume of the sediments over the subsectional area of 1 km by 200 m in the considering zone.

From this figure, the following facts were revealed:

(a). On the sea floor off the west coast, sediments have been deposited on its most part although sea floor down the southern edge of tombolo has been eroded seriously over the range extending roughly 1.4 km along the shoreline.

(b). On the sea floor off the east coast, sediments have also been deposited on its most part although sea floor has been eroded seriously at the northern part of Suribachi-yama over the range of couple hundred meters along the shoreline.

(c). Total amount of sediments deposited on the sea floor off the west coast is roughly 57.6x10<sup>6</sup> m<sup>3</sup> although the one deposited on the sea floor off the east coast is roughly

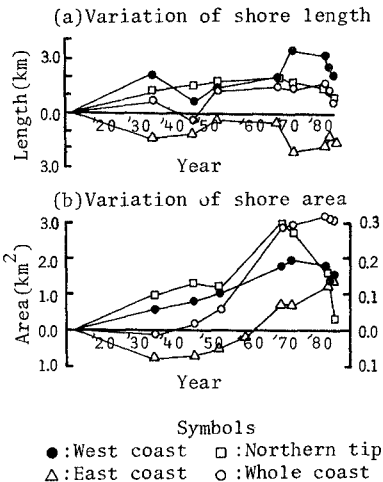

Fig. 11. Variation of shoreline length and shore area in Iwo-jima.

Fig. 12. Volumetric variation of sediments occurred on the sea floor of Iwo-jima.

$36.1 \times 10^6 \text{ m}^3$ . Further, variation pattern appeared on the sea floor are quite similar in both east and west coasts.

These findings together with the results of the analyses done so far possibly indicate that these huge amount of sediments might be the one produced due to the continuous eroding action of dominant waves exerted on the upheaved sea floor, and that these eroded sediments might have been transported by the wave induced currents to form the present bottom configuration in this island.

To examine the suitability of this assumption, similar analysis was made by assuming that the following four types of upheaval have occurred in Iwo-jima for the past 36 years:

Type 1: Island has upheaved 12 m uniformly.

Type 2: Island has upheaved 10 m uniformly.

Type 3: Island has upheaved with an inclination as shown below:

Upheaved 12 m in the northern edge and 2 m in southern edge of the island.

Type 4: Island has upheaved with an inclination as shown below:

Upheaved 10 m in northern edge and 1 m in southern edge of the island.

Table 6 summarized analytical results.

Table 6. Balance of sediments on the sea floor of Iwo-jima.

	West coast			East coast			Unit of $V_e$ and $V_d$ $: \times 10^6 \text{ m}^3$
	$V_e$	$V_d$	R(%)	$V_e$	$V_d$	R(%)	
Case 1	39.177	12.416	31.7	29.025	4.470	15.4	
Case 2	31.087	14.802	47.6	22.423	7.386	32.9	
Case 3	23.254	18.635	80.1	20.104	13.639	67.8	
Case 4	15.098	22,547	141.7	14.352	20.127	140.2	

In this table,  $V_e$  indicates imaginary volume of sediments which was produced by eroding the imaginary sea floor upheaved by adding one of four types of upheaval shown above on the sea floor in 1945 until it gets to the sea floor in 1981. Similarly,  $V_d$  means the imaginary volume of sediments which was deposited on the imaginary sea floor until it gets to the sea floor in 1981. Further, R is the ratio of  $V_d$  to  $V_e$ . From this table, the following facts were revealed:

(a). Source of the sediments which contributed to form the present shoreline and sea floor is the one produced by the erosion of upheaved sea floor.

(b). Upheaval assumed in Type 3 might be the most reasonable one which might have occurred in Iwo-jima for the past 36 years after 1945.

#### 4. Formation of Tombolo at the west coast of Iwo-jima

##### (1). Growth and variation of tombolo at the west coast of Iwo-jima

As stated previously, the channel existed between kamaiwa and west coast had got narrower and narrower since 1945 due to the continuous advancement of west coast and was finally closed in 1968 to form there a huge tombolo.

Figure 13 shows the decreasing rate of the channel width and growth rate of shore area at the west coast before the channel was closed and growth rate of tombolo's width at its neck or the narrowest section of

tombolo and of the shore area after the channel was closed.

Through this figure, following facts were revealed:

(a). After 1945, west coast began to advance seaward drastically at mean rate of roughly 50 m per year until 1968 when kamaui was touched by the tip of the west coast. During this period, shore area at the west coast kept increasing at mean rate of 42000 m<sup>2</sup> per year.

(b). After the channel was closed, both tombolo's width at its neck and the area of tombolo kept increasing at mean rate of roughly 20 m and 8200 m<sup>2</sup> per year, respectively until 1978.

(c). After 1978, tombolo has been in almost equilibrium state having the width of 200 m and area of 1.7x10<sup>6</sup> m<sup>2</sup> although these values have been fluctuating around the respective values stated above.

(2). Experimental verification of the formation of tombolo

Through the results of analyses done so far, the authors derived the following inferences on the formation of tombolo at the west coast of Iwo-jima:

(a). Dominant waves in Iwo-jima which have the direction ranging from N to NE have produced huge amount of sediments by their continuous eroding action on the sea floor of mainly northern part of the island which had been lifted by the inclined upheaval.

(b). Currents induced by these dominant waves have transported sediments southward along both coasts of the island although the currents induced by huge swells which hit Iwo-jima in summer and early fall have transported sediments northward along both coasts of the island.

(c). Sea floor off the west coast has had the topography which helped form tombolo there.

To verify these inferences, it was decided to perform model tests as follows:

Figure 14 shows the experimental zone and observation area chosen off the west coast of Iwo-jima. Based on the depth data in 1945, model of this zone was built with horizontal scale of 1/1000 and vertical scale of 1/500, by using mortar. This model was placed in a wave tank of 12.5 m long by 4.5 m wide by 1.2 m deep and crushed coals with median diameter of 0.27 mm and specific gravity of 1.72 were lain on its surface in 2 cm thick.

In the observation area of 3.0 m long by 1.75 m wide, a base line was placed for the measurement of various terms. On this base line, 25 measuring stations were provided at every 10 cm interval. Further, a model of breakwater built by US Navy in 1945 was also placed at the corresponding location.

Fig. 13. Growth of the shore at the west coast of Iwo-jima.

Capacitance type wave gage was installed off the northern end of observation area to measure incident waves. Video camera was also hung down from the ceiling to get continuous records of wave refraction and direction of shore currents.

Because of the difficulty in handling model floor, it was decided to perform experiments only for the limited case when stormy waves are loaded from a direction ranging from N to NE on the shore of the island which is upheaved uniformly at a constant rate per year.

Further, it was decided to perform experiments in accordance with the following procedures:

(a). Crushed coals are supplied at a certain rate manually off the northern end of observation area whenever supplied coals are washed away.

(b). Effect of upheaval is given by lowering water level up to 2 cm in total at a constant rate.

(c). Special dye is injected manually off the northern end of observation area.

Since it is impossible to hold similarity law in such a model test as this, only the wave conditions were determined by referring to Froude law of similarity. The rests of conditions were all determined through the primary runs which were done by changing conditions by trial and error method so that shoreline on the model shore may agree most satisfactorily with the one shown on the chart in 1981.

Here, agreement was evaluated by the values of the standard deviation of shoreline on the model shore from the corresponding one shown on the chart in 1981. Standard deviation,  $\Delta S$  was calculated by using the data measured at every 30 minute along each line which was extended seaward from each station on the base line so that it might be perpendicular to the base line.

Seven different conditions were tried in primary runs. As a result, it was found that shoreline at the northern shore of tombolo could be reproduced quite satisfactorily on the model shore if the test was kept performed for 9 hours successively under the conditions shown in table 7.

Table 7. Test conditions determined through primary runs.

Incident waves			Upheaval rate	Supply rate of crushed coals
Height	Period	Dir.ec		
2.2 cm	0.5 sec	NNE	0.25cm/hr	6000 cm <sup>3</sup> /hr

Test was done again under the conditions shown in table 7. Due to the limit of space, variation of shoreline will be described here mainly. Variation of shoreline was measured every 30 minute. Figure 15 shows the

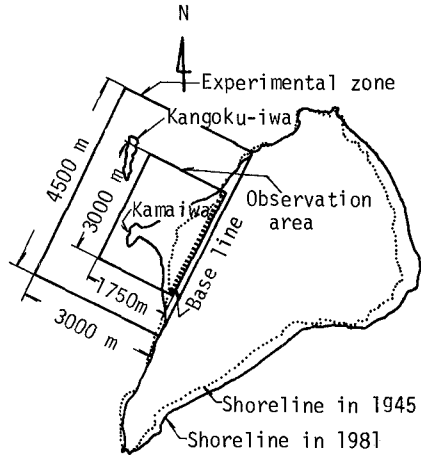

Fig. 14. Experimental zone and observation area chosen for model test.

shorelines measured at every 90 minute. Tip of the west coast began to advance rapidly when it passed roughly 270 minutes after starting the experiment, and finally reached Kamaiwa one hour later. The tip of west coast advanced along the northern slope of a saddle shaped mound which had originally existed along the sea-bed connecting Kamaiwa and west coast. Existence of this saddle resulted in blocking littoral currents there and diverting the course of it into northern tip of Kamaiwa.

As it can be seen from figure 15, shoreline at the northern shore of tombolo has shown quite good agreement with the one in 1981. However, shoreline at the southern shore of tombolo has advanced seaward considerably in comparison to the one in 1981. Further, a sand spit has been formed at the southern lee of Kamaiwa. These might have been formed because waves with the direction of only NNE had been loaded on the model shore.

Figure 16 shows the variation of  $\Delta S$  in the northern shore of tombolo with the lapse of time. In this figure, line with circles mean the values of  $\Delta S$  determined on the basis of whole data measured in the observation area, and do the rests of lines, the values of  $\Delta S$  which were determined on the basis of data measured in each of the 5 subsectional areas which were provided by dividing the observation area at an interval of 500 m to, see regional variation in the values of  $\Delta S$ .

From this figure, it can be seen that values of  $\Delta S$  become small suddenly at every subsectional area if 5 hours have passed after starting the run, and that model shore reaches almost equilibrium state if it has passed 9 hours after starting the run. The values of  $\Delta S$  in each subsectional area are less than 6 cm at the equilibrium state.

This test also indicates that one hour in the run under the conditions corresponds to 4 years in the field. If this time scale is true, upheaval rate and supply rate of crushed coals in table 7 become 31 cm and  $7.5 \times 10^5 \text{ m}^3$  per year, respectively, which are quite reasonable values. Further, it should be noted that the test clearly reproduced on the model floor that it took 23 years for the west coast to reach Kamaiwa and that it took 33 years for the west coast to get to an equilibrium state since 1945. These facts clearly indicates that the author's inferences on the formation of

Fig. 15. Variation of shoreline with the lapse of time.

Fig. 16. Variation of  $\Delta S$  with the lapse of time.

tombolo were verified to be mostly true.

## 5. Conclusion

Growing process of tombolo formed at the west coast of Iwo-jima were investigated by analyzing various data obtained through both literature & field surveys. Inferences for the formation of tombolo derived through the analyses were examined by performing model test, which verified that these inferences were mostly true.

## Acknowledgement

The authors are indebted greatly to the 4th Aviation Group of JMSDF and to the 101 Topographic Battalion of JGSDF for their devoted cooperations which were given in various stages in accomplishing this study.

## CHAPTER NINETY SEVEN

### A MODEL FOR OFFSHORE SEDIMENT TRANSPORT

M.J.F. Stive\* and J.A. Battjes\*\*

#### ABSTRACT

Observation of the two-dimensional breaking of random waves on a beach suggests that under conditions of active surf an important mechanism in the process of offshore sediment transport is the transport by the undertow or return flow, induced by the breaking of waves. It is found that a model incorporating this mechanism exclusively is able to describe the local sediment transport and the resulting bottom variation of a beach under random wave attack to a first approximation. A laboratory verification is made based on measurements of both the dynamics of the water motion and the bottom profile. Finally, a realistic equilibrium state is shown to result from the model.

#### 1. INTRODUCTION

The particular role of a nearly two-dimensional wave motion in the movement of sediment normal to the shore is poorly understood. It is generally assumed that a number of interaction mechanisms between this wave motion and the sediment motion contribute to the formation of the beach profile, also in the three-dimensional topographies that occur on a natural coast. Full account of all mechanisms can be taken if a description of both the horizontal velocity field,  $u(x,z,t)$ , and the sediment concentration field,  $c(x,z,t)$ , in space and time is available, so that the net cross-shore sediment transport,  $\bar{q}(x)$ , may be calculated from

$$\bar{q}(x) = \int_d u(x,z,t) \cdot c(x,z,t) dz \quad (1)$$

where the integration is performed over the instantaneous depth  $d$  and the overbar indicates time averaging. From the cross-shore variation of  $\bar{q}(x)$  the bottom changes may be derived.

Visual and experimental observation of random waves on a two-dimensional beach indicate that one of the more important mechanisms under active surf conditions may be the transport of sediment by the time mean, seawards directed flow near the bottom induced by the breaking of waves. It is shown that this mechanism is so dominant that a model incorporating this mechanism alone describes the bottom variations in the surf zone to a satisfactory, first approximation. This paper describes the properties of this one-mechanism model and its verification based on laboratory measurements both of the wave

motion and of the bottom profile. Furthermore, the equilibrium consequences of the model formulation are investigated.

In the elaboration of the present model simple, available formulations for the model elements have been used. Improved formulations can easily be incorporated without affecting the principle of the model. Extension of the model with other transport mechanisms is a logical step towards a more complete cross-shore sediment transport model. In this respect transport due to the asymmetry of the wave motion should be considered first.

## 2. MODEL FORMULATION

In principle the net cross-shore sediment transport may be calculated from Eq. (1). However, insufficient knowledge of the velocity and concentration field forces us to rely on a simplified form of Eq. (1), using the following observations and assumptions:

- (a) The sediment load,  $s$  ( $= \int_d c dz$ ), is mainly contained in the region near the bottom and as such locally determined.
- (b) The horizontal velocity field,  $u$ , is depth-uniform in the region near the bottom.

With the introduction of mean and (wave-induced) fluctuating components in the sediment load and the near-bottom horizontal velocity, i.e.  $s = \bar{s} + s'$  and  $u = \bar{u} + u'$ , the net sediment transport may be calculated as

$$\bar{q} = \overline{u \cdot s} = \overline{u \cdot \bar{s}} + \overline{u' \cdot s'} \quad (2)$$

Although this result reduces the problem to one which is potentially solvable on basis of our present knowledge we found it useful to reduce the problem further using the following assumptions:

- (c) The contribution due to the correlation between the fluctuating sediment load and horizontal velocity is small compared to that due to the mean (return) flow, i.e.  $\overline{u' \cdot s'} \ll \overline{u \cdot \bar{s}}$ .
- (d) The seawards directed, near-bottom mean flow velocity induced by a breaking wave is large compared to the mean flow velocity induced by a non-breaking wave of the same height, so that in a random wave field  $\bar{u}_{br} \gg \bar{u}_{nonbr}$ .

Based on these assumptions result (2) is simplified further to

$$\bar{q} = \bar{u}_{br} \cdot \bar{s} \quad (3)$$

In this approximation the net sediment transport in the surf zone is directed offshore. Simple, first approximations to the return flow,  $\bar{u}_{br}$ , and the mean sediment load,  $\bar{s}$ , may be as follows.

### the mean return flow in random breaking waves

It is assumed that in a random wave field breaking on a beach the majority of the breaking waves has a quasi-steady depth-similar flow field as described by Stive and Wind (1982) for breaking, periodic waves. Based on the dimensionless flow field presented there and adopting the observation that the flow profile is rather uniform over

the lower depths the return flow velocity in a periodic, breaking wave field is simply modelled as:

$$\bar{u}_{br,periodic} = 1/8 (g/d)^{1/2} H_b \quad (4)$$

where  $g$  is the acceleration of gravity,  $d$  the water depth and  $H_b$  the breaking wave height. The net mass flux below the level of the wave troughs becomes

$$M = 1/8 \rho (g/d)^{1/2} H_b d_t \quad (5)$$

where  $d_t$  is the water depth up to the trough level. This result corresponds closely to the net mass flux result above the level of the wave troughs for a steady, linear wave train on a horizontal bottom:

$$M = E/c \quad (6)$$

where  $E = 1/8 \rho g H^2$  is the wave energy density and  $c$  denotes the wave speed. After introducing the shallow water approximation to  $c$ :

$$M = E/c \approx 1/8 \rho (g/d)^{1/2} H^2 \quad (7)$$

In random waves on a beach the fraction of waves breaking at a point ( $Q_b$ ) varies with position. Battjes and Janssen (1978) have presented an implicit expression for  $Q_b$  as a function of the ratio of the rms wave height ( $H_{rms}$ ) to a local breaking height, which in turn is primarily depth-controlled. A simple, explicit approximation qualitatively close to this relation and quantitatively well in accordance with laboratory observations is:

$$\tilde{Q}_b = 20(H_{rms}/d)^5 \quad (8)$$

The return flow velocity in a random, breaking wave field is simply modelled here as

$$\bar{u}_{br,random} = \bar{u}_{br,periodic} \cdot \tilde{Q}_b \quad (9)$$

#### the mean sediment load in random breaking waves

A reliable, predictive model for the mean sediment concentration or even for the mean sediment load due to random, breaking waves is not available yet. For the present purposes a prediction method is derived based on the sediment concentration measurements and theoretical analyses presented by Nielsen et al (1978, see also Nielsen, 1979) for non-breaking waves and Bosman (1982) for breaking waves. The method is broadly described below and details are given in an Appendix.

Laboratory measurements of time- and bed-averaged concentration profiles under breaking, random waves conducted by Bosman (1982) indicate that (a) in the near-bottom layer the upward decay of the concentration is exponential and (b) the sediment load is mainly confined to and determined by the bottom layer, so that

$$\bar{s} = C_0 \cdot \lambda_1 \quad (10)$$

where  $C_0$  is a reference concentration at the bottom and  $\lambda_1^{-1}$  is the relative concentration gradient in the bottom layer. The bottom reference concentration is found to be nearly linearly proportional to a Shield's type parameter  $\theta'$  (see Appendix Eq. 23...25). Adoption of a diffusion-type model with a constant turbulent viscosity,  $\epsilon_1$ , and sediment fall velocity,  $w_1$ , for the bottom layer region leads to

$$\lambda_1 = \epsilon_1 / w_1 \quad (11)$$

which indicates that  $\lambda_1$  closely corresponds to a characteristic turbulent length scale. In fact  $\lambda_1$  is found to be linearly proportional to the ripple height in the ripple regime and to the wave boundary layer thickness in the sheetflow regime. Since the bottom layer is only weakly influenced by surface breaking, Nielsen's (1979) formulations for the bottom reference concentration and the viscosity coefficient were used for the situation of random, breaking waves, i.e. on basis of Bosman's measurements Nielsen's parameterizations of  $C_0$  en  $\epsilon_1$  were quantitatively adapted. The resulting prediction method for the mean sediment load covers the region of initiation of motion to sheetflow conditions for median grain diameters of say 100  $\mu\text{m}$  to 500  $\mu\text{m}$ . However, the parameterizations were only checked in a very limited region, so the results should be applied with caution. It is stressed that there is an urgent need to conduct and analyse sediment concentration measurements under surf conditions close to reality.

#### practical calculations

With the undertow and the mean sediment load known as functions of the local hydrodynamic conditions and the sediment properties the offshore sediment transport can be calculated. In practical computations the sediment properties may be assumed constant. The hydrodynamic conditions, however, are a function of the horizontal distance from the shore and the offshore wave parameters. These conditions can be derived from numerical calculations with the wave height decay model presented by Battjes and Janssen (1978). This may be regarded as the first discrete step in a practical calculation procedure, illustrated in Fig. 1. The rms wave height,  $H_{\text{rms}}$ , the breaking wave height,  $H_b$ , and the fraction of breaking waves,  $\bar{Q}_b$ , follow directly from the decay model. The local kinematics are calculated in the second step, where the rms orbital velocity,  $u_{\text{rms}}$ , is derived from linear theory and  $\bar{u}_{br}$  from Eq. (9). In the third step the sediment transport is calculated according to Eq. (3) where a proportionality constant,  $b$ , is introduced which should be of order unity if the model is right. It is noted that the sediment transport is locally determined only. Finally, the bottom changes are calculated through application of the mass balance equation for the sediment. This procedure may be repeated for the new beach profile.

Fig. 1 Computation procedure

In the numerical evaluation of the above procedure a second order Runge-Kutta algorithm is used in the wave decay model and a modified Lax scheme in the bottom change calculations.

As a boundary condition on the waterline the present formulation yields  $\bar{q} = 0$ . To simulate the smoothing effect of swash motion on the sediment transport near the waterline  $\bar{q}(x)$  was damped starting from a depth of approximately half the initial wave height in proportion to the mean water depth.

### 3. MODEL VERIFICATION

A laboratory measurement programme aimed at verification of the present model has not yet been initiated. Therefore we rely on available measurement results of which some examples are presented here.

Firstly, model calculations of the wave kinematics on a beach of nearly constant slope (1:40) are compared with measurements in a large scale wave facility (see Fig. 2). The ability of the model to predict the wave height decay is extensively discussed by Battjes and Stive (1984). Here we are interested in the prediction of the return flow and the rms orbital velocity, which were measured 0.2 m above the bottom. The prediction appears to be sufficiently close for our purposes. It is noted that the trend of some theoretical overprediction of  $u_{rms}$  in the outer breaking regime towards negligible overprediction in the actual surf zone is similar to that found and partly explained by Van Heteren and Stive (1984).

Secondly, calculations of bottom changes are compared with measurements on three different beach profiles. The first case concerns a barred profile of relatively fine sediment in a small scale flume. The second case concerns a parabolic profile of somewhat coarser sediment in a small scale flume. The third case concerns the earlier mentioned nearly 1:40 profile of medium sized sediment in a large scale flume. Some characteristic parameters of these three cases are collected in Table 1, where the mean water depth is denoted by  $h$ , the rms wave height by  $H_{rmsr}$ , and the peak frequency by  $f_p$  with the subscript  $r$  denoting reference value in the horizontal part of the flume. In case 2 the initial wave conditions were varied to simulate a wave climate. This variation was accounted for in the computations.

case	source	profile	grain diameter ( $\mu\text{m}$ )	$h_r$ (m)	$H_{rmsr}$ (m)	$f_{pr}$ (Hz)
1	Van Overeem (1983)	barred	100	0.80	0.21	0.39
2	Boer (1984)	parabolic	145	0.80	0.11-0.19	0.40-0.53
3	Stive (1984)	plane	225	4.19	1.00	0.19

Table 1 Characteristic parameters of laboratory experiments

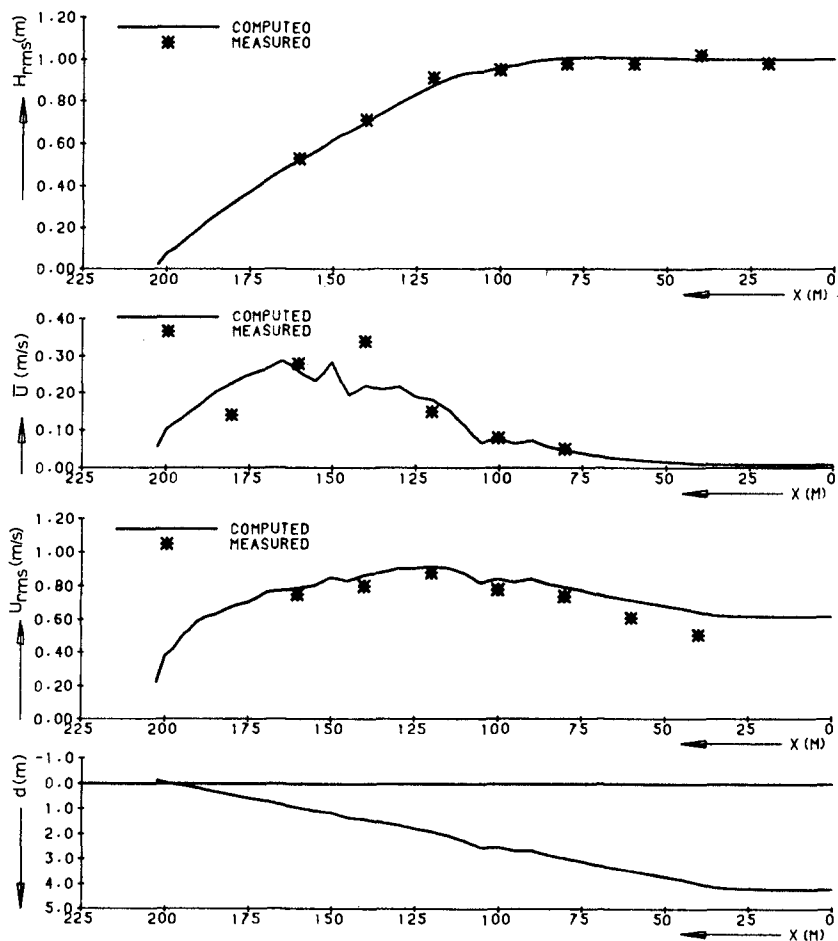

Fig. 2 Measured and computed wave height ( $H_{rms}$ ), return flow velocity ( $\bar{U}$ ) and rms orbital velocity ( $U_{rms}$ ) on a large scale, laboratory beach

The comparison between measurements and computations is presented in Figs. 3...5. In case 1 the resultant profiles themselves are compared, while in the other cases it was judged more informative to compare the actual bottom changes. In general, the relative profile activity and distinct features, such as the offshore movement of a step and the formation of a bar, are predicted well by the computations. The actual quantitative changes are simulated reasonably (although sometimes somewhat shifted in space), if the proportionality constant  $b$  is made to vary between 0.25 and 1.0. The qualitative

predictions of details is surprisingly good at some locations. Apparently, the modelling of the sediment transport as function of the wave conditions is insufficiently accurate to yield a universal value for  $b$ . If, however, for prediction purposes a value  $b = 0.5$  is applied the bottom changes are at most overestimated or underestimated by a factor of two.

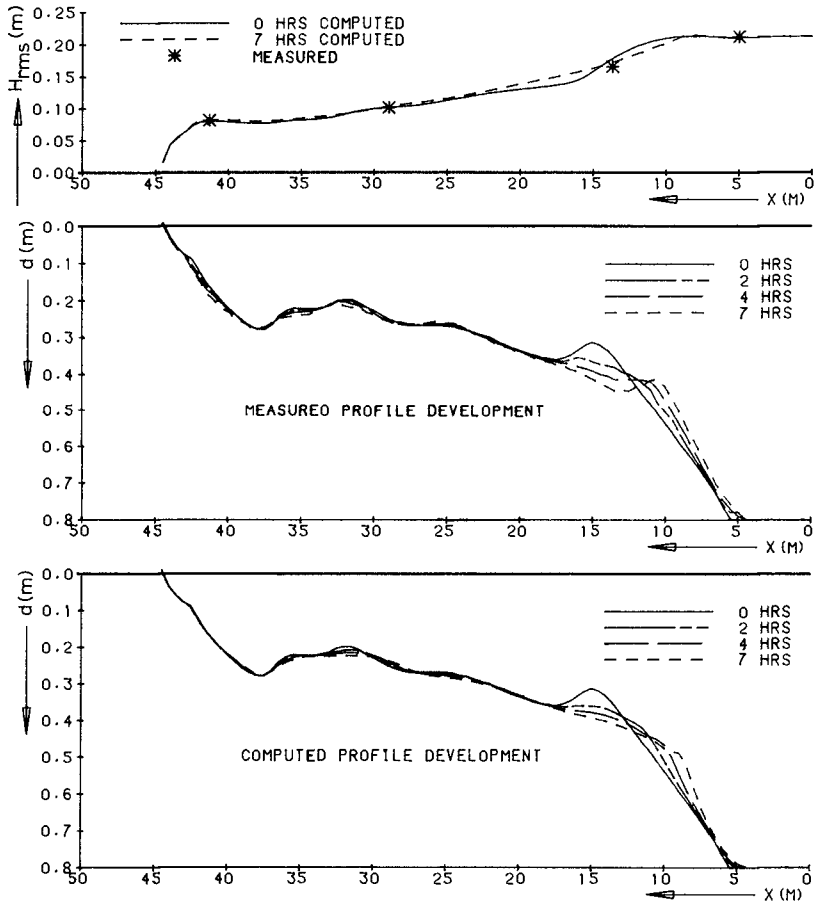

Fig. 3 Measured and computed ( $b = 0.25$ ) profile development on a small scale, laboratory beach: case 1

Finally, a preliminary comparison is presented of calculated and measured bottom changes of a beach acting as a foreshore of a protected dune (see Fig. 6). The dune revetment prohibits sediment transport, so that the sudden increase of sediment transport at the dune foot

Fig. 4 Measured and computed ( $b = 1.0$ ) bottom changes on a small scale, laboratory beach: case 2

causes an erosion hole. The hydraulic conditions during the experiments simulated the conditions of a design storm surge, so that both the water level and the wave conditions varied in time. The variation of the conditions was taken into account in the calculations. It appears that the erosion at the foot is well predicted applying a value of  $b = 0.5$ . This indicates that the presently modelled return flow mechanism plays an important role in the dune erosion process.

Fig. 5 Measured and computed ( $b = 0.25$ ) bottom changes on a large scale, laboratory beach: case 3

4. EQUILIBRIUM STATE

An important aspect in the verification of the present model is the reality of the profile equilibrium state which results from the model formulations. A state of equilibrium is said to be reached when gradients in the sediment transport are absent so that the profile shape is stable. This definition implies that a two-dimensional surf zone is assumed to have a sediment source on the shoreside and a sediment sink at the seaside. The consequences with respect to natural beaches are described below.

Fig. 6 Measured and computed ( $b = 0.5$ ) profile development on a beach at the foot of a protected dune

In order to perform our analysis it is necessary to introduce simplified relations for the model parameters. Firstly, the shallow water approximations to the breaking wave height,  $H_b$ , the orbital velocity,  $u_{rms}$ , and the orbital amplitude,  $a_{rms}$ , are adopted, i.e.

$$\begin{aligned} H_b &= \gamma' d & (\gamma' = \text{constant}) \\ u_{rms} &= \frac{1}{2} H_{rms} (g/d)^{\frac{1}{2}} & (12) \\ a_{rms} &= \frac{1}{2} H_{rms} (g/d)^{\frac{1}{2}} (2\pi f_p)^{-1} \end{aligned}$$

Secondly, in the  $\theta'$ -range relevant to surf zone conditions ( $\theta' \approx 1.0 - 1.5$ ) the mean sediment load,  $\bar{s}$ , is approximately proportional to the orbital amplitude,  $a_{rms}$ , and to the Shields parameter,  $\theta'$ , (see Figs. 8 and 9 of the Appendix), i.e.

$$\bar{s} :: a_{rms} \theta' \quad (13)$$

where  $\theta'$  is defined by Eq. (24). Inserting the results in Eq. (3) yields the following proportionality relation for the offshore sediment transport,  $\bar{q}$ :

$$\bar{q} :: H_{rms}^6 d^{-6} f_p^{-1} D^{-1} \quad (14)$$

where  $D$  is a characteristic grain diameter. For the transport to be constant it is a necessary condition that

$$H_{rms} :: d^{3/4} f_p^{1/8} D^{1/8} \quad (15)$$

The relation between wave energy and water depth may further be elaborated by use of the energy balance equation, i.e.

$$\frac{d}{dx} (E.c_g) + \text{Diss} = 0 \quad (16)$$

where the dissipation term due to wave breaking following Battjes and Janssen (1978) is proportional to:

$$\text{Diss} :: Q_b f_p H_b^2 \quad (17)$$

An approximation to Battjes and Janssen's implicit equation for  $Q_b$  yields

$$Q_b :: (H_{rms}/d)^6 \quad (18)$$

where it is noted that this result differs from Eq. (8) (used in the derivation of Eq. (14)), since here an accurate approximation is sought to  $Q_b$  in the wave decay model.

Using the results (17) and (18) and again adopting shallow water approximations, the energy balance equation gives

$$\frac{d}{dx} (H_{rms}^2 d^{\frac{1}{2}}) :: H_{rms}^6 f_p d^{-4} \quad (19)$$

Combining the governing Equations (15) and (19) and integration yields

$$d \propto \hat{x}^{2/3} f_p D^{1/3} \quad (20)$$

where  $\hat{x}$  is the horizontal distance from the water line. With respect to the dependence of  $d$  on  $\hat{x}$  this result is well in accordance with empirical findings first noticed by Bruun (1954). Also the other dependencies are found to be in at least qualitative accordance with observations (see e.g. Dean, 1984, whose results indicate a quantitative similar grain diameter dependence). These results lend support to the present model.

## 5. DISCUSSION AND CONCLUSION

The present offshore transport model incorporates only one of the mechanisms responsible for cross-shore sediment movement that is expected to exist on beaches under nearly two-dimensional wave attack, i.e. sediment transport due to breaking wave induced return flow. The model is applied to some laboratory beaches exposed to random breaking wave action. Realistic, first order predictions of the bottom changes are obtained. These laboratory findings indicate that in the active surf zone the return flow mechanism dominates others mechanisms. The predictions may be improved by including other mechanisms, e.g. such as due to the asymmetry of the wave motion.

Natural beaches are only confronted with an active surf zone during a relatively small period of time. Moreover, the position of the surf zone varies with the tidal level. Obviously a realistic prediction of the beach profile response under general, natural conditions requires the inclusion of more sediment transport mechanisms than the return flow mechanism alone. If, however, one is interested in the relatively large response of beaches under storm conditions (when the surf zone is extended significantly offshore) the present model is expected to perform satisfactorily. This is confirmed by the fact that the equilibrium profile shape following from the model is in good accordance with field observations.

## ACKNOWLEDGEMENT

This work was done as a part of the TOW Study Programme for Coastal Sediment Transport in the Netherlands. The Programme is financed by the Dutch Government and jointly carried out by the Ministry of Transport and Public Works (Rijkswaterstaat), Delft University of Technology and Delft Hydraulics Laboratory. Thanks are due to J. v. Overeem for making available the results presented in Fig. 6.

APPENDIX: The Mean Sediment Load

As shown by Bosman (1982) sediment concentration distributions in random, breaking waves may be satisfactorily described by a "double layer" or "double first order" model for a rather wide variety of laboratory situations, such as horizontal and sloping bottom, no and net currents, non-breaking and breaking random waves. Based on a diffusion type description for each layer the model leads to an exponential concentration distribution as follows (see also Fig. 7):

$$C(z) = \begin{cases} C_0 e^{-z/\lambda_1} & \text{for } z < A \\ C(A) e^{-(z-A)/\lambda_1} = C_0 e^{-A/\lambda_1} e^{-(z-A)/\lambda_2} & \text{for } z > A \end{cases} \quad (21)$$

Fig. 7 "Double first order" model for the sediment concentration distribution in random, breaking waves (after Bosman, 1982)

where A is the bottom layer thickness. Each layer has a constant turbulent viscosity,  $\epsilon$ , and a fall velocity, w, for the sediment in that layer such that  $\lambda_1 \equiv \epsilon_1/w_1$  and  $\lambda_2 \equiv \epsilon_2/w_2$  (based on diffusion). Bosman's measurements show that the upward exponential decay of the concentration is so strong that the total sediment load,  $\bar{s}$ , is mainly confined to and determined by the bottom layer as follows:

$$\bar{s} = C_0 \cdot \lambda_1 \quad (22)$$

where  $C_0$  is the bottom concentration and  $\lambda_1^{-1}$  is the relative concentration gradient in the bottom layer.

These laboratory flume measurements only cover a limited range of conditions, for instance only one median grain diameter was used. To generalize the results we follow the work of Nielsen (1979). Nielsen gives no explicit formulation for the sediment concentrations or the total load due to random waves and certainly not due to random, breaking waves. He does present semi-empirical expressions for the ripple height,  $\xi$ , and the bottom reference concentration,  $C_0$ , due to random waves. With respect to the effects of breaking we adopt the observation that the sediment concentrations near the bottom and the

geometry of the bottom due to breaking waves do not differ essentially from those due to non-breaking waves. This implies that we may rely on formulations for non-breaking, random waves.

#### bottom reference concentration

As in steady flow the bottom reference concentration is assumed to be determined by the Shields parameter, i.e. the dimensionless bed shearstress, and Nielsen suggests also for random waves:

$$C_o = K(\theta' - 0.05) \frac{2}{\pi} \arccos(0.05/\theta')^{\frac{1}{2}} \quad (23)$$

where K is a constant and the Shields parameter  $\theta'$  is defined as

$$\theta' = \frac{f_w u_{rms}^2}{\Delta g D} \quad (24)$$

where  $f_w$  is a friction factor,  $u_{rms}$  is the rms orbital velocity,  $\Delta$  is the relative sediment density ( $\rho_s/\rho_w - 1$ ) and D is a characteristic grain diameter. The friction factor is given as (Swart, 1974):

$$f_w = \exp[5.2(2.5 D/a)^{0.2} - 6.0] \quad (25)$$

where a is the orbital amplitude. The "arccos" term in Eq. (23) accounts for the fraction of time that the critical stress value of 0.05 is exceeded. Confrontation of expression (23) with Bosman's bed-averaged measurements confirms Nielsen's suggestion. The constant K has a best value of 0.028, the same value as found at the ripple crests under periodic waves.

#### ripple height

Semi-empirically Nielsen derived the following expression for the ripple height due to random waves:

$$\xi/a = 21(\psi)^{-1.85} \quad \text{for } \psi > 10 \quad (26)$$

$$\xi/a = 0.3 \quad \text{for } \psi \leq 10$$

$$\text{where } \psi = \frac{u_{rms}^2}{\Delta g D}$$

#### turbulent viscosity coefficient

Semi-empirically Nielsen derived for periodic waves that the viscosity coefficient made dimensionless by the length scale ripple height,  $\xi$ , or boundary layer thickness,  $0.4 \delta$ , and the velocity scale  $gT$  is a complicated function of the parameter  $a\omega/w_1$ , so

$$\epsilon_1 / [(\xi + 0.4\delta) gT] = f(a\omega/w_1) \quad (27)$$

where  $\omega$  is the angular velocity and T the wave period.

In the length scale quantity  $(\xi+0.4\delta)$  the ripple height,  $\xi$ , dominates in situations with noticeable ripples and the boundary layer thickness,  $0.4\delta$ , dominates in the absence of ripples. The latter is defined as (Jonsson and Carlsen, 1976):

$$\delta/a = 0.072 (2.5D/a)^{0.25} \tag{28}$$

From a comparison with the measurements of Bosman we have found that also in the region  $aw/w_1 > 20$  the lower asymptote (Eq. 6.112) of the expression (Eq. 6.111) suggested by Nielsen (1979) for periodic waves coincides best with the random wave measurements. This asymptote is given as:

$$\varepsilon/[(\psi+0.4\delta) gT] = 0.35 \cdot 10^{-3} (aw/w_1)^{0.68} \tag{29}$$

results

The present prediction method is based on the above described findings. In summary, for the prediction of the mean sediment load,  $\bar{S}$ , expressions (23), (26), (28) and (29) are used. Logically Bosman's measurements correspond well with this formulation (see Fig. 8a). The sensitivity of the method for a variation in grain diameter is shown in Fig. 8b.

Fig. 8 Non-dimensional sediment load as a function of the Shields parameter for  $f_p = 0.5 \text{ Hz}$

## CHAPTER NINETY EIGHT

### A SYSTEM OF MATHEMATICAL MODELS FOR THE SIMULATION OF MORPHOLOGICAL PROCESSES IN THE COASTAL AREA

S. Boer\*, H.J. de Vriend\* and H.G. Wind\*

#### ABSTRACT

A compound mathematical model (COMOR) for the simulation of morphological changes in the coastal area is being developed. The model is very flexible; it can be composed according to the specific demands of the problem which is considered. So far the model is being applied in the advisory practice to predict initial morphological changes. Recent experiences have shown that the model is quite useful, although at present the knowledge of the individual coastal processes and their interactions is still insufficient to utilize it optimally. However, it is foreseen that in the near future such mathematical models will become a powerful tool in coastal engineering.

#### 1 INTRODUCTION

Numerous physical processes, often at different time and length scales, play a part in coastal morphology. When attempting to understand these processes and their mutual interactions, computer simulations can be of great help, especially if the second horizontal dimension is involved.

The progress in mathematical modelling and the increased capabilities of modern computers have contributed substantially to the application of numerical models in coastal research. In the field of simulation of coastal morphological evolution this started with the strongly schematized single-line models (Grijm, 1964; Le Méhauté and Soldate, 1978), but via an extension to multiple-line models (Bakker, 1968; Boer, 1983) the second horizontal dimension came into the picture (Flemming and Hunt, 1976; O'Connor et al, 1981; Watanabe, 1982; Coeffé and Péchon, 1982; McAnally et al., 1984). Although most of these models were developed primarily for research purposes they have proved to be a useful tool in hydraulic advisory practice, as well.

Within the framework of the Coastal Research Group of the applied hydraulic research programme TOW, the Ministry of Transport and Public Works (Rijkswaterstaat), the Delft Hydraulics Laboratory and the Delft University of Technology are developing a system of computer programs (COMOR) which provides the possibility to compose compound mathematical models for the simulation of horizontally two-dimensional morphological changes in the coastal area. The basic idea of the COMOR-system

---

\* Delft Hydraulics Laboratory, the Netherlands

is to assemble the presently available knowledge on the individual physical processes in morphological models.

COMOR-models, so far without time-dependency in the bottom topography, are being applied in hydraulic advisory practice at the Delft Hydraulics Laboratory. They have proved a good support of the usual investigation techniques (desk studies, scale models). Besides, experience with these applications helps to identify and weigh the needs for further research and hence to steer the future development of mathematical modelling in this field.

After a brief description of COMOR and some aspects of the modeling technique the present paper goes into some representative applications. Finally a discussion on the practical applicability is given.

## 2 DESCRIPTION OF COMOR

In order to meet the requirement of maximum flexibility COMOR was given a modular structure. This means that a model consists of a series of computer programs describing the waves, the net currents, the sediment transports and the bottom changes and that these programs are coupled in a neutral way, such that each of them can easily be replaced by another one. Thus it is possible to compose a model according to the specific demands of the problem to be considered. The neutral coupling of the constituent models is realized by using one central data base for all of them. Each model draws its input data from this file and adds its results to it. In practice this means that each computer program suited as a module in COMOR-models needs its own interface (input and output) with the central data base in order to be actually applicable.

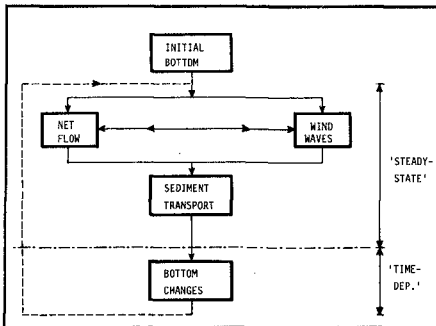

Fig.1 Computation procedure COMOR

logical evolutions the bottom level is changed after a certain time interval. Subsequently waves, currents and transports are computed for the new bottom. In some practical applications it is not necessary to predict the morphological evolution over a long period. The "initial" rate of change of the bottom level (considered at the morphological

Figure 1 outlines the computation procedure underlying COMOR. Starting from the initial bottom configuration in the area of interest and a given set of (boundary) conditions, the waves, the net current field, the sediment transport and the bottom level changes are computed, basically in a quasi-stationary procedure. This implies, that all kinds of composite wave, current and transport computations are allowable but that in any of them the bottom level is kept constant. In the computation of time-dependent morpho-

time scale) then gives sufficient information, provided that it is computed on the basis of a "mixture" of flow and wave conditions that is representative for the period considered. This implies that the effect of the bottom evolution on the waves, currents and transport is left out of consideration. In doing so a number of problems (stability, accuracy, computer-expenses) attending time-dependent computations can be avoided.

3 MODELLING TECHNIQUE

The scheme in Figure 1 outlines the computational procedure followed in COMOR-models, reduced to its basic form. It gives no information, however, on how a model is composed, how it is used and how its results are combined and interpreted. These activities, denominated "modelling technique" here, determine to a large extent the quality of a model application. As a discussion in detail on this modelling technique, however important, would go beyond the scope of this paper, only some of the most relevant aspects will be discussed briefly.

The COMOR-models for initial changes applied so far refer to situations in which, within the area of interest, the morphological changes are influenced by wave-induced as well as tidal currents. This leads to a wide variety of length scales which have to be considered. The area of interest of the morphological models is usually rather small (length scale a few kilometres) compared with the tidal wave length and the distance along which the wave propagation is influenced by the limited water depth. For economical reasons smaller and more refined models are often nested into larger models in order to arrive at a sufficiently accurate description of the tidal motion and the wave field in the area of interest. If this area is small compared with the tidal wave length, the tidal motion can be approximated by a series of unsteady rigid-lid or even steady flow models, with the flow rate imposed at the boundaries. In such cases the tidal model only serves to generate the boundary conditions for the tidal flow component in the detailed flow model covering the area of interest. This leads to a composed model as indicated in Figure 2, with separate modules for the computation of the overall tidal motion, the wave field, the combined wave- and tide- induced flow in the region of interest and the sediment transport there, in this sequence and without feedback. In practice it is not always feasible to follow this procedure throughout. Especially the largest

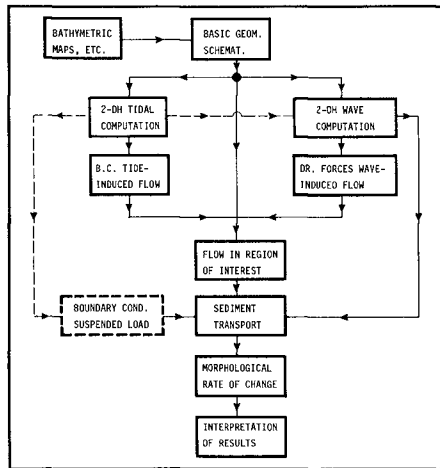

Fig. 2 Flow chart "initial" models

feasible to follow this procedure throughout. Especially the largest

tidal and wave models are rather expensive to be built and calibrated, whence in smaller projects existing models are used as far as possible. As these existing models have usually been developed for other purposes, they will not always fit in with the project objectives. Therefore these largest models are linked up with the detailed models via one or more intermediate sized models.

The selection of the computation methods for the currents, waves and transport to be used should be based on the ability to deal with the physical phenomena involved and the order of accuracy and reliability required. At this point the modellers have to rely heavily on experience, as systematic estimation methods for the relevance of elementary physical phenomena are hardly available. In general the models simulating the wave field, the coastal currents and the sediment transport in the region of interest should be in keeping with each other as well as with the geometrical schematization. At present a variety of computation methods and computer codes is available to describe waves, currents and transport rates. However, little is known yet about the morphological impact of the underlying elementary physical processes. Especially the state of knowledge on the sediment transport under the combined action of waves and currents is such that an accurate sediment transport model is still far from being available. The transport formulae presently applied in coastal morphology are based on the assumption of local equilibrium and relate the sediment transport to local time-mean parameters only. In view of the inaccuracy of the sediment transport model it may seem inappropriate to use highly sophisticated models for the simulation of the waves and coastal currents, as they will hardly increase the accuracy of the morphological computation.

The schematization of the wave climate (deep water wave heights, wave periods and directions) and the tidal motion (tidal cycle and modulation) is one of the major problems in modelling coastal processes, since Monte-Carlo or real-time simulations are far from feasible yet. Even when considering "initial" morphological changes the wave climate and the tidal motion have to be schematized to a limited number of conditions in order to obtain bottom change rates that are representative for the "initial" time span. In the applications so far a single tidal cycle is schematized to a small number of steady state conditions, which are combined with a series of wave conditions during that individual cycle. The horizontally two-dimensional morphological models contain many interactions some of which are non-linear. Therefore the criteria imposed at present on these schematizations, viz. a correct representation of the average annual longshore transport for the waves and the mean flood and ebb-phase transports for the tide, still contain a great deal of arbitrariness and should be applied with caution. The selected schematization of the tidal motion and the wave climate specifies a series of production runs from the results of which the expected net morphological changes in the area of interest are to be derived. To that end a weighting procedure has to be established, in accordance with the schematization procedure.

A practical point of concern is the conformity of the geometrical schematizations in the various constituent models. As a rule these models make use of different computational grids and hence their

geometrical schematizations will show differences. In order to limit these differences as much as possible the original bathymetric data are reduced to a basic geometrical schematization, representing the relevant properties of the actual bathymetry and disregarding irrelevant details. It may be remarked that this choice is by no means always simple. The geometrical schematizations in all constituent models are derived from this basic schematization rather than from the original bathymetric data.

A specific aspect of compound models is the processing of the intermediate model results. The sensitive interaction of waves, current and transport in the computation of the rate of bottom changes poses heavier demands on their accuracy and reliability than in the case of separate application. Besides, additional output quantities are often needed. The wave model for instance has to produce not only wave heights and directions, but also orbital velocities near the bottom and whatever other parameters are needed to model wave effects on the net current and the sediment transport. Similarly, the flow model has to yield not only the magnitude and direction of the net flow velocity, but also other parameters needed for the transport model such as the bottom shear stress.

The last aspect mentioned here concerns the computational procedures applied in the numerical models for the region of interest. Usually only a finite-element procedure or a curvilinear finite-difference procedure provides the possibility to deal with the capriciously shaped coastlines and structures encountered in practice. Moreover these procedures allow for local grid refinements such that the morphological processes in the breakerzone, which is usually rather narrow compared with the total area of interest can be reproduced with sufficient accuracy.

#### 4 PRACTICAL APPLICATIONS

COMOR has been applied in different studies with the following fields of interest:

- design of artificial coastal extensions and islands
- design of sea water intakes and outfalls
- analysis of autonome coastal changes
- design of coastal protection schemes.

Some representative applications in the advisory practice as well as in research projects will be treated hereafter. For each of the applications the problem statement, the predominant physical processes, the simulation of these processes and the principal conclusions are considered.

#### Morphological aspects of an artificial storage basin for the disposal of dredged spoil near Rotterdam, the Netherlands

In the morphological study of a storage basin for the disposal of dredged spoil, reclaimed from the sea by means of a sanddam (see Figure 3), COMOR has been applied to estimate the amount of regular beach nourishment which will be necessary to compensate for the erosion of the sea-exposed dam. The region of interest is a fairly

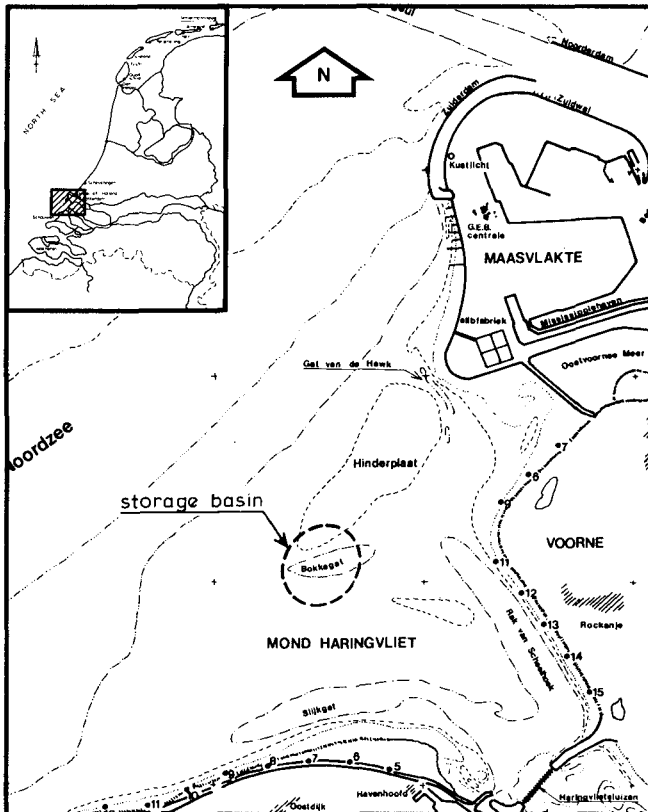

Fig. 3 Future situation

shallow area with a shoal, the Hinderplaat, falling partly dry at low tide. The foreshore shows almost straight and parallel depth contours. The storage basin is projected just at the southernmost edge of the Hinderplaat. The coastal area is exposed to deep water waves coming from directions between N and SW. The wave height distribution near the Hinderplaat is dominated by wave breaking. As such the transport by wave-induced currents is an important phenomenon in the erosion of the sanddam. However, the transport by tidal currents is expected to be important as well as the basin is situated in the immediate vicinity of a tidal gully, the Bokkegat. For this reason, the detailed flow model describes the combined wave-induced and tidal current.

Figure 4 shows the sequence of the constituent models of COMOR for this application. Existing calibrated models have been used for the simulation of the "far field" tidal motion and the wave propagation there. The tidal computations are based on the numerical solution of the vertically integrated two-dimensional long wave equations, discretized on a grid of square meshes (for instance, see Langerak,

1978). Figure 5 shows the tidal flow pattern at the moment of maximum flood flow, computed with the small tidal model.

Fig. 5 Small tidal model; results max. flood flow situation

Fig. 4 Constituent tidal and wave models

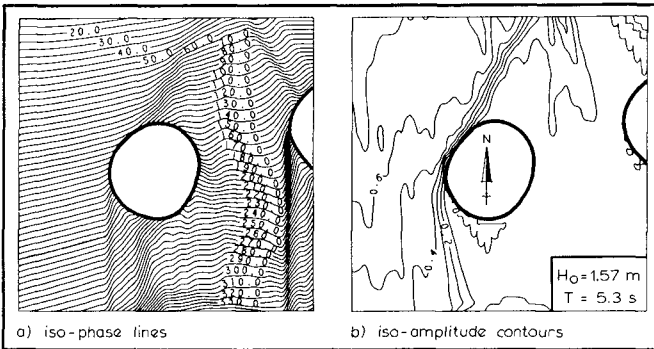

Fig. 6 Small wave model; results for waves from the North

The wave field has been computed with a model based on the parabolic approximation for the propagation of time-harmonic water waves (see Radder, 1979). In the model shoaling, refraction, diffraction and energy dissipation due to bottom friction, currents and wave breaking are included (see Dingemans et al., 1984). In Figure 6 the wave field for waves from the North computed with the small wave model are shown. To simulate the combined wave-induced and tidal flow in the area of interest, a finite element model for friction dominated steady flow (see Wind and Perrels, 1982) is applied. Figure 7 shows the

Fig. 7 Finite-element mesh

finite-element mesh used here. In the detailed flow model the tidal constituents of the flow are imposed via boundary conditions prescribing the inflow and/or the outflow velocities. The wave-induced current is driven by forces inside the area derived from the radiation stresses in the wave field (Longuet-Higgins, 1970; Battjes, 1974). The sediment transport model is based on the local equilibrium transport formulation due to Bijker (Bijker, 1967; Bijker, 1971). The bottom change rates follow from the conservation of sediment mass.

In Figure 8 the results of the computation of the detailed models for the waves from a Northern direction and maximum flood flow are outlined. The current pattern shows a longshore current along the seaward side of the dam, directed to the South-west. Around the basin contraction of the tidal currents takes place. Additional calculations have shown that, as a result of this phenomenon, the longshore current is strongly counteracted by the flood flow. The sediment transport pattern shows no significant transport rates in the sheltering area of the basin. Here the pronounced influence of the wave heights on the transport rates is expressed. Around the basin the bottom changes in a small strip are mainly determined by the longshore current, whereas at higher waterdepths the influence of the tidal motion is predominant: erosion occurs where the tidal flow accelerates and sedimentation where it decelerates. The contour plot of the bottom change rate in Figure 8 exhibits a rather irregular pattern with alternating sedimentation and erosion zones, which is hard to interpret qualitatively. For this reason the initial bottom contours have also been compared with the ones after a given time interval.

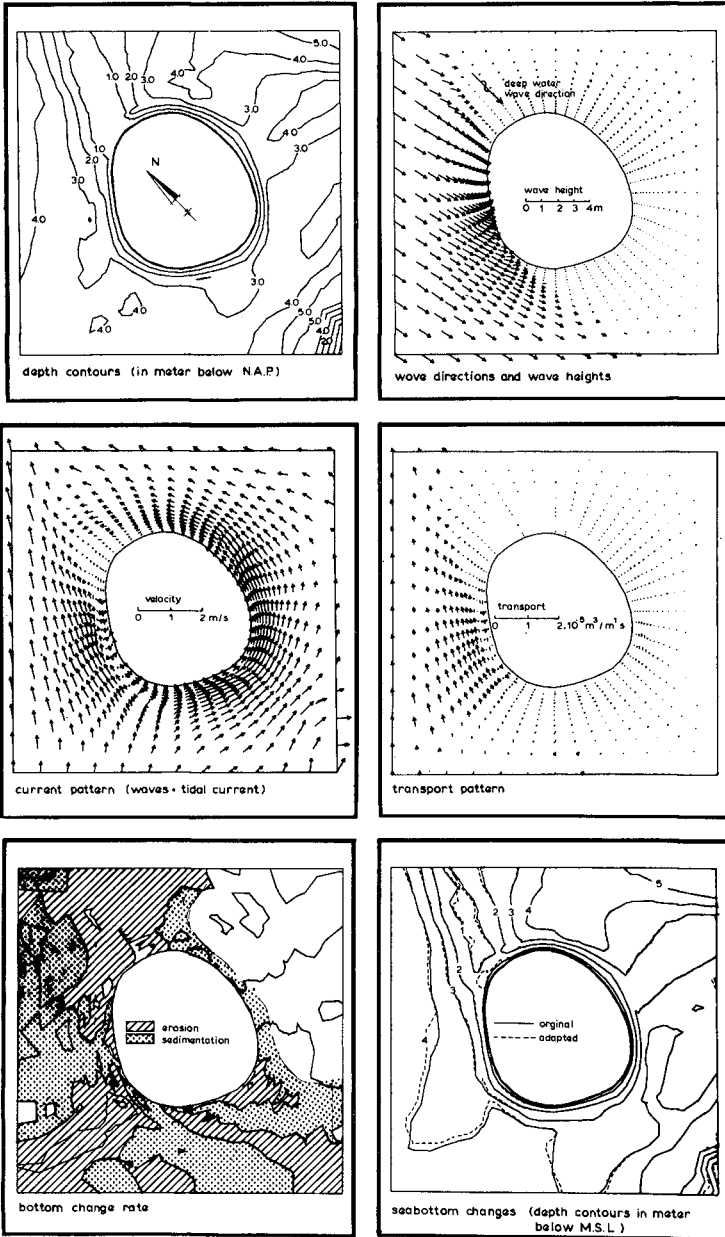

Fig. 8 Detailed models; results at moment of maximum flood and waves from the North

The final computational results of COMOR indicate that the resulting sediment transport pattern and the amount of beach nourishment is strongly influenced by onshore and/or offshore directed sediment transport resulting from the interaction between longshore current and tidal flow. The traditional computation methods viz. the computation of the resulting longshore sediment transport rates for successive cross sections, generally disregard this aspect. As such the COMOR model has contributed considerably to the understanding of the relevant phenomena for this situation.

Sedimentation study of sea water intake for the West Coast Steam Power and Desalination Complex, Umm al Qaiwain, United Arab Emirates

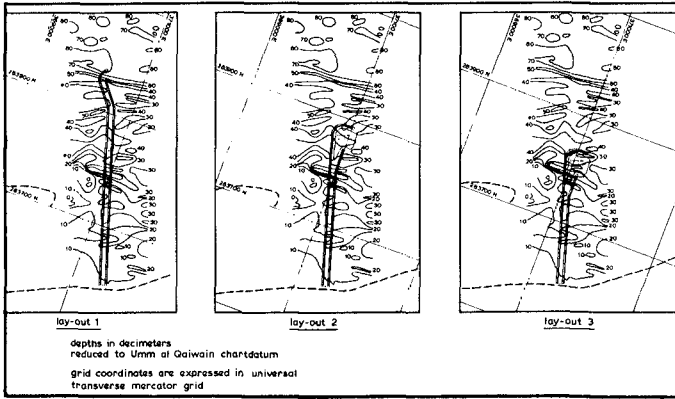

Fig. 9 Evaluated intake layouts

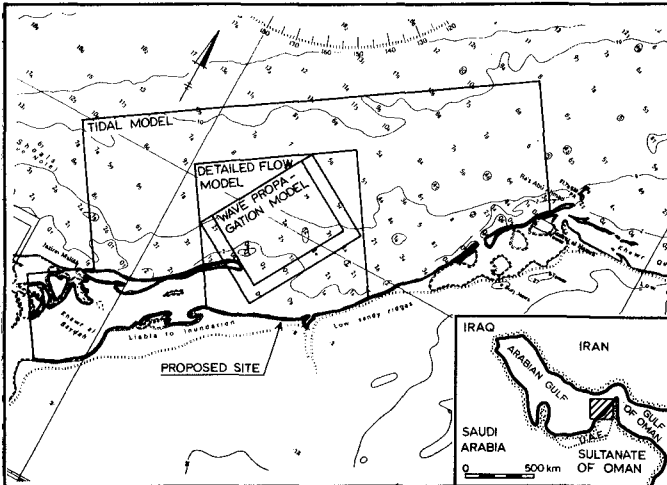

Fig. 10 Site location and constituent models

The sedimentation study was made to select the technically and economically optimal intake layout enabling the continuous withdrawal of up to  $53 \text{ m}^3/\text{s}$  of seawater. Three different intake layouts all consisting of two more or less parallel breakwaters forming a protected intake channel, have been evaluated (see Figure 9). COMOR is applied to determine the general morphologic changes after the construction of the seawater intake. The proposed site of the intake channel is a coastal stretch with a relatively wide and flat beach (Figure 10) exposed to predominant wave action from directions between W and NW. Along this coast a net Eastward longshore transport occurs, forming a spit at the extremity of the island Jazirat-Mallah. In addition, tidal and wave-induced currents carry a significant part of the longshore transport from Jazirat-Mallah towards the Chor Umm al Qaiwain. Part of this sediment is settling down in the area in front of the proposed site. Another part is transported North-east by the ebb current and picked up by the wave-induced longshore current East of the site.

The COMOR model applied in this project includes wave-induced as well as tidal currents. Figure 10 also shows the constituent models, varying in size between  $5 \times 17 \text{ km}^2$  for the tidal model to  $3 \times 5 \text{ km}^2$  for the wave propagation model. The numerical solution procedures in the various models are identical to those in the former application. Tidal computations were carried out for an average tidal situation of which the boundary conditions were derived from field measurements. For the deep water boundary conditions of the wave field, the predominant wave direction was used in combination with the annual extreme wave height. Special attention was given to the reproduction of the diffraction of waves around the head of the intake structure. To reduce computer costs the wave diffraction model covers only part of the detailed model area. In the remaining parts, simple refraction and shoaling computations were performed. The computations with the detailed flow model and the morphological model were carried out for two steady state conditions representing the mean ebb and flood currents. As an illustration, Figure 11 shows the computed wave field and the combined wave-induced and ebb current pattern, for the medium size inlet configuration.

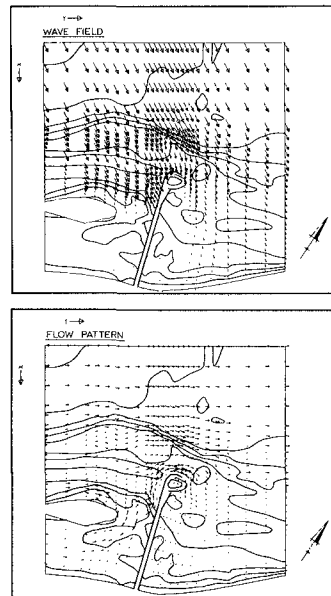

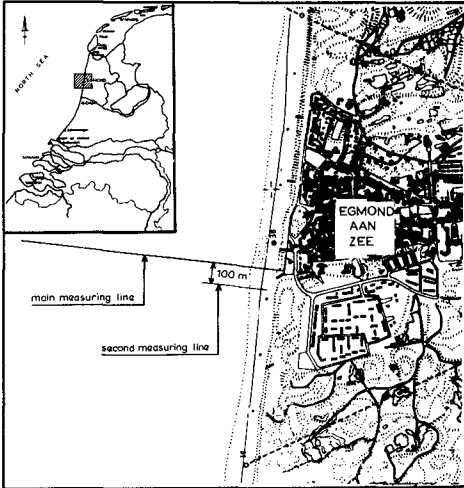

Fig. 11 Computed wave field and current pattern

The principal result of the application of the COMOR-model in this case was the indication that, depending on the layout of the construction, the tidal current and the wave-induced circulation in the

shadow zone could interact in a very unfavourable way, meeting just in front of the inlet (layout 1 in Figure 9) or the inlet could be situated entirely in the longshore transport zone (layout 3 in Figure 9). This indication, rather than the quantitative predictions of the morphological changes resulting from the model, has been used in the advice.

Current and sediment transport analysis at Egmond, the Netherlands

Recently within the framework of TOW two field campaigns on the Dutch Coast near Egmond (see Figure 12) have been conducted. The aims of the field measurements were the following

- to test instruments for the measurements of wave heights, currents and sediment transport in the surf zone;
- to collect data of hydraulic and morphologic phenomena in the near-shore zone.

For details of the 1982 campaign reference is made to Stive and Derks (1984). The location near Egmond was selected because of its longshore uniformity of

Fig. 12 Site location at Egmond

Fig. 13 Geometrical schematization

bottom topography and hydraulic conditions. During both campaigns data on wave heights, currents, vertical tide, suspended sand concentration, wind velocity and -direction, seawater temperature and bottom topography were gathered for conditions ranging from calm weather to 9 Beaufort. Here the COMOR system was applied to study the sensitivity of the measuring data to the "overall" nearshore conditions of the project site. The area covered in the COMOR model is  $700 \times 1200 \text{ m}^2$ . As can be seen in Figure 13 the depth contours are fairly straight and parallel. In the coastal profile a bar can be distinguished at a distance of approximately 400 m offshore.

The wave, current and sediment transport modules in COMOR are identical to those described for the first application. Figure 14 shows the wave field, current pattern and bottom changes resulting from deep

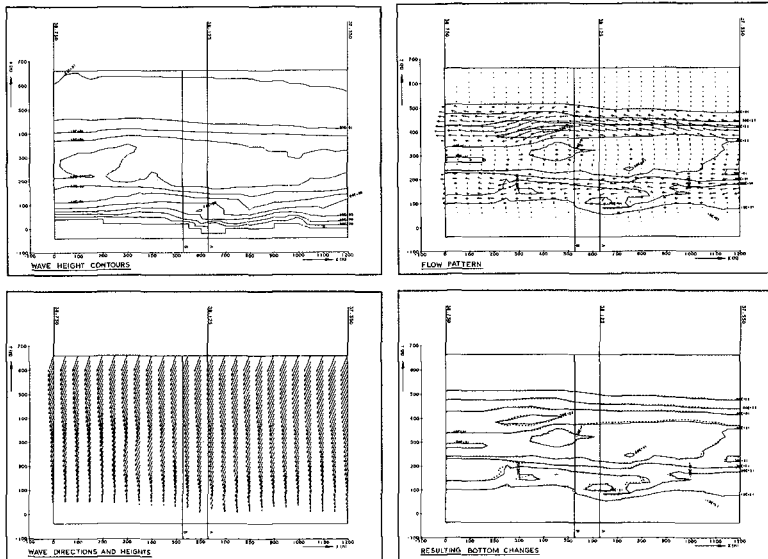

Fig. 14 Computed wave field, current pattern and bottom changes

water waves of North-westerly direction, with a significant wave height  $H_s = 3.88 \text{ m}$  and a peak frequency of  $T_p = 8.5 \text{ s}$ . The current pattern shows two longshore current lanes, one on the bar and the second current close to the shore. Note that the mild variation in the bottom topography has a pronounced influence on the current pattern. It is expected that the influence of the bottom topography on the current pattern will reduce if convection is included. The bottom topography appears to migrate in current direction due to gradients in sediment transport.

Although the analysis of the results is by no means completed, the COMOR model has already contributed considerably to the understanding of the nearshore morphology.

Tidal current and sediment transport analysis at IJmuiden, the Netherlands

For the onset of a study of morphological changes under tidal conditions, the geometry of the port of IJmuiden has been selected. IJmuiden is the gateway to Amsterdam (Figure 15). The tidal period for IJmuiden is on average 12.37 hours. The maximum velocity at a depth of 10 m is in the order of 0.6 m/s. The bottom roughness has been estimated at 0.2 m.

For the computation of the flow field a model for the solution of the Navier-Stokes equations has been used. This model has been developed in cooperation with the Laboratoire National d'Hydraulique, Chatou, France. For details, see Officier, Vreugdenhil and Wind (1985). The turbulent viscosity field is obtained by solving the  $k-\epsilon$  equations. The inflow boundary condition has been assumed to vary sinusoidally with time. The variation in mean water level has not been taken into account (rigid lid approximation) as it is not expected to have a dominant effect on the development of the flow pattern.

Fig. 15 Site location at IJmuiden

Fig. 16 Computed flow field

The flow field shown in Figure 16 results 3.30 hours after slack tide. Near the harbour entrance a flow contraction can be noticed, while downstream of the harbour moles an eddy is visible. A preliminary comparison of the computed flow field with float tracks indicates similar characteristics. For a more detailed comparison field measurements are a prerequisite. It will be clear

that the flow field is by no means stationary. According to a simple rule of thumb the length of the eddy parallel to the shore should be, for a stationary condition, in the order of six times the length of the harbour mole. Due to the tide reversal the growth of the eddy is stopped and the eddy moves towards deeper water. The time dependency of the flow field has implications for the sediment transport. For instance any morphologic study for IJmuiden based on stationary current fields seems not to be warranted.

A first estimate of the sediment transport can be obtained if a sediment transport formula is combined with the flow field. The resulting sediment transport rate is formed by the small difference between the large sediment transport quantities during the ebb and flood cycle. In nature the resulting sediment transport is among others also determined by the net tidal flow and the rate of suspension of the sediment. These effects are under investigation. As a preliminary result in Figure 17 the change in bottom topography is shown if the sediment transport is calculated using the Engelund-Hansen transport formula. The artificial time scale for the change in bottom topography is 24 hours. It is interesting to note that the gully in front of the harbour is moving in current direction. The wave like character of the bottom change is inherent to the local sediment transport concept.

Although the analysis of the tidal morphology is just started, the model performance is positive. It appeared that the Navier-Stokes current model could model could easily be included resulting in predictions of the evolution of the eddies near the port entrance. The effect of evolution of the flow field on the morphology is presently under investigation.

Fig. 17 Computed change in bottom topography

## 5 EVALUATION

Despite the accumulation of a substantial knowledge of the individual morphological processes, the simulation of coastal morphological evolution by mathematical modelling is still in an early stage of development. It is realized that a considerable amount of knowledge, insight and experience remains to be gathered before COMOR may be used as a fully independent quantitatively predictive model. For instance:

- the validity of the depth averaged description of the flow is not satisfactorily verified for coastal currents;
- the transport formulae presently applied in coastal morphology are rather inaccurate;
- little is understood of the time-dependent interaction of waves, currents and transports on the one hand and bottom changes on the other hand;
- the criteria imposed on the schematization of the wave climate and tidal motion contain a great deal of arbitrariness;
- the verification of the compound morphological model is still lacking, hampered as it is by insufficient experimental information.

The aforementioned aspects may suggest that the application of the COMOR model for coastal engineering advisory purposes is at present rather questionable. However the way COMOR is applied so far is

not essentially different from the procedures which are widely used in desk calculations for isolated points of the field. So far the practical applications of COMOR concern only initial morphological changes. The reliability of the model is determined to a high extent by the reliability of the constituent models. In most cases these models have been verified individually, so the reliability of their results can be estimated. Nevertheless the final computational results of the COMOR model must be interpreted with caution. This interpretation is primarily a matter of physical insight and awareness of the model limitations. The results of COMOR must be considered as a support of advice just as the traditional computation methods which are already used in desk studies for years. Applied in this way, COMOR models for initial changes appear to be quite useful in coastal advisory practice, especially in comparative studies (investigation of alternative plans, response to an abrupt change in conditions, etc.) or as a qualitative support of other well calibrated tools (coastline models, scale models, etc.).

## CHAPTER NINETY NINE

### A SIMPLIFIED MODEL FOR LONGSHORE SEDIMENT TRANSPORT

by

James A. Bailard

Naval Civil Engineering Laboratory  
Port Hueneme, California 93043

#### ABSTRACT

An energetics-based longshore sediment transport model is developed which takes the form of a modification to the wave power equation. Instead of being constant, the wave power coefficient is a function of the breaker angle and the ratio of the orbital velocity magnitude and the sediment fall velocity. This modification extends the range of application of the wave power equation to include both field and laboratory conditions.

#### INTRODUCTION

Waves, breaking at an angle to the shore, cause sand to be moved laterally along the beach. On a straight beach with parallel contours, the longshore sand transport is spatially uniform and no planform changes in the beach will occur. If, however, the longshore sand transport is interrupted by a groin or a jetty, sand will accumulate on the updrift side of the structure and erosion will occur on the downdrift side. Coastal engineers are often required to predict the rate of accretion and erosion associated with a structure, thus there is a need for an accurate and easily applied longshore transport model.

Although the wave power equation was developed more than 20 years ago (Inman and Bagnold, 1963), this equation remains the most widely accepted method today for predicting the longshore sediment transport rate (SPM, 1977). The wave power equation linearly relates the spatially-integrated immersed weight longshore sediment transport rate,  $I_{\ell}$ , to what has been termed the longshore component of wave energy flux,  $P_{\ell}$ , i.e.

$$I_{\ell} = K P_{\ell} \quad (1)$$

where the wave power coefficient,  $K$ , is generally assumed to

be a constant equal to 0.77 (Komar and Inman, 1970). The factor  $P_{\rho}$  can be expressed as

$$P_{\rho} = (E C_n)_b \sin \alpha_b \cos \alpha_b \quad (2)$$

where  $E$  is the energy of the incident waves,  $C_n$  is the group velocity of the waves,  $\alpha$  is the incident wave angle, and the subscript  $b$  denotes the value at breaking.

In spite of its widespread application, the wave power equation accurately predicts the longshore sediment transport rate only over a narrow wide range of conditions. For example, laboratory measurements of  $K$  suggest a value of approximately 0.2, while field measurements suggest a value closer to 0.8 (see Figure 1). This difficulty is in part the result of the relative simplicity of the wave power equation. For example, the assumption of a constant wave power coefficient prevents any differentiation between the bedload and the suspended load transports, nor does it allow any accounting of the sediment grain size or the beach slope.

More complex, analytically-based longshore sediment transport models have been proposed which predict the distribution of the longshore transport rate across the surfzone. These models are based on adaptations of stream-based sediment transport models, and include traction-based models (eg. Ostendorf and Madsen, 1976; Swart, 1976), and energetics-based models (e.g. Komar, 1971, 1977; Thornton, 1973; Bowen, 1980; Bailard, 1981). In order to predict the distribution of the longshore sediment transport rate across the surfzone, all of the above models incorporate some form of a breaking wave model and a longshore current model. The resulting equations are generally cumbersome, incorporating a number of undetermined coefficients, and require numerical solution. As a result of the added complexity of these models, none have had widespread application.

The objective of this study was to develop a sediment transport model which preserves the general form and simplicity of the wave power equation, but which extends its range of application. The basis for the model was a simplification of Bailard's (1981) energetics-based longshore transport model. Simplifying assumptions used in the model development were based on an analysis of Nearshore Sediment Transport Study (NSTS) field data (see Gable, 1979, 1980). Both laboratory and field measurements of longshore sediment transport rates were used to calibrate the model.

Figure 1. The wave power equation, shown by the solid line, overpredicts laboratory measurements of longshore transport rate when a constant wave power coefficient is assumed (from Komar and Inman, 1970).

Figure 2. Schematic diagram showing the velocity field parameters in the surfzone.

## THEORY

## Generalized Transport Equation

The basis for the model development was a generalized form of Bagnold's (1963, 1966) sediment transport model for streams. Bagnold's model assumes that sediment is transported in two modes, bedload and suspended load. The bedload transport is assumed to occur as a thin granular-fluid layer which is supported by the bed via grain to grain collisions. The suspended load transport is assumed to take place above the bedload layer, with the sediment supported by fluid turbulence. In both cases, energy is expended by the stream in transporting the sediment. Bagnold assumed that the rate of sediment transport was proportional to the rate of energy dissipation in the stream, with separate proportionality constants, termed efficiency factors, associated with the bedload and suspended load transports respectively.

Bailard (1981) generalized Bagnold's energetics-based stream model for time-varying flow over an arbitrarily sloping bottom. The resulting sediment transport equation was

$$\begin{aligned} \langle \vec{i}_t \rangle = & \rho c_f \frac{\epsilon_B}{\tan \phi} \left[ \langle |\vec{u}_t|^2 \vec{u}_t \rangle - \frac{\tan \beta}{\tan \phi} \langle |\vec{u}_t|^3 \rangle \hat{i} \right] \\ & + \rho c_f \frac{\epsilon_S}{W} \left[ \langle |\vec{u}_t|^3 \vec{u}_t \rangle - \frac{\epsilon_S}{W} \tan \beta \langle |\vec{u}_t|^5 \rangle \hat{i} \right] \end{aligned} \quad (3)$$

where  $\vec{i}_t$  is the instantaneous sediment transport rate vector,  $\vec{u}_t$  is the instantaneous nearbottom velocity vector,  $\rho$  is the density of water,  $c_f$  is the drag coefficient of the bed,  $\epsilon_B$  is the bedload efficiency factor,  $\epsilon_S$  is the suspended load efficiency factor,  $\phi$  is the internal angle of friction of the sediment,  $\tan \beta$  is the bedslope,  $W$  is the fall velocity of the sediment,  $\hat{i}$  is the unit vector directed downslope, and  $\langle \rangle$  indicates a time-averaged quantity.

An important feature of the above equation is that the bedload transport (first bracketed quantity) and the suspended load transport (second bracketed quantity) both consist of a primary component directed parallel to the instantaneous fluid velocity vector, and a secondary component directed downslope. The latter is associated with the downslope component of the sediment load.

## Local Surfzone Transport Equations

In order to predict the sediment transport rate in the surfzone, the local surfzone velocity field must first be specified. Figure 2 depicts a plane contour beach with the x-axis directed shoreward and the y-axis directed parallel to the beach. The slope of the beach is  $\tan \beta$  and the local

wave angle is  $\alpha$ .

For simplicity, the nearbottom velocity field was assumed to be composed of an oscillatory component  $\tilde{u}$ , oriented at angle  $\alpha$  to the x axis, and steady velocity components  $u$  and  $v$ , directed parallel to the x- and y-axes respectively. The total velocity vector,  $\vec{u}_t$ , becomes

$$\vec{u}_t = (\tilde{u} \cos \alpha + u) \hat{i} + (\tilde{u} \sin \alpha + v) \hat{j} \quad (4)$$

where  $\hat{i}$  and  $\hat{j}$  are the unit vectors associated with the x- and y-axes. In addition, the oscillatory velocity component was assumed to be composed of a primary component  $u_m$  with frequency  $\sigma$ , and higher harmonic  $u_{2m}$  with frequency  $2\sigma$ , etc, so that

$$\tilde{u} \cong u_m \cos \sigma t + u_{2m} \cos 2\sigma t + \dots \quad (5)$$

Substituting Equation 4 into Equation 3 and assuming that

$$u/u_m \ll 1; \quad v/u_m \ll 1; \quad \cos \alpha \cong 1; \quad \langle i_x \rangle \ll \langle i_y \rangle \quad (6)$$

the local time-averaged longshore sediment transport rate becomes

$$\begin{aligned} \langle i_y \rangle = & \rho c_f u_m^3 \frac{\epsilon_B}{\tan \phi} \left[ \delta_v + \delta_v^3 + \frac{\tan \beta}{\tan \phi} u_3^* \tan \alpha \right] \\ & + \rho c_f u_m^4 \frac{\epsilon_s}{W} \left[ \delta_v u_3^* + \frac{u_m}{W} \epsilon_s \tan \beta u_5^* \tan \alpha \right] \end{aligned} \quad (7)$$

where

$$\zeta_v = v/u_m; \quad u_3^* = \langle |\vec{u}_t|^3 \rangle / u_m^3; \quad u_5^* = \langle |\vec{u}_t|^5 \rangle / u_m^5 \quad (8)$$

With the exception of  $c_f$ ,  $\epsilon_B$ , and  $\epsilon_s$ , all of the parameters in Equation 8 can be predicted from one of the several breaking wave and longshore current models available (e.g. Longuet-Higgins, 1970). In its full complexity, this procedure results in a complex expression for the cross-shore distribution of the longshore sediment transport rate (Baillard, 1981). Spatial integration of the distribution yields an expression similar in form to the wave power equation except that the wave power coefficient is a complex function of the incident wave, beach, and sediment properties. The complexity of this expression, and

the fact that it requires numerical evaluation has prevented any widespread use of the model.

#### Spatially-Integrated Longshore Transport Equation

The principal obstacle to obtaining a closed-form solution for  $K$  in Bailard's (1981) model were the complex expressions for the wave velocity moments  $u_3^*$  and  $u_5^*$ . Guza and Thornton (1981) have shown, however, that for weak mean currents and a gaussian orbital velocity distribution,  $u_3^*$  and  $u_5^*$  are constants equal to 0.58 and 1.13 respectively. Estimates from NSTS field data generally support these findings except that measured values are closer to 0.60 and 1.25. Based on these findings, one of the simplifying assumptions used in the present model development was that  $u_3^*$  and  $u_5^*$  are constants equal to 0.60 and 1.25.

The longshore current model used in the present development was the radiation stress-based model by Ostendorf and Madsen (1979). In order to keep the solution as simple as possible, a number of simplifications were made with relationship to the model's provisions for finite breaker height and longshore current strength. The resulting expression for the longshore current,  $v$ , is as follows

$$v = v_c v^* \quad (9)$$

where  $v_c$  is a characteristic longshore current strength and  $v^*$  is the dimensionless longshore current distribution expressed as follows (P#0.4)

$$v^* = C_1 \left( \frac{1 - C_2}{C_2 - C_3} \right)^{C_3} x^* + C_1 x^* \quad x^* \leq 1$$

$$v^* = C_1 \left( \frac{1 - C_3}{C_2 - C_3} \right)^{C_2} x^* \quad x^* > 1 \quad (10)$$

The parameters  $C_1$ ,  $C_2$ , and  $C_3$  are the following functions of the lateral mixing parameter,  $P$ ,

$$C_1 = (1 - 2.5 P)^{-1}$$

$$C_2 = -\frac{1}{8} - \left( \frac{1}{64} + \frac{1}{P} \right)^{1/2}$$

$$C_3 = -\frac{3}{4} + \left( \frac{9}{16} + \frac{1}{P} \right)^{1/2} \quad (11)$$

and the dimensionless surfzone position,  $x^*$ , is defined as

$$x^* = \frac{x - x_s}{x_b - x_s} \quad (12)$$

where  $x_s$  and  $x_b$  are the positions of the shoreline and the break-point on the x-axis respectively.

The characteristic longshore current strength,  $v_c$ , is defined as

$$v_c = \delta_c u_{mb} \quad (13)$$

where  $u_{mb}$  is the oscillatory velocity magnitude, obtained from shallow water wave theory, i.e.,

$$u_m = \frac{\gamma}{2} \sqrt{g h} \quad (14)$$

and  $\delta_c$  is the relative longshore current strength parameter defined as

$$\delta_c = \frac{5 \pi \tan \Delta \sin \alpha_b}{8 c_f} \quad (15)$$

The parameter  $\tan \Delta$  is equal to the average beach slope,  $\tan \beta$ , modified for wave setup, i.e.

$$\tan \Delta = \frac{\tan \beta}{1 + \frac{3}{8} \gamma_b^2} \quad (16)$$

The parameter  $\gamma$  is defined as the ratio of the surfzone wave height,  $H$ , to the water depth,  $h$ , and is assumed to have the following distribution

$$\begin{aligned} \gamma &= \gamma_b & x^* \leq 1 \\ \gamma &= \gamma_b \left( \frac{h_b}{h} \right)^{5/4} & x^* > 1 \end{aligned} \quad (17)$$

where  $\gamma_b$  is assumed to be equal to 0.8

Combining Equations 8 and 9 and assuming that Snells Law applies, the following equation was obtained for the cross-shore distribution of the longshore transport rate

$$\begin{aligned}
 \langle i_y \rangle = & \rho c_f u_{mb}^3 \frac{\epsilon_B}{\tan \phi} \left[ \frac{1}{2} \left( \frac{Y}{Y_b} \right)^2 \delta_c v^* x^* + \delta_c^3 v^*{}^3 \right. \\
 & \left. + \frac{\tan \beta}{\tan \phi} \left( \frac{Y}{Y_b} \right)^3 u_3^* x^*{}^2 \tan \alpha_b \right] \\
 & + \rho c_f u_{mb}^4 \frac{\epsilon_s}{W} \left[ \left( \frac{Y}{Y_b} \right)^3 \delta_c u_3^* v^* x^*{}^{3/2} \right. \\
 & \left. + \tan \beta \frac{u_{mb}}{W} \epsilon_s \left( \frac{Y}{Y_b} \right)^5 u_3^* x^*{}^3 \tan \alpha_b \right]
 \end{aligned} \tag{18}$$

The spatially integrated longshore transport rate,  $I_\ell$ , was obtained by spatially integrating Equation 18, i.e.

$$I_\ell = \frac{h_b}{\tan \Delta} \int_0^\infty \langle i_y \rangle dx^* \tag{19}$$

Noting that  $K = I_\ell/P_\ell$ ,  $\tan \alpha_b \approx \sin \alpha_b$ , and

$$\rho c_f \frac{h_b}{\tan \Delta} u_{mb}^3 \delta_c = \frac{5 \pi}{8} \gamma_b P_\ell \tag{20}$$

then the wave power coefficient  $K$  can be expressed as

$$K = \epsilon_B K_1 + \epsilon_s K_2 + \epsilon_s^2 K_3 \tag{21}$$

where

$$\begin{aligned}
 K_1 = & \frac{5 \pi}{8} \left( \frac{\gamma_b}{\tan \phi} \right) \left\{ \frac{c_1}{2(c_2 - c_3)} \left[ \frac{1 - c_2}{c_3 + 2} + \frac{c_2 - c_3}{3} - \frac{1 - c_3}{c_2 - \frac{1}{2}} \right] \right. \\
 & + \frac{25 \pi^2}{256} \left( 1 + \frac{3}{8} \gamma_b^2 \right)^{-2} \left( \frac{\tan \beta}{c_f} \right)^2 \sin^2 2 \alpha_b c_1^3 \left[ \frac{\left( \frac{1 - c_2}{c_2 - c_3} \right)^3}{3 c_3 + 1} \right. \\
 & \left. + \frac{3 \left( \frac{1 - c_2}{c_2 - c_3} \right)^2}{2 c_3 + 2} + \frac{3 \left( \frac{1 - c_2}{c_2 - c_3} \right)}{c_3 + 3} + \frac{1}{4} - \frac{\left( \frac{1 - c_3}{c_2 - c_3} \right)}{3 c_2 + 1} \right] \\
 & \left. + \frac{8}{15 \pi} \left( \frac{\tan \beta}{\tan \phi} \right) \left( \frac{c_f}{\tan \beta} \right) \left( 1 + \frac{3}{8} \gamma_b^2 \right) u_3^* \right\}
 \end{aligned} \tag{22}$$

$$K_2 = \frac{5 \pi}{8} \gamma_b u_3^* \frac{u_{mb}}{W} \left( \frac{c_1}{c_2 - c_3} \right) \left[ \frac{1 - c_3}{c_3 + \frac{5}{2}} + \frac{c_2 - c_3}{7/2} - \frac{1 - c_3}{c_2 - \frac{5}{4}} \right] \tag{23}$$

and

$$K_3 = \frac{25}{36} \gamma_b \tan \beta \left( \frac{c_f}{\tan \beta} \right) \left( 1 + \frac{3}{8} \gamma_b^2 \right) u_5^* \left( \frac{u_{mb}}{W} \right)^2 \quad (24)$$

Equations 22 through 24 were further simplified using the results of Komar (1976). Komar analyzed laboratory and field measurements of longshore currents and found that  $P$  was approximately equal to 0.2 and the ratio  $\tan \beta / c_f$  was approximately equal to 7. Introducing these assumptions into Equations 22 through 24, the following results were obtained

$$K_1 = 0.385 + 20 \sin^2 2 \alpha_b + 0.074 \tan \beta \quad (25)$$

$$K_1 = 0.228 u_{mb} / W \quad (26)$$

$$K_3 = 0.123 \tan \beta (u_{mb} / W)^2 \quad (27)$$

#### MODEL CALIBRATION

The remaining free parameters in Equation 21 which need to be specified are the bedload and suspended load efficiency factors. Bagnold (1966) found that for stream flow,  $\epsilon_B$  and  $\epsilon_S$  were equal to 0.13 and 0.01 respectively. In the present case, these factors were estimated from laboratory and field measurements of  $K$ .

The laboratory data used to estimate  $\epsilon_B$  and  $\epsilon_S$  were selected data from Saville (1949, 1950) and Shay and Johnson (1951). The field data were from Bruno et. al. (1980), Dean et. al. (1983), Komar and Inman (1970), Kraus et. al. (1983), and Moore and Cole (1960). Average characteristics of these data sets are summarized in Table 1.

Initially, a nonlinear least squares procedure was used to estimate  $\epsilon_B$  and  $\epsilon_S$ , however, it was quickly found that the contribution of  $K_3$  to  $K$  was negligible in relationship to  $K_1$  and  $K_2$ . When  $K_3$  was eliminated from Equation 21, the resulting equation was linear in  $\epsilon_B$  and  $\epsilon_S$ , thus a multiple linear regression technique could be used. The resulting estimates for  $\epsilon_B$  and  $\epsilon_S$  and their 95% confidence intervals were

$$\begin{aligned} \epsilon_B &= 0.13 \pm 0.009 \\ \epsilon_S &= 0.032 \pm 0.004 \end{aligned} \quad (28)$$

Combining these estimates with Equation 21, the desired

Table 1. Characteristics of laboratory and field data sets used to calibrate the present longshore transport model.

Laboratory

equation for the wave power coefficient,  $K$ , was obtained

$$K = 0.05 + 2.6 \sin^2 2 \alpha_b + 0.007 u_{mb}/W \quad (29)$$

Figure 3 shows a plot of the observed values of  $K$  versus the values estimated by Equation 29. With the exception of the data from El Moreno Beach (Komar and Inman, 1970), and the single data point from Moore and Cole (1960), the fit is relatively good.

#### DISCUSSION

The advantage of the present model over the wave power equation is that it can be used to predict the longshore sediment transport rate over a wider range of input conditions. Using a constant wave power coefficient equal to 0.77, the wave power equation does an adequate job of predicting the longshore transport rate provided the grain size is between 0.15 and 0.25 mm and the wave height is between 0.5 and 2.0 m. Outside of this range, particularly, under laboratory conditions or for large sand sizes in the field, the power equation is significantly in error.

The present model corrects the above mentioned shortcoming of the wave power equation by separately accounting for the bedload and suspended load transports. As a result, the wave power coefficient becomes a function of the incident breaker and sediment characteristics. Nevertheless, the resulting equation for  $K$  involves only parameters which are already available from the usual longshore transport calculations.

The present longshore transport model has a number of limitations which must be mentioned. First, the energetics sediment transport equations which are used in the model development are vertically integrated and ignore the vertical structure of the sediment concentration and velocity fields. Recent field measurements of vertical distributions of these parameters, substantiate their importance, particularly in relationship to cross-shore sediment transport (Jaffee et. al., 1984). Their importance in relationship to longshore transport processes is unknown.

A second limitation of the model is that the rate of energy dissipation (to which the transport rate is proportional) is computed directly from the drag at the bed. Contributions associated with the breaking wave at the surface are neglected, in spite of their overall dominance (Thornton and Guza, 1983). The implicit assumption is that the bottom boundary layer is the primary factor controlling the upward flux of sediment from the bottom, however, this is only

Figure 3. A comparison of measured wave power coefficients with wave power estimates generated from Equation 29.

conjecture. A possible improvement to the model might be to incorporate a variable drag coefficient to partially account for the energy dissipation of the breaking waves. Alternatively, the rate of energy dissipation could be directly associated with the local gradient in the energy flux (e.g. Thornton, 1973 and others).

A third limitation of the model is that threshold of motion effects for the sediment have been neglected. Seymour (1983) has shown that under most field conditions, threshold effects are not significant, while under laboratory conditions they are significant. Threshold effects could be incorporated into the present model using the statistical method developed by Seymour (1983), but the resulting equations would be more complex.

Additional limitations of the model can be summarized as follows. The distribution of the longshore transport rate was derived from the usual breaking wave assumptions. Analysis of NSTS field data has shown that some of these assumptions are clearly incorrect. For example, one common assumption is that the total velocity variance monotonically decreases towards the shore. Field measurements on dissipative beaches show instead that the velocity variance is nearly constant across the surfzone (Guza and Thornton, 1981; Bailard, 1983). This result has important ramifications concerning the distribution of the longshore current and the longshore sediment transport rate.

A related problem is that beach profile shapes have been shown to have a significant effect on the distribution of the longshore current (McDougal and Hudspeth, 1984). Moreover, proper characterization of the lateral mixing of momentum is still an unanswered question. As a result, the distribution of the longshore transport rate specified in the present model should be considered as only approximate.

The overall effect of the above mentioned limitations on the present model is not known. To some degree, many of these effects have been hidden by the processes of integration as well as by the least squares estimation procedure for determining the bedload and suspended load efficiency factors.

#### CONCLUSIONS AND RECOMMENDATIONS

The following conclusions were reached as a result of this study.

1. A simple modification to the wave power equation has been developed through a systematic application of Bagnold's energetics sediment transport concepts. Instead of being

constant, the wave power coefficient is found to be a function of the incident breaker angle and the ratio of the orbital velocity at the break point divided by the sediment fall velocity.

2. The above modification was found to extend the range of application of the wave power equation. Longshore transport rates under laboratory conditions can be predicted with the same equation used for field conditions. The equation can also be applied to beaches with larger sediment sizes.

3. Although the model describes the distribution of the longshore transport rate across the surfzone, this distribution should be applied with caution. Recent measurements of surfzone waves and currents suggest that a number of the common assumptions used to develop the present model and most longshore current models are not very accurate.

4. There may be a limit to the extent that vertically-integrated energetics-based sediment transport models can be used to describe surfzone sediment transport processes. Vertical distributions of cross-shore velocities and sediment concentrations are clearly important in determining on-offshore sediment transport rates. Their importance in longshore transport processes is unknown.

5. The present model might be improved by including sediment threshold of motion effects, a variable drag-coefficient, and a different formulation for the rate of energy dissipation. While these modifications will probably provide a more accurate prediction of the longshore sediment transport rate, they will also increase the complexity of the model. Most likely, however, significant improvements in modeling surfzone sediment processes will come only through an increased understanding of the vertical structure of the sediment concentration and velocity.

Based on these findings, it is recommended that future work be focused on measuring the vertical structure of the sediment concentration and fluid velocity fields. A parallel effort should focus on developing improved models for wave bore dynamics, surfzone boundary layer dynamics, bedload, and suspended load mechanics, and time-averaged longshore and on-offshore currents in the surfzone.

## CHAPTER ONE HUNDRED

### AN ASSESSMENT OF BEACH NOURISHMENT SEDIMENT CHARACTERISTICS

D.K. Stauble<sup>1</sup>, M. Hansen<sup>2</sup> and W. Blake<sup>1</sup>

#### ABSTRACT

An important component of beach nourishment design is to assess the compatibility of the borrow material with the native beach sediment. One avenue to judge the "success" of a project is the amount of fill retained over a specific period of time after fill placement. Presumably, if the fill material placed on the eroded beach is compatible with the energy of the coastal processes, it will be resorted along the profile but be retained within acceptable limits in the vicinity of the project area.

At present the selection of suitable borrow material is based only on theoretical criterion. Specifically, the Fill Factor and Renourishment Factor are based on models developed by Krumbein (1956), Krumbein and James (1965), James (1974), Dean (1974), James (1975) and Hobson (1977). These methods of judging borrow area suitability have not been fully tested in the field and the Shore Protection Manual (U.S. Army, 1977) warns that they should only be used as a general indication of possible fill behavior.

A review of monitoring reports on selected recent beach restoration and sand by-pass projects revealed a lack of standardization on data collection and analysis. Little evaluation of the actual behavior of fill material on the nourished beach had been carried out. To assess the suitability of the fill material, projects with adequate data were investigated and the short (one year) and long term (two to three years) behavior of actual fill data was described. Detailed collection of native sediment before nourishment, representative borrow material at time of placement and samples at specific times after fill placement were used to determine the redistribution of fill grain size characteristics and determine the accuracy of the present beach fill models.

It was found that present models do not take into account non-normal grain size distributions found at the projects studied or  $\text{CaCO}_3$  shell material. A safety factor assuming loss of fine material from the borrow should be used with the Adjusted Shore Protection Manual Fill Factor Method to give more accurate results. The delta variable in the Renourishment Factor was found to vary between projects and should be calculated for each project. At the present time use of the entire grain size distribution is necessary to understand the sediment redistribution after fill placement.

## INTRODUCTION

Beach Nourishment as a technique for shoreline stabilization and storm protection has become increasingly popular over the past decade. Beaches widened by artificial fill placement act to dissipate erosive wave energy, provide upland property storm protection and supply additional sediment to a usually sediment starved sand budget area. Aesthetically, renourished beaches are also of recreational value to an important coastal tourist industry.

The rapidly rising cost of beach restoration and inlet sand by-passing projects have led opponents to question the long term value of such a "soft" coastal structure. In the past, many projects have been poorly monitored and inadequately documented. This has resulted in a dearth of scientific and engineering data for design and permitting officials to assess project success; and has contributed to costly project delay and redesign.

The high cost of beach restoration projects requires that we be able to predict how the sediment placed on the beach is going to respond to the physical forces acting upon it. The present theoretical beach-fill models have only been tested on a limited basis. Therefore, a more accurate understanding of beach-fill redistribution using actual field data from past projects would be a major contribution to our knowledge of beach erosion control.

Engineering monitoring reports and field collection from several recent beach nourishment projects provided the sediment data used in this study. It was difficult to find projects that had enough usable sediment data to make a comparison study possible. At present, there is no standardization in project monitoring and it was sometimes difficult to compare projects directly since the data provided were obtained in various ways and presented in different formats. The projects selected for this study had minimal similarity in data and were from locations that provided variation in both sediment characteristics and wave climate. The locations used to evaluate monitoring techniques, accuracy of the current beach fill models and to develop monitoring and analysis guidelines for future projects, included beach nourishment projects at Indialantic/Melbourne Beach, Delray Beach, and Hollywood/Hallandale located on the moderate to high wave energy (Tanner, 1960) East Coast of Florida. The Captiva Island project was located on the low to moderate Gulf Coast of Florida and the Ocean City project was located on the high wave energy Atlantic Coast of Southern New Jersey (Figure 1).

## SEDIMENT SAMPLING AND ANALYSIS CONSIDERATIONS

To evaluate a beach for nourishment, one must be able to obtain representative native beach and borrow sediment samples. The question of what is a representative sample arises. There are noticeable differences in the grain size distribution as one proceeds from the dune base, across the beach and continues offshore as described by Bascom (1959). The largest grains are usually found in an area just seaward of the backwash/surf interaction zone, an area of much turbulence. The summer berm crest area also contains significant coarse material due to runup sediment transport dynamics. Finer material is found in the dune area owing predominantly to wind transport processes. Seaward of the mean low water area sediments become finer with increasing distance seaward of the breaker zone. When determining the grain size

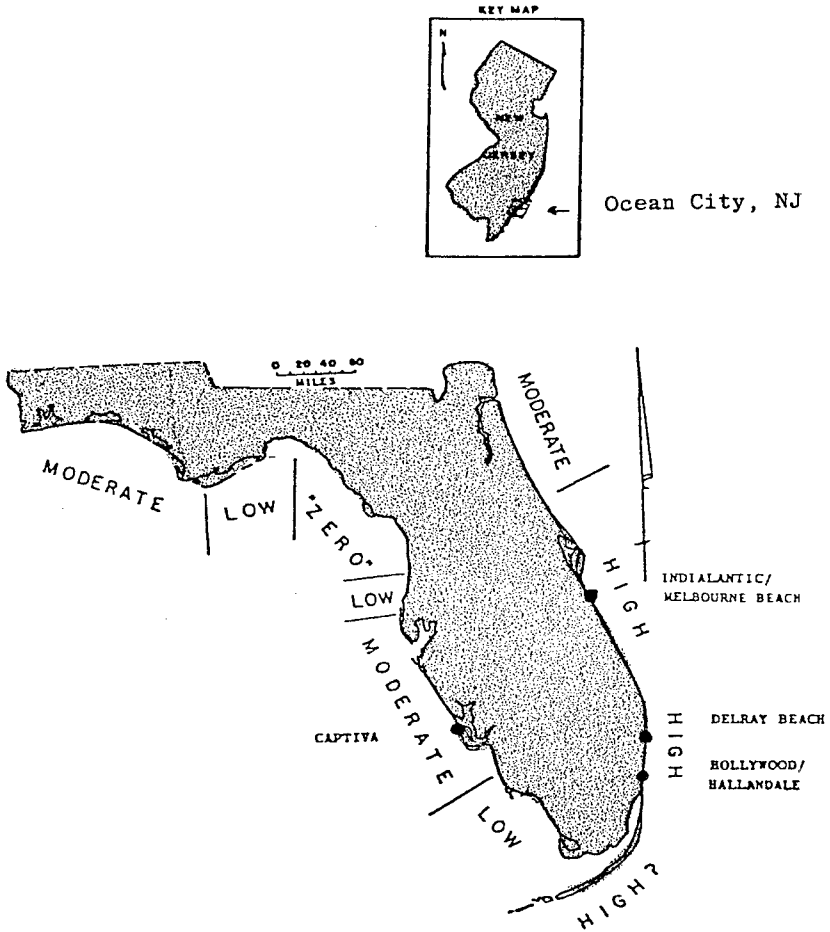

Figure 1. Locations of beach nourishment projects used in this study. Wave energy zones after Tanner (1960).

distribution of the native beach, it has been found that by combining samples from across the beach and nearby offshore areas, the variability in grain-size is reduced (Hobson, 1977). The grain size distribution of these composite samples will vary depending on the location of the included samples.

Analysis of some of this unique field data indicates that location of sediment sampling is critical to give a true picture of the native beach sediment characteristics and post-nourishment fill redistribution. A variety of sampling designs were used in the projects with little standardization (Table 1). A minimal requirement for inclusion in this study was data on the native beach, borrow area and a reasonable interval of post-nourishment monitoring sediment samples. Most monitoring reports used fixed distances from a benchmark, or fixed elevations about NGVD for collection of samples independent of the dynamic coastal processes. It was found that choosing sampling sites along the profile based on hydrodynamic zonation on the beach (ie. area of maximum runup, mid-tide area and mean low tide area) gives the best representative picture of grain size distribution. These zones change over the course of any study depending on tide, wave and profile shape parameters.

Location of sediment sampling is critical to give a picture of the true fill redistribution. A wide variety of sampling designs were used with differences in location, number and frequency of sampling. To reduce variability between the various sampling intervals, a mathematical composite was constructed from data generated after the individual samples have been analyzed either from graphic representation in project monitoring reports or actual field collection. The samples were all sieved at either 1/2 or 1/4 phi intervals. The percentage of sediment in each size class of the different samples was then combined and an average grain size distribution was calculated. This method preserved information on individual samples for later use and allowed for various combinations of composites.

Several types of composite samples, as described by Hobson (1977), were examined to determine which of these samples eliminated the variability and provided the best comparison of behavior over time. Two basic types of composites were chosen after an examination of various combinations of samples available from each project, the intertidal composite and the profile composite:

- 1) The intertidal composites consist of samples from within the intertidal zone, (Figure 2) between mean hightide to mean lowtide, collected around the time of lowtide. This composite gave a good picture of the behavior of the beach-fill since this is the area of fill placement and most of the subsequent reworking.
- 2) The profile composites consist of intertidal samples plus samples collected seaward of the swash zone to approximately a 12 foot depth (Figure 2). This is a common type of composite used on most past projects.

The borrow area sediment sampling and analysis also varied from project to project (Table 1). Some of the projects reported composite samples of cores taken from the borrow area, summarizing vertical and horizontal distributions while others used composites or individual samples from the area of fill placement. The borrow material was obtained from various environments. Indialantic/Melbourne Beach had borrow material with a similar mean grain-size but was more poorly sorted and was sediment dredged from a barrier island to

PROJECTS	SEDIMENT SAMPLE TYPES							
	NATIVE	BORROW	3 MO.	6 MO.	9 MO.	1 YR.	18 MO.	LONG TERM

Figure 2. Sediment sampling locations on two of the projects thru time showing the change in intertidal and offshore samples with change in profile shape.

produce a harbour area. Delray Beach had much finer borrow material whose sorting was slightly poorer than the native beach and was from an offshore source area. Hollywood/Hallendale had a borrow that was slightly better sorted and contained finer material owing to its offshore origin. The borrow at Captiva Island was almost identical to the native beach and was obtained from an ebb tidal shoal. At Ocean City, NJ, the borrow was slightly finer and better sorted than the native beach and was dredged from a flood tidal bay source. When comparing native and borrow materials, there was more variation in the sorting values than there was in the mean grain-size. Table 2 summarizes the characteristics of each project.

Ideally, borrow material should have a grain size distribution congruent only with the intertidal samples where the fill is to be placed (Figure 3). The inclusion of offshore samples, however, results in a skewness to the finer grain-sizes and may not provide a true representative picture of the hydrodynamic effects on the native beach in the area of fill placement. A comparison of the borrow to native frequency curve of figure 3b) shows the standard practice of using the profile composite of the native sediment (including both intertidal and nearshore samples) vs. borrow sample, showing a reasonable match in distribution at all grain sizes. Figure 3a) shows a composite of only the intertidal samples, which gives a better picture of a borrow sediment that is deficient in the medium to coarse sand range, with an excess of fine material.

An examination of the various project data shows a distinct difference in grain size distributions landward and seaward of the low tide area. Sediment collected from the intertidal area (where most fill was placed on the projects examined) was found to be most representative of native beach material and gave a better picture of fill redistribution after placement (Stauble, et. al., 1983). Samples collected seaward of the low tide zone exhibited a distinctly different grain size distribution, tending to be composed of finer, better sorted material. This offshore area post-fill sediment grain size redistribution behaved differently from the intertidal area (Figure 4) in that the offshore sediments remained fined grained with little change in the mean and sorting. The intertidal composites, however, changed their mean and sorting as the coastal processes resorted the sediment and changed the profile shape.

At the present time, the difference between the native and borrow grain size distributions is one of the major determining factors for the project's success. From the data analyzed in this study, it was found that excess fine-grained material in the borrow was quickly winnowed away and transported offshore and/or downdrift of the nourished area. The standard practice of including the finer grained nearshore sediment samples into native beach composites appears to give a false picture on which to compute suitability of borrow material.

#### FILL MATERIAL COMPATIBILITY

Once sediment data is obtained for the native beach and the prospective borrow material, a method is needed to determine how suitable the material will be for placement on the beach. Several beach-fill models have been established to calculate an "overflow ratio" or fill factor which is defined as the volume

PROJECT	VOLUME OF FILL PLACED	LENGTH OF PROJECT	SOURCE AND METHOD OF PLACEMENT	SAMPLING INTERVAL	PROFILES WITH SEDIMENT SAMPLES	SAMPLES ALONG PROFILES	COMMENTS
Indiantic/ Melbourne Beach, FL	195,060m <sup>3</sup>	3.38km	upland source dumped from truck onto beach	1 per week for 2 months, then gradually reduced to every 3 months	3 within project profiles, plus 2 control profiles	dune base, RT, HT, Swash, + 3 offshore samples at 200, 300, 400 meters of high tide line	project completed Jan. 1981
Hollywood/ Hilandale, FL	1,514,432m <sup>3</sup>	8.46km	offshore source 1500 - 300m. 7 borrow sites dredge.	Pre-Construction every 3 months increaser to 1 year	6 profiles	+7, +4, 0, -3, -6, -9, -12ft.	project completed Nov. 1979
Delray Beach FL	1,269,749m <sup>3</sup> (1973) 536,180m <sup>3</sup> (1978) (two areas)	4.93km	offshore source dredged/trucked from stockpile source	Pre (6-73) Borrow (6-73) Post (7-81)	3 profiles	+15 to -3ft (3ft intervals)	project completed July 1978
Captive Island, FL	501,155m <sup>3</sup>	3.05km	source: ebb tidal dredge	Pre, post, 6, 12 18 months	4 within, 1 outside	+6 to -12ft (3ft intervals)	project completed Oct. 1981
Ocean City, NJ	917,520m <sup>3</sup>	3.6km	source: flood tidal delta/ bay area dredge	Pre, post, 2 weeks, each 3 months until 15 months	3 profiles	HT, MT, LT	project completed Aug. 1982

of borrow material required to produce a unit volume of usable fill material with the same grain size distribution as the native material (James, 1975, Hobson, 1977). These beach-fill models require two parameters for calculations: the mean grain-size which is a measure of the central tendency and the sorting which is a measure of the spread of the grain sizes about the mean.

Currently there are three beach-fill models described by the Shore Protection Manual (U.S. Army, 1984): (1) The Shore Protection Manual (SPM) Method proposed by Krumbein and James (1965), (2) The Dean Method (Dean, 1974) and (3) The Adjusted Shore Protection Manual (Adjusted SPM) Method developed by James (1975).

The SPM method, developed by Krumbein and James (1965), compares the ratios of weight percentages of the native-to-borrow composites across the range of observed grain-sizes to determine the grain-size at which the ratio is a maximum (critical grain-size). One major problem with this method is the assumption that the coarse, more stable fraction will be winnowed away to create the compatible grain size distribution.

To overcome problems with the SPM method, Dean (1974) proposed a second method to calculate a fill factor. His approach assumes that selective sorting will winnow fine materials from the fill until the mean of the modified fill equals the native mean. A major problem is that the model predicts stability for all grain-sizes when the borrow materials are coarser and more poorly sorted than native sediments, even though the finer grain-sizes will be removed by winnowing. The SPM method implies that selective sorting will occur in both coarse and fine size fractions, whereas Dean's method implies only removal of material in the finer size classes.

James (1975) created a third fill factor model to correct the basic problems of the first two. This model, known as the Adjusted SPM method (Adjusted SPM), assumes the fill factor to be equal to the "critical ratio" of the SPM method, except when the borrow is coarser than the native sediments. This results in a modified grain size distribution which is as close as possible to the proportions of the native distribution in the finer size classes, but retains the borrow characteristics of the coarser size classes. Typically, the Adjusted SPM method produces fill factors less than the SPM method but greater than Dean's method (Hobson, 1977).

Each of fill factor approaches use many of the same assumptions:

- (1) Sediments native to the beach are considered to be the most stable for the environment.
- (2) Local sorting processes act upon the entire volume of fill to achieve a GSD similar to the native sediments sometime after fill placement.
- (3) Sorting processes change the fill material into native-like sediments by winnowing out a minimum amount of the original fill.
- (4) GSD's of the native and borrow sediments are assumed to be normally distributed for the purposes of simplifying calculations. (Hobson, 1977).

There is some question as to the validity of these assumptions. The native and borrow sediment distribution was not found to be normally distributed in the projects studied. A typical borrow vs. native frequency

curve shows that there was usually excess material in the coarse fraction consisting mostly of carbonate shell and in the fine fraction due to the lower energy environment of the borrow area. Most of the fill was deficient in the medium sand sizes typically found on the native beach (Hansen,1982).

A post-nourishment fill estimate provides a technique to determine the accuracy of the various beach fill models. The fill factor is the volume of borrow material required to produce a unit volume of stable fill material. A fill factor of 2 would mean that 1/2 of the borrow material was unstable, so twice the design volume of sediment would have to be placed on the beach to result in the design beach. The post-nourishment fill estimate is the reverse of this calculation. If 50% of the fill is lost from a project after one year, then a post-nourishment fill estimate of 2 is calculated. By comparing what actually happened to the fill with what the models predict, one can get a better idea of each model's accuracy.

With these values of actual fill behavior estimates, a comparison of the three fill factor models was undertaken to see which one estimates fill behavior the best. Hobson (1977) suggested using a safety factor with the Adjusted Shore Protection Manual Method to account for the proportions of material finer than sand ( $>4 \phi$ ), since these sizes are considered unstable on the beach and are lost soon after fill placement. The safety factor, G, can be calculated to account for these unstable sizes, using:

$$G = \frac{100\%}{\beta \phi} \times R(a) \quad (1)$$

where:  $\beta$  = % of sediment expected to remain (in  $\phi$  units)

Hobson, 1977 suggests  $<4 \phi$  or % sand size contained in sample, this study suggests  $<3 \phi$  or %  $>$  very fine sand.

The use of G has the effect of increasing the Adjusted fill factor when there are percentages of sediment finer than sand ( $>4 \phi$ ) or as found in this study material finer than fine sand. These values still fall between the Dean and SPM fill factors as predicted.

It was found in all of the study projects that the borrow material contained a maximum of only 3% mud-size particles and the cut off point of 4  $\phi$  was insignificant when using the safety factor G. After analyzing the post nourishment fill behavior it was discovered that most of the material finer than 3  $\phi$  was winnowed from the fill on most of the projects. A calculated safety factor using the 3  $\phi$  cut off was used and gave results close to the post-nourishment fill estimates. Table 2 summarizes the fill factor calculations and compares them to the post fill loss estimate.

James (1974) established a technique to predict how often renourishment will be needed and to evaluate the long-term performance of different fill materials. This technique involves the use of a mass-balance equation which compares material going into and out of the nourishment area. This equation is:

$$R_j = e^{-\Delta \left[ \frac{\mu_b - \mu_n}{\sigma_n} \right] - \frac{\Delta^2}{2} \left[ \frac{\sigma_b^2}{\sigma_n^2} - 1 \right]} \quad (2)$$

Site	Post-Hour. Fill Est.	R(s) SPH F.F.	R(d) Dean F.F.	R(a) Adj. F.F.	R(a) with G 4 phi 3 phi
I/MB profile	2.17	1.65	1.00	1.10	1.11 1.40
inter- tidal	2.17	2.20	1.00	1.38	1.40 2.10
Delray Beach	1.7	>10	15	>10	---- ----
Hol/Hal	1.09	-----	----	1.09	---- ----
Captive Island	1.22	1.02	1.00	1.01	1.01 1.20
Ocean City N.J.	No Volume Lost Estimates Available	unstable	----	1.75	1.75 2.3

Table 3. Comparison of post nourishment fill estimates with the Shore Protection Manual (R<sub>s</sub>), Dean (R<sub>d</sub>), Adjusted Shore Protection Manual (R<sub>a</sub>) fill factor models and the Adjusted Shore Protection Manual model with the safety factor G using the 4 phi and 3 phi size cut off for each project. The G of 3 phi gave "overflow" ratios closest to post nourishment estimates.

where:  $R_J$ —relative retreat rate (renourishment factor)  
 $\mu$  and  $\sigma$ —phi mean and phi sorting parameters  
 b and n—subscripts referring to borrow and native sediments  
 $\Delta$ —dimensionless parameter related to selective sorting  
 (winnowing) in the environment.

James suggests that the range of delta values may be from 0.5 to 1.5. He recommends that calculations of the renourishment factor use a value of 1.0 for the delta parameter and that the calculated values should be regarded as only approximate (James, 1975). The "delta" value can be computed from the following equation:

$$\Delta = \frac{\mu_n - \mu'_n}{\sigma_n} \quad (3)$$

where:  $\mu_n$  = the native mean before an erosional event.  
 $\mu'_n$  = the native mean after an erosional event.  
 $\sigma_n$  = the sorting of the native material, where  
 $\sigma_n = \sigma'_n$  is assumed true (James, 1974).

The delta value was computed for the projects from data obtained before and after erosional events as best that can be determined for projects where data was available. This value gave a better estimate of fill behavior than an assumed value of 1.0. It is recommended that a delta value should be calculated for each nourishment project to accurately apply this model. Usually, a beach requiring nourishment is undergoing an erosional period, so by taking sediment samples several times prior to nourishment, the delta value can be determined using equation (2).

### LONG TERM GRAIN SIZE REDISTRIBUTION

An examination of long term grain size characteristics of the fill material has lead to a complex picture of project grain size redistribution. The projects used in this study exhibited a wide range of native-to-borrow grain size distributions and coastal wave energy distributions. A method was developed, using a "post-nourishment fill estimate", based on volume of fill stabilized over a year or longer and the changes in grain size distribution over time, to graph fill behavior.

The inclusion of the safety factor, G, seems to predict more accurate fill factors than the Adjusted fill factors alone. Our findings indicate that safety factor calculations should be shifted to the fine limit of native sediment, not the 4 phi limit suggested by Hobson (1977). Figure 5a-d depicts the grain-size excesses and deficiencies in the borrow material as compared to the native beach at the top half of each figure and actual gains and losses one year later (8 years later for Delray Beach) at the bottom of each figure. If there was excess fine material in the borrow, the intersecting grain-size is shown by the dashed line. In the lower half of each figure, the solid line indicates the 3 phi grain-size at which the G values were calculated. The grain-size at which actual losses of fines occurred (if any) are shown with the crossed line. The 3 phi cut off point was used for the ease of obtaining percent sand at that point. Use of the 3 phi cut off point for calculating G

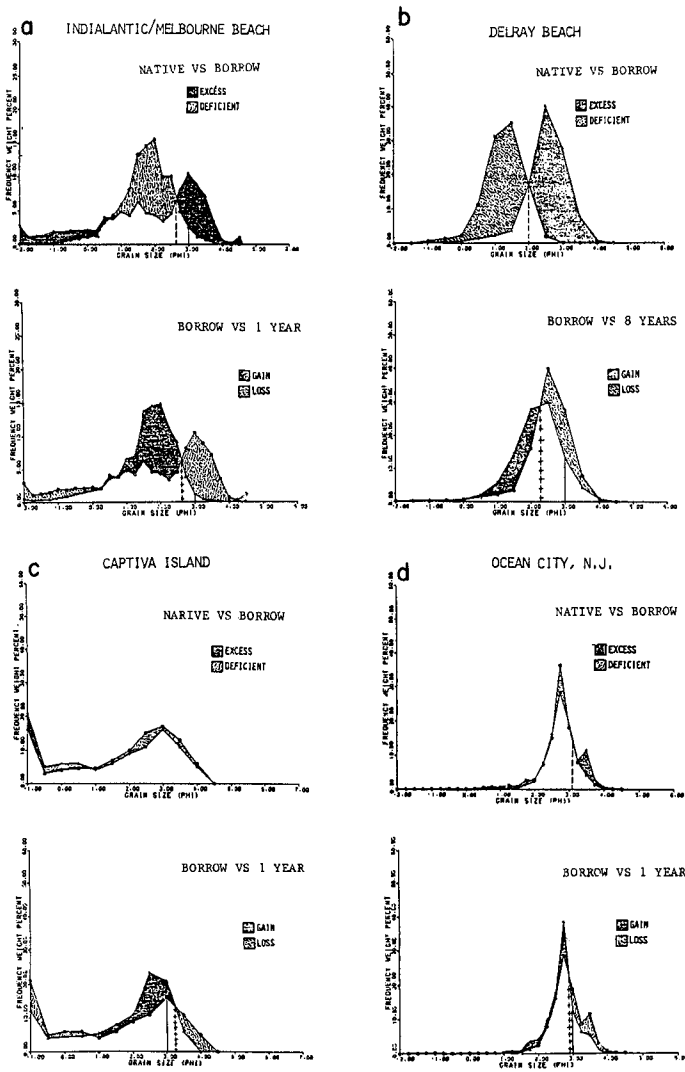

Figure 5. Grain size frequency curves from the four projects comparing 1) the borrow with the native showing the 3 phi cut off and the actual excess fine grain material and 2) the borrow with the one year (8 year for Delray Beach) showing the calculated 3 phi cut off with the actual loss of fine material.

and actual losses correlate well at Indialantic/Melbourne Beach (Fig. 5a), Captiva Island (Fig. 5c) and Ocean City (Fig. 5d). For the projects that had a reasonably good match between borrow and native or borrow that was for the most part slightly finer than native in areas of moderate to high wave energy the 3 phi adjustment gave a reasonable prediction of fill behavior. The correlation was not as good at Delray Beach (Fig. 5b) which had such a large grain-size difference between the borrow and native and resulted in a significant long term change in the grain size distribution. No borrow information was available for Hollywood/Hallandale, but analysis using sediment collected three months after fill placement showed that the native material contained coarser material than the borrow that replaced it even though the borrow was composed of medium sand. From three months to one year later, the beach gained a significant amount of fine material not found in either the native or borrow sediment.

### CONCLUSION

From this study it can be concluded that:

1. Composite samples are needed to remove the variability in sediment distribution across a beach and in a borrow area. Intertidal composite samples are more suitable for use in the models. Offshore sediments include fine sizes and changed little in their grain size distribution over the project life. Fill was placed in the intertidal area in all projects studied and this area had the greatest redistribution of sediment grain sizes.
2. The Adjusted Shore Protection Manual method (recommended in the majority of cases by U.S. Army, 1984), gave the best calculation of actual fill behavior, provided a safety factor (G) was used. A safety factor of 3.0 Phi has been found to give the best results for the projects studied.
3. Fill factor models commonly use only the sediment mean and standard deviation values. The sample mean and sorting alone are not sufficient to describe the variability of the native, borrow and post-fill sediment behavior because natural sediment distributions are not normally distributed as assumed in the models. Frequency distribution plots provide the best means of showing the differences between the native and borrow grain sizes over the entire sediment distribution.
4. Renourishment Factor calculations using computed  $\Delta$  values gave the best match to actual fill behavior.
5. Standardization of collection, analysis and presentation of beach nourishment sediment data is needed for better understanding of project behavior.

It must be noted that grain size information alone is not sufficient to predict success of a project. Compatibility of the borrow material is but one of the factors to be considered in project planning, along with fill placement techniques, knowledge of coastal processes and interaction with other coastal structures (Dean 1983). New guidelines are in the process of being developed (Stable and Nelson, 1984) for monitoring all aspects of a nourishment project. More projects with adequate data need to be examined and a standard data collection and reporting system established. We will then have a better basis

for understanding fill behavior and development of new predictive methods for project success.

## CHAPTER ONE HUNDRED ONE

### LONGSHORE SEDIMENT TRANSPORT ON DEAN BEACH PROFILES

William G. McDougal,<sup>1</sup> A.M., ASCE  
Robert T. Hudspeth,<sup>1</sup> M., ASCE

#### Abstract

Natural beaches exhibit an equilibrium profile that is planar nearshore and non-planar, concave-up offshore. The longshore current on these Dean equilibrium beaches is shown to depend on the location of the intersection between the planar and non-planar profiles and on the dimensionless mixing strength parameter if the eddy viscosity coefficient is linearly dependent on the distance offshore. The effect of the profile intersection on the longshore sediment transport rate is demonstrated for two energetics based sediment transport models; viz. the Bagnold and energetics stress models.

#### Nomenclature

a	local wave amplitude;
A	dimensionless coefficient for Dean profile;
b (B)	dimensional (dimensionless) horizontal distance offshore to profile intersection;
c ( $C_g$ )	wave celerity (group celerity);
$C_f$	dimensionless friction coefficient for bottom stress;
d (D)	dimensional (dimensionless) total water depth including wave setup/down;
g	gravitational constant;
$G_{p(np)}$	dimensionless constant for planar (non-planar) beach profile;
h (H)	dimensional (dimensionless) still water depth;
$i_{1(2)}$ ( $I_{1(2)}$ )	dimensional (dimensionless) sediment transport rate for Bagnold (stress) model;
$I_v(\cdot)$ ( $K_v(\cdot)$ )	modified Bessel function of the first (second) kind of order $\nu$ ;
k	linear wave theory wave number;
K	dimensionless longshore sediment rate coefficient;
L	wave length;
m	roots for planar beach solution;
n	linear wave theory group velocity ratio;
N	dimensionless constant for eddy viscosity;
$P_{p(np)}$	dimensionless mixing strength parameter for planar (non-planar) beach;

<sup>1</sup> Ocean Engineering Program, Department of Civil Engineering, Oregon State University, Corvallis, OR 97331.

$\hat{A}$	dimensionless transport rate coefficient;
$s, S$	planar beach slope;
$s_{xy}$	radiation stress;
$T$	wave period;
$u_o$	magnitude of linear wave theory bottom velocity;
$v(V)$	dimensional (dimensionless) longshore current;
$x, y, z$	Cartesian coordinate system with $z$ positive up from the still water level;
$x_o$	horizontal distance offshore to origin of concave-up profile;
$\zeta$	dimensionless argument;
$\eta$	water surface elevation;
$\theta$	local wave angle of incidence;
$\kappa$	dimensionless wave height to water depth ratio;
$\mu_e$	dimensionless eddy viscosity coefficient;
$\pi$	constant;
$\rho$	fluid mass density; and
$\tau_{by}$	bottom shear stress.

## Introduction

Analytical solutions for longshore currents have been obtained using the concepts of radiation stresses developed for planar beaches (Bowen, 1969; Thornton, 1970; Longuet-Higgins, 1970a,b) and for non-planar, concave-up beaches (McDougal and Hudspeth, 1983a,b). In the nearshore zone inside the breaker line, the non-planar, concave-up type of beach profile seems to be generally more applicable to storm or to other high wave energy conditions. However, Dean's analysis (1977) of a total of 502 different non-storm beach profiles along the Atlantic and Gulf coasts of the United States seems to support Bruun's earlier postulation (1954, 1962) that beach profiles are typically non-planar, concave-up and vary as the horizontal distance offshore raised to the two-thirds power. Unfortunately, the Bruun type of non-planar, concave-up beach profile exhibits a mathematical singularity in the beach slope at the origin which is usually located in the swash zone. Evidently, the offshore bathymetry analyzed by Dean (1977) did not contain enough bathymetric data sufficiently close inshore to this swash zone to better resolve this concern for the mathematical singularity in the beach slope for a concave-up profile. In contrast, the nearshore observations of Komar (p.c.) seem to support the theory that non-storm beach profiles do not exhibit a singularity in beach slope near the swash zone and are often planar for the nearshore portion of the surf zone. One possible resolution of these two apparently conflicting observations is that typical non-storm beach profiles are planar nearshore and non-planar, concave-up offshore. Dean (p.c.) has recently derived a physical explanation for a planar nearshore profile. This type of composite beach profile that is planar nearshore and non-planar, concave-up offshore is probably more realistic of the actual type of beach profiles that exist during non-storm conditions and will be called a Dean beach profile.

An analysis is presented for a Dean beach profile that is planar nearshore and non-planar,  $x^{2/3}$  concave-up offshore. The analysis utilizes the radiation stress concepts and incorporates an integrated, turbulent Reynolds stress tensor that is approximated by an eddy viscosity model. Although there has been some concern expressed about the justification for the various mathematical forms used to represent the turbulent eddy viscosity coefficient in the dynamic equations of motion (Battjes, 1975), the analysis by McDougal and Hudspeth (1984) of seven different mathematical expressions for the turbulent eddy viscosity coefficients demonstrated that numerical results are relatively insensitive to the exact form of the mathematical model used for non-planar, concave-up beach profiles. For this analysis, the mixing length scale of the turbulent eddy viscosity coefficient is assumed to vary linearly (Longuet-Higgins, 1970a) with the total water depth (i.e., still water depth plus wave setup/setdown). This assumed mathematical form for the mixing length scale of the turbulent eddy viscosity coefficient results in a relatively more tractable analytical model for both the planar (Longuet-Higgins, 1970a) and for the non-planar,  $x^{2/3}$  concave-up Dean beach profiles (McDougal and Hudspeth, 1983a). The effects of the location of the intersection between the planar nearshore profile and the non-planar, concave-up offshore profile (i.e.,  $x = b$ ) is examined in some detail by varying the location of this intersection between the two profiles. Specifically, the profile intersection is located inside, at, and outside of the breaker line. Both the Bagnold and an energetics stress model for the longshore sediment transport (McDougal and Hudspeth, 1983b) are used to demonstrate the effects of the location of the profile intersection on the longshore sediment transport rates.

#### Dean Beach Profile

Figure 1 illustrates a Dean beach profile that is planar nearshore and non-planar, concave-up offshore. The horizontal distance to the intersection between the planar and non-planar profiles is located at  $x = b$ . Although the intersection between the planar nearshore profile and the non-planar, concave-up offshore profile is shown in Fig. 1 to be located inside the breaker line ( $x = b < x_B$ ), it may also, in general, be located either at ( $x = b = x_B$ ) or outside of the breaker line ( $x = b > x_B$ ). The still water depth,  $h(x)$ , for the composite beach shown in Fig. 1 is given by

$$h(x) = \begin{cases} s_h x & ; x < b & (1a) \\ \alpha_h (x-x_0)^{2/3} & ; x > b & (1b) \end{cases}$$

where  $s_h$  is the planar bottom slope;  $\alpha_h$  is a dimensional coefficient of proportionality having dimensions of length raised to the one-third power; and  $x_0$  is the location at the still water level of the origin of the non-planar profile. The horizontal distance offshore to the origin of the non-planar profile,  $x_0$ , and to the

Fig. 1 Definition sketch for Dean profile.

intersection between the planar and non-planar profile,  $b$ , may be related to the planar slope,  $s_h$ , and the dimensional coefficient of proportionality,  $\alpha_h$ , by requiring continuity of depth,  $h(b)$ , and of profile slope,  $dh(b)/dx$ , at  $x = b$ , i.e.,

$$b^3 \zeta^3 = (b-x_0)^2 \quad (2a)$$

$$9 (b-x_0) \zeta^3 = 4 \quad (2b)$$

where

$$\zeta = (s_h / \alpha_h) \quad (2c)$$

which gives

$$b = 4/9 \zeta^3 \quad (3a)$$

$$x_0 = 4/27 \zeta^3 = 1/3b \quad (3b)$$

McDougal and Hudspeth (1983a) have shown that the wave-induced setup/setdown,  $\langle \eta(x) \rangle$ , profiles are given by

$$\langle \eta(x) \rangle = \begin{cases} \frac{3\kappa^2}{(8+3\kappa^2)} [h_B - h(x)] - \frac{\kappa^2 h_B^2}{16} & ; x < x_B \end{cases} \quad (4a)$$

$$\langle \eta(x) \rangle = \begin{cases} -\frac{a(x)ka(x)}{2\sinh 2kh(x)} & ; x > x_B \end{cases} \quad (4b)$$

where  $\langle \cdot \rangle$  = time averaging operator;  $a(x)$  is the local wave amplitude;  $\kappa = 2a(x)/[h(x) + \langle \eta(x) \rangle]$  is the constant of proportionality inside the breaker line between the local wave amplitude,  $a(x)$ , and the total water depth,  $d(x) = h(x) + \langle \eta(x) \rangle$ ; and the local radian wave number,  $k = 2\pi/L$ , is determined from linear wave theory according to

$$(2\pi/T)^2 = gk \tanh kh \quad (5)$$

where  $T$  = the wave period and  $L$  = the wave length. In addition, it can be shown that the total water depth,  $d(x)$ , for the non-planar Bruun  $x^{2/3}$  profile may be modeled in a best least-squares sense by a total water depth profile that is proportional to the horizontal distance offshore raised to the one/half power with a partial correlation coefficient of 0.986 for  $0 < x < x_B$ . Consequently, the total local depth profiles [i.e., still-water-depth,  $h(x)$ , plus setup  $\langle \eta(x) \rangle$ ] for both the planar nearshore and the non-planar offshore profiles will be represented by

$$d(x) = \begin{cases} s_d x & ; x < b \\ \alpha_d (x - x_o)^{1/2} & ; x > b \end{cases} \quad (6a)$$

$$(6b)$$

where  $s_d$  is the slope of the total water depth. Again, continuity of the two profiles and of the two profile slopes at the location of the profile intersection,  $b$ , gives

$$b = 0.5 \lambda^2 \quad (7a)$$

$$x_o = 0.25 \lambda^2 = 0.5 b \quad (7b)$$

Nondimensionalizing all length scales by the dimensional surf zone width,  $x_B$ , (dimensional variables will be denoted by lower case letters), the following dimensionless variables (denoted by upper case letters) are introduced:

$$A = \alpha_d / \sqrt{x_B} \quad (8a)$$

$$B = b/x_B \quad (8b)$$

$$D(x) = d(x)/x_B \quad (8c)$$

$$H(x) = h(x)/x_B \quad (8d)$$

$$X = x/x_B \quad (8e)$$

$$X_o = x_o/x_B \quad (8f)$$

$$S_d = b/d(b) \quad (8g)$$

which gives the dimensionless total water depth profile as

$$D(x) = \begin{cases} S_d X & ; X < B & (9a) \\ A(X-X_o)^{1/2} & ; X > B & (9b) \end{cases}$$

Equation of Motion

The dimensional longshore depth- and time-averaged equation of motion given by Liu and Mei (1974) reduces to

$$-\frac{d}{dx} s_{xy} + \tau_{by} + \frac{d}{dx} [\mu_e d \frac{d}{dx} v] = 0 \tag{10}$$

where  $\mu_e$  is the turbulent eddy viscosity coefficient;  $\tau_{by}$  is the longshore component of bottom stress;  $v$  is the depth- and time-averaged longshore current component; and  $s_{xy}$  is the onshore-longshore component of the radiation stress tensor given by linear wave theory as

$$s_{xy} = -0.5 \rho g a^2 n \sin \theta \cos \theta \tag{11a}$$

$$n = 0.5 (1 + 2kh/\sinh 2kh) \tag{11b}$$

where  $\theta$  is the local angle of wave incidence (vide, Fig. 1).

The gradient of the onshore-longshore component of radiation stress may be approximated by

$$\frac{d}{dx} \{s_{xy}\} = \begin{cases} -\frac{5}{16} \rho g \kappa^2 \frac{\sin \theta_B}{\sqrt{d_B}} d^{1/2} \frac{d}{dx} \{d\} & ; x < x_B & (12a) \\ 0 & ; x > x_B & (12b) \end{cases}$$

where  $\rho$  is the fluid mass density;  $g$  is the gravitational constant; and  $\theta_B$  is the local angle of wave incidence at the breaker line.

The bottom shear stress is approximated by

$$\tau_{by} = -\frac{C_f}{\pi} \kappa \rho \sqrt{gd} v \tag{13}$$

where  $C_f$  is an empirically determined friction coefficient of the order of 0.01. The turbulent eddy viscosity coefficient is assumed to vary linearly with the horizontal distance offshore (McDougal and Hudspeth, 1984) according to

$$\mu_e = N \rho x \sqrt{gd} \tag{14}$$

in which  $N$  = a numerical constant. Substituting Eqs. (12) - (14) into Eq. (10) yields

$$\frac{N\pi}{\kappa C_f} \frac{d}{dx} \left\{ d^{5/2} \frac{dv}{dx} \right\} - d^{1/2} v = \begin{cases} -\frac{5}{16} \frac{\kappa\pi d^{3/2}}{C_f} \sin\theta_B \left(\frac{g}{d_B}\right)^{1/2} \frac{d}{dx}\{d\} & ; x < x_B \\ 0 & ; x > x_B \end{cases} \quad \begin{matrix} (15a) \\ (15b) \end{matrix}$$

Nondimensionalizing Eqs. (15) by the following dimensionless variables

$$S_B = d_B/x_B \quad (16a)$$

$$V = v/v_B \quad (16b)$$

where the component of the planar beach longshore current at the breaker line with no mixing is given by (Longuet-Higgins, 1970a)

$$V_B = \frac{5}{16} \frac{\kappa\pi}{C_f} \sin\theta_B \sqrt{gd_B} s_B \quad (16c)$$

reduces Eqs. (15) to

$$\frac{\pi N}{\kappa C_f} \frac{d}{dX} \left\{ D^{3/2} \frac{dV}{dX} \right\} - D^{1/2} V = \begin{cases} -\Delta D^{3/2} \frac{dD}{dX} & ; X < 1 \\ 0 & ; X > 1 \end{cases} \quad \begin{matrix} (17a) \\ (17b) \end{matrix}$$

where

$$\Delta = (x_B/d_B)^2 \quad (17c)$$

Equations (17) may be further expanded for each of the two beach profiles by substituting for the total water depth,  $D(X)$ , using Eqs. (9).

Planar Beach Solutions. The dynamic equations of motion for the longshore current may be obtained from Eqs. (17) by substituting Eq. (9a) to obtain

$$P_P \frac{d}{dX} \left\{ X^{5/2} \frac{dV}{dX} \right\} - X^{1/2} V = \begin{cases} -G_P X^{3/2} & ; X < 1 \\ 0 & ; X > 1 \end{cases} \quad \begin{matrix} (18a) \\ (18b) \end{matrix}$$

where the nondimensional strength of lateral mixing on a planar beach is defined by

$$P_p = \frac{\pi N S_B^2}{\kappa C_f} \tag{18c}$$

and

$$G_p = \begin{cases} B \frac{1}{(2-B)} & ; B < 1 \\ 1 & ; B > 1 \end{cases} \tag{19a}$$

$$\tag{19b}$$

The solutions to Eqs. (18) are (Longuet-Higgins, 1970a)

$$V = \begin{cases} C_{11} X^{m_1} + C_{12} X^{m_2} + \xi G_p X & ; X < 1 \\ C_{21} X^{m_1} + C_{22} X^{m_2} & ; X > 1 \end{cases} \tag{20a}$$

$$\tag{20b}$$

where

$$\xi = \frac{2}{2-5P_p} \tag{20c}$$

$$m_{1,2} = -\frac{3}{4} \pm \left( \frac{9}{16} + \frac{1}{P_p} \right)^{1/2} \tag{20d}$$

provided that  $P_p \neq 0.4$ .

Non-planar Beach Solutions. The dynamic equations of motion for the longshore component of current may be obtained from Eqs. (17) by substituting Eq. (9b) according to

$$P_{np} \frac{d}{dx} \left\{ \chi^{5/4} \frac{dV}{dx} \right\} - \chi^{1/4} V = \begin{cases} -\frac{G_{np}}{2} \chi^{1/4} & ; \chi < 1 - X_0 \\ 0 & ; \chi > 1 - X_0 \end{cases} \tag{21a}$$

$$\tag{21b}$$

where  $\chi = (x-x_0)$  and the nondimensional strength of lateral mixing on a non-planar beach is defined by

$$P_{np} = \frac{\pi N A^2}{\kappa C_f} \tag{21c}$$

and

$$G_{np} = \begin{cases} \frac{2}{2-B} & ; B < 1 \\ 2B & ; B > 1 \end{cases} \tag{22a}$$

$$\tag{22b}$$

p. 152) having solutions given by

$$v = \begin{cases} a_{11}\phi_1(Z) + a_{12}\phi_2(Z) + 0.5G_{np} & ; X < 1 & (23a) \\ a_{22}\phi_1(Z) & ; X > 1 & (23b) \end{cases}$$

where

$$\phi_1(Z) = Z^{-1/8} I_{1/4}(\gamma Z^{1/2}) \quad (23c)$$

$$\phi_2(Z) = Z^{-1/8} K_{1/4}(\gamma Z^{1/2}) \quad (23d)$$

$$Z = X - B/2 \quad (23e)$$

$$\gamma = \frac{2}{\sqrt{P}_{np}} \quad (23f)$$

Evaluation of the longshore component of velocity,  $v$ , on a Dean beach requires solving Eqs. (18) for the planar nearshore component when  $X < B$  and Eqs. (21) for the non-planar offshore component when  $X > B$ . Since both Eqs. (18) and (21) are of second-order, continuity of the magnitude and the slope of the current will be required at  $X = B$  in order to quantify these unknown constants of integration. In order to evaluate the effect of the location of the intersection of the planar and non-planar profiles at  $X = B$ , the unknown constants of integration in Eqs. (20) and (23) will be determined for each of the three separate locations; viz. 1) inside the breaker line ( $B < 1$ ); 2) at the breaker line ( $B = 1$ ); and 3) outside the breaker line ( $B > 1$ ). The matching conditions to be used at the intersection of the two profiles are: 1) continuity of longshore current magnitudes

$$V_{<} = V_{>} ; X = B \quad (24a)$$

and 2) continuity of the gradient of the longshore currents

$$\frac{d}{dX} V_{<} = \frac{d}{dX} V_{>} ; X = B \quad (24b)$$

where  $V_{<}$  is the current for  $X < B$  and  $V_{>}$  is the current for  $X > B$ .

B < 1 Solutions. When the profile intersection is located inside the breaker line,  $B < 1$ , the solutions are given by

$$v = \begin{cases} C_{11} X^m + \xi G_p X & ; X < B & (25a) \\ a_{11}\phi_1(Z) + a_{12}\phi_2(Z) + G_{np}/2 & ; B < X < 1 & (25b) \\ a_{22}\phi_2(Z) & ; X > 1 & (25c) \end{cases}$$

where  $Z$  is defined by Eq. (23e) and

$$a_{11} = G_{np} Z^{3/2} \phi_3(\zeta) \quad ; \quad \zeta = 1 - B/2 \quad (26a)$$

$$a_{12} = \frac{a_{11} [m_1 \phi_1(\zeta) - B \phi_4(\zeta)] - \xi G_p B^{(m_1-1)} + 0.5 m_1 G_{np}}{B \phi_3(\zeta) - m_1 \phi_2(\zeta)} \quad ; \quad \zeta = B/2 \quad (26b)$$

$$a_{22} = \frac{a_{11} \phi_1(\zeta) + 0.5 G_{np}}{\phi_2(\zeta)} + a_{12} \quad ; \quad \zeta = 1 - B/2 \quad (26c)$$

$$C_{11} = B^{-m_1} [a_{11} \phi_1(\zeta) + a_{12} \phi_1(\zeta) + 0.5 G_{np} - \xi G_p B] \quad ; \quad \zeta = B/2 \quad (26d)$$

$$\phi_3(\zeta) = -\frac{\zeta^{-9/8}}{4} [K_{1/4}(\gamma \zeta^{1/2}) + 2\gamma \zeta^{1/2} K_{-3/4}(\gamma \zeta^{1/2})] \quad (26e)$$

$$\phi_4(\zeta) = -\frac{\zeta^{-9/8}}{4} [I_{1/4}(\gamma \zeta^{1/2}) - 2\gamma \zeta^{1/2} I_{-3/4}(\gamma \zeta^{1/2})] \quad (26f)$$

**B = 1 Solutions.** When the location of the profile intersection coincides with the location of the breaker line,  $B = 1$ , the solutions are given by

$$v = \begin{cases} C_{11} X^{m_1} + \xi G_p X & ; X < 1 \quad (27a) \\ a_{22} \phi_2(Z) & ; X > 1 \quad (24b) \end{cases}$$

where  $Z$  is defined by Eq. (23e) and

$$a_{22} = \frac{(m_1-1) \xi G_p}{m_1 \phi_2(\zeta) - \phi_3(\zeta)} \quad ; \quad \zeta = 1 - B/2 \quad (28a)$$

$$C_{11} = a_{22} \phi_2(\zeta) - \xi G_p \quad ; \quad \zeta = 1 - B/2 \quad (28b)$$

**B > 1 Solutions.** When the profile intersection is located outside the breaker,  $B > 1$ , the solutions are given by

$$v = \begin{cases} C_{11} X^{m_1} + \xi G_p X & ; X < 1 < B \quad (29a) \\ C_{21} X^{m_1} + C_{22} X^{m_2} & ; 1 < X < B \quad (29b) \\ a_{22} \phi_2(Z) & ; X > B > 1 \quad (29c) \end{cases}$$

where  $Z$  is defined by Eq. (23e) and

$$C_{22} = \frac{(m_1 - 1) \xi G_p}{m_1 - m_2} \tag{30a}$$

$$C_{21} = \frac{C_{22} [m_2 \phi_2(\zeta) - B \phi_3(\zeta)] B^{(m_2 - m_1)}}{B \phi_3(\zeta) - m_1 \phi_2(\zeta)} \quad ; \quad \zeta = B/2 \tag{30b}$$

$$C_{11} = C_{21} + C_{22} - \xi G_p \tag{30c}$$

$$C_{22} = \frac{C_{21} B^{m_1} + C_{22} B^{m_2}}{\phi_2(\zeta)} \quad ; \quad \zeta = B/2 \tag{30d}$$

Figures 2 and 3 demonstrate the effects of the offshore distance to the profile intersection  $X = B$ , on the longshore current profile,  $V$ , for mixing strengths  $P_p = P_{np}$  equal to 0.1 and 1.0, respectively. Two longshore current profiles are shown for  $B < 1.0$  (viz.  $B = 0.1$  and  $0.5$ ) and one profile each for  $B = 1$  and for  $B > 1$  (viz.  $B = 1.95$ ). These profiles demonstrate that the magnitude of the longshore current profile decreases with increasing magnitude of the dimensionless mixing strength parameter  $P_p$  [cf. Eq. (18c)] for planar beaches and  $P_{np}$  [cf. Eq. (21c)] for non-planar beaches. The horizontal offshore distance,  $X$ , to the maximum longshore current decreases with decreasing values of the horizontal distance to the profile intersection,  $B$ , for  $B < 1$ . However, the magnitude of the maximum longshore current increases with increasing values of the horizontal distance to the profile intersection,  $B$ , for  $B < 0.8$ . The magnitudes then decrease with increasing values of  $B$  for  $0.8 < B < 1.0$ .

Fig. 2 Effect of profile intersection,  $B$ , on the longshore current profile,  $V$  ( $P_p = P_{np} = 0.1$ ).

Fig. 3 Effect of profile intersection,  $B$ , on the longshore current profile,  $V$   $\{P_p = P_{np} = 1.0\}$ .

Figure 4 demonstrates the effect of the location of the profile intersection,  $B$ , on the magnitude of the maximum longshore component of velocity,  $V_{max}$ , for two values of the dimensionless mixing strength parameters.

Fig. 4 Effect of profile intersection,  $B$ , on the maximum magnitude of the longshore current,  $V_{max}$ .

### Energetics Sediment Transport Models

The magnitude of the longshore current is required for the evaluation of the longshore transport of sand. Since the current profiles for the Dean beach profiles differ significantly from those predicted analytically for planar beaches, the corresponding sediment transport profiles should also be expected to differ. The longshore transport profiles of sand are developed using the following two energetics-based transport models: (1) the Bagnold-type model (Bagnold, 1963) which has been widely used in surf zone applications (cf. Inman and Bagnold, 1963; Komar and Inman, 1970; Komar, 1971, 1975, 1977; Thornton, 1973; Bowen, 1978; Walton and Chiu, 1979); and (2) an energy-dissipation model based on the total stress exerted on the sand by the mean wave-induced current (cf. Komar, 1971; Bailard and Inman, 1981; McDougal and Hudspeth, 1983b). The energetics stress model has been calibrated with the Bagnold model for a planar beach in which the dimensionless transport rate coefficient,  $K$ , for the Bagnold model has previously been evaluated by Komar (1975).

#### Bagnold Model

Bagnold (1963) proposed a sand transport model which includes both bed load and suspended load. This model assumes that the orbital wave motion mobilizes the beach sand and wave power is then expended maintaining the sand in motion. The presence of a mean current, regardless of how small, transports the sand. The Bagnold immersed-weight transport rate per unit width of surf zone,  $i_1$ , for small angles of wave incidence is (cf. Thornton, 1973):

$$i_1 = K \frac{d}{dx} \left( \frac{1}{2} \rho g a^2 c_g \right) \frac{v}{u_o} \quad (31)$$

in which  $K$  is a dimensionless transport rate coefficient;  $a$  is the local wave amplitude;  $c_g$  is the wave group velocity; and  $u_o$  is the magnitude of the near-bottom orbital wave velocity. Assuming that shallow-water, linear wave conditions exist ( $c_g = \sqrt{gd}$ ) and that the local wave amplitude is proportional to the total water depth,  $d$ , (i.e.,  $2a = \kappa d$ ), the immersed transport rate in the longshore direction shoreward of the breaker line reduces to:

$$i_1 = \frac{5}{8} K \rho g \kappa d v \frac{d}{dx} d \quad ; x < x_B \quad (32)$$

Nondimensionalizing the longshore transport rate by the breaker line sand transport on a planar beach due to the no-mixing longshore current (cf. Longuet-Higgins, 1970a),  $i_{BL1}$ , the dimensionless longshore transport profile is given by:

$$I_1 = \frac{i_1}{i_{BL1}} = \begin{cases} v \frac{D}{D_B} \frac{d}{dX} \left( \frac{D}{D_B} \right) & ; X < 1 & (33a) \\ 0 & ; X > 1 & (33b) \end{cases}$$

in which

$$i_{BL1} = \frac{5}{2} K \frac{\rho g}{\kappa} \frac{a_B^2}{x_B} v_{LH} \tag{33c}$$

$$v = v/v_{LH1} = v/\frac{5}{16} \frac{\pi \kappa}{C_f} s_d \sqrt{gd_B} \sin \theta_B \tag{33d}$$

where  $\pi$  is a numerical constant and  $C_f$  is a dimensionless friction coefficient of order 0.01.

For a planar beach, the Bagnold model sediment transport profile is given by

$$I_1 = \begin{cases} XV & ; X < 1 \tag{34a} \\ 0 & ; X > 1 \tag{34b} \end{cases}$$

For a concave-up  $x^{1/2}$  beach profile, the Bagnold sediment transport model becomes

$$I_1 = \begin{cases} \frac{1}{2} V & ; X < 1 \tag{35a} \\ 0 & ; X > 1 \tag{35b} \end{cases}$$

Figure 5 demonstrates the effect of the dimensionless profile intersection,  $B$ , as the longshore sediment transport rates,  $I_1$ , computed by the Bagnold model for two extreme values of the dimensionless mixing strength parameter  $\{P_p = P_{np} = 0.1 \text{ and } 1.0\}$ .

Fig. 5 Effect of profile intersection,  $B$ , on Bagnold longshore sediment transport rates,  $I_1$ .

Stress Model

Komar (1971) proposed a swash sediment transport model based on the energy dissipation associated with the bottom stress. Bailard and Inman (1981) also developed an energetics stress model using the bottom stress to estimate the time-dependent bedload transport in the surf zone. These models are both Bagnold-type models conceptually; but since the energy dissipation rate or available power for mobilizing sediment is based on the bottom stress, these models are termed stress models. The immersed-weight transport rate per unit width of surf zone,  $i_2$ , for the stress model for small angles of incidence is (cf. McDougal and Hudspeth, 1983a)

$$i_2 = c_5 \rho |u_o| v^2 \sin\theta \quad (36a)$$

in which  $c_5$  is a constant for a given sediment and

$$u_o = a \frac{k}{\omega} \operatorname{sech}(kd) (\hat{i} + \sin\theta \hat{j}) \quad (36b)$$

in which  $\omega$  = the radian wave frequency.

Note that in Eq. (36a), no shallow-water wave assumptions have been invoked and no restrictions have been placed on the mechanism which generates the longshore current. This model may be used for high wind- or tide-induced flows as well as for wave-induced long-shore currents.

As in Eqs. (33), the transport rate is nondimensionalized by the transport rate at the breaker line from a stress model on a plane beach using the no-mixing velocity determined by Longuet-Higgins (1970a). The dimensionless transport,  $I_2$ , is given by

$$I_2 = \frac{\sin\theta}{\sin\theta_B} \frac{u_o}{u_{oB}} v^2 \quad (37a)$$

in which

$$I_2 = i_2/i_{BL2} = i_2 / (c_5 \rho |u_{oB}| v_{LH}^2 \sin\theta_B) \quad (37b)$$

Employing Snell's law for refraction, the transport rate reduces to

$$I_2 = \frac{a}{a_B} v^2 \quad (38)$$

in which the hyperbolic cosines have been approximated by unity in the surf zone. This transport relationship applies for any type of beach profile and mean current.

Komar (1975) has determined the transport coefficient for the Bagnold model on a planar beach by comparison with observed total transports. The total transport is defined by

$$I_T = \int_0^{\infty} I \, dX \quad (39)$$

The stress model is calibrated by equating the total transport on a planar beach with that for the calibrated Bagnold model. This yields a dimensionless transport coefficient for the stress model,  $R$ ,

which is a function of the lateral turbulent mixing strength parameter,  $P_p$ .

Figure 6 demonstrates the dependence of the dimensionless transport rate coefficient on the dimensionless mixing strength parameter.

Fig. 6 Dimensionless stress transport rate coefficient calibrated with a Bagnold transport rate for a planar beach.

The longshore transport rate given by the stress model for a planar beach (including the calibration coefficient) is

$$I_2 = \begin{cases} \hat{R} X V^2 & ; X < 1 & (40a) \\ \hat{R} V^2 & ; X > 1 & (40b) \end{cases}$$

The longshore transport rate given by the stress model for a concave-up beach is

$$I_2 = \begin{cases} \hat{R} X^{1/2} V^2 & ; X < 1 & (41a) \\ \hat{R} V^2 & ; X > 1 & (41b) \end{cases}$$

Figure 7 demonstrates the effect of dimensionless profile intersection,  $B$ , on the longshore sediment transport rates,  $I_2$ , computed by a stress model for two extreme values of the dimensionless mixing strength parameters.

Fig. 7 Effect of profile intersection,  $B$ , on stress-type longshore sediment transport rates,  $I_2$ .

### Conclusions

Dimensionless longshore current profiles,  $V$ , on equilibrium Dean beach profiles depend on both the location of the dimensionless horizontal distance offshore to the profile intersection,  $B$ , and the dimensionless mixing strength parameters,  $P_n$  and  $P_{np}$ . The maximum dimensionless longshore current,  $V_{max}$ , occurs near a value of  $B = 0.8$ . The dimensionless longshore current profiles,  $V$ , are essentially independent of  $B$  for  $B > 1$ . The longshore current,  $V$ , decreases with increasing values of dimensionless mixing strength,  $P$ . The effect of the dimensionless profile intersection,  $B$ , and mixing strength parameter,  $P$ , is similar for both Bagnold and stress type longshore sediment transport rates.

## CHAPTER ONE HUNDRED TWO

### TIME SCALES OF NEARSHORE PROFILE CHANGES

William A. Birkemeier, A. M. ASCE\*

**Abstract:** Time scales of nearshore profile change are examined using a unique set of highly accurate surveys collected over a 3½ year period at CERC's Field Research Facility. The data are analyzed in terms of the formation and movement of the nearshore bars and with empirical eigenfunctions. The largest and most rapid changes in the profiles occurred during storms. The inner bar (depth of -0.6 to 1.5 m, 1.6 to 4.5 ft) moved offshore during even minor storms and recovered relatively quickly. The outer bar (depth of 3 to 4 m, 9 to 13 ft) formed during the largest storms and recovery was considerably slower, requiring six months or longer. The eigenvector analysis confirmed the importance of storms but identified a seasonal shift of material from the beach and inner bar to the offshore.

#### Introduction

Though it is well known that beach and nearshore changes occur rapidly during storms, and that post-storm recovery occurs more slowly, there is a general lack of field data, particularly from the nearshore zone, to quantify these processes. The objective of this paper is to examine the magnitude and temporal scales of profile change using over three years of highly accurate repetitive nearshore surveys (out to a depth of 8 m, 26 ft, MSL) collected at the Field Research Facility (FRF) of the U. S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center (CERC). The FRF is located on the Atlantic Ocean in Duck, North Carolina (Figure 1) and is described in detail by Birkemeier, et al (4).

#### Field Data

The survey data were collected using the Coastal Research Amphibious Buggy (CRAB), a motorized, 3-wheeled tripod capable of operating to depths of 9 m (30 ft) and in waves up to 2 m (6.4 ft). During the first six months of surveys, which began in January 1981, the position and elevation of the CRAB were determined using a level to read a 12.3 m (40 ft) high stadia board. All surveys subsequent to June 1981 were conducted using a Zeiss Elta-2s Electronic Total Station. The combined CRAB-Zeiss system (5) is unique because it permits highly accurate surveying of the zone of greatest profile activity. The data set includes over 105 surveys each of profile lines 62 and 188, which are located approximately 500 m (1650 ft) on either side of the FRF

---

Figure 1. Location of the Field Research Facility

research pier (Figure 2). Based on monthly surveys of the bathymetry around the pier, these lines are located in a region of shore parallel offshore contours and are sufficiently removed from known pier effects (8). Surveys were generally conducted biweekly and after storms, with actual survey intervals varying from 1 to 44 days. The data provide a detailed record of profile evolution including periods of erosion, recovery and stability. The profile lines are characterized by a beach of poorly sorted, coarse-to-medium size sand and a nearshore zone composed of better sorted medium-to-fine sand. Table 1 summarizes general profile characteristics.

TABLE 1.-Profile Characteristics

Dune Height -	6 to 7 m (20 to 22 ft)
Beach Width -	20 to 45 m (65 to 148 ft)
Foreshore Slope -	1:12.5
Offshore Slope (based on 7.5 to 8 m contours) -	1:164
Maximum Shoreline Variation -	25 m (80 ft)
Maximum Volume Variation -	235 m <sup>3</sup> /m (93.7 yd <sup>3</sup> /ft) of beach

For the purposes of this report, the shoreline is defined as the distance to the mean sea level (MSL) intercept and profile volume changes are computed as cross-sectional changes multiplied by a unit width (1 m or 1 ft) of beach. The volume change given in Table 1 is the cumulative net volume change computed between successive surveys over the entire profile length (900 m, 3000 ft). All of the surveys of

Figure 2. Location of study profile lines

line 188 are overplotted in Figure 3. As can be seen by the plot of maximum vertical change shown in the upper half of Figure 3, most profile activity is restricted to depths less than 7 m (23 ft) with little measurable vertical variation at deeper depths (only 15 cm, .5 ft, maximum variation at 8 m, 26 ft, depth). Because of this tendency for the surveys to "close out" near their offshore terminus, most of the overall volume variation given in Table 1 is attributed to longshore movement of material onto and off of the profiles.

#### Field Observations

Although changes occurred in both cross-shore and longshore directions, this study concentrates only on cross-shore changes resulting from the movement of material between the beach and nearshore; and the formation, movement, and disappearance of bar/trough features. The lack of detailed longshore data is important since rhythmic bar/trough and beach features frequently occur in the study area and undoubtedly affect the profile data and their interpretation. Mason, et al (7) address the formation and rapid movement of a rhythmic inner bar monitored during a detailed nearshore experiment, DUCK82, conducted around profile line 62.

Figure 3. Envelope of 155 surveys of profile line 188 collected between January 20, 1981 and July 27, 1984

Profile changes at the study site occur at time scales ranging from swash periods (6) to annual cycles and longer. Time scales resolvable with the present data vary between a few days and one to two years. Though the profiles have varied in configuration from nearly unbarred to triple barred, they typically exhibit a double bar configuration with a narrow inner bar and a wide outer bar. Figure 4 illustrates five configurations. Most significantly, after 3.5 years the profile configurations have begun to repeat themselves. Though the reoccurrence of nearly similar profile shapes, such as those shown in Figure 5 taken nearly three years apart, is rare, the fact that they reoccur at all is most intriguing.

One of the best indicators of profile configuration and activity is the location and horizontal movement of the bar crest. Large changes to the profile, in terms of volume movements, always resulted in significant bar movement. Bar crest depth, though important, was less useful as an indicator of activity, since large bar movements occurred with little or no change in crest depth.

Figure 6 traces the time history of the shoreline and bar crest positions for both profile lines. This figure shows three major features of the data including: the relative stability of the shoreline, the formation and frequent oscillations of the inner bar, and the long period oscillations of the outer bar. Though the outer bar position has an apparent offshore trend superimposed on a seasonal-like oscillation, it is believed that this is actually the result of storm erosion/recovery sequences at varying time periods of one to two years. The

Figure 4. Typical profile configurations for profile line 62

development and slow movement of the outer bar can be better visualized with Figure 7 which is a perspective view of the data shown in Figure 3.

Minor storms affected the inner bar causing it to move offshore, while larger storms produced major changes in configuration, moving both bars offshore, and depositing sand in deeper water. Storm changes were rapid, occurring over periods of one to five days. Onshore bar movement which occurred during periods of low waves was also found to be post-storm related. The speed and amount of recovery which occurred

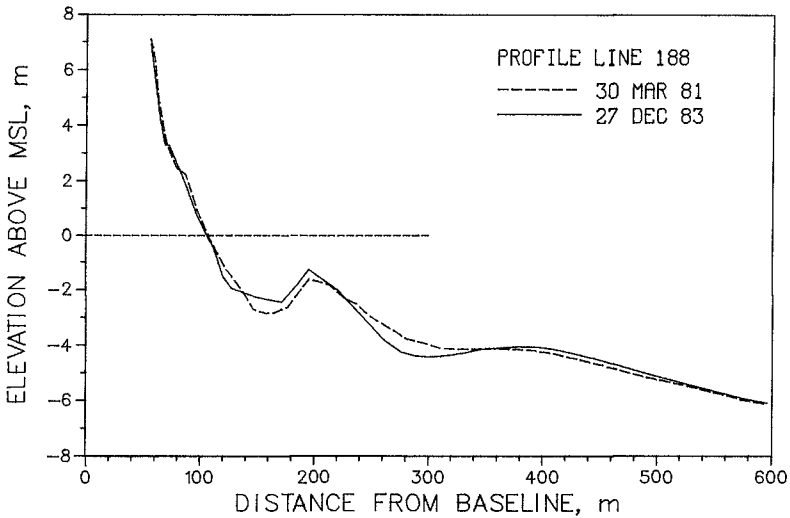

Figure 5. Similar profile shapes for surveys nearly three years apart at profile line 188

Figure 6. Variation in shoreline and bar crest positions

Figure 7. Perspective view of profile line 188 through time

were affected by the wave conditions and by the post-storm configuration of the profiles. All bar features tended to disappear during extended periods of low wave conditions (six months or longer).

An example of the rapid modifications caused by storms is shown in Figure 8. The surveys bracket a series of three storms with the final and most severe storm occurring November 13-15, 1981. This sequence of storms shifted the bar crest 165 m (540 ft) offshore and ultimately caused the profile to change from single to double barred. The November 13-15 storm, which produced 3.5 m (11.5 ft) waves and the highest water level of the study (1.6 m above MSL), also caused the greatest profile changes of the study, resulting in a major rearrangement of the nearshore zone. During this three-day event, the bar shifted 90 m (295 ft) offshore, at a rate that probably exceeded 30 m/da (100 ft/da), with  $150 \text{ m}^3/\text{m}$  ( $60 \text{ yd}^3/\text{ft}$ ) of material moving offshore. Interestingly, the two profile lines never returned to the same single bar configuration that existed prior to the November storm.

In contrast, the slow recovery from the changes caused by the Fall 1981 storms occurred during six months of relatively calm conditions from February to August, 1982 (Figure 9). During this period, the outer bar migrated onshore a distance of 85 m (280 ft) at an average rate of 0.47 m/da (1.5 ft/da). Depth over the bar remained nearly constant at -3.3 m (-10.8 ft) with a total shift of material of approximately  $100 \text{ m}^3/\text{m}$  ( $40 \text{ yd}^3/\text{ft}$ ). The configuration of the profile at the

Figure 8. Rapid offshore movement of sediment resulting from three Fall 1981 storms

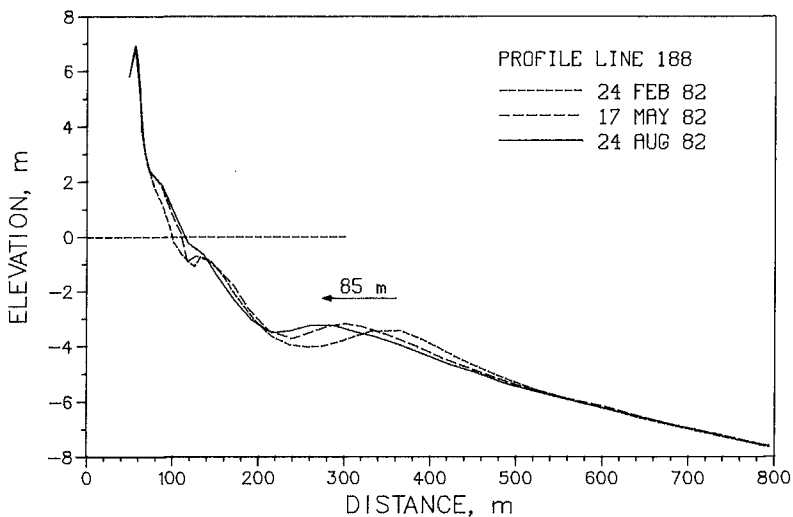

Figure 9. Slow onshore migration of the outer bar during a six month period of low wave conditions

end of the period was reflective, as defined by Wright, et al (12), with no inner bar and only a minor outer bar.

A different cross-shore sequence occurred in 1983. As shown in Figure 6, offshore movement during the fall reoccurred in 1982, but, from October 1982 to March 1983, the outer bar moved farther offshore into deeper water (-4.2 m, -13.8 ft). Though no single storm during this period exceeded the intensity of the November, 1981 storm, there were over 11 minor storms, 5 with significant wave heights in excess of 3 m (10 ft). Onshore movement of the outer bar from this deeper depth did not occur until late fall of 1983 and continued through the end of the study period in July 1984 when the outer bar nearly disappeared.

It is important to note that the observed patterns of bar formation and offshore movement always occur well within the surf zone. For example, the surf zone during the November, 1981 storm extended more than 250 m (820 ft) seaward of the post-storm outer bar position (approximately 600 m, 1970 ft, from the survey baseline, Figure 9). Based on results from DUCK82 (9) and work by Short (10), and others, bar position at these distances from the shoreline is not a function of incident wave periods but of long period, infragravity waves (0.5 to 5 min) with bars forming at either the nodes or antinodes of the infragravity wave.

Onshore movement of the outer bar, in the study area, occurred only when the bar was seaward of the surf zone. This rule does not necessarily hold for the shallow inner bar, as onshore movement of 1.2 m/hr (3.9 ft/hr) has been recorded near line 62 in October 1982 during a storm when the bar was well within the surf zone and waves were 2 m (6.4 ft) high with a 14 sec period.

#### Eigenvector Analysis

One technique which has found recent popularity in analyzing variation in profile shape is that of empirical eigenfunctions. In simplified terms, this statistical procedure separates the variation in a rectangular matrix of data into two sets of orthogonal functions. For the present data, one function (the set of eigenvectors) is spatially dependent, while the other (the eigenvector weightings) is dependent only on time. By requiring each successively higher eigenvector to explain, in a least squares sense, the variance remaining in the data set, only a few eigenvectors are required to explain a high percentage of the variation. Random noise in the data which is uncorrelated with the data set as a whole is filtered out to higher order eigenvectors. Since only a few vectors are usually required to reconstruct the original data, the results of the analysis provides a compact representation of the original data. The procedure is similar, and often compared, to fourier analysis where data are separated into linear combinations of sines and cosines. However, the eigenvector analysis does not assume, a priori, any functional shape.

Detailed discussions of the eigenvector analysis procedure are given by Aubrey (1,3), and by Vincent and Resio (11). Aubrey used the technique to parameterize beach and nearshore profile data and different

wave-based variables. Vincent and Resio used a slightly different procedure to parameterize wave spectra. This study uses the procedure of Vincent and Resio where the eigenvectors are derived from a covariance matrix which is based on departures from the mean.

Though the eigenvector technique has been used by many different investigators to analyze nearshore profile data, it does have a number of significant limitations. First, since it is a statistical technique, the different vectors (modes of variation) do not necessarily have any physical significance, though it may be possible to attribute significance to them. For instance, Aubrey (2) found that his second eigenvector was related to seasonal sediment exchange between the nearshore bar and the beach berm. Secondly, the analysis assumes that every survey is equally spaced in time and that all cases are equally weighted, an assumption that is not usually the case with field data, including the present data set. Finally, when analyzing data from a single profile line, the eigenfunction analysis does not separate cross-shore effects from longshore effects.

Even with these limitations, an eigenvector analysis can be a powerful aid in identifying and parameterizing the major spatial and time dependent variations in a particular data set. The rectangular matrix in our case is an M by N matrix of depths, at 37 specific distances (N) along profile line 188 and for each of 115 surveys (M). The actual survey data were digitized at 17 m (55.77 ft) intervals from a distance of 70 m (229.7 ft) on the profile out to 682 m (2237.5 ft). This offshore limit was chosen because it contains most of the variation (see Figure 4) and because most of the surveys extend at least this far. Surveys which did not reach this limit were either deleted or extended using averaged data from the prior and following surveys. Data extensions were usually less than 100 m (300 ft).

Table 2 summarizes the variance explained by the first five eigenvectors which together account for 91.4 per cent of the variance in the data set. Eigenvectors 1 and 2 explain nearly equal amounts of variance suggesting that there are two basic profile configurations in the data set (in fact, these two eigenvectors are reversed on profile line 62).

TABLE 2.-Variance explained by first 5 eigenvectors

<u>Vector</u>	<u>Variance Explained</u> (per cent)	<u>Cumulative Variance</u> (per cent)
1	37.6	37.6
2	27.2	64.8
3	13.3	78.1
4	10.0	88.1
5	3.3	91.4

The results of the analysis are shown in Figures 10 and 11, which plot the eigenvectors and temporal weightings, respectively. These figures are most easily interpreted by first determining the effect of positive and negative weightings on the different eigenvectors when

Figure 10. First 3 eigenvectors for profile line 188

combined with the mean profile, and then examining the temporal weightings for any significant trends. To determine the effect of a particular vector, multiply the amplitude of the vector at a particular distance on the profile by the weighting on that vector for a particular survey and add the result (which is in meters) to the mean depth at that distance. This has been graphically done for the first three eigenvectors in Figure 12, which shows the mean profile shape and the effect of positive and negative weightings.

From Figures 10 and 12, it can be seen that eigenvector 1 describes the change of the profile from a single bar configuration (when positively weighted) to a double bar shape (when negatively weighted) with a well-defined outer bar and an inner bar just seaward of the shoreline. By examining the weightings on the first eigenvector (Figure 11), vector 1 is of greatest importance (highest and most consistent weightings) during early 1981 and following the November, 1981 storm. This vector then accounts for the shift in profile configuration shown in Figure 8 and describes the relative stability of the profile following the Fall 1981 storms.

When negatively weighted, eigenvector 2 also describes a double bar configuration but the resulting shape is different than that described by vector 1. Both the inner and outer bars are farther offshore (Figure 12). From Figure 11, it can be seen that the weightings on the second vector are positive in early 1981 and negative in 1983. In fact, the second vector has a very low weighting during 1982 when the weighting on the first vector is high. Eigenvector 2 is of greatest importance from October, 1982 to March, 1983, the period corresponding to

Figure 11. Temporal weightings on the first 3 eigenvectors for profile line 188

the second sequence of offshore movement of the outer bar described earlier.

Together, eigenvectors 1 and 2 describe the major cross-shore movements on the profile. Rather than being seasonally controlled, they appear to result from two unique sequences of storm/recovery activity.

Though the third eigenvector explains only 1/2 of the variance explained by vector 2, its weightings have the most well-defined annual cycle, having a negative peak every year around January and February. From Figure 12, the third eigenvector describes a shift of sediment

Figure 12. Effect of the first 3 eigenvectors on the mean profile using a unit weighting

from the beach and nearshore to the offshore (feeding the outer bar) when the weightings change from positive (summer) to negative (winter). The material shifts around a point 308 m (1010 ft) from the baseline at a mean depth of 3.9 m (12.8 ft). While this is a node for the third vector, both eigenvectors 1 and 2 have antinodes near this distance.

#### Summary

This paper uses a unique set of field data to examine the cross-shore movement of sediment. Rapid and major changes to profile shape occurred during significant storms and generally stormy periods. Minor storms caused changes only to the inner bar. The post storm recovery

of the outer bar required in excess of six months of relatively low wave conditions. An eigenvector analysis of the data confirmed these findings. The first two eigenvectors, which combined account for 64.8 per cent of the variance, were attributed primarily to two different double bar configurations which resulted from storm sequences in 1981 and 1982-1983. The third vector accounted for a well-defined annual cross-shore shift of material.

The rate and quantity of material moved has implications for: the frequency and coverage of nearshore surveys, the siting of instruments, and the design of shore perpendicular structures including cable crossings and ocean outfalls. In addition, study results indicate that in order to nourish a beach, fill material must be placed in water depths less than 2 to 3 m (6 to 10 ft), the region of the inner bar, and that the timing of the placement is critical. Placement of material prior to a period of storms will result in offshore movement.

#### Acknowledgments

The data used for this study resulted from the combined efforts of the small but dedicated staff of the Field Research Facility and their tireless hours spent, under usually less than ideal conditions, collecting and processing the data. Results presented herein, unless otherwise noted, are based on research conducted at the Coastal Engineering Research Center, Waterways Experiment Station, under the Shore Protection and Restoration Program, Coastal Engineering Functional Area, Civil Works Research and Development, U. S. Army Corps of Engineers. Permission to publish this information was granted by the Chief of Engineers.

## CHAPTER ONE HUNDRED THREE

### BEACH RESPONSE TO COASTAL WORKS

#### GOLD COAST, AUSTRALIA

H.V. Macdonald\* and D.C. Patterson\*

#### ABSTRACT

The paper outlines the results of comprehensive beach surveys carried out over more than 20 years showing the effects of seawalls, groynes and beach nourishment on the beaches of the beach resort city of Gold Coast, Australia. Beach profile changes and, in particular, quantification of the overall extent of accretion and erosion resulting from groynes which interrupt the longshore movement of sand are outlined. The paper confirms the already known principles of behaviour of these coastal works and documents clearly the full detrimental impact that inappropriate structures can have on a natural sand beach system.

#### 1.0 INTRODUCTION

The city of Gold Coast, one of Australia's richest and most popular tourist centres, extends in a relatively narrow strip along 30 kilometres of predominantly sandy coastline immediately north from Queensland's state border (Figure 1). The city is an amalgamation of several townships originally settled early this century as resorts where the climate, beaches and surf conditions were all highly suited to public recreation. Today the city's economy still depends on tourism, which in turn depends on the existence of adequate beaches.

Figure 1(a). General Locality Plan

\*Engineers, Department of Harbours and Marine, G.P.O. Box 2195, Brisbane, Queensland Australia. 4001.

Figure 1(b). Gold Coast City

1.1 Erosion Problems and Coastal Works

Over the years, residential development located close to the beach has increased substantially in extent and value. The threat of damage to this property from beach erosion caused by the effects of cyclones which regularly affect the area has led to the construction of protective rock seawalls along most of the city's foreshore. Initially the problems were the result only of locating the development too close to the sea within the zone of natural beach movements. However, over the past 20 years, these problems have been exacerbated in some areas by groyne structures constructed at various locations along this coastline which experiences a relatively strong longshore sand transport. Some beach replenishment has been carried out in several badly eroded or more popular recreational areas. A summary of the major coastal engineering works carried out in the area is shown in Figure 2.

Figure 2. Summary of Coastal Works, Gold Coast.

## 1.2 Coastal Management

The principal components of investigation and planning for management of Gold Coast beaches are listed below.

- (a) Commencing in 1964, the Queensland State Government collected field data relating to beach processes and in 1968 commissioned the Delft Hydraulics Laboratory, Netherlands to evaluate the data and report on the erosion problems. In 1970 the laboratory presented its report containing detailed recommendations for beach restoration by sand nourishment and other accompanying works.
- (b) In 1968 the Queensland Government passed its Beach Protection Act and established the Beach Protection Authority to investigate and provide advice to local governments on beach erosion problems. In Queensland, financial responsibility for implementing beach restoration works rests essentially with the various local governments including the Gold Coast City Council.
- (c) The Authority and the State Government adopted the Laboratory's recommendations and the Gold Coast City Council was advised accordingly through extensive discussion and through the provisions of the legislation.
- (d) The Authority has continued its programme of wave recording, beach surveys, aerial photography and daily beach readings (COPE) in the Gold Coast area with particular emphasis being given to those areas affected by works carried out from time to time. Recently, the Authority's engineers reassessed the rates of sand transport along the coast based on the extended wave data record. As well, the survey data was used to identify changes to the beach system since 1962 including the effects of coastal works carried out during that time. This information is passed to the Gold Coast City Council to assist in planning and implementation of appropriate beach protection works in accordance with the approved scheme.

## 1.3 Aims and Objectives

The aim of the paper is to document the coastal protection measures used at Gold Coast in terms of their effects on beaches and on property as well as a comparison of the benefits which accrue in the immediate vicinity of the works with the effects on the coastline as a whole. The ultimate objective is that the decisions on works to be implemented at Gold Coast and other beach areas be based on a full and clear understanding of the impact that some works can and have had on the beach system as a whole.

## 2.0 GOLD COAST BEACH PROCESSES

Analyses of the results of beach surveys together with calculations based on the measured wave climate for the area have been used to provide a good understanding of the natural beach processes along the Gold Coast. In the broader view, the Gold Coast beaches form part of an extensive system of longshore moving sand having its origins up to 150 kilometres to the south. The entire supply of sand to the beaches comes from this longshore movement of sand.

### 2.1 Delft Hydraulics Laboratory Report (Reference 2)

The fundamental conclusions of the 1970 report by the Delft Hydraulics Laboratory were -

- (a) onshore/offshore transfers of up to about 400 cubic metres per metre can be expected during and subsequent to severe cyclone erosion events. However there is no net loss of sand from the beach system during this process.
- (b) because development has been located over the former natural dune system, the beaches contain insufficient sand reserves seaward of the development to accommodate severe cyclone erosion events and require restoration by nourishment of 10 - 15 million cubic metres of sand.
- (c) there is a differential in the longshore transport rates along the Gold Coast, leading to a persistent long term erosion of the beaches of 0.3 million cubic metres of sand per year. The Laboratory's assessed longshore transport rates were -
  - (i) Letitia Spit : approx 0.5 million m<sup>3</sup>/year
  - (ii) Kirra area : approx 0.2 million m<sup>3</sup>/year
  - (iii) Nerang River area : approx 0.5 million m<sup>3</sup>/year

It can be seen that there is an assessed corresponding "loss" to deep water of 0.3 million cubic metres per year between Letitia Spit and Kirra. There is no evidence available to support an accumulation of such an amount of sand offshore in this area.

- (d) construction in 1962-64 of training walls at the Tweed River mouth would trap about 4 million cubic metres of sand on Letitia Spit. Because not all of this effect would have passed to the Gold Coast, this groyne effect would result in a loss of 1.7 million cubic metres of sand from the beaches at the southern end of the Gold Coast.

## 2.2 Beach Protection Authority Report (References 1 and 4)

The recent study of longshore transport rates carried out by the Beach Protection Authority of Queensland concluded that -

- (a) there is little or no longshore transport differential along the Gold Coast and, correspondingly, there would be little or no loss of sand to deep water between Letitia Spit and Kirra. The net longshore rate is uniform at approximately 500,000 m<sup>3</sup>/year.
- (b) any significant changes to the beaches over the past 20 years have been the direct result of coastal works. Specifically, essentially all of the sand trapped on Letitia Spit by the Tweed River training walls would have moved northward to the Gold Coast beaches and therefore represents a loss of sand from those beaches.

## 3.0 BEACH RESPONSE TO COASTAL WORKS

Each beach section of the Gold Coast has a different history of coastal management and therefore has responded uniquely to the coastal works affecting it. It is convenient to consider the coast in three broad units based on both geographic and management considerations. These units are-

- (i) Southern Region - Letitia Spit to Currumbin, affected predominantly by the Tweed River training walls and seawalls.

- (ii) Central Region - Currumbin to Burleigh, affected predominantly by groynes and seawalls.
- (iii) Northern Region - Burleigh to Nerang River, with extensive development protected by seawalls and limited beach nourishment.

Each of these three coastal units are discussed separately below.

### 3.1 Southern Region (incorporating Tweed River Training Walls).

The groyne works undertaken in this region are shown in Figure 3 and include the Tweed River training walls (aimed at improving navigation to the river) and groynes at Kirra (aimed at offsetting erosion caused by the training walls). The river mouth was trained originally around 1900, however the strong longshore transport subsequently re-established the entrance bar. The training walls were extended a further 400 metres during 1962-1964 by the New South Wales Government.

The beaches both updrift and downdrift of the river training works have been monitored in detail since 1962, providing a good understanding of the effects of these works. The beach monitoring has included -

- (i) regular aerial photography including low level work used for photogrammetric contouring during 1962 and 1963.

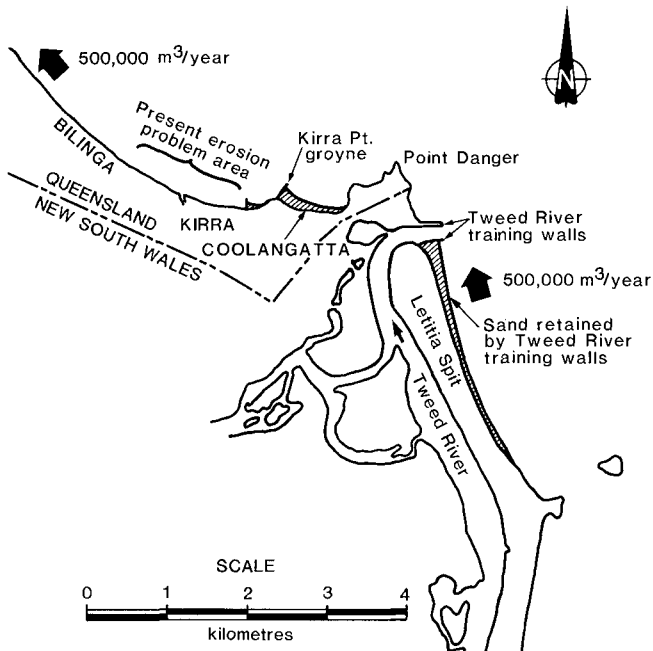

Figure 3. Groyne Works – Southern Gold Coast Region

- (ii) beach and hydrographic surveys by the New South Wales Government (available for 1962 to 1965), the Gold Coast City Council (1984) and the Beach Protection Authority over the period 1964 to 1984.
- (iii) an Authority's COPE station established at Coolangatta in 1982.

**Accretion updrift of Tweed River Training Walls**

To 1983, the coastline immediately south (updrift) of the training walls had accreted by a distance of 250 to 300 metres since wall construction in 1962, with changes to the near-shore profile extending to the 18 metre depth contour (Figure 4). The quantity of accretion varies from a maximum of 4000 m<sup>3</sup>/m near the walls to essentially nil at Fingal about 3 kilometres to the south, totalling 4.8 million cubic metres south of the walls (Figure 5). As well, a new bar has formed across the river entrance, involving the accretion of an additional 1.6 million cubic metres to date.

Figure 4. Accretion Adjacent to Tweed River Training Walls.

Figure 5. Distribution of Accretion Along Letitia Spit.

The time history of total accretion, including that along Letitia Spit and in the new entrance bar, is shown in Figure 6, reaching a total of 6.4 million cubic metres in 1983. The accretion trend indicates that further sand accumulation in this area can be expected, although the rate of such accumulation should decrease as the rate of natural sand bypassing to the Gold Coast beaches increases.

Figure 6. Time History of Updrift Accretion and Downdrift Erosion Resulting From Tweed River Training Walls.

#### Erosion Downdrift of Tweed River Training Walls

The downdrift erosion measured to 1983 extends along about 4.5 kilometres of coastline from Point Danger to Bilinga (Figure 7). The erosion trend indicates that this loss is propagating further downdrift with time. The time history of erosion (Figure 6) indicates a trend similar to that of the updrift accretion, although somewhat (about 10%) less. While this difference may be the result of a minor reduction in the longshore transport capacities between Letitia Spit and the southern Gold Coast beaches, it is considered more likely to be attributable to the limitations of the survey procedures. The measured total downdrift erosion had reached 5.7 million cubic metres by 1983. It should be noted that this quantity, based on the surveyed changes at 21 profile locations, exceeds but is more reliable than the preliminary estimate of 3.5 million cubic metres of erosion outlined in Reference 4 based on only 4 profile locations. This emphasises the need for comprehensive surveys for such analyses.

The measured downdrift erosion has occurred across some 1200 metres width of the nearshore profile, out to depths of about 15 metres (Figures 8 & 9). Sand levels have dropped by up to 5 metres near the beach in the worst eroded area with general erosion by 1 to 2 metres over a broad offshore area in water depths formerly of the order of 5 to 9 metres.

Rock seawalls were constructed at Coolangatta and Kirra to limit the beachline recession there. In 1972 a groyne was constructed at Kirra Point in order to restore Coolangatta's recreational surfing beach (Figure 3).

Figure 7. Distribution of Downdrift Erosion – Point Danger to Bilinga.

Figure 8. Sequence of Surveyed Profiles Updrift of Kirra Point Groyne.

Figure 9. Sequence of Surveyed Profiles Downdrift of Kirra Point Groyne.

### Effects of Kirra Point Groyne

Details of the design and effects of the Kirra Point groyne are outlined in Reference 5 (Robinson & Patterson 1975). The influence of the Kirra Point groyne in accumulating sand extends seawards to about the 6 metre depth contour. Some 300,000 cubic metres of sand have been accumulated on Coolangatta beach above that level. In the deeper parts of the offshore profile unaffected by the groyne, erosion caused by the Tweed River training walls continued progressively (Figure 8) such that there remains an overall net erosion of these profiles (Figure 7).

The trapping of sand by the Kirra Point groyne exacerbated the erosion effects of the Tweed River training walls at Kirra, immediately downdrift, where massive erosion of the beach and dune occurred during storms in 1974. As a result, a rock seawall was destroyed and a camping park area was eroded away as the coastline receded by up to 80 metres. A new seawall was constructed along the new eroded dune alignment to protect roads and facilities.

A second groyne was constructed at Kirra during 1974 (the Miles Street groyne - Figure 3) in an attempt to retain a usable beach in front of the Kirra Surf Lifesavers' Clubhouse. Approximately 1 million cubic metres of sand were pumped from the Tweed River to Kirra Beach to offset the erosion. However, the benefits of this nourishment were temporary because -

- (a) the rate of longshore supply of sand to the nourished area downdrift of the various groyne structures was, at the time, substantially less than the longshore transport capacity which distributed the nourished sand along the coast towards the north.
- (b) the quantity pumped was small in relation to the total quantity eroded in the Kirra area.

*The Tweed River training walls have trapped on Letitia Spit 6.4 million cubic metres of sand that would otherwise have moved northward to the Gold Coast beaches. The construction of groynes at Kirra in an attempt to overcome the resulting beach erosion problem has further interrupted the flow of sand, and has moved the problem area further north.*

- (c) the sand was taken from the zone of beach sand transport within the river which subsequently has progressively infilled with sand from the beaches (Reference 3). Hence the long term benefit to the beaches would be small.

The downdrift beach at North Kirra has never recovered from the combined erosion effects of the training walls and groynes. The sand loss is presently concentrated in this area where erosion of the beach profile by about  $2500 \text{ m}^3/\text{m}$  to 1983 has been surveyed. A rock seawall there is preventing further erosion of roads and property, but at the same time is also preventing the re-establishment of a beach.

### 3.2 Central Region (Currumbin/Palm Beach/Burleigh)

The Currumbin/Palm Beach area is characterised by residential development and associated roadways located close to the beach. At Currumbin, the esplanade road was constructed along the foredune. This road was eroded repeatedly until a rock seawall was constructed to protect it in the 1950's. The frequent lack of a usable beach led to groyne construction connecting Currumbin Rock to the mainland in 1973 (Figure 10).

Palm Beach has experienced long-standing erosion problems largely as a result of residential development being located too close to the beach. Some freehold allotments were originally established on bare areas of dune sand. As a result of periodic dune erosion, rock seawalls have been constructed over the years to protect what remains of the properties. Worsening erosion and the threat of damage to properties led to construction of three groynes over the period 1977 to 1980. A training wall was constructed at Currumbin Creek in 1981 to control the natural cyclical migration of the entrance.

Burleigh Beach extends 2 kilometres between two rocky headlands. A 250 metre long seawall was constructed in 1956 to protect car park and surf lifesaving facilities in the southernmost section. The remaining 1.75 kilometres of esplanade land was left undeveloped, although the natural dunes was levelled after mining for heavy minerals, mown and recreational park facilities installed.

From time to time, sand has been dredged from the creek estuaries at Currumbin and Tallebudgera to the beaches, including some  $0.3 \text{ million m}^3$  to Palm Beach in 1980 to accompany groyne construction. These estuaries form part of the active beach sand transport system.

Monitoring of the beaches and estuaries in this region has been carried out through regular aerial photography and beach and hydrographic surveys by the Beach Protection Authority over the period 1966 to 1983, with intense coverage since 1980. An Authority COPE station has operated at Burleigh since 1980.

#### Currumbin Rock Groyne (1973)

This groyne connected Currumbin Rock to the mainland, thereby preventing the longshore transport of sand through the intermediate area. As a result, about 0.79 million cubic metres of sand accreted on Currumbin Beach (Figure 10) and the entire longshore transport now passes around the seaward side of Currumbin Rock.

Immediately downdrift, within about a kilometre of Currumbin Rock, while the beach line receded, the nearshore profile accreted to carry the longshore transport. Works have been carried out effectively removing sand from the creek estuary and moving the beach line seawards in this area. These combined effects are shown on Figure 10 as a net gain

Figure 10. Distribution of Accretion / Erosion – Currumbin to Burleigh.

of sand to the beach system amounting to about 0.5 million cubic metres to 1983. Of this, a net quantity of about 0.2 million has come from the estuary which will tend to infill again with sand from the beaches unless repeated dredging is undertaken to keep the sand on the beaches.

Further downdrift, erosion has occurred along some 5 kilometres of coast at both Palm Beach and Burleigh. At Palm Beach where beaches were already in poor condition in front of seawalls protecting property, sand levels dropped still further, in some areas, to below the low tide level. A nearshore gutter some 200 metres wide and 2 to 3 metres deep, often carrying strong longshore currents, developed adjacent to the seawalls and persisted through to 1980 (Figure 11).

Figure 11. Effect of Seawall on Beach Profile, Palm Beach.

*Palm Beach in 1980 with residential development protected by rock seawall and no usable beach.*

The Tallebudgera Creek groyne, built in stages between 1977 and 1979, stabilised the northern section of Palm Beach against progressive erosion and is expected to have had the effect of transferring sand losses further downdrift to Burleigh. The groynes built on Palm Beach in 1980 are relatively short in relation to the width of the zone of longshore transport. They have held small quantities of the nourished sand in their immediate vicinity.

Overall, there was a surveyed net erosion of some 1.1 million cubic metres of sand along the downdrift areas of Palm Beach and Burleigh between 1966 and 1983. This is comparable with the total net gain to the beaches of 1.29 million cubic metres adjacent to the Currumbin Rock groyne, of which some 0.2 million has been obtained from the Currumbin Creek estuary. Hence, there is a balance in the overall quantities, with a redistribution leading to accretion in some areas and erosion in others as a result of groyne construction.

The losses of sand along Burleigh Beach occurred first in the offshore parts of the beach profiles, and manifested as significant beachline recession only during and after storms which served to re-establish the normal profile shape but at a more landward location. The net erosion at Burleigh since 1966 had reached typically  $300 \text{ m}^3/\text{m}$  by 1983 with recession of the duneline of up to 20 metres. Despite this, where erosion into the dune has occurred unobstructed by seawalls, the beach itself remains in good condition as a recreational amenity.

### 3.3 Northern Region (Burleigh to Nerang River)

This section of the Gold Coast is characterised by an almost continuous strip of residential development located on the main dune. Properties along most of this coastal section have periodically been subjected to erosion during cyclones. As a result, a seawall extends along almost the entire 14 kilometre length of beach.

The Nerang River entrance is located at the northern end of the Spit. The entrance has migrated progressively northwards for at least 4.4 kilometres over the past 80 years accompanied by growth of the Spit and erosion of Stradbroke Island. In the process, sand transported into the river entrance has been left deposited in the Broadwater and alienated from the active beach system. As well, the groyne effect of the entrance bar has moved progressively northwards with the entrance.

**Beach Nourishment**

In 1974, some 1.4 million cubic metres of sand were dredged from the sand reserves in the Broadwater to Surfers Paradise beach to improve its recreational amenity. The sand was placed on a limited beach length of about 3.5 kilometres at an average rate of 400 m<sup>3</sup>/m creating a new dune and berm in front of the seawall. It would be expected that the effect of this nourishment would distribute progressively in both directions along the coast while the benefit in the central nourishment area would reduce over time.

Figure 12 shows a plot of the time history of the distance to the mean monthly edge of berm from the seawall line over the period 1974 to 1984. This data was obtained from the COPE station at Surfers Paradise. Despite the expected redistribution of the nourished sand, these works have clearly provided a substantial benefit in terms of the usable beach width over this entire period. Recent storms in 1983 and 1984 have eroded the beach significantly as shown in Figure 12 and the profiles of Figure 13, however the erosion has been accommodated within the dune system and a usable recreational beach continues to exist. No detrimental effects resulting from the beach nourishment works have been noted either within the beach system or at the sand source area.

#### 4.0 CONCLUSIONS

The variety and magnitude of works carried out along the Gold Coast and the comprehensive monitoring of the effects of these works over some 20 years have allowed a good understanding of their effects on the coastal system to be obtained. In general, the effects of these works on the beaches of the Gold Coast conform with the already known principles of behaviour. These are summarised below.

##### Groyne Structures

Groynes interrupting the net longshore sand transport have trapped sand on the updrift side and caused an equivalent quantity of erosion on the downdrift side. The extent and time scale of these effects depends on the effective length of the groyne and the total longshore transport intercepted by the groyne. It is apparent that the effective groyne length of river training walls is greater than for equal length groynes on a continuous beach, presumably because of the additional effects of the river flow. Entrance bar development may add significantly to the total quantity accumulated by such training walls, as appears the case at the Tweed River. The quantity of sand accumulated by these walls now exceeds 6 million cubic metres.

The approximate equality of the surveyed quantities of accretion adjacent to the Tweed River training walls and of erosion along the southern Gold Coast beaches supports the conclusions of the recent longshore transport study for the area. That is, that essentially all of the longshore transport along Letitia Spit would normally have passed to the Gold Coast beaches had the training walls not been constructed. Theoretical groyne accretion calculations together with the trends in the surveyed results indicate that the training walls may ultimately trap of the order of 7 million cubic metres of sand and that the majority of the longshore transport is currently bypassing the walls naturally to the beaches to the north. It is expected that this natural bypassing will be restored to at least 90% of its original rate by 1990.

Other groynes along the coast have affected the beaches to varying degrees, depending on their effective lengths and the proportion of the total longshore transport intercepted. Of these, the Kirra Point groyne which intercepted about 70% of the transport, trapping some 0.3 million cubic metres, and the Currumbin Rock groyne which has accumulated about 1.1 million cubic metres, have had the most impact on the beaches.

##### Seawalls

Seawalls serve to restrict the horizontal recession of the beachline resulting from erosion occurring either during storm events or as a persistent trend such as at beaches downdrift of groynes. Their impact on the beaches is largely dependent on their location on the beach profile. The further seaward they are constructed, the greater their influence and the less likely will a usable beach be maintained in front.

On the persistently eroding beaches at North Kirra and Palm Beach, the receding beachline has effectively placed the seawall progressively further and further seaward on the beach profile until no beach exists at all in front of the wall. Clearly, the establishment of fixed seawall alignments on persistently eroding sections of beach will lead eventually to loss of the beach as a useful recreational amenity.

It has been noted at Coolangatta, Kirra and Palm Beach that, once the waves impinge on the seawalls for a significant proportion of the time, wave reflections and accelerated longshore currents can lead to increased scour adjacent to the walls.

### Beach Nourishment

Beach nourishment to Surfers Paradise beach using the native sand derived from a source remote from the active beach system has been highly effective. Despite the fact that the nourishment was limited in its extent and would be expected to distribute along the coast over time, the benefit of these works has persisted for over 10 years and storm erosion continues to be accommodated within the nourished dune system in most areas.

Sand pumping to the beaches from areas such as estuaries within the zone of natural movements of beach sand will provide no lasting benefit to the beaches unless repeatedly carried out.

Restoration of the beaches in the Kirra area and re-establishment of the normal flow of sand along the coast could be achieved by beach nourishment, but would require nourishment to the eroded beaches by a quantity of sand equal to that trapped by the training walls, the source of such sand being remote from the active beach system.

### Beach Management

The Gold Coast erosion problems, namely the threat of property damage and the loss of the adjacent beaches, are the result of inappropriately located development (leading to the construction of seawalls) exacerbated by works (groynes) intended to overcome these problems together with the construction of the Tweed River training walls aimed at improving navigation to the river.

The future beach management policy at Gold Coast will be influenced by the needs of the tourist industry. The variety of works undertaken to date, their obvious effects and those reported from survey results provide the decision-makers with positive evidence of their impact on the coast and allow future works to be undertaken with a clear understanding of these impacts.

The present state of the Gold Coast beaches as a whole is such that the fundamental recommendation of the Delft Hydraulics Laboratory in 1970, namely restoration of the beaches by extensive sand nourishment, is still appropriate despite the expenditure of millions of dollars on coastal works in the area.

## CHAPTER ONE HUNDRED FOUR

### METHOD FOR ASSESSING STORM DAMAGE TO BEACH HOUSES

BY LYNN C. DOYLE, MEMBER ASCE, & WILLIAM L. FOX\*

**ABSTRACT:** Methods and procedures for the assignment of the pro rata share of damages caused by rising water and high winds arising from natural weather phenomena were virtually non-existent following Hurricane Frederic in 1979. Damages to beach front structures were often assumed to be caused by high water. Frederic marked the first natural weather disaster to strike a heavily populated area since the formation of the National Flood Insurance Program in 1970. The damages caused by the winds and rising water from Hurricane Frederic, therefore, created an economic incentive to attempt to distinguish between wind and rising water contributions. This paper presents a method and outlines procedures followed in damage assessments following Hurricane Frederic in an effort to minimize the difficulties insurance carriers and adjustors may have following future similar phenomena. It may, additionally, serve to promote improved design and/or building codes where such phenomena are probable.

#### INTRODUCTION

Houses located on ocean beaches usually incur considerable damage from storms of hurricane strength. This damage may be caused by wind forces, flood water forces, or a combination of these two forces. Insurance companies and adjustors, both wind and flood insurance carriers, sometimes have a difficult problem in assessing the cause of damage and, therefore, prorating costs to these beach houses.

Such difficulties were encountered by adjustors, insurance carriers, governmental agencies and others following the extensive property damage caused by Hurricane Frederic. Frederic, a force 3 hurricane, whose center passed through Mobile, Alabama on September 12, 1979, caused a reported \$2 billion in property damage. Winds were clocked at 140 MPH at Dauphin Island at the entrance to Mobile Bay and rising water was estimated to have been 15 feet above MSL. Hurricane Frederic was the first natural disaster causing both wind and water damage since the birth of the National Flood Insurance Program in 1970. Consequently methodology and procedures to be followed in determining probable cause and in apportioning costs were virtually non-existent. The task of those concerned with the assessment of damages and costs was to develop usable and acceptable criteria and procedures.

This paper outlines a method and provides guidelines which may be used to assess the cause of damage to pile supported beach houses.

\*President and Controller, respectively, Geotechnical Engineering Testing, Inc., 904 Butler Drive, Mobile, AL 36609.

### RATIONALE

The rationale used was that careful observation and documentation of damages as evidenced by erosion of foundation soils, water marks, building orientation, elevations, wind surface area and other material factors would yield a logical and equitable basis for assigning dollar values to the respective causal wind and rising water forces.

### PROCEDURE

In our approach, we observed and recorded data relative to the way in which wind and water loads affected the pile loads and/or capacities. The two forces, quite obviously directly increased the loads on the piles. Less obvious, however, was the diminished load-bearing capacity of the piles due to the erosion of foundation soils.

Our field observations were directed toward the determination and measurement of the following factors:

1. wind velocity and direction
2. still water depth
3. location of the structure relative to wave protection features such as sand dunes and other structures.
4. size of structure
5. orientation of structure
6. pre-storm elevation of structure
7. soil erosion around structure foundation
8. bracing system used (x-bracing or a concrete floor slab fixed to the piles at ground levels, etc.)
9. type of damage to the structure
10. condition of surrounding structures and the general type of damage sustained.

Using the field data as developed for each given case, we were able to hypothesize the magnitude of loads due to wind and water forces and the change in pile capacities due to erosion of foundation soils.

The rising water could affect the piles both through increased loads and through diminished bearing capacity due to erosion. Consequently the contribution of water toward structure damage was considered to be the sum of the absolute values of load and of pile capacity change. Wind contributed to the damage was assumed to be through increased loading only. The contribution of wind and water forces were totalled and each force then was expressed as a percentage of that total.

Damage proration to wind and water forces (and by extension to wind and flood insurance carriers) was made in accordance with those percentages.

### WIND LOADING

Wind loads acting upon the beach houses during storms of hurricane produced a very high lateral force on the structure—especially the foundation piles that are usually used to support beach

houses. The force from wind may be computed from the standard formula:

$$f = V^2k$$

where  $f$  = the unit force from the wind in psf

$V$  = the velocity of the wind in mph

$k$  = a constant usually taken as .003

A plot of unit wind load force vs. the wind velocity is shown by Figure 1. The unit wind force for a storm having a given wind velocity can be multiplied by the vertical projected area of the structure which the wind acts upon to estimate the total load acting on the structure.

FIGURE 1

FIGURE 2

The formula to be used for this load determinations is:

$$P = f A$$

where P= Total load on structure

f= Unit Force from wind

A= Structure surface area perpendicular to the wind.

For a pile supported structure where all the piles are securely fixed to it, the total wind load will be distributed nearly evenly to each pile and this load is computed as:

$$fp = P/\text{No. of Piles} = \text{horizontal force on top of pile}$$

A plot showing the load on single piles (for a given size structure and number of piles) vs. the wind velocity is shown on Figure 2.

FIGURE 3

FIGURE 4

**WAVE LOADING**

Forces from waves acting upon structures are considerably more variable than are the wind loads during a storm of hurricane intensity. Many factors are to be considered for determining wave heights and thus forces from the storm. Some of the significant factors are:

1. Wind Velocity
2. Duration of wind
3. Distance wind travels over water (fetch)
4. Changing direction of wind
5. Water Depth
6. Sea bottom characteristics
7. Wave protection features-jetties, sand dunes etc.
8. Particular theory used for estimating wave heights and forces

For the evaluations made, generally a worst case condition was assumed where load forces for breaking waves were estimated to act on the structure. It was assumed in computations that the waves would have a maximum height of 0.8 times the still water depth. Therefore, if the still water depth could be determined, an estimate of wave height and wave forces could be made. Using methods published in the U. S. Army Coastal Engineering Research Center Shore Protection Manual, estimates were made of maximum wave loads on typical 8 inch timber piles. This water depth load relationship is shown by Figure 3.

The load would act on the pile at about the still water depth. For other size piles the loads would be directly proportional to the pile width. It is our opinion that a breaking wave would only act on a few piles at a single instant when it breaks with the most number of piles being one row of piles that support the structure. A portion of this horizontal load would be transferred to the structure and distributed to the other piles - the amount depending on the location of load application at about the still water depth.

Estimates were also made of the maximum wave force that would act on a vertical solid stationary wall for various water depths. This relationship is shown on Figure 4.

It can be seen from Figure 4 that very high wave loads are placed on the vertical solid wall of a structure and this load may act on all or a portion of the wall at an instant. It is our opinion that most beach house structures located at elevations where waves break upon the vertical walls could not stand up to the very high forces. This is verified by the very heavy seawall structures or jetties that are often constructed where waves break against the wall.

### EROSION OF SOILS AROUND PILES

During flooding of the coastal areas from the storm the water with wave and tidal actions usually move back and forth around the fixed structure. This water movement around fixed objects causes an increase in the water velocity and while this increased velocity does not exert a significant force on the structure, it does erode or scour the soil (usually sand along the beach) away from the foundation or pile. For footing foundations supporting the structure on the soil, erosion below the foundations will cause it to settle and thus the structure would settle and may collapse if the erosion is deep enough. For pile supported structures the erosion around the pile tends to decrease the load supporting ability of the piles— both axial load and lateral load capacity. Our surveys after Frederic indicated that a loss of axial pile capacity was not a significant cause of damage to beach houses. Table 1 shows typical axial pile capacities for a range of pile tip penetrations that may be evaluated if necessary to assess damage to a structure.

The lateral load capacity of piles may be significantly affected by the erosion of supporting soil from around the piles. Not only is the soil resistance on the pile decreased by the loss of soil but the moment or level arm at which the horizontal loads are applied to the soils are increased.

Estimates have been made of the lateral load capacity of typical 8 inch diameter piles having various embedment depths in typical sands we have found along the coast. These lateral load estimates based on one inch of deflection at the ground line are for two conditions. One is for piles having all the lateral load acting at the top of the piles such as a pile without any bracing and this capacity— embedment depth relationship is shown on Figure 5. The other condition analyzed is for a pile with the horizontal load acting on the pile at about eight ft from the top such as a well braced pile and this capacity relationship is shown on Figure 6.

It is noted that the braced pile should have two to three times the lateral load capacity of the unbraced piles regardless of the pile embedment depth.

**EROSION + WAVELOAD SUM VS WIND LOAD**

The method suggested to proportion this damage is to add the average wave load on a pile (estimate number of piles in one row that wave might act on in a given instant and multiply by the individual pile load for the given water depth and divide by the total number of piles supporting the structure to determine the average wave load on each pile) to that lateral load capacity which might be lost by the decrease in embedment depth from erosion for the given pile condition. This load change could be attributed to the water while the wind loading placed on each pile would be attributed to the wind. These loads would be used to obtain a causal percent.

**CONCLUSION**

The estimates of storm load forces that might be applied to a beach house structure during a hurricane may provide a basis for assessing the cause of damage for a particular structure. A survey of the structure after the storm, some basic design data for the structure, and factual data about the storm will be needed. Generally the data needed will be:

1. The wind velocity and direction.
2. The still water depth.
3. The location of the structure relative to wave protection features such as sand dunes and other structures.
4. The size of structure and its orientation.
5. The elevation of the structure before the storm.
6. The amount of soil erosion around the structure foundation.
7. The bracing system used for piles-( X bracing or a concrete floor slab fixed to the piles at ground level etc.)
8. The type of damage that the structure sustained.
9. The condition of surrounding structures and the general type of damage which they sustained.

Using these data and the utilization methods that we have discussed, one should be able to make good judgments as to the cause of the damage-whether it be water or wind.

This method for assessing storm damage to beach houses may be used by insurance companies or adjustors to make realistic judgements of the relative cause of damage to structures which are subjected to both high winds and rising waters during natural weather phenomena. The factors presented and their potential for causing damage to beach house structures may be used to improve the initial design or to strengthen existing structures where such weather conditions are probable.

**EXAMPLES OF DAMAGE ASSESSMENT**

1. For waves breaking against the main beach house structure the very high loads would probably demolish the structure-flood water would be the primary cause of damage.
2. For erosion below foundations of a structure, the beach

Photographs of structure torn from its foundation. Wave and wind loads probably caused the damage.

Photograph of "X" braced structure that has received very little damage at ground level. Erosion of soils was approximately three feet.

Photographs of structure that was originally enclosed at ground level. Wave forces obliterated the ground level enclosure and the water eroded approximately four feet of sands from below the concrete slab. The wind loads, wave loads, and sand erosion probably caused the horizontal deflection of the supporting piles.

Photograph of piles that supported a structure that are broken. Excess wind loading probably caused these piles to break.

Photograph of leaning piles that supported a structure. Excess wind loading and loss of soil resistance from erosion probably caused this failure of the foundation.

Photograph of structure that is essentially undamaged except for leaning piles and obliterated stairs. The leaning piles were probably caused by a combination of excess wind loading and loss of soil resistance due to erosion of about two feet of sands. The obliteration of the stairs was probably caused by wave forces.

Photograph of structure foundation that is essentially undamaged. The wind forces probably tore the structure from the foundation leaving the floor attached to the piles. Most of this damage was caused by the wind forces.

house would probably collapse—flood water would be the primary cause of damage.

3. For a beach house elevated or located where waves did not reach the main structure and the foundations remain undamaged or where piles may be broken but that portion in soil remains plumb and undamaged—wind would be the primary cause of damage.

4. For a beach house where soil erosion occurred and/or waves broke against the piles plus wind loading on the piles— add the loss of pile capacity from erosion for decrease in embedment depth to the wave loading and compare that sum to the total wind load per pile to proportion the cause of damage to wind and water.

5. For some beach house locations where little to no evidence or data remains about the structure to make judgments about the cause—we suggest splitting the cause 50-50 between wind and water.

6. In all cases, use common sense along with as much analytical judgment as possible to assess damages.

## CHAPTER ONE HUNDRED FIVE

### NUMERICAL MODEL FOR DUNE EROSION DUE TO WAVE UPRUSH

J. S. Fisher (1), M ASCE  
M. F. Overton (2), AM ASCE

#### ABSTRACT

The objective of the work presented herein is to quantitize dune erosion as a function of the swash mechanics. In order to achieve this aim, a numerical model is developed which solves the one dimensional continuity and momentum equations for depth and velocity of the swash at the face of the dune. These parameters are then used as input to the dune erosion model which predicts the extent of toe retreat of the dune as a function of time. Since the model is formulated in real time, both short and long term events may be simulated. This is particularly important in terms of understanding the short term event in which the dune and beach face do not achieve an equilibrium profile.

#### INTRODUCTION

The prediction of dune retreat due to storm processes is the subject of increasing concern in coastal engineering. Dunes are often used as the primary defense to coastal erosion and flooding. Previous efforts at predicting the rate of dune erosion have generally depended upon the development of a post-storm equilibrium profile, where the volume of sand lost from the dune is determined by the quantity of sand required to establish this profile, Hughes and Chiu (4), and Vellinga (7). Therefore, if the beach does not reach an equilibrium condition due to the specifics of the storm parameters, ie. storm duration, wave height, and/or storm surge, this method will over-predict the amount of dune retreat.

The model described in this paper is being developed to predict the dune erosion for a single storm, and does not require that there be an equilibrium profile established at the end of the event. The model considers the size and position of the dune on the beach, the degree vegetated, and the strength and duration of the storm swash.

This somewhat unique approach to dune erosion modeling (where time is a true variable) depends upon an estimate of the actual volume of sand eroded from the base of the dune for each individual swash uprush. While there is a large body of literature dealing with the mechanism for beach erosion by wave swash, Dean and Maurmeyer (1), there is virtually no literature dealing with the scour of the dune.

#### METHODOLOGY

In order to quantitize the erosion due to the short term event, it was felt that the interaction between the mechanics of wave swash and sediment scour at the dune toe was of primary importance. A schematic of the idealized model is presented in Figure 1.

FIGURE 1. Schematic of the model components.

Important geometric considerations are the bore height, water depth, still water level, beach slope, dune height, and dune position on the beach. In addition to these geometric factors, the sand grain size and the density of plant roots are input parameters to the erosion model.

The uprush is modeled as a bore on a frictionless inclined beach following the work of Hibberd and Peregrine (3). The one dimensional equations for continuity and momentum are solved using a Lax-Wendroff solution technique yielding the velocity and depth of the bore as it moves up the beach to the dune. The Hibberd and Peregrine model was modified to include as a boundary condition on the landward side, the position of the dune. The dune acts as an impermeable vertical boundary to the uprush. Therefore, the numerical restraint is that the velocity is held to zero at the dune face. The initial conditions within the fluid are that the bore height is 1.6 times the water depth at the seaward boundary, a relationship shown in the data presented by Svendsen Madsen and Hansen (5), and with a velocity determined by the equations of equilibrium for a moving hydraulic jump. Elsewhere in the fluid domain the water depth is the still water level and the velocities are zero. As the equations are integrated in time, the bore propagates uniformly over the water and then decreases in height as it moves up the beach. As the swash hits the dune a reflected wave is formed and propagates seaward combining with the still advancing uprush. Eventually the bore recedes as the natural backwash.

The specific discharge of the uprush (depth times velocity) is considered to be the key parameter in determining the dune scour. Numerical results of the discharge versus time are presented in Figure 2 for three positions of the dune relative to the intersection of the still water level and the beach. The discharge is characterized by a rapid rise in magnitude, a period of relatively constant value (depending on the location of the dune), and a rapid decrease. The general trends are that the maximum value of the discharge decreases rapidly and the length of time that the bore is attacking the dune increases slightly as the distance of the dune toe up the beach increases.

The erosion at the base of the dune is then estimated by relating the volume eroded to the characteristics of the uprush. This is done on a 'per uprush' basis so that the time of uprush attack as well as the storm duration become important parameters in the estimation of the total amount of dune erosion per storm. This approach has been qualitatively evaluated using laboratory data from our 17 m wave flume. The assumption that the volume of scour at the base of the dune (per unit time) is a function of the specific discharge of the uprush appears to be a good first approximation, and is consistent with relationships derived for sediment transport in rivers, Vanoni (6). We are initiating a series of field experiments with prototype dunes at the U. S. Army Corps of Engineers Field Research Facility, at Duck, North Carolina, in order to more thoroughly evaluate this hypothesis.

FIGURE 2. Specific discharge at the toe of the dune versus time for three positions of the dune relative to the intersection of the still water level and the beach face.

The scour at the base of the dune will ultimately cause the dune to fail. The depth of scour necessary to undermine the dune is a function of the properties of the dune sand, the degree of water saturation, and the density of plant roots. The latter can be significant, as shown in the work of Gray and Leiser (2).

This maximum scour is computed as:

$$D = c/ws + (w/ws)(H/2(\tan(\phi)))$$

where  $D$  = maximum depth of scour before the dune fails, m,  
 $c$  = sand cohesion, Pa (function of root density, as shown by Gray and Leiser (2)),  
 $ws$  = specific weight of the sand, N/cu m,  
 $w$  = specific weight of the water, N/cu m,  
 $H$  = dune height, m,  
 $\phi$  = friction angle.

The current model assumes that the volume of sand that fails is distributed at the toe of the dune and that the process of attack of the swash on the face of the dune is repeated. The dune is said to retreat when the volume of sand eroded exceeds that in a column of sand equal to the depth of the scour times the original height of the dune. At this point, the specific discharge of the swash is recalculated given the new position of the dune. This procedure is summarized in Figure 3, a flow chart of the model.

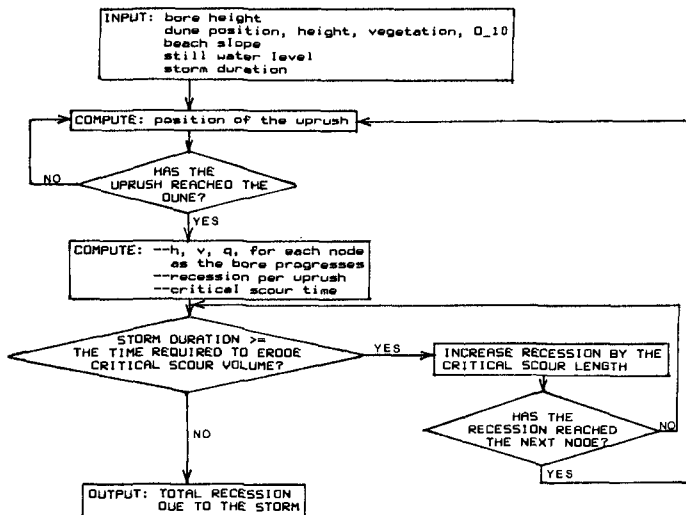

FIGURE 3. Flow chart of the uprush/dune erosion model.

#### SUMMARY

The model described in this discussion is still in the early stages of development. The additional laboratory and field data which will be collected in the next phase of this research will result in changes and refinements to the present form of the model. The ultimate objective of this work is to develop a dune erosion model which can be coupled to a shoreline erosion model such as the one described by Dean and Maurmeyer (1). Thus, the dune model would serve as an erodable landward boundary for the shoreline model.

## ACKNOWLEDGEMENT

### A NEW OSCILLATORY FLOW TUNNEL FOR USE IN SEDIMENT TRANSPORT EXPERIMENTS

David B. King Jr., A.M.ASCE 1  
John D. Powell 2  
Richard J. Seymour, A.M.ASCE 3

#### ABSTRACT

The details of a new oscillatory flow tunnel at Scripps Institution of Oceanography are discussed. The flow tunnel has a large cross-section and large water excursion distance. The piston motion is programmable. The test bed can be tilted. These, and other aspects, make the facility useful to a wide variety of oscillatory flow sediment transport experiments.

#### INTRODUCTION

A new research facility, an oscillatory flow sediment transport tunnel, has recently been completed at the Hydraulics Laboratory, Scripps Institution of Oceanography, University of California, San Diego. The facility simulates many aspects of sediment transport on beaches, and its primary purpose is to be used in experiments which increase the understanding of granular-fluid mechanics in oscillatory flows. The facility is shown in Figure 1. It is built in the shape of a flat U-tube with a long, rectangular, center section and cylindrical risers on either end. When being operated, the facility is completely filled with water, and a piston in one of the vertical risers creates an oscillatory flow which moves sediment in the test section (the center portion of the horizontal section). The main components of the facility, as shown schematically in Figure 2 from right to left, are:

- 1) a hydraulic ram which drives the piston,
- 2) the piston and piston cylinder,
- 3) a flow straightener and turbulence decay section,

- 7) a recirculating pump,
- 8) a second trap, decay section and flow straightener, and
- 9) a reservoir.

### DESCRIPTION OF THE FLOW TUNNEL

#### TEST SECTION

The maximum oscillatory water particle displacement in the test section is 1.75 meters. At a minimum period of 3.5 seconds, the maximum sinusoidal velocity is 1.6 m/s. A maximum steady flow of 0.2 m/s, driven by the recirculating pump, can be superimposed upon the oscillatory flow. The steady flow can be run in either direction.

The test section is 39 cm wide by 40 cm high. The working cross-section with a 10 cm deep sand bed is 39 cm by 30 cm. The test section is 7.0 meters long (four water particle excursion lengths). The test section has clear acrylic plastic side walls (3.2 cm thick) and top wall (5.0 cm thick). These are externally reinforced by steel I-beams. The thick sides and lid were designed to minimize deflection and consequent attenuation of the water column velocity.

At the center of the test section, there is a window on each side that is unobstructed by external supports for 1.75 meters (a maximum excursion length). This can be used for photography or other visual observations. The other windows vary in length from 50 to 75 cm. The bottom (also I-beam reinforced) is made of fiberglass coated plywood.

The top of the entire test section is hinged and sealed with an O-ring. It can be opened with a hand-operated worm screw winch to allow easy access to the test bed. Between experiments, the bed is re-leveled by means of a cart, which rides on the top surface of the side walls (the O-ring sealing surface). The cart has an adjustable wiper blade which extends down to plane the bed. When in operation, the lid is clamped shut at each vertical I-beam support. The lid has a series of small ports which can be used to inject dye into the tunnel and to purge trapped air bubbles.

The test section is an integral part of a deep steel truss framework which was designed for minimum structural deflection with a full water load. When filled with water and unsupported at the ends, the maximum deflection of the truss is approximately 3mm. During construction, an initial camber was fabricated into the truss so that when loaded, the test section would become flat.

#### TRAP AND TURBULENCE DECAY SECTIONS

There are identical sediment traps at each end of the test section. These sections are 1.75 meters long (an excursion length) by 39 cm wide

FIGURE 2: Schematic of the Oscillatory Flow Tunnel showing the important sections.

by 1.41 meters deep. Between each trap and vertical riser, there is a turbulence decay section. The turbulence decay sections are 1.75 meters long, by 39 cm wide by 57 cm deep. One of the two side walls of the trap and decay sections is made of I-beam reinforced clear acrylic plastic (3.2 cm thick). The other side and the bottom are made of I-beam reinforced, fiberglass coated plywood. The top of the trap and decay section is also a hinged clear acrylic plastic lid (5.0 cm thick), sealed in the same manner as the test bed lid. The three lids allow easy access to the entire horizontal portion of the facility.

The sediment traps have servo actuated, horizontal, louvered covers. When a trap is the upstream trap, the louvers close, and the water flows past a flat plate boundary. When the flow reverses and a trap becomes the downstream trap, the louvers open to allow the sand to enter the trap. The louvers are actuated by the same electronics that control the piston motion. An offset can be added to account for a superimposed steady flow.

The sediment is both carried into the trap by gravity and by a small current. This current exits the trap through a one-way valve and then flows beneath a false bottom in the turbulence decay section and finally into the vertical riser. The one-way valve stops any return current when the flow reverses.

The top of the trap covers are nominally 2 cm below the level of the sand bed (32 cm from the top of the channel). However, this elevation has been made adjustable to allow for changes in the sand bed thickness or the distance between the top of the bed and the top of the louvers. The louvers can be set anywhere between 27 and 37 cm from the top of the channel.

There are nine rectangular funnels which cover the bottom of each trap (arranged 3 x 3) with a drain valve beneath each. These allow the sediment to be removed. The three center funnels (on the lengthwise axis of the facility) are each 10 cm wide and are the only ones used to collect data. The sediment that collects in the outside funnels are affected in unknown ways by the side walls of the channel and trap covers. The bottom of the trap is bolted to the sides and sealed with an O-ring. The bottom, with the funnels and drains attached, can be dropped out to allow further access to the trap area.

The turbulence decay section has a false bottom whose elevation is adjustable to match the elevation of the louvers. Beneath the false bottom is the one-way flow section described above. In each turbulent decay section next to the vertical riser, there is a flow straightener. This consists of a cloth screen sandwiched between two pieces of honeycomb. The screen is a fine mesh plankton net (nominal 0.05 mm mesh size opening) which stops sand from reaching the vertical risers (and the piston O-ring). The honeycomb nearest the vertical riser has 4.7 mm (3/16th inch) stainless steel cells. Its primary purpose is to support the screen. The honeycomb on the test section side supports the screen and also (along with the screen) acts to eliminate the large scale turbulence created by the elbow in the flow. This honeycomb is made of packed soda straws (double hole coffee stirrers) 12.5 cm long by nominally 1.5 mm in diameter.

## PISTON

The piston is driven by a hydraulic ram mounted directly above it. The ram moves the piston in response to an electronic input signal which modulates a 2.5 liter per second (40 gpm) Moog electro-hydraulic servo valve. Hydraulic fluid is supplied by a 22 kW, 21 MPa (3000 psi) hydraulic power supply. This system allows the piston to be moved in any reasonable manner, not only sinusoidally as would be the case with a piston rod mounted eccentrically on a flywheel. Thus, Stokes wave motion or random wave motion are easily produced.

Oscillatory water motions are created digitally on an IBM PC XT computer. The computer is equipped with a MetraByte Dascon-1 board that provides the digital to analog converter (DAC), producing a varying +/- 5 VDC signal. This signal is converted to a modulated 2 kHz signal by a Vetter FM Recorder Adaptor and recorded on a standard audio cassette tape. The cassette tapes are then available for repeated use as an input signal for the piston.

During operation, the recorder outputs the demodulated +/- 5 VDC signal. A pair of 10 turn pots (for redundancy), attached to a gear rack on the piston rod, track the piston position. A servo amplifier sums the recorder signal with the negative feedback signal from the position pots. As the input signal changes, the output of the servo amp tends to move away from zero. This signal is fed to the servo valve which opens one of two high pressure hydraulic ports, moving the ram in the appropriate direction and thus changing the feedback voltage which decreases the magnitude (absolute) of the servo amp signal. In this way, the position of the piston is an accurate analog of the input signal. The servo system also allows manual adjustment of the piston position for use during filling and other system checkout. A sight gauge, attached to the outside of the piston cylinder, allows accurate manual positioning.

The piston has a working stroke length of 0.75 meters and a diameter of 0.62 meters giving a displacement volume of 0.22 cubic meters. The piston head is fabricated from clear acrylic plastic to allow for observation of trapped air. The air can be removed by a purge valve in the piston face. The piston cylinder is made from heavy wall steel tubing, precisely machined, coated with aluminum metal spray, and top coated with sprayed fused teflon. The seal is a teflon coated O-ring.

If the piston were to accidentally travel too far in either direction, the hydraulic ram would stop the piston abruptly at the end of the ram's excursion length. Under operation, this could easily cause a water hammer of serious proportions. To avoid this problem, both mechanical and electronic safeguards were installed in the system. An electronic safety circuit automatically shuts the system down if any of a number of conditions occur. These include the piston going outside a specified range, the piston traveling at too high a velocity, the pressure in the tank exceeding a specified limit, or the two feedback pots not agreeing on the piston position. The position feedback pots provide the position signal which is differentiated to obtain the

velocity. The pressure limit is provided by a pressure switch set at 62 kPa (9 psi). The safety circuit uses a series of comparators to monitor these signals. When an unsafe condition is sensed, an electric dump valve to the main hydraulic power supply is opened which bypasses the hydraulic flow to the piston servo system.

Should this safeguard system fail, a passive mechanical system would disconnect the piston face from the water column, and still avoid a water hammer. If traveling upward, before the ram reaches the end of its stroke, the piston will unseat from the piston cylinder. If the piston is traveling downward, before the ram reaches the limit of its stroke, the piston will push out a blow-out plug by shearing four restraining pins. The blow-out plug is the entire bottom of the vertical riser. Thus, water will drop out of the vertical riser, avoiding the over pressure of a waterhammer. Water pressure on the face of the blow-out plug will cause the pins to shear at pressures exceeding +/- 88 kPa (12.7 psi). Along with the piston face, the blow-out plug is made of steel braced clear acrylic plastic for visual inspection of the interior of the vertical cylinder.

#### RESERVOIR

The other vertical riser acts as a reservoir and has the only air-water interface in the system. The air in the reservoir is open to the atmosphere through a quarter turn PVC valve. This valve is open when the tank is being filled and can be opened or closed during operation. If closed, the air in the reservoir acts as an air spring which decreases the power requirements on the piston. By initial adjustment of the water level in the airspring before closing the vent valve, the midpoint of the alternating pressure range can be offset with respect to atmospheric pressure. There is a sight gauge on the reservoir to monitor the water level during filling and experimentation. A second blow-out plug, identical to the one beneath the piston, forms the bottom of the reservoir.

#### STEADY FLOW

A 15 hp, high head centrifugal pump is used to superimpose a steady flow on the oscillatory flow in the facility. The steady flow system is shown schematically in Figure 3. A 35 meter long inertia section is used to reduce pressure from the high head pump. Consequently, the oscillating pressures in the tank cause only a small change in the total head seen by the pump. Since the pump has a relatively flat pressure vs flow curve, the changing pressures in the tank cause a negligible change in the pump flow.

The flow goes through a bank of five different sized valves connected in parallel. This allows a large number of flow velocities (32) in the tank to be easily and reliably reproduced. The flow then goes through a four-way valve which directs the flow to and from either end of the tank. The steady flow enters and leaves the tunnel in the vertical risers and so the water flows through the flow straighteners before reaching the test bed.

FIGURE 3: Schematic of the steady flow system.

The same pump is also used to fill the tunnel. Water is drawn from a wave basin, another facility at the Hydraulics Laboratory. The wave basin has a large expanse of shallow water. Since this acts as a settling basin, the water used in the oscillatory flow tunnel is free of both fine sediment and air bubbles.

#### TILT

In order to simulate the effects of cross-shore sediment transport on a sloping beach, the entire facility can be tilted between  $-5.7$  degrees and  $+9.1$  degrees from the horizontal. The pivot point is located at the bottom of the center of the test section. A hand-operated worm screw jack, which changes the tilt, is located near one of the sediment traps. One degree of tilt is produced by 40 crank handle turns. There are adjustable braces at the ends of each vertical riser to help support the facility and to minimize vibrations.

Physically, the facility is nearly symmetrical about the pivot point. Thus, experiments can be duplicated by completely reversing the flow, tilt, etc., to check for any bias in the system. The only asymmetries are that the facility tilts above 5.7 degrees only in one direction and that there is a piston only at one end. The piston causes larger pressure excursions at one end than the other. However, the flow is driven by the derivative of pressure,  $dp/dx$ , not the magnitude of the pressure itself.

#### FLOW FIELD IN THE WATER TUNNEL

In the water tunnel, the fluid is oscillated in a closed rectangular tube over a test bed. There is no free surface and thus waves are not formed. In the test section, there are thin boundary layers along each wall. The rest of the fluid (the core region) moves irrotationally. The boundary layers do not grow to meet in the middle as they do in steady pipe flow.

The flowfield does not entirely duplicate wave motion in that there are no vertical oscillatory velocities and no horizontal oscillatory variations in velocities. Longshore currents, turbulence associated with breaking waves, percolation flow, etc., are also not produced. However, the horizontal flowfield produced by an Airy wave can be exactly reproduced in the water tunnel, both in the boundary layer and in the core region. The horizontal fluid velocities of a Stokes wave can be exactly reproduced in the core region or at any one elevation in the boundary layer. The flow at all other elevations is closely approximated.

The turbulence generated in this facility is a factor that has been carefully considered. Since the turbulent structure of the surfzone is very poorly known, an attempt has been made to isolate the test bed from all turbulence sources except the turbulence generated at the bed boundary layer. Thus the sediment transport in this facility most closely resembles the cross-shore bed load transport seaward of the breaker zone on a beach. The design requirement has been that the rms artifact turbulence level in the sediment test section should be much much less than the fall velocity of the sediment. The fall velocities of the sediments (grain diameters of .1 to 1 mm) are on the order of 1 to 10 cm/s.

Artifact turbulence could be convected or diffused to the test bed from the flow straighteners. Also the turbulence produced by the side and top wall boundary layers of the test section could diffuse to the bed. The flow straighteners are located two excursion lengths from the ends of the test section. Theory and observation have shown that the turbulence generated by these structures decays before it can diffuse or be convected to the test section. Likewise, theory and observation have shown that the turbulence generated by the side walls of the test section do not influence the test bed other than at the very edges. Since sediment from only the middle 10 cm of the 39 cm wide test bed is used in data collection, results are not affected by the turbulence created by the side (or top) wall boundary layers.

COMPARISON WITH OTHER WATER TUNNELS

A number of other water tunnels have been reported in the literature. The characteristics of these are shown in Table 1. Some of these tunnels have been used without sediment to study the nature of fluid boundary layers. Others have had sand beds and have been used to study the initiation of sediment motion and or the structure and growth of ripples. Only one tunnel, reported in Horikawa, et al, 1983, has been used thus far to measure sediment transport.

As can be seen from Table I, the Scripps tunnel is one of the larger tunnels that have been built and one of the more versatile. It is unique in that it is the only tunnel with a test bed whose slope can be adjusted.

## CHAPTER ONE HUNDRED SEVEN

### BEACH RESPONSE TO LONG PERIOD LAKE-LEVEL VARIATION

by

William L. Wood<sup>1</sup> and Lee L. Weishar<sup>2</sup>

#### ABSTRACT

A 4-year set of beach and offshore profiles, measured at monthly intervals, is evaluated to determine the effect of wind-wave forcing and long period (1 year or greater) lake-level variation on beach profile change in the "tideless" Great Lakes. This evaluation indicates two distinct regions of change in the beach and nearshore area of these profiles. The beach-berm region responds directly to lake-level modulation of wind-wave forcing. This response occurs on two time scales (seasonal and long period), but always in direct relation to mean lake-level variation. The inner-bar actively changes under the influence of wind-waves, but appears to lack a well-defined seasonal pattern. Empirical eigenfunction analysis is applied to these data in order to statistically quantify the significance of these observed changes. This analysis provides confirmation of a hypothesized long-period (years) variation of the beach and berm in direct response to lake-level variation.

#### INTRODUCTION

Changes in beach profile are caused by variations in incident wave energy conditions and by changes in mean water level position. The seasonal onshore-offshore movement of beach sediment, caused by variations in incident wave conditions, has been discussed by numerous investigators [Shepard (9), Bascom (4), Sonu and Van Beek (10), and Aubrey et al. (1)]. Quantification of seasonal beach profile changes has been achieved by Winant et al. (13) and Aubrey (2)

for oceanic coasts. Similar quantification of offshore and beach changes on a tideless coast has been carried out by Weishar and Wood (12).

Beach profile changes caused by variation in mean water level position occur on two time scales. Short-term changes (30 days or less) result from both tidal fluctuations and storm wave set-up. Long-term changes (1 year or greater) are related to eustatic or hydrologic changes along a coast. Bruun (5) developed a conceptual model which assumed that beach and offshore profile slope and position is maintained in direct response to a rise or fall in mean sea-level. This concept, known as equilibrium beach theory, is of special interest for the Great Lakes where annual and longer term variations in mean lake-level range from 50 to 200 cm. Hawley and Judge (8) and Hands (6 and 7) evaluated changes in offshore and beach profile in response to rising lake-level in Lake Michigan. Hands (7) discussed a "general sequence of response to increased water levels" which included shoreward migration of longshore bars and shore recession. Weishar and Wood (12) were able to quantify a relationship between offshore profile adjustment and lake-level rise and fall. Specifically, they showed that profile changes offshore from the inner bar (approximately 100 m offshore) were directly related to the mean annual variation in lake-level. However, Weishar and Wood (12) were not able to find a similar direct relationship between beach recession and advance and, respectively, rise and fall in lake-level. This result seems contrary to expectation from physical reasoning concerning the coastal process-response system.

The primary objective of this paper is to show how wind-wave forcing and long-term lake-level variations affect seasonal and long-term changes in beach profile of sandy "tideless" coasts of the Great Lakes. A 4-year set of precisely measured offshore and beach profiles has been collected at monthly intervals from the southern end of Lake Michigan (Figure 1). Empirical eigenfunction analysis is used to statistically quantify annual and long-term mean lake-level variation influences on beach profile adjustment. Short-term (30 days or less) variability is identified in this paper, but attention is focused primarily on long-term (1 year or greater) variability.

#### PHYSICAL SETTING

This study was conducted along the southeastern shore of Lake Michigan within the Indiana Dunes National Lakeshore, Indiana (Figure 1). This region is characterized by straight, medium-grained sand beaches, with coarse-sand and pebble-sized deposits intermittently present at the beach step and in the swash zone. The beach slopes gently offshore and is terminated onshore by glacial ridges or sand dunes ranging from 10 to 40 m in height. Figure 2 shows a generalized cross section of the beach and offshore region which is characterized by at least two well-defined submarine bars. The outer bar is located approximately 160 m offshore in 2.5 to 3.0 m of water. This bar is relatively stable but may be destroyed

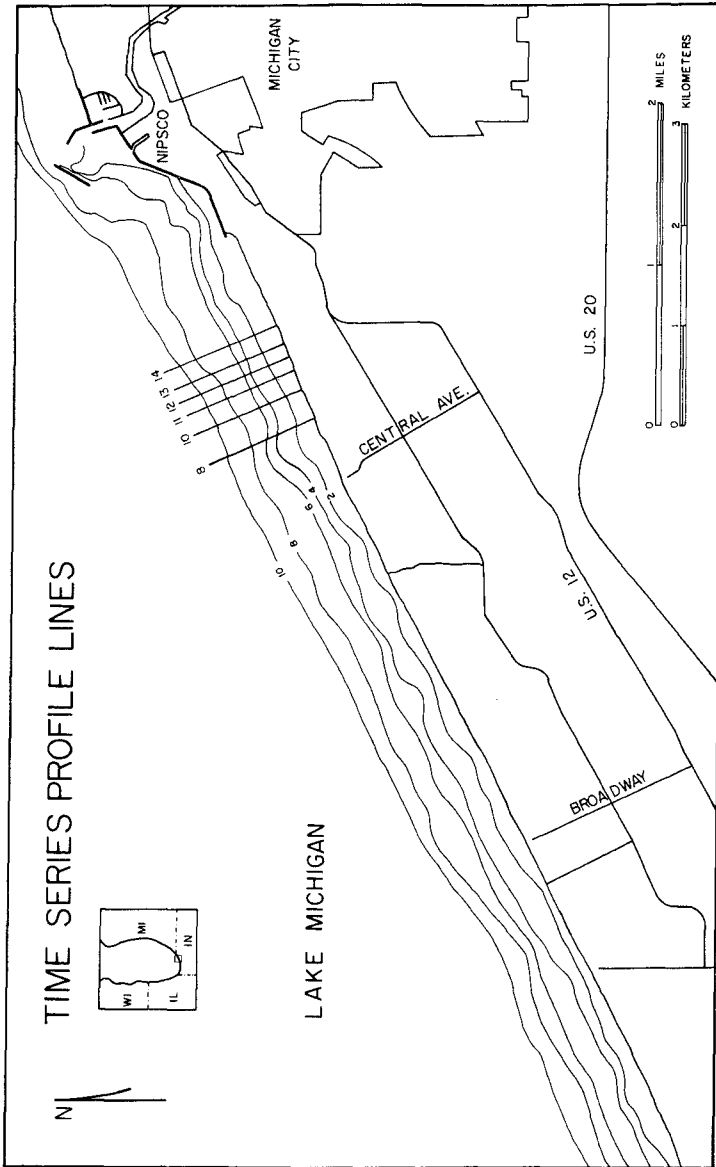

Figure 1. Study site location map.

Figure 2. Beach profile showing characteristic features.

intermittently during passage of high-intensity storm events. The inner bar is located 60 to 90 m from shore in 1.0 to 1.5 m of water. This bar is more active than the outer bar because of frequent occurrence of waves breaking over its crest.

The study area lies within a closed littoral cell approximately 20 km in extent [Corps of Engineers (11)]. This cell is bounded by the Michigan City breakwater updrift (shown in Figure 1) and Burns Harbor breakwater downdrift. Sediment is supplied to this cell from the coastal ridge and dune system shoreward and to a much lesser extent from small streams located within the cell. Predominate wave activity is from the north, which causes a net longshore transport of sand towards the southwest. Net littoral-transport rates along this length of coastline are approximately  $4.6 \times 10^4$  m<sup>3</sup>/yr [Corps of Engineers, (11)].

The beach in this region responds to seasonal variation in incident wave climate. During summer, average wave heights are less than 1.0 m, which results in a gradual onshore buildup of the beach profile. Late fall and winter storm waves reach heights in excess of 3.0 m at the outer limits of the offshore zone. These storm waves overtop the entire back-beach profile, which results in direct erosion of beach ridge and dune slopes. From late December until early April the offshore and beach zones are either covered with ice and snow or protected from wave activity by nearshore ice ridges. Small amounts of fine sediment are deposited along the profile as this ice melts in early spring. Most of this fine sediment is redistributed across the foreshore by initial wave activity following ice melting. In spring, following ice melting, ephemeral bars are observed between the inner bar and beach. These bars migrate shoreward under the influence of waves and eventually attach to shore, forming ridge-and-runnel systems. This migration of sediment initiates change from the eroded winter profile to onshore buildup of the summer beach profile.

The coastlines of the Great Lakes are essentially tideless. Variation in mean still-water level does occur on an annual cycle with a range from 0.2 to 1.0 m. Long-period (4 to 22 years) lake-level variations with a maximum range of nearly 2.0 m are also present on all the Great Lakes.

#### FIELD EXPERIMENT

A series of topographic surveys was initiated in the spring of 1976 to monitor changes in offshore and beachface profiles. Survey data were collected at monthly intervals from May through November of 1976, 1977, 1978, and 1979 along six range lines in southeastern Lake Michigan (Figure 1).

Elevation measurements were taken from dune base to offshore depths in excess of 10.0 m. A conventional theodolite and rod survey was used to measure elevations across the beach at 3.0-m

intervals. The shallow offshore region (0-3.0 m) was surveyed using a combination of rod soundings and fathometer soundings.

For those unfamiliar with the Great Lakes, it is important to note that early-morning lake-surface conditions can be "glassy" calm (no swell or local wind-waves present). Therefore, offshore surveys were conducted only during periods of essentially calm lake surface. Recognition of this condition helps to understand the reproducibility claimed in the following paragraphs.

A fathometer was used to profile the bottom from a depth of approximately 1.0 m to depths in excess of 10.0 m. These fathometer surveys overlapped the rod surveys by about 100 m in the shallow offshore region. All hydrographic surveys were conducted with a Raytheon Model DE-719-RTT precision survey fathometer. This instrument is capable of recording underwater topography in water depths between 0.5 and 125 m with an accuracy of  $\pm 0.5$  percent (of measured depth).

Prior to each run, the unit was calibrated to adjust for temperature effect on the speed of sound in water. Still-water level was measured and recorded so that all bathymetric profiles could be reduced to Low Water Datum (LWD) and changes in water-level elevation would not be misinterpreted as topographic changes.

The method for determining boat position during the fathometer runs utilized base stations set up on the beach. A theodolite was placed directly over a base station and the range line was established by turning a predetermined horizontal angle from an adjacent base station. Three to five buoys were positioned at fixed intervals along each range line. The distance from each buoy to the base station was measured with a Hewlett-Packard Model 3805A Distance Meter. The HP 3805A has a range of 1600 m and is accurate to within .02 m at a distance of 1000 m. A rod sounding was taken at each buoy to provide additional calibration checks.

The hydrographic survey was recorded as a continuous profile while the boat maintained a "constant" speed over the range line. The boat was kept on line by a shore observer siting through the theodolite and communicating with the boat driver by walkie-talkies. Tick marks were placed on the fathometer chart paper as each buoy was passed. Using this procedure, the maximum boat deviation was less than 2.0 m off the range line and maximum offshore deviation was  $\pm 3.0$  m.

#### OBSERVED SEASONAL PROFILE CHANGES

Four years of monthly beach and offshore bathymetric profile data were initially evaluated in order to identify dominant areas of profile change. This evaluation indicated three distinct areas of profile change: the beach-and-berm, the inner-bar, and the

outer-bar regions. Each of these regions was observed to vary independently of the other two.

The beach-and-berm region, in early spring, is typically found in a highly eroded, winter-beach configuration. Ephemeral bars are usually present in shallow water immediately adjacent to the beach. Beach-and-berm buildup begins in late spring and early summer. Ephemeral bars migrate shoreward under the influence of locally generated wind-waves and attach themselves to the beach. The beach-and-berm region continues to accrete throughout the summer months. This accretion results in a widening of the beach and a lakeward movement of the berm crest. This observed sequence of profile change is similar to that described by Bajorunas and Duane (3) for their beach and shallow-water bar region in Lake Superior.

The beach-and-berm region begins to erode in late fall and early winter because of the increase in frequency and intensity of local storms. As this region erodes, the berm crest shifts toward the back-beach while the overall slope of the beach decreases. It is not possible to monitor the offshore region during the late winter months (January-March) because of extensive ice cover. However, the beach-and-berm region remains in an eroded state until the following spring.

The inner-bar region shows no well-defined pattern of seasonal migration. During the 4 years of monitoring, the inner bar was observed to shift onshore and offshore apparently in response to local storms. Although a sequential shoreward migration of the inner bar was observed in summer 1976 (Figure 3), most movement in this region was less well ordered (Figure 4). The monthly movement of the inner bar appears to be independent of movements in the beach-and-berm or outer-bar regions. It is possible that the monthly survey interval was too long to be able to properly characterize inner-bar movement. This possibility is evaluated more thoroughly in the statistical results section of this paper.

The outer-bar region of the bathymetric profile exhibits a consistent seasonal migration pattern. The outer bar migrates onshore from early spring to early winter (Figure 3 and 4). In the following early spring, after ice breakup, the outer bar is observed to be offshore from its early-winter position. Apparently, the outer bar must move offshore during the period from early ice formation to ice breakup. This regular pattern of onshore-offshore migration of the outer bar is observed in each of the four survey years.

#### STATISTICAL ANALYSIS

Empirical eigenfunction analysis results in a set of eigen-vectors (empirical functions) and eigenvalues (mean square amplitudes) of a matrix of data thought to be composed of uncorrelated modes of variability. The primary reasons for using empirical eigen-functions to evaluate beach and offshore profile data are: (1) they

Figure 3. Sequential monthly profiles showing regular migration of the inner-bar.

Figure 4. Sequential monthly profiles showing irregular movement of the inner-bar.

are assumed to be uncorrelated modes of variability of the data field, (2) they afford the most efficient method for compressing a data field, and (3) they simplify understanding procedures of minimum mean square error estimation. The details of this method can be found in many of the references mentioned earlier (see Winant et al. (13)).

In an earlier study Weishar and Wood (12) were successful in establishing a direct relationship between lake-level rise or fall and respectively an advance or retreat of the outer bar. However, they were unable to establish a similar direct relationship between beach recession and advance and respectively rise and fall in lake-level. This result is contradictory to Weishar and Wood's (12) model of beach and offshore profile response to long-term lake-level variation. The reason for this seeming contradiction is that sediment volume changes in the offshore bar system are large compared to beach volume changes. Beach response is, therefore, relatively insignificant in an empirical eigenfunction analysis of an entire cross-sectional profile of the beach and offshore zone. This analysis biasing should be rectified by simply truncating the cross-sectional profile data at a position shoreward of the outer bar trough.

A 4-year set of monthly beach and nearshore profiles, truncated on the offshore side of the inner bar (see Figure 2) was used to generate sets of empirical eigenfunctions. Each set of profile data began at the base of dune-bluff on the back beach and extended down the offshore side of the inner bar to a point where the same number of data points were included in each profile. Analysis of this data set should support the hypothesis that beach response on the "tideless" Great Lakes varies as a direct function of lake-level rise and fall.

## RESULTS

Statistical analysis of the monthly data sets using empirical eigenfunctions resulted in three primary eigenfunctions whose eigenvalues accounted for over 91 percent of the total mean square variance contained within the data (Table 1). The eigenfunction with the largest eigenvalue accounted for approximately 72 percent of the mean square value. This eigenfunction essentially reflects the mean of the beach and nearshore profile and is referred to as the mean-beach function. The time dependence of the mean-beach function shows little variation over the 4-year data interval.

The eigenfunction with the second highest eigenvalue accounted for approximately 9 percent of the total mean square value or 28 percent of the residual variance from the mean-beach function. This function shows a broad undulating minimum extending across the berm and beach and is identified as the beach-berm function. The time dependence of this function shows an annual trend with maxima in spring and early fall and a minimum in July. This

temporal trend corresponds directly with annual lake-level variation which reaches a maximum in July and a minimum in January-February.

The time dependence of the beach-berm function has a pronounced trend, across the zero amplitude line, which is continuous over the 4-year data interval 1976 to 1979. Such variation is characteristic of long period lake-level change. A comparison between the long period (annual) lake-level variation and the mean annual temporal variation of the beach-berm function tends to support the hypothesized relationship presented earlier in this paper. The cross-correlation coefficient between the mean temporal dependence of the beach-berm function and mean lake-level variation is 0.85 which is significant at a level of  $E = 0.01$ .

Table 1. Results of Composite 4-Year Empirical Eigenfunction Analysis

	SR-8	SR-10	SR-11	SR-13	SR-1
Eigen- value 1	74.6	68.5	72.9	64.3	70.5
Eigen- value 2	10.3(40.4)	12.4(39.3)	10.0(37.0)	16.4(45.9)	10.4(35.2)
Eigen- value 3	6.4(25.3)	9.6(29.0)	8.0(29.6)	9.7(27.3)	9.2(31.2)
Eigen- value 4	4.8(18.7)	5.8(18.5)	5.8(21.6)	6.0(16.9)	5.6(19.0)
Eigen- value 5	4.0(15.7)	3.7(11.9)	4.8(17.6)	3.5(9.8)	4.3(14.5)

NOTE: Number in parenthesis is percent of residual mean square variation after removing the first eigenfunction.

#### CONCLUSIONS

The preceding quantitative analysis has shown that long-term (1 year and greater) lake-level variation is a significant source of physical forcing on beach-berm topographic changes. It should be clarified that mean lake-level changes do not physically transport sediment in the beach erosion of the beach and offshore profile. Sediment transport in this region is related to long-term modulation of local wind-wave energy by mean lake-level change. The best correlation between the temporal response of the beach-berm function and lake-level response occurs on an annual time scale.

However, there also appears to be a weaker but significant correlation between monthly variation in lake-level and beach-berm function response. Conversely, temporal response of the inner-bar function has no coherent trend throughout the 4-year monthly data sets. This may be a result of aliasing of data in the inner-bar region. It is reasonable to assume that the inner-bar, located in relatively shallow water (1.0-2.0 m) would be influenced by relatively small wind-wave events. The time scale of meteorologic system movement through the lower Great Lakes (3 to 7 days) is clearly less than the 30-day sampling interval.

As a direct result of this analysis the beach-berm portion of beach and offshore profiles on the "tideless" Great Lakes can be modelled using the same approach suggested by Weishar and Wood (12). However, their model should now have greater sensitivity of predicted response in the beach-berm region. Predictions of long-term coastal adjustment to lake-level and seasonal wave climate can now be extended to the entire beach and offshore profile of a Great Lakes coastline.

## CHAPTER ONE HUNDRED EIGHT

### Beach and Dune Response to Severe Storms

David L. Kriebel and Robert G. Dean

#### ABSTRACT

A numerical model is developed and applied to estimate the frequency distribution of severe erosion events. The proposed method is an extension of existing Monte Carlo storm surge simulation models. Hurricane and tropical storm meteorological parameters are randomly selected to generate a series of synthetic storms; the storm surge for each storm is estimated using a Bathystrophic storm surge model. The storm surge hydrograph is then used as input to a numerical erosion simulation model which determines beach profile response for each storm based on wave energy dissipation per unit volume as a general erosion forcing mechanism. Five 100-year random simulations are performed from which the return periods of storm surge and erosion, i.e. volume eroded and dune recession, are estimated.

#### INTRODUCTION

While major advances have been made in recent years in the development of frequency distributions for storm surge elevations, little progress has been made with regard to forecasting the probabilities of extreme erosion events. Detailed estimates of storm surge frequencies are now commonly made through numerical simulation of the governing equations based ultimately on historical probabilities of the meteorological characteristics of severe storms. For erosion events, on the other hand, it has not been possible to utilize this combined probabilistic-deterministic approach, since little is known concerning the equations or boundary conditions that govern storm erosion.

The goal of this study is to develop a general methodology to forecast the frequency distribution of severe erosion events based on severe storms expected over a wide range of return periods. The proposed methodology includes two phases: 1) the development of a computational method for predicting erosion due to a severe storm of given characteristics, and 2) the incorporation of this method into a larger model which accounts for the probabilities of occurrence of severe storm events. The results of the study are pertinent to current efforts to estimate the extent of erosion expected during a major storm, say with a 100-year return period, which may be required for coastal insurance, zoning, construction regulation, or structural

---

Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611.

design. Likewise, an estimate of the frequency distribution of erosion events will aid in the interpretation of the severity of particular erosion events relative to other possible erosion events.

The most widely used techniques for predicting single-storm erosion are schematic or geometric methods that are adaptations of the so-called Bruun's Rule (Bruun (1962)), which was originally proposed for estimating erosion due to sea level rise. The schematic method most often cited in the literature is that of Edelman (1968); although similar procedures have been proposed by Dean (1984) and others. Typical assumptions used by these methods for predicting storm-induced erosion include: 1) longshore transport gradients are spatially averaged, therefore, beach response is governed by a conservation of the sand volume perpendicular to shore, 2) offshore sand transport is effectively limited by the breakpoint of incident waves, and 3) the post-storm profile is in a dynamic state of equilibrium relative to the peak storm surge level. This last assumption implies that the profile has sufficient time to reach equilibrium during the peak surge. Comparisons of these methods to field data, however, suggest that these methods typically overpredict erosion in some cases by more than a factor of five. In effect, these methods predict the maximum erosion potential of the peak surge, a value that is seldom realized in nature due to the relatively slow response of beaches to changing water levels.

Several researchers, including Swart (1974), Vellinga (1983), and Hughes (1983) have developed more realistic predictive methods based on empirical results of small and large scale laboratory tests. The most useful computational methods, of Swart and Vellinga, use the general schematic arguments of Edelman's method; however, through derived model laws and experimental results, the effects of almost all of the most important parameters in the dune erosion process are quantified.

At present, the literature includes only two general methods for estimating erosion frequencies. Vallianos (1974) applied peak storm surge levels associated with various return periods to estimate beach fill requirements for the same return periods, based on a modified form of Edelman's methods. In a more detailed approach, van de Graaff (1983) used the computational method of Vellinga to predict dune erosion probabilities as the result of seven parameters, each with a known or assumed probability distribution. Two methods are presented for estimating these probabilities; one is a complete integration of seven probability distributions, the other is an approximate method in which mean dune recession is estimated based on water level and wave height distributions. Variability of this estimate is then given by a normal distribution with a standard deviation defined by the other five parameters.

The overall objectives of the present study are the same as those of van de Graaff, namely to obtain a rational estimate of the erosion frequency distribution by combining a computational erosion model with the probabilistic components of forcing parameters. However, the specific methods proposed in this study are quite different

in several aspects. First, the erosion model proposed for estimating single-storm beach response is more deterministic and based on a numerical simulation of simplified governing equations including a proposed process-based sediment transport equation and the equation for continuity of sand. Therefore, the entire time-history of profile response is predicted directly, based on the time-history of the storm surge. The method is based on the equilibrium beach profile theory described by Dean (1984), and, like other methods, it is intended to be simple and schematic and does not attempt to represent many important surf zone processes. Finally, the estimation of erosion frequency distributions is accomplished through a Monte Carlo simulation procedure, which is a logical extension of existing methods for predicting storm surge frequencies. The Monte Carlo procedure has the advantages of simulating nature as realistically as possible and of being based on historical probabilities of meteorological parameters which are well defined in most areas.

Existing Monte Carlo storm surge simulation models, for example Fallah, et al. (1976), generally employ the following steps:

- Input consists of probability distributions of meteorological parameters and astronomical tide amplitudes.
- Artificial storms are assembled through random statistical sampling of the historical probability distributions.
- A deterministic model is used to generate hurricane, wind and pressure fields.
- A second deterministic model is used to generate storm surge.
- The storm surge and astronomical tide are randomly combined to give the total storm tide for each synthetic storm.
- When a sufficient number of storms have been simulated, the distribution of storm tide elevations is estimated through an extreme value analysis.

With the development of an efficient beach and dune erosion model, the methodology is easily extended as depicted in Figure 1. The storm tide for each storm is estimated based on a randomly assembled set of storm parameters. In this study, a simple Bathystrophic storm surge model initially proposed by Freeman, Baer, and Jung (1957) is used for efficiency. Breaking wave heights are also estimated for each storm. The deterministic erosion model is then used to generate the time-dependent erosion for each storm, relative to a common pre-storm profile, based on the time-histories of the storm tide and breaking wave heights. Finally, a frequency analysis is performed on the maximum erosion characteristics to give the frequency distribution of eroded volumes and dune recession.

#### EROSION MODEL - DEVELOPMENT

The beach erosion model is based on the premise that a beach profile will always move toward its most stable, equilibrium form in response to given input or forcing conditions. There is considerable empirical evidence to suggest that the general equilibrium form of beach profile may be approximated by a monotonic curve of the form

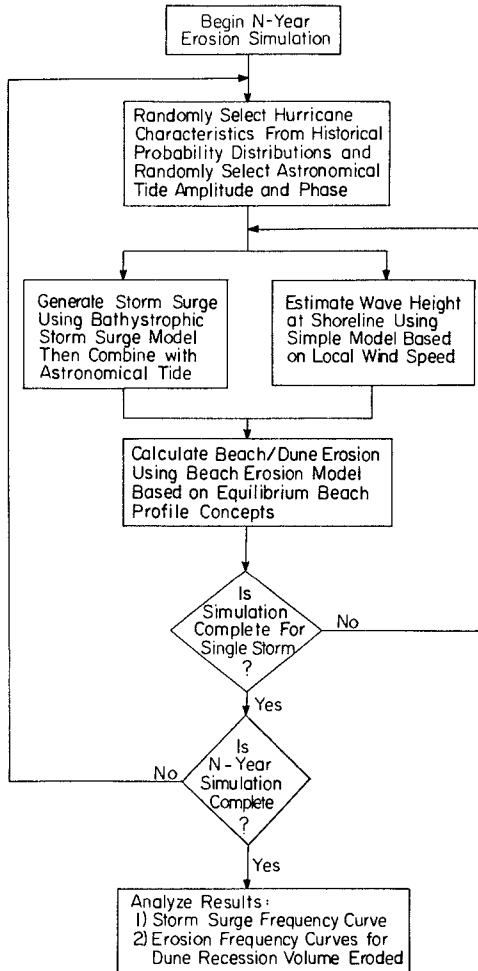

Figure 1. Flow Chart for Monte Carlo Storm Surge and Erosion Simulation.

$$h = Ax^{2/3} \tag{1}$$

which is the result of the uniform dissipation of wave energy per unit volume due to spilling breakers. As shown in Figure 2, the scaling parameter, A, may be theoretically related to a unique value of the energy dissipation per unit volume,  $D_*$ , which exists at all

I. EQUILIBRIUM BEACH PROFILE FORM

based on uniform energy dissipation per unit volume where A is related empirically to sediment size and can be related to  $D_*$  by:

$$A = \left[ \frac{24}{5} \frac{D_*}{\gamma K^2 g^{1/2}} \right]^{2/3}$$

II. ENERGY DISSIPATION PER UNIT VOLUME  $D = \frac{1}{h} \frac{\partial F}{\partial x}$

III. SEDIMENT TRANSPORT EQUATION  $Q = K(D - D_*)$

Figure 2. Basic Concepts for Erosion Model.

points in the surf zone when the profile is in equilibrium. Analysis of over 700 beach profiles has provided an empirical relationship between sediment size and the equilibrium profile characteristics A and  $D_*$  as discussed by Dean (1984).

During a severe storm, the increased water level initially permits waves to break closer to shore. This effectively reduces the width of the surf zone and at the same time increases the energy dissipation per unit volume at all points in the surf zone. The profile is therefore "out of equilibrium" since actual energy dissipation levels are greater than the stable value,  $D_*$ . Based on the assumption that the profile will respond back toward equilibrium, the final result must be a widening of the surf zone until the actual energy dissipation equals  $D_*$ . This result can only be achieved by a net redistribution of sand over time, with erosion occurring nearshore and deposition pushing the breakpoint offshore.

Bakker (1968) and Swart (1974) have previously proposed that the net offshore sediment flux could be represented in terms of the

disequilibrium of geometric profile lengths. In a similar fashion, if energy dissipation per unit volume is assumed to be the general forcing mechanism, then the offshore sediment transport rate may be related to the excess energy dissipation per unit volume as:

$$Q = K(D - D_*) \quad (2)$$

in which K is a proportionality factor to be determined. In a concurrent study, Moore (1982) found K to be on the order of  $10^{-6} \text{ m}^4/\text{N}$ .

For numerical simulation of time-dependent profile response, the equation for sediment flux is coupled with the equation for continuity of sand in the onshore-offshore direction

$$\frac{\partial x}{\partial t} = - \frac{\partial Q}{\partial h} \quad (3)$$

which is then solved numerically. Details of the numerical simulation are presented by Kriebel and Dean (1984). As a brief summary, the surf zone is represented by a series of elevation contours of uniform width,  $\Delta h$ , with the distance,  $x$ , defined from a reference baseline to the center of each contour. The solution proceeds by raising the water level and establishing the offshore limit of the active profile at the breakpoint of incident waves. The energy dissipation per unit volume,  $D$ , and the sediment transport rate,  $Q$ , are then calculated throughout the surf zone. An implicit, linearized finite-difference scheme is used which yields a tridiagonal matrix relating the change in position,  $\Delta x$ , of three adjacent contours. This system is then solved by the so-called double-sweep procedure to determine the change in contour location,  $\Delta x$ , over each time step.

#### EROSION MODEL - RESULTS

General characteristics of the numerical solution appear to be consistent with natural and laboratory beach profile response. If an initial equilibrium profile with linear beach face slope and a distinct berm is subjected to an instantaneous increase in water level which is held steady as the system responds toward equilibrium, then the general solution for either berm recession or volumetric erosion exhibits nearly exponential behavior, approaching equilibrium asymptotically. This behavior agrees quite well with laboratory results of Saville (1957), Swart (1974), Vellinga (1983), and Hughes (1983). Numerical results for 0.2 to 0.3 mm sand and wave heights of 1 to 5 meters indicate that natural erosion time scales are on the order of 10 to 100 hours, thus indicating that equilibrium is probably not attained during typical storm conditions.

For practical application to single storm erosion simulation, the time-history of erosion may be estimated simply by inputting new water level and wave height conditions at each time step over the duration of the storm surge. In the example in Figure 3, the time-dependent erosion is predicted for an idealized storm surge hydrograph applied to a representative beach profile as discussed by

Figure 3. Time-Dependent Erosion Prediction for Idealized Storm Surge.

Kriebel and Dean (1984). In this case the right axis is scaled to the maximum erosion potential of the peak surge - a value that requires the peak surge level to be held steady for almost 300 hours.

This idealized example illustrates the general characteristics of the time-dependent erosion solution and reveals several features that seem representative of nature. First, the erosion potential of the peak surge is not realized during most storm events. Based on idealized cases with peak surge elevations of up to 3.6 m and 36 hour durations, only 14% to 36% of the maximum erosion potential is attained. Second, the erosion rate is maximum at about the time of the peak surge. Offshore transport processes respond at a slow rate relative to changing water levels, thus energy dissipation per unit volume, spatial gradients in sediment flux, and the erosion rate are all maximum at the time of the peak surge. Finally, the maximum erosion lags the peak storm surge. As the water level recedes, energy dissipation remains greater than equilibrium for some time causing erosion to continue.

A preliminary verification of the erosion model is obtained from a hindcast of erosion associated with Hurricane Eloise in the Florida Panhandle. The calibrated, Bathystrophic storm surge model is used to estimate the open coast storm surge and the predicted peak surge of 3.2 meters compares favorably to predictions of 3.2 meters by the National Weather Service (Burdin (1977)) and 2.9 m by Dean and Chiu (1982). This hydrograph is then applied to a schematic profile which is considered representative of the area of interest. A total of 20

test runs are made to simulate various combinations of beach slope, dune slope, wave heights, and water levels - both to test model sensitivity and since exact values cannot be specified for all parameters.

In a summary of results for all 20 test cases in Table 1, predicted volumetric erosion ranges from 20.8 to 38.4 m<sup>3</sup>/m with best estimates of 27.1 to 30.1 m<sup>3</sup>/m based on the parameters that best describe pre-storm and storm conditions. For comparison, Chiu (1977) gives average eroded volumes of 23.3 to 30.1 m<sup>3</sup>/m. Both observed and predicted erosion are in close agreement, especially when compared to the maximum erosion potential of 113 to 289 m<sup>3</sup>/m associated with steady-state peak surge levels.

Table 1. Comparison of Numerical Solution to Observed Erosion

	Volume Eroded m <sup>3</sup> /m	Dune Recession m
Range Predicted	20.8 to 38.4	4.8 to 9.5
Best Estimates	27.1 to 30.1	6.8 to 7.0
Observed (Chiu)	23.3* to 30.1*	2.7 to 6.1 (4.6 m contour) 7.2 to 12.8 (3.0 m contour)
Maximum Potential	112.9 to 288.6	33.5 to 76.2

\*Includes 5m<sup>3</sup>/m to reflect maximum erosion before recovery

As discussed by Kriebel and Dean (1984) dune steepening is not simulated in the model and this is evident in a comparison predicted and observed dune recession values. Predictions range from 4.8 to 9.5 m with best estimates of 6.8 to 7.0 m. Observed dune recession varies depending on the elevation contour and varies from 2 to 13 m with the 3.0 meter contour eroding about twice as far as the 4.6 m contour. However, predicted values are of the correct order of magnitude; this is further evidenced by the 33 to 76 m estimates of the maximum erosion potential of the same dunes.

It is emphasized that the predicted post-storm profiles such as shown in Figure 4 are not in equilibrium relative to the peak surge level and do not have the equilibrium  $Ax^{2/3}$  shape consistent with the 0.26 mm sand in the profile. The true equilibrium profile is attained only after the peak storm surge is maintained for about 1,000 hours after which equilibrium erosion values are up to 10 times the erosion predicted by the time-dependent storm surge.

#### ESTIMATION OF EROSION FREQUENCIES

As noted, the proposed erosion model is incorporated into a general Monte Carlo simulation model, as depicted in Figure 1, to obtain estimates of the frequency distribution of erosion events. Required input parameters include the probability of a hurricane or tropical storm occurring in a given year and the probability

Figure 4. Example of Predicted Post Storm Profile, Hurricane Eloise.

distributions of various storm parameters which include the central pressure, radius of maximum wind, forward speed, direction of motion, and location of the storm track. Synthetic storms are assembled by selecting each parameter based on a separate uniformly distributed random number between 0 and 1. Once a storm is randomly assembled, the surface wind speed, pressure field, and storm surge are simulated at one-half hour time-steps. In this study, a one-dimensional Bathystropic storm surge model is chosen for simplicity and is calibrated through the bottom friction coefficient as described by Marinou and Woodward (1968), or Bodine (1971). The storm surge is then combined with a randomly-phased astronomical tide to produce the total storm tide.

While the storm tide serves as the principle driving mechanism in the numerical solution, an estimate of the breaking wave height is needed to serve as a boundary condition governing the surf zone width. A procedure similar to that used by Dean and Chiu (1982) is employed in which the maximum deepwater significant wave height of the hurricane is first determined according to the method of Bretschneider (1957). The local breaking wave height is then estimated by scaling the maximum deep water wave height according to the ratio of local wind speeds at the shoreline to maximum wind speeds in the storm. With the water surface elevation and breaking wave height at each time-step, the profile change over each time-step may then be determined with the erosion model. This is repeated for

each synthetic storm over the N-year period. Results of the procedure include the peak storm surge, maximum volumetric erosion, and maximum dune recession for each storm. Frequency curves are then determined for each variable based on a simple plotting position formula.

#### APPLICATION OF MONTE CARLO STORM SURGE - EROSION MODEL

As an example of the Monte Carlo procedure, five 100-year simulations have been carried out for Bay County, Florida. The five simulations include 63, 74, 67, 69, and 70 hurricanes and tropical storms respectively for an average of nearly 69 storms per 100 years over the 300 nautical miles of coastline considered. For each storm, the initial profile, representative of pre-Eloise conditions, is re-established so results may then be compared to observed erosion from Hurricane Eloise.

In Figure 5, the storm surge frequency curves of all five runs are presented and show the expected natural variability obtained from the Monte Carlo procedure. Storm magnitudes for lower return periods are well-defined; however, the 100-year storm surge estimate varies by about 1 meter. In order to reduce this variability, the five individual curves are averaged in Figure 6. While this average curve could also be bounded by confidence limits based on observed variability between different Monte Carlo simulations, several more runs would be required to obtain stable estimates of the standard deviations of each return period. The predicted average frequency curve is compared to the results of two other numerical estimates for the same area, indicating the validity of the procedure for estimating storm surge frequencies.

The frequency distributions for volumetric erosion from each of the five 100-year simulations are plotted in Figure 7. As expected, there is some variation between the five curves at 50 to 100 year return periods; however, the erosion curves are closely grouped at all return periods. Again, the five curves are averaged and the mean volumetric erosion, as well as dune recession, are extended to 500-year levels in Figures 8 and 9. Without empirical data on historical storm related erosion events, it is difficult to verify these randomly generated erosion frequency curves. However, the predicted values are in general agreement with guidelines for storm-related erosion given by the U.S. Army Corps of Engineers (1977) where the severity of open coast erosion is broadly classified as:

moderate storm	10 - 25 m <sup>3</sup> /m
extreme storm	25 - 25 m <sup>3</sup> /m
rare storm	50 - 125 m <sup>3</sup> /m

An interesting comparison can be made between the predicted frequency curves, in Figures 6, 8, and 9, and the observed storm surge and erosion characteristics of Hurricane Eloise. Although there is no data to firmly establish the peak storm surge level of Hurricane Eloise for the area of interest, if the predicted value of 3.2 m is accepted then it appears that Eloise may be associated with

Figure 5. Results of Five 100-Year Simulations for Peak Storm Surge.

Figure 6. Comparison of Predicted Storm Surge Frequency Curves.

Figure 7. Results from Five 100-Year Simulations for Volume Eroded.

a return period of about 75 years. However, if observed erosion characteristics with a 9 m dune recession and an eroded volume of  $30.1 \text{ m}^3/\text{m}$  are considered, then from Figures 8 and 9, Hurricane Eloise should probably be classified as a 25 to 50 year storm in terms of its erosion damage. Since Hurricane Eloise was a rapidly moving storm of short duration, a relatively small percentage of its erosion potential was realized.

This conclusion is reinforced in Figure 10 where the peak storm surge is plotted against the predicted maximum volumetric erosion for all storms in one simulation run. It is evident that the largest storm surge levels do not always produce the greatest erosion. Likewise, several relatively small storms can produce significant erosion due to longer durations. The range of erosion values associated with Hurricane Eloise clearly fall below what would normally be expected for a storm of the same magnitude, i.e. peak surge. Certainly, storm duration and magnitude, not just magnitude alone, are important considerations when estimating erosion frequencies.

CONCLUSIONS

A numerical model has been developed which allows a first-order estimate of: 1) the time-dependent beach and dune erosion associated with tropical or extra-tropical storm surge and 2) the frequency distribution of extreme erosion events based ultimately on historical meteorological parameters of severe storms. The proposed erosion model is certainly in the developmental stages. Current research is being directed toward incorporating wave runup, variable beach slopes, and the formation of dune scarps. Also, a detailed

Figure 8. Predicted Frequency Curve for Volume Eroded.

Figure 9. Predicted Frequency Curve for Dune Recession.

Figure 10. Comparison of Predicted Storm Surge and Volume Eroded for One 100-Year Monte Carlo Simulation.

calibration and verification of the model is being performed based on available field data on pre- and post-storm beach profiles from Hurricane Eloise.

Numerical estimates of erosion frequency distributions appear reasonable although verification is impossible without extensive field data on storm erosion. In general, however, the Monte Carlo procedure is well-verified for predicting storm surge probabilities. The method presented is a logical extension of the Monte Carlo technique that may permit the development of erosion frequency distributions for any open coast location in which historical meteorological parameters of severe storms are available.

#### ACKNOWLEDGEMENTS

The support of the National Oceanic and Atmospheric Administration, the University of Delaware Sea Grant College Program, and the Florida Department of Natural Resources is gratefully acknowledged. Ms. Cynthia Vey and Ms. Lillian Pieter provided excellent secretarial and drafting support, respectively.

## CHAPTER ONE HUNDRED NINE

### THE NILE LITTORAL CELL AND MAN'S IMPACT ON THE COASTAL ZONE OF THE SOUTHEASTERN MEDITERRANEAN

by

Douglas L. Inman and Scott A. Jenkins

#### INTRODUCTION

Man's intervention with coastal processes takes many forms. However, the most serious large scale, long term coastal erosion results from the interception by dams of rivers supplying sediment to the coast. This loss of sediment may have catastrophic effects along coasts where streams discharge directly into coastal waters. The Nile littoral cell is an impressive example of the effect of dams on coastal erosion.

The Nile littoral cell is located in the southeastern Mediterranean Sea and extends 700 km from Alexandria, Egypt in the south to Akko, Israel in the north. The sediment load from the Nile River was deposited along the submerged portion of the delta, where it was sorted and transported to the east by the prevailing waves and by currents of the counterclockwise east Mediterranean gyre that commonly flows at about 50 cm sec<sup>-1</sup> over the delta. Prior to 1964, the turbid plume of the flood waters of the Nile River could be traced along the Mediterranean coast for over 700 km to the shores of Lebanon. Fine silt and clay sized material were carried easterly and into deeper water, while sand is carried easterly along the shelf and shore as far as Haifa Bay.

Until 1964, the major sediment source of the littoral cell was the Nile River. Construction of the High Aswan Dam, which began filling in 1964, has resulted in a near absence of Nile River flow into the Mediterranean and a corresponding complete loss of the Nile River as a source of nutrients to coastal waters, and as an active sediment source for the delta and the coastline of the Nile littoral cell. As a result, the Nile Delta is now subject to severe erosion in a number of localities.

#### GEOLOGIC SETTING

The physiography of the Mediterranean basin is best understood in terms of the tectonics of the moving plates of the lithosphere. The complex Mediterranean region results from the collision between the African and the Eurasian plates, a process that is gradually closing the Mediterranean Sea. In the eastern portion of the sea, under-thrusting of Mediterranean seafloor under the Eurasian continental plate has formed a broad zone of plate collision extending from the foot of Italy, eastward and to the south of Greece, Crete and Cyprus. The plate collision has resulted in a mountainous, volcanic belt north of and parallel

---

Center for Coastal Studies, Scripps Institution of Oceanography, La Jolla, California, 92093

to the zone of under-thrusting. The plate collision also has produced a series of transform faults caused by the adjustment of interplate continental fragments (e.g. Nur and Ben-Avraham, 1978; Ben-Avraham, 1978; Jongsma and Mascle, 1981). The tectonics is complicated locally by a spreading center in the Red Sea and its transform faults which includes the major Levant rift zone that cuts through the Gulf of Aqaba and the Dead Sea. Local adjustment faults occur in the Akko region that probably determine the location of Haifa Bay and Akziv submarine canyon.

#### Sea Level Changes

Fluctuations in the level of the Mediterranean Sea have been important factors in the cutting and filling of the Nile Valley, the formation of the delta, and the distribution of Nile River sediments. The Nile valley was cut to its maximum depth during the great Miocene desiccation about 24 m.y. (million years) ago when the Mediterranean was isolated from the world oceans, causing the sea to dry and become a salt pan. At that time the river cut a gorge deeper than the Grand Canyon of the Colorado. The valley began filling over its ancient delta when the Mediterranean filled during the Pliocene about 10 m.y. ago. The present Nile Delta has a sediment thickness of over 3.5 km along the continental shelf, and a sediment volume estimated to be  $350$  to  $387 \times 10^3 \text{ km}^3$  (Said, 1981; Ross and Uchupi, 1977; respectively).

There were many sea level fluctuations during the Pleistocene that resulted in Nile valley cut and fill and in different positions in the delta shoreline. Sea level rose from about -140 m, 15,000 years ago and is still rising at a rate of about 15 cm per century. The present sea level rise is a factor in coastal erosion, possibly accounting for a shoreline retreat of 10 to 15 m per century.

#### Distribution of Recent Sediments

Two major and distinct sediment types are found on the beaches and shelves of the southeastern Mediterranean Sea. A calcareous suite of sediments that consists of shell fragments and other organic detrital material, usually found near its origin, or of carbonate oolites thought to be brought as windblown sand from the western desert (Hilmy, 1951). Off the Nile Delta and elsewhere on the shelf, mounds of living coralline algae contribute coarse debris to the surrounding sediments (Coleman, et al., 1981).

The second sediment type consists of sand, silt and clay brought to the sea by the Nile River before the High Aswan Dam. The clay minerals include montmorillonite, kaolinite and illite. In the past, fine sediments from the Nile River have provided a major portion of the sediment fill of the eastern portions of the Levantine Basin between Cyprus and Lebanon (Venkatarathnam and Ryan, 1971; Nir, 1982a). The sand size fraction of this sediment consists predominantly of quartz with a distinctive admixture of heavy minerals. Amphibole (hornblende) and pyroxene (augite) are dominant and in nearly equal abundance; while the unique yellow-green and brown-violet varieties of augite are diagnostic for Nile sands (Shukri and Philip, 1960).

The Nile River is the only abundant source of sediment in the

eastern Mediterranean, and wherever these sediments are transported they have overwhelmed the sparse supply of calcareous sediment. During floods through the Rosetta mouth some Nile sediment has gone as far west as Ahu Quir headland. However, the prevailing winds, waves and currents of the east Mediterranean gyre have resulted in an easterly and northeasterly transport of Nile sediment. Nile sediment is dominant from Ahu Quir headland for 700 km to Akko on Haifa Bay.

The beach sands from west of Mersa Matruh for 300 km to Ahu Quir headland are calcareous oolites and shell fragments (Hilmy, 1951; El-Wakeel and El-Sayed, 1978). From Ahu Quir Bay to Haifa Bay the beach and shelf sediments are predominantly from the Nile as shown by many studies of mineral distribution (Rim, 1950; Shukri and Philip, 1960; Pomeranchlum, 1966; Nir, 1982a).

A detailed study by Nir (1980) of the sediments in the vicinity of Haifa Bay shows that the quartz sand from the Nile divides into two distinct paths, separated by a series of submarine kurkar ridges. A shallow (out to 15 m depth) band of Nile sand follows the coast around Carmel Head and into the bay forming the beaches and wind blown sand dunes of Haifa bay. Beach accretion and dune formation at Haifa appear to be the sink for the shallow water Nile sand. A deeper (25 m and over) band of Nile sand and silt parallels the coast and appears to extend north of Akko. The transport and final sink for this sediment is not clear. At a lower sea level Akziv submarine canyon may have been the sink for sand bypassing Haifa Bay.

#### SHORELINE CHANGES

Historically the position of the coastline of the Nile Delta has been determined by the relative importance of deposition of sediments during the annual floods of the Nile River which build the delta seaward, versus the action of waves and currents which transport the sediments and erode the delta. Generally, until the beginning of this century the discharge of sediment has exceeded the potential for erosion, and the delta built seaward (Figure 1). However, man's intervention, beginning with construction of barriers in the lower reaches of the Rosetta and Damietta branches and with the construction of the Low Aswan Dam in 1902, changed the pattern to one of erosion. Construction of the High Aswan Dam, which began filling in 1964, has resulted in a complete loss of the Nile River as an active sediment source for the delta. As a consequence, the action of waves and currents, which have remained undiminished, are in the process of eroding and changing the configuration of the coastline of the Nile Delta.

There appears to have been significant accretion of the Nile Delta from at least 1600 to 1898. During that time Rosetta promontory probably extended seaward about 8 or 9 km (Sestini, 1976). The promontory extended 3.6 km (37 m/yr) between the surveys of 1800 and 1898, then remained nearly stationary from 1898 to 1909. From the turn of the century to the present the seaward portion of the promontory has eroded at a progressively more rapid rate. The erosion rates for the periods preceding the surveys of 1926, 1965, 1973 and 1982 being 18, 20, 125 and 211 m/yr, respectively (Figure 1). The "new" Rosetta Lighthouse which was 1 km inland in 1970, became an offshore island in 1976 (Niel-

sen, 1977; Khafagy et al., 1981).

The establishment in 1971 of a series of beach profiles extending from Abu Quir Bay to east of Ras El Bar was an essential part of the erosion study. Repeated surveys along these profiles has proved to be the most effective means of monitoring the erosion. Comparison of beach profiles show that the coastline has retreated off the delta promontories averaging 160 m between 1971-1972 and 211 m/yr between 1973 and 1982 off the Rosetta branch and 143 m/yr between 1943 and 1973 on the Damietta promontory east of Ras El Bar (ARE/UNESCO, 1973). In contrast there has been a modest shoreline advance (accretion) in the embayments, e.g., 8 m/yr (1947-1965) at the Gamasa outlet (Kadib, 1969; Mobarek, 1972; Orlova and Zenkovich, 1974). Although beach profiles have been conducted since 1971 there are few printed details. Hammad et al (1979) give the average loss of sediment from the shoreline to 6 m depth as  $19 \times 10^6 \text{ m}^3/\text{yr}$  for the period 1972 to 1976. Manohar (1981) graphs results for this same period and others that clearly show the rate of erosion is accelerating.

Inman et al (1976), using only the principal wave component from surface marine observations obtained longshore sand transport rates of about  $860,000 \text{ m}^3/\text{yr}$  to the east near Rosetta and Damietta promontories and somewhat lower values between promontories. QueIennec and Manohar (1977) estimate the net transport rate near the promontories to be more than  $3 \times 10^6 \text{ m}^3/\text{yr}$  with lower rates between promontories. Comparisons of photographs of the entrances to Bardawil Lagoon, about 140 km east of Ras El Bar, show that the volume of sand trapped on the west side of jetties and eroded from the east side gives easterly transport rates of about  $500,000 \text{ m}^3/\text{yr}$  (Inman and Harris, 1970; Inman et al., 1976).

Numerous structures have been built along the coast of Israel. Most were built to widen beaches for recreational use and prevent cliff erosion, and others to provide harbors. Ashdod Harbor diverts sand offshore in amounts that suggest longshore transport rates of 215-560,000  $\text{m}^3/\text{yr}$ . Other studies indicate longshore sand transport rates of 400,000, 125,000, and 80,000  $\text{m}^3/\text{yr}$  at Gaza, Hadera and Atlit respectively (Nir, 1982h). from wave measurements Carmel et al (1984b) estimate the transport at Haifa to be about 110,000  $\text{m}^3/\text{yr}$ . These various estimates of longshore transport are discussed further and plotted in Carmel et al (1984c).

#### NILE RIVER DISCHARGES

The Nile River derives its waters from the Lake Plateau of Tanzania and Kenya (White Nile) and from the Ethiopian highlands (Blue Nile). It has a drainage basin of about  $3 \times 10^6 \text{ km}^2$  and a length of 6800 km. The Nile traverses 35 degrees of latitude in its long northerly flow from its source in Tanzania to the Mediterranean Sea. Before the High Aswan Dam, the river discharged annually  $86 \times 10^9 \text{ m}^3$  of water (Hurst, 1952; Said, 1981).

Man's intervention in the flow of the Nile dates back at least to pharaonic times when Senusret had a canal built from the ancient Pelusiac branch of the Nile to the Red Sea (circa 1900 BCE). Modern intervention began with construction of the Delta Barrage below Cairo in

1861. The barrage sluices opened to pass flood waters, of which about 70 percent flowed out the Rosetta mouth and 30 percent through the Damietta. The barrage was the beginning of perennial versus basin irrigation, and the extensive use of Nile silts and clays as nutrients in agriculture. This use continued with the Low Aswan Dam built in 1902, up until the High Dam was completed in 1964, which trapped all of the sediment load.

The Low Aswan Dam was increased in height in 1907 and again about 1929 to a total height of 38 m. The dam is 2 km across and raised the river level for 350 km upstream to the Second Cataract near Wadi Halfa. The Low Aswan Dam was specially provided with sluices to pass the flood waters and their sediment load. However, because of its height and extensive back-up of water, it is not surprising that it trapped some sediment (Hammad et al., 1979). Calculations show that about 60% of the fresh water discharged at the Low Aswan Dam was lost to irrigation and evaporation on its way to the Mediterranean (Sharaf El Din, 1977).

Before 1861, probably much of the fine load and most of the sand was carried during the flood months, and deposited off the Mediterranean delta of the Nile. The erosion of Rosetta promontory which began about the turn of the century was probably in part due to a decreased supply of sediment caused by the Low Aswan Dam (Figure 1).

The flood months of the Nile River are usually taken as July through November, with the maximum monthly discharge of about 17 and  $21 \times 10^9 \text{ m}^3$  during August and September respectively. However, measurements show that the rising phase of the flood in August carries the highest percentage of suspended load. A minimum water discharge of  $1.5 \times 10^9 \text{ m}^3$  occurs in May. The sand content of the suspended load appears to have been about 30% for the free Nile above the dams, and was about 25% at Gaafra below the Low Aswan Dam. This difference would be expected if the Low Aswan Dam trapped sediment, as sand is more sensitive to changes in river gradient behind dams than is the wash load.

The peak flood water level of the Nile has been monitored for millennia, providing the longest time series of annual floods known (Hurst, 1957; Van Atta and Helland, 1977). The levels were accurately recorded because they provided a reliable method of taxing the people for the irrigation and growth of crops. Unfortunately there has been but little measurement of suspended sediments and no measurement of bedload. According to Queleennec and Kruk (1976) there were two series of suspended load measurements separated by several breaks, including one of 17 years, centered around World War II. Series 1 included the years 1928-1931 and 1938, while series 2 spanned the period from 1955-1969. Suspended load measurements for the free Nile flood above the low dam were made at Halfa only during series 1; while measurements for the Nile at Gaafra below both the low and high dams were made during both series 1 and 2. Series 1 measurements occurred during a period of low river flow (1913-1931) while series 2 included a period of high flow (1953-1963).

There have been a number of studies of suspended sediment discharge of the Nile River. All are based on series 1 and 2 data except for Simaika (1970; see Hammad et al, 1979) who seems to have extended the

series 2 data above the Low Aswan Dam from 1955 to some unspecified date by moving measurements from Halfa to Kajnarty. The effect of this move on the quality of data is not discussed. The data of Simaika (1970) and Fahmy (1974) appear to be based on averages of data taken during the relatively short periods of measurement (i. e. 5 and 14 years respectively), and thus do not include a long series of data nor the highest or lowest flow years.

In order to obtain a longer, more representative data base Quelenec and Kruk (1976) correlated the series 1 and 2 suspended sediment data with water discharge for both rising and falling water levels. This gave them a sediment rating curve so that suspended load could be simulated from water discharge, for which there is extensive data. In this way they found that the average annual suspended load of the Nile at Gaafra for the 60 years from 1904 to 1963 to be  $160 \times 10^6$  tons/yr. The lowest sediment load was less than  $50 \times 10^6$  tons/yr in 1913 and the highest was greater than  $300 \times 10^6$  tons/yr in 1954. No sediment has passed the High Aswan Dam since it began filling in 1964. The sediment is deposited and is rapidly filling the headwaters of Lake Nasser behind the dam.

For the sediment budget needed in this study it is necessary to estimate the total load of the free flowing Nile for this century. The data from Simaika has too few years to be representative while that from Quelenec and Kruk (1976) includes the effects of the Low Aswan Dam. Hammad et al (1979) use the data of Simaika and Fahmy to show that the Low Aswan Dam trapped suspended sediment at the rate of  $10.5 \times 10^6$  tons/yr. Thus none of the data is entirely satisfactory for our purposes, and none includes bedload. From standard text such as Schumm (1977) and Richards (1982) it would appear that for rivers with the channel and suspended load characteristics of the Nile, the bedload is between 1% and 10% of the total load.

In lieu of a longer data base, that of Quelenec and Kruk is used here as the best estimate of the long term suspended load of the free Nile. From this the total load is estimated in Table 1 and compared with the measured erosion rate of the Nile delta out to depths of 6m. Since the erosion extends beyond 6m depth, and the erosion rate is increasing with time (Manohar, 1981), the erosion rate of sand must be greater than the measured rate of  $19 \times 10^6 \text{ m}^3/\text{yr}$  along the delta. On the other hand it may not be as great as the  $41 \times 10^6 \text{ m}^3/\text{yr}$  assuming a Nile bedload of 10%. Therefore for purposes of this study it is assumed that the total annual yield of sand of the free Nile was between 20 and  $41 \times 10^6 \text{ m}^3/\text{yr}$ , and was probably about  $30 \times 10^6 \text{ m}^3/\text{yr}$ .

#### DRIVING FORCES: WINDS, WAVES AND CURRENTS

The circulation in the Mediterranean Sea is both geostrophic and thermohaline with salinity, due to an excess of evaporation over precipitation and runoff, increasing to the east where it reaches 39 ‰ in the Levant Sea off Israel. The surface circulation of the east Mediterranean is dominated by the counterclockwise flow of the east Mediterranean gyre that carries water from the straits of Sicily past the Nile delta, into the Levant Sea, to the north and west of Cyprus, and into the Cretan Sea (Sverdrup et al., 1942, p. 649; Orin, 1971;

Table 1. Estimated sediment yield of the Nile River at Gaafra compared with Nile Delta erosion.

\* Assuming bedload to be 1% of total load. \*\* Assuming bedload to be 10% of total load. † Assuming "at rest" volume ratio (solid/whole space) of 0.5;  $\rho_s = 1.59 \text{ tons/m}^3$

Sharaf El Din, 1977; Bethoux, 1980). Surface currents of the gyre impinge upon the shallow Nile delta and sweep across it with velocities of 20 to 100 cm/sec and locally up to 2 m/sec. Prior to the closure of the High Aswan Dam in 1964, the turbid plume from the floodwaters of the Nile River could be traced along the Mediterranean coast for over 700 km from Ahu Quir headland to the shores of Lebanon (Hecht, 1964; Orin, 1969; Sharaf El Din, 1977).

The Damietta promontory of the Nile interacts with the east Mediterranean gyre to form a large eddy that begins at Damietta, extends offshore for up to 35 km and eastward along the coast for about 70 km. The seaward portion of the eddy is a high speed jet over 5 km wide that forms off the promontory and flows northeasterly and then easterly with

measured surface to bottom velocities of over 60 cm/sec (Murray et al., 1981). The eddy drives a field of actively migrating sand ridges easterly over a smooth mud plain. The sand belt begins in depths of 10 m flows northeasterly, turns easterly and finally arcs southeasterly towards the coast between Port Said and Bardawil Lagoon (Coleman et al., 1981). This appears to be a major transport path and sink for Nile sand.

The currents of the east Mediterranean gyre dissipate energy as they flow over the shallow shelf of the Nile delta. There is insufficient current data to make detailed calculations. However the energy loss may be approximated from the drag relation,

$$\text{energy loss/area} = \tau u = c_f \rho u^3$$

where  $\tau$  is the drag force per unit area (newtons/m<sup>2</sup>),  $u$  is the mean current velocity (m/sec),  $c_f = 2 \times 10^{-3}$  is the drag coefficient and  $\rho$  is the density of sea water. Assuming that an average current of 50 cm/sec flows over a shallow (<50 m) area of  $10^4 \text{ km}^2$ , the above relation gives an overall energy dissipation rate of about  $2.5 \times 10^6 \text{ kW}$ .

Tidal ranges are about 30 cm along the coast of the southeastern Mediterranean. The effect of tides is negligible except near large lagoons, where together with wind and evaporation they control water exchanges through the entrances. Tides will not be further considered here.

### Waves

The most common winter storms contain low pressure areas which move from west to east over Southern Europe and the Mediterranean. The track of the storm centers pass progressively over Italy, Greece and southern Turkey, so that the cyclonic winds in the lower quadrants of the storm blow from west to east, progressively covering most of the 2200 km fetch between Sicily and Israel. The storms may occur every 6 to 7 days and their centers are often fast moving, with migration velocities of 900 to 1000 km/day. This migration rate is comparable with the speed of the waves, causing the wave height to be enhanced. The waves typically have deep water heights of 3 to 6 m and periods of 8 to 10 sec and sometimes up to 15 sec (Carmel et al., 1984a). The waves arrive off Abu Quir about one-half day before reaching the Israel coast.

The details of wave directional climate from measurements along the coasts of Israel and Egypt are given in a series of recent reports (Inman et al., 1982; Lowe and Inman, 1983; Carmel et al., 1984a,h,c; Elwany, et al., 1984). Along the Israel coast near Haifa these measurements reveal a bimodal distribution of wave height and energy flux with the winter storm waves approaching from south of the beach normal and the lower summer waves from north of the beach normal. The magnitude of the monthly averaged energy flux ranged from 1 to 7 kW/m with an average annual energy flux of 3.3 kW/m. Thus the Mediterranean coast of Israel is a moderately high-energy coast with a bimodal annual cycle (Carmel et al., 1984h,c).

Because of the shorter fetch, the Nile delta coast of Egypt has a slightly lower wave energy, but a more pronounced, unidirectional flux of energy along the coast. The average annual flux of wave energy incident on the Nile delta coast is about 2.5 kW/m (Lowe and Inman, 1983; Elwany et al., 1984). Correcting for refraction, a deepwater energy flux of 2.5 kW/m, results in a total energy dissipation rate due to waves along the 200 km from Abu Quir to Port Said of about  $0.5 \times 10^6$  kW.

Longshore Sand Transport by Wave Action

Theory and field measurements of waves and the resulting longshore transport of sand show that the sand transport is directly proportional to the longshore power factor of the waves (e.g. Komar and Inman, 1970; Inman et al., 1980).

$$I_1 = K [P \sin \alpha \cos \alpha]_b = K [CS_{yx}]_b \tag{1}$$

where  $K \cong 0.8$  is a dimensionless constant,  $P = EC_n$  is the energy flux of the waves (watts/m),  $E$  is the wave energy per unit area ( $\text{joules/m}^2$ ),  $C_n$  is the wave group velocity (m/sec),  $S_{yx} = E n \sin \alpha \cos \alpha$  is the longshore radiation stress,  $\alpha$  is the angle the breaking wave makes with the shoreline, and the subscript  $b$  indicates that all properties are measured at the breakpoint of the waves. In the above relation,  $Q_1$  is the immersed weight longshore transport rate (newtons/sec) and may be expressed in terms of the "at rest" volume transport rate  $Q_1$  ( $\text{m}^3/\text{sec}$ )

$$Q_1 = I_1 / (\rho_s - \rho) g N_0 \tag{2}$$

where  $\rho_s$  and  $\rho$  are the densities of the solid grains and the water respectively,  $g$  is the acceleration of gravity and  $N_0$  is the volume concentration of sand, equal to about 0.6 for well sorted sand at rest. For quartz sand in seawater the factor  $1/(\rho_s - \rho) g N_0$  has the value of  $1 \times 10^{-4} \text{ m}^3/\text{newton}$ .

The potential for the longshore transport of sand by waves can be calculated from relations (1) and (2) when the wave characteristics at the breakpoint are known. This requires that waves be refracted from deep water to the breakpoint. Application of Snell's law to the refracted waves, and the assumption that the energy flux  $P = EC_n$  is conserved between wave rays gives the relation between deep water and the breakpoint as

$$P_b = P_\infty \cos \alpha_\infty / \cos \alpha_b \tag{3}$$

where the subscript  $\infty$  refers to waves in deep water. Limited studies of wave refraction along the Nile delta coast were made by Inman et al (1976) and Quelennec and Manohar (1977) using wave data from marine observations. A more comprehensive study is in progress by Elwany et al (1984) based on measurements from wave directional arrays. These measurements show that the prevailing deep water direction for storm waves is from about  $N60^\circ W$ , and that the waves commonly have periods of 8 to 10 sec.

A refraction diagram for 8 sec waves from  $N60^{\circ}W$  (Figure 2) shows pronounced zones of wave convergence and divergence that result in strong gradients of wave height and breaker angle along the coast. This means that the longshore transport rate  $Q_l$  is not constant but varies with distance along the coast as shown in the central graph of Figure 2. This variation in  $Q_l$  results in areas of erosion and accretion along the coast. The rates of erosion and accretion are given by the divergence of the drift  $\partial Q_l / \partial l$  (eg Inman et al, 1976) as shown in the lower graph of Figure 2. It is to be noted that positive values of  $\partial Q_l / \partial l$  indicate erosion while negative values indicate accretion.

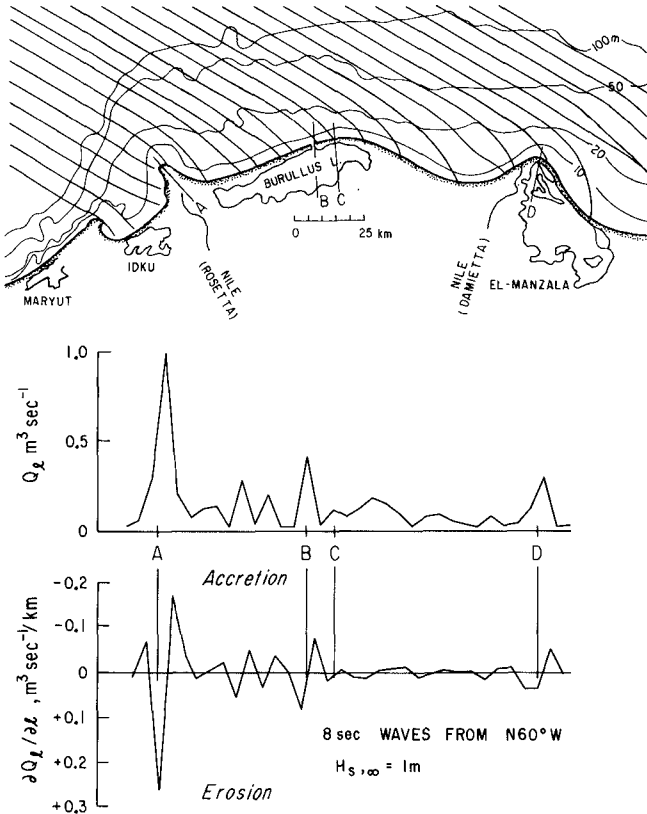

Figure 2. Wave refraction and variation of longshore sand transport (LST) along the Nile delta coast for a 1 m high, 8 sec wave coming from  $N60^{\circ}W$ . Note that the LST (center) is everywhere to the east even though the divergence  $\partial Q_l / \partial l$  shows local zones of erosion (+) and accretion (-) (data from Elwany et al., 1984).

Although Figure 2 is for a single wave condition it illustrates several fundamental aspects of delta morphology. First, there are three general zones of pronounced erosion, that occur off the promontories of Rosetta, Burullus and Danietta. Zones of accretion occur to the east of each erosion zone. Finally, a net easterly longshore transport of sand occurs in the presence of alternate zones of accretion and erosion as  $Q_1$  is everywhere positive and to the east. Several previous studies have wrongly concluded that the presence of alternate zones of erosion and accretion indicated coastal compartments that were closed to net uni-directional transport of material.

The variations in wave intensity and direction and the resulting complex pattern of wave refraction along the delta coast preclude simple interpretations of the wave potential for a net annual longshore transport of sediment. Therefore, for the present it is useful to take a more aloof view and consider the transport potential that the estimated deep water wave energy flux of  $P_\infty = 2.5 \text{ kW/m}$  would produce along the coast. Inspection of relations (1), (2) and (3) show that the longshore sand transport is proportional to the product  $\cos \alpha_\infty \sin \alpha_b$ , which varies along the delta coast. However inspection of the refraction diagrams for prevailing waves (e.g. Figure 2) show that  $\alpha_\infty$  commonly varies between  $45^\circ$  and  $60^\circ$  while  $\alpha_b$  is most commonly between  $20^\circ$  and  $45^\circ$ . Thus the product  $\cos \alpha_\infty \sin \alpha_b$  commonly falls between 0.17 and 0.5, and the longshore transport will commonly fall between 1 and  $3 \times 10^6 \text{ m}^3/\text{yr}$ . Thus a conservative estimate of the net annual longshore transport due to wave action along the delta coast is  $1 \times 10^6 \text{ m}^3/\text{yr}$  to the east.

#### Wind and Cliff Erosion

Wind storms, and the prevailing winds produce significant sand transport along the Nile littoral cell. Some windblown sand is lost to sea, but most is deposited in coastal sand dunes as evidenced by the many dune fields along the coast. The most important fields are the Baltim dunes between Burullus and Ras El Bar, the coastal dunes of the Sinai (Tsoar, 1974), and the smaller dune fields along the Israel coast (Nir, 1982a). The rates of sand loss to dunes has not been carefully monitored.

Nir (1982a) points out that the extensive quarrying of beach sand for construction purposes that lasted through the mid 1960's caused a deficit of about one-third of the total beach resources in Israel. Israel beaches still show a deficit of sand that has indirectly accelerated the erosion at Kurkar seacliffs. Sand quarrying has considerably complicated quantitative sand transport studies along the coast of Israel.

#### BUDGET OF SEDIMENT FOR THE NILE LITTORAL CELL

The littoral cell is a coastal sedimentation compartment that contains a complete cycle of littoral sedimentation including sources, transport paths and sediment sinks (e.g. Inman and Chamberlain, 1960; Inman and Brush, 1973). When transport rates (fluxes) are assigned to the sources, paths and sinks, the cell can be evaluated in terms of the "budget" of sediment which is subject to the usual constraints associated with the conservation of mass. Evaluation of the transport rates

is further constrained by the laws of thermodynamics which govern the partitioning of energy fluxes associated with the forces that drive the sediment. Thus application of the driving forces to the budget of sediment within the framework of the littoral cell permits critical evaluation of the "goodness of fit" of the processes at work in the cell.

The Nile littoral cell extends from Alexandria, Egypt to Akko on Haifa Bay, Israel. The driving forces are the waves and currents associated with the east Mediterranean gyre. The forces transport Nile River sediment from the delta to Haifa Bay. Although many details remain to be clarified, this paper makes clear a number of aspects important to understanding the budget of sediment in the Nile littoral cell. These are stated below in the form of tentative conclusions:

1. Mineralogical studies show that the principal source of sand for the beaches and shelf from Alexandria to Akko was the Nile River. The Nile was also the source of much of the finer sediments on the outer shelf and in the Levant basin (Figure 3).
2. A decline in sediment supply from the Nile to the Mediterranean Sea coast coincided with the construction of the Low Aswan Dam in 1902. Completion of the High Aswan Dam in 1964 resulted in a total loss of Nile River sediment.
3. The net average supply of sand size material to the sea by the "free" Nile appears to have been about 20 to 40 million  $m^3/yr$ . The total supply of all particulate material in the bedload and suspended load was about 160 million tons/yr.
4. Waves and currents associated with the east Mediterranean gyre are the principal driving forces that transport sediment to the east and northeast along the coast. It is estimated that the energy dissipation due to current action over the sediment bottom of the Nile delta is about  $2.5 \times 10^6$  kW, while that associated with wave action nearshore is about  $0.5 \times 10^6$  kW. The relative importance of waves and currents in transporting sediment is not clear.
5. Observations near structures show that the longshore sand transport rates by waves is greatest in the vicinity of the Nile delta ( $\sim 1 \times 10^6$   $m^3/yr$ ), decreases to about one-half off Bardawil ( $\sim 0.5 \times 10^6$   $m^3/yr$ ), and to about one-tenth near Haifa ( $\sim 0.1 \times 10^6$   $m^3/yr$ ). Longshore sand transport rates based on models using measured wave energy fluxes are in general agreement with these transport rates.
6. There is over an order of magnitude difference between the rates of erosion measured from the shoreline to 6 m depth along the Nile delta ( $\sim 20 \times 10^6$   $m^3/yr$ ) and the longshore sand transport by waves ( $\sim 1 \times 10^6$   $m^3/yr$ ). This suggests that currents sweeping across the shallow shelf of the Nile delta are important in transporting sand to the east. The strong eddy off the Damietta promontory appears to be a transport mechanism that moves about  $19 \times 10^6$   $m^3/yr$ . Accordingly, there must be a number of "modern", local sediment sinks within the overall cell. One appears to be between Port Said and Bardawil, the other between Bardawil and El Arish (Figure 3).

Figure 3. Budget of sediment for the Nile Littoral Cell.

The term "modern" is applicable because as the Damietta promontory erodes back, the intensity of the eddy will decrease, causing the sediment transport capacity to decrease.

7. Windblown sand causes a loss of sand from the beaches of the cell as indicated by the many coastal dune fields. Unfortunately, the rates of loss have not been carefully monitored. However, loss by windblown sand may help to explain the absence of widening beaches that otherwise would occur under the overall negative gradient in the longshore sand transport with distance to the east.

8. Cliff erosion is not generally important to the budget of sediment except locally in Israel where it may contribute to the beach sediments north of Tel Aviv.

The above tentative conclusions regarding the driving forces, the sediment sources and sinks, and the sediment transport paths have been placed in the framework of the budget of littoral sediment for the Nile littoral cell in Figure 3. It is apparent that much more detailed study is needed to further quantify the budget. However, Figure 3 should serve as a useful framework for the guidance of future studies.

#### ACKNOWLEDGEMENTS

This report presents the results of an AID sponsored study "Coastal Management and Shore Processes in the southeastern Mediterranean" which is part of the "Cooperative Marine Technology Program for the Middle East." Many people aided in its preparation. We express our gratitude and indebtedness to A. A. Khafagy and M. H. S. Elwany of Egypt and to Z. Carmel, A. Golik, and Y. Nir of Israel.

## CHAPTER ONE HUNDRED TEN

### GRADING EFFECTS IN CONCENTRATION MEASUREMENTS

---

by:  
J. van de Graaff <sup>1)</sup> &  
J.A. Roelvink <sup>2)</sup>

#### ABSTRACT

In analysing measured sediment concentration distributions the effect of the non-uniformity of the bottom material is frequently not taken fully into account. Examples of calculations are given to clarify the grading effect on the parameters that determine the concentration distribution (e.g. diffusion coefficient distribution). Results of a preliminary test series indicate that the particle size affects the diffusion coefficient involved. [ $c(\text{sediment}) = \beta c(\text{fluid})$ ;  $\beta$  size dependent].

#### 1 INTRODUCTION

The CERC formula is an example of an over-all description of the longshore sediment transport rate. A limited range of problems can be solved with the help of this formula since it only describes sediment transports due to wave-driven currents. In more general coastal engineering problems not only wave driven currents but also currents like tidal currents, ocean currents and wind driven currents play an important role. To be able to tackle the latter type of problems, one needs a transport formula to calculate the transport as a function of boundary conditions like water depth ( $h$ ), wave height ( $H$ ), wave period ( $T$ ), current velocity ( $v$ ) and bottom particle size ( $D_{50}$ ). The sediment transport rate for currents more or less perpendicular to the orbital plane of the waves can be simply described as:

- 
- 1) Senior Scientific Officer  
Delft University of Technology, The Netherlands  
2) Student Assistant  
Delft University of Technology, The Netherlands

$$S = \int_0^h v(z) * c(z) dz \quad (1.1)$$

where: S : sediment transport rate  
 v(z) : current velocity (function of z)  
 z : height above the bottom  
 c(z) : time averaged sediment concentration  
 h : water depth

As far as the authors know, only the so-called Bijker formula (Bijker 1971; Van de Graaff and Van Overeem 1979) describes the transport in a physical sense according to Eq. (1.1) and can be used generally in coastal engineering problems. However, although a ready made formula is available, tests have been carried out all over the world in measuring the time average sediment concentration distribution over the water column under wave and current conditions. (Among many others : MacDonald 1977; Nielsen 1979; Bosman 1982.) Such experiments are carried out since it is felt that the concentration distribution as proposed by Bijker is not valid under all conditions.

By analysing concentration measurements one tries to find the underlying 'mechanism' which holds the particles in suspension and causes the measured distribution. Since the suspension mechanism is most likely diameter dependent, it is necessary to take fully into account the grading, the non-uniformity, of the bottom particles.

## 2 SUSPENSION MECHANISM AND 'THEORETICAL' DISTRIBUTIONS

Fig. 1 shows an example of a so-called time and bed averaged sediment concentration distribution over the waterdepth due to (random) waves running over a sloped beach profile. The samples have been taken by suction in a direction perpendicular to that of wave propagation. The 'time and bed averaged' procedure has been developed by Bosman 1982; it means that the suction time is long with regard to the wave period ( $\approx 100 T$ ) and that the suction pipe's intake nozzle is moved to and fro by a carriage over a few ripple lengths ( $\approx 5 \lambda$ ). By this procedure local effects (just above a ripple top quite different concentrations do exist than do above a ripple trough) are smoothed out. In the example of Fig. 1, as well as in the other examples of this paper, the several measuring points have been measured simultaneously.

A distribution like in Fig. 1 is typical for random- as well as for regular waves. The fact that close to the (mostly) rippled bed high concentration rates are found, is caused by the scraping effect of the orbital motion of the waves over the bed.

Fig. 1 Concentration Distribution over Water Depth

Why and how the particles can reach the higher levels in the vertical, is not clear yet. The vertical orbital motion in the waves plays a convective role probably.

Whatever the mechanism may be, in this paper a simple diffusion mechanism is assumed. Assuming a steady state condition, in general the concentration distribution over the depth can be described by the expression:

$$w * c(z) + \epsilon(z) * dc(z)/dz = 0 \quad (2.1)$$

where:  $w$  : fall velocity  
 $c(z)$  : average concentration at level  $z$  above the bed  
 $\epsilon(z)$  : eddy diffusion coefficient  
 $z$  : vertical upward directed ordinate; the bottom being  $z=0$

Assuming uniform material ( $w = \text{constant}$ ) the distribution of  $\epsilon(z)$  over the waterdepth defines the shape of the concentration distribution line over the water depth. The bottom concentration profile fixes the actual position of the concentration profile shape.

As a final aim, the concentration distribution's characterizing parameters ( $\epsilon(z)$  distribution) and the bottom concentration should be related to the boundary conditions. In this paper, however, a more modest aim will be pursued: analysing the effects of non-uniform material on the apparent  $(z)$  distribution.

In the literature some basic  $\epsilon(z)$  distributions have been suggested all leading, in case of uniform bottom material, to typical concentration distributions. Three of those  $\epsilon(z)$  distributions will be mentioned, according to their names as found in literature.

- a) Coleman type
- b) Rouse type
- c) Bhattacharya type

In Table 1 the characteristics of the  $\epsilon(z)$  distributions are given together with the resulting concentration distributions.

	$\epsilon(z)$ distr.	$\epsilon(z)$	$c(z)$	
Coleman	constant	$\epsilon(z)=\text{const.}=\epsilon$	$c(z)=c_b \exp\left(-\frac{w \cdot z}{\epsilon}\right)$	*
Rouse	parabolic	$c(z)=4c_{\text{max}} \frac{z}{h} \left(\frac{h-z}{h}\right)$	$c(z)=c_a \left(\frac{h-z}{z} \frac{a}{h-a}\right)^{4\frac{w \cdot h}{\epsilon_{\text{max}}}}$	**
Bhattacharya	triangular	$c(z)=\frac{z}{h} c_{\text{max}}$	$c(z)=c_a \left(\frac{h}{z} \frac{a}{h}\right)^{w \cdot h/\epsilon_{\text{max}}}$	**

\*  $c_b$  : bottom concentration ( $z=0$ )

Table 1. \*\*  $c_a$  : concentration at reference level  $z=a$   
(  $c(z) \rightarrow \infty$  for  $z \rightarrow 0$  )

The  $\epsilon(z)$  distributions as given in Table 1 hold for sediment. In river flow sediment studies, a distinction is made frequently between  $\epsilon_s$  (sediment) and  $\epsilon_f$  (fluid). In general a simple direct relation between  $\epsilon_s$  and  $\epsilon_f$  is assumed:

$$\epsilon_s = \beta * \epsilon_f \tag{2.2}$$

where:  $\beta$  : a proportionality factor.

A widespread discussion is going on concerning the actual  $\beta$ -value; values  $<1$  as well as  $>1$  have been mentioned. The case  $\beta > 1$  seems to get the greater support at the moment. (See for instance Van Rijn 1982). Furthermore it seems most likely that  $\beta$  is particle size dependent. For coarser material larger  $\beta$  values can be expected.

In a unidirectional flow the relation between  $\epsilon_f$  and  $\epsilon_s$  seems clear. It is felt that the turbulence in the masses of water is also the working agent in holding the particles in suspension (micro-scale). Under wave action a still less understood situation exists. Most likely the micro-scale turbulence is less important than the orbital motion induced processes (macro-scale). However, as

mentioned already, in the wave action case also a simple diffusion process is assumed. With respect to  $\beta$  values a similar approach is chosen as for unidirectional flow, whatever the real meaning of a  $\beta$  value may be under wave action.

In section 5 some results of preliminary tests are reported concerning probable  $\beta$  values.

### 3 RELEVANCY OF GRADING EFFECTS

Trying to fit the real concentration measurements of figures like Fig. 1 with the distributions as predicted by the standard cases of Table 1, leads to large differences. In reality none of the given types holds for most of the measured concentration distributions. A more appropriate  $\epsilon(z)$  distribution should be found and is therefore one of the ultimate aims of concentration analysis studies. The 'theoretical'  $\epsilon(z)$  distributions of Table 1 can, however, be used fruitfully to clarify the effect of the grading of the bottom material. Because of its simple behaviour a Coleman type  $\epsilon(z)$  distribution is chosen in the next example.

Starting from an arbitrary bottom concentration, the resulting concentration distribution over the water depth has been calculated for 5 different graded bottom materials. Fig. 2 gives the particle size distributions involved; standard log-normal distributions have been chosen.

Fig. 2 Particle Size Distributions

In the calculation it is assumed that the particles in suspension close to the bed (bottom concentration) have the same particle size distribution as the original bottom material. Furthermore that amount of sand is assumed to exist of  $k$  fractions, all equal in weight. In each fraction only particles between narrow limits are present in conformity with the particle size distribution. If  $k$  is large enough, the particle size distribution within a certain fraction can be assumed to be constant. For  $k=10$  the characteristic particle size  $D(i)$  of the  $i$ -th fraction ( $1 < i < 10$ ) becomes:

$$D(i) = D(10 \cdot i - 5) \tag{3.1}$$

The fall velocity  $w(i)$  belonging to the particle size  $D(i)$  can be computed with:

$$w(i) = \frac{1}{10} (0.475 \log^2 D(i) + 2.180 \log D(i) + 3.226) \tag{3.2}$$

Formula (3.2) holds for salt water with a temperature of 5° C.

Assuming a constant  $\epsilon(z)$  value  $\epsilon$  over the water depth, the concentration distribution over the depth of each fraction can be computed with:

$$c(z,i) = c(b,i) \exp\left(\frac{-w(i) z}{\epsilon}\right) \tag{3.3}$$

For each fraction the same  $\epsilon$  value is assumed (thus in this calculation  $\beta=1$  for each particle size).

Fig. 3 Concentration Distribution

The ultimate concentration  $c(z)$  at height  $z$  above the bottom yields:

$$c(z) = \sum c(z,i) \quad (3.4)$$

Fig. 3 shows the result for  $\epsilon = 0.002 \text{ m}^2/\text{s}$ ,  $k = 10$  and the diameter distributions of Fig. 2, all with a  $D_{50}$  of  $150 \mu\text{m}$ . Depending on the rate of grading, characterized by the  $D_{90}/D_{10}$  ratio, a variety of concentration curves can be found. For normal beach material the  $D_{90}/D_{10}$  ratio ranges from 2 to 3.

From the calculated contributions of the fractions to the ultimate concentration at level  $z$  above the bottom, the apparent size distribution at that level can be computed. Fig. 4 gives the  $D_{50}$  distribution for some rates of grading.

Fig. 4  $D_{50}$  Distribution over Water Depth

A quick, but rough, idea of the order of magnitude of the mistake made when one does not take into account the non-uniformity of the bottom material in analysing measured concentration distributions, can be found as follows.

Assume one has actual measuring points as indicated in Fig. 3 (see on line (2)). Assume moreover that one does not take into account the grading effect and one is focussed on finding the constant  $\epsilon$  value that explains the position of the measured points as well as possible. So one fits a straight line through the measuring points in Fig. 3. From the slope of that line the apparent (but wrong)  $\epsilon$  value can be found. The ratio  $\epsilon(\text{apparent})/\epsilon(\text{actual})$  is then a measure of the mistake made. In Fig. 5 some results are given. To find  $\epsilon(\text{apparent})$  not a complete fit calculation has been

Fig. 5 Mistakes in  $\epsilon$  Prediction

made, but quite simply, only the real concentrations  $c(0.85)$  and  $c(0.15)$  have been taken into account [  $c(0.85)$  means concentration at elevation  $z=0.85$  h ]. From Fig. 5 it can be seen that, depending on the rate of grading and on the actual  $\epsilon$  value a variety of mistakes can be found. It seems clear that it is absolutely necessary to take grading effects into full account in analysing measured concentration distributions.

#### 4 ACTUAL CONCENTRATION MEASUREMENTS

In Fig. 6 a measured concentration distribution is given as found during a test in a wave flume of the Fluid Mechanics Laboratory of the Delft University of Technology. The boundary conditions are as follows:

- horizontal bed with natural ripples
- water depth  $h = 0.30$  m
- wave conditions:  $H = 0.10$  m;  $T = 1.7$  s
- $D_{50} = 97 \mu\text{m}$ ;  $D_{10} = 75 \mu\text{m}$ ;  $D_{90} = 126 \mu\text{m}$

The measured points have been approximated according to the procedure as briefly described in Appendix I. Starting with the (extrapolated) bottom concentration and taking into account 20 fractions the  $\epsilon(z)$  distribution which describes the approximating curve precisely, can be computed. Fig. 7 presents the resulting  $\epsilon(z)$  curve.

Fig. 6 Concentration Distribution Movable Bed

Fig. 7  $\epsilon(z)$  Distribution

(In the same figure the result is given when one does not take into account the non-uniformity of the bottom material; again large differences can be found.) The size distribution of the samples caught at the various heights above the bottom has been analysed with the help of the Delft University Settling Tube (see for details Slot and Geldof 1984) of the Fluid Mechanics Laboratory. Also the distribution according to calculations has been determined. Fig. 8 gives the comparison between measurements and calculations. Although some differences are found, the conclusion is that the general trend is a rather good fit.

Fig. 8 D10 - D50 - D90 Distribution

In the calculations as described in this section,  $\beta=1$  has been assumed. The suggestion of size dependent  $\beta$  values being greater than 1 as briefly discussed in section 2, may be an explanation of the fact that, especially at greater heights above the bed, the D90 values are underestimated by the calculations and the D10 values slightly overestimated.

In order to gain some insight into possible  $\beta$  values a preliminary test has been carried out in one of the flumes of the Delft Hydraulics Laboratory.

##### 5 EFFECT OF GRAIN SIZE ON $\beta$ -VALUES

The research on concentration distributions is one of the main topics of the 'Sediment Transport' working group of the Dutch Applied Research Program Rijkswaterstaat - Coastal Research (TOW). This TOW program is carried out in

close cooperation between the Public Works Department, the Delft Hydraulics Laboratory, the Delft University of Technology and the Royal Dutch Meteorological Institute. In the framework of the 'Sediment Transport' group a single series of tests has been carried out by the Delft Hydraulics Laboratory in order to get a first idea of the effect of grain size on  $\beta$ -values. The results have been analysed by the authors.

Normal movable bed tests are unsuitable to clarify the mechanism involved. The rate of 'diffusion coefficient production' in an actual case does not depend on the boundary conditions (to be kept constant) like water depth, wave height and wave period only, but also on the form (height and length) of the bed ripples. These bed ripples are, given the boundary conditions, highly diameter dependent. A constant rate of wave and bed induced diffusion activity, equal for several grain sizes, can only be achieved with a fixed rippled bed, covered with such a small amount of particles, that the original bed form is not disturbed. In the tests with a horizontal bottom, wooden fixed ripples have been applied; ripple height: 0.017 m; ripple length: 0.07 m. Seven tests have been carried out with nearly uniform sand; D50-values of 87, 112, 170, 192, 221, 280 and 346  $\mu\text{m}$  respectively. Although uniform material was desired, it turned out from fall velocity tests in the settling tube, that some variations existed. The D90/D10 ratio actually ranged from 1.3 to 1.5. A single test was carried out with well-graded material: D50 = 217  $\mu\text{m}$ ; D90/D10 = 2.15.

In the tests one set of boundary conditions was maintained. Water depth  $h = 0.30$  m; (regular) wave height  $H = 0.08$  m; wave period  $T = 2$  s. In each test a restricted amount of sand was thrown into the flume. Two to five series of simultaneously sucked samples in 4 points were gathered for each material tested. Fig. 9 shows an example of the vertical concentration distribution. Mark the quite similar distribution shape of the curves (1) and (2), despite the fact that for curve (1) the concentrations are approximately a factor 15 less than for curve (2). In case (1) less sand was thrown into the flume.

In a first analysing round, real uniformity was assumed for the 'uniform' material tests. Since in all cases nearly straight lines were found for the concentration distribution over the water depth (see Fig. 9), pointing to a Coleman-type distribution, constant  $\epsilon$  values can be calculated with the help of the proper formula of Table I. Fig. 10a represents the results, showing a distinct dependency of the calculated  $\epsilon$  values on the settling velocity. A nearly linear relationship is found. By extrapolation ( $\rightarrow w=0$ ) an (fluid)-value can be calculated. For the tested materials  $\beta$ -values up to 1.8 can be found for  $w = 0.04$  m/s (D50  $\approx 300$   $\mu\text{m}$ ).

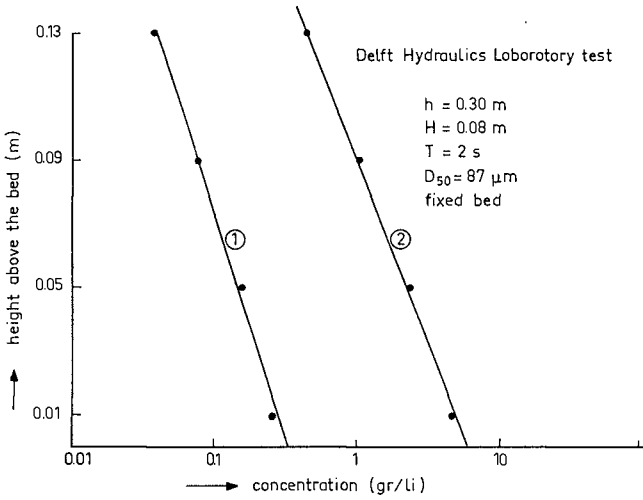

Fig. 9 Concentration Distribution

Fig. 10 Diffusion Coefficient vs. Fall Velocity

In a second analysing round, the real grading of the 'uniform' materials was taken into account. As a hypothesis a linear relationship (to be stated) between  $w$  and  $\beta$  was assumed. The fit procedure described in Appendix I was applied. Due to the grading and the applied fit procedure, a non-constant  $\epsilon$  distribution over the water depth is found this time. The variation over the water depth, however, is not very large. An average value over  $0 < z < 0.09$  m has been calculated. By an iteration process the most appropriate  $\epsilon$ (fluid) value and the  $\beta$ -slope value  $m$  were calculated. Fig. 10b shows the ultimate result.

$$\epsilon \text{ (fluid)} = 0.000337 \text{ m}^2/\text{s}; \beta = 1 + 23.0 * w$$

(5.1)

The relationship that was found to exist between  $\beta$  and  $w$  holds for the set of boundary conditions during the test series.

As long as a similar relationship has not been derived for other sets of boundary conditions, the  $\beta - w$  relationship cannot be used generally. Tests with different boundary conditions, to be carried out in the Fluid Mechanics Laboratory of the Civil Engineering Department of the Delft University of Technology, are being prepared. Since a general  $\beta - w$  relationship is not yet available, the calculations as presented in section 4 cannot be refined at this moment.

## 6 CONCLUSIONS

- The non-uniformity of the bottom material strongly affects the concentration distribution over the water depth under wave action.
- When the concentration distribution is described with the help of a diffusion equation, the diffusion coefficient seems to be particle-size dependent;  $\epsilon$  (sediment) =  $\beta \epsilon$  (fluid), the  $\beta$  coefficient being approximately a linear function of  $w$ .
- However, it is not clear yet whether a similar  $\beta - w$  relationship holds for quite different boundary conditions or not. Further research will have to clarify that topic.

## Appendix I

## FIT PROCEDURE MEASURED CONCENTRATION DISTRIBUTIONS

In behalf of the calculation procedures of this paper (e.g.  $\epsilon$ - and D50- distributions over the water depth) one needs a mathematical description of the concentration distribution over the water depth. Mostly -compare Fig. 1- a restricted amount of measuring points is available. Besides that the measuring points show some scattering. When applying fit procedures with many degrees of freedom, unrealistically high bottom concentrations and strange curves in the upper section of the vertical can be found frequently.

This is unacceptable for the aims, stated in this paper, and when the bottom concentrations have to be related to the boundary conditions also.

The described fit procedure seems rather objective and holds true for tests on model scale at least.

From Fig. 1 ( $z^*$  vs.  $\ln c(z)$ ) it can be seen that:

- highest concentrations occur near the bed
- a gradual decrease in concentration occurs towards higher levels above the bottom.

Looking at the gradients as a function of  $z^*$  for arbitrary concentration distributions, one can schematize the gradients in curves according to Fig. A1. (In Fig. A1 a 'standard' square is assumed. The vertical axis ( $z^*$ ) ranges from 0 to 1 and the horizontal axis ( $d \ln(c)/dz^*$ ) also from 0 to 1. The actual gradients can be found by multiplying with a negative factor). It seems to be better -and easier- to impose some restrictions on the gradient curve than to do so on the original concentration curve.

Fig. A1

Standard Square

Fig. A2  
Possible Fillings

Fig. A3  
Extreme Positions  
Point A

REQUIREMENTS OF GRADIENT CURVES IN STANDARD SQUARE

1) For  $z^*=0$ , the gradient is 1 and at its maximum. At the bottom the largest gradients are assumed to occur. So curves like curve (a) in Fig. A1 are not acceptable.

2) No negative gradients. A negative gradient in the standard square at a certain level above the bottom means that the concentration increases towards higher distances from the bottom. That seems quite unlikely; experiments never showed any clear evidence to that. Also zero-gradients are unlikely. In the standard square minimal  $b$  values (see Fig. A2) of 0.025 are assumed. The value of 0.025 is subjective; however, slightly different values hardly affect the total result as it turned out after analysing a number of test cases.

3) No large gradients close to the bed in the standard square. In Fig. A1 curve (b) seems attractive. At the bed the largest gradient occurs; nevertheless close to the bed also rather large gradients occur. A distribution like curve (b) will never lead to unrealistically high bottom concentrations. However, from actual measurements it turned out that curves like (c) and (d) in Fig. A1 are more likely in some cases. However, with curve (d) extremely high bottom concentrations can be found. So it seems appropriate to make some restrictions. In Fig. A2 and A3 some possible filling-ups of the standard square are given. By assuming a maximum value of 8 for  $p$  (see next section), very high bed concentrations can be avoided.

## RESULTS

The curves in Fig. A2 can be described by:

$$d(\ln(c))/dz^* = q [ b + (1-b) [(a-z^*)/a]^p ] \quad (A.1)$$

where: q : (negative) scale factor  
 b : horizontal ordinate point A ( $0.025 < b < 1$ )  
 a : vertical ordinate point A  
 (in the procedure proposed a can be 1 or 0.9 or 0.8 or 0.7; these values are rather subjective).  
 p : exponent of fit parabola for gradient curve (p can be 2; 4; 6 or 8)

Integration of Eq. (A.1) yields:

$$\ln(c) = q [ bz^* - (1-b)(a-z^*) / (p+1) [(a-z^*)/a]^p + d ] \quad (A.2)$$

where: d is the integration constant

In a computer program the procedure starts with  $a=1$  and  $p=8$ . The 'best' values of the parameters q, b and d are determined with a least squares method. If it turns out that  $b < 0.025$  or  $b > 1.0$ , then b is fixed at 0.025 or 1.0 respectively and the procedure is restarted. The parameters q and d are determined now. In the next step it is checked whether a better result is found with  $a=1$  and  $p=6$ , and so on. Next the procedure starts with  $a=0.9$  and  $p=8$  again. As stated the least a-value is taken to be 0.7.

From test series it turned out that the fit procedure proposed seems to be rather objective. (Compare Fig. 1)

## CHAPTER ONE HUNDRED ELEVEN

### REDESIGN OF ENTRANCE STRUCTURES FOR TWO SMALL CRAFT HARBORS IN OHIO

Rilly L. Edge, Cubit Engineering Limited  
Ren L. Sill, Cubit Engineering Limited  
James A. Swartzmiller, Ohio Department of Natural Resources  
John S. Fisher, Cubit Engineering Limited  
Charleston, S.C.

#### 1.0 INTRODUCTION

Wildwood Harbor and Chagrin River are two areas on Lake Erie at which intensive boating activities occur throughout the recreational months of April through October. At Wildwood Harbor (Figure 1) an enclosed basin exists with a relatively open mouth which allows excessive wave activity to enter. These waves often focus directly on the launch ramp opposite the entrance. At Chagrin River (Figure 2) a major project was recently completed to stabilize the river entrance which had experienced substantial shoaling, and to help prevent winter ice blockage. The jetties and associated spending beach in the River worked well to prevent continuous shoaling and allow the river to flood and carry the ice lakeward; however, significant reflected waves resulted from this construction affecting navigation through the entrance and boats in the adjacent Yacht Basin.

#### 2.0 HYDRAULIC MODEL CONSTRUCTION

Physical models were constructed of both sites to simulate present conditions, and to evaluate solution alternatives. Since the construction technique developed by Cubit is unique, it is described briefly below. For relatively short (6 months) model life expectancies, models are constructed from 2 ft x 8 ft sheets of styrofoam insulation board. This material is light, and easily cut and assembled, thus minimizing model construction time. The procedure used is as follows:

- (a) First, contour maps of the area to be modelled are developed with contour intervals appropriate to the styrofoam thickness. In this case the 1:24 vertical scale for Wildwood meant that a 1 inch thickness corresponds to 2 ft of depth in the prototype. For Chagrin River, the 1:48 vertical scale meant that 1 inch corresponded to 4 ft of depth in the prototype.
- (b) Based on the horizontal scales selected (1:100 for Wildwood, 1:48 for Chagrin River), equivalent 2 ft x 8 ft rectangles are drawn on the bathymetric maps of the site.
- (c) Overhead projection transparencies of the contour map are prepared.

FIGURE 1. MODEL LAYOUT OF EXISTING FACILITIES WITH DATA COLLECTION POINTS INDICATED

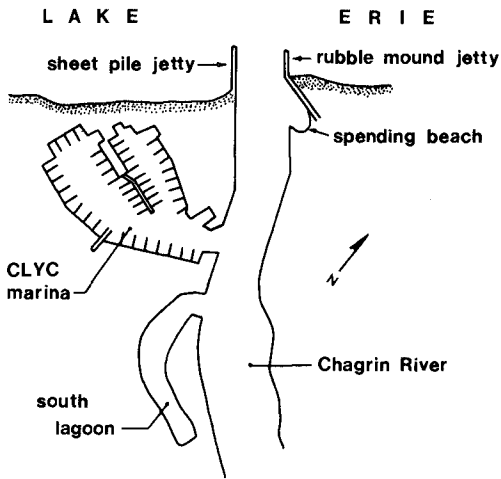

FIGURE 2. MODEL LAYOUT OF EXISTING FEATURES IN THE CHAGRIN RIVER AREA

- (d) These transparencies are projected onto the styrofoam sheets for each contour interval.
- (e) Each individual sheet is marked and cut.
- (f) Pieces are assembled in the basin using a butyl caulk to secure their location.
- (g) The stairstep edges are smoothed with a hot nichrome wire.
- (h) Finish sanding the edges smooth.
- (i) Coat the entire model surface with a veneer of a mortar surface bonding compound (e.g. Surewall brand).

This completes the construction of the model substrate. With the addition of wave maker and plumbing for riverine flow the model is ready for instrumentation and testing.

### 3.0 WILDWOOD HARBOR

A physical hydraulic model was constructed for the Wildwood Park vicinity located within the Cleveland Lakefront State Park and on the shoreline of Lake Erie. The harbor was constructed in the 1950's to protect construction equipment laying a 12 ft diameter pipeline into Lake Fria for the City of Cleveland's raw water supply. Since that time the area has become a major recreational area for swimming, boating and fishing. The pipeline however still poses a problem for the final design since it runs through the mouth of the harbor.

#### A. The Model

Data obtained from the physical model were analyzed with the purpose of reducing the wave problem within the harbor, and in particular, near the location of the boat launching ramp. This study examined the current configuration of the harbor and tested design alternatives designed to reduce the wave action within the marina. The designs which showed the most promise were examined in further detail. Following these analyses, conclusions as to the best alternatives were evaluated based on their impact on the wave conditions in the harbor, constructability, and navigation.

A horizontal scale of 1:100 and a vertical scale of 1:24 were used in constructing the model of the harbor and the immediate offshore area to a depth of 14 ft. Distorted model scaling was utilized to insure adequate depths in the model. The model was 24 ft long and 14 ft wide. To produce the desired wave effects, a wave generator consisting of a rotating offset cylinder was employed. Wave periods from 6 to 8 seconds were used with approach directions and wave heights taken from Resio and Vincent [1976]. This resulted in a prototype wave height of approximately 12 ft and directions varying between normal to the entrance to N 25 degrees W.

The testing program proceeded through several different phases. The initial phase consisted of producing waves with prototype periods of 5 and 8 seconds. Many different design alternatives were tested and both subjective and quantitative data were collected. Visual observations were made of the waves as they traveled from the deeper offshore water between the present breakwaters and into the marina. Observations of the wave activity within the marina itself were also made. The quantitative phase of the data collection process consisted of obtaining wave heights at three separate locations within the marina. These collection points were designated as B, C, and D and are shown in Figure 3. Data were collected through the use of capacitance wave gauges and displayed on a strip chart recorder.

Following the analysis of the results from the preliminary phase, several alternatives were chosen for more in-depth study. Also, wave periods of 6 and 8 seconds were used during this phase. During this stage, varying structure lengths of the selected design alternatives were tested in an attempt to determine the optimum length.

Finally, to observe the effect of the wave approach angle on the selected design alternatives, the wave generator was placed such that it produced waves which approached the marina from a direction of N 25 degrees W. During this third stage, wave periods of 6 and 8 seconds were again tested.

FIGURE 3. MODEL LAYOUT OF ALTERNATIVE 1: OFFSHORE BREAKWATER

## R. Results

The initial testing phase involved thirteen different layouts of the breakwaters and possible additions surrounding Wildwood Park. The first test condition was that of the facilities as they presently exist and this test will be referred to as the "existing conditions" throughout the remainder of this paper.

In distorted physical models of harbors, such as this, it is impossible to effectively scale the wave heights. Because of this fact and also for ease of comparison, the wave data were non-dimensionalized with the existing wave height at each station.

Twelve alternatives were tested, however only three geometries are shown here:

- 1) offshore breakwater,
- 2) spur on west breakwater, and
- 3) west breakwater spur in combination with an east breakwater extension.

In Figures 3, 4, and 5, the geometries are self explanatory without need for additional comment. These conceptual designs exhibited significant wave height reductions, and were studied in some detail.

FIGURE 4. MODEL LAYOUT OF ALTERNATIVE 10: L-SHAPED WEST BREAKWATER

FIGURE 5. MODEL LAYOUT OF ALTERNATIVE 14: ANGLED EXTENSION OF WEST BREAKWATER

Following the initial testing of all alternatives, the three previously mentioned designs were selected for additional testing. One of the original restrictions placed on the project was the requirement that no construction take place over the water supply pipeline. The alternatives that met this requirement were generally less effective in reducing the wave activity within the harbor when compared to some of those that extended over the pipeline. As would be expected, in order to most effectively reduce the wave action, the best solution was found to be the prevention of the majority of the waves from directly entering the marina with a detached breakwater. Once the waves were allowed in the harbor, they were difficult to dissipate without taking up substantial harbor space. On the other hand, the alternatives that were laid over the pipeline and more or less shadowed the harbor entrance prevented waves from entering the harbor directly. Thus, the waves were dissipated before they entered the harbor. Because of the success obtained during the initial phase of testing, it was decided to further examine two alternatives which prevented the waves from entering the marina directly even though they called for construction to take place over the in-place pipeline.

### C. The Second Tasting Phase

The next phase of the testing program consisted of the use of 6 and 8 second wave periods. From the initial testing phase, the arrangements shown in Figure 3 and 4 were determined to be the most feasible solutions to the wave problem. In an attempt to determine the optimum length of the two alternatives, the two structures were tested and examined under the above wave conditions. The various lengths tested for the offshore breakwater and for the L-shaped west breakwater are given below.

<u>Offshore Breakwater</u>	<u>L-Shaped Extension</u>
150'	50'
200'	100'
250'	150'
300'	200'
350'	250'
	300'

The offshore breakwater was positioned such that the water supply pipeline was located in the center of the new breakwater. Consideration was given in the design to a removable center section to give access to the pipeline.

Non-dimensionalized wave heights are plotted as a function of structural length in Figures 6 and 7. The results indicated that for both the alternatives the best reductions in wave activity took place when the length of the added structure equalled or exceeded the width of the harbor entrance channel. Additional lengths of the structure provided diminishing benefits once this length was achieved relative to costs.

The tests also showed that the offshore breakwater had to be slightly longer than the L-shaped west breakwater to achieve the same level of effectiveness within the harbor. Thus, for the same structure length, the west breakwater modification appeared to do a slightly better job of reducing the wave action than the offshore breakwater alternative.

This may be due to the fact that the L-shaped west breakwater allows the waves to enter from only one end whereas the offshore breakwater permits waves to diffract around both ends. Also, with the removal of the harbor spur in the west breakwater modification, this stone could be used in the construction of the new L-shaped west breakwater. Therefore, at a first glance, the volume of new stone required for alternative ten appeared to be less than that for alternative one.

### D. Selection of Concept For Design

The conceptual designs developed from the modal study were evaluated by the Ohio Department of Natural Resources. Their evaluation procedure considered both engineering and non-engineering considerations. They have authorized final design for a minor variation

FIGURE 6. SECOND PHASE NON-DIMENSIONALIZED WAVE HEIGHTS vs. STRUCTURE LENGTH FOR OFFSHORE BREAKWATER

FIGURE 7. SECOND PHASE NON-DIMENSIONALIZED WAVE HEIGHTS vs. STRUCTURE LENGTH FOR L-SHAPED WEST BREAKWATER

of the breakwater configuration shown in Figure 5. This design is a necessary compromise between the most effective concept and the need to maintain access to the 12 ft diameter water supply pipe.

#### 4.0 CHAGRIN HARBOR

##### A. Introduction

The Chagrin River (see Figure 2) which discharges approximately 16 miles east of Cleveland, Ohio, is stabilized on both banks with revetments, sheet piling and a spending beach. Lakeward of the spending beach are parallel rubble mound and sheet pile jetties on the east and west, respectively, which have been constructed to stabilize the shoreline and river channel. The entrance to the Chagrin River is exposed to wind and storm generated waves originating mainly from the north and northwest. These waves approach and enter the Chagrin River between the two jetties and proceed to travel upstream whereupon they enter two inland lagoons where small craft are moored. The waves entering lagoons produce a situation that is unfavorable for the berthing of boats. In fact, numerous mooring lines have broken with the subsequent damage of several boats. The sinking of one vessel has resulted from excessive wave activity within the basin.

As a part of the design to alleviate the wave problem a hydraulic model study was to examine the existing conditions in the Chagrin River and the two lagoons, to confirm model performance, and to evaluate various design configurations and modifications to determine possible solutions for protection of the two lagoons from wave action damage. The possible solutions as well as the existing condition were tested using waves of varying direction and period in an attempt to arrive at a solution that performed well under various conditions.

The Chagrin River model was constructed to an undistorted linear scale of 1:4R, model to prototype. Selection of this scale was based on reducing the effects of bottom friction, the size of the indoor laboratory facility to house the model, flow from the Chagrin River, and the need to properly simulate wave reflection in the two lagoons. To ensure accurate reproduction of reflected wave patterns, a geometrically undistorted model was deemed necessary using Froude's model law.

Available bathymetric data indicate that the harbor is uniformly six (6) feet in depth at the low water design level. In order to best simulate the actual prototype conditions with storms, the water level in the model was raised a scaled amount to represent an increase in depth of one (1) foot so that the depth of water in the main lagoon used for testing procedures was approximately seven (7) feet.

The selection of wave conditions was based on three sources of information. One was the U.S. Army Engineers report on Vermilion Harbor (1970). This report indicated that the storm waves had periods from 4 to 8 seconds with most wave action occurring with the 4 to 5 second waves. These waves generally originate from the north or northeast. A report obtained from the Chagrin Lagoons Yacht Club (3) compiled the wave conditions on the Lake, the river, and the lagoons at various times from December, 1982 through May, 1983. This was used for obtaining

predominant wave directions as well as a comparative analysis of wave heights at the various locations. A report from Stanley Consultants (1979) showed the worst wave conditions occurring in the Chagrin River area had wave periods of four to five seconds.

#### R. Test Program

With this available data, waves with periods of five (5) to ten (10) seconds were chosen to start the testing procedure. After examining the quantitative data and the qualitative comparisons, waves with a 5-second period were selected to best represent the conditions that create a major problem in the two lagoons. Further testing was primarily based on this wave period.

The test data obtained during the testing program included the measurement of wave heights in Lake Erie, the river channel and the lagoons. A schematic of the selected locations where wave heights were recorded is shown in Figure 8. The encircled letters indicate points where wave data were collected throughout the testing program. The letters not encircled are additional data points that were added during the testing program to give a more complete picture of the wave activity in the two lagoons.

The base tests were performed with existing prototype conditions simulated in the model and are termed "present conditions" hereafter. Preliminary tests were conducted with waves varying in period from five (5) to ten (10) seconds to test the model's response and to aid in producing worst case conditions. These results indicated that a wave period of five seconds created substantial wave activity in the lagoons. The wave attenuation in the model as the waves traveled from the lake into the lagoons was found to compare favorably with the observed wave data (3). Additionally, the wave generator was positioned directly in front of the river channel to produce waves that would travel directly up the river. It was reasoned that if a given set of test conditions can be determined to be the worst or more critical in the model, a solution that alleviates this problem should, with minor revisions, solve the problem for the lesser conditions.

The alternatives tested in the model ranged from offshore breakwaters to various spending beaches to the partial and complete closure of the lagoon entrances. For the most part, the alternatives were designed to either prevent the excessive wave energy from entering the river and lagoons or to dissipate the wave energy along the river channel. Brief descriptions of the various alternatives are given in the following subparagraphs. Alternative 1 was that of leaving the existing facilities in their present condition.

Alternative 2 consisted of the placement of a wave absorbing material along the east bank. This represented the removal of the rubble and gabion revetments in that location and the establishment of a smooth sloping beach in its place.

Alternative 3 considered the installation of a rubble mound offshore breakwater. The breakwater spanned the distance of the river channel between the two existing jetties.

Alternatives 4 and 5 involved additions to the present jetties. The two reduced the entrance channel width to reduce the amount of wave energy entering the river channel.

Alternatives 6, 12, 13, 17, and 18 considered the placement and combination of various spending beaches. The spending beaches were located on both sides of the river channel and functioned to dissipate the wave energy at those locations.

Alternatives 7 and 10 consisted of the placement of wave tripping structures along the vertical bulkhead located on the west bank. These structures served to disrupt the waves traveling along the bulkhead and in turn dissipate the wave energy.

Alternatives 8, 9, and 11 involved reductions in the entrance widths to the two lagoons. A reduction in the entrance width should lead to a corresponding reduction in the wave energy that is allowed to enter the lagoons.

Alternative 15 consisted of the placement of wave absorbing material along the entire length of the vertical bulkhead lining the west bank. This simulated the installation of a continuous wave dissipating structure.

Alternative 16 combined two of the previously mentioned alternatives. It utilized the reduction of the lagoon entrances as well as a new spending beach located on the eastern shoreline.

Alternative 19 involved the complete closure of the entrance to the main lagoon. To achieve access to the main lagoon, a channel connecting the main and south lagoons was constructed.

Alternatives 20 and 21 consisted of the placement of riprap along the vertical bulkhead on the western shore. This was intended to disrupt wave travel along the bulkhead and into the lagoons. Additionally, alternative 21 included the installation of a spending beach on the east bank.

Alternatives 24 and 25 involved the cutting of "tooth-like" indentions along the vertical bulkhead as shown in Figure 9. To reduce the reflection and increase the energy dissipation, the cuts were filled with riprap. Also, a spending beach on the east bank was included in alternative 24.

Tests involving the present conditions along with all of the alternatives were conducted during the testing program. In order to appropriately derive the effectiveness of each of the alternatives, the collected wave data were non-dimensionalized by the existing wave heights at each station. The values recorded during the existing condition were used as the denominator in the non-dimensionalization. Therefore, the non-dimensionalized value is an indication of how much wave activity will occur at a particular location as compared to that of the present condition.

FIGURE 8. SCHEMATIC OF THE WAVE DATA COLLECTION POINTS

FIGURE 9. MODEL LAYOUT OF ALTERNATIVE 24: TOOTH-LIKE CUTS ALONG THE BULKHEAD WITH RUBBLE FILL

### C. Results

The most striking observation made during the testing phases was the progression of waves along the vertical bulkhead lining the west bank (the deep side of the river channel) and leading into the two lagoon entrances. As the waves entered the Chagrin River between the jetties, a portion of the wave was dissipated very effectively by the existing spending beach. On the other hand, that portion of the wave traveling down the deeper western side encountered no such interference. Thus, a large amount of the wave energy was able to reach and enter the two lagoons.

Once the waves and their accompanying energy entered the lagoons, various oscillations and formations resembling standing waves were established at numerous locations. The basic reason for such activity is that once inside the lagoons the waves had no place to effectively dissipate their energy. This is due to the fact that the lagoons are lined by a vertical bulkhead which serves to reflect the waves with little energy dissipation.

Tests were also conducted in which the flow in the Chagrin River was simulated. The effects of the river flow were tested in most of the previously mentioned scenarios and for various wave periods. The results indicated that the waves in the river were steepened, and in general, the wave heights measured in the lagoons during the flow tests were the same or less when compared to the tests without flow. The wave activity in the south lagoon was significantly reduced because the river flow assisted in dissipating the wave energy in the river. Therefore, in order to create worst case conditions as far as the wave activity in the lagoons was concerned, particular attention was paid to the results of the tests with no flows.

The majority of the alternatives in varying degrees functioned to produce a reduction in wave activity in the two lagoons. Results for non-dimensional wave heights are given in Table 1 for the 5 sec condition in the main lagoon. Following the tests, it was possible to eliminate most of the alternatives based on several criteria:

1. poor overall performance or poor performance in either lagoon;
2. economically unattractive;
3. structures exposed to winter ice flows in river; and
4. potential navigation problems.

Following performance evaluations and utilizing the above criteria, Alternative 24 was considered the best overall for the Chagrin Harbor system. Since the saw tooth cuts do not extend into the river, they will not be subject to ice damage. Further, the size of the harbor entrances do not have to be reduced and thus the alternative poses no additional navigation difficulties. Finally, the solution is economically more attractive than the offshore breakwater, Alternative 3 and most importantly tests indicated that wave heights were reduced substantially.

TABLE 1  
 PRELIMINARY TEST RESULTS FOR THE MAIN LAGOON, 5-SECOND PERIOD

Non-Dimensionalized Wave Height					
Alternative	$E/E_n$	$F/F_n$	$G/G_n$	$H/H_n$	$I/I_n$

25	0.18	0.03	0.02	0.01	0.06

## 5.0 CONCLUSION

In both cases the models produced several alternatives which were presented to the Ohio Department of Natural Resources as potential solutions to the wave problems. Representatives of the local yacht clubs were invited to work with the model in confirming the natural conditions and identifying acceptable solutions. Based on various design constraints presented by the local officials and State government a single solution was selected for each site. Both projects are now in final design stage and construction should be completed for the 1985 boating season. At that time, prototype results will be available to compare with the results of the model studies.

## CHAPTER ONE HUNDRED TWELVE

### Coastal Changes at Bethany Beach, Delaware

Jennifer E. Dick<sup>1</sup>  
Robert A. Dalrymple<sup>2</sup>

#### Introduction

The coastal processes affecting Bethany Beach, Delaware were studied and the short-term and long-term trends in coastal changes were determined in order to develop recommendations for protecting Bethany against coastal erosion (Dick and Dalrymple, 1983). Bethany Beach is located on the Delaware Atlantic coastline which is a wide sandy bay-mouth barrier beach distinguished by highlands at Rehoboth Beach and Bethany Beach. The shoreline is straight, with only minor bulges and indentations (see Figure 1).

Bethany Beach is a residential and resort community. Privately-owned properties front the publicly-owned beach. Construction of new motels and summer homes is anticipated along with the continued growth of commercial activities to accommodate the increased number of visitors. Bethany is protected by a series of nine groins built between 1934 and 1945. Many of these groins have deteriorated, and are flanked at the landward end. Winter storms severely erode the beach and damage shorefront property. The beach is generally narrow (approximately 45 m wide), especially along the southern portion, and is backed by low dunes (about 15-45 m above NGVD). A timber bulkhead extends along most of the backshore.

#### Wave Climate

The majority of the waves emanate from the northeast to east; higher waves are from east-northeast during winds of 6.7 m/s or greater. Smaller waves predominate during months of southerly winds with speeds less than 6.7 m/s. Wave heights off the coast of Delaware average 1.2 meters from October to March, and 0.3 meter for the remainder of the year (Polis and Kupferman, 1973). The mean swell direction offshore Delaware Bay is from the southeast during the summer months and from the northeast during the winter (Mauer and Wang, 1973). Ocean waves under severe storm conditions have been estimated to be nine meters high in the surf zone (U.S. Army Corps of Engineers, 1956). The recurrence intervals of extreme waves in the offshore area are summarized below:

recurrence interval (years)	<u>5</u>	<u>10</u>	<u>25</u>	<u>50</u>
maximum significant wave height (meters)	11	12	14	15
extreme wave height (meters)	18	21	26	29

(Polis and Kupferman, 1973).

Long-Term Trends

The long-term trends in coastal changes were investigated through comparison of a series of historical aerial photographs. Five photographs dating from 1938 to 1977 were selected for study, three from the U.S. Department of Agriculture, one from NASA and one from the Delaware Department of Natural Resources and Environmental Control (DNREC). In

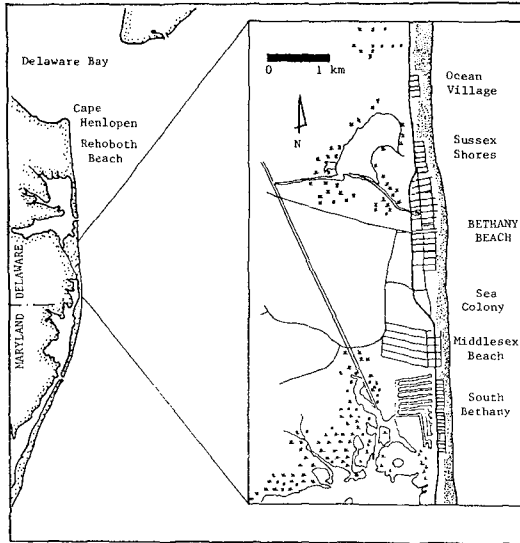

Figure 1: Location Map of Bethany Beach, Delaware.

May, 1938 (the date of the earliest photograph) the groin field had just been enlarged by four groins constructed north and south of the original four groins. Figure 2 clearly illustrates the effects of the groin field on the beach planform. At the time the first photograph was taken the littoral drift was to the north. As the sediment was transported north, the orientation of the shoreline in each groin compartment shifted.

Between May, 1938 and May, 1973, the shoreline straightened out by filling in the groin compartments resulting in slow accretion throughout most of the study area. Before 1968, the rates of change were gradual, in most cases less than a meter horizontally per year. Between 1968

and 1973 the rates increased to between one and five meters per year, averaging about two meters per year.

Figure 2: Position of Shoreline at Bethany Between May 1938 and May 1973

The aerial photogrammetric study of Bethany Beach indicates that the historical trend of shoreline change is slow accretion. It is clear from the early photographs that the groins accumulated sediment, thereby widening the beach. The photographs show that the area of the beach protected by the groins has remained relatively constant; however, there is a possibility that the area north and south of the groins (particularly south) have suffered from increased erosion since the construction of the groins. The irregularities in the shoreline at Bethany do not appear to be caused by the groin field. The indentation just north of the groins is the relict of an inlet located there around 1690 (Kraft et. al., 1976). The convexity of Bethany Beach is identifiable on U.S.G.S. charts from 1918; however, the bulge has become more prominent to the south since the construction of the groins.

#### Annual Trends

The short-term changes for one year were determined from periodic

surveys of the beach face and coastal zone. Thirteen nearshore profiles, both north and south of Bethany Beach as well as within the town proper were surveyed 11 times from May, 1982 to May, 1983 by the DNREC (dates are shown in Figure 4). The exposed beach was measured using standard surveying techniques and the offshore portion was measured using a tathometer and triangulation. According to the DNREC (Williams, 1983) the dry land elevations were measured to within 3.0 cm and the offshore soundings were measured to 6.0 cm. The bathymetric surveys constituted the raw data from which the changes in beach profiles as well as sand volumes were examined.

The survey location stretched from 110 meters south of Bethany proper to about 152 meters north of the corporate limits (see Figure 3). From a baseline on Bethany Beach 13 profile lines were established, separated by 152.4 meters and extending offshore to the -9-meter contour, which is usually considered the depth of closure.

Figure 3: Location of Croins and Profile Lines

Spring to summer profile changes (May 4 - October 18)

It is commonly assumed that sediment shifts seasonally between the berm and the bar so the volume of sand involved remains relatively constant; however, the survey data reveals that the volume of sand did not remain constant at Bethany. Figure 4 illustrates the variations in beach sand volume during the study period. Figure 5 represents the shape of the beach at the time of the first survey. Between May 4 and September 15, 1982, the volume of sand over the survey area increased by  $9.7 \times 10^4$  cubic meters. The change in beach sand volume between

surveys was found by subtracting the elevation of each survey point of the earlier survey from that of the later survey and multiplying by the area between survey points. Between early May and mid-October erosion was generally limited to between the National Geodetic Vertical Datum (NGVD) and the -3-meter contour (see Figure 6). The majority of the survey stations experienced a net accretion of sediment. (The shoreline in Figure 6 has been artificially straightened. This was done so onshore-offshore changes would not be masked by longshore variations due to the convexity of the shoreline at Bethany.) Significant changes in elevation detected offshore could be a result of survey error; however, repetition of the surveys show that survey errors are likely to be smaller than the offshore changes shown in Figure 6. For instance, changes of nearly 55 cm were observed on profile 7 at -9 meters (NGVD).

Figure 4: Incremental and Cumulative Change in Volume of Beach Sand over the Survey Area. (Survey Dates Denoted by Vertical Bars on Abscissa.)

#### Impact of October storm (October 18 - October 29)

An intense low pressure system moved northeastward from the Virginia Capes to southern New England on October 24-26, 1982. The storm, with steady winds of 18-22 m/s and gusts up to 37 m/s, was one of the worst storms on the Delaware Coast in the past 20 years. Wave heights exceeding six meters were observed off Indian River Inlet (10 km to the north) and tides were 0.5 meters above normal.

The profiles were surveyed one week before and three days after the storm. Comparison of the two surveys indicates that  $13 \times 10^4$  cubic meters of sediment were transported out of the survey area (see Figure 4). The gross sediment transport (the absolute value of the changes between surveys) was over  $24 \times 10^4$  cubic meters. Figure 7

Figure 5: Three-dimensional Representation of Bethany Beach at the Time of the First Survey, May 4, 1982. (Exaggerated Scale)

represents the locations of erosion and accretion due to the storm. All 13 profiles experienced a net loss of sand, transforming the overall shape of the beach from slightly convex to concave. The beach face was severely eroded during the storm. The waterline retreated landward an average of 14.8 meters along the survey reach. The maximum retreat was nearly 28 meters on profile six. Figure 8 illustrates the effects of the storm on the beach profile. (Because of the heavy seas it was impossible to obtain closure between the dry land and the bathymetric surveys, so a gap in the survey data exists. All the data points within this gap were interpolated between known values; therefore, the width of the offshore bars in the surf zone is uncertain.) Significant erosion was observed from the bar region to the seaward limit of the survey area. One profile eroded nearly 52 cm at a depth of 8.3 meters.

Extrapolation of the profile data indicates that the profiles would need to be extended an additional 127 meters seaward to reach the depth of closure which is likely to be -10 m. The volume of sediment that would be accounted for if the profiles had been extended out to this depth is estimated to be one fourth of the volume of sand lost from the survey area during the storm.

Winter profile changes (October 29 - March 3)

The October storm began the transformation of the beach into the winter profile configuration. By early December, the beach showed signs of recovery from the storm, but remained in the winter

Figure 6: Location of Erosion and Accretion Along the Profiles Between May 4 and October 18, 1962. (Straightened Waterline, Exaggerated Scale)

Figure 7: Location of Erosion and Accretion due to October Storm. (Straightened Shoreline, Exaggerated Scale)

Figure 8: Profile 10 Before and After October Storm

configuration. The area between the landward limit of the survey and the NGVD which was severely eroded during the storm, experienced universal aggradation during the recovery; however, the foreshore did not return to its pre-storm profile. Although the foreshore accreted, the berm remained lower and narrower than it was prior to the October storm.

Bethany Beach suffered a severe winter in 1983, especially during February when a series of storms occurred. The direction of sediment transport is toward the south during the winter, so the northern seven profiles accreted. By trapping the sediment transported from the north, the northern groin compartments starved the south end of Bethany, causing the southern profiles to erode. This erosion/accretion pattern caused a rotation of the waterline about the middle of the groin field. The waterline moved seaward in the northern half of the study area and landward in the southern half.

During February, the berm and foreshore were eroded and the sediment moved offshore to form longshore bars. Since early May 1982,  $15.4 \times 10^4$  cubic meters of sediment had been transported out of the survey area reducing the volume of sand on the beach to its lowest point for the year. By early March the winter profile was fully developed.

#### Changes in profiles during spring (March 3 - May 5)

At the end of March the volume of beach sand had increased significantly. In one month the volume of sand increased by  $19.3 \times 10^4$  cubic meters, most of which was deposited in the offshore region. It appears that the sand accreted offshore and then moved landward between the end of March and early May, when the beach was beginning the transition from the winter to the summer profile configuration. Material from below the NGVD was transported shoreward creating a higher and wider berm. Increases in berm elevation of nearly two meters were recorded.

A full year passed between the first and last survey. The volume of sand was only slightly greater in May 1983 than in May 1982, of

which most of the difference was offshore. Because of the severe winter and late spring, the beach in May 1983 was seasonally behind the May 1982 beach. The foreshore and berm had not yet developed in May 1983.

Eigenfunction Analysis

Previous studies of beach changes and other phenomenon have been conducted using the empirical orthogonal function (EOF) method. The EOF method is an efficient way to describe beach profile changes; however, it should be emphasized that it is a descriptive process and therefore does not reveal any information regarding the governing processes. The reader is referred to Winant et. el. (1975) for a derivation of the technique.

Winant et. al. (1975) has shown that when the EOF method is applied to beach profile data, the eigenfunctions have a physical interpretation. The first eigenfunction, corresponding to the largest eigenvalue is called the "mean beach function" and represents the average profile. The second eigenfunction, termed "berm-bar function", has a large maximum at the location of the summer berm and a minimum at the location of the winter bar. The third eigenfunction, the "terrace function", has a maximum at the location of the low tide terrace. Higher order eigenfunctions account for a very small percentage of the variance of the profile configuration.

Figure 9 is a schematic representation of the decomposition of a beach profile by the empirical eigenfunction method. The original profile can be described by the summation of each eigenfunction multiplied by its corresponding coefficient. The weight of the coefficient defines the degree of variation from the statistical mean.

Three types of eigenfunctions were calculated on the profile data: the "usual" temporal analysis (Winant et. al., 1975; Aubrey, 1979); spatial analysis of the variations along the beach during each survey; and spatial analysis of the variations along the beach for the changes between surveys.

Figure 9: Eigenfunction Decomposition of the Profiles

### Temporal Analysis

Temporal eigenfunction analysis of beach profile data identifies the seasonal variations along a particular profile during the survey period. The first eigenfunction described the mean profile, accounting for about 99.7% of the variance. The second largest eigenfunction accounted for about 0.2% of the mean square value of the data, or about 70% of the variance with the mean beach function removed. The third largest eigenfunction accounted for less than 0.1% of the mean square value of the data.

The maximum and minimum of the second eigenfunction denote the locations of the greatest change. Figure 10 shows the first three eigenfunctions and the corresponding coefficients for the temporal analysis of profile 2. As expected, the second eigenfunction identified the berm and bar as regions with the most deviation from the mean. The coefficients for the second eigenfunction are consistent for all of the profiles, which indicates that the seasonal variations are described well by the temporal eigenfunction analysis. In Figure 10 the large positive eigenvalue at the berm means that the berm was enlarging during the summer and early fall. The negative second coefficient (see Figure 11) during the winter months indicates that the berm was eroding and the bar region accreting. Temporal analysis revealed berm changes extended from the landward end of the survey about 55 m to just seaward of mean sea level. A bar region about 100 m wide was also identified. Significant values at the offshore end of the second eigenfunctions for all of the profiles signifies that this is an area of considerable change rather than the depth of closure. It is unlikely that survey error would result in such consistent values.

Since the third function identifies the location of the low-tide terrace, it is probable that significant changes in the level of the low-tide terrace can take place in only a few days. This would cause aliasing in data from six-weekly surveys (Winant et. al., 1975).

### Spatial Analysis

Spatial eigenfunctions identified the variations along the beach at a particular time. As expected, the eigenfunction associated with the largest eigenvalues represented the mean profile, accounting for about 99.6% of the total variance. The second eigenfunction usually accounted for about 0.3% of the mean square value of the data, or 70% of the variance of the data with the mean beach function removed. The third eigenfunction accounted for about 0.1% of the mean square value of the data, or 20% of the variance with the mean beach function removed.

The mean beach function identified the major trends along the beach at a particular time. Figure 12 shows the first three eigenfunctions computed for the straightened profile data from 3 March 1983. The mean beach function revealed that the beach was in the winter profile. The berm was indistinct and a small bar can be identified between 45 m and 120 m offshore.

Figure 10: The First Three Eigenfunctions for the Profile Data for Profile 2

Figure 11: The Coefficients Corresponding to the Eigenfunctions from Profile 2 Data

Figure 12: The First Three Eigenfunctions for Profile Data from March 3

The second eigenfunction identified the bar region as an area of substantial variation along the beach. The eigenfunction also described the berm and seaward limit of the survey area as locations with considerable deviations from the mean. The value of the second eigenfunction is nearly zero at the location of the waterline because straightened beach profile data was used. In Figure 13, the coefficients of the second function are positive for the northern four profiles, so in the northern section of the beach the berm and bar were more developed than the mean. The coefficients for the middle five profiles are nearly zero. For this area, the mean function closely described the beach profile configuration. Since the coefficients corresponding to the southern profiles are negative, the berm and bar in the south end of the study area were less distinct.

For most of the surveys, the second coefficient changed signs between the eighth and tenth profiles. The coefficients of the middle region are frequently zero, implying that these profiles are shaped similar to the mean. The reversal in sign indicates that the beach is "rotating" about the middle or mean region. The beach face in the southern end of the survey is steeper with more sediment deposited offshore of the bar region than at the northern end. More sediment is deposited in the berm and bar regions on the northern profiles resulting in a steeper offshore profile. For this reason, the second eigenfunction for the spatial variations along the beach will be called the rotation function.

Although in Figure 12 the shapes of the second and third eigenfunctions are very similar, and in Figure 13 the third

Figure 13: The Coefficients Corresponding to the Eigenfunctions Obtained from March 3rd Data

coefficients resemble the second coefficients, this was not typical for all of the surveys. Because the third eigenfunction accounts for such a small percent of the total variance, it describes weaker deviations from the mean so the configurations of the third eigenfunction and the corresponding coefficients are, in general, less consistent along the beach than the configurations of the second eigenfunctions and coefficients.

#### Difference Eigenfunctions

Spatial eigenfunctions were also computed on matrices formed of the differences in elevation between two surveys. The first eigenfunction in this analysis describes the mean changes along the beach between two surveys. The development of the beach into the summer profile is described by the first eigenfunction with a large maximum at the berm and a minimum at the bar. Because the storm altered the beach profile from its summer to winter configuration, in specifying the areas of greatest change between surveys, the eigenfunction analysis of the difference matrix identified the seasonal variations along the beach which are represented by a maximum at the berm and a minimum at the location of the bar. This describes the same variation as the berm-bar function of the temporal analysis. Therefore, the first eigenfunction of the difference matrix between a summer and a winter survey represents the seasonal changes in the profile, and in fact, it is really the berm-bar function of the temporal analysis. Comparison of the second eigenfunction in Figure 10 and the first eigenfunction in Figure 14 confirms this finding.

Between August 1982 and March 1983 the mean eigenfunctions indicate that there was significant change at the seaward limits of the

Figure 14: The First Three Eigenfunctions for the Difference Matrix for October 19 and October 28

Figure 15: The Coefficients Corresponding to the Eigenfunctions Above

profiles. In half of these: between August and September, December and January, and early and late March, this was the location of the greatest change. Although the mean function accounted for about 60% of the variance, it accounted for a greater percent of the variance during the months with the worst storms, October and February. The second and third functions accounted for 15% and 10%, respectively. Higher order eigenfunctions accounted for a much larger percentage of the variance than in the previous analyses.

The coefficients associated with the mean beach function of the difference matrix reversed sign between the fifth and seventh profiles on several of the surveys. Since the waterline also shifts about the same location it is probable that the sand was transported alongshore between the northern and southern sections. Between mid-October and May, the coefficients associated with the first eigenfunction are consistent along the survey area. This signifies that the predominant process was the same over the survey area during the winter.

#### Conclusions

Although erosion has long been considered a serious problem at Bethany Beach, the shoreline has not changed significantly since the groins were constructed nearly fifty years ago. Historical aerial photographs show that the groins accumulated sediment, thereby widening the beach. Between 1938 and 1977, the shoreline within the groin field accreted an average of 0.4 meters/year. These rates include the artificial beach fill that the State of Delaware placed on the beach between 1954 and 1961. The fill was eroded by the March 1962 storm but then replaced by the U.S. Army Corps of Engineers (U.S. Army Corps of Engineers, 1971). The areas north and south of the groins (particularly south) may have suffered from a reduced rate of accretion or even erosion since the construction of the groins.

Examination of the survey data revealed that substantial changes in beach sand volume occurred during the year, but the annual change in volume was very small. Between June and September, the volume of beach sand increased gradually. A severe storm in October transported  $13 \times 10^4$  cubic meters out of the survey area. The total transport, or the absolute value of the volumes of erosion and accretion, was over  $24 \times 10^4$  cubic meters. In early March, the beach sand volume reached its lowest point for the year. Since early May,  $15.4 \times 10^4$  cubic meters of sediment had been transported out of the survey area. In 3 1/2 weeks, the volume of beach sand increased by  $19.3 \times 10^4$  cubic meters, to the highest volume for the year. Despite the large changes that occurred during the year, the net change in volume over the study period was only 1150 cubic meters.

Considerable changes in elevation were observed in depths previously thought to be below the depth of closure. Changes of up to a meter were detected in water depths of 8-9 meters. Because of the experience of the survey crew and the consistent trends between profiles both temporally and spatially, it is assumed that these are actual offshore changes and not a result of survey error.

During the survey period the position of the shoreline varied by around 30 meters. The shoreline and sediment deposition pattern rotated seasonally about the middle profiles. During the summer months when the sediment transport was northward, the southern profiles accreted and the northern profiles eroded. During the winter, the direction of sediment transport reversed causing the northern profiles to accrete and the southern profiles to erode.

The EOF method efficiently produced quantitative results describing changes in the beach profiles. The usual temporal eigenfunction analysis identified the seasonal transition between the summer and winter profiles as the predominant process affecting Bethany. It also revealed the significance of the changes at the offshore end of the profiles. By employing the EOF method spatially to examine the variations along the beach at a particular time, a rotation function was found that identifies the seasonal rotation of the sedimentation patterns about the middle profiles. The first eigenfunction of the spatial analysis of the differences between surveys identifies the same seasonal variations as the berm-bar function of the temporal analysis. The implication of this finding is that the seasonal movement of the beach can be determined from two surveys, one taken of the summer profile and one of the winter, instead of repeated surveys that are necessary for a temporal eigenfunction analysis.

#### Acknowledgement

The authors would like to express their thanks to the Delaware Department of Natural Resources and Environmental Control for the funding of this research. Special thanks go to Robert Henry and Charles Williams of the DNREC for supplying the field data.

## CHAPTER ONE HUNDRED THIRTEEN

### Procedure for Determining Dredging Requirements in Coastal Inlet Channels

James W. Forman, Jr., M. ASCE <sup>1</sup> and  
Limberios Vallianos, M. ASCE <sup>2</sup>

#### Abstract

In order to assess the technical feasibility of a long term maintenance dredging plan at Oregon Inlet, a simple procedure was devised to evaluate the capabilities of existing ocean going hopper dredges to maintain an ocean entrance channel in an inlet environment characterized by wave climate and resulting influx of littoral material as severe as any Atlantic coast location. The dredging analysis procedure described in this paper was used to evaluate dredge plant capabilities under the operational constraints imposed by depth limitations resulting from the continuous influx of sediment into the project channel, the wave climate, and dredging production capacity in terms of actual hopper capacity and cycle times for different disposal schemes. The shoaling and dredging simulation procedure is described in terms of its application to the proposed navigation project at Oregon Inlet, NC.

#### Introduction

The natural geometry of an inlet's ebbtide delta or ocean bar is the end product of the integrated effects of tidal currents, wave action and the associated sediment transport and deposition. Of particular concern here is the natural elevation of the ocean bar, which represents both the limiting elevation of sediment accumulation resulting from the influx of littoral materials contributed by the adjacent shores and the level below which littoral sediments will assuredly collect if the ocean bar is entrenched by a navigation channel. In this regard, the rate of sediment accumulation increases with increasing channel depths so that, at some depth, the channel is capable of effecting total interdiction of the sediments entering the inlet environment. Therefore, a rational evaluation of a dredging plan requires establishing the rate of sediment influx to the general inlet environment, the rate of sediment accumulation within the channel at specific depths, and the net rate of sediment removal by a floating

Corps of Engineers, Wilmington District, Wilmington, NC 28402

(2) Civil Engineer, Chief, Coastal Engineering Branch, U.S.  
Army Corps of Engineers, Wilmington District, Wilmington, NC 28402

dredge plant having certain production capabilities. The general procedure described herein develops these factors in terms of daily time periods in order to develop a day-to-day simulation of siltation processes and dredging effects.

Daily Littoral Materials Transport Volumes

The volume of littoral materials transported toward Oregon Inlet on a given day depends on the characteristics of incoming waves occurring on that particular day. The alongshore transport of sediment is a function of the wave height squared, the wave period, and the angle at which waves break relative to the shoreline. However, an adequate estimate of the relative magnitude of alongshore sediment transport can be obtained simply on the basis of wave height squared in accordance with the relationship:

$$Q_i = Q_g \left[ \frac{H_i^2}{\sum_{i=1}^n H_i^2} \right] \quad (i=1,2,3\dots n) \quad (1)$$

where:

- i = number of the day during the year
- Q<sub>i</sub> = littoral transport occurring on day i (cu. yds.)
- Q<sub>g</sub> = total volume of alongshore sediment transport to the inlet each year (cu. yd s.)
- H<sub>i</sub> = average wave height for the i<sup>th</sup> day of the year
- n = total number of days during the year (taken as 360 days on the basis of twelve 30-day months)

The total average annual rate at which sand is transported toward Oregon Inlet, Q<sub>g</sub>, has been computed as 2,105,000 cu. yds., see reference (1).

Day-to-day variations in the height of the waves required in the above daily transport equation were obtained by analyzing the wave data recorded by the Coastal Engineering Research Center's wave gage at Nags Head between 1963 and 1977. These data were synthesized into the average duration of waves falling within seven wave height classes given in table 1.

Table 1  
Wave Height Classes

<u>Wave Height Class</u>	<u>Wave Height Range (ft)</u>	<u>Average Wave Height in Range (ft)</u>
1	$0 < H < 1.0$	0.5
2	$1 < H < 1.5$	1.3
3	$1.5 < H < 2.5$	2.0
4	$2.5 < H < 4.0$	3.3
5	$4.0 < H < 6.0$	5.0
6	$6.0 < H < 10.0$	8.0
7	$10.0 < H$	10.0

The probability that waves within each of the seven wave height classes would occur during a given month was obtained by:

$$\left[ \text{Probability } H = H_{m,n} \right] = \frac{(Ovbs)_{m,n} (Dura)_{m,n}}{\sum_{m=1}^7 \sum_{n=1}^{12} \left[ (Ovbs)_{m,n} (Dura)_{m,n} \right]} \quad (2)$$

where:

- m = wave height class (m=1, 2, ..., 7)
- n = Number of month
- (Ovbs)<sub>m,n</sub> = Number of observations of waves within class m during month n
- (Dura)<sub>m,n</sub> = Average duration of waves within class m during month n (in days)

The number of days that a particular wave height class would occur during a given month was computed by multiplying the probability of occurrence of that wave class by the number of days in the month. For simplicity, all months consisted of 30 days, and wave durations were in whole day increments. The end product of the wave data analysis was a wave height-time matrix representing day-to-day variations in wave heights throughout the year, including periods of relatively calm sea conditions and moderate storm events.

#### Channel Sedimentation

A method developed by Galvin (see reference (2)) was adopted as the means of computing the volume of sediments expected to deposit within a channel of given depth. This method relates the sediment transport potential within the dredged channel to that existing on the ocean bar in its natural state. Galvin developed what is termed the "transport ratio" (equation 3), the ratio of the sediment transport capacity of the dredged channel to that of the natural ocean bar channel.

$$\text{Transport Ratio} = \left( \frac{d_1}{d_2} \right)^{5/2} \quad (3)$$

Galvin defines the predredging depth ( $d_1$ ) as the minimum controlling depth that exists over the ocean bar prior to any dredging, whereas  $d_2$  is the depth of the dredged bar channel. Both of these depths, which are defined schematically on figure 1, are measured relative to mean tide level (MTL). For the case in which  $d_1 = d_2$ , no shoaling would occur in the channel; however, if  $d_1/d_2 = 0.5$ , the transport ratio would equal 0.18, which means that for every 100 cu. yds. of sediment that enters the channel domain, only 18 cu. yds. would be flushed out by the currents, leaving 82 cu. yds. as the volume of deposited material. Since the dredging analysis is concerned with the material that remains in the channel, the sediment retention factor is defined as simply:

$$\text{Sediment Retention Factor} = 1 - \left( \frac{d_1}{d_2} \right)^{5/2} \quad (4)$$

Four hydrographic surveys of the ocean bar of Oregon Inlet made in the 1950's, or prior to the initiation of dredging, were used to determine the natural controlling depth of the bar ( $d_1$ ) for use in this dredging analysis. The average controlling depth obtained from these four surveys was 9.5 feet MLW or about 10.5 feet MTL.

FIG. 1  
DEFINITION SKETCH

On a daily basis, the amount of material that would be retained in the ocean bar channel of the inlet would be:

$$\text{Daily Shoal Volume} = c Q_g \frac{H_1^2}{\sum_{i=1}^{360} H_i^2} \left[ 1 - \left( \frac{d_1}{d_2} \right)^{5/2} \right] \quad (5)$$

where all the terms in this equation have been previously defined except for the factor  $c$  which is designated here as the "potential shoaling factor". As stated previously, the rate of sediment accumulation in the bar channel increases with the depth of the cut.

However, until sufficient channel depth is attained to intercept all materials moving into the inlet environment, some material will continue to bypass the inlet via the sloping seaward face of the ocean bar below the bottom of the channel cut. Accordingly,  $c$  is defined as the proportion of the gross alongshore transport entering channel, of which a portion is deposited in accordance with the above equation.

In order to assess the magnitude of the potential shoaling factor, a regression analysis was conducted to establish a basic relationship between inlet bar channel siltation and those factors judged to be most influential in the filling and flushing of the channel. Basic data for the analysis was obtained from information available on four unstabilized, dredge-maintained inlet bar-channel projects (including Oregon Inlet) under the jurisdiction of the Wilmington District.

#### Regression Analysis

Three basic factors were selected as being dominant in terms of influencing the magnitude of shoaling at a particular inlet site having a dredge-maintained ocean bar.

- o Ebbtide flow energy is the primary factor acting to flush littoral materials from the inlet environment and, by so doing, serves to maintain the inlet as a viable coastal feature. Its influence in the analysis is represented by the symbol  $E_{DT}$ , the difference of the mean ebbtide flow energy flux across the ocean bar at its natural elevation and the mean ebbtide flow energy flux through the cross section of the dredged ocean bar channel. It is assumed that the tidal discharge is not significantly altered from one condition to the other. The basic concept reflected in the tidal energy flux difference is that the tidal flow velocities directed seaward over the ocean bar at its natural elevation, in combination with wave agitation, are sufficiently rapid to prevent accumulation of sediments above the natural bar level. Conversely, if a section of the ocean bar is deepened by a navigation channel, the related average local flow velocity is diminished resulting in sediment deposition.

- o The magnitude of wave energy reaching the littoral zones adjacent to the inlet is the primary factor controlling the quantity of littoral material moving toward the inlet and, is the fundamental element influencing the shoaling characteristics of an ocean bar navigation channel. In the analysis, the unrefracted wave energy flux per unit width of wave crest offshore of the area of interest, designated  $E_w$ , is used as the basic measure of the magnitude of sediment transport toward the inlet.

- o The depth of an ocean bar channel determines, in large measure, the degree to which a channel will interdict the littoral sediments entering the inlet environment. In the analysis the measure of sediment entrapment potential, is taken as  $D_R$ , the ratio of the depth of the channel to the depth at which the seaward slope of the ocean bar closes or intersects with the sea bottom. Each of these depths is measured from the natural elevation of the ocean bar or ebbtide delta plateau; therefore,

the ratio  $D_R$  represents the extent to which the ocean bar's seaward slope has been incised by the channel.

The channel sedimentation potential increases or decreases as each of the three factors,  $E_{\Delta T}$ ,  $E_W$ , and  $D_R$  becomes larger or smaller, respectively. Accordingly, the factors were combined to establish a normalized, independent variable  $F_I$  for the regression analysis. The value  $F_I$  will be referred to as the "Filling Index" where:

$$F_I = \left( E_{\Delta T} \times E_W \times D_R \right) \div 10^{14} \quad (6)$$

The denominator  $10^{14}$  is employed so that only the mantissa of the product's true value is used.

A normalized, dependent variable for the analysis was selected as the ratio of the volume of channel filling to the computed volume of the total alongshore sediment influx to the inlet multiplied by 100. This percentage value is referred to as the "volume ratio",  $V_R$  and as explained:

$$V_R = \frac{\text{Volume of Channel Sedimentation}}{\text{Volume of Gross Alongshore Sediment Transport}} \quad (7)$$

The regression analysis was based on data related to four dredge-maintained inlets within the boundaries of the Wilmington District: Oregon, Beaufort, Masonboro (prior to jetty construction) and Lockwoods Folly Inlets. The conditions at these inlets provided for a wide range of  $F_I$  and  $V_R$  values. Specifically, information available consisted of: (a) measured tidal discharges (Oregon, Beaufort, and Masonboro Inlets) or inlet throat cross sectional areas (Lockwoods Folly Inlet) which permitted tidal discharge computations by means of tidal prism-inlet area relations; (b) site wave statistics representing one or more years of wave gage records; (c) detailed alongshore sediment transport analyses for the shorelines adjacent to each of the inlets; and (d) one or more sets of inlet hydrographic surveys, each consisting of a first and second survey taken at different dates. This permitted measurement of the volume of sediment filling within the navigation channels in the time periods between surveys. The criterion for selection of sequential inlet hydrographic surveys was that the navigation channel in the second survey of any set was in the same location as the channel in the first survey. It could then be assumed that the channel was horizontally stable between surveys and that the only changes occurring were decreases in depth resulting from sediment deposition. From the records of inlet surveys, a total of 12 sets (24 hydrographic surveys) was selected that fulfilled the survey criterion, thus establishing 12 primary data points for the analysis.

For Beaufort Inlet, 10 surveys were used spanning the period February 1964 to May 1974, during which the authorized navigation project depth was 36.5 feet at mean tide level. This provided five data points for channel depths exceeding 36.5 feet at mean tide level. However, an additional data point was developed for

Beaufort Inlet by considering the dredging record for that inlet between 1937 and 1960, during which the authorized project depth was 31.5 feet at mean tide level. This additional data point was based on the average annual sediment volume removed from the ocean entrance channel, the average daily wave energy flux over the year, and an average channel depth of 34.0 feet below mean tide level, assuming that the average depth of the channel between dredging operations was 2.5 feet below authorized project depth. With this additional information, a total of 13 data points was available for analysis.

For each inlet selected, the basic tidal energy parameter,  $E_{\Delta T}$ , was developed. This parameter defined by equation 8, represents the difference in the daily ebb flow energy flux between the natural and dredged channel conditions. A detailed development of this parameter is presented in reference (1).

$$E_{\Delta T} = \frac{4T}{3\pi} q_{\max}^3 \left[ \frac{d_2^2 - d_1^2}{d_1^2 d_2^2} \right] \quad (8)$$

where  $T$  = Period of tidal wave  
 $q_{\max}$  = maximum instantaneous discharge  
per unit width of ebb flow area.

The next basic parameter of the independent variable is  $E_w$ , the average daily wave energy flux per unit width of wave crest offshore of the site of interest. This parameter represents the intensity of sediment transport from the adjacent beaches to the inlet environment. A basic formulation of wave energy flux can be found in reference (3). Daily wave energy flux can be expressed in a reduced form as:

$$E_w = 1.769 \times 10^6 (H'_o)^2 T \quad \text{ft. lbs.} \quad (9)$$

where  $H'_o$  = Deepwater wave height  
equivalent to observed  
shallow water wave unaffected  
by refraction and friction,  
given in feet  
 $T$  = Wave period in seconds

The wave data used for each site had been obtained from nearshore wave recordings near each inlet site.

Throughout the evaluation it was assumed that the wave records represented the average wave climates for the various sites. The average monthly significant wave heights were converted to deep water equivalent wave heights ( $H_o$ ) based on wave periods, water depths at the respective wave gages, and computed deep water wave lengths ( $L_o$ ).

The computed daily wave energy flux for each month's average daily deepwater equivalent wave height was multiplied by the number of days in the associated month to arrive at monthly energy flux values. If the quantity of channel fill was being measured, for example, by a first survey dated 15 June and a second survey dated 31 October, the average daily wave energy flux associated with that rate of channel sediment filling was computed as the summation of half of the June energy flux and all the monthly energy values for July, August, September and October, divided by the number of days in the whole period.

The last parameter of the independent variable, the depth ratio,  $D_R$ , is a measure of the degree to which channel depths influence the entrapment of sediments. With reference to figure 1, the depth ratio is given as:

$$D_R = \frac{d_2 - d_1}{d_3 - d_1} \quad (10)$$

The dependent variable,  $V_R$ , is, as previously defined, the ratio of the volume of channel fill ( $V_F$ ) to the volume of alongshore sediment transport ( $V_{ST}$ ). The volume of fill ( $V_F$ ) was determined simply by computing the accumulation of channel fill between the first and second hydrographic surveys in each set of surveys. For the additional Beaufort Inlet data point, representing the average conditions in the period 1937-1960, the volume of fill was computed as the average annual volume of material dredged from the inlet entrance channel. The annual alongshore sediment transport volumes for the various sites were available from detailed sediment budget analysis conducted by the Wilmington District. The annual quantities for each site and published references wherein the analyses can be found are as follows: Oregon Inlet - 2.11 million cubic yards, reference (1); Beaufort Inlet - 0.86 million cubic yards, reference (4); Masonboro Inlet - 1.15 million cubic yards, reference (5); and Lockwoods Folly Inlet - 0.60 million cubic yards, reference (6). The independent and dependent variables were computed for each inlet case. The resulting data points are plotted on the diagram shown on figure 2. Tests of several regression equations and related curves revealed that the best fit of the data points was attained by "Hoerl's" special function distribution given in general form by:

$$V_R = a r_I^b e^{CFI} \quad (11)$$

where:

- a, b and c are coefficients
- $V_R$  = volume ratio
- $r_I$  = filling index

In accordance with this generalized form, the regression analysis provided the following relationship:

$$V_R = 10.036686F_I^{-0.000387} e^{0.108489F_I} \quad (12)$$

which is valid for  $F_I$  values equal to or greater than 2 and has the curvilinear form shown on figure 2.

In order to display the expected channel sediment filling in a dredge-maintained navigation channel through the ocean bar at Oregon Inlet, the regression equation was solved for filling index,  $F_I$ , values corresponding to various channel depths. Channel low water depths corresponding to the  $F_I$  scale are shown along the bottom of figure 2. The daily deepwater equivalent wave energy flux used to compute the  $F_I$  values was derived from a nearshore wave height and period of 3.0 feet and 8.6 seconds, respectively. These represent the mean significant wave characteristics synthesized from the record of wave measurements by a gage located in a water depth of 17 feet at Nags Head, N.C., over the period July 1964 - April 1976. In reference to figure 2, it is readily evident that ocean bar channel depths in Oregon Inlet at and below the authorized channel depths of 20 feet MLW datum have corresponding  $F_I$  values well within the domain of 100 percent entrapment of the alongshore sediment transport from the adjacent beaches.

The results of the regression analysis would fully justify adopting a c factor of 1.0 for the "Daily Shoal Volume" equation selected for the dredging analysis.

In the case of Oregon Inlet, the shoaling dredging simulation was run using C values of 0.5, 0.75, and 1.0 in order to determine the sensitivity of the basic procedure with respect to the magnitude

FIGURE 2  
REGRESSION ANALYSIS  
CHANNEL DEPTH - SEDIMENT FILLING RELATIONSHIPS  
DREDGE-MAINTAINED NAVIGATION CHANNEL  
OREGON INLET OCEAN BAR

of dredging resulting from the analysis. In all cases, the results indicated that an intensive dredging effort would be required to maintain the project channel dimensions requiring a channel having a width of 400 feet and a depth of 20 feet below MLW. It was decided to perform the dredging analyses for Oregon Inlet with a c factor of 0.75. This provided a degree of conservability in the analysis and recognized that there were other processes not accounted for that could cause some increased tidal flushing of the channel.

Verification of the Shoaling Rate Simulation Procedure

The method adopted for computing shoaling in the ocean bar channel was compared to actual shoaling rates experienced following eight maintenance dredging operations at Oregon Inlet by the U.S. Hopper Dredge HYDE. The eight shoaling episodes are designated by the letters A through H on figure 3. Controlling depths, rather than average depths were used in the comparison during the time in which the HYDE was employed at Oregon Inlet. Since the computational method utilizes average depths in the channel, the computed and controlling depths are not comparable on a one-to-one basis. However, the rate of change in the controlling depths is directly related to the rate of change in the average depths.

Controlling depths in the ocean bar channel immediately after each dredging operation ranged from about 14.5 and 18.8 feet below MLW, whereas depths at the end of each shoaling episode varied between 7.2 and 10.3 feet below MLW. The average controlling depth in the channel during the shoaling episodes was 12.8 feet below MLW computed by averaging the after-dredging and end-of-episode controlling depths. Since the average controlling depth was only 3.3 feet below the average natural elevation of the ocean bar (9.5

feet below MLW), the proportion of total littoral drift entering the channel domain would be small in comparison to conditions under which minimal depths of 20 feet below MLW would be permitted. In reference to the line of regression displayed on figure 2, channel depths of 12 to 13 feet below MLW would result in volume ratios,  $V_R$ , of 13 to 17 percent. With reference to figure 3, it is evident that, in general, depths less than the average of 12.8 feet existed for longer periods of time than the depths which were greater than average. Therefore, a volume ratio  $V_R$  amounting to about 13 percent was selected as being representative of the past conditions. On the basis of this, the potential shoaling factor  $c$ , adopted for the verification procedure, was 0.25.

#### Dredging Simulation

Removal of sediment from the inlet ocean bar channel by dredging is represented in the procedure by a daily dredging production rate. The production rate is the volume of material that can be removed from the channel during a single working day. This daily volume is the product of the effective hopper capacity for the dredge being evaluated and the number of dredging and disposal cycles that can be accomplished during a working day. A single dredging and disposal cycle time is determined by:

$$\text{Cycle Time} = \text{Dredging Time} + \text{Haul Time} + \text{Disposal Time} + \text{Return Time} + \text{Turning Time}$$

These times are determined by the operational and physical characteristics of the dredge vessel: the light and loaded speeds and the hopper capacity and filling rate.

In the procedure, a dredge is said to operate on a given day if sufficient depth exist in the channel for safe operations, the wave heights do not exceed allowable levels, and operational and maintenance schedules are met. The safe operating depth is defined by:

$$\text{Safe Operating Depth} = \frac{\text{Loaded Vessel Draft} + 1.2 H}{1} \quad (13)$$

where H is the wave height as previously defined. The vessel draft is the actual loaded draft plus a margin of safety of 1-1/2 to 3 feet. Half the wave height is added to allow for vessel motions when underway.

Wave height limitations were determined through discussions with vessel captains and by comparison of dredge logs and wave records for the Corps of Engineers dredge HYDE and the Gulf Coast Trailing Company dredge MERMENTAU. The HYDE performed channel maintenance dredging during the period 1962 to 1971. Comparison of daily operating logs to wave data collected at the Nags Head Pier, located approximately 25 miles north of Oregon Inlet, showed that

when wave heights reached or exceeded 4.0 feet, the HYDE did not operate. Comparison of wave records from the Field Research Facility at Duck, NC, located approximately 60 miles north of Oregon Inlet, and operating records of the MERMENAU operating at the inlet in 1983, showed the operations were terminated when wave heights exceeded 3.5 feet at Duck. These limiting wave height values were used as a guide in establishing limitations for other dredge vessels considered in dredging studies at Oregon Inlet.

In studies of dredging feasibility at Oregon Inlet, intensive dredging and disposal operations with continuous operations 21 hours per day and 7 days per week were evaluated. In order to account for dredge vessel down time required for scheduled and unscheduled maintenance and taking on fuel, water and provisions, dredging operations were permitted 6 out of 7 days. Together with down time due to wave conditions the average down time per month averaged about 20 percent. This agrees with down time experienced by MERMENAU operations in Oregon Inlet in 1983.

#### Dredging Shoaling Evaluation Procedure

The depth computed by the shoaling - dredging simulation is the net result of shoaling and dredging in the inlet channel. It is assumed that depth changes occur uniformly over the length and width of the channel. Channel length is measured between the 20 foot contours inside and outside the inlet. Channel width and depth are specified project dimensions. In the case of Oregon Inlet the project channel depth and width were 20 feet and 400 feet respectively. The measured channel length was 3,280 feet. From the daily variation of channel depths provided by the shoaling and dredging simulation, monthly minimum and maximum depths are taken to obtain a time history of monthly channel depth variation over the period of analysis.

The simulation also provides an accounting of simulated dredging operations in terms of the number of days per month the dredge operates, the number of dredging days lost due to weather (waves), and quantities of material dredged in cubic yards.

Several alternative dredging schemes for maintenance of an ocean entrance channel at Oregon Inlet were evaluated using the dredging and shoaling simulation. The various schemes varied in terms of the method of disposal and type of dredge vessel considered.

The first alternative considered involved dredging of the channel by trailer suction hopper dredge and pumping the dredged material to adjacent beaches much like conventional beach nourishment techniques. The direct pumpout scheme was evaluated for three different floating dredge plants representing a range of capacities and vessel drafts. Two Corps of Engineers dredges and a class of privately owned split hull hopper dredges with direct pumpout capabilities were evaluated. The shoaling and dredging simulation was applied to evaluate the capabilities and efficiency of each plant to maintain the project

channel at Oregon Inlet. Evaluated were the Corps dredge MARKHAM, a medium sized hopper dredge with a total bin capacity of 2,000 cubic yards and a loaded draft of 23 feet; the Corps dredge HAINS with a total bin capacity of 330 cubic yards and a loaded draft of 13 feet; and the split hull hopper dredge ATCHAFALAYA operated by Gulf Coast Trailing Company with a total bin capacity of 1,000 cubic yards and a loaded draft of 14.5 feet.

Dredging cycle times were determined by:

$$\text{Direct Pumpout Cycle Time} = \text{Dredging Time} + \text{Haul Time} + \text{Hookup and Pumpout Time} + \text{Return Time} + \text{Turning Time}$$

Production rates were based on a working day of 21 hours, a 26 day working month, and wave height limitations of 5 feet for the MARKHAM and ATCHAFALAYA and 4 feet for the HAINS. It was assumed that sufficient initial channel depths existed in the bar channel to allow for safe operations of each dredge at the initiation of maintenance dredging operations. In each case, maintenance dredging was assumed to begin in September, the beginning of the period of highest wave energy and associated alongshore transport to Oregon Inlet. The basic results of the analyses of the various dredges is presented below as an example of the application of the shoaling and dredging simulation procedure.

The production rate of the HAINS, when utilizing the direct pumpout technique is 3,980 cubic yards/day. The average daily influx of sediment to the channel, assuming that only 75 percent of the total littoral drift reaches the channel domain, is 4,330 cubic yards/day. Though the shoaling-dredging simulation accounts for a portion of the daily sediment influx being flushed from the channel by ebb tide currents, the number of days during the year that the HAINS could not work in the inlet due to normal downtime or inclement conditions would make it impossible for this particular dredge to maintain the channel below 20 feet MLW using direct pumpout. In evaluating the HAINS for direct pumpout, initial channel depths of 24 to 28 feet MLW were considered. However, even with the initial depth of 28 feet MLW, the depth in the channel decreased to slightly less than 20 feet MLW by the end of the first year of dredging. With the HAINS continuing to operate at its maximum rate into the second year, the shoaling-dredging simulation predicted that the channel depth would decrease to less than the 15-foot MLW maximum safe operating depth for the HAINS by January. The time variations of the computed minimum and maximum monthly depths in the Oregon Inlet ocean bar channel during direct pumpout maintenance dredging operations by the HAINS are shown on figure 4.

The direct pumpout capacity of the MARKHAM is 14,000 cubic yards/day which is more than three times the average daily influx of sediment to the channel; therefore the MARKHAM would not have to be committed to Oregon Inlet on a year-round basis. However, the channel developed by the MARKHAM at the end of an operation

would have to be of sufficient depth to store materials depositing in the channel during nondredging months to a depth at or below 24 feet MLW. Otherwise, a dredge of smaller draft of shallower draft would have to be used to reestablish the 24-foot MLW depth required by the MARKHAM on its return to the project site.

Though the MARKHAM is capable of dredging to a maximum depth of 45 feet, the practical limit on the dredge of the inlet channel was set at 32 feet MLW or slightly below the toe of the seaward slope of the ocean bar at Oregon Inlet. In evaluating the MARKHAM, various limits were set on the number of months that the dredge would work in Oregon Inlet and on the maximum depth that the dredge would be allowed to cut into the bar. The number of months ranged from 4 to 8, whereas the maximum channel depths considered were 28, 30, and 32 feet MLW. A total of 15 combinations of dredge time and maximum depth were considered. Of the 15 alternatives tested, only two yielded predicted channel depths greater than 24 feet MLW at the end of the 12-month evaluation period. An alternative involving a 7-month commitment of the MARKHAM to Oregon Inlet and a maximum channel depth of 32 feet MLW was selected for the purpose of comparison with other alternative schemes.

The selected maintenance dredging operation for the MARKHAM was simulated over a 3-year period to determine if the dredge would be able to maintain adequate depths over an extended period of time. A plot of the monthly maximum and minimum channel depths for this 3-year simulation is given on figure 5. The depths for a particular month remained fairly constant from year to year, and the channel depth never decreased to less than 24 feet MLW. Thus, it is evident that the MARKHAM could, without difficulty, maintain the Oregon Inlet ocean bar channel using direct pumpout.

The evaluation of the ATCHATALAYA, which has a direct pumpout production rate of 5,900 cu. yds./day, considered five initial depths in the bar channel, namely 20, 24, 26, 28, and 30 feet MLW. Plots of the minimum monthly depths in the inlet channel for each of the five initial depths considered for the ATCHAFALAYA are shown on figure 6. For the 20-foot MLW initial depth, there was not a sufficient depth buffer in the channel to accommodate the difference between the rate of shoaling and dredging that would occur between September and January. Consequently the depth in the channel decreases below the 16-foot MLW safe operating depth for the ATCHAFALAYA. This would result in a cessation of the dredging activity in January. With an initial depth of 24 feet MLW, the ATCHAFALAYA was able to work in the bar channel throughout the year; however, the minimum depth in the channel did decrease to slightly less than 20 feet MLW during the months of January through April. For all the other initial depths considered, i.e., 26, 28, and 30 feet MLW, the shoaling-dredging simulation indicated that the ATCHAFALAYA would be able to maintain channel depths deeper than 20 feet MLW throughout the year. Additionally, the depth in the channel at the end of the yearly dredge cycle was slightly deeper than at the beginning for initial depths of 26 and 28 feet MLW; therefore, during normal littoral transport years the ATCHAFALAYA would be able to maintain the 20-foot MLW bar channel from year to year. Since all of the initial channel depths equal to or greater than 26 feet MLW resulted in acceptable channel depths during the year, the 26-foot MLW initial channel depth was selected.

#### Summary

The procedure discussed in this paper provides a simple method for evaluating the capabilities of different dredge plants for maintaining a channel through the ebb tidal bar of Oregon Inlet, NC. The information required for its application includes the natural controlling depth of the ocean bar, the project channel width and length, the dredge plant capacities and operational characteristics, and a wave record covering the period of analysis.

The results of the procedure provide a time history of channel depths over the period of analysis and a means of evaluating the efficiency of a given dredge plant operating in the inlet. A dredging plan can be optimized by varying the length of the dredging period and the initial channel depths.

#### Acknowledgements

The procedure described by this paper is the product of extensive dredging studies conducted by the Wilmington District in connection with the Manteo (Shallowbag) Bay project. The studies were conducted by the Engineering Division, Coastal Engineering Branch. The District Engineer during the studies was COL. Robert Hughes. Chief of the Engineering Division was Mr. Jaman Vithalani. The Chief of the Coastal Engineering Branch was Mr. Limberios Vallianos.

## CHAPTER ONE HUNDRED FOURTEEN

### The Computation of Bed Shear in a Numerical Model

W. Leeuwenstein\* and H.C. Wind\*\*

#### 1. Introduction

Obstructions located in coastal and offshore waters usually disturb the natural flow pattern. This disturbed flow will, in general, cause local morphological changes in the position of the erodable boundary.

Often these changes should not be allowed to exceed certain limits, for example, when local scour around an offshore construction may endanger foundations.

Local morphological changes result from changes in the local sediment balance, brought about by the flow disturbance.

In the present paper a mathematical model is described which gives the bottom shear stresses and the configuration of the seabed around an obstruction using a computation of the two dimensional turbulent flow field. The obstruction considered is a submarine pipeline laid uncovered on a seabed consisting of non-cohesive sediment. A research project on the local scour near submarine pipelines is being carried out at the Delft University of Technology. Part of the project is the application and extension of an advanced numerical flow model for scour development near pipelines on the seabed exposed to current action. This work is being carried out in cooperation with the Delft Hydraulics Laboratory. The code of the flow model has been developed in a joint venture between the Delft Hydraulics Laboratory and the Laboratoire National d'Hydraulique in France.

The turbulent flow field is computed taking into account the influence of turbulence generated at the bed and by the pipe. The bed shear stresses are assumed to play the key role in the interaction between the flow and the seabed. In the computer model the bed shear is related to the flow through the "law of the wall". The model operation is schematized in the diagram below in which the first loop represents the evolution of the velocity field through a series of hydraulic time steps. After the velocity field is stabilized, in the second loop one morphological time step can be used for the computation of the local seabed changes. In this second loop the computed bed shear is applied together with a sediment transport formula.

After the morphological time step a new bed topography is obtained and a new grid is generated for the next flow computation.

## 2. Theory

### 2.1 Flow Field

A detailed computation of the flow pattern is a prerequisite for the calculation of small scale changes of the seabed. In the present example the changes in the seabed are of the same magnitude as the pipe diameter which is, in general, small relative to the flow depth.

The basic equations describing the flow are the equations of motion and continuity for the fluid. The two dimensional unsteady Navier-Stokes equations for the mean flow are written as:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + \frac{1}{\rho} \frac{\partial p}{\partial x} - \frac{1}{\rho} \left( \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \sigma_{xx}}{\partial x} \right) = 0$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + \frac{1}{\rho} \frac{\partial p}{\partial y} - \frac{1}{\rho} \left( \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} \right) = 0 \quad (1)$$

where  $u$  and  $v$  are the horizontal ( $x$ ) and vertical ( $y$ ) velocity components respectively,  $p$  is the pressure and  $\sigma_{xx}$ ,  $\sigma_{yy}$ ,  $\tau_{xy}$  are the shear stresses in the fluid,  $\rho$  is the density of the fluid. The equation of continuity is:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (2)$$

In the equations of motion the viscous and turbulent shear stresses appear together as

$$\sigma_{xx} = \rho \nu 2 \frac{\partial u}{\partial x} - \rho \overline{u'^2}$$

$$\tau_{xy} = \rho \nu \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) - \rho \overline{u'v'}$$

$$\sigma_{yy} = \rho \nu 2 \frac{\partial v}{\partial y} - \rho \overline{v'^2} \quad (3)$$

where  $\nu$  is the kinematic viscosity of the fluid,  $u'$  and  $v'$  are the turbulent fluctuations associated with the time-averaged velocities  $u$  and  $v$  respectively.

Using Boussinesq's hypothesis the turbulent stresses in Eq. (3) can be written as:

$$-\overline{u'v'} = \nu_t \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \quad (4)$$

where  $\nu_t$  is the turbulent equivalent of  $\nu$  and is commonly known as the turbulent eddy viscosity.

In the present model the eddy viscosity,  $\nu_t$ , is written in terms of the turbulent kinetic energy  $k$  and its dissipation rate  $\varepsilon$ :

$$\nu_t = c_\mu \frac{k^2}{\varepsilon} \quad (5)$$

where  $c_\mu$  is a universal constant with a value of  $c_\mu = 0.09$ .

The kinetic energy,  $k$ , and its dissipation rate,  $\varepsilon$ , are solved from two partial differential equations in  $k$  and  $\varepsilon$ , both containing  $\nu_t$ , and referred to as energy transport equations. For a detailed description of these equations for the standard  $k$ - $\varepsilon$  model, see Rodi (1980).

## 2.2 Boundary Conditions

In the present model the the law of the wall is used at the bed:

$$\frac{u_t}{u_*} = \frac{1}{\kappa} \ln \frac{y_1}{y_0} \quad (6)$$

where:

- $u_t$  = the tangential velocity at a distance  $y_1$ , which is the distance of the first grid line, from the bed,
- $u_*$  = the shear velocity
- $\kappa$  = the von Karman constant
- $y_0$  =  $r_N/33$  with  $r_N$  being the equivalent Nikuradse roughness length

The following boundary conditions are used with respect to the bed in the equations of the  $k$ - $\varepsilon$  model:

$$k = \frac{u_*^2}{\sqrt{c_\mu}} \quad (8)$$

$$\varepsilon = \frac{|u_*|^3}{\kappa y} \quad (9)$$

At the upstream boundary the standard distribution functions for uniform open channel flow are applied with regard to  $u$ ,  $v$ ,  $k$  and  $\varepsilon$ .

A rigid lid is applied along the free surface. The pressure distribution against the lid, which in fact is a fixed boundary without shear, acts on the fluid similarly to the pressure resulting from the free surface elevations, see Alfrink (1982).

## 2.3 Sediment Concentration Field

A spatial distribution of sediment exists as a result of the exchange of sediment between the flow field and the bed and due to further vertical exchanges caused by flow turbulence. Due to gravity forces acting on the grains the sediment concentration, in general, tends to increase towards the bed. In the present model the variation in bottom topography is found using the computed flow field.

The following unsteady equation describing the conservation of sediment is used in the model to derive the bottom boundary condition:

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + (v - v_s) \frac{\partial c}{\partial y} - \frac{\partial}{\partial x} (D_x \frac{\partial c}{\partial x}) - \frac{\partial}{\partial y} (D_y \frac{\partial c}{\partial y}) = 0 \quad (10)$$

where:

$c$  = the sediment concentration  
 $v_s$  = the fall velocity of the sediment in still water  
 $D_x$  and  $D_y$  = the coefficients of sediment diffusion in the  $x$  and  $y$  direction respectively

Combining Eq. (10) with the equation for continuity, Eq. (2), it follows that:

$$\frac{\partial c}{\partial t} + \frac{\partial}{\partial x} (uc - D_x \frac{\partial c}{\partial y}) + \frac{\partial}{\partial y} \{ (v - v_s) c - D_y \frac{\partial c}{\partial y} \} = 0 \quad (11)$$

and that the horizontal and vertical transport through a unit area can be defined respectively as:

$$s_x = u c - D_x \frac{\partial c}{\partial y} \quad (12)$$

$$s_y = (v - v_s) c - D_y \frac{\partial c}{\partial y} \quad (13)$$

Boundary conditions with respect to the concentration field at the free surface ( $y = y_s$ ) for the sediment and for the fluid are, respectively:

$$s_y = s_x \frac{\partial y_s}{\partial x} + c \frac{\partial y_s}{\partial t} \quad \text{and} \quad (14)$$

$$v = u \frac{\partial y_s}{\partial x} + \frac{\partial y_s}{\partial t} \quad (15)$$

leading, with Eqs. (12) and (13) to

$$v_s c + D_y \frac{\partial c}{\partial y} = D_x \frac{\partial c}{\partial y} \frac{\partial y}{\partial x} \quad (16)$$

Similar boundary conditions apply for the bed ( $y = y_b$ ) and assuming a constant porosity,  $p'$ , for the bed thus leads to:

$$s_y = s_x \frac{\partial y_b}{\partial x} + c \frac{\partial y_b}{\partial t} - (1 - p') \frac{\partial y_b}{\partial t} \quad (17)$$

$$v = u \frac{\partial y_b}{\partial x} + \frac{\partial y_b}{\partial t} \quad (18)$$

$$v_s c + D_y \frac{\partial c}{\partial y} = (1 - p') \frac{\partial y_b}{\partial t} + D_x \frac{\partial c}{\partial y} \frac{\partial y_b}{\partial x} \quad (19)$$

From Eq. (19) it is obvious that the term for vertical diffusion, which is in general negative near the bed, will hinder sedimentation.

Assuming that the coefficients of diffusion for water,  $\nu_t$ , (eddy viscosity) and for sediment,  $D_y$ , are equal, sedimentation will be hindered where the eddy viscosity field shows high values for  $\nu_t$ .

Combining Eq. (11) for the concentration field with definitions of the horizontal and vertical transport,  $s_x$  and  $s_y$ , given in Eqs.

(12), (13), respectively, gives, after integration over the flow depth, the equation of continuity of sediment

$$\int_{y=y_b}^{y=y_s} \left( \frac{\partial c}{\partial t} + \frac{\partial s_x}{\partial x} + \frac{\partial s_y}{\partial y} \right) dy = 0 \quad (20)$$

Using Eqs. (13), (16) and (17) leads to

$$\frac{\partial}{\partial t} \left( \int_{y_b}^{y_s} c \, dy \right) + \frac{\partial}{\partial x} \left( \int_{y_b}^{y_s} s_x \, dy \right) + (1-p') \frac{\partial y_b}{\partial t} = 0 \quad (21)$$

The total sediment transport capacity can now be written as:

$$S = \int_{y_b}^{y_s} s_x \, dy \quad (22)$$

Using  $S$  according to Eq. (22) in Eq. (21) gives an alternative formulation with regard to the bottom boundary condition for cases where total sediment load is considered:

$$\frac{\partial}{\partial t} \left( \int_{y_b}^{y_s} c \, dy \right) + \frac{\partial S}{\partial x} + (1-p') \frac{\partial y_b}{\partial t} = 0 \quad (23)$$

For the computation of the bottom changes use has been made of Eq. (23) assuming a stationary concentration field ( $\partial/\partial t = 0$ ). The objective of the study is to analyze the evolution of scour beneath a pipeline. The bottom changes will be restricted to the characteristics of bottom changes due to bed load.

#### 2.4 Bed Load Transport

For cases with bed load transport a suitable bed load transport formula is used to compute  $S$ . The transport capacity  $S$  is calculated using the computed bed shear  $u_*$  and the threshold value  $u_{*c}$ . The value of  $u_{*c}$ , indicating the initiation of bed load transport, has been determined experimentally by many investigators, for instance Shields (1936). In the course of this study three bed load formulae will be considered. The first formula is similar to the Meyer-Peter Müller formula:

$$\Phi = a (\theta - \gamma_s \theta_c)^b \quad (24)$$

where

$$\Phi = \frac{S}{(g\Delta D^3)^{\frac{1}{2}}} \quad \text{and} \quad \theta = \frac{u_*^2}{\Delta g D} \quad (25)$$

The values of the parameters  $a$  and  $b$  have been chosen 13.3 and 1.5 respectively. The parameter  $\gamma_s$  represents the influence of the local bed slope  $dy_b/dx$  on the threshold value  $u_{*c}$  and is defined, using  $\psi$  the angle of internal friction of the sediment, as:

$$\gamma_s = \sin\{\psi - \arctg(dy_p/dx)\} (\sin\psi)^{-1} \tag{27}$$

An example of an empirical formula describing in particular conditions with minor sediment transport is the formula of Paintal (1971):  

$$\Phi = 6.56 * 10^{18} \theta^{16} \tag{28}$$

De Ruyter (1982) has elaborated upon the stochastic description of sediment transport. He has expressed the sediment transport rate as a function of the pick up rate  $N_p$  and the saltation length  $\lambda$ . In dimensionless terms this formula can be expressed as:

$$\Phi = \Pi \Lambda \tag{29}$$

where

$$\Pi = \frac{\pi D^3}{6} \frac{N_p}{\sqrt{\Delta g D}} \text{ and } \Lambda = \frac{\lambda}{D} \tag{30}$$

The formula of  $N_p$  is given in the Appendix by (A3). An important parameter is the dimensionless saltation length  $\lambda/D = a' \theta$ . For  $\theta < \theta_c$  it has been assumed that  $a'$  approaches  $550 \theta_c/\theta$ . For  $\theta > \theta_{cr}$  the value of  $a'$  has been assumed to be equal to 550. The ratio of  $\sigma_\tau/\tau$  and  $\theta_c$  have been estimated at a value of 0.4 and 0.1 respectively. It should be emphasized that the transport rate described by (A1) has been reduced with a factor of 3 for calibration purposes.

FIG. 2 COMPARISON OF BED LOAD TRANSPORT FORMULAE

The tendency of all the transport rates in Fig. 2 is similar, i.e. a rapid decrease in transport rate near the critical Shields value. This implies that for a given shear stress distribution, the transport distributions for the presented transport formulae will also be similar of shape even as the resulting bottom changes. This conclusion will be used in the analysis of the scour underneath the pipe. Finally it may be remarked that although the shape of the bottom changes is similar, the magnitude depends among others on the choice of the transport formula.

3. Examples

As an example has been chosen the scour beneath a submarine pipeline. Characteristic features of the scour hole obtained from laboratory experiments can be found in Figs. 3 and 4. First the equilibrium scour hole will be treated followed by the evolution of a scour hole with time.

FIG. 3a FLOW PATTERN

FIG. 3b COMPUTED BEDSHEAR

FIG. 3c CONFIGURATION OF SCOURHOLE

3.1 Equilibrium Scour Hole

The bed shear has been computed along the bottom of a scour hole for a situation with clear water scour, when the sediment supply towards the area of scour is zero. Although minor movement of individual grains was observed occasionally in the small scale scour test in the laboratory the scour hole can be assumed to show its equilibrium shape. The minor grain movement occurred on the rising slope and was due to fluctuations in the bed shear. The flow field is shown in Fig. 3a. Fig. 3b shows the computed bed shear for a constant viscosity of  $10^{-4} \text{ [m}^2\text{s}^{-1}\text{]}$  and also for an eddy viscosity computed by the  $k-\epsilon$  model. The computed time mean bed shear downstream of the pipe is a little below Shields' mean threshold value which is approximately  $u_*^2/(\Delta gD) = 0.03$  for the grain diameter used in the test. This is in agreement with the observation that the scour hole is in an equilibrium state. The test data of the example are:

- pipe diameter : 50 mm,
- mean current velocity:  $0.25 \text{ ms}^{-1}$
- grain size :  $D_{50} = 700 \text{ }\mu\text{m}$

FIG. 4a SCOUR EVOLUTION

FIG. 4b COMPUTED BED SHEAR

3.2 Scour Development with Time

In this example the evolution of the scour hole has been computed starting with the geometry of a partially developed scour hole.

Five morphological time steps have been made each preceded by a series of hydraulic time steps, covering a total time interval of 5 minutes of the scour process. The computed bed shear is shown in Figs. 4a and 4b together with scour hole configurations as observed during the small-scale test after 240 and 420 minutes scouring respectively. Fig. 4a shows the further evolution of the scour hole, during the 5 minutes after  $t = 420$  minutes, as computed using the bed load concept of the model.

A propagating bed wave or ripple appears as a direct consequence of the use of a transport formulation relating the bed load transport to the bed shear. Its propagation velocity,  $c_b$ , is approximately 0.36 [m/hour] and the height of the crest,  $\Delta_{bt}$ , and the depth of the trough,  $\Delta_{bd}$ , converge to values of 0.014 and 0.007 m respectively, see Fig. 5b. Because of the persistence of the ripple the computations have been terminated after 5 minutes. In order to analyse these bed

time step:  
 $\Delta t_m \approx 1'$

FIG. 5a COMPUTED EVOLUTION OF SCOUR HOLE DUE TO BED LOAD TRANSPORT

FIG. 5b RIPPLE DEVELOPMENT RELATIVE TO LOCAL INITIAL BED

features the computed sediment transport,  $S_b$ , is given in Fig. 6a together with the mean sediment transport,  $S_m$ , during the 3 hour time interval between the two scour hole configurations shown in Fig. 4a. It will be clear from Fig. 6a that the computed bed load transport capacity at  $t = 420$  deviates considerably from the mean value computed over the three hourst time preceding  $t = 420$ . In Section 4 this discrepancy will be further analyzed.

The test data are:

- pipe diameter : 140 mm,
- mean current velocity:  $0,40 \text{ ms}^{-1}$ ,
- grain size :  $D_{50} = 100 \text{ } [\mu\text{m}]$

sediment transport capacity  $[10^{-6} \text{ m}^3 \text{ s}^{-1} \text{ m}^{-1}]$

#### 4. Analysis at the Results and Discussion

In view of the results in the examples treated in Sections 3.1 and 3.2 a first assessment can be made of the role that can be ascribed to bed shear with regard to local seabed morphology.

For the development and the equilibrium state of scour underneath submarine pipelines it can be assumed that the leading parameter is the bed shear. An increasing scour depth can be assumed to be closely related to an increasing bed shear in the direction of flow at least for cases with dominating bed load transport. In line with this assumption an equilibrium scour hole occurs when the bed shear remains constant along the bed provided that the threshold value is exceeded.

The example in Section 3.1 clearly confirms the assumption for an equilibrium scour hole in coarse sediment where the sediment supply upstream of the pipe equals zero. On the rising slope downstream it was observed that minor movement of individual grains still occurred even though the scour depth was practically in equilibrium. This observation is in agreement with the computed bed shear on the slope which in the scour hole is nearly constant and just below the mean threshold value of  $\theta_c = u_{*c}^2/(\Delta gD) = 0.03$  according to Shields (1936).

The example given in Section 3.2, in which the evolution of the scour hole with time was treated, demonstrated the unsatisfactory description of the sediment transport given by formulae like Eq. (24), even though bed load transport has been observed to contribute predominantly to the scour development. The appearance of a wave in the bed is inherent to the transport formulae like Eq. (24), where the sediment transport is so directly related to the bed shear. Fig. 6 clearly demonstrates the reason for the bed wave or ripple developing in the model. This reason is not numerical, but is a direct consequence of the sediment transport concept chosen and the sign of  $\partial S/\partial x$ .

During 5 minutes computing time the wave or ripple propagates in the direction of the flow while a mean degradation of the bed is being computed. All the sediment being transported by means of ripple propagation, the net loss of sediment from the scour hole, is determined by the propagation velocity and the height of the ripple.

Fig. 4b indicates that the ripple converges to a certain height,  $\Delta_b$ , which may enable a computation of the time averaged loss of sediment using:

$$dA = \xi \Delta_b c_b \quad (31)$$

where

- $dA$  = the increase in scour volume per unit width and per unit time and
- $\xi$  = a coefficient depending on the ripple configuration, representing the effective ripple height.

Using Eq. (31) with the computed values for  $c_b$  and the effective ripple height  $\xi\Delta_b$  the scour volume corresponding with the ripple propagation is of the same order as the observed mean scour from  $t = 240'$  to  $t = 420'$  (Fig. 4a).

In the small-scale laboratory scour tests a gradual degradation

of the bed has been observed at the time interval of 180 minutes. In the bed load concept a constant  $dy_b/dt$  means, that during that time,  $\partial s/\partial x$  is approximately constant and  $s$  increases gradually along the bed in the direction of the flow (the theoretical curve  $s_m$  for the transport capacity). Using the bed load concept the computed transport confirms with the curve  $s_b$  which in turn conforms to the bed shear in Fig. 3b. Both curves for the transport deviate considerably, indicating that the concept of bed load as a direct function of the time averaged bed shear is not unconditionally sufficient to describe local scour. Four reasons for this insufficiency are discussed below. These reasons are a) suspended transport, b) stochastic bed shear, c) bed-form roughness and d) transport formulation.

a) Suspended transport

It is obvious that with increasing bed shear sediment will be brought into suspension and a concentration field will develop resulting in additional convective and diffusive sediment transport in addition to the bed load transport. Ripples, appearing as a result of strong bed shear gradients as shown in the example, will, in the very initial phase, be in suspension. Suspended sediment transport will be included in a more extended version of the present program and will be based upon the equations given in Par. 2.3.

b) Introduction of stochastic bed shear

In turbulent flow the bed shear has a stochastic character and consists of a constant time averaged value  $\bar{\tau}$ , which follows directly from the present model, and a fluctuating component  $\tau'$ . Using only  $\bar{\tau}$  for the computation of the bed load transport capacity according to Eq. (24) the contributions of instantaneous bed shear values  $\tau$  (or  $u_*$ ) with a probability  $p(\tau)$ , or  $p(u_*)$ , can be neglected.

Instantaneous values of  $\tau > \bar{\tau}$ , even though their probability may be low, can contribute considerably to the sediment transport capacity.

Laboratory measurements have demonstrated that the significant turbulence downstream of pipelines which can be practically expressed in standard deviations,  $\sigma_u$ , of the flow velocity.

Once the turbulent kinetic energy,  $k$ , is known and assuming  $v' \ll u'$  the standard deviation  $\sigma_u$  follows from:

$$\sigma_u = \sqrt{2k} \quad (32)$$

In the appendix a method is given which, starting with  $\sigma_u$ , through  $\sigma_\tau$  results in an amplification factor,  $A$ , for the sediment transport capacity.  $A$  is a function of the mean bed shear level,  $\beta$ , and the relative level of turbulence,  $\alpha/\alpha_0$ . By multiplying the sediment transport capacity,  $S_{b0}$  and using only the mean bed shear  $\bar{\tau}$  (or  $\bar{u}_*$ ), by  $A$  the sediment transport capacity,  $S_b$  is obtained which also includes the effect of variation of turbulence. In case of  $\bar{\tau} < \bar{\tau}_c$  the Meyer-Peter Müller formula (24) yields a zero transport rate independent of the variation of turbulence. Fig. 7 shows  $A$  as a function of  $\alpha/\alpha_0$  and  $\beta$  and is further explained in the Appendix. Fig. 8 shows the effect of the measured relative turbulence,  $\alpha/\alpha_0$ , for the pipeline example discussed in Section 3.2. Above  $x/\theta = 1.0$  the computed amplification factor increases rapidly due to the low bed shear level,  $\beta = \bar{\tau}/\bar{\tau}_c$ , (see Fig. 7), and, finally,  $\beta$  arrives at values where the

approach leading to a value of the amplification factor is no longer applicable.

FIG. 7 AMPLIFICATION OF SEDIMENT TRANSPORT AS A FUNCTION OF SHEAR STRESS LEVEL  $\beta$ . AND RELATIVE TURBULENCE INTENSITY  $\alpha/\alpha_0$

According to Fig. 8 the amplification factor beneath the pipe is one. This means that introduction of stochastic bed shear does not influence the ripple height. On the lee side locally the amplification factor increases rapidly (Fig. 8). This increase is caused partly by the decrease in  $S_{b0}$  in Eq. (A6). Due to the local effect in the present example it is not expected that introduction of stochastic bed shear will in this case lead to a more uniform erosion on the lee side of the pipe.

c) Varying bed roughness

In the small-scale scour tests with movable bed it has been observed that, in general, the bed becomes smooth underneath the pipe and that the ripple pattern is restarted on the downstream slope.

Although this phenomenon will be less pronounced for larger scale scour its influence on the bed shear, Eq. (6), and the related transport (mechanism) should be taken into account.

FIG. 8 OBSERVED TURBULENCE INTENSITY AND AMPLIFICATION FACTOR

d) Flexible transport formulation

Relaxation of the rigidly formulated (bed load) formulae, Eq. (24) and Eq. (28), by introducing variable coefficients  $a$  and  $b$  indeed makes sense physically. It is known that the value of  $b$ , in particular, decreases when  $\theta$  and, therefore, the transport,  $S$ , increases.

The various influences on the redistribution of sediment transport mechanisms underneath the pipe and downstream will without doubt change the type of transport and its formulation.

The use of a flexible formulation for the sediment transport, though physically justified and even required, is not warranted at present, because of lack of knowledge about the variation of the parameters.

5. Summary and Conclusions

The local morphological changes beneath pipelines originating from hydraulic conditions show variations which are on a relatively small scale compared to the water depth. A numerical model to compute these very local hydraulic conditions is essential for the study of scour problems as for example can occur with a submarine pipeline. A detailed computation of bed shear and turbulence characteristics, as provided by the present model, has been used to obtain the sediment transport capacity along the bed near a pipeline. Although the bed shear is the leading parameter for the sediment transport a combination of the latter with an empirical bed load formula seems to result in a rather rigid schematization of the complex sediment transport for the presented examples of local scour. The computed bed changes include ripple development, at least when a bed load concept is used,

which excludes sediment suspending under the influence of high values of local bed shear. The example with a computation on a flow field around a pipe with an equilibrium scour hole has proved the value of the present model for appreciating the morphological stability of local seabed configurations.

Implementation of the suspended load concept is the next step which will be taken in the further development of the present model.

## 6. Acknowledgements

The authors acknowledge the contributions of Mr. de Ruyter on Fig. 2 and on the Appendix. Discussions with Dr. de Vriend and Mr. van Rijn have appeared to be very fruitful.

APPENDIX: Increase of Bed Load Transport Capacity due to Turbulence

A method is described below to account for the effect of turbulent fluctuations in the bed shear on the bed load transport capacity. In general the instantaneous bed shear will contribute to the bed load transport as soon as the threshold value,  $u_{*c}$ , (or correspondingly  $\tau_c$  or  $\theta_c$ ) is exceeded. The approach starts with a sediment transport formulation based upon the displacement of an individual grain with diameter  $D$ . Let  $N_p$  be the number of grains picked up by the flow per unit of time and of the bed surface. Furthermore let  $\lambda$  be the saltation length of a grains picked up by the flow. When the bed consists of spheres with a volume of  $1/6\pi D^3$ , the bed load transport capacity can be written as

$$S_b = \frac{1}{6} \pi D^3 N_p \lambda \tag{A.1}$$

The saltation length is assumed to be proportional to both the grain size,  $D$ , and the dimensionless bed shear,  $\theta$ , for  $\theta > \theta_c$ , so that

$$\lambda = a' D \theta \tag{A.2}$$

where  $a'$  is a dimensionless constant which, according to de Ruyter (1982), has a value of  $a' \approx 300$  to 800. In the computation the values shown in Section 2 have been used.

According to Ruyter (1982) the pick-up rate,  $N_p$ , can be expressed as

$$N_p = \frac{4\eta}{\pi D^2} \sqrt{\frac{\rho g \Delta t g \phi}{\rho_s D \tau_c}} \sqrt{\sigma_\tau} F_p(r) \tag{A.3}$$

where

- $\eta$  = coefficient
- $tg\phi$  = the friction coefficient for the grains
- $\sigma_\tau$  = the standard deviation of bed shear
- $r$  =  $(\bar{\tau} - \tau_c) / \sigma_\tau$  a measure of the excess bed shear

$$F_p(r) = \frac{1}{\sqrt{2\pi}} \int_0^\infty \sqrt{x} \exp\left\{-\frac{1}{2}(x - r)^2\right\} dx \tag{A.5}$$

The definition of the function,  $F_p(r)$ , originates from the assumption that  $\tau$  is Gaussian distributed with a mean  $\bar{\tau}$  and a variance  $\sigma_\tau^2$ .

An amplification factor,  $A$ , can be defined as the ratio of the bed load transport capacities,  $S_b$  and  $S_{b0}$ , both at the same mean bed shear,  $\bar{\tau}$ , but with different fluctuations,  $\sigma_\tau$ . Here  $S_{b0}$  is used as a reference transport capacity at a "reference turbulence"  $\sigma_{\tau 0}$ .

Combining Eqs. (A.3), (A.4) and (A.5) results in

$$A = \frac{S_b}{S_{b0}} = \sqrt{\frac{\sigma_\tau}{\sigma_{\tau 0}}} \frac{F_p(r)}{F_p(r_0)} \tag{A.6}$$

It is obvious that the relative change in bed load transport capacity due to turbulence is a direct function of  $\sigma_\tau$  and even though the mean bed shear  $\bar{\tau}$  remains constant, its absolute value has an

indirect effect through the function  $F_p$ . The actual value of the constant,  $a'$ , in the formulation of the saltation length,  $\lambda$ , Eq. (A.2), appears to vanish in Eq. (A.6).

For any location along the bed the amplification factor,  $A$ , for the bed load transport can be found with Eq. (A.6) given a value for  $\sigma_\tau$ . Assuming the instantaneous bed shear  $\tau$  to be proportional to the square of the instantaneous velocity  $u$  near the bed one can express  $\sigma_\tau/\bar{\tau}$  as:

$$\frac{\sigma_\tau}{\bar{\tau}} = \frac{\sigma_u}{\bar{u}} \frac{\sqrt{4+2(\sigma_u/\bar{u})^2}}{1+(\sigma_u/\bar{u})^2} \quad (\text{A.7})$$

The variations,  $\sigma_u$ , of the total velocity  $u$  around its mean value  $\bar{u}$  have been measured in a physical model but can also be derived from the turbulent kinetic energy,  $k$ , computed by the present model.

The influence of  $\sigma_\tau$  on the bed load transport capacity can be shown conveniently by defining two parameters,  $\alpha$  and  $\beta$ , which represent the levels of turbulence and mean bed shear respectively.

$$\bar{\tau} = \beta \tau_c \quad (\text{A.8})$$

$$\sigma_\tau = \alpha \bar{\tau} \quad (\text{A.9})$$

Combining Eqs. (A.8), (A.9) with Eq. (A.4)  $r$  is written as

$$r = \frac{\beta - 1}{\beta} \frac{1}{\alpha} \quad (\text{A.10})$$

Given a value for  $r$  the value of  $F_p(r)$  can be found numerically. The values of the amplification factor,  $A$ , according to Eq. (A.6), have been computed and plotted in Fig. 7 for various values for the relative turbulence  $\alpha/\alpha_0$  and at a number of values for the bed shear level,  $\beta$ .

Values of 0.2 and 0.4 have been chosen as examples for the reference turbulence level,  $\alpha_0$ . Measurements of the velocity upstream of the pipe at a distance of 0.01 m from the bed indicate  $\sigma_u/\bar{u} \approx 0.10$ , leading, with Eq. (A.7), to  $\sigma_\tau/\bar{\tau} = 0.2$ . Most of the classical empirical (bed load) transport formulae originate from test conditions with uniform flow conditions with a turbulence  $\sigma_\tau/\bar{\tau} \approx 0.4$ .

The bed load transport capacity computed with empirical formulae should, therefore, be amplified with a factor  $A$  using  $\alpha_0 = 0.4$  as a reference and the actual mean bed shear as the bed shear level  $\beta$ .

The approach given here is limited practically by the extend of the function  $F_p(r)$ . For  $r < -5$ ,  $F_p(r)$  tends to approach zero. With Eq. (A.10) the limits can be indicated in terms of  $\alpha_0$  and  $\beta$  through  $\beta = 1/(1+5\alpha_0)$ .

## CHAPTER ONE HUNDRED FIFTEEN

### Nearshore Sediment Transport: Estimates From Detailed Measurements Of The Nearshore Velocity Field

A.J. Bowen and J.C. Doering\*

#### Abstract

A very wide variety of conceptual models has been used to explain the movement of sediment in the nearshore region. While there is general agreement that the incident waves are primarily responsible for the mobilisation of sediment, many processes have been proposed as the transport agents, for example, wave drift velocities, wave asymmetry, longshore and rip currents, undertow, the downslope component of gravity. As it is currently difficult to make reliable point measurements of sediment transport, many of these ideas can not be tested directly. However, in many cases, detailed measurements of the velocity field in the water can be used to examine at least the relative importance of these possible processes. The situation is complicated by the lack of accepted formulae for sediment transport. The result is that the velocity measurements are also being used to examine the 'reasonability' of the various formulations.

#### Introduction

A major obstacle to further understanding of nearshore sediment dynamics is the lack of instruments which directly measure sediment transport. Although various types of instrumentation are under development, at present the velocity field in the water can be determined much more accurately than any parameter directly related to sediment movement. We now have large data sets from flowmeters at various vertical and horizontal positions on a wide variety of beaches. It is not, however, altogether clear how this data can be best used. The classical approach in coastal engineering is to relate such sedimentary parameters as can be measured, for example accretion rates on a growing spit, to general properties of the incident waves, often properties which only involve measurements offshore in deep water.

\*Dept. of Oceanography  
Dalhousie University  
Halifax, N.S.  
B3H 4J1 Canada

A number of specific models have recently been proposed which can make use of detailed current data, Grant and Madsen (1979), Bowen (1980a) Bailard and Inman (1981). These models, however, raise fundamental questions not only about the nature of the flow, for example, the vertical structure and particularly the scale of the boundary layer, but also about the relative importance of the various possible physical processes. The recent interest in undertow nicely illustrates both sets of problems as the measurement of undertow requires vertical resolution of a quasi-steady flow pattern over an appropriate vertical scale for sedimentary processes. As few appropriate observations exist from the field the significance of undertow is unclear although its possible importance can readily be demonstrated in two-dimensional laboratory experiments.

The overall problem is that there is no single, conceptual model to describe the important processes in any particular nearshore environment; there is no unique hypothesis to test. For example, there is no general agreement as to whether the downslope component of gravity (a physical force whose existence can not be denied) plays any significant role on sandy beaches. One way of using the current meter data that now exists is as the input for simple models based on a variety of assumptions about the relative importance of various processes. The result will be a set of predictive models for the sediment transport in the particular environment in which measurements were made. However, these predictions are not meant to be taken too seriously, the primary objective is to identify the most important processes operating in a particular environment. An initial step is, therefore, to examine the general properties of the velocity fields that have been observed and, in particular, to look at the contrast between the measurements in different coastal environments.

#### Properties of the Flow Field

In terms of sediment transport, the more obvious flow properties of interest are the mean, the variance (a measure of wave energy) and the skewness (a measure of wave asymmetry). Other parameters which might be derived from a record of the instantaneous horizontal velocity vector  $u(t)$  at a given point are, for example, estimates of the bottom stress  $u|u|$  and the sediment transport given by the velocity to some high power  $u|u|^n$  (or a formula in which a velocity  $u_c$  related to a critical stress for movement is subtracted).

A more complex formulation, of particular interest in examining the possible role of gravity, is that of Bagnold

(1966) which explicitly includes the bottom slope. For example, Bailard and Inman (1981) define the bedload transport  $i_b$  as

$$i_b = K(u^3 + \alpha u^2 |u| \nabla h) \quad (1)$$

where  $h$  is the water depth and  $\alpha^{-1}$  the friction angle of the sediment. The basic result expressed is that the sediment is transported more easily downslope than upslope. In the absence of good measurement techniques, the prediction of an instantaneous transport rate is not a result that can readily be assessed. However, the net transport over a long period of time (at least several wave periods) is a prediction of considerable practical interest, focussing attention on the factors that determine the magnitude of terms such as  $\langle u^3 \rangle$ ,  $\langle u^2 |u| \rangle$  where the bracket denotes the time average over a timescale  $T$ .

Note that in this particular model  $u$  is the total velocity and includes any mean,  $u^3$  is then not skewness as normally defined. In other models, more cautious discrimination between the waves and the mean may be necessary (Grant and Madsen, 1979).

Interest in parameters such as  $u^3$  focusses attention on three particular points:

(i) the statistical behaviour of the parameter as a function of time  $t$  and averaging time  $T$ ; the probability distribution of  $u^3$  and relative variation of this parameter, compared to  $u^2 |u|$  for example.

(ii) the factors that contribute to the value and variation of  $u^3$ ; is it primarily the mean and low frequency variation in the 'mean' or is skewness arising from asymmetry in the shape of the velocity distribution?

(iii) theoretical models to examine the variation of these parameters as functions of time and space (particularly space in the sense of water depth). Simple models in which the theoretical distribution of the wave field is either sinusoidal or Gaussian can be readily compared to the scalar moments  $u^2$ ,  $u^2 |u|$  etc.

#### Field Measurements of the Flow Field

In practice observation are made with a limited set of current meters at specific positions in the nearshore region. In the Nearshore Sediment Transport Study (NSTS) on the west coast of the United States the horizontal variation of the flow field was of primary interest and only one flowmeter was deployed at any position (about

0.50 m above the bed). This leads to considerable uncertainty about the relevance of the measurement, particularly that of the mean flow, to conditions close to the bed. Consequently in our recent experiments on the Canadian east coast, at Queensland, Nova Scotia (Bowen, 1980b) and Pte. Sapin, New Brunswick (Canadian Coastal Sediment Study), vertical arrays of three or four electromagnetic flowmeters have been deployed at a single point. This enables us to address some of the uncertainties about our ability to measure flow parameters, such as the high order moments, which have been underlined by Aubrey, Spencer and Trowbridge (1984). These data sets can be used as a basis for a number of fundamental questions: -

(i) How well do we measure  $u$ ,  $u^3$  etc; do the vertical and horizontal distributions of various parameters make any sense?

(ii) Do the simple theoretical models provide guidance as to the quality of measurements necessary?

(iii) Where should measurements be made? In deeper water, a height of 1 m is often used as a standard (but not without problems).

(iv) Does the combination of data and models suggest that any factors can be neglected? For example, a critical stress ( $u_c$ ) or the downslope component of gravity.

Figure 1 shows the on-offshore component of velocity  $u$  at three positions 0.10, 0.45 and 0.80 m above the bed in a depth of 1.40 m of water at Queensland, N.S. The significant wave height is approximately 0.7 m. The obvious result is the very high coherence between the measurements. When the small, and vertically variable, mean flows are removed the statistical properties of the records are essentially identical. This is encouraging. The various sensors have different locations on a support frame which necessarily provides some obstruction to the flow, the lowest sensor is held downwards, the mean flows are slightly different etc. Despite these differences the estimates of velocity are very similar. There is, however, no obvious way of estimating the validity of the measurement of the mean flow, some vertical structure is expected.

The general nature of the statistical distribution of flow speed is shown in Figure 2. Negative values are onshore. The observations are sufficiently close to the Gaussian distribution. (the Gaussian curve of equal variance is shown for comparison) that the ratios of even

moments  $\langle u^4 \rangle / \langle u^2 \rangle^2$ ,  $\langle u^2 |u| \rangle / \langle u^2 \rangle^{3/2}$  are close to that expected for a Gaussian distribution. A similar result was found in the NSTS results (Guza and Thornton, in press).

For a Gaussian distribution the odd moments are zero. In the data, contributions to  $u^3$  arise from two sources, the mean flow and the skewness associated with the stronger onshore velocity under the wave crest, particularly evident in the record QE151BX.

Figure 3 shows low-passed records of  $u^3$ ,  $u^2|u|$  and the ratio  $u^3/u^2|u|$ , the filter removing the variation at the incident frequency. The light lines running horizontally show the mean values over this record. These parameters show a very obvious variability associated with the beat structure of the incident waves. This strong variability at relatively low frequency suggests that rather long records will be required to obtain stable estimates of the values of these high moments.

Figure 1. The on-offshore component of velocity  $u$  at 0.10 (bottom), 0.45 (middle) and 0.80 (top) m at Queensland Beach N.S.

Now Equation 1 can be considered in terms of an equilibrium condition. If the beach profile did not change appreciably during the experiment, which was in fact the case,  $i_b \approx 0$ . Then if the longshore velocities  $v$  are much smaller than  $u$  (again observationally confirmed), from (1)

$$\alpha \frac{dh}{dx} \sim \frac{\langle u^3 \rangle}{\langle u^2 |u| \rangle} \quad (2)$$

For this data set, the ratio is approximately  $-0.013$  so with  $\alpha^{-1}$  of order of  $0.63$  the estimate for the beach slope is  $0.080$  very much of the order of the observed slope of  $1:15$ . This does not imply the model is a complete

Figure 2. Statistical distribution of  $u$  for the bottom sensor, water depths 1.40 (131), 1.28 (132) 0.70 (142) and 0.55 (151) m at Queensland Beach. Observations at one station as the tide ebbed. Negative values are onshore.

Figure 3. Parameters  $u^2|u|$  (bottom),  $u^3$  (middle) and their ratio (top), from the bottom record of Fig. 1. The results have been low passed to remove the variation at the incident frequency. The original record is shown for comparison.

description of the dynamics. Later in the tidal cycle, as the water becomes shallower, the onshore tendency is stronger (Figure 2). As the "equilibrium" is defined in terms of two surveys at successive low tides, an exact model should be the integral of the local sediment transport over the tidal cycle. However, the results do suggest that the effect of gravity can not be excluded from any discussion of sedimentary dynamics.

This model can readily be expanded to include the effects of the critical velocity  $u_c$  needed to move a sediment particle, the appropriate form of Equation (2) is

$$a \frac{dh}{dx} = -\langle u|u^2 - u_c^2| \rangle / \langle |u||u^2 - u_c^2| \rangle \text{ for } u > u_c \quad (3)$$

In Figure 4, the change in the predicted equilibrium slope is shown as a function of  $u_c / \langle u^2 \rangle^{1/2}$  where  $\langle u^2 \rangle^{1/2}$  is the r.m.s. value of  $u$ . Two representative data sets both show that the effects of  $u_c$  are not likely to be

evident until  $u_c > \langle u^2 \rangle^{1/2}$ . Orbital velocities near the shoreline are typically of the order of 0.25 → 1.00 ms<sup>-1</sup> so the effect of critical stress is likely to be important only for particles substantially larger than sand. Figure 4 is, in effect, another version of the explanation for the shoreward movement of large stones on a sandy beach. When  $i_b \approx 0$  for the smaller sizes,  $i_b$  will be onshore for all larger particles as  $\langle |u| |u^2 - u_c^2| \rangle$  is always increased relative to  $\langle |u| |u^2 - u_c^2| \rangle$ .

A rather different approach to the field data is to examine the spatial distribution of parameters relating to sediment transport. To do this sensibly, it is useful to remove the mean flow  $\bar{u}$  from the data and define a velocity  $u_1$  where

$$u_1(t) = u(t) - \bar{u} \tag{4}$$

Mathematically, the higher moments will depend on both the value of the mean  $u$  and the skewness of  $u_1$ . However, in different depth and horizontal positions the relative

Figure 4. The parameters  $\langle |u| |u^2 - u_c^2| \rangle$  (□),  $\langle |u| |u^2 - u_c^2| \rangle$  (●) normalized by their value at  $u_c = 0$  and  $\alpha dh/dx$  (▲).

contributions will vary significantly. In Figure 1, the data suggests that  $u_1(t)$  does not vary greatly with depth (in shallow water)<sup>1</sup> and a comparison between data from different horizontal positions and separate experiments should be of interest.

Figure 5 shows the skewness, defined in the normal statistical sense as  $\langle u_1^3 \rangle / \langle u_1^2 \rangle^{3/2}$ , as a function simply of water depth. The data from<sup>1</sup> inside the surf zone from the NSTS and UK experiments tends to lie on a straight line increasing from zero at the shoreline to a maximum (negative) value in the breaker region with skewness decreasing offshore. However the data for Queensland cuts right across the general trend, but again increases onshore to a maximum close to the break point.

Figure 5. Skewness as a function of depth for data for NSTS (Guza and Thornton, in press), U.K. (Huntley and Bowen, 1975) and Queensland, N.S.

Figure 6. Skewness as a function of the Ursell Number,  $U_r$ .

It is not clear how to normalize this data, there are no simple theoretical models for wave skewness that adequately explain the observed phase shift between the first harmonic and the fundamental. However, the size of the first harmonic relative to the fundamental is given for a Stokes wave by the Ursell Number,  $U_r$  where

$$U_r = ak/(kh)^3 \quad (5)$$

$a$  being the wave amplitude,  $k$  the wavenumber. In Figure 6, the skewness is plotted against  $U_r$  which brings the Queensland data much more in line with that of the NSTS. This is encouraging but the development of a predictor for the skewness is not likely to be a simple matter particularly as it obviously depends on the breaking process.

## Conclusions

The existence of substantial sets of current meter data allows a much more realistic examination of the various ideas and formulae that have been proposed to describe nearshore sediment dynamics than would be possible using any idealized wave theory. Actual observation of the mean flow, the variance and the higher harmonics, both inside and outside the surf zone, provide an immediate assessment of the relative importance of some of the possible processes. As an example, Figure 7 shows the dependence of two transport measures,  $\langle u \rangle$ , representing bed load,  $\langle u^3 | u \rangle$  suspended load (Bagnold, 1966) on the strength of the mean velocity  $\langle u \rangle$ , positive offshore. Here real data from the Queensland experiment has been used to define  $u_i(t)$  and the various mean values added. This defines, for this particular environment, the relative importance of the mean flow and the uncertainty in the transport parameters which will arise from uncertainties in its measurement.

Figure 7. The parameters  $\langle u^3 \rangle$  and  $\langle u^3 | u \rangle$  as a function of the normalized mean flow  $\langle u \rangle / \langle u^2 \rangle^{1/2}$ .

The existing data suggest that the measurement of skewness and high moments of the velocity field are rather more consistent than might have been expected. However, the mean flow is uncertain and only measured with difficulty close to the sea bed. Figure 7 suggests that small velocities do play a significant role in contributing to the moments and good estimates of the mean flow are necessary. As this flow is generally an increasing function of wave height, the strongest signals are expected in severe conditions. As the sediment transport processes are themselves likely to be of most interest in severe conditions, this is convenient but suggests the likelihood of some distinctly uncomfortable moments in future field experiments. The Canadian Coastal Sediment Study has, for example, focussed on measurements in October–November in 1983, October in 1984.

## CHAPTER ONE HUNDRED SIXTEEN

### LABORATORY REPRODUCTION OF SEABED SCOUR IN FRONT OF BREAKWATERS

by

Isao Irie\*, Kazuo Nadaoka\*\*

#### ABSTRACT

Mechanism of scour in front of breakwaters by standing waves in two and three dimensions has been studied theoretically and experimentally to clarify the experimental conditions by which the prototype behavior could be best reproduced in laboratory. The phenomenal reproduction of scour in laboratory is satisfactory if some conditions on the characteristics of waves and bed materials are fulfilled. This enables experimental approach to find out the optimum protection methods against scour in front of breakwaters.

#### INTRODUCTION

Extensive prolongation of breakwaters in many ports in Japan has sometimes caused severe scouring in front of breakwaters. In some crucial cases, the size of scour has developed up to 6 meters in scour depth and almost a hundred meters in scour length measured normal to breakwaters, threatening stability of breakwaters.

To work out the most effective protection methods against those problems, model experiment could be an effective measure. However, no confirmation has been made so far as to whether the phenomena in prototype could be properly reproduced in laboratory.

The objective of the present study is to make clear the mechanism of two and three dimensional scour in front of breakwaters by standing waves through detailed measurement of velocities and bed material movement, to find out the experimental conditions by which the prototype behavior could be best reproduced in laboratory, and to examine the reproducibility of model experiments.

The type of breakwaters constructed at deeper water depth is mostly of caisson type composite breakwater. It has the advantages of experiencing lesser wave pressures because they reflect waves in the form of standing waves and also lesser wave forces upon rubble mounds due to their lower crown height. In the composite breakwater, however, the stability is frequently threatened by scour in front of breakwaters.

The process in which structural destruction due to scour is transmitted would be in falling dominos manner as illustrated in Fig. 1. The process must be checked at some stages so that countermeasures which will be taken against scour are most effective and economical.

In order to achieve the above purposes experimentally, the conditions required for satisfying phenomenal similarity are examined first of all by investigating the mechanism of bed material movement on a flat bed, an artificially roughened bed and a movable bed.

Based upon the required conditions for phenomenal similarity, it is examined whether the size of scour large enough to affect on the stability of breakwaters could be reproduced in laboratory.

BED MATERIAL MOVEMENT ON A FLAT BED BY STANDING WAVES

When progressive waves are reflected by a vertical wall perfectly, a standing wave is produced resulting in the surface oscillation containing loop at the wall and node at  $L/4$  apart from the wall where  $L$  is the wave length. In order to obtain the basic idea on the mechanism of scour by standing waves, characteristics of bed material movement on a flat bed are studied theoretically and experimentally first of all.

A knowledge of the fluid velocity distribution close to the bed is of considerable importance. Figure 2 shows the results of the measurement of the Eulerian drift velocity distribution with a laser-doppler anemometer. It is clearly seen that there exists a thin layer drift from node to loop near the bed and the opposite drift in the upper layer, and this seems to coincide with the theoretical distribution of a second order mean velocity by standing waves given by Longuet Higgins.

Fig. 1 The process in which structural destruction is transmitted up to the main body of breakwater.

If bed materials are to move according to the drift near the bed, bed materials placed on a flat bed should move from nodes to loops according to Fig. 2, however, every materials whose specific gravity is 2.65 were observed to move from loops to nodes.

In order to clarify those contradictory phenomena, a theoretical consideration has been made as follows. Sand particles on a flat bed are not necessarily in the state of motion during a wave period but at a stand still at a certain moment because of the bottom friction. If the oscillatory movement of water particles is completely sinusoidal, no residual shift of sand particles would result after a wave period.

Actually, the motion of water particles is not sinusoidal because of the non-linearity of waves and a net shift of sand particles would result after a wave period.

The following equations of motion are formed;

$$dx_s/dt = u_s \quad (1)$$

$$du_s/dt = 3C_d |u - u_s| \cdot (u - u_s) / 4d(s + C_m) + 1/(s + C_m) \cdot du_0/dt \\ C_m / (s + C_m) \cdot du/dt \pm (s - 1) / (s + C_m) \mu_f \quad (2)$$

where,

$x_s$ : Horizontal position of sand particles.

$u_s$ : Velocity of sand particles.

$u$ : Velocity of water particles in the boundary layer.  
( at  $z = d/2$  )

$u_0$ : Velocity of water particles just outside of boundary layer.

$d$ : Diameter of sand particles.

$s$ : Specific gravity of sand particles.

$C_d$ : Drag coefficient.

$C_m$ : Virtual mass coefficient.

$\mu_f$ : Friction coefficient with the bottom.

The moment at which sand grains start to move from the rest is obtained by judging whether the sum of the first three terms in the right hand side of equation (2) exceeds the fourth term. Here, the coefficients were selected so that  $\mu_{fs} = 0.5$ ,  $\mu_{fm} = 0.1$ ,  $C_d = 0.5$  and  $C_m = 0.5$ .

The velocity  $u$  of water particles is calculated by the following equation;

$$\partial u / \partial t = \partial u_0 / \partial t + \nu \cdot \partial^2 u / \partial z^2 \quad (3)$$

where,

$\nu$ : Kinematic viscosity.

Fig. 2 The Eulerian drift velocities measured by a laser-doppler anemometer.

Fig. 3 Periodical change of velocity and acceleration of water particles 0.5 cm above the bottom.

- $u_0$  : Velocity of water particles just outside the boundary layer.
- $z$  : Height from the bottom.

Figure 3 shows the periodical change of velocity and acceleration of water particles 0.5 cm above the bottom calculated by third order finite amplitude theory. The result of the measurement of water particle velocity is also shown in the figure. The velocity curve is symmetric about zero point whereas the acceleration curve is not symmetrical. It is seen that acceleration inbetween nodes and loops exhibits much higher value in the direction from loops to nodes. This results in the net shift of sand particles toward nodes from loops if the particles are moved having bottom friction because initiation of motion after a stand still is much earlier in this direction.

The results of calculation of net shift of sand grain after a wave period utilizing equation ( 1 ), ( 2 ) and ( 3 ) are shown in Fig. 4. The velocity  $u$  of water particles in the boundary layer calculated by equation ( 4 ) is distorted so that amplitude toward node is higher than opposite phase. Furthermore, acceleration just outside the boundary layer  $\partial u_0 / \partial t$  is distorted as already explained. As the result of these distortions, velocity of sand grains  $u^s$  toward node is always higher than the opposite direction, and this results in the residual shift  $\Delta X$  toward nodes as seen in the figure.

Movements of sand particles on a flat bed were followed by a movie camera and the results are compared with theory as shown in Fig. 5. The rate of shift of sand particles in a wave period has coincided fairly well with the theory.

#### BED MATERIAL MOVEMENT ON AN ARTIFICIALLY ROUGHENED BED

Mechanism of bed material movement on the movable bed for which the scour problems actually occur may be of much difference from that of a flat bed because of the roughness due to sand ripples. In order to examine the effect of the roughness on the movement of bed materials, experiments on the mechanism of bed material movement on the artificially roughened bed were carried out . As shown in Fig. 6, two kinds of roughness were utilized; obstacles of 1.0 cm and 0.5 cm in height were placed at the equal intervals of 5.0 cm and 3.0 cm respectively so that the steepness of artificial roughness is of 1/5 to 1/6 which is the steepness of sand ripples commonly found. Bed materials of various settling velocities were placed at the trough of artificial roughness in the place between nodes and loops of standing waves.

Figure 7 shows the results of the measurement of the Eulerian drift velocities with a laser-doppler anemometer when the height of artificial roughness is 1.0 cm. If the velocity distribution is compared with that in Fig. 2 in which the same wave condition is applied, it is clearly seen that the thickness of drift layer near the bottom has remarkably developed in Fig. 7. In such a velocity field, bed materials once suspended would tend to move from nodes to loops, however, bed materials having the influence of bottom friction would still tend to move in the reverse direction due to non-linearity of waves as already mentioned. Thus, characteristics of net bed material movement would

Fig. 4 Theoretical calculation of net shift of sand grains during a wave period.

Fig. 5 Comparison of experiment with theory on the net shift of sand grains during a wave period.

Fig. 6 Dimensions of artificial roughness.

depend on the relative importance between suspended load and bed load and this was examined experimentally.

Figure 8 shows the results of experiments on the movement of various bed materials, that is, coal grains, finer sand and coarser sand whose median diameters are 0.27 mm ( specific gravity  $\approx 1.58$  ), 0.20 mm ( s.g. = 2.65 ) and 0.33 mm ( s.g. = 2.65 ) respectively.

After the wave action of almost two minutes, the volumes of those materials in each trough of artificial roughness were measured. The volume  $V_L$  of the portion which moved toward loops and the volume  $V_N$  of the portion which moved toward nodes were calculated, and the direction of net movement of bed materials was judged by examining whether the value of  $V_L/V_N$  exceeded one or not. If  $V_L/V_N > 1$ , it means that the direction of net movement is from nodes to loops and this is called L-type movement, and if  $V_L/V_N < 1$ , it means that net movement direction is from loops to nodes and this is called N-type movement.

L-type movement will appear when suspended load is predominant and transported due to the drift from nodes to loops as already seen in Fig. 7. Therefore, relative velocity of water particles  $u_b/w$  will be a dominant parameter for the appearance of L-type movement where  $u_b$  is the amplitude of water particle velocity at the bottom for incident waves and  $w$  is the settling velocity of bed materials.

The reason for the appearance of N-type movement could be considered as follows. As already explained, bed materials on a flat bed are moved from loops to nodes so long as the bed materials experience the effects of bottom friction and this will also applicable in the present case. Another reason for the appearance of N-type movement will be the difference of the vortex formation in the wakes of the obstacles of artificial roughness. Vortices are carried back over the obstacles

Fig. 7 ( Top ) Eulerian drift velocities when artificial roughness is 1.0 cm.  
 ( Bottom ) Change of water particle velocity with time at each corresponding position.

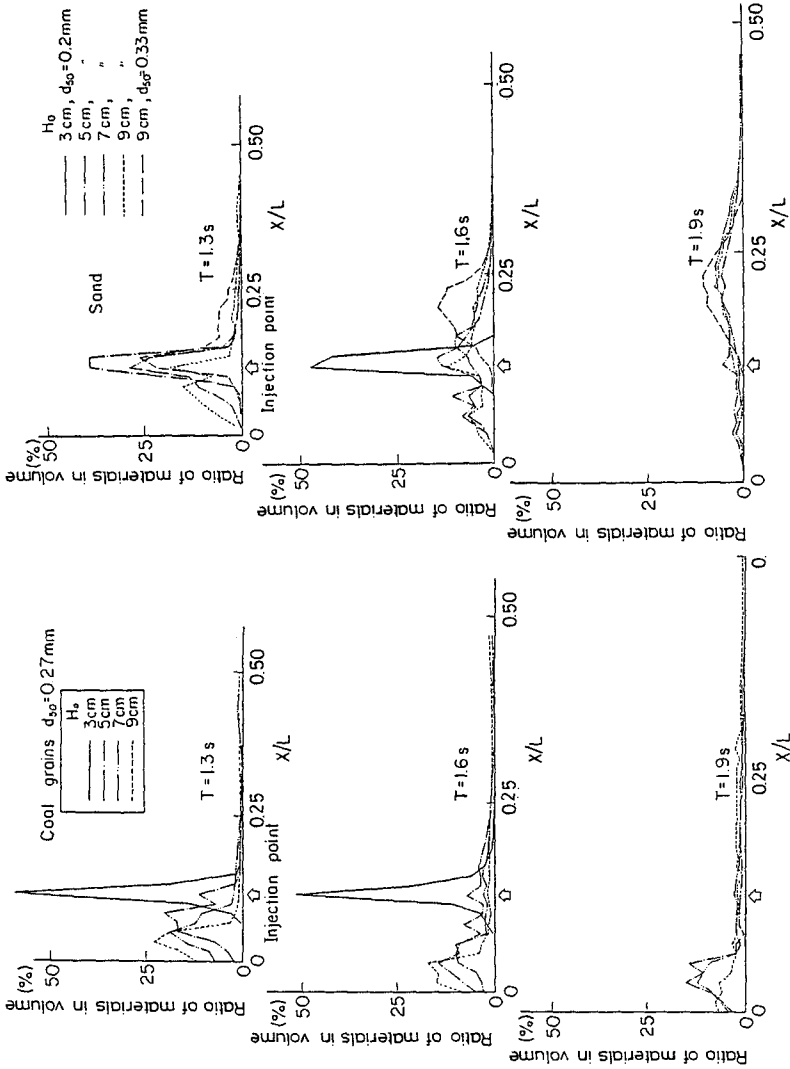

Fig. 8 Movement of various bed materials injected at the trough of artificial roughness.

and then out over the trough when the flow reverses and this process is repeated under the oscillatory motion of water particles. If the motion of water particles is sinusoidal, development of vortices on the both sides of obstacles will be the same and there will be no contribution to the net material movement onshoreward or offshoreward. As seen in Fig. 3 and Fig. 7 in which the changes of water particle velocities with time between nodes and loops of standing waves are illustrated, however, the time from a zero velocity to a maximum velocity is actually longer when the flow is toward loops than toward nodes whereas the amplitudes of the velocity is almost the same in both directions. It is apparent that more vortex development will take place if the time for development is longer on the premise that the amplitudes in both directions are the same. Consequently, vortex development is always greater in the loop side of the obstacles than the other side and much materials will be enrolled in the vortices of loop side and carried out over the obstacles toward nodes when the flow reverses. This would lead to a net bed material movement from loops to nodes resulting in N-type movement.

Thus, at any rate, appearance of N-type depends on the  $U^2/V$ -linearity of waves and this is expressed in the Ursell Number  $U = HL^2/h$  where, H, L and h are wave height, wave length and water depth respectively.

The experimental results of the relations between  $V_L/V_N$  versus  $u_b/w$  are plotted with  $U = HL^2/h$  in parameter as shown in Fig. 9. From the figure, L-type tends to appear when the relative velocity  $u_b/w$  increases for a given Ursell Number and N-type tends to appear when the Ursell Number increases for a given relative velocity. Those characteristics of the appearance of L-type movement and N-type movement seem to endorse the understanding on the mechanism of bed material movement described above.

Fig. 9 L-type and N-type appearance in the bed material movement on a fixed bed. The parameters show the Ursell Number.

## TWO DIMENSIONAL SEABED SCOUR BY STANDING WAVES

If L, N-type movement of bed materials as observed in artificially roughened fixed bed exists also for the movable bed, two types of seabed scour will appear accordingly.

Figure 10 shows the results of experiments of sea bed scour when coal grains ( median diameter  $d_{50} = 0.27$  mm, specific gravity s.g. = 1.58) are utilized as bed materials. Waves from 3.0 to 6.5 cm in wave height and 1.6 sec in wave period were acted on the breakwater wall for 6 hours in the cases from (B-1) to (B-6). Since the rubble mound of breakwater had the berm width of 10 meters ( 25 cm in the model as model scale was 1/40 of the prototype ), only the offshore side from the toe of rubble mound is illustrated in the figure.

Comparison of bottom profiles with wave envelopes depicts that accumulation of bed materials takes place at nodes and erosion takes place inbetween nodes and loops when wave height is smaller than 5.5 cm, that is, in the cases of ( B-1 ) to ( B-5 ), whereas accumulation takes place at loops and erosion takes place at nodes when wave height is much higher, that is, in the cases of (B-6) and (B-7). A geometrical consideration of the balance of volumes of bed materials would indicate that the cases of (B-1) to (B-5) are the consequences of N-type movement and the cases of (B-6) and (B-7) are the consequence of L-type movement.

Similar experiments on the mode of seabed scour was carried out utilizing finer sand (  $d_{50} = 0.20$  mm, s.g. = 2.65 ) and coarse sand (  $d_{50} = 0.33$  mm, s.g. = 2.65 ). In the finer sand, sea bed scour due to both

Fig. 10 Bottom configurations under standing waves of various wave heights.

Fig. 11 Difference of the direction of movement between coal grains and coarser sand in the same velocity field.

Fig. 12 Schematic illustration of two types of scour.

L-type movement and N-type movement appeared whereas in the coarser sand, seabed scour of only N-type movement appeared. The mechanism of the appearance of N-type movement and L-type movement in the movable bed could be considered similar to that in the artificially roughened fixed bed. An interesting experiment was carried out for a better understanding of the appearance of two types of scour mode in the movable bed. As shown in Fig. 11, sand ripples were formed first of all by acting waves of 7 cm in height and 1.6 sec in period for 50 minutes with the water depth of 25 cm and then the movable bed was fixed hard with glue so that no deformation would take place any more. In a trough of sand ripples between nodes and loops, sand of 0.33 mm in median diameter and 2.65 in specific gravity, and also coal grains of 0.27 mm in median diameter and 1.58 in specific gravity were placed half in half within the flume width as shown in the figure and waves were again acted. As seen in the figure, coal grains which are the lighter materials moved toward loop exhibiting L-type movement whereas the coarser sand moved toward node exhibiting N-type movement. In the present case, the drift distribution must have been the same and the only difference is the settling velocity between coal grains and coarser sand. This fact seems to endorse that the mechanism for the artificially roughened bed is also applicable for the movable bed.

Thus, existence of two types of scour, that is, L-type scour due to L-type movement and N-type scour due to N-type movement has been confirmed as shown in Fig. 12. A simple geometric inspection of scour shape with respect to the size of the rubble-mound of usual breakwaters would indicate that the scour of L-type is more critical for the stability of breakwaters.

Figure 13 shows the experimental results of the critical appearance of L, N-type scour in the movable bed where ordinate and abscissa show the relative velocity and the Ursell Number respectively. The numbers attached on the circles and triangles in the figure show the comprehensive slope of the score holes, that is,  $\tan \theta = (h_b / (L/4))$ .

The results of experiments by Xie are also shown in the figure. The relative velocity is more critical for the appearance of L-type or N-type scour than the Ursell Number where those parameters were equally important in the fixed bed.

The most important fact in the figure will be that L-type scour appears when the relative velocity  $u_b/w$  exceeds more or less the value of ten. Since the relative velocity normally exceeds tens or twenties in the prototype, the scour in prototype would have the scheme of L-type scour and thus, the model experiments of scour in front of breakwaters by standing waves cannot be reproduced unless  $u_b/w > 10$  is satisfied.

Utilization of finer materials would reproduce more remarkable scour which is indispensable for the examination of effective protection methods.

Figure 14 shows an example of scour which is reproduced utilizing fine sand of 0.06 mm in median diameter. The scale of the model was 1/50 and waves of 12 cm in height and 1.4 sec in period were acted on the composite type breakwater at the depth of 30 cm.

A remarkable damage of rubble mound would take place when the node of standing waves comes near the toe of rubble mound. It will have a lesser effect of scour if wave period is very long so that the first node of standing waves comes much offshore of the toe of rubble mound.

Fig. 13 Critical appearance of N,L-type scour in the movable bed

Fig. 14 An example of two dimensional scour

## THREE DIMENSIONAL SEABED SCOUR

Diagonal action of waves on breakwaters would result in the drift parallel to the breakwaters and this will affect on the scour. Many researchers have studied on the mass-transport by diagonal standing waves experimentally and theoretically. Authors have also made calculations of three dimensional mass-transport by diagonal partial standing waves in the similar manner and confirmed quantitative validity of the theory through laboratory study.

Those results indicated that mass-transport diverges at nodes and converges at loops forming converged flow parallel to the breakwaters. With roughened bottom, the thickness of the drift due to mass-transport near the bottom was observed to increase having no basic change of directions. Those results depicts that in three dimensional scour under diagonal waves, bed materials at nodes are transported from nodes to loops and also toward downstream parallel to breakwaters so long as suspension is predominant.

Actually, in three dimensional experiments with regular waves, scour took place at nodes as observed in two dimensional cases. The definite difference from two dimensional cases was that the average elevation of the bottom was eroded down due to the transportation of bed materials downstream along the breakwater. This resulted in the remarkable scour near the tip of breakwater and somewhat heavier accumulation in the downstream area along the breakwater.

Figure 15 illustrates the example of scour near the tip( upstream area ) of breakwater with the model scale of 1/40 when waves of 15 cm in height and 1.6 sec in period were acted for 16 hours at 30 degrees to the normal line of breakwater. The bed materials was sand of 0.13 mm in median diameter. The downstream bottom topography became much complicated because of the effects of oscillations in the model basin and also variation of wave height along the breakwater.

Those difficulty of producing uniform scour along the breakwater which is the common feature found in prototype was considerably improved when irregular waves are utilized.

Figure 16 illustrates the result of experiments in which waves of 8 cm and 1.3 sec in significant wave height and period respectively were acted for 11 hours at 30 degrees to the normal line of breakwater. It is seen that the scour took place at nodes of irregular standing waves and no significant scour took place in the offshore area. Furthermore, the scour is most remarkable near the tip of breakwater and gradually diminishes toward downstream area along the breakwater.

In the figure, bottom topography in front of breakwater of Fukui Port facing to Japan Sea is illustrated. Comparison of the scour shape between model and prototype would depict that reproduction of scour in front of breakwater by standing waves is quite satisfactory.

## CONCLUSIONS

1. Due to the non-linearity of waves, bed materials placed on a flat bed move from loops to nodes of standing waves so long as the materials have the effects of bottom friction.

Fig. 15 An example of seabed scour near the tip of breakwater.

Fig. 16 Comparison of scour shape between model and prototype.

2. There are two modes of bed material movement under standing waves when the bottom has the artificial roughness, that is, L-type movement in which bed materials move from nodes to loops and N-type movement in which bed materials move from loops to nodes. Criteria of appearance of those types depend on the relative velocity  $u_b/w$  and the Ursell Number  $U(=HL^2/h^3)$ .
3. In the movable bed, two types of scour due to standing waves exist accordingly, that is, L-type scour in which bottom is scoured at nodes and accumulated at loops and N-type scour in which bottom is scoured inbetween nodes and loops and accumulated at nodes.
4. In order to reproduce the prototype scour in laboratory, it is required that the relative velocity  $u_b/w$  exceeds the value of ten.
5. The scour whose size is large enough to affect on the stability of breakwater can be reproduced if fine materials are utilized.
6. Reproduction of three dimensional scour is satisfactory if irregular waves are utilized.

## CHAPTER ONE HUNDRED SEVENTEEN

### NUMERICAL SIMULATION ON THE CHANGE OF BOTTOM TOPOGRAPHY

#### BY THE PRESENCE OF COASTAL STRUCTURES

by

Masataka Yamaguchi<sup>1</sup> and Yōichi Nishioka<sup>2</sup>

#### ABSTRACT

This paper presents a numerical model for predicting the change of bottom topography caused by coastal structures placed on a sandy beach. The model consists of three sub-models of wave transformation by varying topography and coastal structures, nearshore current and change of bottom topography. The computation of nearshore current patterns induced by the presence of a detached breakwater shows qualitative agreement with the experiment. The effects of wave and structure characteristics on current pattern and topographical change are investigated by consideration of model computation with several configurations of coastal structures such as detached breakwaters or groins. The main conclusions are that the model produces the general features of erosion and deposition caused by coastal structures and that drastic change of current pattern and bottom topography occur when reflected waves from the structures cover a large area.

#### 1. INTRODUCTION

In recent years, shoreline models for predicting the changes in the plane shape of beach following the construction of coastal structures have been extensively used for practical applications. But, there are many limitations such that they neglect onshore-offshore sediment transport and assume parallel movement of the beach profile. In order to solve these problems, a more rational model, in which the effect of waves and nearshore currents in surf zone on sediment transport is explicitly included, is required. At the present stage of study, there are few works done from this point of view except for a numerical model by Fleming and Hunt (1976).

Their model may be useful for practical applications. But, the assumptions made in their model regarding nearshore current and so on seem to be too simplified.

A mathematical model to predict the topographical change caused by coastal structures was developed at our laboratory in 1981 and since then, much effort has been devoted to improving the model (1983a, 1983b and 1984). The model consists of three kinds of submodels of wave transformation by varying topography and coastal structures, wave-induced nearshore current and topographical change of the seabed. This paper presents the description of the latest model and the model computations of the characteristics of nearshore current patterns and bottom modifications caused by detached breakwaters or groins.

## 2. MODEL DESCRIPTION

### (1) Wave transformation model

Wave transformation is computed by the wave ray method, in which the wave ray equation and wave intensity equation are solved simultaneously. The determination of wave direction along a ray is made by solving the wave ray equation expressed by time  $t$ ,

$$\frac{d\alpha}{dt} = \cos\alpha \frac{\partial c}{\partial x} - \sin\alpha \frac{\partial c}{\partial y} \quad (1)$$

in which  $\alpha$  is the wave direction and  $c$  the wave celerity. The computation of wave refraction is made by the wave intensity equation,

$$\frac{d^2\beta}{dt^2} + p_t \frac{d\beta}{dt} + q_t \beta = 0, \quad \beta = K_r^{-2} \quad (2)$$

in which  $\beta$  is the ray separation factor,  $K_r$  the refraction factor, and  $p_t$  and  $q_t$  are the functions of  $\alpha$  and the derivatives of  $c$ . The shoaling factor  $K_s$  is estimated by the well-known formula.

$$K_s^2 = c_{gM} / c_g \quad (3)$$

in which  $c_g$  is the group velocity and subscript 'M' means offshore wave characteristics.

In the model, bottom friction, diffraction, reflection and energy dissipation by wave breaking are approximately taken into account. But, wave-current interaction is not included. The Bretschneider-Reid formula on uniform depth is applied step by step to evaluate wave damping due to bottom friction. The diffraction effect of coastal structures is approximated by applying the Sommerfeld solution for semi-

infinite breakwater or its superposed solution to individual point on each wave ray. The Goda criterion (1975) is used to test whether wave breaking is occurring on each point along a wave ray or not. This is expressed as

$$\frac{H_b}{L_0} = 0.17 \left\{ 1 - \exp \left\{ -1.5 \frac{\pi D_b}{L_0} (1 + 15i^{4/3}) \right\} \right\} \quad (4)$$

in which  $H$  is the wave height,  $L$  the wave length,  $D (=h+\eta)$  the total depth including wave set-up or wave set-down  $\eta$ ,  $h$  the still water depth,  $i$  the bottom slope and subscripts '0' and 'b' mean deep water and wave breaking respectively. It is assumed that the waves break at a depth  $D$  if the wave height  $H$  is greater than  $H_b$  and that the wave height exceeding  $H_b$  does not exist in the surf zone.

The first step in the computation of wave transformation is to determine wave direction and wave height at each point along a wave ray and to cover the entire domain of interest with a great number of wave rays. Wave rays of not only incident waves but also diffracted waves from breakwater tip and reflected waves from structure wall are followed in succession.

The second step is to make linear interpolation of three kinds of wave data separately into each grid point prepared for the computation of nearshore current and topographical change, and to obtain single data of wave direction and wave height on each grid point through the energy composition of these data. Then, the radiation stress is estimated in the usual manner from the assumption of pure progressive waves.

## (2) Nearshore current model

In order to compute nearshore current and wave set-up or set-down induced by waves, vertically integrated conservation of water mass and momentum are used. The conservation equation of water mass is given as

$$\frac{\partial D}{\partial t} + \frac{\partial DU}{\partial x} + \frac{\partial DV}{\partial y} = 0 \quad (5)$$

in which  $U$  and  $V$  are the nearshore current velocity components in  $x$  direction and in  $y$  direction respectively. The momentum equations are as follows.

$$\left. \begin{aligned} \frac{\partial DU}{\partial t} + \frac{\partial DU^2}{\partial x} + \frac{\partial DUV}{\partial y} &= -gD \frac{\partial \eta}{\partial x} \\ + \frac{1}{\rho} \left\{ \frac{\partial}{\partial x} (D\mu \frac{\partial U}{\partial x}) + \frac{\partial}{\partial y} (D\mu \frac{\partial U}{\partial y}) \right\} &- \frac{1}{\rho} \left( \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} + \tau_{bx} \right) \end{aligned} \right\} (6)$$

$$\left. \begin{aligned} \frac{\partial DV}{\partial t} + \frac{\partial DUV}{\partial x} + \frac{\partial DV^2}{\partial y} &= -gD \frac{\partial \eta}{\partial y} \\ + \frac{1}{\rho} \left\{ \frac{\partial}{\partial x} (D\mu \frac{\partial V}{\partial x}) + \frac{\partial}{\partial y} (D\mu \frac{\partial V}{\partial y}) \right\} - \frac{1}{\rho} \left( \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{yy}}{\partial y} + \tau_{by} \right) \end{aligned} \right\}$$

in which  $\rho$  is the density of fluid,  $\mu_e$  the lateral mixing factor and  $S_{xx}$ ,  $S_{xy}$ ,  $S_{yx}$  and  $S_{yy}$  are the radiation stress tensor defined by Longuet-Higgins.

The Longuet-Higgins expression (1970) is used as lateral mixing factor.

$$\mu_e = \kappa \rho l \sqrt{gD} \tag{7}$$

in which  $l$  is the distance measured from the real shoreline and  $\kappa(0.01)$  the constant. The bottom friction is assumed proportional to the squared velocity, taking into account the wave orbital velocity.

$$\left. \begin{aligned} \tau_b = (\tau_{bx}, \tau_{by}) &= \frac{\rho c_f}{T} \int_0^T |w| w dt \\ w &= (-u_{\max} \sin \alpha \cos \sigma t + U, -u_{\max} \cos \alpha \cos \sigma t + V) \\ u_{\max} &= \pi H / T \sinh kD \end{aligned} \right\} \tag{8}$$

in which  $c_f$  is the bottom friction coefficient in the wave-current system and  $\sigma$  the angular frequency. Eq. (8) is estimated by the Nishimura approximation formula (1982) to save the computation time without losing numerical accuracy. It can be written as

$$\left. \begin{aligned} \tau_{bx} &= \rho c_f \left\{ \left( w + \frac{\bar{u}^2}{w} \cos^2 \theta \right) U + \frac{\bar{u}^2}{w} \sin \theta \cos \theta V \right\} \\ \tau_{by} &= \rho c_f \left\{ \frac{\bar{u}^2}{w} \sin \theta \cos \theta U + \left( w + \frac{\bar{u}^2}{w} \sin^2 \theta \right) V \right\} \\ w &= \left( \sqrt{U^2 + V^2 + \bar{u}^2 + 2W\bar{u}} + \sqrt{U^2 + V^2 + \bar{u}^2 - 2W\bar{u}} \right) / 2 \\ W &= U \cos \theta + V \sin \theta, \quad \bar{u} = 2u_{\max} / \pi \end{aligned} \right\} \tag{9}$$

This formula approximates eq. (8) with high accuracy, as far as the wave orbital velocity of the small amplitude wave theory is used.

A finite difference model has been established to solve these equations. Fig. 1 is the coordinate system used in the nearshore current and topographical change computation, in which  $x$  axis and  $y$  axis are taken in the offshore direction and in the longshore direction respectively. Fig. 2 shows the configuration of variables in the finite difference model. Velocity components and bottom friction are defined on the grid sides and all other variables are given at the grid center.

Fig. 1 Coordinate system used in nearshore current computation.

Fig. 2 Configurations of variables in finite difference model.

(3) Topographical change model

The two-dimensional continuity equation of sediment transport may be written as

$$-\frac{\partial h}{\partial t} + \frac{1}{(1-\lambda)} \left( \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} \right) = 0 \tag{10}$$

in which  $\lambda$  (0.3) is the bottom sediment porosity, and  $q_x$  and  $q_y$  are the local sediment transport rate components in  $x$  direction and in  $y$  direction respectively.

The Tsuchiya model (1982) is extensively applied to the evaluation of local sediment transport rate  $q$  in a two-dimensional flow field. The model was derived from the assumption that waves are responsible for the stirring up of bottom materials and that currents transport sediments in their direction. It can be expressed as

$$q = c_0 \frac{\rho}{\rho_d} \left( 1 - \frac{\tau_c^*}{\tau^*} \right) D \sqrt{U^2 + V^2} \tag{11}$$

in which  $c_0$  (0.02) is the average concentration of sediments,  $\rho_d/\rho$  (2.65) the specific weight of sediments,  $\tau^*$  the Shields parameter and  $\tau_c^*$  the value at the critical stage of sediment movement.

The finite difference method used in the numerical integration of eq. (10) is the same as that of eq. (6). In this case, local sediment transport rate components are estimated by redistributing the local sediment transport rate evaluated

at the grid center to the grid sides which define nearshore current components.

#### (4) Boundary condition and computational procedure

The initial condition and conditions for an offshore fixed boundary and an onshore moving boundary used in the model are the usual ones. In the longshore direction, the periodic boundary condition proposed by E. Noda (1974) is imposed on all the variables relevant to the computation. Moreover, no-flow condition is assumed at the structure boundary.

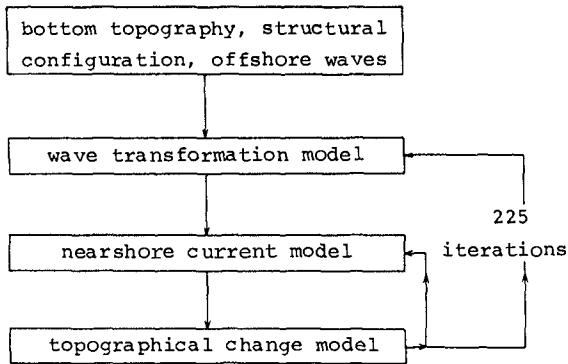

Fig. 3 Schematic diagram of computation flow.

The computer program starts with the determination of the spatial distribution of wave characteristics under the given conditions of offshore waves, bottom topography and structure configuration, and then nearshore current computation is carried out by using radiation stress estimated from the wave transformation model. A steady state solution of the nearshore current was obtained by 1260 iterations. Subsequently, alternating computation between the nearshore current and topographical modification was initiated. During the computation, the wave characteristics were recalculated every 225 iterations in order to take into account the effect of topographical change. The schematic diagram of computation flow is shown in Fig. 3.

### 3. EXPERIMENTAL VERIFICATION OF NEARSHORE CURRENT MODEL

The computation of the nearshore current pattern is compared with the Isobe experiment (1980) for the purpose of verifying the applicability of the present model. The experiment was conducted on a plane beach with the slope of  $i = 0.05$  and

Fig. 4 Comparison of model computation with experiment for nearshore current pattern.

constant water depth of  $h = 25.8$  cm in the offshore region. In the wave basin, an iron plate detached breakwater with the length of  $B = 90$  cm was placed parallel to the shoreline at the water depth of  $h_d = 5.5$  cm. The incident wave height, wave period and incident wave angle of waves used in the experiment were  $H_M = 4.3$  cm,  $T = 1$  s and  $\alpha_M = 90^\circ$  respectively.

The comparison of the computed nearshore current pattern with the experiment is indicated in Fig. 4, in which  $C_r$  is the reflection coefficient of the breakwater. The overall characteristics of the current pattern, such as the formation of a pair of circulation currents with the opposite direction of rotation behind the breakwater, are in qualitative agreement with the experiment. But, the current pattern in the upside of the breakwater is slightly different from the experiment. Further testing is needed to verify the applicability of the present model.

#### 4. NUMERICAL SIMULATION OF BOTTOM MODIFICATION

##### (1) Conditions used in model computation

As shown in Fig. 5, the configurations of coastal structures used in the model computation are from six cases; i) one detached breakwater placed parallel to the shoreline, ii) two detached breakwaters placed parallel to the shoreline, iii) one groin placed perpendicular to the shoreline, iv) two groins placed perpendicular to the shoreline, v) one groin placed oblique to the shoreline, and vi) two groins placed oblique to the shoreline.

Fig. 5 Configuration of coastal structure used in computation.

The nearshore current pattern and change of the bottom topography are computed after 1 to 3 hours of constant wave action. The initial topography is taken as a plane beach with constant slope, although the present model is applicable to arbitrary bottom topography. The study area is divided into 15 points in the offshore  $x$  direction and 54 points in the longshore  $y$  direction with the grid distance of  $\Delta x = \Delta y = 10$  m. The maximum water depth is  $h_{max} = 4$  m and the time step used in the finite difference model is  $\Delta t = 1$  s. The fixed conditions in the computation are the incident wave height ( $H_M = 1$  m), wave period ( $T = 3.5$  s) and beach slope ( $i = 0.04$ ). The variable conditions are the incident wave angle ( $\alpha_M$ ), water depth of the structures ( $h_d$  or  $h_g$ ), reflection coefficient of the structures ( $C_r$ ), action time of waves ( $t$ ), number of structures (1 or 2), length of the structures ( $B$ ), distance between the structures ( $D_d$  or  $D_g$ ) and the angle of structures to the shoreline ( $\beta_H$ ).

The effects of these parameters on current pattern and bottom modification are investigated by comparison with the computed results for the standard condition, but only some of the examples are presented in this paper.

(2) Topographical change caused by detached breakwaters

Fig. 6 is the nearshore current pattern and the resulting topographical change after 1 hour of wave action for the standard conditions in the case of a detached breakwater. A large circulation current with clockwise rotation is formed on the downwave side behind the breakwater. But, a small circulation current found on the upwave side behind the breakwater before the beginning of topographical change computation disappears with the progress of bottom modification. Contourlines in the left side region behind the breakwater advance and bottom topography reveals the tendency of

Fig. 6 Topographical change caused by a detached breakwater.

Fig. 7 Spatial distribution of wave height and wave direction in the case of a detached breakwater.

accretion in this area. On the other hand, contourlines in the area close to the right side of the breakwater retreat, and this results in the tendency of marked erosion in the region. However, the present model does not adequately produce the shoreline change, because swash transport of sediments is not included.

Fig. 7 is the spatial distribution of wave height and wave direction. Wave height decreases in the surf zone and in the shadow zone of the breakwater because of wave breaking and wave diffraction and in the offshore zone, it increases and decreases in space through the effect of diffracted waves.

Fig. 8 indicates the results after 3 hours of wave action. Meandering of the longshore currents is amplified with the progress of topographical modification. Accreting tendency on the left side reduces with the passage of time and the topographical change of the sea bottom approaches a state of

Fig. 8 Effect of action time of waves on topographical change in the case of a detached breakwater.

Fig. 9 Topographical change caused by two detached breakwater.

equilibrium. On the contrary, the eroding tendency on the right side continues and a scoured hole and the local advance of the shoreline are observed.

The results in the case of two detached breakwaters are given in Fig. 9. On the leeside of each breakwater, circulation currents are formed respectively, but their shapes are different from each other because of the effect of mutual interference between the two breakwaters. When the distance between the two breakwaters is longer, the interference effect becomes weaker and the circulation currents take a more similar shape. The feature of bottom modification is a similar situation. Contourlines behind each breakwater reveal slightly different changes. For instance, the scoured hole in the vicinity of the right edge of the right breakwater is deeper than the one on the right edge of the left breakwater.

Fig. 10 Topographical change caused by a perpendicular groin.

Fig. 11 Effect of action time of waves on topographical change in the case of a perpendicular groin.

### (3) Topographical change caused by perpendicular groins

This section describes the bottom modification caused by groins placed perpendicular to the shoreline. Fig. 10 is the current pattern and bottom topography after 1 hour of wave action. In addition to the predominant longshore current moving around the groin tip, a small circulation current and a larger one are found in the frontal region of the groin and in the sheltered region respectively. The former current with the progress of topographical change. As a general feature of bottom modification, contourlines outside the surf zone advance on the left side of the groin and retreat on the right side. The contrary tendency is observed in the surf zone.

After 2 hours of wave action, the variation of nearshore current and bottom topography grows more and more as given

Fig. 12 Topographical change caused by two perpendicular groins.

Fig. 13 Topographical change caused by an oblique groin.

in Fig. 11. As a result, we can see the overturning of contourlines in the vicinity of the groin tip.

The results computed for two perpendicular groins are plotted in Fig. 12. Four circulation currents are formed on both sides of the groins, but the corresponding circulation currents are different from each other in their shape and magnitude because of the mutual interference effect between the two groins. This current characteristics produce slightly different pattern of contourline change in the corresponding region of each groin, compared to the case of one perpendicular groin.

(4) Topographical change caused by oblique groins

Fig. 13 is the current pattern and contourline plots of modified bottom topography in the case of an oblique groin.

Fig. 14 Effect of action time of waves on topographical change in the case of an oblique groin.

Fig. 15 Effect of wave reflection on topographical change in the case of an oblique groin (1).

The predominant longshore current passing around the groin and a clockwise circulation current in the sheltered region of the groin are observed as the case of a perpendicular groin, but a small circulation current in the upwave region of the groin toe is no longer formed. Contourlines in the upwave region advance and contourlines in the vicinity of the groin tip retreat, similar to those produced by a perpendicular groin. The difference is that the time for variation of bottom topography becomes slower compared to the case of a perpendicular groin.

After 3 hours of wave action, the current pattern and bottom topography are modified as shown in Fig. 14. The tendency mentioned above is promoted with the passage of wave action time, and isolated bars and locally-scoured holes are formed in the vicinity of the groin tip.

Fig. 16 Effect of wave reflection on topographical change in the case of an oblique groin (2).

Fig. 15 shows the effect of waves reflected from the groin, in the case where reflection coefficient is taken as 1. A small circulation current is formed at the toe of the groin on the upwave side by the influence of reflected waves. However, the overall characteristics of current pattern and bottom topography are not so different from Fig. 13, although the undulation of contourlines in the upwave region becomes greater by the influence of diffracted waves associated with reflected waves. This is because the region of reflected waves is confined in a smaller area for the present configuration of a groin.

In the case where the region of reflected waves is larger, the current pattern and bottom topography are drastically altered in the upwave region, as illustrated in Fig. 16. A clockwise circulation current with a large scale is formed in the upwave region and remarkable modifications of bottom topography take place.

Fig. 17 and Fig. 18 are the results computed after 1 to 3 hours of wave action in the case of two oblique groins. We can see the current pattern with the predominant longshore current going around the oblique groins and a circulation current with a slightly different scale formed behind each groin, as in the case of two perpendicular groins. The difference of the circulation current pattern was brought about by the mutual interference between the two groins and this affects the topographical change of the sea bottom in the area enclosed by the two groins. As a general feature, it can be said that the topographical change in this area is slower compared to that in the other area. Moreover, the progress of bottom modification tends to give rise to the reinforcement of nearshore current velocity and the greater variation of its direction in space at most sites investigated.

## 5. CONCLUSIONS

The main conclusions of this study are summarized as follows.

- i) A numerical model for predicting the change in bottom topography caused by the presence of coastal structures was proposed by combining three submodels of wave transformation, nearshore current and topographical change of the sea bottom.
- ii) The model produces the general characteristics of erosion and deposition caused by the presence of coastal structures.
- iii) Drastic changes of current patterns and bottom topography occur when the reflected waves from coastal structures cover a large area.
- iv) Experimental verification of the computed results is needed to check the applicability of the proposed model.

and to improve the model.

## 6. ACKNOWLEDGEMENT

A part of this study was accomplished with the support of the Scientific Research Fund of the Ministry of Education, for which the authors express their appreciation.

## CHAPTER ONE HUNDRED EIGHTEEN

### NORTH SEA TIDE AND STORM SURGE INVESTIGATION

Prof. Dr.-Ing. Winfried Siefert<sup>+)</sup>

#### Abstract

An extensive investigation of tide and storm surge measurements in the coastal waters of the southeastern North Sea (German Bight) is now being concluded, giving new hints to tidal behaviour in a complex area, consisting of extended tidal flats, interrupted by islands, sand banks, estuaries and gullies. The analysis was promoted by the "German Coastal Engineering Board" (KFKI) and will be the basis of further investigations of the storm surge conditions in tidal estuaries.

Tidal records and high and low water values of 130 gauges in an area of 12.000 km<sup>2</sup> (5.000 sq.mi.) were used to evaluate

- cotidal lines in the German Bight
- mean tide curves
- regressions between different locations
- neap and spring tide conditions
- secular changes over the last 80 years
- storm surge development.

#### Tidal Character in the German Bight

The tidal motion in this area is induced by the amphidromic tide in the southeastern North Sea (fig. 1). It was believed that the tides in the triangle off the German coast proceed from the West to the East and then to the North, but it turned out that this is not the case: Coriolis and centri-

<sup>+) Strom- und Hafengebäude Hamburg, Lentzkaai, 2190 Cuxhaven,</sup>

Figure 1. Cotidal Lines in the North Sea for Mean HW Conditions (Deutsches Hydrographisches Institut, 1982)

fugal forces lead to deformations of surface gradients resulting in a motion mainly from the West to the East, so it will be shown that the general conditions of fig. 1 are not realistic near the coastlines.

The area of investigation is given on fig. 2, including the long-term and seasonal tide gauges, indicated by black dots. They cover an area of  $80 \times 80 \text{ km}^2$  ( $50 \times 50 \text{ sq.mi.}$ ), most of them in the three estuaries and on the tidal flats in a zone, 10 to 20 km wide. Fig. 3 to 8 show some of the results

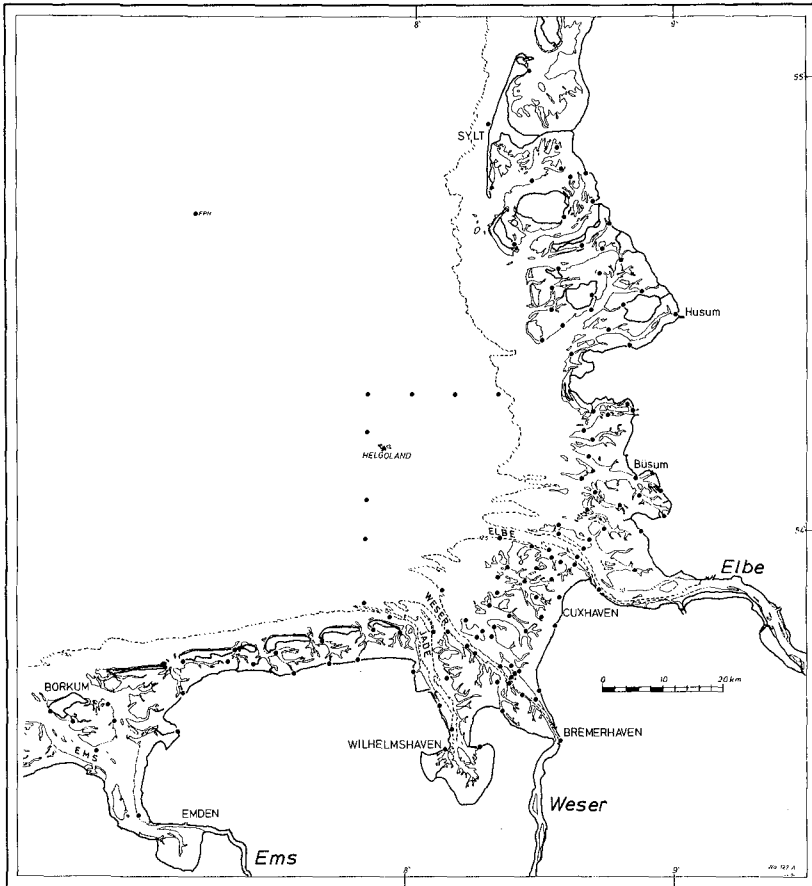

Figure 2. Long-term and Seasonal Tide Gauges in the South-eastern North Sea

that are to be published in the near future in detail (3).

Fig. 3 indicates the lines of mean HW occurrence from 20 to 20 minutes, showing no full agreement with fig. 1: HW time is more or less propagating from the West to the East, signs of a rotation (due to an amphidromic point) cannot be realized. There is another very interesting result: The tide curves off the coast are usually asymmetric with values

Figure 3. Cotidal Lines in the German Bight for Mean HW Conditions; Measurements 1975/79

$T_F/T_E$  between 0.8 and 1.0 (fig. 4). It has to be taken into account that the curves in the North Sea - at least in water depths between 30 and 50 m - are not symmetric and that the asymmetry does not increase with the propagation to the coast, but decrease. An expected decrease is found in the estuaries; in some areas we even find longer ebbs than floods! Moreover, we are able to define the flats and

Figure 4. Flood Duration  $T_F$  over Ebb Duration  $T_E$  in the German Bight for Mean (Semi-diurnal) Tides

gullies as a system of neighbouring flood- and ebb-dominated areas (see fig. 5). The former are characterized by longer flood than ebb duration ( $T_F > T_E$ ) and coastwards decreasing low water levels, combined with residual currents across the tidal flats towards the latter. The lines of mean HW levels, computed for 1975/79 and given in cm above gauge datum on fig. 6, rise with 10 cm/10 km from the Northwest to the

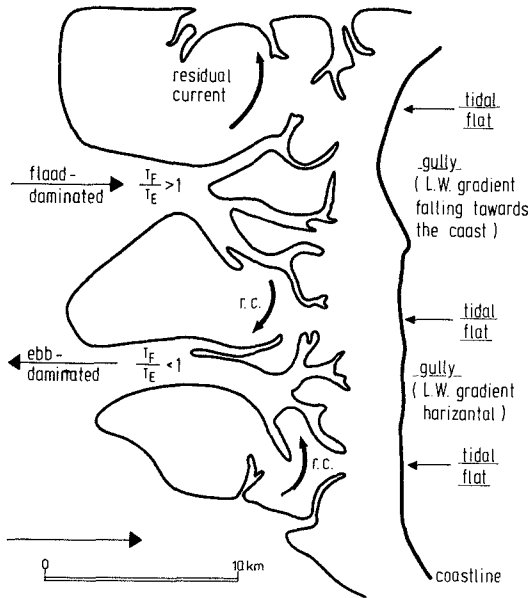

Figure 5. Array of Tidal Flats with Typical Pattern of  $T_F/T_E$  and Residual Currents

Southeast, becoming very complex in the eastern tidal flats and in the estuaries of Weser and Elbe. The highest mean HW levels are found in the bights west of the Weser and north of the Elbe estuaries. The mean tidal range on fig. 7 increases significantly from the deeper water zones towards the coastline (measurements from 1.3 m to 3.8 m with remarkable gradients in the northernmost wadden sea. Near-coast spring tidal range is about 60 cm higher.

The mean tide curves differ a lot. Fig. 8 gives some examples: Different heights and shapes, due to the topographical and current conditions. These curves of 130 tide gauges enabled us to calculate lines of constant water levels in the German Bight for all tide phases. As far as we know it is the first time that this could be done by such an amount of field data. And the result stated what had to be expected

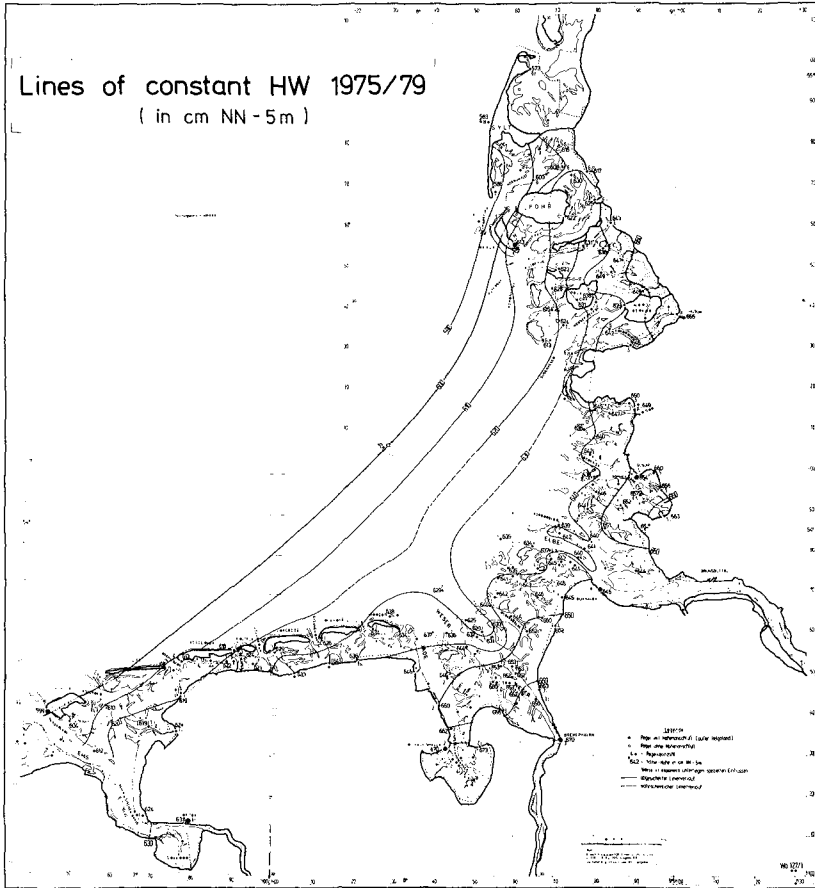

Figure 6. Mean HW Levels in the German Bight for 1975/79

by the cotidal lines on fig. 3: The amphidromic tide in the southeastern North Sea (fig. 1) does not rule the movements in the German Bight in a strong manner as was believed: We can assume a border of main influence (sketch on fig. 9). In the area between that border and the coastline, the tidal movement is stimulated from the West, and there should be only weak interactions across the assumed border. That

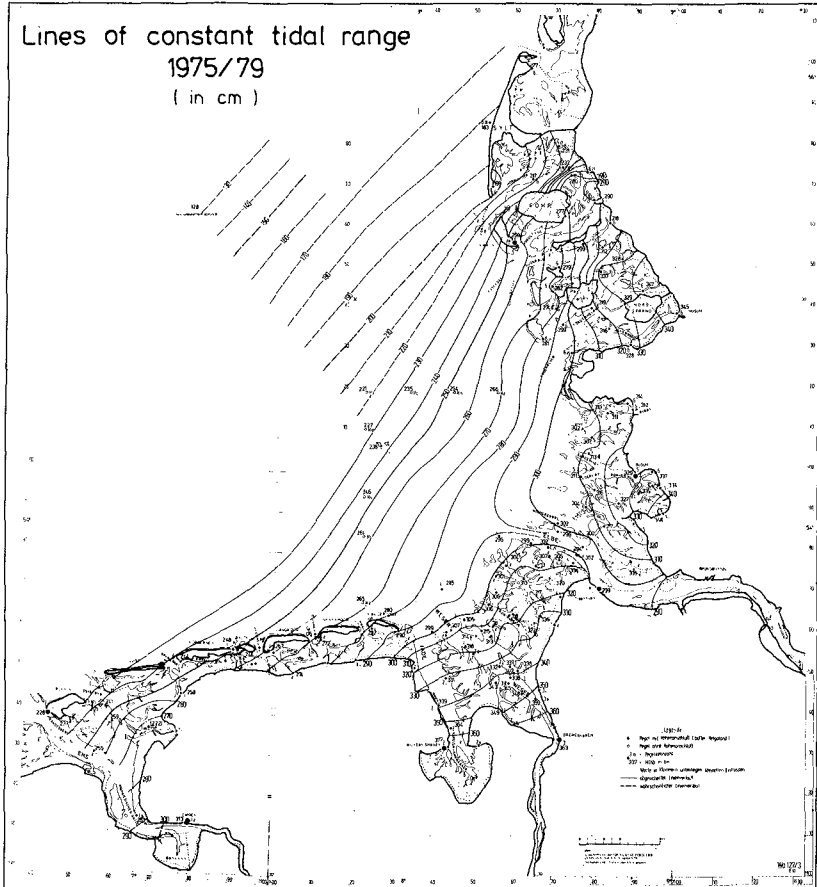

Figure 7. Mean Tidal Range in the German Bight for 1975/79, Given in cm

leads to a predominant west-east tidal motion (and south-west-northeast for the northern area), in agreement with current measurements and ice tracer observations. This is underlined by the effect that we can define a zone of about 6.000 km<sup>2</sup> (2.500 sq.mi.), where the water levels behave in an interesting way: During LW time at Borkum (BOR on fig. 9) the indicated zone is characterized by constant water levels

Figure 8. Examples for Different Mean Tide Curves in the German Bight (See Fig. 2):

- 1: Borkum: outside tidal flats
- 2: Bensersiel: straight coastline, protected by islands
- 3: Wilhelmshaven: bight effect
- 4: Steertloch: bight effect, south of Büsum
- 5: Hörnum: southern tip of Sylt, island effect
- 6: Osterley: east of Hörnum, island and tidal flat effects

(variances only within 10 cm), and they are the lowest in the whole German Bight at this tide phase. At HW time in Borkum the same area can be defined as of constant water level, being the highest at that phase. Conclusions are:

- Water is "pumped" into the inner bight during flood phases, building up a ridge with slopes to the North

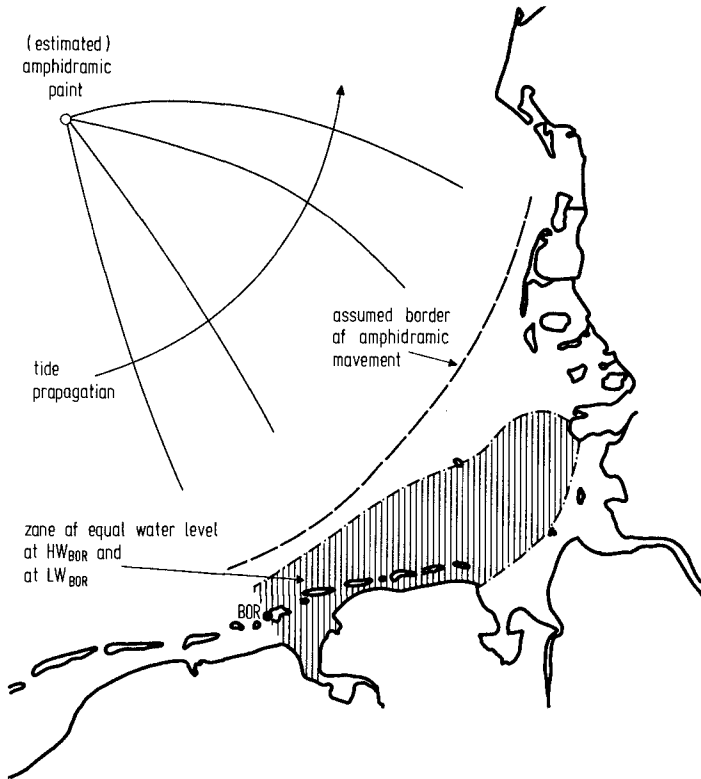

Figure 9. Mean Amphidromic Behaviour in the Southeastern North Sea and Zone of Special Conditions

Figure 10. Definition Sketch, Mean Tide Curve and Storm Surge

- and to the Southeast;
- water is moving out of the indicated zone, finally forming a trough;
  - wind induced currents from westerly directions can easily fill up this trough; so storm surges usually start somewhere around  $LW_{BOR}$ , and constant wind conditions lead to higher surge values during LW than during HW (surge being defined as on fig. 10);
  - no conservative tidal wave profil appears near the coast; consequently linear wave theory should not be applied to coastal tides.

In this context it is very interesting that computations of the Danish Hydraulic Institute in its numerical North Sea model show that the origin of the discussed trough lies west of the Dutch coast, i.e. in the sphere of the neighbouring (southern) amphidromic tide, migrating along the coast into the German Bight, thereby steadily deepening.

#### Recent HW and LW Changes

During the last decades tide and storm surge investigations along the German North Sea coast and in the estuaries have rapidly been intensified. But there are some gauges with records of more than 100 years as well, and two of them will have their bicentennial jubilee in 1986 (Cuxhaven and Hamburg). So much historic data is available. On the other hand the development of the last 15 years is to be of high interest: We can evaluate distinct changes in water levels since 1970 recognizable both in HW and LW. Three typical examples for the German Bight are given for the islands Bor-kum (BOR) and Helgoland (HEL) (fig. 11) and for Cuxhaven (CUX) at the seaward boundary of the Elbe estuary (fig. 12):

- HW BOR: rising until 1970, the constant
- HEL: rising until 1950 (?), then constant
- CUX: rising until today, with an increase during the last decade.

Figure 11. HW and LW Developments (3 Years Running Means) at Helgoland (HEL) and Borkum (BOR)

LW BOR: rising until 1950, constant until late 1960ies, the falling

HEL: constant until late 1960ies, then falling

CUX: rising until 1950, then slowly falling, with an increase in the late 1960ies.

The result is: at the islands 10 to 50 km in front of the coast HW has been constant since 1970, while at the coast (CUX is typical!) HW is rising remarkably. At the same time

Figure 12. HW and LW Developments (3 Years Running Means) at the Elbe Estuary (Cuxhaven, CUX) and 100 km (60 mi.) upstream (Hamburg, HBG)

LW is falling at the islands and at the coast; so the tidal range increases rapidly.

In the tidal estuaries the HW and LW developments are governed by seaward and regime conditions. The seaward influence in the Elbe is shown in fig. 12. Hamburg (HBG) is situated 100 km upstream from Cuxhaven, and qualitatively

the developments are the same as in CUX. Especially the LW data also seems to show strong effects of deepening of fairway. The same is realized in other estuaries in Europe.

So this yields two conclusion: either all estuaries have been deepened since 1970 resulting in round about the same amount of LW-change, or something must have happened outside the estuaries. The latter idea was first published by the author in 1976 and emphasized later (2).

During the last years the number of indications about changes of tidal characteristics in the North Sea is rising:

- At the German coast we measure tidal ranges that have never occurred before;
- tidal current velocities in the outer parts of the estuaries (seaward of fairway improvements) increased;
- shapes of mean tide curves have changed distinctly.

The question is, whether the amphidromic tide in the southeastern North Sea is constant or not, and if not: why? This problem can not yet be solved, but we are trying to find a solution.

#### Storm Surge Tendencies

The coasts of the southeastern North Sea had to be protected against severe storm surges with high dikes and other defence constructions. The heights of these events steadily rose during the last 500 years due to secular water level increase of about 20 cm/100 years.

During the same period since 1960, when the mean tide conditions changed in front of the coast, the heights and frequencies of storm surges increased, as indicated by fig. 13 and 14: Ten years overlapping means have risen by 20 to 30 cm within a period of 30 years at stations 10 to 20 km off the coast (BOR, AW) and at the coast (CUX) as well (fig. 13), the main portion being during the last 20 years, accompanied by a distinct increase of the storm surge num-

ber (fig. 14): 10 events in three years until 1960 to 15 up to 20 since 1965. So this development is in phase with the rise of mean HW levels in this area (fig. 11, 12). The reasons are different, of course: Storm surge growth is the result of two developments: the number of storm has been increasing during the last decade, as has at the same time the frequency of the critical wind directions (e.g.  $270^{\circ}$  for the Ems,  $280^{\circ}$  to  $290^{\circ}$  for the Weser and Elbe).

All these tendencies, concerning mean tidal conditions at all gauges as well as storm surge heights and frequencies,

Figure 13. Mean Heights of Storm Surges Higher than 1.5 m above HW at the Entrances of Ems (BDR), Weser (AW) and Elbe (CUX) (10 Years Overlapping Means)

Figure 14. Number of Storm Surges in Cuxhaven Higher than 1.5 m above HW or Surge Heights above 2.0 m (Running Sums over 3 Years)

result in a rising danger for the coast of the south-eastern North Sea and especially for the estuaries including for instance Bremen and Hamburg (1).

#### Outlook

The detailed evaluation of field tide data of an area in front of the coast resulted in a number of new experiences and helps to improve explanations for certain proceedings. So we are encouraged to intensify the studies, starting in 1985, with

- more detailed investigations within the area of fig. 2,
- extension to the Dutch and Danish coasts and - if data is available - into the North Sea, both for the mean situation of 1975/79,
- a second evaluation of data of 1982/86 for the whole enlarged area,
- a comparison of the tide conditions in both periods to find hints about possible changes.

## CHAPTER ONE HUNDRED NINETEEN

### Suspended Sand Transport on a Dissipative Beach

John P. Downing\*

#### ABSTRACT

Field studies were conducted in November 1979 to measure suspended sand transport on Twin Harbor Beach, Washington U.S.A. This beach has an average slope of 0.02 and is composed of well-sorted sand with a mean diameter of 0.21mm. The significant height of breaking swells approaching the beach at small angles can be estimated from variance spectra of water level by  $4.36 \sigma_{\eta}$ . In the surf zone significant wave heights are linearly related to the local mean water depth by  $\gamma = H_s/h = 0.45$ . Variance,  $\sigma_{\eta}^2$ , in the gravity wave band (0.048 to 1.0 Hz) is proportional to water depth squared. Low-frequency variance (less than 0.048 Hz) although not systematically related to water depth, is usually largest in the inner surf zone where breakers are small.

Sand suspension is correlated with strong offshore flows that recur at about one-fifth the incident wave frequency. Vertical mixing of sand in the water column by these water motions rather than turbulence generated by shear at the bed associated with individual wave oscillations is a key mechanism in sand transport on dissipative beaches.

The largest sediment loads occur in the inner surf zone where low-frequency motions dominate the breakers. Maximum longshore transport rates, however, were measured in the middle of the surf zone because of the higher longshore current speeds there. The suspended load probably accounts for as much as 45 percent of the litoral drift on a dissipative beach exposed to moderately-high swells approaching the shore at small angles.

#### INTRODUCTION

Sand transport by shoaling waves and nearshore currents in the surf zone is a key process controlling the plan and profile of sandy shores. Nearshore circulation and sand transport vary from one coastal area to another depending upon beach morphology, sediment size, and wave climate. These variations form a continuum of surf dynamics between steep reflective beach systems and gently-sloped dissipative ones. Reflective beaches have narrow surf zones with plunging and collapsing breakers whereas dissipative beaches have wide surf zones with spilling breakers, low frequency current and water level oscillations, and bar-trough morphologies. Several intermediate states of surf dynamics have been scaled with a parameter:

$$\epsilon = A_1 \omega_1^2 / g \tan^2 \beta \quad (1)$$

\* Northern Technical Services, Inc., 14715 N.E. 95th St., Redmond, WA 98052. Formerly: School of Oceanography, University of Washington

(1, 6, 19, 20 and 21) where:  $A_i$  = breaker amplitude,  $\omega_i$  = incident wave radial frequency;  $g$  = gravitational acceleration, and  $\tan \beta$  = beach slope. Dissipative beaches are in the range  $33 < \epsilon < \sim 400$  (20).

The Nearshore Sediment Transport Study (NSTS), begun in 1977, was designed to expand the data base on nearshore sediment dynamics for engineers and coastal managers. As part of NSTS an instrumentation system consisting of: 1) an array of optoelectronic sensors, 2) an electromagnetic current meter, 3) a resistance wave gauge, and 4) a portable data acquisition system was installed on Twin Harbors Beach, Washington U.S.A. (4) in November 1979. Water level, current and sediment concentration data were acquired to characterize the fields of suspended sand and horizontal water motions across a dissipative open-ocean beach.

#### SITE DESCRIPTION

Twin Harbors Beach is on the exposed part of a large barrier spit that forms the seaward margin of Grays Harbor, (Figure 1). The coastline follows a beach ridge complex formed by rapid marine and eolian accretion in the past 5,000 years (2).

Figure 1 Twin Harbors Beach location map and bathymetry of the study area.

The nearshore bathymetry at the experiment site was determined from 14 rod and level surveys conducted between January and November 1979 along the rangelines shown on Figure 1. The beach is divisible into three zones. The upper beach face has no berm and is relatively steep,  $0.06 < \tan \beta < 0.15$ . In the zone between 25 and 200 m, the profile is featureless and concave up with constant slope (0.01-0.03); see Figure 2. Mean beach slope is irregular seaward of about 200 m because longshore bars and troughs form there during storms. Fluctuations in beach elevation, during the survey period were largest in the outer zone, where 2.0 m fluctuations were measured. Sand level fluctuations landward ranged from 0.2 to 0.3m during the year.

Figure 2 Mean beach profile at range 5 January through November 1979.

The mean grain size and sorting coefficient of sand at the experiment site are 0.21 mm (2.22 Phi) and 0.05 mm (0.38 Phi), respectively (15).

Twin Harbors Beach is exposed to the swell and wind wave regime of the northeast Pacific. The net longshore transport rate near the site estimated by the U.S. Army Corps of Engineers (18), is  $2.2 \times 10^6$  cubic yards per year to the north. This exceeds the net transport rates on all California and east coast beaches for which historical data exist by a factor of 2 to 4 (17). In accordance with the scheme applied to exposed Australian beaches by Wright et al. (19), Twin Harbors Beach has a very dissipative surf zone with  $\epsilon$  values between 80 and 240.

#### INSTRUMENTATION

Figure 3 shows the instrumented mast used for this investigation. Detailed descriptions of individual sensors are given by Downing in (3 and 4). Water level was determined with a surface piercing resistance wave sensor; horizontal current velocity was measured with a MARSH-McBIRNEY electromagnetic current meter and suspended sand concentrations were detected with an integrating infrared back-scatterometer. Analog voltage signals from these sensors were sampled at the rate of  $10 \text{ Hz}$ , digitized with 12-bit resolution, and recorded on floppy disks with a portable data acquisition system. Twelve-bit digitization produces nominal resolution of one part in 4096 for each measured parameter.

The sensor array was installed on survey range no. 5, 180 m from benchmark-BM 5 (Figure 4). The sensors were mounted on a rigid mast held in place by three guy wires attached to anchor stakes driven into the beach sand. The vertical positions of the sensors were measured relative to the sea bed at the instrument mast. The orientation of the current meter probe was established with a magnetic compass and spirit level and is accurate to  $\pm 2^\circ$  of azimuth and  $\pm 0.5^\circ$  relative to vertical. The X axis of the probe was aligned with the local isobaths as determined by the beach surveys. Table 1 lists the vertical positions of the sensors with respect to the beach face.

Figure 3 Sediment transport instrument installation.

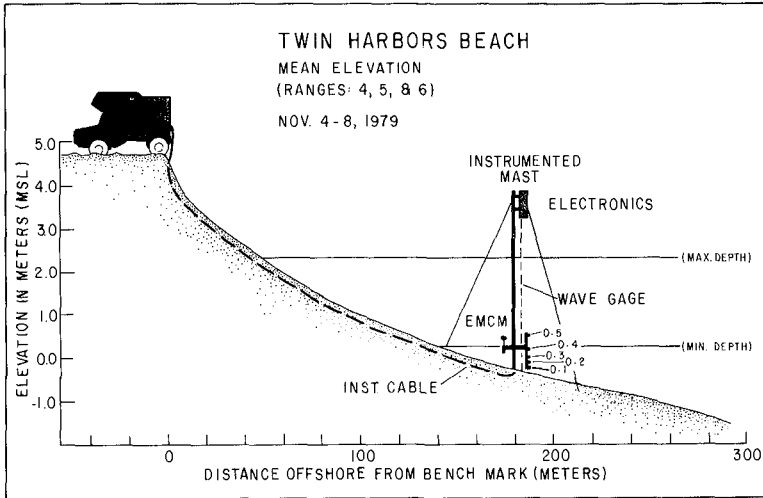

Figure 4 Location of instrumentation on range No. 5.

Table 1. Sensor Locations.

Sensor	Range	Parameter	x (m)	z (m)
EMCM	5	U V	180.2	0.18
Water Level	5	h	180.0	0-3.5
OBS-1	5	C <sub>s</sub>	180.2	0.025
OBS-2	5	C <sub>s</sub>	180.2	0.055
OBS-3	5	C <sub>s</sub>	180.2	0.115
OBS-4	5	C <sub>s</sub>	180.2	0.235
OBS-5	5	C <sub>s</sub>	180.2	0.535

Notes:

x = Distance offshore from survey baseline.      V = Shore-normal velocity.  
 z = Elevation above sea bed.                      h = Water Depth.  
 U = Alongshore velocity.                          C<sub>s</sub> = Suspended sand concentration.

DATA PROCESSING

The coordinate system for computations consists of an X axis, positive onshore; an alongshore Y axis, positive to the north; and a Z axis which is positive up. The origin of the Z axis is the bed elevation at the instrumentation mast.

The binary data were block-averaged over a 0.4-second time window to reduce the bandwidth from 5.0 to 1.25 Hz. The block-averaged time series of  $\langle t \rangle$ , U and V(t), and C<sub>s</sub>(t) were Fourier transformed using a

Cooley-Tukey algorithm to determine the distribution of variance with frequency. Prior to the transformation, records of 1024 points were demeaned, linearly detrended, and tapered with a cosine window. The raw spectral estimates of four sequential non-overlapping records were ensemble averaged and then smoothed by averaging over a four point spectral window. The resulting spectral estimates have 32 degrees of freedom and represent the mean variance in a bandwidth of 0.0098 Hz.

For the purpose of comparing wave heights across the surf zone, a statistic,  $H_s$ , called the significant breaker height was computed from the spectral density functions (SDF),  $S_\eta(f)$ , for each record. This statistic represents  $4\sigma_\eta$  ( $\sigma_\eta$  equals the square root of the variance) in the frequency band from 0.047 to 1.25 Hz. The variance in this frequency band was computed from the SDFs of  $\eta(t)$  by summing the estimates,  $S_\eta(f_n)$ , from  $n = 20$  to 512:

$$\sigma_\eta^2 = \sum_{n=20}^{512} S_\eta(f_n) \quad (2)$$

This is equivalent to computing  $\sigma_\eta$  from a band-passed record of  $\eta(t)$ .

Conversions of voltage levels to scientific units were made with the instrument gains and offsets determined from laboratory calibrations made before and after the experiment (4). Computations of instantaneous suspended sand flux in kg/m/s were made by evaluating the integrals:

$$Q_x(t) = U(t) \int_0^h C_s(z,t) dz \quad (3)$$

$$Q_y(t) = V(t) \int_0^h C_s(z,t) dz \quad (4)$$

where the units of  $C_s$  are mass per unit volume and  $h$  is the instantaneous water depth.

Several assumptions were made to simplify these computations. First, it was assumed that sand concentration varied linearly between sensors. At the bed, the concentration was estimated by extrapolating the gradient between the lowest two sensors to the bottom.  $C_s$  at the surface was set equal to zero. This assumption results in under estimation of the suspended load since the vertical gradients are exponential. It was further assumed that horizontal velocity was vertically uniform. As will become clear later, this assumption was not valid when applied to the computations of shore-normal transport rates. The assumption was unavoidable, however, because only one current meter was deployed.

## RESULTS

Wave, current and suspended sand data were acquired during five periods (runs) on the 6th, 7th and 8th of November, 1979. The duration of runs ranged from 1 to 3.5 hrs. and with the exception of Run no. 4, all were completed during ebbing tides.

The surf during this period originated from a large low-pressure disturbance that occurred in the Northeast Pacific Ocean between the 2nd and 4th of November. Sustained winds of 40 knots blew over a fetch more than 4,000 miles long during the most intense part of the storm. Twelve to fifteen second swells began to break on Twin Harbors Beach during the afternoon of November 4th and continued to produce a moderate surf until the afternoon of November 7th.

#### Wave Conditions

The results of spectral analyses of the water level records are summarized in Table 2 which gives the frequencies and corresponding periods of maxima and minima of the smoothed SDFs. Examples of time series of water level and SDFs representative of conditions in the outer, middle, and inner surf zone are shown in Figures 5 and 6. Spectral density decreases with frequency as  $f^{-3}$  to  $-7/3$  and the primary spectral peak is between 0.0093 and 0.0267 Hz (37.5 and 107 s). A secondary peak associated with the incident swell occurs between 0.067 and 0.105 Hz (9.5 and 15 s). Periods associated with these spectral peaks averaged over all the records are 13.3 and 67 seconds.

Minima are consistently present in the SDFs of  $(t)$  at about 0.048 Hz ( $T = 21.5$  s). This is considered to be the low frequency limit of free surface and velocity fluctuations associated with the incident waves. Water motions and free surface oscillations with frequencies less than 0.047 Hz are called low frequency oscillations. The maximum significant wave height of 1.0 m was measured during the first part of Run no. 2 in a mean water depth of 2.17 m and a corresponding offshore distance of 114 m. About half of the waves early in Run no. 2 were unbroken and the offshore distance of 114 m is taken as the width of the surf zone ( $x_b$ ) during the experiment. Wave heights are linearly proportional water depth and ranged from 0.21 m at  $x/x_b = 0.35$  to 1.0 m at  $x/x_b = 1.0$ .

#### Currents

The longshore current, during 94 percent of the experiment was towards the south with an average speed 0.27 m/s. During two 13.7 min periods it reversed direction and flowed to the north usually less than 0.01 m/s. The maximum 6.83-minute average longshore current was 0.66 m/s.

The persistent southerly longshore current indicates that waves approached the beach from the northwest throughout the experiment and that cellular circulation, rip currents, and large horizontal eddies did not occur during most of the study. Shore-normal current components were offshore during all runs with mean and maximum speeds 0.15 and 0.37 m/s respectively. The implications of a net offshore flow are discussed in a later section.

#### Suspended Sand Concentrations and Transport

Measured transport rates varied between 0.01 and 1.00 Kg/m/s during the experiments and are representative of offshore distances ranging from  $X = 0.35-1.0$ . Figure 6 shows time series of sand concentrations in

the water column at three locations across the surf zone. Sand suspension on this beach is a transient phenomena which occurs at time intervals much longer than the period of the incident waves. The duration and number of sand suspension events increases with decreasing water depth, and they are associated with prolonged periods of offshore flow.

The vertical distribution of suspended sand in the water column has two distinct forms. During quiescent intervals between suspension events, the water column is lightly charged with sediment and the concentration of sand is vertically uniform; see Figure 7. During suspension events, when large quantities of sand are mixed in the water column, there is a strong concentration gradient to about 10 cm above the bed. Above this level sand concentration is more vertically uniform.

DISCUSSION

The variance spectrum of water level is convenient to compute, and an empirical check was made to determine how closely measured significant breaker heights can be approximated from the total variance in the gravity wave band. Measurements of the crest to trough heights of 434 spilling breakers across the surf zone indicate that  $H_s$  is best approximated by  $4.36 \sigma$ . This approximation is probably site specific but indicates that a useful wave height parameter can be easily computed from the variance spectrum.

The variation of  $H_s$  with local depth is linear, and the breaking criteria,  $\gamma$ , is  $0.45 \pm 0.05$ . Because several formulas for computing orbital velocities, setup and runup, include the "constant,"  $\gamma$ ; a comparison of field-determined breaking criteria is given in Table 3. These data indicate that  $\gamma$  varies with beach and surf conditions and should be selected cautiously.

Table 3. Wave breaking criteria.

Beach Slope ( $\tan \beta$ )	$\gamma$	Beach	Reference
0.011	0.42	Goolwa, Aust.	(20)
0.014	0.6	Saunton, G.B.	(7)
0.02	$0.45 \pm 0.05$	Twin Harbor Beach, WA	This study

In Figure 9 computed values of wave energy,  $E_w$ , and total energy,  $E_t$ , have been plotted versus water depth to illustrate possible wave energy decay processes. A least squares fit is drawn through the  $E_w$  values to indicate the trend of wave decay. The distance between this curve and the plotted values of  $E_t$  provides an estimate of the energy associated with low frequency motions. A gradient of wave energy is developed across the surf zone and dissipation is manifested in the growth of low frequency oscillations in water level with attendant fluctuations in the shore-normal current. The energy transfer from high to low frequency, revealed by the present analysis, is not systematic. There is considerable variability in low-frequency energy across the surf zone which cannot be characterized by a convenient parameter such as  $H_s$ . High values of total energy are more likely in the outer surf zone but are not restricted there. Peak values appear at regularly spaced intervals across the surf zone suggesting a standing wave with antinodes at  $h = 0.80$  m and  $h = 1.60$  m ( $X = 0.53$  and  $0.82$ ).

Figure 8 Graph of wave energy,  $E_w$ , and total energy,  $E_t$ , versus water depth.

The mean shore-normal velocity component at  $Z = 18$  cm is 0.15 m/s offshore. Offshore flow at mid-depth is predicted by some theories and laboratory experiments (12 and 16), but is not consistent with most other field data (6) except that from Goolwa Beach, Australia (20). It appears that the mass transport under shoaling waves on highly dissipative beaches can be balanced by nearshore circulation other than eddies and rip currents (10). The total loss of sand from the beach on a weekly basis computed from the profile data (5 to 8 November) was only  $0.06 \text{ m}^3$ . This is nearly three orders of magnitude less than the sand loss of  $50 \text{ m}^3$  per week calculated from the shore-normal transport data, a large discrepancy. In order to balance the sand budget, it appears there must be onshore sand transport near the bed since there is rarely enough suspended sand above  $z = 18$  cm to balance the loss at mid-depth. This result underscores the importance of measuring velocities at several elevations, especially nearer the bed, when monitoring total transport.

#### Variation of Sand Transport and the Total Load

The changing character of the wave induced water motions and sand suspension across the surf zone, Figure 5, and their effect on longshore sand transport is more evident when time and space averaging of the currents and suspended load is done. The 6.8-minute average values of  $V$ ,  $M$  and  $Q_y$  for all runs were grouped according to their location across the surf zone into bins 10 meters wide. Average values for these parameters in each of the bins were normalized by their respective maxima, and their variation across the surf zone is shown on Figure 9.

In the mid- to outer surf zone,  $x = 75-115$  m, the longshore current is large and decreases linearly to 1/10 of the maximum value in the inner surf zone. The suspended sand load is uniformly low in the outer surf zone,  $x = 85-115$  m, and increases near shore. Longshore sand flux is low in the outer zone, primarily because there is little suspended sand available for transport by the high currents there.  $Q_y$  peaks in the mid- to inner zone where the suspended load is moderately high and longshore current speeds are nearly maximum. Near shore the sediment load reaches a maximum but the longshore current is minimal, producing only moderate transport. This general trend of high longshore transport in the mid-surf zone with decreased rates both on and offshore supports Komar's (9) model for the total longshore transport.

Komar (9 and 10) has reviewed the energetics approach to sand transport prediction and indicates that equation 4 represents the longshore transport resulting from radiation stresses as well as nearshore currents from the tides and winds. The total longshore transport is given by:

$$Q_s = 2.5 (EC_n)_b \frac{\bar{V}_l}{U_m} \quad (4)$$

where  $Q_s$  is the at-rest volume of sand transported per day ( $m^3/day$ );  $EC_n$  is the wave energy flux at the breaker zone;  $\bar{V}_l$  is the mean longshore current in the middle of the surf zone and  $U_m$  is maximum orbital velocity under the breakers. The advantage of this equation is that breaker angles which are difficult to measure do not appear explicitly. Maximum orbital velocity is given by (10):

$$U_m = \gamma/2 [g (\bar{\eta} + h)]^{1/2} \quad (5)$$

A comparison of total measured advective sand transport with total predicted longshore transport was made to estimate the contribution of the suspended load. The total transport estimate is made with the wave conditions observed during the early part of Run no. 2, since the instrument was located in the zone of initial wave breaking. The quantity  $(\bar{\eta} + h)$  is replaced by the measured mean water depth  $\bar{h}$  which includes setup  $\bar{\eta}$ , and the breaking parameter,  $\gamma$ , is taken as 0.7 times the measured value since RMS wave heights are used in Komar's formula. Likewise the wave energy flux is computed with

$H_{rms} = 0.7 H_s$ ; so  $EC_n = \frac{1}{8} \rho g H_{rms}^2 \sqrt{gh}$ . The longshore current velocity

Figure 9 Variation of longshore current speed, suspended load, and sand transport across the surf zone.

at the mid-surf position is given by the average of the longshore velocities measured in water depths between 0.7 and 1.0 m. The values used for computing  $Q_s$  are:  $H_{rms} = 0.59$  m;  $\bar{h} = 2.1$  m;  $\bar{V}_1 = 0.25$  m/s and  $U_m = 0.64$  m/s. The predicted total longshore transport rate is 1,930 m<sup>3</sup>/day.

In making the estimate of advective sand transport, the surf zone was subdivided into twelve shore-parallel bands, 10 meters wide. Transport rates in each band are equal to the average of measured values in the band. Values in the inner surf zone are obtained by linear extrapolation of the innermost measurements to zero at the shoreline. In this way, a value of 915 m<sup>3</sup>/day was estimated for the suspended load transport during the experiment. This comprises 47 percent of the total load predicted above.

#### Wave-sediment Interaction

Suspension events appear to be the major process which makes sand available for advective transport on Twin Harbors Beach. More than 190 suspension events were recorded during the ten hours of measurements. These events nearly always occurred during offshore flow that persists for several wave periods (Figure 6). Three of these events have been selected for description and are illustrated in Figure 10.

For each event, the time histories of sand concentration at the lowest four sensors and horizontal current speed are shown with a sequence of  $C_s$  profiles. The suspension events occur as follows:

- 1) The water column is relatively clear during initial offshore acceleration of the flow.

- 2) High concentrations and gradients develop near the bed and sand is mixed into the water column as bores propagating shoreward interact with the seaward flowing current. There is usually a lag of several seconds between the occurrence of high sand concentrations near the bed

and their occurrence in the upper water column ( $z > 24$  cm). Maximum sediment loads usually lag peak offshore current speeds and the passage of the larger bores.

3) The decay of suspension events is most often characterized by a loss of suspended load with a uniform decrease of concentration at all levels.

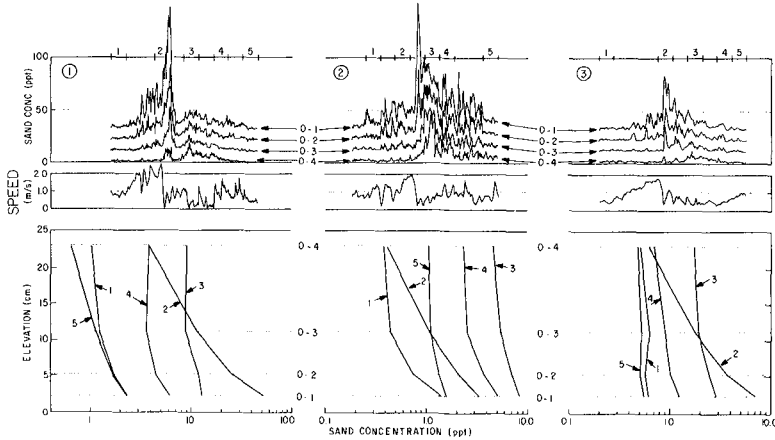

Figure 10 Sequential suspended sand profiles during suspension events. Numbered intervals on upper axis are six seconds long; current speeds are the resultant of X and Y-velocity components. Concentration profiles are six-second averages.

Several important aspects of the water motion producing these suspension events could not be measured for the present study. These include the vertical velocity component and the local convective accelerations. These respects of water motion appear to be critical to our full understanding of the suspension process (8). Further it appears that the approach to the problem of suspended sand transport taken in previous investigations (11 and 13) may not be productive on natural dissipative benches since wave by wave sand suspensions are a small part of the total load.

CONCLUSIONS

At Twin Harbors Beach:

1) The significant height of breaking swells approaching the beach at small angles can be estimated from variance spectra of water level by  $4.36\sigma_\eta$ . In the surf zone significant wave heights are linearly related to the local mean water depth by  $\gamma = H_a/h = 0.45$ . Variance,  $\sigma_\eta^2$ , in the gravity wave band (0.048 to 1.0 Hz) is proportional to water depth squared. Low-frequency variance (less than 0.048 Hz) although not systematically related to water depth, is usually largest in the inner surf zone where breakers are small.

2) Sand suspension is correlated with strong offshore flows that recur at about one-fifth the incident wave frequency. Vertical mixing of sand in the water column by these water motions rather than turbulence generated by shear at the bed associated with individual wave oscillations is a key mechanism in sand transport on dissipative beaches.

3) The largest sediment loads occur in the inner surf zone where low-frequency motions dominate the breakers. Maximum longshore transport rates, however, were measured in the middle of the surf zone because of the higher longshore current speeds there. The suspended load probably accounts for as much as 45 percent of the littoral drift on a dissipative beach exposed to moderately-high swells approaching the shore at small angles.

#### ACKNOWLEDGMENTS

I thank Professors Dick Sternberg and Clive Lister for their insight and productive suggestions about this research. Rex Johnson and Stan Woods were the skilled craftsmen who made the instruments. Harvey Smith provided energetic support in the field. Financial support was provided by a NOAA grant administered by the National Sea Grant College Program and the Nearshore Sediment Transport Study, a multi-institutional effort (#SGNOAA NAB1 KA-D-0030).

## CHAPTER ONE HUNDRED TWENTY

### Field Investigations of Suspended Sediment Transport in the Nearshore Zone

R.W. Sternberg\*, N.C. Shi†, and John P. Downing††

#### ABSTRACT

The suspended sediment distribution and longshore sediment transport characteristics at Leadbetter Beach, Santa Barbara, California were investigated using a series of miniature optical backscatter sensors which can measure particle concentrations as high as 180 gm/l and have 10 Hz frequency response. Vertical arrays of sensors were maintained at up to four positions across the surf zone during 7-25 February 1980 and were operated concurrently with pressure sensors and current meters. Data were collected on a daily basis over 2-4 hour periods.

The data were analyzed to reveal concentration profiles of suspended sediment, the average suspended sediment loads, and the longshore particle flux in relation to varying wave conditions. Results show that sediment transport occurs as individual suspension events related to incident wave motions and infragravity motion oscillations within the surf zone; suspended sediment concentration decreases approximately logarithmically away from the seabed; the maximum values of longshore transport rates occur in the mid-surf zone; and the measured suspended sediment longshore transport rate is equal to the total longshore transport rate as predicted by existing transport equations.

#### INTRODUCTION

As part of the Nearshore Sediment Transport Study (NSTS) carried out at Leadbetter Beach, Santa Barbara, California, in January-February 1980 (7), an extensive series of suspended sediment measurements were made concurrently with observations of wave motions (currents and water level fluctuations), sediment characteristics, and beach profiles. The total NSTS experiment was broad in scope, integrating a wide variety of research objectives (20,21,22). This project emphasized suspended sediment transport, with major objectives of characterizing the temporal and spatial suspended sediment distribution across the surf zone and investigating the relationship between surf zone physical processes and the littoral transport of suspended sediment. In addition, the longshore transport models of (16,17) were evaluated with respect to the longshore component of suspended sediment flux measured during a range of incident wave conditions.

STUDY AREA

Leadbetter Beach is a relatively straight sandy beach located directly updrift from the breakwater-harbor area of Santa Barbara, California (Fig. 1). It was selected as a study site because the approaching wave direction is reasonably constant due to the narrow window between the offshore Channel Islands and because the high angle of wave incidence provides a nearly unidirectional longshore current from west to east, i.e., from the study site towards the Santa Barbara breakwater which represents a total sediment trap. Semidiurnal tides have a mean range of 110 cm and a mean tide level of 85.3 cm (MLLW). The beach has a steep slope and the surf zone is narrow. The textural properties of the beach sand indicate that it is fine to medium (mean = 0.236 mm) with a sorting coefficient of 0.40.

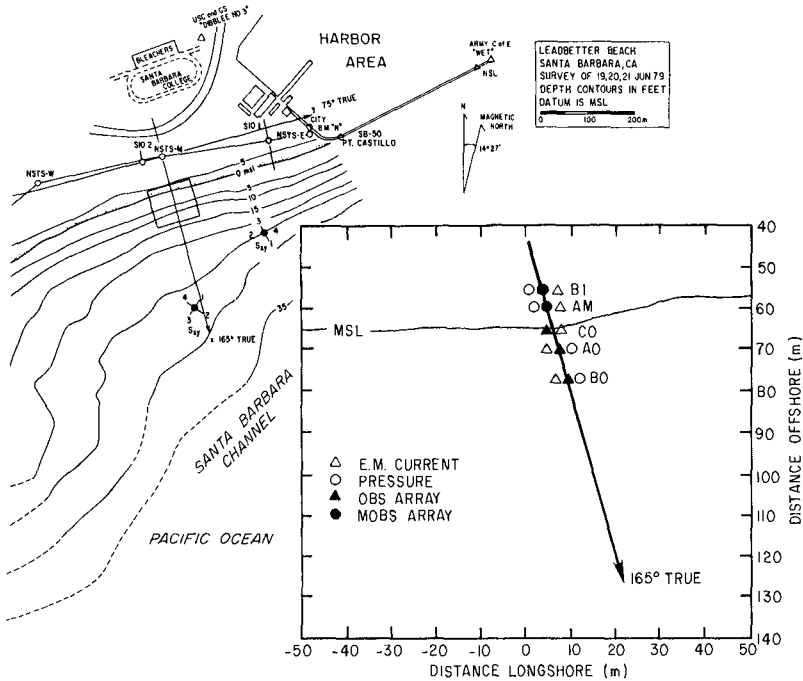

Fig. 1. Study site, including main cross-shore transect and expanded view showing instrument locations.

## TECHNIQUES

## Suspended sediment sensors

Suspended sediment concentration was measured with an optical backscatter sensor (OBS) developed at the University of Washington (4). An OBS sensor consists of a stainless steel housing 19 mm in diameter by 11 mm in length (Fig. 2). It houses an infrared emitting diode (IRED) with peak radiant intensity at 950 nm, a silicon photo-voltaic cell with peak spectral response at 900 nm, and an appropriate filter to limit transmittance from incident light. The optical components are encapsulated in the sensor head with clear epoxy resin. When operating, a scattering volume of 1.3 cc is irradiated through a 5.6 mm aperture at the geometric center of the photo-detector by a IR-beam with a half-cone angle of  $14^\circ$ . Backscattered radiation ( $110\text{-}165^\circ$ ) is converted to photocurrent by the detector oriented in a plane normal to the emitter beam axis and located close to it.

Fig. 2. OBS sensor and cut-away view.

A representative calibration curve for an OBS sensor using a beach sand with median diameter of 0.165 mm is shown in Figure 3. The response of the instrument is linear in the concentration range of 0.1 to 100 ppt by weight. The response of the instrument is minimal to air bubbles injected into the calibration tank (indicated in Fig. 3 by arrows). Each optical sensor was individually calibrated with Leadbetter Beach sediment before and after the Santa Barbara experiment. The instrument response was linear in the concentration range from 0.1 to 150 ppt and 0.1 ppt is the threshold of detection.

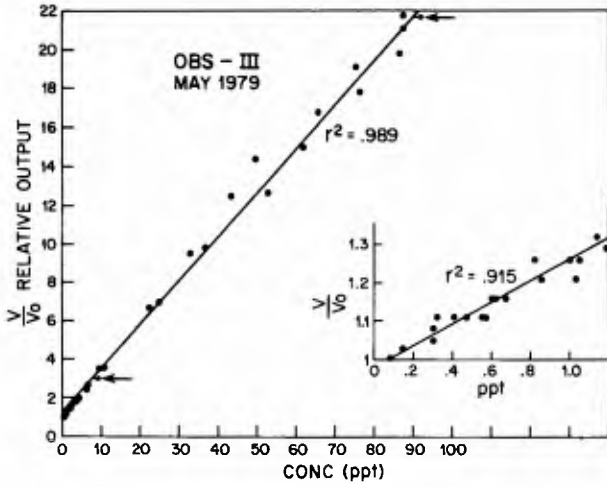

Fig. 3. Calibration curve and expanded scale for values <1.2 ppt.

Fig. 4. MOBS (left) and OBS sensor arrays.

### Sensor arrays

To meet the program objectives vertical arrays of OBS sensors were placed on a transect across the surf zone; vertical arrays were constructed in two sizes. An OBS array consists of five sensors mounted in a steel tube with a logarithmic spacing between sensors (Fig. 4). The total length of the array is 51 cm and the spacings between sensors is 3, 6, 12, and 30 cm. This configuration was used in the outer surf zone where water depths were  $>0.5$  m. Plastic "shields" were fitted on the lower sensors to minimize damage from moving cobbles in the surf zone resulting from storm conditions.

A miniaturized version of the OBS array was used in the inner surf zone where water depths were generally  $<0.5$  m. The miniature array (MOBS) consists of five OBS sensors mounted on a structural rod and encapsulated in plastic. The length of the MOBS array is 16 cm and the spacings between sensors is 3, 3, 5, and 5 cm (Fig. 4).

Up to five suspended sediment sensor arrays (OBS and MOBS) were deployed in proximity to current meters and pressure transducers placed along a primary cross-shore range line (Fig. 1). The OBS sensor arrays were cantilevered into the flow from pipes jettied into the bottom. Sensor electronics were buried in the seabed beneath each OBS sensor array and connected to the shore laboratory with a multiconductor cable. The MOBS sensor arrays were suspended from a tripod structure jettied into the upper beach face. A current meter and pressure gauge or wave staff also were mounted on each tripod. Sensor electronics were strapped on the tripod well above the sea surface and the multiconductor cable connecting the sensor electronics to the shore was buried.

All arrays were mounted vertically with the lowest sensor 3.5 cm off the seabed and the highest sensor located at 64.5 cm and 19.5 cm above the seabed for OBS and MOBS arrays, respectively. The elevation of each array was monitored before and after each data series.

OBS arrays (AO, BO, and CO) were located 6 m west of the main range line and on the same isobath as an EM current meter ( $z \approx 45$  cm) and a pressure sensor ( $z \approx 20$  cm); MOBS arrays (AMO, BMO) were located within 50 cm of an EM current meter positioned at  $z = 4$  cm (Fig. 1). All sensor output signals were transmitted continuously to the shore station and subsequently scanned and recorded in the NSTS data system.

### Data collection

The basic strategy of the sampling program was to maintain a cross-shore transect of OBS and MOBS arrays over as wide a range of wave conditions as possible. Data were collected on a daily basis between 7 and 24 February 1980. Each data series consisted of a time series of approximately 2-4 hours duration with one or more of the sensor arrays operating. Figure 5 shows the data series collected by individual sensor arrays relative to significant wave height ( $H_s$ ), which varied from about 0.3 to 1.8 m over the duration of the experiment.

ANALYSIS

Data set

During the experiment, 15 suspended sediment data series were collected (Fig. 5). Each consisted of continuous sampling of all operational sensor arrays, along with measurements of velocity, water level, and beach profiles (made by other NSTS investigators). For a variety of reasons it was not possible to analyze all of the data collected. Several data series were collected during periods of very low tides when sensors were not continually submerged. Also, some suspension events of nearshore sand were obscured in data collected during a severe storm because the quantity of very fine sediment in the surf zone due to storm drain flooding in Santa Barbara increased the background signal levels.

After inspecting all of the data records a data quality index was used to choose the data series that were analyzed. The primary considerations were that the data series spanned a range of wave conditions, had low background signals from washload, provided reasonable coverage

across the surf zone, and required a minimum amount of editing. Six data series (13.1, 13.2, 14.1, 14.2, 23.3, 24.1, Fig. 5) were chosen for analysis. Within these six data series, thirty segments representing different tide levels were chosen arbitrarily for averaged data analyses (34-min averages). For a tabulation of this data set see (24).

#### Suspended sediment

Three categories, high frequency data analysis, averaged data analysis, and sediment transport calculations and predictions, were employed. Initially, the raw data from all sensor outputs were block averaged to a 2 Hz sampling rate and converted to scientific units. An example of a 6 1/2-min data series is shown in Figure 6. Data included

Fig. 6. A 7-min time series during data series 24.1.

are (A) water depth  $h$ , (B) on-offshore velocity component  $u$ , (C) longshore velocity component  $v$ , (D-H) suspended sediment mass concentration at five levels above the seabed, (I) total immersed weight suspended sediment load  $G_s$  and depth of erosion required to supply the suspended load  $b$ , (J) immersed weight suspended sediment longshore transport per unit width of seabed  $i_{\ell s}$ . The values of  $(G_s)$ ,  $(b)$ , and  $(i_{\ell s})$  were computed every 1/2 s using the following equations:

$$G_s = \frac{\rho_s - \rho}{\rho_s} g \int_0^h C dz \tag{1}$$

$$b = \frac{\int_0^h C dz}{\rho_s C_b} \tag{2}$$

$$i_{\ell s} = G_s v \tag{3}$$

where  $\rho_s$  and  $\rho$  are sediment and fluid density;  $g$  is acceleration of gravity,  $C$  is suspended sediment mass concentration,  $h$  is total depth, and  $C_b$  is the volume concentration of the seabed (0.6), and  $v$  is longshore component of velocity.

The second category of analysis involved the computations of mean values of various sediment parameters. The averaging period for these computations was taken as 2048 s or approximately 34 min. This period is thought to be sufficiently long to give stable averages and yet short enough to minimize tidal variations during the averaging period. The mean suspended sediment concentration at each level above the bed  $(\bar{C})$  and the mean immersed weight suspended sediment load  $(\bar{G}_s)$  were determined by averaging the values of  $C$  and  $G_s$  over 2048 s.

The third category of analysis included computations of immersed weight suspended sediment transport rate from the field measurements and the prediction of the total longshore transport rate using the methods of (16,17). The local immersed weight longshore transport rate of suspended sediment  $(\bar{i}_{\ell s})$  occurring at each sensor array was computed as shown in equation (4) and the total longshore transport rate of suspended sediment  $(I_{\ell s})$  was determined by summation of the individual measurements of  $\bar{i}_{\ell s}$  made across the surf zone (eq. 5). Equations 6 and 7 outline the computational methods for predicting the total longshore transport rate of sediment as developed by (16,17):

$$\bar{i}_{\ell s} = \bar{G}_s v \tag{4}$$

$$I_{\ell s} = \sum \bar{i}_{\ell s} \Delta X \tag{5}$$

$$I_{\ell} = KP_{\ell} \quad \text{where } K = 0.77 \text{ and } P_{\ell} = (EC_n)_b \sin \alpha_b \cos \alpha_b \tag{6}$$

$$I_{\ell} = K'(EC_n)_b \frac{\bar{v}_{\ell}}{u_m} \quad \text{where } K' = 0.28 \tag{7}$$

where  $X$  is distance from shoreline,  $(EC_n)_b$  is the wave-energy flux at the breaker,  $\alpha_b$  is the breaker angle,  $v_l$  is the longshore current velocity at the mid-surf position,  $U_m$  is the maximum horizontal orbital velocity evaluated at the breaker zone,  $K$  and  $K'$  are dimensionless coefficients determined empirically, and other terms are as defined above.

Because of the small number of sensor arrays deployed, measurements of  $\bar{I}_{1s}$  made at different stages of the tide (and hence for different values of  $X/X_b$ ) during a data series were combined to increase data coverage across the surf zone.

#### Waves and currents

Various characteristics of the waves at breaking are required to calculate the littoral transport rate (eqs. 6 and 7). These include breaker height, breaker depth, breaking angle, and bottom oscillatory velocity. As all the variables were not measured throughout the experiment (e.g., angle of breaking), predictions of breaker characteristics for each data series were made using offshore pressure data. Waves measured at the offshore wave array (see Fig. 1) were subjected to computer analysis that included considerations of refraction and breaking. Where possible the predicted breaking characteristics were compared to the observed breakers to test the methods; however, the predicted breaker characteristics were used for calculations of littoral transport. The detailed procedure for this analysis and a data tabulation is given in (24). The measured longshore velocity used in eq. 7 was estimated by plotting values of  $\bar{v}$  obtained from the current meters placed across the surf zone and interpolating between points to  $X/X_b = 0.5$ . The values of  $P_1$  and  $(EC_n)_b \bar{v}_1 / u_m$  (eqs. 6 and 7) were computed using rms rather than significant wave conditions to be consistent with other studies.

### RESULTS AND DISCUSSION

#### Suspended sediment

Some general observations of suspended sediment characteristics from data series 24.1 are summarized as follows:

- 1) The suspended sediment concentration near the seabed ( $z = 3.5$  cm) varied over a wide range and reached  $180 \text{ kg m}^{-3}$  during individual suspension events (Fig. 6D). The depth of erosion ( $b$ ) required to supply the measured suspended load is approximately 1-2 cm and is comparable to the mixing depth evaluated in various sand tracer studies (9,18).
- 2) The concentration decreased systematically away from the seabed (Fig. 6D-H).
- 3) Individual suspension events were in phase with bores propagating across the surf zone. Where the offshore directed flow prior to an incoming bore attained significant magnitude (i.e., the threshold of grain motion was exceeded), a sediment suspension event was initiated and then reinforced by the passage of a bore propagating shoreward.

4) The frequency and duration of sediment suspension events were strongly correlated with incident wave conditions. Low frequency oscillations of onshore/offshore velocity and water level were observed in many data records. Large temporal variations in the magnitude of suspension events also occurred; they appear to be of greatest magnitude in relation to major offshore flows of water corresponding to troughs in the low frequency signals.

Four representative suspended sediment profiles from data series 24.1 are shown in Figure 7. Two are from the breaker region ( $X/X_b = 0.84, 0.96$ ) and two are from the mid-surf zone ( $X/X_b = 0.49, 0.60$ ). The position of the lowest sensor in these profiles was 3.5 cm above the seabed which is over 150 grain diameters above the boundary ( $Md = 0.23$  mm); thus any particles measured by the sensors are considered as suspended load (6,23). The dominance of suspended load transport at  $z = 3.5$  cm is also suggested by the maximum measured volume concentration of solids being 0.07 which is below the minimum volume concentration (0.08 or 0.09) considered necessary to produce a bedload transport layer supported by intergranular collisions (1,2,8). A generalized suspended sediment profile (11,12), collected shoreward of the breaking point, which was considered to be representative of suspended sediment profiles

Fig. 7. Vertical profiles of mean values of suspended sediment from two sensor arrays during data series 24.1. Time of day indicates beginning of each averaging period and  $X/X_b$  indicates relative position across the surf zone where  $X_b$  equals breaking point. Open circles and dashed line are explained in the text.

associated with plunging breakers, is included (Fig. 7). The profiles plotted from data series 24.1 generally are similar to previous results (11,12). The mean concentration measured at  $z = 10$  cm for data series 24.1 ranges from approximately  $2\text{--}12 \text{ kg m}^{-3}$ , compared to  $3 \text{ kg m}^{-3}$  reported by (11,12), and the concentration increases logarithmically toward the seabed.

Sediment transport

The longshore transport rate of suspended sediment ( $I_{\ell s}$ ) was determined for each of the six data series (Fig. 8). Values of  $I_{\ell s}$  were plotted according to their relative position within the surf zone ( $X/X_b$ ), and the area encompassed by the points is proportional to  $I_{\ell s}$ .

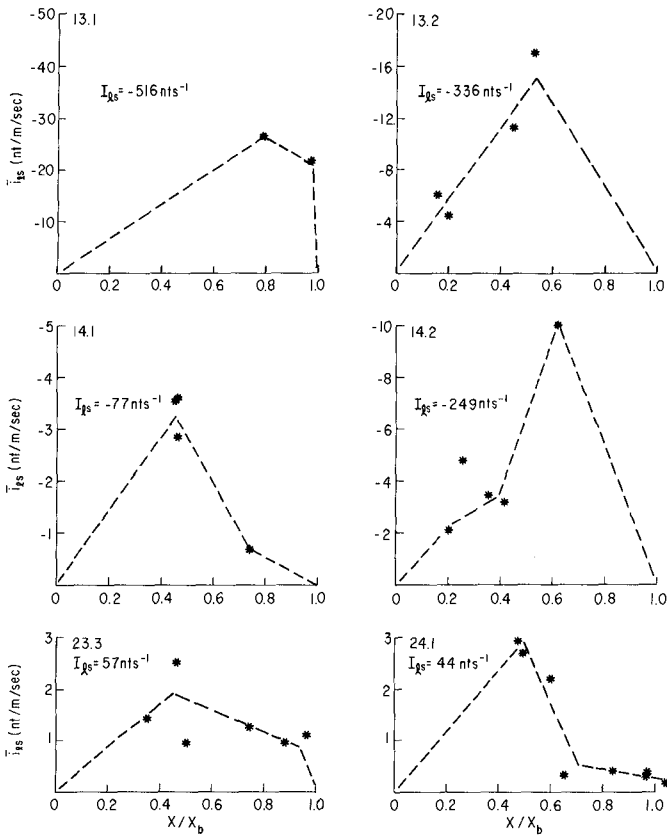

Fig. 8. Cross-shore distribution of  $I_{\ell s}$ . The total longshore transport rate ( $I_{\ell s}$  from eq. 3) is noted for each curve.

The curves have been extended to zero at the positions of  $X/X_b = 0$  and 1.0. Thus, any swash zone transport or transport beyond the breaker point was not considered. The shapes of the curves, although irregular, follow a general pattern, with maximum longshore transport approximately in the mid-surf position. The data points tend to be grouped on either the shoreward or the seaward side of  $X/X_b = 0.5$ , and no single data series spanned the width of the surf zone. Nevertheless, visual inspection of the six data series appears to justify the way in which the curves are extrapolated to zero. This general distribution of  $I_{\ell s}$  suggested by previous field measurements (3,11), laboratory measurements (19), and theoretical predictions (14). The area under each curve multiplied by the width of the surf zone represents the measured value of  $I_{\ell s}$  (Fig. 8 and Table 1).

Table 1. Longshore transport calculations.

Data Series	Average $P_{\ell}$ (nt/s)	Average $(ECn)_b v_{\ell}/u_m$ (nt/s)	Width $X_b$ (m)	Beach slope $\beta$	Measured $I_{\ell s}$ (nt/s)	K	K'
13.1	-203	-1470	34	0.041	-516	2.54	0.35
13.2	-374	-2360	48	0.041	-336	0.90	0.14
14.1	-229	-462	55	0.037	-77	0.34	0.17
14.2	-278	-618	60	0.037	-249	0.89	0.40
23.3	19	207	55	0.022	57	3.00	0.28
24.1	17	75	35	0.021	44	2.59	0.59
Average				0.033		1.71	0.32

It is also of interest to know how the longshore transport rate of suspended sediment compares with the estimated total littoral transport rate. Assuming that equations 6 and 7 predict the total longshore transport rate ( $I_{\ell}$ ), as discussed by (16), the ratio of  $I_{\ell s}$  to  $I_{\ell}$  represents the contribution of suspended sediment to the total. In Figures 9A and B the values of  $I_{\ell s}$  from this study (solid circles) have been superimposed on a plot from (16).

In Figure 9A the data from this study tend to fall above the predictive line while the agreement in Figure 9B is excellent. The average value of K is 1.71, approximately twice the value determined from previous studies (eq. 6,  $K = 0.77$ ), whereas that of K' is 0.32 which is within 14% of the value determined previously (eq. 7,  $K' = 0.28$ ).

According to (16), equation 7 (Fig. 9B) is the more fundamental of the two sand transport relationships and should be applicable regardless of the origin of the longshore current ( $\vec{v}_1$ ), e.g., tide or wind generated, and currents of the cell circulation, or of oblique wave approach. It was also pointed out by (16) that it is usually easier to measure the longshore current than the breaker angle needed in the evaluation of  $P_{\ell}$  in equation 6. Further, it was demonstrated (18) that equation 7 is applicable where the longshore current was the net result of two opposing currents. The close agreement between the results of this study and previous studies (Fig. 9B) suggests that all of the longshore transport at Leadbetter Beach can be accounted for by suspended

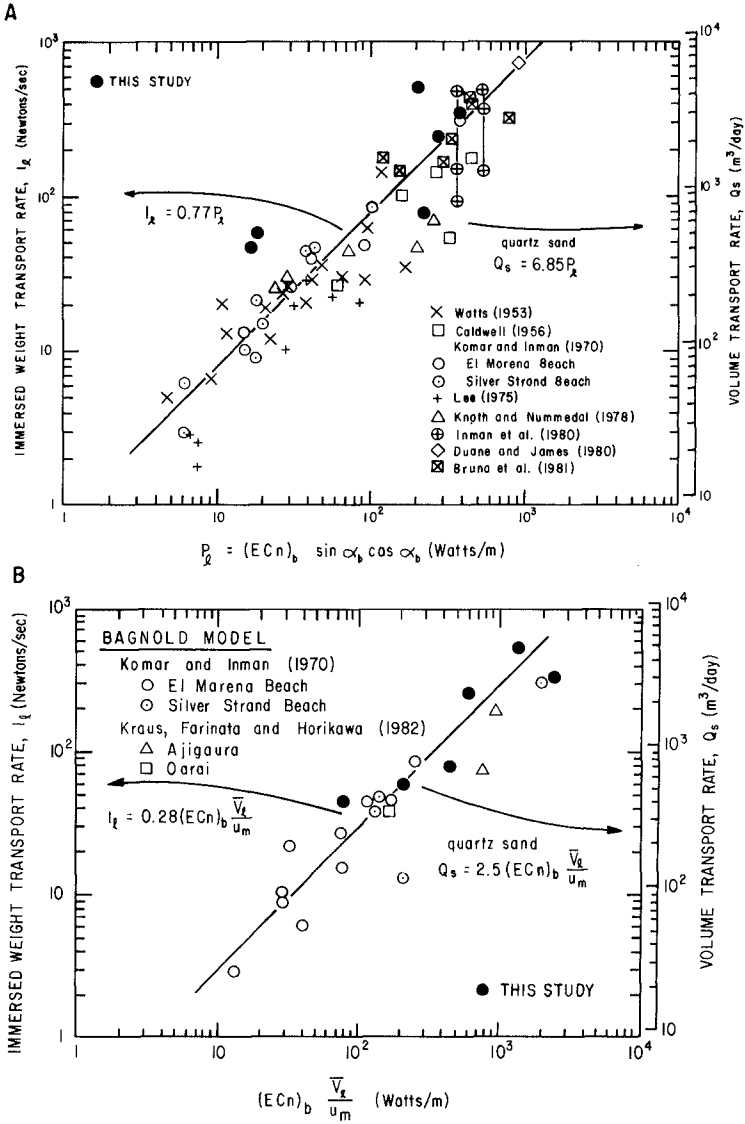

Fig. 9. Measurements of sand transport rates on beaches compared with wave conditions expressed as  $P_x$  of eq. 6 (A); eq. 7 (B) (16). Data from this study are superimposed on each curve.

sediment transport and that equation 7 adequately predicts the total immersed weight longshore transport rate of suspended sediment in the surf zone.

The ratio of  $I_{ls}$  to  $I_l$  is significantly higher than has been generally measured or estimated by other investigators (Table 2).

Table 2. Ratio of suspended sediment to total longshore sediment transport rate.

Study	Lowest Measurement (cm)	$\frac{I_{ls}}{I_s}$
Komar (1978) (15)	7.6-10	0.07-0.26
Inman et al. (1981) (9)	10	0.15-0.20
Kana and Ward (1981) (13)	5	1.0
		storm post-storm
Downing (1983) (3)	3.5	0.30
This study	3.5	0.47
		1.0

Although it would be expected that physical processes in the surf zone would have a major influence on sediment suspensions and hence might account for the differences observed above, there are also major differences in sampling techniques that play an important role.

The relative quantities of suspension transport versus bedload transport was analyzed by (15) who developed an equation to estimate the ratio  $I_{\text{susp}}/I_{\text{total}}$  ( $= I_{ls}/I_l$ ). The important parameters in this equation are the mean volume concentration ( $\bar{c}$ ), beach slope ( $\tan \beta$ ), and ratio of breaker height to breaker depth ( $\gamma$ ). The analysis included pump data (5,25) and diver collected data (10). Sediment samples were collected no closer than 7.6 cm from the seabed and the results suggest that the value of  $I_{ls}/I_l$  is  $<0.26$ .

In another study (9) using diver-operated samplers, suspended sediment samples were not collected within 10 cm of the seabed; the ratio of  $I_{ls}/I_l$  was 0.15-0.20. Bulk water samplers (13) were mounted from a pier with the lowest 5 cm above the seabed. During storm conditions the ratio of  $I_{ls}$  to  $I_l$  was high, similar to our results. During post-storm conditions, however, the value of  $I_{ls}/I_l$  decreased to 0.30.

A study (3) using sensors and methods similar to the present study obtained a much lower  $I_{ls}/I_l$  ratio (0.47). Except for the experimental site being a wide dissipative beach rather than a narrow, reflective beach, the two studies were similar; the difference in  $I_{ls}/I_l$  is quite possibly related to dynamic processes.

For the present study the mean values of  $c$  for all data (average of  $G_s$  converted to volume concentration) is  $1.46 \times 10^{-3}$ ,  $\tan \beta = 0.033$ , and  $\gamma = 0.53$ . Using these values in the equation of (15) gives an estimate of  $I_{ls}/I_l \approx 0.92$  which is in agreement with the results shown in Figure

9B. This further suggests that our observations are consistent with previous analyses (15) and that  $I_{\ell s}/I_{\ell}$  is predictable on the basis of mean volume concentration, beach slope, and the breaker height to breaker depth ratio.

#### CONCLUSIONS

1. Sediment transport in the nearshore zone occurs as individual suspension events associated with bores propagating landward. Sediment concentrations as high as  $180 \text{ kg m}^{-3}$  are measured at 3.5 cm off the seabed under passing bores and may be greater than  $50 \text{ kg m}^{-3}$  at 55 cm elevation. Individual suspension events occur abruptly and may last only seconds. Temporal variations of the magnitude of suspension events are observed in most data records. These variations in magnitude appear to be related to the bore amplitude and low frequency oscillations of the velocity component within the surf zone.

2. Mean concentration profiles show an approximately logarithmic decrease away from the bed.

3. Maximum erosion depths required to supply each suspension event are approximately 1-2 cm, comparable to the mixing depth evaluated in various sand tracer studies.

4. The longshore transport rate of suspended sediment is maximum within the mid-surf region and decreases towards both the breaking point and the shore. Suspended sediment transport appears to be high in the swash-backwash region of the shore; however, detailed data analysis has not been completed.

5. The total immersed weight longshore transport rate of suspended sediment accounts for all of the total longshore transport rate as predicted by the equations developed by (16,17). The suspended sediment transport rate as measured during the experiments at Leadbetter Beach can be predicted by equation 7.

#### ACKNOWLEDGEMENTS

We would like to thank S. Woods and R. Johnson for their expert advice and fine craftsmanship in fabricating the instrumentation used for this study. H. Smith provided energetic assistance in gathering the field data and B. Jaffe assisted in the early stage of data analysis. This research was supported in part by a National Sea Grant (NOAA) contract #SGNOAA NA81 KA-D-0030 and Office of Naval Research Contract N00014-84-C-0111.

## CHAPTER ONE HUNDRED TWENTY ONE

### SEDIMENT RESPONSES TO NATURAL WAVES

Alexander F. Nielsen and Angus D. Gordon\*

#### ABSTRACT

This paper is concerned with wave-induced seabed forcing functions and sediment responses on the Australian South East Continental Shelf. The transfer of surface displacement energy to near-bed oscillatory water movement energy is examined with respect to linear and second order wave theories. Seabed sediment responses are examined by comparing field bedform size data to laboratory data with a view to determining characteristic spectral parameters that may be applied with existing theories to predict sediment responses under natural wave spectra. A rippled bed incipient motion criterion incorporating the contribution to boundary shear stress made by the presence of bedforms as well as particle size is developed empirically from field data using dimensional analysis techniques.

#### 1. INTRODUCTION

Continental shelves are a rich source of consumables including food, minerals, oils and aggregate sands. Increasingly, they are being seen as a resource also in terms of wastes disposal, typically including dredge spoil, toxic substances and sewage. As advances in technology allow expansion in shelf resource utilisation the need to further the understanding of shelf processes increases. Of particular interest are the interactions between shelf sediments and sea bed mounted structures.

The present understanding of shelf sediment movement is based mainly on theoretical studies and laboratory experiments. While these studies have produced considerable advances in the understanding and theoretical description of sediment movement in a wave and current environment, they have mostly been carried out only for periodic, progressive, near-sinusoidal wave motions. The superposition of steady currents, where relevant, is normally based on a wholly theoretical approach. The theoretical treatment of natural wave spectra is complex and laboratory data are not readily available as random wave generators for flume and water tunnel experiments have only recently been developed.

---

\* Coastal Branch, New South Wales Public Works Department, 140 Phillip Street, Sydney, 2000, Australia.

To meet the challenge of providing sound advice on proposed continental shelf developments off South East Australia, the application of monochromatic, theoretical and laboratory work to field conditions was studied with respect to three areas of particular interest:

- . the synthesis of natural sea surface displacements and seabed water motions;
- . the determination of characteristic parameters from natural wave spectra which enable the application of monochromatic theories of sediment motion to situations where finite spectral bands exist;
- . the threshold of sediment movement under natural wave spectra on a rippled bed.

## 2. FIELD DATA

Concurrent studies off Sydney being carried out for various projects by the authors made available field data sets in 24, 60 and 80 metres water depth (Figure 1). At each site a Marsh McBirney 585 adaptive recording electromagnetic current meter was installed on the seabed in a metal frame with the sensor 1 metre above the bed. Details of the recording and calibration data are given in Gordon and Hoffman (in prep) and Nielsen (1984). Three years of data were collected at the 24 metre site while 6 months data were taken at the two deeper sites.

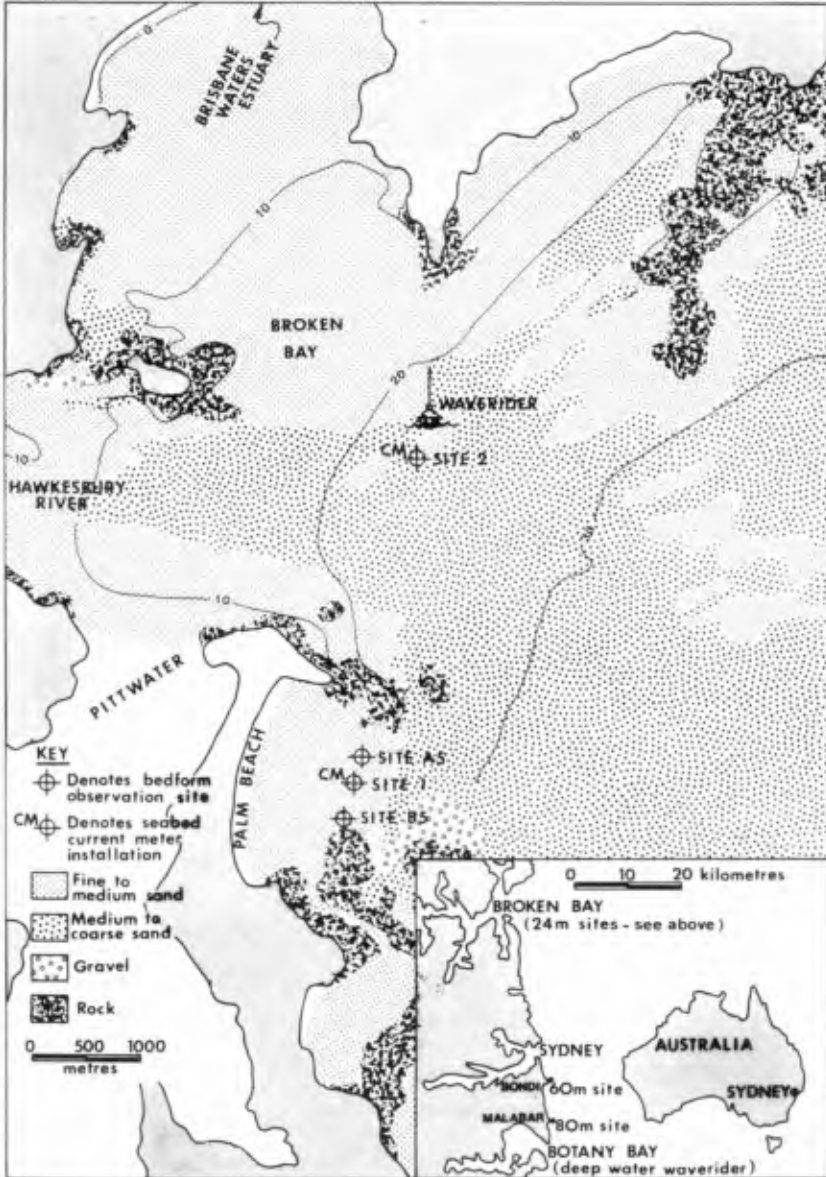

Two Datawell 700 mm diameter waverider buoys were used. One buoy had been operating for some 13 years in deep water off Botany Bay, 7 km south of the 80 metre site (Youll, 1981). The other was installed adjacent to the 24 metre site (Site 2, Figure 1).

Seabed surface features were mapped using an Atlas Deso 20 Fathometer and Klein side-scan sonar equipment calibrated by sediment sampling, bottom photography and diver observation (Gordon and Hoffman, 1984, and in prep.). Seabed observations at the 60 and 80 metre sites were made using a time lapse camera system synchronised with the current meter recording program. Seabed observations at the 24 metre sites were made by divers. The sediment characteristics at each site are given in Table 1.

### 3. RESULTS

#### 3.1 Synthesis of Sea Surface Displacements and Near-bed Wave-induced Water Motions

Sea surface displacement energy spectra were compared with seabed wave-induced current velocity spectra utilising wave theories to examine the modification with depth that occurs to the spectral energy distribution and to develop a technique for generating seabed spectra at sites remote from the sea surface wave data collection point.

For each waverider and current meter record a spectral energy/frequency distribution was obtained using a fast Fourier transform technique. Spectral estimates were made at 0.1 Hz frequency intervals and cross-spectral correlations were carried out at the three water depths as follows (see Nielsen (1984) for detailed discussion of these parameters):

$$\left[ \frac{u}{H} \right]_f = \frac{1}{2} \cdot \left[ \frac{M_c(o)}{M_w(o)} \right]^{1/2} \cdot \left[ \frac{S_c(f)}{S_w(f)} \right]^{1/2} \quad \text{Eqn. 1}$$

where:

(u)f = maximum, wave-induced, near-bed horizontal water particle velocity with period 1/f;

(H)f = wave height with period 1/f;

M(o) = is the area under the spectral energy/frequency distribution graph;

S(f) = is the normalised spectral estimate at frequency band f;

Subscript c = current meter; and

subscript w = waverider.

These empirical values were compared with theoretical computations based on both Stoke's 2nd Order and Airy theories at the 24 metre site and with Airy theory at the 60 and 80 metre sites. A typical cross-spectral correlation for a set of concurrent waverider and adjacent current meter records at the 24 m site is shown in Figure 2. Here the correlation was virtually exact compared with Stoke's 2nd Order wave theory over the frequency range encompassing most of the current energy. Some two thousand current meter records were correlated with the deepwater waverider data, and statistically analysed and compared to Airy Theory (Figure 3). In general it can be seen that Airy theory applied to the deepwater waverider data over-estimates near-bed velocities, particularly at the shallower depths. This effect at the 24 metre site is attributable to wave height attenuation through wave refraction and shoaling. Further attenuation can be attributed to friction and diffraction. These results and other factors are discussed in more detail in Gordon and Hoffman (in prep.) and Nielsen (1984).

CROSS-SPECTRAL CORRELATION BETWEEN SELECTED NEARBY WAVERIDER AND CURRENT METER RECORDS

FIGURE 2

ACROSS SHELF CROSS-SPECTRAL CORRELATIONS BETWEEN DEEPWATER WAVERIDER AND CURRENT METER RECORDS

FIGURE 3

The results of the analyses showed that a reasonable approximation of wave-induced seabed current energy can be made by spectral transfer of waverider data to the seabed using monochromatic wave theories to obtain values of the velocity/wave height ratio in Equation 1. Where refraction, diffraction, shoaling and the effects of bottom friction are significant, the theoretical values of the velocity to wave height ratio may be adjusted on the basis of numerical modelling. However, where wave height attenuation is severe the application of simple numerical models may not be appropriate (Nielsen, 1984).

### 3.2 Characteristic Spectral Parameters for Sediment Motion

To apply the existing understanding of sediment transport processes to natural field situations it was first necessary to examine the appropriateness of characterising natural energy spectra in terms of displacement and frequency parameters. It was considered that an examination of bedform response to near-bed velocity spectra could be used to indicate and evaluate such characteristic parameters if appropriate; there being considerable data available from flume and oscillating water tunnel experiments concerned with bedform response to periodic, progressive, near-sinusoidal water movements.

Laboratory data were examined and it was found that the bedform curves of Mogridge and Kamphuis (1972) described and quantified well the existing understanding of bedform generation and degeneration under monochromatic wave conditions (Figure 4). Also, Nielsen (1984) reviewed the field data of Inman (1957) and compared them to the bedform curves of Mogridge and Kamphuis. To obtain a good agreement between these data and the laboratory results it was necessary to increase Inman's calculated significant hydraulic parameters by a factor of 1.5. Inman's hydrodynamic data were based on fathometer records and that, coupled with the considerations of depth effect on surface displacement energy, is considered to have resulted in his over-estimation of near-bed velocities and displacements.

At the 80 metre site no bedform generation was observed during the 6 month deployment period. The film indicated that sheet flow rapidly followed the onset of transport. This is believed to be due to the high fines content (Table 1) and the high level of biogenic activity at the site which together produced a partly cohesive bed (Gordon and Hoffman, in prep.).

While at the 60 metre site some bedform activity was noted these bedforms were poorly developed and the resolution of the film was such that no accurate measurements of bedform size could be made (Gordon and Hoffman, in prep.).

The most reliable field data set comprised forty-three separate events for which bedform geometric data were obtained at four locations adjacent to the 24 metre site (Figure 1).

The bedform observations were taken by divers and included measurements of ripple wavelength, height, and crest orientation, assessments of ripple asymmetry, general bedform configurations and whether the sand grains on the bed were active or inactive. The data

COMPARISON OF DATA FROM INMAN & BOWEN (1963), KENNEDY & FALCON (1965), HORIKAWA & WATANABE (1967), CARSENS ET AL. (1969) & LOFQUIST (1980) WITH BEDFORM CURVES MODIFIED AFTER MOGRIDGE & KAMPHUIS (1972) FIGURE 4

are summarised in Table 2 and detailed in Nielsen (1984). The ripple wavelengths were measured by placing a scaled ruler over and normal to the ripple crests. Most of the wavelength measurements over 100 mm were made to the nearest 50 mm. The accuracy of wavelength measurements is considered to be  $\pm 25$  mm for those measurements recorded to 50 mm, and  $\pm 10$  mm for measurements recorded to 10 mm. Ripple heights were measured by placing a second scale vertically and normal to the ruler across the ripple crests, measuring down to the ripple troughs. In most cases, these measurements were taken to 10 mm (or in inch, equivalent to 25 mm) and the accuracy of these measurements is considered to be  $\pm 10$  mm. Ripple orientations were measured by diver compass sightings along the ripple crests. Measurements were made to magnetic north with an estimated accuracy of  $\pm 15^\circ$ . It is to be noted that the bedform patterns on the seabed where measurements were taken were not always uniform. The divers assessed the bedform distributions and took measurements where "average" bedform characteristics prevailed. The accuracies quoted above do not apply to the variations in bedform size parameters observed at the measurement sites.

The water particle velocity measurements could not necessarily be taken simultaneously with the bedform measurements. As bedform measurements were made at meter servicing times, most (70%) of the bedform measurements were made within seven hours of the velocity readings. As waverider data were generally available every six hours, bottom velocities and bedform data could be related through the waverider records, using the method for bottom transfer (section 3.1), when there were large elapsed times between the two.

As reported by Inman (1957), the sand ripples observed in this study varied widely in size, shape and duration. Some ripples were uniform with long parallel crests, others occurred in complex patterns. During some observations the ripples, while active, appeared not to change much in time, whereas during other observations the ripple bed erupted and disappeared under large wave surges only to rapidly reform following the passage of the surge. It was difficult in most cases to ascertain if the ripples measured were formed by the waves present at the time of measurement. One reason for this was that to avoid decompression procedures the divers had a limited bottom time to observe the ripple behaviour. If the ripples were active it was not necessarily clear if they were changing to a new equilibrium with the wave forces or whether they had attained a stable form. In some cases, a judgement could be made as to whether the ripples were in equilibrium with the wave climate by comparing ripple orientations to wave directions. In other cases this was not possible. In the main the divers, including the authors, were experienced investigators.

A convenient way of describing ripple geometry is by the ripple steepness  $\eta/\lambda$ . The bedform curves of Mogridge and Kamphuis indicate that there is a maximum attainable value of ripple steepness. They found that while this maximum value varied according to the specific gravity of the sand particles, for quartz sand under the range of natural field hydraulic conditions pertaining to this study, 0.16 is the maximum attainable value of steepness for wave-generated ripples (based on regular, near-sinusoidal, periodic fluid motion). This result is generally in agreement, albeit at the lower end of the

range, with results from other studies (Nielsen, 1984).

The data on ripple steepness are presented in Figure 5. These data portray a scatter around an average value of  $\eta/\lambda = 0.18$ . For most of the data the maximum measured value of  $\eta/\lambda$  was 0.25. However, a few extreme values of  $\eta/\lambda = 0.4$  were measured. Measurement error in part may account for the scatter portrayed. It is significant to note that the scatter reduced with increasing ripple wavelength. This tendency was observed also by Inman (1957, see his Figure 14); the higher values of  $\eta/\lambda$  reported by Inman were associated with the smaller ripple wavelength measurements. Inman also observed less scatter for data obtained from coarser sediments, a tendency also suggested in these data.

To determine the characteristic spectral parameters, the field data were plotted initially against the bedform curves of Mogridge and Kamphuis using significant hydraulic spectral parameters with Tf peak (not presented). It was found that the dimensionless wavelengths and wave heights of the field data points were considerably larger, on average by a factor of 2.15, than those of the laboratory data. The reason for the departure from the laboratory results was considered to lie in the choice of the velocity and displacement parameters used in the calculations of the data point co-ordinates. Consideration of the authors' diving observations while collecting the seabed data and the consistency with Inman's results suggested that maximum rather than significant spectral parameters would be more appropriate.

Goda (1974) showed that the ratio of maximum to significant wave height parameters has a mean value of 1.65 and a standard deviation of 0.26. He also showed that the ratio of the period parameter associated with the maximum wave to the period associated with the peak spectral

FIGURE 5

estimate lies in the range of 0.5 to 1.4. Adopting maximum spectral velocity parameters, it was found by iterative procedures that a period parameter of value 1.3  $T_{peak}$  produced a reasonable agreement between the field data and the bedform curves of Mogridge and Kamphuis (Figure 6).

The bedform investigation, therefore, suggested that maximum spectral hydraulic parameters should be used when applying existing theories based on monochromatic wave studies to shelf bed response under natural wave action; the inference being that these maximum spectral parameters should be used also for sediment entrainment and transport calculations.

### 3.3 Incipient Motion on a Rippled Bed

There are very little laboratory data and virtually no field data on the threshold of sediment movement on a rippled bed; most of the experimental work has been directed towards evaluating incipient motion criteria on flat beds.

Eagleson and Dean (1959) and Carstens et al. (1969) analytically considered the general condition of the threshold of motion. Their analyses were based on the hydrodynamic forces of drag and lift and the submerged weight on a typical protruding particle. Additional surface forces arising from the inertial reaction of the particles and of the fluid around the particles were not included because initial movement under wave action was observed to occur at the maximum, horizontal, near-bed velocity; that is, when acceleration in the flow is negligible.

The difficulty in applying the method, however, lies in the calibration of the constants. Where boundary layer effects become significant with oscillating flow over a duned bed, the analytical solution to the incipient motion criterion becomes very complex. It was therefore considered practical to determine empirically a threshold criterion using dimensional analysis techniques.

It was considered that for flow over a rippled bed, the important dimensionless variables were:

- (1)  $\frac{\rho u^2}{\gamma_s D}$  The sediment Froude number, being derived from the ratio of hydrodynamic surface forces on the sediment to the submerged weight of the sediment, which is essentially Shields parameter.
- (2)  $\frac{u D}{\nu}$  The particle Reynolds number upon which the sediment Froude number is dependent.
- (3)  $\frac{u R}{\nu}$  The bedform Reynolds number; a dimensionless variable introduced to take account of the effect of bedform height on bed roughness and, hence, the shear stress on the bed.

This set of dimensionless variables includes all the relevant characteristic parameters proposed by Mogridge and Kamphuis (1972) except for  $\rho_s$ , which was considered constant as the only relevant data found were observations made on quartz sand beds.

COMPARISON OF DIMENSIONLESS BEDFORM SIZE DATA WITH BEDFORM CURVES OF MOGRIDGE & KAMPHUIS (1972) FIGURE 6

The field data from the 24 metre site are plotted on Figure 7 using maximum spectral velocity parameters to determine the co-ordinates of the field data points. Unfortunately, insufficient data of good quality were available to confidently define curves of constant particle Reynolds number at incipient motion. Dashed curves, therefore, have been interpolated from these data to highlight the conceptual understanding of the relationship between the sediment Froude number, particle Reynolds number and bedform Reynolds number at incipient motion and to indicate the inaccuracy in determining this relationship from these data.

These curves not only take account of those observations where the sediment was described as being at the threshold of movement, such as "just active" or "crests flipping", but also of both the "inactive" and "active" observations. For a particular curve of constant particle Reynolds number, all data lying to the upper right hand side of the curve represent a seabed condition which is either "active", with higher or lower values of particle Reynolds numbers than the curve, or "inactive" with particle Reynolds numbers higher than the value of the curve. On the lower left hand side of a particular curve, active seabed conditions occur when the particle Reynolds number is of a lower value than that of the curve, and for an inactive seabed condition that falls within this region of the graph, the particle Reynolds number may have any value.

For small bedform Reynolds numbers, that is, for small bedform heights approaching a flat bed, the interpolated bedform curves suggest values of sediment Froude number for incipient motion in the order of 100, which values are two orders of magnitude higher than would be calculated following the method of Komar and Miller (1974). However, the behaviour of the curves is not known for conditions approaching a flat bed as the hydraulic conditions near a flat bed are quite different to those of a rippled bed. For a flat bed there is no flow separation or vortex formation as observed on rippled beds, therefore, the nature of the respective boundary layers must be quite different (Carstens et al., 1969).

Additional factors considered to be important with respect to defining the location of the curves of the critical particle Reynolds numbers at incipient motion include the adopted grain size parameter and the value of bedform height. Incipient motion occurs at ripple crests. While grain size data for the ripple crests were not taken, the divers observed that the grain size on the ripple crests was different to that in the troughs. Inman (1957) and Cook and Gorsline (1972) found that the crest grain size is in the order of 0.05 mm coarser than the average grain size for sands finer than 0.5 mm. The grain size adopted will affect the values of particle Reynolds number and sediment Froude number. Bedform height data are much more difficult to measure than bedform length data, which is reflected in the wider range of scatter in bedform height data in Figure 6. In addition to bedform height being more difficult to measure, there is a greater spectral variability in bedform height than in bedform length under natural wave motion. Both of these factors will affect the determination of the proposed bedform Reynolds number and hence the accuracy to which the curves of constant particle Reynolds number defining incipient motion can be determined.

NOTES :  $U_{m,100}$  = Spectral maximum, near-bed (100 cm above), wave-induced, maximum horizontal orbital velocity.  
 $U_{m,0} = 1.2 U_{m,100}$ ; the maximum velocity at dune crest (after Corstens et al., 1969).  
 Numbers to each data point are particle Reynolds numbers.  
 Comments to data points are additional diver observations not included in Tables 2 and 3.

RELATIONSHIP BETWEEN SEDIMENT FROUDE NUMBER, PARTICLE REYNOLDS NUMBER AND BEDFORM REYNOLDS NUMBER DEFINING INCIPENT MOTION ON RIPPLED BEDS  
 FIGURE 7

#### 4. CONCLUSIONS

The cross-spectral correlation analysis showed that by using an appropriate wave theory, it was possible to synthesise spectra of seabed oscillatory water particle motions with those of sea surface displacements. Further, this could be achieved at stations remote from the wave data collection site by applying suitable wave refraction, attenuation and shoaling factors obtained by monochromatic theories.

An examination of seabed response to natural wave spectra suggested that for applying monochromatic sediment entrainment and transport theories, calibrated to laboratory results, to shelf bed sediment transport studies, the appropriate characteristic spectral parameters are:

$$H_m = 1.65 H_s; u_m = 1.65 u_s; T_m = 1.3 T_p$$

This assumed that the bedform response mechanism was indicative and therefore typical of sediment movement mechanisms including incipient motion and entrainment. That the data were limited to a single water depth, a narrow band of slight wave conditions due to diving safety provisions, limited variation in quartz sand grain sizes and the difficulty of taking precise diver measurements, dictates that in the definition of these characteristic parameters, the constants 1.65 and 1.3 be seen as preliminary figures only. Further, it must be recognised that the overall aim was to develop a method of calculating sediment movements on the Continental Shelf for engineering projects.

The incipient motion investigation indicated that incipient motion on a rippled bed occurs at considerably lower energy conditions than on a flat bed for fine to coarse sands. The criteria for incipient motion on a duned bed include both particle roughness and bedform roughness, both affecting the level of shear stress at the bed. While trends in the field data are apparent, further data are required to confidently define the relationships between the Shields parameter, particle Reynolds number and bedform Reynolds number for incipient motion on a rippled bed.

#### 5. ACKNOWLEDGEMENTS

This paper is published with the permission of the New South Wales Public Works Department. The authors are indebted particularly to the following Departmental officers who also performed diving duties and made bedform measurements; Bandu Sena, John Hoffman, Doug Lord, Mike Nolan, Mike Geary, Bob Sneddon, Jim Lawler and Bruce Fidge.

## CHAPTER ONE HUNDRED TWENTY TWO

### Shore Approach at the Danish North Sea Coast, Monitoring of Sedimentation in a Dredged Trench

Karsten Mangor\*  
Torben Sørensen\*\*  
Erling Navntoft\*\*\*

#### 1. Introduction

The Danish Natural Gas and Oil Transmission system included the landing of a 30' Gas pipeline and a 20' Oil pipeline in a common shore approach at the Danish North Sea Coast. The location of the site is shown in Figure 1.1.

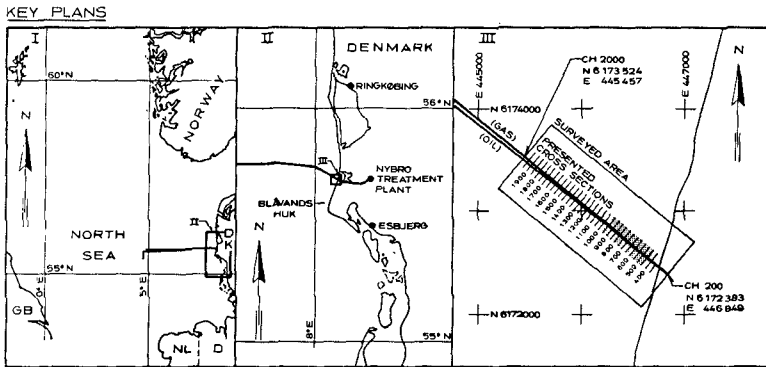

Figure 1.1 Key plans of the North Sea Shore Approach Site.

The two pipes were pulled ashore in a common pre-dredged trench into a sheet piled cofferdam across the beach. The trench was 1600 m long and had a volume of about 600,000 m<sup>3</sup>. The dredging and the backfilling were monitored closely together with wind, wave, and current conditions over the four months dredging and installation period. After termination of the pulls and backfilling the trench was left for natural backfilling. The backfilling was monitored for one year together with the environmental conditions.

\* K. Mangor, Senior Hydraulic Engineer, Danish Hydraulic Institute (DHI), Agern Allé 5, DK-2970 Horsholm, Denmark.

\*\* T. Sørensen, Director, DHI.

\*\*\* E. Navntoft, Senior Hydraulic Engineer (Ph.D.), DHI.

The monitoring during the construction period was performed by the contractor Saipem/Volker Stevin and by the client, Danish Oil and Natural Gas Company, (D.O.N.G. A/S) with assistance from the Danish Coast Authority (KI). The monitoring activities, which continued after the final check of the backfilling within the construction contract, were initiated by DHI and partly financed by the Danish Council for Industrial and Scientific Research (STVF). The monitoring was performed in co-operation between D.O.N.G. A/S, KI and DHI.

All data from the monitoring program are presented in the report:

North Sea Shore Approach  
Monitoring of Sedimentation in a Dredged Trench  
August 1984  
Prepared by DHI for STVF.

## 2. General Description of the Site

### 2.1 Site Conditions

The sandy coastal area at the shore approach site appears as follows: Backland with heather covered dunes, foredunes being partly covered with beach grass, a 150 m wide sand beach and a 1200 m wide breaker zone with three bars.

This appearance together with geological and historical evidence shows that the beach at the landfall site has accreted and is now largely in dynamic equilibrium with long term rates of supply and loss and sediments being equal.

During severe storms the coast profile will be smoothed resulting in beach erosion and seawards movements of the bars. After the storm the coast profile will normally restore again after some time.

The project exploited ten years of yearly coast profiling every kilometre performed by the Danish Coast Authority. Combining 10 x 10 profiles located symmetrically around the pipeline using the foot of the dunes as the common reference point, the low envelope was established. As the profiles represent calm weather conditions a storm erosion of 1,2 m and the required wall time cover of 1,0 m was added to the low envelope in order to obtain the top of pipe profile, see Figure 2.1.

Figure 2.1 Seabed Variations and Pipeline Profile.

The required minimum distance between the gas pipe and the oil pipe was 5 m out to chainage 800, whereafter the minimum distance increased 1 m per 100 being 17 m at chainage 2000 at the end of the trench. The gas pipeline is located towards north with a straight alignment in the direction  $310^{\circ}$ . The normal to the coast is  $285^{\circ}$ , thus the trench formed an angle of  $65^{\circ}$  with the coast.

## 2.2 Environmental Conditions

The Shore Approach site is fully exposed to the North Sea environment. Because of the extremely high longshore sediment transport in the area the Shore Approach was considered one of the major challenges of the entire Danish Natural Gas and Oil Transmission system.

The gross longshore sediment<sub>3</sub> transport in the area has been evaluated at approximately 1.5 mio. m<sup>3</sup> per year, with an average during the spring and summer months of approx. 100,000 m<sup>3</sup> per month. The net longshore transport is southgoing. Variations with factors of 2-3 should not be considered as unnormal. During the worst day a transport exceeding 100,000 m<sup>3</sup> may be expected.

On basis of the environmental conditions the construction period for the sea bound Shore Approach works were selected to March through June.

## 3. Collected Data

The collected data consists of bathymetric surveys, bottom samples, wind, wave and water level data. A summary of the data collection programme is presented in Table 3.1.

YEAR MONTH	1982												1983

WATER LEVEL $\leftarrow$ , H.+L. WATERS $\rightarrow$																			

Table 3.1 Summary of the data collection programme.

### 3.1 Soundings

All soundings were performed by echo sounder combined with various types of electronic positioning systems.

The complete sounding campaigns of the dredged area have consisted of three longitudinal profiles, one in the gas pipe centre line and one on each side spaced 2-300 m. Moreover cross-sections perpendicular to the gas pipe alignment with a distance of 25 to 50 m and a length of 3-400 m on each side of the centre line were performed.

Beyond above-mentioned complete sounding campaigns the Contractor performed soundings currently during the dredging period March through June 2, 1982.

On basis of the described sounding campaigns, sounding plans have been prepared at a scale of 1:1000. On the basis of the sounding plans cross-sections for every 50 m have been prepared. These cross-sections have formed the basis for the calculations of the sedimentation, which is described in Section 4.

### 3.2 Bottom Samples

Bottom samples have been collected before the dredging of the trench. After the dredging of the trench samples have been collected in and off the trench in connection with some of the mentioned surveys, see the summary in Table 3.1. All bottom samples were collected by a grab sampler which penetrates 10-15 cm into the bottom.

The sea bed soils consist of alternating layers of fine and medium to coarse sand covering sandy gravel.

Fine sand: Mean Grain Size :  $d_{50} = 0.14-0.21$  mm  
Uniformity Ratio :  $d_{60}/d_{10} = 1.27-1.47$

Medium to coarse sand: Mean Grain Size :  $d_{50} = 0.28-0,80$  mm  
Uniformity Ratio :  $d_{60}/d_{10} = 2.17-2.78$

The samples taken in the trench are of two different categories:

Category 1 : Dark greyish green MUD with varying contents of fine sand and silt and shell fragments.  
Mean Grain Size :  $d_{50} = 0.02$  to 0.1 mm  
Organic Content : 3- 14%.

Category 2 : SAND, fine to medium, grey, varying small contents of mud.  
Mean Grain Size :  $d_{50} = 0.14-0.23$  mm

Category 1 is found at the bottom of the trench in areas where practically no backfilling has taken place. Category 2 is found at the bottom and to the sides in areas which have experienced considerable backfilling. It is assumed that the trench finally was filled completely with Category 2 varying with thin layers of Category 1.

### 3.3 Wind measurements

Wind measurements from the nearby Blåvandshuk Light House have been collected for the total monitoring period.

3.4 Wave Measurements

Waves were measured from March 13, 1982 to June 20, 1983 at 12 m water depth about 2 km north of the Shore Approach site. The measurements were performed by a Datawell Waverider buoy. In periods where wave records are missing, see Table 3.1, the wave heights have been estimated from the wind data using correlations between  $H_s$  and the wind speed for various direction intervals. The correlations were established from the periods with simultaneous recordings of waves and wind.

The wind direction was used as offshore wave direction. Refraction calculations was performed using the DHI wave refraction model - SPEC-FRAC - in order to obtain wave conditions at breaking,  $H_{s,b}$ ,  $\theta_b$ . The breaking criteria  $H_{s,b} = 0.8 h_b$  was used, where  $h_b$  is the water depth at the breaking point.

The distribution of the breaking waves in the six periods in which backfilling has been measured, ref. Section 4, are presented in Figure 3.1.

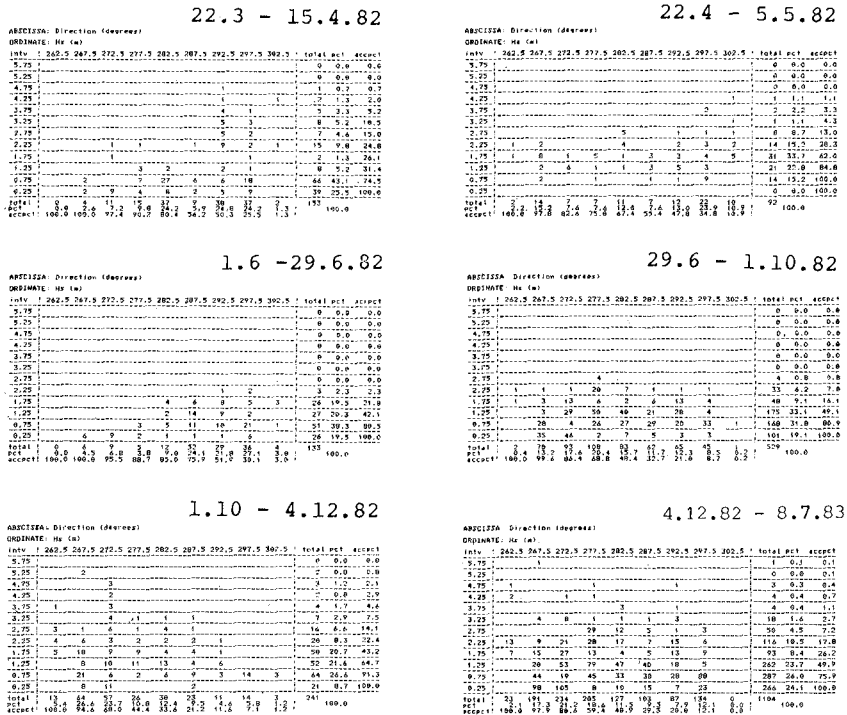

Figure 3.1 Distribution of breaking waves in six periods.

### 3.5 Current and Wave Induced Orbital Velocity

Current and wave induced orbital velocities have been measured by an electromagnetic current recorder of the type Marsh McBirney. The recorder was mounted in a rack which was placed at the sea bed at the same position as the wave recorder. The sensor of the Marsh McBirney recorder was situated 1.5 m above the sea bed.

Because of combination of financial, technical and weather-caused difficulties the wanted continuous time series of above-mentioned parameters were not obtained. The periods of data coverage are presented in Table 3.1. It was originally planned that the direction of the orbital velocities should be used as the wave direction at 12 m water depth, however, for above-mentioned reasons the wave directions were established by the refraction calculations.

The current outside the breaking zone has two main components: tidal and storm surge currents. The main directions of the tidal currents are directed N-S and the maximum tidal currents at mean spring are approx. 0.2 m/s. The storm surge currents are also directed N-S with the north-going being the dominating. The following exceedance frequencies have been estimated.

Exceedance percentage	Storm surge current
1%	0.25 m/s
5%	0.17 m/s
50%	0.07 m/s

### 3.6 Water Level Conditions

The tide is semi-diurnal with a mean tidal range of approx. 1.0 m.

The following relation between the storm surge and the wind speed for westerly winds may be used as a good first estimate: storm surge =  $7 \times U_{\text{wind}}$ , the wind speed  $U_{\text{wind}}$  in m/s gives the surge in cm.

## 4. Measured Sedimentation

Sedimentation or backfilling in the trench during a certain period has been calculated by multiplying the backfilling area for a cross-section  $A_3$ , by the distance between the cross-sections, see Fig. 4.1. By this method the sedimentation distribution along the trench, i.e., approximately perpendicular to the coast, has been calculated.

The sedimentation and other profile characteristics have been calculated according to the sketch presented in Figure 4.1.

Figure 4.1 Definition of Cross-Section Characteristics.

Cross-sections of some characteristic areas for the available periods are presented in the Figures 4.2, 4.3 and 4.4, see summary Table 4.1.

Period	Charac. Area Chainage	2nd bar 700	Trough 2nd to 3rd bar 1000	3rd bar 1150-1200	Offshore 3rd bar 1700
22.3 to 15.4.82		Not dredged	Partly dredged	Fig. 4.2	Fig. 4.2
22.4 to 05.5.82		Not dredged	Not dredged	Fig. 4.3	Fig. 4.3

1.10 to 3.12.82	Fig. 4.4		Fig. 4.4	Fig. 4.4	Fig. 4.4
3.12.82 to 8.7.83					

Table 4.1 Summary over presented cross-sections.

Figure 4.2 Cross-sections from 3rd and offshore 3rd bar, period 23.3 to 15.4.82.

Figure 4.3 Cross-sections from 3rd and offshore 3rd bar, period 22.4 to 5.5.82.

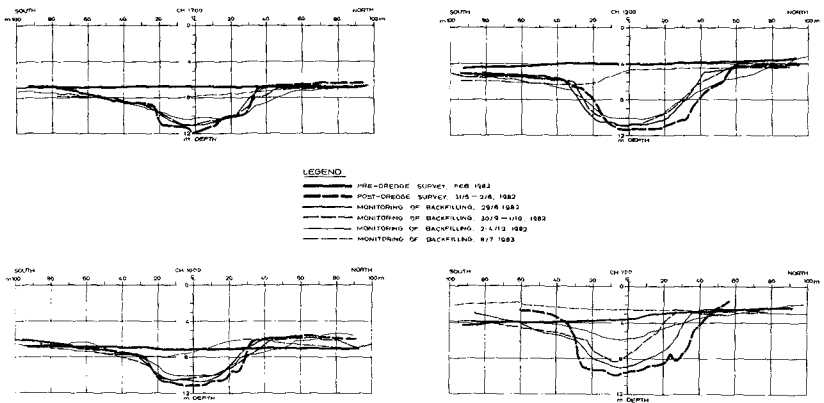

Figure 4.4 Cross-sections from 2nd bar, trough between 2nd and 3rd bar, 3rd bar and offshore 3rd bar, four periods.

The mean sea bed profile, the profiles of the trench in the beginning and the end of the periods, the distribution of the trench volume at the beginning of the periods and the distribution of the measured backfilling during the periods are presented in Figure 4.5.

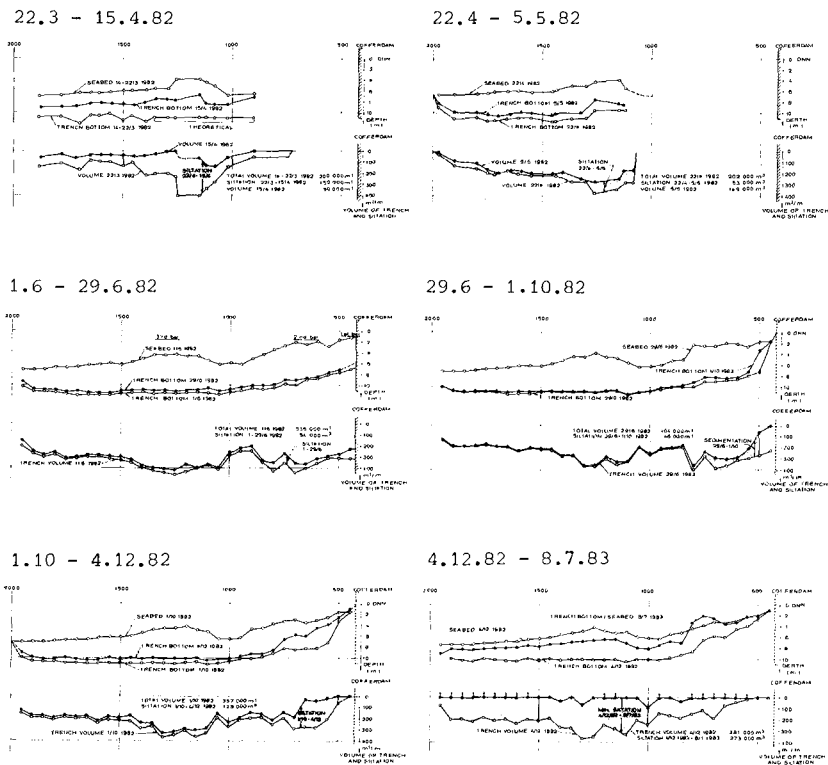

Figure 4.5 Seabed and trench bottom profiles and distributions of trench volume and siltation for six periods.

The backfilling distribution in the profiles is varying considerably because of variations of the wave conditions in the backfilling period. The backfilling is concentrated in the bar areas, in rough weather at the outer bar, see f.ex. the distribution in the period 23.3 to 15.4.82 in Figures Nos. 4.2 and 4.5, in mild periods at the two minor bars, see f.ex. the distribution in the period 29.6 to 1.10.82 in Figures Nos. 4.4 and 4.5.

5. Calculated Longshore Transport by CERC-Formula

The gross longshore transport in the backfilling periods have been calculated inserting the three hourly breaking wave parameters ( $H_{s,b}$ ,  $\alpha_b$ ), see in Figure 3.1, in the CERC-formula:

$$Q = 1228 H_{s,b}^{5/2} \sin 2\alpha_b$$

$H_{s,b}$  in m gives  $Q$  in  $m^3/3 h$ .

By assuming the bulk of the transport in the profile taking place between the depths  $0.7 h_b$  and  $1.3 h_b$  a simplified theoretical distribution of the longshore transport in the profiles has been evaluated. This distribution fits reasonably well with the measured distributions of backfilling. By subtracting the transport which takes place in areas with no trench from the calculated gross transports, one obtain corrected transport amounts, which should be directly comparable with the total measured backfilling amounts. It has been assumed that all longshore transport are trapped in areas with an intact or partly filled trench.

The corrected longshore transport is presented as function of the measured backfilling in Figure 5.1.

Figure 5.1 Calculated Longshore Transport (CERC) versus Measured Backfilling.

## 6. Improved Calculation of Longshore Transport

Finally the measured backfilling rate for the period March 22, 1982 to April 15, 1982 has been compared to the gross longshore sediment transport for the same period calculated by a method recently presented by J. Fredsøe, /1/. This method enables the calculation of the sediment transport - bed load as well as suspended load - in the combined flow field of a steady current superimposed by waves. Briefly the method considers the wave boundary layer at the flow bed as it grows up and collapses cyclically with the wave motion in the combined flow. By application of the momentum equation to the boundary layer and a few additional simple principles the temporal variation of the layer is calculated and subsequently the temporal variation in the bed shear stress and eddy viscosity distribution over the depth. The bed load transport rate is immediately related to the bed shear stress as is the concentration of suspended load at the bed and both respond with zero time lag to the variations in the bed shear stress. The concentration distribution over the depth is assumed to be described by the one-dimensional diffusion equation with the sediment diffusivity equal to the eddy viscosity. This equation is solved numerically with depth and time yielding the cyclic variation of the suspended load concentration at any particular depth. The corresponding instantaneous suspended load transport rate is the product of flow velocity and suspended load concentration integrated over the flow depth and is thus cyclic as well. The instantaneous transport rates - bed load as well as suspended load - are averaged over a wave cycle and added to yield what is termed the sediment transport rate. All calculations are carried out by automatic computer. For further details reference is made to /1/.

The steady current is the longshore current which is assumed to be exclusively wave generated. As an approximation it is calculated as proposed by Longuet-Higgins, /3/, for a coast with no bars but with the following modifications :

- The reference velocity  $V_o$  is determined as for a coast with no bars but with the coastal slope equal to the bed slope at the point of breaking
- The velocity distribution across the surf zone is calculated as for a coast with slope 1:130 and no bars, see Fig. 6.1.b.
- Only the outermost breaking line is taken into account, even though wave breaking may occur up to three times before reaching the coastline.

After breaking at wave height  $H_B$  the wave height  $H$  is assumed to be modified with the distance  $\Delta x$  from the breaking lines as,

$$H/H_B = 0.35 + 0.65 \exp(-0.12 \Delta x/H_B)$$

see e.g. /2/. As the decayed wave runs up the front slope of the following bar the wave height increases again with diminishing depth and breaking occurs once again and so forth until the coastline is reached.

In this way the steady current as well as the wave agitation are calculated at a number of points across the surf zone for the wave conditions occurring during the period 22.3 - 15.4.82.

The sediment transport rate at each point is calculated corresponding to each significant wave height and angle of incidence at breaking as depicted on Fig. 3.1 using that the normal to the coast has the direction  $285^{\circ}$  and assuming the sediment grain size to be 0.2 mm and the water temperature  $5^{\circ}\text{C}$ . With the duration of each wave condition as shown on Fig. 3.1 the gross transport rate has been calculated for each point. The results are shown on Fig. 6.1.a and compared to the measured backfilling during the same period. The calculated longshore transport comes out in volume solid material during the period whereas the backfill is measured as volume of material in deposit. It has been converted to volume solid material by assuming a porosity of 40%. It is noted that the measured backfill is about 2 times the calculated gross transport. In this connection it should be mentioned that:

- The measured backfill has not been reduced by the volume originating solely from the deformation of the trench and is therefore not equal to the gross longshore transport.
- Longshore currents from other sources than obliquely incident breaking waves have been ignored and may not be so, especially during and after a stormy period as occurred within the period considered.

With this in mind the discrepancy between the calculations and the measurements is not really that discouraging. Efforts continue to improve the method of calculations, primarily by improving the method of calculating the longshore currents.

Fig. 6.1 (a) Longshore transport for period 22.3-15.4, 1982 by J. Fredsøe's model /1/ and natural backfill during the same period.

(b) Coast profile as observed during same period.

## CHAPTER ONE HUNDRED TWENTY THREE

### FIELD INVESTIGATIONS IN THE TOW STUDY PROGRAMME FOR COASTAL SEDIMENT TRANSPORT IN THE NETHERLANDS

H. Derks\* and M.J.F. Stive\*

#### ABSTRACT

Field campaigns were conducted in 1981 and 1982/83 on the Dutch coast near Egmond. Measurements were made of surface elevations, water velocities and sediment concentrations in 3 to 8 surf zone locations and 2 to 5 offshore locations simultaneously. A total of 50 measurement series was obtained under a variety of weather conditions, resulting in offshore wave heights of 0.2 to 4.6 m. A description is given of the field set-up, the instruments and measurements, and the collected data. The quality of the various measurement systems and the data produced has been investigated extensively by intercomparison of instruments and devices in the field. The results are reported here.

#### 1.0 INTRODUCTION

The TOW Study Programme for Coastal Sediment Transport in the Netherlands aims to improve our knowledge of the phenomena governing the sediment transport in the coastal zone in order to develop methods for a detailed and accurate prediction of the coastal morphology. The TOW Programme is financed by the Dutch Government. The organization of the Programme is a joint effort of the Public Works Department (Rijkswaterstaat), the Delft University of Technology and the Delft Hydraulics Laboratory. The Programme includes theoretical studies, laboratory investigations and investigations in the field. The different subjects are covered by 8 task groups.

Within the above framework the Field Experiments Task Group has so far conducted two field campaigns on the Dutch coast. In this paper a summary is given of the objectives, the set-up of the campaigns, the instruments involved, the measurements, the collected data, the data analysis and the quality of the data as measured by the instruments under different conditions.

#### 2.0 OBJECTIVES

The collection of simultaneous data on waves, currents and sand transport phenomena in the nearshore area requires an extensive measurement system. No sufficient information was available on the requirements for the well functioning of such a system as a whole. A general objective of the present study was to test such a measurement system in nature in order to study the functioning of the different

---

\* Delft Hydraulics Laboratory, Delft, the Netherlands

Photo 1 Surf zone measurement stations 1982/83 campaign

Photo 2 Close-up of surf zone measurement station

parts of the systems. Execution of measurements had to be possible during conditions of windforce 8 Beaufort and higher. The constructional provisions had to be sufficient for the safe exposure of the measurement set up to the conditions present at the Dutch coast during the winter season. Occurrence of storms of windforce 10-11 Beaufort is normal then.

In detail the objectives of the field investigations can be distinguished as follows:

- collection of data to study the hydraulic and morphologic phenomena in the nearshore areas of the coast.
- collection of data to study the functioning of devices and instruments for the measurement of wave heights, waterlevels, currents, sediment concentrations and bottom configuration under various conditions inside and outside the surfzone.
- testing of the system for data acquisition and data analysis at the site.
- testing of the various constructional provisions.
- collection of experience in the execution of field campaigns.

The latter 4 objectives were covered by the Field Experiments Task Group. The study of the hydraulic and morphologic phenomena is being covered by the other task groups in the TOW programme.

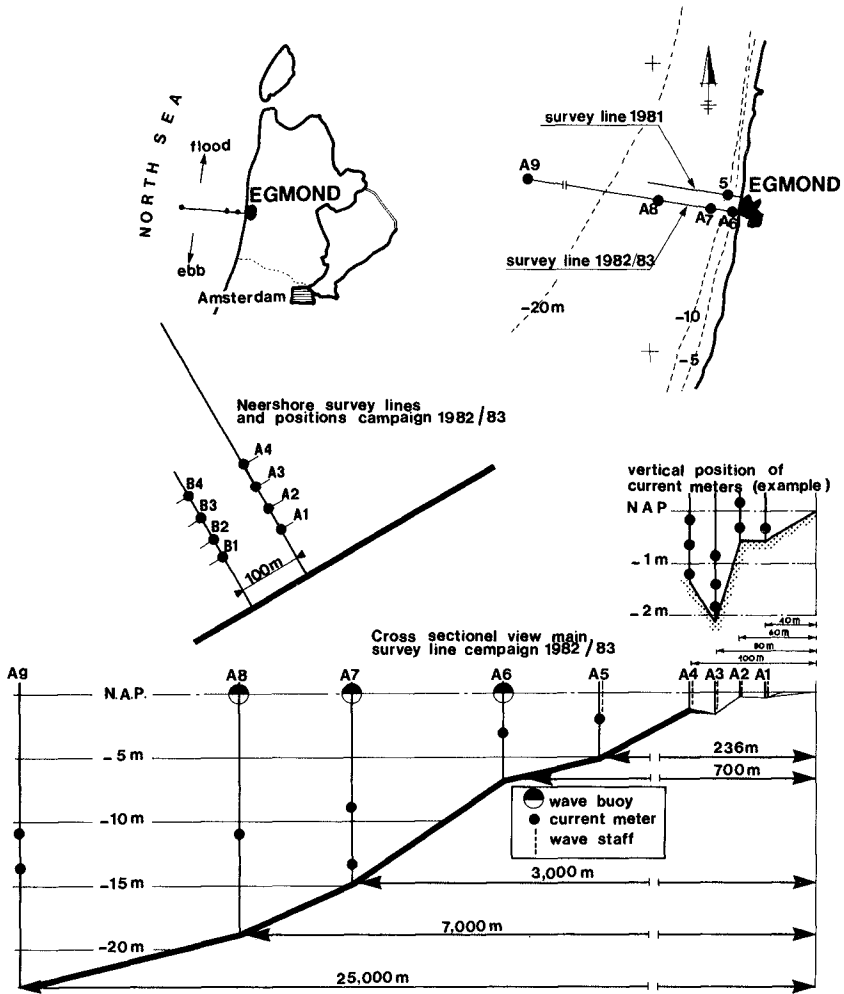

Fig. 1 Location and measurement set-up

### 3.0 FIELD CAMPAIGNS

#### 3.1 Set-up

Both field campaigns were conducted on the Dutch coast near Egmond. The location near Egmond was selected because of its relative uniformity in bottom topography and hydraulic conditions alongshore. The first campaign was held in May and June 1981 during relatively calm weather conditions. The second campaign was held from September 1982 to January 1983 when weather conditions were relatively rough.

Simultaneous measurements of surface elevations, velocities and sand concentrations were carried out along a main survey line perpendicular to the coast. In the 1981 campaign 3 surf zone stations and 2 offshore stations were present. In the 1982/83 campaign 4 surf zone stations and 5 offshore stations were installed, while also a second survey line was added 100 m south of the main line with 4 additional surf zone stations (see Fig. 1). The surf zone stations consisted of a working platform on scaffolding, lightly constructed of steel pipes that had been driven into the bottom by fluidizing the sand. From the platforms the instruments could be installed on sensor piles. The platforms were mutually connected by a foot jetty, which was also used for the cable connections with the shore. An impression may be obtained from Photos 1...4. In the offshore region instruments were either placed on or moored to the bottom. In this case signals were transmitted to the shore by radio, with the exception of self-recording tidal current meters. Data acquisition was done directly inshore of the main survey line in a facility of portable cabins by means of a HP 1000 computer and subsystem.

#### 3.2 Instruments and Measurements

Whether an instrument meets the measurement requirements, in general, will have to be judged on the data produced by that instrument under the desired conditions. In this respect a problem arises when no representative data measured by other instruments are available, such as is the case with data collected in the surf zone during a severe storm. By means of theory the order of magnitude of a phenomenon can be estimated. It is also possible to calibrate instruments under controlled conditions which are a close approximation of reality. However, the confidence that a signal produced by a device is sufficiently representative can only be based on information provided by the measuring practice itself.

Therefore the instrumental set-up is chosen in such a way that the data collection is done under a great variety of external conditions, whereby the variety of positioning is small and the signals are measured simultaneously by as many instruments as possible.

By intercomparison of signals collected by identical instruments the variability of a certain phenomenon with place can be determined. Hereafter intercomparison of signals collected by non-identical instruments can give information about the influence on the representation of signals caused by other factors specifically those related to the measuring principle of the instrument. Finally, the general review

Photo 3 Surf zone stations under storm conditions at intermediate tidal level

Photo 4 Surf zone stations under storm conditions and at high tidal level

of the results of all measurements of this kind provides an impression of the reliability of the representation of a signal by a measuring device under certain conditions.

The phenomena of interest in the conducted field campaigns of 1981 and 1982/83 are:

- surface elevations;
- mean waterlevels;
- instantaneous water velocities in the surf zone;
- mean current velocities outside the surf zone;
- sand concentrations in the surf zone;
- bottom topography.

Surface elevations were measured by means of Plessey wave staffs and Data Well waveriders. Common aspects of the functioning of both instruments are unexpected disturbances of the measuring signal, zero stability, response of instruments under several wave conditions. With respect to the Plessey wavestaff the effect of the presence of a protective pipe mounted around the staff was studied also.

Absolute values of the mean water level were measured by means of Plessey wave staffs, Vega pressure sensors and a TPD tidal recorder. Point of interest is the inter-exchangeability of the values. Relative values of the mean waterlevel were measured by DAG 6000 self contained pressure meters.

Instantaneous water velocities were measured by means of the following instruments

- Marsh McBirney (USA) - electromagnetic current meter
- Colnbrook (UK) - electromagnetic current meter
- NSW (GFR) - electromagnetic current meter
- Vector Akwa (Neth) - acoustic pulse travel time current meter
- ASTM (Neth) - acoustic doppler shift current meter.

The following aspects being characteristic for the functioning of the instruments in the surf zone were studied:

- representation of velocities by different meters under various conditions
- effects on the representation of velocities under high concentrations of entrained air and sand particles
- characteristics of the represented velocities in situations when the sensor is subject to sudden transitions of air to water and vice versa (measurements in passing wave crests)
- representation of velocities during measurements in one vertical in 5 points simultaneously
- effects on the measurement of the horizontal velocity signals caused by interaction of the vertical velocity component and the shape of the probe.

Mean current velocities outside the surf zone were measured by NBA and Flachsee underwater current meters usually in one point in the vertical. In one location the distribution of the mean velocity in the vertical was studied by means of two current meters.

Sand concentrations were measured by means of a suction sampler system and the ASTM acoustic backscatter meter. One point of interest is to know the conditions for the correct functioning and calibration of both instruments. A large number of practical aspects of the functioning still has to be cleared. Another important aspect is to have sufficient knowledge of the processes involved in the variation of the sand concentration over time and depth. The ASTM is capable of producing instantaneous values of the sand concentration measured in a point.

The bottom configuration was measured periodically by levelling (by foot) and echosounding (by boat). From this system no detailed information about instantaneous changes of the bottom topography in time and place is obtained. Therefore, echosounding equipment of 1 MHz working frequency was installed in the measuring locations in the surf zone and its capability of producing additional information about the instantaneous local bottom elevation was studied.

Directions of wave crests inside the surf zone were measured by video recording the wave field in the surf zone using a reference system for the wave crest positions. Information about the direction of breaking wave crests can be obtained from the images by determining the angles made by the passing wave crests.

#### 4.0 COLLECTED DATA AND DATA ANALYSIS

Data acquisition was done at the site by means of a HP 1000 computer and subsystem. This computer was implemented with facilities for data analysis techniques. Also facilities for plotting of the results were available. The availability of data analysis and plotting facilities at the site proved to be an essential part in checking the quality of the measured data. Already at the site a start was made with a selected number of time series analysis which serve as an inventory of the collected data. The total volume of work involved in making this inventory was such that the greater part was done at Delft Hydraulics Laboratory on the same HP system after the ending of the measurements.

The total number of instruments used during the 1982/83 campaign was 34. The total number of measurement series of both campaigns amounts 52. The measurement series are varying in duration from 40 minutes to 13 hours. The weather conditions vary from calm weather to windforce 9 Beaufort, and there is variation in the number of instruments and their distribution over the different measuring positions. The collected data are inventorized in Derks (1982, 1983). A summary of the collected data is given in the table below.

campaign	number of measurement series	duration of measurement series	number of parameters	offshore significant wave height
1981	5	5 hours	20-25	0.2-1.5 m
1982/83	20	30-45 minutes	10-20	0.3-2.5 m
	17	1- 3 hours	10-20	0.3-2.5 m
	10	3-13 hours	35-45	0.2-4.6 m

Table 1 Collected data

Analysis of the collected data is principally carried out by and under responsibility of the different task groups. Current study aspects are wave energy decay between 3 km offshore and the beach (see Battjes and Stive, 1984), low frequency velocity characteristics (see Gerritsen and Van Heteren, 1984), wave driven currents and sediment transport in the horizontal plane (see Boer et al, 1984) and wave kinematics and directionality (see Van Heteren and Stive, 1984). An important aspect is the assessment of the quality of the data as measured by the various measurement systems. Since there are no absolute standards, in general, a judgement of the performance of instruments and devices must be made by intercomparison of signals. As described above this aspect was covered in the set-up of both campaigns. The evaluation was conducted by the Field Experiments Task Group and is reported in Derks (1982, 1984). A summary of the results is given in the following section.

## 5.0 PERFORMANCE OF MEASUREMENT SYSTEMS

### 5.1 Surface Elevations

In deep water, at distances of 700, 3,000 and 7,000 m offshore, surface elevations were measured by means of Data Well wave riders, floating vertical accelerometer buoys moored by an elastic cable. During the Egmond measurements it was noted that disturbances of the signal occurred during high sea. Under these conditions the radioconnections could be interrupted by capsizing of the buoy. No data are available for intercomparison of the buoys with other measurement systems.

In shallow water up to distances of 250 m offshore, surface elevations were measured by means of Plessey wave staffs, resistance staffs mounted at fixed positions. The signal produced by this instrument showed a lot of irregularities during the measurements. Spurious peaks of large steepness and amplitude and sudden changes of the mean signal level occurred. During the 4 months measurements the calibration factors also showed a significant variability. In general wave height distributions and spectra could be determined by careful screening of the signals and by eliminating the peaks on basis of their steepness. Intercomparison of the results determined by the Plessey wave staff and the Vega pressure meter at positions with a local depth of 1-2 m showed that the pressure is not hydrostatic. Cross spectral analysis shows that the coherence value is very close to 1 at the frequency range from 0-0.5 Hz, while the gain value over this range drops almost

linearly from 1 to 0. The presence of the perforated protection pipe resulted in 10% lower values of the significant wave height ( $H_{1/3}$ ) although the total variance of the signal is not influenced.

## 5.2 Mean Water Level

Comparative measurements were made with the Plessey wave staff - Vega pressure sensor and the Plessey wave staff - TPD tidal recorder in combined positions. As a consequence of the irregularities shown by the wave staff signal and the large variability of the calibration factors, no correct water levels could be determined from the Plessey wave staff signal.

Other combinations of instruments were not studied. The signals measured by the TPD tidal recorder, the Vega pressure sensor and the DAG 6000 pressure sensor individually showed no irregularities.

## 5.3 Instantaneous Water Velocities inside the Surf zone

### Criteria for intercomparison of signals

The functioning of a number of current meters in the surf zone was studied by intercomparison of signals produced by pairs of instruments. The instruments were placed on the same elevation. The mutual horizontal distance between the two instruments was varied up to a range of 2.50 m. The signals were measured in two or three orthogonal directions whose orientation was according to the direction of the main survey lines of the measurement set-up. The differences between a pair of signals produced by instruments in two different positions however, are not fully due to the functioning of the instruments, but partially due to the spatial variability of the velocity signal. In order to be able to make a correct judgement this spatial variability was studied. This was done by intercomparison of signals produced by pairs of identical instruments.

The measurements were carried out with a pair of electromagnetic Marsh McBirney current meters and a pair of acoustic Vector Akwa current meters under a variety of conditions of wave height and water depth. As a consequence the differences in the concentrations of sand and air were relatively large.

The results of the measurements showed that the signals of the water velocity inside the surf zone in general have the following characteristics:

- (1) the time averaged value of the velocity component parallel to the coast is relatively large while the variance of the signal is relatively small. In other words the velocity signal parallel to the coast has a relatively large static component and a relatively small dynamic component. The velocity signal perpendicular to the coast has just reverse characteristics.
- (2) From the measurements with pairs of identical current meters it appears that the spatial variability of the velocity signal in the surf zone within a horizontal distance of 2.50 m is as follows (see also Fig. 2 for an example):

Fig 2 Spatial variability of onshore velocity derived from two closely spaced, identical Marsh McBirney current meters

basic characteristics	velocity component parallel to the coast	velocity component perpendicular to the coast
mean value	relatively small variation	relatively large variation
variance	relatively small variation	relatively small variation
coherence and gain between signals in the same direction	relatively small	relatively large

Most suitable for the intercomparison of signals produced by closely spaced current meters in the surf zone are those characteristics that show the least spatial variability with distance and the highest coherence and gain mutually. In this sense the coherence and gain of the velocity signals perpendicular to the coast, the mean value of the velocity signal parallel to the coast as well as the variance of the signals in both directions are the most suitable criteria.

The comparison of velocity signals provides a relative measure of the similarity between two velocity signals. Influences that affect both instruments equally, are not detected. A more absolute judgement of the quality of the measured signals can be obtained by means of the intercomparison of the separate velocity signals and the signal of the local surface elevations.

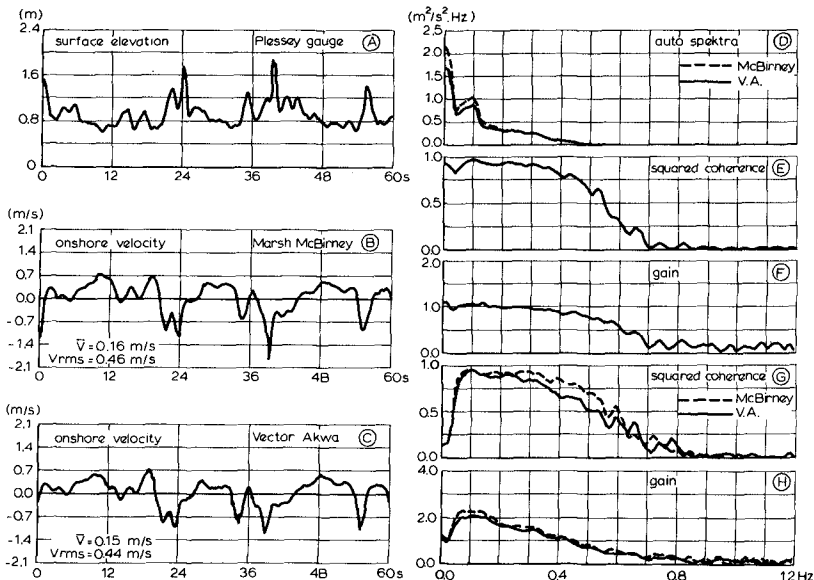

Representation of the velocity signals in the surf zone by different currentmeters

(1) In the present study information on the quality of the velocity signal in the surf zone, as represented by the different currentmeters, is obtained in two ways:

- a) directly from cross spectral analysis between two velocity signals,
- b) indirectly from cross spectral analysis between the separate velocity signals and the local surface elevation.

From a) it appears that although the measuring principles of the inspected currentmeters in some cases may be very different, the represented signals are quite similar. It appeared that unless special conditions are present, the difference between two signals produced by non identical currentmeters is of the same order of magnitude as the difference between two signals produced by identical instruments.

The results of b) indicate that the currentmeters also in a quantitative sense give a good representation of the velocity signal. An example is given in Fig. 3. An illustration of the results that may be obtained is given in Fig. 4.

A,B,C recorded time series of surface elevation and onshore velocities  
 D,E,F cross-spectra between onshore velocities  
 G,H cross-spectra between surface elevation and onshore velocity

Fig 3 Intercomparison of closely spaced (1.70 m apart) current meters

Fig. 4 Instantaneous longshore velocities and surface elevation

- (2) Of the inspected current meters the Marsh McBirney electromagnetic current meter gives the best representation of the velocity signal in the depth region 0,2 m away from the bottom up to the wave trough level. The influence of high concentrations of entrained air and sediment in the water appears to be small. Disturbances of the signal were observed when the sensor was close to the sand bottom ( $< 0.2$  m). Unless the instrument is provided with a special proximity execution (optional), disturbance of the measured velocity signal happens when the electromagnetic field of another electromagnetic current meter comes too close (distance  $< 0.50$  m). When the sensor is positioned above the level of the wave troughs of the Marsh McBirney current meter seems to respond reliably.
- (3) The representation of the velocity signal by the NSW electromagnetic current meter is equivalent to that of the Marsh McBirney current meter, however no data are available about characteristics of the represented signal when the sensor is positioned above the level of the wave troughs.
- (4) The representation of the velocity signal by the Colnbrook electromagnetic current meter is not equivalent to that of the Marsh McBirney current meter. Although the coherence values calculated in the intercomparison of Colnbrook signals and Marsh McBirney signals are equivalent to the values calculated in intercomparison of signals from identical instruments, mean values, gain values and the variances show systematic differences. This may be caused by the instability of calibration factors. It is also recommended to check the exact position of the volume of measurement of the Colnbrook probe, since the disc-shaped Colnbrook probe, being different from the spherical probe of the Marsh McBirney, may generate an electromagnetic field of different

shape. From the calculated coherence values it could be seen that the shape of the signal represented by the Colnbrook current meter is hardly influenced by highly concentrated entrained air and sediment. When the probe is positioned above the level of the passing wave troughs disturbance of the Colnbrook signal occurs so the characteristics of the signal are not suited for measurement of velocity in passing wave crests. Also disturbances of the signal occur when the Colnbrook probe is positioned close to the bottom or close to the electromagnetic field of other instruments.

- (5) The Vector Akwa acoustic current meter gives the best representation of the velocity signal in the depth region near the bottom. In the upper depth region the quality of representation is somewhat less compared to the Marsh McBirney current meter. This is probably caused by the presence of air bubbles. The influence of high concentrations of sediment on the representation of the signal by the Vector Akwa current meter is negligible. Strong disturbances of the signal occur during measurements in breaking waves when the sensor is positioned above the level of the wave troughs. Compared to the Marsh McBirney currentmeter, the instrument's response seems less reliable in this region.
- (6) The representation of the velocity signal by the ASTM acoustic (doppler shift) current meter in general is equivalent to the Marsh McBirney current meter. It appears from the available data that the representation of the velocity signal by the ASTM current meter is not influenced by entrained air and sediment in the water. The applied range of measurement positions extends from 0.20 m above the bottom up to the surface level. In comparative conditions the ASTM current meter does not show any disturbances of the signal like the Marsh McBirney current meter in positions close to the bottom or like the Colnbrook current meter in positions close to the water surface. No information is available about the characteristics of the represented signal when the sensor position is above the wave trough level.

#### 5.4 Mean Current Velocities outside the Surf Zone

Mean current velocities and direction of current outside the surf zone were measured by means of Flachsee and NBA automatic current meters. Comparative measurements between the instruments were not made. The mean current velocity was determined every 10 minutes. By means of the NBA current meter both mean values and instantaneous values of the current direction were recorded. By means of the Flachsee current meter only instantaneous values of current direction could be measured. Rupture of mooring constructions during rough weather conditions may cause loss of instruments. In the present study 3 NBA current meters were lost this way.

#### 5.5 Sand Concentrations in the Surf Zone

From the present study no clear conclusions appear whether the pumping system or the ASTM can be used for determining representative figures on the sand concentration in the surf zone. This was mainly

caused by the fact that during the measurements the knowledge about the sand concentration governing processes was insufficient. As a consequence it was not possible to indicate the requirements that had to be put on the measurement system. In the present study measurements were only done in single points. Intercomparison between results produced by the ASTM and the pumping system could not be made as it is presently known that only values obtained by averaging over the bed are useful for this purpose.

Generally it can be said that the pumping system in principal seems to offer a useful method for determining sand concentration values in the surf zone. From the point of view of measuring technique the system in its actual shape is not easily manageable during extensive measurements especially when the weather is rough. Under these conditions it is desirable to have a continuous analog electric signal of the measured sand concentration. Also it is necessary to improve the reliability of the functioning of the pumping system. In its present shape the functioning of the system is too vulnerable.

From the present study it appears that concentration values over  $100 \text{ kg/m}^3$  have to be measured. For the functioning of the pumping system these values are not critical. The ASTM however also needs to be adjusted for measurement of similar values. Unlike the pumping system the ASTM is capable of producing instantaneous values of sand concentration.

#### 5.6 Bottom Topography

The present system for measurement of bottom topography consists of periodically levelling and echo sounding (by boat) of the beach profile in fixed lines. This system offers rather limited results. A dense net of highly accurate bottom positions determined at short time intervals cannot be obtained by this system. A structural improvement of the measuring system for bottom topography is not expected to be possible at short terms.

A contribution to improve the existing system is offered by using 1 MHz echo sounding equipment in fixed positions inside the surf zone. With this equipment the bottom elevation can be monitored instantaneously offering possibilities to study short term relations between local bottom elevation and other parameters. It appeared from the measurements that this system effectively can be used for detecting locally instantaneous bottom elevation in the surf zone at a higher accuracy than is possible by means of leveling or echo sounding by boat. Also, with this system measurements can be performed under conditions when the other systems can not be applied.

#### 5.7 Wave Crest Directions in the Surf Zone

From the 1981 measurements it appeared that indeed it is possible to obtain information about the wave crest directions in the surf zone by means of the applied system (3.2). However, the system is selective as in the wave field only the crests of breaking waves can be distinguished. This implies that only information is obtained about

the direction of the breaking wave crests. Of course wave directions in the surf zone also can be obtained from the horizontal velocity vector and the surface elevation.

## 6.0 CONCLUSIONS

The 1981 and 1982/83 campaigns together yielded a total number of more than 50 measurements. The collected data are being studied in order to enlarge the existing knowledge and to improve theories of the surf zone processes.

In addition to the above mentioned study purposes the data have been used to investigate the accuracy of the representation of the measured signals collected by the different measurement systems. The conclusions of the latter study are as follows:

- (1) On basis of the results of the present study it is possible to select and design systems for accurate measurement of instantaneous water particle velocities in the surf zone under conditions up to windforce 10-11 Beaufort. The measurement positions in the horizontal and vertical plane (including positions above the level of the wave troughs) can be freely chosen. It is necessary to check some minor matters concerning the functioning of the available current meters.
- (2) The results of the present study are not sufficient to design a system capable of producing accurate values of the sand concentration in the surf zone that are representative for a certain time and place. In order to achieve such a system it will be necessary to improve the reliability of the functioning of the pumping system. Moreover it is necessary to have sufficient knowledge of the processes determining the sand concentration. The study on these aspects and the comparative study between the pumping system and the ASTM should be continued.
- (3) The available system for the measurement of bottom topography produces periodic readings of bottom positions by means of echo sounding and levelling. Sufficiently detailed readings in time and place presently cannot be obtained by this system. The available 1 MHz echo sounding equipment can produce valuable additional information on instantaneous bottom elevation in a number of measurement positions. The study of the use of this equipment should be continued.
- (4) It is recommended to study the accuracy of the available systems for the measurement of mean water levels.
- (5) In the used system for measurement of surface elevations, consisting of moored Data Well wave riders and Plessey wave staffs mounted in fixed positions, disturbances of the signals occur. Problems related to the wave buoys possibly can be solved in combination with the selection of a measurement system for wave directions. It is recommended to use other wave staffs.

## ACKNOWLEDGEMENT

This study was carried out under responsibility of the Field Experiments Task Group in the TOW programme. The field work was done as a joint effort of Adviesdienst Hoorn of Rijkswaterstaat (Public Works Department) and Delft Hydraulics Laboratory. Thanks are due to the numerous people involved in the execution of the measurements. Special thanks are due to Mr. F.J. Keuper and Mr. Th. Kos of Adviesdienst Hoorn for their invaluable efforts and kind cooperation in organizing and conducting the measurements.

## CHAPTER ONE HUNDRED TWENTY FOUR

### Field Observation on Suspended-load in the surf zone

Kazumasa KATOH<sup>1</sup>, Norio TANAKA<sup>2</sup> and Isao IRIE<sup>3</sup>

#### ABSTRACT

Both the concentration of suspended-load and the current velocity have been measured continuously in the surf zone. In order to measure the concentration of the suspended-load in the surf zone, a optical densitometer has been developed. The current velocity was measured by means of electromagnetic current meters. According to data analyses, the mean concentration of the suspended-load is high in the final breaking zone and in the breaker zone. In the final breaking zone, the concentration fluctuates with the period of the incident waves. On the other hand, it fluctuates with the period longer than 40 seconds in the breaker zone and it becomes high when the current is offshoreward. The directions of the net transport of the suspended-load in the middle layer in and near the surf zone are offshoreward.

#### 1. INTRODUCTION

The surf zone is a very complicated field with respect to fluid motion owing to the breaking waves, the long period waves, the nearshore currents and the strong turbulences due to wave breaking. The scale and internal structure of this velocity field are being revealed gradually in the field and in the laboratory with the developments of current meters such as electromagnetic current meters and laser doppler velocimeters. The surf zone is also a very important field for sand movement. Scale of fluctuations and structures of sand transport should be corresponding to those of fluid motion. For examples, the sands suspended by the action of the incident waves or its breaking are transported by the nearshore currents. The fluid motion due to long period waves may affect on the sand transport to form the nearshore rhythmic topography such as multiple longshore bars, large cusps and crescentic bars.

---

1) Chief of Storm Surge and Tsunami Laboratory, 2) Director of Marine Hydrodynamics Division, 3) Chief of Littoral Drift Laboratory, Port and Harbour Research Institute, Ministry of Transport, 1-1,3-Chome, Nagase, Yokosuka, Japan.

The relationships between the sand movement and the characteristics of fluid motion in the surf zone, however, are not satisfactorily known so far, since in most of the cases the sand movement in the surf zone were measured as the time averaged values, which were difficult to be connected with the features of fluid motion. In order to understand these relationships between the sand movement and fluid motion, they must be measured continuously in the surf zone at the same time.

Therefore, both the concentration of suspended-load and the current velocity have been measured continuously in the surf zone at Ooarai Beach in Japan and the relationships between them are examined in this paper.

2. INSTRUMENTS USED IN THE FIELD OBSERVATION

\* **Densitometer** : In order to continuously measure the concentration of suspended-load in the surf zone, a densitometer was developed ( see Fig. 1 ). This consists of ten pairs of luminous and photo-electric cells mounted vertically and separated 5 centimeters apart each other. The vertical interval of these pairs of cells is 5 centimeters at the lowest part and becomes larger upward, being 20 centimeters at the highest part as seen in Fig. 1. The distance from the lowest pair of cells to the highest one is 1.20 meters. The pairs of cells are numbered upward from the lowest one, that is, the n-th pair of cells is denoted by the symbol of  $C_n$  (  $n = 1, 2, 3, \dots, 10$  ). A time constant of response of each pair is 0.1 second and ten pairs of cells are controlled periodically in order with a period of 0.03 second. After the field observation, a calibration of the densitometer was carried out in the laboratory, with the sand taken from the beach under the condition of the water

Fig. 1 Densitometer and its arrangement with electromagnetic current meters.

temperature as same as that of the field. The range of calibration was from 0ppt to 20ppt. Figure 2 shows the typical result of the calibration for  $C_3$ . The relation between the output voltage and the concentration can be approximated by a dashed curve as shown in Fig. 2. The same tendency was obtained for the other pairs of cells. In the data analysis, however, a linear relation for each pair, e.g. shown by a straight line in Fig. 2, is utilized in order to convert the output voltage into the concentration.

\* Current meters : Three electromagnetic current meters of two-components type were used to measure the current velocities.

\* Wave meters : Two capacitance type wave meters were used to measure the wave profiles.

\* Set of instruments : The densitometer was installed outside a tower which was constructed with members of steel pipe of 5 centimeters in diameter shown in Photo. 1. Three electromagnetic current meters were vertically installed inside the tower to measure the on-offshore and vertical components of velocity. A horizontal distance from the densitometer to the electromagnetic current meters was 1.0

Fig. 2 Typical result of calibration for densitometer ( $C_3$ ).

Photo. 1 Observation tower

meter. After installing these instruments to the tower on the land, the frog-men carried the tower into the surf zone, and put it on the sea bed by adjusting the direction from the densitometer to the electromagnetic current meters to be parallel to that of the shoreline.

3. SITE OF FIELD OBSERVATION ( OARAI BEACH )

The field observation was carried out at Oarai Beach in Japan during the periods of August 26 to 27, 1982. This beach is located in the north end of a sandy coast of about 70 kilometers long facing to the Pacific Ocean ( see Fig. 3 ), and is adjacent to Oarai Port. The observation point was located about 220 meters south from the jetty which has a function of preventing the sand from entering Oarai Port. The observation point was almost the same level as the datum line ( see Fig. 4. ). The characteristics of the beach materials ( sand ) are that the medium diameter is  $d_{50}=0.24$  millimeter; the sorting coeffi-

Fig. 3 Location of Oarai Beach.

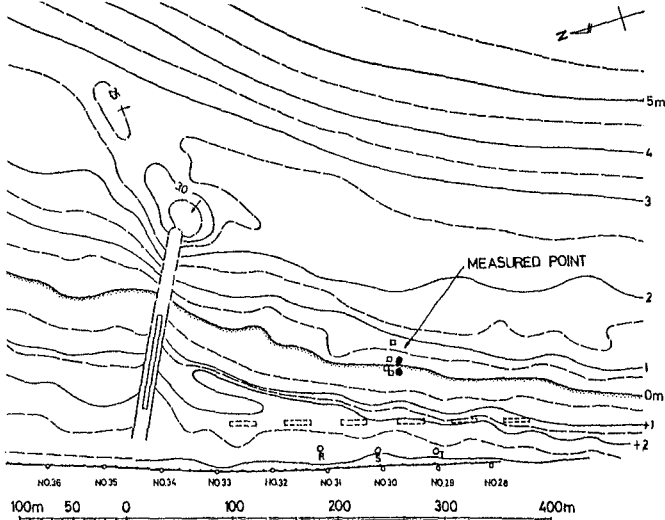

Fig. 4 Beach topography of investigated site relative to datum line and measurement points.

Fig. 5 Significant wave height, wave period and tidal level during the field observation.

cient is  $S_0=1.34$ ; the skewness parameter, which indicates the degree of asymmetry of grain size distribution, is  $S_k=1.12$ .

Figure 5 shows the significant wave height, wave period (measured at the depth of 30 meters under the datum line) and the tidal level (measured inside Ooarai Port) during four days, in which the field observation of two days is included. In this figure, symbols of A - E indicate the times while the field observation was carried out (hereinafter referred to as A - E). During these observations, the significant wave height was 0.7-1.0 meter and the wave period was around 5.5 seconds in deep water. The direction of the incident waves at the measurement points was nearly normal to the shoreline and the longshore currents could not be noticed as far as the visual observation could be made.

A detail of the measurement points are shown in Fig. 6, in which opened marks indicate the measurement points of A, B, C, D and closed marks indicate those of E. The arrangement of the densitometer and the electromagnetic current meters is shown in Fig. 1. The beach profile along the measurement line shown in Fig. 6 was surveyed just after the final observation of E, and is shown in Fig. 7. In this figure, the highest and the lowest water levels and the water level in each observation time are also shown.

When the tidal level was relatively low, the pairs of cells from  $C_7$  to  $C_{10}$  and the upper two current meters frequently emerged above the water surface. Then, the data obtained at the lower part are analyzed.

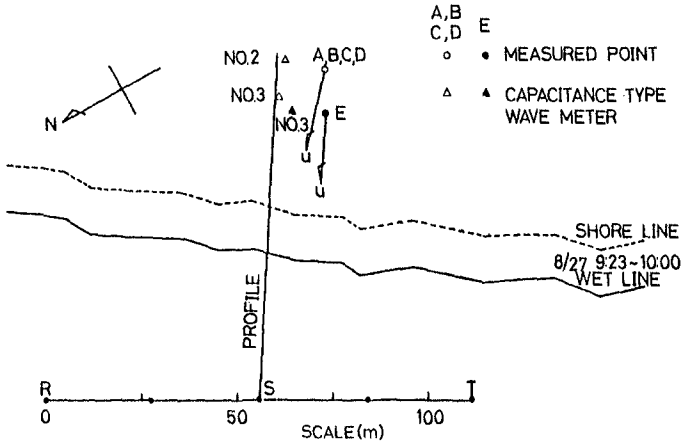

Fig. 6 Detail of measurement points.

Fig. 7 Beach profile, tidal level during the field observation and measurement points.

4. RELATIONSHIP BETWEEN CONCENTRATION OF SUSPENDED-LOAD AND TIDAL LEVEL

Figure 8 shows the typical examples of the concentration of suspended-load, which were measured at C<sub>1</sub> to C<sub>3</sub> ( in the region of 15 to 25 centimeters above the sea bottom ) in B and D. One more example will be shown in Fig.13. When the concentration is low in B, the concentration of C<sub>1</sub> is negative, that of C<sub>3</sub> is about 8ppt and that of C<sub>2</sub> is

Fig. 8 Typical examples of concentration of suspended-load ( C<sub>1</sub> - C<sub>3</sub> in B, D )

Fig. 9 Relationship between tidal level and occurrence frequency of concentration of suspended-load exceeding 20ppt.

reasonable, although these concentrations fluctuate similarly. This might have been due to that the surface conditions of the luminous and photo-electric cells were different from those in calibration, e.g. the surface of glass was blurred, which yielded the bias voltage in the output signal.

As seen in Fig. 8, the concentration of suspended-load in the region of 15 to 25 centimeters from the sea bottom frequently becomes more than 20ppt, even if we don't take the above errors into account. The high concentration occurs three times in the upper figure, zero time in the middle figure and many times in the lower figure. That is to say, the occurrence frequency of the high concentration depends on the case. Then, the occurrence frequency of the concentration exceeding 20ppt per 10 minutes are examined in the analog record of every ten minutes, and the results are plotted in Fig. 9. In this figure, the significant wave height and the tidal level are also shown. The high concentration occur most frequently of about 40 times in D with the lowest tidal level, whereas it is rare of several times in E and the first half of C during which the tidal level is higher. In A, B and the second half of C with medium tidal level, the frequency is around ten times. Generally speaking, the high concentration is rare at a high tide and is frequent at a low tide. In short, there is a negative correlation between the occurrence frequency of the high concentration and the tidal level. This situation is considered to be related to the position of a wave breaker zone which shifted with the tidal level.

The relative position of the observation points shifted from the inside of the surf zone to the out side of it, and vice versa due to the change of the tidal level. Then taking into account the relative distance from the shoreline to the observation point, the occurrence frequencies of the high concentration exceeding 20ppt are plotted in the upper part of Fig. 10. In this figure, a mean velocity and a distribution of the breaking point of the incident waves are also shown. A method of measurement of the breaking point will be mentioned in the next section. The bottom slope of 1/70 shown with dashed line in Fig. 7 is considered for estimating the relative distance. Based on this result, the on-offshore distribution of the occurrence frequency are shown with a curve after considering the followings:

(1) As seen in Fig. 9, the significant wave height is about 0.9 meter in B, D and E, while it is 0.7 meter in A and 1.1 meters in C.

(2) The difference of the incident wave height induced the displacement of the wave breaker zone, that is, the incident waves broke in the surf zone relatively nearer to the shoreline in A and relatively farther from the shoreline in C.

(3) Therefore, in order to obtain the standard on-offshore distribution of the occurrence frequency, the positions of the occurrence frequency in A and in C must be shifted in

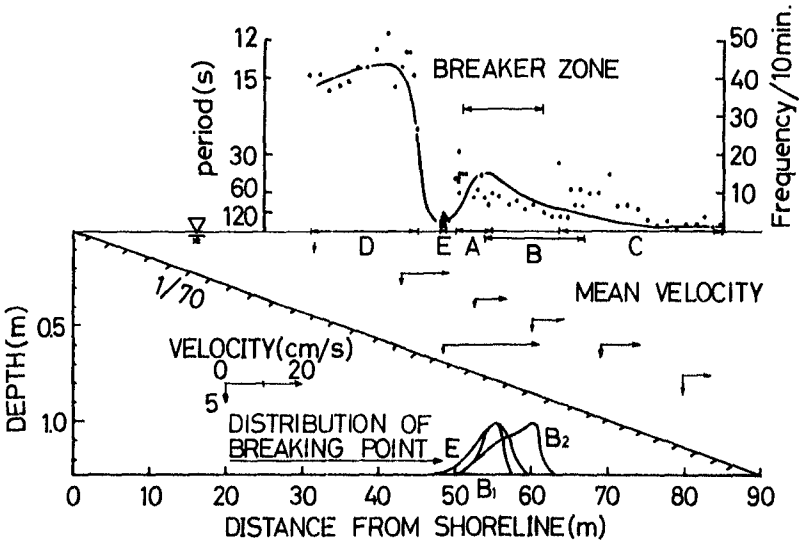

Fig. 10 On-offshore distribution of occurrence frequency of high concentration and mean velocity.

the offshore direction and in the onshore direction, respectively.

As seen in Fig. 10, the on-offshore distribution of the occurrence frequency has two peaks. The onshore-side peak, represented by the data obtained in D, indicates that the mean period of the occurrence of the high concentration is 12 to 16 seconds. The significant wave period, which is calculated by the zero down-crossing method by using every 17 minutes' wave profile data measured at the point of No.2, is  $14.2 \pm 1.6$  seconds. That is, the mean period of the occurrence of the high concentration is almost the same as the significant period of the incident waves. Although the visual observation on the situation around the observation point in D could not be made because it was the middle of the night, the final wave breaking may have occurred there since the water depth at the observation point was about 50 centimeters. The other peak of the occurrence frequency is located at the breaker zone. The mean period of the occurrence at the breaker zone is longer than 40 seconds, which is obviously longer than the period of the incident waves.

#### 5. LONG PERIOD FLUCTUATION OF SUSPENDED-LOAD IN THE SURF ZONE

It has been reported that the concentration of the suspended-load becomes high with the period longer than that

of the incident waves in the breaker zone ( Brenninkmeyer 1974, Wright et al. 1982 ). In this section, the long period fluctuation of the concentration of the suspended-load will be examined.

Figure 11 shows the result of a cross-spectral analysis between the on-offshore velocity component and the concentration of the suspended-load which were measured at  $C_1$  in B, during which the observation point was located in the breaker zone. For this analysis, the analog data are digitalized with the interval of 0.1 second, which yield the digital data of 1 second interval by being calculated the mean value of every series of 10 digital data. A sampling interval and a number of data used in the cross-spectrum analysis are  $\Delta t=1$  second and  $N=2048$  ( about 34 minutes ), respectively. The equivalent degree of freedom with a filter used for smoothing is  $r=16$ . The vertical coordinate in the upper figure is for the values of spectral density of

Fig. 11 Cross-spectrum between on-offshore velocity and concentration (  $C_1$  ).

the velocity. In order to show the spectral density of the concentration in the same figure, the concentration data ( ppt ) have been divided by 50 in advance.

As seen in Fig. 11, there are two pronounced spectral peaks in both the velocity and the concentration at the frequencies of 0.015Hz ( 67 seconds ) and 0.008Hz ( 125 seconds ). At these frequencies, the coherences of the velocity versus the concentration are high and the phase differences between them are nearly 180 degrees. Therefore, it can be said that the concentration of the suspended-load becomes high when the velocity is negative, i.e. the direction of the current is offshoreward. There is, however, no spectral peak in the concentration at the frequency of the incident waves.

The breaking positions and the breaking types of the incident waves were visually observed in B, and the results were recorded with a voice on a magnetic-tape, on which the velocity and the concentration of the suspended-load were also recorded at the same time by means of a Data Recorder. Figure 12 shows the wave breaking type and the on-offshore distribution of the wave breaking position. In this case, the mean period of wave breaking is about 19 seconds, which is calculated by dividing the visual observation time by a total number of waves observed, being longer than that of the incident waves. Then, the waves of small size may have been ignored in the visual observation since the rate of the spilling type is low. As seen in Fig. 12, the measurement position was located inside the breaker zone and at its position the incident waves broke most frequently.

Figure 13 shows the typical example of the records; the upper figure is the on-offshore velocity; the lower figure is the concentration of the suspended-load. The arrows in the middle part of Fig. 13 show the time when the incident waves broke. The opened arrows indicate that the incident waves broke at the offshore-side of the observation point,

Fig. 12 Wave breaking type and on-offshore distribution of wave breaking position.

Fig. 13 Typical example of on-offshore velocity, concentration and breaking position.

while the black arrows indicate that they broke at the onshore-side. Moreover, the figure under the each arrow is the distance in meter from the observation point to the breaking point. All the breaking type in Fig 13 were judged as plungings. According to Fig.13, whenever the concentration of the suspended-load exceeded 20ppt, the incident waves broke at the offshore-side of the observation point which is indicated with the opened arrow. At these times, the concentration suddenly increased, and rapidly decrease except a period of 20 to 60 seconds. This evidence can be explained as follows: The abundant suspended-load due to the wave breaking at the offshore-side of the observation point is transported in forming the suspended-load cloud to the observation point by the onshoreward current under the wave crest. Subsequently it is transported to the offshore direction by the offshoreward current under the wave trough. Since the concentration of the suspended-load rapidly decrease in the second stage, the state of the suspended-load cloud should be maintained without enough diffusion during this process. Almost all of the suspended-load, however, deposit by the time when the following wave crest passes through the observation point without breaking.

During the period of 20 to 60 seconds, the concentration of the suspended-load gradually increased to be more than 20ppt and gradually decreased to be a low level. The condition of the incident waves, which broke at the offshore-side and at the onshore-side of the measurement position alternatively, is different from that of the other periods. Furthermore, the maximum offshoreward velocity occurred at nearly 30 seconds and the duration of the onshoreward velocity was relatively short. Then, the followings are inferred: The tendency of transportation of the suspended-load from the offshore to the observation point is weak due to the short duration of the onshoreward velocity. In this case, the suspended-load due to the wave

breaking at the onshore-side likely to be transported to the observation point. The repetitive wave breakings in a short period has an effect of maintaining the sand in suspension over a long time.

#### 6. NET TRANSPORT OF SUSPENDED-LOAD

At first in this section, the mean velocity is examined. As seen in Fig. 1, the height of the electromagnetic current meters from the sea bottom differed from case to case, e.g. that of the lowest one was 8 centimeters in E and 39 centimeters in the other. The electromagnetic current meters in the upper part occasionally emerged above the water surface when the wave trough passed at the observation point during the relatively low tidal level. Therefore, the records obtained by the lowest current meter in level are used for calculating the mean velocity. Figure 14 shows the changes of the mean velocity of the on-offshore component in 5 minutes during each observation case. The onshore direction of the velocity is defined as positive.

The mean velocity in A, B, C are almost constant of 10 cm/s offshoreward. In the first half of D the mean velocity is 15 cm/s offshoreward, while it is nearly zero in the second half of D. In E the mean velocity gradually changes from about 40 cm/s offshoreward to about 25 cm/s offshoreward.

Taking into account the relative distance from the shoreline to the observation point, these mean velocities are shown together with the vertical mean velocities in Fig. 10. A number of data shown is not enough to give the whole

Fig. 14 Changes of mean velocity of on-offshore component in 5 minutes.

structure of the mean velocity in the surf zone. However, comparing with the experimental results of the mean velocity on the constant sloping beach which were measured by means of a laser doppler velocimeter ( Nadaoka et al. 1982 ), we can see the feature of that the horizontal and vertical mean velocities below the trough level of the incident waves are offshoreward and downward respectively everywhere.

If we assume that the suspended-load will be transported with the same velocity as fluid particles, a net transport of the suspended-load  $Q_{snet}$  passing through a vertical cross section can be estimated as follow:

$$Q_{snet} = \int_0^t \int_{-h}^{\eta} cu \, dz \, dt \tag{1}$$

where  $c$  is the concentration of suspended-load and  $u$  is the horizontal velocity. Since the vertical arrangement of the three electromagnetic current meters were limited, only the time integration is considered hereinafter. In the calculation of the net transport of the suspended-load, the concentration measured at  $C_3$  is used because it is judged based on the analog record of  $C_3$  that there is almost no effect of the entrainment of air bubbles due to the wave breaking on the concentration measured. As seen in Fig. 8, the bias voltage has been considered to be contained in the record of  $C_3$ . Then in the calculation, the concentration is corrected as that the minimum concentration becomes to be 0ppt in each observation case.

The time integration in eq.(1) is conducted numerically with the digital data of both the horizontal velocity component and the concentration of 0.5 second interval which is the mean values of every 5 digital data of 0.1 second interval. The solid lines in Fig. 15 show the accumulation of the net transport of the suspended-load in each

Fig. 15 Accumulation of net transport of suspended-load

observation case. A horizontal axis is for a lapse time and a vertical one is for the accumulation of the net transport passed through the vertical cross section of 1 meter in longshore length and 0.1 meter in height. The accumulation of the net transport was negative, offshoreward, in all cases and the absolute value of it became large in the order of C, B, E, A, D. In the case of D, the onshore net transport occurred in the final 40 minutes because the absolute quantity decreased.

By using the mean velocity and the mean concentration in 5 minutes, the time integration is conducted for D and the result is shown with a dashed line in Fig. 15. The absolute quantity of the dashed line for D is larger than that of the solid line for D. This difference in the final accumulation is considered to be due to that the concentration of the suspended-load is higher when the direction of the current is onshoreward. The same tendency of the difference between the results of the different calculations is also noticed in the case of A, but the difference is small, being about 10 percent. In the remaining cases, the results of the different calculations are almost the same each other.

The net transports of the suspended-load per one minute, which can be estimated by the slope of the tangent to the solid curves in Fig. 15, are shown with closed arrows in Fig. 16, by taking into account the relative distances from the shoreline to the observation point. In the upper part of Fig. 16, the mean concentrations at  $C_3$  during 10 minutes are

Fig. 16 Mean concentration at  $C_3$  in 10 minutes and net transport of suspended-load.

also shown. As seen in this figure, the directions of the net transport of the suspended-load are offshoreward except at the location nearest to the shoreline. These offshoreward net transport should cause the considerable change of the bottom profile. The bottom profile, however, scarcely changed during the field observation. Then, we cannot help considering the onshoreward transport at the other points of the observation point.

Let's examine the location where the onshoreward net transport of the sand occurs. In the outside of the surf zone where the bed-load is predominant, the skewness of the velocity fluctuation becomes greater to the breaker zone from the offshore due to the wave shoaling, which makes the tracers on the sea bottom to move onshoreward ( Nadaoka et al. 1982 ). Therefore, it is considered that the bed-load should be transported in the onshore direction in the outside of the surf zone.

In the surf zone, the skewness of the velocity fluctuation becomes smaller to the shoreline and the direction of the mean velocity is offshoreward near the sea bottom, and the tracers on the sea bottom are transported to the breaker zone ( Nadaoka et al. 1982 ). Therefore it is difficult to consider the onshoreward transport of the bed-load near the sea bottom. The onshoreward net transport of the suspended-load in the upper layer seems to be rather the most probable. This is because the concentration of the suspended-load in the upper layer becomes higher when the wave crest passes ( Tanaka et al. 1979 ) and the detailed measurement in the flume by means of a laser doppler velocimeter shows that the mean velocity above the level of the wave trough is onshoreward ( Nadaoka et al. 1982 ). As seen in Fig. 16, the net transport of the suspended-load is onshoreward at the location nearest to the shoreline or nearest to the mean water surface which located at the onshore-side of the final breaking zone. This evidence supports the above consideration. By considering the positions of both the breaker zone and the final breaking zone, the directions of the net transport of the sand inferred are shown with opened arrows in Fig. 16.

The mean concentration of the suspended-load is about 7 to 8ppt in the breaker zone and about 15ppt in the final breaking zone, respectively. These results agree approximately with the former ones obtained by the direct sampling of the suspended-load in the field ( Tanaka et al. 1979 ). The mean concentration around the offshore-side peak of it distributes asymmetrically with respect to the breaker zone, decreasing gradually offshoreward. This is considered to be because the sand suspended in the breaker zone is transported in the offshore direction by the mean velocity of the same direction.

## 7. CONCLUSIONS

The field observation was carried out at Ooarai Beach in

Japan, in order to understand the relationships between the fluid motion due to the incident waves and the concentration of the suspended-load. Both the fluid motion and the concentration have been continuously measured at the same time in the surf zone. The main two conclusions obtained in this paper are as follows:

The mean concentration of the suspended-load is high in the final breaking zone and in the breaker zone. In the final breaking zone, the concentration fluctuates with the period of the incident waves. On the other hand, it fluctuates with the period longer than 40 seconds in the breaker zone and it becomes high when the current is offshoreward.

The directions of the net transport of the suspended-load measured in the middle layer in and near the surf zone are offshoreward. For this transport of the sand, the compensatory transport of the sand is inferred such as that the bed-load is onshoreward at the outside of the breaker zone and the suspended-load is onshoreward in the upper layer in the surf zone.

In the field observation, the fluid motion and the concentration of the sand were measured only at one fixed point. In order to examine the relationships between them in more detail, it is necessary to measure them at many points at the same time. The effect of the longshore currents on the suspended-load and the mechanism of the suspension of the sand from the sea bottom are subjects for a future study.

In the field observation, the authors received kind assistances from Mr. Kazuo Nadaoka, Tokyo Institute of Technology, and the member of the Littoral Drift Laboratory, Port and Harbour Research Institute. The authors should like to express their grateful thanks to them.

## CHAPTER ONE HUNDRED TWENTY FIVE

### SEDIMENTATION IN DREDGED CHANNELS AND BASINS.

#### PREDICTION OF SHOALING RATES

C.M.Vicente <sup>1)</sup> and L.P.Uva <sup>2)</sup>

#### 1 - ABSTRACT

A method is presented for predicting shoaling in dredged channels and basins where deposition of finer sediment fractions carried in suspension by tidal currents occurs.

The method is based on the analysis of hydrographic surveys of different dates, which show the hydrographic evolution of dredged areas located in the site or in its vicinity. It can also be applied to experimental dredged pits.

Results obtained from the analysis of surveys are worked out by using mathematical expressions deduced from a simplified hypothesis, empirically based. Parameters are determined which can be used to predict shoaling either when new dredgings are made or when previously dredged sites are deepened.

#### 2 - DESCRIPTION OF METHOD

The basic assumption, of empirical nature, considers that the shoaling rate is proportional to the relative bottom elevation. This proportionality is expressed by

$$dC/dt = K(C_e - C) \quad 1)$$

where:

$C$  is a variable that represents the different bottom elevations at instant  $t$ ;  $C_e$  is a constant that represents the bottom natural equilibrium elevation in the zone studied, and  $K$  is a constant sedimentation coefficient that expresses the proportionality already mentioned.

---

1) Research Officer, Laboratório Nacional de Engenharia Civil, Av. do Brasil, 101; 1799 Lisboa Codex, Portugal.

2) Research Assistant, Laboratório Nacional de Engenharia Civil, Lisboa, Portugal.

To establish this assumption three aspects were considered which experience in the field of the maintenance of dredged zones in estuaries has shown to be very general:

- Sedimentation occurs whenever dredging is carried out to make deeper a zone previously in natural equilibrium;
- The sedimentation rate increases as a function of the thickness of the dredged layer;
- The bottom tends to shoal back to its natural equilibrium elevation corresponding to the situation prior to the first dredging operation whenever maintenance dredging is discontinued for a sufficient number of years.

When applying the method it is assumed that the natural equilibrium elevation  $C_e$  and the sedimentation coefficient  $K$  are constant throughout the zone under analysis and do not significantly vary in the course of time. So that this may be true, the following conditions seem to be required:

- The zone analysed must not be too large so that there can be approximate uniformity of the characteristics of sediments in suspension and of hydrodynamic conditions, concentrations and salinities.
- The time interval between two surveys must not be less than one year so that the semidiurnal and fortnightly tidal variations as well as the seasonal variations which hydrodynamic conditions, concentrations and salinities ordinarily present can be eliminated or markedly filtered.

By integrating equation 1), one obtains:

$$C = C_0 + (C_e - C_0) \cdot (1 - e^{-Kt}) \quad 2)$$

This expression is graphically represented by a family of curves, each one giving the time variation of a point of the bottom with the initial generic elevation  $C_0$  (Fig. 1).

The existence of a curve for each initial elevation  $C_0$  enables expression 2) to describe the evolution of a zone with different bottom elevations. The shoaling rate decreases as elevation  $C$  increases, the evolution of erosion prone zones located above natural equilibrium elevation ( $C > C_e$ ) being also reproduced.

The family curves have the elevation  $C_e$  as asymptote.  $C_e$  represents the elevation to which all points at different depths will tend if they are let to evolve naturally during a sufficiently long period.

From expression 2) it may be deduced that, if the evolution of each point in a set follows a family curve, then the mean elevation of that set will also be represented by one of the curves.

It is of interest to compare expressions 1) and 2) with other expressions and empirical methods described in the technical literature on this subject.

A) Lyakhnitsky and Smirnov [2] presented a shoaling coefficient similar to  $K$ . It was defined by

$$\epsilon = \frac{S}{\Delta h}$$

where  $S$  is the mean thickness of the silt layer settled to the bottom of the channel during one year, and  $\Delta h$  is the thickness of the dredged layer.

B) The Balanin formula presented by Djunkovski and Smirnov [1] describes the time variation of shoaling in a dredged channel. It can be expressed through

Fig. 1 Family of curves  $C=C_0+(C_e-C_0)(1-e^{-Kt})$

$$h_t = \frac{1 - (1-p)^t}{(1-p)^t} \cdot (H - H_0)$$

where

$h_t$  is the thickness of the sediment deposit after  $t$  years;  
 $H_t$  is the channel depth;  
 $H_0$  is the initial natural depth;  
 $p^0$  is a coefficient characteristic of sedimentation at the place in question.

If  $t=1$  year, we obtain

$$\frac{h}{H - H_0} = \frac{p}{1-p}$$

which shows that with Balanin's formula the shoaling rate ( $h$ ) is proportional to the thickness of dredging, that is, to its depth with reference to the bottom natural equilibrium elevation ( $H - H_0$ ), as established in 1).

C) Perestrelo [3] in his studies of shoaling of dredged basins in the Tagus estuary empirically fitted exponential curves expressed as in 2), to the points that showed the time evolution of the mean bottom elevation.

This author used this expression only to characterize dredged zones of approximately constant depth. He also considered that, contrary to the present method, the shoaling coefficient depends on the dredged depth.

D) One of the empirical procedures used in USA and cited by Trawle [4] considers the shoaling rate to be proportional to the area of the dredged channel section, measured below the bottom natural equilibrium elevation. This procedure agrees with expression 1) if the section can be considered nearly rectangular, i. e., when the channel bottom width is much larger than the width of its side slopes.

From the analysis of expression 2) it can be concluded that there are two procedures to obtain the values of  $K$  and  $C_e$  which characterize the family of curves (Fig. 1):

- a) From the evolution of mean elevation of a deep zone;
- b) From the variation between times  $t_1$  and  $t_2$ , of the elevation of a set of points of a zone with varied depths.

Using procedure a) one immediately extracts parameters  $K$  and  $C_e$  from the exponential equation which best fits the evolution of bottom mean elevation.

Using procedure b) parameters are obtained as follows: let  $t_1$  and  $t_2$  ( $t_1 < t_2$ ) be the dates of the two surveys, and  $C_1$  and  $C_2$  elevations at times  $t_1$  and  $t_2$  respectively. Then from 2) we have:

$$C_2 = C_1 + (C_e - C_1) \cdot (1 - e^{-K(t_2 - t_1)}) \quad \text{i.e.}$$

$$(C_2 - C_1) = A C_1 + B$$

In case the basic assumption holds, the straight line indicated should fit shoaling at different depths. The straight line coefficients are:

$$A = e^{-K(t_2 - t_1)} - 1$$

and

$$B = (1 - e^{-K(t_2 - t_1)}) \cdot C_e$$

From coefficients  $A$  and  $B$  one obtains parameters  $K$  and  $C_e$ .

### 3 - APPLICATIONS

Both procedures were applied. Procedure a) was applied to the evolution of the mean elevations of two zones. Data concerned Macao outer harbour in the south coast of China (Fig. 2) and a dredged basin in the Tagus estuary in the west coast of Portugal.

Both sets of data correspond to periods during which no main tenance dredging was carried out. To these data could be fitted exponential regression curves such as those already mentioned, and high correlation coefficients were obtained (Figs. 3 and 4). Data used in Fig. 4 were taken from Perestrelo's work [3] referred to above.

Procedure b) was applied in three sites: three applications in a channel of Aveiro lagoon (Mira channel) located in the west coast of Portugal (Fig. 5); one in a dredged channel in the Tagus estuary (Fig. 6); one in Macao, in the Ka-Ho experimental dredged pit (Fig. 2).

The calculation was as follows: a mesh was established with about one thousand points, equally located in the two hydrographic surveys of dates  $t_1$  and  $t_2$  to be compared; the points were grouped according to the elevation ranges of the earlier survey; in each range the mean values of elevations  $C_1$  and of the corresponding shoaling ( $C_2 - C_1$ ) were determined; the regression line best fitting the set of points so defined was determined; parameters  $K$  and  $C_e$  were determined from the coefficients of the lines following the expressions indicated.

In Figs. 7 to 11 the results of instances of application corresponding to such grouping are presented. The amplitude of each range is 0.20 m.

The number of points in each range varied; that is why weighted values were considered in the linear regression. This aspect is clearly shown in the example of Table 1. Notice that the largest deviations from the fitted line were found in ranges to which corresponded a small number of bottom points.

The hydrographic surveys were made at time intervals varying between 1 and 6 years. During those intervals no maintenance dredging was made.

Linear regression was also established between variables  $C_1$  and  $(C_2 - C_1)$  by considering the points not grouped (Examples in Figs. 12 and 13).

Fig. 2 Location map of Macao - Macao outer harbour and Ka-Ho experimental dredged pit.

Fig. 3 Application of procedure a). Macao outer harbour.

Fig. 4 Application of procedure a) to a dredged basin in the Tagus estuary.

Application of the procedure b) brought to light the following aspects:

- It was always possible to establish a good linear correlation between the mean values of depth  $C_1$  and shoaling ( $C_2 - C_1$ ). From the line obtained one could deduce with close approximation the mean shoaling for sets of points contained in each depth range.
- Higher correlations were obtained when surveys were made at larger time intervals.
- In the case of Aveiro lagoon for which three surveys of the same zone were available,  $K$  and  $C_e$  were found to take very close values in the two successive time intervals defined by these three surveys. In the periods 1975-80 and 1980-81,  $K$  values were found to amount to 0.108 and 0.121  $\text{year}^{-1}$ , whereas  $C_e$  values were 1.39 and 2.00 m.

Fig. 5 Location map of Mira channel - Aveiro lagoon.

- A study of the distributions of deviations between shoaling values observed and those calculated by the regression line, considering points not grouped, showed that distributions were similar in all cases analysed regardless of the place and of the time interval between two surveys (Examples in Figs. 14 and 15).

Ninety per cent of the deviations fell in a range of  $\pm 50$  cm. It is assumed that  $\pm 25$  cm is the range of deviations corresponding to inaccuracies in surveys and in their comparison. The remainder is believed to be due to the approximations inherent in the basic assumption which disregards the influence of other variables besides depth influencing the shoaling rate.

Fig. 14 Deviation histogram. Mira chanel (Aveiro lagoon). Surveys: Sep. Oct. 1975 and Sep. 1981. Points not grouped.

The occurrence of identical deviation distributions in all the cases analysed explains why the correlation coefficient improved as the time interval between two surveys increased. With large time intervals shoaling takes higher values, and the relative value of deviations decreases. This aspect is shown in Figs. 12 and 13.

- The fact that high correlations are usually not found except when referred to mean values of the two variables will not permit as a rule to predict shoaling accurately enough at a given point but only in a zone or at a numerous set of points of the bottom. This limitation does not seem to be very inconvenient since the practical purpose of the method is to predict the evolution either of reaches only or of the whole of dredged channels and basins.

#### 4 - CONCLUSIONS

High correlations could be established between mean values of depth and of shoaling in different dredged zones where deposition of finer sediment fractions carried in suspension by tidal currents occurs. In every case data were fitted by empirically based expressions that were worked out to represent the variation of bottom elevations with space and time.

The results of the comparison of surveys can be used to predict volumes of maintenance dredging of channels and basins to be established or deepened in the zone under study. It is assumed that this zone will not be subjected to long term variations of sedimentation characteristics.

The procedure to be used for this prediction consists in the definition of the sedimentation coefficient  $K$  and equilibrium elevation  $C_0$ , based on the analysis of two or more surveys. Once these parameters are known, annual maintenance rates for different alternative dredging elevations  $C_0$  can be estimated by using the expression derived from 2), with  $t = 1$  year.

It is worth mentioning that procedure b) requires only two surveys provided they are carried out within an interval of at least one year during which no dredgings are made. Such a feature makes it largely adequate to practical use due to ordinary limitations as regards field data to characterize shoaling conditions.

## CHAPTER ONE HUNDRED TWENTY SIX

### SURVEY TECHNIQUES USED TO MEASURE NEARSHORE PROFILES

Christopher G. Gable (1) and Jerome R. Wanetick (2)

#### Abstract

The three most common survey techniques used to measure nearshore profiles are (1) conventional boat-sonic depth sounder; (2) hydrostatic pressure profiler; and (3) the self powered Coastal Research Amphibious Buggy (CRAB). Theory of operation and methodology used for each technique are summarized and evaluated. Three separate field tests using survey data from each technique are evaluated for system repeatability. Data reduction, sea surface correction, and filtering methods for boat-depth sounder survey data are examined.

#### 1. Introduction

The measurement of nearshore profiles is extremely important to coastal engineers concerned with navigation and shore protection structures, cross and longshore sediment transport, and seasonal shoreline changes. Accurately surveying the nearshore region between a relatively stable point on the beach to a depth of little or no elevation change is a frequent problem to the coastal engineer. As described by Seymour (1984), in many coastal engineering applications of nearshore surveying, the absolute elevation is not as important as the changes in elevation since the previous profile. Wave orbital velocities responsible for mobilizing the sediment decrease with increasing water depth, thus the amount of change in sand elevation is expected to decrease with distance offshore. In general, the bottom slope decreases with offshore distance such that the small changes in deeper water are integrated over a large area resulting in very significant sand volume changes. For example, a net change of 30,000 cubic meters over approximately one kilometer of beach represents an average change in depth of only 3 cm. This results in the paradox that the greatest accuracy of measurement is required at the greatest distance away from the known reference elevation.

Surveying the dry portions of the beach to a depth of 1 meter use conventional land surveying methods, using rod, level, and chain techniques with sufficient accuracy of plus or minus 1 cm. Surveying the underwater portion of nearshore beach profiles (-1 to -10 meters) has presented significant accuracy problems. The boat-depth sounder

- (2) Development Technician, Ocean Engineering Research Group, Scripps Institution of Oceanography, University of California, La Jolla, CA 92093

method is unable to operate thru the active surf zone region (-1m to -3m depth) and uses the sea surface as the vertical datum. Surface waves with a broad range of frequencies must be filtered out of the profile. Two other recently developed survey systems eliminate the sea surface reference uncertainty by measuring the bottom profile directly. The Hydrostatic Profiler, developed at Scripps Institution of Oceanography, is a portable system using the hydrostatic pressure principle to measure vertical differences between a pressure sensor that follows the profile on the ocean bottom and a reference sensor on the shoreline. The two pressure sensors are connected by a fluid filled tube and horizontal distance determined by measuring the extension of the tube. The Coastal Research Amphibious Buggy (CRAB) of the U.S. Army Coastal Engineering Research Center (CERC) is a self-powered stable platform that traverses the ocean bottom carrying a laser reflector above water. A total station survey instrument located over a known bench mark on land, shoots the reflector at discreet points to obtain precise X,Y,Z data from the dry beach to a depth of 10 meters.

This paper will briefly summarize and evaluate each of these survey techniques. Theory of operation, methodology, advantages, limitations, accuracy in repeatability, and depth sounder data filtering methods using actual field data are discussed.

## 2. Boat-Depth Sounder Method

### 2.1 Theory of Operation and Field Techniques

Surveys of the dry beach out to wading depth use the conventional rod, level, and chain technique. By selecting times of low tide, wave, and current conditions, it is possible to extend the rod and level technique seaward to a depth of about 1 meter with an accuracy of plus or minus 1 cm. The nearshore bathymetry (-1 to -10 meters) is usually measured by some type of Automated Bathymetry System (ABS). An ABS consists of state-of-the-art electronic equipment including a sonic depth sounder, depth digitizer, range-range positioning navigation system, printer, data logger, and cassette recorder. The ABS is secured to a small survey boat (Figure 1) and requires one boat operator, one field electronic engineer, and a minimum of two experienced surveyors for proper operation. Boat-depth sounder surveys are best performed during the highest possible tide to provide both overlap and data quality control with the rod and level survey. The general procedure for conducting these overlapping surveys is described in Nordstrom and Inman (1975) and shown in Figure 2.

Both the depth sounder and digitizer measure and record the elapsed time interval between transmission of an acoustic pulse and receipt of a return echo from the seafloor. To precisely relate this time interval to water depth, a speed of sound adjustment is made at the survey site. This adjustment is accomplished by conducting "bar" checks, a process of lowering a target ("bar") on a calibrated line to known depths below the depth sounder transducer. Both the depth sounder and digitizer are adjusted to display the proper depth precisely.

To assure that the survey boat remains on the correct range azimuth and to duplicate each survey line monthly or seasonally; a transit and

Figure 1 Automated Survey System

Figure 2 Survey Overlapping Procedure  
(from Nordstrom and Inman, 1975)

electronic positioning responder is set over each profile bench mark. The transit operator gives course corrections to the boat operator via FM radio as shown in Figure 3. Two range survey targets are placed on-range on the beach to provide the boat operator a visual line. Offshore distance is measured directly from the responder located over the bench mark. The second positioning responder is located over a bench mark a sufficient distance up or down the beach to provide an accurate measure of the distance off-line at each position fix.

An Automated Bathymetry System used for an extensive series of nearshore surveys for the Nearshore Sediment Transport Study (NSTS) in Santa Barbara, California, is described in detail by Dean et al. (1982) and Gable (1981).

Bruno and Gable (1976) describe a series of nearshore surveys made at Channel Islands Harbor, California, using a more primitive but widely used "standard" survey method. For this method the survey boat operator is directed along the profile azimuth visually with on-line targets and course corrections updated via FM radio from an on-shore sextant operator. Every ten seconds, the analog depth strip recorder is marked and vessel position recorded on a plane sheet via plane table and alidade as shown in (Figure 4).

These boat supported survey systems, which use the sea surface as the vertical datum, suffer from the presence in the analog and digital record of surface waves with a broad range of frequencies. The measurement of the instantaneous sea level needed to adjust the depth sounder record is subject to numerous errors. These errors include the measurement of tide levels at locations several miles away, high frequency wind driven waves causing water level set-up, and waves of longer period (1-15 minutes) associated with surf beat and trapped edge waves.

## 2.2 System Evaluation

The advantages of using the boat-depth sounder techniques include: (1) the ability to survey over the sand-rock interface; (2) precise X,Y position with plus or minus 3 meter accuracy using microwave positioning equipment; (3) continuous depth sounder, analog and/or digital record; (4) proven electronic and survey equipment readily available for purchase or lease; and (5) after initial set up, rapid successive profile data is collected.

The disadvantages include: (1) wave and sea level uncertainties; (2) the inability to detect small relief features due to wave motion and data filtering techniques; (3) the inability to accurately survey thru the active surf zone; (4) the technique is highly labor and capital intensive; and (5) vertical motions of the boat relative to mean sea level, caused by waves of any frequency, introduce errors that are difficult to remove objectively.

## 2.3 Repeatability Test and Filtering Techniques

To determine the system accuracy of the depth sounder survey method, a series of three repetitive surveys were run over the same range line on the same day. An Automated Bathymetry System of the type described previously was used to collect the depth sounder data. All data was collected from Range W-8 at Leadbetter Beach, Santa Barbara,

Figure 3 Course Correction Procedure

Figure 4 Plane Table Survey Procedure

California, on 25 February, 1980. within a 45 minute period. All depth sounder data presented in Figures 5-9 have been corrected for tide. The three depth sounder repeatability runs presented in Figure 5 is the raw digital depth data. The variance in the raw data increases with distance offshore and is very close to the measured sea surface variance with a significant wave height of 41 cm. The average range at the indicated distances is 20.1 cm. The general trend of the beach slope can be seen; however, all bottom detail is lost due to the high signal to noise ratio. If a running mean filter is used on each survey run (Figure 6), this signal to noise ratio and variance is significantly reduced. The average vertical range is decreased by almost a factor of three. Varying the number of points to be averaged over each iteration determines the best fit for each data set. Fifteen points per iteration provided the best fit for this particular data set. Most high frequency noise has been filtered; however, some low frequency noise still remains masking small bottom features that may actually exist. The variance can be reduced even further with a corresponding loss of bottom detail by averaging more points per iteration. In Figure 7, a classical least squares has been applied to the digitized distance-elevation pairs to fit a polynomial curve to each raw survey data run. A seventh order polynomial was found to best fit this data set. The variance at distance 200, 300, 400, and 500 meters is smaller than that of the running mean fit. The average range of the polynomial fit is half that of the running mean. Taking the simple average over a specified distance interval of all three raw data runs is a technique also routinely used by some investigators in an attempt to filter out the sea surface changes. As seen in Figures 8 and 9, the averaged survey data is more coherent but the signal to noise ratio is still quite large compared with the running mean and polynomial fits of these averaged data.

### 3. Hydrostatic Profiler Method

#### 3.1 Theory of Operation and Field Techniques

The hydrostatic profiler is a profiling system which uses the hydrostatic pressure principle to measure vertical differences between a pressure sensor that follows the ocean bottom and a stationary reference sensor on the beach. The two pressure sensors are connected by a fluid filled tube and the horizontal (offshore) distance determined by measuring the extension of the tube. A schematic of the profiler configuration and theory of operation is provided in Figure 10. The hydrostatic profiler has six main components: (1) a highly sensitive pressure transducer and thermistor assembly at each end of the cable; (2) a cable containing the necessary electrical conductors, strength members, and a fluid filled tube that provides a hydraulic path between the transducers; (3) a winch mounted into the bed of a four wheel drive truck to house the reference sensor and to store and retrieve cable (Figure 11), (4) a pinch wheel distance counter (Figure 12); (5) a sled to carry the profiling transducer (Figure 13); and (6) a portable data logger to record data from all sensors. Visual target cones are set on the beach designating the range azimuth to be followed. The profiler sled is towed offshore using an inflatable surf rescue boat (Figure 14). The boat must stay on the correct range azimuth while pulling the sled and cable out to maintain an accurate horizontal (longshore) position. The profiler sled is lowered to the ocean bottom at the desired offshore position or depth. The data logger is activated and the sled is automatically winched shoreward at specified increments (usually every 5 meters). At each distance increment the profiler sled is stopped and remains stationary for a 1 to 2 minute period. This stationary period is needed to average out pressure fluctuations in the tube caused by acceleration of the fluid while winching. The profiler is finally stopped at an offset point on the beach which was previously surveyed horizontally and vertically to a known bench mark. This offset point is the initial point from which the entire profile is referenced. The theory of operation, design specifications, calibrations, operational deployment, signal processing, and performance evaluation of the profiling system is described in detail by Seymour and Bothman (1984).

#### 3.2 System Evaluation

The advantages of using the hydrostatic profiler to measure nearshore profiles include: (1) the total elimination of sea surface elevation uncertainties by measuring the ocean bottom directly; (2) the ability to survey discreetly from deep water (~10m) through the active surf zone; (3) precise offshore distance measurements of plus or minus 1 meter and depth data of plus or minus 5 cm. (4) the profiling system is highly mobile, requires minimum manpower to operate, and can be easily transported to remote survey sites; and (5) small relief features (bars, troughs, etc.) are easily detected with very high resolution.

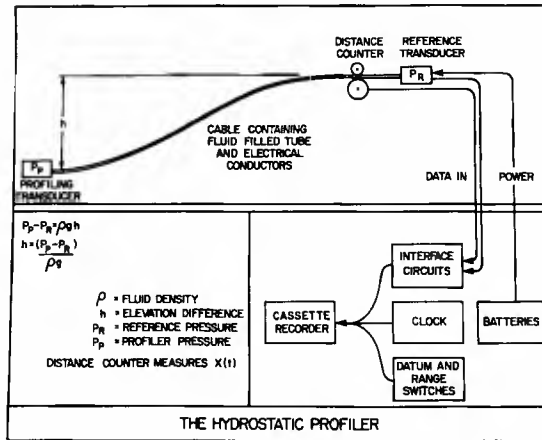

Figure 10 Schematic of Profiler Configuration (from Seymour and Bothman, 1984)

Figure 11 Cable Winch System on Four Wheel Drive Truck

Figure 12 Pinch Wheel Distance Counter and Winch System

Figure 13 Profiling Transducer Sled

Figure 14 Profiler Deployment

The disadvantages include: (1) the longshore position of the profiler is very dependent on the skill and quality of deployment; (2) the profiler sled and cable is dragged over the ocean bottom and can be easily caught on obstructions such as rock, reef, wreckage, or debris; (3) data quality decreases with high waves, strong currents, and steep beaches due to cable strumming and high signal to noise ratio; (4) the offshore distance is limited by a fixed cable length and (5) equipment set-up and surveying time for one profile line takes a minimum of two hours.

### 3.3 Repeatability Test

To determine system accuracy, a series of three repetitive surveys were run over Range 181 at the CERC Field Research Facility at Duck, North Carolina, on 25 July, 1984, within a six hour period. The environmental conditions were ideal for such a test with low wave and current conditions. The hydrostatic profiler sled was deployed offshore each time by CERC's CRAB. There was no attempt to reoccupy identical positions. Therefore, elevations were compared by linearly interpolating data at five meter distances.

As shown in Figure 15, the variance at distance 200 and 400 meters for the three runs is quite small. The variance of 8.54 cm at distance 300 meters is due to actual elevation change of the offshore bar-trough system. The average range for all three distances is 7 cm.

Figure 15 Hydrostatic Profiler Repeatability Test

#### 4. Coastal Research Amphibious Buggy (CRAB) Method

##### 4.1 Theory of Operation and Field Techniques

The CRAB is a 10.6 meter high vehicle which uses three hydraulically driven tires on the legs of a tall tripod (Figure 16). Power is supplied by an automobile engine on the platform above the maximum waterline. This vehicle, when combined with an electronic total survey station, allows rapid, accurate surveying of the surf zone and nearshore waters out to depths of 9 meters. The primary function of the CRAB is to support a prism cluster above water. The exact distance from the prism cluster to the bottom of the tripod wheels is measured precisely before each survey. Visual range targets are set on the beach designating the range azimuth the CRAB operator is to follow. A Zeiss Elta-2 electronic total survey station is set up over a known bench mark. This compact instrument contains an electronic distance meter, a self-reading electronic theodolite, a micro-processor, a rechargeable power supply, and an interchangeable solid-state memory. The instrument is aimed at the prism cluster mounted on the CRAB to obtain a data point (Figure 17). Within seconds the distance to the CRAB and the horizontal and vertical angles are automatically measured. The micro-processor instantaneously calculates the X,Y,Z coordinates of the position under the CRAB and stores them into memory. Direct instrument read-out allows the surveyor on-shore to help guide the CRAB operator in maintaining accurate horizontal position. Data points are measured discreetly along the profile range approximately every 10 meters. Each data point takes about 10 seconds to measure and one entire profile about 45 minutes to complete. A detailed description of the CRAB specifications, data processing, and system evaluation is provided in Birkemeier and Mason (1984).

Figure 16 CERC's Coastal Research Amphibious Buggy (CRAB)

Figure 17 Zeiss ELTA-2 Survey Instrument Sighting on CRAB

#### 4.2 System Evaluation

The advantages of using the CRAB profiling system include: (1) the total elimination of sea surface elevation uncertainties by measuring the ocean bottom directly, (2) the ability to survey discreetly from deep water (-10m) through the active surf zone; (3) precise instantaneous X,Y,Z data at discreet points; (4) ability to operate in high wave and strong longshore current conditions; (5) ability to conduct surveys with reduced long term cost, minimum manpower, and high accuracy of plus or minus 5 cm.

The disadvantages include: (1) the CRAB traverses over the ocean bottom and can easily be caught or damaged on obstructions such as rock, reef, wreckage or debris. (2) depth of profile is limited by fixed superstructure CRAB height of 11 meters; (3) high initial expense in CRAB construction and instrumentation purchase; (4) the size of the CRAB and cost of transportation make the system highly immobile and must be used for long periods within a limited geographic area; and (5) small relief features are not always detected due to wide wheel base.

#### 4.3 Repeatability Test

To determine system accuracy, a series of three repetitive CRAB surveys were run over Range 183 at the CERC Field Research Facility at Duck, North Carolina, on 8 July, 1982, within a 4 hour period. Environmental conditions were moderate with 70 cm significant wave height and 9 second significant period. Longshore current velocities were low. The CRAB made no attempt to reoccupy identical positions. Therefore, elevations were compared by linearly interpolating data at five meter distances. As shown in figure 18, the variance at distance 200, 400, and 700 meters is quite small. The variance of 15.52 cm between distance 100 and 200 meters is due to actual elevation change of the berm. The average range for all four distances is 11.5 cm.

Figure 18 CRAB Repeatability Test

## 5. Discussion and Conclusion

The three survey techniques most frequently used to measure nearshore profiles are: (1) boat-depth sounder; (2) Hydrostatic Pressure Profiler; and (3) the Coastal Research Amphibious Buggy (CRAB). The sea sled technique, discussed by Sallenger et al. (1983), is presently used for special studies and not routine nearshore surveys. The sea sled is identical in principle to that of the CRAB; however, it is not self powered and is physically much smaller. Repeatability data from sea sled surveys was not available to include in this paper and therefore not discussed.

The boat-depth sounder technique is the most widely used and accepted method. All equipment is electronically proven and readily available worldwide. The field data collection and data processing techniques will vary with investigator. For example, surveys conducted to support Sea Grant's Nearshore Sediment Transport Study (NSTS) used a highly electronic automated survey system. To help filter out the effects of waves and low frequency oscillations, each profile line was surveyed three times and the depth and distance determined by averaging the values obtained over a five meter interval. The Army Corp of Engineers generally use electronic navigation equipment or a standard plane table technique for positioning with an analog or digital depth recorder. Each profile is surveyed only once and the raw data tabulated with no sea surface filtering whatsoever, or is manually hand smoothed. The classical least squares fit, running mean, and averaging techniques in filtering tide corrected depth sounder data, remove all bias and subjectivity that is inherent to the normal hand smoothing and manual digitizing techniques. However, due to the continual problem of using sea level as the vertical reference and correcting for both high and low frequency noise, depth sounder data will always possess a degree of uncertainty and ocean bottom detail will always be masked by sea level fluctuations. A highly controlled repeatability test conducted during small wave conditions using an automated survey system shows that the average range in digital depth was 20 cm.

As a result, depth sounder surveys are adequate for profile studies where gross seasonal changes or shoreline erosion trends are the goal. However, if confident measurements are required with fine detail and low volume error, such as sediment transport and bedform studies, the Hydrostatic Pressure Profiler or CRAB is highly recommended. The repeatability test for both of these survey systems show that the average range was less than 10 cm while all bottom detail was preserved. These systems follow the ocean bottom directly producing highly accurate detailed maps of the nearshore region.

Finally, it is acknowledged that the field data presented in this paper is not the ideal data set. Survey data from each technique was collected at different locations, times, and conditions. A future experiment has been designed to specifically address the repeatability of each technique simultaneously on the same beach.

## 6. Acknowledgements

The financial support provided by the Sea Grant Program and the Army Corps of Engineers is greatly appreciated. The authors would also like to thank W.A. Birkemeier of the CERC Field Research Facility for providing CRAB survey data and S.L. Elgar of Scripps Institution of Oceanography for providing valuable ideas on filtering depth sounder data.

## CHAPTER ONE HUNDRED TWENTY SEVEN

### LONGSHORE VARIABILITY OF WAVE RUN-UP ON NATURAL BEACHES

R. A. Holman\* and A. H. Sallenger, Jr.\*\*

#### ABSTRACT

The longshore variability of wave run-up from a natural beach is examined using data from a large field experiment at the Field Research Facility in Duck, North Carolina, in October, 1982. Two particular runs were selected for intensive analysis. These were chosen to represent a dissipative and a reflective surf zone condition, so have Iribarren numbers 0.97 and 1.81 respectively. The dissipative data run showed much more uniform statistics in the longshore than did the reflective run. Also, the dissipative run was dominated by the infragravity band energy while the reflective run was dominated by the incident band. Selection of several important frequency bands for frequency-domain EOF analysis showed that the lower frequency peaks appeared to be associated with leaky modes (very long longshore wavelengths) and the pier had little influence. On the other hand, higher frequencies were clearly influenced by the pier in both amplitude and phase. An interesting subharmonic peak from the reflective run appeared to be a low (but not zero) mode standing edge wave.

A new technique, time exposure photography, is introduced. It allows the quick determination of longshore variability such as would be produced by a dominant standing edge wave. It can also be used to image offshore bathymetry and sand bar systems.

#### INTRODUCTION

Wave run-up, the time-varying motion of the water's edge relative to still water level, is generally considered composed of two components, the set-up and the swash. If we denote the time series of run-up as  $\eta_R(t)$ , then

$$\eta_R(t) = \bar{\eta} + R(t),$$

where  $\bar{\eta}$ , the time average of the time series, is the set-up and

\* Associate Professor, College of Oceanography, Oregon State University, Corvallis, OR, 97331.

\*\*United States Geological Survey, Menlo Park, CA, 94025.

$R(t)$  is the swash. Both of these quantities are of considerable interest to engineers. The combination of set-up and swash must be considered for the determination of safe set-back distances for structures on a coast. The velocities of the swash may provide the major erosive force on sediment or artificial structures.

While run-up at a point is a useful quantity to measure, it is longshore gradients of run-up which provide clues to some of the most interesting nearshore dynamics. Bowen (1969) showed how longshore gradients in set-up would force longshore currents, and so could generate rip currents at set-up minima. For the swash, it is the longshore phase relations which are most useful in that they can be used to define a longshore wavenumber,  $k_y$ , of the motion. This is particularly relevant to the understanding of the infragravity band in nearshore wave spectra (frequencies from 0.003 to 0.05 Hz). There has been a great deal of recent debate whether these long period motions are in the form of discrete free waves trapped to the shoreline, called edge waves, or alternately in non-trapped waves called leaky modes. For a particular frequency,  $\sigma$ , these possibilities are distinguished by

$$\begin{aligned}\sigma^2 &\leq gk_y && \text{- edge waves} \\ \sigma^2 &\geq gk_y && \text{- leaky modes.}\end{aligned}$$

The wave for which the equality holds is called the cutoff mode. Thus measurement of the longshore structure, hence longshore wavenumber, of the motions is the most direct way to resolve the controversy.

It is the intention of this paper to examine the longshore variability of run-up from a natural beach based on an extensive dataset obtained at Duck, North Carolina in October, 1982. We will first describe the general experimental layout and the field techniques used. Two runs, representing very different incident wave conditions, are then selected for intensive study. These data are analyzed both in terms of their general statistics and in terms of frequency through frequency-domain EOF analysis. In the final section we present a new technique, time-exposure photography, to quickly describe longshore variability in swash statistics. The technique also has application to the remote sensing of offshore bathymetry.

#### THE FIELD EXPERIMENT

In October 1982 a large field experiment was carried out at the CERC Field Research Facility (FRF) at Duck, North Carolina (Mason et al, in press). The FRF is located in the middle of 100 km stretch of barrier islands with the only topographic perturbation in the longshore being the pier itself which extends 560 m offshore and causes some interruption of the natural contours (Miller et al, 1983). The average beach face slope was approximately 1:10 although this value varied significantly through the experiment and on several

occasions (when the shoreline was very rhythmic) in the longshore. A bar system was present approximately 50 m offshore although the position and amplitude of the bar varied in response to storms. Bar morphology varied from linear to crescentic. A typical example of morphology in the vicinity of the pier is shown in Figure 1.

Figure 1. Typical bathymetry in the environment of the pier for October, 1982 (right hand figure). On the left is a blow-up of the beach immediately surrounding the pier, showing the longshore locations of ranges referred to later.

Run-up data were collected using longshore-looking time-lapse photography from super 8 movie cameras mounted on scaffolding on the pier, approximately 13 m above mean sea level. Large markers were placed in pairs, spaced 10m in the cross-shore direction, every 50 m down the beach for 300 m on either side of the pier. Additional single markers were placed at odd multiples of 25 m. The markers served as a reference for the beach profile grid and provided scale for the film images.

A data run usually consisted of running two movie cameras synchronously, one pointed to the north and one to the south. A frame was shot every second for a total run length of 35 min, or 2100 frames. Slight differences in the digitizing interval were corrected by carefully timing the length of each run, counting the number of frames taken, and calculating the average  $\Delta t$ . Laboratory studies have shown no noticeable drift in this number through a 35 min period.

Digitization of the film data for any of the longshore locations is accomplished with a computer-assisted digitization scheme described in Holman and Guza, 1984. Replicate digitizations by different operators, performed on a number of films, showed the standard deviation on set-up and significant swash height measurements presented here to be approximately 10%. Inter-calibration of the film technique with the dual resistance wire runup sensor on a low-slope beach showed some systematic differences in measured means and standard deviations, with the film technique registering a slightly higher mean, and a 35% larger standard deviation (83% larger variance) than the wire sensor (Holman and Guza, 1984). This is partly related to the sensitivity of the wire sensor to the height of the wire above the beach, and partly to the subjective interpretation of rundown of the films.

Beach surveys were carried out using the FRF Zeiss Elta-2 electronic total station system. This gives profile data, corrected to mean sea level, with an accuracy of better than 0.5 cm over the area of filming. These data were used to transform the raw cross-slope runup data to a vertical signal. All data presented in this paper will be in terms of the vertical component of runup. The profile data were also used to define a foreshore beach slope,  $\beta$ , as the mean slope over the 5m width of beach surrounding the mean sea level at the time of the run. Profile data were collected at least every two days and up to twice per day when the profiles were changing rapidly.

Incident wave data were collected from a waverider buoy positioned 3 km offshore in approximately 20 m depth. Incident significant wave height is calculated as  $H_0 = 4\sigma$ , where  $\sigma$  is the standard deviation of a twenty minute time series. Incident period is the period associated with the peak energy in the spectrum. Tide data is provided by a NOAA tide gauge attached to the end of the pier. Raw tide gauge data, consisting of spot measurements of sea surface elevation every six minutes, showed a standard deviation of 0.04 m during storms. Mean sea level was estimated from the average of the 6 consecutive measurements corresponding to the data run. The tide gauge was outside the surf zone for all but the largest storms.

#### OBSERVATIONS

Figure 2 shows the incident wave height and period statistics for the month of October, 1982, and indicates the duration of the experiment. Through the three weeks of the experiment, more than 80 films were exposed. Given the wealth of data available, it was decided to select two particular runs for intensive analysis for this paper. The two runs chosen were picked to represent different sorts of surf zone conditions. Run 19, shown in figure 2 as occurring near the beginning of the first major storm, is representative of dissipative conditions, with a wide surf zone of spilling breakers.

The deep-water incident wave height was 2.4 m with a peak period of 12 seconds. The longshore average beach slope was 0.10. By contrast, run 56 represents fairly reflective surf zone conditions. The incident wave height was 0.7 m, period 12.5 seconds, and average beach face slope 0.10.

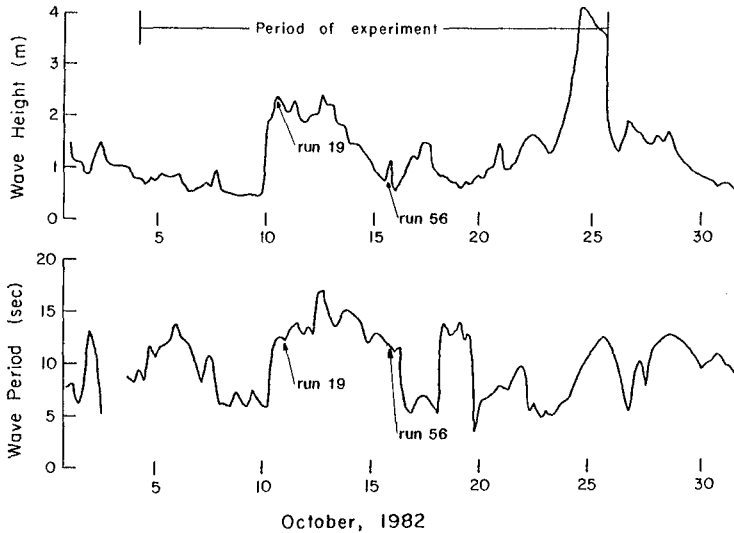

Figure 2. Significant wave height and peak period measured at the offshore waverider in 20 m depth. Noted are the duration of the entire experiment and the times of the two runs selected for intensive analysis.

Several non-dimensional measures exist which express the degree to which a surf zone is dissipative or reflective. One of these, the Iribarren number  $\xi_0$ , is given by

$$\xi_0 = \frac{\beta}{(H_0/L_0)^{1/2}}$$

where  $H_0$  is the deepwater significant wave height and  $L_0$  the deepwater wavelength associated with the peak period in the incident spectrum. For run 19 the Iribarren number was 0.97, while for run 56 it was 1.81. Previous papers had shown that  $\xi_0$  or a similar parameter is an important parameter in swash dynamics (Guza and Inman, 1975; Holman and Sallenger, in press). Thus it is of interest

to look for systematic differences between these two data runs.

Figure 3 shows the significant swash height and the set-up statistics for runs 19 and 56 as a function of longshore distance. Several general observations can be made from these figures. The first is regarding the influence of the FRF pier, located at  $y=0$ . For run 19 there are systematic differences in both these quantities across the pier with the significant swash height changing from  $1.49 \pm 0.13$  (error bars being one standard deviation) to the north of the pier to  $2.01 \pm 0.22$  to the south, and set-up changing from  $1.24 \pm 0.18$  to the north to  $0.80 \pm 0.14$  to the south. Interestingly, the incident waves approached from  $20^\circ$  north of the local beach normal, so the higher swash was actually in what should have been a shadow zone. We can only speculate that this arises from refraction over the complicated bathymetry associated with the pier.

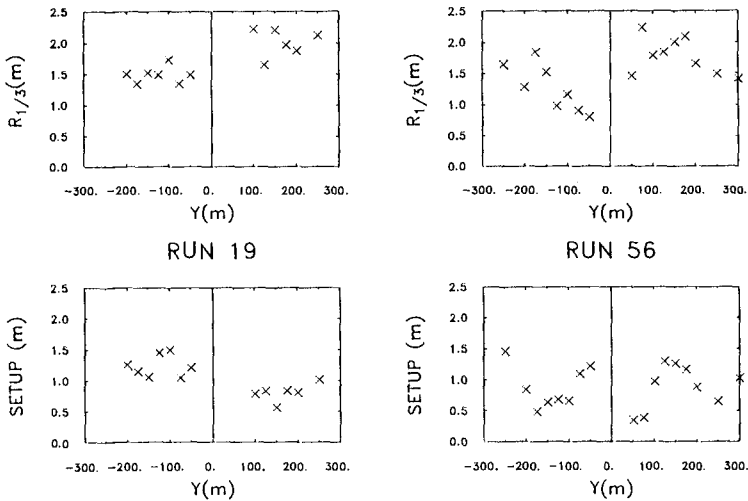

Figure 3. Significant swash height and set-up statistics for runs 19 and 56 as a function of longshore distance. The solid line at  $y=0$  is the FRF pier.

For run 56 the swash height varies from  $1.27 \pm 0.37$  north of the pier to  $1.78 \pm 0.30$  to the south. Again the larger swash is to the south despite an angle of incidence  $8^\circ$  to the north of local normal. The set-up data for this run show uniform statistics across the pier, from  $0.89 \pm 0.34$  to the north, to  $0.89 \pm 0.36$  to the south.

The second general observation regarding this figure is that if we consider the sides of the pier separately, the statistics associated with the dissipative conditions are a great deal more uniform in the longshore than those associated with the reflective conditions. The average standard error (standard deviation divided by the mean) for run 56 was 31.1%, about 2.4 times the value, 13.1%, for run 19. While one cannot make a conclusion about longshore uniformity based on two examples, the trend of reduced longshore variability during dissipative conditions has been noted by others including Wright and Short, 1983, and Garrow, 1985. Note that a small longshore variability in bulk statistics does not indicate that longshore dependent processes such as edge waves are not operating, just that their statistics vary little when averaged through all frequencies. The frequency dependency of these data will be examined in the next section of the paper.

The final point to note regarding figure 3 is that despite a large difference in the incident wave height between these two runs (2.4 versus 0.7m), the set-up and swash statistics are not strongly different. In other words, the relative set-up and swash (normalized by the incident wave height) for the high Iribarren number day is much larger than for the low Iribarren number day. This dependence of non-dimensional run-up statistics on Iribarren number was noted also in Holman and Sallenger, in press (not surprisingly, since that paper was based on the same dataset).

#### FREQUENCY-DEPENDENT ANALYSIS

To understand the longshore variability of statistics in greater detail, it was necessary to resolve the data into the frequency domain and perform frequency-dependent analysis. Figures 4 and 5 show the spectra for each longshore range for runs 19 and 56, respectively. Spectra for individual ranges are plotted according to the indicated axes but are each displaced vertically 0.615 orders of magnitude from the previous. Spectra labels correspond to the longshore locations shown in figure 1. Also shown are the frequency bands, labelled at the bottom of the figure, which will be used for subsequent frequency-domain EOF analysis. These frequency bands are 0.005 Hz wide for the infragravity band (20 dof) and 0.01 Hz wide for higher frequencies (40 dof).

Systematic differences are evident between the spectra for the two days. For the reflective day, run 56, the single dominant peak is at the incident frequency and is just the standing wave component of the incident waves. For lower frequencies, the infragravity band is low energy and without significant structure. On the other hand, the spectra for the dissipative day, run 19, are dominated by the infragravity band. The spectral peak associated with the incident band, while still present, is of lower energy. There is also some structure through the infragravity band.

Analysis for each data run proceeded on a frequency band by frequency band basis. The results from only the three most important bands for each run will be presented in this paper. For run 19, band C (0.07-0.08 Hz) was taken to represent the incident waves. Band 8 (0.035-0.040 Hz) was selected since it appeared particularly energetic, especially in the north end of the array. Finally, band 4 (0.015-0.02 Hz) showed some signs of a significant peak, but, more

Figure 4. Displaced spectra for all longshore ranges digitized for run 19. Each spectrum is displaced 0.625 orders-of-magnitude above the previous. Letters at right refer to longshore ranges indicated in figure 1, labels at bottom refer to individual frequency bands marked by the dotted lines (labels mark the upper limit of their band).

importantly, was found to be significant in data taken by offshore sensors described in this volume by Sallenger and Holman, in press. For the reflective day, run 56, the incident peak (band C, 0.07-0.08 Hz) was clearly important. Also common to all sensors was a low-frequency hill (band 1, 0.000-0.005 Hz). Finally, in a number of the spectra there are suggestions of a small peak at the

subharmonic frequency (band 8, 0.035-0.040 Hz, one half of the incident band frequency). Since Guza and Inman, 1975, have suggested the importance of the subharmonic on reflective beaches, further investigation of this band was indicated.

The longshore structure of each band was found using the technique of frequency-domain empirical orthogonal functions or EOFs (Wallace and Dickenson, 1972; Wang and Mooers, 1977; Holman and

Figure 5. Same as figure 4, but for run 56.

Bowen, 1984). If the cross-spectra between pairs of ranges  $j$  and  $k$  for a particular frequency range is given by

$$U_{jk} = C_{jk} + iQ_{jk} \quad j, k = 1, N$$

where  $C$  and  $Q$  are the cospectral and quadrature spectral estimates

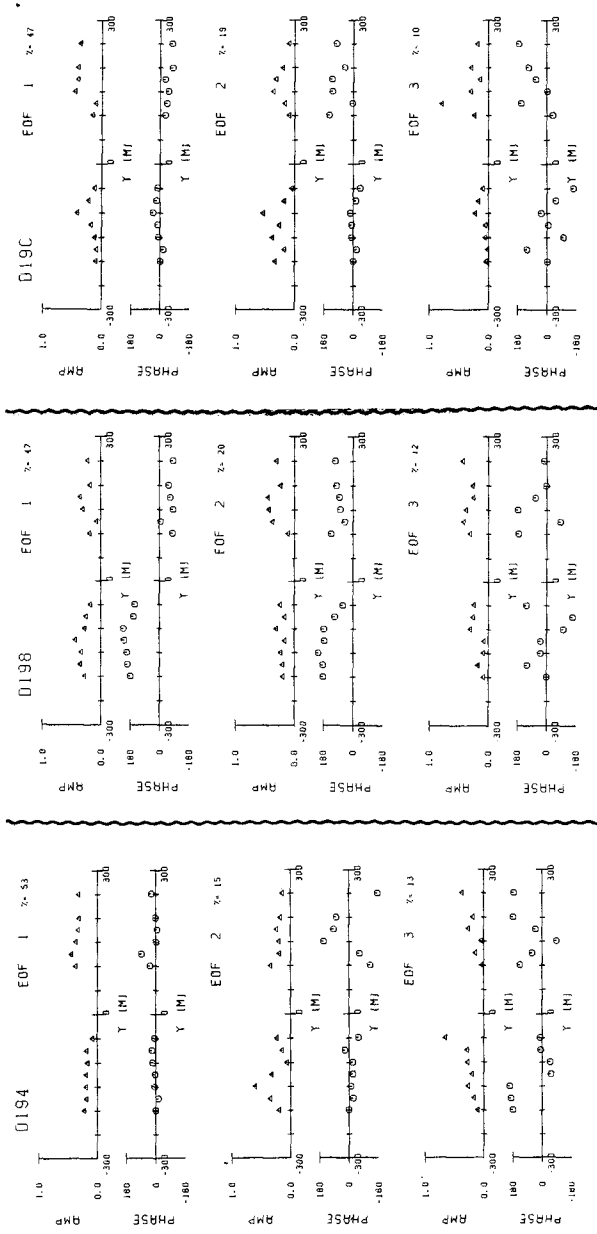

Figure 6. Frequency-domain EOFs for three dominant frequency bands for run 19. The band labels, at the top of each set of EOFs, correspond to figure 4. Band D194 is 0.015-0.020 Hz, band D198 is 0.035-0.040 Hz, and band D19C is the incident peak at 0.07-0.08 Hz. The amplitude and phase functions for the first three EOFs are slow in each case, along with the percent of the band variance explained by each.

Figure 7. Same as figure 6 but for run 56. Band D561 is from 0.000-0.005 Hz, band D568 is 0.035-0.040 Hz, and band D56C is 0.07-0.08 Hz.

and  $N$  is the number of ranges, the EOFs are just the eigenvectors of  $U_{ij}$ . The eigenvectors will be complex, so can be expressed in terms of an amplitude and a phase. The amplitude is generally normalized to unit vector length and the phase expresses the relative phase amongst the ranges.

Figures 6 and 7 show the results of this analysis for the selected bands for runs 19 and 56 respectively. The first three EOFs, along with the percentages of the variance for the frequency band explained by each EOF, are shown in each case. We will examine each band in turn.

Band 4 of run 19 is dominated by the first EOF, with 53% of the variance being explained. The amplitude for this mode shows a definite change across the pier. However, the phase (with the exception of one point) is uniform alongshore. Thus the energy in this band is associated with a very small longshore wavenumber, possibly zero. The cutoff wavelength separating the edge wave and leaky mode regimes is approximately 5 km for this band. For the 500 m length of this array this is equivalent to a  $36^\circ$  phase shift over the array length. While the present data cannot exclude the possibility that this is a very high mode edge wave, the phase information seems to indicate a leaky mode.

Band 8 of run 19 shows a rather more interesting picture. Again, the first mode dominates with 47% of the variance. For this mode, the amplitude shows more variability. Moreover, the phase shows a dramatic jump across the pier. A phase jump of  $180^\circ$  is suggestive of a wave standing in the longshore, possibly a standing edge wave. However, without indications of a second zero crossing away from the pier, the wavelength cannot be estimated and the edge wave hypothesis confirmed. Also it is interesting to note that if the pier, with its related pilings and bathymetry discontinuities, is thought to be a potential reflector of longshore-propagating wave motions, then the pier should be associated with a zero-crossing in longshore velocity, not in elevation.

Band C of run 19 represents the incident wave band. All EOFs indicate the localized effect of the pier on the wave amplitude. The phase of the first mode is relatively uniform although there is some indication that the wave arrives first near the pier (waves propagate "down-phase" in this analysis). This may be due to the greater water depths surrounding the pier. Note that there is no indication of southward progression expected from the  $20^\circ$  north angle of incidence.

Band 1 of run 56 corresponds to the very low frequency hill in most of the run 56 spectra. While there are some indications of variability in amplitude (the shoreface was also rhythmic), the phase of the first mode is uniform longshore. This is expected since these low frequencies are associated with long wavelengths. Since the wavelength of the cutoff edge wave is of the order of 62 km, these

Figure 8. Normal photograph of Short Sands Beach. Swash and breakers from such a snapshot give just one realization of dissipation in the swash or over a sand bar.

Figure 9. Ten-minute time exposure of the same scene taken immediately after Figure 8. Longshore variability of swash dissipation is obvious, but did not reproduce well from color slide.

data can say little to distinguish between edge waves and leaky modes at this frequency. However one can probably conclude that this mode is not a mode 0 or 1 edge wave, whose wavelengths would be less than a few kilometers.

Band 8 for run 56 represents the subharmonic band of the incident peak. Interestingly the energy contained in this band is much more evenly distributed among the EOFs. While the first EOF provides a somewhat confusing picture in phase, the second EOF is rather intriguing. The phase for this mode appears to make  $180^\circ$  phase jumps about every third point. This seems particularly apparent to the north of the pier (not in the shadow zone). This phase behaviour is consistent with a standing wave motion with a wavelength of 150 m. The wavelength of the cutoff mode for this band is 1100 m, so this motion lies clearly in the edge wave regime. While the appropriate beach slope for use in the edge wave dispersion relation is unclear, one can conclude that this motion is probably a standing edge wave of mode number that is low but greater than zero. This bears on the work of Guza and Davis, 1974, who predicted a mode zero edge wave based on theoretical and lab work.

Finally, band C of run 56 shows the incident wave behaviour. This band clearly shows the rather confusing effect of the pier on the incident waves. For all modes, the amplitude and phase show a strong variation away from the pier and on either side of the pier.

#### TIME EXPOSURE PHOTOGRAPHY

The analysis of time series taken from different longshore locations reveals a great deal about the nature of wave motions in the nearshore. However it is often very difficult to collect suitable datasets, and the analysis can be somewhat long. An intriguing objective was to find a technique which could quickly show longshore variability in bulk wave statistics. Such a technique could resolve a dominant standing edge wave, for example, if one were present. A technique that does fill these needs is time-exposure photography. While a single snapshot provides only one realization of the wave field, a time exposure over a long period of time will average the image. For the case of waves in the nearshore the time exposure will be dominated by the white foam of breaking waves, so will essentially be an image of average breaking dissipation. The appropriate averaging time will depend on the time scales of variability. For normal incident waves, modulations generally occur on the time scale of minutes, so it was felt that a ten minute exposure would give an adequate averaging.

Figures 8 and 9 show an example of this technique. Figure 8 is a snapshot of an 800 m long bounded beach on the Oregon coast, Short Sands Beach. Individual wave breaking and run-up are easily distinguished. Figure 9 shows a ten minute time exposure of the same scene taken from the same vantage immediately following the snapshot.

The individual swashes now contribute to a broad white blur. Intriguingly, the width of this blur on the foreshore seems to vary in the longshore direction. Near the center of the beach the swash signal is its widest, while at points approximately  $1/4$  and  $3/4$  along the length of the beach, there are indications of a narrow swash zone. Beach surveys show little longshore variability, so the photographic signal appears to be the signature of a standing wave motion with two half-wavelengths trapped in the bay.

As a sidelight, it appears that this same technique can be used to effectively image offshore bathymetry. An offshore bar system is suggested by figure 8, but its structure is obscured by the complicated breaking pattern. However, in figure 9 the averaging of the time exposure has greatly simplified the apparent image of the bar system allowing one to easily distinguish the extent of the bar and the shoreward trough. The rather sharp delineation of the recommencement of breaking on the foreshore may indicate a step in the profile. It is apparent that this technique can be used to good advantage to map at least the general morphology and possibly, with further research, actual depths. The time exposure technique should be a very useful tool in the study of morphology changes during storms.

#### CONCLUSIONS

This paper presents data on the longshore variability of wave run-up on natural beaches. From the simplest point of view this variability can be viewed as noise, showing uncertainty in run-up data collected at a single point. However it is through the phase relationships of this variability that a number of important questions can be answered about wave motions in the nearshore. The most important application is in the distinction between edge waves and leaky modes as the agents of fluid motion in the surf zone.

The longshore variability of swash was examined for two data runs selected from a much larger dataset collected at Duck, North Carolina, in October, 1982. The runs were selected as examples of dissipative and reflective surf zones. The data are all from within 300m of a pier.

The bulk run-up statistics of set-up and significant swash height were clearly influenced by the presence of the pier and its associated bathymetric discontinuities, being significantly different on either side of the pier. Interestingly, the swash height was higher on what should have been the shadow side of the pier, indicating odd refractive effects over the complex bathymetry. The longshore variability of these statistics was much larger for the reflective day (the higher Irribarren number).

Frequency-domain EOF analysis was used to examine the structure of three dominant energy peaks for each of the two data runs. This

analysis tended to reinforce the importance of the pier to phase and amplitude, although for low enough frequencies the dominant modes tended to show very long wavelengths, probably associated with leaky modes. An interesting peak at the subharmonic frequency of the reflective day appeared to be a standing edge wave with wavelength 150 m.

A new technique of time-exposure photography is shown capable of pointing out dominant variabilities in wave statistics such as would be associated with a standing edge wave. The technique also shows a great deal of promise for imaging offshore sand bar morphologies. Ease of logistics would allow the evolution of morphologies to be monitored through storms.

#### ACKNOWLEDGEMENTS

Data collection for this paper was carried out under contract 12-08-0001-A-0022 from the U.S. Army Engineers Waterways Experiment Station, Coastal Engineering Research Center and the U.S. Geological Survey. The analysis work and development of the time exposure technique was supported by the Office of Naval Research, Coastal Sciences program under contract NR 388-168. Special thanks go to Aage Gribskov, Sara Culley and Eric Grann for help with the acquisition and digitization of the film data. Also, thanks to Harriet and her pals at the pier for donuts and other support.

## CHAPTER ONE HUNDRED TWENTY EIGHT

### DUCK82 - A COASTAL STORM PROCESSES EXPERIMENT

Curtis Mason,<sup>1</sup> Asbury H. Sallenger,<sup>2</sup>  
Robert A. Holman,<sup>3</sup> and William A. Birkemeier<sup>4</sup>

**Abstract:** In October, 1982, a multi-agency nearshore processes experiment was conducted at Duck, NC to measure the nearshore morphological response to storm-induced waves and currents. The experimental setting for a series of companion papers is described, as are the oceanographic and meteorological characteristics of the storms. Rapid changes to the nearshore bar system occurred during the early stages of the first storm, and the bar developed a pronounced crescentic configuration during subsequent periods of high waves. Much of this activity is attributed to the effects of infragravity waves having periods greater than 30 seconds.

#### Introduction

Background. In recent years, several field experiments have been conducted to define nearshore processes and sediment transport patterns under "normal" wave and wind conditions. Large arrays of wave and current measuring sensors, combined with bathymetric surveys, have provided preliminary evidence of complex relationships between forcing processes and sediment response. To date, however, lack of both rugged instrumentation and a means to survey nearshore areas during high wave conditions have precluded measurements of storm-related nearshore processes.

To document the response of a typical East Coast site to extra-tropical storms (northeasters), a cooperative experiment known as DUCK-82, was conducted in October, 1982 at the Field Research Facility (FRF) of the U. S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center, Vicksburg, Miss. Participating in the experiment were investigators from the FRF, the U. S. Geological Survey, Oregon State University, and the University of Washington. Newly developed sensors and equipment were deployed which, for the first time, allowed a comprehensive analysis of the processes affecting the magnitude and time scale of short-term nearshore response.

The objectives of the experiment were to define the two and three-dimensional response of a coastal area extending from a well developed

fore-dune system to about the 7 m (22 ft) water depth; to measure the waves, currents, winds, and other forces producing this response; and to determine the relative importance of these forces in controlling the observed sedimentary response.

This paper discusses the experimental setting and methods, the meteorological and oceanographic characteristics of two storms affecting the study area, and the resulting nearshore morphological response. Finally, five ICEE-84 papers addressing other aspects of the experiment are introduced. Birkemeier (3) provides perspective for these short-term studies by describing long-term changes to selected profiles at the same site.

#### Experiment Description

Site. The Field Research Facility is located near Duck, NC on the northern end of North Carolina's Outer Banks (Figure 1), a long narrow string of barrier islands fronting the Atlantic Ocean. Offshore contours (6 to 15 m, 19 to 49 ft, water depths) in the vicinity of the FRF are generally straight and shore-parallel, although there is a deep trough in the immediate vicinity of the FRF research pier (1). Along the beaches and in water depths less than about 6 m (19 ft), changes in morphology can be large and rapid.

Figure 1. Location of study area

Sediments in the area vary greatly in size. The foreshore typically exhibits a bi-modal size distribution comprised of a coarse (~1 mm) fraction interspersed with finer (~0.3 mm) sands, with a median size of about 0.75 mm. Offshore, sands decrease in median size from about 0.2 mm on the nearshore bar to less than 0.1 mm in 20 m (65 ft) of water.

#### Experimental Design

Nearshore Process Data Collection. The experimental design required

a wide variety of instrumentation to be operated simultaneously and at frequent intervals during storms. Four Marsh-McBirney electromagnetic current meters and seven Baylor staff wave gages were located on the FRF pier (Figure 2), and a Waverider<sup>®</sup> buoy wave gage was located 3 km (2 mi) offshore in 20 m (65 ft) of water. A Weathermeasure anemometer located on the FRF building at an elevation of +19 m (+62 ft) MSL provided wind speed and direction information.

Figure 2. Experiment configuration

A large sea sled specially designed for storm use (9), Figure 3, was towed by a double-drum winch and triangular line arrangement along a shore-normal transect about 457 m (1485 ft) north of the pier to measure storm-induced waves, currents, and suspended sediment. Mounted on the sled was a vertical array of electromagnetic current meters (0.5, 1.0 and 1.75 m, 1½, 3 and 5½ ft, above the bottom), a pressure wave gage, and an optical suspended sediment meter. Data from these instruments were telemetered to a shore-based data collection system. Movie cameras at the shore end of the pier provided data for measurement of wave runup (5).

**Nearshore Surveys.** Fifteen profile lines were established within the survey area near the north boundary of the FRF (Figure 2) to determine the three-dimensional morphological response to storms. The profiles were 23 m (75 ft) apart, over 300 m (975 ft) long, and extended over a longshore distance of 320 m (1040 ft). The southernmost profile was 340 m (1105 ft) north of the FRF pier, sufficiently distant to be outside any pier influence. The center profile was surveyed with the USGS sled system using a Hewlett-Packard infrared total station and optical prisms on top of the sled's 10 m (33 ft) mast. Approximately 20 minutes were required to measure each profile. Since the sled had

Figure 3. USGS sea sled

previously operated in plunging breakers in excess of 5 m (16 ft), it was anticipated that profiles could routinely be obtained throughout any storm expected to occur at the site.

The other 14 profiles were measured using the FRF's Coastal Research Amphibious Buggy (CRAB), Figure 4, and Zeiss Elta-2 total station system (2). The CRAB is a motorized 10.6 m (35 ft) high wheeled tripod supporting an operating platform and a set of optical prisms which reflect the Zeiss' infrared beam. Vertical and horizontal accuracy of this system is about  $\pm 5$  cm, and about five hours were required to measure the three-dimensional morphology. CRAB operations were suspended when wave heights exceeded 2 m (6½ ft), and strong longshore currents occasionally prevented the CRAB from crossing the triangular tow line of the sea sled to obtain data near the sled profile line.

To define micro-scale processes of foreshore deposition and erosion, a tightly-spaced grid of steel pins was emplaced for high-frequency sampling of bed elevations within a small portion of the main survey area (6).

#### Storm Characteristics

Figure 5 shows the time history of waves and winds prevailing at the FRF site during October. Fortuitously for the experimental plans, two northeasters provided typical storm conditions in mid and late

Figure 4. Coastal Research Amphibious Buggy (CRAB)

October, 1982. The first of these storms began to affect the study area early on the morning of 10 October. Northeast winds reached a maximum sustained speed of 13 m/s (30 mph), and wave heights rapidly increased to over 2 m (6½ ft) by 1000 on the 10th. As the storm moved offshore, winds slowly abated, and within 24 hours had decreased to only about 7 m/s (16 mph). However since the storm center moved almost due east (Figure 6), it continued to generate large waves, and significant wave heights in excess of 2 m (6½ ft) were measured by the Waverider<sup>R</sup> buoy until 0200 on the 13th. The maximum height of 2.6 m (8½ ft) occurred at 1200 on the 12th.

Peak wave periods during the early part of the storm averaged about seven seconds (Figure 5), reflecting the locally-generated nature of the waves. As the storm moved offshore, a gradual shift in the peak period to higher values occurred. On the evening of the 11th, the peak period was 13 seconds, and by noon on the 12th it had reached 17 seconds. Wave spectral plots (Figure 7) clearly show the shift in peak period that occurred between the 10th and 11th, as well as the concurrent change from a multi-modal to a uni-modal spectra.

Longshore currents measured along the sled line were southward during the storm, reaching a maximum of about 1 m/sec (3 ft/sec) on the 10th. As the storm moved eastward, the wave approach angle changed from northeast to southeast, producing a change in the longshore current direction such that by the 12th, currents were directed northward.

The second storm of the season, between 23 and 25 October, was considerably more severe than the first. Winds from the northeast increased gradually to a maximum sustained speed of 23 m/sec (51 mph) on the evening of the 24th (Figure 5), with a concurrent increase in significant wave height to a maximum of over 4 m (13 ft) shortly thereafter. Peak periods remained between 6 and 9 seconds (Figure 7), with

Figure 5. Wind and wave conditions, Oct 82, Duck, NC

only slight indications of energy at longer periods.

Longshore currents were directed southward at about 0.5 m/sec ( $1\frac{1}{2}$  ft/sec) during most of the storm, but reversed direction at about 2200 on the 24th, reaching a maximum northward speed of 0.7 m/sec (2 ft/sec) at 0500 on the 25th. Radar images obtained during the storm clearly show that the direction of wave approach changed gradually from a northeast angle on the 24th to a southeast angle by 0730 on the 25th,

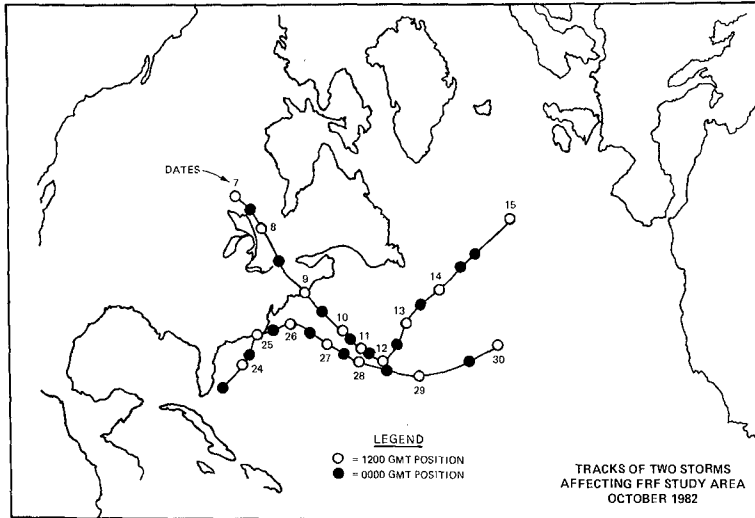

Figure 6. Storm tracks, Oct 82 (after NWS)

and wind data indicate a similar shift in direction (Figure 5) as the storm center moved northward past the site (Figure 6).

#### Morphological Response

This section describes the two and three-dimensional response of the nearshore study area to the storm of 10-15 October 1982, and the two-dimensional response to the storm of 23-25 October.

The first three-dimensional survey was completed on 7 October prior to the first storm. The next was completed on 13 October, when wave conditions had subsided sufficiently to allow deployment of the CRAB. Full surveys were also completed on the 15th and 19th. Profile data from the single sled profile line were obtained twice daily throughout the first storm and the subsequent recovery period, but a severely abraided tow line precluded sled operations during the second storm. Therefore, CRAB profiles were used for interpreting late-October nearshore profile changes.

#### Inner Bar Changes

Prior to the first storm, nearshore morphology was characterized by a well-developed berm and relatively small nearshore bar (Figure 8a). The bar crest was about 0.3 m (1 ft) above the trough level, and was positioned only 13 m (42 ft) offshore. The bar was relatively linear and shore-parallel, although some irregularities were apparent at the northern end of the survey area (Figure 9a).

During the storm, the bar crest at the sled line migrated offshore 57 m (185 ft), Figure 8a. Thirteen meters (42 ft) of this migration

Figure 7. Wave spectra, FRF offshore Waverider<sup>R</sup>, October 1982

occurred over a six hour period on the 10th, yielding a very rapid migration rate of 2.2 m/hr (7 ft/hr). Between the 10th and 11th, the bar was stable, while between the 11th and 12th, it again migrated off-shore, at a rate of 1.4 m/hr (4½ ft/hr). Since the CRAB could not operate due to high waves, the three-dimensional characteristics of the inner bar during the storm could not be determined, although seaward movement of the entire bar crest is hypothesized.

Figure 8. Sea sled profiles, 7-16 October 1982

Figure 9. Three-dimensional plots of nearshore bathymetry

On the 13th, the day after the period of peak incident energy, the nearshore bar appeared to be roughly crescentic (Figure 9b). Between the 13th and 15th, the crescentic shape became better developed and by the 15th had reached a classic crescentic configuration. The longshore wave length was approximately 205 m (666 ft) and the cross-shore distance to the crescentic bar crest was about 70 m (227 ft).

In addition to becoming better developed, the bar system also appeared to have migrated northward about 40 m (130 ft), Figures 9b and 9c. This migration and the developing crescentic form caused nearshore profiles to change very differently depending upon longshore location. For example, between the 13th and 15th, the bar at the sled line showed an apparent landward migration of 36 m (117 ft), whereas during the same period only 69 m (224 ft) northward the bar migrated offshore 18 m (58 ft). These changes were occurring very rapidly even though wave energy was decreasing. For example, over a 24 hour period on the 13th and 14th, the bar crest on the sled line migrated onshore at the rate of 1.2 m/hr (5 ft/hr). Between the 14th and 16th, this rate decreased to 0.5 m/hr (1½ ft/hr), Figure 8b.

Between 15 and 19 October, the inner bar migrated landward, and by the 19th had disappeared, leaving a platform similar to that of 7 October.

#### Outer Bar Changes

Prior to the first storm, there was no indication of an outer bar on the profile. However, during that storm a small amount of deposition occurred about 350 m (1137 ft) seaward of the baseline (Figure 10). During the second storm, the trough deepened and widened, and the bar crest rose and migrated farther offshore. The net result of both storms was the formation of an outer bar about 360 m (1170 ft) from the baseline. The bar remained stable between storms, and did not acquire a crescentic configuration during storms.

Figure 10. CRAB profile 62 - 7-27 October 1982

## Discussion

Figure 11 shows the significant breaker locations and bar crest distances throughout the storm. The surf zone width reaches 900 m (2925 ft), whereas the bar migrated no farther than 70 m (227 ft) from the shoreline. It is important that during the storm, waves were breaking continually across the surf zone, and were not reforming and breaking on the bar crest. Therefore, it is clear that the inner bar could not have formed according to a plunging breaker hypothesis, where a bar is formed at the breaker position by scouring of a trough by the breaker. The inner bar (located within the landward 10 percent of the surf zone) became better developed and migrated offshore in the presence of spilling breakers. The outer bar was also well inside the surf zone during the storm.

Figure 11. Time history of bar crest and breaker positions and depths

Sallenger, et al (11) indicate that the inner bar movement could have been caused by a standing infragravity wave with a period between 55 and 75 seconds. The inner bar would have formed at either the first node or antinode of the standing wave pattern as described by Bowen (4). Sallenger, et al (11) also hypothesized that crescentic development of the inner bar may have been forced by standing infragravity edge waves as the storm waned. Sallenger and Holman (10) provide evidence that infragravity waves were indeed very important during the storm. However, additional analysis of the wave and current data is required before the relationship between infragravity waves and bar response can be confirmed.

### Related Results

Since the DUCK82 experiment consisted of several related areas of investigation, the ICCE-84 proceedings contain papers summarizing results to date, which are introduced below. Two of these papers concern wave characteristics measured during the storms, while the three remaining papers discuss cross-shore and/or beach face sediment transport processes.

As mentioned previously, Sallenger and Holman (10) confirmed the existence of significant currents associated with infragravity waves during the first storm. RMS cross-shore flows due to waves with periods greater than 20 sec exceeded 0.5 m/sec (1½ ft/sec) over the bar crest. Holman and Sallenger (5) also investigated infragravity wave activity during the second storm, when surface water level setup and significant swash heights exceeded 1.5 and 2.5 m (5 and 8 ft) respectively. Although offshore wave periods were less than 10 seconds, runup data collected on the shoreface indicated that dominant oscillations were of much longer periods, with approximately 75 percent of the variance in the infragravity band.

Using data collected from the sled-mounted current meters and optical suspended sediment meter, Jaffe, et al (7) concluded that suspended sediment transport played a major role in the cross-shore profile changes. A strong coupling was found to exist between material suspended high in the water column and the onshore phase of wave-induced flows such that a net onshore flux of particles occurred even though the mean flow was offshore. Richmond and Sallenger (8) found that during the first storm, different sediment sizes could be transported in opposite cross-shore directions under the same incident wave field. The field data corroborated sediment transport patterns predicted by Bowen's (4) equations as derived from Bagnold's theory on sediment transport. Finally, Howd and Holman's (6) high frequency sampling of swash zone bed elevations showed coherent perturbations to the fore-shore slope with RMS heights of nearly 5 cm which were progressive upslope, with periods of 8 to 10 minutes.

### Summary and Conclusions

A comprehensive nearshore processes experiment was conducted which, for the first time, documents detailed temporal and spatial storm-related processes and morphological response. Two-dimensional profile response measurements indicate that large and rapid changes occurred. As wave heights increased, the inner bar became better developed and migrated offshore at very rapid rates (>2 m/hr, >6 ft/hr). Development of the outer bar also showed a dependence upon wave heights, with minor changes when offshore waves were less than 2.5 m (8 ft), and significant changes when heights exceeded 3.5 m (11 ft). During the waning stages of the first storm, the inner bar rapidly developed a crescentic morphology, with parts of the bar migrating onshore at rates of over 1 m/hr (3 ft/hr). Neither the inner nor outer bars appeared to be related to breaking wave processes, since both bars were well within the storm surf zone. Rather, based on frequent quantitative measurements of wave and current conditions, the inner bar formation seems to be better explained by the effect of infragravity waves, which appear to play the leading role in controlling the response of nearshore sedimentary features to storms.

The rapid response of bar morphology to changing wave conditions indicates the need for more rapid sampling of surf zone morphology. It appears that previously held concepts of a slowly responding system may be erroneous. Only with a much-improved spatial and temporal sampling scheme can this be verified, since even with the frequent sampling conducted during this experiment, there is no guarantee that the dominant time scale of bar response was captured. The problem is further complicated by the apparent ease with which natural bar systems become three-dimensional. The development of instrumentation to measure three-dimensional morphology during storm conditions should be given high priority in the future.

## CHAPTER ONE HUNDRED TWENTY NINE

Offshore Breakwater, Wheatley, Ontario

G.T. Beaulieu<sup>1</sup>, M.G. Skafel<sup>2</sup>, W.F. Baird<sup>3</sup>

The safe entry during storms to the fishing harbour at Wheatley on Lake Erie was compromised by breaking waves at the harbour entrance. These waves approach the entrance from a narrow easterly sector due to storm tracks, fetch limitations, and refraction. Using a physical model, a small offshore breakwater was selected as the best solution to eliminate the breaking waves. During the six years since construction, the breakwater has performed satisfactorily and has had a negligible effect on the littoral processes as determined from regular bathymetric surveys.

### Introduction

The harbour at Wheatley, Ontario (Fig. 1) is primarily used by commercial fishing vessels. Prior to 1978, storm waves from easterly directions broke over the bar at the harbour entrance producing hazardous conditions for these vessels. During these storms, fishing vessels returning to port had difficulty maintaining control and entering the harbour safely. In several cases vessels had to seek shelter at other harbours, the nearest being over two hours away.

The objective of this study was to find an entrance configuration that would eliminate wave breaking and reduce the wave height to an acceptable level over the bar at the harbour entrance. The solution was to build an offshore breakwater.

### Wheatley Harbour

Wheatley Harbour (Fig. 2) is the most important freshwater commercial fishing harbour in Canada. The harbour is the home port for approximately 45 fishing tugs and provides berthage for up to four transient tugs. The typical vessel size which utilizes the harbour is about 20 metres in length, 4.2 metre beam and 2.0 metre draft.

The entrance channel is dredged to a depth of 3 metres and has a minimum width of 21 metres. Ice generally restricts fishing activity in January and February.

The shoreline to the east of Wheatley Harbour consists of eroding clay bluffs and sand beaches. The net movement of littoral material is towards the southwest and has been estimated to be about 50,000 m<sup>3</sup>/year (2). As a result of this transport material, about 4,700 m<sup>3</sup> of sand on average had to be dredged from the entrance channel each year.

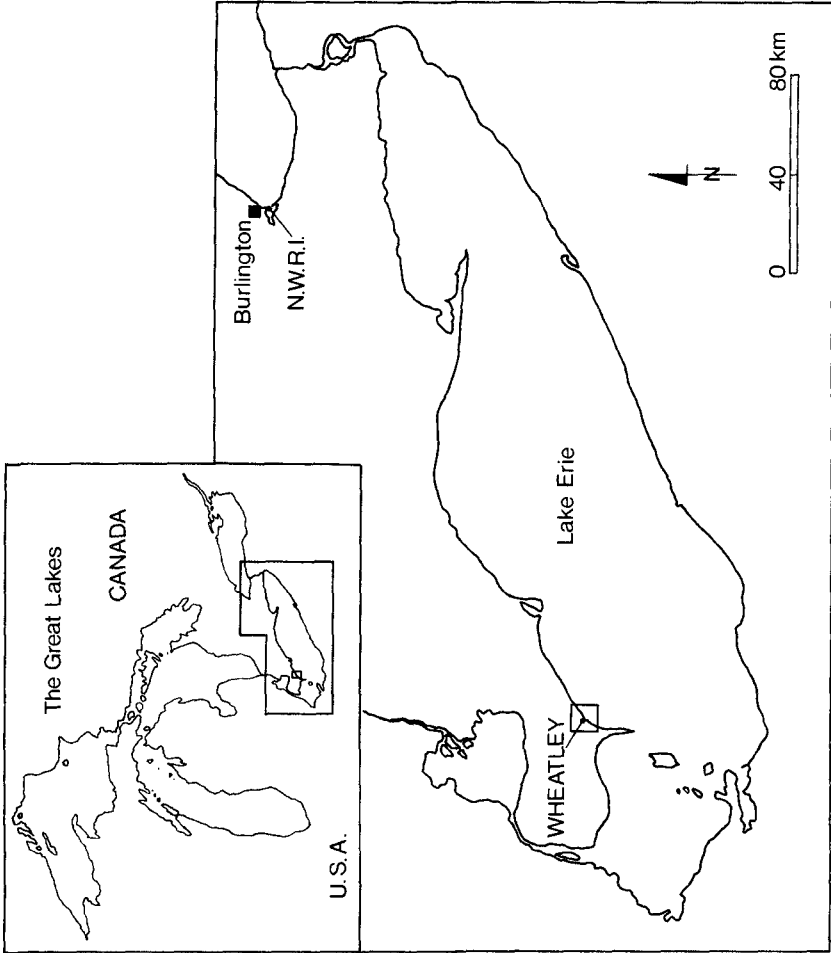

Figure 1. Location Map.

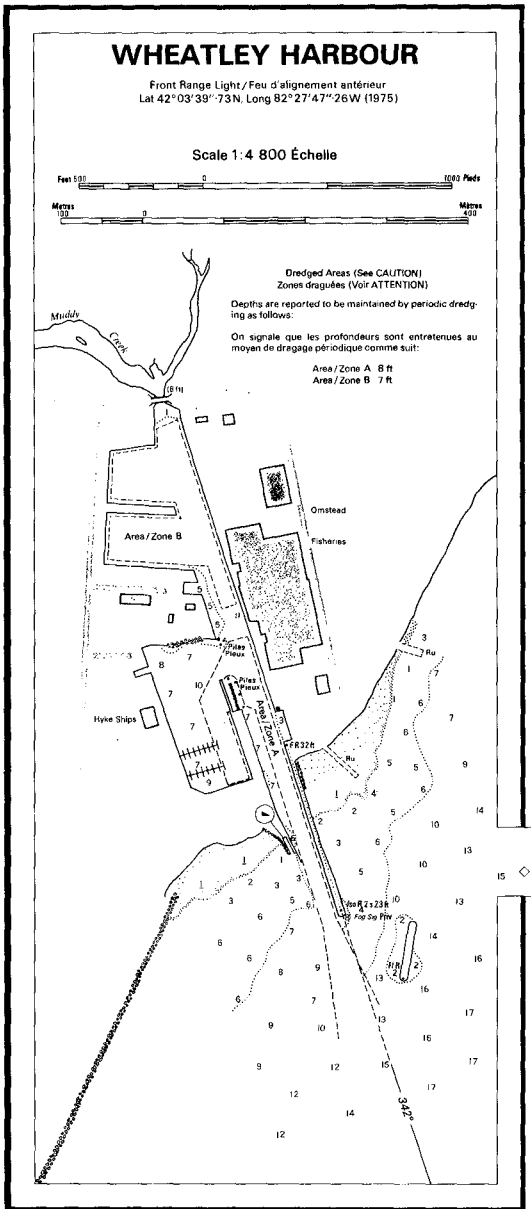

Figure 2. Hydrographic Chart, Wheatley Harbour.

Figure 3

Hindcast scatter diagram

Figure 4. Breaking Wave at Harbour Entrance, Model.

### Wave Climate

The harbour is exposed to waves generated by northeast, east, southeast and south winds. The most severe conditions are from easterly storms which generate waves of from 5 to 7 second periods with deep water significant heights of 6 to 12 feet (1.8 to 3.7 metres). The wave climate was hindcasted (Fig. 3) using a procedure based on Bretschneider's equations (1).

Refraction analysis showed that the large waves, which cause the navigation problem, approach the harbour entrance from a small sector of 90° to 105° true.

### Model Study

A fixed bed model of the harbour and its approaches to the 4 metre contour was constructed to a geometric scale of 1 to 60 in the Hydraulics Laboratory at the National Water Research Institute (3). Irregular waves were used to simulate prototype waves from the east sector. A refraction analysis was used to define the wave direction at the model boundary.

The model tests, combined with the wave climate, indicated that severe breaking wave conditions could be expected during four storms in an "average" year. This conclusion was verified in discussion with the local fishermen. Reproduction in the model of the severe breaking condition is shown in Figure 4.

It was established that the significant wave height should be less than 1.2 metres to prevent breaking and to ensure safe entry and exit from the harbour. By keeping the waves as large as possible, but under this limit of 1.2 metres, the structure would have a minimal effect on the littoral processes.

Numerous offshore breakwater configurations were studied in the model until a suitable configuration was determined.

The variable design features in each breakwater configuration were length, distance from the harbour entrance structures, and orientation.

### Recommended Solution

The structure that was recommended met the following design criteria:

- it was sufficiently far from the entrance not to represent a hazard to navigation;
- it provided protection during easterly storms to eliminate breaking waves (reduced the significant wave height to less than 1.2 metres);
- it did not reduce the wave height more than necessary, to interfere as little as possible with littoral processes;

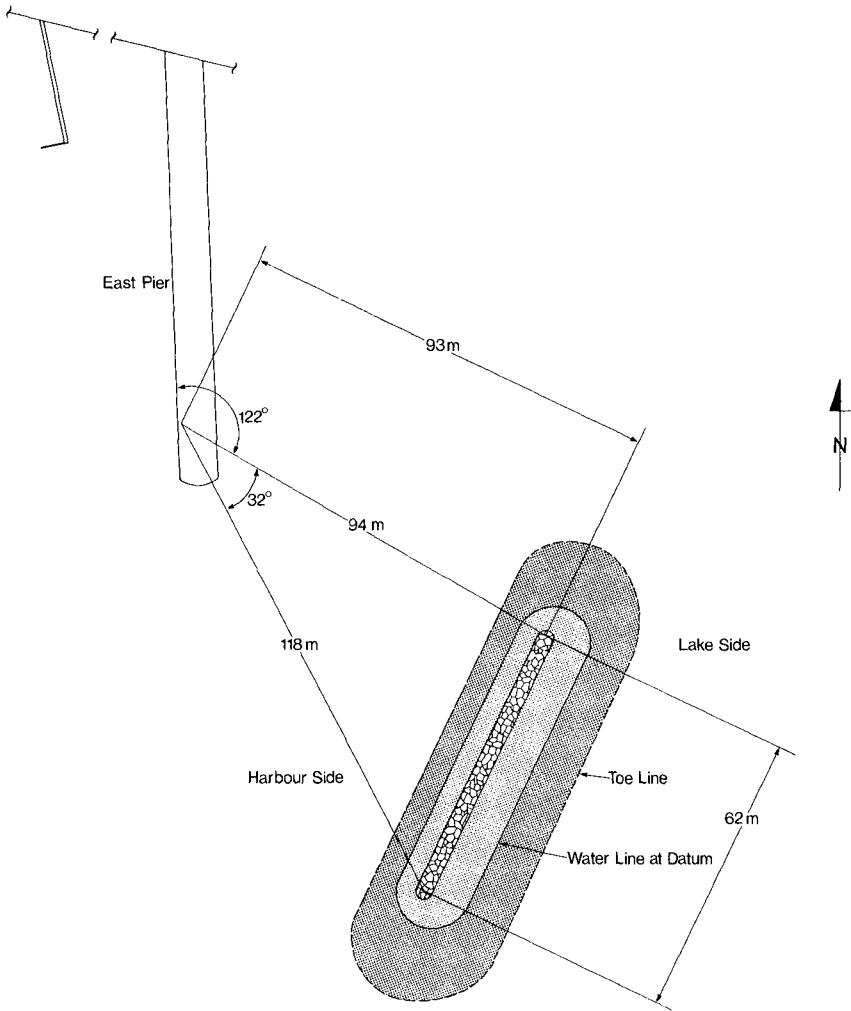

Figure 5 Layout plan, recommended solution

Figure 6. Cross-Section of Recommended Breakwater.

Figure 7. Oblique Aerial Photo of Wheatley Harbour.

Figure 8 2 and 4 metre contours

- it represented the least cost of all structures meeting the above criteria.

A breakwater approximately 62 metres long was selected, located as shown in Figure 5 and Figure 7. It consists of a rubble mound core protected by two layers of armour stone. The core material is 22 kg to 360 kg shovel quarry run material, with 50 percent greater than 225 kg. The armour stone is 3.6 - 5.4 tonnes with 70 percent of the stone greater than 4.5 tonnes (Figure 6).

The top elevation of the breakwater is at 3 metres above datum which is about 2.5 metres above average lake level and about 1.5 metres above the all-time average monthly high.

The breakwater was constructed in the summer of 1978 at a cost of \$320,000 (Canadian). During its six years of existence, wave breaking has been reduced so that fishing vessels are now able to return to the harbour under storm conditions. The fishermen of Wheatley Harbour are entirely satisfied with the structure.

#### Changes to the Nearshore

The major uncertainty with the offshore breakwater as a solution to the navigation problem was the effect on the movement and deposition of littoral material. Hydrographic surveys have been conducted regularly since the construction in 1978. To illustrate the changes that have occurred, the 2 metre and 4 metre contours from the various surveys have been reproduced in Figure 8. The location of the contours has remained relatively stable since 1978. There has been minimal shoaling behind the breakwater and in the channel.

#### Summary

A relatively small offshore breakwater has been precisely positioned off Wheatley Harbour to provide protection from breaking waves approaching from a narrow easterly sector. This solution allows fishing tugs to enter the harbour safely during storm conditions. Little or no interference with the movement of sediment in the littoral zone has been observed since the breakwater was constructed six years ago.

## CHAPTER ONE HUNDRED THIRTY

### ON PREDICTING INFRAGRAVITY ENERGY IN THE SURF ZONE

Asbury H. Sallenger, Jr.\* and Robert A. Holman\*\*

#### Abstract

Flow data were obtained in the surf zone across a barred profile during a storm. RMS cross-shore velocities due to waves in the infragravity band (wave periods greater than 20 s) had maxima in excess of 0.5 m/s over the bar crest. For comparison to measured spectra, synthetic spectra of cross-shore flow were computed using measured nearshore profiles. The synthetic spectra were calculated assuming a white runup spectrum of mode-4 edge waves of unit amplitude, although the results would be essentially the same for standing waves or any edge-wave mode above 2. The structure, in the infragravity band, of these synthetic spectra corresponded reasonably well with the structure of the measured spectra. Total variances of measured cross-shore flow within the infragravity band were nondimensionalized by dividing by total infragravity variances of synthetic spectra. These nondimensional variances were independent of distance offshore and increased with the square of the breaker height. Thus, cross-shore flow due to infragravity waves can be estimated with knowledge of the nearshore profile and incident wave conditions.

#### Introduction

Waves in the infragravity band, usually defined as wave periods greater than 20 s, can be energetic in the surf zone when offshore waves are large (for example, Holman et al., 1978; Wright et al., 1979; Guza and Thornton, 1981; Holman, 1981; Holman and Sallenger, in press). In fact, within the swash and inner surf zones, energy in the infragravity band has been observed to exceed, sometimes greatly, the energy of waves in the incident band, wave periods less than 20 s. In view of the significance of energy in the infragravity band, flows caused by infragravity waves are likely important to sediment transport in the surf zone (Bowen and Inman, 1971; Short, 1975; Wright et al., 1979; Wright et al., 1982; Sallenger et al., in press). In this paper, we focus on the prediction of the magnitude of cross-shore flows due to infragravity waves.

\* U.S. Geological Survey, Menlo Park, CA 94025

\*\*Oregon State University, Corvallis, OR 97331

Several studies have tried to quantify the relationship between the magnitude of waves in the infragravity band and parameters characterizing offshore wave conditions. Guza and Thornton (1981) found that significant swash oscillations due to infragravity waves increased with increasing offshore wave height. Using a much larger data set, Holman and Sallenger (in press) showed that infragravity swash oscillations could be predicted better by the Iribarren Number

$$\xi_o = \tan\beta (H_o/L_o)^{-0.5} \quad (1)$$

where  $\beta$  is foreshore slope and  $H_o/L_o$  is deep-water wave steepness.

Runup data, such as used by the two studies discussed above, are particularly useful in determining the relationship between the magnitude of infragravity waves at the shoreline and offshore wave characteristics. This is because infragravity waves in the surf zone have the cross-shore structure of standing waves or high-mode edge waves (Suhayda, 1974; Holman, 1981). Measurements at the shoreline, such as runup, are not affected by offshore decay of energy or by offshore nodal positions which vary with frequency. To use offshore measurements, such as measurements of flow, we must account for the effects of the standing wave structure.

In the present study, cross-shore flow data were obtained across the surf zone during a storm. To account for offshore position of the flow measurements, we nondimensionalized measured variances of cross-shore flow in the infragravity band by computed variances based on a white runup spectrum of edge waves (or standing waves) of unit amplitude. We will show that the nondimensional variances are predictable by incident wave characteristics.

In the following section, we discuss the significance of nondimensional flow variances and how the variances were calculated. After presenting the experimental methods and setting, we discuss measured cross-shore flow data and how flow varied over the barred profile during the storm. Next, we show how well synthetic infragravity spectra, based on the white runup spectrum, matched the measured spectra, and, similarly, how well total variances in the infragravity band of the synthetic spectra matched that of the measured spectra. Finally, we show how nondimensional variances varied with incident wave conditions.

### Theory

As discussed above, a difficulty of interpreting data from fixed locations in the surf zone is that the waves in the infragravity band appear to be standing. The shape of the infragravity part of the spectrum is strongly dependent upon the cross-shore position at which the record was obtained. In order to interpret the offshore flow data, we have calculated synthetic spectra based on a white runup spectrum of mode-4 edge waves with unit shoreline amplitude. The results would be essentially the same for standing waves or edge

waves of any mode above 2. The calculations were performed as described in Holman (1981). Cross-shore flow variances were found numerically for different distances offshore and for different frequencies within the infragravity band. Using these calculated variances, synthetic spectra were computed for distances offshore corresponding to measured spectra. These synthetic spectra offer a means to interpret the measured infragravity spectra in that valleys and peaks associated with standing wave motions can be directly compared to measured spectra.

For a particular distance offshore, we can also compare total variances in the infragravity band of measured and synthetic spectra. A nondimensionalized infragravity variance is given by

$$\lambda^2 = \frac{\int_0^{\zeta} U_{vr}^m(f) df}{\int_0^{\zeta} U_{vr}^c(f) df} \quad (2)$$

where  $U_{vr}^m(f)$  and  $U_{vr}^c(f)$  are measured and computed cross-shore velocity spectra respectively, and  $\zeta$  is the frequency separating incident and infragravity bands. As mentioned above,  $\zeta$  is usually taken rather arbitrarily as 0.05 Hz. Here, we have defined  $\zeta$  for each incident wave condition by determining, visually, the low frequency side of the dominant incident wave peak. Periods of incident wave peaks varied from 10 to 18 s. Using a 20 s (0.05 Hz) cutoff for the spectrum with the 10 s dominant incident wave may underestimate the amount of energy in the infragravity band.

$\lambda^2$  is a measure of the level of energy in the infragravity band, and is independent of position offshore and profile configuration. Thus,  $\lambda^2$  can be directly compared to offshore wave parameters. However,  $\lambda^2$  assumes a white runup spectrum and would not be a useful quantity if the runup spectrum had only one, or a few, energetic frequencies in the infragravity band. It is possible that if a broad band of infragravity energy is forced when offshore waves become large,  $\lambda^2$  may be a useful quantity even if the runup spectrum is not uniformly white. Below we find reasonable correspondence, for data obtained during a storm, between  $\lambda^2$  and a parameter characterizing incident wave conditions.

#### Experiment Setting and Methods

The experiment, known as DUCK82, was conducted during October 1982 at the Field Research Facility (FRF) of the US Army Corps of Engineers in Duck, North Carolina. The FRF is located on a long straight beach of a barrier island. Mason et al. (this volume) present details of the experiment setting, and introduce papers on other investigations conducted during the DUCK82 experiment.

Flow data were obtained using the USGS sled system (described in detail in Sallenger et al., 1983). The system consists of an instrumented sled that was towed along the bottom, both offshore and onshore, with a double-drum winch and triangular-line arrangement. Three electromagnetic current meters (Marsh-McBirney model 512) in a

vertical array and a pressure sensor were mounted onto the frame of the sled and the data were telemetered to a shore receiving station. The nearshore profile was measured using an infrared rangefinder on the beach and optical prisms mounted on top of the sled's mast. The sled system was set up 500 m north of the FRF pier, presumably outside the influence of the pier (Mason et al., this volume).

The flow data discussed here were obtained with a current meter mounted on the sled 1 m above the bottom. For a given day, records were obtained at five to eight locations across the surf zone. Each record was 34.1 minutes long. A set of records was obtained around high tide to minimize depth variations during the runs.

### Results

Much of the cross-shore flow data discussed here were taken during a storm, October 10-12, 1982. The remainder of the data were taken immediately following the peak of the storm, Oct. 13, and on a relatively calm day when nearshore morphology was not highly three-dimensional, Oct. 20. Details of the meteorological and wave characteristics of the storm and post-storm period are given in Mason et al. (this volume). An example of the bar response during the storm is shown in Fig. 1A. The bar migrated offshore at rates up to 2.2 m/hr. Following the storm, the bar morphology developed into a classic example of a crescentic bar. Mason et al. (this volume) and Sallenger et al. (in press) discuss the storm-induced response of the nearshore morphology.

RMS cross-shore flows due to waves in the infragravity band exceeded 0.5 m/s (Fig. 1B). We defined infragravity RMS cross-shore flow as

$$U_{rms\_ig} = \left( \int_0^{\zeta} U_{vr}^m(f) df \right)^{0.5} \quad (3)$$

Note that maxima in cross-shore flow occurred at the crest of the bar. These flow maxima are evidently the result of mass transport over the shallow water of the bar crest.

Relative magnitudes of cross-shore flows due to infragravity waves and incident waves are shown in Figure 1C. At places within the inner surf zone, cross-shore flow variances in the infragravity band approached or exceeded variances in the incident band. Note that for everywhere on the profile, ratios of variances in the infragravity band to those in the incident band for October 12 are greater than ratios for October 10. Since variances in the incident band are limited by wave breaking (the breaker zone occurring several hundred meters farther offshore than our seawardmost measurement location), Figure 1C indicates that infragravity energy became increasingly important during the two days. Below, we will try to quantify a relationship between infragravity energy and characteristics of offshore waves.

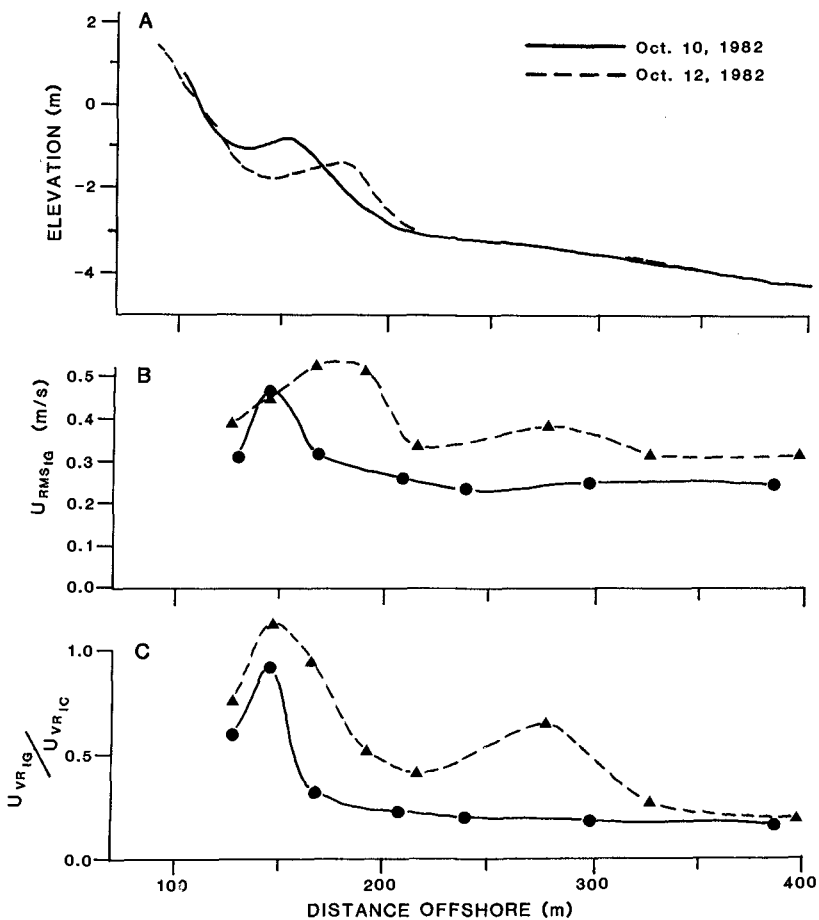

Figure 1. A. Nearshore profiles measured with the USGS sled system for two of the storm days. B. Measured RMS cross-shore flows of the infragravity band. C. Ratios of variances of the infragravity band to variances of the incident band.

We present four spectra from a single day (Figs. 2 and 3) to illustrate the correspondence between measured and synthetic spectra. The locations of each measurement station on the nearshore profile are shown in Figure 4. As discussed above, the synthetic spectra are based on a white runup spectrum of unit amplitude. The measured spectral structures agree reasonably well with the synthetic structures. For example, spectral valleys, which indicate positions of zero crossings (nodes), of the measured spectra coincide closely with valleys of synthetic spectra. Energy levels of synthetic spectra were adjusted by moving the spectra vertically in order to fit the lower energy peaks of the measured spectrum. For a given set of records, all obtained on the same day under basically the same incident wave conditions, the calculated spectra are moved vertically the same amount. Any dominant peaks in the measured spectra would rise above the synthetic spectra. (Alternatively, the energy levels of synthetic spectra could have been adjusted by multiplying by the mean of  $\lambda^2$  for a given day which would yield a best fit between the measured and synthetic spectra). Much of the infragravity energy in the measured spectra fits the synthetic spectra; however, at some frequencies energy in the measured spectra exceeds the energy in the synthetic spectra. At these frequencies, there should be peaks in the runup spectrum, that is, the runup spectrum was not white. These dominant peaks appear to have been induced by the bar offshore; their significance will be discussed elsewhere.

For a particular distance offshore, we define a synthetic infragravity variance as

$$U_{vr,ig}^c = \overline{\lambda^2} \int_0^{\zeta} U_{vr}^c(f) df \tag{4}$$

where the overbar indicates that  $\lambda^2$  is averaged for all offshore positions for a given day. A measured infragravity variance is given by the numerator of equation 2. In Figure 5, we compare measured and synthetic infragravity variances for different distances offshore. Only two days are shown, but the correspondence is similar for all days. Since the shapes of the curves for each day are nearly the same,  $\lambda^2$  (equation 2) is roughly constant for a given day and independent of distance offshore.

For five different days with greatly varying incident wave conditions, values of  $\lambda^2$  were calculated. In Figure 6 we show how mean  $\lambda^2$  for a given day varied with the square of the offshore significant breaker height,  $H_b$ .  $H_b$  was calculated from offshore wave characteristics using Komar and Gaughan (1973). There is good correspondence between  $H_b^2$  and  $\lambda^2$ . Linear regression gives

$$\overline{\lambda^2} = 0.45 H_b^2 - 0.60 \tag{5}$$

with  $r = 0.99$ . For equation 4 to be dimensionally correct, a factor of unity with dimensions of  $m^{-2}$  is multiplied times the slope.

Figure 2. Surf-zone spectra from October 12, 1982. X indicates distance offshore in meters from a baseline; the shoreline relative to this baseline is about 110 m. The number preceded by the J is the run number. 95% confidence limits are shown. The location of each measurement station is shown in Fig. 4.

Figure 3. Surf-zone spectra from October 12, 1982. X indicates distance offshore in meters from a baseline; the shoreline relative to this baseline is about 110 m. The number preceded by the J is the run number. 95% confidence limits are shown. The location of each measurement station is shown in Fig. 4.

Figure 4. Station locations for October 12. The numbers refer to the J numbers shown on the spectra of Figures 2 and 3.

Figure 6. Nondimensional cross-shore flow variances of the infragravity band,  $\lambda^2$  equation 2, averaged for all offshore positions for a given day are dotted against the square of the breaker height.

Figure 5. Measured and synthetic variances of the infragravity band. Synthetic variances are defined by equation 4. Measured variances are defined by the numerator of equation 2.

### Discussion

Recall that for  $\lambda^2$  to be applicable, the shoreline spectrum should be white, although we have shown in the discussion of the spectra that the runup spectrum was not white. The implication is that nondimensionalizing cross-shore flow variance, as done in equation 2, is reasonable when the runup spectrum has significant energy across the infragravity band even when that energy is not perfectly white.

It should be interesting to add additional data to Figure 6 to determine whether the relationship is similar for other morphologies and other beaches. However, since we plot against a dimensional quantity in Figure 6 the universal applicability of equation 4 is probably limited. As an alternative, we have plotted the dimensionless Iribarren number,  $\xi_0$  (equation 1) which seems to parameterize many surf zone processes, against  $\lambda^2$ , but the correspondence is not as good as with  $H_b^2$  (correlation coefficient of 0.56 compared to 0.99).

Knowing the shape of the profile and the breaker height, one can calculate reasonably well the flow due to infragravity waves in the surf zone, at least for the location studied. Since we can also calculate the RMS cross-shore flow in the incident band, incident waves being limited by depth in the surf zone, we can estimate the total oscillatory velocity field. The calculation of total oscillatory flow should be useful for numerical modelers who usually focus on modeling only incident band flows and waves. It should also be useful for sediment transport applications.

### Conclusions

1.  $U_{rms}$  due to infragravity waves was maximum over the bar crest where it exceeded 0.5 m/s. Cross-shore flow variance due to infragravity waves approached or, in places, exceeded variance in the incident band.

2. As in some earlier studies, calculated spectra, based on a white runup spectrum compared reasonably well with measured spectra.

3. Cross-shore flow variance due to waves in the infragravity band were nondimensionalized by dividing by computed variances based on a white runup spectrum. The nondimensional variances increased with the square of the offshore breaker height.

### Acknowledgments

We thank the many persons who contributed to the success of the DUCK82 experiment including Jeff List, Tom Reiss, Peter Howd, Bruce Richmond, Bruce Jaffe, Beth Laband, and the U.S. Army Corps of Engineers crew at the Field Research Facility. We thank David Barnes for doing most of the calculations reported in this paper. Our part of the experiment and the data analysis were funded jointly by the

U.S. Geological Survey and the U.S. Army Corps of Engineers Waterways Experiment Station.

## CHAPTER ONE HUNDRED THIRTY ONE

### SEDIMENT TRANSPORT ON THE SOUTH-EAST AUSTRALIAN CONTINENTAL SHELF

Angus D. Gordon and John G. Hoffman\*

#### ABSTRACT

Engineering projects on the continental shelf off Sydney, Australia, have stimulated investigation into the sediment transport system of the shelf. Investigation activities associated with these projects have included: definition of sea bed morphology, sediment distribution and bedform characteristics; monitoring of steady and wave induced currents; wind data collection; suspended sediment sampling; bottom camera sediment movement investigations and analytical studies of sediment reaction to sea bed forcing functions. Sea bed velocity exceedence relationships for both wave oscillations and steady currents have been determined at depths of 24 m, 60 m and 80 m. Thresholds of sediment movement have been defined. Relative sediment transport computations have been undertaken and studies of suspended sediment concentration profiles are in progress so that absolute transport rates can be determined. The prevailing conditions, which include a mainly south bound current, are seldom sufficient to induce entrainment of shelf sediments. Transport events mainly result from major storms in the Tasman Sea which produce both high energy waves and north bound currents. Although these events are rare and short lived, the combined wave and current shear produced at the sea bed during the events gives rise to entrainment conditions which result in their dominance of the shelf sediment transport system.

#### 1. Introduction

The coincidence of a number of engineering studies on the continental shelf off Sydney, Australia, has provided the opportunity to study shelf bed characteristics and sediment transport under the combined action of currents and the prevailing wave spectra. This paper examines the forcing functions on the sea bed outside the surf zone in water depths from 24 metres to 80 metres. It also documents the response of the sediments to the forcing functions. The location of the study area is shown in Figure 1.

#### 2. Physiographic Setting

The S.E. Australian continental shelf off Sydney varies in width from 20 to 40 kilometres. Its surface comprises a mixture of unconsolidated sediments and bedrock reef (Figure 2). Seaward of the

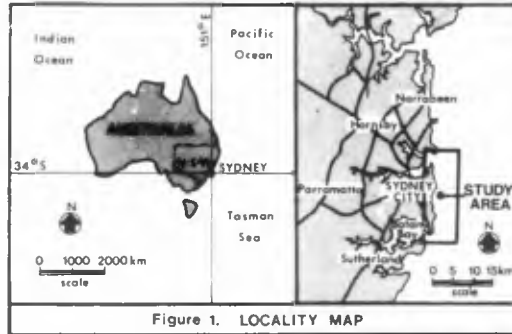

Figure 1. LOCALITY MAP

surf zone, the profile is generally concave up with slopes of 1:50 in 20 metres depth and 1:100 in 80 metres depth. Typically, the 20 metre contour is 1 km and the 80 m contour 10 km offshore. There are locations where the profile is considerably steeper. This occurs where extensive rocky cliff formations are the predominant coastal feature. In these locations the 20 metre contour is often less than 200 metres offshore with the 80 metre contour some 3 km offshore (Figure 2).

Sea bed sediments gradually become finer from medium sands in the surf zone with typical values of  $d_{50}$  of 0.35 mm to a  $d_{50}$  of 0.18 mm in 14 m depth. These fine sands continue out to depths of 25 to 30 m. From 30 m out to about 60 m, a diverse suite of sediments are found. They range from fine sand to coarse sand and gravel. Deeper than 60 m, fine sands with some silt content predominate. Shell contents are highly variable but are generally highest near areas of exposed reef. Shelf sediment types and their distribution are shown in Table 2 and Figure 2.

Morphological anomalies associated with sediment features occur in certain locations. These features include convex upwards sand lobes, cross shelf sand ridges and mid shelf sand bodies with rhythmic asymmetric morphology (Figure 2).

### 3. Shelf Data

Data were obtained from an extensive side scan sonar and sediment sampling survey of the Sydney coast (Gordon and Hoffman, in prep, (a)) and from detailed studies at three sites across the shelf (Nielsen, 1984; Gordon and Hoffman, in prep, (b)). Table 1 summarises the instrumentation used and the data collected at the three sites. All instruments were calibrated before and after deployment and cross spectral checks between the electromagnetic current meters and the waverider buoys were also carried out (Nielsen and Gordon, 1984).

Water depth	Period of data collection	Instrumentation and sampling schedules *				
		Waves	Currents	Wind	Sediments	Seobed morphology and bedforms
24m	24 months	Waverider buoy. 1/2 s x 18m x 6h.	Marsh M <sup>c</sup> Birney X-Y current meter. 1s x 10m x 7h.	Dynes anemograph. Continuous.	Surface samples, diver and vibro coring.	Side-scan sonar and diver observations.
60m	6 months	Waverider & dynamic pressure sensor. 1/2 s x 18m x 4h	Marsh M <sup>c</sup> Birney X-Y current meter. 1s x 8m x 4h.	Lambrecht anemometer. Continuous.	Surface samples, vibra and box coring, suspended sediment samples.	Side-scan sonar, RCV video & time lapse camera. 32s x 8m x 4h.
80m	6 months	Waverider & dynamic pressure sensor. 1/2 s x 18m x 4h.	Marsh M <sup>c</sup> Birney X-Y current meter. 1s x 8m x 4h.	Lambrecht anemometer. Continuous.	Surface samples, vibra and box coring, suspended sediment samples.	Side-scan sonar, RCV video & time lapse camera. 32s x 8m x 4h.

\* Sampling schedule : As x Bm x Ch = burst sampling at intervals of A seconds continuously for B minutes every C hours

4. Forcing Functions

The forcing functions which may influence sediment transport on the Sydney shelf are:

- steady currents due to -
  - (a) the onshelf component of ocean currents;
  - (b) wind induced currents; and
  - (c) wave induced mass transport;
- tidal currents; and
- oscillatory currents induced by surface gravity waves.

4.1 Ocean Currents

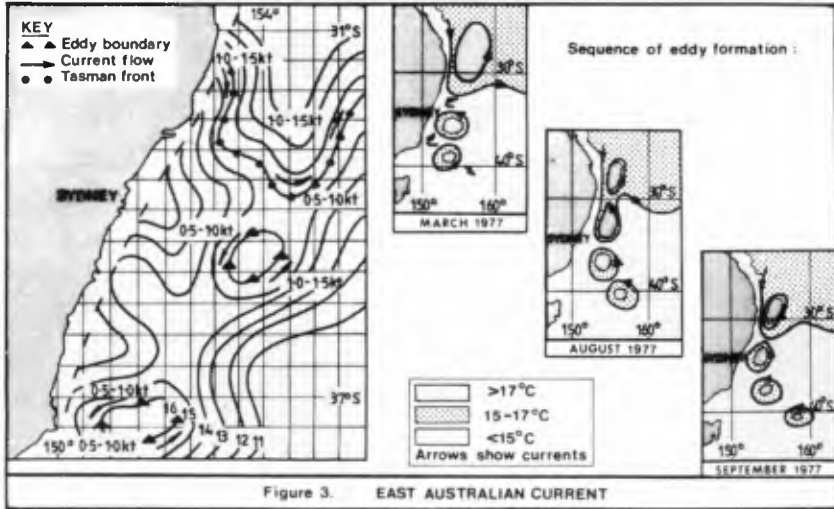

The S.E. Australian shelf is influenced by the offshore East Australian Current. Originally believed to be a southbound flow along the western extremity of the Tasman Sea, it is now known to consist of a complex system of migrating eddies (Nilsson and Cresswell, 1980; see Fig.3).

4.2 Wind Induced Currents

Local winds induce currents which act to modify the prevailing onshelf regime. Rotation of these currents from the prevailing wind direction can occur due to the Ekman effect (to the left in the southern hemisphere). At the shelf bed near the coast, compensating currents in the form of upwellings and downwellings may also be experienced.

Analysis of the study data showed that a direct correlation exists between the anemometer information and the induced change of current behaviour (Figures 4 and 5) for events when the wind speed exceeds 7 m/s for a duration of more than 5 hours. At lesser wind speeds or durations, no clear trend was discernible.

The lag between the commencement of the wind event and the impact on the prevailing current regime is typically between 4 and 24 hours. Prevailing current strength and direction as well as wind strength, direction and duration determine the lag period. Subjective judgement

was required in determining onset of these events. The present data set is considered insufficient to explore the lag question further.

Data for shore parallel wind events with wind speeds greater than 7 m/s and duration greater than 5 hours which produced approximately shore parallel currents were used to compare observed bottom currents with those predicted by Bretschneider's (1967) method:

$$\frac{\bar{V}}{U} = \sqrt{\frac{k}{k^*} \sin\theta} \tanh\left[\frac{Ut}{D} \sqrt{kk^* \sin\theta}\right]$$

- where  $\bar{V}$  = depth averaged current
- $U$  = sustained wind speed
- $k$  = surface stress parameter ( $3 \times 10^{-6}$ )
- $k^*$  =  $n^2 g D^{-1/3}$
- $n$  = Manning factor (0.025)
- $D$  = water depth
- $t$  = duration of wind speed
- $\theta$  = angle between wind and shore normal

The resulting observed and predicted currents, corrected to 1 m above the sea bed, are presented in Figure 6 and show reasonable agreement. Hence, based on the limited data set available, a tentative relationship between wind speed/duration and induced sea bed current magnitude at the 60 m and 80 m sites was determined (Figure 7).

Figure 6. PREDICTED AND OBSERVED BOTTOM CURRENTS

Figure 7. SUGGESTED RELATIONSHIP BETWEEN WIND SPEED / DURATION AND INDUCED SEA BED CURRENT FOR SYDNEY SHELF

### 4.3 Wave Induced Mass Transport

The depth of water in the study area is such that in general the wave induced mass transport is negligible and was therefore neglected. The time series data from the current meter records supported this approach. That is, changing wave conditions produced no discernible change in steady current direction or strength.

### 4.4 Tidal Currents

The steep nearshore slopes, the relatively narrow shelf and the small ocean tidal range (mean value 1.2 m) combine to produce weak tidal currents on the shelf. Hamon (1984) carried out a tidal analysis of the study data. He showed that longshore tidal components are in the order of 1 cm/s and offshore components are negligible. Therefore, as with the wave induced mass transport, tidal currents are not considered to be a significant factor in shelf sediment transport in the study area.

### 4.5 Wave Oscillations

The S.E. Australian continental shelf experiences a moderate to high energy wave environment. Deep water significant wave heights of 1.5 m are exceeded 50% of the time and spectral peak periods are typically between 8 and 12 seconds (Figures 8 and 9). During severe storms however, the significant wave height can reach 10 to 12 metres with peak periods of 14 to 16 seconds. A synoptic chart for a typical storm in the Tasman Sea is shown in Figure 10.

An analysis of the study data and a comparison with 10 years of waverider data at Sydney (Youll, 1981; Figure 8) was undertaken. This showed that the two data sets produced almost identical wave height exceedence curves (Gordon and Hoffman, in prep, (b)), indicating that the study data could be taken to be representative of the long term wave climate.

Figure 8. DEEP WATER WAVE CLIMATE

Figure 9. TYPICAL WAVE ENERGY FREQUENCY SPECTRA

Comparison of the directional wave oscillation records from the electromagnetic current meters with the long term directional statistics based on surface observations produced an interesting result. Particularly at the 60 and 80 m sites the depth dependent high frequency filtering showed that the majority of the recorded longer period energy comes from the south-east to south sector; the Lower Tasman Sea generating area. This contrasts with several years of wave directional data obtained at the surface which suggest that there is only a weak bias towards this sector (Fig. 11). It does however explain previously noted anomalies associated with attempts to match surf zone sediment transport calculations on the N.S.W. coast to recorded shoreline changes using the sea surface observations (Gordon et al, 1978).

4.6 Combined Forcing Functions

Seabed wave oscillations combine with steady currents to entrain sediment whilst the steady currents act to transport the suspended material in the direction of the current. The electromagnetic current meters and sampling schedules selected enabled the determination of both the steady currents due to wind and ocean movements (Figure 12) and the wave induced oscillations one metre above the bed (Figure 13).

Exceedence curves of near bed steady and oscillatory currents at depths of 24 m, 60 m and 80 m are shown in Figures 14 to 16. These indicate steady current components ( $U_C$ ) and the root mean square and 1% values of both the maxima of the oscillatory components ( $U_W$ ) and of the vector addition of the steady and oscillatory components ( $U_{C+W}$ ). The latter analysis was undertaken record by record (at one second intervals), taking into account the directions of both the steady and oscillatory components. The wave oscillation velocity parameter  $U_{1\%}$  was selected based on the arguments put forward by Nielsen and Gordon (1984) that this parameter is the most appropriate for determining sediment entrainment under natural wave spectra. The ratio  $U_{1\%}$  to  $U_{rms}$  was investigated over some 70 records. Based on the statistical mean of the results, the relationship adopted was:  $U_{1\%} = 1.75 U_{rms}$ . This suggests that seabed wave oscillatory velocities in this depth of water do not fit a Rayleigh distribution (Rayleigh gives  $U_{1\%} = 2.15 U_{rms}$ ).

Figure 15. VELOCITY EXCEEDENCE RELATIONSHIPS - 60m SITE

Figure 16. VELOCITY EXCEEDENCE RELATIONSHIPS - 80m SITE

5. Sediment Transport

Sediment transport on the Sydney shelf was analysed by considering the following questions:

- . What is the availability of sediment, both in terms of areal extent and sediment type?
- . Under what hydraulic conditions do the various sediments move?
- . How often are these conditions exceeded?
- . What is the direction and magnitude of both the gross and net sediment transport?

5.1 Availability

Side scan sonar, fathometer and seismic studies were used to determine the availability of sediments (Figure 2). Surface sediment sampling and R.C.V. video studies provided the detailed surface sediment data. In all, some 650 bottom surface samples and some 41 sub-bottom cores were obtained. Grain size distributions were determined hydraulically in a calibrated fall velocity tube (Gordon and Hoffman, in prep, (a)). Table 2 shows sediment characteristics at various water depths.

5.2 Threshold of Movement

Two thresholds of movement under combined waves and currents are recognised: the threshold of motion and the threshold of transport (Figure 17). The former occurs when the oscillatory shear is sufficient to result in sediment oscillation without net translation, a phenomenon observed in both the R.C.V. and diver studies. The latter (transport) occasionally occurs when the steady currents produce sufficient shear to initiate bed load transport. More commonly on the Sydney shelf however, the threshold of transport is only exceeded when the wave induced motion entrains the sediment. The entrained sediment is then transported by the prevailing steady current.

Entrainment may be caused by boundary layer flow instabilities around bed forms (Nielsen, 1979) or simply result from the combined wave and current shear exceeding that required to lift sediment particles from the bed.

Study site data showed that significant bedforms are present most of the time at the 24 m site (Nielsen and Gordon, 1984); they were also noted from the R.C.V. film and from the side scan survey out to about 40 metres depth. At the 60 metre site, bedforms were only observed on 18 occasions during the 6 months time lapse camera deployment. At the 80 m site no hydraulically induced bedforms were recorded on any of the instruments.

It was noted from the bottom cameras and the samplers that on many occasions fine sediments were in suspension without there being noticeable changes to sea bed conditions. Significant sediment transport events involving major bed changes did, however, occur at all sites. At these times, the current meter data showed that the threshold of motion, as defined by the modified Shields curve (Madsen and Grant, 1976), had been exceeded (Gordon and Hoffman, in prep, (b)). The bed at the deeper sites tended to rapidly progress from a flat bed, pock marked by animal burrows, to a sheet flow condition. During these events, both the coarse and fine fraction of the sediment were captured in the suspended sediment sampler array.

Flume studies under steady flow conditions and mechanical soils tests carried out to examine the progression from no transport to sheet flow indicated that the higher silt content of the sediments at the deeper sites caused them to behave in a semi-cohesive manner until the bed shear was sufficient to directly entrain both the fine and coarse fractions.

It was noted that bedform development and geometry is more marked in the regions where the sediments include significant shell hash (> 5%). This effect appears to be proportional to the coarse shell fragment content of the sediment. It was not, however, a feature of sediments where the shell fraction was medium to fine.

Table 2 presents the results from the threshold of motion studies from flume tests under steady flow and from the bottom camera and diving data. To date, velocity has been used as the parameter for defining thresholds. Although the methods of Madsen and Grant have been used to calculate shear stress, it is recognised that further work is required before meaningful determination of this parameter can be undertaken. In particular, the calculation of both an appropriate friction factor for semi-cohesive flat beds with appreciable biological activity and the determination of the relevant boundary layers and velocity distribution for wave spectra require further research.

It was found that calculations using Jonsson based approaches were sensitive to determination of friction factor and in particular to which velocity parameter was chosen to represent the wave spectra, e.g.  $U_{rms}$  or  $U_{1\%}$ .

TABLE 2. SEDIMENT GRAIN SIZES, THRESHOLDS OF MOTION AND TRANSPORT AND TRANSPORT VELOCITIES

Water depth (m)	Sediment					Comment	Threshold of motion ( $U_{ms}^{-1}$ )		Threshold of transport ( $U_{ms}^{-1}$ )		Transport velocity ( $U_{ms}^{-1}$ ) at activity levels			
	grain size (mm)			silt content	shell content		steady currents	currents* and waves	steady currents	currents* and waves	5	6	7	8
	d <sub>16</sub>	d <sub>50</sub>	d <sub>84</sub>											
24	0.30	0.24	0.16	1%	31%	medium fine sand	0.20	0.14	0.40	0.22				
40	0.75	0.62	0.35	2%	35%	coarse sand with shell fragments	0.26	0.10	0.35	0.18

80	0.19	0.17	0.15	32%	33%	fine silty sand, fine shell fraction	0.30	0.10*	0.38	0.13*	0.10*	0.13*	0.20	

\*  $U_c + U_w$

5.3 Exceedence of Threshold

Diver observations and the time lapse camera data were used to determine the exceedence of threshold. Camera data were subjectively assessed and classed into various activity levels (Figure 18). The hydraulic parameters associated with these levels were then determined. The suspended sediment sampling bottles attached to the current meter frames provided data on the grain size of the sediment being transported at various heights (up to 2.1 m) above the seabed. The camera data and sample bottles indicated that the fine fraction of the sediment tended to be in suspension at activity levels of 4 to 5 whilst activity levels of 6 to 7 were required for the coarser fraction. (Because of the inherent problems of such sampling devices, no attempt was made to use the samples collected in the bottles as a measure of sediment transport or to develop depth/concentration relationships.)

When considered in terms of shear stress, this result contradicts the implications of the Shields curve which suggests that the finer material should be more difficult to entrain. Although the Shields approach was developed for steady flow conditions only, Madsen and Grant (1976) and others have suggested that it can be applied, with suitable choice of parameters, to oscillatory motion.

Figure 18. SEDIMENT ACTIVITY LEVELS FROM CAMERA OBSERVATIONS

Two possible explanations for the observed phenomenon are suggested. The first is that fine sediment seen in suspension at low activity levels comes from a remote source; the second is that for the finer fraction, bottom pressure variations associated with wave motion can induce rapid pore pressure fluctuations in this semi-cohesive material. This may result in a bed instability which would effectively lower the shear stress required for entrainment of the finer fraction thus inducing a leaching action. The available data base was insufficient to resolve this matter.

Table 2 presents the threshold data and the estimated velocities associated with the designated activity levels at the 60 m and 80 m sites. The velocity estimates were obtained by taking the statistical mean of  $U_{1\frac{3}{8}}$  velocities associated with each event, at each designated activity level.  $U_{1\frac{3}{8}}$  was selected as the relevant spectral parameter based on bottom observations that the thresholds of motion and transport are associated with extreme spectral parameters (Gordon and Hoffman, in prep, (b); Nielsen and Gordon, 1984).

#### 5.4 Transport

Whilst some bed load transport was observed at the 24 m site, suspended transport was observed to be the dominant mechanism at all sites. For the purposes of this study, the oscillatory motion of sediment without net movement taking place was not considered to constitute sediment transport.

Shelf sediment transport was estimated by considering the time averaged flux of suspended sediment:

$$\bar{Q} \approx \int_0^h U_0(z) \bar{C}(z) dz$$

where  $\bar{Q}$  = time averaged transport

$U_0(z)$  = average velocity at height  $z$  above the bed

$\bar{C}(z)$  = time averaged concentration at height  $z$  above the bed

$h$  = bottom zone thickness

This was applied to each individual record for which it had been determined that threshold had been exceeded (Table 2 and camera data).

Nielsen et al (1982) suggested the relationship:

$$\ln \bar{C} = \ln C_0 - \frac{\bar{w}h}{\sqrt{E_B} E_S} \tan^{-1} \sqrt{\frac{E_S}{E_B}} \frac{z}{h}$$

where  $\bar{C}(z)$  = time averaged suspended sediment concentration at elevation  $z$ .

$C_0$  =  $\bar{C}(0)$

$\bar{w}$  = average settling velocity of sediment

- $h$  = water depth  
 $E_B$  = diffusivity due to boundary layer turbulence  
 $E_S$  = diffusivity due to non boundary layer turbulence

and showed that:

$$C_0 \approx 0.008 \left( \frac{\tau'}{\rho g (s-1)d} \right)^{2.5} \quad \text{for } r = 2.5d$$

Although Nielsen's (1979) work was confined to flume tests and the later work (Nielsen et al, 1982) to prototype measurements in the vicinity of the surf zone, some deep water data exist (Glenn, 1983) which was useful in scaling Nielsen's approach to the deeper shelf sites. This was necessary due to the lack of concentration profile data at these sites.

Absolute values of sediment transport have not been determined; further studies of the concentration profiles are being undertaken. This work is initially being carried out at the 24 m site. At the deeper sites, the six months data show that sediment transport events are rare. For example, at 60 metres, twelve events ranging in duration from 4 to 56 hours occurred where transport is considered to have taken place. At the 80 metre site, only six events of duration 8 to 16 hours were recorded. It should be noted that Figure 18 presents the number of recordings obtained, not the number of continuous events. For each event, a record was taken each four hours.

A significant finding of the study was that resultant net transport on the shelf is to the north and is determined by storms in the Tasman Sea. It had been generally believed that net transport was to the south since the net movement of water on the shelf is in that direction. During Tasman Sea storms, the wave induced seabed shear dominates and results in the entrainment of bed material which is then transported by the prevailing currents. As a majority of storms which impact on the shelf are a product of low pressure systems in the Lower to Central Tasman Sea (Figure 10), a strong coast parallel wind shear to the north is generated. This wind field gives rise not only to the waves which induce entrainment but also a short lived north bound shelf current (see Section 4.2). Near the coast, the Ekman effect rotates this current to produce a set up which is balanced by a downwelling. Hence, whilst the midshelf current during the storms is directly to the north, nearshore there is an additional offshore component at the sea bed due to the downwelling phenomenon. Overall, the net movement of sediment is therefore to the north and offshore near the coast but swings more towards the north further offshore.

The side scan sonar records include features consistent with net northerly sediment transport and with the modifying near-coast downwelling effect (Gordon and Hoffman, in prep (b) and Figure 2).

Sedimentological studies carried out by Roy (1984) suggest that average annual sediment transport is small; his estimates of accretion rates on identified depositional features on the shelf are in the order of 2 to 5 mm/year.

## 6. Conclusions

- . Transport on the shelf off Sydney mainly occurs during storm events in which wave activity produces sufficient seabed shear to cause entrainment. The dominant southerly steady current on the shelf seldom induces sufficient seabed shear to entrain sediment. On the occasions when wave induced shear results in entrainment, the mechanism producing the waves also tends to give rise to a short duration north bound current and hence the net movement of sand sized material is to the north. Near the coast, modification to the current pattern due to downwelling results in movement which is to the north and offshore.
- . Side scan sonar data have identified a number of sediment features which are believed to be related to this movement; the implied stability of these features suggests that transport rates on the shelf are small. This is supported by the sedimentological evidence and by the sediment transport calculations.
- . Estimates of absolute values of sediment transport on the Sydney shelf require further studies on concentration profiles and improved estimates of bottom shear stress.
- . Extreme wave spectral parameters are considered the most appropriate for examination of threshold of movement in these environments.

## CHAPTER ONE HUNDRED THIRTY TWO

### BEACH FORESHORE RESPONSE TO LONG-PERIOD WAVES

P. A. Howd\* and R. A. Holman\*\*

#### ABSTRACT

A field experiment has been carried out to test the hypothesis that infragravity and lower frequency waves influence patterns of erosion and deposition on the beach foreshore. The data show coherent fluctuations in the foreshore sediment level which can be related to low frequency wave motions. The fluctuations have heights of up to 6 cm with typical time scales of 8 to 10 minute periods. They can be characterized in two ways: by the progression of the fluctuation up the foreshore slope (landward), and by the decrease in the root-mean-square (RMS) height of the fluctuations as they progress landward.

Analysis of runup time series obtained by time-lapse photography concurrent with the sediment level measurements reveals long-period waves of undetermined origin which are positively correlated with the sediment level fluctuations. This strongly suggests that the waves are responsible for forcing the sediment level fluctuations.

#### INTRODUCTION

##### Background

The beach foreshore is a complex environment. There are numerous physical processes which interact to produce the profile observed at any moment in time. The recent works of Bowen (1980), and Holman and Bowen (1982) demonstrate the role of infragravity (and longer) waves in determining surf-zone profiles, but no recent study has been made of the role of long waves in determining the foreshore profile. This paper reports on one aspect of such an influence.

Patterns of foreshore profile response to tidal fluctuations began to be reported after World War II. Grant (1948) hypothesized that the changes in beach foreshore saturation, due to either tides or storm surges, would cause distinctive changes in the profile. He reasoned that saturated beaches would be more apt to erode since backwash would be undiminished by percolation. On unsaturated beaches, backwash should be diminished by percolation and deposition would be favored. Emery and Foster (1948) studied the change in the

\* Graduate Student at Large, College of Oceanography, Oregon State University, Corvallis, Oregon

\*\*Associate Professor, College of Oceanography, Oregon State University, Corvallis, Oregon

foreshore groundwater profile over a tidal cycle and concluded that there was significant exchange of water between the runup and the beach, and that this exchange could influence patterns of erosion and deposition.

Duncan (1964) drew upon these conclusions and produced what has become accepted as the best conceptual explanation of foreshore profile change due to tidally induced changes in the beach groundwater. He found that the beach groundwater level lagged the rise in sea level. The foreshore should then steepen during flood tide as deposition occurs on the unsaturated upper foreshore and erosion occurs on the saturated lower foreshore. During ebb tide the opposite sedimentation pattern holds. The upper foreshore erodes due to the effluence of the groundwater lagging behind the falling tide. His field study supports this hypothesis as do the results of others (Strahler, 1964; Harrison, 1969).

Studies of small scale morphology on the beach foreshore have been carried out intermittantly. Tanner (1965, 1977) and Broome and Komar (1979) discuss the existence and formation of backwash ripples. These low-aspect ripples (wavelength of about 50 cm, height approximately 1 cm) can be formed under hydraulic jumps in the backwash on gently sloping beaches. They are not characterized by active migration.

Waddell (1973) conducted a study of the interaction between runup processes, beach groundwater and the sediment level response on the foreshore. He measured sediment level at two locations, one meter apart, on the upper foreshore of a low-energy, medium-sand beach. Simultaneously, he measured runup and the beach groundwater at a series of locations. He found significant fluctuations in sediment level and presented evidence that the oscillations were sandwaves progressing down the foreshore slope due to bedload transport in the backwash phase of the runup. Waddell (1976), referring to the same data, concluded that standing waves in the inner surf-zone were responsible for periodic fluctuations in the beach groundwater level. These groundwater oscillations created "a zone which was periodically saturated or nonsaturated." He then invoked Duncan's (1964) hypothesis and concluded that nonsaturation, or a low in the groundwater oscillation, encouraged deposition and that the subsequent saturation of the location lead to erosion, the result being the observed periodic oscillations. He did not explain how this theory could account for the apparent seaward progression of the oscillations.

Sallenger and Richmond (in press) conducted a field study in Monterey Bay, California with the aim of characterizing sediment level oscillations on a steep, coarse-grained, high-energy foreshore. They measured the sediment level at a series of locations that stretched across the upper two-thirds of the swash-zone, finding sediment level oscillations at periods of six to fifteen minutes occurring at locations above and below the mean swash position. They reported that the oscillations progressed landward during a period of net seaward transport, thus ruling out the possibility of lower flow

regime bedforms such as sand waves. The width of foreshore monitored allowed them to show a landward decrease in the RMS height of the oscillations.

#### Goals

The purpose of this study was to test two hypotheses regarding foreshore sediment level oscillations with periods on the order of ten minutes. The first of these hypotheses is that infragravity or longer waves are capable of influencing the foreshore profile. The second hypothesis is that the profile response is not limited to the zone of intermittent saturation, groundwater fluctuations playing a lesser role than has been thought.

To test these hypotheses a field experiment was carried out on a high-energy, coarse-grained beach. The location chosen differed from that of Sallenger and Richmond (in press) in that it was on an open coast rather than within a major embayment known to have seiches. The goals of the field study were to document forcing (or non-forcing) of the sediment level oscillations by long period waves, to show that the oscillations are independent of any long term erosional or depositional trends on the foreshore, and that the oscillations are not directly related to the saturation of the foreshore.

#### EXPERIMENT SETTING AND METHODS

The field experiments were conducted during September 1981 and October 1982 at the U.S. Army Corps of Engineers, Coastal Engineering Research Center (CERC), Field Research Facility (FRF) on the outer banks of North Carolina near the town of Duck (Figure 1). The beach is interrupted only by piers for at least 50 km on either side. The nearest pier (belonging to the FRF complex) is 500 m from the experiment location. The surf-zone morphology in the region of the experiment is characterized by a single linear bar during conditions similar to those of the study periods. The average mid-foreshore slope during the studies was approximately 1:10. The foreshore is composed of medium to coarse sand with an average grain diameter of approximately 1 mm (Figure 2). During the two experiments the waves were oblique to the beach and had significant wave heights very close to 1 m as measured at a waverider buoy anchored in 20 m of water. There was little wind and waves were of the swell type. The tide range was approximately 0.9 m and semidiurnal. Figure 3 summarizes the environmental conditions surrounding the experiments.

On September 19, 1981, 19 stakes 1 cm in diameter and 1.5 m long were driven into the foreshore in the locations shown in Figure 4. The foreshore topography was dominated by a series of cusps, one of which is evident from the contours. The primary shore-normal line of eleven stakes had a spacing of 2.0 m.

In October 1982 an array containing eight shore-normal lines of stakes was established on the foreshore (Figure 5). The eight shore-normal lines were spaced 5 m apart. The second line from each

Figure 1. Location map. The field study was conducted at the Coastal Engineering Research Center Field Research Facility just north of the town of Duck, North Carolina. The beach is uninterrupted from Cheseapeake Bay to the north to Oregon Inlet to the south.

Figure 2. Grain size distribution. Cross-shore grain size distribution on a transect several meters south of the study site on 28 October 1982. The foreshore is composed of sand with an average diameter of approximately 1 mm. Data courtesy of Bill Birkemeier, CERC-FRF.

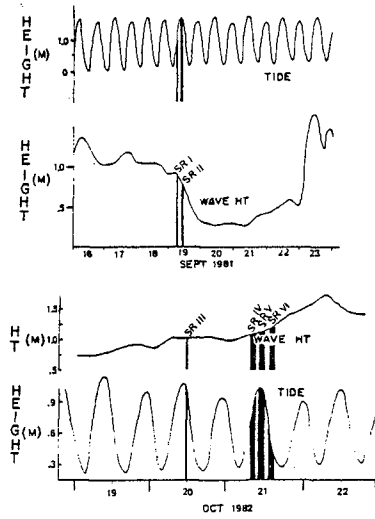

Figure 3. Environmental conditions. The significant wave height was measured by a waverider buoy in 20 m of water. The tides are semidiurnal and have a range of 0.75 to 1.3 meters.

Figure 4. Foreshore topography and stake locations for the 1981 experiment (DS I and DS II). The primary stake transect was located in the trough of a cusp. The stakes are numbered according to their distance seaward from the landwardmost stake and are spaced at 2.0 m intervals.

end of the grid had shore-normal stake spacings of 2.5 m while the remaining lines had 5 m spacings. The foreshore contours show a remnant cusp in the backshore separated from the active, featureless foreshore by a well defined berm crest. A contour map of the surf-zone topography from 19 October 1982 shows a bar approximately 20 m from shore. The mapping, done by the FRF staff using their CRAB (Birkemeier et al., 1981), shows the bar to be linear along shore. There was little evidence to suggest that there was any appreciable change in the topography over the two day period.

Fluctuations in sediment level relative to the stake tops were measured using a modified meterstick. A hinged baseplate approximately 10 cm in diameter was affixed to one end of the meterstick to prevent penetration of the sediment surface. A moveable pointer was fitted to the meterstick and was used to determine the length of stake exposed. The stake tops were referenced to a known elevation using an infrared rangefinder. The resolution of the technique, employing different measurers and different metersticks was  $\pm 1.5$  mm in the upper swash-zone and  $\pm 2.5$  mm in the lower swash-zone. Resolution of the measurements made on stakes not subjected to runup was  $\pm 0.5$  mm. The differences are primarily due to the time available to make the measurement and the saturation of the sediment.

During both the 1981 and the 1982 experiments, time-lapse motion pictures were used to record the wave runup on the foreshore. This method allows for digitization of the runup at a series of longshore locations as well as the identification of the saturated portion of the foreshore. The results of a comparison of the film techniques and a dual-resistance wire runup meter are presented by Holman and Guza (1984).

The 19 September 1981 experiment consisted of two sixty minute segments, one centered on mid-flood tide, DS (Data Segment) I, the second centered on high tide, DS II. The stakes on the primary shore-normal line were measured to the nearest millimeter at approximately 48 second intervals. Measurements were made after the backwash cycle when the stake was either suberial or the velocity of the water covering the location was low. The landwardmost stakes were measured only after they had been exposed to runup action. The times at which the measurements were made were recorded to the nearest 0.2 minute ( $\pm 6$  seconds).

The 1982 experiment consisted of one 35 minute segment near high tide on 20 October (DS III) and three 90 minute segments centered on mid-flood, high, and mid-ebb tides on 21 October (DS IV, DS V, and DS VI, respectively). Again, the stakes in a shore-normal line were measured at approximately 48 second intervals after the backwash cycle. Measurements were recorded to the nearest 0.2 minute. Stakes on the B-line (Figure 5) were those measured most frequently. The number of stakes measured varied according to the number of people measuring and the width of the swash-zone.

Figure 5. Foreshore topography and stake locations for the 1982 experiment (DS III to DS VI). The B line of stakes were those used in the study. The active portion of the foreshore was seaward of 17.5 m. A remnant cusp was perched landward of the berm crest. The foreshore is linear and has a slope of slightly greater than 1:10.

#### FIELD STUDY RESULTS

All the data show sediment level fluctuations superimposed on longer term trends. Figure 6 shows a representative set of time series of change in sediment level at a location versus time for the primary, shore-normal line of stakes. The stakes are numbered using their distance from the landward baseline, thus higher numbers refer to stakes further seaward. The trends are due either to the tidal cycle sedimentation patterns or to longer scale foreshore evolution such as changes related to storm cycles. On a shorter time scale, the fluctuations are periodic, and decrease in amplitude in a landward direction from a maximum height of greater than 6 cm to near zero. The stake locations on the lower foreshore show fluctuations occurring more rapidly than those at the upper, landward stakes. The fluctuations are visually progressive, and are coherent over at least 15 m in a longshore direction.

Statistical analysis quantifies these visual observations. The records were processed using linear interpolation to give time series with a constant interval of 12 seconds. The trend and mean were then removed so that they would not mask the analysis of the oscillations.

Figure 7 presents the relationship between root-mean-square (RMS) height and the distance from the top of the swash action for the 1982 data. The RMS heights of the fluctuations were computed as

Figure 6. Sediment level time series, DS I. The time series are reported relative to the initial elevation at each location. Several things are obvious. There are trends in the records, the oscillations decrease in amplitude in a landward direction, and they seem to progress.

two times the standard deviation of the record. All segments show the landward decrease in the RMS height of the oscillations, which ranged from a maximum of  $> 4$  cm at the seawardmost stake to near 0 cm for the landward stakes.

Crosscorrelation analysis was used to compare the detrended and demeaned time series. This analysis computes the correlation between two series of data at a series of lag times (Davis, 1973). It is not a frequency specific calculation as is the measure of coherence reported in association with cross spectral analysis. The lag associated with the maximum value in crosscorrelation is a measure of the shift of one series which results in the two series being most alike.

Figure 8 summarizes the results of the analysis as contour plots of crosscorrelation as a function of distance and lag time. Negative lags indicate that events at that location preceded the events at the reference stake. The contours indicate a change from negative lags for stakes below the reference point to positive lags above. This indicates landward progression of the fluctuations.

The flood-tide data, DS I and DS IV, both show lags which indicate landward migration of the oscillations (Figures 8A and 8D). Adjacent stakes in the mid-forshore have crosscorrelation maxima ranging from 0.54 to 0.79 while stakes which are farther from one another have values which range from essentially zero to 0.43. The lowered crosscorrelation values between non-adjacent stakes are

Figure 7. RMS heights of the sediment level fluctuations versus distance seaward for the 1982 data. Note the decrease in the RMS height in a landward direction for all the runs. The RMS height was computed as twice the standard deviation of the run.

primarily due to the loss of the high frequency oscillations present in the records obtained in the lower swash-zone.

The three high-tide segments also have maxima associated with landward migration of the fluctuations (Figures 8B, 8C, and 8E). Again, the values of the maxima are highest between adjacent stakes and decrease for non-adjacent stakes due to the loss of higher frequency fluctuations at the upper swash-zone locations.

Crosscorrelation was also used to compare the runup data to the sediment level fluctuations. Problems were encountered as the result of the large difference in the periods of dominant motion. The dominant runup period was near 8 seconds, while the dominant sediment level oscillations had periods from 2 to 8 minutes. Low pass filtering of the runup records helped alleviate this problem. Figure 9 shows the low-passed runup data along with the sediment level data for segment III. There are three obvious low frequency events in the runup time series that can be directly traced to the sediment level data. In all cases the lag associated with the best fit between the two types of series show motions in the runup precede the motions in the sediment level records. This would have to be the case if the runup is forcing the sediment level response. In general, the cross-correlation values are lower than those between adjacent stakes and sensitive to the characteristics of the filter applied to the runup time series. This is not surprising due to the assumed complexity of the transfer function between the runup and the profile response.

Figure 8. Crosscorrelation vs. time and distance. The crosscorrelation was computed between each time series and a reference time series from near the center of the section of the foreshore monitored during the experiment. Negative lags refer to shifting the reference series back in time, positive lags refer to forward shifts, thus the elongation of the contours from lower left to upper right indicates landward progres-

sion of the fluctuations. Values greater than 0.2 are significant at a minimum of 95% for all the plots at any lag shown. A: DS I, flood tide 19 September 1981. B: DS II, high tide 19 September 1981. C: DS III, high tide 20 October 1982. D: DS IV flood tide 21 October 1982. E: DS V high tide 21 October 1982. The results of DS VI were less characteristic and are discussed elsewhere (Howd, 1984).

Spectral analysis was done to allow specific frequency bands to be examined and compared between simultaneous records. Due to the record length containing as few as three cycles of the sediment oscillations, and the fact that the sampling interval allowed resolution of only those periods greater than 100 seconds, the technique was of limited use. The results are subject to considerable error.

Figure 10 shows a typical spectrum of runup. The distribution of energy is shown over a wider range of frequencies. As is typical for low wave conditions on a steep beach, the incident runup peak is clearly visible at 0.1 Hz. The dominant peak at approximately 0.0625 Hz is the subharmonic of the incident waves ( $f = 0.12$  Hz). The reason for the difference between the incident wave frequency as recorded in the swash zone ( $f = 0.10$ ) and in the inner surf zone ( $f = 0.12$ ) is unknown but has been seen in other data from steep beaches (Sallenger, pers. comm.). Low frequency peaks are also present.

Figure 9. Detrended time series of sediment level and runup. The runup time series has been converted to a vertical excursion using the average foreshore profile and low pass filtered to exclude motions with periods of less than 70 s. The correspondence between the runup series and the sediment level time series at the seawardmost stake is obvious.

Figure 10. Runup spectrum, DS V. The spectrum shows the incident runup peak near a period of 10 seconds (0.1 Hz.), a peak at 16 seconds (0.0625 Hz.) thought to be the first subharmonic of the 8 second period incident waves (period measured in the surf zone), and several lower frequency peaks.

## DISCUSSION OF FIELD DATA

The sediment level fluctuations maintain their form despite the high energy of the swash-backwash action. This suggests that the forcing of the shape must be continued past the initial formation of the features. The data show that sediment level oscillations do occur on the foreshore of a beach in apparent response to long period waves. The origin of the waves is unknown, but recent work by Lanvon et al. (1982) documents the shoaling of shelf waves with similar periods on beaches in Australia.

The fact that the oscillations are present on all sections of the foreshore subject to swash action discounts the hypothesis presented by Waddell (1976) for the origin of these features. If Waddell's (1976) hypothesis were true, then on a foreshore of the steepness of the beach studied here, the long period wave would need to have an amplitude of greater than 1 m in order to force fluctuations of the saturation line that would extend over the range required. There was no evidence that such high-amplitude, low-frequency waves existed at the time of the study. The oscillations were also measured seaward of the lowest position of the saturation line. It should be noted that the beach on which Waddell did his study was of considerably lesser slope and a wave of smaller amplitude would be required.

An alternative explanation for the formation of the sediment-level oscillations is the formation of antidunes in the lower swash-zone. Antidunes form in supercritical flow, such as may occur during the latter stages of backwash. The migration of the form as an antidune is dependent on maintaining supercritical flow above the bedform. This could not be the case in the upper swash-zone. Furthermore, the direction of antidune migration is opposite to the direction of sediment transport. The observed oscillations migrate landward without regard for the direction of net sediment transport. So while antidunes may explain the initial formation of the oscillation, they do not explain the migration of the form on the foreshore.

A simulation model, presented elsewhere (Howd, 1984 and Howd and Holman, in prep), suggests that the sharp discontinuity in slope at the step-zone is necessary for the formation of the fluctuations. The existence of sharp discontinuities (apparently in equilibrium) in the foreshore slope in this area implies the existence of large local gradients in hydrodynamic characteristics. Thus small horizontal dislocations of the swash zone caused by infragravity waves may induce rapid response and slope adjustments, namely a perturbation which progresses upslope. Sallenger (personal communication) noted that in one experiment the step migrated landward past several of their stakes. The sediment level oscillations present prior to the passage of the step disappeared when the location became seaward of the step. This would suggest that the oscillations are generated in the lowermost foreshore near the vicinity of the step. The magnitude of the oscillation is related to the degree of disequilibrium, that is to the difference between the existing slope and the equilibrium slope, and to the time available for a response.

## SUMMARY AND CONCLUSIONS

The primary objective of this field study was to document the influence of long-period waves on the beach foreshore profile. The data collected show such an influence. Oscillations of sediment level were recorded with maximum heights of up to 6 cm at time scales of 8 to 10 minutes. The oscillations decrease in amplitude as they migrate landward. Cross-correlation analysis showed the landward progression of the fluctuations and suggested that the oscillations in sediment level were the result of corresponding long period waves in the runup.

The fluctuations have been observed over the entire extent of the active swash-zone. Their occurrence below the zone of periodic saturation discounts the theory presented by Waddell (1976) for the origin of these features. An alternative explanation is based on disequilibrium conditions existing in the vicinity of the step-zone. The foreshore response to the disequilibrium is hypothesized to be the formation and migration of the observed fluctuations. It is obvious that the foreshore is capable of responding rapidly and in a very coherent manner to subtle changes in the dynamics of the swash-zone.

## CHAPTER ONE HUNDRED THIRTY THREE

### THE ROLE OF SUSPENDED SEDIMENT IN SHORE-NORMAL BEACH PROFILE CHANGES

Bruce E. Jaffe\*, Richard W. Sternberg\*\* and Asbury H. Sallenger\*

#### ABSTRACT

Field measurements of suspended sediment-transport were made across a dissipative surf zone during a storm. A correlation between high suspended mass in the water column and periods of onshore flow caused a net onshore transport of suspended sediment even though the mean near-bottom flow was directed offshore. The observed onshore migration of a nearshore bar was predicted by gradients in the cross-shore suspended-sediment transport.

#### INTRODUCTION

The response of the nearshore profile to cross-shore sediment transport has been the focus of numerous theoretical and laboratory studies (e.g. Bowen, 1980; Watanabe et al., 1980). However, due to measuring difficulties, few field data have been obtained of cross-shore sediment transport and the accompanying beach profile changes. In this study, measurements of cross-shore suspended-sediment transport were made across the surf zone during a storm. Nearshore profiles were taken both before and after the transport measurements. We attempt to relate gradients in the cross-shore transport of suspended sediment to profile changes. We show that a bar migrated onshore due to net onshore suspended-sediment transport even though mean currents were directed offshore.

#### EXPERIMENT SETTING AND METHODS

An extensive field study investigating nearshore processes was conducted in the fall of 1982 at the U.S. Army Corps of Engineers Field Research Facility (FRF) in Duck, N.C. The FRF is located on a long straight beach of a barrier island (Fig. 1). Mason et al. (this volume) provide details on meteorology, deepwater waves and three-dimensional morphology at the FRF during the experiment. Surf-zone data were collected 500 m north of the FRF pier using the U.S. Geological Survey sea sled (Sallenger et al., 1983). The sled is moved both onshore and offshore using a double-drum winch and triangular line arrangement (Fig. 2). As the sled moved, the nearshore profile was measured with an infrared rangefinder on the beach and reflecting prisms mounted on top of the sled's 10 meter mast. The sled was also used to transport instruments to different positions in the surf zone. Instruments mounted on the sled included a pressure sensor, three bidirectional electromagnetic current meters

Fig. 2 Experiment set-up at the U.S. Army Corps of Engineers' Field Research Facility.

oriented to measure the cross-shore and longshore flow at 0.5, 1.0, and 1.75 meters above the bed, and a vertical array of five optical backscatter (OBS) sensors (Fig. 3). The OBS sensors measured suspended-sediment concentrations from 0.1 to 80 gm/kg at 0.10, 0.13, 0.19, 0.31, 0.61 m above the bed. The OBS array was mounted on an outrigger extending 0.85 m from the north side of the sled.

Data presented in this paper were collected as follows. First, the nearshore profile was measured. Second, 34.1 minute long records of sled instruments, sampled at 2 Hz, were obtained at seven stations distributed across the surf zone. Sled stations were occupied in a random sequence of offshore distances. Measurements were obtained around high tide to minimize sea level changes. To complete the data set, a second nearshore profile was taken six hours and thirty minutes after the first profile.

Fig. 3 Sled instrumentation. Shown are three current meters (CM), a pressure sensor (PS), and an array of optical backscatter (OBS) sensors (photo courtesy of Bruce Richmond).

The OBS sensors, which were used to measure suspended-sediment concentrations, were developed by John Downing and others at the University of Washington (Downing et al, 1981). The small sensor size (2.2 cm in diameter) allows for measurement of the vertical variation in suspended sediment. The OBS irradiates a 1.3 cm<sup>3</sup> conical volume and detects the intensity of backscattered light. Intensity of backscattered light is a function of sediment concentration and grain size. For a given concentration, smaller grains, with a larger ratio of surface area to volume, will backscatter more light than larger grains. Since backscatter intensity is a function of grain size, OBS sensors were calibrated in the laboratory with sand collected at the FRF 210 meters offshore from the baseline. The calibration sand had a mean diameter of 0.14 mm, typical for sand seaward of the bar at the FRF. Calibrations of the OBS sensors could be described by two linear segments with a break in slope around 2 ppt (Fig. 4). Since the grain size of bed material was coarser in the trough, this calibration would underestimate suspended-sediment concentrations in the trough if all of the bed material was suspended. For a description of the calibration technique see Downing et al, 1981.

Fig. 4 Calibration curve for the optical backscatter sensor positioned 0.13 m above the bed. The calibration could be described by two least squares fits. The least squares fits only used concentrations below 30 ppt by weight because concentrations exceeded 30 ppt less than five percent of the time.

## OBSERVATIONS

On October 13, 1982, during the final stages of an extratropical storm (northeastern), deepwater significant wave heights at Duck were 1.6 m and peak wave periods were 12 to 15 s (Mason et al, this volume). A surf-zone width ( $X_b$ ) of 350 meters was calculated from a breaker height computed using measured deepwater wave characteristics (Komar and Gaughan, 1973), the nearshore profile, and measured ratios of surf-zone breaker height to depth. Visual observations were consistent with the calculated  $X_b$ . The surf zone was strongly dissipative, with three or four bores present at one time. We made measurements at  $X/X_b$  ranging from 0.1 to 0.65, where  $X$  was the cross-shore distance from the shoreline to the measurement location (Fig. 5E). These positions included three dynamically different regions; 1) the area seaward of the bar 2) the bar 3) the longshore trough. At measurement locations, mean water depths ranged from 2.1 to 4.3 m and RMS wave heights from 0.70 to 1.41 m (Figures 5C and 5D).

Measurements of horizontal water velocities were separated into mean and fluctuating vector components. The mean current speed at 0.50 m above the bed was highest in the longshore trough, 0.46 m/s, and decreased offshore except for sled station 6 where a strong longshore current increased the mean speed (Fig. 5A). Mean currents were directed offshore and to the north at all measurement stations. Standard deviations of current speeds, measures of the combined strengths of the oscillatory and turbulent fluctuations, are shown in figure 5B. The standard deviation calculation included infragravity oscillations.

Time-series measurements of suspended-sediment concentration showed that sand suspension occurred as intermittent events at all measurement positions. Figure 6 presents a 10 minute segment of a data record from sled station 6 ( $X/X_b = 0.5$ ) showing water depth, cross-shore and longshore velocities at 0.5 m elevation and suspended-sediment concentrations at four elevations above the bed. This record is typical in that it shows long periods of low suspended-sediment concentrations interrupted by shorter periods of high concentration. A comparison of records from different stations shows that the high concentration suspension events occurred more frequently and were of shorter duration in deeper water. Since all of the measurement positions were well within the calculated plane-bed regime (Komar and Miller, 1975), suspension events were not due to vortices associated with small-scale bedforms.

Although suspension was intermittent, the time-averaged concentrations systematically varied with distance above the bed and cross-shore position (Fig. 7). Seaward of the bar crest, the mean concentration at 0.13 m above the bed decreased landward from 1.8 gm/kg at sled station 7 to 1.1 gm/kg at sled station 4. Just landward of the bar crest mean concentrations at 0.13 m increased greatly to concentrations equal to that measured at the most seaward station. Lowest concentrations occurred in the longshore trough. At all sled stations, concentrations decreased monotonically from 0.13 to 0.61 m above the bed and concentration gradients generally decreased in shallower water.

The data collection sequence was sled station 7, 3, 1, 5, 2, 4.

Fig. 6 Data time series from sled Station 6 ( $X/X_b = 0.5$ ). From the bottom, the hydrostatic approximation to sea level ( $h$ ), cross-shore velocity ( $u$ ), longshore velocity ( $v$ ), and suspended-sediment concentrations ( $gm/kg$ ) at four levels above the seabed. Subscripts are elevations above the seabed in centimeters.

Mean concentrations at 0.10 m above the bed (not shown in figure 7) were within 0.1 ppt of the concentrations at 0.13 m. Concentrations were less at 0.10 m than at 0.13 m except at sled station 7. We were unable to find calibration errors for the OBS sensors that would explain the mean concentration decrease between 0.13 and 0.10 m. Still, we thought it unusual that the concentration would decrease towards the bed, so we did not use the 0.10 m readings when calculating suspended masses and fluxes.

The bar migrated onshore between 1519 hours and 2150 hours as its landward flank accreted and the seaward flank and longshore trough eroded (fig. 8D). Maximum vertical changes for the seaward flank, landward flank, and landward side of the longshore trough were -0.21, 0.18, and -0.31 meters, respectively. These profile changes are large compared to the measurement error of the sled system, which has been determined to be 0.045 m (Sallenger et al., 1983). To check the applicability of the 0.045 m figure, we estimated the total measurement error in the system on Oct. 13th. Bed elevations during occupation of a sled station were compared with bed elevations predicted by linearly interpolating the two measured profiles to the time of the occupation. The elevation differences were 0.01 to 0.05, with an average of 0.03 m, which is close to the 0.045 m standard deviation of change calculated by Sallenger et al, 1983.

Fig. 7 Time-averaged suspended sediment concentration profiles. Each point represents the average of 4096 concentration measurements (34.1 minutes of data collected at 2 Hz). The data collection sequence was sled station 7, 3, 1, 5, 2, 4.

#### CALCULATIONS AND DISCUSSION

In order to calculate a suspended mass, concentrations were estimated in regions the sensors did not measure. Concentrations were linearly interpolated between sensors. Above the highest sensor, concentrations were estimated from a linear extrapolation from values at 0.31 m and 0.61 m. When the extrapolation produced a concentration greater than zero at the seafloor, the concentration at the seafloor was set equal to zero and concentrations linearly interpolated between the value at 0.61 m and the seafloor. Concentrations below the lowest sensor were also linearly extrapolated from the sensors at 0.13 and 0.19 m. With these estimations, concentrations were integrated over the total water column to obtain a suspended mass. In general, the suspended mass decreased moving onshore in the inner sixty-five percent of the surf zone with the notable exception of the sled station just landward of the bar crest where suspended mass was higher than at each of the other stations (Fig. 8A).

Fig. 8 A) Cross-shore variation in suspended mass B) Cross-shore variation of mean cross-shore velocities at 0.5 m above the seabed C) Comparison of suspended-sediment flux calculated from average and instantaneous quantities (D) Comparison of measured profiles with changes predicted by cross-shore gradients in suspended-sediment flux. The data collection sequence was sled station 7, 3, 1, 5, 2, 4.

Time-average cross-shore suspended-sediment fluxes were calculated for each measurement location in two manners. Fluxes, utilizing the high frequency measurements, were calculated using

$$\bar{c} \bar{u} = \frac{1}{34.1} \int_{t=0}^{t=34.1 \text{ min.}} \int_{z=0}^{z=h} c(z,t) u(z,t) dz dt \quad (1)$$

where  $c$  is suspended-sediment concentration,  $u$  is cross-shore velocity,  $z$  is elevation above the seabed, and  $h$  is the time-varying seasurface. Fluxes, given by the products of the time-average quantities, were also calculated using

$$\bar{c} \bar{u} = \int_{z=0}^{z=h} \left( \frac{1}{34.1} \int_{t=0}^{t=34.1 \text{ min.}} c(z,t) dt \right) * \left( \frac{1}{34.1} \int_{t=0}^{t=34.1 \text{ min.}} u(z,t) dt \right) dz \quad (2)$$

Both calculations were performed using the vertical structure of velocity and concentration. Concentrations were extrapolated in the same manner as they were for suspended mass calculations. We assumed the oscillatory component of the cross-shore velocity was constant with elevation above the bed. This assumption overestimates velocity in the wave boundary layer, but, if the boundary layer was 0.05 m thick, the assumption would increase the flux by less than ten percent. The cross-shore mean current was linearly extrapolated to zero at the bed from the velocity at 0.50 m above the bed. The choice of a linear extrapolation was supported by the shapes of the velocity profiles.

Since near-bottom mean currents were offshore in the inner sixty-five percent of the surf zone, fluxes calculated using equation 2 were offshore at all measurement stations (Fig. 8C). However, fluxes calculated using equation 1 were onshore at four of the seven measurement stations (Fig. 8C).

The different results from the two methods of calculating the cross-shore flux occurred because a correlation existed between velocity fluctuations and concentration fluctuations. Rewriting the equations in terms of mean and fluctuating parts illustrates that eq. 1 includes the fluctuation correlations while eq. 2 does not. In the following analysis, an overbar denotes a time-averaged quantity and a prime denotes a fluctuating quantity.

The concentrations at an instant in time is composed of a mean concentration and a fluctuating concentration

$$c = \bar{c} + c' \quad (3)$$

Likewise, the cross-shore velocity at an instant in time is

$$u = \bar{u} + u' \quad (4)$$

Equation 1 multiplies the concentration and velocity before time averaging. Using the above notation, equation 1 can be written as

$$\overline{cu} = \overline{(\bar{c} + c')(\bar{u} + u')} \quad (5)$$

$$= \bar{c} \bar{u} + \overline{c'u'} + \overline{c'u} + \overline{c'u'} \quad (6)$$

The second and third terms in Eq. 6 drop out because, by definition, the time average of the fluctuations is zero. This leaves

$$\overline{cu} = \bar{c} \bar{u} + \overline{c'u'} \quad (7)$$

In equation 2 the fluctuating quantities vanish before multiplying concentrations and velocities. Following the same procedure as above, equation 2 can be written as

$$\bar{c} \bar{u} = \overline{(\bar{c} + c')(\bar{u} + u')} \quad (8)$$

Subtracting equation 8 from equation 7 gives  $\overline{c'u'}$ , a measure of the correlation of concentration and velocity fluctuations. For lack of a better term,  $\overline{c'u'}$  is referred to as a flux coupling. A low value for the flux coupling indicates a randomness of fluctuations relative to each other while a high value indicates a high degree of correlation.

The cross-shore flux coupling was positive (onshore) at every measurement position and increased with increasing water depth (Fig. 9). Again the position landward of the bar crest, sled station 3, was most active and had the highest flux coupling. The coupling of high suspended-sediment concentration with periods of onshore flow caused a net onshore transport of suspended sediment in the presence of a net offshore transport of near-bottom water.

Bed elevation changes were predicted from the cross-shore variation in the suspended-sediment transport calculated using equation 1. Convergences and divergences of the cross-shore transport contribute to accretion and erosion, respectively, of the nearshore profile. There was a convergence of cross-shore suspended-sediment transport on the bar's landward flank and a divergence on the bar's seaward flank (8D). The cross-shore suspended-sediment transport could account, qualitatively, for the migration of the bar landward in the presence of the mean offshore near-bottom currents. To see how much of the profile change could be attributed to the cross-shore suspended-sediment transport, average profile change between sled stations were calculated using a simplified form of the erosion equation.

$$\Delta\eta = \frac{1}{\phi} \frac{1}{\rho_s} \frac{\Delta Q_{sx}}{\Delta x} \Delta t \quad (9)$$

where  $\eta$  is the bed elevation in meters,  $\phi$  is the porosity of the bed material equal to 0.40,  $\rho_s$  is the density of the sediment in  $\text{kg m}^{-3}$ ,  $Q_{sx}$  is the mass flux of suspended sediment in  $\text{kg m}^{-1} \text{s}^{-1}$ ,  $x$  is the cross-shore distance, and  $t$  is time in seconds. We assumed that

Fig. 9 Cross-shore variation of the longshore ( $\overline{c'v'}$ ) and cross-shore ( $\overline{c'u'}$ ) flux couplings. Flux couplings were calculated by subtracting Eq. 2 from Eq. 1. The data collection sequence was sled station 7, 3, 1, 5, 2, 4.

the 34.1 minute record of flux was representative for the six hour and thirty minute period between profiles. Profile changes calculated using equation 9 were compared to the observed profile changes. Figure 10 shows the relationship between predicted and measured average bed elevation changes between stations. Profile changes were calculated using both the total water column and only the lowermost 0.75 m to indicate the contribution of the flux extrapolations in the upper water column. Away from the bar, the observed erosion is not predicted. Possibly gradients in the longshore suspended-sediment transport or in the longshore and cross-shore bedload transport caused the observed erosion. Accretion was predicted on the landward flank of the bar and erosion on the seaward flank. The measured average profile changes exhibited the same pattern and were of similar magnitude.

Fig. 10 Comparison of measured average bed elevation changes between sled stations with average changes predicted from convergences and divergences in the cross-shore suspended-

## CONCLUSIONS

Measurements showed that a strong coupling existed between high suspended mass in the water column and periods of onshore flow such that a net onshore transport of sediment occurred even though the mean flow was in an offshore direction. In the vicinity of the bar crest, gradients in the cross-shore suspended sediment transport could account for changes in the nearshore profile. These results suggest suspended sediment is very important in surf zone processes.

## ACKNOWLEDGMENTS

This work was supported by the U.S. Geological Survey and a fellowship while at the University of Washington from Texaco Inc.. We would like to thank the staff of the FRF for excellent field support throughout the experiment. Jim Smith and Arthur Nowell of the University of Washington were instrumental in guiding the early stages of data analysis. Helpful criticism of the manuscript were given by Bruce Richmond, Ed Clifton and Raphael Jaffe. Jeff List and David Barnes contributed many hours of time to brainstorming, wild speculations, and ultimately towards putting the work in its proper perspective. The first author is forever grateful to his wife, Trish, whose warm body and pleasant disposition balanced the cerebral abstractions of research. Lastly, many thanks to Jack.

## CHAPTER ONE HUNDRED THIRTY FOUR

### CROSS-SHORE TRANSPORT OF BIMODAL SANDS

Bruce M. Richmond\* and Asbury H. Sallenger, Jr.\*

#### ABSTRACT

Foreshore sediment level and sediment size were monitored as part of an extensive nearshore processes experiment - DUCK 82. Changes in foreshore texture were compared with computed values of onshore transported material based on current measurements from the surf zone and sediment transport theory (Bag-nold, 1963, 1966). Preliminary results indicate reasonable agreement between predicted size of sediment transported onshore and beach texture changes. It is also demonstrated that coarse sediment may move onshore while finer material may simultaneously move offshore.

#### INTRODUCTION

Theoretical (Bowen, 1980) and field (Murray, 1967) studies have shown the possibility of oppositely directed sediment transport for different sized material under oscillatory flow. As waves shoal, oscillatory water velocities become asymmetric with a strong landward flow followed by a slower and longer seaward return flow. Because of its higher peak flow, the landward-directed current is able to transport coarser material than the seaward current. Zenkovich (1967) discussed a hypothetical situation where 1 mm diameter particles were in equilibrium with the local conditions. Particles finer than 1 mm moved seaward while coarser particles moved landward with particles of 4 mm diameter having the greatest landward thrust. In a tracer study using three different particle sizes, Murray (1967) demonstrated under conditions of shoaling wind waves that finer grain sizes had a greater tendency to move offshore. Bowen (1980) showed theoretically that when a sediment of a given grain size is in equilibrium with a given slope and wave regime (net sediment transport rate is zero for this size) any coarser material should move onshore and finer material offshore.

Sonu (1972) working at Nags Head, N.C. described variations of foreshore profile and beach sediment texture over a period of several months. He discussed a sequence of texture changes associated with storm and recovery cycles which can be summarized as follows: a) The passage of a storm resulted in a foreshore composed of unimodal fine sediment. b) In the early stage of beach recovery, coarse material with a unimodal distribution appeared in the lower foreshore.

\* U.S. Geological Survey, Menlo Park, CA 94025

c) Continued accretion was accompanied by the addition of finer material leading to a strongly bimodal sediment composition. d) At the well-developed accretive state, finer sands were the dominant beach sediment. Sonu proposed that the length of time for the above cycle to occur was on the order of 2-3 months.

In this paper, we present field data from the Outer Banks of North Carolina on beach profile and sediment texture changes. This study was in conjunction with other studies on surf-zone processes during the DUCK 82 experiment (Mason and others, this volume). The experiment site at the Field Research Facility (FRF) of the U.S. Army Coastal Engineering Research Center at Duck, N.C. offered an excellent opportunity to examine mobility of different grain size populations under a variable wave climate. A wide range of sediment sizes is present including a terrigenous (non-biological) pebble fraction (Figure 1). We compared measured foreshore grain size to grain-sizes predicted to move onshore by a sediment transport model (Bagnold, 1963, 1966; Bowen, 1980).

Figure 1. Cross-shore sediment distribution along the USGS sled line.

EXPERIMENT DESIGN AND METHODS

The data collection effort involved sampling foreshore sediments and measuring sediment-level variations while gathering nearshore wave and current measurements (Figure 2). Foreshore sediment levels were measured relative to the tops of 1-cm-diameter aluminum rods spaced 2.5 m apart in a shore-normal line. This line was part of a 35 by 40 meter foreshore grid described more fully in Howd and Holman (this volume). Uniform foreshore sand samples 6 mm thick were collected by a "cheese-slicer" device while beach gravels were hand sampled. Offshore samples were obtained with a grab sampler deployed from the CRAB (Coastal Research Amphibious Buggy). Foreshore sediment and sediment levels were monitored at variable intervals depending on the beach response and the goals of a particular experiment, although measurements were made at least daily.

Twice-daily nearshore profiles were obtained with the USGS sled system (Sallenger and others, 1983). Electro-magnetic flow meters attached to the sled provided current information. The data were telemetered to a shore receiving station. The length of each data run was 34.1-minutes ( see Sallenger and Holman, this volume).

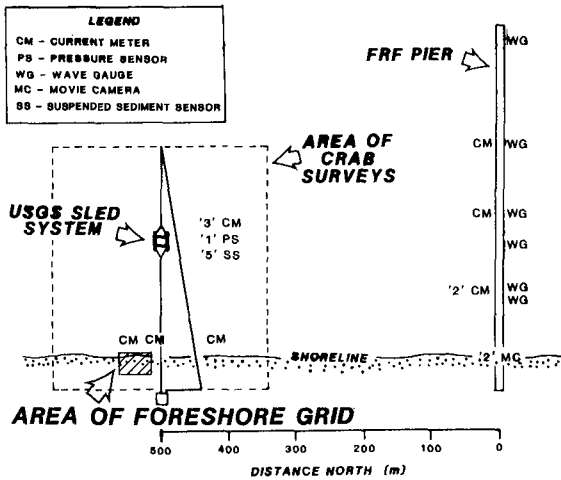

Figure 2. Map showing experimental set-up for the DUCK 82 experiment. The foreshore grid is 35 by 40 meters (it is discussed more extensively in Howd and Holman, this volume). FRF=Field Research Facility, CRAB=Coastal Research Amphibious Buggy. The USGS sled is not drawn to scale.

### Calculation of Sediment Transport

Although the mechanisms of sediment transport and deposition on the beach face differ from those in the nearshore, the sediment moving onshore through the inner surf zone should be an indicator of the material deposited on the foreshore. Bagnold's (1963, 1966) total-load transport model was used to predict at which grain size a reversal in transport direction would occur at an inner surf-zone station close to the swash zone. The reversal size is that size at which coarser material should move onshore and finer material offshore. These predictions were compared with actual changes of foreshore grain size. Bagnold's model was selected because it has been used successfully to explain some characteristics of cross-shore sediment transport (Bowen, 1980).

From Bowen (1980), the total immersed weight transport is

$$i_t = i_s + i_b \quad 1$$

where the suspended load equals

$$i_s = \frac{\epsilon_s C_D \rho u^3 |u|}{W - u\beta} \quad 2$$

and the bedload is given by

$$i_b = \frac{\epsilon_b C_D \rho u^3}{\tan \Phi - \frac{u\beta}{|u|}} \quad 3$$

These equations were simplified as follows:

$$i_s \approx \frac{\epsilon_s C_D \rho}{W} \left( \overline{u^3 |u|} + \frac{\overline{|u^5| \beta}}{W} \right) \quad 4$$

$$i_b \approx \frac{\epsilon_b C_D \rho}{\tan \Phi} \left( \overline{u^3} + \frac{\overline{|u^3| \beta}}{\tan \Phi} \right) \quad 5$$

$$i_t \approx C_D \rho \left( \frac{\epsilon_s}{W} \overline{u^3 |u|} + \frac{\epsilon_s}{W^2} \beta \overline{|u^5|} \right) \quad 6$$

$$+ \frac{\epsilon_b}{\tan \Phi} \overline{u^3} + \frac{\epsilon_b}{\tan^2 \Phi} \beta \overline{|u^3|} \right)$$

Where:

$C_D$  - drag coefficient (0.005; Bowen, 1980),  $i_t$  - total immersed-weight transport rate of solids,  $i_s$  - suspended-load transport rate,  $i_b$  - bedload transport rate,  $u$  - instantaneous cross-shore velocity (from sled measurements),  $W$  - fall velocity of sediment grains (variable),  $\beta$  - local slope (variable),  $\epsilon_s$  - efficiency of suspended-load transport (0.025; Bailard, 1981),  $\epsilon_b$  - efficiency of bedload transport (0.21; Bailard, 1981)  $\rho$  - fluid density ( $1027.0 \frac{kg}{m^3}$ ),  $\tan \Phi$  - friction angle of sediment (0.63).

Input velocities were derived from a current meter at a height of one meter above the bed and local slope was measured from the sled profile taken nearest in time to the current measurements. Sediment settling velocity was varied at 0.005 m/s increments to determine at which "size" a reversal in sediment transport direction would occur.

## RESULTS

Two data sets are discussed; the first considers foreshore texture changes for ten different days in October 1982, and the second examines nearshore profile and texture changes during a storm on Oct. 12th.

In the first example mid-foreshore sediment size was compared to the predicted size of sediment moving onshore past the landwardmost sled position for ten different days (Table I). In all cases the landwardmost sled position was immediately seaward of the swash zone. Significant wave heights determined from a waverider buoy in 18 meters of water three km from shore varied from a low of 0.7 m to a high of 2.3 m. In all cases the beach modal sizes were greater than or equal to the calculated values. Modal size is used because it corresponds to the most frequently occurring particle diameter and represents actual size of sediment present (mean grain size may be a size that is poorly represented in a bimodal sample).

Decreasing wave height was associated with a coarsening of the beach sediments and, conversely, increasing wave heights were followed by a fining of the foreshore. The initial coarsening may be due to the high mobility of the coarse sediments and close proximity to the probable source - the nearshore trough (Figure 1). The predicted reversal size is generally smaller than the actual foreshore sediment size which is consistent with the model because the calculated size represents the finest size which should be moving onshore. This is readily apparent on Oct. 14th where the predicted reversal size is 0.08 mm and the actual middle foreshore size is 4.1 mm. Finer material however, was deposited higher on the foreshore. It should be noted that there is a natural size grading across the foreshore, generally from coarse to fine as one travels landward across

the foreshore, which accounts for some differences between observed and predicted sizes. Although only one sample per day is used in this analysis, there were samples periodically taken at 5 m intervals across the foreshore which confirmed the general fining or coarsening trends reported.

Table I. Variation between predicted and observed (two values indicate a bimodal sample) sediment changes.

Date/1982	Modal Mid-foreshore Sediment Sizes (mm)	Predicted Reversal Size* (mm)	Significant Wave Height (m)
10-10	0.35	0.36	2.2
10-11	0.42	0.36	2.3
10-12	0.71 0.30	0.38	2.1
10-13	1.41	0.39	1.6
10-14	4.10	0.08	1.1
10-15	0.71	0.18	0.7
10-17	0.35	0.08	1.5
10-20	1.41 0.30	0.42	1.2
10-21	0.40	0.30	1.3
10-22	0.71 0.30	0.18	1.5

\*The calculated size at which a reversal in transport direction occurred.

Figure 3 is a photograph of a trench from the upper foreshore on Oct. 15th illustrating alternating coarse and fine laminations and the bimodality of the beach sediment. The upper coarse layer and the overlying finer laminations were deposited during the previous few days and represent a portion of the Sonu sequence discussed earlier. A major difference between these observations and Sonu's is the more rapid development in this study (a matter of days rather than weeks or months).

Figure 3. Foreshore trench from Oct. 15th, displaying variations in texture and planar laminations.

One of the questions from the the first example is what is the source for the coarse sediment-does it represent onshore transported material or is it an erosional lag? In this second example, we compare profile changes to sediment grain-size changes. The observed sediment sizes are then compared to values predicted to move onshore by the sediment-transport model.

October 12, 1982, was the third day of an extra-tropical storm (northeaster). During the storm, northeast winds reached a maximum sustained speed of 13 m/s at the study site, and maximum significant offshore wave heights reached 2.5 m (Mason and others, this volume). On Oct. 10th, the first day of the storm the foreshore underwent severe erosion with vertical losses greater than 1 m locally. Continued erosion occurred on the 11th but at a much reduced rate. By Oct. 12th offshore significant wave height was 2.5 m and peak period was 15.2 s; both foreshore accretion and erosion were occurring although erosion dominated. Available sediment sizes (Figure 1) varied from fine sand (offshore bar) through medium and coarse sand (inner nearshore and beach) to granules and pebbles (trough).

Several profile and sediment-size changes occurred during the rising tide (Figure 4a). The middle and upper foreshore underwent erosion while the lower foreshore accreted. Coarse sand, granules and pebbles were deposited on the lower foreshore while finer sands were removed from the middle and upper foreshore. The size distributions of the sediments (surficial and subsurface) eroded from the upper foreshore were such that they could not have supplied the volume of coarse material deposited on the lower foreshore. This implies that fine material was removed from the foreshore while, simultaneously, coarse material was derived from an offshore source. During this same period the offshore bar, which was composed of fine sand, was migrating offshore (Figure 4b; Sallenger and Holman, this volume; Sallenger and others, in press). The most reasonable interpretation is that coarse material was transported onshore to accumulate on the lower foreshore, while finer material was transported offshore, both from the upper foreshore and in the offshore-migrating bar.

The predicted direction of sediment movement for given size classes at selected locations across the nearshore profile are presented in Figure 4b. From the landwardmost sled position, sediment coarser than 0.4 mm (medium sand) is predicted to move landward. This landward transported coarse material probably contributed to the observed coarsening of the lower foreshore. The granules and pebbles deposited on the lower foreshore were considerably coarser than the 0.4 mm predicted reversal size. However, the reversal size indicates only the finest material moving onshore. Elsewhere along the profile the coarsest material predicted to move offshore was medium sand at a point just seaward of the bar crest. All material coarser than very fine sands was calculated to move onshore at the seawardmost sled position and near the deepest part of the trough. The seaward migration of the bar was presumably the result of offshore-transported medium and finer sands.

Figure 4a. Foreshore profile and texture changes for Oct. 12th.

Figure 4b. Offshore profile changes and predicted directions of sediment transport for different grain-sizes at selected sled locations.

#### CONCLUDING REMARKS

Field evidence from a mixed sandy nearshore supports theoretical predictions that different size classes of sediment can be transported in opposite directions under the influence of the same flow field. Using a sediment transport model, coarse sand was predicted to move onshore as coarse sediment was observed to be accumulating on the foreshore.

The two major parameters responsible for variation in the sediment transport direction are the slope and current velocity. Negative slopes (i.e., a landward slope) introduces some inconsistencies. Onshore transport directions for all sizes studied were predicted for a sled position on the landward sloping bar surface on Oct. 12th. This conflicts with field evidence, based on profile change, of offshore sediment transport for this general location. Theoretically, if the mean offshore currents are strong enough, seaward transport should occur over a landward sloping feature.

The Bagnold efficiency factors,  $\epsilon_s$  and  $\epsilon_b$ , are another uncertainty. However, we varied these factors within the limits suggested by Bailard (1981) and these changes resulted in reversal size changes of  $\pm .25 \Phi$  --acceptable variations for this study.

Although the results are strictly applicable only to the experimental conditions, they are significant in terms of the transport of any natural sediment or exotic materials such as dredge spoil or beach nourishment fill.

#### ACKNOWLEDGEMENTS

We would like to thank the entire staff of the FRF for their excellent support in the field. Peter Howd (formerly of OSU) spent many long hours, often under very adverse conditions, measuring sediment levels. David Barnes assisted with the computer programming and Ralph Hunter and Bruce Jaffe made many valuable comments on the manuscript. W. A. Birkemeier (FRF) kindly supplied the sieve data for the offshore samples.

## CHAPTER ONE HUNDRED THIRTY FIVE

### DEPOSITIONAL EFFECTS OF OFFSHORE BREAKWATER DUE TO ONSHORE-OFFSHORE SEDIMENT MOVEMENT

Hideaki Noda \*

#### ABSTRACT

Physical parameters controlling the development of tombolo behind offshore breakwaters are clarified on the basis of the results obtained by laboratory tests. Especially, the depositional effects are evaluated by taking a permeable type structure into account. They are wave characteristics, sediment size, the water depth where the structures are to be placed and its dimension. The amount of sand deposition behind the structures is presented by non-dimensional parameters such as the relative distances from the initial shoreline to the structure and to the breaking point of waves, the ratio of the gap width to the wave length in deep water and the ratio of the length of the offshore breakwater to the wave length in deep water.

#### INTRODUCTION

In considering depositional effects of an offshore breakwater by waves and currents on a beach, it is well known that offshore breakwaters act as barriers to littoral drift, blocking the natural sediment movement along the shoreline. However, sand transported from offshore sea beds by onshore-offshore sediment movement is also deposited within the protected lee of an offshore breakwater constructed on a coast where the littoral drift is not predominant, as shown by Toyoshima<sup>2)</sup>.

To gain some insight into the mechanisms, this paper deals experimentally with changes in the shoreline caused by the construction of offshore breakwaters and the amount of sand deposition within the protected lee of the breakwaters.

In addition, the distributions of the wave height and direction are measured and the currents behind the structures are observed by using floats. The results are utilized to estimate the distribution of the radiation stresses and the currents behind the offshore breakwater.

Finally, triangular-shaped groynes placed behind gaps of the structure are experimentally examined as a beach control measure.

LABORATORY EXPERIMENTS

## DESCRIPTION OF TWO MODELS

Two kinds of models were selected as the subject of the study; one was a wave flume which was designed to estimate the amount of sand transported shoreward through the permeable-type offshore breakwater and the other a wave basin which was designed to evaluate the amounts of sand transported shoreward both through the structure and from the gap between adjacent units.

The wave flume equipped with a flat-type wave generator was used; its dimension was 23 m long, 0.5 m wide and 0.6 m deep. The sediment used in the experiments was the well-sorted sand with a median diameter of 0.2 mm and a specific gravity of 2.65. The initial beach profiles constituted by this sand were uniform slope of 1/10.

The methods of the wave flume experiments are to measure the changes of the beach profiles and to estimate the volume of sand intruding into the protected area through the breakwater by using the results of the profile changes. The profiles of beaches were measured by an equipment which was developed to measure a number of depths of the bottom as soon as possible by combining a profile indicator with a personal computer as shown in Fig. 1. After the beach profile was deformed by the wave and reached the equilibrium state, the permeable-type breakwater was installed in the surf zone of the equilibrium profile and shifts in the profile were obtained until the equilibrium profile was reformed again. Table 1 is a list of wave conditions used in the experiments.

The second experiment was made by use of a wave basin measuring 12 m long, 5 m wide and 0.6 m deep. The beach was characterized by the same initial slope and sand as those of the first experiment. In order to examine the relationship between the depositional effects of the offshore breakwater and the wave behavior, the following quantities were measured: the change in shoreline shape, the amount of sand deposited in the protected lee, the distribution of the wave height and the wave direction, the distance from the breaking point to the initial shoreline and the velocity of the current behind the breakwater.

## BEACH PROFILE CHANGE IN TWO-DIMENSIONAL CASE

In the experiments, two types of wave characteristics were selected to study the effect of wave action on the changes of the beach profile. As shown in Table 1, one is the B-type wave which forms a storm profile with a longshore bar and the other the S-type wave which develops a swell profile. The reason for using the two kinds of waves is to investigate the difference of sand volume deposited within the protected area by using the same waves (B-B or S-S) or the

Fig. 2 Changes of beach profiles for various locations of offshore breakwater

different waves (B-S or S-B) before and after placing the structure.

Figs. 2-(a) and (b) show an example of the profile changes obtained from different waves (S-B) before and after installing the breakwater, in which  $X$  and  $X_b$  are the distances from the initial shoreline to the center of the offshore breakwater and that to the breaking point, respectively. The beach profiles at the top of this figure show the equilibrium beach profile (solid line) which was developed by the actions of the B-type wave after the equilibrium profile (dotted line) was formed by the actions of the S-type wave. As an expected result, it was found that the great recession of the final shoreline takes place in the case where there is no breakwater, while the progression of the final shoreline is caused by placing the breakwater. Fig. 2-(b) shows the similar results for B-S waves. Fig. 3 shows the relationship between the amount changes within the protected area and the relative distance of the located offshore breakwater, and  $V$  is the amount of sand deposited after placing the breakwater. In addition, the symbols shown in the upper left of this figure indicate that the experiments were carried out by using the same waves (B-B or S-B) or the different waves (B-S or S-B) before and after placing the breakwater.

This figure summarizes the depositional effects of the sediment intruding shoreward through the permeable breakwater and the amount of sand deposition depends on both the wave characteristics and the values of  $X/X_b$ . The location to maximize the amount of deposition is found when the breakwater is located at  $X/X_b=0.5$  to  $1.0$  for all cases of wave types.

Fig. 2 Measured relationships between  $V/V_0$  and  $X/X_b$

## CHANGE OF BEACH CONFIGURATION IN THREE-DIMENSIONAL CASE

Table 2 is a list of wave conditions used in the wave basin experiments. The method of the experiments was conducted as follows: after having the B-type waves act on the beach with a uniform slope of 1/10 and then installing the offshore breakwaters on the various locations inside the surf zone, the final equilibrium beaches were formed by the actions of the same waves. The waves used in Run A were designed to correspond to those of the two-dimensional experiment (B-B) so that quantitative evaluations can be made by comparing both data. The reason why steeper waves were used in Run B was to emphasize the depositional effects due to the onshore-offshore sediment transport, considering that the wave used in this experiment ( $H_0/L_0 = 0.087$ ) had a tendency to cause greater erosion.

Table 3 is a list of non-dimensional quantities related to the distance from the initial shoreline to the center of the offshore breakwater  $X$ , the length of the breakwater  $l_B$  and the width of gap between the breakwaters  $B$ . Fig. 4 shows the definition sketch for the offshore breakwaters and the beach configuration. Fig. 5-(a) and (b) are the examples of the bathymetry in the initial ( $t=0$  hr.) and the final ( $t=16$  hrs.) states, respectively.

Fig. 6 shows a few examples obtained in these experiments. In these figures, the solid and chain lines show the initial and final shorelines, while the various dotted and broken lines indicate the equi-depositional contour lines (unit cm) obtained from the difference between the final and initial bathymetries. These three figures result from different locations of the structure but correspond to the same wave condition (B-B). It is found that well-developed tombolos and the maximum deposition occur when the offshore breakwater is located at  $X/X_b = 0.56$ . As shown by Shinohara and Tsubaki<sup>1)</sup>, bi-modal tombolo develops in the case of a short distance between the initial shoreline and the location of the structure ( $X/X_b = 0.39$ ).

From the condition of continuity, the total volume of sand deposition,  $Q$ , in the region abb'a' shown in Fig. 4 becomes

$$Q = Q_0 B + V l_B \quad (1)$$

where  $Q_0$  represents the total volume of sand deposition per unit width of the gap transported through the gap and  $V$  the total volume of sand deposition per unit length of the breakwater resulting from sand intrusions through the permeable breakwater. An alternative form of Eq.(1) may read

$$\frac{Q_0}{V} = \frac{Q}{V B} - \frac{l_B}{B} \quad (2)$$

in which  $Q_0/V$  indicates the ratio of the total volume of sand deposition per unit width of the gap transported shoreward from the gap to that of sand deposition resulting from sand intrusions through the permeable breakwater. The

(b)

Fig. 5 Bottom topographies at the initial and final state

value of  $Q_0/V$  can be calculated by using the measured values of  $Q$  and  $V$  on the basis of Eq.(2).

Fig. 7 shows the relationship between  $Q/Ad$  and  $X/X_b$  obtained from Runs A and B, and also the same relationship between  $V/Xd$  and  $X/X_b$  obtained from the case of B-B in the two-dimensional experiments, in which A is the area of abb'a' shown in Fig. 4 and  $d$  the median diameter of sand size. A comparison of the results in Run A with those of two-dimensional experiment (B-B) having the same wave condition as that of Run A in this experiment (B-B) and the estimation of  $Q_0/V$  on the basis of Eq.(2) shows that the total amount of sand deposition per unit width of the gap transported shoreward from the gap is about three times that of the sand deposition resulting from the wave intrusion through the permeable breakwater itself. Therefore, the results suggest that the non-dimensional volume of sand deposition directly depends not only on the values of  $X/X_b$  but also on the values of  $l_p/B$ , the ratio of the length of the offshore breakwater to the width of the gap. There is, however, an exception;  $Q_0/V = -0.34$  for  $X/X_b = 0.75$ . This fact indicates that the amount of the sand transported seaward from the gap is about three times that of the sand intruding shoreward through the permeable breakwater, although  $Q/Ad=0$  balances the sand budget within the protected area (see Fig. 7).

Fig. 8 shows two beach profiles, one at the center of the breakwater and the other at the center of the gap for  $X/X_b = 0.75$ . In this figure, it is found that a large amount of sand existing near the shore-

Fig. 8 Changes of beach profiles

line behind the gap is taken away by waves and currents, since the progression of the shoreline takes place and a tombolo is developed near the center of the breakwater but the scour of its lee just behind the offshore breakwater occurs and the regression of the shoreline behind its gap is greatly eroded.

#### MEASUREMENT OF WAVE AND CURRENT CHARACTERISTICS

An attempt was made to investigate the mechanism of sand deposition due to the onshore-offshore sediment transport, the measurements of wave parameters and the resulting currents in the protected area were made under the condition of Run B-2 in which the maximum amount of sand deposition in the area of the protected lee was observed.

Fig. 9 shows the results of measured wave height and direction in various locations. In this figure, the local variation of wave height is expressed by the ratio of wave heights measured in each location,  $H$ , to the incident wave height  $H_I$ . Both the direction and the length of each solid line segment with an arrow head represent the direction of waves and the ratio  $H/H_I$ , respectively. Each contour line corresponds to a certain value of this ratio. The following may be found from this figure : 1) a partial clapotis is developed in the area seaward of the offshore breakwater, 2) diffraction of waves is observed in the vicinity of the gap, and 3) transmitted waves intruding through the breakwater are recognized just behind the offshore breakwater.

By introducing a rectangular co-ordinate system  $(x,y)$ , in which the orientation of the co-ordinate system is chosen so that the x-axis lies roughly perpendicular to the initial shoreline as shown in Fig. 10, the radiation stresses in the measuring points of the wave height are expressed by

$$\begin{pmatrix} S_{xx} & S_{xy} \\ S_{yx} & S_{yy} \end{pmatrix} = E \begin{pmatrix} n \cos^2 \theta + n - 0.5, & -0.5 n \sin 2\theta \\ -0.5 n \sin 2\theta, & n \sin^2 \theta + n - 0.5 \end{pmatrix} \quad (3)$$

where  $\theta$  is the angle between the wave direction and x-axis,  $n$  the ratio of the group velocity to the wave velocity and  $E$  the wave energy. In addition, the non-dimensional friction terms  $(R_x, R_y)$  related to the wave-induced currents are given by

$$\begin{aligned} R_x &= -\frac{1}{\rho gh} \left( \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{yx}}{\partial y} \right) \\ R_y &= -\frac{1}{\rho gh} \left( \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \right) \end{aligned} \quad (4)$$

in which  $\rho$  is the density of water,  $g$  the acceleration of gravity and  $h$  the water depth. The radiation stresses based on Eq.(3) can be calculated by using the measured wave

Fig. 9 Distribution of wave height expressed by the ratio of  $H/H_I$

Fig. 10 Definition sketch of co-ordinate system

Fig. 11 Distribution of  $S$  estimated by radiation stresses

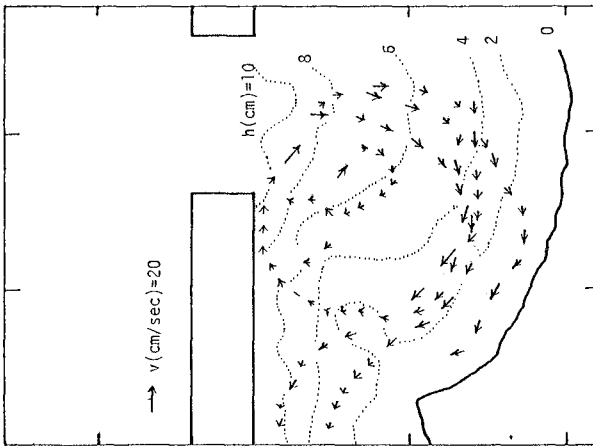

Fig. 13 Current pattern measured by float

parameters and then the friction terms in Eq.(4) can be also computed based on the numerical results of the radiation stresses calculated above and by use of a finite difference numerical method.

Fig. 11 describes the spatial distribution of the vectors  $S$  estimated on the basis of Eq.(4), in which the magnitude

and direction of the vector  $S$  are calculated by  $S = (R_x^2 + R_y^2)^{1/2}$  and  $\theta_s = \tan^{-1}(R_y/R_x)$ , respectively. Fig. 12 shows the observed current pattern in which the velocity and direction of currents are expressed by a segment of a solid line with an arrow head. Comparison of Fig. 11 with Fig. 12 suggests that the circulation estimated in Fig. 11 shows a similar pattern to that of the wave-induced currents in the shoreward region of the gap. It seems that such a numerical method serves for estimating wave-induced currents in the protected area. Furthermore, it appears that the circulation observed in Fig. 12 contributes to the sand accumulation within the protected lee of the breakwater, the development of tombolo and the retreat of the shoreward area of the gap by onshore-offshore sediment movement.

#### SOME MEASURES FOR EROSION IN LANDWARD AREA OF GAP BETWEEN OFFSHORE BREAKWATERS: AN ATTEMPT

Since the offshore breakwater had such a defect that the shoreward area of gap between adjacent units was eroded in all the cases of the experiments, some measures were tested to protect the area from landward retreat. One of the measures was to place triangular-shaped jetties in the area, considering that the jetty is effective from the view-point of preventing the circulation of currents which appears to develop tombolo.

Experiments were made by using the same wave basin as mentioned in the foregoing section. The wave condition was the same as Run B in three dimensional case, and the locations where the offshore breakwaters were placed were the same as Runs B-2 and B-3 (see Tables 2 and 3). Fig. 13 shows a schematic diagram of the triangular-shaped jetty which was placed behind the gap of the offshore breakwaters. Here,  $X_j$  is a distance from the initial shoreline (chain line) to the head of the jetty.

Fig. 14 shows the changes of

Fig. 13 Schematic diagram

Fig. 14 Comparison of changes in shoreline and Bottom configuration for the cases with jetty

the shoreline form and the bottom topography for various values of  $X_j/L_0$  under the same wave condition as Run B-2 and  $X/X_b=0.56$ .

Comparison between these figures and the middle figure in Fig. 6 (no jetty) indicates that the landward retreat takes place in the tip part of tombolo, while the scour in the surroundings of the gap and the offshore breakwater is reduced considerably. Furthermore, a remarkable fact is that the regression of shoreline in the area can be prevented when the jetties are placed at  $X_j/L_0=0.23$ .

Fig. 15 summarizes the results of the sand volume deposited in the protected area,  $Q/Ad$  vs.  $X_j/L_0$ . In the case of  $X/X_b=0.56$ , the sand volume deposited in the area decreases slightly with increase in the values of  $X_j/L_0$ . Furthermore, a noticeable result is that the non-dimensional sand volume in all cases with the jetty is small compared to those without the jetty, while the landward retreat of the shoreline behind the gap can be prevented in the former cases. Contrastly, in the case of  $X/X_b=0.78$ , the sand volume for the experiments with the jetty always exceed that for the experiments without the jetty.

It is clear that an appropriate location for constructing jetties is largely confined by wave characteristics, width of gap, length and location of the offshore breakwater. It also appears that the relative location of the offshore breakwater and jetty plays an important role in the development of the current pattern.

Fig. 15 Relationship between  $Q/Ad$  and  $X_j/L_0$

CONCLUSION

The following may be concluded from the laboratory tests on the depositional effects of the offshore breakwater due to onshore-offshore sand transport:

1. the optimum locations at which the effective deposition of sediment behind the offshore breakwaters develops are at  $X/X_b=0.5$  for B-type waves and at  $X/X_b=1.0$  for S-type waves in the results of two-dimensional tests.
2. there is found no sand that intrudes shoreward through the permeable type of the offshore breakwater when the structures are placed seaward beyond the breaker line of waves. On the contrary, a large amount of sands may be carried away offshore when the offshore breakwaters are placed near the shoreline.
3. the total amount of sand deposition per unit width of the gap transported shoreward from the gap is about three times that of sand deposition intruding through the permeable breakwater, when the dimensions and location of the breakwaters are chosen appropriately.
4. the current pattern induced by the wave action behind the structures may be predicted by applying the concept of radiation stresses.
5. construction of the triangular jetties may be utilized as one of the measures to prevent the scour in the surroundings of the breakwaters or the landward retreat behind the gap.

ACKNOWLEDGMENTS

The author would like to express his appreciation to Mrs. K. Noda, Y. Shimizu and N. Kurose for their assistance in the laboratory experiments, and expresses appreciation for financial support of the Grant-in-aid for Scientific Research of Ministry of Education.

## CHAPTER ONE HUNDRED THIRTY SIX

### PERMEABLE GROYNES: EXPERIMENTS AND PRACTICE IN THE NETHERLANDS

W.T. Bakker\*, C.H. Hulsbergen\*\*, P. Roelse\*, C. de Smit\*\*\*  
and J.N. Svasek\*\*\*

#### ABSTRACT

This paper reports on model experiments and up to 20 years of practice in nature with a permeable groyne system, consisting of single or double permeable rows of wooden piles perpendicular to the beach, without bottom protection. This system costs only 10 to 25% of the impermeable stone groynes which have for centuries been used in the Netherlands.

Model experiments confirm that wave-induced currents in the protected areas are reduced to 65%, and tidal currents even to 50%, depending on the pile screen configuration. Prototype measurements could not lead to straightforward conclusions with statistical significance: the effect of the pile screens on beach evolution is partly merged into natural fluctuations and trends. Wooden pile screens do not prevent the shoreward motion of tidal channels, which can cause washing out of piles. Furthermore, constructional failures, which in the future can be avoided, at some places resulted in negative experience. It is concluded that permeable pile screens deserve serious consideration as a first flexible and cheap phase in combating coastal erosion. Its application however should be based on a thorough analysis of the local coastal current climate.

#### 1 INTRODUCTION

Holland has to defend its low-lying land against the wind-swept waters of the North Sea. Large portions of its natural defence line, the coastal dune ridge, are subject to erosion [Bakker and Joustra, 1970], as a result of long-term or cyclic beach recession and short-term storm-surge dune erosion. In the past centuries many different structures have been applied in order to contribute to the coastal defence system, among which about 500 stone groynes. Traditionally, these structures are founded on willow matting and consist of rubble stone covered by hand-set stones. Especially in the SW province of Zeeland, where the tidal range reaches 4 m, the groynes were heightened by constructing single or double wooden pile rows on their crests. There is good reason to state

---

\* Ministry of Transport and Public Works/Rijkswaterstaat, the Netherlands  
\*\* Delft Hydraulics Laboratory, the Netherlands  
\*\*\* Svasek B.V. Engineering, Rotterdam, the Netherlands

that the recession of the coastline is indeed retarded by these massive groynes; their effectiveness has been studied in practice [Bakker and Joustra, 1970], theoretically [Bakker, 1968] and experimentally [Hulsbergen, Bakker, and van Bochove, 1976].

However, four main disadvantages of massive groynes are obvious, viz.:

- They are very expensive.
- They tend to induce deep erosion pits seaward of the groyne-head because of locally increased currents.
- They may stimulate rip-currents and seaward loss of sand.
- Extensive lee-side erosion may occur on the adjacent unprotected coastline.

Since 1965 a new type of groyne has been applied in the Netherlands in order to cope with these problems: it merely consists of wooden piles driven into the beach with mutual distances of about one pile diameter, so that permeable pile screens are formed, aligned perpendicularly to the beach, without bottom protection. These "permeable groynes" will further be referred to as "pile screens" or simply "screens", whereas traditional massive structures will be indicated as "groynes". The purpose of the pile screens is discussed in chapter 2.

The pile screens were initially constructed as an experiment, and different geometrical variations (length, height, distance, single or double rows, etc.) have been applied. In 1972 analytical and laboratory studies were performed in order to gain a better understanding of their effect in various hydraulic and geometrical settings; the results are outlined in chapter 3. Design and cost aspects are discussed in chapter 4.

Some of the pile screen projects, which were implemented since 1965, have been a success; others failed. This is discussed in chapter 5. In some cases it is difficult to distinguish the proper screen effect from the large-scale background morphologic development. Chapters 6 and 7 aim to analyze and summarize the experience gained so far.

## 2 PURPOSE OF PERMEABLE PILE SCREENS

In contrast to massive groynes, which seek to form a complete obstruction to the longshore current and to the longshore sediment transport, permeable pile screens are meant as an artificial hydraulic resistance in order to reduce the longshore current velocity and thus reduce the rate of longshore sediment transport. This may be explained as follows.

The longshore sediment transport concept [Bijker, 1971] is based on the notion that sediment is stirred up from the bottom by a shear stress which is produced by the combined action of waves and currents; the currents may be a combination of wave-induced and tidal currents. Once stirred up, the sediment is transported by the currents while being kept in suspension by waves and currents for some time. Hence, by reducing the current velocity (by means of the screens), both the stirring-up and the transporting phases of the sediment transport mechanism will be reduced, virtually without directly reducing the primary wave action.

With respect to the disadvantages of massive groynes as mentioned in chapter 1, the purpose and the expectation of permeable pile screens

can be summarized as follows:

- low cost structures
- less pronounced current concentration seaward of the head, provided that the permeability is adapted along the screen length
- reduced tendency to form rip-currents, for the same reason
- the ability to reduce the longshore sediment transport in a gradual way is an important asset in order to reduce the lee-side erosion behind massive structures: by an adequate screen field lay-out the total sediment deficit of the lee-side area will be distributed over a larger distance, thus decreasing the rate of recession.

### 3 LABORATORY EXPERIMENTS

Preliminary calculations, taking into account the bed shear stress and the estimated hydraulic resistance of the pile screens, showed that velocity reductions of 30% would result for 50 to 75% open screens, 200 m long and 400 m apart; a further reduction would require progressively more piles per unit beach length [Hulsbergen and ter Horst, 1973]. In view of the uncertainty involved in the underlying assumptions, and because of the lack of detail in terms of the resulting current pattern, in 1972 fixed-bed laboratory tests were deemed necessary in order to find out to what extent pile screens of various geometrical forms reduce the coastal currents under different hydraulic boundary conditions.

The model set-up is shown in Figs. 1 and 2. Horizontal and vertical scales are both 40, and the velocity scale is 6.32 according to Froude. The coastal profile is typical for Zeeland, where tidal currents of 1 m/s occur in a water depth of 10 m close to the beach, and where the tidal range is appr. 4 m. The model bed consists of smooth concrete and has straight parallel depth contours. A variety of prefab model pile screen configurations (Fig. 3) have been installed in grooves which are 1.25 m apart. (All units in this chapter are in model measures unless otherwise indicated).

The model piles are 6 mm in diameter and their mutual clearance varies from 6 mm at the landward end to 19 mm near the seaward tip. The piles may be combined to short screens (3.5 m long) or long screens (5 m long), either as a single row, or in double rows 8.75 cm apart. The mutual screen distance varies from 3.75 m to 10 m.

Several hydraulic conditions have been installed, of which the most important are:

- H.W. and current only (most of the tests)
- H.W., a current, and a wave generated current in the same direction as the tidal current; regular wave period  $T = 1.04$  sec, wave height at (spilling) breaking  $H_{br} = 3.0$  cm, angle of incidence at breaking  $\alpha_{br} = 8^\circ$ .

For a variety of special velocity measurements with screen configurations and hydraulic conditions different from those mentioned above, reference is made to [Hulsbergen and ter Horst, 1973].

The main test results for the present purpose are expressed in terms of the relative velocity  $V_{rel}$ , i.e. the ratio of the longshore current velocity with screens over the longshore current velocity without screens, measured on the same spot and with the same hydraulic condition. Combining some of these results, the following conclusions are drawn.

FIG.1 Model basin

FIG.2 Cross-section of model

FIG.3 Screen configurations

FIG.4 Effect of more screens

FIG.5 Effect of screen concentration

FIG.6 Effect of screen length

FIG.7 Effect of waves

For current only:

- a. In general the investigated screens cause an appreciable reduction of the longshore current velocity; near the beach  $V_{rel}$  is only 50%, but further seaward  $V_{rel}$  increases, and even grows up to 115% just seaward of the tip.
- b.  $V_{rel}$  diminishes, but not proportionally, as the number of screens per unit length of beach is increased (Fig. 4, short screens).
- c.  $V_{rel}$  diminishes as the screens are concentrated (e.g. double rows at 10 m intervals instead of single rows at 5 m intervals), without increasing the amount of material per unit length of beach (Fig. 5, long screens).
- d. Lengthening of screens causes a reduction in current velocity at that depth, but this is partly at the expense of the reduction as it existed in the short screen range (Fig. 6, average  $V_{rel}$  values for short and long screens).
- e. The aforementioned screen effects cause an increase of the perpendicular gradient in the longshore current profile which may lead to an increasing offshore sediment transport. Especially short screens have this disadvantage.

For a current and a wave-generated current in the same direction:

- f. As compared to current only there are important differences; one must discriminate between the areas inside and outside the surf zone (the waves start breaking at approximately 2 m from HW mark).
- g. Outside the surf zone, concentration of screens without increasing the amount of material per unit length of beach causes  $V_{rel}$  to decrease, just as for current only. Inside the surf zone, however, concentration of screens causes  $V_{rel}$  to increase (for explanation see point i).
- h. Outside the surf zone, the value of  $V_{rel}$  is lower than for current only (Fig. 7, screen type C). This can be explained by noting that orbital motion in the plane of the pile screens effectively hinders the tidal current to flow through the openings between the piles.
- i. Inside the surf zone, the value of  $V_{rel}$  is larger than for current only (Fig. 7). This can be explained by the different mechanism of generation of a tidal current and a wave-generated current:
  - a tidal current, once hindered by a screen, restarts slowly by the gradual diffusion of mass and momentum from the outside main stream towards the retarded water near the coast;
  - a wave-generated current on the other hand, once slowed down by a screen, is fed immediately with momentum and mass by the breaking waves themselves which travel right into the retarded zone.

One overall conclusion is that it makes a great deal of difference to the efficacy of permeable pile screens whether there are waves, and if so, from what direction. Perpendicularly incident waves increase the velocity reduction of the screens; obliquely incident waves, however, generate a longshore current to which the screens form only a limited hindrance. For the test conditions it seems that screens of type C show an overall good performance. With an adequate formula, e.g. [Bijker and Svasek, 1969] or [Bijker,

1971], the above hydraulic results may be transferred to longshore sediment transport quantities, and thence into predictions for coastal development without and with screens.

#### 4 DESIGN, CONSTRUCTION AND COSTS

The functional design of pile screens should be based on the required reduction of the longshore sediment transport, and thus on the required reduction of the current velocity parallel to the coast. So, one should start with a careful analysis of the natural coastal current climate, and one should well discriminate between tidal and wave generated currents (see chapter 3). Starting from such analysis, and taking into account the computational and experimental results as outlined in chapter 3, for a particular location an optimum is found for the screen geometry in terms of pile screen length, mutual distance of screens and piles, and height of piles.

Obviously, aspects of local materials, construction operations and costs may interfere with the ideal functional design. In the Netherlands only wooden piles (oak or tropical) with round or square cross-section (0.25 - 0.30 m) have been used. Piles of square cross-section may be placed in a diamond pattern rather than orthogonally in order to save material for the same hydraulic resistance. These piles may be subject to borers and/or marine growth; concrete may be an alternative.

The toplevel of the piles is partly determined by the workability conditions (waves and tides). The total length of the piles must allow for natural variations in local bed elevation; as a rule 60% of the total length is in the bed. A typical screen is shown in Fig. 8. When a double screen is applied (which is cheaper than 2 single rows), their mutual distance is 3 m. In order to allow traffic on the beach an oblique opening is provided. The piles may be jettied or rammed with a conventional rig on the dry beach. Beyond the low water line there are several options, viz. working from a floating barge, from a mobile platform (Fig. 8), from a temporary jetty, or working over the top of the finished part (double screens only). The costs of screens increase rather fast if they extend seaward of the low water line. A rough idea is given in Fig. 9, where three screen configurations are shown with their cost per 1000 m<sup>1</sup> of beach length as compared to typical traditional massive groynes.

#### 5 APPLICATIONS OF PILE SCREENS IN NATURE

Since 1965 permeable pile screens have been applied on ten locations in the Netherlands (Fig. 10).

- On the SW coast of Walcheren, the recreational beach of Flushing (Fig. 10, ①) is situated at the leeside of a protruding remnant of an old dike, and is since long subject to leeside scour. Additional to periodical sand supply (1952, 1966 and 1975), in 1975 the old deteriorated groyne system was replaced by three double pile screens. It is hard to specify their effect because of the many artificial changes of this beach. There are slight indications that the rate of sand loss is decreasing.
- On the SW coast of Walcheren near the village of Zoutelande (Fig.

FIG.8 Construction of screens

\$ 2,500,000/1000 m beach length

\$ 80,000/1000 m of beach length

\$ 600,000/1000 m. of beach length

FIG.9 Costs of groynes and screens

FIG.10 Locations of screens

10, ②), in 1968 the existing coastal protection (consisting of heavy massive groynes with piles on top) was extended in SE direction by means of three long double screens and two short single screens (Fig. 11, and lower photo on Fig. 8). Since then the discontinuity in the coastline, caused by the leeside scour resulting from the original system, was evened out. Even some accretion occurred directly southward of the former end of the groyne system. The leeside scour shifted to the end of the new screen system. This project indicates that these pile screens do have the expected effect.

- The NW coast of Walcheren borders the estuary of the Eastern Scheldt (Fig. 10, ③, ④, and Fig. 12), and reacts intensely upon the dynamic behaviour of its tidal channels. Although generally eroding, accretion may also occur during long-term fluctuations. In 1968 the deteriorated groynes near the village of Domburg (Fig. 12, ③ and Fig. 13a) were replaced by pile screens. Originally the landward part of the screens consisted of a single row of piles (Fig. 13b), whereas the seaward part was double. As mussel growth on the seaward piles increased the flow resistance even more (Fig. 14), unfavourable current concentrations resulted both seaward and landward of the dense sections (Fig. 15). The resulting current velocity during H.W. on the beach was even higher than before the screens were there. Therefore, in 1977-1978 all screens were doubled, and at the SW end some extra screens were placed. At the SW end the beach accreted, but in the NE part the beach receded. An explanation has not been found. An overall picture of beachline behaviour since 1920 in this area is given in the lower part of Fig. 13. For a number of ranges perpendicular to the coast, the position of the point half way between the H.W. line and the L.W. line is indicated as a function of time. Further, in Fig. 13 is indicated: the moment of the landward extension of the old groyne stone heads with pile screens, the moment of construction of new screens, and the moment of doubling these screens. From Fig. 13 a diminution of the erosion in the last decade can be observed; however, long-term fluctuations may have played a role.
- The first application of pile screens in the Netherlands dates from 1965, near the village of Oostkapelle on the NW coast of Walcheren (Fig. 10, ④ and Fig. 12, ④). The existing row of stone groynes with horizontal crowns had caused leeside erosion in northward direction; therefore a row of short screens was built in 1965 (Fig. 16). These screens and their effects were drastically affected by large scale autonomous morphological developments in this area (Fig. 16). Between the main tidal channel "the Roompot" of the Eastern Scheldt estuary and the local near-shore flood channel "the Urk", a shoal developed right in front of the beach with screens. This shoal urged the "Urk" channel closer inshore, and seaward extension of the screens could not prevent this development. Later on, the shoal even merged with the beach (Fig. 16, 1981), and some more additional screens were built. This could not prevent that during the last phase of the shoreward moving "Urk" channel heavy damage occurred to the screens, and even some 12 m long piles were washed out.
- The development of the west coast of the island of Schouwen is de-

terminated by the secondary tidal channel "the Krabbengat" (Figs. 12 and 17), which moves landward during the last centuries. Periods of erosion and accretion alternate, under the influence of changes in the tidal estuaries of the Eastern Scheldt to the South of Schouwen, and the Brouwershavense Gat to the North. In 1968 long screens were erected along the northern part of the beach (Fig. 10 (5), Fig. 12 (5), and Fig. 17), and soon a spectacular accretion occurred, even with new dune formation on the beach. The landward piles were consequently pulled somewhat (Fig. 18) because they tended to disappear under the sand. It is not clear, however, to what extent this accretion is due to the pile screens alone. The original recession of the beach stopped about 5 years before the screens were placed: probably the areas of accretion and erosion tended to shift under the influence of "the Krabbengat". Furthermore, the estuary of the Brouwershavense Gat was closed in 1972, of which the effects cannot accurately be assessed.

- In 1975 the above mentioned row of screens was extended southward with short double screens (Fig. 10 (6), Fig. 12 (6) and Fig. 17). The long-term trend of erosion however did not change. Also out-flanking behind the landward end of the screens near the dunes occurred (Fig. 19). Another negative aspect was observed in that rip-currents tended to concentrate along the screens (Fig. 20).
- Just south of the new entrance to Europort (Fig. 10, (7)) a new coastal defence system was necessary in order to protect the reclaimed harbour area [Svasek and de Nekker, 1977]. Instead of the original design, which consisted of a section of 4000 m of rubble mound breakwater, an artificial beach and dune combination was proposed, saving about 80 million dollars on construction costs. In order to maintain the artificial beach, an artificial sand supply of 400,000 m<sup>3</sup>/yr would be required [Svasek and Versteegh, 1977]. Further optimization calculations resulted in a project with seven pile screens (Fig. 21) plus a limited sand supply of 200,000 m<sup>3</sup>/yr [Bijker et al., 1981]. Four double pile screens extended to the depth contour of MSL - 3 m, and three short single screens down to MSL - 0.5 m were placed in between. The 0.3 m diameter piles were spaced 0.3 m apart. To determine the pile length, a seasonal depth variation of 1 m was assumed. As the planned sand supply of 200,000 m<sup>3</sup>/yr was not effectuated, a local erosion of about this same rate should be expected. Based on frequent detailed soundings and beach levelings in the area concerned, a comparison was possible (Fig. 22) between the calculated erosion (with pile screens but without sand supply), and the observed erosion which amounted to 220,000 m<sup>3</sup>/yr. This is in good agreement, taking into account the feasible accuracy of the levelings and soundings. As the area concerned is approximately 600,000 m<sup>2</sup> large, the average erosion in 2 years was about 0.6 m with local scour of more than 1 m. About 2½ years after construction, the most southern two long screens lost about 30% of their piles (mainly in the deepest section) during a severe storm.

The main causes for this failure are:

- Artificial feeding was omitted, causing the bed to be eroded locally below the storm season profile, for which an overdepth of 1 m was designed.
- The tidal channel "Gat van Hawk", which was shoaling and stable

FIG.23 Screens near Bergen (8)

FIG.25 Screens on Ameland (10)

in position at the time of design, moved unexpectedly in shoreward direction.

- Some of the washed-out piles did not meet the design length requirements.

Later on, this pile screen project was abandoned.

- In 1974 near Bergen (Fig. 10, ⑧) five single short screens were erected with mutual distances of 150 to 200 m (Fig. 23). These screens, only covering the beach width of 120 m, were designed to mitigate the leeside scour just south of a long row of stone groynes. Afterwards the general beach elevation increased with 0.5 to 1.0 m. The proper screen effect is hard to tell, because in the same time windscreens of reed were placed and reshoveling of the beach occurred.

From regular levelings it appeared that just seaward and landward of the screens erosion occurred, the latter caused by outflanking.

- The island of Texel suffers from severe erosion, and has been extensively defended with stone groynes. The area under consideration (Fig. 10, ⑨) is subject to heavy erosion, the dune foot receding at a rate of 15 m/yr. The classical groynes, with a flat crown at about MSL, are extended in landward direction if the coast keeps eroding; furthermore in that case the system is extended with more groynes (short ones in first design) along the beach.

In 1973, some of the relatively recent stone groynes were extended in landward direction (following further dune foot recession) with pile screens instead of stone groynes; furthermore some intermediate pile screens were constructed (Fig. 24a). Rather strong outflanking occurred near the dune foot, probably boosting the dune foot erosion rather than stopping it (Fig. 24b). For this reason the pile screens were removed in 1980.

- Also in 1973, on the island of Ameland (Fig. 10, ⑩) four single pile screens were constructed. These screens - in combination with other coastal defence systems - link the continuous bottom protection along the main tidal channel "the Borndiep" with the beach (Fig. 25a). The coastal erosion in the area covered by the screens stopped indeed, whereas in the vicinity erosion proceeded. Just as on Texel however outflanking occurred near the dune foot (Fig. 25b).

## 6 EVALUATION OF THE EFFECT OF PILE SCREENS IN NATURE

With respect to reporting on experience with coastal defence systems the general difficulty remains how to tell the proper effect from the background noise.

With respect to impermeable groynes some proof is available of its potential to combat erosion [Bakker and Joustra, 1970]. However, the system presently under investigation is a "softer" system and its effect may easily merge into the effect of nature. This so much the more as essentially where groynes are applied, nature shows either heavy fluctuations or heavy erosion. In the case of heavy erosion the present system failed in the sense that without these screens the same or maybe a more favourable effect could have been achieved (Oostkapelle; Texel). Therefore only the cases with heavy natural fluctuations remain to be analyzed, yielding the results mentioned in chapter 5.

Besides it is a fascinating thought that the use of impermeable groynes near Oostkapelle probably would have given worse results: the contraction and the turbulence near the head of the groyne could have prevented the favourable incorporation of the migrating shoal with the beach.

Having no statistically significant evidence regarding the screen effect, the question still remains: should the use of pile screens be advised for coastal defence?

In the first place, as long as no really predictive mathematical (large-scale) coastal models are available, the words of Schijf regarding coastal protection plans still apply: "Postpone till tomorrow what not necessarily has to be done today".

However, given the fact that something should be done at a certain site applying the best available knowledge, pile screens might come in the picture. First checkpoint should be an evaluation of the risk of washing out of piles by shoreward motion of tidal channels. One might face situations that even the maximum practical pile length will not be enough to guarantee constructional stability. It should be kept in mind, that pile screens cannot prevent this channel motion.

If this risk is acceptable, or if it can be eliminated (for instance by periodical sand supply), the authors feel, that the use of pile screens deserves serious consideration.

- Based on theoretical and experimental evidence (chapter 3) positive effects can be expected; especially in areas with a large tidal range, piles have effect during a longer part of the tidal cycle than stone groynes with flat berms.
- Most of the negative experience can be attributed to constructional failures, which in the future can be avoided. For instance, in Oostkapelle and Europort the piles were too short at the site where the washing-out occurred, because at these locations no heavy erosion had been foreseen. It seems to be of much importance that the screens are well incorporated in the dunes, implying some temporary removal of sand. At present, mussels are regularly removed from the screens.
- Although an objective financial balance of the use of pile screens is hard to make (as the effects are not clear and a financial value can hardly be assigned), the feeling exists, that this balance is positive and that, for instance, it has been a wise decision to protect the Schouwen area with pile screens instead of impermeable groynes.
- Pile screens form a much more flexible construction than stone groynes: piles can be added, lifted or removed, and in the case of very heavy erosion one can make - if absolutely necessary - stone berms in a later stage, thus postponing the expense. Furthermore a combination of pile screens and sand supply is feasible.

## 7 CONCLUSIONS

### I Advantages of permeable pile screens are:

- a. Low cost (Fig. 9).
- b. Reduced longshore current velocity, as demonstrated by model tests (Figs. 4, 5, 6, 7).
- c. Flexible construction, which may easily be adapted to changing

beach elevation (Fig. 18).

- d. A more continuous beach line (as compared to the saw-tooth beach line with impermeable groynes). This is an advantage, in the sense that the point of most erosion determines the safety of the coastal protection.
- e. A more gradual velocity gradient and less turbulence near the seaward end (as compared to impermeable groynes).

#### II Problems encountered are:

- a. Failure on the seaward side: washing-out of piles.
- b. Failure on the landward side: outflanking near the dune foot. (Fig. 19).
- c. Mussels, often causing a diminution of the permeability of the outer region of the screens. Where the inner region consists of a single screen this may lead to higher local current velocities than before the screens were constructed (Figs. 14, 15).
- d. Attraction of rip-channels, with consequent seaward sand loss (Fig. 20).

#### III Proposed remedies against the problems are:

- a. Careful analysis with respect to morphological changes in the coastal area (are tidal channels moving to the coast? Does lee-side erosion occur?). Piles should be embedded for 60 percent of the total length below the lowest beach level to be expected.
- b. Pile screens should be sufficiently extended landward of the existing dune foot, even if this includes a temporary removal of much sand
- c. Regular removal of mussels.

## CHAPTER ONE HUNDRED THIRTY SEVEN

### Study of the Evolution of Dredged Material Discharges by Means of Radioactive Tracers

F. Tola, A. Caillot, G. Courtois, P. Gourlez, R. Hoslin, J. Massias,  
M. Quesney, G. Sauzay\*

#### Abstract

The choice of a dumping area for dredged materials must be carried out taking into account the general movement of sediments in order to evaluate the risk they represent for the zone itself, the harbour-works and the coastal area.

The use of radioactive tracers allows to study, in situ, transfer properties under tidal currents of fine sediments resuspended during the release, the distribution over the sea-bed of coarse particles and their future evolution due to currents and waves.

In this way, parameters such as transport axis, mean velocity, dispersion, dilution and bed-load transport rates are determined.

Four experiments which took place at OCTEVILLE, ANTIFER (FRANCE), SINGAPORE and ZEEBRUGGE (BELGIUM) during the ten past years illustrate the method.

#### I - Introduction

The construction or enlargement of a harbour and its access channel and future keep up need voluminous and expensive dredging work. In France, keep up itself represent per year, 40 million cubic meters of dredged materials at a total cost of 600 M.F. (about 70 millions U.S. dollars).

These operations modify the sedimentologic equilibrium of the environment and generate an increase of turbidity because of fine sediments removal. Besides, the discharge of dredged spoils on a dumping area next to the dredging site rise this problem of an eventual return of silt sediments to the harbour or the littoral and thus induce silting and pollution leading to additional tasks which may be avoided.

In order to forecast the effects of such discharges on the environment a good knowledge of sediments behaviour concerning both suspension and bed-load transport, is necessary. Yet up to now, the wide range of parameters, the complexity of liquid-solids interactions and the more or less cohesive nature of bed materials make almost impossible pure

des Radioéléments, (S.A.R.), Centre d'Etudes Nucléaires de Saclay,  
B.P. 21 - 91190 Gif sur Yvette, France.

theoretical calculations and hydraulic model simulations. Thus, to be reliable such models must at least be calibrated by measures in nature, carried out on the future dumping area and for conveniently chosen and well known hydrological conditions.

Such in situ measures are possible thanks to RADIOACTIVE TRACERS. The technology, developed and improved throughout almost 250 experiments during the last 30 years has give rise to numerous publications (A. Caillot, 1970; G. Courtois, 1970; F. Tola, 1982). Only the principal features will be therefore recalled, the purpose of the present paper being mainly to illustrate the method by typical examples.

## 2. Methodology

A small quantity of labelled particles representative of natural sediments (similar granulometric distribution and hydrodynamic properties) is introduced in the medium, either directly or mixed to some hundreds of tons of dredged materials contained in a hopper (Fig. 1).

Figure 1 - Labelling and Injection of Silt Sediments.

The transport of radioactivity is used to determine sediments movement in the course of time. Material carried away in suspension is measured by means of vertical arrays of radiation probes attached to two tracking vessels which perform longitudinal and transversal detection of the plume. For bed measures, a single probe is fixed on a sledge which is then towed over the bed (Fig. 2). A location device allows regular plot of fix on a 1/5000 scale chart.

Figure 2 - Detection Equipment of Tracking Vessels.

When studying dredged material discharges we are interested on the following points:

- behaviour of fine sediments (silt and very fine sand) carried away in suspension,
- distribution of sand particles over the sea-bed,
- disposal efficiency,
- future evolution of deposited materials.

Sediments in suspension are followed during 3 to 4 hours. We proceed to bed detection 18 to 24 hours after release takes place in order to allow mixing of the radioactive tracer to natural sediments.

5 to 9 Ci of gold 198 (half life 2.7 days,  $\gamma$  energy of 410 keV) are sufficient to label 1 kg of silt sediments or 0.5 to 1 kg of crushed glass simulating sand particles.

Information collected during this type of experiment is completed by measures carried out from point injections of small quantities of labelled materials in several points of the site and for different hydrological conditions. A clear scheme of the general movement of dredged spoils is thus obtained.

In order to study transfer properties of a silt suspension, sediments are labelled with gold 198 as previously. The following parameters are determined:

- trajectory of the center of gravity,
- mean transport velocity,

- vertical concentration profiles,
- horizontal dispersion (which may be represented by the longitudinal and transversal standard deviations  $\sigma_x$  and  $\sigma_y$ ),
- dilution, that is maximum concentration in function of time,
- particles sedimentation, when it takes place.

To study the evolution of deposited materials we use glass labelled with iridium 192 (half life 74 days,  $\gamma$  complex spectrum of energy 296 to 885 keV), allowing experiments lasting 5 to 6 months and thus increasing considerably the amount of data obtained. Only 0.5 to 1 Ci of iridium 192 is sufficient to label 0.25 to 1 kg of glass, per point; that is ten times less than the maximum activity permitted (G. Courtois, R. Hours, 1964). Such low quantities allow easy preparation, transport and manipulation of radioactive products as well as a rapid integration of the tracer to natural sediments.

Qualitative and semi quantitative informations are obtained, such as:

- main transport axis and, eventually, secondary ones,
- mean velocity of particles gravity center,
- dispersion parameters, dimensions of the spot,
- tidal currents and waves effects (bed-load transport, saltation, resuspension),
- burying (sedimentation), mostly during slack water,
- presence of morphological factors (sand banks, deeps, channels) which will either act as a trap of particles or canalize them in a privileged direction.

Lastly, the mean transport thickness is determined thanks to the "total count rate balance" method (G. Sauzay, 1968), thus allowing to quantify the entrainment rate.

Radioactive tracers experiments are completed by intensive hydraulic and meteorological measurements such as currents and wind direction and intensity, waves height, period and direction and tides amplitude. In this way, data concerning sedimentary movements can be linked to local conditions.

### 3. Illustration of the Method by S.A.R. Main Studies

Four experiments which made use of radioactive tracers techniques and took place respectively at OCTEVILLE, ANTIFER (FRANCE), SINGAPORE and ZEEBRUGGE (BELGIUM), have been selected to illustrate the method. Their detailed description is available in a recent publication (F. Tola, 1984) from which we reproduce the most striking features.

#### 3.1 - Evolution of dredged material discharges off OCTEVILLE

Dredged materials resulting from the upkeep of LE HAVRE harbour are discharged off OCTEVILLE at a depth of 14 m. They are mainly composed of silt sediments ( $< 40 \mu\text{m}$ ) and fine sands (60 to 350  $\mu\text{m}$ ), improperly incorporated to sedimentologic equilibrium, recirculation of which may affect the coastal environment and ANTIFER oil installations located 15 km N.N.E of the dumping area. On request of LE HAVRE authorities, several radioactive tracers experiments were carried out in order to appraise the real risks:

1°) Transport in suspension and sea-bed distribution of dredged spoils discharges

70 tons of dredged material contained in a hopper at an initial concentration of 150 g/l (73% silt, 27% fine sand) were discharged during a spring tide flood. Fine particles, mainly silt sediments less than 40 μm, form a suspension subject to dispersion due to turbulence, swell and velocity gradients, conveyed Northwards towards ANTIFER and covering almost 7 km in 3 h without settling (Fig. 3). By that time the cloud is spread over an elliptical surface 1 km and 250 m main axis (± 26), with uniform vertical concentration profiles less than 16 g/l.

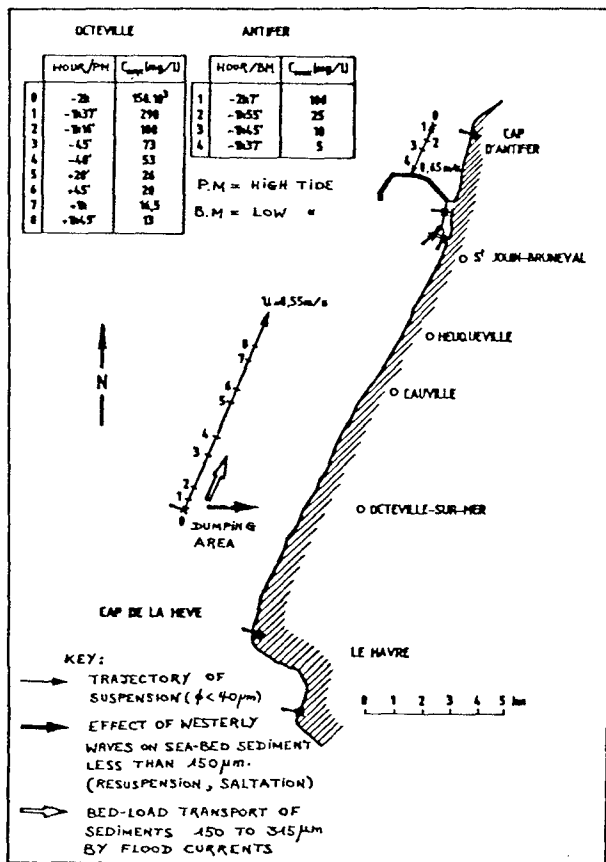

Figure 3. Sedimentary Movements at OCTEVILLE and ANTIFER

However, materials discharged off OCTEVILLE may be highly concentrated and therefore have an initial rigidity which will oppose to dilution when released. Mud with a rigidity greater than some  $N/m^2$  would settle next to the point of immersion.

Detection performed 18 h later shows that sand particles are superficially distributed over the sea-bed, up to 1 km N.N.E, the distance covered before settling depending on the grain size (Fig. 4):

Figure 4. Distribution of Sand Particles over the Sea-bed 18 h after Immersion: Lines of Equal Concentration and Transport Diagrams.

- 50% of sand particles ( $\phi > 105 \mu m$ ) lay at less than 100 m from the point of immersion, - 75% of them ( $\phi < 80 \mu m$ ), at less than 200 m,
- only particles less than  $80 \mu m$  settle at more than 200 m and reach the limits of the spot (1000 m). Mean fall velocity corresponding to  $d_{50} = 105 \mu m$  is 0.7 cm/s, while it is found to be equal to 1.1 cm/s in calm water.

### 2°) Evolution of deposited materials

Two injections of glass particles labelled with iridium 192 were performed next to OCTEVILLE dumping area and a third one in front of CAUVILLE. In the first case the granulometric distribution of the tracer is close to that of dredged materials (80 to 315  $\mu\text{m}$ ), while in the last one it is close to that of natural sea-beds sediments (170 to 1000  $\mu\text{m}$ ).

Compared to sea-bed sediments which are rather motionless, dredged materials seem quite movable under the same hydrological actions (Fig. 3):

- W to N.W. waves ( $H_s = 2$  to 4.5 m) developed during storm periods ensure resuspension of fine particles which are then conveyed and dispersed in the coastal direction. 70% of sand ( $\phi < 150 \mu\text{m}$ ) cover in this way more than 500 m in 3 1/2 months;
- spring tide currents disperse particles less than 350  $\mu\text{m}$  in a N.N.E. direction (flood predominance);
- by calm weather, N.W. waves disperse sand particles towards the coast (S.E.).

### 3.2 - Evolution of ANTIFER dredging material discharges

About 30 million cubic meters of dredged materials derived from the construction of ANTIFER oil terminal installations are discharged 2.5 to 6 km North, at a depth of 17 to 22 m.

According to their nature, initial concentration and intensity of currents, which during spring tides may exceed 2 m/s in flood and 1.4 m/s in ebb, sediments will either deposit where release takes place or, on the contrary, be conveyed in suspension, bed-load or saltation. Transport in a Southwards direction would lead to the silting up of the channel access and the harbour-works as well as pollution of the coastal area.

Radioactive tracers experiments allowed to estimate the risk of recirculation of sand spoils.

### 1°) Transport in suspension and sea-bed distribution of sandy material discharges

About 100 tons of sediments (10% silt and 90% 50 to 550  $\mu\text{m}$  sand) were released from a hopper dredger, off Cape of ANTIFER, by maximum spring ebb currents, since such hydraulic conditions exhibit a high risk for the harbour-works.

The tracer, representative of fine sand 50 to 350  $\mu\text{m}$ , was followed in suspension immediately after release took place and its distribution over the sea-bed measured 18 h later.

Only sand particles less than  $125 \mu\text{m}$ , which represent 15% of the total mass, is carried away in suspension. But contrarily to silt sediments, they will cover at the most 1600 m before settling (Fig. 3), since 40 min after immersion takes place there is no tracer in suspension at detectable concentrations ( $4 \text{ mg/l}$ ).

Thus, within 40 min time, the almost entire mass of sand spoils is distributed over the sea-bed up to 1600 m S.S.W. from the immersion point. 18 h later, that is after two floods the following evolution is observed (Fig. 5):

- only 30% of the total mass still remains on the sea-bed: sand particles less than  $200 \mu\text{m}$  (critical entrainment velocity  $u_* \leq 1.25 \text{ cm/s}$ ) have been resuspended by flood currents, transported N.N.E. and dispersed beyond the limits of the spot at non detectable concentrations,

- sediments lying on the bed are distributed along a S.S.W.-N.N.E. axis, 1/3 of them are still up to 1600 m S.S.W. from the point of immersion while the remaining 2/3 were retrieved up to 1800 m N.N.E.

Figure 5. Distribution of Sand Particles over the Sea-Bed 18 h after Immersion at ANTIFER.

On the whole, flood currents have entrained 90% of dredged materials N.N.E. (70% at more than 1800 m), that is, a transport ten times greater in regards to ebb.

## 2°) Evolution of deposited materials

Two immersions of glass particles labelled with iridium 192 were performed at a depth of 20 m and the tracer followed during 113 days. These experiments confirmed previous results, mainly, flood predominance next to ANTIFER dumping area.

Therefore, sand spoils released at more than 2.5 km North from ANTIFER oil installations represent a fairly low danger for the harbour-works.

### 3.3 - Study of transfer properties of a suspension of silt sediments at SINGAPORE

At SINGAPORE, ground levelling and littoral extension for urbanization purposes lead to sea disposal of some million cubic meters of silt sediments near the shore. CHANGI airport was built in this way over a site of 660 ha constituting an artificial beach 12 km long. Actually, 15 million m<sup>3</sup> of materials coming from the interior (LOYANG and TAMPINES) are discharged through a pipeline 750 m off BEDOK (Fig. 6).

Such procedure will undoubtedly increase the turbidity of the surrounding areas and could create potential danger to the environment. Besides, transfer and settling of fine particles during a west going tide may pollute recreational areas and generate considerable siltation in the port.

Figure 6. General Map of SINGAPORE

On request of P.S.A. authorities and A.I.E.A. financial support radioactive tracers experiments were carried out in order to study the behaviour of silt sediments in suspension and determine the risk they represent for the coastal area and the harbour-works. Thus, two punctual and instantaneous injections of mud labelled with gold 198, at an initial concentration of 18 g/l, were performed off BEDOK during a west going tide (lasting 16 h, with velocities 0.4 to 0.5 m/s). The cloud so formed was followed during 3 1/2 h over a distance of 6.5 km, by that time dilution being of a  $2.5 \times 10^{-6}$  factor.

These experiments were completed by local velocity measures and float-tracking. They allowed to determine the trajectory and mean transport velocity of sediments, dispersion parameters and dilution (Fig. 7).

For fully established tidal conditions, a lowly concentrated suspension of silt sediments ( $\phi < 40 \mu\text{m}$ ) has very similar transfer properties as fluid particles. They are conveyed by currents over large distances with negligible retard and without settling, while turbulence effects ensure uniformity of vertical concentration profiles over a depth of 10 m within 30 min.

Below a critical threshold, depending on sediments physico-chemical properties and concentration, the energy of turbulence is no longer sufficient to maintain particles in suspension and sedimentation takes place. Indeed, this mainly occurs at the on-coming of tide turn since then velocities decrease and vanish.

Results derived from radioactive tracers experiments were extrapolated to a continuous discharge of silt sediments during ebb and lasting at least 9 hours (Fig. 8): The plume would reach the shore and the harbours entry respectively 4 1/2 and 9 hours after the beginning of injection, followed by siltation during slack water.

- It follows a double risk:
- pollution of the sea-shore by mud particles,
  - silting-up of harbour works during slack water.

Figure 7. Evolution of Horizontal Dispersion Parameters and Maximum Concentration of a silt Sediment Suspension ( $\phi < 40 \mu m$ ).

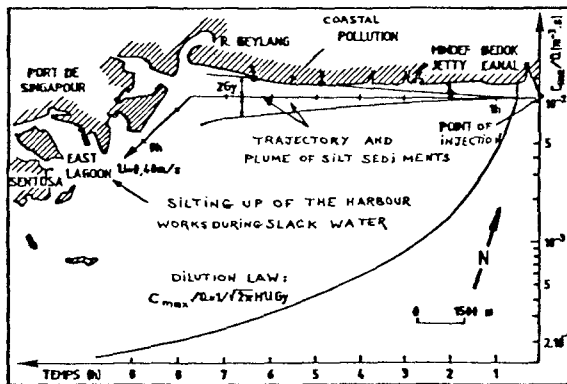

Figure 8. Trajectory, Mean Velocity, Dispersion and Dilution of a Continuous Release of Silt Sediments off BEDOK (SINGAPORE).

#### 3.4 - Sedimentary movements along the Belgian littoral

In 1974, the Belgian government planned to equip ZEEBRUGGE with a modern harbour and a new channel allowing access of greater ships. In order to limit its effects on littoral sedimentologic equilibrium, this task was carried out considering results of a wide research program including radioactive tracers measures. On the whole, 17 injections were decided by HAECON N.V - GHENT both for optimization of dredging operations as well as studying the behaviour of fine sediments resuspended during the discharge and the evolution of spoil disposals (Fig. 9).

##### 1° Dredging disposals at SIERRA VENTANA

In order to forecast the risk of siltation of the future channel because of recirculation of dumped spoils, labelled sediments (60% silt and 40% glass particles simulating sand) previously mixed to 2250 tons of dredged materials of density 1.49 were discharged from a suction hopper dredger during a spring tide ebb. Sediments carried away in suspension were followed during almost 3 1/2 h, while distribution of deposited materials was measured 24 h later.

Silt sediments and a fraction of fine sands (33%) form a lowly concentrated suspension convected and dispersed southwards towards the future channel (Fig. 9, point D5). Sand particles will most probably deposit before reaching it, contrarily to silt sediments which covered 7 km in 3 h with a mean velocity of 0.6 m/s. The experience was unable to put forward their sedimentation. However, this seems rather unlikely, at least during spring tides, given the absence of slack in the area concerned and the intensity of currents which may reach 1.5 m/s. Thus, silt sediments will be carried away by flood currents and dispersed Northwards. Further experiments (D3-4) confirmed such presumptions.

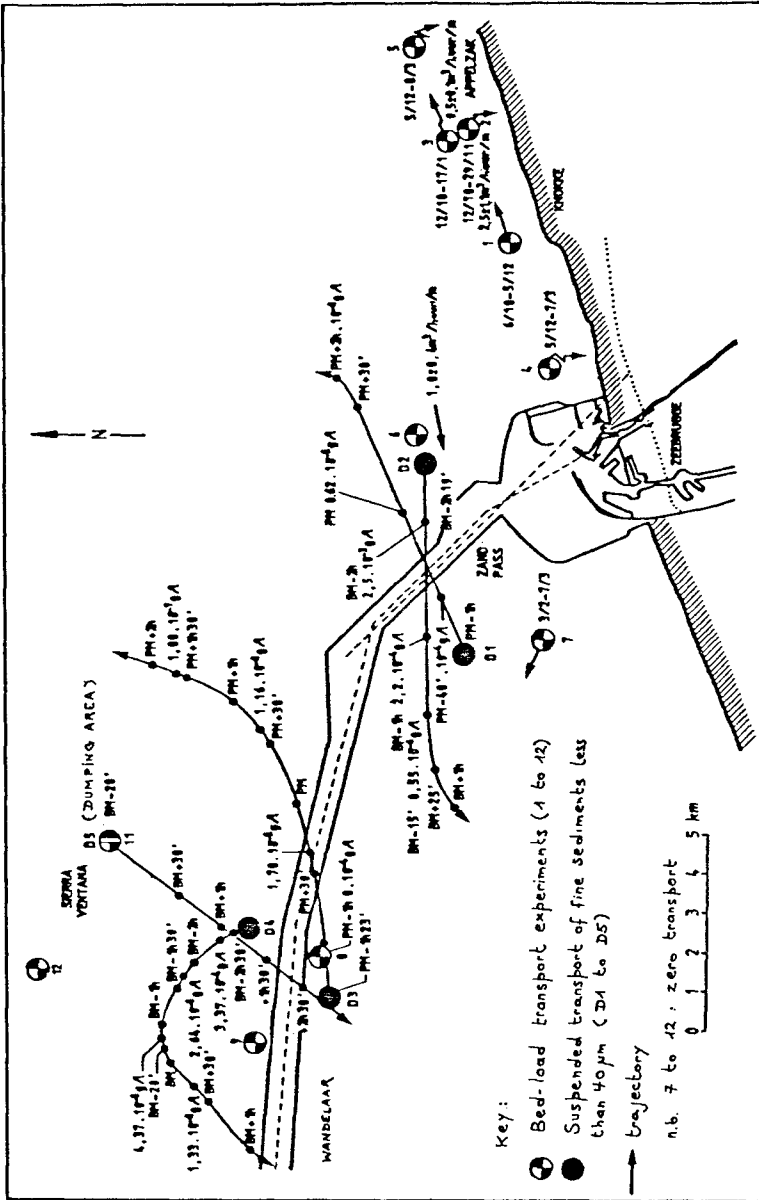

Figure 9. Radioactive Tracers Studies of Sedimentary Movements at ZEEBRUGGE.

About 27% of dumped spoils, that is, 67% of sands settle at less than 1000 m from the point of immersion and over 400 m width (Fig. 10) without any further evolution, sediments being almost insensitive to currents and waves even during storms ( $H_s = 5.5$  m).

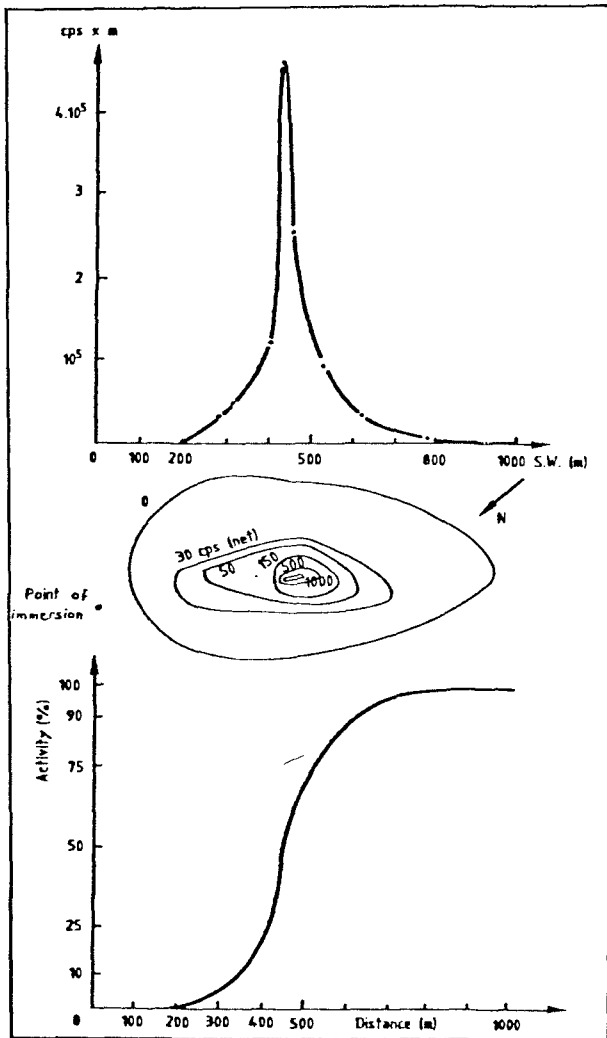

Figure 10. Seabed Distribution of Dumped Spoils at SIERRA VENTANA 24 h after Release Takes Place.

2°) General movement of sea-bed materials off ZEEBRUGGE

12 immersions of glass labelled with iridium 192 were carried out in different points from 5 to 18 m depth, and the tracer followed for a period of 4 months during which violent storms alternated with spring tides.

These experiments allowed to study the behaviour of sea-bed sediment of 160 to 315  $\mu\text{m}$  mean diameter and quantify their transport (Fig. 9, points 1 to 12). Their movement is not identical in every point nor occasionated by the same hydraulic actions:

- near the littoral and by less than 5 m depth (points 2 and 4), swell effects ( $H_s = 5.5$  m) ensure resuspension, dispersion and transport towards the coast of sediments less than 250  $\mu\text{m}$ ,
- between 5 and 10 m depth, added to wave effects during storms as previously, spring tide currents give rise to a rapid but superficial bed-transport: respectively 35 and 22 m/day with a mean transport thickness of 7 to 8 cm in points 1 and 6 (Fig. 11). The resulting movement is oblique relative to the coast-line. At APPELZAK (points 1 and 3), there is flood predominance with a net transport Eastwards of 0.5 to 2.5  $\text{m}^3/\text{day}/\text{m}$ . Next to the ZAND PASS (points 6 and 7), there is ebb predominance, with a net transport of 1.8  $\text{m}^3/\text{day}/\text{m}$  towards the channel east from it,
- beyond 15 m depth (points 8 to 12), sand particles are unaffected by waves but dispersed along a S.W.-N.E. axis, by alternate effects of flood and ebb currents, although the resulting transport is negligible (less than  $2 \times 10^{-3}$   $\text{m}^3/\text{day}/\text{m}$ ). Resuspension is not significant, excepted North from the future channel (point 9) where spring tide currents give rise to resuspension of sediments less than 300  $\mu\text{m}$  including 30% of cohesive materials ( $\phi < 40 \mu\text{m}$ ). The corresponding critical entrainment velocity is equal to 1.4 cm/s.

Figure 11. Evolution of Transport Diagrams and Gravity Center. ZEEBRUGGE, Points 1 and 6.

Main quantitative results are summarized on the following table:

Bed-load Transport and Resuspension of Fine Sands off ZEEBRUGGE

Measure Point (see figure 9)	1	2	3	4	6	7
Tracer grain size ( $\mu\text{m}$ )	160-315					
Period of observation before resuspension (days)	19	14	49	61	34	34
Mean transport thickness (cm)	7	8	6	5	8	3
Mean transport velocity (m/day)	35	6	2	1	22	1.4
Entrainment rate ( $\text{m}^3/\text{day}/\text{m}$ )	$2.5 \pm 1.1$	$0.5 \pm 0.1$	$0.1 \pm 0.03$	$0.05 \pm 0.01$	$1.8 \pm 0.4$	$0.04 \pm 0.03$
Transport direction	E	S	E	S	W.SW	W.SW
% of sediments resuspended by waves	95	84	56	40	75	80
Waves magnitude $H_s$ (m)	3.2	5.5				
Maximum grain size of particles resuspended ( $\mu\text{m}$ )	300	250	220	220	250	250
Depth (m)	5	5	5	5	9	5 to 6

3°) Transport of silt sediments in suspension

Four punctual and instantaneous immersions of mud labelled with gold 198, at an initial concentration of 20 g/l, were performed on both sides of the ZAND PASS and the futur channel for flood and ebb spring tide conditions (Fig. 9, points D1 to D4).

The suspension so formed was tracked over a distance of 7 to 10 km within 3 h preceding tide reversal, during which there is no significant sedimentation. Besides a dilution of a  $10^5$  factor a few minutes after injection, spring tide currents 0.5 to 1.5 m/s are sufficient to maintain sediments in suspension at concentrations close to natural turbidity and transport them over large distances.

Yet, next to the ZAND, and more generally, close to the coast, tide turn is accompanied by slack water which may last almost 1 h during which sedimentation takes place. Even if the possibility of resuspension must not be set aside, there is still a risk of silting up of the channel. On the contrary, at WANDELAAR or more generally, as we go away from the coast, slack water is less pronounced and the risk of siltation slighter.

Sediments transport is accompanied of vertical diffusion and horizontal dispersion. As it was the case at SINGAPORE, vertical concentration profiles become rapidly uniform after what, for constant depths and permanent current conditions, maximum concentration evolution follows the classical two-dimensional law:

$$C_{max} = M_0 / 2\pi \sigma_x \sigma_y$$

(Figs. 7 and 12).

Horizontal dispersion is represented by standard deviations  $\sigma_x$  and  $\sigma_y$  of longitudinal and transversal activity profiles (Fig. 13a and b). These parameters are found to be independent from the depth of the point of measure and not only functions of time, but also of velocity, acceleration and their time and space variations.

Figure 12. Dilution of a Suspension of Silt Sediments off ZEEBRUGGE.

A comparison of results from different experiments is given in figure 14. Since hydraulic conditions vary from one experiment to another, so does dispersion parameters when expressed in function of time.

For permanent current conditions, values of  $\sigma_x$  and  $\sigma_y$  are well fitted by a power law:

$$\sigma_i = k_i \cdot t^{n_i}, \quad i = x, y,$$

where coefficients  $k_i$  and  $n_i$  are constant but differ according as  $i = x$  or  $y$ . This is the case for SINGAPORE and OCTEVILLE. Velocity variations will affect coefficients  $k_i$  and  $n_i$ , inducing an increase of exponent  $n_i$  and a decrease of  $k_i$ , as it is the case for ZEEBRUGGE experiments.

Lastly, horizontal dispersion seems to increase with currents intensity and velocity variations, being greater in points D1, D2 and D3 of ZEEBRUGGE then it is in point D4 or at SINGAPORE.

## 4 - Conclusion

In the past, dredging operations and dumping conditions were mainly based on local habits and empirical experience. Nowadays, the necessity of practicing voluminous spoil discharges at least prices, yet limiting environmental pollution and the risk of recirculation of materials, requires quantitative evaluation of dredging efficiency. Experience shows that radioactive tracers are well suited for such a task. Besides, our present knowledge on dynamic properties of sediments is improved.

## CHAPTER ONE HUNDRED THIRTY EIGHT

### A PRE-DREDGING SAND MOBILITY STUDY USING A RADIOISOTOPE TRACER

A DAVISON\*

#### ABSTRACT

The wave-driven movement of sand across the alignment of a proposed navigation channel was investigated using radioactive chromium-51 labelled tracer sand. The mean particle velocity and thickness of the mobile layer were determined over a two-month period, and an annual infill rate estimated.

Wave height and period were measured concurrently. Despite two storms, during which near-bed oscillating velocities of  $1.5 \text{ m s}^{-1}$  were calculated, the sand transport at 10 m (BMWL) appears to occur within the wave boundary layer. Onshore transport in the direction of wave propagation, due to mass transport velocity and wave asymmetry effects, was easily identified.

Tidal currents up to  $1.2 \text{ m s}^{-1}$  (at 3 m above bed) had less than the expected effect on the tracer dispersion pattern.

#### 1. INTRODUCTION

The operating economics of modern bulk carriers demand that vessels be able to enter and leave ports at full capacity under most tidal conditions. Navigation channels must provide a minimum underkeel clearance of one metre. The potential of any port, in terms of size or draught of vessels which can enter, can be limited by the water depths in the approach channels, critical sections of which may be at some distance from the berths. [1] Maintenance dredging operations to keep these channels open must not be excessive.

At present, the main shipping channel for deep draught vessels entering and leaving the Port of Brisbane follows a long and complex path through Moreton Bay to avoid the extensive sand shoals which block the northern approaches. The Port of Brisbane Authority (PBA) has proposed that a new channel be dredged which could provide an alternative and more direct access (Figure 1(a)(b)). This channel would

---

\* Australian Atomic Energy Commission, Isotope Applications Research Group, Private Mail Bag, Sutherland, NSW, Australia 2232.

effectively "cut the corner", reduce the distance travelled by ships to and from the south by 40 km and require only 15 km of maintenance dredging as opposed to 30 km on the old route.

The new route would involve upgrading an existing tidal channel which is presently used by shallower draught vessels and constructing a shorter (3 km) section through a sand bar to link it with the open sea. In this critical section, water depth on the bar at low tide is 9 m, but a depth of 17 m is required for deep draught vessels.

### 1.1 Regional Sand Migration

In this region of the east coast of Australia, it is generally recognised that there is a northward movement of sand. Extensive studies carried out by the Delft Hydraulics Laboratory [2] and the Queensland Department of Harbours and Marine (QHM) Coastal Protection Branch [3] revealed that  $5 \times 10^5$  t of sand moves past the nearby Gold Coast each year, pushed by currents in the surf zone generated by the predominantly south-easterly swell which, in southern Queensland, strikes the coast at an oblique angle. Evidence of this northward littoral drift can be seen where the training walls extending seaward of the entrance to the Tweed River have interrupted the sand flow. In the 16 years since their construction, approximately  $8 \times 10^6$  t of sand has been trapped behind the southern wall, starving the upstream Gold Coast beaches of their normal sand supply, and resulting in heavy beach erosion.

It is likely that similar quantities of sand are moving on the seaward side of Moreton Island and that the sand shoals in the northern reaches of Moreton Bay are the result of centuries of littoral drift. Sand has moved around Cape Moreton, along the northern beaches of Moreton Island, and has been deposited across the bay entrance. Tidal currents and wave action have moulded the 400 km<sup>2</sup> deposit into an ebb and flood delta cut by several deep tidal channels. Each tidal channel has its own smaller but identifiable ebb and flood fan. It is uncertain whether the deposit is now simply a "sink" for the sand or whether the shoals provide a bypass for all or some of the sand to beaches near Caloundra and further north. If bypassing is occurring, the critical section of the proposed navigation channel would cut across the sand migration route at right angles.

### 1.2 Sand Mobility at Channel Site

The hydrodynamics over the shoal system are complex. Local wind waves up to 2 m with 3 to 5 second periods can be generated in the bay; swell waves up to 5 m with 8 to 12 second periods resulting from storms at sea can cross the site; the diurnal tidal range is  $\approx 2$  m and generates reversing tidal currents with velocities up to  $1.2 \text{ m s}^{-1}$ . The

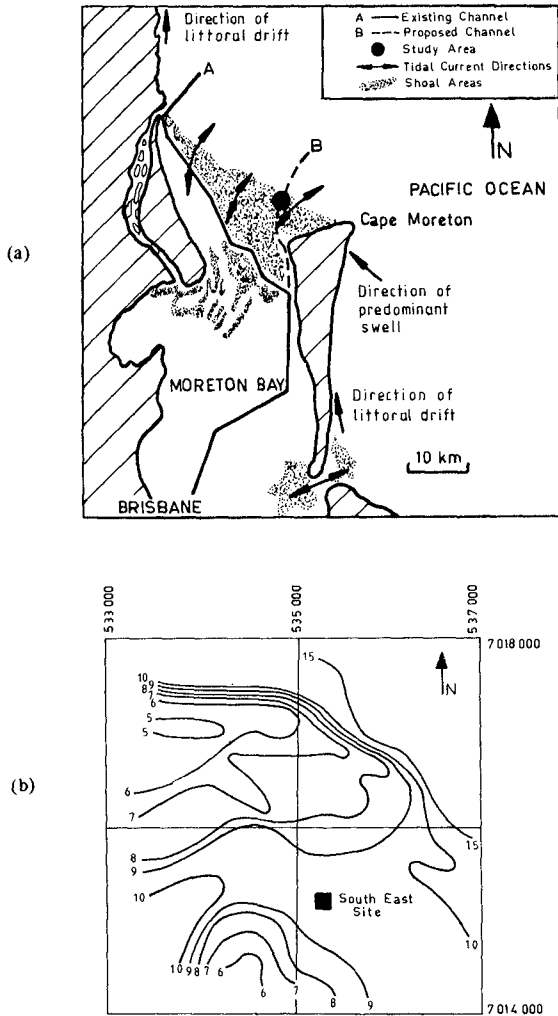

Figure 1. (a) Existing and proposed navigation channels through the Moreton Bay shoals. (b) Depth contours over the ebb fan of the North East tidal channel.

conditions indicate a high bed mobility but the many variables involved make calculation or mathematical modelling of sand migration rates from hydrodynamic data difficult. Ebb oriented dune-forms exist in the deeper regions of the tidal channel. Some lower bed-forms occur on the fan itself but no clear indication of the major direction of sand migration can be defined.

Determination of siltation rates using a mobile bed hydraulic model equipped with tide and wave generators is expensive and some preliminary field data are required for precise tuning. Radioactive tracer techniques provide an alternative method to acquire qualitative and quantitative on-site data. The PBA contracted the AAEC Isotope Application Research Group to carry out on-site tracing tests. These were carried out between 26 April 1983 - 1 July 1983.

## 2. AIMS OF THE INVESTIGATION

Although there are many factors which could cause channel infill, and recognising that construction of the channel could radically alter the sediment movement pathways in the location, a possible cause of siltation would be the littoral-drift/bay-bypass mechanism. The radiotracer study was designed to investigate the presence of this mechanism.

The principal aims of the investigation were:

- (i) To determine the direction of sand movement
- (ii) To determine the rate of sand movement
- (iii) To determine the rate of channel infill caused by any identified sand movement normal to the channel alignment.

## 3. SEDIMENT TRANSPORT RATES BY RADIOACTIVE TRACER TECHNIQUES

Quantitative sediment transport rates by the spatial integration method may be determined from

$$Q = 2VD \text{ td}^{-1}\text{m}^{-1}$$

where V = mean particle velocity ( $\text{md}^{-1}$ )

D = mobile bed thickness (m)

and a bulk density factor of 2 is assumed.

Radioactive sand tracer is released onto the ocean floor. The spatial distribution of tracer is determined at suitable time intervals. The centroid of each complete scan is calculated. Shift in centroid location over the corresponding time interval gives the mean particle velocity (V).

The mathematical concept of bed-load movement is applied even though the actual particle movement may be a series of 'hops' in suspension followed by long periods in

which the particle remains buried in the sediment layer. This mobile layer has a thickness in ocean waters which depends on wave climate, particle size, ripple height and particle roughness. Its thickness (D) is determined from the vertical dispersion of tracer into the sea bed, measured by the count recovery method or by coring.

### 3.1 Choice of Tracer

Chromium-51 ( $t_{1/2} = 27$  days;  $\gamma = 0.32$  MeV) was chosen as the most suitable radioisotope for preliminary investigations in Moreton Bay. Direct underwater detection is possible but the energy is low enough to reduce the need for bulky shielding during transport and tracer release procedures.

### 3.2 Tracer Sand Preparation

Two kilograms of sand were taken from the shoals, washed, graded (0.2 mm median diameter), nitric acid-washed, to remove shell grit (5%), etched in hydrofluoric acid to remove iron and manganese oxides, and dried. Ammonium dichromate solution was added until the sand was just moistened. The ammonium dichromate was decomposed by heating to 600°C; this produced an even coating of green chromium sesquioxide on the sand. Wet and dry self-abrasion followed by repeated washing removed all loose oxide and oxide deposited on the high spots on the grains. Microscopy showed that the residual oxide was extremely well attached on fissures and etched pits. Laboratory tests showed negligible levels of chromium in supernatant water after extended periods of violent agitation. It is therefore unlikely that any label would detach under marine conditions. No significant density change is involved since residual chromium content is 0.35%.

Figure 2. Tracer release technique. Vials of chromium-51 labelled sand are transferred from lead delivery pots into brass holders preloaded with two electric detonators. Detonation on the sea bed breaks the vials and releases the tracer sand.

Neutron activation of the label to chromium-51 was carried out in the X-202 bulk irradiation facility in the AAEC's materials testing reactor HIFAR.

### 3.3 Tracer Release

For preliminary tests a site, located 1 km south-east of the proposed channel line (Figure 1b) was chosen as representative of the area.

Mean water depth at this site was 10 m BMWL. The detonation technique was used to inject tracer sand into the sea bed (Figure 2) over a slack water period on 28 April 1984. Twelve vials, with a total activity of 1.45 Ci 50 (GBq) were used. Total mass of tracer was 0.6 kg. This technique is quick and simple. Release was complete in 30 minutes. The incorporation of tracer into the bed material.

### 3.4 Tracer Monitoring and Determination of Mean Particle Velocity $V$

The subsequent lateral movement of the tracer was followed over a period of two months. A waterproof scintillation detector was mounted on a sledge and dragged over the sea bed on fixed lines. The sledge position was fixed using HIFAR navigation equipment, and shore stations at Caloundra and Woorum as reference points. Usually, the tracks ran along fixed arcs of  $\approx 27$  km radius with Caloundra as the central point. The navigation equipment is accurate to  $\pm 3$ m. Count rates were corrected for radioactive decay and superimposed over the tracks provided by the PBA surveyors. Isoactivity contours were drawn and centroid and lateral movements of the tracer determined. In tracer studies, in an ocean environment, tracer advection in one direction can be masked by tracer diffusion in all directions. Successive scans show considerable overlap and centroid shifts are often tens of metres. Recently the very accurate navigation systems available have made it possible to track on a 10 m grid spacing at up to 30 km from shore stations, and to reveal these small shifts. By endeavouring to limit the initial area of the labelled zone, tracing on such a tight grid does not become arduous and most complete scans can be accomplished in one day of fair weather.

The areal disposition of the tracer relative to two reference points connected by a line parallel to the proposed channel alignment for the period 4 May to 1 July 1983 is shown in Figure (3). Tidal action stretched the concentration contours in the ebb and flood directions. There is also an identifiable movement in a north-westerly direction along the wave orthogonal and across the line of the proposed channel. This movement, attributed to wave generated mass transport velocity and wave asymmetry

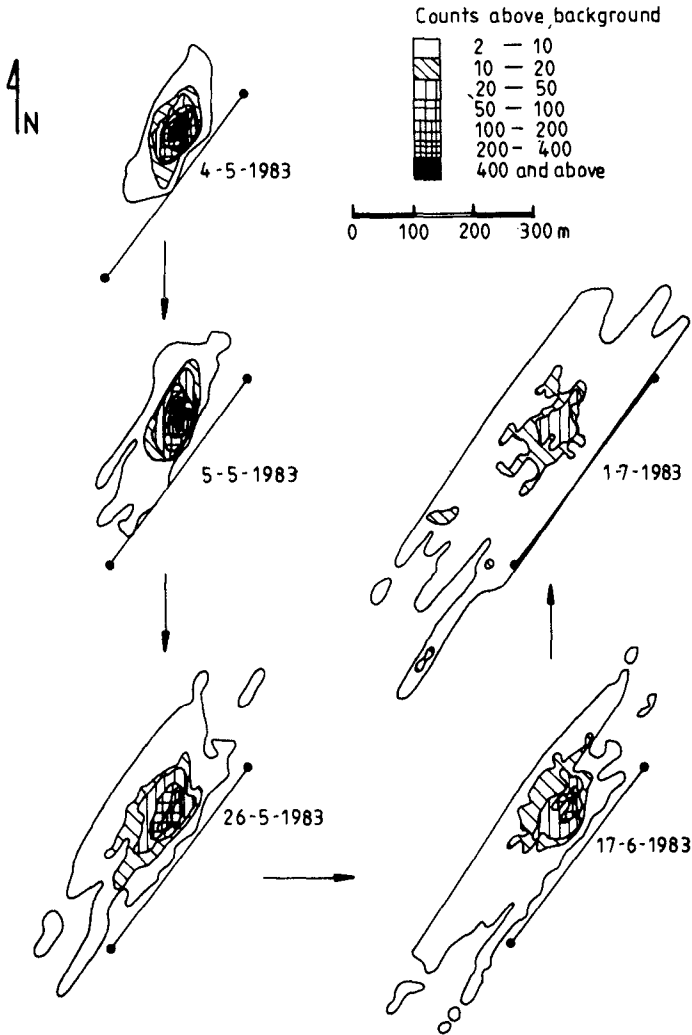

Figure 3. Lateral dispersion of labelled zone over the two month test period. Movement is shown relative to two reference points joined by a line parallel to the channel alignment.

effects, can be regarded as "onshore" transport.

The movement normal to the direction of the tidal currents and across the channel alignment is plotted as a function of time in Figure 4 (a). The integrated count along the lines at 10 m intervals from the reference line are plotted on the vertical axis for each complete scan. The Lateral shift of the centroid position is plotted as a function of time in Figure 4 (b) and indicates a steady movement towards the north-west.

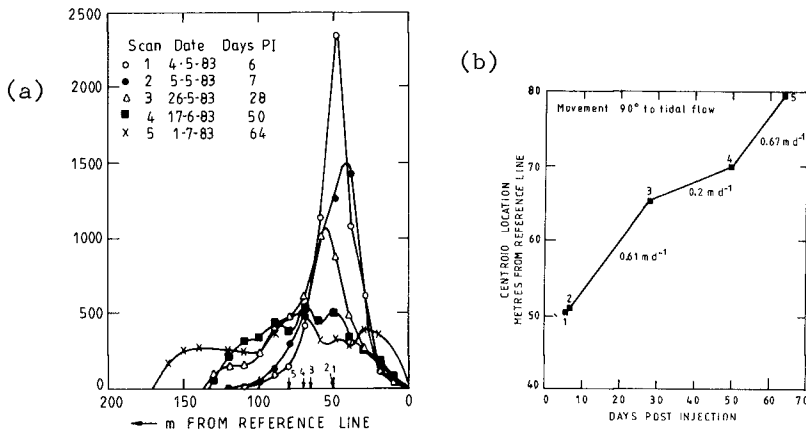

Figure 4. (a) Lateral distribution of tracer  
(b) Centroid location as a function of time after tracer release. Mean particle Velocities are indicated.

During the 56 days, following an initial 7-day period of tracer incorporation, there was a lateral shift of 28.8m, resulting in a mean particle velocity ( $V$ ), normal to the channel alignment, of  $0.52 \text{ m day}^{-1}$ :

### 3.5 Thickenss of the Mobile Layer (D)

As tracer sand becomes incorporated into the bed material the total activity which is apparent to a sledge mounted detector falls absorption by bed material of the  $\gamma$ -ray emission from tracer particles.

The ratio of apparent activity : injected activity (% recovery) is a function of the  $\gamma$  energy of the isotope employed and the incorporation thickness.

The detector response to buried tracer is described by the equation

$$\frac{\alpha ND}{\beta f_0 A} = 1 - e^{-\alpha D}$$

where  $\alpha$  is the absorption coefficient at the relevant  $\gamma$ -energy for a sandwater mix;  $N$  is the number of counts recovered;  $f_0$  is the detector response where tracer is a surface layer only;  $A$  is the total activity injected;  $D$  is the depth of tracer incorporation; and  $\beta$  is a non-homogeneous distribution factor [4]. The factors  $\alpha$  and  $f_0$  were determined in a laboratory tank from the count rate reduction observed when a plane source of chromium-51 was buried under increasing thicknesses of sand. Under these circumstances

$$f = f_0 e^{-\alpha d}$$

where  $f$  is the observed count rate and  $d$  is the covering thickness;  $d$  can also be regarded as the mean depth of tracer incorporation. The total thickness depends upon the vertical distribution factor  $\beta$ . A value of  $\beta = 1.25$  was used in this study. The value of  $\alpha$  and  $f_0$  for chromium-51 and the detector used was found to be  $17.9\text{m}^{-1}$  and  $2.8$  counts  $\text{s}^{-1} \mu\text{Ci}^{-1}\text{m}^{-2}$  respectively.

Figure 5 shows the measured mean tracer particle depth ( $d$ ) and the derived total thickness of the mobile layer ( $D$ ) as the ratio of apparent activity : released activity expressed as percentage.

Figure 5. Calibration curves used in the determination of the mean particle burial depth ( $d$ ) and overall thickness of the mobile layer ( $D$ ).

The percentages of total possible counts recovered per complete scan, together with the mobile bed thickness calculated from these values, are plotted as a function of time

in Figure 6. After an initial period of seven days, incorporation was apparently complete and remained constant at a depth (D) averaged over the whole labelled zone of 0.25 m. A similar period for full tracer penetration was found during tests in Swansea Bay, Wales [5].

Figure 6. % Counts recovered and derived thickness of mobile layer (D) plotted against time after tracer release. The mobile layer thickness determined from cores is shown to the right.

Cores were taken from the labelled zone after 50 days using a vibration corer powered by compressed air. These cores were sliced into 0.02 m sections and the chromium-51 content measured in the laboratory (NaI crystal with multi-channel analysis). Active particles were found evenly distributed over the range shown in Figure 6. The deepest particle was 0.27 m below bed level, corroborating the value of 0.25 m found by the count recovery method.

Unlike tracer tests involving mud, relatively few active particles are employed during sand tracer tests. A prohibitive number of cores would be necessary to obtain a complete vertical distribution profile.

### 3.6 Sand Transport Rate

The wave driven transport rate normal to the tidal current and channel alignment can be calculated from the values of  $V$  and  $D$ .

$$\begin{aligned}
 Q &= 2VD \\
 &= 2(\text{tm}^{-3}) \times 0.52 (\text{md}^{-1}) \times 0.25 (\text{m}) \\
 &= 0.26 \text{ tonnes d}^{-1} \text{ m}^{-1}
 \end{aligned}$$

Based on this transport rate a 3000 m channel cut through the fan will intercept  $2.85 \times 10^5$  tonnes of sand per year. This preliminary value, calculated from data acquired over only a two-month period and a single central downstream location, appears reasonable and equivalent to  $\approx 60\%$  of the

known littoral drift rate.

An extended study is in progress using iridium-192 labelled tracer sand ( $t_{1/2} = 74$  days) which has been released as a 2000 m line source.

3.7 Current and Wave Data

Sections of the record of velocity and direction of the diurnal tidal current measured 3 m above the bed are shown in Figure 7. The region is ebb dominated. Both ebb velocity and duration exceed that of the flood tide. The ebb-flood and flood-ebb current direction change occurs through the south-eastern seaward sector.

Figure 7. section of tidal current velocity and direction record.

Wave height ( $H_g$ ) wave period ( $T_g$ ) and the near bed maximum oscillating current velocity ( $U_b$ ), calculated from linear wave theory, are shown in Figure 8. A period of "heavy" weather ( $S_1$ ) and two storms ( $S_2, S_3$ ) are indicated. A value for  $U_b$  of  $1.55 \text{ m s}^{-1}$  was calculated for the peak of both storms  $S_2$  and  $S_3$ .

Figure 8. Wave height, wave period and calculated oscillating near bed current during test period.

The deepwater wave climate for the area, from data accumulated over several years [ 3 ], is compared with the slightly more energetic climate recorded during the study in Figure 9.

The records indicate that criteria for the initiation of movement for 0.2 mm sand under steady (tidal) or oscillating (wave generated) currents were exceeded at all times.

Figure 9. Annual wave climate ———, and wave climate recorded during test period -----.

#### 4. CONCLUSIONS

Movement of sand towards the north-west and across the proposed channel alignment has been identified.

The values found for the mean particle velocity ( $V = 0.52 \text{ m d}^{-1}$ ) and thickness of the mobile layer ( $D = 0.25 \text{ m}$ ) result in a sand transport rate of  $0.26 \text{ tm}^{-1}\text{d}^{-1}$ . This value is strictly only applicable to the central 600 m of channel and for the two months during which sand movement was monitored. Variation in water depth over the fan is small and the wave climate during the test period was representative of the annual average. It is therefore not unreasonable to extrapolate the measured value in both time and space. On this basis a 3000 m channel will intercept  $2.85 \times 10^5$  tonnes of sand per year, equivalent to 60% of the known littoral drift rate.

On first examination a remarkable feature of the study is the relatively low advection rate of the 0.2 mm bed material, and deserves further comment. The labelled zone remained compact throughout and exhibited little stretching in the direction of the tidal currents. No offshore transport could be detected but onshore transport in the direction of wave propagation and across the line of tidal flow was apparent.

Behaviour of this kind is characteristic of transport processes occurring very close to the bed where steady current velocities are weakest and where wave mass transport velocities supplemented by wave asymmetry effects are strongest, and in the direction of wave advance.

During the storm events  $S_2$  and  $S_3$  maximum near-bed orbital velocities calculated from linear wave theory were  $1.5 \text{ m s}^{-1}$  which would have eliminated bed ripples and caused a sheet flow condition similar to that observed by Jonsson (6) utilising equivalent velocities in wave tunnel studies.

Considerable quantities of sand would have been mobilized in oscillating motion both as bedload and suspension in agreement with the measured mobile layer thickness of 0.25 m. However the superimposed steady (tidal) current has little advective effect on this dense slurry apparently trapped in the wave boundary layer. Weakening of the steady current velocities within the wave boundary layer has been predicted by Fredsøe (7) and measured by Bakker and Doorn (8) in a flume. Under these circumstances steady current velocity profiles with roughness lengths of the order of the wave boundary layer thickness are obtained. Similar effects have been observed in field studies (9).

Upward transfer of sediment to heights above the bed, where the steady current could cause advection, is suppressed by the steep density gradient between the near bed slurry or rheological layer (10) and the water immediately above.

It is of interest to note that, while the depth of water at the study site was 10 m (BMWL), the beach profile closure depth is 9.5 m (BMWL) on this part of the east coast of Australia (11). This value should be compared with the water depth at the boundary between near shore and shoal zones as defined by Hallermeier. This boundary is at the deepest water depth where "suspension" processes can occur under extreme wave conditions, and is calculated to be 9.0 m (BMWL) (12).

## CHAPTER ONE HUNDRED THIRTY NINE

### DEVELOPMENT OF A SEDIMENT TRANSPORT MEASURING SYSTEM

Eberhard Renger \*

#### ABSTRACT

A new method for continuously recording sediment concentrations with high accuracy has been developed. It is proposed to apply the method for in-situ measurements in connection with investigations of tidal control and sediment transport induced by shipping traffic.

The operating principle is as follows: at the measurement location, sediment laden water is continuously sucked-in by means of a pump and is forced under pressure into a hydrocyclone ( solid bowl centrifuge ) through a delivery pipe of varying length. Here the extracted sediment flux (particle size  $\approx 5 \mu\text{m}$ ) is delivered by the shortest route to a settling tank and continuously weighed under water (wet-weighing). Following calculation and appropriate adjustment to the sample discharge (  $Q$  ) the weight increase for selected time intervals (  $\Delta G (\Delta t)$  ) yields the mean concentration for the time interval (  $\bar{c} (\Delta t)$  ) in weight / unit volume (  $\text{mg/l}$  ) (direct measurement, calibration not required ).

Details and experiences of the 3 major development stages will be described. A fully-automatic instrument for continuously measuring nonsteady sediment movement is now available. The instrument may be installed above as well as below water as desired.

#### 1. INTRODUCTION AND PROBLEM DEFINITION

In connection with investigations of tidal control to reduce sedimentation and of sediment transport induced by shipping traffic in the inner German Bight / North Sea, it is necessary to continuously record instationary sediment transport over long periods at different measuring stations. Owing to a lack of information concerning the spatial distribution and temporal variation of sediment

---

\*Senior Research Engineer, Landesamt für Wasserhaushalt und Küsten Schleswig-Holstein, Kiel - Germany

movement in the investigation areas, it was necessary to develop an overall concept which was realised in practice according to the following stages:

1. Selection and partial development of a suitable method of continuously recording sediment concentrations and the specification of a minimum performance
2. Preliminary experiments concerning the measurement of the instationary nature of sediment movements at a single point of measurement. This was necessary in order to estimate the most appropriate measurement frequency and measurement duration.
3. Simultaneous test recordings at various depths in the same cross-section in order to assess the importance of vertical variations in the transport (number of instruments !)
4. Simultaneous test recordings at various measuring points in a horizontal plane at the same cross-section in order to assess the importance of horizontal variations in the transport (number of instruments !)
5. Further development of the measuring technique in order to obtain optimal conformity with the overall objective with due consideration of the above-mentioned experimental tests

Since each stage of the investigation depended to a large extent upon the results of the experiments, it was necessary at the outset to ensure a high degree of flexibility in research planning and conduct. In accordance with the latter, the following basic principles were specified:

- a) Adoption of uncomplicated and readily available instrument components as building blocks
- b) On-the-spot evaluation of test results in order to ensure an optimal progress of the experiments
- c) Well-conceived stage planning in order to ensure overall optimisation of the investigation aim and solution possibilities

In this paper, attention will be mainly confined to the development stages of the measuring technique.

## 2. SELECTION CRITERIA FOR THE MEASURING TECHNIQUE

In order to prescribe the measuring technique, a study of existing investigations was first carried out (1),(2),(3). The following basic information led to constraints regarding the technical problems of measurement concerned with here:

- 1) Existing data concerning grain-size distributions for suspended sediment and bed samples reveal mean frequency maxima ranging between about 50 and 100  $\mu\text{m}$ .
- 2) At the present time, existing indirect recording techniques require extensive calibration by means of sampling and laboratory analyses (weighing), especially under consideration of particle dependence.
- 3) The determination of sediment balances (residual transport) depends predominantly upon the number of instruments used.

For these reasons, the continuous partial flux analysis with sediment weighing was selected as the most suitable method of investigation ((4), and Fig.1).

With the aid of a pump and a suitable extraction and feed system, a sample discharge is continuously forced under pressure through a hydrocyclone (solid bowl centrifuge). The separated particle stream falls within seconds by gravity into a settling tank and is continuously weighed. Following calculation and appropriate adjustment to the sample discharge ( $Q$ ), the weight increase for selected time intervals ( $\Delta G (\Delta t)$ ), directly yields the mean sediment concentration for the time interval ( $\bar{c} (\Delta t)$ ) in weight / unit volume ( $\text{mg/l}$ ).

The development of the measuring technique and the corresponding instrumentation took about 2 years. This essentially involved 3 major stages of development (see Fig.3).

### 3. HYDROCYCLONES AS SOLID BOWL CENTRIFUGES

Fig. 2 :

Hydrocyclone flow diagram

As described by TRAWINSKI in (5) the hydrocyclone can be regarded as operating as a solid bowl centrifuge in which the casing is not rotated, but rotation of the suspension is produced by its being fed into the cyclone tangentially under pressure. Depending on the degree of solids recovery to the underflow, the cyclone can act either as clarifier or as classifier. The rejects are thickened in any case.

Fig.2 demonstrates schematically the working of a hydrocyclone. The suspension fed into it forms a primary vortex along the inside surface of the cylindrical and conical wall, aiming to leave the cone apex. As this is throttled, only part of the stream is discharged as underflow, carrying the coarse particles or even all of the solids with it. The bulk of the liquid - being cleaned by the residual fine particles with it - is forced to leave the cyclone through the overflow nozzle by

forming an upward-spinning secondary vortex surrounding the core of the casing. Inside the core, a low pressure is generated, collecting all the air that has been carried in as bubbles or dissolved in the feed water. Even vapor will enter this visible air core. Because of the increase in circumferential speed in the secondary vortex, higher centrifugal forces are generated, resulting in a highly efficient secondary separation. The rejected fine particles settle radially and join the primary vortex, from which most of them are discharged finally through the spigot formed by the cone apex. The separation inside a hydrocyclone therefore takes place as a result of two process stages, the final cut point being determined mainly by the acceleration of the inner secondary vortex.

### 4. SELECTION OF MEASUREMENT CYCLONES

The separation efficiency of hydrocyclones is mainly determined by the cyclone geometry (diameter, length) and the discharge. The normal measurement specifications for standard cyclones require information regarding concentrations,

particle distribution as well as discharge for the feed. These three design parameters must be estimated by theoretical or empirical methods before instrument construction and specified for the selection of the cyclone. In respect of this, following relationships must be considered:

1. The natural particle distribution of between 0 and approximately 500  $\mu\text{m}$ , with a mean maximum of between 50 and 100  $\mu\text{m}$ , lies within the optimum working range of hydrocyclones. The smaller number of large particles occur very seldom and may therefore be legitimately excluded by means of a prefilter so as to protect the equipment from blockage. Parts of the equipment susceptible to blockage include the slot-shaped inlet nozzle ( $\text{max } d < \text{slot-width}$ ) and the circular underflow nozzle ( $d \leq 1/5$  nozzle diameter). Other than this, no strict requirements are necessary for optimal performance of the equipment.
2. The natural concentration of the sample discharge ( Q ) of between about 0 and 10 g/l maximum, with a predominant peak between 50 and 500 mg/l, results in an optimum degree of selectivity in the separation process. The absolute magnitude of the latter, as related to the frequency of occurrence, is a decisively important factor for the dimensioning of the sediment scale. For optimal performance, the accuracy of weighing, measurement frequency, size of the settling tank and flushing frequency must be counterbalanced.
3. The discharge ( Q ) is essentially proportional to the diameter of the hydrocyclone. Since the size of the separated material also increases with the diameter of the hydrocyclone the sediment stream to be weighed becomes less representative owing to the restricted range of particle size. The fine-grained fraction ( $< d_p$ ) of the residual turbidity in the hydrocyclone overflow increases, and since this cannot be measured at the present time, it must be treated as an error in instrument measurement. Consequently, the optimisation demands a minimization of the discharge ( Q ).

It should be noted that the sub-optimization of the hydrocyclone and the magnitude of the sample discharge ( Q ) as a function of the sediment scale both play a predominant role. Owing to the unknown sediment fluxes, further development of the method in the hydraulics laboratory was not undertaken. By adopting readily available instrument components, initial tests and measurements in the field were immediately carried out. By this means, first impressions of actual sediment movements, as referred to in section 1, could be obtained simultaneously.

## 5. OVERALL OPTIMISATION OF THE MEASURING SYSTEM

### 5.1 Components of the measuring technique

The in-situ measuring instrument with on-line facilities is comprised of the following sub-units (compare with Fig.1 , Fig.3 and Table 1 ):

- a) Extraction and feed equipment with intake arrangement, delivery pump, feed pipe, support, power supply, positioning facility
- b) Hydrocyclone and disposal unit with discharge measurement, overflow pipe, inlet regulation, pressure controls
- c) Settling tank and sediment scale with tank adjustment, filling equipment, flushing device, constraining fixtures
- d) Instrument control and data recording with underflow regulation, tank flushing, operation monitor, data acquisition, data storage, concentration computations, in-situ data logging

As indicated in Table 1 , the three development stages involve different dimensions of the sample discharge ( Q ) and weighing apparatus. Accordingly, the instrument components listed under a) to d) are differently dimensioned. A detailed technical description will be avoided here.

### 5.2 Determination of sediment concentrations

As described in Sections 3 to 5 , only the sediment stream in the hydrocyclone underflow is continuously weighed at present. All fine particles (smaller than the separation grain diameter  $d_T$  ) as well as organic material enter the hydrocyclone overflow and are only occasionally monitored by manual sampling (discontinuously) followed by laboratory analysis.

The sediment concentration for particles larger than (  $d_T$  ) is calculated as follows:

$$\bar{c} (> d_T) = \frac{\Delta G}{\Delta t \cdot Q} \quad (\text{mg/l}) \quad (1)$$

where:  $\bar{c} (> d_T)$  = mean sediment concentration for particles ( $> d_T$ ) in the time interval ( $\Delta t$ )

$\Delta G$  = weight increase in the time interval ( $\Delta t$ )

$\Delta t$  = time interval for computing mean sediment concentrations (  $\bar{c}$  ) (held constant during a sequence of measure-

ments, however may be arbitrarily chosen up to the maximum filling - time of the settling tank )

Q = magnitude of the sample discharge

According to the particular stage of development I to III, these measurement parameters vary. Beyond stage II, wet weighing must take account of buoyancy forces (compare with Table 1). The different combinations of hydrocyclone and weighing apparatus are shown to scale in Fig.3 .

### 5.3 Stage I - Trial tests with a large-scale equipment

In order to become acquainted with the handling and performance of hydrocyclones and the measuring technique as well as the variance of the particle discharges, a full-scale instrument was installed for trial tests (compare with Fig.3,I ). Owing to the present inability to control the underflow discharge of about 20 ml/s, a through-flow settling tank with a free surface was selected. With a realisable settling area (  $A_c$  ) of about 12 dm<sup>2</sup> together with the corresponding volumetric capacity (  $V \approx 40$  l ), a separation grain-size of about 25  $\mu$ m was specified. All finer particles were already eliminated from the measurements by means of an exterior large cyclone. The large sample discharge ( Q ) of about 12 l/s ensured a relatively large sediment delivery to the settling tank. Despite hydraulic related disturbances of the scale, measuring intervals of 5 minutes were possible. The test results yielded detailed information concerning the particle flux (  $d > d_T$ ,  $d_T = 25 \mu$ m ). Data was recorded by means of a simple printer.

### 5.4 Stage II - Trial tests with a mobile instrument

In order to quickly obtain information regarding the spatial distribution of sediment movements over a cross-section, the simultaneous operation of three mobile sediment measuring instruments was necessary (types due to stage II, see Fig.3 ). Corresponding considerations concerning a minimization of instruments led to a drastic reduction of the required sample discharge ( Q ) from 12 to 0.7 l/s. This was achieved by regulating the hydrocyclone underflow. Following preliminary tests with filters (stage IIa) and special valves (stage IIb), hydraulic regulation of the underflow by means of pressure control was eventually adopted. By immersing the lower part of the hydrocyclone beneath the free surface of the settling tank, the underflow (water) was completely choked. The sediment (  $> d_T$  ) escaped with negligible delay due to density currents alone. By this means, the free surface-area of the settling tank could be reduced by a factor of 10 to 3 dm<sup>2</sup>.

The improved selectivity (separation grain-size  $d_T=7\mu\text{m}$ ) obtained with the smaller sample discharge of  $0,7 \text{ l/s}$  considerably increased the measurement range in the direction of fine sediments. Owing to the reduced sample discharge, however, the sediment flux in the underflow decreased by about one-tenth. In order to maintain the same accuracy of measurements ( resolution, measurement frequency ), it was necessary to reduce the weighing range by the same factor (one-tenth).

By taking advantage of the above-mentioned instrument reductions, a completely submerged suspension of the weighing container was possible. As a result, hydrodynamic disturbances during weighing were eliminated. In addition, the accuracy of measurement could be increased by a further order of magnitude (see Table 1) by taking advantage of buoyancy forces during weighing. The weighing was carried out with high precision laboratory scales and a hand-held-computer was used for data acquisition.

With this instrument configuration, which may be termed semi-automatic, several dozen tides were monitored ( see Fig.4 ). The measurements revealed large spatial and temporal variations in sediment concentrations. Correspondingly, the filling times of the settling tank to maximum capacity also differed ( from about 0.5 to 5 hrs in the EIDER Estuary / North Sea ). Changing of the settling-tank, followed by underflow stabilization for the next period of measurement, lasted on average between about 2 to 5 minutes.

### 5.5 Stage III - Fully-automatic sediment concentration measuring instrument SEDIWA

---

The valuable experiences gained in instrument handling, precision and measured results during the development stages I and II led to a further optimisation of the equipment ( Fig.3, Stage III and Table 1 ). The long-term installation of several instruments, especially on poorly accessible and submerged mountings, necessitated a further minimisation of instruments, improved operating stability and full automation (compare with Fig's 3 and 5 ).

The selection of a mini-cyclone with a discharge capacity of  $0,16 \text{ l/s}$  reduced the separation grain-size (  $d_T$  ) to  $5 \mu\text{m}$ . Due to the new reduction in the sample discharge of about one-fifth, a corresponding increase in the weighing accuracy of around  $\pm 20 \text{ mg}$  will be necessary. This can only be justified, however, provided the hydraulic disturbances for the instrument and environment are relatively small. Owing to the fact that underflow pressure was several tenths of a bar, the hydraulic regulation of the underflow had to be abandoned. The corresponding effects of oper-

Fig.4 :  
 Simultaneous records of suspended sediment concentration and water level (tidal curve)

ating pressure fluctuations upon the several meters high water column of a free-surface buoyancy tank would adversely affect the separation process.

The necessity of including a submerged scale in a pressure-stabilized instrument configuration required a transition to a closed excess-pressure chamber in the hydrocyclone underflow. By this means, a highly sensitive underwater weighing cell ( $\pm 15 \text{ mg}$ ) could be developed and installed. The weighing container, which is about the size of a beaker, has a maximum filling capacity of approximately 200 g of sediment ( $> 5 \mu\text{m}$ ). Depending on the rate of sediment accumulation, the filling time is of the order of several hours.

Emptying of the container (compare with Fig. 5 c) is achieved by simply opening the flushing valve located at the base of the chamber. By choking the overflow, the excess pressure of about 1 bar in the chamber falls drastically. This leads to a strong flushing jet in the cyclone underflow which re-empties the full settling tank within about 1 minute. Following the flushing phase, the valve is closed again. The chamber pressure and the underflow discharge immediately stabilize and the measuring procedure resumes without delay.

Fig. 5 :  
 a) filling ...      b) operation ...      c) flushing .. of SEDIWA  
 - submersible sediment measuring system -

For fully-automatic operation, a control unit with data acquisition is provided. Together with time and weight measurements, the magnitude of the sample discharge (in general constant) is continuously monitored by means of a discharge meter in the return-flow line behind the cyclone overflow. The calculation of sediment concentrations (according to Equation (1), section 5.2), including processing of the measured data, is achieved by means of simple software.

With this type of instrument, several series of measurements lasting a number of days have already been successfully carried out in the absence of personnel (compare with Fig.4). The continuous recording over several tides provided valuable information for the subsequent analysis of the wide-ranging data relating to instationary sediment movement.

#### 6. MERITS OF SEDIWA AND CONCLUSIONS

1. Flow sampling, i.e. delivery of the total material to be investigated (water with contents) for further detailed examination
2. Continuous extraction, i.e. the possibility of detecting special events (eg. detection of transient peaks)
3. Sediment sample collector, i.e. availability for subsequent (eg.) sediment-petrographical analysis
4. Accumulative weight method, i.e. especially for temporally dependent analysis and evaluation (integration, balances), the relative influence of errors becomes increasingly less
5. Minimum time discretization, i.e. optimum suitability to highly instationary sediment movement
6. Absolute measurement technique, i.e. recordings in weight / unit volume (avoids calibration)
7. Larger range of material, i.e. weighing of all particles greater than  $d_{\pi} = 5 \mu\text{m}$  (separation grain-size of the hydrocyclone = cut point)
8. High precision, i.e. by minimising the sample discharge ( $Q$ ) and with pressure-stable isolation of the hydrocyclone underflow, including weighing unit as well as weighing under buoyancy, a highly sensitive weighing cell may be employed
9. Immersed installation, i.e. minimisation of support and serving facilities
10. On-line measurement technique, i.e. as a consequence of cyclonisation followed by immediate submerged weighing of sediment, complete availability of the com -

puted concentration values only a few seconds after sampling (also later, as desired)

11. Full automation, i.e. hydraulic delivery technique, reduction of mechanical parts to only a flushing valve, waterproof electrics and electronics, presence of personnel not required

## 7. ACKNOWLEDGEMENTS

This work was carried out as part of two coastal engineering research programs of the Landesamt für Wasserhaushalt und Küsten Schleswig-Holstein by request of the Ministry of Food, Agriculture and Forests. Support for this study was provided by the KFKI (Kuratorium für Forschung im Küsteningenieurwesen) and the BMFT (Bundesministerium für Forschung und Technologie), which is greatly acknowledged by the author. The firm ME (Meerestechnik + Electronic) contributed to this work by optimizing the technical layout of the prototype SEDIWA.

## CHAPTER ONE HUNDRED FORTY

### EFFECT OF RIP CURRENT BARRIER ON HARBOR SHOALING

by

Tamio O. Sasaki\*, M. ASCE and Hiroshi Sakuramoto\*\*

#### ABSTRACT

Prototype experiments on rip currents and sediment transport around structures were conducted at two fishery harbors on microtidal high energy beaches facing the Pacific Ocean. The purpose of the experiments was to examine the performance and mechanism of rip current barrier structures on harbor shoaling. Based on the results of five experiments, the wave breaker heights during which varied from 1.1 m to 3.0 m, it is concluded that shore-parallel rip current barriers are effective if their length is greater than the surf zone width and if they are located outside the surf zone. When the above conditions are satisfied, the rip current barrier is a cost-effective measure against shoaling of small craft harbors.

#### 1.0 INTRODUCTION

Two case studies are presented which demonstrate the mitigating effect of rip current barrier structures on the shoaling of small craft harbors. A rip current is a fast and narrow current that carries sediment offshore. One of the major reasons why harbor breakwaters and jetties cause beach erosion on adjacent beaches, offshore sediment loss to form rip head bars, and shoaling inside of harbors is the formation of rip currents induced by and adjacent to the structures (Fig. 1a). The construction of sand traps is often adopted as a protection measure where the longshore drift dominates, (e.g., at Channel Island Harbor, Bruno and Gable, 1976; Pointe Sapin Harbor, Pratte et al., 1982). However, the detailed functioning of a sand trap is not well understood, and a large amount of maintenance dredging may be necessary.

The present paper focuses on the role of rip currents in the shoaling process, based on field observations. Then the rip current barrier concept to block rip currents is presented as a possible cost-effective solution (Fig. 1b). The study sites, Taito Katagai Fishery Harbors, are respectively located on the southern end and middle of the Kujukuri Coast, facing the Pacific Ocean (Fig. 2).

## 2.0 STUDY SITES AND RESULTS

Kujukuri Coast is a 55 km-long, very shallow coast bounded at both ends by eroding sea cliffs, Byobugaura and Taito Point (Fig. 3), 10 km and 2 km long, respectively. The average beach slope up to the 20 m depth is about 1/100. The dominant drift of sand is from both ends to the middle of the coast (Sunamura and Horikawa, 1977). The beach consists of fine sand (0.2 - 0.3 mm). The tidal range is 1.0 - 1.5 m.

## 2.1 Taito Fishery Harbor

An extreme case of harbor shoaling occurs at Taito Fishery harbor (Figs. 3 & 4). Taito Fishery Harbor originally had two shore-normal breakwaters that extended about 150 m seaward. As seen in Fig. 4, the harbor was totally filled with sediment soon after construction. To recover harbor functioning, extension of the breakwaters and construction of "wing-like" breakwaters which stop rip currents from flowing directly offshore was tried (Figs. 5 & 6). As a result, accretion at the root of the north breakwater has increased and sediment shoaling has been mitigated.

Fig. 1a Schematic diagram of induced rip current and harbor shoaling due to presence of a breakwater.

Fig. 1b Schematic diagram of a rip current barrier. Accretion at the feet of the breakwaters increased and shoaling in the harbor decreased.

Fig. 4 Taito Harbor totally filled with sediment.

Fig. 5 Recovered Taito Harbor after rip current barrier construction.

### Field Observation of Rip Currents

Observations of the rip currents at the site were conducted in November and December 1979, and January 1980. The breaker heights were 3.0, 1.1 and 1.7 m, respectively. The circulation patterns shown in Fig. 7 were obtained from photographs of successive dye patch dispersion patterns (Fig. 8). The photographs were taken with a Hasselblad 500EL camera mounted on a hovering helicopter. A total of 10 - 20 kg of fluorescent dye was released at 6 - 12 points within and outside of the surf zone.

Several very regular nearshore circulation patterns and barrier-induced rip currents were found on the north side of the harbor during the Dec. 1979 and Jan. 1980 experiments (middle and bottom of Fig. 7). However, at the east side, a typical blocked rip current as shown in Fig. 1b was not found except in the Jan. 1980 experiment, due to the size and orientation of the south rip current barrier. In CASE-791124, the eastern rip current barrier was ineffective, and thus a rip current developed seaward. The wave height was large in this case, so that most of the harbor structures were inside the surf zone.

### 2.2 Katagai Fishery Harbor

Another example is Katagai Fishery Harbor, located about 30 km north of Taito harbor. Sediment transported alongshore on the neighboring beaches arrives at both sides of the harbor. Therefore, the entrance jetties had to be extended year by year before 1974 due to accretion (Fig. 9). The length of the jetties reached 600 m; the total entrance channel length is about 1 km. This harbor was originally built to have a common entrance with the Sakuta river. The annual rate of shoreline advance was about 6 m/year at both sides of the jetties. The annual rate of accretion estimated by Sunamura and Horikawa (1977) for the central part of the Kujukuri coast is  $494,000 \text{ m}^3/\text{year}$ .

Figure 10 shows the change in nearshore topography from 1974. Major accretion occurred at depths less than 4 - 5 m; however, significant accretion took place deeper than 6 - 7 m as well. Angled plan shape breakwater construction started in 1975. The breakwaters are connected to the jetties by piers. This structure plan shape was designed based on results of laboratory experiments to maintain the entrance by a flushing. (A similar concept and shape appear in Maza et al. (1977) as a convergent jetty.) This angled breakwater did not give a good solution under prototype conditions. As shown in Fig. 10, large accretion occurred on the lee side of the breakwater and thus the amount of required maintenance dredging increased.

### Field Observation of Rip Current and Sediment Transport

Field observations of the nearshore current and sediment transport were conducted on October 1978 and March 1980 to study the underlying mechanism of the barrier (Table 1) before and after the rip current barrier construction. Several plan shape alternatives were compared by numerical modeling of the nearshore current system (Sasaki, 1975). As a result, rip current barriers as seen in Fig. 11 were finally adopted.

25 Mar. 1980	13:10	ENE	7.2	S65°E	9.8	1.6	280

Rip currents were observed by a tethered balloon system (Sasaki et al., 1976) on 14 Oct. 1978. The dispersion of dye patches was obtained from time-lapse photography (Fig. 12). The associated current velocity is given in Fig. 13. Dye released at the foot of the north jetty moved along the jetty, then reached the harbor entrance. The dye patches on the south side also moved with the rip current then formed rip heads underway to the harbor entrance. The maximum velocity of the rip currents was 40 - 50 cm/s. The dye northward from the injection point dispersed in the bore.

Sediment movement was observed with fluorescent tagged sand tracer. One thousand kg of tracer was injected on both sides of the jetties, and samples were taken 2, 4, 6, 8, and 24 hr after injection. The distribution of tracer numbers (Fig. 14) shows very similar patterns to the current (Fig. 13). The tracer study was conducted the day before the current measurement; however, the incident wave directions were almost the same on 13 and 14 October (Table 1). The maximum drift velocities on both sides of the jetties were 7 cm/s and 1 cm/s, respectively.

One major empirical conclusion of this prototype experiment is that the sediment movement pattern is predictable based on current measurements. Thus, current measurement were conducted to determine the sediment movement after the construction of the rip current barriers.

#### Current around Rip Current Barrier

Nearshore current measurements were made on 25 March 1980 by using a helicopter-mounted camera instead of the balloon. Fluorescent dye was released at 7 points, 3 kg at each point in the surf zone and 2 kg at each point outside the surf zone. Figure 15 shows the dispersion of the dye patches around the vicinity of the rip current barriers. The rip current barriers block the rip currents effectively and produce forced circulation cells (Fig. 16). The velocity field is given in Fig. 17.

Fig. 11 Plan of Katagai Harbor. Harbor basin is located about 1 km inland from the entrance.

Fig. 12 Dispersion of dye released at the feet of the jetties. Numbers denote elapsed time in min. after injection. Rip heads are outlined.

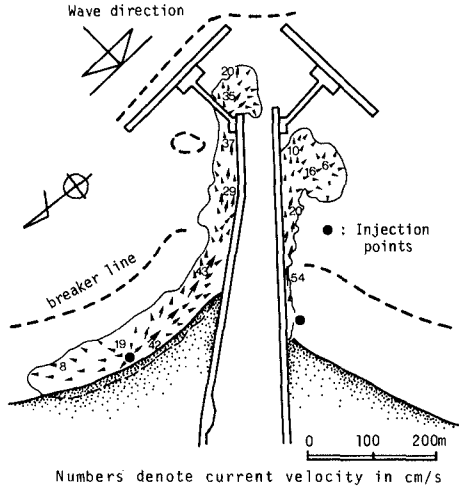

Fig. 13 Velocity distribution of rip currents derived from dye patch movement on 14 Oct. 1978.

Fig. 14 Tracer movement 6 hr after injection on 13 Oct. 1978. Tracer entered the channel mouth.

Fig. 15 Dispersion of dye patches around rip current barriers.

Because the south rip current barrier is short compared with the north barrier, the effectiveness of the barrier is limited. The shore-normal structure attached to the barrier is a portion of the proposed jetty to the separate harbor entrance channel from the Sakuta river.

#### Effect of Rip Current Barrier on Mitigation of Harbor Shoaling

Sounding charts were compared for surveys taken before and after rip current barrier construction (Fig. 18). General accretion is seen offshore and north of the harbor. On the other hand, an eroded area appears on the south side of the harbor. The offshore accretion may be the result of rip head bar formation during storms. Several sounding charts (e.g., bottom of Fig. 10) show huge rip channels. This tendency is consistent with the action of angled breakwaters and indicates that rip current barriers of this size are not effective in storms.

In the lee of the north barrier, accretion continues to take place, and thus the rate of accretion at the harbor entrance is decreasing. At the south, due to the geometry of the barrier, the mitigation effect is imperfect, and further extension of the barrier is deemed necessary.

### 3.0 CONCLUDING DISCUSSION

Prototype experiments on the rip currents and sediment transport at two fishery harbors on the Kujukuri coast, Japan, were conducted to test the effect of rip current barriers for mitigating shoaling. Rip currents are always induced along shore-normal structures, and they carry sediment offshore to form rip head bars as well as deposit sediment inside harbors to cause harbor shoaling.

To mitigate harbor shoaling and sediment loss offshore, some control of rip currents is needed. A rip current barrier is defined as a shore-parallel structure that blocks the path of a rip current. It reduces the current velocity and turns the current direction shoreward to form a forced cellular circulation (Fig. 1b).

Field observations of the breakwater-induced rip currents at Taito Fishery Harbor under conditions of a 3 m breaker height suggest that if the barrier is outside the surf zone, it will be effective in blocking rip currents (Fig. 7). Field observations of induced-rip currents and sediment transport without a rip current barrier and of rip currents with a rip current barrier carried out at Katagai Fishery Harbor suggest that the rip current barrier is effective only under moderate wave conditions. Rip head bars under storm conditions were still formed after the rip current barrier construction.

A rip current barrier can be regarded as a cost-effective solution to mitigate harbor shoaling; however, to make it a final solution, deeper and longer structures to act as a total sand trap are required. The minimum length of a proposed rip current barrier should be greater than the radius of the induced design nearshore circulation cells, that is, approximately the surf zone width. In the case of Katagai Fishery Harbor, rip current barriers would be effective under wave conditions of 2 - 3 m breaker wave heights, which at this beach correspond to a 200 to 300-m surf zone width.

Fig. 16 Rip current barriers at Katagai Fishery Harbor. Arrows show measured rip currents.

Fig. 17 Flow field derived from dye dispersion.

Fig. 18 Comparison of bottom contours before and after rip current barrier construction.

Because the Kujukuri coast has an exceptionally gentle beach slope, it would be very expensive to build barriers extending to the deep offshore. For such situations, an "island-type" fishery harbor has been proposed, where the harbor is located far offshore like an island and connected to the mainland by a bridge (Sakai, 1984). However, rip current barriers are feasible on moderately sloped or steep beaches.

#### 4.0 ACKNOWLEDGEMENTS

This study was performed as part of a contract with the Chiba Prefectural Government. The authors acknowledge permission to publish given by the Fishery Harbor Division, Fishery Department of Choshi Fishery Harbor Office of Chiba Prefecture, and T. Sugawara, Chief of the Second Fishery Engineering Laboratory, Agricultural Engineering Research Station, Ministry of Agriculture, Forestry and Fishery. Also thanks are due to proofreading by Dr. N.C. Kraus of the Nearshore Environment Research Center, Tokyo.

The findings in the present paper are not to be construed as an official Chiba prefectural government position.

## CHAPTER ONE HUNDRED FORTY ONE

### SHORELINE CHANGE AT OARAI BEACH: PAST, PRESENT AND FUTURE

Nicholas C. Kraus<sup>1</sup>, Hans Hanson<sup>2</sup> and Soichi Harikai<sup>3</sup>

#### ABSTRACT

Large breakwaters and groins are being constructed at Oarai Harbor, Japan. As a result the beach is significantly deforming. The first part of this paper documents past and recent shoreline change at Oarai. The general characteristics of the offshore waves, breaking waves, and longshore current pattern are described and used to explain qualitative features of the observed shoreline change. The second part presents results of numerical simulations of shoreline change at the site which occurred over different time periods. The model includes three sources of wave diffraction, a rigorous formulation of the seawall boundary condition, and sand bypassing at groins. The modeling of historical shoreline change was reasonably successful. As an exercise in investigating problems associated with prediction, the model was used to forecast the shoreline position at the site five years from now. The prediction of the wave history was the main problem encountered. A simple intuitive method was devised to estimate the probable range in variation of the wave history, and the results are discussed in connection with the shoreline forecast.

#### 1. INTRODUCTION

Since 1977, the fishing harbor at Oarai, Ibaraki Prefecture, Japan, has been undergoing expansion for conversion to a ferry and cargo port, to be completed around 1990. Figure 1 shows past and planned construction. Extension of the harbor breakwater and construction of the large detached breakwater for improvement of navigation have resulted in considerable changes along the sandy beach to the south.

  2. Lecturer, Department of Water Resources Engineering, Univ. of Lund, Fack 725, Lund S-220-07, Sweden.
  3. Research Engineer, INA Civil Engineering Consultants Co., Ltd., 22-1 Suido-cho, Shinjuku-ku, Tokyo 162, Japan.

Oarai Harbor suffers from chronic and troublesome accretion of sediment. To describe it, we can do no better than to quote from an article by Hiroi (1921): "A small harbor at Isohama (presently Oarai), in Ibaraki Prefecture, built in 1911 - 1916, is an instance of failure to keep off the inroad of drifting sands. The breakwaters (see Fig. 1 here), when built, had enclosed a water surface of about 30 acres, nearly all of which is now dry ground. The entrance, which is 240 ft in width, had a depth of 13 ft at the low water of ordinary spring tide. The prevailing winds are from NE, raising waves which cause the travel of sand and shingle along the beach lying to the east of the harbor. Accumulation of the sand began to take place as the breakwaters progressed, and by the time the latter were completed, nearly 370,000 cu. yds. of sand were found deposited in the harbor, which makes the yearly inroad of sand 74,000 cu. yds. The harbor has since been entirely invested by sand . . ."

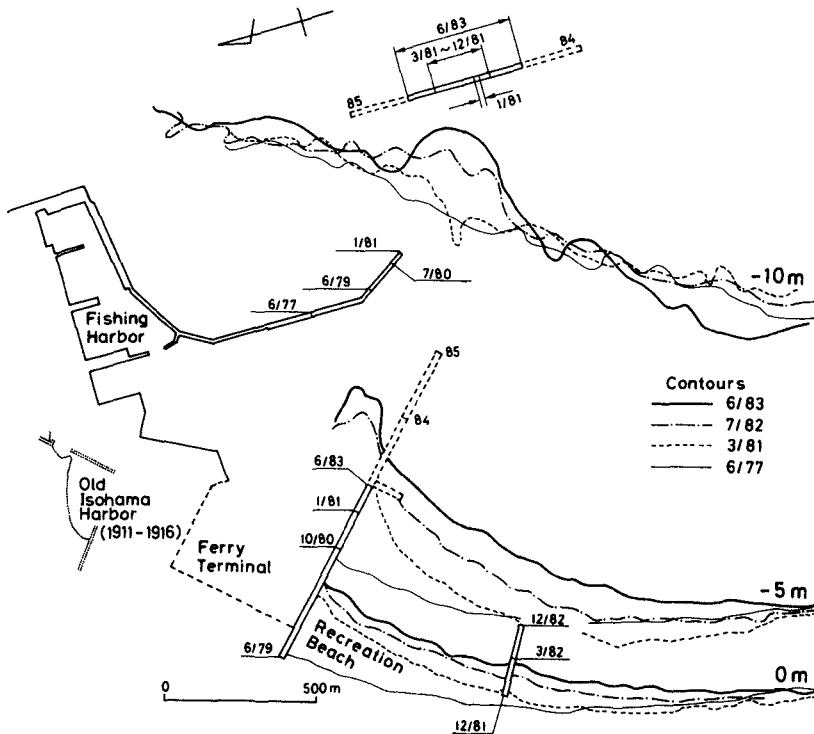

Fig. 1 Construction and contour change at Oarai.

In modern times, prior to construction of the detached breakwater and short groin, long-term sediment-related problems took the form of harbor shoaling and rapid shoreline advance at the long groin, together with erosion along the beach 1 to 3 km to the south of the harbor. Construction of the detached breakwater and short groin (Fig. 2) appear to have had a positive effect in reducing the rate of shoreline advance near the long groin. An apparent negative effect has been the gradual movement of the area of maximum erosion further south. The area of maximum erosion is presently located about 3 km to the south of the long groin, along what had once been a fairly wide sandy beach. The beach within 5 km to the south of the harbor contains two large seawalls (north seawall, approx. 1.5 km long; south seawall, 800 m long), two large impermeable groins, and numerous groups of armor blocks positioned in rows along the beach to provide shore protection and footing protection for the seawalls.

Fig. 2 Oarai harbor and the beach to the south.

The present paper, a continuation of the study of Kraus & Harikai (1983), consists of two parts. The first part presents a case study documenting the wave climate, currents, and past and present shoreline positions. The general features of the long-term shoreline change are then related to construction of the harbor breakwaters and groins. The second part presents results of simulations of the shoreline change.

## 2. CASE STUDY

### 2.1 Background

Oarai Harbor lies on a north-south-oriented coast about 150 km north of Tokyo. The area has served fishermen since ancient times owing to the shelter given by the rocky Oarai Headland against the predominant NE and ENE incident waves. The harbor has a long history of sediment shoaling. Hiroi (1921) and Ijima et al. (1961) report the complete burial of early harbor structures shortly after their construction in 1916 (Fig. 1). Using radioactive tracers, Ijima et al. (1961) found that a large portion of the infiltrating sand comes from the discharge of the Naka River, 2 km to the north. Through a series of hydraulic model experiments, Arakida et al. (1978) concluded that sand is also transported north toward the harbor due to the circulation cell produced by diffraction at the harbor breakwater tip (see also Mizumura, 1982).

### 2.2 Waves

The Oarai Harbor Management Office operates an ultrasonic wave gage and a strain gage, located at a depth of 20 m and connected to shore by cable. The strain gage, which measures the wave direction, does not function if the significant wave height falls below about 40 cm. Statistics for 100 waves are computed and recorded automatically at 2-hr intervals. Figure 3 gives a histogram plot of the frequencies of the significant wave height, direction, and energy flux for a 4-yr period.

Fig. 3 Wave height, direction, and energy flux ( $EC_g$ ).

A wave data set covering four years at 6-hr intervals was formed from the records. This data set, termed the RDS (Raw Data Set) consists of triplets of values of the significant wave height, direction, and period ( $H$ ,  $\theta$ ,  $T$ ). The RDS contains gaps due to instrument down-time and limitations of the strain gage. For the numerical modeling, a data set without gaps was required. This data set, termed the CDS (Complete Data Set) was fabricated by first separating the available data from the RDS by month, giving four sets of 120 triplets, including blanks, for a 30-day month. Values were then randomly selected from the triplets available in the four sets for each month, and the gaps filled. The random selection and placement was done by computer and the results slightly 'cleaned' by hand. The respective distributions of  $H$ ,  $\theta$ , and  $T$  of the CDS closely approximate those of the RDS.

As part of the NERC project (Horikawa and Hattori, 1984), the breaking wave height was measured at five locations alongshore (circled Nos. 1-5 in Fig. 2). Measurements were made weekly for periods of about 30 months (Nos. 1, 2, 3) and 18 months (Nos. 4, 5) between May 1980 and Dec. 1982. The significant breaking wave height,  $H_b$ , was measured by sighting over a graduated staff placed at the mean water shoreline; the average of ten of the higher waves was used. The frequency distributions of the average long-term breaking wave height at the five stations is shown in Fig. 4. The frequency of smaller wave heights increases with approach to the long groin, i.e., with penetration into the wave shadow zone produced by the headland and harbor structures.

Fig. 4 Frequency distributions of significant breaking wave height alongshore (locations given in Fig. 2).

Fig. 5 Frequency distributions of longshore current magnitude alongshore.

### 2.3 Longshore Current and Sand Movement

The direction and speed of the longshore current were measured with floats, performed together with measurement of the breaking wave height. The frequencies according to direction are shown in Fig. 5. The longshore current is directed more often to the north than to the south and this tendency increases with approach to the long groin.

Waves incident at the site, arriving mainly from the northern sector, should produce a current moving to the south. The observed northward-moving longshore current is evidence of the large circulation cell produced by the headland and harbor structures. At some location near the edge of the diffraction shadow zone on the beach, the current reverses direction: at this location the beach will erode. The area of erosion is expected to move south with enlargement of the shadow zone due to extension of the detached breakwater. The northward-moving longshore current weakens deep inside the shadow zone, and sand is deposited there.

### 2.4 Shoreline Change

Shoreline positions on survey charts were digitized at 25-m intervals for plotting, analysis, and use in the shoreline simulations. The shoreline positions measured in summer and winter surveys are displayed in Figs. 6a & b. It is seen the shoreline near the long groin has steadily advanced, independent of season, if the interval of one year is selected as the time scale. Figure 6c shows the shoreline position during the four seasons of 1982. Although a general trend for accretion near the long groin is observed, the pattern of shoreline change is masked by short-term fluctuations such as those caused by sequences of storms and calm weather, and by changes in wave direction.

From Figs. 6a & b, it is seen that the north seawall served an important function in protecting the residential area behind it during the 1970's. With construction of the long groin (which blocks the northward-moving littoral drift) and extension of the harbor breakwater and detached breakwater (which increases the area of the diffraction zone where sand will be deposited), an expansive sandy beach has formed in front of the seawall. In contrast, on a recent inspection of the site in April 1984, the beach approximately 3 km south of the long groin was found to be severely eroding. Rubble mound blocks and the 800-m long south seawall in this area were being undercut and flanked.

Figure 7 plots the mean rate of change of the shoreline position for surveys taken before and after start of construction of the detached breakwater, based on 17 and 13 surveys, respectively. After start of construction, the rate of shoreline advance decreased by 50% near the long groin; the rate of advance increased somewhat in the region 1-2 km from the groin, and the formerly stable section of beach roughly centered at the 3-km mark began to erode (necessitating wider coverage in the shoreline surveys). The reduced rate of increase near the long groin is attributed to the low waves (weak longshore current) in this area deep in the shadow of the harbor breakwaters and to reduction of transport onshore through trapping by the detached breakwater. Trapping seems apparent, as judged by the change in 10-m contours in Fig. 1.

Fig. 7 Measured mean rate of shoreline change for periods before and after construction of the detached breakwater.

### 3. NUMERICAL MODEL

#### 3.1 Background

The 1-line (shoreline) numerical model was used to simulate changes in the beach planform at Oarai. The purpose of the 1-line model is to reproduce the large-scale features of shoreline change that take place over a relatively long period. The temporal and spatial scales of the major types of beach change numerical models are discussed by Kraus (1983). In the present case, application of the 1-line model for periods of several months to several years is justified by the clear trend in shoreline movement shown in Figs. 6a & b.

The basic model used is that of Kraus and Harikai (1983), who modeled shoreline evolution at the site for the period between 1977 and 1980. A number of refinements to and extensions of the model were made for carrying out the present study. We plan to present a description of the numerical model in another paper. Here we simply list the major improvements and changes: (1) The calculation procedure for the breaking wave height and angle alongshore was refined (Kraus, 1983, 1984) and extended to account for three sources of diffraction -- at the tip of the harbor breakwater and at both tips of the detached breakwater. (2) A seawall boundary condition which conserves sand volume and preserves transport direction was incorporated (Hanson and Kraus, in press). (3) The angle of the groins to the shoreline was taken into account (Perlin and Dean, 1978), and a simple prescription was introduced to permit sand bypassing at the groins. The changes in the model necessitated recalibration and verification.

#### 3.2 Shoreline Model

The governing equation for the shoreline position  $y$  is given by

$$\frac{\partial y}{\partial t} + \frac{1}{D} \left( \frac{\partial Q}{\partial x} \mp q \right) = 0 \quad (1)$$

in which  $x$  is the longshore coordinate,  $t$  is the time,  $D$  is the depth of closure (beyond which the profile is assumed not to move),  $Q$  is the longshore sand transport rate, and  $q$  is the cross-shore transport rate onshore (-) or offshore (+). The predictive expression for the longshore transport rate is taken as

$$Q = \frac{H_b^2 C_{gb}}{16(\rho_s/\rho - 1)(1-p)} \left( K_1 \sin 2 \theta_{bs} - 2K_2 \frac{\partial H_b}{\partial x} \cot \beta \cos \theta_{bs} \right) \quad (2)$$

in which  $C_{gb}$  is the wave group velocity at the breaker line,  $\rho_s$  ( $\rho$ ) is the sand (water) density,  $p$  is the sand porosity,  $\theta_{bs}$  is the angle of the breaking wave crests to the shoreline and  $\tan \beta$  is the beach slope. The coefficients  $K_1$  and  $K_2$  are treated as parameters in calibration of the model.

The first term in Eq. (2) corresponds to the CERC formula (CERC, Chap. 4, 1977) and describes the sand transport due to obliquely incident waves. The second term describes the transport due to a systematic variation in wave height alongshore. The second term has been found to be of importance for describing the shoreline change near structures, where diffraction dominates (Ozasa and Brampton, 1980; Kraus and Harikai, 1983; Mimura et al., 1983; Kraus, 1983). Gourlay (1982) gives a review of various derivations of Eq. (2).

The Shore Protection Manual (CERC, 1977, Chap. 4) recommends a value equivalent to  $K_1 = 0.77$  for root-mean-square height. Several theoretical evaluations of  $K_2$  have been given, resulting in different values, depending on the assumptions made (Gourlay, 1982). Experience of the authors in shoreline modeling, results of the NERC tracer experiments (Kraus et al., 1982), and other reports (Gourlay, 1982) indicate that  $K_1$  is more likely to be in the range 0.1 to 0.6.

Considering the uncertainty in the values of  $K_1$  and  $K_2$  and the multitude of approximations and simplifications in the model, it is appropriate to treat  $K_1$  and  $K_2$  as site-specific parameters to be determined by calibration. Modeling experience indicates that the ratio  $K_2/K_1$  lies in the range 0.5 to 1.5. The parameter  $K_1$  acts principally as a time scale adjustment factor. The parameter  $K_2$  controls the relative strength of the two terms in Eq. 2.

The depth of closure  $D$  in Eq. (1) also acts to adjust the time scale of shoreline movement. This characteristic depth in the model is related to the width of the beach through which sand is transported alongshore. Hallermeier (1983) has given expressions for calculating the depth of the seaward boundary where significant longshore transport and intense on-offshore transport take place. The simplest version has been found suitable for use with the shoreline model (Kraus and Harikai, 1983). It is

$$\frac{D}{H_s} = 2.28 - 10.9 \frac{H_s}{L_s} \quad (3)$$

in which  $H_s$  and  $L_s$  are the significant wave height and wavelength of waves in the shoaling zone, here assumed to be equivalent to those of the deepwater wave. In the simulations,  $D$  is recalculated at each change in the wave input.

The cross-shore transport rate,  $q$ , is the final quantity remaining to be specified before calculations can begin. Unlike the longshore transport rate, there are no predictive expressions available. Reflecting this situation, there have been only a few attempts to model shoreline change including cross-shore transport (Komar, 1973; Ozasa and Brampton, 1980; Kraus and Harikai, 1983). In the present case, we are faced with the need to account for the sand that moves around the harbor breakwater from the north. The amount, its time dependence, and its distribution are complicated functions of the discharge at the Naka River, wave conditions, and stage of construction of the detached breakwater. We described the onshore transport with the following convenient utilitarian expression:

$$q = q_0 / (1 + ((x - 2 \cdot x_0) / x_0)^{p_0}) \quad (4)$$

in which  $q_0$  (units:  $m^3/s-m$  alongshore) is used as a fitting parameter together with  $K_1$  and  $K_2$ .

### 3.3 Breaking Wave Model

The wave model for one diffraction source has already been described (Kraus, 1983, 1984). The introduction of three sources required additional assumptions to define the local breaking wave direction and wave height; we plan to present the procedure elsewhere. In essence, the wave model consists of solving the following equation:

$$\frac{H_b}{h_b} = \frac{K_D K_R K_S}{h_b} H_{tip} = \gamma \quad (5)$$

in which  $h_b$  is the depth at breaking,  $K_D$ ,  $K_R$ , and  $K_S$  are respectively diffraction, refraction, and shoaling coefficients for linear waves,  $H_{tip}$  is the incident wave height at the tip of the structure and  $\gamma$  is a breaking wave index. A multiple iteration is performed over  $h_b$  and either one or two angles entering in  $K_D$  and  $K_R$ , depending on the level of approximation desired and run time considerations. At convergence, both the breaking wave height and angle are determined at a given point alongshore. The model was favorably compared with laboratory measurements and with measurements made at Oarai prior to construction of the detached breakwater (Kraus, 1983, 1984).

## 4. RESULTS OF SHORELINE SIMULATION

### 4.1 Recalibration of the 1-Diffraction Source Model

In order to examine the extent to which the various refinements altered the model, the model was recalibrated for the same period used by Kraus & Harikai (1983) (11 Jul 79 - 21 Feb 80) and with the same wave conditions. Best results were obtained with values of the transport parameters ( $K_1$ ,  $K_2$ ,  $q_0$ ) of (0.1, 0.1,  $4.0 \cdot 10^{-6} m^3/s-m$ ) as opposed to the previously determined values of (0.3, 0.4,  $2.5 \cdot 10^{-6} m^3/s-m$ ). The reduction in  $K_1$  and  $K_2$  is mainly due to (1) the improved calculation of the breaking wave angle, which causes an increase in magnitude of the angle (an increase in  $\theta_{bs}$  requires a decrease in  $K_1$  to maintain the same time scale) and (2) the improved, volume-conserving seawall boundary condition. The results of this exercise demonstrate the fact that the transport parameters depend on the model used as well as on the characteristics of the particular site.

#### 4.2 Calibration & Verification of the 3-Diffraction Source Model

For modeling periods after start of construction of the detached breakwater (Jan. 81), three sources of wave diffraction had to be used. Also, it was found during calibration runs that the distribution of onshore transport,  $q(x)$ , appeared to have a different character than for the pre-1981 period. Inspection of the outputs of many runs with different combinations of transport parameters indicated a visual best fit with  $K_1 = K_2 = 0.1$ ,  $q_0 = 4.5 \cdot 10^{-6}$   $m^3/s\text{-m}$ , and  $x_0 = 300$  m,  $p_0 = 4$ .

Verification runs with these and other values were made for the 2 1/4-year period from 11 Mar 81 to 15 Jun 83. Figure 8 shows results for the final shoreline position obtained with the calibrated model, together with the shorelines computed using other values of the transport coefficients. The simulated final shoreline obtained with the calibrated model agrees well with the actual shoreline up to 2 km from the long groin, but it shows too much advance along the beach 2 to 4 km from the long groin. The results of the calibrated model are far superior to those obtained using the other values of the transport coefficients.

Fig. 8 Measured and calculated shoreline change for the verification interval.

The calculated mean rate of shoreline change along the beach is shown in Fig. 9. It can be compared with the measured rate for the same period, the solid curve in Fig. 7. The rate of shoreline change up to 1 km from the long groin is well reproduced. However, the location of the calculated maximum rate of erosion is at about the 1.5-km point, instead of at 3 km, and the calculation gives an essentially stable shoreline from about the 3-km point. The lack of agreement suggests the need to use a more sophisticated refraction routine for the irregular bottom topography for the region far from the harbor structures, where diffraction is no longer the dominant wave transformation.

Fig. 9 Calculated mean rate of shoreline change for the verification interval 11 Mar 81 - 15 Jun 83.

Figure 10 compares calculated shoreline positions using the calibrated model and different averaging intervals of the wave input over the verification period (energy flux-weighted averages at the gage). In general, for the region near the long groin, the agreement deteriorates with increase in the averaging interval defining the representative wave conditions. The calculated shoreline in the region distant from the groin appears to be governed by the location of the eroded sector, which, in turn, is produced by the relatively fixed distribution of the breaking wave angle alongshore. Although recalibration of the model for a given averaging interval may improve the result somewhat, because of the sensitivity of the wave calculation to the incident wave angle, the result is expected to be inferior to that obtained by updating the wave information at simulated 6-hr intervals (cf., Le Mehaute et al., 1983, Kraus & Harikal, 1983).

Fig. 10 Shoreline change calculated by using different time-averaged wave inputs for the verification period.

### 4.3 Forecast Shoreline Change

Although the verification simulation had a mixed outcome of success, it was decided to use the model to predict future shoreline change as an exercise for investigating problems associated with forecast-type simulations. Engineering-oriented forecasts of shoreline change cannot be found in the open literature, probably because of the legal aspects involved. The main technical problem is the treatment of the wave input, i.e., how the time history of the waves should be forecast.

In the present work, two additional problems emerged. First, due to active construction at the site, the construction schedule and structure positions had to be estimated for automatic update in the model. (These affect the location of the diffraction sources and bypassing at the groins.) The second problem concerned the possible trapping function of the detached breakwater of sediment that would normally move south around the harbor breakwater and then onshore. We speculate that the detached breakwater traps most of this sediment. To investigate the potential trapping function,  $q_0$  was varied in different series of forecast runs.

Treatment of the the wave time history in shoreline numerical modeling has been considered by Le Mehaute, Wang & Lu (1983) and Kraus & Harikai (1983). In the former study it was demonstrated that the results of shoreline modeling depend on both the interval at which the wave data are input and the order of the input. In the latter study it was shown that time averaging of the wave data for Oarai for intervals greater than about 5 days gave rather poor results. The acceptable interval for updating wave information in a model will depend on the steadiness of the waves at the site in question, in particular, for wave direction.

In forecasting shoreline change, the assumption is made that the time sequence of wave events and the wave conditions in the future will have much the same character as in the past. It is valuable to have a long wave record with which to accurately describe the average and time-varying wave conditions. One must also keep in mind possible long-term cycles in the wave climate (e.g., Kuhn and Shepard, 1983), as well as infrequent extreme events.

Noting that the exact time history of wave events is not predictable, Le Mehaute et al. (1983) introduced a Monte Carlo procedure to provide measures for the possible deviation. Their approach is a sound conceptual solution to the problem. However, our experience gives us the impression that direct application of the Monte Carlo method might yield a range of shoreline change which is too narrow.

Basically, we would like to estimate the maximum range of shoreline movement resulting from wave histories which do not differ "too greatly" from the past time history. The "not too great" differences should incorporate variations in both wave conditions (energy flux) and sequence of wave events. In other words, how can we estimate limits of variations in the future wave data set? We took the direct approach of manipulating the individual distributions of wave height and direction, while leaving the period distribution unchanged for simplicity.

For a simple estimation of the limits of the maximum range of deviation of the forecast waves, it was assumed that wave height and direction distributions would be shifted by a certain amount from the past distribution (given by the CDS). As a limit of the shift, we took one half of the standard deviation of the respective distributions, i.e.,  $H$  was allowed to vary between  $H \pm H_{SD}/2$ , and similarly for  $\theta$ , where the subscript SD denotes the standard deviation. This procedure provides deviations in the energy flux. To estimate the effect of sequencing, the CDS was ordered with respect to increasing and decreasing  $H$  and  $\theta$ . In all data sets generated, only one quantity was manipulated and the other two quantities were left unchanged to form a new triplet of values of  $H$ ,  $\theta$ , and  $T$  at 6-hr intervals.

The transport parameters  $K_1$  and  $K_2$  were held at 0.1 as determined in the calibration, but  $q_0$  was varied to produce different series of runs. The resultant shorelines for the 5-yr forecast period using  $q_0 = 2.0 \cdot 10^{-6}$  are shown in Fig. 11. The heavy line denoted by  $H$ ,  $\theta$ ,  $T$  gives the result using the CDS. The greatest deviation from the CDS prediction occurs for the runs with  $H \pm H_{SD}/2$ , corresponding to severe and mild wave conditions, respectively (neglecting the correlation with wave period and direction). All runs gave a shoreline advance near the groin. The amount of advance is less than that which occurred over recent 5-yr periods. Except for the run with decreasing  $\theta$ , all runs produced an eroded beach starting from about 2 km from the long groin. Other series with different  $q_0$  had much the same qualitative features.

Fig. 11 Results of shoreline forecast simulations.

The forecast shoreline changes both near and far away from the long groin are in general agreement with recently observed trends at the site. However, the inability to predict the time-dependent behavior of  $q_0$  introduces a great uncertainty into the forecast, and the results should be interpreted appropriately in light of that uncertainty.

## 5. CONCLUDING DISCUSSION

The large harbor breakwaters being built at Oarai for the purpose of improving navigation exert a great effect on the near and distant sandy beach. The observed shoreline change can be well understood on the basis of long-term measurements of the waves and currents. The 1-line numerical model was reasonably successful in simulating the observed shoreline change in spite of the complications of multi-sources of wave diffraction, the wide area of coverage including a seawall and two groins, and problems with estimating onshore sand transport. The forecast shoreline change for the next five years was in general agreement with the present trend in evolution of the shoreline.

In order to make more accurate predictions of shoreline change for Oarai, the following four topics should be addressed. (1) The necessity of including a 2-dimensional refraction routine for the region far from the long groin should be investigated. (2) The south seawall should be included in the model and the model range should be extended well past the south seawall. (3) The trapping efficiency of the detached breakwater should be empirically estimated (as from bottom surveys, and possibly tracer experiments). (4) The expected limits of variation of the wave time history should be more objectively determined from the statistical properties of the CDS, and the joint probability distribution of wave height, direction, and period should be utilized.

## ACKNOWLEDGMENTS

We would like to express our deep appreciation to the staff of the Oarai Harbor Management Office for making available the wave and shoreline data, and for kindly providing other information and assistance. We would also like to thank Prof. M. Hom-ma, Director of NERC, for bringing the interesting article of Hiroi to our attention. Finally, NCK would like to thank Prof. M. Hattori of Chuo University for arranging a hospitable 2-month stay at his institution, during which time this paper was completed.

## CHAPTER ONE HUNDRED FORTY TWO

### MECHANISM OF BEACH PROFILE DEFORMATION DUE TO ON-OFFSHORE SAND DRIFT

BY

Wi-Gwang Pae<sup>1)</sup> and Yuichi Iwagaki M. ASCE<sup>2)</sup>

#### ABSTRACT

In the present study, two-dimensional laboratory experiments were performed to investigate the sediment transport due to waves on a fixed sloping beach. Polystyrene particles and glass balls were used as tracers to determine the mass transport velocity near the bottom and the net transport velocity of sediment moving on an impermeable slope. Relationships between the mass transport velocity of water and the net sediment transport velocity are investigated experimentally. The mechanism of two-dimensional beach deformation from an initial uniform slope toward an equilibrium profile due to bed-load movement is discussed on the basis of spatial distributions of the net sediment transport velocity. In addition, some results of experiments using a movable bed are presented to confirm the validity of a beach deformation model derived from the discussion of the tracer experiments.

#### 1. INTRODUCTION

Hydraulic characteristics in the on-offshore direction on a beach are very complicated; fluid forces which cause sediments to move vary with time, and the direction of the net transport velocity of water (mass transport velocity) is spatially changed. Moreover, the value of the mass transport velocity is dependent upon both space and time. Owing to these complexities in the hydraulic characteristics on the beach, the mechanism of sediment transport in the on-offshore direction due to waves is not so easy to understand as that in the longshore direction.

In general, the beach profile deformation is caused by the spatial difference of the net transport rate of the bottom sediment. When the net transport rate of the bottom sediment is spatially uniform, the bottom configuration does not change even if the instantaneous velocity of water particles is large. In this study, a model of the beach profile

1) M. Eng., Postgraduate, Dept. of Civil Eng., Kyoto University, Kyoto 606, Japan

2) Dr. Eng., Professor, Dept. of Civil Eng., Kyoto University, Kyoto 606 Japan

deformation is presented on the basis of the spatial distribution of the net transport velocity of bottom sediments.

Stokes (1847) is the first one who pointed out that a steady second order drift velocity (mass transport velocity) exists in an inviscid irrotational wave field. Longuet-Higgins (1953) treated the problem on the mass transport in a finite-length channel with due consideration of fluid viscosity. In his solution, the whole flow field was divided into three regions; the interior, the surface, and the bottom boundary layers. The boundary conditions are no-slip at the bottom, zero-stress on the surface, and zero net mass transport in the whole field. In the bottom boundary layer, the mass transport velocity is given as the sum of both the second order Eulerian mass transport velocity and the Lagrangian drift resulting from the first order irrotational motion inside the boundary layer. In the interior region, the mass transport velocity is derived by using the classical matching principles of standard boundary layer problem; that is, the limit value of the boundary layer solution equals the boundary value of the interior solution.

The mass transport velocity on a sloping beach is considered to play an important role in the transport of bottom sediments. Rijker, Kalkwijk and Pieters (1974) modified Longuet-Higgins' solution in the uniform depth by incorporating the shoaling effect. The theoretical values, however, are found to be considerably larger than those obtained in their experiments. Wang, Sunamura and Hwang (1982) investigated the drift velocity at the breaking point under different types of breaking waves on a rigid, plane beach. According to their results, independently of breaker types, the drift velocity profile at the breaking point is similar to that of Longuet-Higgins, but the offshore drift velocity in the main flow column shows a more uniform vertical distribution than that in the offshore region. Iwagaki, Pae and Moriguchi (1982) investigated the net transport velocity of solid particles on a smooth sloping beach to determine the relationship between the mass transport velocity of water and the net transport velocity of bottom sediments. Their experimental results show that there are distinct correlations between the net transport velocities of glass balls and of polystyrene particles for the regions shoreward and seaward of the breaking point.

## 2. EXPERIMENTAL APPARATUS AND PROCEDURE

### 2.1 Experimental Apparatus

The wave tank used is 30 m long, 50 cm wide, and 75 cm deep. One side of the wave tank has a glass wall 15 m in length. A rigid impermeable bottom of two different surface conditions, smooth and rough, was used. The slope of beach was 1/20 only. In case of the rough slope, the surface was uniformly roughened with spherical particles of 3 mm in diameter. The wave height was measured by using two wave gauges of capacitance type. One wave gauge was installed at a location in the region of uniform water depth to measure incident waves. The other gauge

was installed at a point on the slope where two holes were opened to feed solid tracer particles slowly onto the bottom.

Polystyrene particles and glass balls with four different diameters were used as tracers. The properties of these particles are shown in Table 1. Polystyrene particles with a diameter of approximately 3 mm were coloured with paint. The glass balls were also coloured for each diameter.

Pairs of these tracer particles were simultaneously lifted up onto the sloping bottom through the two holes at a speed of 0.05 cm/sec by means of an apparatus devised by the authors. Fig. 1 shows this device of a constant speed feeder of tracer particles, which has three rods moved vertically by a small-sized variable speed motor. By the upward motion of the two short rods, tracer particles are lifted up and injected onto the bottom surface.

## 2.2 Experimental Procedure

Typical waves with three kinds of deepwater wave steepnesses were generated. Table 2 shows the characteristics of the waves and the water depth in the experiment.

Pairs of holes, through which the tracer particles were fed as mentioned before were made in the bottom plate at intervals of 40 cm in line with the direction of wave propagation. Movements of the polystyrene particles and glass balls, slowly pushed out on the bottom surface, were filmed by using a 16 mm movie camera (Bolex, H-16, EBM Electric) at a speed of about 24 frames/sec. Colour film was used to obtain informations from the coloured tracers. Trajectories of the particles moving on the bottom were traced from the film with the aid of a film motion analyzer (Motion Analyzer 160, NAC). To reduce the error caused by picture distortion, the particles were traced within the region of  $\pm 10$  cm from the center of each hole in the direction of wave propagation and within the region of  $\pm 1.5$  cm in the transverse direction. The error in reading the instantaneous location of tracers under these conditions was found to be about 3-4%. Transport distances of tracers during one wave cycle were divided by the wave period to obtain net transport velocities.

## 3. EXPERIMENTAL RESULTS AND DISCUSSIONS

### 3.1 Mass Transport Velocity on Bottom of Sloping Beach

Fig. 2 shows the mass transport velocity of polystyrene particles on the bottom of a roughened sloping beach with a nonlinear parameter of waves proposed by Goda(1983). In this figure, the dotted line denotes the theoretical values of the mass transport velocity at the edge of the bottom boundary layer by Longuet-Higgins i.e.  $(5/4)\sinh^2 kh$ . Symbols denote experimental data. A family of curves were determined by the

Fig. 2 Mass transport velocity of water on bottom of a sloping beach with a nonlinear parameter of waves proposed by Goda(1983).

method of least squares on the basis of the experimental data.

According to the paper by Goda(1983), the larger the value of the nonlinear parameter becomes, the more the nonlinearity of waves becomes remarkable. It is shown in Fig. 2 that the mass transport velocity on the bottom becomes small with an increase in the value of this parameter. In this connection, it is said that the mass transport velocity on the bottom of a sloping beach becomes small with an increase in the nonlinearity of waves.

3.2 Relationship between Mass Transport Velocity and Net Transport Velocity of Glass Balls

Figs. 3(a) and (b) show the relationships between the mass transport velocity and the net transport velocity of glass balls on a roughened beach of 1/20 slope. Assuming that the relationship is linear, it is expressed as follows:

$$(\bar{U}_b/\sqrt{gH_0})g = a(\bar{U}_b/\sqrt{gH_0})p + b \tag{1}$$

in which  $(\bar{U}_b/\sqrt{gH_0})g$  denotes the non-dimensional net transport velocity of glass balls and  $(\bar{U}_b/\sqrt{gH_0})p$  that of the polystyrene particle, and both  $a$  and  $b$  are constants. The values of  $a$  and  $b$  in case of the roughened beach of 1/20 slope are listed in Table 3 and Table 4, in which  $k_s$  denotes the roughness height (3mm), and  $D$  the diameter of a glass ball.

Table 3

Values of best-fit parameters  $a$  and  $b$  in the region of Fig. 3(a).

$k_s/D$	$a$	$b$
1.30	0.68	2.35
1.00	0.41	1.25
0.73	0.27	0.94
0.61	0.50	1.65
0.00*	0.56	0.50

Table 4

Values of best-fit parameters  $a$  and  $b$  in the region of Fig. 3(b).

$k_s/D$	$a$	$b$
1.30	1.42	0.06
1.00	0.68	0.79
0.73	0.24	0.92
0.61	0.28	0.40
0.00*	0.67	2.05

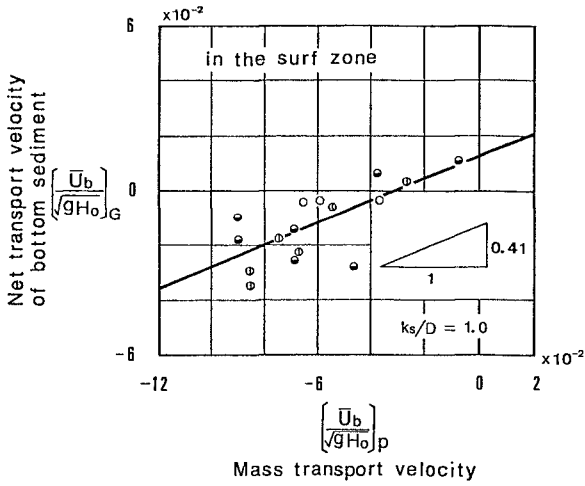

\* : Data on a smooth sloping beach.

In the region offshore from the breaking point, the value of  $a$  becomes large with an increase in  $k_s/D$ . In the surf zone,  $a$  does not change so much as in the offshore region.

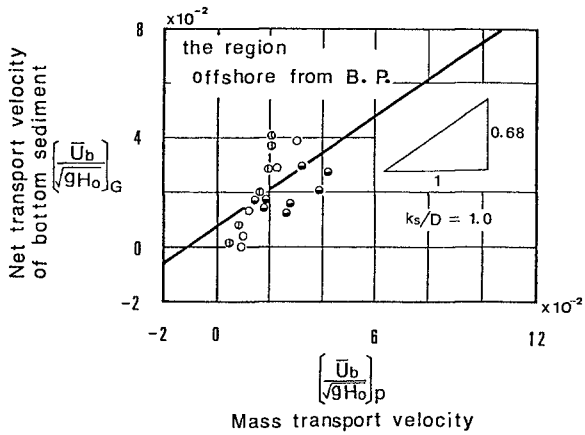

3.3 Spatial Distribution of Net Transport Velocity of Glass Balls

Figs. 4(a) and (b) show the spatial distributions of the net transport velocity of glass balls with a parameter of  $k_s/D$ . In these figures, the abscissa is the ratio of still water depth on the slope to

(a) in the surf zone

(b) in the region offshore from Breaking point

Fig. 2 Relationship between mass transport velocity and net transport velocity of glass balls ( $H_o/L_o$ :  $\circ$  0.007,  $\phi$  0.022,  $\bullet$  0.040).

that at the breaking point, and the ordinate is the non-dimensional net transport velocity of glass balls. The positive component of  $(\bar{U}_b/\sqrt{gH_0})g$  indicates the onshore transport. The data on a smooth sloping beach are plotted for reference.

From Fig. 4, it is shown that firstly, the position where  $(\bar{U}_b/\sqrt{gH_0})g$  becomes zero appears at three or four locations in case of the roughened slope, and at two locations in case of the smooth slope. Secondly, a dynamic equilibrium point near the plunging point of breaking waves where  $h/h_b$  is 0.6-1.1 appears independently of both the bottom surface condition, smooth or rough, and the bottom sediment condition, relatively large or small to the bottom roughness. Thirdly, this dynamic equilibrium position corresponds to the place where sediment accumulates because the transport direction of bottom sediments offshore from this position is onshore and that onshore from this place is offshore. Fourthly, the position where the net transport velocity becomes zero in the offshore region has a qualitative difference due to the existence of roughness. That is to say, in case of the smooth surface, this position becomes a dynamic equilibrium point which corresponds to the "Null point" defined by Cornaglia(1889), Eagleson and Dean(1961), and other investigators. However, in case of the roughened surface, this position means a static place corresponding to a critical water depth for sediment movement.

#### 3.4 Effect of Wave Steepness on Depth of Dynamic Equilibrium Point

Fig. 5 illustrates the effect of the deepwater wave steepness on the water depth in the dynamic equilibrium position. From this figure, two main points are found; the first is that the offshore equilibrium position appears in all cases of  $H_0/L_0$ , and the second is that the water depth of the offshore equilibrium position becomes shallow with a decrease in the deepwater wave steepness. On the other hand, the water depth in the onshore one is also affected by the deepwater wave steepness as well as in the offshore position.

### 4. MECHANISM OF ON-OFFSHORE SEDIMENT TRANSPORT

#### 4.1 Discussions on Mechanism of Beach Profile Change

In this section, the mechanism of on-offshore transport of sediment as bed-load by wave action is discussed on the basis of the present experimental results. In addition, an attempt is made to explain the change of beach profile obtained in the existing experiment.

Considering the specific gravity of the tracers, it may be assumed that the net transport velocity of the polystyrene particles during a wave period closely approximates the mass transport velocity of water, and that the velocity of the glass balls represents the net transport velocity of bottom sediments induced by wave action. As shown in Tables 3 and 4, there exists a clear correlation between the mass transport

Fig. 4 Spatial distribution of net transport velocity of glass balls,  $(U_b/\sqrt{gH_0})_G$  ( $ks/D$ :  $\bullet$  1.30,  $\circ$  1.00,  $\square$  0.73,  $\triangle$  0.67).

Fig. 6 Mechanism of beach profile deformation on basis of spatial distribution of net transport velocity of glass ball.

Fig. 5 Effect of deepwater wave steepness on water depth of dynamic equilibrium position ( $ks/D$ :  $\bullet$  1.30,  $\square$  1.00,  $\triangle$  0.73).

velocity of water near the bottom and the net transport velocity of the bottom sediments moving probably by rolling on a sloping bottom.

Here the mechanism of beach profile deformation is discussed on the basis of the spatial distribution of the net transport velocity of glass balls because the glass balls used in the present experiment have almost the same specific gravity as that of sand grains. Fundamental assumption in this model is that the bottom sediment is moved as bed-load.

Fig. 6 illustrates the mechanism of beach profile deformation on the basis of the spatial distribution of the net transport velocity of bottom sediments. The upper figure in Fig. 6 is the typical spatial distribution of the net transport velocity of sediments. This distribution is necessary to discuss the beach profile change, because the spatial difference of the net transport velocity of sediments causes beach profile deformation. The middle figure in Fig. 6 is the spatial distribution of the gradient of  $(\bar{U}_b/\sqrt{gH_0})g$ . This gradient is directly related to the change of bottom profile configuration. The lowest figure in Fig. 6 is the beach profile predicted by the continuity relationship between the time variation of the bottom elevation and the spatial variation of the net transport rate of bottom sediments.

From the upper and the lowest figures in Fig. 6, two points are found; the first is that the region offshore from the breaking point will be always eroded, and the second is that the offshore position of two dynamic equilibrium points represents the place where sediments accumulate. These two characteristics always appear in the beach profile evolution, independently of both the deepwater wave steepness ( $H_0/L_0$ ) and the condition of bottom sediments ( $ks/D$ ).

To elucidate the mechanism of sediment transport by wave action on a movable bed, an attempt is made to explain the process of beach profile change in model tests by considering the mass transport obtained for the spherical particles moving on a roughened slope. Beach deformation from an initial uniformly sloping beach to a final equilibrium profile can be classified into three types as shown in Fig. 7 according to Sawaragi and Deguchi (1980). In Type I, accumulation occurs in the offshore region and erosion on the beach face, so that a bar is formed. In Type II, erosion occurs on the beach face and accumulation both on the back beach and in the offshore region, but the bottom in the region deeper than the place where the accumulation occurs in the offshore region has two different profiles, either accretive or erosive. In Type III, accumulation occurs on the beach face and erosion in the offshore region, so that a step is often formed.

The behaviour of the glass balls in the present experiment may correspond to that of coarse sediment transported as bed-load. As far as the present results are concerned, accumulation takes place near the location where the value of  $h/h_b$  is 0.6-1.1, and the region offshore from the breaking point is eroded, independently of the deepwater wave steepness. Accordingly, when sediments are transported as bed-load, a uniformly sloping beach may probably change in the process of Type II-2 in Fig. 7 at the initial stage regardless of wave characteristics.

Fig. 8 Examples of beach profile deformation ( $d_{50} = 1.0$  mm, initial uniform slope:  $1/10$ ).

Fig. 7 Classification of beach process from uniformly sloping beach to equilibrium beach (Sawaragi and Deguchi, 1980).

Fig. 9 Examples of beach profile deformation ( $d_{50} = 1.0$  mm, initial uniform slope:  $1/20$ ).

On the other hand, when sediments are transported mainly in suspension, the beach profile is expected to change in the process of Type I or II-1, because the mass transport of water on a sloping beach is in the offshore direction in a middle layer above the bottom, and hence the suspended sediment is easily transported offshore. This explains the reason why fine sediments are easily transported offshore and form a large longshore bar.

#### 4.2 Some Results of Model Beach Profile Deformation

In terms of a parameter of the still water depth to deepwater wave height ratio  $h/H_0$ , the region where  $h/h_b$  is 0.6-1.1 corresponds to the region where  $h/H_0$  is 1.0-1.4.

Figs. 8 and 9 show some results of the beach profile deformation in case of initial uniform slopes 1/10 and 1/20 for each deepwater wave steepness. Sand of 1 mm in  $d_{50}$  was used in these movable bed tests in order to get the condition of bed-load movement of bottom sediments. To investigate the beach process in detail, the beach profile was measured at short time intervals.

From these results of movable bed tests under the same wave condition as in the fixed plane roughened beach, two main points are found; that is, the first is that a uniformly sloping beach with sand of relatively large diameter of 1 mm begins to change into the profile which has an accretive portion at the location where  $h/H_0$  is 1.0-1.2 at the initial stage. At the first stage toward an equilibrium state, this profile is formed in all cases, independently of both the deepwater wave steepness and the initial uniform slope. However, at the next stage, the beach profile changes under the influence of the wave steepness. The effect of the initial beach slope is seemed to be related to the speed of beach profile change, namely the deformation speed of the beach profile becomes rapid rather in case of 1/10 initial beach slope than in case of 1/20 initial beach slope. The second is that under the condition of bed-load movement of bottom sediment, in the process of the beach profile deformation the region offshore from the breaking point is always eroded independently of both  $H_0/L_0$  and the initial beach slope.

#### 4.3 Discussions on Validity of Present Model

Fig. 10 shows the system of interactions among fluid characteristics, sediment movement and bottom configuration in the beach process. Each relationship clarified mainly in the unidirectional flow is briefly described as follows: relation (1) means the effect of the fluid field on the movement of bottom material, i.e. the fluid forces acting on the bottom sediments. In case of the wave field, the representatives in the relation (1) are considered to be the bottom shear stress, the mass transport velocity of water and the turbulence intensity by wave breaking. Relation (2) shows that for example, the von Karman constant diminishes as the concentration of suspended particles increases, Hino(1963). Relation (3) is the continuity condition of bottom sediment represented by the relation between the spatial gradient

of the sediment transport rate and the time variation of the bottom elevation. Relation (4) means the effect of the gravity force on the sediment movement, that is to say, the on-offshore component of the gravity force of the bottom sediment becomes large with an increase in the slope of beach. Relation (5) shows that the fluid field is affected by the bottom configuration, i.e. the energy loss becomes different due to the bottom configuration. Relation (6) is not clear at present.

Fig. 10 System of interactions among fluid characteristics, sediment movement and bottom configuration.

From the results of the present investigation, when the sediment is transported as bed-load, the mechanism of beach profile deformation at the first stage from an initial uniform slope to an equilibrium state will be determined by the interaction between fluid characteristics and sediment movement and, therefore, can be explained on the basis of the spatial distribution of the net transport velocity of glass balls on a uniformly sloping beach.

However, at the second stage from a uniform slope to an equilibrium state, the mechanism of beach profile deformation will be governed by various interactions among fluid characteristics, sediment movement and bottom configuration.

## 5. CONCLUSIONS

In the limit of the present investigation, the following conclusions are drawn.

The mass transport velocity of water near the bottom on a roughened beach of  $1/20$  slope becomes small with an increase in the nonlinearity of waves.

The linearity between the mass transport velocity of water and the net transport velocity of bottom sediment is made clear by using tracers of polystyrene particle and glass balls.

When the sediment is transported as bed-load, the mechanism of

beach profile deformation at the first stage from a uniform slope to an equilibrium state can be predicted on the basis of the spatial distribution of the net transport velocity of glass balls.

At the second stage from a uniform slope to an equilibrium state, the mechanism of sediment transport has to be investigated on the basis of hydraulic characteristics of flow fields for the deformed bottom configuration.

Under the condition of bed-load transport of sediment, in the process of the beach profile deformation, the region offshore from the breaking point is always eroded independently of both the deepwater wave steepness and the initial slope of a beach.

## CHAPTER ONE HUNDRED FORTY THREE

### BEACH FILL BY TURNING THE COURSE OF SANDBARS

BY

Heie Focken Erchinger \*

#### ABSTRACT

The paper describes the littoral drift along the Eastfrisian Islands. The inlets between the islands are crossed by offshore bars which migrate round the deep channel of the inlet northwards on a bow. Their point of approaching the next island scatters. That causes periods of accretion during the approach of the bars on the beach and of erosion in certain beach sections without bar approach and sand supply.

When an offshore bar approaches a beach it moves a swash channel ahead as a rule. This causes a rising beach erosion by currents and wave wash and hinders the settling of the bar on that beach section. This paper reports a field study on influencing the migration of a bar by building a sand dam through such a swash channel. It was intended to feed the eroded section of the beach by the steered approach of the bar. The accretion by the desired approach of the bar on the eroded beach section was higher than expected and measured more than 270 m<sup>3</sup>/m.

#### 1.0 Introduction

On sandy coasts the littoral drift often crosses inlets as bars. Their point of approaching the beach of the next islands is important for the natural nourishment of the beach. The scattering approach causes periods of beach erosion in sections passed by offshore bars without approach. In case of severe erosion of the beach and the front dune expensive protective measures are often necessary.

In 1982 on the Isle of Langeoog, one of the Eastfrisian Islands on the German North Sea coast (Fig. 1), the winter storms effected a severe erosion of the beach and the barrier dune.

As an offshore bar was passing that section we looked for a possibility to steer the bar directly onto the beach. We imagined it could be reached by a sand dam through the swash channel as a connection from the beach to the offshore bar. That should interrupt the currents in the swash channel and influence the wave climate as a refraction groyne.

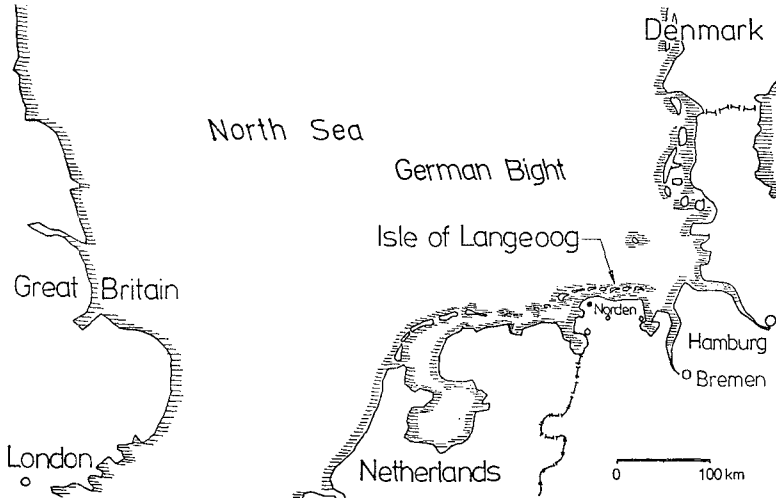

Fig. 1: The Isle of Langeoog - one of the Eastfrisian Islands on the Southern North Sea Coast -

## 2.0 LOCAL CONDITIONS

### 2.1 Littoral drift along the Eastfrisian Islands

Along the seven Eastfrisian Islands the littoral drift moves from west to east. The tidal inlets between the single islands are passed by sand bars migrating round the deep channel of the inlet northwards on a bow. When the bars leave a western island at first the influence of the strong ebb current in the deep channel of the inlet dominates and pushes them far to the north. Then the effect of the wave wash increases and moves the bars across the channel and towards the beach of the next island (Fig. 2). The point of the approaching that island depends on the inlet and sea conditions.

The migration of the bars depends on tidal currents as well as on storm conditions and wave action. In average they move about 430 m per year (6). Their volume and their point of approaching the beach is scattering (Fig. 3). As the beach is heightened and widened by

an approaching bar, the strenght of the dune-beach-system against wave action rises after the bar approach and on the further way of the littoral drift from that section (3). But on the opposite side of this section without sand supply erosion of the beach and the front dune takes place. That happened 1982 near beach profile 24 on the isle of Langeoog.

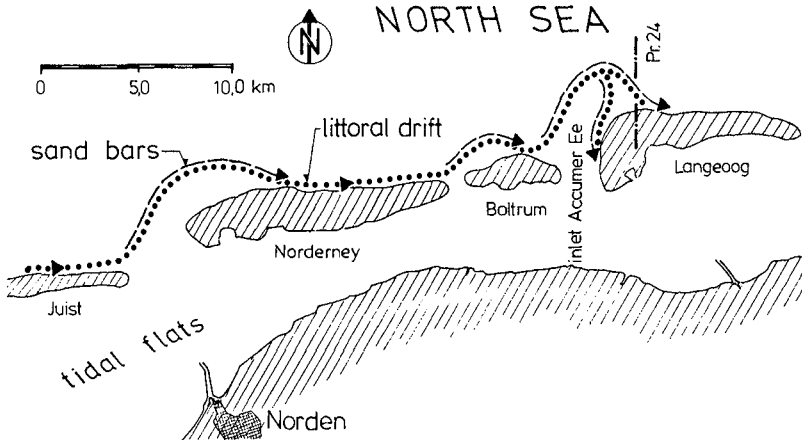

Fig. 2: Littoral drift along the Eastfrisian Islands.

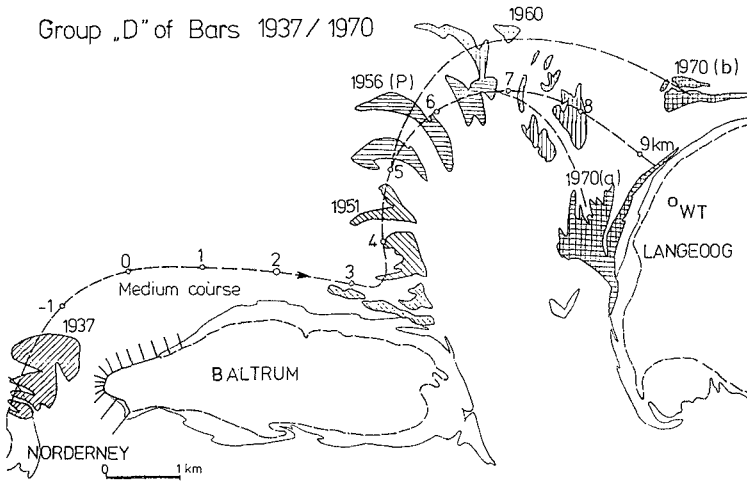

Fig. 3: Island to island migration of offshore bars and scattering of beach approach (6).

## 2.2 Beach conditions on the Isle of Langeoog

The Isle of Langeoog is a dune island with natural beaches and barrier dunes as natural protective structures against flooding the low lying land and the village during storm surges. This function of the barrier dunes is important, as the storm surge water level can increase to 3.8 m higher than MHW. The barrier dunes must be wide enough to keep a sufficient strength after very severe storm surges, when the extremely strong wave attack might have eroded a 10 to 20 m wide strip of the frontdune.

On the Isle of Langeoog the sand bars approach the beach on its west end. That normally effects an overall sand balance on this beach(7). But in spring 1982 we found the barrier dunes near the village eroded by wave attack during the winterly storm surges. The beach in front of them was steep and narrow, so further erosion had to be expected. To prevent the slight barrier dune from further erosion and from breaking through protective measures had to be carried out. Normally sand bars feed the beach, but in 1982 the bar passed the eroded beach section near Profile 24 in a distance of 350 m. Its approach could be expected in an acute angle further to the east.

The following solutions seemed to be conceivable:

- a construction of a revetment and groynes,
- an artificial beach fill,
- a nourishment of this beach-section by turning the migration of the bar directly onto the beach.

A revetment and groynes could not be taken into consideration seriously as the erosion would be temporary until the next bars approach the beach. Besides such constructions would have infavourable effects by lee-erosion and reflexion and also by disturbing the natural dune-beach-landscape and its development according to nature. Last not least they would be very expensive.

An artificial beach fill in the normal manner must include the fill of the swash channel to prevent a high rate of erosion by the rising velocity of the currents in the partly filled narrow channel. Such a fill needs 600 m<sup>3</sup>/m sand, that is a volume of 600,000 m<sup>3</sup> on the about 1 km long beach section.

As the creation of a dam through the swash channel and the fill of the backbeach was calculated only to need less than 40 % of that volume of sand it was decided to try the turning of the migration of the bar.

Fig. 4: Aerial view of the newly created connection of the offshore bar to the beach of the Isle of Langeoog by means of a sand dam.

### 3.0 SAND MOVEMENT

#### 3.1 Movement of the bar

Under wave action the sand of the bar moves on its outer slope in easterly direction and deposits at its end. During higher tide water levels another part of the eroded sand is washed across the surface of the bar by wave wash and deposits on the landward steep slope. This material might be moved further by tidal and wave currents in the swash channel mainly to the east end of the bar (1). That effects the approach of the bar in an acute angle further to the east.

#### 3.2 Currents in the swash channel

No tidal currents faster than 0.4 m/s were measured in this swash channel which is 100 m wide and 1.8 m deep at half-tide- water level.

During wave attack they would be higher and more effectively. But the currents in the swash channel hindered the deposit on the beach as the currents move the sand to the end of the bar. Therefore it should be favourable for the deposit of the bar to stop the currents in the swash channel. This could be effected by filling a dam across the channel.

During constructing the dam by hydraulic dredging the sand loss by the tidal currents had to be calculated. In the swash channel the rate of sandtransport was found as

0.1 m<sup>3</sup>/h by a current of 0.4 m/s and as  
2.2 m<sup>3</sup>/h by a current of 1.0 m/s (2,4).

These dates show, that it is possible to build the dam across the channel by hydraulic dredging with a usual capacity of the dredger pump of more than 500 m<sup>3</sup>/h.

#### 4.0 THE DAM AND ITS EFFECT

##### 4.1 Fill of the backbeach and the dam

In July 1982 the 300 m long dam was filled with 120 000 m<sup>3</sup> sand, medium grain size 0.2 mm, with a shape of a groyne (fig. 6) with a 20 m wide crest 80 cm above MHW. The dam should close up the swash channel and put an end to the currents as well as effect an influence on the wave climate by this type of a refraction groyne a discribed by FÜHRBÖTER (4) on the ICCE 1974 in Copenhagen.

But not only the dam but also the backbeach at the toe of the barrier dune was filled by 100 000 m<sup>3</sup> sand. As the approach of the bar would last a while, which depends on the storm conditions and the wave action, the backbeach was filled to prevent a rupture of the slight dune during the early winterly storm surges.

To get sand with the same grain size it was taken from the forebeach 5 m below MHW and 2.5 km to the east.

##### 4.2 Approach of the bar and the dam

During the following winter 1982/83 37 storm surges have been registered. That means more than three times the normal number of about 11 storm surges per year. During the autumn happened a severe erosion of the artificial fill of the backbeach. But during the further stormes after December accretion began and rose by the approaching bar just in the desired beach section.

Fig. 7 shows, that five months after building the dam the bar had moved 75 m right onto the beach. The dam had turned to the east round its root at the beach and still kept its function as a refraction groyne. In February 1983 after long lasting strong wave attack the bar and the dam had been deposited on the beach totally, so that

the beach has become wide and strengthened. After the winter storms the further accretion has continued, but not with such high rates as during the wave attack of the storm surges (5).

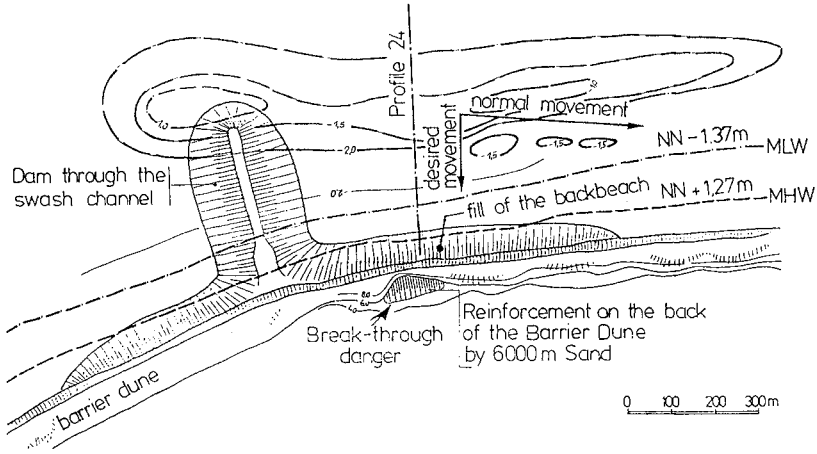

Fig. 5: Sand dam through the swash channel from the beach to the offshore bar and fill of the backbeach.

Fig. 6: Dam through the swash channel

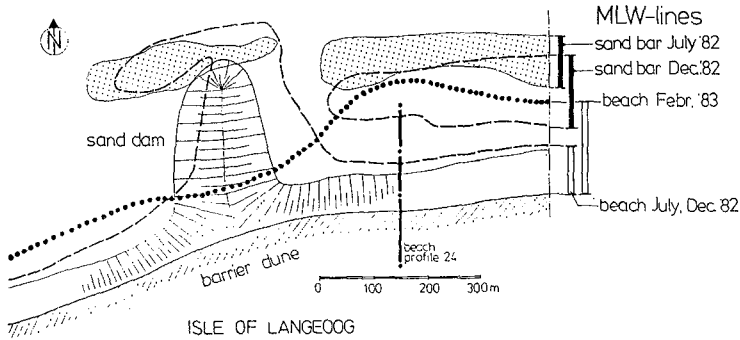

Fig. 7: Approach of the bar and accretion of the beach after steps of measurement in July 82, Dec. 82, Febr. 83.

The development of the beach was observed in beach profile 24 (Fig.8). The following dates have been registered compared with the original profile of July 1982:

	accretion (+) or erosion(-) m <sup>3</sup> /m	result m <sup>3</sup> /m
July 1982 artificial beach fill	+ 93	93
Dec. 1982 erosion of the back-beachfill	- 63	30
Febr.1983 accretion	+ 232	262
July 1983 accretion	+ 44	306

Fig. 8: Cross section of the beach and the fore beach with the approaching offshore bar after measurements in July 82, Dec. 82, Febr. 83 and July 83 in beach profile 24.

Fig. 9: Development of beach profile 24 - Erosion and, since Dec. 82, accretion of the beach by the approaching bar regarding to the original cross section -.

The accretion by the approach of the bar was higher than expected and measured more than 270 m<sup>3</sup>/m. This succes shows, that it is possible to influence the migration of the bar and to accelerate its approach by the combined effect of interrupting the currents in the swash channel and influencing the waves by a refraction groyne.

## CHAPTER ONE HUNDRED FORTY FOUR

### BEACH AND SURF ZONE EQUILIBRIA AND RESPONSE TIMES

L. D. Wright<sup>1</sup>, S. K. May<sup>2</sup>, A. D. Short<sup>3</sup>, and M. O. Green<sup>1</sup>

#### ABSTRACT

Analyses were performed on a 6½ year time series of daily wave data, daily beach state data and monthly beach and surf zone profile data. Beach state changes, which involve the relatively rapid redistribution of sediment already stored locally, are predictable in terms of Dean's (3) simple parameter  $\Omega = H_b / (w_s T)$  where  $H_b$  is breaker height,  $w_s$  is sediment fall velocity and T is wave period. Each of the six beach states has a different equilibrium range of  $\Omega$  values and the direction of change (erosion or accretion) depends on the departure from the equilibrium association. Empirical eigenvector analyses performed on the profile data permitted separation of different response components. The lower order vectors expressing the grosser aspects of the profile features such as beach volume and surf zone gradient displayed maximum variance at periods in excess of 2 years whereas much shorter response times characterized the higher order components such as bar-trough shapes and asymmetries. We infer that the fast response, and more predictable, components of beach and surf zone change largely involve smaller scale sediment exchanges between the beach and surf zone whereas the slower responses are related to larger scale exchanges between the surf zone and the inner continental shelf.

#### INTRODUCTION

Beach changes can involve changes in beach volume or beach state or both. Beach state, as used here, refers to the six common beach states (5, 6, 8, 9, 10, 11; Fig. 1). These include the reflective (steep) and dissipative (flat) extremes as well as 4 intermediate states which are (in order of decreasing surf energy): longshore bar-trough (LBT); rhythmic bar-and-beach (RBB); transverse bar-and-rip (TBR); and ridge-and-runnel/low tide terrace (LTT). Each state is dominated by a different set of hydrodynamic mechanisms. At a

Figure 1. Plan and Profile Characteristics of the Six Common Beach States.

somewhat crude, first order level beach state exhibits a reasonable degree of dependence on Dean's (3) parameter  $\Omega = H_b / (w_s T)$  where  $H_b$  is breaker height,  $T$  is wave period and  $w_s$  is sediment settling velocity (9). However, variations in  $\Omega$  can only partially explain the short term temporal variations in beach state or in beach profiles. Rates and directions of beach response are governed not only by the short-term history of  $\Omega$ , but equally by antecedent beach state. Long-term (> 1 year) cycling of sediment between the inner shelf and the surf zone add further complexity to attempts at gaining short-term predictability.

The purpose of this paper is to present the most recent results in the development of a general model for predicting short-term changes in beach and surf zone morphodynamics, emphasizing moderate to high energy natural systems. To this overall end, we have examined the equilibrium relationships between beach state and  $\Omega$ ; rates of change of both beach state and beach volume as functions of disequilibrium; and response times and frequency-response characteristics for different types and scales of change.

#### TECHNIQUES

Time series spanning 6½ years of daily wave data and beach state observations, and biweekly to monthly beach and surf zone leveling transects at 8 locations on the moderate to high energy Narrabeen Beach near Sydney in southeastern Australia, supplemented by shorter time series from other beaches, provided the basic data set of our analyses. The daily data were subjected to harmonic and spectral analyses to identify dominant response cycles. Using smoothed time series, time derivatives of  $\Omega$ , beach state and beach volume were estimated. To evaluate the degree to which beach state can be predicted in terms of  $\Omega$ , discrete discriminant analyses were performed utilizing a record of 1,545 cases. Empirical eigenvector analyses were performed on the beach profile data to characterize the time-varying profile features. Weightings on the dominant eigenvectors were subjected to spectral analyses to determine the dominant frequencies of variation of each vector.

#### SHORT-TERM CHANGES IN BEACH STATE

A 20-month section of the time series of daily significant wave height,  $H_s$ , daily estimated  $\Omega$  values, daily beach state, and subaerial beach volume,  $V_b$ , as observed on mid-Narrabeen Beach is shown in Figure 2. From Figure 2, it is apparent that wave conditions and beach state change rapidly whereas subaerial beach volume responds much more slowly. In addition, any given state can occur at any time of the year regardless of whether subaerial beach volume is normal, accreted, or eroded.

The time interval required for a full-state (i.e. one complete state) response to changing wave conditions averaged 7 days for Narrabeen Beach. Harmonic and spectral analyses show that the largest amount of beach change is associated with 'cycles' of 70 to 120 days.

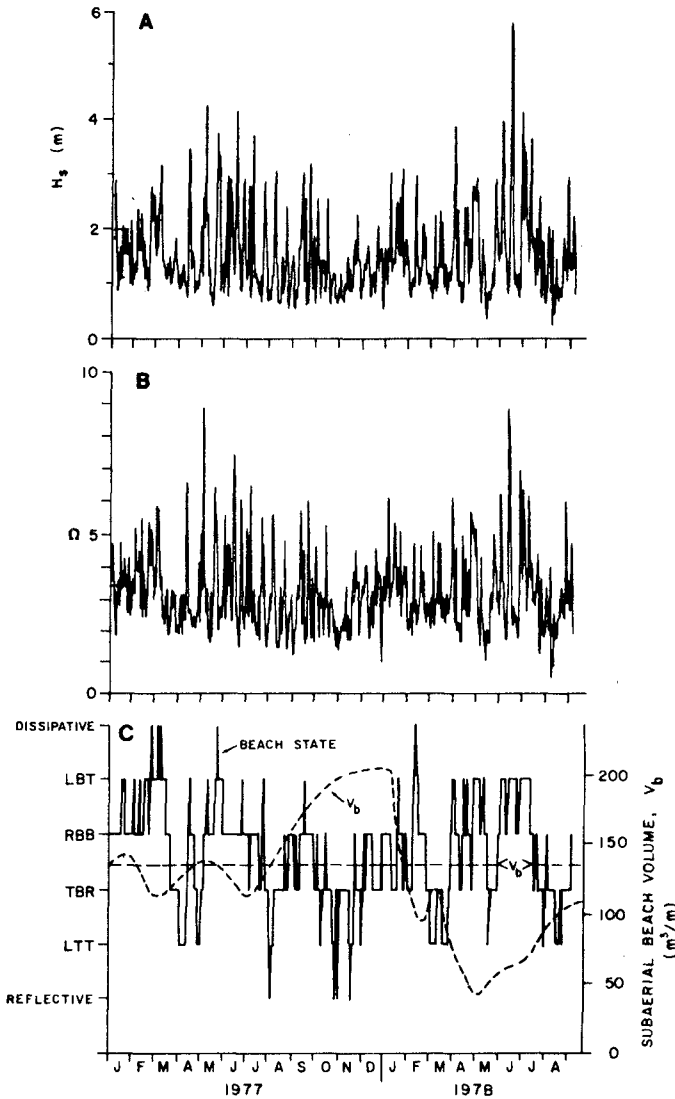

Figure 2. Time series of daily significant deepwater wave height (A), daily  $\Omega$  values (B), and daily beach state (C). Subaerial beach volume is also shown in C.  $\langle V_b \rangle$  indicates the long-term mean subaerial beach volume.

However, a pronounced secondary peak in amplitude of beach state change occurs in the period band of 15-20 days. This response results from the normal passage of pressure systems. In this response band, beach state changes lag changes in  $\Omega$  by 4 days.

Discrete discriminant analyses were used to test the degree to which day-to-day variability in beach state can be predicted in terms of  $\Omega$ . Two  $\Omega$  values were used in the analyses: the immediate value occurring on the day the particular state was observed and a weighted mean value  $\bar{\Omega}$  expressing recently antecedent conditions. The weighted mean value was computed from

$$\bar{\Omega} = \left[ \begin{array}{c} D \\ \sum_{i=1}^{D} 10^{-i/\phi} \end{array} \right]^{-1} \sum_{i=1}^{D} (\Omega_i 10^{-i/\phi}) \quad (1)$$

where  $i=1$  on the day before state observation and  $i=D$  on  $D$  days before observation. The parameter  $\phi$  depends on the rate of memory decay; the weighting factor decreases to 10% at  $\phi$  days before observation. The immediate value of  $\Omega$  made a negligible contribution to explaining daily beach state changes. However, the antecedent conditions as expressed by  $\bar{\Omega}$  showed a very strong association when  $\phi=5$  days and  $D=30$  days.

Table 1 summarizes the means and standard deviations of  $\bar{\Omega}$  associated with each state. Although the means of  $\bar{\Omega}$  differ significantly between states, the overlap between similar states (e.g. rhythmic bar and beach and transverse bar and rip) is too large to permit highly successful prediction of all six states. Predictability, in terms of discriminant functions which are overwhelmingly dominated by  $\bar{\Omega}$ , is substantially increased when adjacent and similar pairs of states are combined into fewer classes. To produce three broader groups we combined the reflective extreme with the low-tide-terrace/ridge and runnel state, the transverse bar and rip state with the rhythmic bar and beach state, and the longshore bar-trough state with the dissipative extreme. The rationale for this simplification is discussed more fully by Wright et al. (12). The central tendencies of  $\bar{\Omega}$  for each of the three recombined groups are presented in Table 2. The probability distributions of  $\bar{\Omega}$  for each class are shown in Figure 3 from which clear separation can be seen. Predicted state corresponded to the observed state in 68.5% of the 1,545 cases examined when the simplified classification was used. The success rates of predicting the reflective and dissipative end members were 85% and 78% respectively.

By examining cases where the time derivatives of both state and  $\Omega$  were near zero, it was possible to define the equilibrium conditions associated with each state. The equilibrium values,  $\Omega_e$ , of each state are summarized in Table 3. Directions of change (erosional or accretionary) are predicted in terms of "instantaneous" or short-term time averaged departures of  $\Omega$  from the equilibrium value appropriate to the inherited beach state prevailing at the time change begins.

Figure 3. Frequencies of association between  $\bar{\Omega}$  values and the three merged beach state classes.

Figure 4. Beach State Equilibria and Directions and Rates of Change. The central curve indicates the mean equilibrium associations between state and  $\Omega$ . If a beach lies to the right and below the stable region in terms of the combination of preexisting state and prevailing  $\Omega$ , subaerial erosion will take place to produce more dissipative conditions. If the combination is above and to the left, then subaerial accretion can be expected.

The inferred equilibrium associations and directions of change are indicated by Figure 4. In general, it is possible to predict probable states in terms of recently antecedent wave conditions with reasonable success. Furthermore, the direction of change can be predicted when the instantaneous combination of state and  $\Omega$  is in sufficient disequilibrium as to lie outside the "stable region" of Figure 4.

VARIATIONS IN BEACH AND SURF ZONE PROFILES

The same 6½ year data set includes monthly beach and surf zone profiles which provide a relatively long time series of subaerial beach volume and profile shape. In contrast to the relatively fast changes in beach state, beach volume changes are slow and involve sediment exchanges across the inner shelf. The largest changes in the subaerial beach volume of Narrabeen Beach have amplitudes in excess of  $100 \text{ m}^3 \text{ m}^{-1}$  and occur over time intervals of 2 to 4 years. Changes in profile dimensions and shape express in part the relatively rapid changes in state and in part the much slower changes in gross sediment volume.

Empirical eigenvector analyses provided an objective, quantitative characterization of changing profile shapes. Basically, the analysis transforms a set of intercorrelated variables into a new coordinate system in which the axes are linear combinations of the original variables and are mutually orthogonal. Two types of analyses were conducted: (1) in the first ("fixed datum") the eigenvectors express profile variability referenced to a fixed datum; (2) in the second ("floating datum") the profile variability is referenced to the instantaneous position of the shoreline and is independent of absolute degree of accretion or erosion. The latter analyses best express profile shape and can be related to beach state. The lower order eigenvectors ( $E_1, E_2$ ) express the grosser aspects of the profile such as beach volume, width and gradient. More complex profile features such as bar-trough configurations, asymmetries, and steps are expressed by progressive addition of higher vectors ( $E_3, E_4, E_5$ ). The additive properties of the vectors are illustrated by Figure 5.

Figure 5. Additive Properties of the Eigenvectors (Floating Datum Case).

The physical meanings of the first four fixed datum eigenvectors are illustrated in Figure 6. Most of the variance in the profile of Narrabeen Beach is accounted for by eigenvector 1 which expresses beach width and sediment volume; that is, in essence, a sand storage function. As illustrated by Figure 6, a positive weighting on eigenvector 1 indicates an accreted profile (relative to the mean) whereas a negative weighting indicates an eroded profile. The amplitudes of profile changes associated with eigenvectors 2-4 are small relative to those associated with eigenvector 1. However, these higher modes of profile behavior are more closely related to profile shape. A positive weighting on eigenvector 2 indicates a steeper beach with a well developed berm fronted by bar-trough topography. A negative weighting corresponds to overall profile flattening.

Figure 7 shows power spectra of the weightings on the four fixed datum eigenvectors. The maximum and only consequential variance in eigenvectors 1 and 2 is seen to occur at periods of two or more years. Temporal variations in eigenvector 1 directly parallel variations in subaerial beach volume (Fig. 2); the weightings on this vector are coherent and in phase between all profiles along Narrabeen Beach indicating that a shore-normal rather than a longshore redistribution of sediment is responsible for the changes.

The floating datum modes of profile variation are independent of absolute sand storage volume and beach width and are therefore better able to describe the behavior of profile shape. Figure 8 shows the nature of the profile shape effects described by the first five floating datum eigenvectors. Table 4 indicates the profile shape "signatures" of each of the six beach states (Fig. 1) expressed in terms the signs of the weightings on the eigenvectors. The first eigenvector expresses the overall flattening (+ weighting) and steepening (- weighting) of the surf zone and beach and thus characterizes the relative degree of dissipativeness or reflectivity of the system. This mode of variation is most effective in discriminating between the two extreme beach states (Table 4). Pronounced bar-trough topography yields positive weightings on both eigenvectors 2 and 3 (Figs. 8 and 5); the absence of bars is expressed by negative weightings on both of these vectors. Accordingly, the strongly barred states (LBT, RBB) are distinguished from the other states on the basis of the weightings on eigenvectors 2 and 3 in combination. Adjacent (in Fig. 1) and somewhat similar intermediate states are discriminated between in terms of the higher vectors. For example, eigenvector 4 distinguishes between the longshore bar trough state (+ weighting) and the rhythmic bar and beach state (- weighting) while eigenvector 5 distinguishes the rhythmic bar and beach state from the transverse bar and rip state.

The results of spectral analyses performed on the time series of the weightings on the floating-datum eigenvectors are shown in Figure 9. The power spectrum of the weightings on eigenvector 1 shows the dominant peak to be centered at periods between 24 and 42 months. This suggests that the largest amplitude variations in overall profile gradient or "dissipativeness" are related to the same long-period processes that produce the major variations in gross sand storage. The existence of a secondary but significant peak at about 2.3 months

indicates that profile gradient is also responsive to higher frequency forcings. The dominant variations in eigenvectors 2 through 5 occur at periods of 2 to 6 months. This corresponds to the period band of the largest amplitude fluctuations in beach state as discussed earlier. However, it must be noted that eigenvectors 2-5 all exhibit appreciable variance at periods of 2 years or more. We can infer from this that even the higher-order aspects of profile shape --and hence beach state-- are significantly overprinted by slow oscillations in inshore sediment storage.

#### DISCUSSION AND CONCLUSIONS

The state, profile configuration, and sand storage of a beach and surf zone system as observed at any given time are consequences of the time integration of numerous antecedent processes having different space and time scales. We have attempted to deal, albeit superficially, with part of the complexity of this problem by separating the total response into components, each of which has its own characteristic space scale and temporal frequency. Others before us have performed similar analyses on beach profiles with the aim of elucidating seasonal (e.g. 1, 4, 7) as well as tidal cycle (e.g. 2) responses. We are concerned not only with the temporal behavior of the profile and of the volume of sediment stored therein but equally with the temporal behavior of the three-dimensional beach and surf zone state. Our interest in beach state lies in the fact that beach state is an indicator of the dominant surf zone process signature (9) and influences the mechanisms and probability of beach erosion or accretion (8). Furthermore, changes in beach state permit at least short-term quasi-equilibrium with changes in wave conditions to be achieved, by virtue of surf zone process modification, without major changes in the gross sand storage properties of the beach. This has the potential of temporarily arresting or impeding the large-scale response of the profile to larger scale (larger than scale of surf zone) and longer term disequilibrium. Conversely, however, beach state is subject to changes induced by large scale, low frequency sediment fluxes. For example, the introduction of sediment into a surf zone from alongshore or from seaward of the surf zone can cause a reflective or intermediate beach which is in equilibrium with low to moderate waves to become dissipative.

The range, rate and frequency of response of a particular mode of beach variability depends in part on the frequency and intensity of the forcing involved, in part on the degree of disequilibrium induced by changing morphodynamic conditions, and in part on the scale and associated "time constant" of the mode of variability. Modes of change which involve the redistribution of relatively small quantities of sediment over relatively small distances have short response times in comparison to modes, such as the sand storage function for example, which involve large exchanges of sediment and require more total work. Beach state changes can take place, at least within a limited range of intermediate states, by means of localized short-range redistribution of the sediment already contained in the surf-zone and intertidal beach. Accordingly, and as illustrated by Figure 2, beach state can change rapidly and frequently and, for this reason, can be roughly predicted in terms of recently antecedent wave conditions. Major

shifts in state from fully dissipative to fully reflective or vice versa are more closely linked to total inshore sand storage and to overall flattening and steepening and are thus much lower in frequency.

In the case of the moderate energy Narrabeen Beach dealt with in this paper, we see that beach state and the associated higher modes of profile change respond quickly whereas gross sediment storage and overall inshore gradient respond slowly. Changes in the fixed-datum sand storage function and to some extent in the floating datum gradient function (eigenvector 1) involve the import and export of large quantities of sand to and from the beach and surf zone system. Since Narrabeen Beach is headland-bounded, these sediment transfers must occur in the cross-shore dimension and must thus involve exchanges between the surf zone and the inner shelf. As illustrated conceptually by Figure 10, we infer that the slow-response modes of variability involve large-scale cycling of sediment across the inner shelf. On the Australian east coast the "closure" depth to which the sediment exchange is active is probably between 20 m and 30 m. It is obviously shallower on less energetic coasts. The actual physical processes responsible for alternating shoreward and seaward transport over the inner shelf remain to be identified.

Figure 10. Scales and frequencies of beach, surf zone, and inner shelf responses. Rapid, relatively high frequency temporal changes in beach state and higher-order modes of profile variability largely involve the short-range redistribution of sediment already contained within the beach/surf-zone system. Low-frequency variability in sand storage and associated effects involves large-scale and slow exchanges of sediment between the surf zone and the inner shelf.

## CHAPTER ONE HUNDRED FORTY FIVE

### Quantification of Shoreline Rhythmicity

Holly C. Garrow\*

#### Abstract

The study of beach morphology, for example, its changes with wave and tide conditions, is facilitated by the development of simple numerical values which characterize the morphology. Multivariate (EOF) analysis of topographic contour data is a means for determining important morphologic components which vary independently. If these components correspond to familiar shoreline features the researcher considers important, then the development of each component can be quantified by its significance, or weighting, in each sample. Alternatively, the components may be complicated and not useful in quantifying beach morphology. A study of these morphologic components, however, can provide insights into the dynamics of the beach system.

If multivariate analysis produces complicated components, an alternative approach, of subjectively identifying shoreline characteristics of interest, can be taken. The characteristics may be the same as those frequently used in past studies, such as beach slope or sand volume. It is likely, though, that EOF analysis of topographic data will suggest more sophisticated characteristics which should be used. Some of these, for example, mean shoreline position or amplitude of a rhythmic shoreline, may be easily quantified, whereas, others such as longshore position of rhythmic features or cusp width relative to embayment width, may be more difficult to quantify.

Both of these analysis approaches were applied to beach survey data obtained over a period of ten months (including the El Niño winter of 1982/83) on Siletz Spit, Oregon. The shoreline was rhythmic with an 800-850 m wavelength throughout the duration of the study. Rhythmic topography has been associated with significant past beach and dune erosion at this site. Hence, it is of interest to describe the beach morphology quantitatively, and relate three dimensional beach changes to wave and tide conditions.

Field observations and EOF analysis determined three important characteristics of shoreline morphology: overall accretion/erosion of the shoreline, amplitude of the rhythmic topography, and longshore position of the rhythmic features. EOF analysis was not able to separate these three morphologic components. They were quantified, respectively, by mean distance offshore to a specified contour, the standard deviation of a contour about that distance, and the weights of the first eigenvector calculated by EOF analysis of topographic contour data normalized to the same mean and standard deviation.

Mean shoreline position was shown to move onshore with increasing wave height, as expected. Rhythmicity amplitude varied inversely

\*College of Oceanography, Oregon State University, Corvallis, OR  
97331

with the wave height, but there is evidence to believe this is not the case for all winters on Siletz Spit. Rhythmic topography formed and increased in amplitude under depositional conditions during the ten months of this field study. Due to differences between the rates of change of mean shoreline position (up to 5 m/2 wks) and of rhythmicity amplitude (up to 10 m/2 wks), rhythmic topography should be able to develop under erosional conditions as well.

In many beach systems, EOF analysis of topographic contour data should not be expected to produce simple morphologic components which correspond to familiar shoreline features. EOF analysis can be an aid in furthering one's understanding of the dynamics of a beach system and can be a useful guide in subjectively identifying important shoreline characteristics. In some instances, EOF analysis of a modified data set may allow one to quantify one or more of these characteristics.

### Introduction

Simple numerical values are needed to describe beach morphology before three dimensional beach changes can quantitatively be related to wave, tide, or other 'environmental' forces. In general, two approaches can be taken to determine useful values which characterize the beach morphology. Both require data documenting beach topography in three dimensions.

One approach is a multivariate analysis of beach profile data collected at different longshore locations and/or different times (Winant et al., 1975; Aubrey et al., 1980; Wright et al., in press). This provides an objective determination of important and independent components of beach morphology. It also weights each component, depending on its importance. Ideally, the components correspond to familiar features such as a straight beach profile with an offshore bar (if beach profiles are analyzed) or perhaps a shoreline with cusped protrusions (if topographic contours of the beach are analyzed). The weightings then provide a measure of how well developed that feature was at the time of the survey. However, depending on the field site, numbers of samples taken, and duration of the study, the components may be complicated and not represent morphologies of interest.

An alternative analysis approach is to determine, subjectively, characteristics of the topography which are of interest, such as foreshore beach slope or average surf zone beach slope, beach volume, or the horizontal or vertical amplitude of cusps. Many such characteristics are easily quantified, but others, for example, longshore positions and spacing of a rhythmic shoreline pattern, can prove to be more elusive.

The goal of the present investigation was to apply both of these approaches to examine the origin and development of large scale rhythmic shoreline forms. In particular, much attention was given to determine the applicability of multivariate analysis of topographic contour data to studies of three dimensional beach topography. To this end, a ten-month long field study was undertaken on the Oregon

coast to document changes in beach topography. The field site was an 830 m long stretch of beach on Siletz Spit, 30 km north of Newport, Oregon (Fig. 1). Eleven evenly-spaced beach profiles were obtained at two-week intervals during times of low Spring tides. Other data utilized in analyses of the observed beach topography changes include direct measurements of the incident waves (obtained every six hours), continuous tidal measurements, and local weather conditions, all measured at Newport.

This study was part of a larger effort to improve our understanding of rhythmic topography. Also included in the larger study, but presented elsewhere (Garrow, 1985), were the analyses of 24 historical air photo mosaics, more extensive statistical analyses of the survey data, evaluations of the proportions of infragravity and incident wave energy on the foreshore (from time-lapse films of wave run-up), and the development of a model for the formation of rhythmic topography at this site.

#### Field Techniques and Observations

Eighteen beach surveys, each consisting of eleven evenly-spaced beach profiles, were carried out on a bi-weekly basis between September 1982 and June 1983. Beach profile locations were constant throughout the study with all elevations referenced to a local base line and datum. Profiles were determined using 'Emery Boards' (Emery, 1961). The absolute x,y,z, coordinate system was established using an Omni-1 Total Station. Because of the high energy winter wave conditions on the Oregon coast, beach profiles often extended only 5 to 10 m seaward of estimated MLLW.

Seven storms, with deep-water significant wave heights greater than 5 m, occurred during the study. This period of time is especially interesting due to the El Niño phenomenon and its associated anomalous environmental conditions. Sea level anomalies up to 1.1 m occurred, associated with thermal and shelf wave phenomena (Huyer et al., 1983; Enfield and Allen, 1980), and up to 0.28 m due to low barometric pressures. Normal tides on the Oregon coast range from 2 to 4 m.

Figure 1. The field site was located on Siletz Spit, Oregon. It was approximately 2 km south of the Siletz Inlet and 8 km north of Government Point.

Contour maps from the survey data show the cycle of beach response to winter storms. Initial surveys showed a typical summer profile which rapidly eroded in early October. While there were moderate-scale fluctuations throughout the winter, significant accretion did not occur until near the end of the field program in June.

A common feature throughout the study period was a large scale rhythmicity in the shoreline. While the amplitude of the rhythmicity varied, statistical analyses showed that the wavelength was stable at 800-850 m. Additional characteristics of the rhythmic topography are: 1) localization of the rhythmicity to 3-4 km south of Siletz Inlet, and 2) variations in the longshore locations of rhythmic features, including longshore migration of a well developed rhythmic morphology (Garrow, 1985).

Important to the problem of understanding variations in beach morphology is the ability to quantify these variations in simple terms. Our visual and survey observations suggested that beach variability was composed of three components; average accretion or erosion, variations in the amplitude of rhythmicity, and variations of the longshore position or phase of the rhythmicity (as noted, the wavelength appeared stable). Empirical orthogonal eigenfunction analysis, a multivariate technique of data analysis, was applied in an attempt to separate these components of beach morphology variations.

#### Multivariate Analysis of Topographic Data

Empirical orthogonal eigenfunction (EOF) analysis is a mathematical technique which may simplify one's original data by reducing the number of variables which need to be considered. Explanations of the details of EOF analysis (also referred to as R-mode analysis) can be found in most texts considering mathematical analyses of multivariate data (ex. Davis, 1973). Aubrey (1979) provides brief reviews of the mathematics involved.

This technique has two main goals, both attained through simple, though voluminous, matrix algebra. First, one must realize that the variables in the original data set are not linearly independent and, hence, are redundant. That is, if one calculated the correlation between all pairs of variables, it is unlikely that all correlations would be zero. With this in mind, one goal is to determine a new set of variables (eigenfunctions or eigenvectors) which are independent. For example, if the original data set (or data matrix) had four variables, perhaps  $\beta_f$  (beach foreshore slope),  $\beta_s$  (average beach surf zone slope),  $H_{1/3}$  (significant wave height), and  $T$  (incident wave period), then each of the new variables would have four elements. A new variable may look like [-2 -5 4 0.5], indicating that it is composed of 'a lot' of  $H_{1/3}$ , and 'a lot of the opposite (-)' of  $\beta_s$ , since 4 and -5 are large, relative to 2 and 0.5. This particular example indicates the typically moderate correlation between increasing wave height and decreasing average beach slope in the surf zone.

The second goal is to define the fewest new variables possible, which will completely describe the original data, such that all sam-

ples can be written as the linear sum of the new variables. Mathematically, the phrase 'completely describes,' means that the new variables must account for all of the variance in the original data set. The importance of each new variable can be considered as how necessary it is in reconstructing the original data set. It is described by the percentage of the total variance (in the original data) for which it accounts. If four new variables were determined by EOF analysis, then one may explain 80% of the variance, another 15%, another 4.99%, and the fourth, only 0.01%. In this case, it could be said that three new variables could be used to describe the original data. In fact, for many applications, only two new variables would suffice. In addition to the percentage of total variance explained by each factor, EOF analyses also evaluate the importance of each new variable to the individual samples. Thus, if one wished to reconstruct sample #6 from the new variables, they may need to 'weight' one new variable by 85%, another by 12%, and the others by 2% and 1%, respectively. However, the 'weightings' for reconstruction of sample #7 may be 70%, 25%, 5%, and 0%. These weightings can be useful in that they show the change in importance of a new variable (or synonymously of a certain relationship between the original variables) from sample to sample.

This technique can be applied to the analysis of beach profile data if one evisions a topographic data set from the study site in which each variable represents one of the 11 profile ranges. EOF analysis of this matrix will produce 11 or fewer eigenvectors, each with 11 elements, which account for all of the variance in the data. Each vector will represent an alongshore topographic pattern or morphology. The hope is that most of the variance in the data set will be accounted for by several dominant morphologies which may be associated with known or hypothesized nearshore processes.

In deciding to perform such an analysis, the question arose as to what the actual elements of the data matrix should be. A number of possibilities were tried and evaluated with the specific goal of better understanding the nature of shoreline rhythmicity at the field site. As noted in the previous paragraph, the variables in all of the matrices evaluated represented longshore position. Several different types of elements were evaluated and discarded. These included: 1) elevations at different offshore distances, 2) local beach slope at different offshore distances, and 3) local alongshore beach slope at different offshore distances. An inverse approach of using the offshore distance to particular topographic contours proved successful.

Cross-shore distances to a particular contour as a function of time, therefore, were used to study the variability of rhythmicity through the 18 separate surveys. If the changes in beach morphology through time are relatively simple, then the mean contour calculated from such a matrix should describe a reasonable longshore topography and EOF analysis of such a matrix should produce one or two meaningful eigenvectors to account for most of the variance.

One's understanding of the results of this analysis on the Siletz Spit data set is enhanced by first examining results of this

analysis approach on hypothetical data matrices representative of ideal beach topographies. The first, and simplest, case is that of a straight beach extending different distances offshore at different times (accreting and eroding). The mean contour is straight, and EOF analysis determines a single dominant eigenvector. This vector is straight alongshore, and the weightings indicate the amount of accretion (positive weights), or erosion (negative weights), about the mean contour location at each time. An additional eigenvector is present in this, and all of the following cases, though it accounts for less than a few percent of the variance. This vector represents noise in the data.

A more interesting case for the study of longshore rhythmicity is that of a cusped shoreline exhibiting sinusoidal topographic contours. One can imagine a number of changes such a shoreline might experience, including variations in amplitude and longshore phase, as well as combinations of these with general erosion and accretion.

If the sinusoidal pattern remains stable in the longshore, but varies in amplitude, the analysis produces a sinusoidal mean and a single sinusoidal eigenvector 180 degrees out of phase with the mean (Fig. 2a). The vector weightings describe 'how much' of the vector must be added to, or subtracted from, the mean to regain the original data. In this simple beach environment, the vector weights can be used directly to describe the amplitude of the rhythmicity present at the time of each survey.

Results from a rhythmic shoreline exhibiting changes in both on/offshore position and amplitude through time is just a combination of the above cases. There is a sinusoidal mean and two dominant eigenvectors (Fig. 2b), one representing variations in amplitude, the other representing erosion or accretion. The percentage variance explained by each of these vectors depends on the relative magnitudes of amplitude variation and changes in on/offshore position.

Figure 2. a) Mean contour and first eigenvector of data depicting a stable longshore rhythmic pattern with amplitude variations; b) Mean contour and first and second eigenvectors of data depicting a stable longshore pattern with amplitude variations and overall on/offshore movement.

The previously discussed characteristics of rhythmicity at the study site suggest that a still more realistic hypothetical set of circumstances would include longshore migration, or phase shifting, of the sinusoidal contours. Three cases will be explored using random phase variations within 90, 180, and 360 degree ( $1/4$ ,  $1/2$ , and full wavelength, respectively) envelopes. One-hundred synthetic contour lines were generated in each case. No on/offshore migration of the beach is included in the analyses discussed here; inclusion of this signal does not alter the basic results.

The mean contour and the first and second eigenvectors calculated by the EOF analyses for the 90 degree, 180 degree, and 360 degree phase variation cases are shown in Figures 3a, b, and c, respectively. Any apparent distortion of the mean contour from a perfect sinusoid occurs because the wavelength is not an even multiple of the spacing between variables (beach profiles). It can be noted that the amplitude of the mean decreases with increasing phase shift envelope. Eigenvectors 1 and 2 are sinusoidal and exactly 90 degrees out of phase in all instances. They are also out of phase with the mean by approximately 25 and 205 degrees. This phase offset from the mean accounts for the longshore phase shifting in the data. As phase variation in the data increase, the second vector becomes increasingly important. The 90, 180, and 360 degree phase envelope examples, respectively, have eigenvector 2 to eigenvector 1 ratios, of percents of variance accounted for, of approximately 0.07, 0.14, and 0.06. With longshore migration of a rhythmic shoreline, factor scores still indicate 'how much' of a vector must be added to the mean to regain the original data. However, they now include the longshore location of rhythmic features relative to the mean. When analyzing real data, the meaning of the vector weights must be evaluated subjectively, based on the shapes of the mean and dominant eigenvectors, and the phase relations between them.

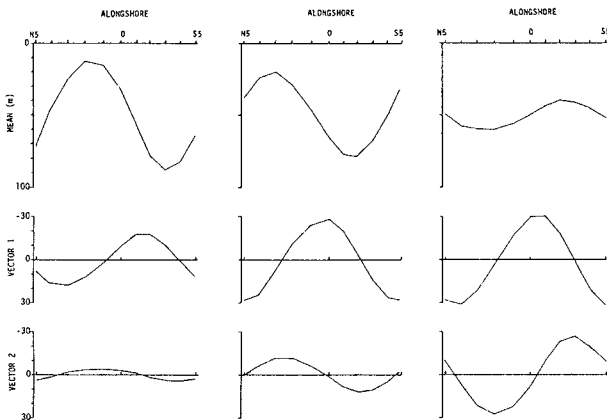

Figure 3. Mean contours and first and second eigenvectors for data depicting a longshore rhythmic pattern with amplitude variations, and a) 90° envelope phase shifting; b) 180° envelope phase shifting, c) 360° envelope phase shifting.

Finally, the influence of noise in the data was investigated. For the case of a matrix consisting solely of random noise, the mean contour is a straight line. EOF analysis produces the same number of eigenvectors as there are variables, all accounting for approximately equal amounts of variance. The vectors themselves are irregular when plotted. In an effort to determine how much noise could be present in a matrix based on a longshore rhythmic beach system and still yield interpretable results, many analyses were run on matrices similar to those just discussed, but including amplitude variations, on/offshore variations in beach position, and varying amounts of noise. It was determined that noise can hinder interpretations of the mean and eigenvectors when it is of the same order of magnitude, or larger than the amplitude of the rhythmic signal. In general, this condition can be identified by the need for more than two or three eigenvectors to account for more than 90% of the variance.

#### EOF Analysis of the Field Data

For analysis of the Siletz Spit topographic data, EOF analysis was run for seven different elevation contours spaced 0.5 m apart. Plots of the means and eigenvectors are shown in Figure 4. All mean contours appear rhythmic with approximately the same lengthscale of 800-850 m. For higher elevation contours, those nearest the dunes, the first eigenvectors show lower amplitude rhythmicity and account for less of the total variance in their matrices than do the first eigenvectors for contours further offshore.

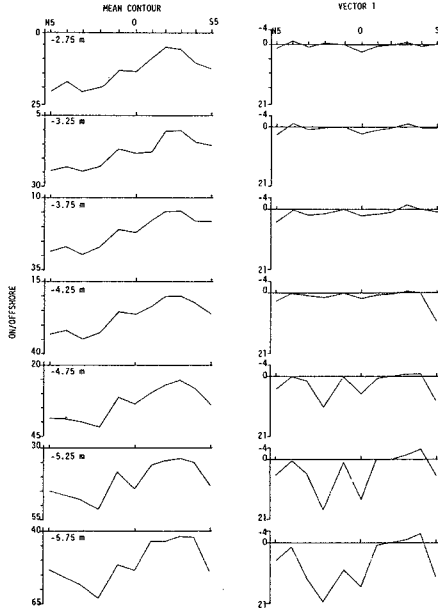

Figure 4. The mean contours and first eigenvectors for each of the seven Siletz Spit contour data sets.

The results of EOF analysis of the seaward-most data are shown more fully in Figure 5. The alongshore patterns are more irregular than those of the synthetic analyses, as would be expected in a natural system, but they definitely reflect some characteristics of the shoreline rhythmicity. The mean contour is obviously rhythmic with a longshore wavelength of 800-850 m and an amplitude of approximately 20 m. Two eigenvectors account for 83% of the variance in the data suggesting that although there is some noise in the system, it is probably much less than the amplitude of the rhythmicity signal. The shapes of the first two vectors are reassuringly similar to those determined in analyses of the hypothetical rhythmic shoreline with amplitude variations and phase shifting of the pattern. Eigenvector 1 departs from the expected phase relation with the mean for this model in the southern part of the area. The nature of the departure suggests that phase shifting at this site was possibly accompanied by small changes in the wavelength of the rhythmicity. Eigenvector 2 also departs from the expected phase relation with the mean, but it is 90 degrees out of phase with vector 1 for most of its length and this is consistent with the model. The amplitudes of the mean, first eigenvector and second eigenvector are 20 m, 25 m, and 15 m, respectively. This is very reminiscent of the synthetic data set with 180 degree phase shifting. The percentages explained by the first two vectors from the Siletz data are also similar to this hypothetical case. The ratio of percent explained by eigenvector 2 to that explained by eigenvector 1 de-emphasizes the noise in the natural system. The ratio for the hypothetical example with a 180 degree phase envelope is 0.15, and for the Siletz field site is 0.17.

Examination of eigenvector 1 shows it to have a mean of 6.4 m, implying an associated on/offshore movement of the contour. Sites labelled S1, S2, S3, and S4 have values near zero, while sites to the north have larger values indicating a greater on/offshore fluctuation in position. Figure 6 shows plots of the sum of the mean contour and

Figure 5. The mean contour and the first and second eigenvectors for the seaward-most contour of the Siletz Spit data set.

the most positively and most negatively weighted first eigenvectors in the data set. From these it is concluded that a change from large positive to large negative for vector weights would describe erosion in the north, a broadening of the embayment in the south, and migration of the cusp to the north with a concurrent decrease in amplitude. Though examination of vector 1 alone suggests that it might describe variation in the wavelength of the rhythmicity, it does not appear to do so within this data set. Eigenvector 2 has a mean near zero and shows most variation in the northern half of the study area. Figure 7 shows plots of the most positively and most negatively weighted second vector in the data set added to the mean contour. A transition from large positive to large negative second eigenvector weights represents a straightening of the beach to the south, a large increase in topographic complexity to the north, and a concurrent decrease in amplitude and northward migration of the southernmost embayment. Vector by vector reconstructions of the data, such as this, can prove extremely enlightening in understanding both the significance of the vectors and the dynamics of the beach system.

Figure 6. The sum of the mean contour and the most positively weighted (top) and most negatively weighted (bottom) first eigenvectors (solid lines). For reference, the mean contour is shown as a dotted line.

Figure 7. The sum of the mean contour and the most positively weighted (top) and most negatively weighted (bottom) second eigenvectors (solid lines). For reference, the mean contour is shown as a dotted line.

This analysis confirms the visual and survey observations that there are three primary components in the beach variability data. These are general accretion or erosion of the shoreline, amplitude of a dominant 800-850 m wavelength rhythmic pattern, and longshore location or phase of the rhythmic pattern through approximately 180 degrees (or 400 m). EOF analysis is useful in verifying the importance of these components, as demonstrated here and in the analyses of the synthetic data. Furthermore, it is capable of separating accretion/erosion and rhythmicity amplitude variations in a simple two-component system where these morphologies are independent.

Unfortunately, in an interdependent multiple component system, or a phase varying sinusoidal system (both of which apply to the Siletz data), the resulting eigenvectors fail to provide a simple separation of the three topographic parameters.

#### Quantification of the Components of Beach Morphology

To study the relationships between topography and wave and tide conditions, it is desirable to separate the three morphologic components and express each by a meaningful numerical parameter. On/offshore position, and amplitude of rhythmicity, can be described by the mean and standard deviation of the distance offshore to a contour at a given time (Fig. 8). For a truly sinusoidal pattern, the standard deviation of a contour produces a low estimate of rhythmic amplitude. In light of the variations found in natural systems, however, it seems to be a satisfactory descriptor. One possibility for quantification of longshore position of the signal would be longshore location of extrema. The signal produced by the real data is sufficiently noisy to preclude this approach. Recall that for any rhythmic shoreline exhibiting less than about 200 degrees of longshore phase shifting, EOF analysis produces a single eigenvector which describes much of the topographic variation. Vector weights for each excursion are meaningful numerical descriptors of the overall topography. In this instance, if the on/offshore movements of the shoreline and amplitude variation signals can be removed from the data, then the first eigenvector calculated by EOF analysis should describe only the phase shifting, or longshore migration of the rhythmic pattern.

Figure 8. On/offshore position of the shoreline and amplitude of rhythmicity can be described by the mean and standard deviation of the distance offshore to a contour at a given time. The weightings of the first eigenvector of the normalized data matrix can be used as quantitative descriptors of longshore position of the rhythmic pattern.

To this end, the seaward-most contour data was normalized to the same mean and standard deviation. This normalization results in varying amounts of noise for different excursions, increasing the noise in low amplitude (mid-winter) data sets relative to higher amplitude data sets. Figure 9 shows plots of the mean contour, first, second, and third eigenvectors from EOF analysis of the normalized data. Because of the increased noise, 5 vectors are necessary to account for 90% of the variance. For the non-normalized data, the same amount of variance is explained by only 3 vectors. Longshore migration of the rhythmic pattern is described mostly by eigenvector 1. Eigenvectors 2 and 3, primarily 'fine-tune' the shape of the topographic features by narrowing cusps and broadening embayments. Comparison of the first vector weights of the normalized data (Fig. 8) to topographic maps of the beach for each excursion (Garrow, 1985), confirms that these weights can be used as quantitative descriptors of longshore position of the rhythmic pattern. Large negative weightings describe a number of the winter beaches when the embayment was located in the north central part of the site.

Figure 9. The mean contour and the first, second, and third eigenvectors from EOF analysis of the normalized  $-5.75$  m contour matrix.

Careful analysis of the topographic data reveals three primary components of topographic change on Siletz Spit and suggests three independent and quantitative parameters to describe them. On/off-shore position of the shoreline is best described by the mean distance offshore to a predetermined contour for each excursion. The amplitude of rhythmic topography is most simply and accurately described by the standard deviation of a contour about its mean offshore distance. The longshore position of rhythmic features is best expressed by the weights of the first eigenvector as calculated by EOF analysis of the contour data set in which each sample is normalized to the same mean and standard deviation.

### Waves, Weather, and Topography

Relationships between parameters which represent important characteristics of shoreline morphology and the wave, tide, or weather conditions permit us to: 1) improve our understanding of which variables are important in producing rhythmic topography, 2) make estimates of the response times for the beach morphology components, and 3) learn something about the way in which rhythmic topography forms. Regression analysis between the available topographic and environmental variables confirms some well established trends, but also provides new insights and surprises. The values used to represent wave and weather conditions in this investigation are the means for the time periods between surveys.

Though the linear correlation between mean significant wave height and the position of the mean shoreline is not high ( $-0.720$ ), the expected relationship exists (Fig. 10). As significant wave height increases, the mean shoreline position moves onshore (decreases) as a result of beach erosion. It is suggested that the correlation is as low as it is due to the rather slow response time of the mean shoreline to changes in incident wave conditions. Although the bi-weekly sampling precludes comments on very rapid responses, the mean shoreline position changed, at most, five meters between surveys.

Of interest, the amplitude of the rhythmicity also shows a negative correlation ( $-0.614$ ) with mean significant wave height (Fig. 11). This is opposite to the relationship observed previously during major episodes of erosion on Siltz Spit. At those times, erosion resulted from embayments impinging on the foredune during storms with incident wave heights exceeding six or seven meters (Rea, 1975; Komar and Rea, 1976; McKinney, 1977; Komar, 1983).

Figure 10. Mean Significant wave height versus mean shoreline position showing a negative correlation between these variables.

Figure 11. Mean significant wave height versus rhythmicity amplitude. The negative correlation between these variables differs from a positive correlation observed during major erosional episodes of the 1970's.

The winter of 1982/83 was characterized by anomalous weather and tide conditions due to El Niño. Consideration of three well documented periods of significant dune erosion on Siletz during the 1970's (McKinney, 1977), reveals a fundamental difference in conditions between those periods and the 1982/83 winter. First, incident wave conditions do not differ appreciably between the 'erosive' winters and the winter of 1982/83. Incident wave periods during the three major erosive storms varied from 9 to 17 sec. and significant breaking wave heights ranged from 6 to 7 m. However, barometric pressures in the winter of 1982/83 were anomalously low. Monthly mean barometric pressures for January through April were the lowest since sometime before 1971 (Huyer et al., 1983). This difference reflects that storm centers were closer to the Oregon coast in 1982/83, being located off the central California coast, than during the periods of major erosion when they were located in the North Pacific, just south of the Aleutian Islands in the Gulf of Alaska (McKinney, 1977). It is speculated, then, that incident wave characteristics related to the proximity of a storm center may be important in determining the amplitude of rhythmic topography on Siletz Spit.

Of interest, the amplitude of the rhythmicity in the 1982/83 winter showed larger responses to incident wave conditions than did the mean shoreline position. Up to 10 m of change occurred during any two-week period. The relationship between mean shoreline position and rhythmicity amplitude can reveal whether the rhythmic topography is erosional or depositional in origin. The correlation between these two morphology components is +0.841, indicating that the amplitude increased as the shoreline prograded (Fig. 12). However, spectral analyses of the high water lines on air photo mosaics obtained in previous years (Garrow, 1985) suggest a possible negative correlation between these same two variables. The photographs showing significant spectral peaks were taken during August, September, October, February, and April of the several years of photo availability. The high spectral energy found on the fall and mid-winter

Figure 12. Mean shoreline position versus rhythmicity amplitude. The positive correlation indicates rhythmic topography was of a depositional origin during the time of this study.

photographs indicate that the rhythmic topography may also form, as well as show rapid growth under erosional conditions. It is probable, however, that the development of rhythmicity to very large amplitudes is most likely to occur under erosional conditions. This seems likely, given the more rapid response of rhythmicity amplitude than of mean shoreline position to changes in significant wave height.

### Conclusions

Empirical orthogonal eigenfunction analysis of a matrix containing offshore distances to an elevation contour provides a means for determining the important morphologic variables in an area. These may not correspond to single morphologies deemed important by the researcher if these morphology components do not behave completely independently over the period represented by the measurements. They will also not correspond if longshore migration of a sinusoidal pattern occurs during the time of study. Reconstruction or partial reconstruction of the original data by summing weighted eigenvectors or 'new variables' with the mean can provide insights into the significance of the vectors and the dynamics of the beach system.

Three important morphologic components were identified on Siletz Spit: overall accretion or erosion of the shoreline, amplitude of an 800-850 m wavelength rhythmic topography, and longshore position or phase of the rhythmic features. EOF analysis was useful in verifying the importance of these components but was not able to provide a simple separation of them.

It was determined that the mean shoreline position and rhythmicity amplitude can be quantified, respectively, by the mean distance offshore to a specified contour and the standard deviation of the contour about that distance. Longshore position or phase of the rhythmic pattern can be described by the weights of the first eigenvector, calculated by EOF analysis, of a contour data matrix in which each contour is normalized to the same mean and standard deviation. This should also apply for other, similar systems showing less than about 200 degrees of longshore migration.

This quantification permitted evaluation of the effects of various wave and weather conditions on the shoreline morphology. As expected, the mean shoreline position moved onshore as wave height increased. The amplitude of the rhythmicity was inversely correlated with wave height, though there is some question as to whether this is true for all winters on Siletz Spit. During the winter of 1982/83, rhythmic topography formed and increased in amplitude under depositional conditions. Again, there is some question as to whether this is always the case at this site. Mean shoreline position was shown to change, at most, 5 m during a two-week period, whereas, rhythmicity amplitude changed by as much as 10 m. This difference in rates of change should make formation and development of rhythmic topography possible under erosional conditions, as well as under the depositional conditions observed during this study.

## CHAPTER ONE HUNDRED FORTY SIX

### Modelling of the Depositional Patterns in Hangzhou Bay

Su Jilan\* and Xu Weiwei\*\*

Prediction of depositional patterns in estuaries is one of the primary concerns to coastal engineers planning major hydraulic works. For a well-mixed estuary where suspended load is the dominant transport mode, we propose to use the divergence of the distribution of the net suspended load to predict the depositional patterns. The method is applied to Hangzhou Bay, and the results agree well qualitatively with measured results while quantitatively they are also of the right order of magnitude.

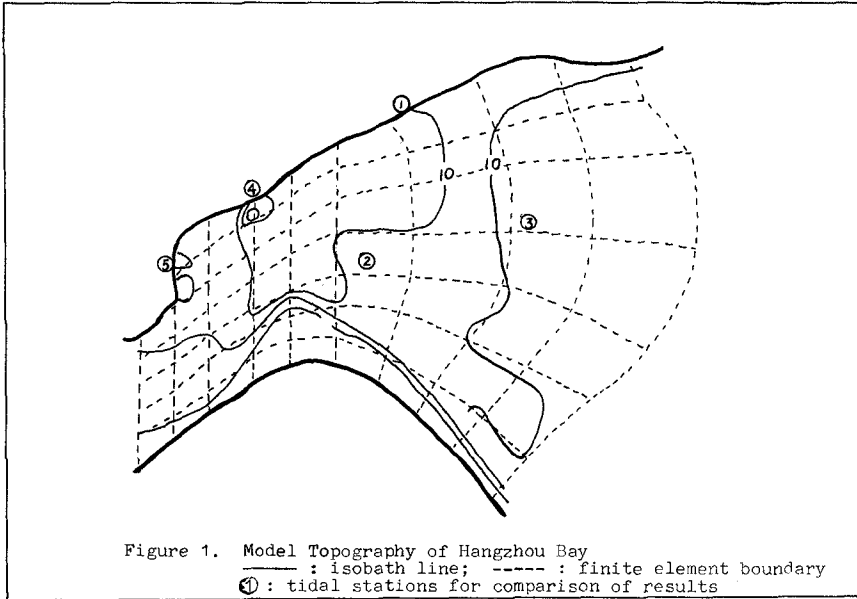

#### Introduction

Hangzhou Bay is the outer part of the Qiantangjiang Estuary. It is about 100 km long and is funnel-shaped such that the width decreases from 90 km at the mouth to 20 km at the western end (Fig. 1). The famous Qiantang bore starts to form at about 10 km further upstream of the Hangzhou Bay. In order to improve the resources management of the estuary several alternative major reclamation projects have been proposed. One of the primary concerns to the engineers studying the feasibilities of these projects is the effect of the hydraulic works on the depositional patterns in the Qiantangjiang Estuary. Because of the complicated nature of sediment transport in tidal situations, so far no successful modelling of the depositional patterns of the estuary has been published.

The annual sediment load of Qiantangjiang is about seven million tons. However, because of its proximity to the Changjiang river, suspended sediment from Changjiang plays a very important role in this estuary. Sediment in Hangzhou Bay is predominantly fine and medium silt. The median size of the suspended load ranges from 10  $\mu\text{m}$  to 13  $\mu\text{m}$  while that of the bed material is 16  $\mu\text{m}$  with only small percentage of clay size particles (Feng Yinjun and Xie Qin-chun, private communication). Since Hangzhou Bay is shallow (Fig. 1) and its tide is strong, the principal mode of sediment transport there is through suspended load. We were thus motivated to use the divergence of the vector field of the suspended load as a measure of the depositional

\*Professor, Second Institute of Oceanography, National Bureau of Oceanography, Hangzhou, China

\*\*Assistant Research Scientist, Second Institute of Oceanography, National Bureau of Oceanography, Hangzhou, China

patterns. This approach avoids the complication, as well as uncertainty, associated with solving the sediment transport equation.

#### Formulation of Problem

The tidal range at the mouth of the Hangzhou Bay is around 3 m and the average discharge of Qiantangjiang is only about 920 cubic meters per second. The Bay is thus a well-mixed estuary. Salinity in the Bay is rarely lower than 10 ‰ and it is usually less than 30 ‰ at the mouth because of the influence of the Changjiang discharge.

For the study of sediment transport in a well-mixed estuary like Hangzhou Bay where the bed material may be regarded as noncohesive, it is appropriate to choose the suspended load formula by Bagnold. According to Yalin (5), for uniform bed material of a specific size, Bagnold's equation can be written as

$$\vec{q} = 0.01 |\vec{\tau}| |\vec{U}| \vec{U} / w \quad (1)$$

where  $\vec{\tau}$  is the bed stress,  $\vec{U}$  is the vertically averaged velocity, and  $w$  is the settling velocity of the grains. The bed stress is related to the Chézy coefficient  $C$  as

$$\vec{\tau} = \rho g |\vec{U}| \vec{U} / C^2 \quad (2)$$

where  $\rho$  is the water density and  $g$  is the gravitational acceleration. Combining Eqs. 1 and 2 we obtain

$$\vec{q} = 0.01 (\rho g / C^2 w) |\vec{U}|^3 \vec{U} \quad (3)$$

The net suspended load of a uniform-sized bed is

$$\langle \vec{q} \rangle = 0.01 (\rho g / C^2 w) \langle |\vec{U}|^3 \vec{U} \rangle \quad (4)$$

where  $\langle \rangle$  denotes averaging in time over a tidal period  $T$ .

The current in Hangzhou Bay is dominated by the semi-diurnal tidal component. Hunter (3) showed that  $\vec{q}$  is dominated by contributions from both the residual current and the quarter diurnal tidal current component, the former being about 1.7 times as large as the latter if both current are of the same magnitudes. Since the amplitude of  $M_4$  is about 5 per cent of that of  $M_2$  in the Hangzhou Bay, a good prediction of the distribution of  $M_4$  current, as well as residual current, will likely serve our purpose except during storms when the wind-driven currents may be dominant. The average river discharge gives a residual current of the order of only  $5 \times 10^{-3}$  m/s, and hence we will ignore the river discharge. Residual currents due to other sub-tidal sources are also ignored. The only part of the resi-

dual current considered in this study will be that due to the  $M_2$  tidal action.

The vertically integrated equations describing the tidal motion in a homogeneous sea are

$$\zeta_t + \nabla \cdot [(h + \zeta) \vec{U}] = 0, \quad (5)$$

$$\vec{U}_t + \vec{U} \cdot \nabla \vec{U} + f \vec{k} \times \vec{U} = -g \nabla \zeta - \vec{\tau} / \rho (h + \zeta), \quad (6)$$

where terms like wind stress and lateral friction have been neglected.  $\vec{k}$  is the unit vector in the upward direction;  $f$  is the Coriolis parameter;  $\zeta$  is the free surface elevation;  $h$  is the mean water depth. For our study the flooding and drying of the tidal flats was not modelled. We simply increased the water depth there somewhat, and at the same time the bottom friction coefficient was also increased to compensate for the distortion of the topography. At the open boundaries the surface elevations are prescribed for all time. For this study only the  $M_2$  constituent of the surface elevation was forced at the open boundaries.

Analysis of systems of hyperbolic equations by Zhu et al. (6) showed that an additional boundary value has to be given at the open boundary if the flow there is into the domain of interest. However, this is impractical for ocean problems. On the other hand, when numerical methods are used to solve the equations an additional condition is usually imposed at the open boundary because of the requirement of the numerical scheme, which now introduces an over-determinancy during the outflow phase at the boundary. For finite element schemes solutions can be obtained without imposing additional condition at the open boundaries. In any case, the solutions are usually reasonably good in practice because the advective terms, which are responsible for the complicated nature of boundary conditions, are usually of secondary importance in ocean problems.
