As it was stated the outer part of the channel represent the major problem due to its sedimentological instability.

As we can see in Fig. 1 the existing channel turn to the south as it reach the end of the island area.

This behavior is somewhat unexpected because the tide and the current shows a symetric pattern in the angle formed by the norther shore and the West island shore.

Nevertheless, only after a good knowleged of the nature of the sediment of Banco del Norte, it will be possible to understand the problem. Previous works in the area, and spetially bottom sounding performed before, show us that this "Banco del Norte" remains identical along the time. The only possible reason for that, it would be that the surface of such a bank were harder than the original southen part.

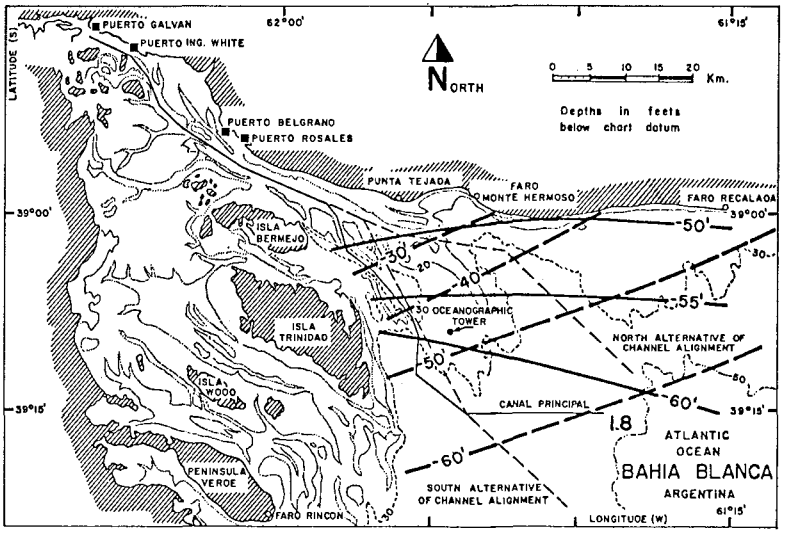

Fig. 2 Cotidal lines for high and low water

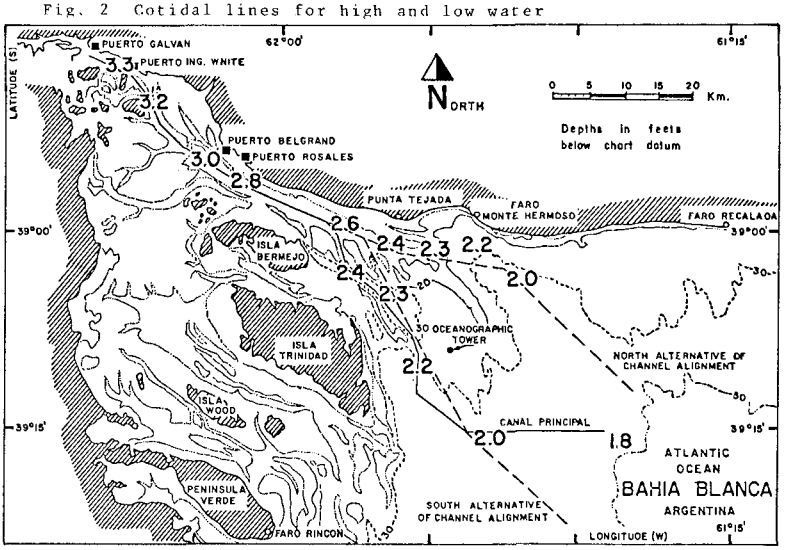

Fig. 3 Mean tidal amplitude

Moreover, if we consider in such alignment a new channel cutting Banco del Norte, it would be a good solution because the current will increase keeping the channel almost free of sedimentation.

For this reason we include the norther alignment in order to provide a new and shorter alternative for the access channel to the harbor complex.

The present paper deal with the hydrosedimentological studies carried out in this outer area.

What it was done and the resulting test carried out shows the difficulties with what we have to deal in order to estimate the sedimentation rate on a navegation channel dredged through a bank in an area with large waves and tidal currents.

4. FIELD SURVEY

The field survey was rather extensive and covered all the major aspect of the hydrosedimentological parameters.

The first work was a complet sounding of the area following the existing channel and the new alternative of alignments, previously selected from the existing data. The sounding extended over more than 1000 Km. was taken as a reference sea bottom level for all the future works.

Previously to the bottom sounding, 11 tidal gage station were installed adding to the two existing ones, which were recovered after the one mouth survey. The tidal data was first analized to get the chart datum level and to reduce the soundings.

Moreover determination of sea levels, tidal amplitudes, phase lags and harmonic analysis were carried out to provide information for navigation and hydrodinamic studies. Cotidal lines for high and low water are shown in Fig. 2 and the averaged tidal amplitudes in Fig. 3. As it can be seen the tidal flood go tinto the bay from south to north and the tidal ebb from NW to SF, also a large change in amplitude is recorded from the inner part to the outer part as a result of the funnel shape of the canal principal.

Current velocities and directions were measured at hourly intervals generally during 13 hours periods, at different points of the vertical at 22 stations, repeting most of them during both spring tide and neap tide conditions.

The variation of the current velocities in magnitude and direction under different tidal and meteorological conditions, were measured, generally during 14 days periods, using a non wave afected self-registered current meter, positioned at 10 stations.

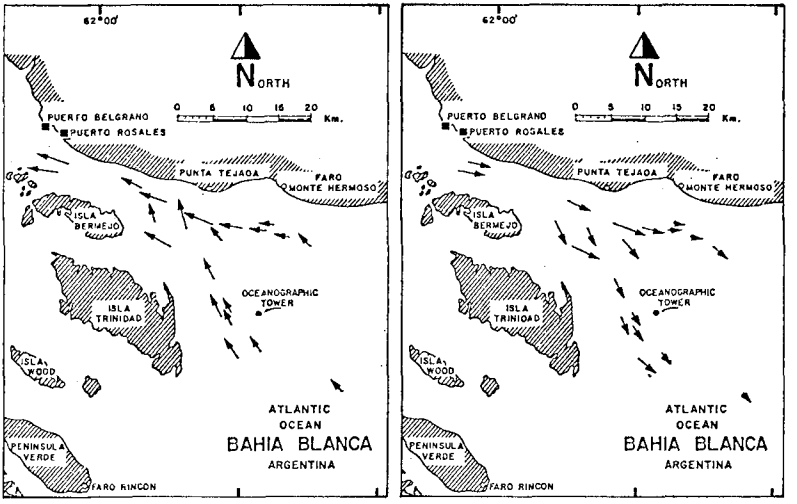

Fig. 4 Mean current pattern

The currents patterns, Fig. 4 shows in the inner part a larger velocity during ebb flow than during flood flow, ranger in the order of 0,7 - to 1,0 m/s. In the outer region the velocities decrease to the order of 0,3 m/s and the direction remains almost reverse within an angle of 10-15°. Further off shore the current directions rotate rather than reverse.

The climatological conditions at Bahía Blanca were obtained from the Servicio Meteorológico Nacional. Local winds statistic was obtained from Comandante Espora Station of the Navy.

A proper description of the wave climate in the estuary was required to design the navigation channel and for the hydrosedimentological computations. Since no wave measured data were available for the project, a Datawell waverider were first installed at the entrance of the bay for a six month period.

It was later moved to Banco del Norte, where is recording since more than one year. A wave staff was also installed on the measurement tower near buoy 8 (See Fig. 1)

Until the processing and analysis of the wave data of at least one year record has been completed other information had been used. For that the wave climate was divided in 2 categories: waves generated locally from onshore winds blowing from SW to NE directions and incoming ocean waves (swell) originating off shore from E-S directions.

The wave characteristics for onshore wind conditions were determined from the JONSWAP sepectrum (Ref. 1)

The ocean waves offshore Bahía Blanca were estimated by hindcasting on the basis of a mathematical model for the Argentina Sea developed by the Argentina Navy Meteorological Service.

On a 90 m. depth and for a period from May 1976 to January 1981, daily waves heights, periods and directions were computed, adding up a record of about 1700 data.

The ocean waves were refracted to get the shallow ocean waves climate for different points along the channels alternatives.

To this end, a mathematical model was used based on linear wave theory (Ref. 2)

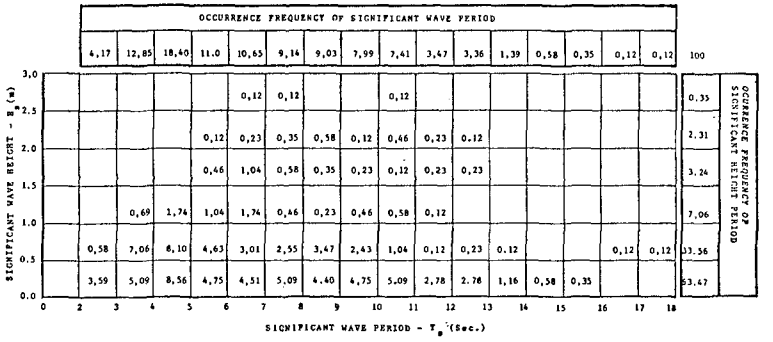

Fig. 5 Waves dispersion diagram

After the comparison with the one year measured data, a rather good correlation was verified, spetially in the local wind waves.

In Fig. 5 the dispersion diagram is illustrated which was prepared on the basic of the Draper analysis and wave spectrums.

Suspended sediment measurement were done by means of a turbidity meter and water samples at six points in each vertical, at the same locations of the current meter stations. Seabed samples were taken at several locations and at all current meter stations.

The grain diameter D50 varies from 30μ to 300μ showing three types of sediment in the full area. There are zones with full sand with D50 = 200μ , other areas with a mixture of sand and silt with D50 = 100μ and some small areas in which the sediment is composed basical by fine sand, silt and clay.

Other measurement related with the subbottom characteristics

were also done, like subbottom seismic profiles by uniboom and sparken technics, and vibrocoring in different location from which were obtained 6 m of samples and in some special points like the area of installing of the measurement tower a case drill hole up to 20 m. soil depth.

Most of this information, also usefull for sedimentation studies,was related with the dredgability of the soil in the channels alternatives.

5. THE PILOT DREDGE

After the analysis of the data collected from all the area along the existing channel and the alternatives was concluded, the pilot dredge was located. The selected area was the so called northern route because for the southern alignment other areas could be take as a control area, like channel sections between buoys 13-14 and 7-8.

Therefore a test channel of 2000 m long and 70 m wide, having a minimum depth of 13,5 m below datum, was dredged during December and January 1981-1982.

Fig. 1 shows the location of the pilot test dredge.

After the channel was completed, a bathymetric survey were done as well as current measurement both on the bank and on the channel by means of two self recording meter during 15 days.

The wave climate was controlled by the wave gage installed at Banco del Norte.

All this information together with a regular sounding each three mont, let us to check the sedimentation estimation rate providing a proper tool for the calibration of the sedimentation formula. An spetial measurement programm for the one year survey was carried out in January 1983, which includes measurements of currents, suspendend sediments and bed samples of 1 m core.

6. SEDIMENTATION ESTIMATES

A sedimentation estimates metodology was developed on the basis of the existing knowledge for areas were the combined action of currents and waves acts on the sea bottom sediment. With this metodology an estimation of the sedimentation rate were carried out for all the different sections of the channel, taking into account the different wave action and current patterns that are present in each of them.

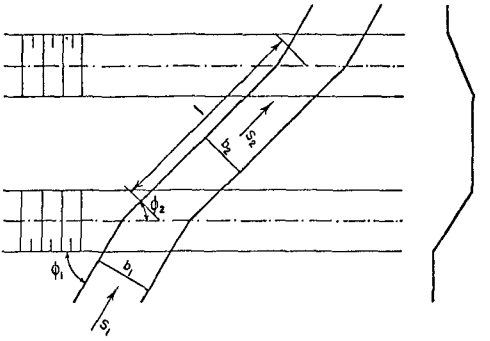

Fig. 6 Channel, definition sketch

Change in the current filled when the flow cross a dredged channel with a given angle, was estimulated on basis of the current refraction research conducted at HRS Wallingford (Ref. 3)

That approach was used for every section and for the pilot channel, where the previous estimation was obtained.

The sedimentation in a channel section can be determined by the difference in sediment transport entering and leaving this section.

Looking to the sedimentation mechanism it can be distinguished into the following three groups of processes.

1. Sedimentation due to the combined effect of waves and currents.

2. Sedimentation due to gravity infill at channel slope.

3. Sedimentation or erosion due to an extra inflow which results from changing hydraulic boundary conditions along the channel alignment.

From the three mechanism recalled, the first one is the most important, particulary in the outer area.

Therefore in the following only we will refer to this one.

The sediment transport by waves and currents approaching a channel under an angle ϕ in general decrease due to the decrease of turbulence in the channel.

The mathematical formulation for the adaptation of the suspendend sediment in the channel has been given by Fredsøe (1976) Ref. (4) and Bijker (1980) Ref. 5.

As a general approach, sediment transport can be classified in bed load and in suspended load. The suspended load could be of two origen: the fine sediment from the bed putted in suspension by the current and the wash load which is very fine sediment(fine silt and clay)already in suspension.

Looking to the channel scheme Fig. 6 the volume of sedimentation in the time Δt, can be estimated as:

$$V = (S_1 - S_2(\ell)\frac{b_2}{b_1} b_1)\,\Delta t \qquad (1)$$

where

S_1 = total load in the bank in equilibrium

$S_2(\ell)$ = total load at a distance ℓ along the streamline from the upstream side slope

in which assuming that the bed load adapts instantaneously to the hydraulics characteristics in the trench, we can write:

$$S_1 = S_{f_1} + S_{s_1} \qquad (2)$$

and

$$S_2(\ell) = S_{f_2} + S_{s_2}(\ell) \qquad (3)$$

where

$S_{f_{1\ 2}}$ = bed load in equilibrium in bed and trench

S_{s_1} = suspended load in equilibrium in the bank

$S_{s_2}(\ell)$ = suspended load at a distance ℓ along the streamline from the upstream side slope

Following Bijker, the suspended load in a trench due to currents and waves, can be written as:

$$S_s(\ell) = (S_{s_1}\frac{b_1}{b_2} - S_{s_2})\exp(-\frac{wE\ell}{V_2 h_2}) + S_{s_2} \qquad (4)$$

where

S_{s_2} = suspended load in equilibrium in the trench

$$E = \frac{h_{*1}(h_{*2} - h_{*1})}{h_{*2}(1 - \exp(-h_{*1})) - \beta h_{*1}(1-\exp(-h_{*2}))} \qquad (5)$$

and h_{*1}, h_{*2} = value of h_* outside and in the channel respectivily = $\frac{wh_1}{\varepsilon_1}$ and $\frac{wh_2}{\varepsilon_2}$

where

$$\varepsilon = 1/6\ V_{*cw} h \tag{6}$$

and

V_{*cw} = shear velocity under combined effect of wave and current according to Bijker (1967)

$$V_{*cw} = V_{*c}\left(1 + \frac{1}{2}\left(\xi \frac{U}{V}\right)^2\right)^{1/2} \tag{7}$$

$$V_{*c} = \text{shear velocity under current alone} = \frac{V g^{1/2}}{C} \tag{8}$$

w = fall velocity of sediment

h_1, h_2 = depth in the bank (1) and channel (2)

ℓ = distance from the channel boundary along the flow trajectory.

U' = maximum orbital wave velocity at the bottom

V = depth averaged current velocity

$$\xi = (fw/2g)^{1/2}\ C \tag{9}$$

fw = wave friction coefficient =

$$= \exp\left(-5{,}977 + 5{,}213\left(\frac{A}{r}\right)^{-0{,}194}\right) \tag{10}$$

(if $A/r \leq 1{,}47$, $fw = 0{,}32$)

A = orbital excursion at the bottom

$$\beta = \frac{Cb_1}{Cb_2} \tag{11}$$

Cb_2, Cb_1 = bottom concentration outside and in the channel respectively.

For the calculation of the suspended and bed load in equilibrium, on the bank and in the channel, we can use different formulae. The first approach used, was to estimate the total load by means of the Engelund-Hansen formulae and then divided the result in to bed and suspended transport by means of the so call Bijker-Einstein, so

$$S = \frac{0{,}05\ (V_{*cw})^4\ C}{g^{5/2}\Delta^2 D_{50}} \tag{12}$$

where

$$C = \text{Chezy coefficient} = 18 \log \left(\frac{12\,h}{r} \right) \qquad (13)$$

r = bed roughness

$$\Delta = \text{relative density of bed material} = \left(\frac{\rho s - \rho w}{\rho w} \right)$$

D_{50} = particle diameter (50% by weight)

and according to Einstein modified by Bijker since

$$S = S_f + S_s$$

$$S_s = 1{,}83\, S_f \left(I_1 \ln \frac{33h}{r} + I_2 \right) \qquad (14)$$

where I_1 and I_2 are the well known Einstein integral.

Following this approach it was estimated the sedimentation along the different alignment of the designed channel, taking into account the different wave and current influence for each section, so waves and current where schematized in group, with their associated percentage of occurrence. Therefore, the following formulae was applied

$$V_s = \sum_{w,c} V_{wc} p_w(H,T)\; p_c(V,\phi)$$

where

V_s = total yearly sedimentation

$p_w(H,T)$ = Wave percentage of height H and period T

$p_c(V,\Phi)$ = Current percentage of speed V and direction ϕ

V_{wc} = sedimentation volume due to waves and currents.

This approach was applied to the pilot dredge taking in to account, because their short lenght compared with the navegation channel, the sediment input from the both ends of the same and taking the field measurement current data for the bank and channel.

The result of this calculation, show an average value for the yearly sedimentation of about 0,80 m.

After seven month from the basic sounding of the pilot dredge, the sedimentation was higher. Fig. 7 and Fig. 8 shows some cross

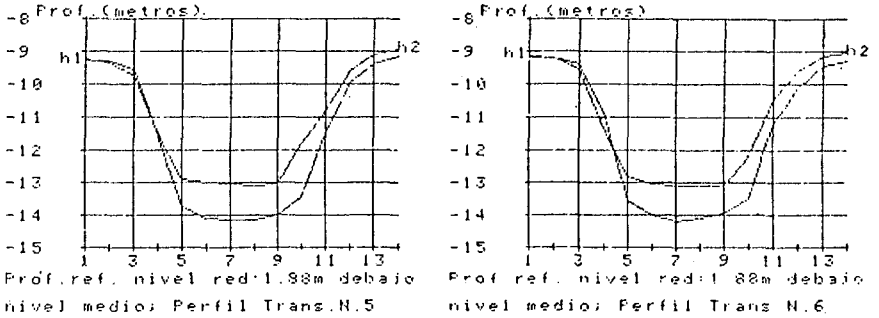

Fig. 7 Pilot dredge, comparison of cross sections after seven months.

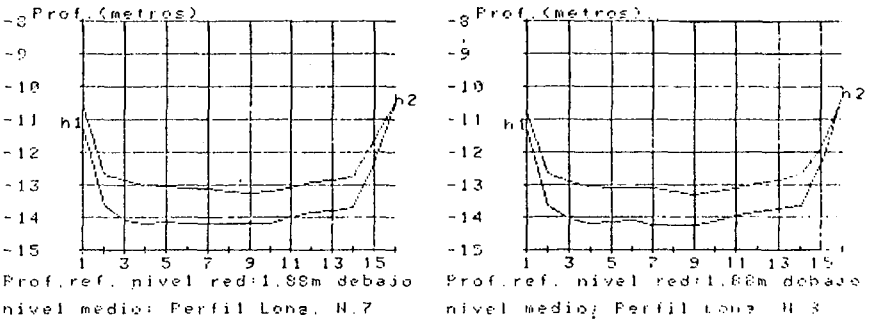

Fig. 8 Pilot dredge, comparison of longitudinal sections after seven month.

and longitudinal section of the channel. The averaged sedimentation observed in seven month is about 1 m.

After this dissapointment, we went back to ower estimation formulae and reanalized them.

First we found that the Engelund-Hansen formula it is very sensitive to the roughness of the bottom, parameter very difficult to estimate.

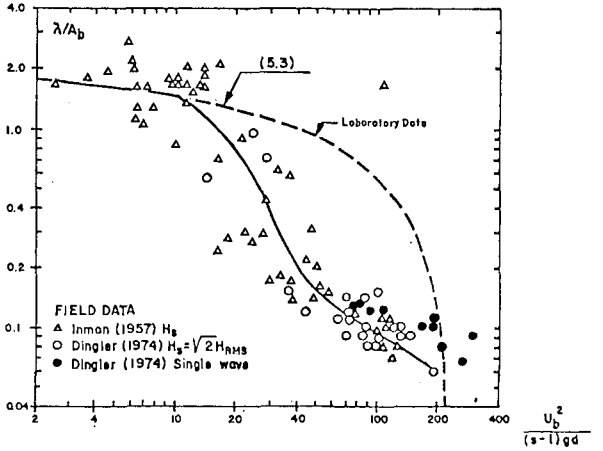

Fig. 9 Ripples height due to waves

Few data from the nature are obtained about the ripples height and wave length from the wave action.

Inman and Dingle data Fig. 9 shows that the prototipe result does not follow the laboratory test. Therefore the first thing to do was to change to another formulae, like the Bijker bed load for current and waves.

$$S_f = \frac{5\, D_{50} V \sqrt{g}}{C} \exp\left(-\frac{0,27 \Delta D_{50} g}{\mu V_{*wc}^2}\right) \qquad (16)$$

where

μ = ripple coefficient = $\left(\frac{C}{C'}\right)^{3/2}$

C' = Chezy coefficient for the grain size D_{90}

and taking, according with Einstein the suspended load, for which the bed concentration can be computed as:

$$Cb = \frac{S_f C}{6,34 V\, r\sqrt{g}} \qquad (17)$$

with a suspended vertical concentration distribution as follows:

$$C(z) = Cb \left(\frac{h-z}{z} \cdot \frac{r}{h-r}\right)^{z_*} \quad (18)$$

where

$$z_* = \frac{w}{kV_{*cw}} \quad (19)$$

k = Von Karman coefficient

The result of this calculation shows a less dependence with the bed roughness but now an overestimation of the sedimentation.

Looking to the results got from the Engelund-Hansen, and the Bijker approach, we come to the conclution, that the problem were located in the fact that in both methods the suspended load were overestimated.

The reason of that is because the calculation of the turbulent diffusion coefficient out of the wave boundary layer, is made as produced by the combined effect of the wave and current.

As it was shown by Kennedy experiments and by ISVA measurements, the sediment concentration due to waves decrease very fast as we go up from the bottom, confirmed that out of the wave boundary layer the turbulent diffusions is very small.

On the other hand, also the bed concentration could be overestimated if we consider that it came from the bed load by wave and current. Therefore, we also modified the bed concentration for the suspended load, taking it as due to the current alone. So the wave and current action only affect the bed load.

ROUGHNESS r (m)	BIJKER – EINSTEIN			FIELD DATA

Fig. 10 Sedimentation estimate in the pilot dredge, using different aproach, after seven months

In Fig. 10 we can see the result of these different approach, for different roughness criteria applied to 7 month for the pilot dredge from February to September 1982.

7. CONCLUTIONS

From the result got up to now, we can conclude, that for the estimation of the sedimentation in a channel in the open sea, it is still necessary to have a test channel.

It is also very important to have a complete picture of the hydrodynamic behaviour of the area, for which a simultaneous and complete field survey its neccesary.

We point out, also that in order to follow up in the knowledgement of the sedimentation by waves and currents an effort it has to be done in field measurements, like the ripple formations and suspended sediment concentration.

In such a way, we have planning to make careful measurement of concentration in the field, near the bottom, both on the banks and in the channel.

The formula currently applied has to be checked, but in the mean time we can conclude that the Bijker formula can be used but taking for the suspended load the turbulent diffusion coefficient as derived from the current alone.

SPENDING BEACH BREAKWATER AT SALDANHA BAY.

Ir. D. Zwemmer*, Ir. J. van 't Hoff**

1. ABSTRACT.

This paper describes the design and construction of a sand breakwater at Saldanha Bay exposed to the severe swell conditions of the south Atlantic.

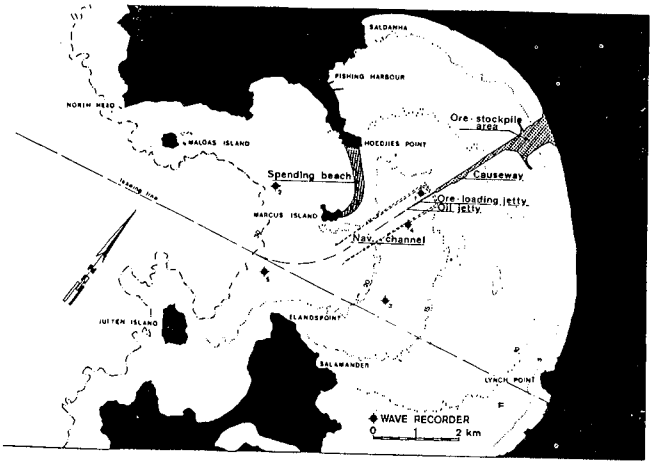
The design of this spending beach breakwater was aimed to establish a seaward profile with sufficient "playroom" to incorporate profiles resulting from extreme wave conditions.
As far as the construction is concerned the emphasis is put on the sandlosses during execution of the works.
Finally the designed profile is compared with the actual established beach profile.

2. INTRODUCTION.

Saldanha Bay is situated some 110 km North West of Cape Town, South-Africa, on the Atlantic Coast. The bay has a wide entrance between protruding peninsulas which makes it one of the best natural harbours of the southern part of the African Continent. Through the centuries the bay has been used as a harbour of refuge by passing explorers and East Indiamen. Had it not been for the lack of fresh water, Saldanha Bay would have been developed as a major port long ago. Because of its proximity to deep water and the relatively few engineering works required, Saldanha Bay was chosen to be developed as harbour terminal of the iron ore export scheme, undertaken by the South African Iron & Steel Industrial Corporation Ltd. (Iscor).

* D. Zwemmer. Director Ingenieursbureau Ir. L.W. Lievense, Breda. The Netherlands.
** J. van 't Hoff. Head engineering department. Van Oord-Utrecht N.V. The Netherlands.

In order to enlarge the existing sheltered area of the inner bay, the northern peninsula Hoedjies Point was extended by a breakwater to Marcus Island situated in the middle of the entrance to Saldanha Bay (see illustration 1).
This breakwater was designed and constructed as an artificial sand beach on which the waves would spill and thus gradually dissipate their energy, hence the name "spending beach breakwater". This article describes the design and construction of the "spending beach".



ill. 1. General lay out of harbour configuration at Saldanha Bay.

3. BASIC INFORMATION.

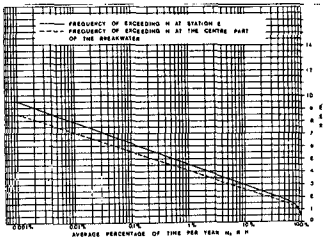
3.1. Waves.

During a period of two years, preceeding the design period, wave heights were measured at five different locations in the bay (ill. 1). Simultaneously "deep sea" wave heights, directions and periods were measured. The measurements were executed by the Council of Scientific and Industrial Research (C.S.I.R.).

At measuring station 2 situated just seaward of the proposed breakwater, at a depth of approximately 25,00 m below C.D. the results show the following:

Table nr. 1	Station 2			
Frequency exceeded %	H_s	$\bar{H}_s > H_s$	T_s	$\bar{T}_s$
	m	m	sec.	sec.
50	1,75	-	13,4	-
10	2,90	3,70		15,3
5	3,40	4,10		15,7
1	4,50	5,15		16,6

The maximum significant wave height recorded at station 2, was H_s = 4,90 m, corresponding with a deep sea wave height (significant) of H_s = 8,50 m. The wave height probability curves given in illustration 2 show the freguency of exceeding of H_s at station 2 and the centre part of the breakwater.



ill. 2. Wave height probability curves in station 2 and in the centre part of the breakwater.

The predominant deep sea wave directions are south-south-west and south-west. Measurements obtained by means of clinometer-readings show SSW 43,9 % of the time, SW 37,0 % and S 10,1 %.

Due to the configuration of the entrance of the outer bay, the combined effect of refraction and diffraction, forces the incoming deep sea swell to pass Marcus-Island with only a slight variation in wave direction.

A diffraction-refraction model built to acquire an insight into the wave reduction in the lee of the proposed breakwater, was also used to obtain photographs of the wave pattern of the area between Marcus Island and Hoedjies Point peninsula. Photographs were taken for different deep sea wave directions and periods. Aerial photographs taken of the actual wave crest patterns of know deep sea conditions, showed good correlation with the corresponding photographs of the model tests. An example hereof is given in illustration 3.

3.2. Wind.

Wind speed and direction were measured at Elandspoint, situated due south of Marcus Island, during the period March 1971 to February 1974.

The SSW-direction is the predominant wind direction with an average wind speed of 7 m/sec. The average windspeed during spring is 8,5 m/sec.

3.3. Tides.

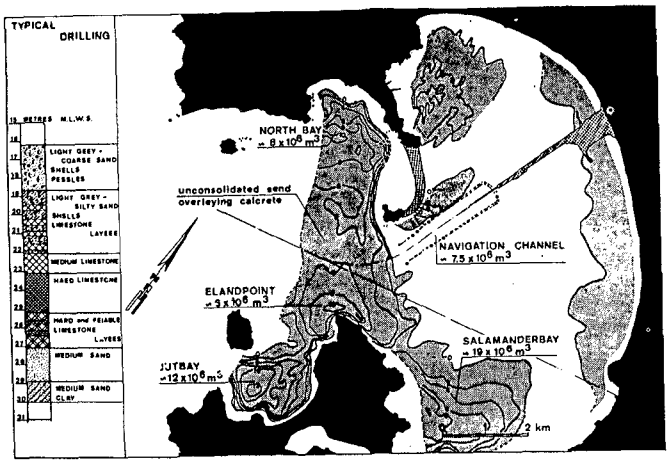
The tides are as follows: MHWS : 1,76 / MHWN : 1,26 m / MLWN : 0,76 m / MLWS : 0,26 m ; all related to C.D.

3.4. Currents.

As only a few current measurements were made, only approximate values of currents could be established. Currents at a depth of 10 m in the north channel went up to 0,15 m/sec. during ebb-tide and to 0,24 m/sec. during flood-tide. The direction of the tidal currents was almost perpendicular to the line Hoedjies Point - Marcus Island. Wave induced currents could not be distinguished.

3.5. Geology of the sea-bed.

A seismic survey related to some borings in the area of the proposed breakwater showed that the bottom generally consists of compacted sands on top and in between layers of calcareous material varying in hardness. At the lee side (north-east) of Marcus Island some loose sand layers could be distinguished. At some places (Blinkklip Rock) granite outcrops stick through the bottom layers. The shoreline of both Hoedjies Point and Marcus Island consists of huge outcrops of solid granite and boulders.



ill. 3. Loose sediments overlaying calcareous material, sandwinning areas.

3.6. Available building material.

As millions of m^3 of sand were required to build the spending beach breakwater, intensive soil investigations were carried out, comprising several sonar surveys, drilling/probing using a self elevating platform

and a shallow water structure placed on the bottom, also washborings were made using a floating platform.

In the Saldanha Bay area the basement is formed by the so called "Cape Granite". Drilling results showed that the buried granite surface is highly irregular. In this basement the valleys are filled in with recent and subrecent material, gently sloping down in the seaward direction. The infill material consists mainly of loose and compacted sands with layers of cemented, sand and calcrete, differing in hardness.

The areas where loose sediment is overlaying calcareous layers, are indicated on illustration 3, being the outcome of an extensive sonar survey. As main sandwinning areas could now be distinguished:
- Salamander bay area of which approximately 19 x 10^6 sand could be obtained and the
- navigation channel, with a total quantity of 7,5 x 10^6 m^3 including large quantities of cemented sands and calcareous materials.

A typical drilling of the area of the navigation channel is also given in illustration 3. The medium grain size diameter of the numereous samples varied considerably. The Salamander bay area showed some small areas of decomposed granite (600 μ) excellently suitable as building material for the breakwater.

4. DESIGN.

4.1. General.

In an early stage of the design, after discussion with the Delft Hydraulic Laboratory, it was decided not to execute an extensive model study as this could not give sufficient reliable results within the available time, but to establish a design based on the knowledge obtained from literature and on the measurements of comparable existing beaches. In the design two main items can be distinguished:
a. the horizontal alignement and
b. the seaward profile.

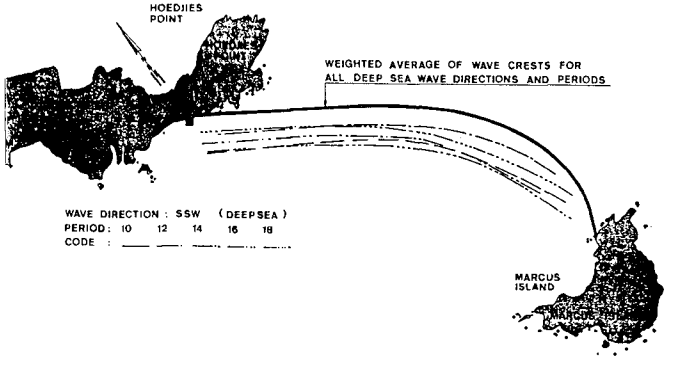
The horizontal alignement of a beach in general, must be designed in such a way that the predominant wave direction will always impinge perpendicular to the beach in order to prevent lateral transport of material.
It shall be clear from the geography of the bay that the location of Marcus Island in relation to Hoedjies Point offered a unigue possibility to build an artificial cove as a natural extension of North Bay beach (see illustration 1).
As other kidney-shaped beaches exist in the area, it was quite a challenge to try to design an artificial beach which could withstand the incoming ocean swell having its origin in the "roaring forties".

The seaward profile in general depends on the size of available sediment and the local wave conditions. Since wave conditions vary continuously, a single stable equilibrium profile cannot exist. The eguilibrium state will thus be of dynamic nature, continuously adapting itself to the momentary wave climate.

The design was aimed to establish a seaward profile, with sufficient "playroom" to incorporate profiles resulting from extreme wave conditions.

4.2. Horizontal alignment.

For different deep sea wave directions and wave periods, the wave crest patterns between Hoedjies Point and Marcus Island, as observed in the model test, are shown in illustration 4. The low-water line of the proposed breakwater was determined parallel to a fictive wave crest being the weighted average of the different wave directions and periods.
Taking into account the extended low water line of North Bay beach and the location of Marcus Island, the low water line of the proposed breakwater was now fixed, reflecting the kidney-shape like so many beaches in the area.
The width of the beach was determined by two factors. Firstly by the variation of the low water line being dependent on the wave direction and secondly by the variation of the seaward profile being dependent on the wave height.



ill. 4. Wave crest patterns according to model studies.

When a wave approaches the beach at an angle a longshore transport is generated. This breaking wave and the movement of sediment is caused by the component of the wave in the longshore direction and the longshore current generated by the breaking wave. Tidal currents in the area of the proposed breakwater could be considered negligible.
The longshore transport, being dependent on the wave energy and the angle of wave approach, should gradually decrease and finally come to a stop as the shoreline is shaped into line with the incoming wave-crests. Studies of a.o. Bascom, Inman, Rusnak showed large variations in beach-profile and large areal movements of sand in relative short periods of time. It was therefore assumed that the horizontal alignment should adapt itself rather rapidly to a change in wave direction.

The width of the beach (shore) should thus be able to "accomodate" all the low water lines corresponding with the different deep sea wave directions. For other kidney shaped beaches in the area, although no beach measurements were taken over long periods, the verbal opinion of local fishermen indicated only minor changes in the low water line.

4.3. Seaward profile.

4.3.1. General.

The design problem was approached as being two-dimensional, i.e. the design of a cross-section which remains in equilibrium when subjected to local wave conditions, consistent with size and amount of available material.
This two-dimensional approach was considered acceptable due to the fact that tidal currents after the closure of the gap between Hoedjies Point and Marcus Island should be negligible, while generated longshore transport should always fade out the source of its origin, i.e. decrease the angle of wave approach by re-shaping the beach.

The main profile changes are limited to be inshore zone. A seaward profile is considered stable when in the long run the offshore transport equals the onshore transport of material. As the waves tend to change periodically, the profile adapts this change and in general a "summer" or step profile and a "winter" or bar profile can be distinguished. Under rough weather conditions a "winter" profile is formed with a shore line which may move landwards over a considerable distance. Large quantities of sand are then transported in the direction of the sea, where they are "stockpiled" in the form of one or more sand ridges or "bars". In calme weather the waves will gradually shift this sand back towards the shore.
There is accumulation of coarse sediment in zones of maximum wave energy dissipation and deposition of fine sediment in areas sheltered from wave action. This phenomenon is called sediment sorting.

4.3.2. The offshore region.

Waves travelling towards the projected breakwater, eventually reach a depth where the water motion near the bottom begins to effect the sediment on the bottom.
The water motion immediately above the sediment bed then exerts enough shear to move sand particles. This depth is called the incipient depth and is determined by the sediment size and wave characteristics. Initially only very fine material oscillates in the direction of the wave and as the water depth decreases coarser sand particles will be moved back and forth in ripples.

In order to determine the incipient depth it is necessary to calculate both the orbital velocity immediately above the seabed and the threshold velocity at which erosion of the bed material takes place. The orbital velocity is calculated as follows:

$$U_z = 0{,}7 \frac{\pi \times H}{T} \quad \frac{\cosh . \frac{2\pi (h - z)}{\lambda}}{\sinh . \frac{2\pi h}{\lambda}}$$

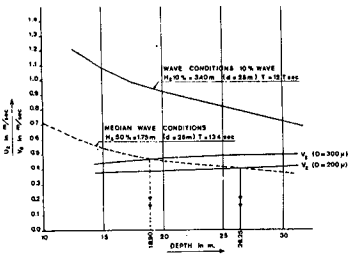
The threshold velocity at which movement of sand grains occurs, is computed as follows:

$$v_e = 4{,}5 \left[\log \frac{12\ h}{4\ d_{50}} \right] \sqrt{d_{50}} \quad \text{while} \quad \frac{v_e}{v_z} = \frac{\log 32 - \log d_{50}}{\log 8\ (h-z) - \log d_{50}}$$

Since no sudden major sand transport takes place in the offshore region (no "storm" and "summer" profiles), it is assumed that the bottom configuration is determined by median wave conditions. Table nr. II gives the median wave conditions for the different water depths, as well as the H_s 5 % wave conditions.

Table nr. II	H_s 50 % T, = 13,4 sec.		H_s 5 %, T = 15,7 sec.	
h in m	H_s in m	λ in m	H_s in m	λ in m
deep	1,84	280	3,47	384,5
30	1,73	202	3,35	246
25	1,75	188	3,40	236
20	1,79	171	3,56	207,5
17,5	1,82	160	3,64	192,3
15,0	1,87	148	3,73	180,7
12,5	1,93	140	3,89	165,3
10	2,01	126	4,08	146,3

It is assumed that transport of bottom material takes place above the "apparent" bottom in a band of approximately 0,75 x the height of the ripples. The ripple height is approximately 0,10 x the water depth. The graph of illustration 5 shows that for median wave conditions 200 μ sand starts to move at a depth of 26,25 m and 300 μ sand at a depth of 18,90 m.



ill. 5. Critical velocity for D = 200 μ and D = 300 μ

The equilibrium slope developing in the offshore region can be estimated using the following equation:

$$\sin \alpha = \frac{k}{J} \cdot f_1 \left(\frac{h}{\lambda_0}\right), \text{ wherein } \frac{k}{J} = \frac{15{,}23\ H_0^2}{T \cdot \lambda_0 \cdot d_{50}^2} \cdot \left(\frac{d_{50}^2}{T}\right) \cdot 0{,}57 \text{ and}$$

$$f_1 \left(\frac{h}{\lambda_0}\right) = \frac{\cot gh^2 \left(\frac{2\pi h}{\lambda}\right)}{\sinh^2 \frac{2\pi h}{\lambda} + \frac{2\pi h}{\lambda_0}}$$

The results of the calculation are given in table III.

Table nr. III waterdepth	H_s . 50 % d_{50} = 300 μ	H_s . 50 % d_{50} = 200 μ	H_s . 5 % d_{50} = 300 μ
30 m			1 : 28
25 m	1 : 76	1 : 54	1 : 17
20 m	1 : 49	1 : 34	1 : 12
15 m	1 : 29	1 : 20	1 : 7
12,5 m	1 : 18,5	1 : 13	1 : 4

4.3.3. The breaking depth.

To estimate the depth at breaking, it is recommended by the Shore Protection Manual to use the empirical relationship between d_b/H_b and H_b/gT^2 as derived from various beach slopes.

Station 2:
$\bar{H}_s > H_s$ 1 % = 5,15 m
h = 25 m
T_s = 16,6 sec.

$\lambda_0 = 430$ m

$\frac{h}{\lambda_0} = \frac{25}{430} = 0{,}0581 \rightarrow \frac{H}{H_0^1} = 1{,}0 \rightarrow H_0^1 = 5{,}15$ m

$\frac{H_0^1}{\lambda_0} = \frac{5{,}15}{430} = 0{,}012$

slope 1 : 50	H_b = 7,11 m	d_b = 7,96 m
slope 1 : 30	H_b = 7,62 m	d_b = 8,08 m
slope 1 : 20	H_b = 8,14 m	d_b = 7,81 m

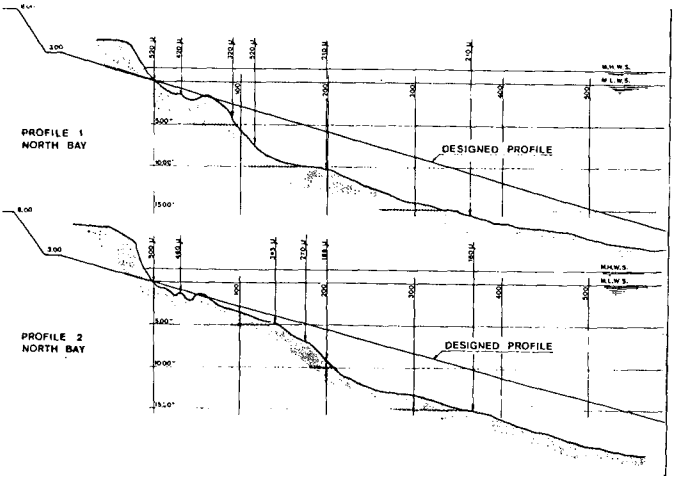
For $\bar{H}_s > H_s$ 50 % slope 1 : 50 d_b = 3,30 m

4.3.4. The inshore region.

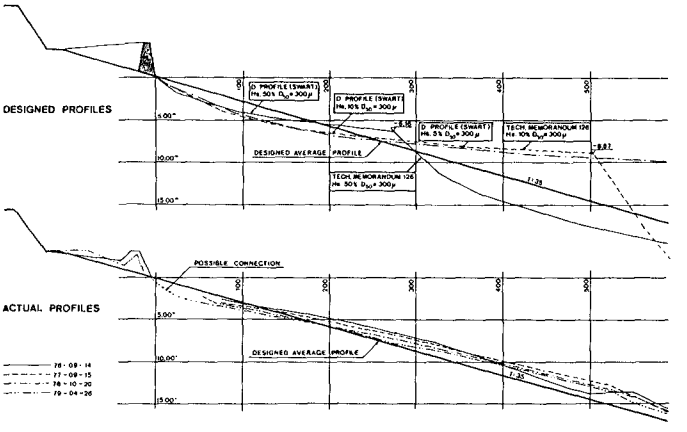
At the time of the initial design, "inshore" eguilibrium profiles could not be calculated theoretically. A great number of underwater profiles of existing beaches in the Saldanha Bay area and at other locations were compared with regard to wave attack and median sand grain diametcr. This comparison indicated that an inshore profile slope of 1 : 35 with a sand of d_{50} = 300 μ should be a safe estimate. In illustration 6 the designed profile is compared with the actual profiles of North Bay beach. The so called "sorting effect" of the sand grains along the profile should result in steeper slopes and thus increased safety. In 1974 mr. D.H. Swart published a method of calculating the eguilibrium profile of the so called D-profile (developping profile). In illustration 7 the theoretically calculated D-profiles (part below still water level) are given for H_s 50 %, H_s 10 % and H_s 5 % wave conditions.

4.3.5. The foreshore (beach face).

Numerous field studies showed that there is a good correlation between median sand diameters and the slope of the foreshore. The foreshore (beach) slopes of the existing beaches around Saldanha Bay are corresponding closely with the data of these field studies. For an exposed beach and a medium grain size diameter of the sand of 300 μ, the slope of the foreshore shows 1 : 35.



ill. 6. Comparison of designed profile with the actual profiles of North Bay beach.



ill. 7. Theoretically calculated D-profiles, spending beach design and actual profiles.

4.3.6. The "set-up".

"Set-up" due to wave action is that phenomenon whereby the average water level along the beach rises above that encountered under so called still water conditions. According to Bowen the set-up "z" depends on the breaker height H_b and amounts to a maximum of $z = 0{,}25\ H_b$.

Assuming again the $\bar{H}_s > H_s$. 1 % wave conditions:
$\bar{H}_s > H_s$ 1 % : 5,15 m (at station 2), T_s = 16,6 sec, λ_0 = 430 m.
H_b = 7,62 m.

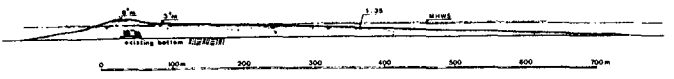
$$Z = 0{,}19 \left[1 - 2{,}82 \sqrt{\left(\frac{H_B}{gT^2}\right)} \right] . H_B = 1{,}23 \text{ m}$$

Since a "storm" profile could develop in a very short space of time the breaker depth d_b must be measured below C.D. ≙ M.L.W.S. The maximum height of the set-up "z" must be added to M.H.W.S. The maximum height of the wave run-up thus becomes 1,50 m (tide) + 1,23 m = 2,73 m$^+$ C.D. The design height of the berm crest was established at 3,00 m$^+$ C.D.

4.3.7. The back-shore.

Inland of the upper limit of wave set-up is called back-shore. The inland crest or berm crest could be overtopped by extremely high waves in which case the overtopping water flows down the so called deflation plane. Initially this plane was given a width of 20,00 m in order to take care of the changes in horizontal alignment. The final safety barrier (dike) was given a height of 8,00 m$^+$ C.D. (see ill. 8). As a result of the applied construction method, a stone wall was dumped at the proposed low water line up to a height of 4,00 m$^+$ C.D., the width at the crest being approximately 6,00 m. This relatively small stonewall consisted of quarry run 0-4000 kg. The stone crest was incorporated in the construction by filling the now 120 m wide plain between this stone crest and the root of the safety barrier up to a level of 3,10 m$^+$ C.D.

It shall be clear that this small stone wall prevented the foreshore (beach slope) to develop initially. It was assumed that the stone wall would finally disperse, due to wave action, below a level of M.H.W.S. with a seaward slope of approximately 1:4 - 1:6, thus offering an additional safety. The presence of this stone wall should also fix the horizontal alignment. Only the sand profile seaward of this wall could adapt itself to changes of incoming waves, resulting in varying depths just seaward of the wall. The final design profile is given on illustration 8.



ill. 8. Designed cross-section of spending beach breakwater.

5. CONSTRUCTION.

5.1. General.

For the construction of the spending beach breakwater about 20 million m^3 of sandfill was required.

The main volume of sand was obtained from the winning area due east of Salamander Bay (see illustration 3) while an additional amount of approximately 7 million m^3 became available during the dredging of the navigation channel.
The initial programme showed the construction time of the breakwater to be one year. However, during the first months of construction it appeared that the estimated production quantities in the winning areas were far too optimistic. This was mainly due to the fact that the sand grains were more cemented than anticipated which lowered the concentration of the sand-water mixture flow towards the suction pipes of the trailhoppers. As a conseguence additional dredgers had to be mobilized in order to finalize the construction in time.

The breakwater was built in two stages. The first building stage comprized the dumping of sand in the profile by means of hopper dredgers up to a level of 6,6 m⁻ M.L.W.S. for which approximately 15 million m^3 of sand was required. The second building stage, being the closure of the upper part, was realized by the joint-effort of shallow draft hoppers and two big cutter-suction dredgers.

The closing started from Hoedjies Point in the lee of which the two cutter-suction dredgers operated initially. After the above water part protruded some 600 to 800 m from Hoedjies Point, one of the cutter-suction dredgers was moved in the lee of this above water part to recover sand from the underwater stockpile as well as the sand that was forced out of the profile due to wave action. It only took three months to close the "superstructure" of the spending beach breakwater, sometimes loosing some meters in the battle against a roaring Atlantic swell but always recovering guickly when the swell subsided.

5.2. The first building stage (see bottom up to 6,60 m⁻ M.L.W.S.)

The underwater mound was built of dredged material dumped into profile by hopper suction dredgers, the big hopper dredgers filling in the deeper parts and the smaller hoppers the shallower areas, always taking into account loaded draft and wave conditions. The local seabottom consisted of calcareous material interchanged with cemented sand layers and some loose sand. The original water depth varied from 16,00 m to 20,00 m below chart datum with steep granite slopes towards Marcus Island and Hoedjies Point. The dumping of sand by means of the different types of trailhoppers was carefully programmed and adjusted weekly in order to obtain a seaward under water profile closely approximating the designed profile.
On the 30th October 1975 the underwater mound was considered to be completed, having at that time an average height of 6,60 m⁻ M.L.W.S.
The guantities dumped into the underwater mound together with the spending beach stockpile, measured by shiploads, showed the following:

. "Humber River" (big trailhopper)	10,200,000 m^3
. "Willemstad" (med. trailhopper)	3,900,000 m^3
. "Volvox Zelandia" (transmundum type)	3,300,000 m^3
. "Geopotes 12" (transmundum type)	1,100,000 m^3
. "Queen of Holland" (cutter-suction) *)	1,900,000 m^3
Total	20,400,000 m^3

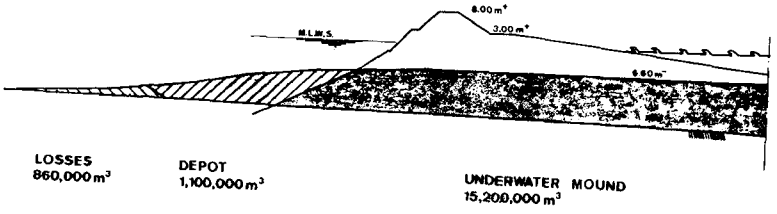
*) During the first vain attempt to close the spending beach, the cutter-suction dredger "Queen of Holland" pumped 1,900,000 m^3 into the spending beach, which quantity settled mainly below a level of 6,60 m minum M.L.W.S. and as such had to be added to the underwater mound.

The total quantity of 20,400,000 m^3 could be divided into 19,100,000 m^3 for the underwater mound and 1,300,000 m^3 for the spending beach underwater stockpile, situated at the lee side of the underwater mound along a distance of 800 m from Hoedjies Point.

The volumes of sand, including sandlosses, measured in situ as the difference of the initial soundings and the soundings at the day of completion of the underwater mound (30th October 1975) were as follows:

. underwater mound	15,200,000 m^3
. stockpile spending beach	1,100,000 m^3
. sandlosses (measured outside profile)	900,000 m^3
Total	17,200,000 m^3

In the cross section of illustration 9 the underwater mound, stockpile and sandlosses are indicated. The locations of the stockpile areas which were prepared during the first building stage and used for the closure of the upper part during.



ill. 9. Cross section of spending beach after completion of stage I, including sand stockpile and sandlosses.

The difference between the so called shipload quantities and the actual in situ measured quantities, totalling up to 3,200,000 m^3, can be attributed to the following:

a. Settlement of the subsoil as a result of the sandweight. Taking into account the results of the drilling in this area an average settlement of 0,15 m over an area of 1,800 x 400 m was considered as reasonable: 1,800 x 400 x 0,15 ≈ 100,000 m^3.

b. Too high estimates of shipload quantities as a result of:
   1) sand remaining in the ship holds during discharging (dumping).
   2) ratio between solid and loosely packed sand.
   3) loss of very fine material during the dumping process. This very fine material settled in a large area outside the beach profile in a thin layer on top of the existing seafloor not noticeable by echosounding.

The experience gathered at Saldanha Bay justified a reduction of 18 % for the bigger trailhopper dredgers and 12 % for the "transmundum" type of trailhopper dredgers. These reduction applied to the given quantities, give:
0,18 (10,200,000 + 3,900,000) + 0,12 (3,300,000 + 1,100,000) = 3,100,000 m^3.
Total: (100,000 + 3,100,000) = 3,200,000 m^3.

Sandlosses underwater mound.

According to the in- and out surveys of the construction area the total volume of sand which eventually arrived outside the construction limits was 900,000 m^3 which is 5 % of the total measured quantity. A more complete insight in the distribution of the volume of sandlosses as found after stage I of the spending beach was completed, can be obtained from illustration 10. This illustration shows the quantities of sand leeward of the underwater mound including losses and stockpiled sand per section of 100 meter across the length of the breakwater. The outer boundary of the transported sediment is also indicated; as an average the sand was transported upto ca. 500 m behind the stockpile area.
The biggest quantities of sandlosses were found near Hoedjies Point. This is explained by the fact that the construction of the underwater mound started from Hoedjies Point and from there was gradually extended towards Marcus Island.
It is interesting to note that these sandlosses did not contribute to the volume of sand in the stockpile area. The total quantities dumped in this area as measured from the shiploads and reduced with the above mentioned reduction factors were as follows:

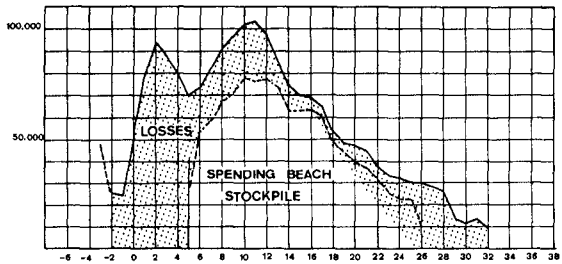
. "Humber River"	1,200,000 x 0,82 =	980,000	m^3
. "Willemstad"	100,000 x 0,82 =	80,000	m^3
. "Beachway"	35,000 x 0,88 =	30,000	m^3
. "Geopotes 12"	50,000 x 0,88 =	40,000	m^3
		1,000,000	m^3

which quantity approximately equals the measured quantity of 1,100,000 m^3 in the stockpile area.

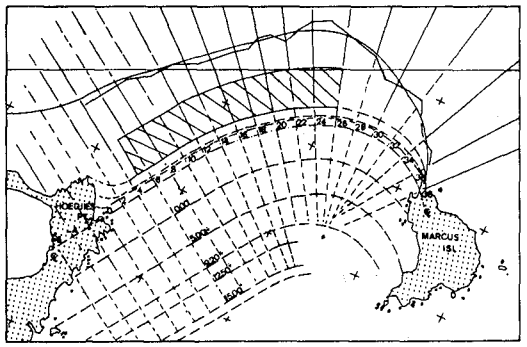
5.3. The second building area stage (6,60 m^- C.D. up to 3,50 m^+ C.D.).

5.3.1. The temporary breakwater.

The first vain attempt to close the gap between Hoedjies Point and Marcus Island, resulted into a small beach around Hoedjies Point, shading off into part of the underwater mound.
This beach in conjunction with the depth contours of the underwater mound, existing during June-September 1974, caused a most unfavourable refraction-diffraction pattern, focusing the waves at the area of Smitwinkel Bay, in which the village of Saldanha and her different fish-factories are located. During the winter-period of 1974, storms caused therefore considerable damage to moored ships, guaywalls, small jetties etc. As the second building stage was scheduled for the period November 1974 - April 1976, a second winter-period had to be confronted. To secure the shelter of the existing fishing harbour area, it was therefore decided to build a so-called temporary breakwater. This breakwater, protruding from the lee side of Hoedjies Point, served at the same time as the outer limit of the sand stockpile nr. I behind Hoedjies Point (see illustrations 11 and 12).



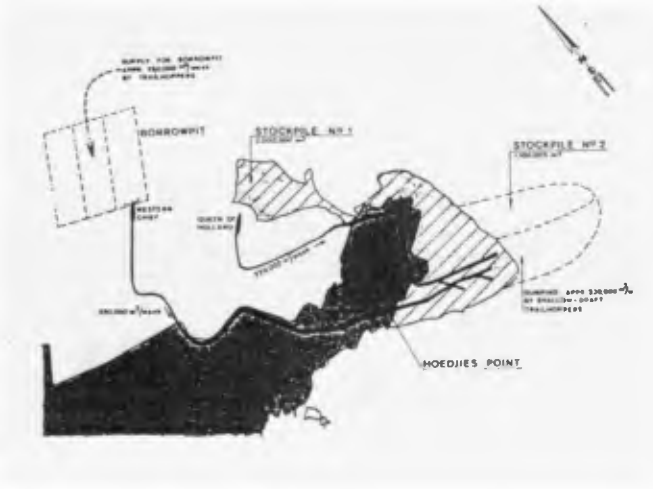
DISTRIBUTION OF SAND VOLUME LEEWARD OF UNDERWATERMOUND BEFORE START OF CONSTRUCTION STAGE II



OUTERBOUNDARY OF TRANSPORTED SEDIMENT

ill. 10. Distribution of transported sediment.

ill. 11. Aerial photograph of Hoedjies Point at the beginning of the second building stage.



ill. 12. Operation of cutter suction dredgers at the beginning of the second building stage.

5.3.2. Working scheme and sand production.

The required amount of material for this second building stage comprized approximately 5,000,000 m^3.
To minimize the sandlosses a continuous high production was essential. For the "final attack", which started from Hoedjies Point two cutter-suction dredgers were used, having a joint production of approximately 500,000 m^3 per week, assisted by three transmundum type, shallow draft hoppers with a total weekly production of about 250,000 m^3.
Both cutter-suction dredgers operated initially in the lee of Hoedjies Point. One of these dredgers was operating in an earlier prepared stockpile (2 million m^3) while the other obtained his material from a borrowpit, continuously refilled by the bigger trailhopper dredgers. (See illustrations 11 and 12.) While the "above-water" part of the breakwater was striding along towards Marcus Island, the three transmundum type hoppers were used to dump immediately in front of the above-water part, taking full advantage of their horizontal sliding bottom doors.
A second underwater stockpile has been prepared behind the first 800 m to 900 m of the future breakwater, which stockpile was increased by the losses during the construction of the adjacent superstructure. As the construction of the superstructure progressed one of the cutter-suction dredgers, advanced from the stockpile no. 1 into the created shelter of the partly finalized breakwater. The complete sand transport scheme is given on illustration 12. The working scheme was adapted weekly in order to optimize the output of this expensive dredging fleet.

5.3.3. The superstructure.

The construction of the temporary breakwater in the lee of Hoedjies Point has learned that a stone wall located at the proposed low water line, with its crest at approximately 4,00 m^+, protruding seawards like a knife-edge, considerably restricted the amount of sand washed away from the head.
It proved that a relatively small stone wall (average 120 ton/m^1), combined with the pumping of sand at the seaside some 150 m distance behind this head, offered the best progress. The wave forces transported the sand along the seaward profile as well as longitudinally towards the "knife-edge" of the stone head.
Directly in the lee of the protruding stone-wall the sand settled and here bulldozers were used to push up the sand towards the backside of the wall. Sand accretion also took place in the deeper areas just in front of the head. As soon as the level here reached 0,00 m, stone was backtipped, shifting the spear head (knife-edge) forward again, as can be seen on illustration 13. This illustration also gives an impression of the enormous size of the breaking waves as compared to the size of the truck. Every 50 m a pipe branched off running through the small stone wall towards the seaside. It very quickly became clear that for the majority of the time, the seaward outlets had to be operated, making use of the waves to carry out the further transport of the spoil.
Hydraulic fill directly in the centre part of the spending beach was restricted to a distance of 150 m, backwards from the head in order to minimize sandlosses. The cutter production system was gradually improved during the course of the construction i.e. the lay out of the discharge pipelines and rubble mound dam and also the progress of the rubble mound.

The "safety barrier" with its crest up to 8,00 m^+ C.D. was made in the orthodox way by hydraulic fill in between aand walls.

ill. 13. Protruding stone wall shifted forward and acting as knife-edge. Note the size of the breaking waves.

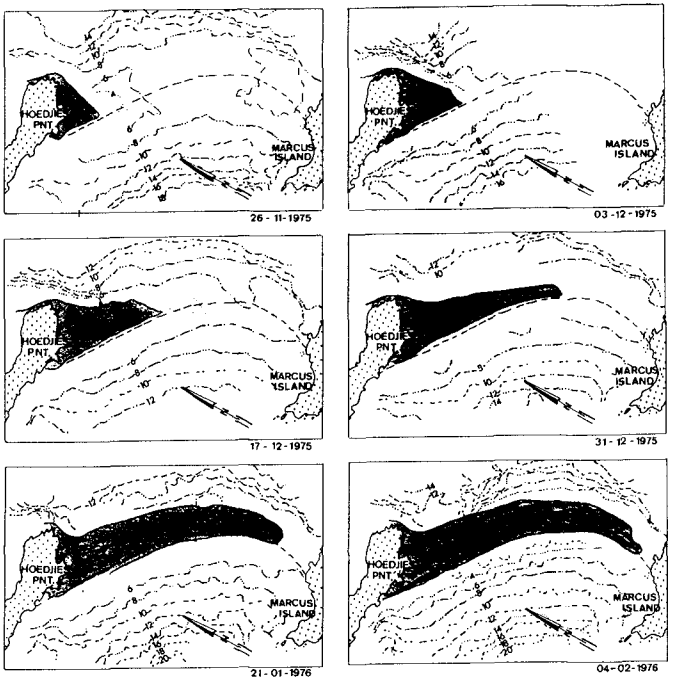
The above described construction method made it possible to realize the closure in 14 weeks with a minimum loss of sand and two months ahead of schedule. The progress is made visible in illustration 14.

The maximum significant wave height encountered during construction was H_s = 3,30 m (7-12-1975). At station no. 2, some 1,500 m seaward of the crest line of the spending beach, the Datawell wave rider buoy measured a maximum wave of H_m = 5,05 m (T_s = 14,5 sec) at that day.

The amount of stone per m^1 increased during periods of heavy wave attack. It only happened once that an earlier reclaimed area had to be returned to the sea.

On December 17th 1975, while about 800 m of the 1,900 m gap between Hoedjies Point and Marcus Island was brought above water, current measurements were executed over the remaining part of the underwater mound (average depth 6,60 m^-). Wave conditions were moderate H_s = 1,75 m. Tide difference 1,30 m. Maximum current measured over a full tidal cyclus 0,30 m/sec.

Grain-size diameter.
During construction of the underwater mound a great number of bottom (grab) samples was taken mainly at depths between 7,00 m^- and 8,00 m^- C.D. The median grain-size diameter varied between 110 μ and 220 μ. The material of the superstructure however, proved to be much coarser. The average of six drillings made in the sand stockpile nr. 1 showed 53 % above 210 μ and 35 % above 420 μ. Samples taken from the cutter-suction dredger "Western Chief" gave an average of 370 μ for the median grain-size diameter. Unfortunately no bottom aamples on the seaward slope were taken after completion.



ill. 14. Progress of superstructure of spending beach breakwater.

As a result of the way of execution (pipe outlet on the seaside), the so called sorting effect started already during execution: the finer sand particles being washed away more easily by the waves and the bigger sand particles settling earlier. It can therefore be concluded that the median grain-size diameter of the seaward slope on average is in excess of 300 μ.

5.3.4. Sandlosses second building stage.

Sand losses of the superstructure were calculated up to 4-2-1976, being the data the connection with Marcus Island was realized. The quantities brought into the superstructure during the period from 30-10-1975 up to 4-2-1976 measured as follows:

. Transmundum type of trailhoppers 2,220,000 m^3	
Reduction factor to obtain solid m^3 x 0,88	~ 2,000,000 m^3
. Cutter-suction dredgers	~ 5,100,000 m^3
Calculated solid m^3	~ 7,100,000 m^3

The volumes of sand measured in situ as the difference between the depth soundings of 30-10-1975 and 4-2-1976 ~ 5.600.000 m^3

The total losses comprise 21,1 % of the total sand production during the second building stage.

The losses were defined as quantities shifted outside the reguired profile by wave action, currents etc. The majority of the losses of the first 900 meters of spending beach accumulated in the stockpile area number II and were recovered by the cutter suction dredger "Queen of Holland" in building the second half of the superstructure.
As the construction of the superstructure proceeded the dredging process improved. This can be illustrated by comparing the sandlosses which occurred during the construction of the first 900 meters with the sandlosses which occurred during the construction of the remaining second half of the superstructure. They were respectively 29,7 % and 11,8 % of the corresponding sand productions.
This reduction in losses can be ascribed to
- less wave action during the construction of the second half of the superstructure
- improvement of the fill distribution in the reclaim area.

6. CONCLUSION.

After the construction was finished, echo soundings were performed at regular intervals during the period 1976-1979 in order to establish the seaside slope of the spending beach breakwater. An example of these actual measured profiles is given in illustration 7.

1) Comparison between the designed profile and the actual measured profiles show a good correlation.

2) This seaward profile up to a depth of approximately 6.00 m^- is very simular to Swarts D-profiles. Correlation with Technical Memorandum 126 is poor, specifically in the shallower areas.

3) None of the numerous echo soundings show an underwater bar which could be explained by the fact that the wave seasons have only minor differences.

4) The relatively small stonewall - used during construction to minimize sandlosses - has shaped into a protective layer around the area of low water and as such fixes the low water line of the seaward profile.

SAND MOVEMENT INTO CARMEL SUBMARINE CANYON, CALIFORNIA

by

J.R. Dingler and R.J. Anima[1]

ABSTRACT

Carmel Submarine Canyon heads in shallow water near Monastery Beach at the southeast corner of Carmel Bay, California, U.S.A. Very coarse sand, shaped into large oscillation ripples, covers the narrow shelf between the beach and the canyon; when this sand enters the canyon head, it lies at angles as great as the angle of repose. In some areas, these sand slopes show evidence of active grain flows in the form of downslope-coarsening, inversely graded deposits.

The results of a dyed-sand tracer study adjacent to the canyon show that sand moved canyonward during the summer of 1979. Initially the dyed sand, which had been shaped into an oscillation ripple in the center of a 20-m by 60-m grid, moved offshore en masse. After a few days, though, the dyed sand dispersed with the center of mass moving canyonward.

As wave-transported sand accumulates along the canyon rim, the upper slopes oversteepen, thereby causing some of the sand to avalanche downslope. Systematic changes in sand levels along three lines of rods over 15 months document preferential deposition of sand along the upper slopes; the greatest change occurred at the top of the lines (12-15 m depth) and the least at the bottom (30-40 m). Greater accretion during the spring months than during the summer months probably reflects the more energetic springtime wave climate.

Between October 1981 and October 1982, 5.7 m^3 of sand was deposited per meter alongslope on the middle line, which gives a calculated depositional rate of approximately 500 m^3/yr in the study area. Although we have monitored this area for over a year, we have not yet documented any large-scale events capable of flushing sand out of the canyon head. The only erosive event we have observed was a small grain flow we generated while digging on the slope.

INTRODUCTION

Submarine canyons funnel sediment from the continental shelf

[1]U.S. Geological Survey, Menlo Park, California 94025

to deep water. Whenever a submarine canyon extends into shallow water, its head intercepts longshore-moving beach sand, removing it from the littoral zone. Inman and Frautschy (1966) described how such canyon heads terminate littoral cells along the southern California coast.

Instead of moving directly to deep water, most sand remains in the canyon head for an indefinite period of time probably ranging from months to years. Filling of the head continues until a combination of air, land, and sea conditions flushes sand into deeper water (Inman et al., 1976); investigators think that the sediment entrained by such an episodic event generates a turbidity current. Although no one has observed such a current, Inman et al. (1976) described strong, pulsating flows that finally produced a down-canyon flow strong enough to carry off their recording sensors. Divers who inspected the sensor mounts reported large sand losses from the canyon head.

Sand slowly accumulates in the canyon head, moving downslope from the canyon rim. Dill (1964) showed that slow gravity creep takes place in fine sand and decaying kelp in the head of Scripps Canyon. Dill (1966) attributed grain flows, seen in San Lucas Canyon, to steepening of sandy slopes beyond the angle of repose (33°). Dingler and Anima (1981) showed that grain flows down angle-of-repose slopes could produce the inversely graded, sandy deposits found in the head of Carmel Canyon.

After waves transport littoral sand to the canyon rim, gravity becomes the driving force. Gravity creep or sand avalanching redistribute sand within the canyon head, and sediment gravity flows remove sand to deeper water. This paper describes how sand moves into the head of Carmel Canyon from the littoral zone, and how small grain flows redistribute the sand onto slopes that dip at angles as great as the angle of repose.

SETTING

Carmel Submarine Canyon heads in shallow water in the southeast corner of Carmel Bay, California (Fig. 1). The canyon is one of several that cut into the continental shelf along central California; it enters the larger Monterey Canyon west of Monterey in a water depth of 2012 m (Shepard and Emery, 1941). Carmel Canyon is an extension of the adjacent land canyon that contains San Jose Creek (Shepard and Dill, 1966, p. 88). Shepard and Dill presumed that the sandy shelf between the beach and canyon rim is a filled part of the ancestral canyon.

Tributaries enter Carmel Canyon along its entire length; the shallow, nearshore ones lie close to a series of coarse-grained pocket beaches, collectively named the Carmel River State Beach. At its closest point, the canyon head lies less than 200 m from Monastery Beach, the southern most of the pocket beaches within the State Beach. Wave-generated ripples cover the narrow shelf

Figure 1: Section of a physiographic diagram of the head of Carmel Submarine Canyon and surrounding land (Alpha et al., 1981). Inserts show the location of the study area along the California coast.

between the beach and canyon (Hirschaut and Dingler, 1982). Water depth at the canyon rim, or shelf break, varies with location; it is less than 15 m at its shallowest point.

Although the wave climate at the canyon head is restricted by its location within Carmel Bay, storm waves from the northwest reach the area. Dingler (1981a) estimated from berm height that breaking waves higher than 3 m reached Monastery Beach too infrequently to produce a storm profile there commonly.

On land, Santa Lucia Granodiorite (Bowen 1965) is the principal rock type throughout the area. The conglomeratic Carmelo Formation (Bowen, 1965) crops out on both sides of Monastery Beach, and both the Carmel River and San Jose Creek drainage basins include other sedimentary rocks. Underwater, sand covers most of the bedrock, but granodiorite crops out in several localities around the canyon, and one sedimentary outcrop occurs along the east wall of the canyon head. Figure 2 shows the onshore distribution of rock types and the location of major underwater outcrops known to us.

Most of the sand on Monastery Beach, the adjacent shelf, and upper canyon slopes is very coarse to granular, but fine sand exists in some of the more quiescent areas. Along most shore-normal transects, grain size decreases from the beach to the rim and increases downslope to about 35 m (Fig. 3); below that depth grain size quickly drops below sand size.

A transect along the 15-m bathymetric contour from the rocks on the north passes through five zones with differing biota, texture, and surface expression before reaching the southern extent of the east wall (Fig. 4). Diopatra ornata tubes densely populate a substrate of fine sand in zone 1. The second zone has fine to coarse sand with clumps of red algae and partially exposed tubes of Platysereis bicanaliculata. This zone gradually merges into zone 3, which is different from the other zones in that it has no exposed biogenic sedimentary structures, though Platysereis exist within the sand. The shore-normal transect shown in Figure 3 passes through zone 3. When viewed from a distance, much of the sand appears to have slope-parallel stripes spaced 1 to 2 m apart. These, we believe, are the deposits of small avalanches. Zone 4 is similar to zone 2. Zone 5, which is offshore of a small kelp bed, contains both Diopatra and algae with a fine-sand substrate. Along the south wall, zone 5 terminates at granitic outcrops.

EXPERIMENTAL METHOD

Scuba divers conducted the experiments and made all the measurements and observations described herein. These included injecting dyed sand and sampling for it over time, emplacing aluminum rods and measuring them, and measuring dips on the sandy slopes. Figure 5 shows the location of the dyed sand sample area

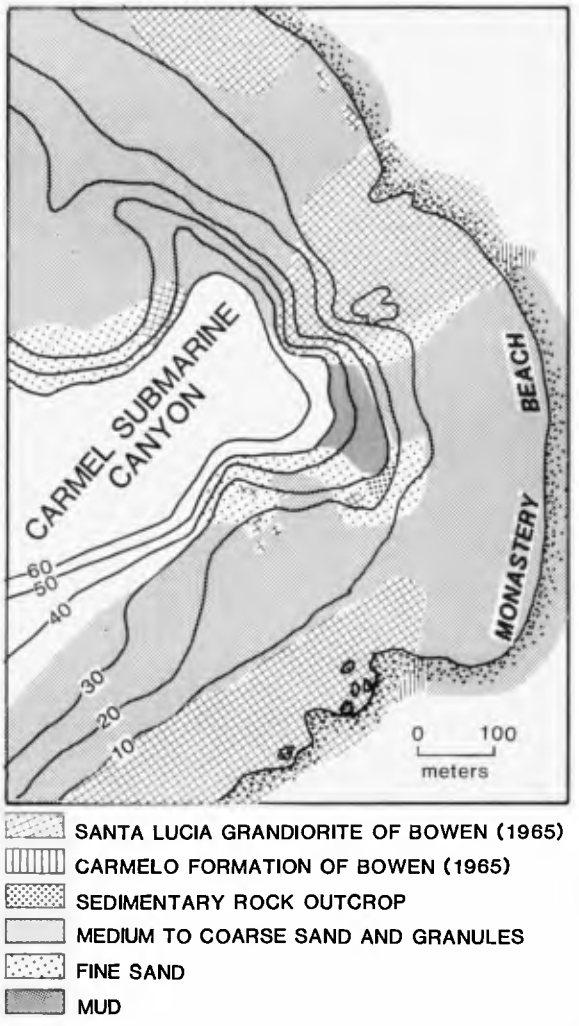

Figure 2: Distribution of rock types in the vicinity of Carmel Submarine Canyon.

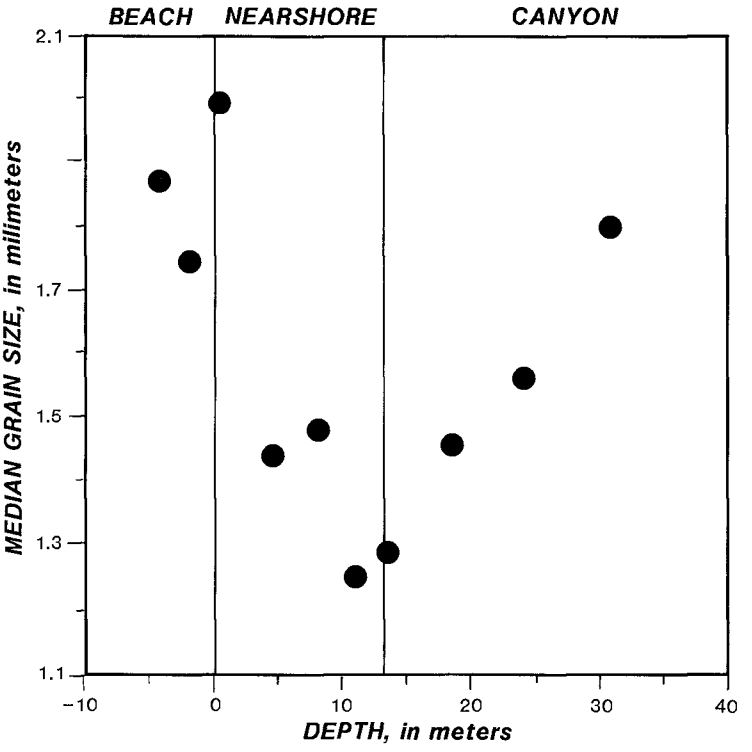

Figure 3: Grain-size distribution of sediment along a shore-normal transect that starts at Monastery Beach and ends within the canyon head. See Figure 5 for transect location.

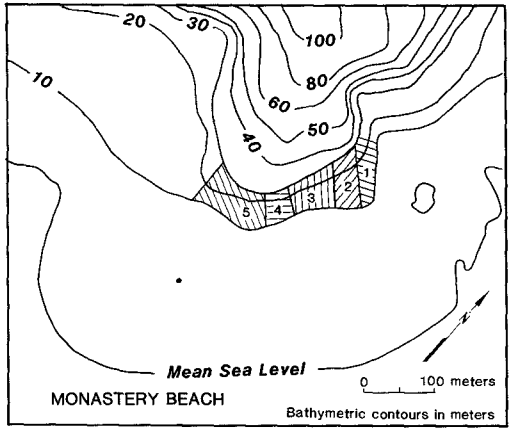

Figure 4: Bathymetric map of the head of Carmel Submarine Canyon and adjacent shelf. The east rim of the canyon is zoned on the basis of grain size and biota (lined areas). Because of this distribution we assume that active transport is greatest in zone 3 and negligible in zones 1 and 5. See text for further explanation.

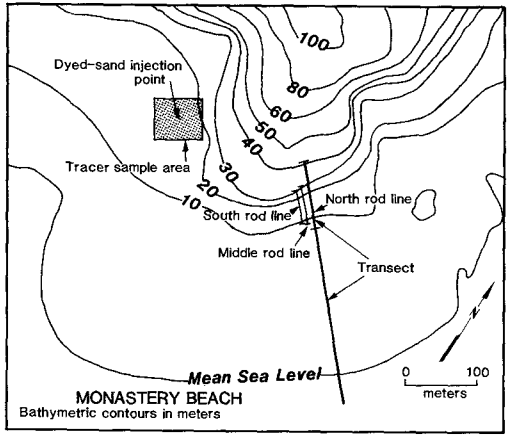

Figure 5: Location of dyed-sand tracer study adjacent to the south wall of Carmel Canyon and line of rods on the eastern slope. Line across shelf together with the north line represent the transect of Figure 3.

and the rod arrays. All measurements were made during fair weather.

To determine the transport direction of sand near the head of the canyon, we injected 161 kg of dyed sand on the shelf adjacent to the south rim prior to starting any experiments on the canyon slopes. We collected the sand from the center of a 70-m by 60-m grid, dried it, dyed it a fluorescent color, and returned it to the collection point. Injection consisted of replacing two meters of a ripple crest with the dyed sand. At irregular times, divers collected a surficial sample from each of 35 grid points; these samples were split and the dyed grains counted under an ultraviolet light.

Based on the biological and sedimentological patterns, we assumed that the most active part of the upper slope was in zone 3. To measure the rate of deposition there, divers drove aluminum rods into the sand on the slope, leaving part of each rod exposed. The rods formed lines that started on or near the shelf break and went downslope. In April 1981, we emplaced one line of 26 rods spaced 1 m apart at the site of one of our man-made avalanches (Dingler and Anima, 1981). Three months later we added a longer parallel, line about 5 m north of the first one. These two lines ended at a depth of 30.5 m. In May 1982 we added a third line about 15 m north of the second one. This last line had rods spaced 2 m apart, extending from the shelf to a depth of 36.6 m.

Two divers can measure the rods on two lines in one dive. Between the installation date and 15 October 1982, we measured the south line of rods 13 times, the middle line 12 times, and the north line 4 times. Once, the divers also measured slope angle using a dipmeter developed by Dingler (1981b). Accuracy of the rod measurements is roughly 1 centimeter and that of the dip measurements is 1 to 2 degrees. Because a dip error of 1° equals an error in elevation of 1.7 cm, we relied on the rod measurements in this study. Besides, the rod data can be used with one set of dip measurements to calculate dips at any time.

RESULTS

After injecting dyed sand on 30 April 1979, we inspected or sampled the grid on 3, 7, and 15 May, 7 June, 3 and 7 July, 3 and 16 August, and 26 September 1979. On the first two days most of the dyed sand remained in one ripple crest that had migrated about one wavelength (about 1 m) offshore. Some dyed sand also showed on the next offshore ripple and a few grains had dispersed toward the canyon. We saw no grains onshore of the injection point. The dyed-sand ripple crest had disappeared by 15 May, and dyed grains were scattered over the inner part of the grid with the greatest visible concentration being offshore and canyonward of the injection point. By 7 June, dyed grains had reached the boundaries of the study area with the highest concentration again

being offshore and canyonward (Fig. 6). This pattern continued through the study period.

The curves in Figure 7, which are based on dip measurements from 11 May 1982, are the slope profiles above 30.5 m of the three lines. The slopes parallel one another; the slight deviations near the top could reflect variations in location of large ripples that extend onto the upper part of the shelf break. Figure 8 contains selected data from the middle line; the rod-height data, which are representative of data from the other lines, have been converted into net deposition by subtracting the measured heights from the initial rod heights.

DISCUSSION

Determining depositional rates in the canyon head was the goal of this study. Although our coverage of the canyon head was limited, our three lines of data show how the sand that moves into the canyon head is distributed. Assuming that the depositional rates along the lines are representative of the east rim, an average volume is calculated and seasonal fluctuation noted.

Other investigators assumed that waves drove the sand from the beach to the canyon. Our dyed-sand experiment supports this assumption to the extent that sand near the canyon rim preferentially moves canyonward through a zone of wave-formed ripples. Wallin (1968) thought that the Carmel River was a major supplier of littoral sand to Monastery Beach, but Howell (1972) concluded, using wave refraction diagrams, that sand moved south from the Carmel River and north along Monastery Beach. As shown in Figure 9, these littoral sand streams turn seaward before reaching the large rock exposure just north of the canyon.

After not finding any through paths when diving amongst the rocks and analyzing sand samples from the midforeshore along Carmel River State Beach, we also conclude that little sand crosses the rocky area north of Monastery Beach. Along the northern part of Carmel River State Beach, south of the Carmel River, grain size increases to the south (Fig. 9). This trend is opposite to the downdrift distribution produced by littoral transport. However, the observed distribution would be produced by a southward increase in the granodiorite contribution relative to the littoral contribution.

At Monastery Beach, the mouth of San Jose Creek is usually deflected to the north, indicating a northward movement of littoral sand before it moves offshore. The sources of this sand are San Jose Creek and the local granodiorite, but we do not as yet know the proportions of each.

Once the sand reaches the canyon rim, it piles up until the upper slope oversteepens. Then a grain flow redistributes the sand downslope; the distance downslope varies from a few to tens

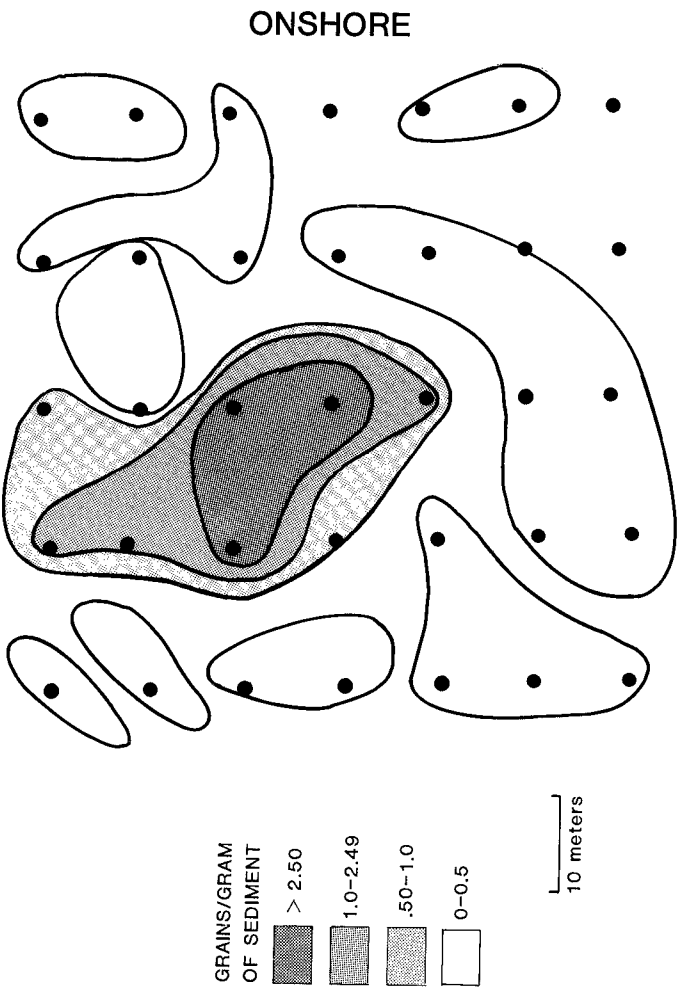

Figure 6: Distribution of dyed sand 38 days after injection on 30 April 1979. See Figure 5 for location of sampling grid.

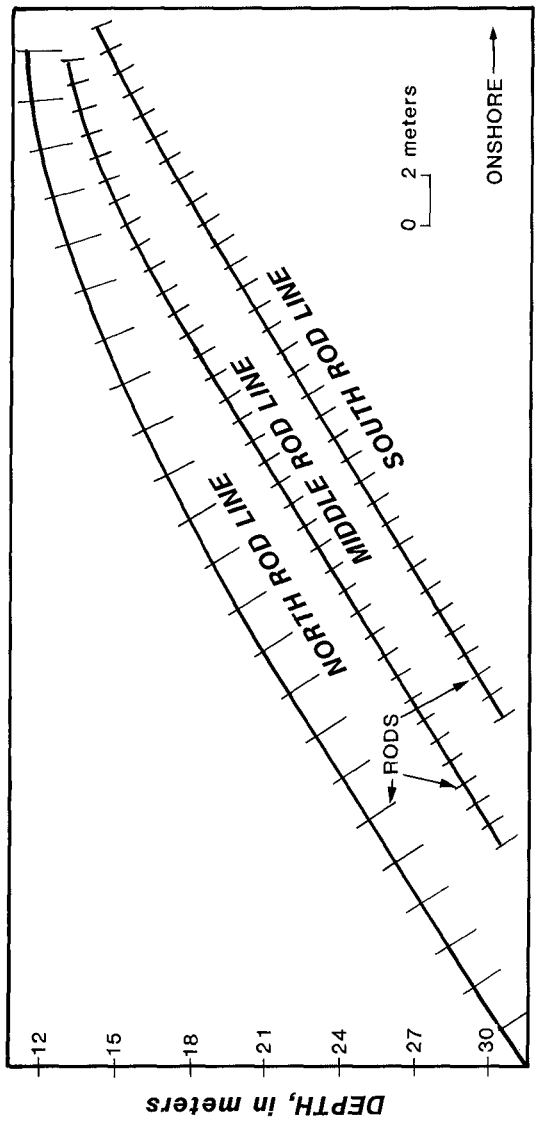

Figure 7: Bottom slopes along the three lines of rods located in Figure 5. Rods are not drawn to scale; those along the north line are 2 m apart and the others are 1 m apart.

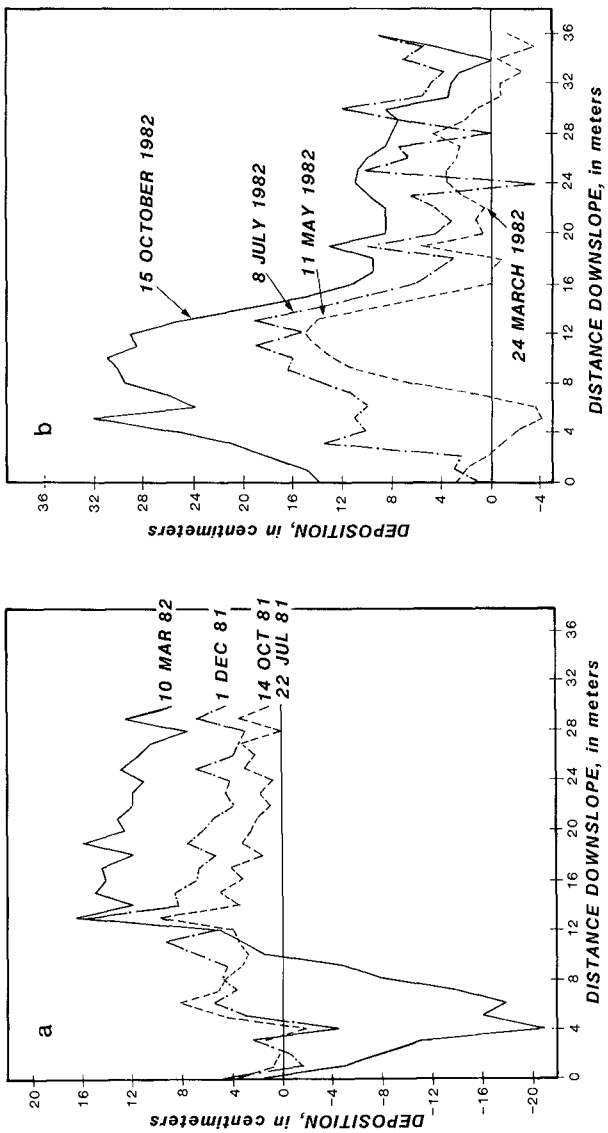

Figure 8: Net deposition at each rod on the middle line (a) from 22 July 1981 to 10 March 1982; (b) from 24 March 1982 to 15 October 1982. See Figure 5 for rod line location. Deposition between 10 and 24 March 1982 is unaccounted for because of accidentally generated grain flow on the latter data. See Figure 13 and text for more details.

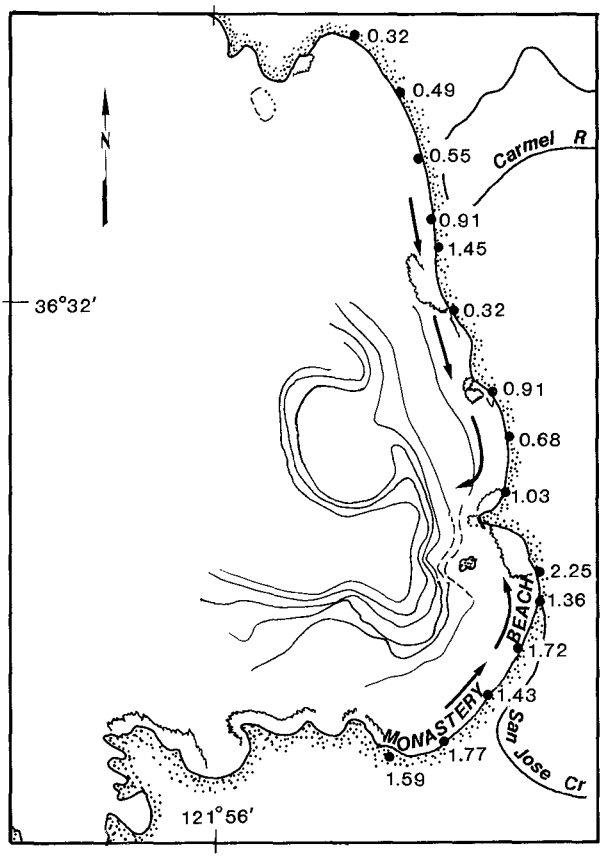

Figure 9: Littoral zone sand transport paths (arrows) into the head of Carmel Submarine Canyon (from Howell, 1972). Dots locate our textural samples, and the adjacent numbers give the mean grain size in millimeters.

of meters. We base this interpretation on systematic changes in deposition down the three lines of rods (Fig. 8). The greatest deposition takes place just over the rim (away from the ripples), and the least at the bottom. This process recurs at least on a monthly basis, and thus, the canyon rim slowly accretes.

Deposition Q_l, in units of volume per length alongslope, was calculated from the eguation:

$$Q_l = \Delta x(0.5z_1 + \sum_{i=2}^{n-1} z_i + 0.5z_n)$$

where Δx is the spacing between rods, n is the number of rods, and z_i is the amount of deposition at the ith rod. Figure 10 shows both the incremental and net deposition on the middle line, and Figure 11 recasts the incremental data in terms of average rates. These figures illustrate the seasonality of the canyon-head deposition: deposition was rapid in the late spring and early fall of 1982 and slow before and after the spring high. This trend appears on the south line, which also had relatively rapid deposition in the spring of 1981. This pattern probably mirrors the intensity of the wave climate, so fluctuations, such as hetween fall 1981 and fall 1982, would be expected because wave climate is variable.

Lateral variations also occur, even over the few meters between rod lines, as shown by the net deposition on the three lines between 11 May 1982 and 15 October 1982 (Fig. 12). During this time the most deposition took place on the south line, and the least on the north one. Using the data from the middle line, the depositional rate in the study area was 364 m^3/yr if all the sand moved through zone 3 (64 m wide), and 791 m^3/yr if it moved through zones 2-4 (139 m wide).

We have not found any evidence of large-scale slope erosion during our studies in Carmel Canyon. However, Shepard and Emery (1941, p. 101) speculated that erosive events must occur in the head of Carmel Canyon. They measured over 5 m of fill from 1934 to 1939, a rate that would fill the head within a few years unless there was an erosive event.

During one of our dives on 24 March 1982, we accidentally generated a grain flow along the southern line that redistributed much of the sand that had heen deposited during our study. While trying to dig out some buried rods near the middle of the line, we created a scarp-recession grain flow (Hunter, 1977). Sand fell into the upslope side of the hole and continued to flow downslope past us. Above the initiation point, previously buried rods appeared at a rate of more than one per minute; near the top of the rod array the height of the scarp had increased from a few centimeters to more than 30 cm. Figure 13 shows the approximate magnitude of erosion, assuming that a wedge of sand 25 cm thick at the top rod covered the rods hefore the grain flow. Although this grain flow only disturbed a small part of the slope, on a larger

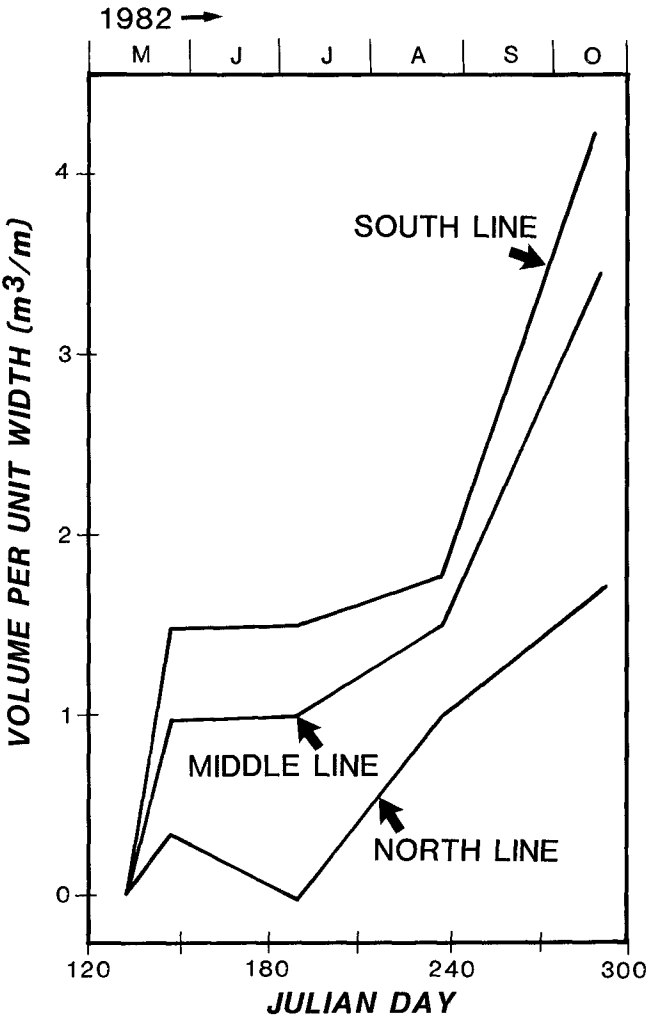

Figure 12: Net deposition on the three lines between 15 May 1982 and 15 October 1982.

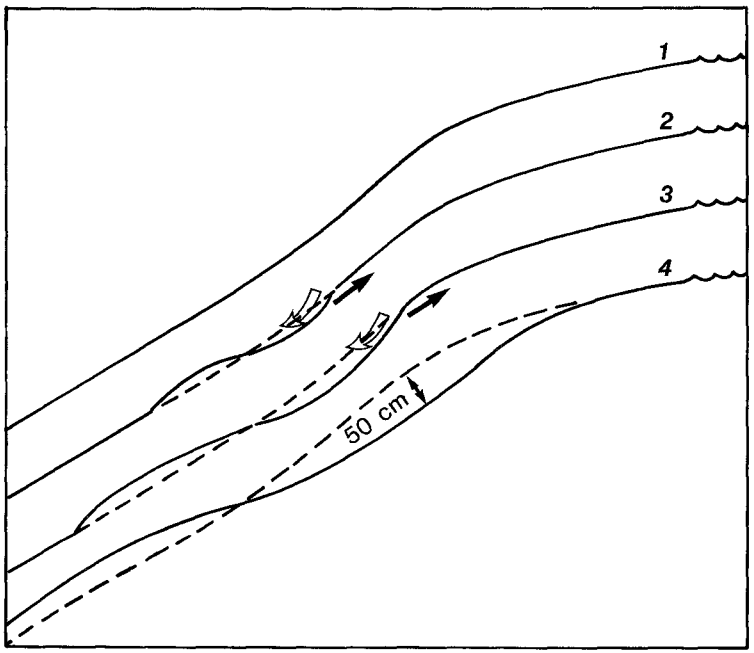

Figure 13: Changes in slope profile due to an accidentally generated scarp-recession grain flow on 24 March 1982. Maximum erosion was on the order of 50 cm. Profile 1 shows the slope before we disrupted it. Profile 2 shows sand falling into the hole we made and flowing downslope. Profile 3 shows the location of the scarp partway through the grain flow. Profile 4 shows the final profile. The dashed line in 2, 3, and 4 represents the original profile. Open arrows show the direction of sand flow; solid arrows show the direction of scarp recession. Scale is approximate.

scale this mechanism could easily initiate turbidity currents on angle-of-repose slopes.

CONCLUSIONS

1. Sand sporadically reaches the Carmel Submarine Canyon rim from the adjacent shelf. Sand entering the littoral zone comes from San Jose Creek and weathering of local granodiorite outcrops.

2. After reaching the Carmel Submarine Canyon rim, the sand collects until the slope becomes too steep. Then the sand avalanches, coming to rest farther downslope. Subsequent deposits may cause the slope below the rim to oversteepen, producing another avalanche. In this manner the slope slowly accretes seaward.

3. The depositional rate along the east rim of Carmel Submarine Canyon is on the order of 500 m^3/year.

ACKNOWLEDGMENTS

We thank the many people who dove with us during this study; Dave Molzan and Don Hirschaut were our principal aides. Gary Hill and Herman Karl reviewed this manuscript and made several relevant suggestions.

Suspended Sediment Discharge on a Non-Tidal Coast

by J. P. Coakley[1] and M. G. Skafel [2]

Abstract

A field study was conducted on a non-tidal sand beach to measure the relationship between wave energy and the longshore transport of suspended sediment. The range of suspended sediment concentrations was similar to that reported elsewhere. The relation between longshore transport and longshore energy flux derived from this data set is about half that amount predicted by such widely quoted sources as Komar and Inman (1970).

Introduction

In recent times an increasing effort has been directed toward finding a universal mathematical expression for the rate of sand transport on beaches. Although the basic concepts of this phenomenon are well known, the problem still remains largely unsolved. For instance, it is well known that large volumes of sediment are displaced and transported along coasts through the action of currents which are induced when waves break in shallow water. It is also well known that the sand particles making up this longshore transport are moved either as bed load (i.e. material sliding or rolling while supported by, or in contact with, other grains on the bottom) or suspended load (i.e. material totally supported by the flow medium). Given these concepts as starting points, various relationships have been proposed to provide quantitative values for sand transport alongshore, based on variables related to the forces released when waves break on a beach (see, for example, Galvin and Vitale (1976)). However, for a variety of reasons, not the least of which is the complexity of the physical situation where turbulence and the variable nature of the bottom materials and geometry usually defy generalization, the goal of a generally-accepted universal relationship for longshore sediment transport has still not been achieved.

It is recognized, however, that, to be credible, such a relationship must be founded upon an adequate data base involving field measurements of those aspects of the physical situation that are most relevant, namely incident wave energy and the resulting longshore sediment transport. Because accurate measurement of the total transport (suspended and bed-load) still remains practically impossible on non-tidal beaches, it was decided that the longshore flux of suspended particles in the surf zone could serve as a reasonable estimate for the total transport in such cases. Furthermore, this is a parameter that is more amenable to direct measurement.

[1,2]Shore Processes Section, Hydraulics Division, National Water Research Inst., Canada Centre for Inland Waters, Burlington, Ontario, Canada.

The goal of this report is to describe the relationships obtained for a site in Lake Ontario between the suspended sediment flux under moderate to intense wave conditions and breaker zone wave energy calculated from concurrent wave measurements. It is also meant to provide a realistic indication of the scale of littoral processes on non-tidal coasts such as the Laurentian Great Lakes compared with that of marine and tidal areas.

Study Site Description

The site at which the measurements described here were taken is located at the extreme western end of Lake Ontario on a large bay-mouth bar separating Burlington Bay from the main body of the lake (Fig. 1). The shoreline is regular and trends approximately NNW, or perpendicular to the direction of maximum fetch (ENE, fetch - 400 km) for Lake Ontario. Waves reaching the site therefore can attain heights of more than 3 m and tend to approach the shore at close to right angles.

The local bottom topography in the inner nearshore zone (<3 m depth and <70 m from shore) is characterized by rhythmic sets of crescentic longshore bars (about 120 m long and 1 m high). Systematic monitoring of bathymetric profiles at the site since 1976 indicates that these structures are very sensitive to wave conditions, while, on the other hand, the bottom topography further offshore shows relatively minor changes during this period.

The nearshore bottom is composed of well-sorted sand, with grain sizes within the 5 m contour averaging 2.0ϕ (0.25 mm diameter). Coarser material (up to gravel size) often occurs in the vicinity of the beach step (<1 m depth) and on the subaerial beach face. Bottom slopes in the area range from 0.05 to 0.02 in the inner nearshore zone. The overall slope out to 300 m averages 0.017.

Methodology

The field measurement program was initiated in the fall of 1977. The methodology has been described in previous publications (Coakley and others, 1978, Coakley 1980). Briefly, the method entailed the collection at three vertical elevations (10, 30 and 100 cm above the bed) of 45 second averages of suspended sediment concentration, based on 2ℓ pumped samples of water/sediment suspensions; water depth values; and current velocity records (two orthogonal horizontal components) along a fixed nearshore transect, during periods of moderate to high wave activity. The transect extended approximately 100 m over water, terminating at a water depth of about 3.5 m. The instrument platform was a robust, open-work sled, equipped with a vertically-articulated boom protruding 1.5 m into the oncoming wave field, to which the suspended sediment sample intake, as well as the current sensors, were attached. The sled was manipulated from shore along the transect, stopping at up to ten regularly-spaced stations. A complete run took exactly 1 hour to complete, thus allowing replicate runs of the same storm to be carried out. A schematic illustration of the field layout is presented in Fig. 1.

Continuous records of wave parameters at the study site were also collected using a fixed, linear array of three surface-piercing wave gauges installed approximately 225 m from the shoreline in about 5 m of water (outside the breaker zone for all waves encountered). Wave measurements were made either immediately prior to, or during a sled experiment.

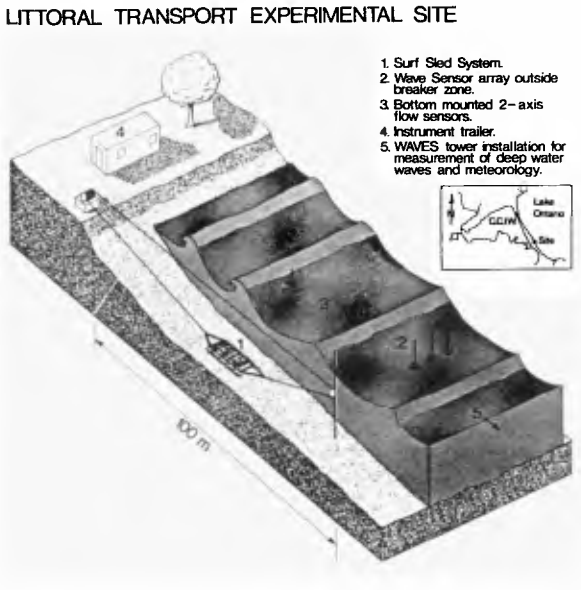

Figure 1 Perspective view of the experimental site, showing sled cableway, sled, wave sensor array and other instruments.

Description of the Data Set

1. Wave Data

The time series of instantaneous water elevations at the wave gauges were analyzed to obtain variance spectral densities, using the fast Fourier transform technique. Characteristic (significant) wave heights and peak periods were calculated for each experiment. Covariance spectral calculations allowed the determination of phase angle of the waves between wave gauge pairs as a function of frequency, and from this the direction of the peak of the spectrum was found. For each experiment, this latter value was used to characterize the wave direction at the location of the gauges.

The wave data at the gauges are summarized in Table 1. The characteristic or significant wave height is H_c, the period of the peak of the spectrum is T_p and the angle the waves make with the shore normal is α. (The wave parameters for experiment 7-1 were manually estimated from the time series.)

The bathymetric charts prepared from monitor surveys done after major storms at the experiment site were examined to determine the best way of transferring the wave information from the location of the gauges to the breaker zone. The nearshore bathymetry, as described previously, was irregular, with both small-and large-scale structures. Furthermore, the waves were "sea" as opposed to "swell" and, for this reason, a distinct breaker line was not always readily apparent.

Detailed wave ray calculations were done, but due to the irregular nearshore bathymetry, the resulting ray patterns did not give a consistent description of the waves inshore the wave gauge site. Several of the more common breaking criteria (such as the depth of breaking being equal to 1.28 times the breaking wave height) were tried in conjunction with the ray computations. These criteria were found to be ineffective in defining the surf zone as observed in the field. In the end, the method that gave the most consistent results and that was used here is as follows:

The bathymetry between the wave gauges and the shore was assumed to have straight contours parallel to the water's edge. The location and water depth of the breaker line was determined based on visual observations in combination with the position of normal breaker-line indicators, namely longshore bars. Snell's law was used to calculate the wave direction at the breaker line, and the shoaling and refraction coefficients were evaluated to get the breaking wave height.

The breaker line wave conditions, derived from the gauge data, are shown in Table 3. The depth at breaking is d_b, and the characteristic wave height at breaking is H_b; the other parameters have the same definitions as in Table 1, or as defined later.

2. Suspended Sediment Discharge

The data retrieved by the sled consisted of the following:

† Wave angle anomalously high.

S: Spilling. P: Plunging. n.r.: not recorded.

** $\xi = \dfrac{d_b/\lambda_b}{(H_b/L_o)^{1/2}}$ the surf similarity parameter, where L_o is the deep water wavelength.

(i) Up to 30-2ℓ samples of suspension collected at 10 stations along the surf-zone transect; at three fixed elevations for each station.

(ii) Depth profiles along the transect measured by a recording pressure transducer mounted on the sled.

(iii) 45-second time-records of flow velocities collected for each of the three vertical sampling elevations measured at each station.

Mass/volume concentrations were later obtained gravimetrically from the samples. These concentration values were combined with the calculated time-averaged longshore component of flow to provide point discharge values at each of the three elevations comprising each station.

In Coakley (1980), an integration was done using 10 cm spaced point values which were interpolated through a computerized procedure in which the three measured points were fitted to a theoretical (exponential) distribution. Further appraisal of this technique in the light of the small number of points on the curve (3), as well as the frequent apparent deviation of the points from the expected theoretical curve, led us to abandon this technique. To obtain the results presented here, the water column was simply divided into four compartments with the time-averaged concentration/longshore current data points assumed to be representative of the space halfway to adjacent data points. Values for concentration above the top compartment (165 cm above the bed) were arbitrarily set to zero. This appeared reasonable as concentration values even at the top position sampled (100 cm) were almost always very low (< 100 mg/ℓ). The product of concentration and flow for each block was then summed to obtain total discharge for that station.

The values predictably are slightly different from those previously reported (Coakley, 1980) based on the curve-lifting procedure, but the differences are less than 20 percent in most cases. However, several cases (exp. 3-1, 9-1, 9-2, 13-1) where redigitizing and recalculation were necessary, show larger discrepancies, and differ from previously published figures by up to a factor of 3.

The vertically summed discharge values for each station were then summed horizontally over the transect length, using a simple half-interval product summation. The discharge values for each station and for the entire transect (expressed in kg/hr) are presented in Table 2, for each experiment run.

Data Screening

From the above, it is seen that a complete data set for each station should ideally contain a depth record, three 45-second averages of onshore-offshore and alongshore currents and three values for concentration at the three different sample elevations. In addition, such complete stations should occur, if not at all stations occupied, at least at enough stations to provide adequate coverage of the transect length.

This was, as could be expected, not achieved in a considerable number of experiment traverses. The data set was prone to missing values in any of the four measured variables. Such lapses were due mainly to mechanical failure in the hostile environment of the surf zone, where suspended sand and algal debris

tended to clog the moving parts of sensors, and occasional freezing of sample tubing made pumping impossible.

Data evaluation and screening was therefore a necessary step. Several entire runs or stations had to be left out of the present analysis due to large-scale absence of essential data components. Lesser gaps could be filled mainly by interpolation and extrapolation. Other experiment runs were virtually gap-free. Table 2, therefore, shows only the 13 experiment runs which survived the screening process. Only these will be considered in the calculation of suspended sediment discharge. Not shown on Table 2 are four other partial data sets which will be used in a later section only in examining the sediment suspension/wave energy relationship (Fig. 3). These data sets had no flow records, but wave and concentration data were recorded. The wave data for these four experiments are shown at the bottom of Table 1.

The Combined Data Set

In Table 3, the measured and derived parameters associated with the incident wave field and suspended sediment discharge are presented. The parameter, I_ℓ, is defined as the total immersed weight of suspended sediment discharge over the transect length, and is expressed in Newtons per second (Komar and Inman, 1970). It was obtained by converting the discharge figures shown in Table 2 to immersed weight quantities. P_ℓ is the value calculated for the lateral thrust times the phase speed (Longuet-Higgins, 1972), also called the longshore component of wave energy density flux, expressed in Newtons per second. The relationship used to calculate P_ℓ is:

$$P_\ell = \frac{gH^2_{rms} \cdot c_g \cdot \sin\alpha \cos\alpha}{8.0}$$

where $H_{rms} = H_b/1.416$, c_g = wave group celerity, and α =the angle between the wave orthogonal and the beach normal (all values at breaking). Also shown on the table are subjective breaker descriptions and a calculation of surf-zone width based on the position of the calculated break-point with respect to the strand-line on the day of the experiment.

Several of the experiments showed discrepancies between the transport direction of suspended sediment measured by the sled (as denoted by the sign of the discharge quantities in Table 2) and the expected direction as indicated by the sign of the wave angle, α (Table 3). The cases where this occurs are Exp. 2-2, 6-1, 9-2, 11-1, and 13-1. In addition, one experiment (4-1) showed a wave angle of 19.4° which is anomalously higher than the range of values measured. While most of these discrepancies could be explained in view of the spatially varying conditions in a surf-zone characterized by an irregular bathymetry and low wave angles, they nonetheless present problems for further analysis and interpretation of the data set. These problems will be addressed to some degree in the Discussion section.

Correlation Between Suspended Sediment Transport and Longshore Wave Energy

The values shown in Table 3 were plotted on log/log paper (Fig. 2), after the method of Komar and Inman (1970). Only the seven data points remaining after exclusion of those showing discrepancies have been plotted. Also

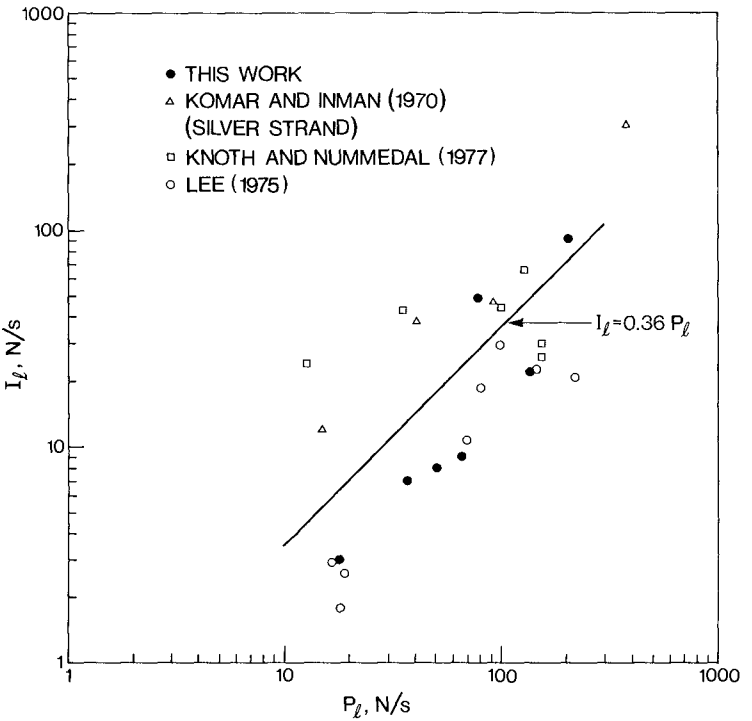

FIGURE 2. IMMERSED WEIGHT SUSPENDED SEDIMENT DISCHARGE vs LATERAL THRUST x PHASE SPEED.

shown for comparison are the data points for total transport listed in Komar and Inman (1970) for Silver Strand Beach, a beach of comparable slope to Van Wagners Beach, and those of Knoth and Nummedal (1977) for North Bull Island, South Carolina, and those of Lee (1975) for Lake Michigan.

The linear regression of I_ℓ against P_ℓ was calculated for the seven solid points, and was found to be:

$$I_\ell = 0.36\, P_\ell$$

and is plotted on Fig. 2.

This value of the coefficient of P_ℓ is therefore slightly less than one-half that calculated by Komar and Inman (1970) for the total transport of sand on marine beaches on the Pacific coast of North America (I_ℓ=0.77 P_ℓ). Our coefficient is, however, over twice the value of 0.15 that we obtained from the tabulated data of Lee (1975). The data of Knoth and Nummedal (1977) does not fit this type of model.

The correlation coefficient for the regression using the seven data points shown in the figure was calculated to be: r=0.84, compared to 0.99 (calculated by us) for the data tabulated by Komar and Inman (1970), p. 5921. The value of r=0.84 for the correlation coefficient is very significant, i.e. it exceeds the 99 percent confidence level (Fisher, 1970, p. 211).

Suspended Sediment Concentration vs. Wave Energy

The suspended sediment discharge figure calculated was based on the summed products of concentration and longshore velocity averaged over the sampling interval and integrated over the water depth and transect length. In view of the obvious difficulty in reconciling, with consistency, the calculated longshore flow direction with the measured flow especially in beaches with low wave angles and irregular bottom topography, it might be useful to examine the relationship between wave energy (total) and a non-directional parameter, such as mean concentration.

Figure 3 shows a plot on semi-log paper of total incident wave energy density (E) versus the vertically and horizontally averaged suspended sediment concentration termed the global concentration, or $\bar{C}^*$. This plot was based on a total of 17 data points, which included the four experimental runs referred to earlier where the flow components were not recorded, due to sensor malfunction.

The plot shows an obvious correlation between the two parameters, and the linear regression of $\bar{C}^*$ on ln E was calculated to be:

$$\bar{C}^* = -903 + 206 \ln E$$

where $\bar{C}^*$is in mg/ℓ and E in N/m. The correlation coefficient is 0.85. The value of the correlation coefficient is very significant at the 99 percent confidence level, and thus indicates concentration of suspended sediment can be well predicted using wave data alone. It should be kept in mind, however, that such a relationship is also dependent on the grain size of the beach in question, and care should be taken in extrapolating it to other beaches.

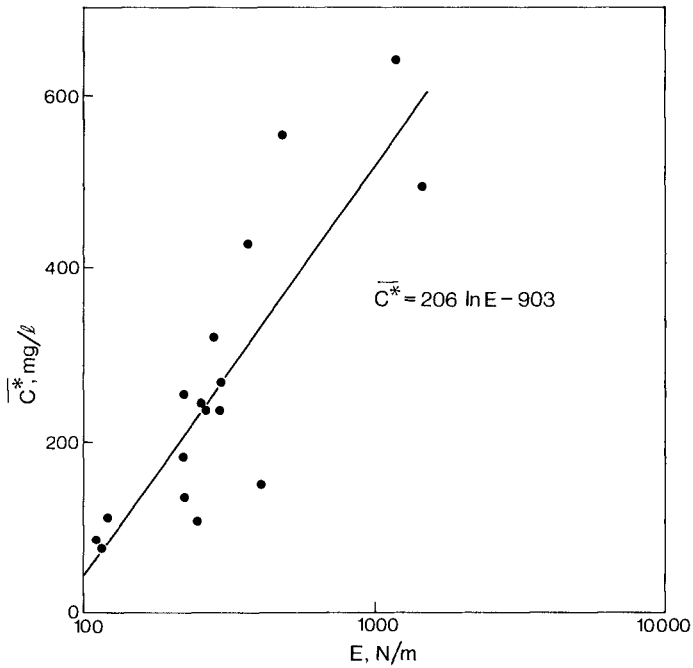

FIGURE 3. GLOBAL CONCENTRATION vs WAVE ENERGY DENSITY

Discussion

The results presented above were obtained using only screened data. Also, they were based on time-averaged point measurements of 45 s duration measured sequentially at three elevations (over a period of 3 min.), and were repeated at a series of stations across the surf-zone in succession; a process which took approximately one hour. There are several areas on which such an arrangement could be criticized, for instance:

- The discharge figures assume that the measurements are synoptic and that the transport has reached a steady-state condition, i.e. taking place at the same time across the entire zone and basically unchanging with time. The measurements covered a time-period of one hour while the vertical profile at each station took three minutes. From our knowledge of surf-zone dynamics, it is more likely that the process varies both in time and space even in a fully-developed storm and thus it should be sampled simultaneously over the zone for most accurate results.

- The time-duration of the sampling of sediment concentration and flow was only 45 s for operational reasons. The work of several researchers (Downing and others, 1981; Meadows, 1976, and Leonard and Brenninkmeyer 1978) indicated the presence of long-period events in surf-zone dynamics at time-scales ranging from fractions of the wave period to more than 120 s. This would imply that time series of 45 s, such as ours, might be subject to some inaccuracies.

These problems in experiment design, coupled with other complications introduced by irregular bottom topography, difficulty in defining accurately the wave angle at breaking, and in determining the width of the surf-zone with any accuracy, are probably all factors in the considerable variability which characterizes the data set. For this reason, the results presented above must be considered only as first-order approximations of a complicated and highly variable process, but which indicate, at least, the scale and overall trends in suspended sediment transport on beaches. Furthermore, the results must be considered as site-specific (to this particular Great Lakes beach) until more general insights into the influence of sediment grain-size, beach geometry and bottom topography can be included.

There appears to be no justification, therefore, for a more sophisticated treatment of the data than the conservative screening and empirical analysis featured in the previous section. Still, some pertinent and useful comments can be made on the results.

The data confirm that a statistically significant relationship exists between suspended sediment transport and the longshore component of wave energy density flux. We have also shown that a considerable quantity of sediment can be moved as suspended sediment (up to 88,600 kg/h (Table 2)) during intense Lake Ontario storms. We are, however, no closer to determining how large a proportion of the total littoral transport at the site this figure represents, since no reliable estimate of the bedload transport or the total drift at the site was possible. There is a danger in trying to obtain such a total drift estimate by applying empirical relationships, such as that of Komar and Inman (1970), since their base data were collected on marine coasts having no proven process-related affinity to beaches in the Great Lakes. Assuming that the total

transport is adequately represented by suspended transport (Kana, 1977), then the longshore sediment transport at Van Wagner's Beach is approximately half of the total transport on ocean beaches studied by Komar and Inman (1970). Furthermore, if the latter value is only regarded as an order of magnitude estimate, as suggested by Greer and Madsen (1978), then the results of this paper are in excellent agreement to that degree of accuracy.

Examination of the magnitude of the suspended sediment concentration and transport measurements reported by others (Kana, 1977 and 1978; Fairchild, 1977; Downing and others, 1981) provides an interesting comparison. Table 4 lists comparable statistics from these sources, along with values obtained in this study. In spite of the fact that procedures differed greatly, the statistics all include either average concentrations and/or suspended sediment discharge. The average concentrations are all of similar magnitude. Fairchild (1977) is larger because it is a measure of concentration very near the bed. The ranges of discharge measurements are all overlapping. The wave conditions reported by the various authors are quite different from the ones in this study. The wave heights in this study as a group form the high end of the range of all wave heights reported elsewhere. The waves are also relatively steep, because they were locally generated storm waves. The longshore energy flux values, on the other hand, are of the same order as those reported by Komar and Inman (1970). The difference is accounted for by the relatively small wave angles reported here.

Kana (1977) reported a marked difference in suspended sediment concentration depending on breaker type: "plunging waves entrain almost one order more sediment than spilling type breakers". Examination of Table 3 reveals that in our study there was only one case of clearly plunging breakers: the majority are a combination and a few are spilling only. Spilling waves entraining less sediment and the fact that waves reported here tended to be at least partly spilling would suggest that less transport is to be expected and thus is supportive of the lower value of the coefficient (0.36) found in this study. In a recent paper, Hallermeier (1982) points out that more effective transport apparently occurs for high values of ξ, the surf similarity parameter (Battjies, 1975). High ξ corresponds to swell conditions, and since the values of ξ were small for our experiments as shown in Table 3, correspondingly smaller measured transport rates are to be expected. It would appear, as more evidence is gathered, that the characterization of the beach and breaking conditions using the surf similarity parameter might lead to better prediction of transport rates. This approach is discussed in a paper in these Proceedings by Sayao and Kamphuis (1982).

Concluding Remarks

Suspended sediment, longshore current, and wave data have been collected during moderate to severe early winter storms at Van Wagner's Beach, Lake Ontario. This data set is distinguished from others in that the site is a non-tidal beach characterized by offshore bars; the wave heights were some of the largest encountered during experiments of this type; the angles of wave approach were relatively small.

The range of suspended sediment concentrations and the range of transport rates encountered are similar to those reported elsewhere. However, the relation between longshore transport and longshore energy flux derived from this data set suggests that about half the amount of sediment is moved in suspension for a comparable energy flux as was reported for total transport by

TABLE 4. Representative Suspended Sediment Transport Values from Several Published Sources

Komar and Inman (1970). This difference is not unreasonable given the complexity of shore processes and the difficulty of obtaining true measures of transport.

The controversy over the question of bed load versus suspended load has not been addressed. It is clear, however, that at our site substantial volumes of material are moved by suspended load.

MODEL TESTS ON LITTORAL SAND TRANSPORT RATE

by

J.W. KAMPHUIS[1] and O.F.S.J. SAYAO[2]

ABSTRACT:

This paper is an analysis of two sets of experimental results on littoral sand transport. A littoral sand transport expression is proposed, relating littoral transport rate to surf similarity parameter and hence to wave energy dissipation rate. The expression indicates that the 'constant' in the CERC formula is dependent on the mobile bed beach slope and on the breaker index. The expression is also compared with some of the few published field measurements.

INTRODUCTION

One of the most important problems facing the engineer involved in coastal protection and harbour design is that of estimating the littoral sand transport along a shoreline. Usually, field measurement data are not available or not of sufficient accuracy and most empirical formulas do not take into account all the wave and sediment parameters in a satisfactory fashion.

Littoral sand transport tests were performed at Queen's University in a three-dimensional mobile bed coastal model with two different types of sand. Earlier tests by Readshaw (1979), and reported by Kamphuis and Readshaw (1978) used sand with a median diameter of 0.56 mm. The longshore sediment transport rate was found to be dependent on the beach profile characteristics and the rate of wave energy dissipation, as well as on the usual wave and sediment parameters.

[1] Professor of Civil Engineering, Queen's University, Kingston, Ontario, Canada.

[2] Associate Professor of Ocean Engineering, Universidade Federal do Rio de Janeiro, Brazil.

The present series of tests was performed in the same wave basin under similar test conditions. A finer sand of median diameter 0.18 mm was used. The results of these tests in combination with the earlier tests are the topic of this paper.

More details regarding both sets of experimental results may be found in Sayao (1982) and Sayao and Kamphuis (1983).

EXPERIMENTAL EQUIPMENT AND PROCEDURE

The three dimensional wave basin at the Coastal Engineering Research Laboratory, of Queen's University at Kingston is shown in Figure 1.

Monochromatic waves were produced with a piston type wave generator. Wave filters and splitters, were placed immediately in front of the wave generator to prevent formation of transverse standing waves and to filter out high frequency components. Wave guide walls were constructed and aligned along wave orthogonals calculated from refraction theory. Openings were cut in these training walls at several locations to facilitate filling and draining of the central test basin and the reservoir surrounding the central testing area. Three capacitance-type wave probes were used to measure the wave heights in the constant depth portion of the test basin, between the toe of the beach and the wave filters. Wave heights in the breaking zone and at any other location along the beach profile were measured with a fourth capacitance-type wave probe mounted on a transversely travelling trolley placed on the beach side of the travelling carriage. Beach profiles were measured with a blunt-ended point gauge mounted on a separate trolley also placed on the beach side of the travelling carriage. An initial model beach was shaped twice during the present test series by screeding and compacting sand to a thickness of 0.13 m. over a sloped concrete floor. The grain size distribution curves for the materials used for both sets of tests are shown in Figure 2.

The present experiments consisted of a total of 14 series of tests, each of several seasons of a predetermined duration varying from 15 to 110 minutes. The wave parameters were changed after every series and could be paired together to form a regular seasonal cycle as described in Kamphuis and Readshaw (1978). Although the beach initially had a uniform slope of 1:10, a beach profile was allowed to "develop" with time and each subsequent test was started on the beach profile remaining from the previous test. Slow, continuous recession of the shoreline was observed and at the end of series 5, after approximately 83 model hours of profile development, the initial slope of 1:10 was reshaped. Testing then resumed for another 87 model hours up to the end of test series 14.

During the experimental investigation the alongshore sediment transport rate was recorded continuously. Other data measured included breaker characteristics such as the breaker height H_b , the

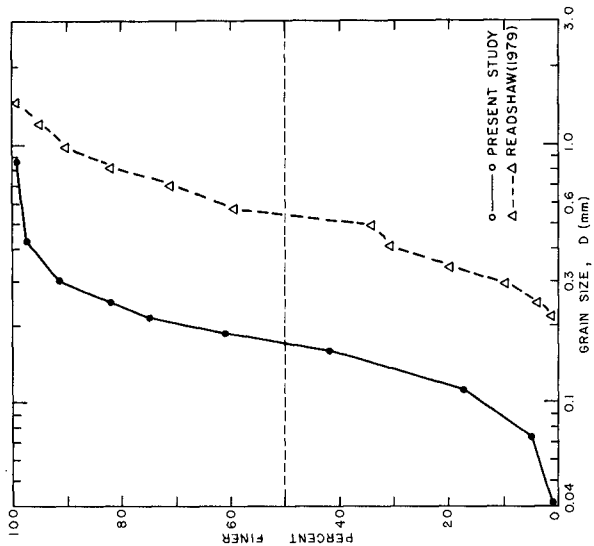

FIG. 2 GRAIN SIZE DISTRIBUTIONS

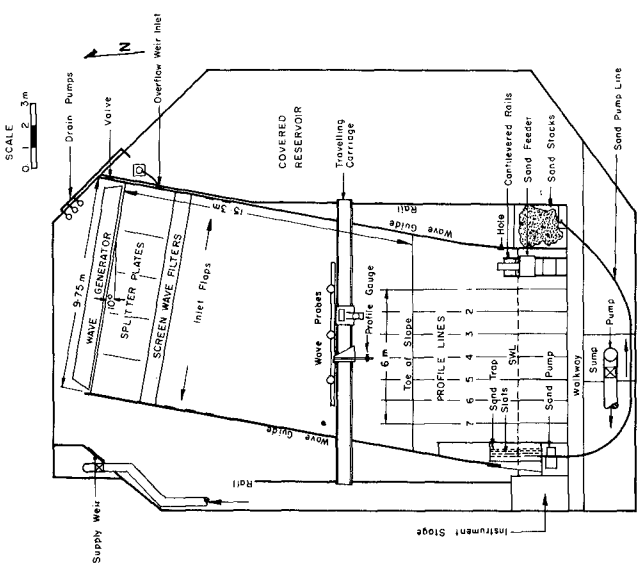

FIG. 1 PLAN VIEW OF THE WAVE BASIN

depth below still water level at the breaking point d_b, the breaker distance λ_b measured from the still water level shoreline, the velocity of wave propagation at the breaking point C_b and the incident angle of breaking α_b. Analysis of the measured breaker characteristics have been reported in detail in Sayao and Kamphuis (1982). It is to be noted that all these parameters have been evaluated for beach profiles rather than for plane beaches.

EXPERIMENTAL RESULTS

The experimental results are summarized in Table 1. A more detailed description of the present tests as well as Readshaw's (1979) data may be found in Sayao (1982) and Sayao and Kamphuis (1983).

Dimensional Analysis

Dimensional analysis for littoral transport rate yields:

$$\Pi_{Q_s} = \phi_{Q_s} \left(\frac{H_b}{L_o}, m, \frac{H_b}{D}, \frac{\rho_s}{\rho} \right) \quad (1)$$

where

$$\Pi_{Q_s} = \frac{Q_s}{\rho H_b^2 (H_b/T) \frac{1}{2} \sin 2\alpha_b} \quad (2)$$

Q_s is the dry mass littoral sediment transport rate, in kilograms per unit of time, ρ the water density, ρ_s the sediment density, H_b the wave height, L_o the deep water wave length, T the wave period, D the particle size and m the beach slope. The definition of beach slope m for mobile bed models has been the subject of considerable debate. From the present experiments - Sayao and Kamphuis (1983) - it was found that the most convenient form of beach slope definition,

$$m = \frac{d_b}{\lambda_b} \quad (3)$$

was also the definition which described surf zone phenomena, including littoral drift rate most accurately. This definition is called "mobile bed beach slope" throughout this paper.

Relationship between Beach Slope and Relative Grain Size

Figure 3 shows the mobile bed beach slope as a function of relative grain size parameter for the combined data set of the present tests and Readshaw's (1979) tests. Even though the data are scattered, a definite relationship between these two parameters is evident. From regression analysis the curve fitted through the data

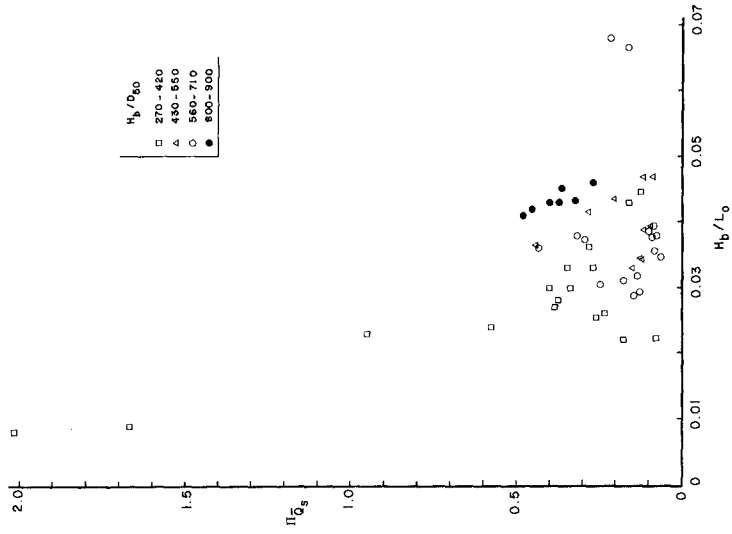

FIG. 4 AVERAGE DIMENSIONLESS TRANSPORT RATE AS A FUNCTION OF BREAKER STEEPNESS

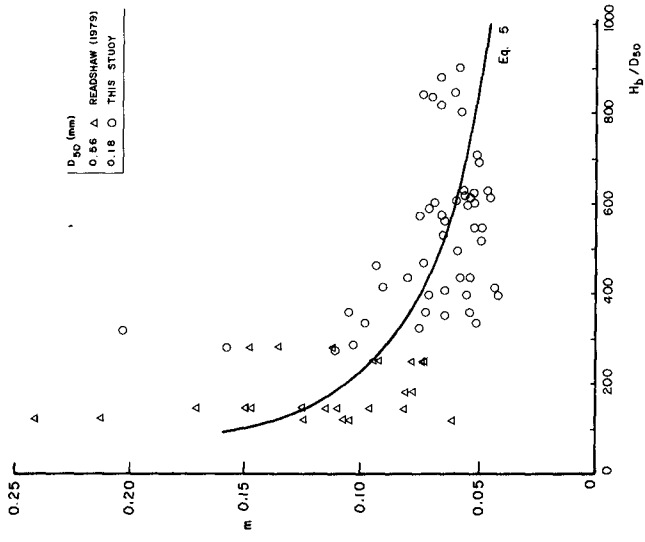

FIG. 3 MOBILE BED BEACH SLOPE AS A FUNCTION OF RELATIVE GRAIN SIZE

is:

$$m = 1.5 \left(\frac{H_b}{D_{50}} \right)^{-1/2} \qquad (4)$$

with $r^2 = 0.42$. The scatter of the data is further reduced if the wave steepness is included as a parameter, see Sayao (1982). It may be concluded that:

$$m \sim \sqrt{\left(\frac{D_{50}}{H_b} \right)} \qquad (5)$$

for medium and fine sands. This result agrees with earlier findings by other authors, reviewed in Sayao and Kamphuis (1982a) and with the well known fact that steeper beach slopes are formed by coarser sediments.

From the above analysis it may be concluded that the mobile bed beach slope m as a dimensionless variable for littoral transport includes much of the influence of relative grain size and hence the two are not completely independent as required by dimensional analysis. Thus, relative grain size and beach slope should not both be included in Equation 1. It was decided to retain beach slope in the relationship. Grain size can be re-introduced at a later stage to account for additional effect of grain size.

Since the model experiments were conducted using sand as the model material in order to avoid serious scale effects resulting from incorrect modelling of the density ratio (see Kamphuis 1975), Equation 1 may be rewritten in simplified form as:

$$\Pi_{Q_s} = \phi_{Q_s} \left(\frac{H_b}{L_o} , m \right) \qquad (6)$$

Figures 4 and 5 show the dimensionless average mass rate of littoral transport ($\Pi_{\bar{Q}_s}$) as a function of each of the dimensionless variables of Equation 6, the wave steepness and the mobile bed beach slope. "Average" refers to sediment transport rate averaged over a test with constant incident wave conditions. Both the present set of results as well as Readshaw's (1979) results are plotted.

For Readshaw's tests, the depth at the breaking point d_b and the breaker distance λ_b had not been measured directly and these quantities were determined by measurement from his published beach profiles. Figure 4 shows a decrease in $\Pi_{\bar{Q}_s}$ with breaker steepness. Also for the same value of the breaker steepness, Readshaw's coarser

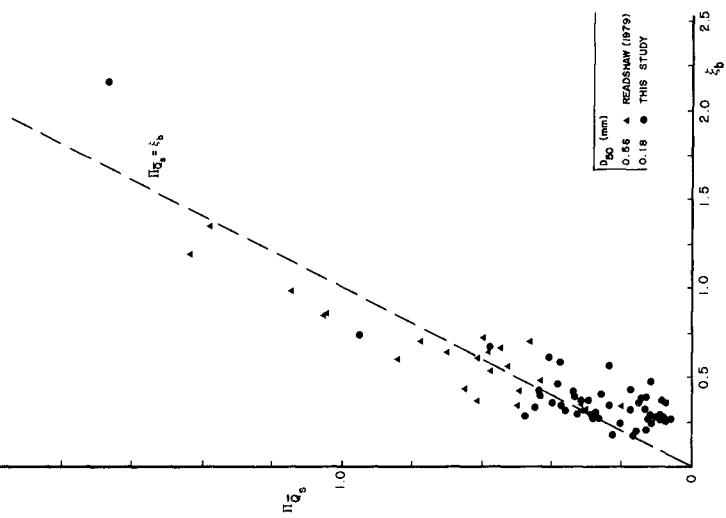

FIG. 6 AVERAGE DIMENSIONLESS TRANSPORT RATE VS SURF SIMILARITY PARAMETER, MEDIUM AND FINE SAND

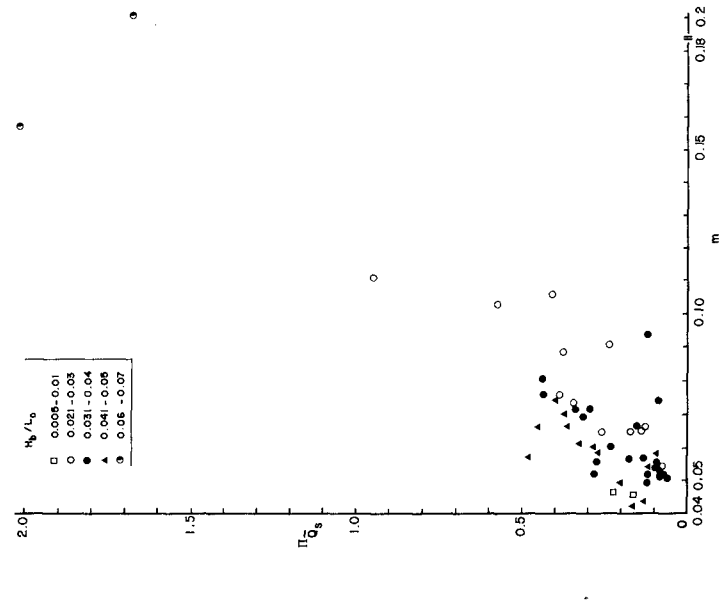

FIG. 5 AVERAGE DIMENSIONLESS TRANSPORT RATE AS A FUNCTION OF BEACH SLOPE

material produced higher dimensionless littoral transport rates, and two distinct curves for $\Pi_{\bar{Q}_s}$ versus H_b/L_o could be drawn. Figure 5 shows an increase of $\Pi_{\bar{Q}_s}$ with mobile bed beach slope.

Figures 4 and 5 indicate that some of the variation in $\Pi_{\bar{Q}_s}$ resulting from the breaker steepness may be compensated by the change in $\Pi_{\bar{Q}_s}$ resulting from the beach profile slope. The influence of the breaker steepness and beach slope on the dimensionless average mass rate of littoral transport might therefore well be expressed by:

$$\Pi_{\bar{Q}_s} \sim \frac{m}{\sqrt{(H_b/L_o)}} = \xi_b \qquad (7)$$

where ξ_b is the surf similarity parameter.

Kamphuis and Readshaw (1978) first proposed that dimensionless littoral transport rate is related to the rate of energy dissipation in the breaking zone and hence to the surf similarity parameter.

Littoral Transport Rate and the Surf Similarity Parameter

Figure 6 shows the dimensionless average mass rate of littoral transport as a function of surf similarity parameter, for the present results with fine sand and for Readshaw's (1979) results with the coarser material. The surf similarity parameter was defined from Equations 3 and 7 as:

$$\xi_b = \frac{m}{\sqrt{(H_b/L_o}} = \frac{d_b/\lambda_b}{\sqrt{(H_b/L_o)}} \qquad (8)$$

A strong straight line relationship between the dimensionless average mass rate of littoral transport and the surf similarity parameter may be seen and hence a good approximation of Equation 6 is:

$$\Pi_{\bar{Q}_s} = \kappa \cdot \xi_b \qquad (9)$$

where κ is a dimensionless constant. Numerical values for κ were found from regression analysis and are given in Table 2. Some variation in κ was noted possibly depending on grain size.

TABLE 2

VALUE OF κ

Experimental Data	Number of Points	Regression Analysis r^2	κ
Readshaw (1979)	24	0.83	1.09
Present results	50	0.83	0.84
Combined data set	74	0.81	0.94

Substitution of Equations 5 and 8 into Equation 9 yields:

$$\Pi_{\bar{Q}_s} = \kappa \cdot \xi_b \sim \frac{\sqrt{(D_{50}/H_b)}}{\sqrt{(H_b/L_o)}} \qquad (10)$$

This implies that the dimensionless littoral transport rate is proportional to the square root of the grain size, for medium and fine sands which agrees with Bajorunas (1970) and Castanho (1970). Laboratory tests conducted by Larras and Bonnefille (1965), reviewed in Sayao and Kamphuis (1982a) revealed that littoral transport rate goes through a maximum when related to the grain size, Lepetit (1972) and Bonnefille (1976). Thus for very coarse sands, Equation 10 will not be valid, and in the limit, for large rocks, the fluid is no longer capable of moving any material.

Equation 10 also shows that dimensionless average mass rate of littoral transport is inversely proportional to the square root of the breaker steepness. This inverse proportionality has been proposed earlier by Saint-Marc and Vincent (1954), Larras (1957) and Le Méhauté and Brebner (1961).

RELATIONSHIP BETWEEN LABORATORY AND FIELD DATA

Immersed Weight, Dry Mass and Alongshore Energy Flux Factor

An attempt to compare the present method and Equation 9 with field data is now presented. Unfortunately, at the present time, only few field data have been published and the quality of these few field data sets was questioned by Greer and Madsen (1978) and Bruno et al (1981). The relationship for dimensionless average mass rate of littoral transport (Equation 9) may be rewritten as:

$$\frac{g\,\bar{Q}_s}{\rho g\,H_b^{\,2}\,(H_b/T)\,\frac{1}{2}\,\sin 2\alpha_b} = \kappa \cdot \xi_b \qquad (11)$$

The average dry mass transport rate $\bar{Q}_s$ may be converted to immersed weight littoral transport rate I_ℓ by the following relation:

$$I_\ell = \frac{\rho_s - \rho}{\rho_s}\, g\, \bar{Q}_s \qquad (12)$$

For quartz sand with $\rho_s/\rho = 2.65$ and using the small amplitude expression for wave energy

$$I_\ell = \frac{8\kappa}{1.6}\,\frac{H_b\,\xi_b}{T}\,E_b\,\frac{1}{2}\,\sin 2\alpha_b \qquad (13)$$

Substitution of Equation 8 into Equation 13 yields

$$I_\ell = \frac{5\kappa}{\sqrt{2\pi}}\, m\, \sqrt{gH_b}\;\; E_b\,\frac{1}{2}\,\sin 2\alpha_b \qquad (14)$$

Longshore wave energy flux factor P_ℓ , is normally defined as follows:

$$P_\ell = \frac{1}{16}\,\rho g\,H_b^{\,2}\,n_b\,C_b\,\sin 2\alpha_b \qquad (15)$$

Using $n_b \approx 1$ for shallow water and C_b as given by small amplitude theory, shown to be correct in Sayao and Kamphuis (1982), P_ℓ becomes:

$$P_\ell = \sqrt{gd_b}\;\; E_b\,\frac{1}{2}\,\sin 2\alpha_b \qquad (16)$$

Now I_ℓ and P_ℓ may be related using Equations 14 and 16:

$$I_\ell = \frac{5\kappa}{\sqrt{2\pi}}\, m\, \sqrt{\gamma_b}\;\; P_\ell \qquad (17)$$

Equations 9, 14 and 17 are simply different expressions of the same relationship for littoral transport rate proposed in the light of the present findings. Equation 17 may be written in dimensionless form as:

$$K_p = \frac{I_\ell}{P_\ell} = \frac{5\kappa}{\sqrt{2\pi}}\, m\, \sqrt{\gamma_b} = 2\,\kappa \cdot m\,\sqrt{\gamma_b}\;. \qquad (18)$$

which shows that the value of K_p is not constant as expressed in the

CERC formula - U S Army Corps of Engineers (1977) - but varies as a function of the mobile bed beach slope and the breaker index. Figure 7 shows a plot of K_p versus $m\sqrt{\gamma_b}$ for the combined results of Readshaw (1979) and the present tests. Figure 7 is equivalent to Figure 6, but contains a little more scatter. Using a value for $\kappa \simeq 1$ (see Table 2), the curve fitted in terms of K_p becomes:

$$K_p = 2\, m \sqrt{\gamma_b} \qquad (19)$$

which was found valid for the model data, with $r^2 = 0.78$.

Preliminary Comparison of Experiments with Field Data

Existing field data on littoral drift have been compiled by Das (1971). The measurements were expressed in terms of immersed weight transport rate and longshore wave energy flux factor. Komar and Inman (1970) found

$$K_p = \frac{I_\ell}{P_{\ell r}} = 0.77 \qquad (20)$$

where $P_{\ell r}$ is P_ℓ evaluated using H_{rms}. The present CERC formula in which Komar's data as well as other available field data sets are used finds K_p equal to 0.78 (Bruno et al, 1981). If the significant wave height is used to calculate P_ℓ, then the comparable value for the CERC formula 'constant' becomes:

$$K_p = \frac{I_\ell}{P_{\ell s}} = 0.39 \qquad (21)$$

assuming the wave heights near breaking to be Rayleigh distributed. Equation 21 is also shown in Figure 7.

A comparison will be made between the present model results and the field data of Komar (1969), see also Komar and Inman (1970). For this comparison of field and model data it is assumed that the monochromatic model wave height H may be compared with the significant wave height H_s in the field. This has become a common assumption in the past for mobile bed model studies performed at Queen's University, as well as at other hydraulics laboratories.

Unfortunately, for Komar's field data, only typical beach profiles for each location were given (see Komar, 1969). For Silver Strand beach the wave data were collected at the same time as the

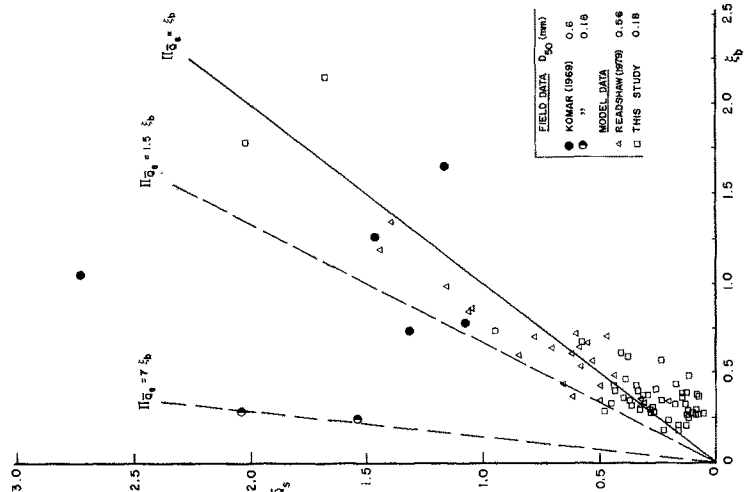

FIG. 8 COMPARISON OF FIELD AND MODEL DATA ON LITTORAL TRANSPORT RATE

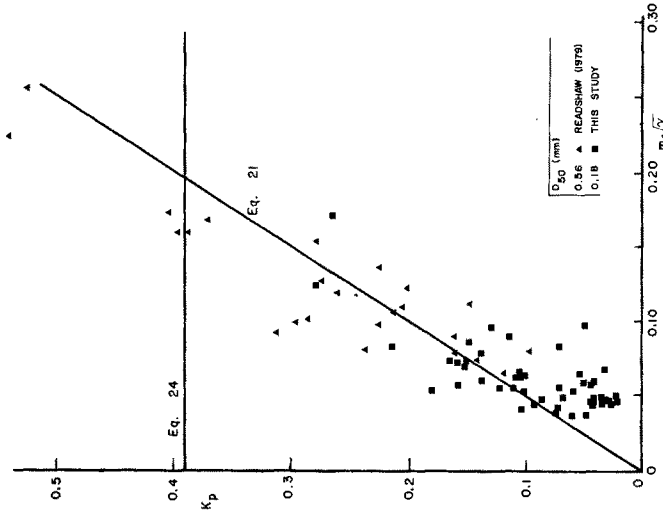

FIG. 7 VARIATION OF COEFFICIENT IN THE CERC FORMULA WITH BEACH SLOPE AND BREAKER INDEX

beach was surveyed. For El Moreno, the wave climate was considered for this study to vary on a seasonal basis, i.e. it was assumed that the profile surveyed in May 1968 was also valid for Komar's measurements of May 1966 and May 1967. Out of the 14 orginal data points only seven can be used in the present comparison. Table 3 shows the parameters used for calculating $\bar{\Pi}_{Q_s}$ based on Komar's (1969) own field measurements using

$$\bar{\Pi}_{Q_s} = \frac{1}{5} \frac{\sqrt{gd_b}}{H_b/T} \frac{I_\ell}{P_{\ell s}} \qquad (25)$$

(1) SSB: Silver Strand beach, D_{50} = 0.18 mm
EMB: El Moreno beach, D_{50} = 0.6 mm
(2) From typical beach profiles given in Figure 9 of Komar (1969)
(3) Averaged daily values from data given in Appendix IV of Komar (1969)
(4) Averaged daily root mean square values from data given in Appendix IV of Komar (1969)
(5) Averaged daily values given in Table 1 of Komar (1969)
(6) Calculated using significant breaker height

The results were plotted in Figure 8 for which $\Pi_{\bar{Q}_s}$ was calculated using $(H_b)_s$ for the field data points (i.e. $(H_b)_{rms}$ was multiplied by $\sqrt{2}$). It may be seen from Figure 8 that Equation 9 is also valid for the field results, but that the value of κ based on the model results would underestimate the littoral transport rate by a factor of about 7 when compared with the Silver Strand field results and by a factor of about 1.5 when compared with the widely scattered El Moreno field results.

The fact that Equation 9 is valid for the field results is not surprising since there is no reason why field sediment transport rates should not be related to rate of energy dissipation. The fact that κ for the field results is higher than for the model is also reasonable. In the model (and on prototype beaches of large grain size), the sand is moved almost solely by bed load transport. For finer sands in the field, additional transport results from material suspension. In the model and the coarse material prototype, the driving force is related to shear stress. In the finer material prototype, additional consideration must be given to stirring of material into suspension by the turbulent breaker, to the settling mechanisms and fall velocity and to the effect of excess pore water pressures in the beach at the breaking zone, locally causing liquefaction of the sand mass and much higher rates of sediment transport.

The model results indicate that as D increases, m increases, ξ increases and hence Q_s increases. But the suspension and liquefaction mechanisms would indicate that as D increases, concentration of particles in suspension decreases and hence Q_s decreases. The first mechanism is taken into account with ξ, the second with κ. Further field comparisons are obviously necessary to prove the above preliminary hypothesis to be correct. No better comparisons can be made until more field measurements of littoral sand transport rate become readily available in which wave characteristics and beach profiles are simultaneously recorded.

For the sake of completeness a simple dimensional plot of I_ℓ versus $P_{\ell s}$, as suggested by the CERC formula (U S Army Corps of Engineers, 1977), is also produced in Figure 9. No strong relationship is evident.

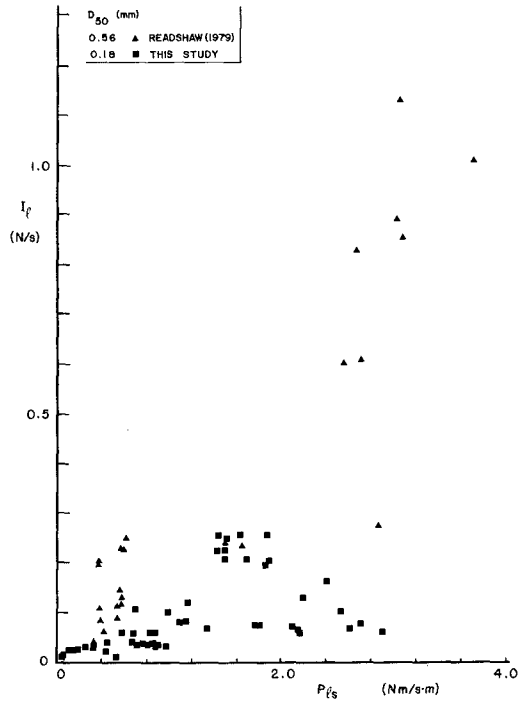

FIG. 9 I_ℓ VERSUS $P_{\ell S}$, FOR MODEL DATA OF MEDIUM AND FINE SAND

CONCLUSIONS

a. Littoral transport rate for medium and fine sand models may be expressed as

$$I_{\bar{Q}_s} = \kappa \xi_b \tag{9}$$

or

$$\frac{\bar{Q}_s}{\rho H_b^2 (H_b/T) \frac{1}{2} \sin 2\alpha_b} = \kappa \frac{m}{\sqrt{H_b/L_o}} \tag{26}$$

where κ was found to be approximately equal to one for the model studies.

b. The beach slope to be used for calculations of littoral transport rate in mobile bed models is

$$m = \frac{d_b}{\lambda_b} \tag{3}$$

which was found to be related to grain size

$$m \sim \sqrt{\frac{D_{50}}{H_b}} \tag{5}$$

c. Another form of Equation 26 is:

$$I_{\ell} = 2 \kappa m \sqrt{\gamma_b} P_{\ell_s} \tag{27}$$

which indicates that the "constant" in the CERC formula is not constant but varies with beach slope and breaker index.

d. Preliminary analysis of some field results indicates that Equation 9 is also valid for prototype beaches but that the value of sediment transport (and κ) for the field results is higher than for the model. This is hypothesised to be a result of additional transport in the field by material suspension.

ρ_s	sediment density

THE RATE OF LONGSHORE SEDIMENT TRANSPORT AND BEACH EROSION CONTROL

Yoshito Tsuchiya, M. ASCE*

ABSTRACT

The main purpose of this paper is to propose an ideal methodology for beach erosion control from the viewpoint of controlling the total rate of longshore sediment transport. For this, a new formulation of the rate of longshore sediment transport is made. The total rate is directly proportional to the longshore component of wave power in field coasts, but not in laboratory ones.

How to control the total rate of longshore sediment transport is considered. There are two ways applicable for practical purposes. The first is to decrease the breaker depth by changing the bottom topography, and the second to decrease the incident angle of breaking waves by changing either the bottom topography or the inclination of shoreline to the incidence of predominant waves. Two typical, but ideal examples are explained for beach erosion control by this methodology.

INTRODUCTION

Beach erosion has advanced actively in many countries of the world, especially in Japan(Tsuchiya, 1980) due to decrease in sediment input from rivers and by construction of coastal structures. Various works have been employed widely to prevent beaches from erosion, but few general concept of beach erosion control has been proposed.

The methodology of beach erosion control must be established by the knowledges of sand drift, as well as of beach processes. By wave power approach, formulations of the total rate of longshore sediment transport have been made by many authorities. Komer and Inman(1970) investigated the applicability of the Bagnold model(1963) for sand transport on beaches to find out some correlation between the model and empirical relation of the total rate of longshore sediment transport. Recently Kamphuis and Readshaw(1978) studied the total rate of longshore sediment transport in terms of the total thrust which is the longshore gradient of the alongshore component of radiation stress. More recently Seymour, Domurat and Pirie(1980) did the same approach which was compared with their observed results of longshore sediment transport and radiation stress.

A very simple model for the formulation of the rate of longshore sediment transport is first explained. Then, an ideal methodology for

* Professor, Disaster Prevention Research Institute, Kyoto University, Kyoto, JAPAN

beach erosion control is proposed from the viewpoints of controlling the total rate of longshore sediment transport and providing stable sandy beaches which have the lowest wave reflection coefficient to reduce the offshore sediment transport effectively.

THE RATE OF LONGSHORE SEDIMENT TRANSPORT

On the whole, movements of sediments are thought to be composed of alternating motion and these sediments are transported downstream by longshore currents even as they are undergoing sliding or saltation due to wave action. Thus, the mechanism of longshore sediment transport can be expressed as

$$q_x = \underset{\text{Wave motion}}{\overset{\uparrow}{\bar{c}_o}} \cdot d \cdot \underset{\text{Longshore currents}}{\overset{\uparrow}{u(y)}} \tag{1}$$

in which q_x is the rate of longshore sediment transport, u the velocity of longshore current in the x-direction, and $\bar{c}_o$ the averaged concentration of sediment. Einstein(1972) indicated that the motion of sediment transported by fluid can be expressed universally by a formula for sediment load. When the formula used to determine the rate of sediment transport by winds and currents(Tsuchiya and Kawata, 1971) is applied, the averaged concentration can be expressed as

$$\bar{c}_o = c_o \left(\frac{\rho}{\sigma}\right)\left(1 - \frac{\tau^*}{\tau_c^*}\right) \tag{2}$$

in which c_o is approximately equal to 0.2 although it varies slightly with the Shields parameter τ^*. τ_c^* in Eq.(2) is the value at the critical stage of sediment movement, and τ^* is given as

$$\tau^* = \frac{\tau/\rho}{(\sigma/\rho - 1)\, gD} \tag{3}$$

where

$$\tau/\rho = (1/2)\, f\bar{v}^2 \tag{4}$$

in which f is the coefficient of bottom friction, D the size of the sediment, σ/ρ the specific gravity of the sediment, g the acceleration of gravity, and $\bar{v}$ the maximum water particle velocity of waves on the sea bottom. The value for $\bar{v}$ can be expressed approximately by

$$\bar{v} = \begin{cases} \alpha\sqrt{gd}, \quad \alpha = \dfrac{1}{2}\left(\dfrac{L}{T\sqrt{gd}}\right)_B \left(\dfrac{H_B}{d_B}\right) & \text{for} \quad 0 \le Y \le 1 \\ \dfrac{1}{2}\left(\dfrac{H}{H_o}\right)\left(\dfrac{L}{L_o}\right)\left(\dfrac{H_o L_o}{Td}\right) & \text{for} \quad 1 \le Y < \infty \end{cases} \tag{5}$$

in which the subscript o refers to wave quantities at the deep-water limit and B to the breaker point, L is the wave-length, H the wave-height, T the wave-period, d the water depth, $Y = y/y_B$ the dimensionless variable, and y_B the width of surf-zone. Use of the equation for longshore currents of Longuet-Higgins(1970), allows us to rearrange the distribution of longshore sediment transport in the y-direction as

$$\frac{q}{\sqrt{gd_B}d} = \begin{cases} \dfrac{5\pi}{16} c_o \left(\dfrac{\alpha}{f}\right)\left(\dfrac{\rho}{\sigma}\right)\left(\dfrac{d_B}{D}\right)(\tan\beta \ \sin 2\vartheta_B)(1-R^2F_r^2Y^2)YU(Y) \\ \qquad\qquad \text{for} \quad 0 \le Y \le 1 \\ \dfrac{5\pi}{16} c_o\left(\dfrac{\alpha}{f}\right)\left(\dfrac{\rho}{\sigma}\right)\left(\dfrac{d_B}{D}\right)(\tan\beta \ \sin 2\vartheta_B \ (1-\dfrac{R^2F_r^2}{Y}) \\ \qquad\qquad \text{for} \quad 1 \le Y < \infty \end{cases} \tag{6}$$

in which $U(Y) = u/u_B$ where u_B is the velocity of longshore currents at the breaker line, tanβ is the average slope of the sea bottom, and R and F_r are

$$\left.\begin{aligned} R &= \frac{1}{2}\left(\frac{H_B}{H_o}\right)\left(\frac{L_B}{L_o}\right)\left(\frac{H_o}{H}\right)\left(\frac{L_o}{L}\right) \\ F_r^2 &= 16\pi\left(\frac{d_B}{H_B}\right)^2\left(\frac{L_o d_B}{L_B^2}\right)\frac{(\sigma/\rho-1)d}{fd_B}\tau_c^* \end{aligned}\right\} \tag{7}$$

The theoretical distribution of longshore sediment transport across the surf-zone in the dimensionless form given by Eq. (6) is shown as a

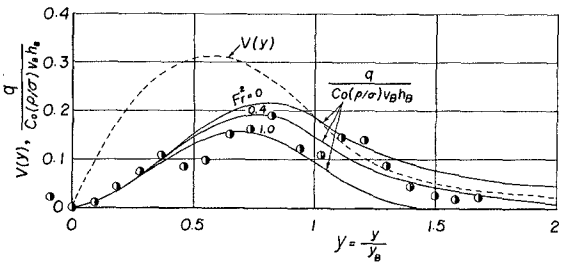

Fig. 1 Offshore distributions of the rate of longshore sediment transport and longshore current velocity

function of Y in Fig. 1 for a comparison with the experimental data obtained by the authors(1978), as well as with the velocity distribution of longshore currents. In the figure, the constant value of P is assumed to be 0.2 for the theory of longshore currents. Favorable agreement for the offshore distribution of longshore sediment transport is seen between the theoretical curves and experimental values. After integrating Eq. (6) with respect to Y over the domain of sand drift between the critical water depth for null sediment mevement and the shoreline(neglecting the so-called swash transport) the total rate of longshore sediment transport Q_x is given by

$$Q_x = C\left(\frac{\rho}{\sigma}\right) \ I(R, F_r) \ d_B^2 \sqrt{gd_B} \ \sin 2\vartheta_B \tag{8}$$

in which

$$\left.\begin{aligned} C &= \frac{5\pi}{16}\frac{c_o\alpha}{f} \\ I(R, F_r) &= a_o - b_o F_r^2 - d_0 (RF_r)^{\alpha_o} + e_o (RF_r)^2 \end{aligned}\right\} \tag{9}$$

Here $a_o = 0.298$, $b_o = 0.124$, $d_o = 0.373$, $e_o = 0.207$ and $\alpha_o = 1.11$ when $P =$

0.2.

The function of $I(R, F_r)$ is shown in Fig. 2. In field coasts, the value of F_r is normally very small, because the parameter F_r includes the ratio of sediment size to wave length. Therefore, the value of $I(R, F_r)$ becomes nearly constant, say 0.3. Then the total rate of long-

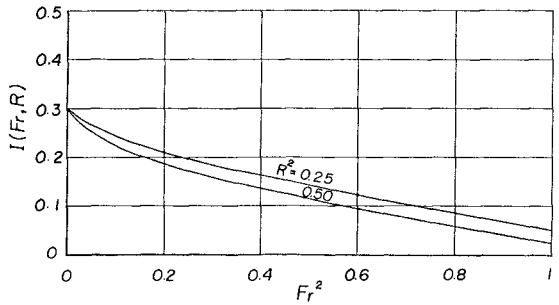

Fig. 2 Change in $I(R, F_r)$ with the parameter R and F_r

shore sediment transport is directly proportional to the longshore component of wave power. This is consistent with the usual empirical relationship for the total rate of longshore sediment transport which

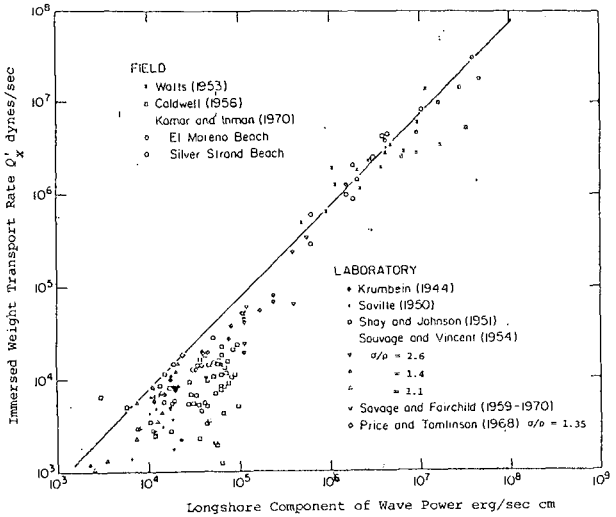

Fig. 3 Data on the immersed-weight sand transport rate as a function of the longshore component of wave power (Komer and Inman, 1970)

was derived by wave power approach. But, in laboratory experiment, the value of $I(R, F_r)$ is more smaller than that in field coasts. The value depends on characteristics of waves and sediment. It has been pointed out that the usual empirical relationship is not applicable for laboratory data of the total rate of longshore sediment transport, so that the data are plotted below the relationship. For example, Fig. 3 which was prepared by Komer and Inman(1970), shows a relationship between the immersed-weight sand transport rate and longshore component of wave power in which the laboratory data are shown below the relationship for the field data.

METHODOLOGY FOR BEACH EROSION CONTROL

Now, consider how to control beach erosion from the viewpoint of controlling the total rate of longshore sediment transport. As explained in Eq. (8), the total rate of longshore sediment transport is expressed by

$$Q_x = C' d_B^2 \sqrt{g d_B} \sin 2\theta_B \tag{10}$$

in which C' is a constant. The total rate of longshore sediment transport is expressed in terms of the breaker depth or breaker height, incident angle of the breaker and some other parameters included in the constant C' in Eq. (10). This formulation indicates that as already explained the total rate of longshore sediment transport is directly proportional to the longshore component of wave power.

An idea of controlling the total rate of longshore sediment transport can therefore be proposed for the conditions of changes in coastal sediment sources. For the conditions of decrease in coastal sediment sources the total rate of longshore sediment transport must be reduced in the given conditions. To reduce the total rate of longshore sediment transport the longshore component of wave power must be decreased effectively along the coast. To reduce the total rate of longshore sediment transport, in other words, two ways would be applicable from Eq. (10) for more practical purposes. The first is to reduce the breaker depth by changing the bottom topography to decrease the total rate of longshore sediment transport. And the second is to reduce the incident angle of breakers by changing either the bottom topography or the inclination of the shoreline to the incidence of predominant waves.

Table 1 A classification of beach erosion control

Method	Practical Works
To reduce the breaker height	To change the bottom topography Offshore beach nourishment Sand groin etc. To construct structures Submerged breakwater Floating breakwater Offshore breakwater etc.
To reduce the incident angle of breakers	Headland control Offshore breakwater etc.

A classification of beach erosion control is shown in Table 1. For controlling the breaker height or breaker depth, there are two ways such as to change the bottom topography and to construct structures. The former is offshore beach nourishment and sand groin, and the latter submerged, floating and offshore breakwaters. For controlling the incident angle of breakers, on the other hand, there are two ways such as headland control and offshore breakwater.

An example of wave reflection coefficients of wave absorbers and natural beaches is shown in Fig. 4, in which K_r is the reflection coef-

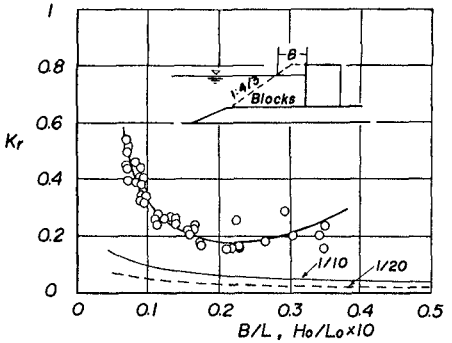

Fig. 4 Wave reflection coefficients of wave absorbers and natural beaches

ficient, B/L the ratio of the width of absorber to wave length, H_o/L_o the wave steepness at deep water limit, the thick solid curve indicates experimental values of reflection coefficient of wave absorbers with concrete blocks (Tanimoto, Kitatani and Osato, 1979), and the other two thin solid curves are those of sloping beaches of 1/10 and 1/20 respectively. It is well-known that the efficiency of natural sandy beaches in wave energy dissipation is very higher than other wave absorbers, and is nearly independent of wave periods. To reduce offshore sediment transport, emphasis is placed on the reduction of occurrence of reflected waves in considering how to control beach erosion.

From the viewpoint of controlling the total rate of longshore sediment transport, a possible method can be expected for application to practical beach erosion control. In this case, attention should be made in selecting suitable methods of beach erosion control by which be formed stable sandy beaches having the lowest coefficient of wave reflection to reduce the offshore sediment transport by reflected waves most effectively. From the viewpoint of applicability, the second one of the proposed methods would be more applicable for beach erosion control, because the inclination of shoreline can be changed easily by construction of artificial headlands or offshore breakwaters. Especially natural-like sandy beaches will be formed between headlands if necessary conditions for their formation are satisfied.

IDEAL EXAMPLES OF BEACH EROSION CONTROL

Two typical, but ideal examples can be explained for beach erosion by this methodology. The first is for beach erosion due to the decrease in sediment sources such as recent beach erosion near river mouths which has recently been remarkable in many countries of the world, especially in Japan(Tsuchiya, 1980). Surppose that a river is running into the sea as shown in Fig. 5, and the predominant waves are coming from the

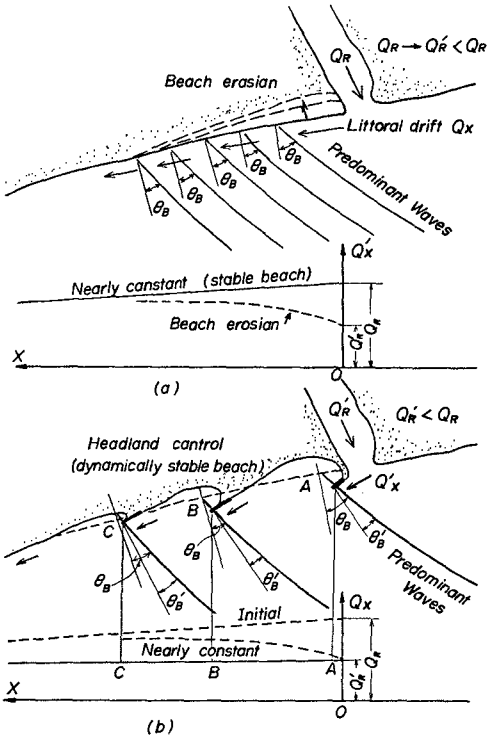

Fig. 5 Beach erosion control for the decrease in sediment input from a river

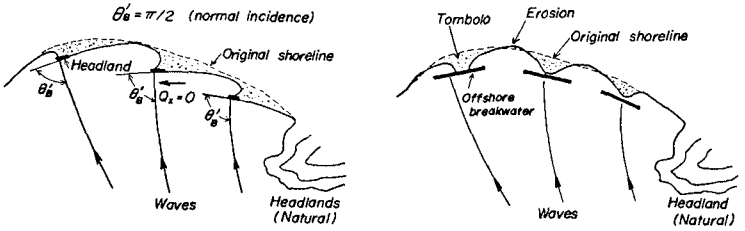
direction of which the incident angle is θ_B, producing the total rate of longshore sediment transport Q_x. The sediment input from the river was Q_R, but has recently been reduced Q_R'. Beach erosion has therefore advanced on the coast downstream of longshore sediment transport, the left-side coast of the river as shown in the figure.

The total rate of longshore sediment transport by the predominant waves can be assumed to be nearly constant so that the decrease in sediment input from the river takes place beach erosion. Consider how to control the beach erosion from the viewpoint of controlling the total rate of longshore sediment transport. For this the total sediment transport rate must be reduced along the left side coast, according to the decreased sediment input from the river.

There may be many ideas for this, but a possible solution of them is expected as shown in Fig. 5(b), in which a series of headlands is constructed at suitable angles and distances to make the total sediment transport rate decrease at the given total rates. This is to reduce the incident angle of the breakers from θ_B to θ_B' as shown in the figure. It may then be expected that a series of dynamically stable beaches(Silvester, Tsuchiya and Shibano, 1980) be finally formed, and they have the lowest coefficients of wave reflection to reduce the offshore sediment transport most effectively.



(a) Headlands (b) Offshore breakwaters

Fig. 6 Beach erosion control for the lack of sediment sources

The second example is for beach erosion due to the lack of sediment sources by reclamation of river mouth areas or by construction of large coastal structures. A solution for such beach erosion can be proposed by this methodology as shown in Fig. 6, in which a series of headlands (Silvester, 1976) or offshore breakwaters(Detached breakwaters, Toyoshima, 1974) is employed to make the total rate of longshore sediment transport vanish. By construction of such a series of headlands or offshore breakwaters, statically stable beaches(Silvester, Tsuchiya and Shibano, 1980) be finally formed between them.

CONCLUSION

Based on the formulation of the total rate of longshore sediment transport, an ideal methodology of beach erosion control has be proposed, and two typical, but ieal examples have been shown for controlling beach erosion due to the decrease or lack of sediment sources.

I must hereby remember the following two concepts;
"Water shall not be compelled by any fortse(force), or it will return that fortse onto you" which was introduced by Professor Per Brunn

(1972) in his theme lecture at the 13th Coastal Engineering Conference, and

"How to copy nature" which was emphasized by Professor Richard Silvester(1979) in his special lecture at the 1978-Annual Meeting of the Disaster Prevention Research Institute, Kyoto University.

The study reported in this paper was supported by Grant-in-Aids for Scientific Research, from the Ministry of Education, Science and Culture of Japan, under Grant Nos. 542044 and 57850167.

SEDIMENT TRANSPORT UNDER SHEET FLOW CONDITION

by

Kiyoshi Horikawa[1], Akira Watanabe[2] and Sadakazu Katori[3]

ABSTRACT

A series of laboratory experiments in an oscillatory tank was carried out to investigate the sheet flow of sediment. Objectives of the study were to determine the criterion for inception of sheet flow, and to evaluate the sediment transport rate under the sheet flow condition. In order to proceed with the investigation, it was necessary to develop devices appropriate for tracing the sediment particle movement, and for measuring the extremely dense sediment concentration in the moving layer of sheet flow. The chief results are: 1) the criteria for the inception of sheet flow given by Manohar (1955) and by Komar and Miller (1974) are both applicable to materials composed of spheroidal particles, and 2) the average rate of sediment transport for sheet flow is well described by an empirical relationship given by Madsen and Grant (1976) for the bed load transport rate on a plane bed in oscillatory flow.

INTRODUCTION

The prediction of beach profile change is, at present, one of the most important subjects in the field of coastal engineering. In order to proceed with the prediction of beach evolution, appropriate formulae must be developed for evaluating the sediment transport rate in the surf zone as well as in the offshore zone. The characteristics of waves, currents, and movement of sediment particles in these regions are evidently completely different depending upon the location. For example, Dingler and Inman (1976) presented diagrams of various types of bed configurations appearing in the shallow water region. These are the relict, rippled, transition, and sheet flow regimes. The rippled bed gives way to the sheet flow regime in the surf zone, in particular under storm conditions. Although studies on sediment transport in the sheet flow condition are necessary to understand beach profile change in the surf zone, very few investigations have been reported on this particular phenomenon.

3. Research Engineer, Nearshore Environment Research Center, 1202 Famille Hongo Building, 1-20-6 Mukohgaoka, Tokyo, 113, Japan

The authors therefore initiated a series of laboratory investigations using an oscillatory flow tank to isolate the fundamental aspects of sheet flow. In this paper, the main results on the items listed below will be discussed. These are:

1) Criterion for inception of sheet flow,

2) Sediment concentration in the layer moving as sheet flow,

3) Advection speed of sand particles in the moving layer, and

4) Sediment transport rate under the sheet flow condition evaluated on the basis of items 2) and 3).

EXPERIMENT LAYOUT

The experiments were performed in an oscillatory flow tank. There are two reasons for using such an apparatus. First, sheet flow occurs in the surf zone where the environmental conditions are difficult to control, and where the fluid flow is complicated. Secondly, in order to produce sheet flow on a horizontal bed while at the same time avoiding the complication of wave breaking, a very large flume would be necessary. Therefore, it is convenient to use a tank such as ours in which the amplitude (max. 75 cm) and period (1 to 10 s) of the oscillatory flow can be varied over a wide range covering the scale of the prototype.

Figure 1 shows a schematic diagram of the oscillatory flow tank and the various measuring apparatus used. The oscillatory flow is produced by a piston. The flow section is 25 cm wide, 25 cm high and 200 cm long. Sediment materials were placed along the bottom plane of the test section as described in the next paragraph. The period, amplitude, and mean velocity of the oscillatory flow in the test section were evaluated from readings of a wave gage at the vertical riser of the oscillatory tank, as shown in Fig. 1. A motor-driven 35 mm camera was used to record the particle concentration in the upper layer of the flow, and to determine the particle advection speed throughout the flow. An electro-resistance sediment concentration detector was used to measure the concentration in the lower layer of the sheet flow. The instruments and techniques are discussed in detail as they appear below.

Figure 2 shows two types of setups in the test section. A vinyl chloride plate was introduced to reduce end effects. For the heavier materials, the test section was narrowed to obtain a higher flow velocity. Six kinds of bed material were used to study the inception criterion; three consisted of natural sands, and three of plastic particles. The characteristics of the test materials are given in Table 1. For studying the transport rate, only sand (1) in Table 1 was used (Toyo-ura standard sand, median grain size 0.2 mm).

CRITERION FOR INCEPTION OF SHEET FLOW

A series of runs was carried out under various flow conditions to determine the inception of sheet flow. The inception criterion was visually defined as the initiation of the plane-bed mode by two procedures. The first was to increase stepwise the amplitude of the flow velocity by reducing the period of oscillation while holding the horizontal amplitude of the piston constant. In this process, the generation, development, and disappearance of bed ripples were visually observed. The second procedure was to decrease the amplitude of the flow velocity from the already existing condition of sheet flow. During the latter process, the regeneration of bed ripples was observed. Figure 3 shows sample results. The horizontal and vertical axes in this diagram are the near-bottom orbital amplitude, and the period of oscillatory flow, respectively. It is seen that the two procedures give essentially the same inception criteria, and that, therefore, sheet flow can be detected fairly precisely.

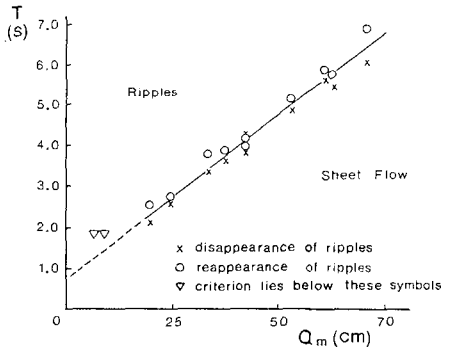

Fig. 3 Experimental results for criterion of sheet flow (sand (1)).

As far as the authors can determine, three criteria for the inception of sheet flow have been reported (Manohar, 1955; Komar and Miller 1974; Dingler and Inman, 1976). These are summarized in Table 2, for which the expression given for Manohar's criterion was derived by the authors on the basis of the original form. In Table 2, $\hat{U}$ is the maximum orbital velocity, $s = (\rho_s - \rho)/\rho$, ρ_s and ρ are the densities of the sand and fluid respectively, d is the grain diameter, ν is the kinematic viscosity of the fluid, g is the gravitational acceleration, and f_w is the wave friction coefficient of Jonsson (1966).

TABLE 2 Criteria for inception of sheet flow.

Manohar (1955)

$$\Theta \equiv \frac{\hat{U}^2}{sdg} = \frac{2 \times 10^3}{\sqrt{\hat{U}d/\nu}}$$

Komar · Miller (1974)

$$\Psi \equiv \frac{f_w \hat{U}^2}{2sdg} = \frac{4 \cdot 4}{(\hat{U}d/\nu)^{1/3}}$$

Dingler · Inman (1976)

$$\Theta = 240$$

Figure 4 gives a comparison of the criteria of Manohar (1955) and of Dingler and Inman (1976) with the present data and with Manohar's data obtained using an oscillatory plate. The vertical and horizontal axes are the non-dimensional parameters, Θ, and the Reynolds number based on the grain size, Re, respectively. From this figure it is seen that Dingler and Inman's criterion is likely to give a rough estimate of the criterion for inception of sheet flow. Manohar's criterion is seen to describe the data well except for those data pertaining to the cylindrically-shaped plastic particles (open triangles at upper right of Fig. 4; plastic (1) and (2), Table 1).

Figure 5 gives a comparison of Komar and Millers' (1974) criterion with the laboratory data, where the vertical and horizontal axes are, respectively, the Shields parameter Ψ and the Reynolds number based on the grain size, Re. In this diagram, Manohar's (1955) data were plotted together with the present data for reference. In general, Komar and Miller's criterion is seen to fairly well describe the trend of the experimental results. The data for sand (1) indicates a tendency for the inception criteria to level off at the lower Reynolds numbers, which is not reproduced by the expression of Komar and Miller. Although it appears from the present experimental results that the criterion of Manohar (1955) is somewhat superior to that of Komar and Miller, we must reserve judgement until more data are available.

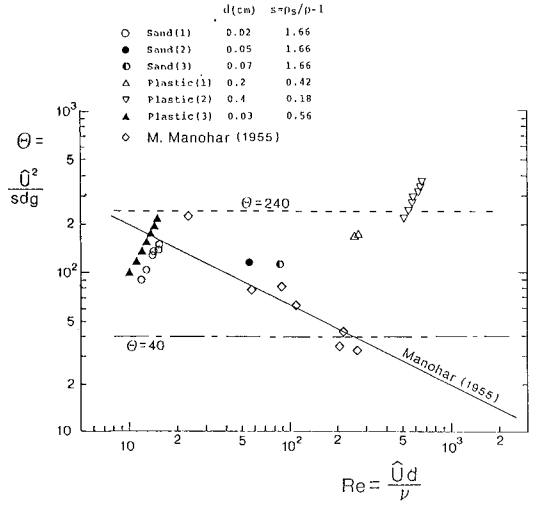

Fig. 4 Criterion for inception of sheet flow (Θ ~ Re).

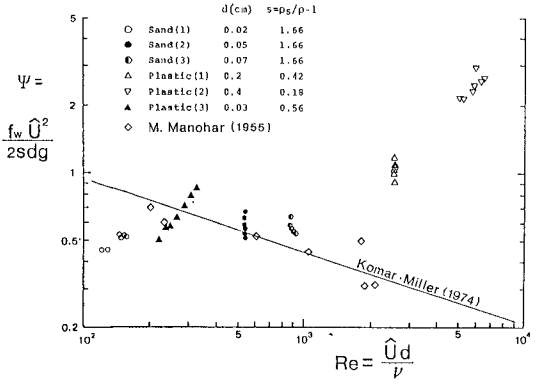

Fig. 5 Criterion for inception of sheet flow (Ψ ~ Re).

The main reason for the apparently anomalous results with the cylindrical plastic particles is that these particles did not move as easily as the other (spheroidal) particles. It can be concluded that the criterion for the inception of sheet flow is closely related to the shape of the sediment particles. More data are needed to determine an appropriate criterion for inception of sheet flow for odd-shaped particles.

SEDIMENT CONCENTRATION IN SHEET FLOW

Sediment Concentration Measuring Techniques

In order to measure the concentration of suspended sediment produced by wave action, photoelectric concentration meters are usually employed. However, this type of meter can not be applied to measure the sediment concentration in the sheet flow moving layer, because 1) the sediment concentration is too high to be measured by conventional apparatus, and 2) the meter itself disturbs the flow. Therefore, measurements were made employing a photographic technique and a newly developed electro-resistance type sediment concentration meter.

A photographic technique was used to measure the suspended sediment concentration in the upper layer. As shown in Fig. 6, a copper plate (0.1 mm thick, 1 cm wide and 20 cm long; painted black) was placed vertically and parallel to the flow direction, at a distance of 1 cm from the inside of the glass wall of the oscillatory tank. Successive pictures of sand particle movement during oscillatory flow were taken at certain intervals for 15 to 20 frames over the flow period using a motor-driven camera and a stroboscopic lamp. The sand particles passing through the 1 cm-wide section between the copper plate and glass wall were counted on the pictures.

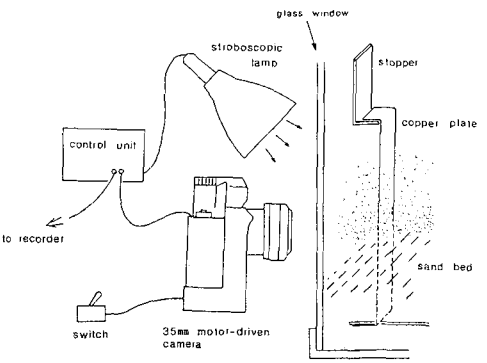

Fig. 6 Experimental arrangement for measuring grain movement in upper layer.

In the vicinity of, or inside the moving layer of sheet flow, the sediment concentration is extremely high and therefore a special measuring device was developed for the present investigations. The measurement principle is based on the fact that the electrical resistance of a water/sand mixture is a function of the concentration of sediment particles. A schematic of the measurement device is given in Fig. 7. In order to calibrate the instrument, a cylindrical tank (diagrammatically shown in Fig. 8) was used. This calibration tank is suitable for generating a uniform and constant suspended sediment concentration. The concentration can be varied over a wide range.

A typical calibration curve of the instrument is given in Fig. 9, where the horizontal axis C' is the relative volumetric concentration defined as C' = 0 for water only, and C' = 1.0 for sediment settled in still water. The vertical axis is the ratio between the output voltage V for a certain value of C', and the voltage V_o for C' = 1. The linearity of the calibration curve is adequate to measure the sediment concentration over a wide range of concentration. Another advantage of the device is the small size of the sensor, which minimizes disturbance of the flow field.

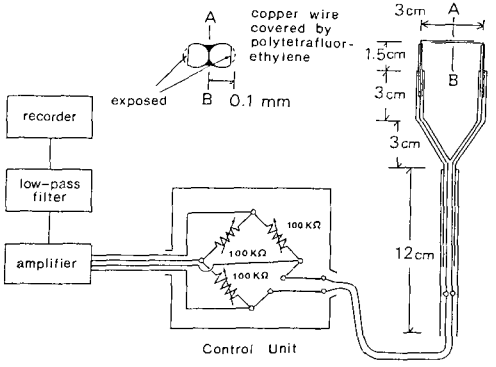

Fig. 7 Electro-resistance type sediment concentration meter.

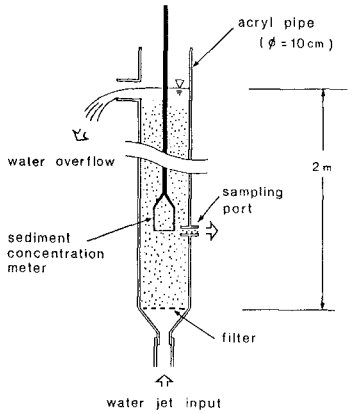

Fig. 8 Calibration apparatus for sediment concentration meter.

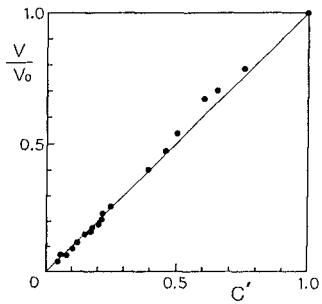

Fig. 9 Calibration curve for electro-resistance type sediment concentration meter.

Measured Concentration

Table 3 indicates the eight oscillatory flow conditions tested which produced the sheet flow regime in the bed material. The data obtained using the photographic technique will first be presented. This concerns the sediment concentration in the upper layer. Figures 10(a) and 10(b) exhibit some vertical distributions of sediment concentration under constant orbital amplitude and constant velocity amplitude, respectively. The vertical axis, y, is the elevation above the surface of the initial bed. The horizontal axis, $\bar{C}_N$, is the number of sand particles contained in a rectangular body of water with a horizontal cross section of 1cm by 1cm and a vertical length of 1 mm, averaged over one oscillatory cycle. Here the value $\bar{C}_N = 1.0$ corresponds to a mass concentration of 167 mg/liter.

From Fig. 10(a), it is seen that the suspended sediment concentration increases with increase in the velocity amplitude (that is, an increase of bottom shear stress) under the condition of constant orbital amplitude. Figure 10(b) indicates that the elevation which the sediment particle reaches above the bed decreases with a decrease in the oscillation period under the condition of constant velocity amplitude. This result is believed due to the fact that for shorter periods, the flow reverses direction before turbulence is fully generated along the bottom. The vertical distribution of the concentration of the sediment located higher than 7 mm above the bed is expressed well by an exponential function of distance from the bed.

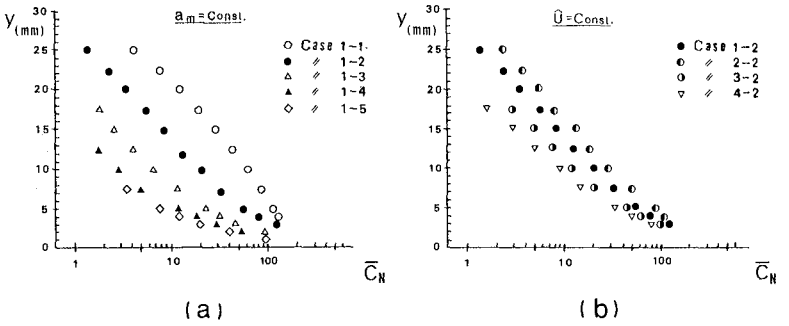

Fig. 10 Distribution of average concentration in upper layer.

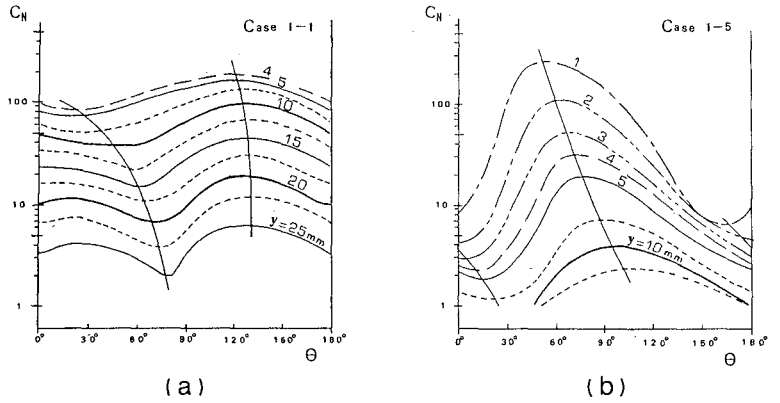

Fig. 11 Variation of concentration with phase angle.

Time variations of sediment concentration at selected elevations for two particular cases are shown in Figs. 11(a) and (b). Here the vertical axis, C_N, is the number of sediment particles in a certain volume of water, and the horizontal axis, θ, is the phase of oscillatory flow. The phase $\theta = 0^\circ$ corresponds to the time when the velocity changes direction, and $\theta = 90^\circ$ corresponds to the time when the velocity reaches a maximum. Figure 11(a) is a typical result, while Fig. 11(b) is atypical. The trends of the phases of maximum and minimum concentration are indicated by solid lines. On the basis of the data of all eight cases shown in Table 3, it can be concluded that the phase of the sediment concentration in the vicinity of the bed is almost equal to that of the oscillatory flow velocity, although the phase of concentration tends to move ahead as the flow period increases. The phase difference between the sediment concentration and the oscillatory flow velocity increases with increase in elevation.

Now, the sediment concentration in the moving layer of sheet flow will be considered. Figure 12(a) shows the vertical distributions of sediment concentration at various phases for Case 1-1, measured by the electro-resistance concentration meter. According to these plots, the sediment concentration changes considerably in the layer spanning 3 to 5 mm above and below the location of the initial bed surface. The minimum sediment concentration above the initial bed surface occurs a little after the phase of $\theta = 0^\circ$ (minimum flow velocity); the maximum concentration occurs at approximately $\theta = 90^\circ$ (maximum velocity).

The curves of sediment concentration at the phases of 90° and 120° have an inflection point in the layer just below the initial bed level. This phenomenon is presumably caused by strong vortices appearing near the bed. It can be observed from Fig. 12(a) that sand particles lifted up at the phase of high velocity fell to the bottom during the stages of velocity deceleration.

ADVECTION SPEED OF SAND PARTICLES

The advection speed of the sand particles was measured under the same conditions as those of the sediment concentration measurements. A number of pictures were taken at certain constant intervals with various shutter speeds by using a motor-driven 35mm camera. The advection speed of the moving particles was determined by tracing individual particles on successive frames.

In the upper layer, the camera was focused on interior particles to eliminate the influence of the glass wall. In the lower layer, because of the extremely high concentration, the advection velocity could not be obtained by direct observation of individual particles.

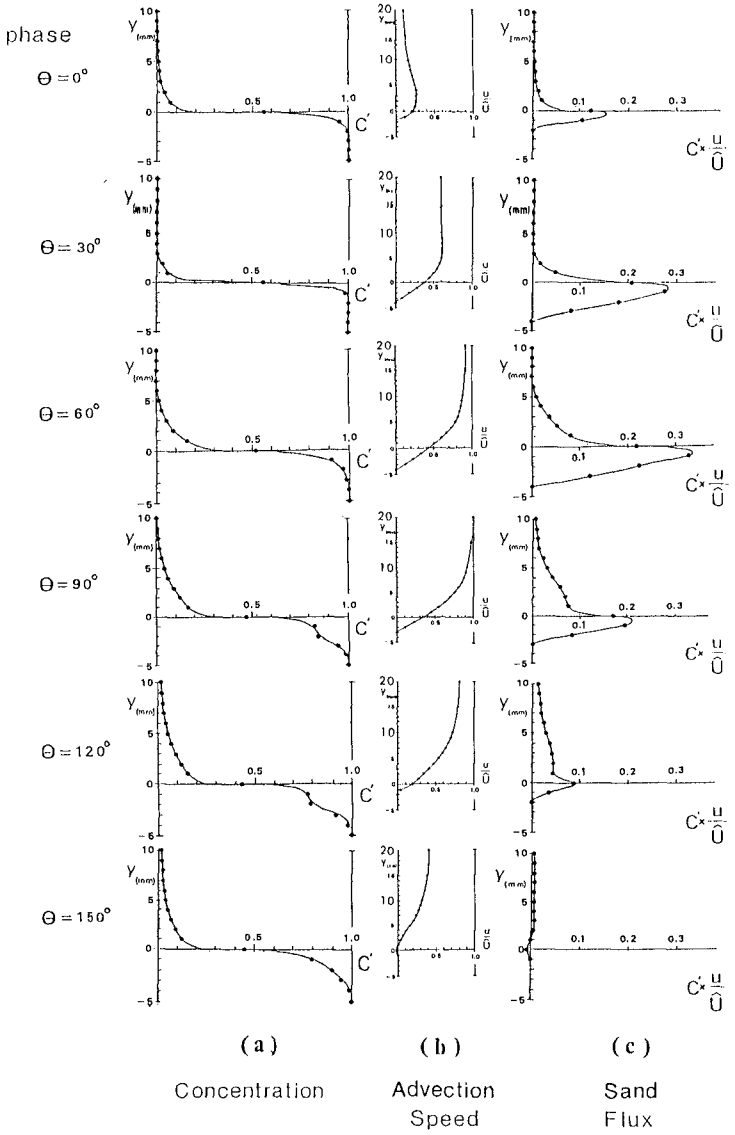

Fig. 12 Vertical distribution of concentration, advection speed, and sand flux.

Therefore, an extrapolation procedure was used as follows: 1) Amplitudes of motion down to an elevation of 2 mm from the initial bed were obtained by means of the normal camera technique. The depth at which the amplitude became zero was determined by measuring the position of the electro-resistance probe at maximum concentration (no sand dilation) for given flow conditions. The vertical distribution of amplitude in the lower layer not amenable to direct measurement was then estimated by curve fitting. 2) The phase of the motion during the time which the sand was assumed to move was determined by using the same photographic technique as described above, but using more readily visible plastic particles. 3) The advection velocity in the lower layer was then calculated using the amplitudes and phases derived by the above separate procedures.

Figure 12(b) shows curves of the vertical distribution of advection speed u normalized by the amplitude of the main flow velocity $\hat{U}$, at various phases in a half cycle of the oscillatory flow. It is seen that the vertical distributions of advection speed of sediment particles are quite similar to those of water particle velocity inside the oscillatory boundary layer flow: the sand advection speed in the upper layer ($y \geq 20$ mm) is almost always equal to the main flow velocity, whereas it decreases in amplitude and advances in phase with decrease in elevation. The gain in phase approaches about 45° at the lowest elevation of the moving layer, corresponding to that of the laminar boundary layer flow velocity. However, the advection speed in the lower layer does not vary sinusoidally in time, but changes intermittently, having significant magnitude only over a limited time duration at certain phases of the oscillatory cycle. This is due to the intense frictional forces between sediment particles.

SEDIMENT TRANSPORT RATE

The flux of sediment concentration is defined as the product of the concentration C' and the advection speed u at each elevation and each phase. Figure 12(c) gives the vertical distributions of the concentration flux (divided by the amplitude of main flow velocity, $\hat{U}$) thus obtained at the various phases for the present case. It is realized from this figure that the moving layer in the vicinity of the initial bed surface with a thickness of the order of 10 mm contributes significantly to the sediment transport rate.

The instantaneous sediment transport rate through a vertical cross-section was evaluated from the verical integration of concentration flux at each phase. Taking the average of the instantaneous transport rate over a half cycle of oscillatory flow yields the mean transport rate for each experimental case. In this way, a total of six data points for the mean sediment transport rate under the sheet flow condition were obtained.

Madsen and Grant (1976) treated bed load movement induced by oscillatory flow and proposed a formulae to relate the nondimensional transport rate Φ to the Shields parameter Ψ, based on a Brown-type formulae of bed load transport rate in a uni-directional flow. The relation is given by

$$\Phi = \frac{\bar{q}_s}{wd} = 12.5\ \Psi^3 \tag{1}$$

where $\bar{q}_s$ is the sediment transport rate averaged over a half wave cycle, w is the fall velocity of the sediment particles, and d is the grain size. The definition of the Shields parameter Ψ is given in Table 2. This relation was found to agree well the experimental data of Kalkanis (1964) and Abou-Seida (1965), obtained using an oscillatory plate moving horizontally in a sinusoidal manner in a still water basin.

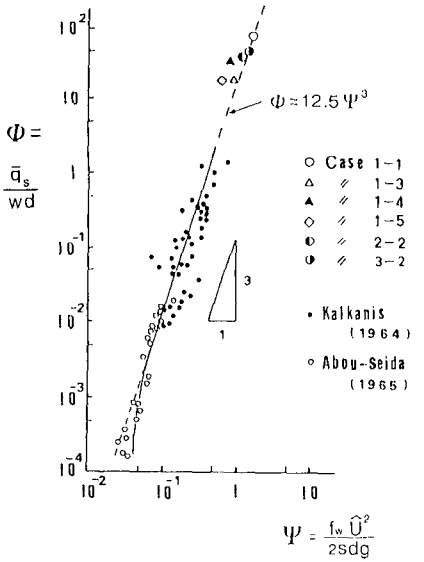

Fig. 13 Relation between non-dimensional transport rate and Shields parameter.

In Fig. 13, the present results, obtained under the sheet flow conditions, are plotted on a figure given by Madsen and Grant (1976). It is seen that the formula proposed by Madsen and Grant fits the present data quite well. However, since the amount of data obtained under the condition of high Shields parameter is scarce, further effort is needed to accumulate more data on the sediment transport rate of sheet flow.

It should be emphasized that the beach configuration is transformed due to the net rate of sediment transport, i.e., the difference between onshore and offshore transport rates. It is clear from Fig. 12 that the magnitudes of the instantaneous sediment flux are significantly different even for the same main flow velocity, depending on whether the flow is at the stage of acceleration or deceleration (compare $\theta = 30^{\circ}$ and 150°, or $\theta = 60^{\circ}$ and 120°). This implies that a more detailed examination of the sediment movement is required in order to establish a transport formula which can estimate the instantaneous or net rate of sediment transport under the asymmetrical variation of flow velocity such as occurs in the surf zone.

CONCLUSIONS

In order to elucidate the fundamental aspects of the sediment transport phenomena under the sheet flow condition, a series of laboratory experiments was performed in an oscillatory flow tank utilizing specially developed measuring devices and techniques. In particular, the electro-resistance type concentration detector was found capable of measuring exceptionally high concentrations which can not be measured by conventional photoelectric concentration meters.

From the experimental results, the following conclusions were obtained:

1) The criteria for the inception of sheet flow given by Manohar (1955), and by Komar and Miller (1974) agree favorably with the laboratory data (for spheroidal particles) in general. However, the shape of the sediment particles seems to exert significant influence on the criterion, as expected.

2) In the range of experimental conditions reported, the thickness of the moving layer of the sheet flow is of the order of 10 mm.

3) The data for the mean rates of sediment transport under the sheet flow condition agree with a bed load relation given by Madsen and Grant (1976). The upper limit of validity of this expression was thus extended.

4) Since the instantaneous transport rate differs between accelerating and decelerating phases of motion, further study is necessary to establish a formula for the net transport rate.

ABSTRACT

A comparison is made between the measured infilling of two test pits off the coastline of San Francisco and predictions using a coastal bedload transport model. The model, based on the work of Madsen and Grant (1967), relates the bedload transport to the bottom shear stress through an empirical relationship based on laboratory experiments. The bottom shear stress is estimated from the bottom currents created by waves and low frequency currents. The model applies beyond the breaker zone in contrast to littoral transport.

The test pits, dredged as part of the Southwest Ocean Outfall Project for San Francisco, were located 1.6 km (1 mi) and 3.2 km (2 mi) offshore in 13 m (42 ft) and 16 m (53 ft) of water. The depth of the pits relative to the natural seabed was about 8.4 m (25 ft). The comparison was conducted for a period up to 2 months in the fall of 1978.

The paper discussed the quality and scope of available data required as input to the model and shows how regional wave data were transformed to augment local measurements. Uncertainties in model results stemming from limitations in the input data are presented. With suitable adjustment of the scale of the gravitational term in the expression for the Shields parameter, overall agreement between computed and measured bedload was accomplished within the limits of accuracy of the bathymetric surveys. A sensitivity analysis of selected input conditions and coefficients was also conducted.

INTRODUCTION

Over the past two decades there has been a marked increase in construction of facilities in the coastal zone and continental shelf. In engineering such facilities, the effects of marine bedload sediment transport on the facility or, conversely, the effects the facility will have on bedload transport are often important. For example, where trenching of the sea floor is needed for installation of large outfalls, cooling water intakes, or other structures, it is often necessary to estimate the amount of overdredging and the time frame for construction as determined by the local rate of bedload transport and siltation. In other cases, it is important to estimate the probable effects on local shoaling or scour caused by large offshore structures such as artificial islands and breakwaters. Where new navigation channels are planned, it is advantageous to examine various geometries of the channel and associated turning basins to minimize future maintenance dredging requirements. In light of these needs, various methods have evolved to evaluate marine bedload transport and siltation during the engineering phases of projects.

The purpose of this study to evaluate computed siltation rates, due to marine bedload transport, through comparison with measured data. The data available was typical of the quality available for engineering studies, and, as such, was not of optimum quality. Thus, this is a practical test of the present state-of-the-art for computing siltation rates.

The field data for this study was collected as part of the Southwest Ocean Outfall Project (hereafter SWOOP). The SWOOP project is part of a series of projects comprising the Clean Water Program of the City and County of San Francisco, California. The objective of the Program is to provide an efficient means for collecting and disposing both sanitary and storm wastewater flows resulting from the present and future needs of San Francisco. The Southwest Ocean Outfall will disperse these wastewaters at diffuser sections located well offshore in the Pacific Ocean. The outfall, a single conduit with an inside diameter of 3.7 m (12 ft), will be embedded throughout its length in a trench excavated as much as 8.4 m (25 ft) below the existing sea floor.

In order to evaluate some of the marine soil behavior, monitor marine siltation, and judge the effectiveness of floating marine equipment in the wave and current environment of the site, a Test Pit Program was conducted. Two test pits were excavated by a derrick barge to depths of approximately 8.4 m (25 ft) below the existing sea floor at locations 150 m (500 ft) south of the proposed outfall centerline. Test pit numbers 1 and 2 were located approximately 1.6 km (1 mi) and 3.2 km (2 mi) offshore in water depths of about 13 m (42 ft) and 16 m (53 ft) below mean lower low water (MLLW), respectively. Detailed bathymetric surveys were conducted on an approximately bi-weekly interval. Waves and near bottom currents were continuously measured in-situ. Figure 1 shows the location map of the project, and Figure 2 is a more detailed project map showing the test pits and oceanographic monitoring stations.

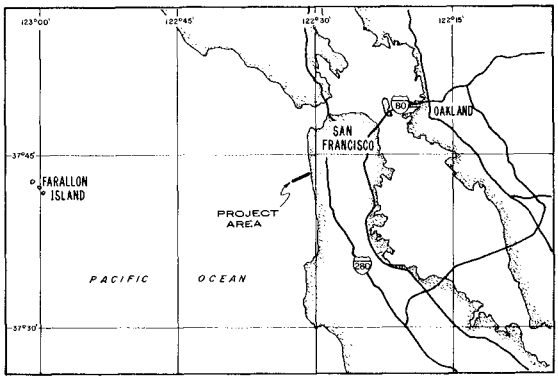

FIGURE 1

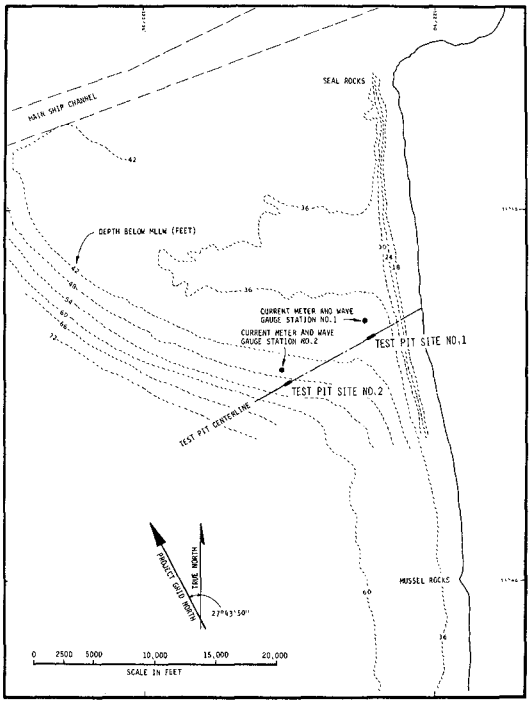

FIGURE 2

The original intent of the test pit program was to relate the measured siltation rates to the wave and current conditions in an empirical manner. However, the availability of this rather unique data set was an incentive to test a deterministic methodology to calculated siltation rates. The method developed by Madsen and Grant (1976) was selected as the basis for a computer program to calculate marine bedload transport and siltation within the test pits from the wave, current, and sediment data available from the SWOOP test pit program.

MEASUREMENTS

The measurements conducted during the SWOOP test pit program included waves, bottom currents, and sea floor sediment samples in addition to detailed bathymetric surveying. The methods, equipment, and techniques employed to make these measurements are discussed below.

Bathymetric surveying was conducted from the 20 m (60 ft) survey vessel POLARIS, using Raytheon Model DE719 survey fathometer with a hull-mounted, narrow-beam transducer. Horizontal positioning was accomplished with a Motorola Mini-Ranger III navigation system coupled to a data processor, terminal printer, and ship track plotter. Detailed surveys of the test pits were run using a grid with line spacing of about 24 m providing both primary and tie-lines. Tide height corrections were initially based on data collected visually from a shore station. Later, predicted tide levels for San Francisco was used as the two were well correlated. Considering all factors, such as position fixing, sea and swell, tides and variations in seawater sound velocity, the absolute accuracy in resolving depth was approximately ±0.3 m (±1.0 ft). Greater accuracy was obtained for differential depths between successive surveys, e.g., accuracy in resolving cut and fill at each test pit was approximately ±0.15 m (±0.5 ft) (Murphy, et al., 1979).

Bathymetric surveys were conducted at approximately two-week intervals from 4 September to 16 November 1978. The results of surveys conducted on 15 September, 4, 19 and 31 October and 16 November were used in the present study.

Seventy-seven sediment samples were obtained from the dredge clamshell, and 15 directly from within the test pits by SCUBA divers. SCUBA dives were made on September 5, September 20, and November 15, 1978. Thirty-nine of the 77 samples collected aboard the derrick barge and all of the diver-collected samples were seived to determine grain size distribution.

Two in-situ oceanographic instrument moorings were placed approximately 305 m (1,000 ft) north of the test pits at water depths of 13 m (41 ft) and 16 m (52 ft) below MLLW. An ENDECO Model 105 recording current meter was located 3 m (10 ft) above the sea floor on each mooring, and set to monitor at 30-minute intervals. Interocean Model WG/100 analog recording pressure transducers were incorporated in each mooring to measure waves. These operated only intermittently, and their data were of limited use to this study.

The current meters and wave gauges were initially installed on 15 August 1978, serviced on 20 September and 28 October and recovered on 15 November 1978, yielding a continuous record of currents for a period of 93 days. Due to numerous electrical and mechanical failures, only 21 days of data from one of the wave gauges was useful.

The lack of measured onsite wave data was partially offset by obtaining NOAA visual wave observations from Southeast Farallon Island, approximately 40 km (25 mi) offshore of the site (Figure 1). These observations consisted of swell height, period and direction, sea height and direction, and wind speed and direction, thrice daily. The steep offshore slopes around this island and its position well seaward of the project location made these visual observations reasonable estimates of the general sea and wind conditions.

DATA ANALYSIS

The data collected were analyzed both for engineering results and for the specific research aims of the present study, as discussed below.

The bathymetric records were reduced and corrected for tidal height by hand, and plotted according to the navigation data. In preparing successive bathymetric charts of each test pit, it was observed that the sea floor depths and morphologies beyond the edge of the test pits did not change significantly. Therefore, only changes in the shape and depth within the test pits were noted on subsequent charts. Examples of these charts are shown in Figures 3 and 4.

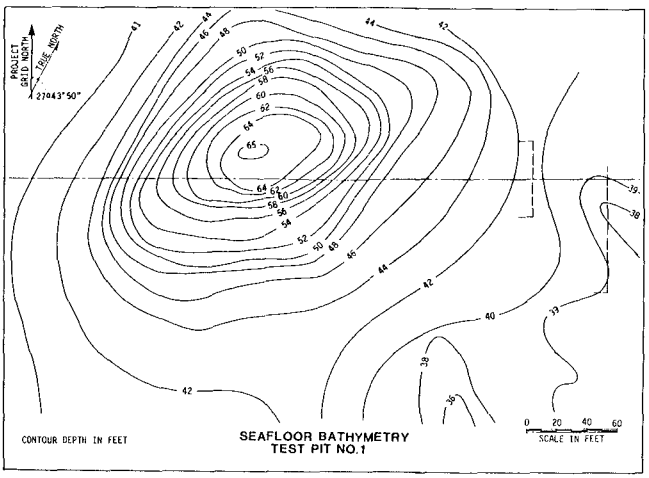

FIGURE 3

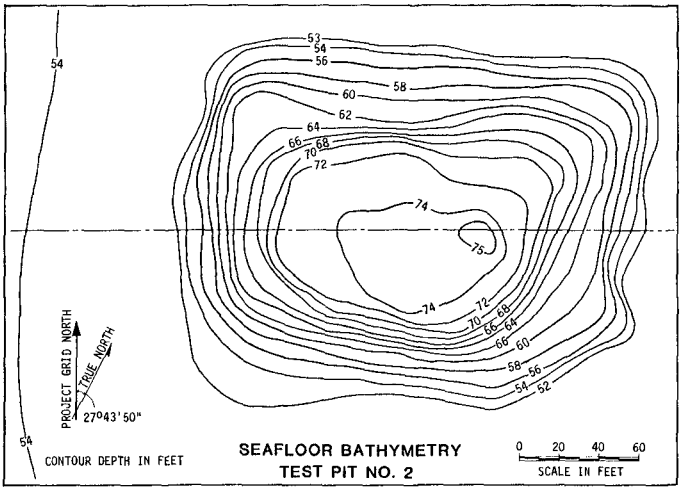

FIGURE 4

Sediment samples were analyzed using standard seiving procedures. The range of results are shown on Figure 5. Two shadings are used on this figure. One defines a band of gradation curves for the dredged sediments, and the other, gradation curves for sediments recovered by divers during the monitoring program, representing material recently deposited within the test pit. In general, both were very similar.

The film records from the current meters were processed to produce digital time series of speed and direction. Figure 6 shows a progressive vector diagram of currents at Test Pit No. 2 from the period 28 October through 15 November 1978. The figure shows net northeasterly drift with tidal oscillations.

As the field experiments were not planned to support a detailed sediment transport study, data on the vertical structure of the benthic boundary layer were not collected. For the purposes of the calculations, it was assumed that the current meters measured flow near the top of the benthic boundary layer. Data from other more detailed studies (Niedoroda, 1980; Niedoroda and Swift, 1981) suggest that 3 m is a reasonable estimate of the average boundary layer thickness at these distances from the shore. The method for computing marine bedload transport, described later, requires the depth averaged flow velocity over the thickness of the benthic boundary layer. In the absence of more detailed data, this was taken to be 80 percent of the measured values.

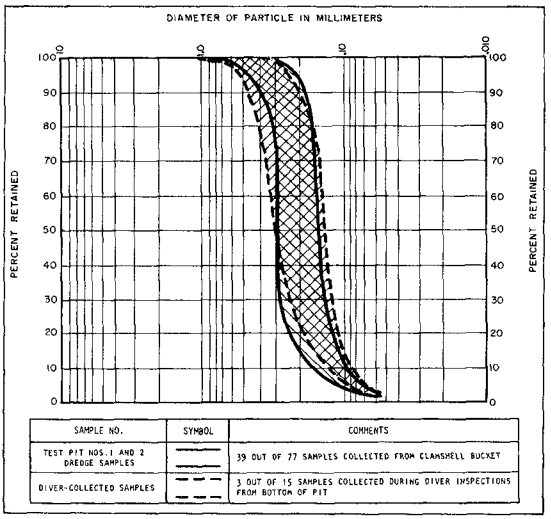

FIGURE 5

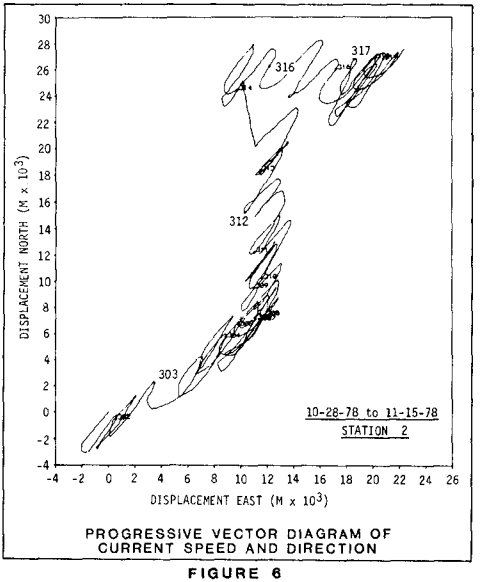

FIGURE 6

The primary wave data used in this study came from the NOAA visual observations recorded at Southeast Farallon Island, 31 km (19.5 mi) south of Pt. Reyes and 42 km (26 mi) west of San Francisco; near the edge of the continental shelf. Refraction drawings show essentially no modification of wave heights of open ocean waves arriving there. The other Farallon Islands to the NNW are too small and distant to affect the waves from that direction. With care, it should be possible to make valid incident wave observations from Southeast Farallon.

The data from South Farallon Island were transferred to the test pit sites by the following procedure. As part of the previous coastal engineering investigation, a series of refraction drawings using 10 and 12 second wave periods had been generated, and used to evaluate the propagation of directional components of waves from 10 severe storms to the outfall site. Because of the dominance of the partial sheltering influence of Pt. Reyes, the storm waves were divided into directional components. For each storm, the incident height and direction, and the refracted height and direction at the site were found, and the "response curves" of Figure 7 generated. For varying incident wave direction, these curves give both the reduction in wave height and the change in wave direction due to refraction.

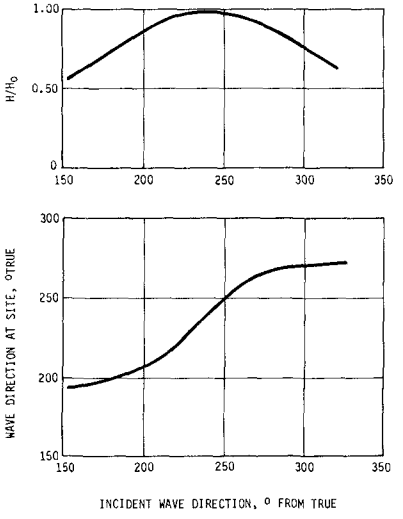

FIGURE 7

The actual location of the site referred to above is about 2.4 km (1.5 mi) west of the offshore test pit (No. 2); corresponding to the location of the outfall diffuser. Results of the wave spreading and refraction analysis at this site were considered representative

because wave heights and directions measured at pits 1 and 2 showed smaller differences than the uncertainty in both the raw data and the refraction analysis.

The response or transfer curves of Figure 7 were applied to both sea and swell. Strictly speaking, this is not correct for the swell, because the curves were generated using a directionally spread wave typical of sea, not the more narrowly spread swell. In this case it was believed important to include the effect of directional spreading, even if slightly overestimated for swell, due to the importance of Pt. Reyes in providing partial sheltering from the predominant NW and NNW sea and swell.

The sediment transport analysis considers the combined effect of currents and one wave train. As both sea and swell were generally present and recorded separately, it was necessary to combine the two. Adding wave energy densities gives the following relationship for the equivalent wave height (H_e).

$$H_e = (H_w^2 + H_s^2)^{1/2}$$

where H_w and H_s are the height of the sea and swell, respectively.

This relationship ignores the effect of wave and swell directional differences on the near-bottom kinematics, but most of the time, the waves and swell were nearly from the same direction (i.e., NNW and NW).

In summary, the quality of the raw wave data, although poor by some standards, was better than that often available for engineering projects. A comparison of the significant wave heights computed by this method from the Southeast Farallon data with data measured at Test Pit No. 1 is given in Figure 8. When the significant wave height

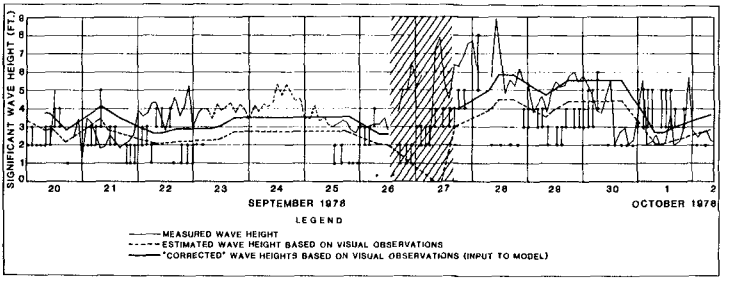

FIGURE 8

as measured (thin, irregular line) was compared to that from the corrected visual observations (heavy, dashed line), it was found that a 30 percent difference existed. This comparison excluded the period from the evening of 26 September to the evening of the 27 September, where the visual wave heights reported are suspect. The visual wave height estimates were thus corrected by a factor of 30 percent and are shown on this figure as a solid, heavy line.

MARINE BEDLOAD TRANSPORT CALCULATIONS

Several methods are available for computing marine bedload transport due to the combined effect of waves and current. The method selected for this study is given by Madsen and Grant (1976). This method was selected because: it incorporated the experimental work done by Jonsson (1966), Kalkanis (1964), Abou-Seida (1965), and several other researchers; the method is relatively straightforward to apply; and the input parameters were available from the field measurements.

The Madsen and Grant (1976) method uses the Einstein-Brown relationship to compute instantaneous bedload transport when the critical Shields parameter for sand entrainment is exceeded. The bottom shear stress formulation is the quadratic stress law where the instantaneous current is the vector sum of the near bottom wave orbital and the depth-mean benthic boundary layer velocities. The drag coefficient is in the form of Jonsson's combined wave-current friction factor.

A computer model was written to apply the method. The computer model used a two-dimensional 20 x 20 grid with 4.6 m (15 ft) spacing between grid points (the square defined by the grid points are referred to as elements) upon which the depths and local wave orbital velocities and near bottom depth-mean currents were specified. The orbital velocities were computed using Airy (linear) wave theory. The magnitude of the bottom boundary layer currents varied with depth to satisfy continuity. It was assumed that the structure of the near bottom flow is large in comparison to the size of the test pits and that no significant flow perturbations (e.g., large scale eddies) developed within the pits. A uniform mean sediment diameter of 0.22 mm was used throughout. A constant bedload flux boundary condition was imposed to eliminate erosion or deposition near the grid boundaries.

The bedload transport calculation was accomplished according to the following scheme. Wave and current data were entered at two-hour intervals. The instantaneous near bottom wave orbital and benthic boundary layer velocities were computed at each grid point for 17 sub-time intervals over a wave period (the near bottom current magnitude was also adjusted for the local depth). During each of the 17 sub-time intervals, the bottom stress (and in its nondimensional form, the Shields parameter) was computed from the resultant current. If the computed Shields parameter exceeded the critical Shields parameter, the instantaneous bedload transport was computed through the Einstein-Brown relationship. Otherwise the transport was set to zero for that sub-time interval.

Once the sediment transport flux at each grid point, for each of the individual sub-time intervals, was computed they were summed over the wave period, then divided by the wave period to determine the time-averaged rate of bedload transport. The calculation was done for all 400 grid points. The sediment continuity equation was then applied to each element to compute the net change in depth over the 2-hour time step. The program then read the wave and current data for the next two-hour interval and the above sequence was repeated.

It is important to note that gravitational effects were included in the Shields parameter in a bottom slope term (see Madsen and Grant, 1976, Appendix I). Madsen and Grant suggest a value of 0.07 for the coefficient in the term, while Fredsoe (1979) suggests a value of approximately 0.1 but points out that its actual value is poorly known. Evaluation of this coefficient was an important outcome of the present study.

In applying the results of the above-described program to the project data a problem arose with respect to defining an undisturbed seabed to serve as the datum for measuring siltation. The computer program showed small but significant erosion around the test pit lips; however, the data from the bathymetric surveys did not indicate any change in sea floor elevation outside of the pit. Therefore, computed erosion of the sea floor outside of the test pits was neglected when comparing the computed and measured values of siltation.

RESULTS

Prior to discussing results, it is important to review sources of error and uncertainty. The successive bathymetric surveys claimed accuracy in differential depth measurements of approximately ±0.3 m, corresponding to a volume difference over the area of siltation in the test pits of approximately 125 m^3 or a total error of approximately 250 m^3 (±) in estimating siltation from successive bathmetric surveys. The time history of infilling rates and associated error bars are shown in Figure 9. Inaccuracies in the wave data have been noted previously. The only complete time series of wave data is the transformed NOAA visual data. When these transformed data were used in raw form, they are identified as Wave Data 1. Where the wave heights have been increased by 30 percent (Figure 7) as previously discussed, they are referred to as Wave Data 2. Furthermore, in some numerical experiments the measured currents were used; whereas in others, depth mean bottom boundary layer current velocity was estimated as 0.8 times the measured current.

Measured and computed siltation rates for Test Pit No. 1 are shown on Figure 9 (the measured values with corresponding error bars). The dashed curve shows computed siltation rates using Wave Data Set 1 and the full value of the measured currents. The dash-and-single-dot curve shows the siltation rate computed using Wave Data Set 2 and the the measured currents. The dash-and-3-dot-curve shows the siltation rates using Wave Data Set 2 and the estimated depth mean value of the near bottom currents. In computing each of these curves, the value of the gravitational constant in the Shields parameter equation was 0.1. From the data shown on this figure it was concluded that Wave Data

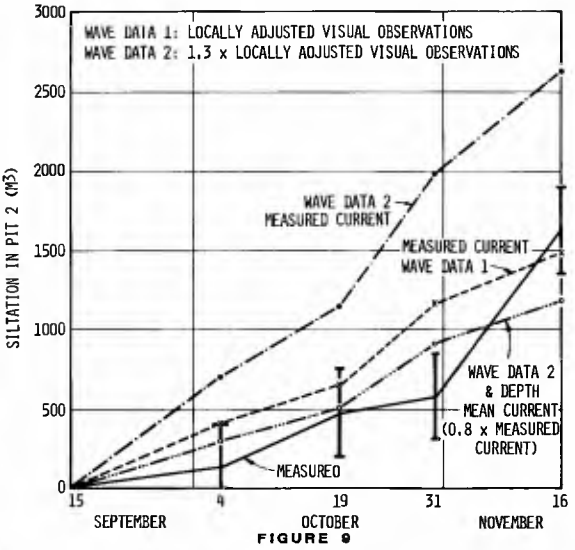

FIGURE 9

Set 2 and the depth mean value of the near bottom currents was most appropriate. Each of these curves could be adjusted by changing the value of the gravitational constant in the Shields parameter equation.

A series of numerical experiments were conducted to evaluate the gravitational constant (c_s) in the equation for the Shields parameter. Perfect overall agreement could be accomplished for measured and computed siltation at Test Pit No. 1 using the value of c_s of 0.123, as shown in Figure 10. It should be noted that computed

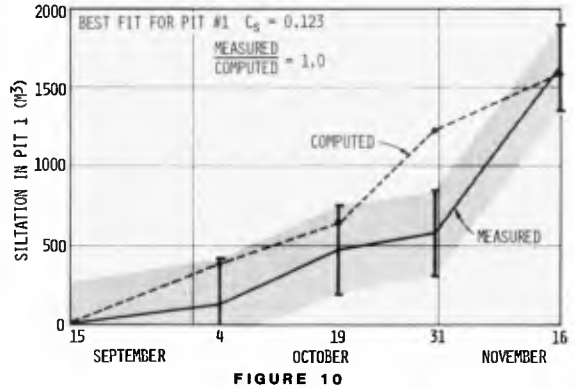

FIGURE 10

values of siltation are higher than those measured at the intermediate surveying dates. However, at two of these three points, the computed values lie within the range of error in the surveyed values. When this value of the gravitational constant in the Shields parameter equation is applied to data from Test Pit No. 2, the amount of siltation was underestimated (Figure 11). In order to accomplish perfect agreement in the overall measured and computed siltation for Test Pit No. 2 a value of c_s of 0.193 was required. In this case, the projected siltation for the intermediate survey data is less than the measured value. Nevertheless, the computed value is within the measurement error.

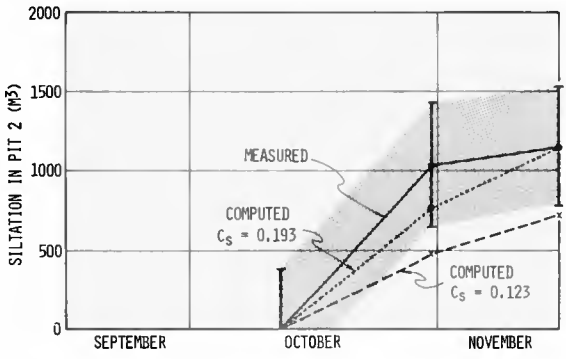

FIGURE 11

Figure 12 shows corresponding data for both Test Pit No. 1 and Test No. Pit 2. A value of c_s of 0.14 yields the best qualitative agreement for the data from both test pits. The difference between measured and computed siltation values is about 14 percent for Test Pit No. 1 and 28 percent for Test Pit No. 2. The value of the coefficient was selected to fit the data at Test Pit No. 1 better than that at Test Pit No. 2 because of the larger number of surveys and longer duration of measurements at Test No. Pit 1. Considering the rather large uncertainties in all of the measurements in this study, as well as those typical of marine engineering studies, the agreement between measured and computed siltation rates is reasonably good.

The computed siltation rates have been shown to depend on wave heights, wave periods, near bottom currents, and the gravitational constant in the equation for the Shields parameter (c_s). A series of numerical experiments were conducted to reveal the sensitivity of the computed siltation rates to variations in these parameters. Figures 13, 14, 15, and 16 show the sensitivity of siltation to variations in wave height, wave period, depth mean near bottom currents, and c_s, respectively. Figure 13 shows that siltation calculations are extremely sensitive to wave height and therefore errors in measurement of wave height significantly affect the reliability of projections. Figure 14 shows a more complex relationship to variations of wave period. If wave periods are higher than their true

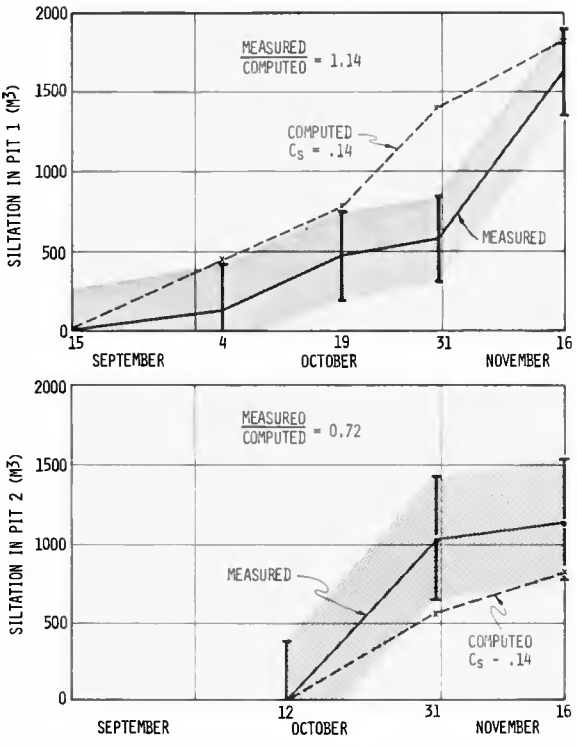

FIGURE 12

value the computed siltation rate decreases because the increase in wave period results in lower wave orbital velocities. If the wave period is decreased from its true value, the computed rate of siltation first increases and then dramatically decreases. This trend illustrates that given the depths of the test pits there is a narrow band of shorter wave periods for which near bottom orbital velocities are increased. Waves with even shorter periods produce lower near-bottom wave orbital velocities due to the depth-decay in orbital velocities. Figure 15 shows that computed siltation rates are less sensitive to variations in the magnitude of depth averaged near bottom currents than they are to waves. Figure 16 shows a linear relationship between the siltation rate and the constant in the gravitational term of the Shields parameter equation.

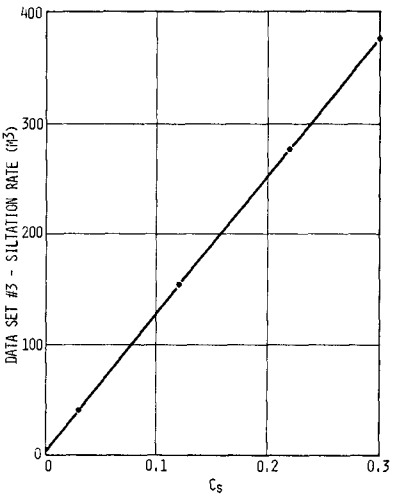

FIGURE 16

CONCLUSIONS

The Madsen and Grant analysis, based in part on laboratory experiments, appears to provide a sound basis for estimating bedload transport caused by the interaction of waves and currents beyond the breaker zone. Input data required of the analysis are commonly collected for coastal engineering projects or developed from other data sources as illustrated herein for the wave data.

The effect of bottom slope was important in this study and was varied (by varying the multiplicative coefficient in the term) to achieve better agreement between the predicted and measured siltation. The value of the coefficient for best fit for net sedimentation in each test pit was 0.12 for Test Pit No. 1 and 0.19 for Test Pit No. 2. The value of the coefficient for best fit for net sedimentation in both pits was 0.14. This value resulted in a maximum difficiency between measured and predicted sedimentation of about 25 percent.

The accuracy of predictions of marine bedload transport and corresponding erosion or siltation is controlled by the accuracy of input parameters in the following order: wave height, current speed and direction, bathymetry, sediment diameter, and wave period.

FIELD INVESTIGATION OF BEACH PROFILE CHANGES AND THE ANALYSIS USING EMPIRICAL EIGENFUNCTIONS

Hiroshi HASHIMOTO* and Takaaki UDA**

ABSTRACT

In order to investigate the response of beach profiles to incident waves, computations by the empirical eigenfunction analysis proposed by Winant et al. are performed. The analysis of the data obtained at Ajigaura Beach over three years from 1976 to 1979 indicates that beach profile changes due to longshore and onshore-offshore sediment transport are separable by the empirical eigenfunction method. The beach profile changes due to longshore sediment transport has a time lag of 12 weeks with respect to the change of wave direction at Ajigaura Beach. It was found theoretically that this time lag was due to the sand waves propagating in the longshore direction. Regarding as onshore-offshore sand transport, the second eigenfunction is associated with the beach changes due to onshore-offshore sand transport caused by the change of wave height.

I. INTRODUCTION

The movement of beach sand can be decomposed into two directional modes, namely, onshore-offshore movement and longshore movement. These modes respond to temporal changes of wave height, wave direction and longshore current. Accordingly, beach profiles should be analyzed as a time series in order to obtain a detailed understanding.

Winant et al.[1] studied beach changes at Torry Pines Beach by introducing an empirical eigenfunction method. The present authors[2),3),4)] are conducting an on-going study of beach processes at Ajigaura Beach. Field observations have been carried out over seven years at Ajigaura Beach, yielding data of the onshore-offshore profile, wave height and wave direction. In this paper the response of beach profiles to the wave characteristics is investigated using the empirical eigenfunction analysis.

II. METHOD OF FIELD INVESTIGATIONS

Field investigations were conducted at Ajigaura Beach, which lies on the southern part of 10 km long Tokaimura Coast, facing the Pacific Ocean in the central region of Japan, as shown in Fig.1. The sandy beach has a gentle slope of 1:40 and is blocked by a locky headland at the south end. The median grain size of the beach sand is about 0.24

** Chief Research Engineer, Coastal Engineering Division, Public Works Research Institute, Ministry of Construction, Tsukuba, Japan

mm. The prevailing winds in summer are from the south at Ajigaura Beach, causing southerly wave incidence, whereas the other seasons are characterized by northeasterly winds and the arrival of high waves.

A 100 m long pier was constructed on the beach in July, 1972 to furnish a fixed platform for measurements of waves, nearshore currents and bottom profiles in the surf zone. In February, 1976, the pier was extended to a length of 200 m to allow coverage of the full breaker zone as shown in Fig.2. Field measurements have been conducted at weekly intervals from June 25, 1975 to the present. Measurements were taken of the onshore-offshore profile, longshore profile, longshore current, wave height and wave direction. The onshore-offshore beach profile was measured at three meter intervals over a distance of 240 m as shown in Fig.2. Depth measurements along the pier were taken by sounding lead, while standard surveying method were used shoreward of the pier. Ground elevations along the shore over a distance of 100 m to both sides of the pier were also measured at 10 m intervals. Wave heights were measured at the head of the pier and at Kashima Port located 50 km to the south. The wave direction near the breaking point was observed at weekly intervals using an alidade positioned on top of a 30 m high dune located about 300 m from the shoreline. The longshore current in the surf zone was measured by tracking drifting floats released at three points along the pier.

III. METHOD OF ANALYSIS

The beach profile data are statistically analyzed using empirical eigenfunctions, which give a representation of the bed elevation h(y,t) as a linear combination of products of functions of the distance normal to the beach, y, and functions of time, t.

The data are represented as h_{yt}, where the subscript y is a distance index ranging from 1 to n_y, the total number of measuring points, and the subscript t is a time index from 1 to n_t, the total number of recording times. By the method, the set h_{yt} is expanded as

$$h_{yt} = \bar{h}_y + \sum_k C_{kt} e_{ky} \tag{1}$$

where $\bar{h}_y$ is the temporal mean of the beach profiles. Profile changes at the offshore end are considerably large because the spacial range of profile measurement is insufficient. Therefore, the variation of beach profile subtracted the mean beach profile from the original data is used in order to reduce the influence of end effects. In Eq.(1) the empirical eigenfunctions e_{ky} form an orthogonal set,

$$\sum e_{my} e_{ny} = \begin{cases} 1 & m=n \\ 0 & m \neq n \end{cases} \tag{2}$$

In order to generate these functions, a symmetric correlation matrix, A, is formed with the elements,

$$a_{ij} = \frac{1}{n_y n_t} \sum_{t=1}^{n_t} h_{it} h_{jt} \tag{3}$$

The matrix A possesses a set of eigenvalues λ_k and a corresponding

set of eigenfunctions e_{ky} which are defined by the matrix equation,

$$Ae_k = \lambda_k e_k \tag{4}$$

The time functions, C_{kt}, are then evaluated as

$$C_{kt} = \sum_y h_{yt} e_{ky} \tag{5}$$

IV. ANALYSIS OF ONSHORE-OFFSHORE BEACH PROFILES

The eigenfunction analysis was conducted by using the onshore-offshore data sets collected at Ajigaura Beach from February 5, 1976 to March 23, 1979. The total number of recording times is $n_t = 164$ and that of measuring points $n_y = 80$. The eigenvalues λ_k are given in Table 1. Here, the interpretation of the physical meaning will be given about the first and second eigenfunctions.

The first and second eigenfunctions are shown in Fig.3. The mean profile $\bar{h}_y$ is also shown in the figure. The mean beach profile has a gentle slope of 1:40 and shows scouring around the pier piles. The first eigenfunction e_1 has a positive value over almost the full region of the shore and takes a maximum at about y=160 m. The time function C_1 corresponding to the first eigenfunction and its average over five weeks are shown in Fig.4. Because the eigenfunction e_1 takes a positive value over a broad region of the shore, the increase of the time function C_1 indicates accretion on the beach and its decrease indicates erosion. The time function C_1 increased almost continuously for a year from February, 1976 to February, 1977. This means that the overall accretion occured on the beach during the period. Then, function C_1 decreased from February, 1977 to February, 1978 with the erosion of the beach.

Two causes of such beach changes are 1) longshore sand transport, and 2) onshore-offshore transport. In order to know the dominant cause, the relationship between the time function C_1 and the wave direction was investigated first. Figure 5 shows the temporal changes of wave direction measured counterclockwise from the east. A broken line shows the averaged value over 5 weeks. It should be mentioned that the mean shoreline is oriented at a direction of $8^\circ 54'$. Therefore, the wave direction with respect to the beach normal (β) is given by

$$\beta = \theta - 8^\circ 54' \tag{6}$$

The wave direction has a predominant annual change. In summer waves are from southern direction and northern waves are predominant in the other seasons. The time function C_1 increased almost continuously for a year from February, 1976 to February, 1977. This increase corresponds to the northern wave incidence from November, 1975 to November, 1976 with the time lag of about 3 months. Similarly the decrease of the function C_1 from February, 1977 to February, 1978 corresponds to the southern wave incidence with the time lag of some 3 months.

Oblique wave incidence generates longshore current. Measurements of longshore current were done at weekly intervals from June, 1975 to April, 1976 and from October, 1976 to March, 1979. Mean longshore current velocities averaged over the breaker zone are shown in Fig.6.

A positive velocity indicates a southward current. Northward current prevailed in summer and southward current in the other seasons. The changes of longshore current direction correspond fairy well to the changes of wave direction. It is thus concluded that the variation of the first eigenfunction is due to the longshore sand drift.

Since it is seen that the time function C_1 correlates the wave direction according to Fig.4 and Fig.5, a crosscovariance analysis is carried out between the average over five weeks of the time rate of the time function C_1, that is $\overline{dC_1/dt}$, and wave direction $\bar{\theta}$ in order to know the response of the beach profile to the change of wave direction. The cross-covariance function $R(\tau)$ is defined by

$$R(\tau) = C_{YX}(\tau) / (\sigma_X \cdot \sigma_Y) \tag{7}$$

$$C_{YX}(\tau) = \lim_{N\to\infty} \sum_{s=1}^{N} \{Y(s+\tau) - m_Y\}\{ X(s) - m_X\} \tag{8}$$

where σ_X and σ_Y are the variation of X and Y. m_X and m_Y are the average. The result of the cross-covariance analysis is shown in Fig.7. Here, $\bar{\theta}$ and $\overline{dC_1/dt}$ are substituted into X and Y in Eq.(8), respectively. The number of the total data is N = 163 weeks and the maximum lag τ_{max} = 20 weeks. The cross-correlation coefficient has a positive value when $\tau \geq 0$, and the maximum correlation is obtained at τ=12 weeks, though the coefficient is small because of large fluctuation of variables. Since wave direction has an one-year periodicity and does not have a definite periodic change of 12 weeks, the maximum correlation between $\bar{\theta}$ and $\overline{dC_1/dt}$ at 12 weeks is significant. This means that there is a time lag of 12 weeks between the change of wave direction and the beach profile change. Figure 8 shows the relationship between wave direction $\bar{\theta}$ and $\overline{dC_1/dt}$ with the time lag of 12 weeks. The following relation was obtained by the regression analysis,

$$\overline{dC_1(t)/dt} = -0.42 + 0.067\ \bar{\theta}(t-12) \tag{9}$$

Waves from the north generate the southward sand drift. This littoral drift accumulates over Ajigaura Beach because it is blocked by rocky cliffs at the end of the coast. It can be concluded that the increase of the time function C_1 corresponds to the accumulation caused by the longshore sand drift from the north, and that the eigenfunction e_1 represents the profile changes produced by the longshore sand transport.

The second time function C_2 corresponding to the second eigenfunction e_2 and its average over five weeks are shown in Fig.9. The second time function C_2 has a distinct periodicity. Since such periodic changes seem to correspond to onshore-offshore sand transport, the relationship between significant wave height and the time function C_2 was investigated. Figure 10 shows the weekly maximum value of the daily maximum significant wave height $\bar{H}_{max,max}$ at Kashima Port located about 50 km south of the beach. Broken line indicates averaged wave height over 5 weeks. It may be seen that the change of the function C_2 is correlated with significant wave height. In order to know the relation, a cross-correlation analysis was carried out between $\overline{dC_2/dt}$ and significant wave height $\bar{H}$. For the averaged significant wave height $\bar{H}$, wave heights defined by two different manner were used. One of them is the weekly mean value of the daily maximum significant wave height denoted by $\bar{H}_{mean,max}$ and the other is the weekly maximum of it denoted

by $\overline{H}_{max,max}$. The averaged significant wave height $\overline{H}$ and $\overline{dC_2/dt}$ are substituted into X and Y in Eq.(8), respectively. The obtained cross-covariance coeffecient is shown in Fig.7. Here, wave height data from May, 1977 to March, 1979 are used because of the lack of the measured wave height during March and April in 1977, and then N is equal to 100 weeks. In Fig.7 the maximum of the absolute value of the cross-covariance coefficient is obtained at $\tau = -1$ week when used the weekly mean of the daily maximum significant wave height, $\overline{H}_{mean,max}$, and $R(-1) = -0.47$. It is reasonable to consider that the time lag only becomes positive. Here, the time lag may be approximated to be zero, since the difference of the cross-covariance coefficient at $\tau = 1$ and $\tau = 0$ is small. The existence of the time lag may be attributed to the averaging of the time function C_2 two times. Figure 11 shows the relationship between $\overline{dC_2/dt}$ and $\overline{H}$ with no time lag. The following relation was obtained by the regression analysis,

$$\overline{dC_2/dt} = 1.13 - 0.55\overline{H}_{mean,max} \qquad (10)$$

where $\overline{H}_{mean,max}$ has an unit of meter. It is found that the critical wave height on onshore-offshore sand movement due to the component of the second eigenfunction is given by $\overline{H}_{mean,max} = 2.05$ m. Since the second eigenfunction e_2 takes on a positive value near the shoreline as shown in Fig.3, the increase and decrease of C_2 indicate accretion and erosion, respectively, near the shoreline. Consequently, it is concluded that the second eigenfunction is associated with beach changes due to onshore-offshore sand transport caused by the change of wave height.

Equation (10) expresses the relationship between significant wave height and the time rate of the time function C_2. It is possible to examine the same kind of relation by using wave steepness instead of wave height. Figure 12 shows the cross-covariance coefficient between wave steepness and the time rate of the time function C_2. The maximum of the absolute value of the cross-covariance coefficient is obtained at $\tau = 7$ weeks. This means that the change of beach profile occures seven weeks later compared with the change of wave steepness. However the physical meaning of the relation is not known at the present study.

V. THEORETICAL SOLUTION OF BEACH CHANGES DUE TO LONGSHORE SEDIMENT TRANSPORT

In the previous section it was found that the first time function C_1 had a time lag of 12 weeks compared with the change of wave direction. This time lag is considered to be due to the effect of longshore sediment transport because of the correlation between the first eigenfunction and wave direction. The rate of longshore sediment transport is mainly decided by wave height and wave direction. If the beach exists in an open coast without any obstructions, the beach does not change with the variation of wave direction. However at Ajigaura Beach it is blocked by a rocky headland in the south end. Therefore, it is suggested that large accretion or erosion, and time lag occured due to the movement of sand in the north-south direction.

It may be permissible to use the one-line model to analyze the problem, considering that the first eigenfunction e_1 has a positive value over almost full region of the shore.

The beach change due to the first eigenfunction, h'(y,t), is expressed as

$$h'(y,t) = \bar{C}_1(t)e_1(y) \tag{11}$$

Integrating Eq.(11) with respect to y, then the following relation is obtained,

$$A(t) = \int_0^\infty h'(y,t)dy = \bar{C}_1(t)\cdot\int_0^\infty e_1(y)dy \tag{12}$$

where A is the change of cross sectional area due to the beach change expressed by the first eigenfunction. In Eq.(12) the upper limit of integration is infinite, but it is impossible to integrate $e_1(y)$ from 0 to infinite, since the onshore-offshore profile of $e_1(y)$ is not known when $y \geq 240$ m. However, it may be possible to change the upper limit of the integration approximately from infinite to 240 m, because the function e_1 decreases zero uniformly near y = 240 m. Then, the integration of Eq.(12) gives 22.0 m.

On the other hand, the change of cross sectional area, A, has a linear relationship with the shoreline position as shown in Fig.13. The solid line in the figure is the relation :

$$A = 4.55y_s - 346 \tag{13}$$

where A has an unit of m , y_s is the shoreline position and has an unit of m. According to the above linear relationships given by Eq.(12) and Eq.(13) concerning $\bar{C}_1$, y_s and A, the shoreline position can be used for an independent variable instead of time function $\bar{C}_1$. The equations of one-line model of change of shoreline position is expressed by

$$\frac{\partial q}{\partial x} + h\frac{\partial y_s}{\partial t} = 0 \tag{14}$$

$$q = F\left(-\frac{\partial y_s}{\partial x} + \tan\theta\right) \tag{15}$$

where x is the longshore distance and the origin is at the south end of the coast, where the sediment transport rate is equal to zero, y_s the shoreline position, q the sediment transport rate, h the characteristic height of beach profile change, θ the wave direction.

F is the coefficient and is given by

$$F = \frac{w}{8}(H^2C_g)_0K_r^2\alpha \tag{16}$$

where w is the unit volume weight of sea water, $(H^2C_g)_0$ the energy flux in the deep water, K_r the refraction coefficient, α the Savage coefficient ($\alpha = 0.217$ m^3/t).

Since wave characteristics change temporally, the change of coefficient F should be analyzed first. Here, the data set taken at Kashima Port will be used, because wave measurement at Ajigaura Beach is not continuously taken. Figure 14 shows the temporal change of the coefficient F calculated from the daily mean value of significant wave height at Kashima Port. F is the order of 10^4 m^3/d. Though the change of F is considerably large, F may be assumed to be a constant in later analysis. Because wave angle changes its sign from positive to nega-

tive year by year and therefore it has an important effect on the erosion and accretion. On the contrary, F only affects the rate of beach profile changes.

Boundary conditions are given by

$$\frac{\partial y_s}{\partial x} = \theta \qquad \text{at } x = 0 \tag{17}$$

$$y_s \to 0 \qquad \text{at } x \to \infty \tag{18}$$

In Eq.(17) $\tan\theta$ is approximated by θ since the wave angle θ is small. In addition, we have such relation that

$$\theta(0,t) = \bar{\theta}(0) + \theta_o \cos\omega t \tag{19}$$

because wave angle has a periodic feature of one year as shown in Fig.5. Substituting Eq.(15) into Eq.(14) assuming that F is a constant, then we have the diffusion equation,

$$\frac{\partial y_s}{\partial t} = \frac{F}{h}\frac{\partial^2 y_s}{\partial x^2} \tag{20}$$

The solution of Eq.(20) subject to the boundary conditions given by Eq.(17) to Eq.(19) reduces Eq.(21), by the Laplace transform.

$$y_s(x,t) = -\theta_o\sqrt{\frac{F}{\omega h}}\exp\left(-\sqrt{\frac{\omega h}{2F}}x\right)\cos\left(\omega t - \sqrt{\frac{\omega h}{2F}}x - \frac{\pi}{4}\right) \tag{21}$$

Equation (21) is similar to Bakker's solution, who derived a solution of change of shoreline position near a groin during one storm period. It should be noted that the present problem has a much longer time scale than Bakker's one. The time lag between the change of shoreline position and the change of wave direction is given by

$$\delta = \sqrt{\frac{\omega h}{2F}}x + \frac{\pi}{4} \tag{22}$$

The phase velocity of the shoreline change has in the form

$$V = \sqrt{2F\omega/h} \tag{23}$$

The solution given by Eq.(21) shows that the amplitude of change of shoreline position decreases exponentially in the longshore direction and the change propagates with the phase velocity V.

Here, the time lag and the phase velocity will be estimated. The frequency ω is equal to 0.0171 (rad/d) since a periodic change of 1 year prevails in change of wave direction. The amplitude of wave direction may be assumed 0.13 rad from Fig.5. The characteristic height of beach profile is equal to $h = 4.55$ m from the relationship of Eq.(13), and F is 3.97×10^4 m^3/d, that is the averaged value estimated at Kashima Port. The estimated time lag at the location of the pier, which locates about 1 km north from the boundary, is $\delta = 14.7$ weeks, and this corresponds to the measured one of 12 weeks fairly well.

The amplitude of change of shoreline position becomes 92.5 m at $x = 0$ m and 34.3 m at the location of the pier. The shoreline changes at $x = 0$ m have not been measured so many times that it is impossible to

compare the predicted amplitude with measured one. However, it seems to be too large according to the survey data, which have been carried out once a year since 1975 at Ajigaura Beach. The cause may be due to the fact that wave diffraction around the headland located at south end of Ajigaura Beach was ignored in the theoretical analysis. On the other hand, at the location of the pier the measured amplitude of shoreline change is some 30 m and it corresponds with the predicted amplitude fairly well.

The phase velocity can be calculated from Eq.(23), and it becomes V = 17.3 m/d. The phase velocity can also be estimated from the results of longshore beach survey. Figure 15 is the x-t diagram, which shows the temporal change of longshore beach profile from December 8, 1977 to August 3, 1978. The abscissa is the measured date and the ordinate is the longshore distance from the pier, of which position is denoted by 0. The number in the figure shows the ground elevation. The dotted lines show the longshore propagations of sand waves and the propagation velocity is defined by the gradient of this line. There are four sand waves in the figure. It is found that the sand waves propagating from north to south correspond to the northern wave incidence with time lag of some 3 months, and vice versa for those propagating from south to north due to the comparison between Fig.5 and Fig.15. However, the solution given by Eq.(21) only predicts the sand waves propagating from south to north. Therefore the phase velocity is only derived from the second and fourth sand waves and they are given by 9.6 m/d and 11.4 m/d, respectively. The averaged velocity becomes 10.5 m/d. The phase velocity has a same order of predicted one. However, the cause of the existence of the sand waves propagating southward is not known in the present study and further study will be needed on the problem.

VI. CONCLUSIONS

Field measurement data of beach profiles taken over three years at Ajigaura Beach were analyzed by applying the empirical eigenfunction methods in order to understand the relation of beach profile with wave height, wave direction and longshore current. The results indicate that beach profile changes due to longshore and onshore-offshore sediment transport are separable by the empirical eigenfunction method. The beach profile changes due to longshore sediment transport has a time lag of 12 weeks with respect to the change of wave direction at Ajigaura Beach. It was found that this time lag was due to the sand waves propagating in the longshore direction. Regarding as onshore-offshore sand transport, the second eigenfunction is associated with the beach changes due to onshore-offshore sand transport caused by the change of wave height, and that the critical wave height is H ≈ 2.05 m.

EXPERIMENTS ON BEACH PROFILE CHANGE WITH A LARGE WAVE FLUME

By

Ryoichi Kajima*, Takao Shimizu**

Kohki Maruyama** and Shozo Saito***

ABSTRACT

Two-dimensional beach profile changes were investigated with a newly constructed prototype-scale wave flume. The flume is 205 m long, 3.4 m wide and 6 m deep. Sand of two grain sizes was used in the experiments. Analysis of the results was made through use of the parameter C, introduced by Sunamura and Horikawa (1974) to classify beaches as either erosional and accretionary. Beach profile changes obtained in the flume were similar to those in the prototype (field). Net sand transport rate distributions were classified into five types, two of which do not seem to have been observed in laboratory (small-scale) experiments. A simple model describing the five types was developed for evaluating two-dimensional beach profile changes.

INTRODUCTION

Construction of harbor and cooling water facilities of power stations can produce significant changes along the coast. Consequently, the development of coastal change prediction methods is very important to maintain the functions of these coastal structures and to preserve the coastal environment. In particular, studies on two-dimensional beach profile changes resulting from cross-shore sand transport occupy a very important position. However, most of the numerous investigations and results concerning two-dimensional beach changes have been based mainly on rather small-scale experiments. The consequences of unavoidable scale effects associated with these experiments are not easy to determine.

This study is aimed at providing prototype-scale data for two-dimensional beach changes by means of a newly constructed large wave flume. The general similarities and differences between previous and the present experimental results will be discussed. It is shown that net sand transport rate distributions as determined from successive profile changes can be classified into five types, and that these distributions can be simulated by a simple model.

LARGE WAVE FLUME (CRIEPI FLUME)

Flume

The wave flume is shown in Fig. 1. It is made of reinforced concrete, and is 205 m long, 3.4 m wide, and 6 m deep in the 115 m-long generator-side flat section, which is joined to a shoreward section of 1/15 slope. The top of the flume is 1.5 m above ground level. Trucks for carrying or dumping bed materials can be driven in directly through the access slope adjacent to the end of the flume. The wave generator is of the piston type as shown in Fig. 2, with no water behind the blade. Seals for preventing water infiltration are installed along the side and bottom edges of the blade. The blade is driven by oil pressure supplied from two pumps, each driven by a 370 kw electric motor under the control of an electric-hydraulic servo mechanism. The system is capable of producing waves up to 2 m in height.

Because the blade and its supporting frame are fairly heavy (weighing a little over 10 ton), unusually rapid motion is dangerous. Therefore, an automatic, slow starter-stopper was installed. In the event that either an earthquake, water leakage, oil pressure drop, excess oil temperature rise or an overload is sensed, the blade automatically stops and the cause is indicated by lamps on the control board in the operation room. Usually the flume is run from the operation room near the center and at the side of the flume. In addition, the flume is equipped with a vehicle for measurement, and filtration equipment (maximum capacity: 120 m^3/hr).

Wave Generator

An example of waves generated in the flume is given in Fig. 3. The wave generator is designed to produce a maximum wave 2 m in height and 5 s in period in a water depth of 4.5 m, according to the wave generation theory of Biesel and Suquet (1951). Because a very large thrusting force is required, the hydrostatic force is compensated by two balancing actuators (each with maximum thrust force of 40 ton), and the dynamic force to produce waves is generated by a servo-actuator (maximum thrust force is 30 ton). The stroke length needed for the maximum wave is 2200 mm. The compensation of the volume change in the balancing cylinders and the oil pressure variation in the servo-valve is done by the accumulators. The maximum stroke length of the actuators is as 2400 mm including a $\pm$100 mm allowance. The displacement of the piston of the servo-actuator is detected through a rack and pinion gear, and counted by a rotary encoder.

For the surface contact of the water seals, a high-polymer tape 24 mm in width and possessing a very low friction coefficient is used. The tape is kept in contact with the slipping wall of the flume by air

Buoy type	8.2	D	B			D
Pressure type (strain gauge)	6.8	D	B	−3.8	D	D

* : Relative error in wave height
A : Good
B : Acceptable
C : Marginally accaptable
D : Unacceptable

pressure (1.5 kg/cm^2) transmitted through waterproof urethane rubber. For reducing wear of the tape, the surface of the slipping wall of the flume is faced with stainless steel plates 5 mm thick.

Measuring System

The wave flume is equipped with a measuring vehicle (weight: 5 ton, maximum speed: 45 cm/s). Because measuring devices applicable to the field must be used, a thorough investigation of the accuracy and serviceability of the instrumentation was required. Seven types of wave gauges were tested to determine their suitability. The wave records from the various gauges were compared to the output of a video tape recorder. Characteristics of the gauges are shown in Table 1 (Shimizu et al., 1983). It was decided to use capacitance (type-2) wave gauges and an ultrasonic (in the air-type) wave gauge. For the measurement of water particle velocities, electromagnetic current meters were adopted. Ultrasonic depthmeters with secondary transmitter-receivers for calibration (calibration distance = 200 mm) were used for the subsurface bottom, and a sand surface detector of the surface contact type was also used for the profile above the water level.

The horizontal position of the vehicle and the vertical position of the post supporting the depthmeter are detected using rotary encoders. The depth was measured every 50 mm in the horizontal direction by raising or lowering a post according to the output of the depthmeter while moving the vehicle. For the measurement of the microscale topography such as sand ripples, the same system was utilized except that the sampling interval was reduced to 1 mm. The data acquisition system on the carrier is controlled by a 20 kB microcomputer. For data processing, mainframe computors (FACOM M200 and M160F) are used.

EXPERIMENTAL RESULTS

Procedure

Coarse sand (median diameter D_{50} = 0.47 mm) and fine sand (D_{50} = 0.27 mm) were used in the experiments. Material properties are summarized in Table 2. Initial profiles of all cases were formed as uniform slopes of $\tan\beta$ (= 5/100 or 3/100). Conditions of the test cases are summarized in Table 3. The water depth at the flat section of the flume was 3.5 m in CASES 2-1 to 2-3, while in the other cases this depth was 4.5m.

Measurements were made of the beach profile, wave height, water velocity and time-averaged concentration of suspended load. The breaking point, breaker type, run-up point, run-down point and number of waves in the surf zone were also observed. In general, measurements of the beach profile were made along the center line of the wave flume. In order to examine the two-dimensionality of the beach profiles, measurements of the beach profile in CASE 1-1 were made along three lines; one was the center line of the flume, and the others were 1.1 m to either side of the center line. It was found that the difference between measured profiles was within $\pm$5 cm. It was thereby confirmed that the measurement profile along the center line represents the two-dimensional beach profile in the wave flume.

Table 2 Properties of sand.

Material			coarse sand		fine sand	
Median diameter D_{50} (mm)			0.47		0.27	
Sorting coefficient $So=\sqrt{D_{75}/D_{25}}$			1.57		1.35	
Skewness parameter $Sk=\sqrt{D_{25}D_{75}}/D_{50}$			1.03		1.03	
Specific gravity			2.69		2.71	
Void ratio	wet sand	compacted	34 %	39 %	35 %	41 %

3-3			12.0	0.65	80.0
3-4			3.1	1.62	76.1

* Ho is estimated from the wave height at the uniform depth section.

Beach Profile Change

Figure 4 shows beach profiles at the final stages. Saville (1957) also conducted experiments using a prototype-scale wave flume, and published profiles of four cases. The profile of his case, T = 11.33 s, H = 1.8 ft, closely resembles the present CASE 3-1. In the other three cases, the beach profile changes reached the toe of the slope. In Fig. 4, it can be seen that profiles in most of our cases were not affected by the finite length of the slope. In laboratory experiments (e.g., Sunamura and Horikawa, 1974), accretion outside the surf zone is often observed under conditions of fine sand and steep slope. But in our cases corresponding to this situation (CASE 3-1 to CASE 3-3), erosion occurred outside the surf zone. In CASE 3-4, accretion occurred outside the surf zone, but the beach profile was considerably different from typical laboratory experimental results, especially near the bar.

In Fig. 4, locations of breaking points are indicated by triangles, an open triangle for the initial stage, and a solid triangle for the final stage. Plunging breakers were observed in almost all cases, except that plunging breakers with some characteristics of collapsing or spilling breakers were observed in CASE 1-3 and CASE 3-4, respectively. Battjes (1974) classified breaker types using the surf similarity parameter ξ_o,

$$\xi_o = \tan\beta \,/\sqrt{H_o/L_o} \tag{1}$$

where $\tan\beta$ is the beach slope, and H_o and L_o are the wave height and wave length in deep water, respectively. The critical value between spilling and plunging breakers was given as $\xi_o = 0.5$. However, in the present experiments, at the initial state of beach profile change the critical value was found to be $\xi_o = 0.15$. (A detailed discussion is given by Maruyama et al., 1983)

In CASES 2-1, 2-2, and 2-3, all with a gentle slope of $\tan\beta = 3/100$, secondary breaking was observed, particularly in CASE 2-1 shown in Fig. 5. Bars were formed in all cases and, in CASE 2-1 a smaller bar also formed near the secondary breaking point. In addition, a berm formed in all cases except for CASE 1-8 and CASE 3-4.

Sunamura and Horikawa (1974) found that shoreline changes could be classified by means of the nondimensional parameter C:

$$C = (H_o/L_o)\,(\tan\beta)^{0.27}\,(D_{50}/L_o)^{-0.67} \tag{2}$$

where, $\tan\beta$ is the average beach slope from the initial shoreline up to the critical water depth of sediment movement. In the present paper, $\tan\beta$ is equivalent to the uniform slope of the initial beach. The demarcation value of C between recession and advance of shoreline was 4 - 8 for laboratory measurements, and 9 - 18 for field measurements. Sunamura (1980a) eliminated noncredible data and added new data, and found that the demarcation value of C for field data was 18.

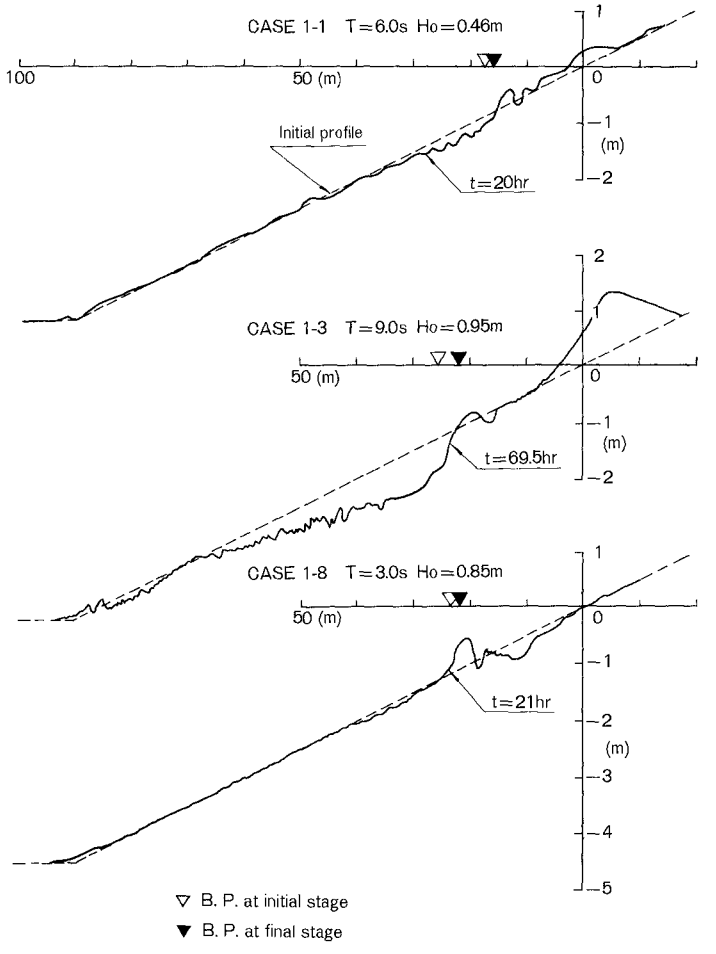

Fig. 4(a) Beach profile changes (steep beach with coarse sand).

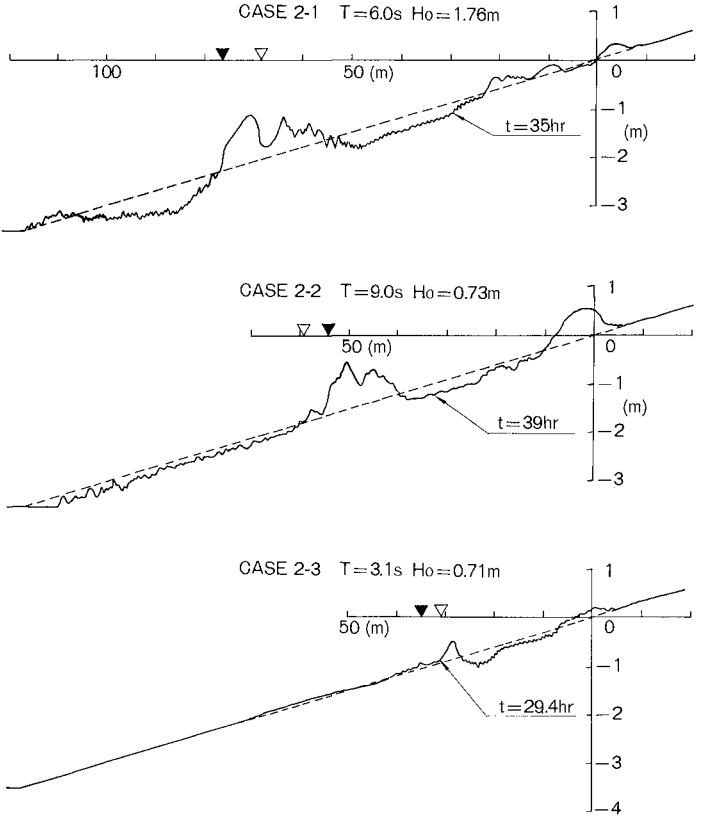

Fig. 4(b) Beach profile changes (gentle beach with coarse sand).

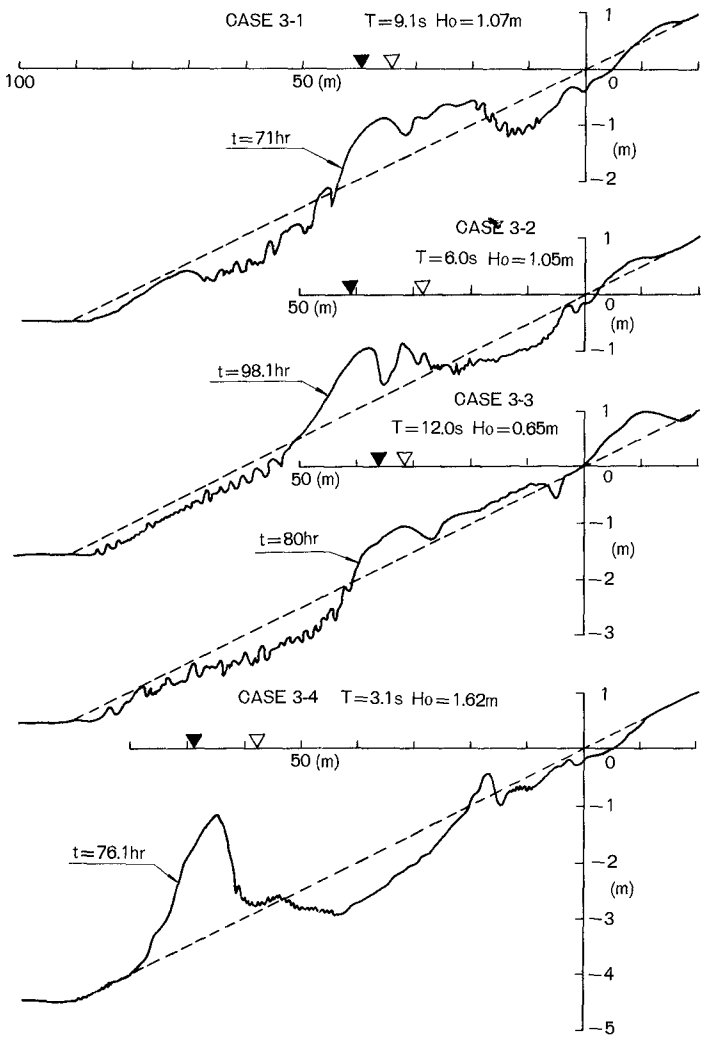

Fig. 4(c) Beach profile changes (steep beach with fine sand).

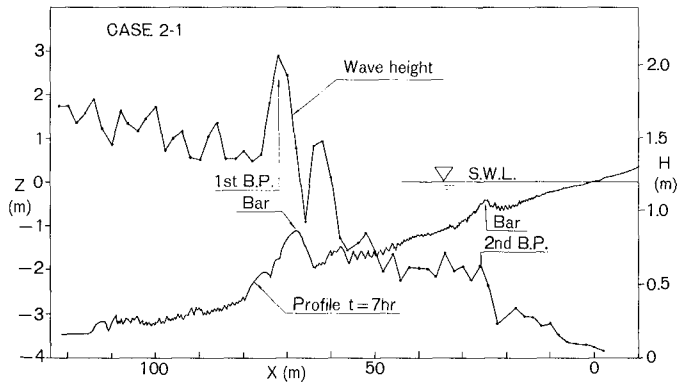

Fig. 5 Distribution of wave height in CASE 2-1.

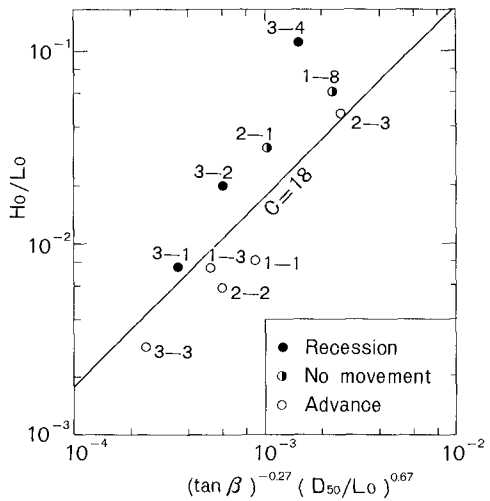

Fig. 6 Classification of shoreline change.

The results of applying this method to the present data are shown in Fig. 6. The transition from recession to advance of the shoreline is defined by C = 18, which is similar to the field data result. Consequently, the authors consider that processes of beach profile change in this wave flume are similar to those in the prototype. In CASES 1-8 and 2-1, by consideration of the parameter C, the shoreline was expected to recede. However, this situation did not occur (as shown in Fig. 6). It is believed that the shoreline change was produced by the waves near the shoreline rather than the deep water waves. In CASE 2-1, secondary breaking might also have influenced the shoreline change.

The critical water depths at which noticeable profile changes were observed are compared with the results of some previous studies described by Horikawa (1978) in Fig. 7. The results for CASE 2-2, CASE 3-2 and CASE 3-4 are excluded because in CASE 2-2 and CASE 3-2 the profile changes extended to the toe of the slope, and in CASE 3-4 the profile change did not reach the equilibrium state. It was found that the critical water depths for profile change agreed with the criterion of completely active movement given by Sato and Tanaka (1962), namely,

$$H_o/L_o = 1.35\,(D_{50}/L_o)^{1/3}\,(\sinh 2\pi h/L)\,(H_o/H) \tag{3}$$

where, h is the critical water depth of sediment movement and H and L are the wave height and wave length at the water depth h, respectively.

Net Sand Transport Rate

Net sand transport rate distributions for each case were calculated from successive beach profiles. Beach profiles and distributions were classified into three types as shown in Fig. 8. Type I (erosion type), Type II and Type III (accretion type) correspond to the beach profile classification of Sunamura and Horikawa (1974). In addition, the present experimental results for Type I and Type III were subdivided into Mono-crested and Bi-crested types. Bi-crested distributions of Type I and III tend to transform to Mono-crested distributions with time as the breaking point moves seaward or shoreward.

It was found that each type of net sand transport rate distribution could be classified according to the parameter C, as plotted in Fig. 9. The condition of transition from Type I to Type III occurs at C = 18. Furthermore, the Mono-crested and Bi-crested distributions could be classified by a newly proposed parameter P as follows:

$$\left.\begin{array}{ll} \text{Mono-crested distribution} & P > 10^{-3} \\ \text{Bi-crested distribution} & P < 10^{-3} \end{array}\right\} \tag{4}$$

$$P = (\tan\beta)^{-0.27}\,(D_{50}/L_o)^{0.67} \tag{5}$$

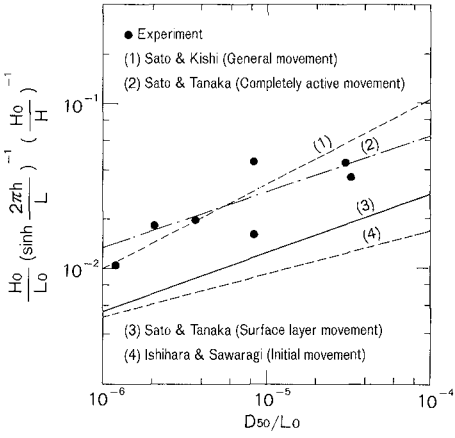

Fig. 7 Comparison between experimental results and various expression for sediment movement inception.

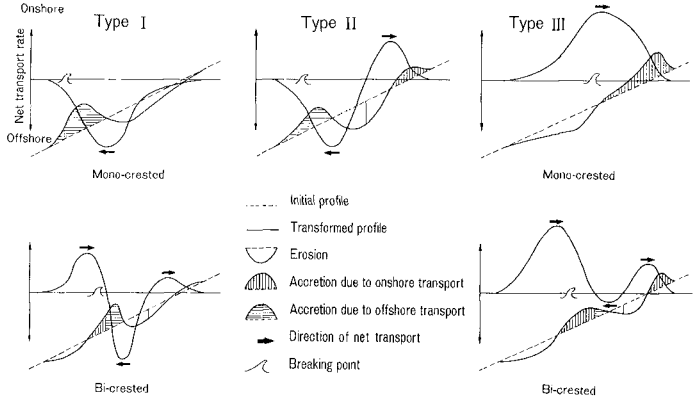

Fig. 8 Types of net transport rate distributions.

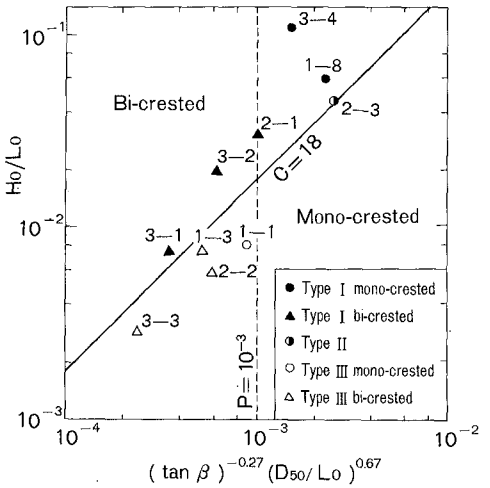

Fig. 9 Net transport rate distribution types classified by parameter C and P.

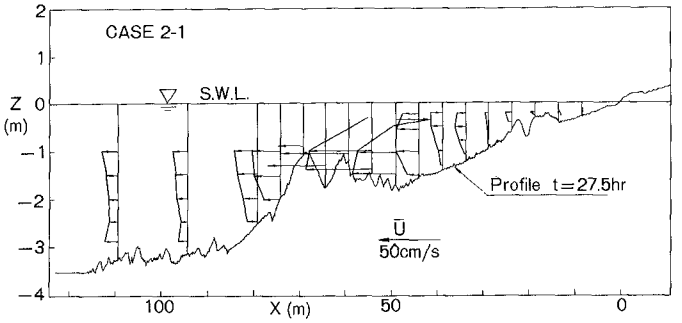

Fig. 10 Distribution of time averaged horizontal velocity of CASE 2-1.

Sawaragi and Deguchi (1980) classified into four types the net transport rate distributions obtained in rather small-scale experiments. Type II-2 of their classification corresponds to the Bi-crested distribution of our prototype-scale experiments. However, in laboratory experiments, Bi-crested types are rarely observed. One reason for this discrepancy may be that values of the parameter P in such laboratory experiments are different from those in prototype-scale experiments. For example, in almost all laboratory experiments conducted by Sunamura and Horikawa (1974), P was greater than 10^{-3}.

MODEL OF BEACH PROFILE CHANGE

At the present time, motions of the waves and fluid near and inside the surf zone have not been examined in sufficient detail to estimate the net sand transport rate directly from these quantities. Accordingly, as a first step in grasping the overall magnitude of sand transport in the present experiments, we constructed a rather simple model that directly relates the distribution of the net transport rate with the conditions of the waves and the beach, using the data corresponding to the cases with coarse sand (D_{50} = 0.47 mm). [Swart (1974) and Sunamura (1980b) proposed models based on the same basic ideas. However, application of their models is restricted only to erosional beaches, and consequently, their models can not express the growth of bars and berms.]

In the present model, it is assumed that the distribution of on-offshore sand transport rate Q (transport rate per unit width perpendicular to wave propagation) extending from the swash zone to outside the surf zone can be interpreted as the sum of relatively independent components of net sand transport (Q_1, Q_2 and Q_3) as follows,

$$Q = Q_1 - Q_2 + Q_3 \tag{6}$$

where

Q_1: net onshore transport outside the surf zone caused by nonlinearity of the fluid motion under waves

Q_2: net offshore transport inside the surf zone caused by time-averaged seaward-directed currents

Q_3: net onshore transport in the swash zone caused by wave run-up.

Figure 10 shows a typical distribution of time-averaged horizontal velocity for CASE 2-1. Strong seaward currents were observed throughout the surf zone, and the maximum velocity of these currents reached about 0.5 m/s. It is believed that these seaward currents have a great influence on the net sand transport rate Q_2.

The five types of net transport rate distributions shown in Fig. 8 then correspond to different relative magnitudes of the above components. According to the assumptions, the net transport rate distribution can be expressed as follows:

$$Q = Q_1 - Q_2 + Q_3$$

$$= A_1 \exp[-((x-x_1)/B_1x_b)^2] - A_2 \exp[-((x-x_2)/B_2x_b)^2] + A_3 \exp[-((x-x_3)/B_3x_b)^2] \quad (7)$$

Here x is the distance from the shoreline of the initial beach profile, and x_b denotes the breaking point. In Eq. (7), 1st term gives a peak A_1 near the breaking point ($x = x_1$); the 2nd term gives a peak A_2 near the center of the surf zone ($x = x_2$); and the 3rd term gives a peak A_3 near the shoreline ($x = x_3$). Each Gaussian distribution has a characteristic width of B_1, B_2, and B_3, respectively. For example, if either B_1, B_2 or B_3 is equal to 0.2, the width of the distribution is nearly equal to the width of the surf zone.

It is also assumed that the peaks A_1, A_2, and A_3 decrease exponentially with time from their initial values of A_{10}, A_{20} and A_{30},

$$A_1 = A_{10} \exp[-\alpha_1 t], \quad A_2 = A_{20} \exp[-\alpha_2 t], \quad A_3 = A_{30} \exp[-\alpha_3 t] \quad (8)$$

where t is the time, and α_1, α_2 and α_3 are decay coefficients. The tendency of the net transport rate distribution to transform from Bi-crested to Mono-crested types may be simulated by means of α_1, α_2 and α_3.

The continuity equation of two-dimensional beach profile change is

$$\frac{\partial h}{\partial t} = -\frac{\partial Q}{\partial x} \quad (9)$$

where h is water depth. Therefore, substituting Eq. (7) into Eq. (9) and integrating Eq. (9) over time starting from the initial beach profile, the beach profile at a given time can be obtained.

The initial distributions of net transport rate corresponding to the cases with coase sand were calculated from the difference between the initial profiles and those after three hours, and A_{10}, A_{20}, and A_{30} were determind by the least squares method. The results are shown in Table 4. In determination of these values, B_1, B_2 and B_B were assumed as shown in Table 4.

Table 4 Parameters of the model.

CASE	1—1	1—3	1—8	2—1	2—2
χ_b (m)	18.0	26.2	22.8	69.2	57.5
χ_1 (m)	24.8	32.7	27.8	78.4	57.5
χ_2 (m)	18.8	14.7	19.8	64.4	37.5
χ_3 (m)	0.8	−1.3	5.8	29.4	5.5
B_1	0.45	0.45	0.15	0.15	0.45
B_2	0.30	0.30	0.075	0.075	0.30
B_3	0.15	0.15	0.30	0.30	0.15
A_{10} (m^3/hr/m)	0.83	1.28	0.14	1.91	0.68
A_{20} (m^3/hr/m)	0.49	−0.26	1.11	2.65	0.22
A_{30} (m^3/hr/m)	0.11	1.18	−0.06	0.33	0.45

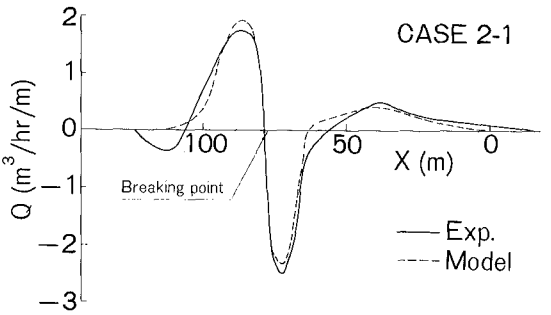

Fig. 11 Net transport rate distribution approximated by Eq. (7).

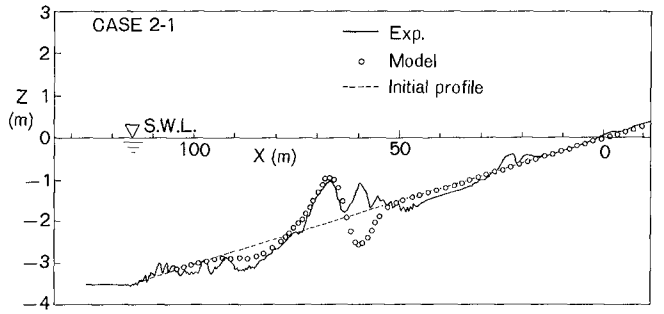

Fig. 12 Beach profile calculated by the model.

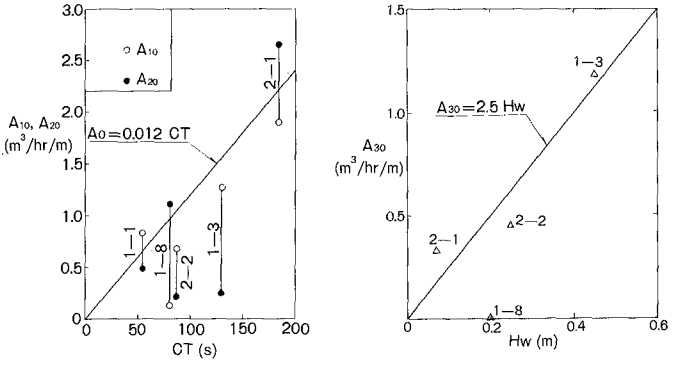

Fig. 13 Properties of the initial peak parameters A_{10} to A_{30}.

An example of the net transport rate distribution approximated by Eq. (7) is compared with the measured distribution in Fig. 11. It was found that the distributions of net transport rate in the other cases were also well approximated by Eq. (7).

Figure 12 is an example of the predicted from Eq. (9) and measured profiles for CASE 2-1 after 20 hours of wave action. The profile change outside the surf zone is well simulated by this model. On the other hand, the local profile change near the plunging point is not so well reproduced. In numerical calculation, the assumption was employed that the locations x_i, where each transport rate component Q_i has a peak, do not move when the bottom profile changes. To improve this model, therefore, it is necessary to take account the effect that the center of the Gaussian distribution of each component of Q can move with changes in the beach profile.

In order to generalize the present model, the dependence of the parameters A_{10}, A_{20} and A_{30} on the experimental conditions was investigated. The results are shown in Fig. 13. The parameter A_{10} in the accretionary cases and A_{20} in the erosional cases, which correspond to the most dominant components, appear to have a positive correlation with the product of the parameter C and the wave period T. The parameter A_{30}, which represents the onshore transport in the swash zone, appears to be related to the wave height at the shore-line H_w.

CONCLUSIONS

1) Shoreline change in these prototype-scale experiments was predicted by the parameter C (Eq. 2) of Sunamura and Horikawa (1974). The demarcation value of C separating recession and advance was confirmed to be 18 (Fig. 6).

2) The critical water depth of the beach profile change agreed well with the criterion of completely active movement (Eq. 3) given by Sato and Tanaka (1962).

3) The observed net transport rate distributions were classified into 5 types (Fig. 8). They could be identified by the parameters C and P (Fig. 9).

4) The net transport rate distributions were well approximated by the sum of three Gaussian distributions (Eq. 7). The parameters of this model were related to the wave and beach conditions (Fig. 13).

ACKNOWLEDGMENTS

We would like to extend our appreciation to Professor K. Horikawa, University of Tokyo, and Professor S. Hattori, Chuo University, for valuable discussions and advice. We are also grateful to Professor Nath, Oregon State University, for kindly supplying information about the wave flume at that institution. In addition, we would like to thank Dr. N. C. Kraus, Nearshore Environment Research Center, for critically reading the manuscript, and Miss T. Kohno for typing.

DESCRIPTION OF BEACH CHANCES USINC AN EMPIRICAL PREDICTIVE MODEL OF BEACH PROFILE CHANGES

Takaaki UDA* and Hiroshi HASHIMOTO**

ABSTRACT

In order to analyze beach profile changes due to longshore and onshore-offshore sand transport, here is proposed a new model named the "empirical predictive model of beach profile change", which is an application of the empirical eigenfunction method. The analysis of the profile data obtained at the Misawa fishery port in Ogawarako Coast over five years from 1973 to 1977 indicates that profile changes due to longshore transport and to onshore-offshore transport can be separated. The model is shown to be effective in the analysis of profile changes near coastal structures.

I. INTRODUCTION

Recently many investigations about predictive models of beach profile changes due to littoral drift have been conducted. Pelnard-Considère[1] introduced an one-line theory and predicted the shoreline changes near a jetty, Bakker[2] developed a two-line theory and analyzed beach profile changes due to longshore and onshore-offshore sand transport near a jetty.

The present authors[3),4)] applied the one-line model for coastline changes to the Fuji Coast and to the planning of artificial beach nourishment at Kanazawa Beach. As a consequence of these analyses, it was concluded that if coefficients of the model are suitably selected, the shoreline change due to longshore sand transport can be predicted fairly well. However, the one-line theory cannot predict the profile variation when both longshore and onshore-offshore sand transport are significant.

In this paper, in order to consider such problems more closely, we analyzed shoreline changes near the breakwater of the Misawa fishery port with the one-line theory, and also applied the empirical eigenfunction method to the analysis of beach changes.

II. BEACH PROFILE CHANCES DUE TO THE CONSTRUCTION OF MISAWA FISHERY PORT

The Misawa fishery port lies on the southern part of the 100 km long Ogawarako Coast, facing the Pacific Ocean in Aomori Prefecture, as shown in Fig. 1. The construction of the port was started in November, 1973

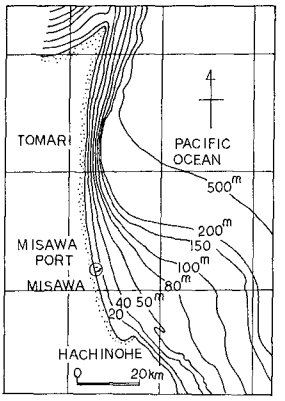

Fig. 1 location of Misawa fishery port

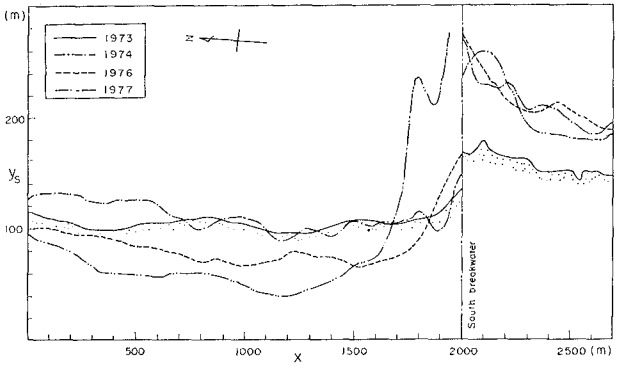

Fig. 2 Shoreline changes near Misawa port

and completed in December, 1977. Since the net sediment transport along this coast was toward the north,[5] accretion and erosion occurred, respectively, to the south and north of the breakwater of the port after its construction.

The beach profile near the port was measured once a year over five years from 1973 to 1977 at 50 meter intervals alongshore. Figure 2 shows the changes of the shoreline near the breakwater from 1973 to 1977. Over these five years, the shoreline advanced offshore by about 60 meters on the south coast of the breakwater, whereas it retreated landward by some 60 meters on the north coast. The shoreline near the north side of the breakwater advanced offshore more than 100m due to the diffraction of waves around the breakwater.

The detailed shoreline changes are shown in Fig. 3. The dates of construction stages are also summarized in Fig. 3. With the progress of the construction, the shoreline inside the port advanced offshore. Figure 4 shows typical examples of beach profiles along the P-P' section in Fig. 3. It is found that the accretion height amounted to approximately four meters in the port, and the profile changes extended from three meters above the mean sea level to eight meters below the sea level. The change of bottom elevation around the port was calculated from the measured profile data of 1973 and 1974, as shown in Fig. 5. Positive and negative values indicate accretion and erosion, respectively. According to Fig. 5, erosion occurred in the north and accretion in the south coast of the breakwater, respectively, implying sand movement from the south to the north at the head of the breakwater.

In addition, the relationship between the changes of the sectional area, A, of beach profile (such as the dotted area in Fig. 3) and the shoreline position, y_s , is shown in Fig. 6, and is approximated by

$$A = 11\ y_s \qquad (1)$$

This relation indicates that the characteristic height of the beach change is about 11 meters.

III. WAVE CLIMATE OF OGAWARAKO COAST

The wave climate of Ogawarako Coast has been measured at Takahoko by the Ministry of Transport[6], which is located about 24 km north of the Misawa port. The wave height was measured at the depth of 17.5 meters using an ultrasonic wave gauge, and the wave direction was measured by the deformation of a ball caused by the water particle velocity. The directional probability density of the wave height calculated from the measured data over seven years from 1971 to 1977 is shown in Table 1. The prevailing directions of the incoming waves are ENE, E and ESE. We calculated an effective directional sum of the wave energy flux to define characteristic wave heights which would give the same wave energy flux as the directional sum over one year. It was found that characteristic wave heights were 1.45, 1.34 and 1.17 meters in the ENE, E and ESE directions, respectively, and the corresponding predominant periods were 9.0 seconds in the ENE and E, and 7.5 seconds in the ESE.

Since the shoreline near the breakwater is oriented about 5° counterclockwise from the north, the northward component of the wave energy flux has the magnitude of the same order as the southward component, although the northward component is slightly larger.

IV. NUMERICAL SIMULATION OF SHORELINE CHANGES BY THE ONE-LINE THEORY

The one-line theory was applied to the shoreline changes near the Misawa port. The fundamental equations are,

$$\frac{\partial q}{\partial x}+h\frac{\partial y_s}{\partial t}=0 \tag{2}$$

$$q=F\left(-\frac{\partial y_s}{\partial x}-\tan\theta\right) \tag{3}$$

$$F=\frac{1}{8}\alpha w_0 K_r^2 H_i^2 C_{gi} \tag{4}$$

where q is the longshore sediment transport rate per unit length, h the characteristic height of beach change, y_S the position of shoreline, θ the wave direction, α the Savage coefficient, H_i the incoming wave height, and Cg_i the incoming wave group velocity.

First, the coefficient α was calculated from the volume changes and longshore component of wave energy flux at the site. The relation between volume changes per unit time, Q_z , and longshore component of wave energy flux, E_z , is expressed as follows:

$$Q_z=\alpha E_z \tag{5}$$

It was assumed to calculate the volume changes that northward sediment transport was fully blocked by the breakwater, and that shoreline changes outside of the survey area decreased exponentially with distance from the breakwater. The result is $Q_z = 1.56 \times 10^6$ m^3 for four years. Since the longshore component of wave energy flux of this coast is northerly, and given by $E_z = 1.93 \times 10^6$ ton.m/(m.year), we obtain $\alpha = 0.02$ using Eq. (5). This value corresponds fairly well to the traditional value of Savage coefficient, $\alpha = 0.217$.

The simulation of shoreline changes is carried out by solving implicit finite difference equations as follows,

$$\frac{1}{\Delta x}(q'_{i+1}-q'_i)+\frac{h}{\Delta t}(y'_{si}-y_{si})=0 \tag{6}$$

$$q'_i=F_i\left[-\frac{1}{\Delta x}(y'_{si}-y'_{si-1})-\tan\theta_i\right] \tag{7}$$

where the subscript i denotes a step of longshore distance, and the prime represents a time step. The boundary conditions, $q = 0$ at the breakwater and $y_S \to 0$ at $x = -2000$ meters were applied. The shoreline profile of the year 1973 was used as the initial condition. In this computation the time step was $\Delta t = 10$ days, the longshore width of the cell was $\Delta x = 50$ meters and the height of profile change was set $h = 11$ meters as discussed in the previous section.

For the seasonal changes of wave climate, the predominant wave height and wave direction for each month were given. The diffraction coefficient around the breakwater was once calculated for the initial topography to determine the longshore distribution of the coefficient, F, and this distribution was assumed unchanged.

Figure 7 shows the results of the shoreline simulation. Here, we set $\alpha = 0.18$ instead of 0.20, since $\alpha = 0.20$ resulted in overestimation of the shoreline changes. The calculated shoreline of 1976 agrees fairly well with the measured profile for $x < 1000$ meters although their difference increases near the breakwater. The measured and calculated shorelines of 1977 agree well for $x \leqq 1300$ meters, but the difference rapidly increases towards the breakwater.

Concerning the causes of the difference of measured and calculated shoreline changes, it should be mentioned that three-dimensional beach changes occurred in reality near the breakwater, since this south breakwater was extended in several stages and another breakwater was constructed 300 m north of it in 1977 as shown in Fig.3. The sand at the south of the breakwater moved along it and accumulated near its tip. Behind the breakwater, suspended sediment was also deposited in a relatively calm area. These phenomena are not considered in the calculation of coastline changes by the one-line theory, and it is necessary to use a three-dimensional model which takes into account the changes of wave, current and beach topography for the simulation in this region.

The shoreline change can be predicted to some extent, if suitable coefficient of the model are selected. However, the one-line theory does not have the capability for predicting changes of the onshore-offshore profile. Therefore, we apply the empirical eigenfunction method to the analysis of the beach profile changes in the next section.

V. EMPIRICAL PREDICTIVE MODEL OF BEACH PROFILE CHANGES

Winant et al.[7] studied beach changes at Torry Pine Beach by introducing an empirical eigenfunction method. They represented the bed elevation as a linear combination of products of functions of the offshore distance and of functions of time. The present authors[8] also applied this method to the analysis of data obtained at Ajigaura Beach. The results from the latter work indicates that the accretion caused by longshore movement of sand can be clearly separated from onshore-offshore movement.

The empirical eigenfunction method is essentially the same as the principal components analysis employed in the multivariate statistical

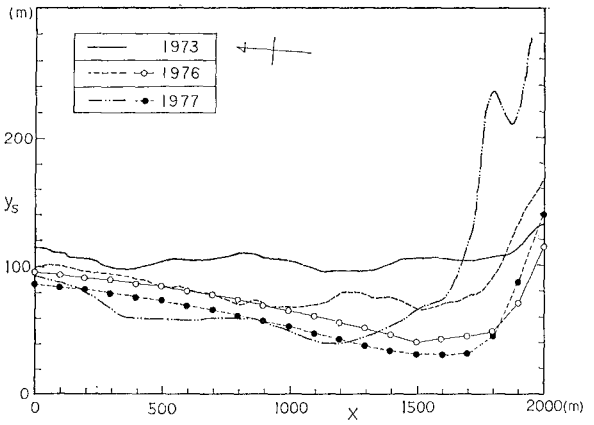

Fig. 7 Results of the shoreline simulation(The calculated shorelines of 1976 and 1977 are indicated by -○- and -●-,respectively. The measured profiles are shown by the solid, broken and chain lines.)

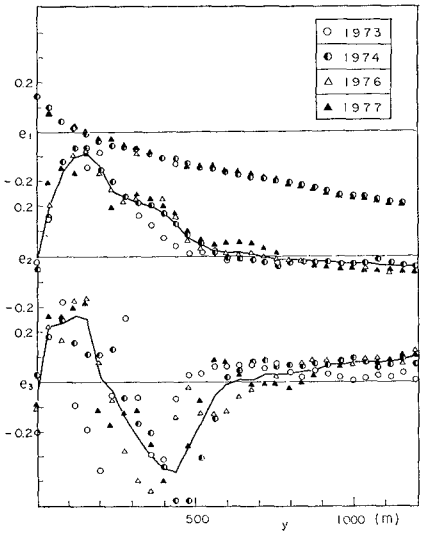

Fig. 8 Onshore-offshore profiles of the first, second and third eigenfunctions, e_1, e_2 and e_3

analysis. In the analysis of Winant et al., beach profile data at certain time intervals were used and the characteristic time changes were obtained. On the other hand, by analyzing beach profile data at certain longshore intervals, one can get the spatial characteristics of the profiles.

We now apply the empirical eigenfunction method to the bed elevation $h(x,y,t_0)$ which is a function of the offshore distance y, and longshore distance x at a certain time t_0. The expansion is expressed as follows,

$$h(x,y,t_0) = \sum_{k=1}^{n} e_k(y,t_0) \cdot C_k(x,t_0) \tag{8}$$

in which the empirical eigenfunctions e_k form an orthogonal set,

$$\sum_{y} e_m(y,t_0) \cdot e_n(y,t_0) = \begin{cases} 1, & m=n \\ 0, & m \neq n \end{cases} \tag{9}$$

In order to generate these functions, a symmetric matrix, A, is formed with the elements,

$$A_{ij} = \frac{1}{n_x n_y} \sum_{m=1}^{n_x} h(m\Delta x, i\Delta y, t_0) \cdot h(m\Delta x, j\Delta y, t_0) \tag{10}$$

where n_x and n_y are the total numbers of measuring points in the alongshore and offshore direction, respectively. The matrix A possesses a set of eigenvalues λ_k and a corresponding set of eigenfunctions $e_k(y,t_0)$, which are defined by the matrix equation,

$$Ae_k = \lambda_k e_k \tag{11}$$

The functions $C_k(x,t_0)$, which define the longshore changes of beach profile, are then evaluated as

$$C_k(x,t_0) = \sum_{y} h(x,y,t_0) \cdot e_k(y,t_0) \tag{12}$$

The method is useful to analyze spatial changes in beach profiles, such as the profiles around a breakwater or of a rhythmic topography. In some cases, it is desirable to use the data of changes of beach profile for the analysis of characteristic beach changes instead of the beach profile itself.

Although the functions e_k and C_k indicate beach characteristics at a certain time, they give the information of the characteristic beach changes. As far as accretion and errosion occur gradually, the functions e_k have approximately unchanged profiles and only the functions C_k change according to the time progress.

Figure 8 shows the onshore-offshore profiles of the first, second, and third eigenfunctions, e_1, e_2 and e_3. The solid line gives the average value over the four years indicated. The eigenfunction e_1 does not depend on the time. The eigenfunctions e_2 and e_3 show relatively larger time variations, but they can be reasonably approximated by the solid lines. Consequently, one can say that all the eigenfunctions e_k do not depend on the time for $k = 1$, 2 and 3.

The second eigenfunction e_2 has a positive value over a broad region of the shore and takes its positive maximum value near the shoreline as shown in Fig. 8.

The ratio of eigenvalues λ_k relative to the first eigenvalue λ_1 are $\lambda_2/\lambda_1 = 2.25 \times 10^{-2}$, $\lambda_3/\lambda_1 = 2.38 \times 10^{-3}$, and $\lambda_4/\lambda_1 = 7.38 \times 10^{-4}$. The contribution of each eigenfunction decreases by one order as compared to the preceeding eigenfunction.

Figure 9 shows the longshore changes of the function C_1 and C_2, which correspond to the first and second eigenfunctions, e_1 and e_2, respectively. The function C_1 shows almost no changes in 1973. However, the region having relatively small value expands gradually on the north coast of the breakwater year by year. This means that the beach slope of this region gradually became smaller. The function C_2, which indicates the longshore changes of the beach profile, is similar to the shoreline profile shown in Fig.2. The correlation between the function C_2 and the shoreline position y_s is drawn in Fig.10 and is given by

$$C_2 = \begin{cases} 0.065(y_s - 134), & y_s < 134m \\ 0.15(y_s - 134)^{0.75}, & y_s \geq 134m \end{cases} \qquad (13)$$

It is concluded from this that the second eigenfunction, e_2, corresponds to the profile changes due to the longshore sand transport.

We can calculate by the one-line theory the shoreline position, y_s, with a certain tolerance, which yields the value of the function C_2 through Eq. (13). Since the onshore-offshore profile is known at least approximately, we can then predict the three-dimensional beach changes due to the longshore sand transport from the products of the eigenfunction e_2 and the function C_2.

The function C_3 corresponding to the third eigenfunction e_3 is shown in Fig. 11. The absolute value of the function C_3 is smaller than that of the function C_2. As the third eigenfunction e_3 takes its positive value shoreward of the shoreline and a negative value in seaward, a positive value of the function C_3 implies accretion on the nearshore beach and erosion in the offshore zone as schematically shown in Fig. 12. On the south side of the breakwater, sand moved along the breakwater and accumulated at its offshore side. Accumulation also occurred near the shoreline but did not exceed that in the offshore. Therefore, the third eigenfunction is considered to correspond to the profile changes due to the sand movement along the breakwater.

The change of the function C_3 is supposed to be controlled by two factors which characterize respectively the profile changes near the shoreline and in the offshore zone. We selected the offshore distance y'' from the location of the four meter depth to the shoreline as shown in Fig. 12, and examined the relationship between y'' and the function C_3. The reason for the selection of this particular depth is that it approximately corresponds to the depth where the third eigenfunction e_3 takes its minimum value. As found in Fig. 13, we have the relation

$$C_3 = 0.0215(285 - y'') \qquad (14)$$

This indicates the possibility that the onshore-offshore profile changes might be represented by change of the offshore distance y'' between two characteristic lines. Since the function C_3 is determined by Eq. (14) if the offshore distance y'' is given, and the profile of the third eigenfunction e_3 is known, the three-dimensional beach changes around the breakwater can be evaluated.

As a typical example, we calculated the profile of the beach that lies 200 meters north of the south breakwater, using the measured shore-

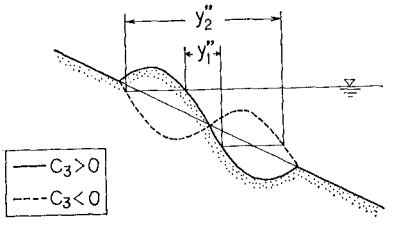

Fig. 12 A typical example of onshore-offshore profile changes

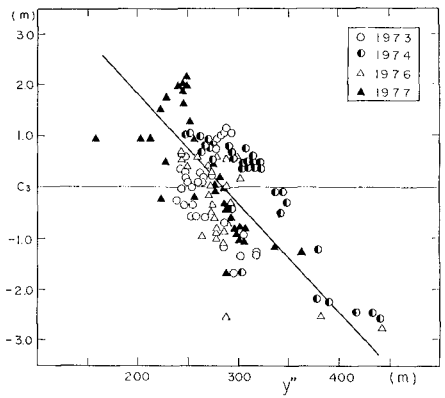

Fig. 13 Relationship between the distance y" and the function C_3

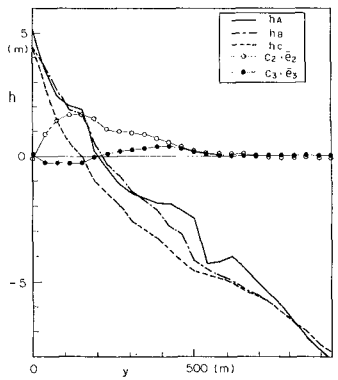

Fig. 14 Comparison of the measured beach profile and that calculated by the products of the eigenfunction e_k and the function C_k (h_A= measured beach profile, h_B= calculated beach profile, h_c= mean beach profile, C_2e_2, C_3e_3 = variation of beach profile corresponding to the second and third eigenfunctions)

line position. The shoreline position, y_s, and the offshore distance, y'', were given by 218 and 553 meters, respectively, at this location. By substituting these values into Eq. (13) and Eq. (14), C_2 and C_3 were found to be 4.16 and − 1.1 meters. In addition, C_1 is set to be 26.5 meters, which is the average taken over four years. Figure 14 shows the measured beach profile and the profile calculated by the products of the eigenfunctions e_k and C_k. The solid line, h_A, indicates the measured beach profile, the chain line, h_B, indicates the calculated beach profile, and the broken line, h_C, gives the mean beach profile. The calculated profile agrees fairly well with the measured one at the depth shallower than 2 meters, whereas thier disparity increases near the breakwater.

VI. CONCLUDING REMARKS

In order to discuss the beach profile change due to longshore and onshore-offshore sand transport, a new model was proposed, the empirical predictive model of beach profile change, by applying the empirical eigenfunction method. The model was applied to analyzing the data obtained at the Misawa fishery port.

As a consequence of this analysis, it was found that the first eigenfunction e_1 corresponded to the mean profile. The second eigenfunction e_2 turned out to correspond to the profile changes due to longshore sand transport, because its value was positive over a broad region of the shore, and the second time function C_2 corresponding to it, which gave longshore change of the beach profile, was correlated with the shoreline position, y_s. In addition, it was shown that the third eigenfunction e_3 corresponded to the profile changes due to the influence of the breakwater, because e_3 took positive values near the shoreline and negative values in the offshore zone, and the function C_3 was correlated with the offshore distance y'' of the four meter depth line from the shore.

Consequently, a basis of the two-line theory was substantiated, and the possibility of the development from a one-dimensional prediction model to a three-dimensional model of beach profile change was demonstrated.

MODELING ON-OFFSHORE SEDIMENT TRANSPORT IN THE SURFZONE

by James A. Bailard[1]

ABSTRACT

An energetics-based surfzone sediment transport model was evaluated in its ability to predict on-offshore sediment movements using current meter and beach volume measurements from the Nearshore Sediment Transport Study at Torrey Pines Beach, California. The magnitude of pertinent wave velocity moments were also evaluated from the same data set. These moments were found to be adequately represented by linear functions of the significant wave height. Because of the apparent noise in the beach volume measurements and the limited duration of the current meter records, the results of the model evaluation were inconclusive. However, a simplified version of the model, when coupled with estimated wave velocity moments, was found to mimic observed on-offshore sediment movements as a function of significant wave height.

INTRODUCTION

Waves breaking on a beach cause sediment to be transported both parallel to (longshore) and perpendicular to (on-offshore) a beach. Although on-offshore and longshore sediment transports are manifestations of the same process, past investigations have generally treated them separately for reasons of simplicity. Fortunately, this separate approach has been relatively successful, because wave refraction causes the waves to have near normal incidence to the beach at breaking, and the mean longshore and on-offshore currents are generally much weaker than the oscillatory velocity mangitude. As a result, the longshore transport has been found to be relatively well modeled (e.g., Inman and Bagnold, 1963; Komar, 1971) as the product of an oscillatory velocity-induced sediment load and a transport velocity proportional to the longshore current. Similarly, the on-offshore transport may be modeled as a balance between gravity, the asymmetry of the oscillatory velocity distribution, and the on-offshore steady current (e.g., Inman and Frautschy, 1966; Bowen, 1980; Bailard, 1981).

Although the above processes have been qualitatively understood for some time, relatively greater progress has been made in quantitatively predicting the longshore transport rate. Predicting the on-offshore transport rate has proven more difficult because: models predicting oscillatory velocity asymmetries and mean on-offshore currents inside the surfzone has been lacking; the effect of the downslope component of

[1]Naval Civil Engineering Laboratory, Port Hueneme, California 93043

the sediment load on the on-offshore sediment transport has generally not been adequately represented and the dynamic near-equilibrium of on-offshore transport on a stable beach tends to magnify the importance of second order effects such as the vertical velocity structure and the threshold criteria for sediment movement.

Because of these difficulties, most models have sought to correlate on-offshore sediment transport with incident wave properties. Some examples of this type of approach include: the wave steepness models by Dean (1973) and Hattori and Kawamoto (1981); the wave height models by Saville (1957), Aubrey (1978) and Short (1978); and the wave power model by Short (1978). A few models have considered a greater degree of detail in the fluid sediment motions, and include those by Inman and Frautschy (1966), Bowen (1980) and Bailard (1981). All three of the latter models are based on adaptations of Bagnold's (1963, 1966) sediment transport model for streams, with Bailard's (1981) model being the most complete in that nonnormal wave incident in the presence of longshore currents is considered.

A common aspect of Bowen's (1980) and Bailard's (1981) energetics-based models is the importance of several surfzone velocity moments in determining the direction and magnitude of the on-offshore sediment tranport. These moments are defined in terms of idealized monochromatic waves. However, they can be extended to spectral wave inputs as well (Guza and Thornton, in review). Using Stokes' second-order wave solution and Longuet-Higgins (1953) bottom streaming model to estimate the wave velocity asymmetry and mean on-offshore current, respectively, Bowen (1980) and Bailard (1981) were able to qualitatively describe the equilibrium beach profile as a funciton of the incident wave amplitude, the wave frequency, and the sediment fall velocity. Small amplitude, long period waves were found to produce a steep beach while large amplitude, short period waves were found to produce a flat beach. Large diameter sand grains with high fall velocities were also observed to produce steeper beaches than smaller diameter sand grains with lower fall velocities. These results qualitatively confirmed observed beach behavior, but neither the nonlinear wave solution nor the mean current solutions are considered valid inside the surfzone.

Because of the inability of existing wave shoaling models to accurately describe wave velocity asymmetry and mean on-offshore currents inside the surfzone, little is known about these quantities. Two recent studies describing limited field measurements of wave velocity moments (Huntley and Bowen, 1975; Guza and Thornton, in review) suggest that the magnitudes of these moments may be a function of the incident wave conditions, the beach slope, and the local water depth. Analysis of more comprehensive data sets are needed to test this hypothesis.

A lack of appropriate field data has also restricted the evaluation of existing on-offshore sediment transport models. Recently, however, a series of large-scale field experiments have been conducted as part of the Nearshore Sediment Transport Study (NSTS). The first of these experiments was conducted at Torrey Pines Beach, Calif., during November 1978. During this time, simultaneous measurements of deepwater wave characteristics, surfzone nearbottom velocity distributions, and beach profile changes were measured. Details of the experiment are described in Gable (1979).

The success of Bowen's (1980) and Bailard's (1981) total load surfzone models in qualitatively describing the variation of the equilibrium beach slope with wave and sediment characteristics suggested that Bagnold's energetics approach may be useful in quantitatively predicting the on-offshore sediment transport. Consequently, a study was initiated to test the ability of Bailard's (1981) total load sediment transport model to predict daily on-offshore sediment movements using data from the NSTS experiment at Torrey Pines Beach, Calif., in November 1978. The objectives of the study were threefold. First, the model was tested in its ability to predict daily beach volume changes using relatively short (1- to 2-hour) surfzone current meter records. Second, a relationship was sought between average values of surfzone velocity moments and incident wave characteristics. Lastly, a simplified on-offshore model was combined with the average surfzone velocity moments to predict the on-offshore sediment transport as a function of significant wave height.

SEDIMENT TRANSPORT MODEL

Bailard's (1981) total load sediment transport model is based on an adaptation of Bagnold's (1963, 1966) energetics-based total load sediment transport model for streams. The latter is generalized for time-varying flow over an arbitrarily sloping bottom, resulting in

$$\langle \vec{i}_t \rangle = \rho c_f \frac{\varepsilon_B}{\tan\phi} \left\langle \left|\vec{u}_t\right|^2 \vec{u}_t \right\rangle - \frac{\tan\beta}{\tan\phi} \left\langle \left|\vec{u}_t\right|^3 \right\rangle \hat{i}$$

$$+ \rho c_f \frac{\varepsilon_S}{W} \left\langle \left|\vec{u}_t\right|^3 \vec{u}_t \right\rangle - \frac{\varepsilon_S}{W} \tan\beta \left\langle \left|\vec{u}_t\right|^5 \right\rangle \hat{i} \qquad (1)$$

where $\vec{i}_t$ = instantaneous sediment transport rate vector

ρ = density of water

c_f = drag coefficient of the bed

ε_B = the bedload efficiency factor

ϕ = internal angle of friction of the sediment

$\tan\beta$ = the bed slope

ε_S = suspended load efficiency factor

W = is the fall velocity of the sediment

$\vec{u}_t$ = instantaneous nearbottom fluid velocity vector

$\hat{i}$ = unit vector directed upslope

$\langle\ \rangle$ = time-average

Note that both the bedload (first bracketed quantity) and the suspended load (second bracketed quantity), consist of a primary component directed parallel to the instantaneous fluid velocity vector and a secondary component directed downslope. The latter is associated with the downslope gravity component of the sediment load.

Equation 1 is assumed to be valid for any nearbottom velocity field and can be used with data from a two-axis (x and y) current meter to directly predict the time-averaged sediment transport rate vector at the current meter location.

Figure 1 depicts a plane contour beach with the x-axis directed shoreward and normal to the beach and the y-axis directed parallel to the beach. The slope of the beach is tan β. For modeling, it is convenient to use a monochromatic wave representation for the nearbottom water velocity field as a means of simplifying Equation 1. Bailard (1981) assumed a velocity field composed of an oscillatory velocity component $\tilde{u}$ oriented at an angle α to the x-axis and a steady velocity component $\bar{u}$ oriented at an angle θ to the x-axis. The total velocity vector $\vec{u}_t$ then becomes

$$\vec{u}_t = (\tilde{u} \cos \alpha + \bar{u} \cos \theta)\, \hat{i} + (\tilde{u} \sin \alpha + \bar{u} \sin \theta)\, \hat{j} \qquad (2)$$

In addition, the oscillatory velocity component is assumed to be asymmetrical being composed of a primary component u_m with frequency σ and a secondary harmonic u_{m2} with frequency 2σ so that

$$\tilde{u} \sim u_m \cos \sigma t + u_{m2} \cos 2\sigma t + \ldots \qquad (3)$$

An analysis of surfzone current meter records at Torrey Pines Beach showed that $\bar{u} \ll u_m$ and $\sin\alpha \ll 1$, thus substitution of Equations 3 and 4 into Equation 1, yields the idealized on-offshore transport equation

$$\langle i_x \rangle = \rho c_f u_m^3 \left\{ \frac{\varepsilon_\beta}{\tan \phi} \left[\Psi_1 + \frac{3}{2} \delta_u - \frac{\tan \beta}{\tan \phi} u_5^* \right] + \frac{u_m}{w} \varepsilon_s \left[\Psi_2 + \delta_u u_3^* - \frac{u_m}{w} \varepsilon_s \tan \beta\, u_5^* \right] \right\} \qquad (4)$$

where

$$\delta_u = \frac{\bar{u}}{u_m} \cos \theta \qquad (5)$$

$$\Psi_1 = \frac{\langle \tilde{u}^3 \rangle}{u_m^3} ; \qquad \Psi_2 = \frac{\langle |\vec{u}_t|^3 \tilde{u} \rangle}{u_m^4} \qquad (6a,b)$$

$$u_3^* = \frac{\langle |\vec{u}_t|^3 \rangle}{u_m^3} \; ; \qquad u_5^* = \frac{\langle |\vec{u}_t|^5 \rangle}{u_m^5} \tag{7a,b}$$

For weak mean currents, Snell's law and the spilling wave hypothesis can be used to estimate the magnitudes of α, u_m, u_3^*, and u_5^* throughout the surfzone as a function of incident wave conditions.† Unfortunately, the two skewness parameters Ψ_1 and Ψ_2, as well as the normalized mean onshore current δ_u, cannot be estimated from present surfzone wave shoaling models. One of the objectives of this study was to examine measured surfzone values of Ψ_1, Ψ_2, and δ_u using data from the NSTS Torrey Pines experiment (Gable, 1979). In this respect, the present study was a continuation of the study by Guza and Thornton (in review), who showed that the quantities defined in Equation 4 are meaningful only for monochromatic waves incident from a single direction α. On an actual beach the incident waves compose a spectrum with varying energy content at different frequencies and wave angles. As a result, Guza and Thornton (in review) defined equivalent quantities for Ψ_1, Ψ_2, u_m, u_3^* and u_5^*, which may be estimated from the measured current meter data as follows: Assuming that the current meter time series, $\vec{u}_t$ is composed of mean components $\bar{u}$ and $\bar{v}$, and oscillatory componets, $\tilde{u}$ and $\tilde{v}$, i.e.

$$\vec{u}_t = (\tilde{u} + \bar{u})\,\hat{i} + (\tilde{v} + \bar{v})\,\hat{j} \tag{8}$$

then

$$u_m^2 = 2\,(\langle \tilde{u}^2 \rangle + \langle \tilde{v}^2 \rangle) \tag{9}$$

$$u_m^3\,\Psi_1 = \langle \tilde{u}(\tilde{u}^2 + \tilde{v}^2) \rangle \tag{10}$$

$$u_m^4\,\Psi_2 = \langle |\vec{u}_t|^3\,\tilde{u} \rangle \tag{11}$$

$$u_m^3\,u_3^* = \langle |\vec{u}_t|^3 \rangle \tag{12}$$

$$u_m^5\,u_5^* = \langle |\vec{u}_t|^5 \rangle \tag{13}$$

†Note, however, that Guza and Thornton (in review) found that the commonly assumed spilling wave hypothesis did not lead to an accurate estimate of u_m.

DATA ANALYSIS

Data Set Description

In November 1978, a month-long field experiment was conducted at Torrey Pines Beach as part of the Nearshore Sediment Transport Study (NSTS). Torrey Pines Beach, Calif., is a plane-contoured beach with a concave profile. The slope of the beach face is approximately 0.05, decreasing to about 0.02 within the surfzone. The sand on the beach is moderately well sorted with a mean diameter of 0.17 mm. The beach exhibits little or no bar-trough features. The experiment consisted of the simultaneous measurement of incident wave conditions, nearbottom water velocities distributions, sand tracer movements, and beach profile changes. The incident wave climate was measured in 10 meters of water with a linear array of pressure sensors. Nearbottom water velocities were measured using dual-axis (x and y) electromagnetic current meters, while the beach profiles were measured with a rod and transit onshore and a fathometer offshore.

The current meters were placed in a cross-shaped pattern within the nearshore area. Referring to Figure 2, 7 current meters were placed in a line perpendicular to the beach, ranging in depth from 0.25 meters to 6 meters relative to mean sea level (MSL). Ten other current meters were placed in a line parallel to the beach at a depth of about 1 meter relative to MSL. The beach profiles were measured at five ranges along the beach. Further details of the experiment can be found in Gable (1979).

Model Evaluation

One of the objectives of the present study was to evaluate the ability of Equation 1 to predict daily beach volume changes using NSTS data. Following the approach used by Seymour and King (1982), daily beach volume changes were computed by integrating the beach profile changes across 100 meters of beach face. The seaward extremity of the integration interval roughly coincided with the location of the shore-parallel current meters so that a simple box model analysis could be used to estimate the beach volume changes. In the present study the flux of sand into or out of the seaward edge of the box was assumed to be predicted by Equation 1 using the measured current meter data from each shore parallel current meter. The measured beach volume changes used in the present study are those tabulated by Seymour and King (1982).

Equation 1 has 3 free parameters: the bed friction coefficient c_f, the bedload efficiency factor ε_B, and the suspended load efficiency factor ε_S. In the present study, a value of 0.005 was selected for c_f, based on an analysis of longshore current data at Silver Strand Beach, Calif., (Bailard, 1981). This beach has a bed slope similar to that found at Torrey Pines Beach (0.034) and is located 15 miles to the south. Thornton and Guza (1982) analyzed longshore current data at Torrey Pines Beach and concluded that $c_f = 0.01 \pm 0.01$. Thus because of the large uncertainty interval, the Torrey Pines data set could not be used to directly estimate the size of c_f.

The bedload and suspended load efficiency factors ε_B and ε_S are the remaining two free parameters in Equation 2. Rewriting Equation 1 to isolate these factors, we obtain

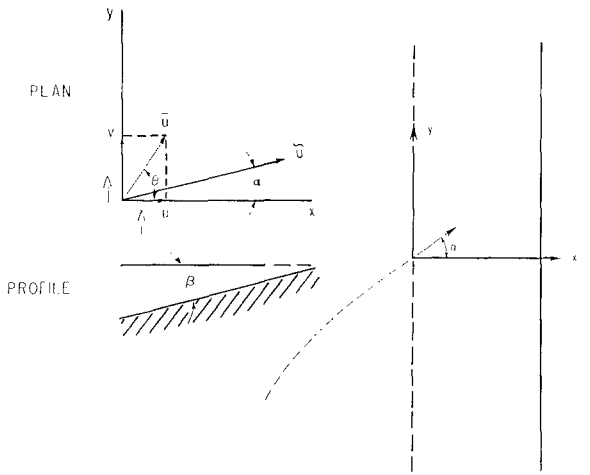

Figure 1. Schematic diagram showing the position of the beach (solid line), the breakpoint (dashed line), the wave angle α and the oscillatory and steady water velocities $\tilde{u}$ and $\bar{u}$ (from Bailard and Inman, 1980, with permission).

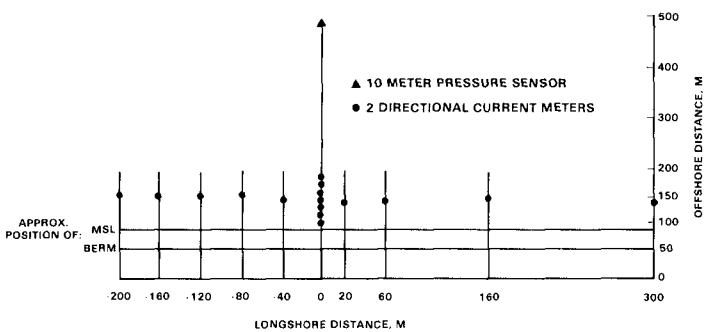

Figure 2. Relative current meter and pressure sensor positions for the NSTS Torrey Pines experiment (adapted from Seymour and King, 1982).

$$\langle i_x \rangle = \varepsilon_B I_A + \varepsilon_S I_B - \varepsilon_S^2 I_C \tag{14}$$

where

$$I_A = \frac{\rho c_f}{\tan \phi} \left\langle \left|\vec{u}_t\right|^2 \vec{u}_t \cdot \hat{i} \right\rangle - \frac{\tan \beta}{\tan \phi} \left\langle \left|\vec{u}_t\right|^3 \right\rangle \tag{15}$$

$$I_B = \frac{\rho c_f}{W} \left\langle \left|\vec{u}_t\right|^3 \vec{u}_t \cdot \hat{i} \right\rangle \tag{16}$$

$$I_C = \frac{\rho c_f}{W^2} \tan \beta \left\langle \left|\vec{u}_t\right|^5 \right\rangle \tag{17}$$

Equation 14 expresses the on-offshore transport rate in terms of the immersed weight transport. The volumetric transport rate Q_x may be related to the immersed weight transport rate $\langle i_x \rangle$ by the following equation

$$Q_x = \frac{\langle i_x \rangle}{(\rho_s - \rho) g N_o} \tag{18}$$

where ρ_s = density of the sand grains

g = gravity

N_o = "at rest" volume concentration of sediment assumed here to be 0.6

The procedure used to estimate the bedload and suspended load efficiencies ε_B and ε_S was as follows. First, daily estimates of I_A, I_B and I_C were obtained from 64-minute records for each of the 10 shore-parallel current meters. These estimates were averaged together to form a single daily estimate, assumed to be representative of the general experiment area. Table 1 contains a summary of the estimated values for I_A, I_B, and I_C. Next, a correlation analysis was conducted to determine the lag time between the predicted volume changes and the measured changes. Using previously estimated values of $\varepsilon_B = 0.21$ and $\varepsilon_S = 0.025$ (Bailard, 1981), Equation 14 was used to predict the beach volume changes which were then correlated with measured volume changes using lag times of zero and 1 day. The maximum correlation ($R^2 = 0.19$) occurred with a lag time of 1 day, as was found by Seymour and King (1982) for several other models using the same data set. The lag time result was insensitive to a range of values of ε_B and ε_S, although R^2 varied as would be expected.

A nonlinear least-squares estimation procedure (Draper and Smith, 1966), was used to estimate ε_B and ε_S from the lagged data in Table 1.

The estimation procedure required constructing a contour map of the mean square error S, defined as

$$S\ (\varepsilon_B\ \varepsilon_S) = \frac{1}{n-2} \sum_{i=1}^{n} (V_{meas} - V_{pred})^2 \qquad (19)$$

where n = number of data pairs (17)

V_{meas} = measured beach volume change with a 1-day lag time

V_{pred} = predicted beach volume change

Figure 3 shows a plot of S versus ε_B and ε_S. The minimum mean square error occurred at $\varepsilon_B = 0.10$ and $\varepsilon_S = 0.020$. These estimates are similar in size to those estimated by Bailard (1981) ($\varepsilon_B = 0.21$ and $\varepsilon_S = 0.025$) based on longshore transport data, however, the 95% confidence limits on ε_B and ε_S are much broader in the present study reflecting in part the low degree of correlation between the measured and predicted beach volume changes. In both cases, however, the predicted values of ε_B and ε_S fall within each other's areas of uncertainty.

Figure 4 shows a plot of the measured and predicted beach volume changes as a function of time. The figure also shows a plot of the signficant wave height as a funciton of time. The beach volume changes shown in Figure 4b were predicted from Equation 1 using the procedure described above. The beach volume changes shown in Figure 4a were predicted by the simplified Equiation 4 and will be discussed later.

Comparing the predicted and measured beach volume changes, Figures 4b and 4c respectively, it is clear that the measured volume changes are not well predicted by the model. Only the maximum erosional event on 12 November was predicted by the model and then at a reduced magnitude. The erosional and accretional events on November 6, 7 and 20 are clearly not predicted by the model.

The low degree of correlation between the measured and predicted beach volume changes raises questions about the ability of Bailard's (1981) sediment transport model to predict on-offshore sediment transports. It should be recognized, however, that predicting the on-offshore sediment transport rate is a severe test of a model because the net transport represents a small difference between two relatively large instantaneous on and offshore sediment transports. Small biases in either the onshore or offshore direction can significantly influence the predicted direction and magnitude of the net transport. Additional factors which may account for the lack of correlation include the temporal and spatial variability of the measured wave velocity moments and the apparent nosiness of the measured beach volume data.

Considering the wave velocity moments, a sensitivity analysis was performed whereby, for selected days, estimates of the on-offshore transport rate were calculated for consecutive 64-minute segments of time. For a day with moderate waves (November 4), the standard deviation of these estimates was 22% of the predicted mean for four consecutive segments. For a day with larger waves (November 12), this value

increased to 46% for three consecutive segments. In addition, individual current meters showed a much wider range of variation (up to 800%) between consecutive hours. These results suggest that although the beach may generally be in a state of near dynamic equilibrium, small changes in the incident wave conditions or the tide may significantly influence short-term local on-offshore movements. Moreover, for the data set studied, it appears that current meter records of 1 to 4 hours may not be of long enough duration to accurately estimate the daily beach volume changes.

Another factor which may account for a low correlation between predicted and measured beach volume changes are potential inaccuracies in the measured beach volume changes. These changes were calculated from the integrated difference between the daily beach profile measurements. Although the precision of these estimates is difficult to assess, daily variations as great as ± 10 m^3/m-day are seen in Figure 4c without a corresponding change in the significant wave height (4d). Seymour (in review) also noted the relative noisiness of the Torrey Pines data set compared with later NSTS data sets measured at Leadbetter Beach, CA, and Virginia Beach, VA.

Because of the above uncertainties, the evaluatuion of Bailard's (1981) sediment transport model was judged inconclusive. Other data sets with longer current meter records and more accurate beach profile measurements are needed before an accurate evaluation of the model can be made. It may also be that it is inherently difficult to predict macro-scale beach volume changes using a micro-scale sediment transport model.

Velocity Moment Magnitudes

The above discussion concerned the ability of Equation 1 to predict on-offshore sediment transports. Equation 4 is a greatly simplified version of Equation 1, and is potentially more useful for modeling on-offshore sediment transports. Unfortunately, this equation still contains a number of surfzone velocity moments, of which little is known. These moments include the wave velocity skewness parameters Ψ_1 and Ψ_2, the normalized onshore current δ_u, and the normalized velocity magnitudes u_3^* and u_5^*.

Of these quantities, only u_m, u_3^*, and u_5^* can be estimated from linear wave theory. For normally incident waves having a Gaussian distribution and weak mean currents, u_3^* and u_5^* can be shown to be equal to 0.562 and 1.13, respectively (Guza and Thornton, in review). Similarily, assuming wave saturation and spilling waves, linear wave theory predicts that

$$u_m = \frac{\gamma}{2}\sqrt{g\,h} \tag{20}$$

where $\gamma = H/h$

h = local water depth

H = local wave height

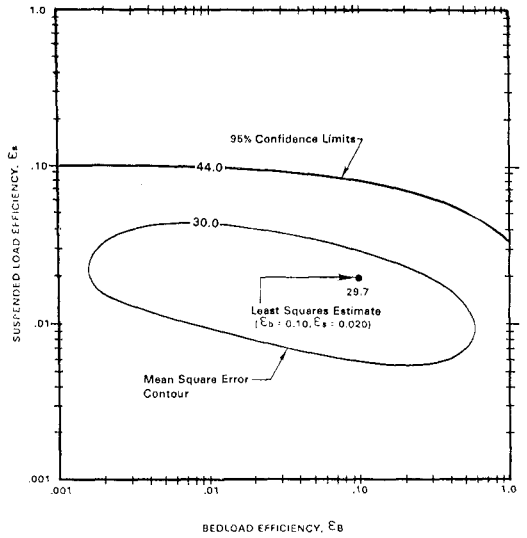

Figure 3. Least squares estimated bedload and suspended load efficiency factors, ϵ_B and ϵ_S.

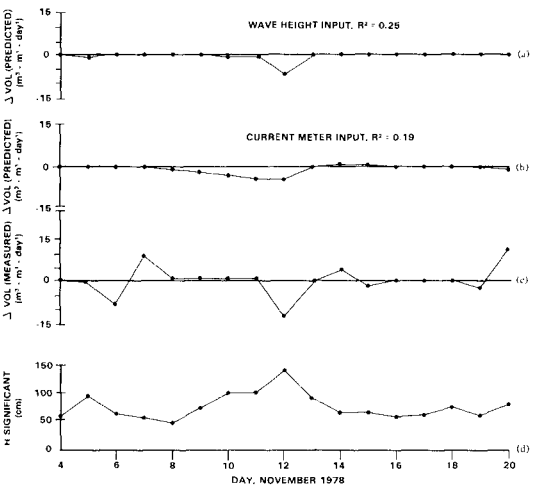

Figure 4. Comparison between predicted beach volume changes (a, b) and measured beach volume changes (c). The volume changes shown in (a) were predicted from Equation 4 using the measured wave heights (d), while the volume changes shown in (b) were predicted from Equation 1.

Equation 20 suggests that u_m should decrease from a maximum at the breakpoint to zero at the beach. In fact, field measurements at Torrey Pines Beach have shown that u_m is almost constant across the surfzone, due to the presence of low frequency surf beat motions within the inner part of the surfzone (Guza and Thornton, in review). The remaining parameters in Equation 4 (Ψ_1, Ψ_2, and δ_u) are zero for linear waves but nonzero for nonlinear waves. Measurements (Huntley and Bowen, 1975, Guza and Thornton, in review) bave shown that they are in fact nonzero under actual field conditions and may vary in magnitude and sign with varying incident wave conditions.

One of the objectives of the present study was to investigate these surfzone wave velocity moments using the NSTS Torrey Pines data set and determine whether their magnitudes can be estimated from incident wave conditions. Values for the parameters Ψ_1, Ψ_2, δ_u, u_3^* and u_5^* were estimated from 64-minute-long records for each of the seven shore perpendicular current meters closest to shore. Because of the temporal and spatial variability of these quantities, mean surfzone values were obtained by averaging the results of all seven current meters. Table 2 is a summary of these average surfzone velocity parameters and the incident wave characteristics for each of the 9 days investigated. The wave characteristics were obtained from Guza and Thornton (1980, 1982, in review) and Seymour and King (1982) who analyzed pressure sensor records measured in 10 meters of water.

Linear and second-order wave theories suggest that the even velocity moments u_m, u_3^*, and u_5^* should be related to the significant wave height, while the odd velocity moments Ψ_1, Ψ_2, and δ_u should also be related to the wave period and the average beach slope. It can be hypothesized that the odd velocity moments may be a function of a surf similarity parameter such as that introduced by Battjes (1974), Guza and Inman (1975), and others. This parameter, ε, can be defined as

$$\varepsilon = a\,\sigma^2 \Big/ g \tan^2\beta \qquad (21)$$

where a = half the breaking wave height

For small values of ε, less than 2.0 to 2.5, reflective conditions with surging breakers are observed, while for larger values of ε, dissipative conditions are observed.

For the conditions found at Torrey Pines Beach during the NSTS experiment, dissipative conditions prevailed, but it could not be determined whether the odd wave velocity moments were a function of ε. The range of significant wave heights varied from 55 to 140 cm; however the peak wave period varied much less, ranging from approximately 10 to 14 seconds. The variation in mean beach slope during the experiment was also very small, so that the slope was approximately a constant 0.02. As a result, the surf similarity parameter ε was primarily a function of the significant wave height H_s. This suggested that for the Torrey Pines data set, a relationship might be sought between all of the relevant surfzone velocity moments and the significant wave height H_s.

After plotting the mean surfzone values of Ψ_1, Ψ_2, δ_u, u_m, u_3^* and u_5^* versus H_s (Bailard, 1982), a linear relationship between variables

Table 2. Average Surfzone Velocity Parameters and Incident Wave Characteristics

Date (Nov 1978)	H_s (cm)	S	Ψ_1	Ψ_2	δ_u	u_m (cm sec^{-1})	u^*_3	u^*_5
4	55	0.00126	0.206	0.204	-0.131	58.2	0.550	1.25
6	65	0.00148	0.197	0.240	-0.124	59.2	0.603	1.20
7	59	0.00117	0.234	0.362	-0.088	51.8	0.594	1.35
10	101	0.00163	0.097	-0.019	-0.160	69.8	0.731	1.26
11	99	0.00303	0.106	-0.152	-0.250	78.4	0.687	1.11
12	140	0.00341	0.134	-0.035	-0.210	87.2	0.574	0.940
13	91	0.00124	0.222	0.326	-0.100	69.3	0.587	1.27
17	62	0.00194	0.232	0.352	-0.081	56.9	0.574	1.24
19	73	0.00128	0.223	0.350	-0.070	56.1	0.574	1.28

was suggested. Using regression analysis, the following equations were obtained:

		Correlation Coefficient R^2	
$\Psi_1 = 0.303 - 0.00144\ H_s$		0.98	(22)
$\Psi_2 = 0.603 - 0.00510\ H_s$		0.83	(23)
$\delta_u = 0.458 - 0.00157\ H_s$		0.96	(24)
$u_m = 31.9 + 0.403\ H_s$		0.99	(25)
$u_3^* = 0.548 + 0.000733\ H_s$		0.99	(26)
$u_5^* = 1.50 + 0.00346\ H_s$		0.99	(27)

where u_m is measured in cm/sec and H_s in cm.

Equations 22 through 27 show that for the conditions found at Torrey Pines Beach, Ψ_1, Ψ_2 and δ_u decrease markedly with increasing wave height. This is in direct contrast to Stokes' second-order wave solution and Longuet-Higgins' (1953) bottom-streaming solutions, which predict increasing values of these variables with increasing wave height. The remaining parameters, u_m, u_3^*, and u_5^*, behave more as would be predicted by linear wave theory, with u_m increasing with increasing wave height and u_3^* and u_5^* being relatively constant. Typical observed values of u_3^* and u_5^* were 0.6 and 1.2, respectively (very close to the theoretical values based on a Gaussian wave distribution).

ON-OFFSHORE TRANSPORT SIMULATION

The simplified on-offshore sediment transport model Equation 4 contains the wave velocity skewness parameters Ψ_1 and Ψ_2, the mean on-offshore current δ_u, the orbital velocity magnitude $\tilde{u}_m$, and the normalized total velocity magnitudes u_3^* and u_5^*. Combining Equation 4 with Equations 22 to 27, the average surfzone on-offshore transport rate and direction can be predicted as a function of the significant wave height and the sediment fall velocity. The other free parameters in Equation 4 include the bed drag coefficient c_f, the bedload efficiency ε_B, and the suspended load efficiency ε_S. For the present study these variables were assumed to be equal to 0.005, 0.21, and 0.025, respectively, based on an analysis of field and laboratory data (Bailard (1981).

Figure 5 shows a plot of the predicted on-offshore sediment transport rate as a function of the significant wave height. The sediment fall velocity was assumed to be equal to 4 cm/sec, which is appropriate for the sand found at Torrey Pines Beach. The bedload-transport rate is depicted by the dashed line, the suspended load transport rate by the dotted line, and the total load transport rate by the solid line. Figure 5 suggests that, for conditions similar to those at Torrey Pines Beach during the NSTS experiment, sand is moved onshore when the significant wave height is less than approximately 90 cm and offshore when

it is greater. The maximum onshore transport rate (0.8 m^3m^{-1} day^{-1}) occurs when H_s is equal to approximately 59 cm. For waves with a significant wave height greater than approximately 150 cm, the transport rate is larger by a factor of 10 and directed offshore. Under most conditions, the predicted bedload and suspended load transports are both in the same direction. Near the null point (H_s ~ 90 cm), however, the bedload is directed offshore while the suspended load is directed onshore.

Qualitatively, Figure 5 confirms some aspects of observed beach behavior. During prolonged periods of small waves, a beach is seen to slowly accrete. With the appearance of the first large swell, however, the beach can cut back dramatically within a few days. Figure 5 also qualitatively supports Short's (1978) observations at several Australian beaches that the neutral point wave height separating accretion from erosion was equal to 120 cm. Although the present study suggests a neutral point wave height of 90 cm, the magnitudes are similar.

The simplified on-offshore transport model represented by Figure 5 can also be used to predict beach volume changes at Torrey Pines Beach from the measured signficant wave heights. Referring to Figure 4, the predicted beach volume changes (4a) can be compared with the measured changes (4c). As with the more complex model (Equation 1), only the erosion event on 12 November is predicted but at a decreased magnitude. The degree of correlation, R^2, between predicted and measured beach volume changes is 0.25 for the simple model versus 0.19 for the more complex model. The simple model is thus somewhat better in predicting the measured changes.

Neglecting for a moment the observed relationship between the beach slope and the sand size, the relative effect of different sediment fall velocities on the total load sediment transport rate may be predicted from Equations 4 and 22-27. Referring to Figure 6, increasing the fall velocity is seen to decrease the magnitude of the on-offshore transport rate. As a result, a beach with fine sand would be expected to experience more rapid beach volume than an equivalent beach with coarse sand.

DISCUSSION

The applicability of these results to other sites and to other wave conditions is unknown; however, it is hypothesized that the results are relatively site and time specific. For monochromatic waves and plane contour beaches, the surfzone hydrodynamics have been analytically shown to be a function of the incident wave height, direction, and period, as well as the beach slope. For random waves, the shapes of the energy and directional spectrums may also be important. During the NSTS Torrey Pines experiment, the waves were almost normally incident with a near uniform period. Moreover the beach slope changed little during the month. The only parameter that varied to any significant degree was the wave height, which varied by a factor of 3. As a result, Figure 5 cannot be easily extended to more general conditions.

Qualitatively, however, it can be hypothesized for that there may be a family of curves, similar in shape to those in Figure 5 but which vary with beach slope. Flat beaches typical of large waves and fine sand would be expected to have a neutral point corresponding to a larger

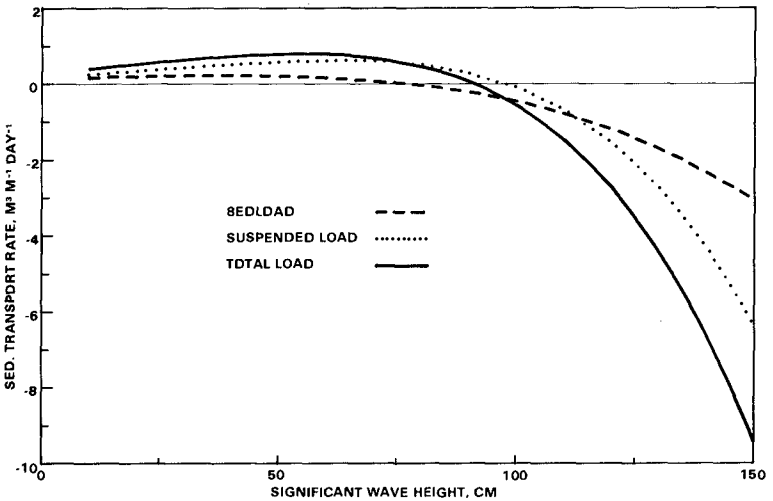

Figure 5. Predicted on-offshore sediment transport rate as a function of significant wave height. The individual contributions of the bedload and suspended load transports to the total transport are shown by the dashed and dotted lines, respectively. The point of neutral transport (equilibrium) occurs at a significant wave height of 90 cm.

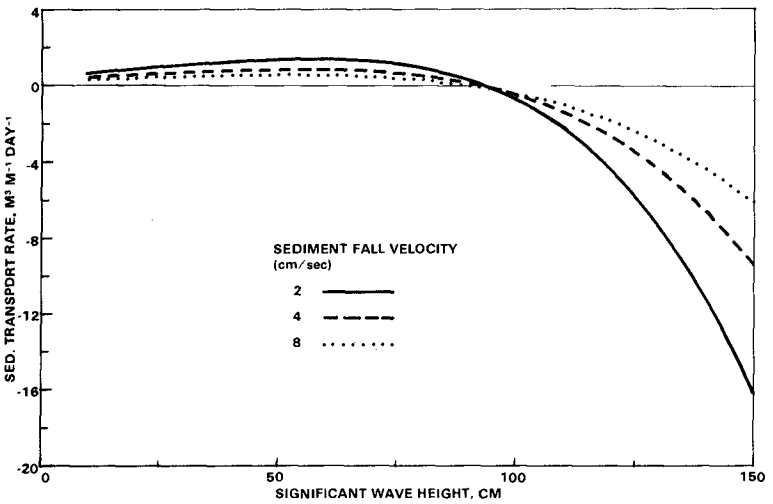

Figure 6. Predicted total load on-offshore sediment transport rate as function of significant wave height and sediment fall velocity. Greater rates of transport are found for smaller sized sediments.

wave height and would exhibit greater rates of change for a given wave height. Steep beaches typical of small waves and course sand would have smaller neutral point wave heights and would exhibit less rapid change for a given wave height. Figures 5 is believed to represent transition conditions. Partial support for the above hypothesis is provided in the study by Aubrey (1978), who found that future beach profiles at Torrey Pines Beach were best predicted when the existing beach profile shape and the incident wave height were known. Presumably, additional data sets having a wider range of beach slope and wave conditions are needed to develop a more complete beach profile predictive capability.

Further discussion is needed concerning possible errors in the estimated surfzone velocity moments. The odd moment quantities Ψ_1, Ψ_2, and δ_u, in effect, represent small differences between large numbers, so they are especially sensitive to small errors in the measured current meter data. Because of this sensitivity, considerable care was exercised in prescreening the data. The quantity u_*^3 was found to be particularly sensitive to data errors and was used as an indicator of bad sections of data. In spite of this care, the data itself could be subject to an inherent bias due to current meter inaccuracies.

One error in particular may be that the mean on-offshore currents are a manifestation of a current meter rectification process which has been hypothesized to occur in combined oscillatory and longshore currents.* Some evidence, however, suggests that rectification may not be too significant. Wright et al. (1978) reported measuring onshore currents in the upper part of the water column inside the surfzone and offshore currents near the bottom. These measurements were made with small ducted fan current meters unlike the electromagnetic current meters used in the NSTS experiments and, presumably, would not be subject to the same rectification characteristics. Nevertheless, until more exhaustive studies are done on the response of the electromagnetic current meters in combined oscillatory and steady flows, the magnitudes and directions of the mean on-offshore currents are open to question.

It is disappointing that the present sediment transport model is not more accurate at predicting the measured beach volume changes. The reason for its lack of accuracy is unknown. The variability in the estimated on-offshore transport rates between consecutive hourly data sets suggests, however, that the on-offshore transport rate may vary significantly on an hourly basis due to small changes in the incident wave field and the tide. The latter changes the position of the surfzone relative to the existing beach profile, which can significantly alter the breaking wave characteristics. As a result, it may be intrinsically difficult to test the capability of a micro-scale on-offshore sediment transport model to predict daily beach volume changes using current meter records of very limited duration.

In addition, some of the measured beach volume changes seem to be anomalous in light of our present limited knowledge. In particular, the large on-offshore rates of sand movements during periods of small waves

*From personal communication with R. T. Guza and D. G. Aubrey.

on November 6, 7, and 20 are difficult to understand. It would appear that wave energy should have been insufficient to generate this volume of sediment transport. One possible explanation may be a temporary local convergence or divergence of the longshore transport rate. Another explanation may be inaccuracies in the beach profile measurements.

CONCLUSIONS

Based on the results of this study, the following conclusions can be made:

1. An evaluation of the ability of Bailard's (1981) surfzone sediment transport model to predict daily beach volume changes was not possible due to inadequate surfzone current meter record lengths and to apparent noiseness in the beach volume estimates.

2. Average surfzone wave velocity moments were found to be well represented by linear functions of significant wave height. Additional data sets are needed to determine their relationships to wave period and average beach slope.

3. Predicting beach volume changes using a highly simplified form of Bailard's (1981) surfzone sediment transport model appears promising in that observed on-offshore transport is qualitatively supported. Analysis of additional surfzone current meter data sets having different wave and beach slope characteristics is necessary before a useful predictive capability can be developed.

SEDIMENT TRANSPORT AND BEACH TRANSFORMATION

Tomoya Shibayama, A.M. ASCE *

and

Kiyoshi Horikawa, M. ASCE **

ABSTRACT

Laboratory and field investigations were performed in order to formulate a predictive model of two-dimensional beach profile change. The observed transport was classified into six types, and transport formulas were deduced for each type based on a microscale description of sediment movement caused by wave action. A numerical model of two-dimensional beach transformation was then developed. Beach profile changes calculated with the model were then compared with the laboratory results. The model was found to give reasonable results except in the vicinity of the wave plunging point. The sediment transport calculation is based on a sinusoidal velocity profile. The model appeares to give good results as long as the wave motion can be reasonably approximated by linear wave theory.

1. INTRODUCTION

Surface waves traveling in shallow water over a sandy bed produce back and forth sand movement. Various attempts have been made to establish quantitative relationships for the sand movement and fluid motion. For example, Madsen and Grant (1976) found a clear relationship between a nondimensional averaged transport rate and the Shields parameter by extending the results of unidirectional flow sediment transport. However, in order to achieve the goal of developing a practical calculation method for sediment formula due to wave action, more precise observations are required to understand the complex mechanism of sediment movement. If the spatial and temporal variations of net sediment transport can be predicted, then two-dimensional beach transformation can be estimated. Here we report results of a study of the theoretical and empirical relationships of wave sediment transport and of two-dimensional beach profile change. The study is based on laboratory and field

** Professor, Dept. of Civil Eng., University of Tokyo, Bunkyo-ku, Tokyo 113 JAPAN

observations. The results are restricted to on-offshore sediment transport; longshore transport is left for future work.

The various topics of the investigation are presented in the following order. 1) A simple classification of sediment transport patterns based on the dominance of a bed load or a suspended load, and on the direction of the sediment transport is described; 2) A bed load formula is presented; 3) A formula for calculating the suspended load created by vortices in the vicinity of sand ripples is introduced; and 4) A simple quantitative model for predicting two-dimensional beach transformation is presented, and comparisons are made with laboratory results.

2. SEDIMENT TRANSPORT

2.1 Sediment transport types and classification

The bed configuration, in particular the presence of ripples, is considered to be one of the main factors necessary to suspend sand. The ripples also govern the sediment transport direction. Therefore, precise observations of sand movement and bed form patterns were made for a wide range of flow conditions in order to classify the sediment transport as a function of flow conditions.

The experiments were carried out both in a wave flume and in an oscillatory flow tunnel. The laboratory conditions are shown in Table 1. Well-sorted sands were used as bottom materials except for Cases 3 and 4 in the oscillatory tunnel, for which polystyrene particles were used. The sediment movement was recorded using either an 8-mm movie camera or a 16-mm high-speed motion analysis camera.

Field observations were carried out at Sabigahama Beach on Miyake Island, and at Ajigaura Beach and Oarai Beach, both in Ibaragi Prefecture, Japan. The field conditions are shown in Table 2. The transport mode was observed directly and recorded using an underwater 8-mm movie camera and an underwater 35-mm camera.

Based on both the laboratory and field observations, the sediment transport due to nearly sinusoidal wave action was classified according to predominance of bed load or suspended load, and according to the direction of sediment transport. We found it convenient to classify the sediment transport into six types as shown in Fig. 1.

1) Bed Load (BL): The bed is practically flat and no suspended sand clouds exist: sediment particles move along the bed surface. The direction of sediment transport is the same as the water flow.

2) Bed Load Suspended Load Transient (BST): Suspended sand clouds are formed above a rippled bed. Both bed load and suspended load exist.

Table 1: Laboratory conditions

WAVE FLUME

Case	Period (s)	Deep water wave height (cm)	Initial slope	Sand grain diameter (mm)
1	1.5	10.0	0.1	0.2

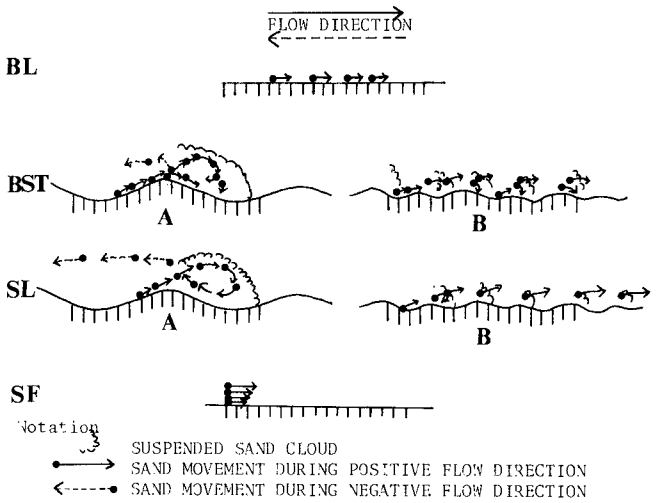

Figure 1: Sediment transport types

2-a) Ripple length and the water particle orbital diameter nearly equal (BST-A), sand particles suspended during the positively directed flow are first confined within a vortex, and then are transported towards the negative direction after the flow direction changes. We here use "positive" to indicate water flow direction in the first half wave period, and "negative" for the second half wave period. The transport of sediment which started moving during the first half wave period is either in the positive or negative direction depending on whether the bed load or suspended load is predominant.

2-b) Ripple length much smaller tban the water particle orbital diameter (BST-B), sand particles suspended during positively directed flow are not confined within a vortex, and are therefore transported in the positive direction. Both suspended sand and sand moving along the bed move in the positive direction.

3) Suspended Load (SL): Suspended sand transport is predominant.

3-a) Ripple length and water particle orbital diameter nearly equal with sediment suspended during the first half wave period being transported in the negative direction (SL-A).

3-b) Ripple length much smaller than water particle orbital diameter with transport in the positive direction (SL-B).

4) Sheet Flow (SF): Ripples disappear. Sand particles move as a layer. The sediment transport direction is the same as the water flow.

In the SL and BST modes, the sediment transport direction changes depending upon the ratio of ripple length to water particle orbital diameter. The laboratory and field observations suggest that when the ripple length and the orbital diameter are of the same order, i.e., the latter is less than about three to five times the former, suspended sand clouds which were formed on the down-flow flanks of ripples are first confined witbin strong vortices. Then the sand clouds are transported in the negative direction during the period of negative flow, and are deposited on the bed under gravitational force (type A). When the ripple length is smaller than the water orbital diameter (i.e., the latter greater than about three to five times the former) suspended sand clouds formed on down-flow flanks of ripples are not confined in vortices and are transported in the positive direction during the period of positive flow (type B). In the BST mode, a part of the bed load is suspended to form sand clouds and some particles are deposited on the bed immediately after suspension.

The above-described types were classified by means of three parameters as will now be described. In order to discuss the BL type, the initiation of sediment movement must be considered. Madsen and Grant (1976) analyzed laboratory data and found that the Shields parameter was an important descriptor. The Shields parameter is expressed in terms of the maximum value of the near bottom water velocity, and is defined as

$$\psi_m = \rho f_w u_b^2 \,/\, 2(s-1)\rho g d \qquad (1)$$

where f_w is Jonsson's (1966) wave friction factor, u_b the maximum value of near bottom velocity, s the sediment specific gravity, g the gravitational acceleration, ρ the fluid density and d the sediment diameter. Madsen and Grant showed that the critical value of Shields parameter corresponding to the initiation of sediment movement is a function of a quantity S. This quantity S depends only on the sediment and fluid properties, and is given by

$$S = d\left[(s-1)gd\right]^{0.5} / 4\nu$$

where ν is the kinematic viscosity of the fluid. For sediment particles of specific gravity 2.65 and diameter 0.2 to 2.0 mm , the critical value of Shields parameter is 0.03 to 0.05.

Komar and Miller (1975) analyzed laboratory data concerning initiation of ripple formation (under low shear stress) and the dissapearence of ripples (under high shear stress). They found that the limiting value of Shields parameter for the existance of ripples changes according to the sediment diameter. For sediment diameters 0.2 to 2.0 mm, the limiting value of Shields parameter for the disappearance of ripples varies from 0.4 to 0.8. However, in the present observation of the initiation of ripple formation, the critical condition was not sufficiently described by the Shields parameter and sediment diameter. The critical condition was also found to be a function of both time and the initial bottom configuration. The critical condition for the initiation of ripple formation is a very difficult problem.

The SL and BST transport types were further divided into two sub-types (A and B) depending upon the ratio of ripple length to water orbital diameter. Nielsen (1979) gave a functional relationship between this ratio and the nondimensional water velocity. According to his result, this ratio is nearly constant when the square of the dimensionless velocity, $u_b^2/(s-1)gd$, is less than 25. Thus, sub-types A and B can be classified by using the square of the dimensionless velocity.

The parameter u_b/w is the ratio of maximum fluid velocity near the bed to the sediment particle fall velocity. Laboratory observation suggests that suspended sediment particles move at almost the same speed as the water particles. This implies that the parameter u_b/w is an indicator of the distance that a sediment particle travels when suspended. Thus the parameter u_b/w is related to suspended sediment movement.

The parameter ψ_m is related to the bed shear stress. Figure 2 shows the resulting classification of the laboratory and field data. This figure shows that the transport modes are well described by the two parameters, u_b/w and ψ_m.

For the limiting boundary between no-movement and BL, and BL and BST, the bed form pattern is the key factor, with the Shields parameter determining the transition. For BST and SL types, both u_b/w and ψ_m determine the limiting boundaries.

For the critical value for sub-types A and B of SL, a value of the square of the dimensionless velocity equal to 25 roughly corresponds to a value of the Shields parameter ψ_m in the range 0.125 to 0.25, if the wave friction factor is 0.01 to 0.02. An example with the value $\psi_m = 0.19$, which corresponds to $f_w = 0.015$, is also indicated in Fig. 2 (labelled "Nielsen").

It should be noted that the transition from SL-A to SL-B cannot be clearly classified by the dimensionless velocity alone. The transition is also related to the water orbital diameter. When the orbital diameter increases, the mode SL-B appears at lower velocities. Due to the same reason, the BST-B type appears when the water orbital diameter becomes longer than the ripple wave length.

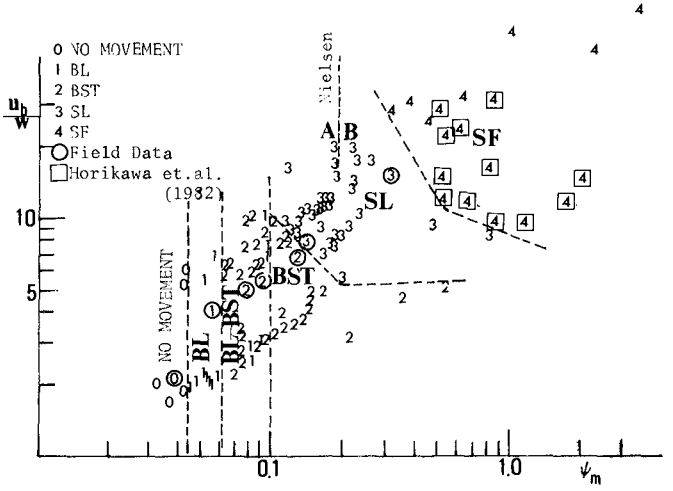

Figure 2: Transport type classification

2.2 Bed load

Vincent (1957) and Abou-Seida (1965) measured the bed load transport rate in a wave flume. Manohar (1955), Kalkanis (1962), and Abou-Seida (1965) performed experiments using an oscillatory plate in a tank of still water. In these experiments, the sediment was collected in a sampler which was set into the bed and the average transport rate over one wave period was evaluated. No consideration of transport direction was included. Sleath (1978) used an oscillatory plate and measured the quantities of bed material in motion at each instant of a cycle. Horikawa et al. (1977) measured the bed load using a sand trap which was buried in the bottom of a wave flume. They correlated the results with the beach profile change.

Madsen and Grant (1976) proposed an empirical relationship between a dimensionless time averaged rate of sediment transport and the Shields parameter, based on analyzing the laboratory data of Kalkanis (1962) and Abou-Seida (1965). They used a quasi-steady application of the Einstein-Brown sediment transport relationship and Jonsson's (1966) wave friction factor, and obtained an expression for the bed load transport rate due to sinusoidal wave motion. In the present work, experiments were performed to measure quantities of sand in motion and the water particle velocity at each instant of the wave cycle in a flume. The results were compared with a formula derived by modifying the Madsen-Grant transport formula. The Madsen-Grant formula, which was based on an analogy of quasi-steady undirectional bed load transport, was supported by the present experiments which measured the history of sand transport rate within one wave period.

Madsen and Grant (1976) used a quasi-steady assumption with Brown's formula and obtained a similar relationship for oscillatory flow, namely,

$$\Phi(t) = 40\,\psi^3(t) \tag{2}$$

$$\psi(t) = \tau(t) \,/\, (s-1)\rho g d \tag{3}$$

in which Φ is the dimensionless sediment transport rate, ψ is the Shields parameter, and τ is the bed shear stress.

Assuming a sinusoidal velocity change, they obtained a relationship between the time-averaged dimensionless transport rate and the Shields parameter as

$$\overline{\Phi} = 12.5\,\psi_m^3 \tag{4}$$

in which

$$\overline{\Phi} = \bar{q}_s \,/\, wd \tag{5}$$

$$\psi_m = \tau_m \,/\, (s-1)\rho g d \tag{6}$$

where $\bar{q}_s$ is the time-averaged volumetric rate of sediment transport and w is the sand particle fall velocity. The quantity τ_m is the maximum bed shear stress given by

$$\tau_m = f_w \rho u_b^2 / 2 \tag{7}$$

We now use the observation that a sand particle moving as bed load will not stop until the flow direction changes. When sand particles are accelerated, the transport rate is estimated with Eq. (2). Assuming a sinusoidal velocity change, we get

$$\Phi(t) = 40\,\psi_m^3 \sin^6 \sigma t \tag{8}$$

in which $\sigma = 2\pi/T$, where T is the wave period. For the time interval after the volume of moving sand attains a maximum, sand

particles once started in motion will not stop during the interval. We have

$$\Phi(t) = \Phi_m \, u(t) \, / \, u_b \tag{9}$$

in which Φ_m is the maximum value of transport rate. Assuming a sinusoidal velocity change,

$$\Phi(t) = 40 \, \psi_m^3 \sin\sigma t \tag{10}$$

The transport rate averaged over the first half wave period is thus estimated from

$$\overline{\Phi} = 2\left(\int_0^{T/4} 40 \, \psi_m^3 \sin^6\sigma \, t \, dt + \int_{T/4}^{T/2} 40 \, \psi_m^3 \sin\sigma \, t \, dt\right) / T \tag{11}$$
$$= 19 \, \psi_m^3$$

Experiment 1 was performed in a wave flume 11 m long, 0.2 m wide, and 0.3 m deep. In the middle of the flume, a volume of sand was placed 0.04 m deep and 0.8 m long over the full flume width. Sand samples were well sorted and their median grain size was 0.7 mm. The wave conditions were as follows: wave height in the inspection section was 7.1 to 10.7 cm, wave period 0.94 to 1.44 s, and water depth 15.4 to 16.7 cm.

During the experiment runs, no sand ripples formed and the sand was transported as bed load. Polystyrene particles of diameter 2 mm and specific gravity 1.02 were injected into the water to measure the water particle movement. In order to measure the number of moving sand particles, a flat plate 2 cm long with a skirt to prevent local erosion was installed on the sand surface. The movement of sand particles which crossed the plate, and the motion of the polystyrene particles over the section, were observed using a CANON 16-mm movie camera utilizing a film speed of 48 frames per second. The relation between the wave phase and the film was determined by using a timing light system with a wave gage. The number of sand particles which crossed the section and the polystyrene particle movement was obtained by analyzing the 16mm film. The near bottom velocity was then estimated from the movement of the polystyrene particles.

An example of the results obtained in Experiment 1 is compared with calculated values of the instantaneous transport rate in Fig. 3. The surface profile, the near bottom velocity and the number of the sand particles crossing the section at each instant of a wave period are shown in the figure. Sand particles did not start moving until the Shields parameter exceeded 0.05. When the transport rate was calculated from the velocity records, it was assumed to be zero when the motion was accelerated, and the instantaneous Shields parameter was less than 0.05. When the motion decelerated and the Shields parameter fell below 0.05, the transport rate was not taken to be zero because particles can continue in motion. Using Eqs. (2) and (9), a value of the sand flux was calculated.

As seen in Fig. 3, which is a representative result from thirteen runs, the agreement between the calculated and the measured values indicates the validity of the calculation scheme. The result also indicates that when the fluid decelerates, Eq. (9) gives a better approximation than Eq. (2) alone. However the real physical phenomena appears to be described by some intermediate combination of the two equations. From the laboratory observations, as the wave period becomes shorter, Eq. (9) becomes more applicable. The present model (Eqs. (2) and (9)) also seems to give a better estimate than Eq.(2) alone of the average transport rate integrated over the period of onshore flow direction.

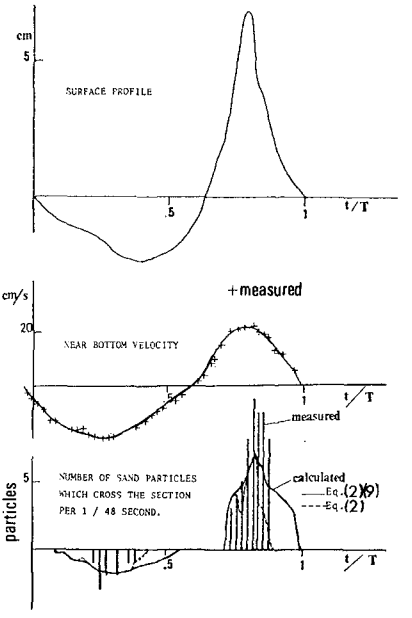

Figure 3: Result of Experiment 1

2.3 Suspended load

Hom-ma and Horikawa (1963) measured auspended sediment concentrations and interpreted the results with a diffusion equation approach. Nakato et al. (1977) studied sediment concentration and velocity fluctuations using an Iowa-type concentration meter and a hot-film anemometer. The above two experiments concern the concentration distribution. Nielsen (1979) attempted to calculate the suspended load using the product of concentration and velocity distributions, but the results were far from satisfactory.

Concerning sand movement above a rippled bed, Inman (1957) studied ripple formation and suggested that suspended sand cloud formation is an important factor in considering sediment transport due to waves. Inman and Bowen (1971) found that there exists an offshore sand transport as suapended load due to ripple asymmetry and resulting differences in intensity of the vortices. Sunamura, et al. (1978) observed sand movement over ripples and described precisely how the sand is confined within vortices formed behind sand ripples and moved by the wave oscillatory flow.

Here, the rate of sand suspension is estimated by application of the Madsen-Grant transport formula and is compared with laboratory data. When strong vortices are created on the onahore sides of ripples, suspended sand clouds form.

When the flow velocity is in the onshore direction, sand is transported along the offshore flanks of the ripples as bed load and then suspended at the crests of the ripples. The suspended sand forms a suspended sand cloud as shown in Fig. 4. Because of the ripple asymmetry, vortices created on the offshore sides of the ripples are weak. For our purposes, a strong vortex is taken as a circulation strong enough to produce suspended sand clouds. From here on, only strong vortices will be treated.

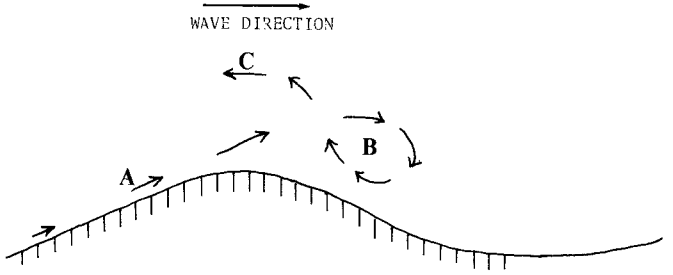
We now consider the time interval $t_i \leqq t \leqq t_e$ during which suspended sand clouds are formed. The time t_i indicates the time when clouds start to form and t_e indicates they stop increasing in size. The time average transport rate for a half wave period is estimated in the same manner as bed load to be

$$\bar{\Phi} = 80\psi_m^3 \left(\int_{t_i}^{T/4} \sin^6\sigma t \, dt + \int_{T/4}^{t_e} \sin\sigma t \, dt\right) / T$$
$$= C\psi_m^3 \qquad (13)$$

From the laboratory observation, suspended sand cloud formation starts at 0.05T to 0.15T and ends at 0.45T to 0.50T. Therefore the constant C varies from 16 to 19. We here set $t_i = 0$ and $t_e = 0.5T$ which gives the maximum value of C. Equation (13) then becomes

$$\bar{\Phi} = 19\psi_m^3 \qquad (14)$$

Experiment 2 was performed to study suspended load. The same flume was used as in Experiment 1 for bed load. In the middle of the flume, a volume of sand was placed which was 4 cm thick, 80 cm long and 20 cm wide. Sand samples were well sorted and their median grain size was 0.2 mm. The wave height was 5.8 to 8.3 cm, and the period 0.84 to 1.30 s.



A: Sand is transported along the offshore flank of the ripples
B: Sand forms a suspended sand cloud
C: The cloud is transported in the offshore direction

Figure 4: Formation of suspended sand cloud

When waves were generated, sand ripples formed after 200 to 300 wave periods. The resultant ripple lengths were 3.0 to 5.7 cm and the height were 0.35 to 0.90 cm. The ripples were asymmetric and strong vortices were generated on the onshore sides of the ripples; vortices formed on the offshore sides were much weaker.

In order to obtain the rate of sand suspension at the crests of ripples, the distribution of suspended sediment concentration above the rippled bed must be measured. A concentration meter was installed close to the bed. It could measure the spatially averaged concentration of the suspended sand clouds. Here, the same assumption as Sunamura et al. (1979) was applied. They assumed that the concentration within the cloud is homogeneous. This assumption is reasonable because of the strong mixing effects of vortices. This condition was seen in precise observations of sand movement by Sunamura et al. and in the present experiment. The concentration was averaged over the time during which the suspended sand cloud was formed.

The concentration of the clouds was measured with a KENEK suspended sand concentration meter which optically measures the suspended sand concentration. The output of the meter was recorded on oscillograph paper together with the output of the wave gage. The cross-sectional area of the suspended sand cloud was obtained from 16-mm films. The amount of suspended sand in the cloud was estimated as the product of the concentration and the cross-sectional area of the cloud.

The results for the rate of sand suspension are shown in Fig. 5 together with the laboratory data of Sunamura, et al. (1979), and a more recent result, Sunamura (1982). Sunamura (1979, 1982) directly determined the net sediment transport rate by measuring the sand weight. The agreement between Eq. (14) and the laboratory data is good. This result implies that the suspended load can be estimated by Eq. (14) for the bed load moving along the ripple flanks.

2.3 Sediment tansport formulas

Simple formulas for the six types of sand transport are now given using the above results. The description of the suspended load requires the introduction of two quantities. The quantity α is the ratio of suspended load originating from the bed load to the bed load. The quantity β is the ratio of suspended sediment confined by a vortex to the suspended sediment. These two quantities are a function of sediment diameter, specific gravity, near bottom velocity, ripple geometry, vortex circulation, etc. Figure 6 shows a schematic diagram for the two parameters.

For type BL, Eq. (6) is used directly. For type SL-A, Eq. (14) is used taking into consideration the number of ripple lengths the suspended sand clouds travel in the second half wave period. Therefore the quantity N is introduced, which is the maximum integer not exceeding the quantity D/λ, where D is the orbital diameter of water particles and λ the ripple wave length. Thus N indicates how many ripple lengths the cloud travels during a half wave period. We then obtain the formula

$$\bar{\Phi} = -19N\psi_m^3 \qquad (15)$$

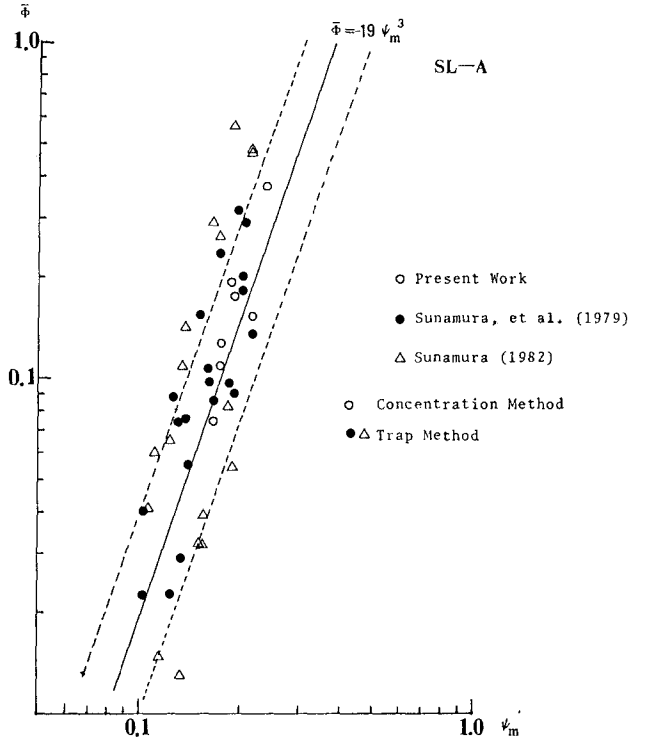


Figure 5: Rate of sediment suspension

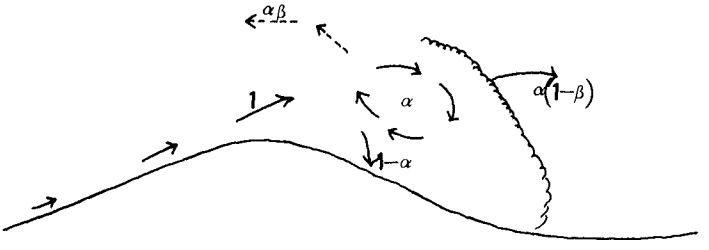

α : ratio of suspended sediment to bed load

β : ratio of suspended sediment confined by vortex to suspended sediment

Figure 6: Explanation of two parameters

Figure 7 shows a comparison between Eq. (15) and the laboratory results. Good agreement is seen. In type BST-A, a part of the bed load is suspended to form clouds and some of the sand particles are deposited on the bed immediately after suspension. We obtain

$$\bar{\Phi} = (1 - \alpha)19\psi_m^3 - 19\alpha N\psi_m^3 = (1 - \alpha - N\alpha)\ 19\psi_m^3 \qquad (16)$$

for type BST-A. Values of α must be determined empirically. For types SL-B and BST-B, the suspended sand clouds formed along the down-flow flanks of ripples are transported in the same direction as the water flow. The formula for type SL-B and BST-B is

$$\bar{\Phi} = 19\ \psi_m^3 \qquad (17)$$

For type SF, Horikawa et al. (1982) performed experiments to determine transport rate. As shown in Fig. 8, Eq. (11) fits their data.

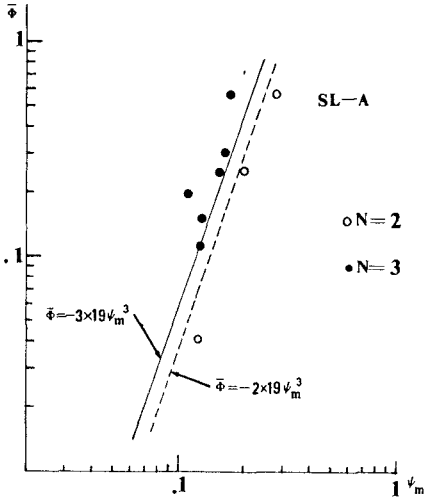

Figure 7 : Comparison with laboratory data, SL-A type

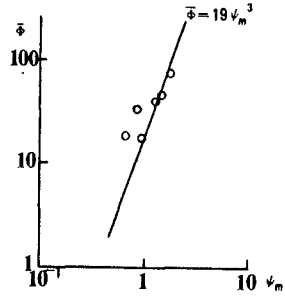

Figure 8: Transport rate for SF type

Figure 9 shows the six types of transport and their respective calculation. Although the results are too simple for general use at present, the approach of reducing the complex phenomena into simpler divisions as done here is considered to be promising.

3. TWO-DIMENSIONAL BEACH TRANSFORMATION

The transport formulas derived in the previous section are now applied to predicting beach profile change by comparing the calculation with laboratory results.

Many works had been done to analyze two-dimensional beach transformation. For example, Johnson (1949) classified beach profiles into bar and step types and first gave governing parameters by which beach type can be classified. Eagleson et al. (1963) were the first to attempt to calculate beach profile change, but the calculated results did not agree with the measured results. This is probably because they did not consider the effect of ripples. In this study, beach profile change will be discussed based on the sediment transport mechanism of ripples.

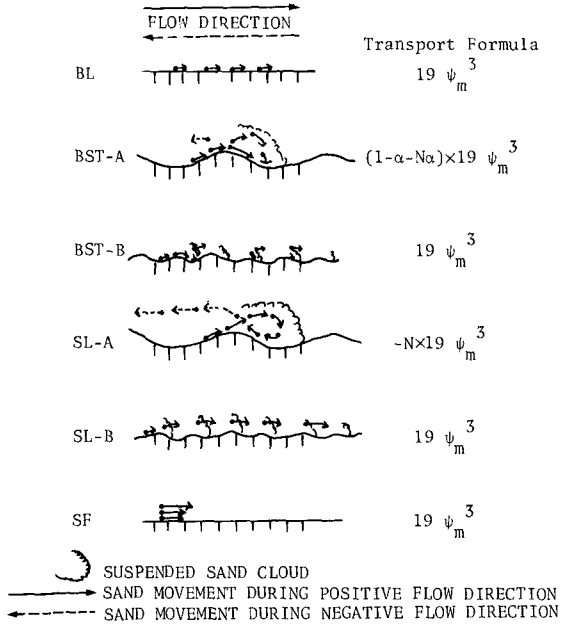

Figure 9: Sediment transport formula

In the present calculation, the above transport formulas were applied to the entire area of the beach because the same transport mechanism was observed in most areas (e.g., the transport in the breaking region was different and therefore an exception). Figure 10 shows the procedure of the computer simulation. The calculation can be started from an arbitrary initial beach profile. Wave transformation and velocity fields are calculated from the incident wave condition and bottom profile. Using the above results, the sediment transport rate can be calculated. Then the beach profile change can be calculated using the continuity equation for bed material.

In order to calculate, the following assumptions were made based on the laboratory and field investigations (see Fig. 11):

1) The wave transformation is given by linear wave theory using incident wave conditions and water depth in the offshore region. The wave breaking condition is given by Madsen (unpublished lecture notes) as

$$H_b/L_b = 0.142 \tanh\left[(0.8 + 5i)\, 2\pi h_b / L_b \right] \qquad (18)$$

where H_b is the breaking wave height, and L_b is the wave length at the breaking point. The wave height after breaking is assumed to decrease proportionate to the distance between the breaking point to the maximum run-up point. The run-up height, R, from the still water level is given by Hunt (1959) to be

$$R = 1.01\, i \sqrt{H_0 L_0} \qquad (19)$$

where i is the beach slope.

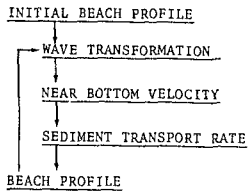

Figure 10: Procedure of computer simulation

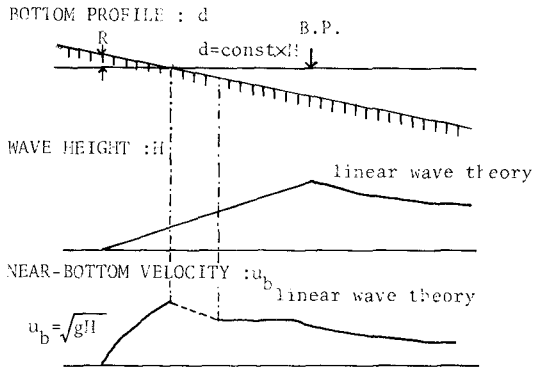

Figure 11: Assumptions for simulation

2) The maximum value of the near-bottom velocity is calculated from linear wave theory using the wave height and water depth where the wave height is less than the water depth (Region 1). In the swash zone, where beacb surface is situated above the still water level (Region 2),

$$u_b = \sqrt{gH} \tag{20}$$

is adopted as suggested by Ogawa and Shuto (1981). Here H is the local wave height. In the transition zone between Regions 1 and 2, the maximum velocity is assumed to change proportional to the distance from Region 1 to 2.

3) The sediment transport rate is calculated from the formulas in the previous section. Due to the non-linear effect of wave motion over gently sloping beaches, the maximum value of the water velocity in the onshore direction is greater than that in the offshore direction. From observation in the laboratory, the transport rate of sand which started moving during the onshore directed flow is much larger than the sand which stared moving during offshore directed flow. Therefore, we calculate only the sand which started moving during onshore directed flow. The value for BST type transport is calculated assuming a linear relationship with the Shields parameter. This means that the value changes from 0 to 1 proportionate to the Shields parameter in the area of BST transport type; i.e., $\alpha = (\psi_m - \psi_1)/(\psi_2 - \psi_1)$, where ψ_2 is the maximum Shields parameter which corresponds to BST transport type for specific u_b/w, and ψ_1 is taken as the minimum value in Fig. 2. In order to calculate the parameter N, the ripple wave length was obtained from an expression given by Nielsen (1979):

$$\lambda / D = 1.1 - 0.172 \left[u_b^2 / (s-1)gd \right]^{0.34} \tag{21}$$

The time step for the calculation is selected to be 6 s for a step-type and 1 min. for a bar-type beach. This was found acceptable for the present condition. When beach profile was calculated from transport rate, beach profile was smoothed if transport rate rapidly changed comparing with those of vicinity places.

Three sets of laboratory experiments were performed to examine the model. During the experiments, bottom profile change, suspended sediment concentration, near bottom velocity and surface profile were measured. In order to measure the near bottom velocity, polystyrene particles were injected and a 16-mm camera was used to record the movement of this tracer.

Figure 12 shows the laboratory results of beach profile change. Figure 13 shows the results of the simulation. The two results show reasonable agreement. Figures 14 and 15 give detailed comparisons of the wave height, near bottom velocity, transport rate and beach profile change.

The prediction with this model gave a good approximation to the profile change in the offshore region, but the estimate was not so good in the surf zone. This is mainly caused by the fact that in the surf zone, pure sinusoidal wave motion is no longer present, and the effect of wave breaking is very strong. The agitation due to breaking waves suspends the bed material, and the concentration of the suspended sediment in the vicinity of breaking point is high. In order to improve this model, the velocity field in the surf zone should be evaluated more precisely. A study based on this point of view was made by Shibayama and Horikawa (1982).

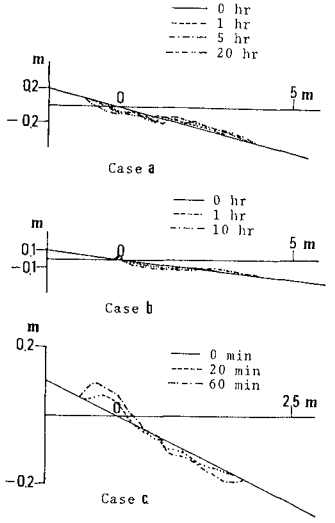

Figure 12: Laboratory results

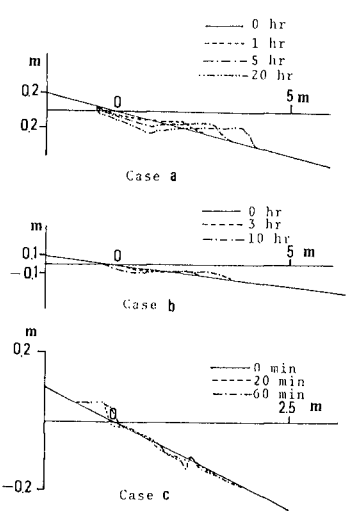

Figure 13: Simulation results

5. CONCLUSIONS

The main results of the present study are as follows:

1) Sediment transport can be classified into six types according to whether bed load or suspended load is predominant, and according to the sediment transport direction.

2) The transport type can be classified by three parameters, the Shields parameter, the ratio of maximum fluid velocity to sediment particle fall velocity, and the ratio of water particle orbital dismeter to ripple wave length.

3) By using certain assumptions and empirical information, bed load and suspended load under waves can be estimated by expressions originally derived for unidirectional bed load transport.

4) Net sediment transport formulas were developed. These expressions were applied to predict two-dimensional beach profile change in the laboratory. Reasonable agreement was obtained in regions where the wave motion can be reasonably approximated by linear wave theory.

ACKNOWLEDGEMENT

The authors thank Dr. N. C. Kraus of the Nearshore Environment Research Center for his advice in correcting an early version of the manuscript.

A PROCESS-RESPONSE MODEL FOR HURRICANE WASHOVERS

John R. Suter,[1] Dag Nummedal,[1] Amy K. Maynard,[1] and Paul Kemp[2]

ABSTRACT

The passage of Hurricane Allen over Padre Island in August 1980 presented an excellent opportunity to study the effects and controls of coastal morphology on hurricane deposits. In the Caribbean Sea, Hurricane Allen achieved a central pressure of 899 mb, making it the second strongest Atlantic hurricane ever recorded. Once in the Gulf of Mexico, the storm approached the Texas coast from the east-southeast, building a significant storm surge. Near Brownsville, the storm stalled, spending much of its energy offshore before making landfall early on August 10th near Brazos Santiago Pass at the southern tip of Padre Island.

Surge gauges show that peak recorded storm tides of about 3 m occurred at Port Mansfield, some 35 km north of landfall. Analysis of tide data indicates a time lag of some 14 hours on the rising storm tide between the Gulf and south Laguna Madre. This is due both to the limited tidal exchange across Padre Island and to set-down in the lagoon due to southward-directed cyclonic winds. By contrast, measurements taken in Corpus Christi Bay, some 180 km north of landfall, show that at that point Gulf and bay tides were in phase. The cross-barrier water level differential at South Padre Island (up to 1.5 m) greatly facilitated hurricane breaching of the island.

Oblique and vertical aerial photography show that Padre Island was breached in many places, with about 40 major hurricane channels still open several days after the storm. Surge heights were sufficient to inundate all of South Padre Island except for isolated "dune islands" resulting in broad and often coalescing washover deposits. The more continuous dune ridge on North Padre Island resulted in smaller, discrete washovers. Intensity, distribution, and morphology of washovers are functions of storm tide elevation, its phase relationships, island topography, and lagoonal water depth. The relationship is complex, yet precise enough to permit prediction of the island's response to the impact of a given storm.

Introduction

Normal, day-to-day physical processes along the northwestern shores of the Gulf of Mexico are relatively low energy. The area is micro-tidal (Hayes, 1979), and the broad, low gradient continental shelf serves to dissipate much of the incident wave energy. In this environment, storm related processes are usually dominant.

The barrier islands of the Texas coast are affected by two types of storms: extratropical cold fronts ("northers") and tropical storms and hurricanes. Both storm types have significant impact on coastal sedimentary environments, but along the Texas coast major effects on the barrier islands of the Gulf shoreline, such as breaching, overwashing, and dune planation are mostly the result of hurricanes.

The last such storm to impact the Texas coast was Hurricane Allen, which made landfall over Padre Island on August 10, 1980 (Figure 1). Oblique and vertical aerial photography showed that the island was breached in many places, and that a variety of washover deposits were laid down. Tide gauge data indicate a time lag of some 14 hours on the rising storm tide between the Gulf of Mexico and the south Laguna Madre. This time lag, or phase difference, set up a cross-barrier water level differential of up to 1.5 m. In this paper, we simulate the currents that could have resulted from storm surge, examine the regional variability in washover types, and discuss the interactions between the storm surge and island morphology.

Hurricanes as Geologic Agents

The importance of hurricanes as geologic agents has been recognized by many workers, and a number of excellent case studies exist in the literature (e.g., Hayes, 1967; Scott and others, 1969; McGowen and others, 1970; Nummedal and others, 1980). A general review of hurricane effects on the Texas coast was presented by McGowen and Scott (1975). Hurricanes are accompanied by torrential rains and high winds, but long term geologic effects are usually the result of the super elevated sea level known as storm surge. Surge height controls the extent of flooding, and permits higher breakers to be brought closer to shore, increasing the incident wave energy.

The sea level variation associated with hurricanes is governed by a number of independent factors, which can be broadly grouped as meteorologic, or those pertaining to a given storm, and geographic, or those relating to the area affected. Meteorologic parameters include the central pressure index (the ratio of pressure in the storm's center to that on its periphery), which causes the bulge-up of water called the "inverse barometer effect", and the frictional stress of the hurricane winds on the water surface, which results in a set-up at the coastline. These factors are functions of a storm's size, intensity, overwater duration, and angle of approach (Simpson and Riehl, 1981).

A given hurricane will produce greatly different surge heights depending upon where it makes landfall, primarily as a result of shoaling of the surge on the continental shelf, and local shoreline configuration. Embayed coastlines will experience a greater surge than open, straight coasts, and broader continental shelves produce greater surges in their corresponding land areas that narrower ones. Figure 2 shows the magnitude of this "shoaling factor" for the Northwestern Gulf of Mexico

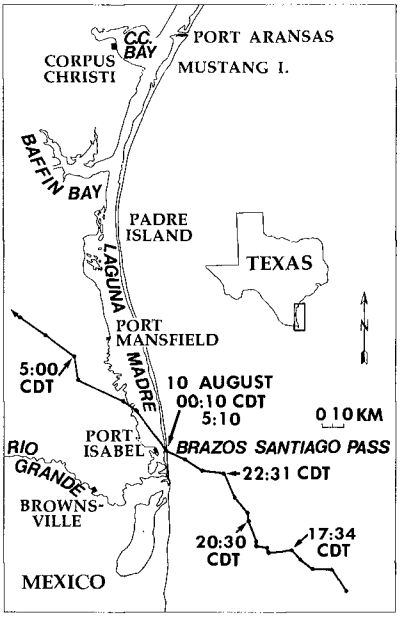

Figure 1. Plan view of Padre-Mustang Barrier Island System along the South Texas coast, northwest Gulf of Mexico. Also shown is the track of Hurricane Allen as it approached landfall (radar data from National Weather Service).

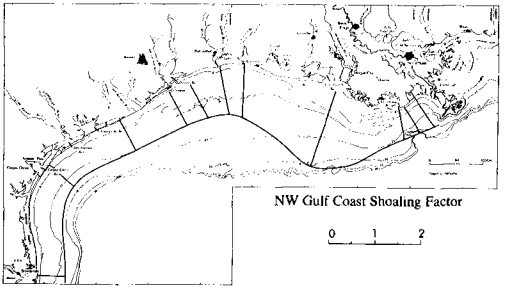

Figure 2. Distribution of the hurricane surge shoaling factor along the northwest coast of the Gulf of Mexico (after Jelesnianski, [1972]).

(Jelesnianski, 1972). From this, it can be seen that a landfalling hurricane will produce a considerably higher surge off the western Louisiana coast than at South Padre Island, Texas.

Superimposed on the storm surge are the effects of astronomical tides and wave set-up. Wave set-up is the nearshore water super elevation produced by the shoaling and breaking of a wave train. These factors combine to produce the actual storm tide (after Coastal Engineering Research Center, 1973). In some areas, wave set-up and/or astronomical tides can be of great significance, but in the northwestern Gulf of Mexico, storm surge is overwhelmingly dominant for large storms. Values given in this paper refer to actual storm tide levels.

Studies of hurricanes on the Gulf coast have led to a general geological effects model for storm impact, separating storm processes and coastal responses in chronological order (Hayes, 1967; McGowen and others, 1970; Nummedal and others, 1980). Storm approach is accompanied by rising waters, waves and wind, which attack the barrier islands, resulting in dune erosion, island breaching, and deposition of washovers on the surge flood. The counterclockwise circulation of the storm (Figure 3) causes the greatest energy to be concentrated in the right front quadrant. Thus, surge heights and storm effects are always greatest north of landfall. As the storm moves onshore, wind shifts produce changes in currents south of the eye, and modification of flood deposits begins. Storm aftermath is marked by the surge ebb, as well as high rains inland.

Storm Tide of Hurricane Allen

Hurricane Allen deviated somewhat from the generalized pattern discussed above. Allen became a hurricane in early August of 1980. While still in the Caribbean Sea, it achieved a central pressure of 899 mb, making it the second strongest Atlantic hurricane on record (an unnamed storm in 1935 attained a central pressure of 892 mb; U.S. Army Corps of Engineers, 1980). Once in the Gulf of Mexico, Allen headed more or less directly for the south Texas coast.

The U.S. Army Corps of Engineers maintains a network of continuously recording tide gauges, as well as surge and crest gauges, along the coast of Texas. Figure 4 shows the distribution of Hurricane Allen's storm tides, as measured by surge and crest gauges, which record peak water levels. Highest open coast storm tide for Allen was slightly less than 3 m at South Padre Island, while the highest bay tides were over 3 m near Corpus Christi. In most plots of this type, the highest storm tides occur in bays or lagoons, where local funneling and wind stress in restricted basins are pronounced (Simpson & Riehl, 1981). Possibly Allen's storm tides may have been higher in the area between South Padre Island and Baffin Bay, but no readings exist for that stretch of coast.

The relatively diffuse nature of Hurricane Allen's surge contrasts sharply with the more peaked asymmetric pattern of the storm tide of Hurricane Carla in 1961 (Figure 4). Carla was a large, intense storm and produced the highest storm tides ever measured on the Texas coast, almost 4 m. The more intense surge felt to the north of landfall is a pattern typical of a direct approach. The diffuse pattern of Allen's surge can be explained in terms of the offshore stallout and subsequent weakening of the storm, as well as the lower data density.

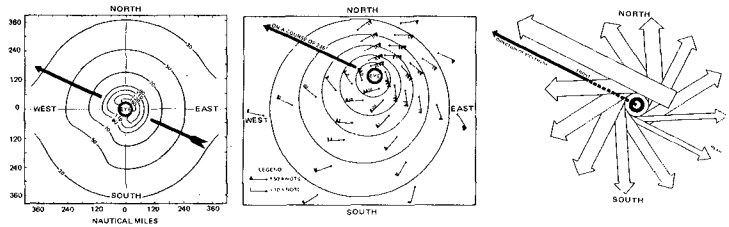

Figure 3. Distribution of pressure, surface winds, and waves within a typical northern hemisphere tropical storm (from Crutcher and Quayle [1974]).

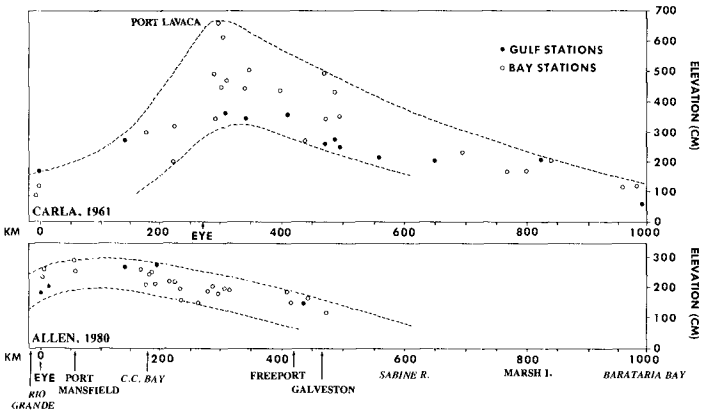

Figure 4. Distribution of observed maximum storm tides along Texas coast for Hurricanes Allen and Carla. Note the peaks occur to the north (or east) of landfall, and that bay tides are much higher than on the open Gulf. Data from Harris (1963) (Carla) and U.S. Army Corps of Engineers (1980) (Allen).

As the storm neared the Texas coast, it stalled offshore for over 24 hours before making landfall (Figure 5). During this time, the storm weakened considerably. Central pressure had risen to 945 mb just before landfall. As a result, the storm surge flood stage was considerably prolonged and diffused.

Early in the morning of August 10, Allen moved onshore just north of Brazos Santiago Pass on South Padre Island, thus spending most of its energy on the least populated stretch of the Texas coast. The major effects of the storm on Padre Island can be understood by a consideration of the regional and local geology.

Regional Geology of the Texas Coast

The southernmost links in the Texas barrier island chain are Mustang and Padre Islands (Figure 1). Taken as a whole, from Aransas Pass in the north of Brazos Santiago Pass in the south, over 200 km of unbroken barrier island faces the Gulf of Mexico. At one time, the two islands were separated by a series of inlets at the southern end of Corpus Christi Bay. Most stable tidal inlets on the Texas coast are located at the southeastern tip of the estuarine basin, where their positions are maintained by north winds during frontal passage. However, deepening of Aransas Pass in the 1920's to accomodate shipping to the Port of Corpus Christi diverted enough of the tidal flow to result in the choking off of the Packery Channel/Corpus Christi Pass inlets (Price and Parker, 1979). Presently, tidal exchange between the Gulf and estuaries in this area occurs only at the northern and southern extremes, and through two shallow artificial cuts, Mansfield Pass in Central Padre Island and Corpus Christi Fish Pass in Mustang Island.

The Padre-Mustang barrier system creates and maintains the extensive Corpus Christi Bay and Laguna Madre estuarine complex. Corpus Christi Bay occupies the valley of the Pleistocene Nueces River, while the linear Laguna Madre lies on a drainage divide. Both are actively infilling with sediment; the process being more apparent in the shallow lagoon, which averages less than one meter in depth and is in fact often emergent in its central reaches. This difference in back barrier basin morphology produces significant variations in hurricane responses.

The Padre-Mustang Barrier system itself displays a north-south morphologic dichotomy. Mustang, North, and Central Padre Islands are relatively broad, high-profile features with continuous foredune ridges of up to 10 m. In the vicinity of Mansfield Pass, island topography changes to a narrow, lower profile with poorly developed, discontinuous foredunes. Morton (1977, 1979 b) showed that regional variations in barrier island types could be correlated with positions relative to deltaic headlands. Near the deltas, thin, transgressive, low profile barriers occur; while within the interdeltaic embayments, thicker, broader, high profile barrier islands are formed (Figure 6). The regional distribution of erosional and stable landforms shown in Figure 7 can be explained by envisioning that wave refraction around deltaic headlands would produce cells of longshore drift convergence in the embayments. Throughout the Holocene, the decreased delivery of coarse sediments has combined with the wave energy concentration at the headlands and compactional subsidence of deltaic deposits to produce headland erosion. Longshore drift convergence concentrated sand in the embayments, producing the accretionary high profile islands. Today, the process has effectively straightened

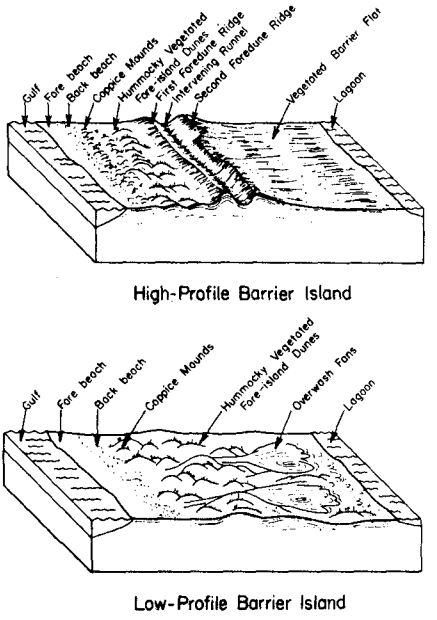

Figure 5. Diagram of high- and low-profile barrier island types. Mustang and North Padre Islands are high profile, while South Padre Island is low-profile, and thus more vulnerable to hurricane washover (from White and others, 1978).

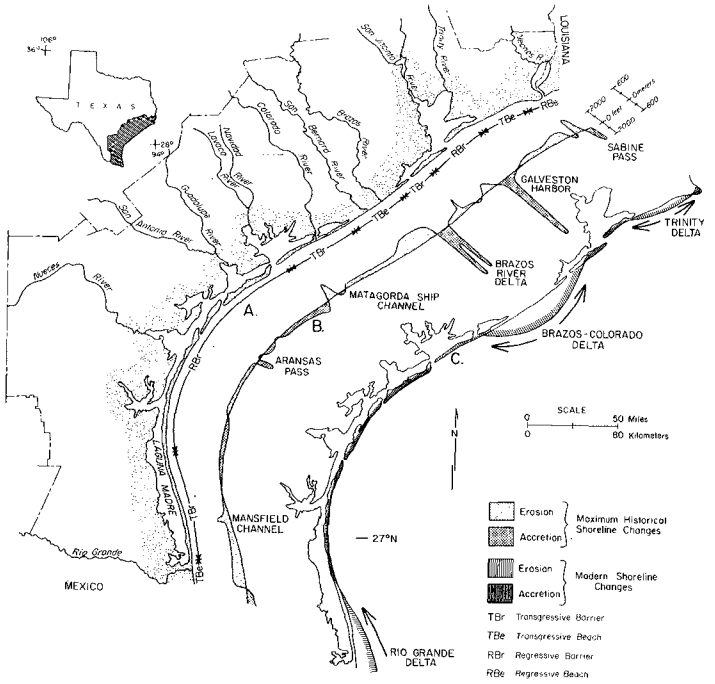

Figure 6. Maps showing (A) morphogenic provinces of the Texas coast, (B) maximum shoreline changes between 1850-83 and 1973-75, and (C) hypothesized late Holocene shoreline showing major promontories and long-shore drift cells. Maximum rates of erosion and low profile barriers occur near deltaic headlands, while accretion and high profile barriers occur in embayments. Long-shore drift convergence is now in the area of 27° N. From Morton (1979b).

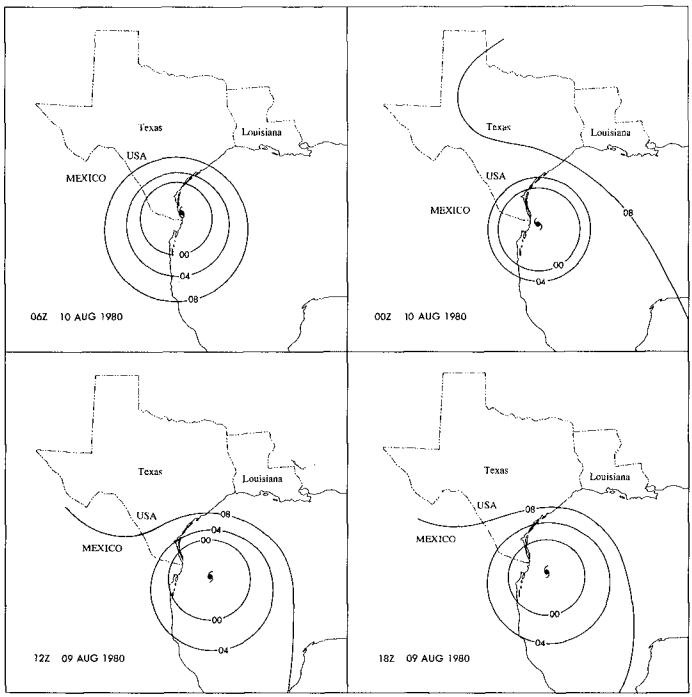

Figure 7. Series of simplified weather maps showing leisurely approach and weakening of Hurricane Allen offshore as it made landfall (data from National Weather Service).

out the Texas Gulf shoreline, and the pattern of drift has changed, converging now on Central Padre Island.

South Padre Island formed on an abandoned lobe of the Holocene Rio Grande Delta (Brown and others, 1980) while Central and North Padre and Mustang Islands formed in the embayment between the Rio Grande and Brazos-Colorado deltas (Brown and others 1976, 1977). South Padre is actively eroding (Morton, 1977) while the remainder of Padre and Mustang Islands are stable, owing to the current longshore drift convergence pattern. This contrast between the island types is well displayed by their response to Hurricane Allen.

Storm Surge Simulations

In the immediate vicinity of landfall, continuous recording tide gauges at Cameron Pier on the Gulf side and Gulf Intracoastal Waterway Marker 75 in Laguna Madre showed marked differences in water level response (Figure 8a). Significant and continuous rise in water levels began on late August 8th on the Gulf side, but lagoonal waters rose some 14 hours later. This time lag, or phase difference in the gulf and lagoon surges, is attributed to the southward directed cyclonic winds of the hurricane piling waters toward the southern outlet at Brazos Santiago Pass. Once Gulf water levels exceeded 1 m, washover of South Padre Island began, causing the lagoonal water levels to begin rising. Peak water in Laguna Madre exceeded 2.5 m before the shift in winds as the hurricane made landfall drove the waters back through hurricane channels.

Similar measurements taken at Brazos Santiago Pass to the south and at Aransas Pass to the north do not display this pattern (Figures 8b, c). There, Gulf and lagoonal surges are in phase. The set-up of water at the south end of Laguna Madre and the passage of surge waters through the inlet at Brazos Santiago combined to produce the in-phase measurements recorded there. Corpus Christi Bay has a considerably different morphology than Laguna Madre, and experienced lesser winds due to its distance from landfall.

The time lag between Gulf and lagoonal surges on the rising storm tide suggests that gravity-driven currents may have been quite strong once breaching of the island occurred. Figure 9 shows simple current velocity simulations derived from the surge level differentials using the Manning equation.

The roughness factor, n, is assumed to be 0.03, the value given by Chow (1959) for sandy streams, and also the average of that measured by Watson and Behrens (1976) during tidal current measurements in the newly dredged Corpus Christi Fish Pass. Barrier width is set at 900 m, we assume that the entire water level differential corresponds to the drop across the barrier, and lagoonal water levels are assumed to be horizontal.

Flow regime 1 simulates the currents for unconfined sheet overwash, with a flow depth of 30 cm. Velocities increase during the rising storm tide, peaking at 55 cm/sec at midnight August 8, and persisting for almost 24 hours. This period should represent the time of most active transfer of Gulf water into Laguna Madre. Due to the lesser elevation differentials, ebb velocities are generally slower, peaking at 46 cm/sec, and shorter lived.

Since a very large number of hurricane channels were cut across

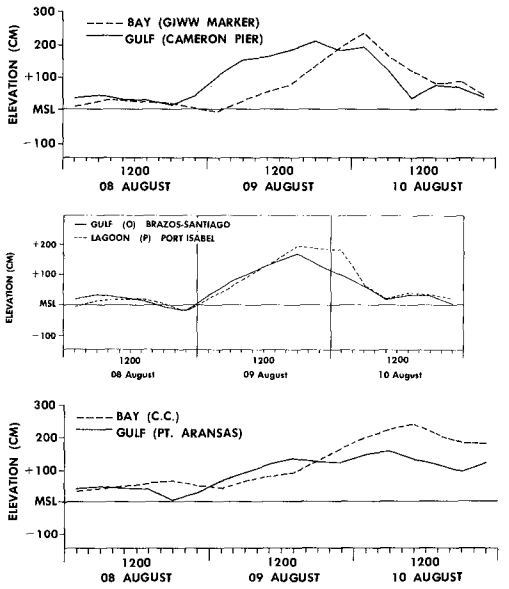

Figure 8. Time series of water surface elevations during impact of Hurricane Allen on south Texas coast, taken from continuous recording tide gauges. A) South Padre Island, B) Brazos Santiago Pass, C) Aransas Pass and Corpus Christi Bay. See Figure 1 for locations.

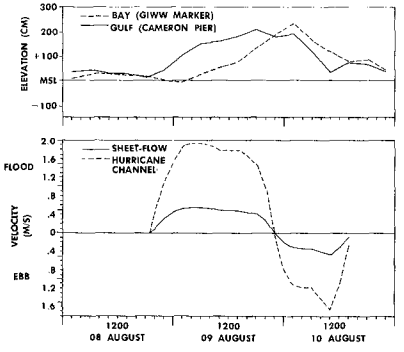

Figure 9. Current velocity simulations for flow across South Padre Island, based on Manning equation. Data from Figure 8A. Flow Regime 1 is for 30-cm deep sheet overwash; Flow Regime 2 refers to 2-m deep hurricane channel.

Padre Island, perhaps a more realistic picture is given by flow regime 2, which corresponds to flow in a confined hurricane channel of 2 m depth. Calculated velocities, as expected, are much higher. During surge flood, a strong lagoonward current of up to 1.92 m/sec persists for almost 24 hours. Maximum simulated ebb velocities reached 1.62 m/sec as surge waters returned to the Gulf.

These simulations represent the simplest case, and refer only to gravity driven currents. More sophisticated techniques should include consideration of wave pump (Bruun and Kjelstrup, 1979) and wind stress. Morton (1979 a) analyzed back barrier bedforms, and estimated wind driven currents in the range of 1.3 to 1.9 m/sec, very similar to those calculated here. The interaction of such intense currents produces the complex patterns of sediment dispersal seen on the back barrier flats.

Greater surge flood currents and the longer duration of the flood versus the ebb cast light on the timing of island breaching. The morphology of hurricane deposits on the back barrier clearly indicates that they are laid down on the surge flood, so it is likely that most of the breaches are initiated on the seaward side of barriers. However, breaches are also known to have occurred from the back side on surge ebb currents as shown by the opening of Pass Drury, Alabama after Hurricane Frederic in 1979 (Nummedal and others, 1980).

Another problem lies in the origin of widespread coarse grained deposits on continental shelves known to occur after major storms. Hayes (1967) suggested that these sediments were deposited by density currents in the ebb surge out of hurricane channels, while Morton (1981) contended that wind induced shoreface bottom return flow (Csanady, 1976; Swift, 1976) was responsible. The morphology of South Padre Island washovers indicate that there was a moderate amount of seaward sediment transport during the storm surge ebb. Current measurements during earlier storms (Forristal and others 1977; Murray, 1970) indicate that seaward shoreface currents peak before or during lamdfall. Therefore, we suggest that both mechanisms provide sediment for the inner shelf graded storm beds.

Washover Channels

The north-south dichotomy of form of the Padre-Mustang system is well illustrated by Figure 10, which shows the location and number of hurricane washover channels cut across the island by Hurricane Allen. Mapping of the channels was done primarily from high altitude photographs taken by NASA ten days after landfall.

Clearly, the vast majority of the breaches occurred along the southern portion of the barriers, due both to the proximity to the point of landfall and the low profile nature of South Padre Island. Surges of over 2 m were experienced all along the barrier system, but foredune height and ridge continuity prevented breaching in the higher profile segments further north.

The abrupt disappearance of washover channels on the northern section of the system is difficult to explain fully, but relates to a gradual transition to a continuous foredune ridge from south to north, and to the resolution of the 10 km sampling interval. Sudden reappearance of major channels at 170 km is due to re-opening of the old tidal inlets that once separated the two islands.

Spacing of the channels presents intriguing problems. Most workers

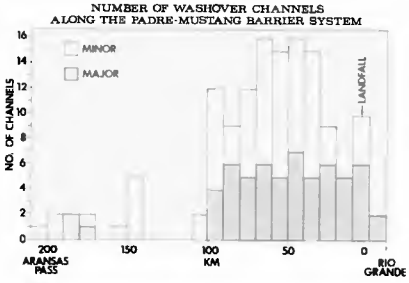

Figure 10. Locations of hurricane channels cut across Padre-Mustang Barrier System by Hurricane Allen. Major channels are those cut below mean sea level, minor channels are less deep.

Figure 11. Vertical aerial photograph showing irregular periodicity of washover channel spacing on Central Padre Island (photo taken 8/20/80).

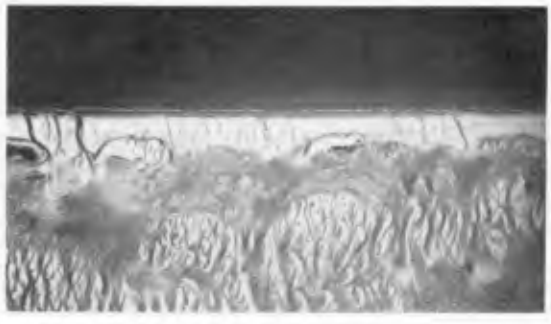

Figure 12. Vertical aerial photograph of washover terrace on South Padre Island, fed by multiple minor and major channels. Note regular channel spacing (photo taken 8/20/80).

attribute locations of washovers to island topography, but there is certain periodicity to the location of the channels within the heavily breached southern area. A series of major washover channels spaced approximately 2.5 km apart begins abruptly at 100 km, coinciding almost exactly with the beginning of the emergent portion of the Laguna Madre. Periodicity also exists in the spacing of minor washover channels in some areas (Figure 12).

This suggests the possibility that some surf zone phenomenon may be enhancing surge levels at regular intervals, and controlling or contributing to location of island breaching, as suggested by Dolan and Hayden (1981). This argument is complicated by the fact that the position of breaches is largely inherited from previous storms. Locations of Hurricane Allen channels coincide with those cut by Hurricane Beulah in 1967. It appears that periodic phenomena are operating, but that pre-existing topography also determines washover location.

Morphology of Washovers

Surge height elevation and barrier geometry not only control the number of hurricane breaches, but also the form of the resulting washover deposit. A variety of washover deposits were laid down by Hurrican Allen. Their type and location can be systematically related to geomorphologic characteristics of the barriers.

Along the higher profile portions of Mustang and Padre Islands, surge heights were insufficient to breach the foredune ridge. Minor discontinuities, such as aeolian blowouts, were attacked and relatively small, discrete interdune fans were deposited (Figure 13). Locally, interdune fans were laid down at two different levels as the storm surge rose, creating a double washover contained within the foredune ridge. Other examples of interdune fans occurred in areas of South Padre with extensive back island fields.

At the other end of the spectrum, washover terraces occurred in areas where the foredune ridge is discontinuous to absent (Figure 12). On south Padre Island, a continuous washover terrace is created by coalescing washover deposits fed by numerous hurricane channels. This contrasts with other examples of such deposits which are generally the result of sheet overwash, such as can be found along other low profile barriers of the Texas and Louisiana coasts (Morton, 1979 a; Boyd and Penland, 1981).

Where the foredunes are extant but discontinuous, channelization of surge resulted in the cutting of major hurricane channels which deposit the washover fan (Figure 14). These washovers are an order of magnitude larger than interdune fans, and are a major features. The form and thickness of the washover fan is determined by the relationship between surge strength and water depth within the back barrier basin. Those deposits laid down by Hurricane Allen have considerable variability in detail, but all are more or less heart shaped owing to flow onto the broad, low gradient back barrier flats of Central and South Padre Islands. Figure 14 approaches the ideal form of such features. Nowhere on Padre Island were any flame shaped washovers (Morton, 1979; Nummedal and others, 1980) seen. These have been reported from the Matagorda Peninsula of Texas (Morton, 1979 a) and Dauphin Island, Alabama (Figure 15; Nummedal and others, 1980). In both of these cases, there was considerable water depths in the back barrier basin at the time of breach-

Figure 13. Oblique aerial photograph of small interdune fan deposited within dune ridge on Mustang Island (photo taken 8/20/80).

Figure 14. Vertical aerial photograph of washover fan fed by major hurricane channel on South Padre Island. Dunes create channelization of flow (photo taken 8/20/80).

ing. As the surge waters crossed the barriers and encountered the deeper water, a hydraulic jump occurred, and the flame shaped washovers were deposited. Lack of these features on South Padre Island is attributed to much different morphology of the back barrier and the shallower Laguna Madre.

The last major washover type was of limited extent due to its specialized nature. The reactivated tidal delta occurred only in the area of juncture between Mustang and Padre Islands, where major breaks in the foredune ridge are located in the choked off tidal inlets (Figure 16). These deposits are the largest washovers laid down by Hurricane Allen, and actually represent modifications of pre-existing flood tidal delta deposits. As such, they would be very difficult to distinguish as washovers in ancient deposits. However, they are illustrative of the fact that interdune fans are not the only type of hurricane deposit that can be expected in high profile barrier islands. Indeed, deposits of this type may be the most significant stratigraphically. Examination of barriers along the Texas coast reveals an extensive series of large, arcuate forms on the back sides of barriers which probably represent washover modified flood tidal deltas (Andrews, 1970). Differences in older and younger deposits no doubt reflect variations through time in island morphology and storm intensity and numbers.

Summary and Conclusions

Hurricane Allen's impact on the south Texas coast confirmed many of the previous concepts of geologic effects of hurricanes on barrier islands. Aerial photography and ground observations revealed that four main types of washover deposits occurred: interdune fans in areas with continuous foredunes, washover terraces in areas with few foredunes, washover fans in areas where the foredune ridge is discontinuous, and reactivated tidal deltas in relict tidal inlets. A number of factors control the form and location of the washovers including storm surge height, barrier island topography and geometry, position relative to storm landfall, and water depth in the back barrier basin. Further analysis may reveal the existence of periodic phenomena interacting with these factors to control washover location. The relationships cannot be easily quantified, but can be easily understood conceptually and applied by coastal planners, engineers, and geologists.

In closing, it is worth mentioning that effects of hurricanes on barrier islands is a subject of increased importance in the years ahead. If there is indeed a secular warming trend caused by inceased CO_2 levels in the atmosphere (Hansen and others, 1981), it can be expected that hurricanes will increase in both number and intensity (Nummedal, 1982). Such increases, coupled with rising sea levels accompanying the global warming and the major population shift to coastal areas, would make the prospect of major hurricane problems in the future a gloomy one indeed.

NATURAL BAR-BYPASSING OF SAND AT A TIDAL INLET

Walter J. Sexton[1] and Miles O. Hayes[1,2]

ABSTRACT

Captain Sam's Inlet, a shallow unstable inlet, periodically migrates up to three kilometers (km) alongshore over a 30- to 40-year period. As the inlet migrates, sediment accumulates at the seaward terminus of the tidal inlet to form a wave-modified ebb-tidal delta that trends downdrift. Continued sediment accumulation on the tidal-delta shoal and subsequent lengthening of the tidal channel in a downdrift direction results in an unstable channel configuration. The ebb delta is eventually breached on its updrift side, releasing a sediment package for inlet bypassing.

The sediment-bypassing process was initiated at Captain Sam's Inlet after the final landfall of Hurricane DAVID in September 1979. Initially, the newly formed updrift hurricane channel scoured 1.1 m, migrated updrift, and became the predominant tidal channel at the inlet with eventual abandonment of the prehurricane, main ebb channel. These two channels outlined a portion of the ebb-tidal delta that was freed for bypassing. The initial sediment volume contained in the bypassing shoal, above the -0.6 m (-2 ft) MSL contour, was 47,000m^3. The sediment volume of the bypassing shoal did not change significantly until final attachment to Seabrook Island. This channel dominance and the wave-induced migration of the bypassing sediment package aided the bypassing of sand at the inlet. Immediately after filling of the prehurricane, main ebb channel on the delta, the downdrift beaches began accreting. The accretion continued throughout the bypassing process. The tidal prism and cross-sectional area reflected little change during the bypass, showing evidence of the system's overall stability.

INTRODUCTION

Sediment bypassing at tidal inlets is an essential process in maintaining a balanced sediment budget along a barrier island chain. Since bar-bypassing was first identified (Bruun and Gerritsen, 1959), few field studies have been conducted documenting the process.

Captain Sam's Inlet, located on the central South Carolina coastline, is a small tidal inlet with a downdrift-trending ebb-tidal delta (Fig. 1). Previous studies of the inlet (Hubbard, 1977; FitzGerald, 1980) indicated that large volumes of sediment frequently migrate across the inlet. This sediment migrates in the form of a nearshore bar from the updrift side of the inlet to the downdrift side.

Continued sediment accumulation on the tidal delta and progressive extension of the main ebb channel in a downdrift direction results in an unstable channel configuration. The ebb delta is eventually breached on its updrift side, releasing a packet of sediment for inlet bypassing (Fig. 2).

Utilizing the previous material published on tidal inlet dynamics, work done by Bruun and Gerritsen (1959), who first identified tidal inlet sediment bypassing, and observations made by Hubbard (1977) and FitzGerald (1980) at Captain Sam's Inlet, a preliminary understanding of the sediment bypassing process was possible. Hubbard (1977) determined a simplified model of bar-bypassing from the observations made at Captain Sam's Inlet and other similar tidal inlets along the South Carolina coastline (Fig.2).

The objective of this study was to quantitatively study the actual process of bar-bypassing which occurred at Captain Sam's Inlet during the switch in channels due to Hurricane DAVID. Utilizing bathymetric maps, beach profiles, and current and tide data collected during the bypass, quantitative calculations of sediment volumes and tidal inlet hydraulics were possible.

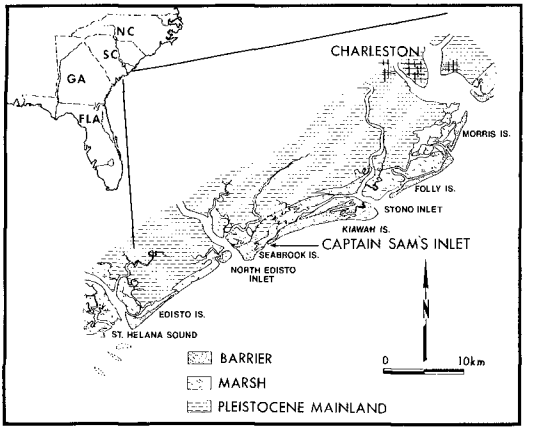

FIGURE 1. Location map of Captain Sam's Inlet, South Carolina. Captain Sam's Inlet is a small tidal inlet in comparison with its neighboring tidal inlets, Stono and North Edisto. The difference in inlet size is partially the result of the relationship between the cross-sectional geometry of the inlet and the back-barrier system.

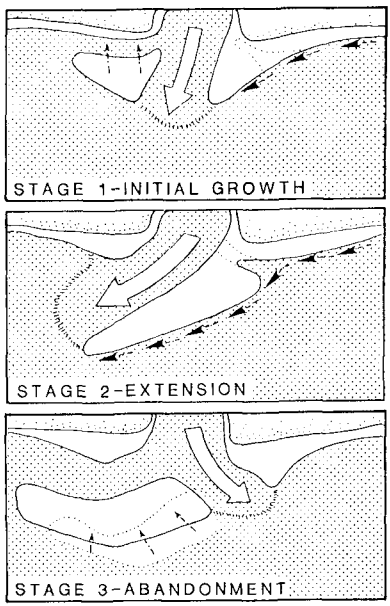

FIGURE 2.

A simplified three-stage model of bar-bypassing (after Hubbard, 1977):

1) Initial growth, sediments accumulating, forming a downdrift-trending delta.

2) Continued accretional growth, approaching an overextended configuration.

3) Breachment of the overextended delta, abandonment of the prebreachment main channel, followed by landward migration of the nearshore bar (swash bar).

PHYSICAL SETTING

The study area is influenced by prevailing winds from the south-southwest and storm winds generally from the northeast. Winds from the south-southwest occur 28 percent of the time. Even though northeast winds are less frequent than the prevailing south-southwest winds, their greater strength results in significant waves, energy flux, and longshore transport directed to the southeast in the study area (Finley, 1975).

Winds of hurricane strength [exceeding 75 miles per hour (mph)] have a frequency of occurrence along South Carolina of one event every 14 years (Myers, 1975). These winds are relatively rare at Captain Sam's Inlet, but can cause significant geomorphic changes on local beaches (Sexton and Moslow, 1981). Average wave heights on the South Carolina coastline are 50-60 centimeters (cm) (Finley, 1976; Kana, 1977). Tides at Captain Sam's Inlet range from 1.4 meters (m) (neap tide) to 2.2 m (spring tide) and are semidiurnal in nature. The tidal range is mesotidal (2-4 m), using Davies (1964) classification. These tides rarely reach heights above 2.2 m except during storm conditions.

Net longshore transport of sediment on the South Carolina coastline is predominantly from the northeast to the southwest (Finley, 1976; FitzGerald, 1977; Kana, 1977; Knoth and Nummedal, 1977). This

dominance of southerly transport is evidenced by numerous south-southwest-trending geomorphic features (e.g., recurved spits, tidal inlets) along the South Carolina shoreline. Transport rates are on the order of 75,000-300,000 m^3/yr. These values are based on measurements taken during several studies on the South Carolina coast, both on central portions of barrier islands and near tidal inlets (Finley, 1976; Kana, 1977; FitzGerald, 1977; Knoth and Nummedal, 1979).

Sediments are fine-grained quartz sand (mean grain size = 2.82 phi units or 137 microns) and are well sorted. Samples taken at dunes were very well sorted, and sorting of the sand in the intertidal area of the inlet improved when exposed to active wave swash (e.g., top of bypassing shoal, active beach face).

DATA BASE

BATHYMETRIC MAPPING

Three bathymetric maps were produced from surveys of Captain Sam's Inlet during September 1979, January 1980, and June 1980. The inlet was surveyed with a Hewlett-Packard 1038 total-station microwave transit. This instrument has a horizontal accuracy of six millimeters (mm) per km and a vertical accuracy of 0.3 mm/km. The precise nature of these surveys allowed quantitative comparisons of sediment volumes at the inlet.

BEACH PROFILES

A sampling grid of 11 beach profile stations was established at the beginning of the study. Profiles of the beach and inlet configuration for the 11 stations were taken six times throughout the 10-month study using the Emery (1961) method.

CURRENT MEASUREMENTS

Tidal currents were monitored six times during the 10-month field study. The first five current surveys were taken using a ducted impellar current meter, modified after a design presented by Byrne and Boon (1973), whereas the final tidal current survey was conducted using a Marsh-McBirney Model 201 electromagnetic flowmeter. Tidal currents were monitored for a minimum of 13 hours during each survey, beginning one hour before slack low water and running until the next slack low.

AERIAL PHOTOGRAPHS AND COASTAL CHARTS

Historical shoreline changes at Captain Sam's Inlet were determined using 12 historical charts dating from 1696 to 1924 and seven photo mosaics dating from 1939 to 1979. Also during the 10-month bypass, seven overflights were made for observation and oblique photography.

BAR-BYPASSING AT CAPTAIN SAM'S INLET, SEPTEMBER 1979 THROUGH JUNE 1980

On 4 September 1979, Hurricane DAVID made final landfall on the southern portion of the South Carolina coast. The storm was a moderate hurricane and maximum winds reached 90 mph (Sexton and Moslow, 1981). The associated storm tides (0.5-1.0 m above normal), and waves caused considerable damage to the southern and central coastline of South Carolina. At Captain Sam's Inlet, a new channel was scoured through the ebb delta to the north of the previous main tidal channel (Fig. 3). This newly formed channel was important because, as shown in previous studies of the area (Hubbard, 1977; Hayes et al., 1979), it initiated the bar-bypassing process.

Within two weeks of the landfall of Hurricane DAVID, a field study was initiated to monitor the bar-bypass process. On September 17 and 18, detailed bathymetric surveys of the inlet were made (Fig. 4) and 11 beach profile stations were established on the adjacent beaches as shown in Figure 4.

Utilizing the bathymetric map surveyed during the study, the volume of sediment contained in the bypassing shoal above the -0.6 m (-2 ft) mean sea level (MSL) contour area shown on Figure 3 was calculated using the prismoidal formula (Hodgman, 1947):

$$V = 1/6\ H(S_0 + 4S_1 + S_2)$$

where V = shoal's volume
H = height of shoal (difference between top and base contours)
S = plane variable.

The total volume for the shoal, released for bar-bypassing above the -0.6 m contour, was 47,510 m^3.

FIGURE 3. Photo mosaic of Captain Sam's Inlet and vicinity taken at low tide on 23 September 1979. The area mapped is bordered in black and the white arrow points to the hurricane channel.

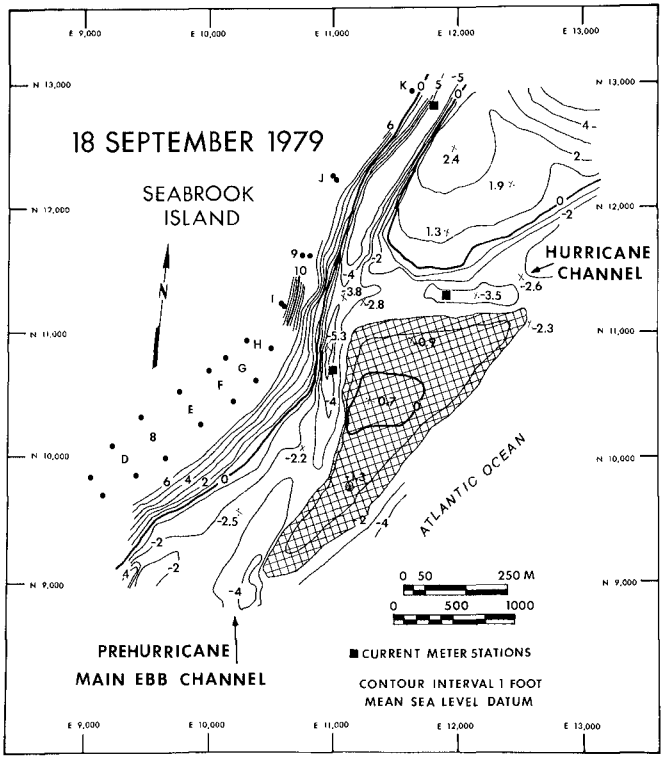

FIGURE 4. Bathymetric map of Captain Sam's Inlet, surveyed in September 1979, 14 days after hurricane landfall. Note the positions and depths of both the prehurricane, main ebb channel and hurricane channel. The hatched area on the delta was used for sediment-volume calculations and outlines the bypassing shoal.

Beach profiling across the ebb-tidal delta was quite unique and was possible only because of the shallow tidal channels at the inlet. Review of the beach profiles provides a cross-sectional view of the geomorphic form of the inlet whereas the bathymetric map is a plan view. From the beach profile data taken in September 1979, a variety of beach configurations were identified (Fig. 5).

The beach profile plot for Station E (Fig. 5) begins in a field of immature, prograding beach ridges and traverses a low-amplitude foredune ridge onto a steep beach face. Seaward of the active beach face lies a 110-m-wide bay that terminates at the toe of the southern

portion of the delta at the inlet. Beach profile Station J (Fig. 5) is positioned along the most unstable section of coastline at Captain Sam's Inlet. Previous studies (Hayes et al., 1976; Sexton and Hayes, 1980) measured erosion rates of 40-60 m/yr in this vicinity. At Station J there is a large (2.5 m) erosional scarp with a narrow beach face that slopes into the Kiawah River. Seaward of the river lies the broad intertidal recurved spit platform.

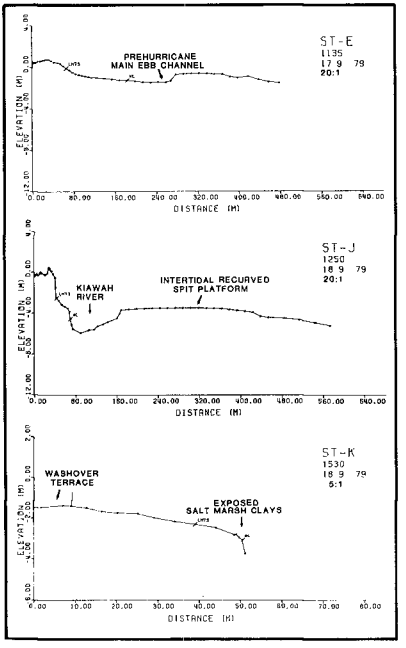

FIGURE 5.

Plots of beach profiles monitored in September 1979. Station locations are shown in Figure 4. The variety of beach configurations located in the small area indicate the high degree of variability in shoreline conditions. Also observe the total distance of each profile and the changes in vertical exaggeration (5:1; 2:1).

During the four months following the hurricane, the inlet was monitored closely to document the change that had occurred. In early January 1980, a second bathymetric map was constructed (Fig. 6). The morphology of the inlet area had changed significantly since September (Fig. 4). Some of the more outstanding changes were:

1) The hurricane channel had scoured 0.7 m deeper and had shifted 80 m to the north.

2) A new middle channel had formed, truncating the northern tip of the bypassing shoal.

3) The bypassing shoal had migrated 215 m landward and 164 m downdrift in a southwesterly direction.

4) The prehurricane, main ebb channel had been filled with as much as 1.3 m of sediment.

5) Sediment volumes contained in the bypassing shoal, the volume above the -0.6 m MSL contour, had not changed significantly since September remaining at approximately 50,000 m^3.

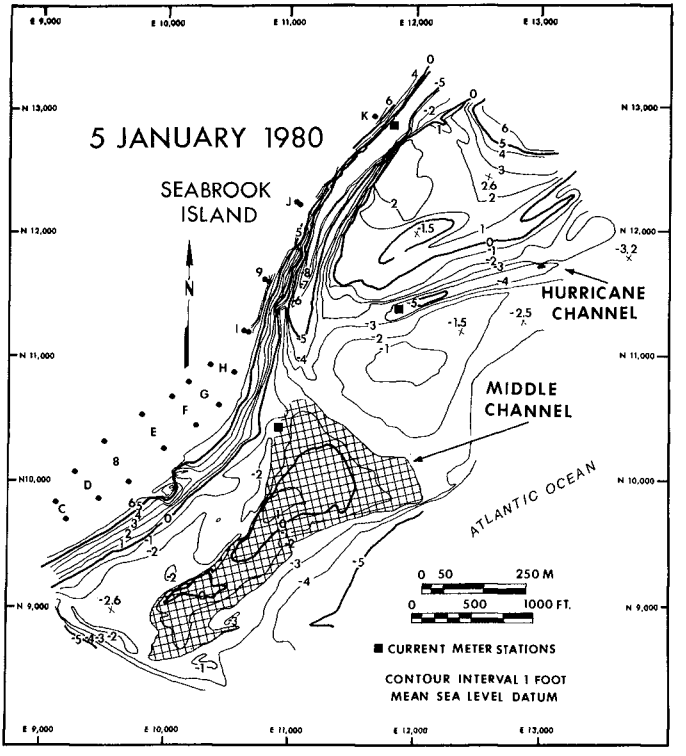

FIGURE 6. Bathymetric map of Captain Sam's Inlet surveyed in January 1980. The hatched area on the map was used for sediment-volume calculations for the bypassing shoal.

The tidal currents active in the tidal channels at the inlet had shown several distinct patterns. Shortly after the hurricane channel was formed, the current velocities in the channel were very erratic. Velocity changes of over 100 cm/sec were recorded in less than one hour while other channels were recording velocities of less than 50 cm/

sec during the same period. By December 1979, the current velocities in the hurricane channel were the same as those measured in the Kiawah River indicating that the hurricane channel was becoming the main channel for the inlet. The current velocities in the prehurricane, main ebb channel were flood dominant with low values when compared to the currents in the hurricane channel. This indicates that the prehurricane, main ebb channel was functioning as a marginal flood channel (Hayes, 1980). Also, during the first four months of the bypass, the cross-sectional area of the inlet's throat reduced slightly from 492.5 m^2 to 472m^2 or about four percent.

During the last six months of the monitoring program (January-June 1980), the bypass process was essentially completed. Results from the final bathymetric survey are shown in Figure 7. During the six month period since January 1980, the bypassing shoal had migrated onshore with little additional downdrift migration to the south. Previously (between September 1979 and early January 1980) shoal migration was dominantly in a downdrift direction. The bypassing shoal had attached to Seabrook Island on its northern end, and only a narrow trough separated the remaining portion of the shoal from the island. The newly formed middle channel was well formed, with the formation of an ebb-tidal delta seaward of the channel. The northern portion of the tidal delta, north of the middle channel, had accreted as evidenced by the filling of the hurricane channel. The volume of sediment contained in the bypassing shoal above the -0.6 m MSL contour was 34,817 m^3. The volume of sediment in the bypassing shoal had been reduced by 27 percent since January. The reduction of the total sediment volume in the ebb-tidal delta at the end of the process can be accounted for by accretion of the downdrift beaches where the shoal was attaching to the shoreline.

Results of the tidal currents monitored toward the end of the bar-bypassing process indicated that the tidal exchange measured in the inlet's throat closely resembled the currents monitored on the ebb delta in the middle channel. In conjunction with the current readings during the entire bypass, little change in the salinity of the seawater through the inlet was recorded, reading consistently around 32 parts per thousand.

The cross-sectional area of the tidal inlet throat had increased slightly by six percent to 503.5 m^2. The tidal inlet had once again regained a single channel configuration on its delta, similar to that prior to the landfall of Hurricane DAVID.

DISCUSSION AND SUMMARY

A review of the bar-bypassing process that occurred at Captain Sam's Inlet is shown in Figure 8. Prior to the bar-bypass process, the inlet had a single channel configuration on its delta (Fig. 8A). Through the process, the inlet had as many as three active channels on the delta (Fig. 8C). Toward the end of the bypass, the inlet once again regained a single channel configuration on its delta lobe (Fig. 8F).

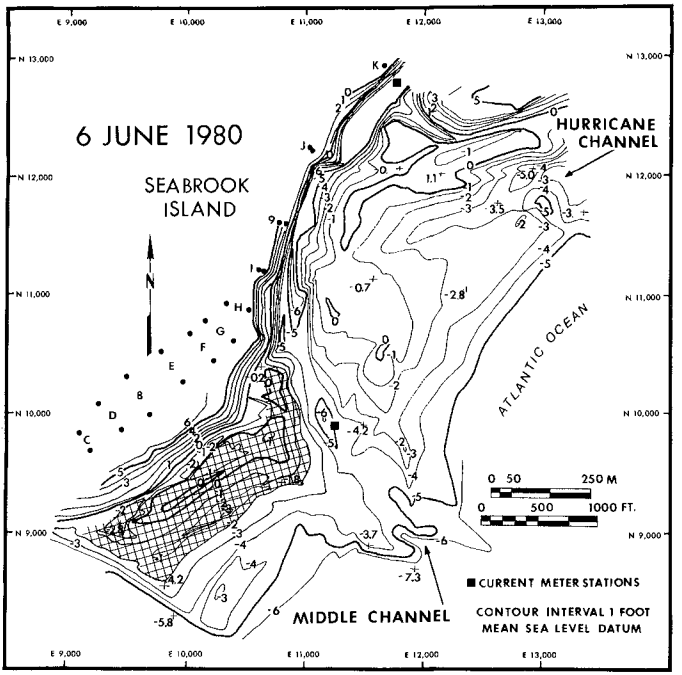

FIGURE 7. Bathymetric map of Captain Sam's Inlet in June 1980. The hatched area was used for sediment-volume calculations for the bypassing shoal. An ebb-tidal delta had formed seaward of the inlet at the location of the middle channel while the hurricane channel had been filling.

Sediment volumes calculated from the three bathymetric maps for the bypassing shoal is shown in Table 1. The volume of sediment contained in the bypassing shoal above the -0.6 MSL contour remained constant until the end of the bypass procedure. Stability in sediment volume was achieved even though the northern one-third of the bypass shoal was truncated from the main body of the shoal by the formation of the middle channel (Figs. 6 and 8C). Three possible explanations for the sediment volume stability are:

1) The addition of sediment to the bypassing shoal from longshore and onshore sand transport.

FIGURE 8A.

Low-tide photo of Captain Sam's Inlet taken on 7 December 1978. The inlet had only one channel active on the delta at this time.

FIGURE 8B.

Oblique low-tide photo taken on 6 September 1979, following Hurricane DAVID. The channel scoured by the storm is marked by the white arrow.

FIGURE 8C.

Aerial photo taken at low tide on 8 November 1979. The inlet had three channels active on the delta with the middle channel (marked by the white arrow) forming during the first two months of the bar-bypass.

FIGURE 8D.

Oblique aerial view of Captain Sam's Inlet taken on 21 December 1979. The prehurricane, main ebb channel was nearing abandonment.

FIGURE 8E.

Low-tide photo taken on 11 April 1980. The hurricane channel had filled with sediment and the middle channel was clearly the dominant channel active at the inlet.

FIGURE 8F.

Aerial photo taken at low tide on 29 May 1980 at Captain Sam's Inlet. Only a narrow trough separates the bypassing shoal from the mainland.

2) Movement of the bypassing shoal into shallow water, therefore exposing more of the shoal above the -0.6 m MSL contour.

3) The addition of sediment from the eroding scarp formed during the migration of the inlet system.

Of the three possible explanations, the third appears to be the most responsible for adding sediment to the system during the bypass. A total sediment volume of 43,152 m^3 (calculated from beach profile data) was eroded during the bypass due to the migration of the inlet system. This value would provide a substantial sediment supply to the bypassing shoal during the 10-month process.

TABLE 1. Sediment volume of the bypassing shoal, calculated above the -0.6 m ft) MSL contour at Captain Sam's Inlet.

MAP 1 September 1979	MAP 2 January 1980	MAP 3 June 1980
47,510 m^3	47,689 m^3	34,817 m^3

After the delta was breached during the hurricane, the shoal, freed for bar-bypassing at the inlet, migrated in a south-southwesterly direction for a total of 215 m (using the -0.6 m MSL contour), with the majority of the migration occurring during the first four months. Landward migration of the shoal caused 1.3 m of fill in the prehurricane, main ebb channel, but this tend was reversed toward the end of the study after the middle channel stabilized and scoured 1.2 m of sediment from the same general location at the inlet (Fig. 9).

Measurements made from the three bathymetric maps showed the hurricane channel initially scoured and migrated in a northerly direction. During the later stages of the bar-bypassing, the hurricane channel began to fill with sediment and migration continued to the north (a total of 175 m).

The currents monitored in the prehurricane, main ebb channel resembled that of an active marginal flood channel on an ebb-tidal delta (Hayes, 1980), which are dominated by flooding currents. The currents active in the marginal flood channel (prehurricane, main ebb channel) tended to lag in a flood direction, whereas currents in the main ebb channel were still flowing seaward. This flood dominance influenced the bar-bypassing procedure by assisting in the filling of the channel.

The cross-sectional area of the inlet below MSL showed little change throughout the study (Table 2). There was a slight overall enlargement of the inlet's throat toward the end of the study (31 m^2 or 6 percent). O'Brien (1969, 1972) found that, based on Pacific

Coast data, inlets tend to stabilize and balance by enlarging their cross-sections and varying the tidal prism and supply of sand to the inlet. This slight enlargement in the cross-section during the bypass may be the result of Captain Sam's Inlet regaining its single-channel, stable configuration. O'Brien and Dean (1972) also developed an index on the stability of tidal inlets to closure relative to deposition on filling with sediment. Essentially, they found that the stability or resistance of tidal inlet to closure depends on three main factors:

1) $\Delta L/L$ on the depositional length (L) of the inlet's channel.
2) The storage capacity of the inlet.
3) The inlets ability to transport sediment out of its channel.

These factors have a significant impact on Captain Sam's Inlet. When the inlet has a single channel on the tidal delta, the depositional length (total single channel length) of the channel is high; therefore, it would tend to be unstable. Also since the inlet is shallow and narrow, it would have a low storage capacity. When the length of the single channel on the delta is long, the frictional drag on the tide would reduce the efficiency of the tide to transport sediment out of the channel. These three principles are very important at Captain Sam's Inlet during the bar-bypass process.

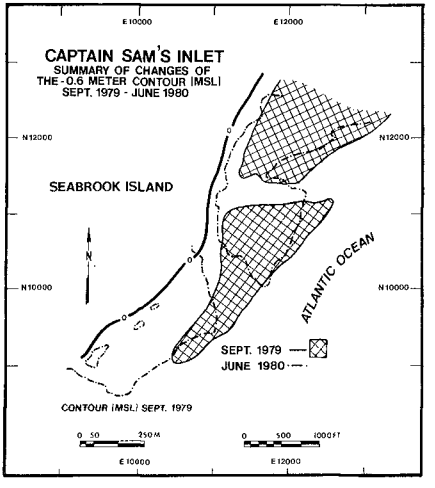

FIGURE 9.

Comparison map of the bathymetry of Captain Sam's Inlet showing changes in the -0.6 m (-2 ft) MSL contour, comparing maps surveyed in September 1979 with June 1980. Note the south-southwesterly migration of the bypassing shoal with eventual attachment to Seabrook Island.

TABLE 2. Values for the tidal prisms (in m^3) and cross-sectional areas (in m^2) for Current Station 3 (Fig. 4), the inlet's throat, at Captain Sam's Inlet.

Date	Tidal Prisms		Cross-Sectional Areas
	Ebb	Flood	
September '79	6,533,023 m^3	6,679,296 m^3	492.5 m^2
November '79	6,084,268 m^3	4,838,493 m^3	472.0 m^2
May '80	4,537,472 m^3	5,024,484 m^3	503.5 m^2

CONCLUSIONS

This paper documents sediment bypassing at a small, natural tidal inlet in South Carolina. The process of bar-bypassing occurs at Captain Sam's Inlet in conjunction with the continual migration of the entire inlet system.

The following conclusions are offered:

1) Periodically, Captain Sam's Inlet attains a long unstable, single-channel configuration that results in the formation of shorter, more efficient channels initiating bar-bypassing.

2) Channel formation and abandonment facilitate bar-bypassing at the inlet, as opposed to continuous channel migration.

3) In this study, the volume of sediment contained in the shoal that bypassed remained constant until final attachment to the mainland. This is partially due to the addition of sediment to the downdrift side of the inlet from erosion during overall inlet migration.

4) Major changes in the inlet tidal prisms or cross-sectional areas were not observed during the bar-bypass process, although a slight enlargement of the channel cross-section toward the end of the process could indicate inlet stability.

5) The bypassing of sand at the inlet did transfer significant amounts of sand (approximately 50,000 m^3) across the inlet to the downdrift barrier island, creating a zone of rapid accretion.

Although Captain Sam's Inlet exhibits many characteristics of a short-lived inlet (eventual closure), the stable nature of the inlet's throat indicates that the inlet attains a state of equilibrium despite the radical behavior of the delta portion of the system.

ACKNOWLEDGMENTS

Financial support for this work came from the National Sea Grant Program, Seabrook Island Company, and the Kiawah Island Company. We would like to thank Bill Ficken and the staff at Research Planning Institute for their assistance in both field work, data reduction, and report preparation.

SHOALING WITH BYPASSING FOR CHANNELS AT TIDAL INLETS

Cyril Galvin, M. ASCE*

ABSTRACT

A channel dredged at the mouth of a tidal inlet is subject to rapid shoaling because of longshore transport, but this shoaling is slower than would be computed from simple trapping of all the moving littoral drift. The reduction in shoaling rate is due to the bypassing of littoral drift which occurs simultaneously with shoaling. This report presents a systematic method for computing the rate of shoaling in channels subject to shoaling with bypassing. The method also permits estimates of the effect of the dredged channel on the downdrift beaches.

INTRODUCTION

Stable Tidal Inlet. A **tidal inlet** is a waterway that connects a large body of water (usually the ocean) with a smaller body of water (Figure 1). The tidal inlet tends to shoal because ocean waves drive sand into the inlet channel, but a stable inlet channel is kept open because tidal currents prevent the wave-driven sand from depositing.

Waves bring sand to the inlet by the process of **longshore transport.** Longshore transport can occur from the ocean beaches on both sides of the inlet, but usually there is a dominant direction of longshore transport (say from left to right in Figure 1) that permits identification of an **updrift side** (the side from which sand is driven) and a **downdrift side** (the side toward which sand is driven). At a stable tidal inlet, the joint action of the waves and tidal currents results in natural **bypassing** of the sand across the inlet channel from the updrift side to the downdrift side, at a more or less steady rate, when averaged over a period of years.

The tidal currents which maintain an inlet are those which result from the daily rise and fall of tides in the ocean. As the tide rises in the ocean, water flows from the ocean to the bay; as the tide falls in the ocean, water drains from the bay to the ocean. The volume of water which enters the inlet from the time of low water slack to the time of highwater slack is the **tidal prism.** It has been known for a long time that the inlet cross section is proportional to the tidal

*Coastal Engineer, Box 623, Springfield, Virginia 22150, U.S.A.

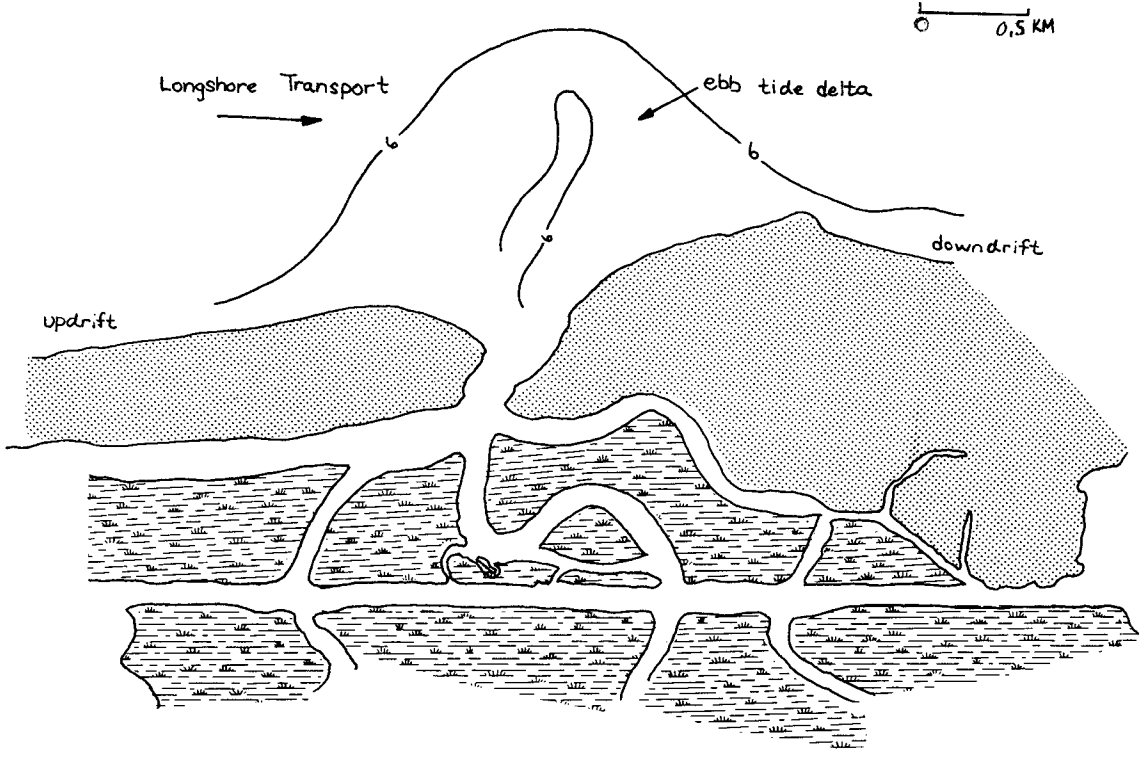

Figure 1. TYPICAL EBB TIDE DELTA AT TIDAL INLET (ADOPTED FROM BREACH INLET, FORT MOULTRIE, S.C. USGS QUAD.)

prism (LeConte, 1905; O'Brien, 1931; Jarrett, 1975). However, the maximum velocity through that section does not vary much with the size of the tidal prism, being on the order of 1 meter per second in naturally stable sandy inlets over a considerable range of tidal prisms.

There is a minimum size to the cross section of an inlet below which the channel will shoal and eventually seal off. This minimum cross section, or the corresponding minimum tidal prism, is proportional to the magnitude of the longshore transport; channels subject to larger longshore transport rates require greater tidal prisms to keep the channel open. Escoffier (1940), Keulegan (1967), O'Brien and Dean (1972) and others have examined the hydraulics of flow in tidal inlets in order to estimate the minimum stable cross section.

Tidal inlets are common on many coasts. For example, on the Atlantic coast of the United States, there are at least 37 permanent tidal inlets between Montauk Point, New York, and Miami, Florida, a shoreline distance of about 2050 kilometers. On many coasts, such as the east coast of India, shallow tidal inlets are the only waterways connecting the open sea with safe harbors along hundreds of kilometers of coast.

Definition of Depth. Seaward of these inlets, tides and waves create an **ebb tide delta.** Minimum depth for navigating through a tidal inlet is usually the sand bar at the crest of this delta. This minimum depth is the **controlling depth,** and the cross section of the channel which contains the minimum depth is the **controlling section.** Natural bypassing by waves and currents transports sand along the ebb tide delta in the downdrift direction (Figure 1). If the controlling section is deepened by dredging, the channel will begin to shoal, mostly from the updrift side. At the same time, because of the relatively shallow depth and flat side slopes of the dredged channel, some sand will be transported out of the channel, mostly to the downdrift side. The difference between the incoming and outgoing transport rates produces shoaling in the channel.

The initial rate of shoaling is a function of the natural controlling depth (d_1) and the initial dredged depth (d_2). At any time after dredging there will be an existing depth (d) such that (Figure 2)

$$d_1 < d < d_2 \tag{1}$$

In applying the analysis in this paper, all depths should be measured from Mean Sea Level (or Mean Tide Level) rather than chart datum, since chart datum is typically Mean Low Water or some lower elevation.

The design question is: how long will it take d to decrease from an initial overdredged value of d_2 to some project depth, d_p, where d_p is defined as the minimum depth for practical navigation by the design vessel. This time interval will be called the duration of project depth, and indicated by the symbol t_p. Time t has a value t = 0 on the day when dredging is completed.

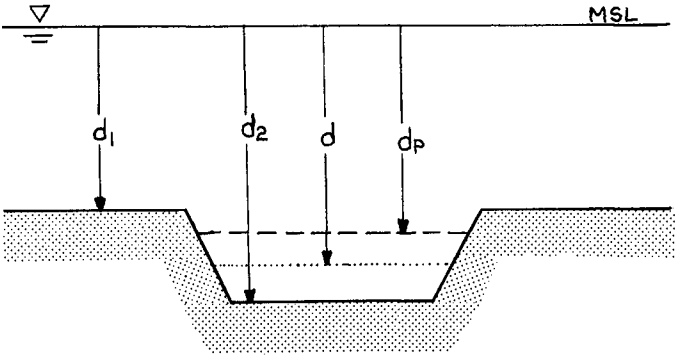

Figure 2. DEFINITION OF DEPTHS AT CONTROLLING SECTION

Purpose. The purpose of this paper is to present and illustrate by example a simple technique to obtain a rational estimate of t_p, the duration of project depth at the controlling section in the dredged channel.

The remaining text of this paper is organized into 4 principal sections. An analysis section derives the shoaling rate equation and presents Lent's solution of this equation. Lent's solution permits direct calculation of t_p. The justification for specific steps in the analysis section is presented in the following discussion section. An applications section follows the discussion to show by examples how to use the results in practical problems. Finally, the text ends with a summary section.

ANALYSIS

Bypassing Sediment Transport Ratio. As a starting point for this analysis, sediment transport rate is assumed to be proportional to the rate of energy expended by the flow:

$$\text{Transport} = \text{Coefficient} \times \text{Shear} \times \text{Velocity} \qquad (2)$$

This equation is assumed to describe sediment bypassing across the ebb tidal delta in the downdrift direction. After the channel has been dredged, the channel traps a greater percentage of the longshore transport due to the greater depth, and bypassing is reduced. The ratio

of the bypassing rate after dredging to the bypassing rate before dredging is defined as the **bypassing sediment transport ratio,** or the transport ratio for short.

$$\underset{\text{Ratio}}{\text{Transport}} = \underset{\text{Ratio}}{\text{Coefficient}} \times \underset{\text{Ratio}}{\text{Shear}} \times \underset{\text{Ratio}}{\text{Velocity}} \tag{3}$$

The flow is assumed to be well into the turbulent regime with low relative roughness both before and after dredging so that to a first approximation

$$\text{Coefficient Ratio} = 1 \tag{4}$$

This reduces the solution of (3) to the task of finding expressions for the shear ratio and the velocity ratio.

The shear in equation (2) is taken to be bottom shear induced by the wave orbital velocity on the ebb tidal delta. The general equation for such shear is

$$\text{Shear} = \text{coefficient} \times U^2 \tag{5}$$

where U is the amplitude of the wave-induced orbital velocity on the ebb tidal delta, and the coefficient incorporates a friction factor, density of seawater, and a dimensionless number depending on the definition of the friction factor. As in equation (4), it is assumed that the coefficient does not change significantly after dredging so that

$$\text{Shear Ratio} = U_{after}^2/U_{before}^2 \tag{6}$$

U is known from small amplitude shallow water theory, so that

$$\text{Shear Ratio} = (H_2^2 d_1)/(H_1^2 d_2) \tag{7}$$

The subscripts 1 and 2 refer to conditions before and after dredging, as on Figure 2. Equation (7) can be further simplified using the appropriate form of energy conservation in shallow water (Green's Law) to get

$$\text{Shear Ratio} = (d_1/d_2)^{3/2} \tag{8}$$

Equation (8) is one of the two ratios needed to solve equation (3). The required second ratio is the velocity ratio, which is derived as follows. Let the symbol, q, indicate the unit tidal discharge in the ebb channel at the controlling section. Thus,

$$\text{Velocity} = q/d \tag{9}$$

$$\text{Velocity Ratio} = (q_2 d_1)/(q_1 d_2) \tag{10}$$

The velocity ratio (10) depends on how the unit discharge in the ebb channel is affected by dredging. Two particular end conditions are possible. If the dredging merely increases the channel area, and the tidal prism remains the same, then the ratio q_s/q_1 remains unity and

$$\text{Velocity Ratio} = d_1/d_2 \text{ for constant discharge} \tag{11}$$

On the other hand, it is possible that the dredging may make the channel more efficient and increase the tidal prism. An upper limit to the velocity in this case is expected to be close to the predredging velocity, since scour by the ebb flow maintains the channel against longshore transport. In this case,

$$\text{Velocity Ratio} = 1 \text{ for constant velocity} \tag{12}$$

The transport ratio (3) can now be solved using equations (4), (8) and (10).

$$\text{Transport Ratio} = 1 \times (d_1/d_2)^{3/2} \times (q_2 d_1)/(q_1 d_2) \tag{13}$$

This may be simplified to

$$\text{Transport Ratio} = (d_1/d_2)^m \tag{14}$$

where $$3/2 \leq m \leq 5/2 \tag{15}$$

to account for the two possible end conditions for the velocity ratio given by equations (11) and (12).

Equation (14) is a specific expression for the bypassing sediment transport ratio immediately after the channel has been dredged to a depth d_2. Since the assumptions and reasoning which lead to (14) hold even better for any lesser depth, d, the symbol d_2 in (14) can be replaced by d to indicate the transport ratio for any post-dredging depth.

Shoaling Rate. The objective of this section is to derive an equation for shoaling rate. Shoaling rate will depend on the bottom area of the channel and the quantity of longshore transport reaching that channel bottom. To describe these factors, the following definitions are useful.

- Q longshore transport rate
- R fraction of Q which takes place above depth d_2
- C length of dredged channel (Figure 3)
- W width of dredged channel (Figure 3)

The amount of littoral drift carried into the dredged channel by longshore transport from the updrift side is RQ. Note that RQ is also the bypassing across the channel before dredging, or in other words, the denominator of equation (3).

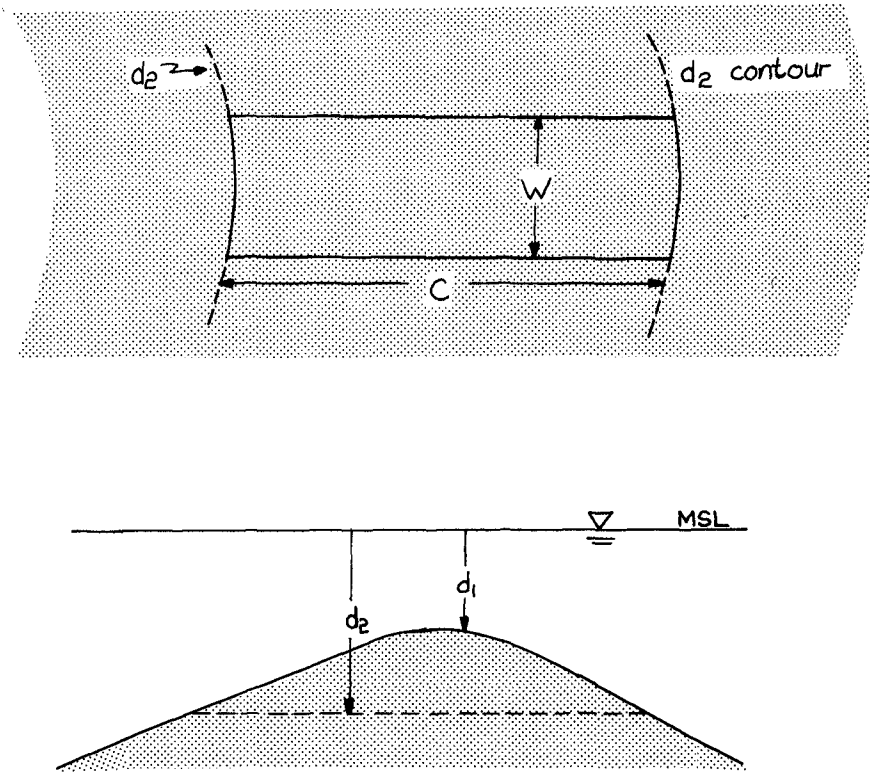

Figure 3. DEFINITION OF CHANNEL DIMENSIONS ACROSS EBB DELTA

The volume of sand trapped by the dredged channel per unit time is the trapping rate. From the above definitions,

$$\text{Trapping Rate} = RQ - \text{Bypassing after, above } d_2 \tag{16}$$

$$= RQ\ [1 - \text{Transport Ratio}] \tag{17}$$

The trapping rate given by (17) is a volume rate. To convert this volume rate to a shoaling rate, divide (17) by the bottom area of the channel, CW. For convenience, define K to be a characteristic shoaling rate.

$$K = RQ/CW \tag{18}$$

Thus, dividing equation (17) by CW and substituting equations (14) and (18) into the result gives

$$\text{Shoaling Rate} = K[1 - (d_1/d)^m] \tag{19}$$

Duration of Project Depth (Lent's Equation). The shoaling rate is mathematically equivalent to the time derivative of the depth

$$d(d)/dt \equiv \text{Shoaling Rate} \tag{20}$$

The duration of project depth, t_p, is obtained by integrating (20)

$$\int_0^{t_p} dt = t_p = \int_{d_2}^{d_p} \frac{d(d)}{\text{Shoaling Rate}} \tag{21}$$

An exact integral solution of (21) has not been found after some searching, but an approximate solution has been developed by Arnold H. Lent (personal communication, 30 Dec 1982). Lent's solution is as follows.

$$t_p \cong \frac{1}{K}\left[(d_2 - d_p) + \frac{d_1}{m}(\ell nA - \ell nB)\right] \tag{22}$$

where

$$A = (d_2 - d_1)/(d_p - d_1) \tag{23}$$

$$B = \frac{1 + \frac{m-1}{2}\left(\frac{d_2 - d_1}{d_1}\right)}{1 + \frac{m-1}{2}\left(\frac{d_p - d_1}{d_1}\right)} \tag{24}$$

Equation (22) approximates equation (21) with a degree of accuracy that exceeds the probable sounding accuracy of measured channel depths.

To find t_p by using equation (22), the values of K, m, d_1, d_2, and d_p must be obtained. The value of K is given by equation (18). The value of m depends on the likely effect of the proposed dredging on the velocity ratio, but is expected to be in the range given by equation

(15). The value of d_1 is the controlling depth obtained from soundings. The value of d_p is the requirement of the user, and the value of d_2 is the design choice to be tested.

DISCUSSION

Qualitative Evaluation. In order to obtain the principal results of the preceding section in minimum space, discussion of key assumptions necessary in the derivation was deferred to this section. But before examining the key assumptions, it is useful to observe that, however equations (21) and (19) were obtained, they agree qualitatively with intuition and experience.

The qualitative agreement is illustrated by the shape of the curves on Figure 4. Figure 4 plots depth on the vertical axis against time on the horizontal axis for three combinations of d_1 and d_2 (d_1 equals 4 feet, 6 feet, and 8 feet, each combined with the same d_2 value of 12 feet). The curves on Figure 4 are numerical solutions of equation (21) using equation (19) for the shoaling rate. Two values of the exponent, m, are used, corresponding to equations (11) and (12), i.e., the constant velocity case (m = 3/2) and the constant discharge case (m = 5/2). The curves on Figure 4 agree qualitatively with intuition and experience in at least 4 ways:

a. The maximum rate of shoaling occurs right after dredging (the curves are steepest at the deepest depth).

b. The channel shoals faster when post-dredging velocity is reduced (constant discharge, m = 5/2) than when the post-dredging velocity is not reduced (constant velocity, m = 3/2).

c. The channel shoals fastest when no bypassing occurs. This is equivalent to $m = \infty$ in equation (19) and plots as the dotted straight line on Figure 4.

d. Shoaling approaches d_1 more slowly when the depth of the dredged cut ($d_2 - d_1$) is smaller, d_2 being held constant.

Transport Equation. The starting point of the analysis is equation (2) which states that bypassing sediment transport rate is proportional to work done by the waves on the bottom. In the absence of an inlet, the bypassing rate is simply the longshore transport rate. The usual "energy flux" method of predicting longshore transport (Galvin and Schweppe, 1980) is, in effect, an assumption that sediment transport rate is proportional to the power supplied by waves to the surf zone. This is physically analogous to equation (2).

The form of equation (2) is also that used by Bagnold (1966) in his stream power hypothesis for sediment transport, which Bagnold assumes involves bed load transport. The proportionality between transport rate

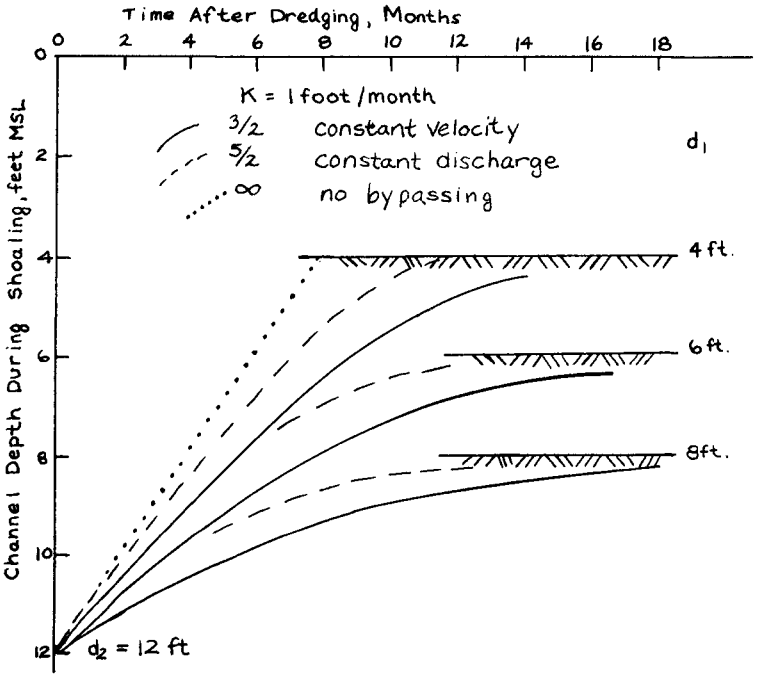

Figure 4. EFFECT OF BYPASSING ON CHANNEL SHOALING FOR THREE CHANNELS DREDGED TO 12 FEET MSL

and bottom shear required by equation (2) has been verified experimentally by Parsons (1972) for sediment grains in laminar flow.

Coefficient Ratios. The friction coefficients in equations (2) and (5) are assumed not to change after depth is increased by dredging. Increase in depth decreases the relative roughness of the flow on the typical friction factor diagram (shown in all hydraulics text books). For the moderate to high Reynolds numbers and small relative roughness expected in the navigation channel, such friction factor diagrams predict little change in f for large percentage changes in relative roughness. Thus, the assumption involved in equation (4) appears justified.

Velocities. There are three velocities to consider in the bypassing with shoaling process involved here. First, there is the ebb current velocity where it passes the controlling section of the navigation channel. This current has a characteristic maximum value of about 1 meter/second. (Flood currents are usually lower than ebb currents when they pass through the controlling section because flood flows are commonly more widely distributed over the ebb delta.)

Second, there is the bottom velocity due to the orbital motion of water particles under waves. The wave-induced bottom particle velocity on the ebb delta has a characteristic maximum amplitude, U, which approaches the magnitude of the maximum ebb current. The periodic reversal of the wave-induced velocity during the passage of each wave makes this velocity more effective in initiating sediment motion than tidal currents, but to first order, the wave-induced motion does not cause a net current.

Finally, there is the velocity of the longshore currents. The magnitude of longshore currents is only a fraction of U, with characteristic values on the order of 0.25 meters/second on open coast beaches. These velocities will be further diminished where they cross the controlling section of the navigation channel due to the deeper water there. Thus, the magnitude of the longshore current is distinctly less than the other two velocities involved in shoaling with bypassing.

The derivation assumes that wave-induced velocities stir up the sediment and that ebb currents distribute the sediment in the channel. The waves provide the shear component of equation (2) and the tides supply a convective velocity. This differs from the usual formulation of (2) in which the velocity that produces the shear is also the velocity causing the convection, but here the shear velocities are periodic and do not provide net transport. The longshore aspect of the motion is imposed on the shoaling equation (19) through the coefficient K which incorporates the longshore transport rate, Q, as given in equation (18).

Note that if U is used to obtain the velocity ratio, the velocity ratio will simply be the square root of the shear ratio (8). This results in a transport ratio exactly of the form given by equation (14) with the exponent m equal to 9/4, which is within the limits on m given by equation (15).

The use of linear shallow water wave theory to estimate U in equation (7) is technically not permissible because the waves on the ebb delta will have a height-to-depth ratio that is not negligible. However, linear theory has been used to describe such conditions many times before with adequate results (for example, Longuet-Higgins, 1970). Further, in the dredged cut, the height-to-depth ratio will be reduced, making linear theory more applicable.

Bypassing Mechanisms. During the meeting at which this paper was delivered (the 18th International Conference on Coastal Engineering), there were two descriptive papers on sediment bypassing at inlets (Sexton and Hayes, 1982; FitzGerald, 1982). Both these papers describe bypassing as the movement of discrete bars of sediment, usually initiated by a shift in the ebb channel from a downdrift location to an updrift location. This well-described process of discrete transport differs from the more continuous bypassing process of this paper, in which the longshore transport continually moves sand across the rim of the ebb delta and through the ebb channel. (This continuous longshore transport may in fact be accompanied by the motion of small bed forms.)

While bypassing undoubtedly occurs as described by Sexton and Hayes (1982) and FitzGerald (1982), it appears that the volume rate of this transport, when averaged over the time for the shifted ebb channel to complete one cycle, is only a fraction of the estimated annual longshore transport rates at the sites. Approximate estimates suggest that 10 to 30% of the longshore transport may be accounted for by the bar bypassing described in those papers.

Further, since dredging makes the ebb channel more efficient, it is less likely to shift in position. The deeper depths of the dredged channel are also expected to inhibit discrete bars moving across the channel. Therefore, in the dredged condition under investigation, most of the bypassing is expected to occur by relatively continuous longshore transport.

APPLICATIONS

Tabulation of t_p'. The following subsections show by example how to apply the analysis to practical problems. To aid in computing the duration of project depth, t_p, it is useful to rewrite equation (22) in dimensionless form.

$$t_p' = Kt_p/d_1 = d_2' - d_p' + \frac{1}{m}(\ell nA - \ell nB) \quad (25)$$

where $$d_p' = d_p/d_1 \quad (26)$$

$$d_2' = d_2/d_1 \quad (27)$$

and K, m, A, and B are defined by equations (18), (15), (23), and (24), respectively.

Equation (25) has been tabulated for m = 3/2 (Table 1) and m = 5/2 (Table 2) over a range of values of d_p' and d_2'. Ordinarily, in typical inland waterways, d_p' would be only slightly less than d_2', the difference due to the allowable overdredging which is rarely more than 2 or 3 feet. However, in dredging shallow tidal inlets in the active littoral zone, significantly more overdredging may be required to maintain floatation of the dredge and to reduce the frequency (and thus cost) of maintenance dredging.

Tables 1 and 2 list the values of t_p', defined by the right hand side of equation (25), as a function of d_p' and d_2', defined by equations (26) and (27). (The selection of m determines which of the two tables is used.) Any combination of d_1, d_p, and d_2 will give values of d_p' and d_2', and these give a value of t_p' either by direct reading of the table or by interpolation if necessary.

In the dimensionless form of equation (25), deep channels and shallow channels with variable amounts of overdredging can be conveniently covered by the same tables. The unit used for depth (feet, meters) does not matter as long as it is not changed during any single calculation, and as long as K is expressed in the same unit per time.

Example 1: Shoaling.

(a) Existing Condition: A permanent shallow draft tidal inlet is located in a relatively sheltered site on a large bay. The controlling depth is 1.5 meters chart datum, which corresponds to a mid tide depth of 2.5 meters. The longshore transport is estimated to be 50,000 cubic meters/year, with 80% of it occurring during the 4 month monsoon season. Characteristic storm waves have breaker heights of about 2.5 meters.

(b) Desired Improvements: A local company wishes to ship high value ore through the inlet during the non-monsoon season. The ore will be transported in barges needing a 4.0 meter project depth, measured from mid tide elevation. To get the barges through the inlet, the company plans to dredge a channel 30 meters wide and 150 meters long.

(c) Question: The shipper would like to dredge only once a year, right at the end of the monsoon season. How deep must he dredge (what is d_2?) in order to maintain a navigable depth for the 8 months until the start of the next monsoon?

Table 1. DIMENSIONLESS DURATION OF PROJECT DEPTH FOR m = 3/2 (Constant Velocity Condition)

Row Number	d_p'	d_2' =	t_p' = 1.10	1.20	1.33	1.50	1.75	2.00	2.25
1	1.05		0.50	1.05	1.49	1.91	2.40	2.81	3.17
2	1.10		x	0.55	0.99	1.41	1.90	2.30	2.67
3	1.20		x	x	0.44	0.86	1.35	1.76	2.12
4	1.30		x	x	0.09	0.51	0.99	1.40	1.77
5	1.40		x	x	x	0.23	0.72	1.13	1.49
6	1.50		x	x	x	x	0.48	0.89	1.26
7	1.75		x	x	x	x	x	0.41	0.77
8	2.00		x	x	x	x	x	x	0.37

Table 2. DIMENSIONLESS DURATION OF PROJECT DEPTH FOR m = 5/2 (Constant Discharge Condition)

Row Number	d_p'	d_2' =	t_p' = 1.10	1.20	1.33	1.50	1.75	2.00	2.25
1	1.05		0.31	0.66	0.96	1.26	1.62	1.94	2.24
2	1.10		x	0.35	0.65	0.95	1.31	1.63	1.92
3	1.20		x	x	0.30	0.60	0.96	1.28	1.57
4	1.30		x	x	0.06	0.36	0.72	1.04	1.34
5	1.40		x	x	x	0.17	0.53	0.85	1.15
6	1.50		x	x	x	x	0.36	0.68	0.98
7	1.75		x	x	x	x	x	0.32	0.62
8	2.00		x	x	x	x	x	x	0.30

(d) Solution: Based on the preceding description:

d_p = 4.0 m
d_1 = 2.5 m
C = 150 m
W = 30 m
t_p = 8 months

To use the table, it is necessary to find the dimensionless duration of project depth, t_p'. This term is defined by equation (25) as a function of K and d_1. Thus, K is needed. K is defined by equation (18) as a function of R, Q, C, and W. To estimate R, the fraction of longshore transport occurring above depth d_2, compare d_2 to the breaker depth of storm waves. The characteristic storm waves are given above as 2.5 meters, which will break in about 3.25 meters. Since this breaker depth is above d_2, assume R = 1.0. The value of Q during the nonmonsoon months is, from the data given above,

$$Q = 0.20 \times 50{,}000 \text{ cubic meters/8 months}$$

$$= 1250 \text{ cubic meters/month}$$

Thus from (18)

$$K = 1.0 \times 1250/(30 \times 150)$$

$$= 0.28 \text{ meters/month}$$

From equation (25)

$$t_p' = (K/d_1)t_p = (0.28/2.5)8$$

$$= 0.90$$

From equation (26)

$$d_p' = 4.0/2.5 = 1.6$$

This value of d_p' falls between rows 6 and 7 on the tables. Table 1 is the most favorable (gives the longest duration of project depth for a given d_2). Examination of Table 1 shows that t_p' = 0.90 between rows 6 and 7 is equivalent to d_2' somewhere between 2.00 and 2.25. Thus based on Table 1, the dredged depth d_2 must be at least twice the controlling depth (5.0 meters at least) in order for the channel to last the 8 months.

If a more exact solution is required, equation (25) can be solved by trial and error for t_p' = 0.90 and d_p' = 1.60. Such a solution for the favorable case of m = 3/2 yields d_2' = 2.14, which indicates d_2 = 5.35 meters.

Example 2: Bypassing

(a) Existing Conditions: Same as in Example 1.

(b) Desired Improvement: Same as in Example 1.

(c) Question: The property owner downdrift of the inlet in question is worried about the interruption in longshore transport due to the trapping of sand in the dredged channel. If d_2 = 5.1 meters, what will be the maximum reduction in bypassing rate?

(d) Solution: From equation (17), the maximum reduction in bypassing will equal the maximum trapping rate right after dredging for the case of m = 5/2 (constant discharge).

$$\text{Max Trapping Rate} = RQ\,[1 - (d_1/d_2)^{2.5}] \tag{28}$$

$$= 1250\,[1 - (2.5/5.1)^{2.5}]$$

$$= 1040 \text{ cubic meters/month}$$

This type of calculation can indicate the rate at which downdrift beaches need replenishment following dredging, if the dredged material cannot be placed directly on the downdrift shore.

SUMMARY

The basic contribution of this paper is to provide an organized method of computing the duration of project depth in a channel overdredged through a tidal inlet.

The duration of project depth, t_p, is predicted by equation (22). To solve this equation, the following data are required: the controlling depth before dredging, the project depth needed for navigation, the proposed depth of dredging, and the length and width of the channel. These parameters are defined in Figures 2 and 3 as d_1, d_p, d_2, C, and W, respectively. In addition, the longshore transport above the depth d_2 must be known, and the effect of dredging on the ebb velocity in the channel must be estimated (the value of m in equation (15)).

The analysis developed here can be used for the following practical problems:

a. computing the duration of project depth (use equation (22) or Tables 1 or 2).

b. testing whether a proposed depth of dredging will last a desired length of time (see example 1).

c. estimating the decreased rate of bypassing caused by a given channel (see example 2).

Based on the techniques used here, a typical shallow draft channel across the ebb tide delta has a lifetime measured in months, but due to bypassing the life of the channel is significantly longer than would be the case for complete trapping of longshore transport.

ACKNOWLEDGEMENTS

The problem implied by the title of this report was originally posed by Stanley Maisel, Chief, Planning Branch, New York District, Army Corps of Engineers. Dr. Arnold H. Lent, Technicare Corporation, Solon, Ohio 44139, provided the approximate solution given as equation (22). Mr. L. K. Ghosh, Central Water and Power Research Station, Pune, India, raised several questions which resulted in improvements to the present manuscript. Data shown in Figure 4 and Tables 1 and 2 were computed by S. J. Weinheimer, J. R. Hill, and D. J. Galvin, Jr. Figures were drawn by P. E. Politi and the manuscript typed by Sheila Zukor.

DREDGING TO MINIMIZE WAVE PENETRATION INTO A HARBOUR

BY

H.P.RIEDEL[1] & A.P.BYRNE[2]

ABSTRACT

Wave protection within a new harbour development has been achieved by shaped dredging in place of long breakwaters. The dredging shape was initially established through wave refraction calculations and then confirmed and optimized in a physical three dimensional model. The cost of additional dredging for the specified shape was A$100,000 compared to estimated breakwater costs of A$1,000,000.

1. INTRODUCTION

For the development of offshore gas reserves near Dampier, northern Western Australia, the developers, Woodside Offshore Petroleum, required a supply base harbour to be established. A harbour site was selected at the southern end of Mermaid Sound. See Figure 1. The site is protected from Indian Ocean swell and subjected to a relatively mild short period wave climate because of limited fetches. However, the area is subjected to cyclones with their associated winds, waves and storm surge.

The harbour site has natural protection from three sides and is only directly exposed to waves on the western side. Preliminary design had allowed for a breakwater to provide protection from the west. During detailed design, shaped dredging was investigated as an alternative to breakwater type protection.

As an aid to design of the facility, a three-dimensional physical model had been constructed to optimise the layout with respect to wave protection and to assist in the determination of design waves for seawall, revetment and breakwater design. In the modelling process it was found that a conventional channel approach as shown in Figure 2 tended to concentrate wave energy in the northeast corner of the basin. A breakwater length of approximately 200 metres was required to reduce waves to an acceptable height in the basin during cyclones.

[2] B.E. Riedel & Byrne Consulting Engineers Pty., Ltd., Perth, Australia.

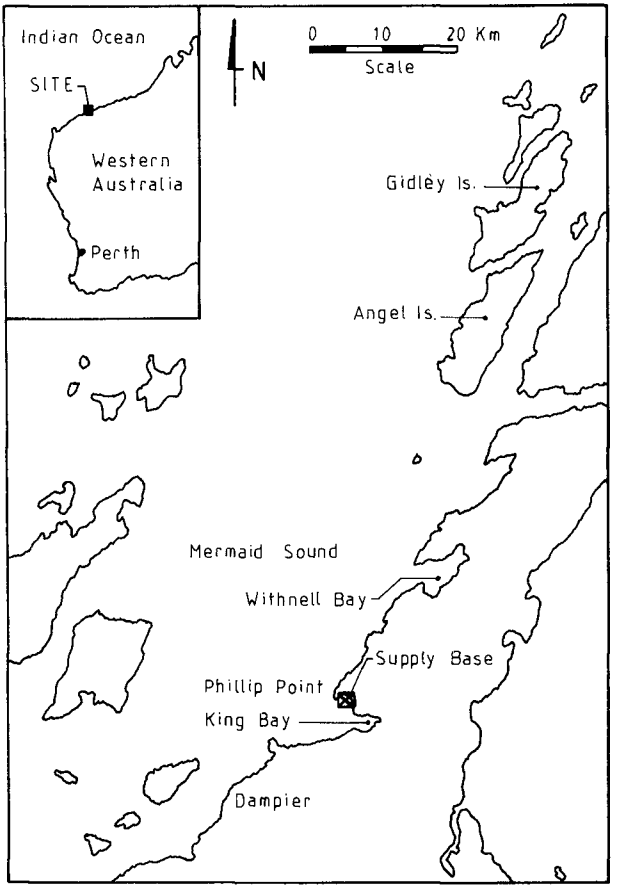

Figure 1. Location Diagram

It was therefore decided to investigate the possiblity of reducing wave heights by shaping the entrance channel so that it would act as a diverging lens. Initially, variations in channel shape and alignment were investigated by mathematical wave refraction calculations. These calculations indicated that shaped entrance channel dredging would reduce wave heights in the basin.

The calculations were confirmed in the physical model where both refraction and diffraction could be simulated.

2. CONCEPTUAL SUPPLY BASE LAYOUT

The layout shown in Figure 2 was chosen to utilise the natural wave protection in the lee of Phillip Point. The alignment and position of the basin was primarily controlled by geotechnical constraints so that rock dredging was minimised. The channel alignment and width were chosen to minimise the extent of dredging keeping in mind safe navigation for the vessels using the supply base.

Whilst the supply base design required that damage be negligible for a cyclone of 50 year return period intensity, it was not intended to provide a haven for vessels during a cyclone. There were therefore two sets of design criteria for wave activity in the harbour:

(i) that wave heights along the supply base wharf be less than 0.5 metre aligned with berthed vessels or less than 0.3 metres beam on for operational (non-cyclonic) conditions.

(ii) that wave heights be minimised to give the most economic, safe design of revetments and breakwaters for cyclonic conditions.

The design wave for operational conditions is generated from the western sector with H_{sig} = 0.9 m and a wave period of 3.5 seconds.

Cyclone generated waves can arrive at Phillip Point from any direction between west and north. The largest and longest period waves arrive from the north and are generated outside Mermaid Sound and propagated to the site. The supply base is well protected from these waves. Shorter period waves are generated within Mermaid Sound. For cyclone conditions these have a significant wave height of 2.5 metres and period of 5 to 6 seconds.

The conceptual layout provided satisfactory wave conditions for operational conditions. However, for cyclone generated waves approaching from the west, wave heights at the northeast corner of the basin were large and for some test conditions even amplified. Without a breakwater at Phillip Point, waves as high as 3 metres were recorded.

In order to reduce waves to a nominal 1 metre height, a 200 metres long breakwater would have been required. The 1980 cost estimate was A$1 million.

3. ALTERNATIVE CHANNEL DESIGNS

Since in the physical model it was apparent that the navigation channel was focusing wave energy into the basin, methods of altering the channel were investigated in the hope of reducing the breakwater length. Wave refraction calculations were carried out for several channel alignments and finally for a channel with a large hole dredged in its northern side. Figure 3 shows the range of channels used for wave refraction calculations. The refraction calculations indicated a significant improvement for both a straightened channel and a channel with the adjacent dredged hole. Figure 4, a typical forward ray refraction diagram, shows the diverging lens effect of the dredged hole.

The refraction calculations excluded the effects of diffraction and wave reflection which would be expected to have some influence.

These calculations were sufficient to show that wave heights could be reduced significantly in the harbour basin by redesigning the approach channel. Confirmation of these calculations was necessary in the physical model where the effects of diffraction and reflection were included.

4. MODEL TESTING

The dredged hole was modified to a shape shown in Figure 5 which could realistically be dredged. Extensive model tests were then conducted in the three dimensional physical model at an undistorted scale of 1:100. Both the straightened channel and the channel with the adjacent dredged hole were modelled. A total of 75 tests were completed to investigate the two channels and the improvements in wave conditions inside the harbour with a range of breakwater lengths. Earlier modelling had been conducted on the channel shown in Figure 2.

Figure 6 shows the 2 metre wave height contours in the harbour basin for the original channel and the two improved channel shapes identified by the refraction calculations for a typical test condition. The approach channel with the adjacent dredged hole gave consistently calmer wave conditions than a straightened channel to the harbour basin. This channel was chosen for detailed model testing and design and resulted in the design wave for the revetments being halved in height without the need of a costly breakwater.

Earlier model testing had shown that a 200 metre long breakwater was required to reduce the design wave heights to these levels with the original approach channel.

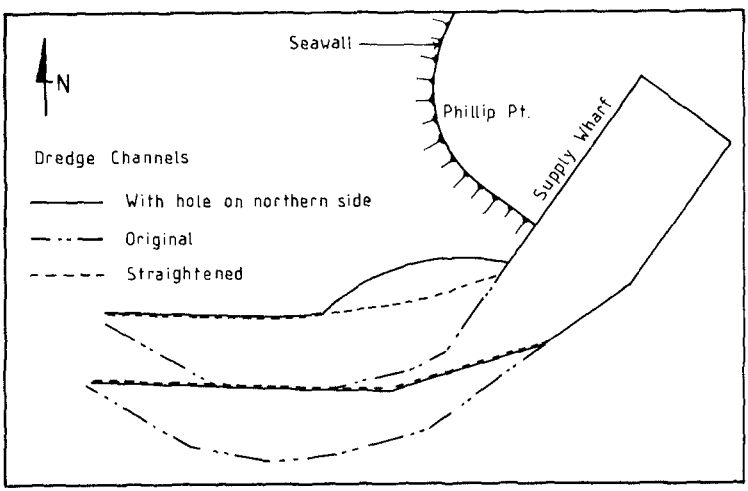

Figure 3. Channels Used in Wave Refraction Calculations

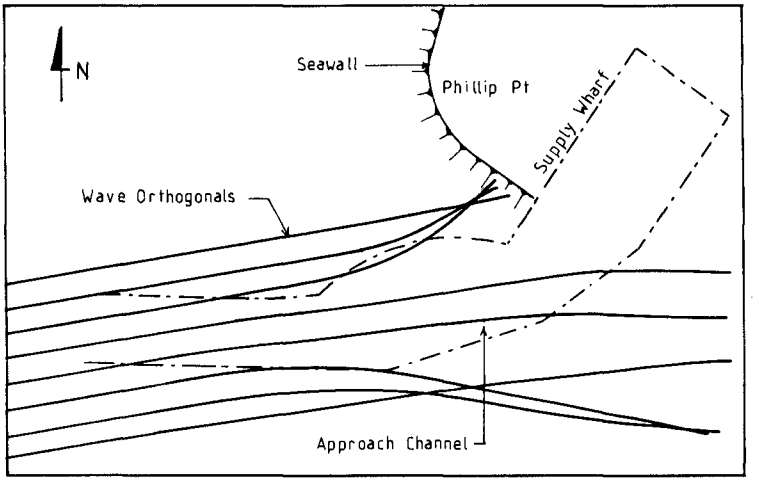

Figure 4. Typical Wave Refraction Diagram for Preferred Solution

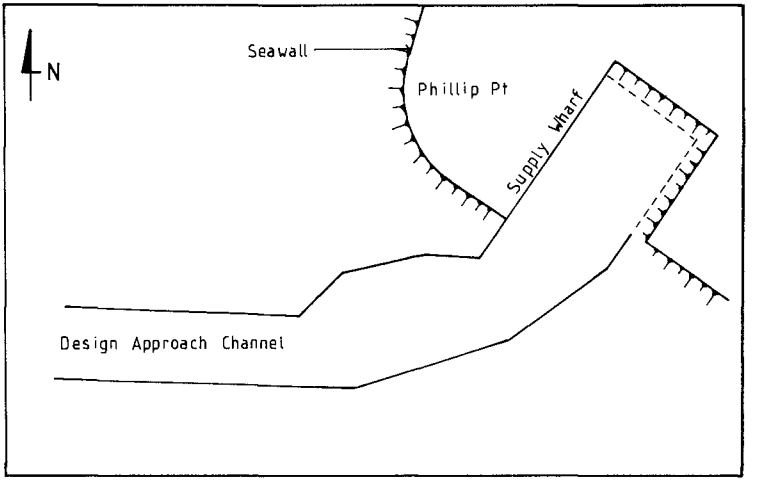

Figure 5. Design Approach Channel

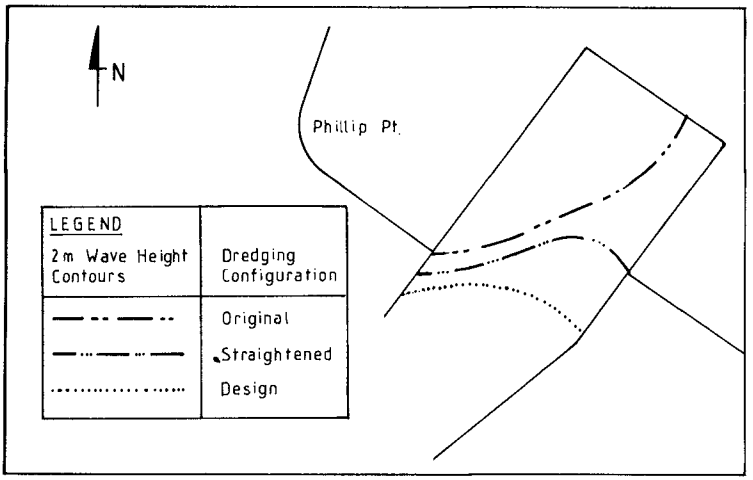

Figure 6. Comparison of Wave Height Contours for Typical Cyclone condition.

5. ECONOMIC CONSIDERATIONS

For the operation of the supply base there was no need for a breakwater under non cyclonic conditions with the original channel. However, during a cyclone if the breakwater were not present the revetments lining the harbour basin would have had to be constructed of much larger rock and to a higher crest elevation if damage during a cyclone were to be negligible. This would have required higher levels of reclamation so that the additional cost would have been in excess of A$0.5 million. Also any future extension of facilities to the eastern side of the basin would need to be designed for these high waves.

A 200 metre long breakwater would have cost about A$1 million in 1980.

By comparison, a dredge hole positioned so that all material to be removed was relatively soft and easily dredged with available plant, cost about A$100,000. The dredging of the hole was an extension of dredging that had to be carried out for the approach channel regardless of the final design.

6. CONCLUSIONS

Shaped dredging can be an effective method of changing wave conditions in the lee of the dredged area. For the North West Shelf project it was possible to effect substantial cost savings by the use of shaped dredging rather than a breakwater to provide wave protection for the Supply Base.

Caution must be applied to ensure that shaped dredging does not cause an unacceptable worsening of wave conditions adjacent to the site under investigation.

Dredged entrance channels and harbour basins may have a profound effect on waves propagated over them. The effects of wave concentration should always be checked in the design stage.

Abstract

Flume test data is presented for the depth of scour in deep water near a vertical cylinder placed in a uniform sand and a fine calcareous ocean sediment. The ratio of the depth of scour to the cylinder diameter at equilibrium is shown to depend only on the ratio of the shear velocity to the critical shear velocity at which bed motion is initiated.

Protection against scour by placing collars around the cylinder is shown to be of marginal value.

1 INTRODUCTION

Scour around cylindrical piles has long been of importance in the design of bridge piers and ocean jetties (Durant Claye 1873). In most cases investigators have emphasised the influence of the water surface effects and further, most tests have been carried out with sand as the foundation material. With the growth of the off-shore industry there is an increasing need to estimate scour around piles in water which is many pile diameters deep and where the foundation material is made of calcareous particles of a fine sandy consistency by the ocean. Further, scour tolerances on off-shore structures are such that attention must be focused on the range of shear velocities from the inception of scour to values at which bed load motion commences.

Such data do not appear to exist and this need has led to the above general investigation of scour around plain vertical circular cylinders and cylinders with protective collars. The sediment used is typical of that found along the whole of the Western Australian continental shelf in water between 50m and 200m (see H.A. Jones 1973). The photograph in Figure 1a shows that the particles are an approximate size of 0.1mm, are angular in nature and possess irregular shapes. A typical size fraction of these sediments is shown in Figure 1b and Figure 1c shows the size fraction of the fine river sand used in the control experiments.

Recent measurements of velocities very close to the ocean bottom (Caldwell and Chris 1979) have revealed that the bottom boundary layer possesses a "law of the wall" region above the viscous sublayer in which the familiar velocity scaling,

$$u = 2.5u_* \ln \frac{z}{z_o}$$

is applicable, where u is the velocity, u_* is the shear velocity, z is the vertical distance from the bed and z_o is the bottom roughness parameter. These measurements imply that a useful experiment of the scour depth may be carried out in a laboratory flume, provided the depth of water is kept large compared to the cylinder diameter.

The dominant feature responsible for scour around a pile is the large scale eddy system created by the pile itself. It is generally accepted that this eddy system causes the scour around the pile to commence at about half the critical threshold velocity. Shen, Schneider & Karaki (1966) reported that depending on the pile type and free stream

SAND FIGURE 1c

Sand sample particle distribution used as a control soil sample.

conditions, the eddy structure may be broken down into regions of a forward horseshoe vortex, a wake vortex amalgamation and a trailing vortex system.

The horseshoe vortex filament is the major influence on scour around a cylindrical pile. The variations in the intensity of the horseshoe vortex and in the strength of the downflow, and the interaction between them were examined qualitatively by Melville (1975) and reinterpreted by Jain & Fischer (1979).

The horseshoe vortex was reported to be initially small and comparatively weak. When the scour hole forms, however, the vortex rapidly grows in size and strength as additional fluid attains a downward component and the strength of the downflow increases. The expanding cross sectional area increases but, at a decreasing rate as the scour hole enlarges. The rate of increase in the cross sectional area is controlled by the quantity of fluid supplied to the vortex from the downflow ahead of the cylinder. This downflow is determined by the free stream velocity.

The scour resulting from this flow pattern leads to an increasing depth of scour with increasing flow velocity. However, as shown by Shen et al (1969), there is some doubt whether scour continues once the critical shear velocity is exceeded. Their results are at variance to those of Jain and Fischer (1980), but there is some evidence that once an active bed load has been established the rate of filling equals the rate of scouring and a type of scour equilibrium is reached. The reader is returned to the article by Breusers, Nicollet and Shen (1977) for a good comprehensive summary.

Thomas Zdenek (1967) examined the influence of protective collars and presented data for two collar sizes. The results showed that scour still occurred around the pile under the collar but of a lesser depth. With the collar directly on the bed at $u_* = u_{*_c}$ and $D_c/b = 3$, where u_{*_c} is the critical shear velocity, D_c is the diameter of the collar and b is the diameter of the cylindrical pile, the scour depth was reduced to 24.6% of the scour which was recorded when no collar was present.

A similar reduction was observed by Tanaka and Yano (1967).

Scour around deep ocean structures can thus not be determined from previous work. Little data exists for small surface Froude numbers, although an introductory discussion may be found in Carstens and Sharma (1975). Experiments on interlocking-type soils in flows with a small surface Froude number are thus required. Such an investigation was carried out and is described in this paper.

2 EXPERIMENTAL DESIGN

Scour behind a vertical cylinder depends on the sediment structure and composition, the mean velocity field, the turbulent velocity field in the water column and the shape of the structure. Defining the depth of scour as d_s and the diameter of the cylinder as b it is possible to write,

$$d_s/b = f(u_*, u_{*c}, u, g', d_{50}, h, \nu) \tag{1}$$

where u_* is the shear velocity, u_{*c} is the shear velocity at which bed motion is initiated over an unobstructed bed, u is the free stream velocity, g' (= $(\frac{\Delta\rho}{\rho})g$) is the effective acceleration due to gravity of the sediment particles, $\Delta\rho$ is the density difference between the sediment and the water, ρ is the density of the water, d_{50} is the median particle size, h is the depth of flow and ν is the kinematic viscosity.

In writing equation (1) it is assumed that the sediment structure and particle size distribution are characterised by the parameters u_{*c} and d_{50}. Cohesive soils are not considered in the present discussion. Further, the mean flow profile and the turbulent kinetic energy field are assumed to be that described by the "law of the wall" and so are completely characterised by the shear velocity u_*.

Invariance to a transformation of the dimensions requires that equation (1) may be written in the form:

$$d_s/b = f(u_*/u_{*c}, u_*^2/g'd_{50}, h/b, ub/\nu, d_{50}/h), \tag{2}$$

where the dimensional groups have been chosen to reflect the most likely force balances. In the order in which the groups appear in equation (2) the following interpretations are noteworthy:

a) u_*/u_{*c} is the ratio of the applied shear velocity to the value at which motion is initiated on a flat bed. This ratio captures the influence of the drag force exerted by the flow on the sediment bed as a fraction of the stress required to move the sediment without flow disturbances due to the structure. Scour usually commences at shear velocities well below the critical value because the cylinder induces a locally higher value immediately adjacent to the perimeter. The value of u_{*c} captures the erosion resistance characteristics of the sediment and so will not only depend on the sediment type and size, but also on its gradation and the final packing.

b) $u_*^2/g'd_{50}$ is the ratio of the inertia force on a sediment particle associated with the turbulent fluctuations of the flow to the effective weight of a sediment particle. The turbulent fluctation possesses velocities of the order of u_* and so the inertia term is merely a reflection of the form drag (pressure $0(\rho u_*^2)$ multiplied by the area presented by the particle) on the sediment particle.

c) h/b is the depth to cylinder diameter ratio. The importance of this parameter lies in the fact that as this boundary layer flow is intercepted by a vertical structure, the stagnation pressure at the leading edge of the structure will vary from ρu^2 in the core flow to 0 at the sediment base. This pressure difference is experienced by the flow over the velocity transition layers leading to a vertical pressure gradient at the leading edge of the structure of $0(\rho u^2)$. This pressure gradient induces a vortex motion of radius r_o which is swept around the pile forming a trailing vortex pair in the wake of the structure. The velocities associated with this trailing vortex pair combine with the mean flow causing a local increase of u_* in the immediate lee of the structure.

d) ub/ν is the cylinder Reynolds number. For Reynolds number larger than about 10^3 little effect may be expected until a value of 10^5 is reached. For values greater than 10^5, the separation is retarded by the turbulent boundary layer and the rear wake is somewhat narrower than that which would be expected from a laminar boundary layer. The pressure field in the wake arising from this separated flow combines with that from the trailing vortex pair to produce the observed total flow.

e) d_{50}/h is the relative roughness of the bed material. In coarse materials this parameter determines the turbulent structure in the bottom boundary layer. For the calcareous sediment and the sand under study the median diameter d_{50} ranges from 0.04 - 0.125mm and 0.25mm respectively implying that for smooth flat beds the flow is hydrodynamically smooth and the parameter d_{50}/h is of minor importance. For strongly roughened or pitted surfaces, however, a new parameter e/h must be added. The variable e is used to designate the roughness height of the undulations.

In the strictest sense the depth of scour will depend on all of the above parameters as well as possibly the sediment structure. However, interest here is centered around deep water structures for which h/b is large. Assuming experiments are not carried out at the critical Reynolds number, it may thus be expected that equation (2) reduces to the form:

$$d_s/b = f(u_*/u_{*c}, u_*^2/g'd_{50}) \tag{3}$$

and all other variables would be small scale effects. The experiments were designed to investigate the form of the function in equation (3).

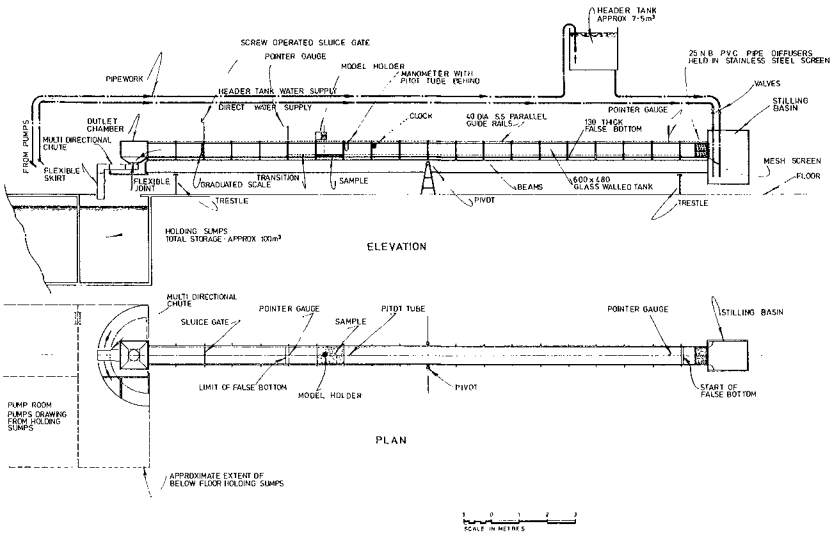

FIGURE 2 General arrangement of test flume.

3 EXPERIMENTAL PROCEDURE

The model tests were carried out in the Hydraulic Laboratory of the Department of Civil Engineering at The University of Western Australia. The experiments necessitated the construction of a 20m tiltable glass walled flume, the installation of a pitot-static tube and the design of sediment sample preparation techniques.

Experimental Flume and Apparatus

The general layout of the experimental test flume is shown in Figure 2. The flume consisted of a 20m long test section with a cross-section 600mm wide and 480mm deep. All tests were carried out with the flume in a horizontal position. The supply of water for the flume came from the laboratory storage tanks beneath the laboratory floor and was routed to the header tank of the flume via two pumps. Under normal operating conditions the system allowed the level in the flume to be kept constant to approximately $\pm$2mm. From the header tank the water moved through a converging entrance into the flume section through a multiple pipe diffuser installed in the first bay of the test section. The purpose of the pipe diffuser was to dissipate any wave action and uneven flow that may have arisen from the introduction of the water into the header tank.

The normal way of operating the flume was to set the downstream sluice gate at predetermined openings (15mm, 30mm, 50mm, 85mm, 100mm and 115mm) and then to adjust the two valves at the inflow to yield a full depth test. In this way it was possible to repeat experiments with almost identical flow conditions.

The flume was fitted with two surface rails accurately aligned allowing equipment to be positioned accurately within the flume. The pointer gauge, the pitot tube and the test section were all fitted in the flume from specially constructed trolleys running on the rails.

In order to be able to fit a 100mm deep sediment tray into the flume bed for the tests, it was necessary to construct a false bottom for most of the upstream part of the flume. This false bottom was constructed for 3m upstream and 1m downstream of reinforced P.V.C. sheeting. Upstream of this the flume bed was lined with bricks which were covered with a thin grout to yield constant depth of flow. The false bottom was painted and then while the paint was still wet, sprinkled with dry sediment. After drying, the surface remaining on the paint very closely resembled a smooth sediment surface with the same roughness properties as the sediment itself. Great care was taken to ensure that all the joints were smoothly aligned and that the sediment test section which fitted into the

false bottom through a cavity was accurately placed. The small gaps left were filled with plasticine to ensure a smooth, flat bed.

Sediment Tray

It was realised at the outset of the experiments that it would not be possihle to deposit sediment in the total length of the flume. Although this would have been advantageous in that it would have allowed tests to be carried out above the critical shear velocity, the logistics for obtaining such large quantities of deep ocean sediment and further of depositing the sediment in the flume made this impracticable. It was therefore decided to construct a test pan 100mm deep and 1m long which fitted across the flume. The material was sieved and redeposited into this test tray as described below after which time the tray was lifted with a small crane and positioned into the cavity of the false floor. The tray was constructed of reinforced fibreglass with a strong structural base to ensure no movement of the tray base occured during installation of the tray.

The Pitot Tube

The velocity in the flume was measured with a standard pitot-static tube with an outside diameter of 4mm. The pressure difference in the pitot tube was measured with a differential manometer. This manometer was filled with turpentine which had a specific gravity at room temperature of 0.808. The use of turpentine and water allowed accurate measurement of velocities even down close to the viscous sub-layer. The surface tension effect was minimised by choosing 10mm diameter tubes for the manometer. This meant that the instrument also had a large damping time allowing easy determination of the mean velocity profile.

Test Cylinders

The test cylinders were straight circular cylinders with diameters of 25mm, 50mm and 100mm with and without circular metal collar discs 3mm thick. The discs had diameters twice, three and four times the diameter of the cylinders and were made to allow for positioning at various heights above the upper surface of the sediment when the model structure was in position.

The leading edge of each of the model cylinders was fitted with a sharp V lip which was ground to a very fine edge in order that the whole circumference of the model would cut through the sediment with minimum disturbance during installation. A small hole was drilled through the upper flange of the model to allow the air to escape as the cylinder

was inserted into the sediment. This avoided possible compaction of the soil within the centre of the cylinder and the consequent disturbance of the soil adjacent to the cylinder wall by bearing capacity failure.

Sample Preparation

The 100mm thick calcareous sediment samples were prepared by a wet "sand rain" technique in an attempt to reproduce the natural method of in-situ deposition of the coastal sediments. This method is similar to the conventional dry "sand rain" technique used for uniform granular samples (Jewell et al (1980)).

A mass of 1.00kg of the sediment which had been packed wet and sealed after collection at sea was wet further to a moisture content of approximately 60% and moulded into a slurry. This slurry was spread uniformly onto a No. 14 mesh screen of exactly the same dimensions as the sample tray and then washed through the sieve with fine water jets into the tray below. After allowing at least 45 minutes for the finest particles to settle, all water more than approximately 5mm deep over the sample was siphoned off and the next layer was rained in until the prepared sample was at least 5mm above the top of the tray top lip. When the sample was required in the flume for testing, the excess water was siphoned off, the skirt removed from the tray and the soil above the top lip of the tray cut off. This was achieved by moving a vibrating cutter fitted with a vacuum system across the top of the tray producing a smooth surface without evidence of tearing or drag marks on the sample surface. The prepared sample tray was then weighed and lifted into the flume for testing. The average void ratio achieved by this method in the large sample trays was 1.73 which was somewhat higher than the understood typical field value of 1.35, with the layering and structure being reproduced rather well.

The control tests were carried out with clean, dry, uniform sand sieved to provide a d_{50} of 0.2mm. This was poured slowly into the sample tray which had previously been filled with water, vibrated vigorously on a vibrating platform normally used for preparing concrete test cubes, trimmed to height with a straight edge and then lifted into the flume for testing. The particle size distribution for this sand was almost linear between 0.125mm and 0.3mm.

Flume Performance

In order to verify the performance of the flume a number of tests were carried out to check the logarithmic profile above the smooth plastic false bed, the fixed sand sediment bed and the actual sediment tray. Table 1 summarises the results from this test and gives

TABLE 1 Flume performance data.

Code	Bottom			Flow Depth	Water Temp.	Flow Vel.	Shear Vel.	Measured roughness	$\frac{9z_o u_*}{\nu}$	Date of Test

Test Result Summary: Flume Performance

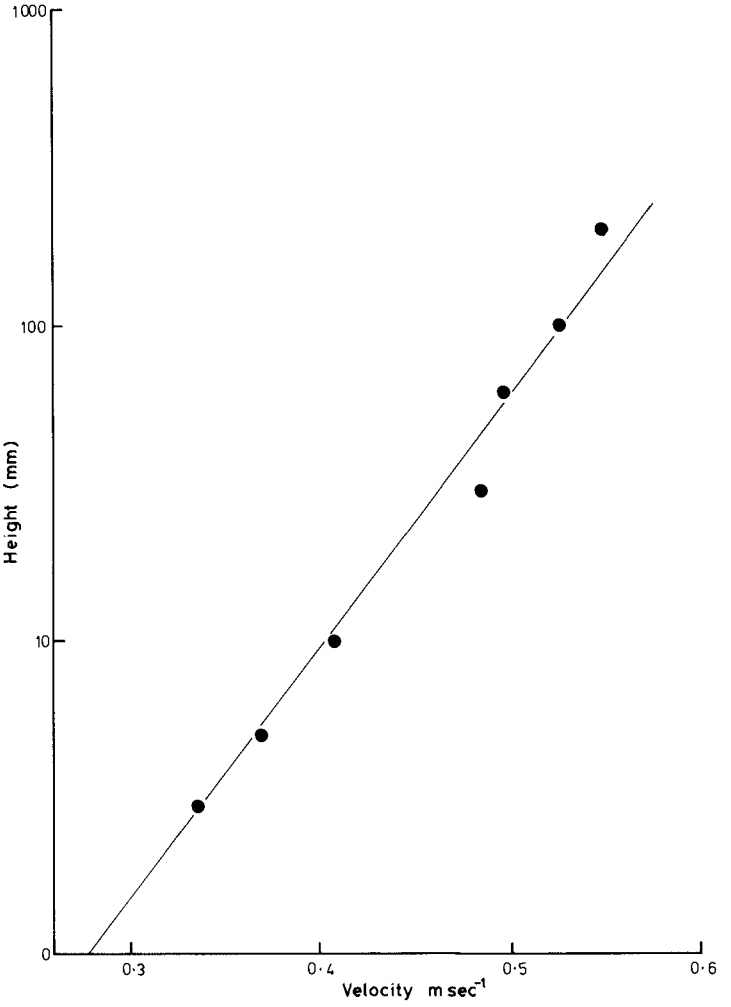
the flow depth, the water temperature, the flow velocity at 100mm, the shear velocity as calculated from the slope of the velocity profile, the measured roughness as calculated from the intercept of the velocity profile with the velocity axis and the last column gives the ratio of the measured roughness length, z_o to that predicted for a smooth bed. The velocity profiles were logarithmic as shown in Figure 3, and in general the effective roughness was in good agreement with the theory (see Table 1).

Test Results

All together 22 scour tests were carried out with the following configurations:

a) Circular cylinders in uniform sand.
b) Circular cylinders in ocean sediment.
c) Circular cylinders with a circular collar disc at the level of the ocean sediment surface.
d) Circular cylinders with a circular collar disc at a given distance off the ocean sediment surface.

In each case the soil tray was placed into position and the flume carefully filled with water with the sluice gate closed. The model cylinder was then inserted into the sediment, care being taken not to unnecessarily disturb the sediment. The tests were started by setting the sluice gate to a 15mm opening and adjusting the depth of flow with the upstream valves. Normally, tests were carried out with sluice gate openings at 15, 30, 50, 85, 100 and 115mm. Each test was recorded on video tape for later reference. The velocity corresponding to each sluice gate setting was measured at a height of 100mm from the channel floor with the pitot tube attached to the manometer and the shear velocity was determined by assuming a logarithmic velocity profile. The scour contours were sketched as the experiment proceeded and the depth of the deepest scour hole was recorded for each equilibrium situation. The velocity was raised in the channel until either scour had reached the sediment tray bottom (100mm) or until the shear velocity was equal to or a little greater than the critical shear velocity. Tests for shear velocities above the critical value could not be carried out as the experimental apparatus had no provision for upstream sediment replenishment.



Velocity distribution over a fixed sediment bed.

4 RESULTS

The Critical Shear Velocity

The critical shear velocity is defined as that shear velocity at which the particles on the bed begin to consistently move. In the case of the sand bed the initiation of motion was well defined and little ambiguity existed regarding the determination of the critical value of the velocity. Two separate tests, specifically conducted to determine the critical shear velocity, yielded values of 13mmsec^{-1} and 15mmsec^{-1} respectively. These values may be compared with the prediction from the Shield's diagram (Vanoni, 1975) of 13mmsec^{-1} for a uniform sand of 0.2mm median diameter. A value of 13mmsec^{-1} was chosen for the data reduction of the sand scour tests.

The determination of the critical shear velocity for the calcareous sediment was made difficult by the very patchy nature of the initiation of the bed particle motion. Distinct from sand this material formed small scour depressions when close to the critical shear velocity. These depressions deepened to about 1mm and widened to an elongated ellipse with a size of about 300mm in length and 10mm wide. At this stage further movement stopped and the activity shifted to other parts of the bed. It was therefore difficult to judge the exact value of the critical shear velocity, but two test trays yielded critical shear velocities of 24mmsec^{-1} and 23mmsec^{-1} respectively. During the whole range of the other scour tests conducted these values were repeatedly confirmed and so a critical velocity of 23mmsec^{-1} was chosen for all the data reduction.

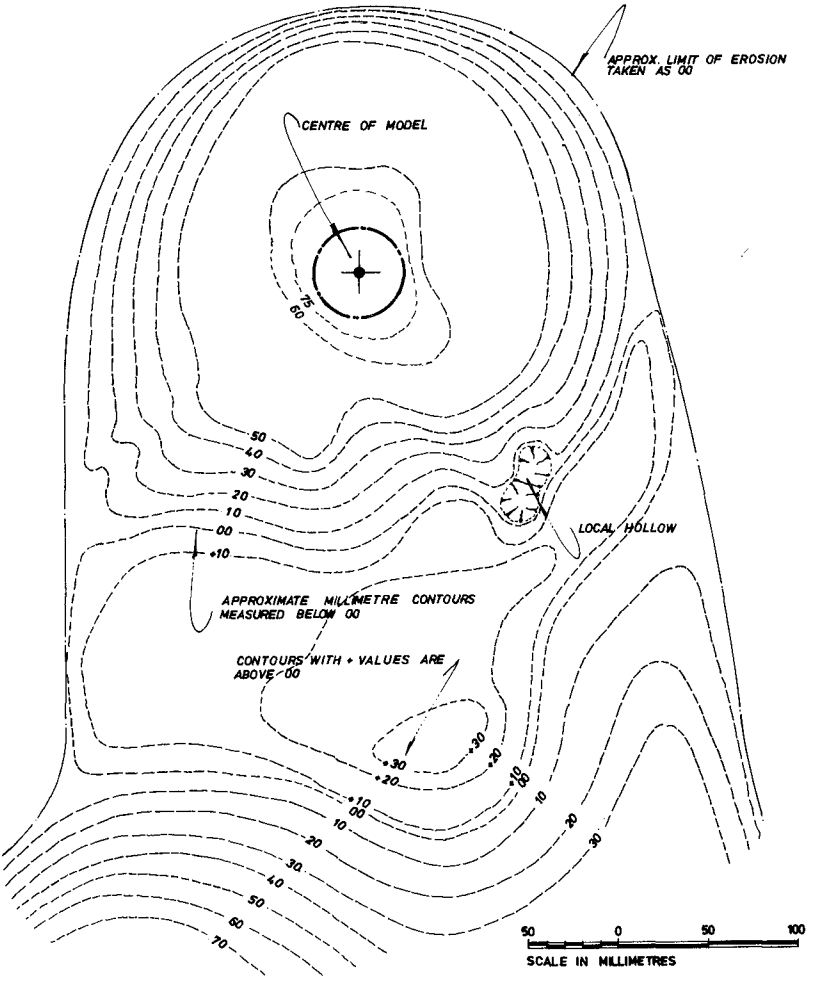
This value of the critical shear velocity for the calcareous sediment may be compared to the prediction of 12mmsec^{-1} from the Shield's diagram for a uniform sand with an equivalent diameter of 0.06mm. The calcareous sediment therefore derived from the interlocking of the particles an appreciably higher resistance to erosion than sand of equivalent size.

Scour Near A Circular Cylinder: Sand

Three sand scour tests were conducted mainly as control to enable comparisons with published data.

The scour patterns from all the tests were geometrically similar. The final depression for a test with the 50mm diameter cylinder is shown in Figures 4a and 4b where it is seen that the majority of the material which scoured out from near the cylinder was redeposited immediately to the rear of the scour depression.

FIGURE 4a Photograph of sand scour depression around 50mm cylinder at maximum u_*.



Sketch of sand scour depression contours around 50mm cylinder at maximum u_*.

The vortex motion and turbulence was seen to lift the sediment into suspension near the cylinder wall and the mean current carried the material out of the depression. This removal of material from the base of the depression always resulted in a slope adjustment further up the depression which replenished the areas where scour had taken material away. This process, as shown in Figure 4a, was symmetric and the scour depression was cone-shaped. Interesting radial depressions formed around the perimeter of the cone due to the presence of radial vorticity, but no detailed investigation of this mechanism was undertaken (see Figure 4b).

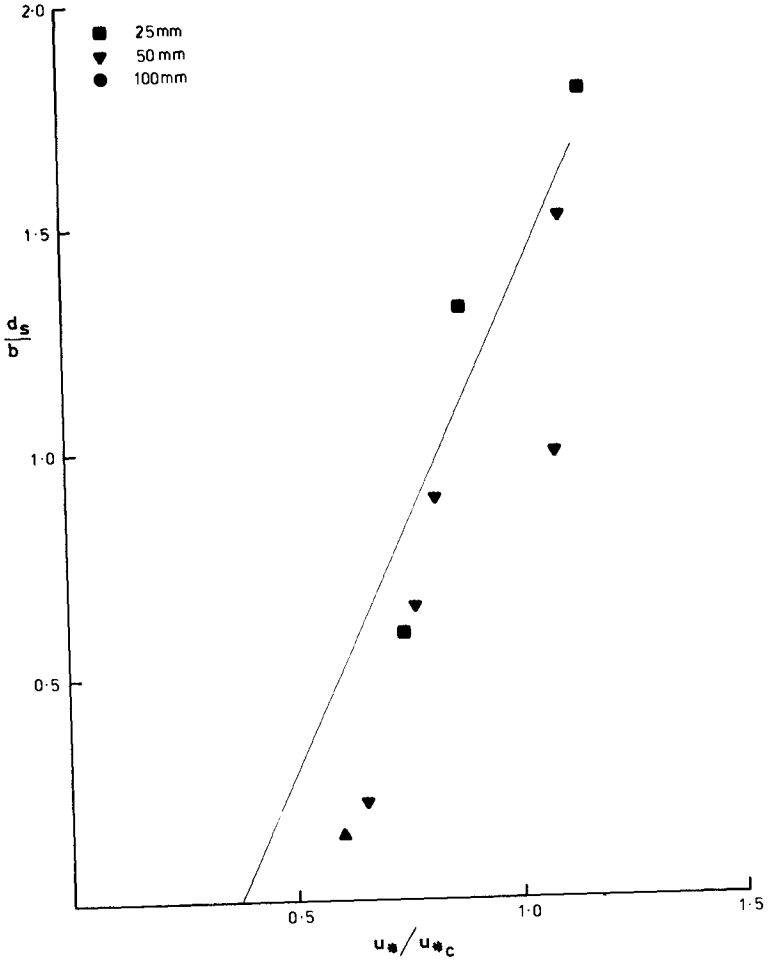
The equilibrium maximum scour depths are shown in Figure 5 for the tests with 25mm, 50mm and 100mm diameter cylinders. The data was plotted according to equation (3) and it is seen to display a linear trend with scour commencing at a value of $u_*/u_{*_c} = 0.5$.

Scour Near A Circular Cylinder: Sediment

The evolution of scour was characterised by a beginning of scour at the rear and either side of the cylinder. This happened at a u_*/u_{*_c} of approximately 0.3 to 0.4. As the velocity in the channel was raised the scour depression deepened at the rear and moved forward around the perimeter of the cylinder. The mode of deepening was similar in all cases. Small depressions would form locally, deepen up to 5mm and then broaden to the outer boundary of the depression. This led to sheet like striations at the edge of the scour depression as is seen in Figure 6a. This photograph also clearly shows a local depression next to the cylinder in the deepest part. The forward bank tended to be very steep and the spoils from this scour did not resettle in any of the experiments, but were swept downstream into the sump (see Figure 6b). This is further evidence that the particles interlock, giving the bed an erosion resistance far greater than the equivalent sand. The shear stress required to break this interlocking is considerably higher than that required to transport the particles once loose. This is in contrast to the sand case, in which the scoured sand was mostly deposited immediately in the lee of the scour depression indicating that the scour stress was only marginally higher than the transport stress.

The thickness of each scour layer evident in Figure 6a is many times greater than the individual layering introduced during sample preparation and it is not likely that the sample preparation formed the layers.

It is seen from Figure 7 that the data from the different tests form a linear correlation between d_s/b and u_*/u_{*_c} independent of the internal particle Froude number. The line of best fit is given by the equation:



Dimensionless plot of scour depth against the shear velocity for a circular cylinder in 100mm deep sand.

FIGURE 7.

$$d_s/b = B(u_*/u_{*c} - 0.374) \quad (4)$$

where the constant B = 2.18.

Effects of Collars on Scour Depth

Visualisation of the flow with dye streaks clearly showed the formation of a horseshoe vortex around the front of the cylinders which was then swept around the perimeter of the cylinder. In the wake the vortex filaments combined to give a fairly confused wake with a peak outward flow at the bed of about half diameter in the lee of the cylinder and spaced approximately one third cylinder apart.

It was postulated that placing a metal collar around the cylinder should protect the bed from this increased flow intensity and so a series of experiments were conducted with differing collar to cylinder diameter ratios and at three levels; tests were carried out with the collar level with the bed, 20mm from the bed and one with the collar at 60mm from the bed.

Scouring for all collar ratios, with the collars at bed level, started at a u_*/u_{*c} of about 0.4 with this initial scour occuring downstream of the collar within the wake region. Initial scour did not occur as for the plain cylinder but rather resembled a surface scraping process in the wake region well away from the collar perimeter. As the flow was increased, the scour area widened and moved upstream up to the collar eventually undermining the downstream half of the collar area. For collar to cylinder diameter ratios of 3 and 4 the scour depression widened very considerably as seen in Figure 8, leading to a depression width of 2-3 times the diameter of the collar. Reduction of the diameter ratio led to progressive movement of the scour depression upstream under the collar into the cylinder. For the case of a ratio of 2 scour occured around nearly three quarters of the cylinder immediately below the collar.

The equilibrium depth for a particular shear velocity was always achieved by a central deepening and then a progressive widening. The final scour depths are shown in Figures 9a, b and c for the different collar to cylinder diameter ratios.

From these diagrams it is seen that scour commenced at much the same value of u_*/u_{*c} as with no collar, but the rate of scour was slower until d_s/b of about 1 where upon scour seemed to increase. Although it was not possible to attain in the present facility, the data indicate a trend back towards the cylinder without collar curve for ratios of d_s/b

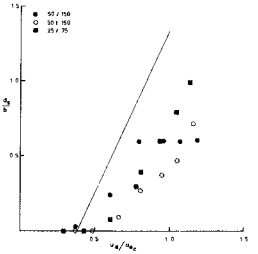
FIGURE 9a



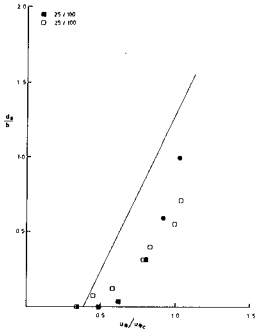


FIGURE 9c

larger than about 1. The scour retardation seemed to be more marked the larger the value of d_s/b.

To investigate the transition back to the plain cylinder case, the effective d_s was increased by raising the collar 20mm above the sediment bed. The results from these tests are shown in Figure 10. All ratios of d_s/b are included and it is seen that there is a general trend back to the plain cylinder line until at d_s/b of about 1.5 the scour depth is back to that found in the plain cylinder case. The scour process in the raised collar tests differed very little to that described above for the level collar tests. For the ratio d_s/b = 3 and 4 the scour developed at the perimeter of the cylinder after which it became localised in the region directly under the collar. For the ratio d_s/b = 2 the scour was very erratic, most probably due to the added turbulence caused by the edges of the collar.

The tests with the 50mm diameter cylinder indicated a disappearance of the effect of the collar at d_s = 75mm to 80mm. Subtracting the 20mm, would imply that a 50mm diameter cylinder with a collar at 60mm height would show no effect of the collar. The results shown in Figure 10 substantiate this conclusion, indicating that the horseshoe vortex is affected by plates or collars for a distance above the bed of about 1.5 times the cylinder diameter. This is considerably larger than the horseshoe vortex diameter ratio of 0.25 predicted by Qadar (1981).

FIGURE 10

5 DISCUSSION AND CONCLUSION

The work carried out in the present investigation has brought to light the importance of the parameter u_*/u_{*c} for the determination of the depth of scour. It appears that the other parameter, the internal sediment Froude number, plays only a minor role. In order to test this hypothesis further, all available data from the literature for circular cylinders in model tests were reduced onto the same graph. Figure 11 is the resulting variation, with the data plotted being obtained directly from the publications of Breusers (1977), Chabert and Engeldinger (1956), Jain and Fischer (1980), Qadar (1981), Shen et al (1966) and of course the present results. The experimental data plotted in Figure 11 is listed in Table 2 and is from tests the details of which are included in Table 5. The soil types range from the present calcareous sediment with a $d_{50} \simeq 0.06$mm through sands varying in diameter from 0.2mm up to a maximum diameter of 3mm (test of Chabert and Engeldinger (1956)). This means that the range of u_{*c} covered in Figure 11 is from about 12mmsec^{-1} to about 35mmsec^{-1}. Similarly the range of cylindrical pile diameters covered by the data is from 25mm to 200mm.

Only those data which represent ratios of flume depth to cylinder diameter of greater than 3 were included in the presentation. An exception to this case is some of the data from Shen et al (1966) which included ratios marginally smaller than three. However, these values were corrected for the smaller depth to diameter ratio by a formula suggested by Breusers et al (1977) who postulated the depth of scour to the depth to diameter ratio $d_s/b = 1.5 \tanh h/b$.

All the data show a very definite trend about the line of best fit derived from the sediment experiments (Figure 7). The scatter is not unusually severe for sediment transport or scour type experiments and it is believed that the most important correlation is captured in Figure 11. This means that the influence of different void ratios, soil structure and soil scour on the resistance is all provided for through the value of the critical shear velocity.

Unfortunately there is very little data available from larger laboratory experiments or from bridge pile monitoring of large depth to cylinder diameter ratios, and for values of u_*/u_{*c} less than unity. The work by Qadar (1981) would indicate that the horseshoe vortex diameter is determined by the diameter of the cylinder and to a much smaller degree by the height of the bottom shear region. This would suggest that the present results should scale to prototype situations. However, the present results suggest a considerably larger vortex diameter than predicted by Qadar (1981).

FIGURE 11.

The mechanisms for scour in the sediment and in the sand were discussed in section 4 where the very different nature of the two mechanisms was pointed out. In the case of sand, scour is achieved by the suspension of the material and subsequent slumping. By contrast, in the case of the sediment it appeared that the eddying in the horseshoe vortex caused local scour which deepened at first and then broadened to form a sheet like scour depression. The failure of the soil was much more hy lateral or horizontal scouring by the fluid as it swept past the near vertical sediment walls. There was very little evidence of the sediment slumping at any stage of the scour process. It is therefore quite remarkable that the sediment data and the sand data show the same correlation between d_s/b and u_*/u_{*_c}. This implies that, even though the mechanisms are different, it is the turbulent kinetic energy that is ultimately responsible for the scour. Similarly it is the single parameter u_{*_c} which determines the resistance of the soil to scour.

Installation of a protective collar hecame effective for collars at least twice the diameter of the cylinder. However, even for the large collars, scour holes formed and deepened to a depth comparahle to plain cylinders for u_*/u_{*_c} larger than unity, hut by the action of the wake rather than the horseshoe vortex. For collar diameters equal to twice the cylinder diameter the effect of the collar became negligible for d_s/b beyond a value of 1.5.

INCIPIENT MOTION OF PARTICLES UNDER OSCILLATORY FLOW

by

L Lenhoff*

ABSTRACT

This paper is aimed at the establishment of a generally applicable criterion for the onset of grain motion under the influence of oscillatory flow. Data from previous studies are used in a dimensional analysis and an empirically derived relationship between the dimensionless parameters R* (shear Reynolds number) and D* (dimensionless grain parameter) is proposed as a criterion to be used in coastal engineering problems.

This study forms part of a larger programme by the Sediment Dynamics Division of the National Research Institute for Oceanology in Stellenbosch, RSA, which is aimed at the re-evaluation and updating of the input parameters and relationships for the predictive equations for coastal sediment transport.

1. INTRODUCTION

Coastal sediment transport formulae are based mainly on the transport formulae derived for uniform flow. In contrast with the initiation of sediment motion under wave action, the conditions for movement under unidirectional steady flow have been widely studied by numerous researchers during the past years and well established criteria for the beginning of movement exist. The applicability of the criteria for incipient motion under uniform flow to oscillatory motion is, however, questionable.

A number of excellent studies with respect to oscillatory flow have already been done. The problem, however, is a complex one, mainly due to the numerous variables involved. Therefore most authors preferred to base their criteria on experimental rather than purely theoretical analyses. Although each individual study was obviously well designed and the results were very convincing, the different criteria are not always compatible, mainly due to

---

* Sediment Dynamics Division, National Research Institute for Oceanology, CSIR, Stellenbosch, RSA.

differences in experimental set-up and initial conditions employed. The subsequent different ranges of applicability also make direct comparisons difficult. Different authors also presented their results in different ways and for comparative purposes all the criteria should be written in the same form. This was done by Silvester (1974) who calculated the critical near bed velocity at the onset of movement under specific boundary conditions, using the empirical formulae derived in a number of previous studies. He concluded that little correlation exists between the different criteria, mainly because some criteria were used outside their ranges of applicability.

Despite this apparent lack of correlation, it was nevertheless felt that the vast amount of data which are available may still yield satisfactory results if they are analysed within a general theoretical framework and the results brought together on a single curve.

All the relevant available studies were subsequently investigated with special emphasis on the quality of the data. Aspects which were carefully looked at were, for example, the experimental procedure, sediment characteristics, parameters directly measured during the experiment and the authors' definition of incipient motion.

2. EVALUATION OF AVAILABLE DATA

The data which were used in this study can be broadly subdivided into four groups based on the experimental set-up, namely, those tested with:

(i) The simple harmonic motion of sediment particles through still water.

(ii) Water oscillating in a U-tube over bed material.

(iii) Progressive waves over bed material in a conventional wave flume.

(iv) Direct measurement of water movement on the sea floor due to surface waves, that is, prototype data.

According to these four types of data, the different data sources which were used in this study can be grouped as follows:

Oscillating bed material	U-tube	Wave flume	Prototype
Bagnold (1946) Manohar (1955)	Ishihara and Sawaragi (1962) Carstens et al. (1967) Rance and Warren (1968)	Vincent (1959) Horikawa and Watanabe (1967)	Davies and Wilkinson (1978)

3. DEFINITION OF INCIPIENT MOTION

The determination of the actual onset of movement during an experiment is normally done by visual observation. Unfortunately the definition of incipient motion is not clear cut. Normally it relates to the proportion of moving grains on the bed surface. Manohar (1955), for instance, found that at a certain critical velocity a few particles were dislodged from their position of equilibrium and moved a short distance from their initial position. This movement of a few particles in the top layer was defined as initial movement.

Vincent (1959) considered the initial motion condition to be characterised by the displacement of the very first grains.

Carstens et al. (1967) defined incipient motion on a flat bed when approximately 10 per cent of the surface particles were rolling back and forth.

Rance and Warrent (1968) considered the dislodgement and small downstream movement of the first one or two grains to be the onset of motion.

This variation in definitions is a major handicap in any comparative study. Even when the onset of motion is properly defined within a single experiment, the assesment of the exact onset of motion is difficult and subjective. In addition, the particles in the sandy bed are not of uniform size, and consequently the onset of motion will be largely dependent on the grain size distribution of the bed material. This is clearly illustrated by the prototype data of Davies and Wilkinson (1978). Although the wave period stayed essentially constant during their observations, the measured horizontal orbital velocity at incipient motion varied by a factor two.

4. RE-ANALYSIS OF DATA

As it is the purpose of this paper to bring data from different sources together on one universal curve, a considerable scatter must therefore be expected. The question at this stage would be which parameters to use in the dimensional analysis to obtain the most acceptable results for application in coastal engineering studies. Various relationships have been used in the past to present the results of studies on incipient motion. A typical example is the critical sediment number (N_{SC}) as defined by Carstens et al. (1967), namely,

$$N_{SC} = \frac{U_{OC}}{(\Delta_S \, d \, D_{50})^{1/2}} = f(T, D_{50}, \rho_W, \rho_S) \quad \ldots \quad (1)$$

where U_{OC} = horizontal orbital velocity at bed at onset of movement

D_{50} = median grain diameter of bed material

ρ_W = density of fluid

ρ_S = density of material

Δ_S = relative buoyant sediment density = $(\rho_S - \rho_W)/\rho_W$.

The main disadvantage of this parameter in defining incipient motion lies in the fact that it does not contain the bed roughness in any way and can therefore not be used for a unique determination of the critical shear stress. Since the sea bottom is normally rippled in the areas of coastal engineering interest, the ultimate goal would be to extend any incipient motion criterion to ripple bed conditions. The sediment number can therefore hardly be unique for flat bed as well as rippled bed conditions.

The parameters which were chosen for the graphical presentation of the data in this study are the shear Reynolds number R* and a dimensionless grain diameter D* (by analogy with Bonnefille and Pernecker (1966) where

$$R_* = \frac{U_* \, D_{50}}{\nu} \quad \ldots \quad (2)$$

and

$$D_* = \left(\frac{\Delta_S g}{\nu}\right)^{1/3} D_{50} \quad \ldots \quad (3)$$

with U_* = shear velocity

ν = kinematic viscosity of fluid.

The choice of R* enables the inclusion of the bed roughness since

$$U* = \left(\frac{\bar{\tau}}{\rho_w}\right)^{1/2} \quad \ldots (4)$$

with $\bar{\tau}$ = mean shear stress = $^1/_4\ \rho\ f_w\ U_o^2$ ... (5)

and $f_w = f(a_o/r)$ where

a_o = maximum orbital excursion from mean position of the motion of water particles at the bed

r = bed roughness

f_w = wave friction factor

The procedure by which the data were re-analysed depended for each set on the parameters which were directly measured during the original experiment. In the case of oscillating bed material as well as the oscillating water tunnel, the angular velocity (ω) and the horizontal displacement (a_o) were usually directly measured at the onset of motion. The subsequent determination of R* and D* in such cases is straighforward, using the standard relationships for simple harmonic motion and equations (2) an (3).

In experiments which were done in conventional wave flumes the wave height (H), wave period (T) and the water depth (h) at the incipient motion condition were normally observed. It was felt that all the data which were obtained by means of progressive waves should be treated in the same manner and for this purpose the Vocoidal water wave theory of Swart (1978) was employed. A computer program which used the Vocoidal theory was written to calculate R* and D* for any combination of T, d, H, D_{50} and ρ_s.

The generalised procedure of analysis may therefore be summarised as follows:

(i) Computation of the wave properties U_o and a_o.

(ii) Computation of the bed roughness r using the following formulae:

$r = 2\ D_{90}$ (flat bed; Kamphuis, 1975)

$r = 25\ \Delta_r\ \left(\frac{\Delta_r}{\lambda_r}\right)$ (rippled bed; Swart, 1976)

where Δ_r = ripple height

λ_r = ripple length.

(iii) Computation of a_o/r.

(iv) Computation of orbital Reynolds number

$$R = \frac{U_o a_o}{\nu}$$

(v) Determination of the wave friction factor f_w using empirical relationships based on more than 600 data sets (Swart, in preparation, 1982).

(vi) Calculation of R* and D* using equations (2), (3), (4) and (5).

5. RESULTS

A total number of 643 data points consisting of combinations of R* and D* at the onset of movement were calculated in the above manner. Figure 1 shows a logarithmic plot of the results together with a best fit curve through the data points. This empirical curve was found to be very closely simulated by the following parabolic equation:

$$\log_{10} R* = 0{,}092(\log_{10} D*)^2 + 1{,}158 \log D* - 0{,}367 \quad .. \quad (6)$$

It is also possible to test the validity of equation (6) by making use of laboratory and field measurements of sediment load under waves in conjunction with appropriate predictive sediment load equations which include an incipient motion criterion. For this purpose the Ackers and White sediment load formula for steady flows, as modified for application in the coastal area (see Swart and Fleming, 1980) will be used.

The original formula for the prediction of sediment transport rates under steady-state conditions was (Ackers and White, 1973):

$$S = 1{,}45\, U\, D_{35}\, C \left(\frac{Pfg/\rho}{U^3_{fg}}\right)^n \left(\frac{Pcg/\rho}{U^2_{cg} U_r}\right)^{1-n} \left(\frac{Fgr}{(Fgr)crit} - 1\right)^m \quad ... \quad (7)$$

where C, n, m and $(F_{gr})_{crit}$ are grain size dependent parameters, for which empirical relationships are given by Ackers and White; F_{gr} is the sediment mobility = $(U^n_{*fg}\, U^{1-n}_{*cg})/(\Delta_s\, g\, D_{35})^{1/2}$;
P is the stream power; U_r the resultant velocity (= U for steady state) and U* is the shear velocity = $(\tau/\rho)^{1/2}$; subscripts "fg" and "cg" respectively denote the "fine grain" and "coarse grain" versions of the properties. The

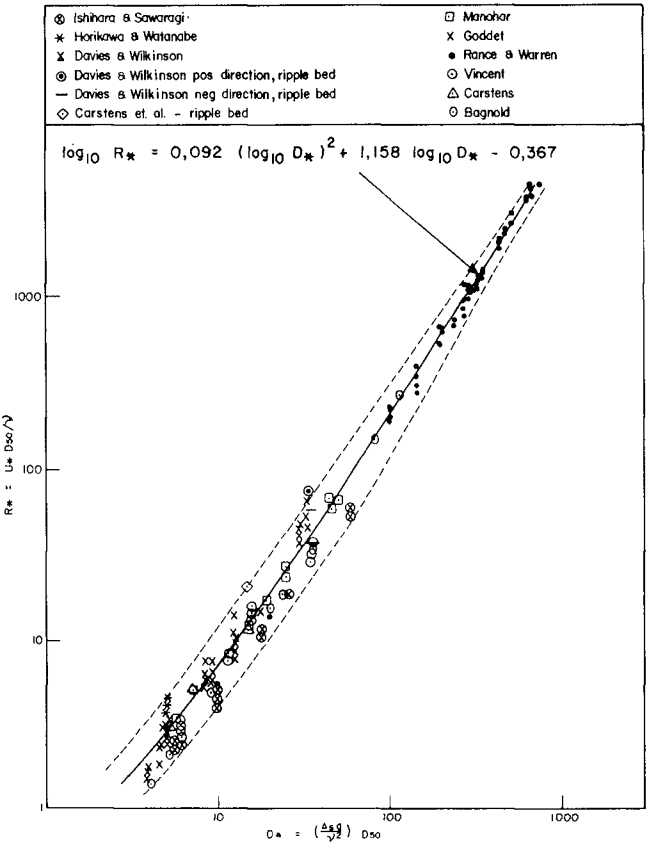

FIG. 1 INCIPIENT MOTION OF SEDIMENT PARTICLES UNDER OSCILLATORY FLOW - EXPERIMENTAL RESULTS

value for fine-grained sediment is obtained by using the actual bed roughness r, as described before, whereas the value for coarse-grained sediment is obtained by using the grain size D_{35} instead of r in the appropriate equations. For steady state conditions the efficiency term reduces to $(U/U*_{fg})^n$.

Various adapted versions of the original steady-state Ackers and White formula were in use in 1980, varying only in the way in which the effect of waves was included in the stream power and mobility terms (Swart, 1976; Willis, 1978; Van de Graaf and Van Overeem, 1979). Swart and Fleming (1980) discussed these versions and came to the conclusion that all three methods quoted above had shortcomings. They then suggested a fourth alternative which used the better aspects of each method and discarded the rest. The main points of improvement of this latter method as opposed to the earlier modifications were the following:

(1) The average effect of the inclusion of waves on the mean mobility number is calculated by integrating the instantaneous mobility number with respect to time, that is,

$$F_{wc} = \overline{F_{gr}(t)} = {}^1/_T \int_0^T F_{gr}(t)dt \quad \ldots \quad (8)$$

where F_{wc} is the mean sediment mobility for combined current and wave action.

(2) The instantaneous value $E_f(t)$ of the efficiency term, as given in equation (9) is averaged to obtain the mean value E_{fwc} of the efficiency term for combined current and wave action, namely,

$$E_{fwc} = \overline{E_f(t)} = {}^1/_T \int_0^T E_f(t)dt \quad \ldots \quad (9)$$

$$\text{where } E_f(t) = \left(\frac{P_{fg}(t)/\rho}{U*_{fg}(t)^3}\right)^n \left(\frac{P_{cg}(t)/\rho}{U*_{cg}(t)^2\, U_r(t)}\right)^{1-n} \quad \ldots \quad (10)$$

Values for the instantaneous resultant velocity at the bed $U_r(t)$ and the instantaneous shear stress at the bed $\tau(t)$ are found by vector addition of the contributions by the waves and the currents.

By equating measured sediment load data under known wave conditions to the right-hand side of this adapted version of equation (7), values for the critical sediment mobility $(F_{gr})_{crit}$ were calculated. Since $(F_{gr})_{crit}$ is simply related to R* by

$$(F_{gr})_{crit} = R_* D_*^{-3/2}, \quad \ldots (11)$$

corresponding values for R_* could be computed.

The results of this calibration technique for the threshold of motion can be seen in Figure 2. The threshold values calculated in the above manner agree very well with the threshold criterion proposed in terms of equation (6). The result is also extremely significant in the sense that it illustrates the efficiency of the adapted Ackers and White formula for the prediction of sediment load under waves, provided that equation (6) is used to define the critical sediment mobility.

Equation (6) can be rewritten in terms of a non-dimensional shear velocity V_*,

where $V_* = U_*/(g\Delta_S \nu)^{1/3}$ ... (12)

This implies that

$$R_* = U_* D_*/(\Delta_S g \nu)^{1/3} = V_* D_* \quad \ldots (13)$$

Equation (5) therefore reduces to

$$\log V_* = 0{,}092(\log D_*)^2 + 0{,}158 \log D_* - 0{,}367 \quad \ldots (14)$$

The relationship between V_* and D_* as obtained from equation (14), as well as the scatter observed in the data, is indicated in the following table where V_* represents the value obtained from equation (14), while V_{*max} and V_{*min} corresponds to the upper and lower envelopes of the experimental data:

D_*	V_*	V_{*max} [1]	V_{*min} [1]
4	0,51	1,00	0,31
10	0,63	1,35	0,40
20	0,83	1,75	0,55
50	1,22	2,70	0,86
100	1,75	3,20	1,50
200	2,75	3,75	2,50
500	4,60	6,00	4,00
700	5,71	6,43	4,86

Comment: 1) These numbers reflect the maximum variability in the data.

The scatter indicated by this table may look appreciable for low values of D_* but is in fact of the same order of magnitude as that observed in the Shields diagram for steady flow and may be attributed to experimental errors and the use of different definitions for incipient motion.

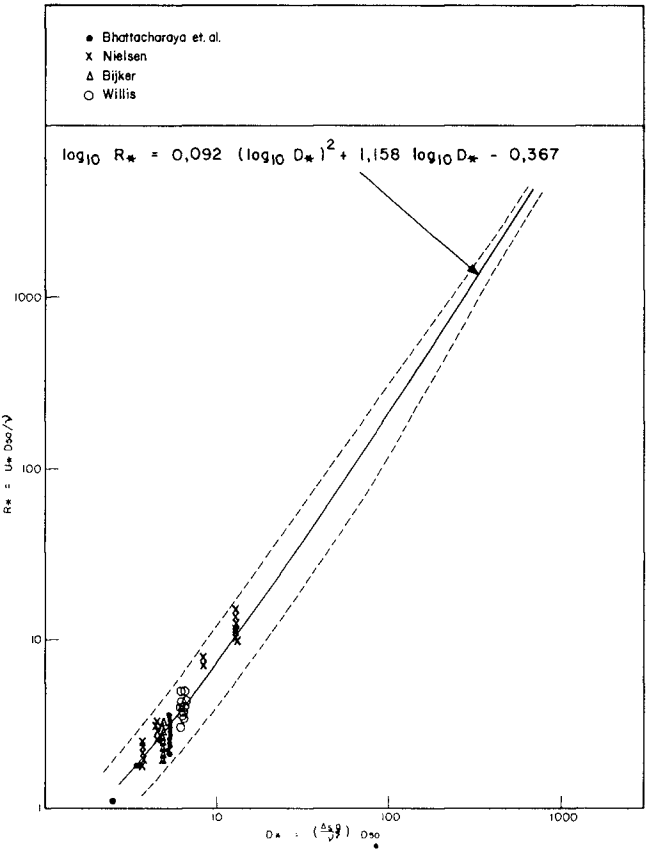

FIG. 2 COMPARISON WITH THRESHOLD VALUES COMPUTED FROM SEDIMENT LOAD DATA

6. COMPARISON WITH UNIDIRECTIONAL FLOW CRITERIA

The conditions for movement under unidirectional steady flow have been widely studied by numerous researchers and well established criteria for the beginning of movement exist. The work by Shields (1936) and Ackers and White (1973) are probably the most widely used and acknowledged in this respect. A direct comparison between these two criteria and the results of this study can now be made. Figure 3 shows the original Shields and Ackers and White data points together with the curve defined by equation (6). The envelope encompasses data scatter for oscillatory flow. The unidirectional data can be seen to fall well within the scatter of the oscillatory flow data points. It can therefore be concluded that there is no significant difference between the criteria for uniform flow and the criterion of oscillatory flow as derived in this study. A single criterion can be applied with the same degree of accuracy for both flow conditions. Consequently it is reasonable to assume that the criterion developed in this study can be applied for wave-generated flows, current-dominated flows and all combined flow modes in between, provided that the correct definition of the shear velocity is used in equations (6) and (14).

7. CONCLUSIONS

The main conclusions drawn from the present study are as follows:

(1) An empirical criterion, equation (6) or (14), was derived for the onset of grain motion on either a flat or a rippled bed under the influence of wave action.

(2) It was shown that the new criterion is not only valid for incipient motion due to waves but also does not differ from widely used incipient motion criteria for steady-state conditions (Shields, 1936; Ackers and White, 1973). In addition, provided that the correct definition of the bed shear is used, it also applies to the case of combined current and wave action. It can therefore be seen as a fairly universal criterion for the onset of grain movement.

(3) Comparison to sediment load data via the adapted Ackers and White sediment load formula given by Swart and Fleming (1980) yielded values of the incipient motion mobility number which would have been required to allow the sediment load formula to predict the measured sediment load. These indirectly calculated incipient motion data fall within the scatter of the original data used to derive equation (6). This serves as a very strong independent proof of the adapted Ackers and White sediment load formula given by Swart and Fleming (1980).

RESUSPENSION OF DEPOSITED COHESIVE SEDIMENT BEDS

By Ashish J. Mehta[1], M. ASCE and Emmanuel Partheniades[2], M. ASCE

ABSTRACT

Surficial layers of estuarial fine, cohesive sediment beds are deposited from flow and often are in a state of partial consolidation. A series of laboratory investigations were carried out to elucidate the erosional behavior of deposited cohesive sediment beds in flumes using kaolinite. A significant feature of such beds is that they are stratified with respect to the density and the cohesive shear stength. Under a given bed shear stress, erosion occurs at a continuously decreasing rate up to a depth at which the bed shear stress equals the shear strength. This bed shear stress is therefore also equal to the critical shear stress for erosion at that depth. An expression for the rate of erosion relating this rate to the difference between the bed shear stress and the critical shear stress has been obtained. The critical shear stress increases both with depth and with the bed consolidation time. The rate of erosion decreases with increasing consolidation time.

INTRODUCTION

The sediment at the bottom and in suspension in most estuaries is typically fine, cohesive in nature (14). Cohesive sediments are comprised primarily of particles in the clay and silt size-range plus organic matter and waste materials. Surficial layers of cohesive sediment beds in estuaries generally consist of partially consolidated material deposited from flow (9). Such layers have a high water content and very low cohesive shear strength which tends to exhibit a non-uniform variation with depth below the bed surface. The shear strength is however too low for it to be measured, for example, with such device as a penetrometer (13). The bed can exhibit two modes of failure. The first, known as surface erosion, involves floc-by-floc rupture and entrainment of the surficial sediment. The second, known as mass erosion, results from a dynamic shear loading of the bed. In this case the plane of failure lies deep in the bed, and failure results in an almost instantaneous entrainment of the sediment above the plane. Under typical estuarial environment, erosion occurs predominantly at the surface and is considered here. Until recently,

[2]Prof. of Hydr. Structures, Aristoteles Univ. of Thessaloniki, Greece; and Prof., Dept. of Engr. Sci., Univ. of Florida, Gainesville, FL.

the erosional behavior of deposited beds was not investigated adequately (9). Attempts to relate the rate of erosion with standard soil indices such as the Atterberg limits were unsuccessful because these indices do not properly account for the resistance to erosion which essentially depends upon the strength of the inter-particle electro-chemical bonds (12, 14). Resistance to erosion must be characterized by physico-chemical parameters, some of which have been identified more recently (8).

Laboratory investigations were carried out at the University of Florida in order to investigate the erosional behavior of deposited cohesive sediment beds. The main findings are summarized below. Details are given elsewhere (1, 7, 11, 16).

APPROACH

The rate of surface erosion, ε, expressed as the mass of sediment eroded per unit bed area per unit time, is related to the time-rate of change, dz/dt, of the depth of erosion, z, below the initial bed surface according to:

$$\varepsilon = h\frac{dC}{dt} \tag{1}$$

$$\frac{dC}{dt} = \frac{\rho(z)}{h}\frac{dz}{dt} \tag{2}$$

where h = depth of flow, dC/dt = time-rate of change of suspended sediment concentration, C, and $\rho(z)$ = depth-varying dry density of the bed. Several investigators measured the variation of dC/dt with time t for deposited beds in a closed system and observed that, under a constant bed shear stress, τ_b, dC/dt (and therefore ε) generally decreases continuously with t, beginning with a relatively high value when erosion commences (9). For a certain range of τ_b and "large" t ranging from a fraction of an hour to several hundred hours depending upon the type of fluid-sediment mixture and the magnitude of τ_b, the rate of erosion, ε, becomes equal to zero or approaches zero. In other words, C becomes constant or approaches a constant value asymptotically. Given the bed density distribution $\rho(z)$, the magnitude of the constant value of C and the rate of approach of C to this value depend upon τ_b (which defines the erosive force), and upon parameters which characterize the resistance to erosion. Important among the latter is the cohesive shear strength of the bed with respect to erosion.

In the reported studies, resistance to erosion was varied by two means: 1) by varying the conditions for bed preparation, and 2) by varying the salinity of the fluid. Time-concentration data obtained under a wide range of τ_b values have been used together with the bed density in order: 1) to elucidate the mechanics of the resuspension behavior of deposited beds, and 2) to obtain an expression for the rate of erosion in terms of the bed shear stress and parameter(s) characterizing resistance to erosion.

APPARATUS AND MATERIAL

The experiments were performed in two flumes: a rotating annular flume and a flow recirculating flume. The two main components of the annular flume (Fig. 1) are: an annular fibreglass channel (0.21 m wide, 0.46 m deep, and 1.5 m in mean diameter) containing the fluid-sediment mixture, and an annular ring of slightly smaller width positioned within the channel and in contact with the fluid surface. A simultaneous rotation of the two components in opposite directions generates a uniform turbulent flow field free from floc-disrupting elements such as pumps and diffusors in which very high shearing rates generally prevail. By a proper adjustment of the speeds of the two components the rotation-induced secondary currents are eliminated, and the distribution of the bed shear stress across the channel width is found to be uniform (5). The steel recirculating flume, open at the top (Fig. 2), is 18 m long, 0.6 m wide and 0.9 m deep, with an underflow-type control gate at the downstream end. The return pipe diameter is 0.2 m. One side of the flume is made of glass panels for visual observations (1).

A commercial kaolinite with a cation exchange capacity of approximately 12 milliequivalents per hundred grams was used in all tests. The median diameter of the deflocculated sediment was 1 micron, with a range of 0.2 to 40 microns. The fluids were: 1) distilled water as well as salt water of 35 ppt concentration using commercial grade sodium chloride in the annular flume, and 2) tap water with a very low total salt concentration of 0.28 ppt as well as salt water of 35 ppt concentration in the recirculating flume. Kaolinite readily flocculates even in distilled water. The sediment was equilibrated with the fluid for atleast two weeks prior to each test series. The depth of flow was maintained at 31 cm in the annular flume and 23 cm in the recirculating flume. Fluid temperature varied with the ambient. The mean was approximately 26°C.

EXPERIMENTS AND RESULTS

There were four experimental series. These are described in the order in which they were performed.

Series 1 Experiments

These experiments were carried out in the annular flume using kaolinite in distilled water (7). Two types of beds were used: the first was deposited gradually from suspension while the flume was in motion and the bed shear stress was kept slightly less than τ_{bmin}, i.e., the shear stress at which the entire amount of initially suspended sediment deposits eventually (6). The second was prepared outside the flume at a density close to that of the deposited sediment and subsequently placed and leveled into the flume. The main difference between these two beds was with respect to the vertical distribution of their cohesive shear strength. In the formation of the first bed there was a preferential deposition whereby larger and more cohesive flocs deposited first while the smaller, less cohesive flocs deposited later. For this reason the first bed may be referred

Fig. 1. A View of the Annular Rotating Flume.

Fig. 2. A View of the Open, Flow Recirculating Flume.

to as stratified, a situation commonly encountered in estuaries. In contrast, the second bed may be termed uniform, since it had practically constant properties in the vertical direction.

Figure 3 shows the time-concentration relationship for the case of a stratified bed eroded under a shear stress τ_b = 0.207 Nm^{-2}. The ordinate gives the suspended sediment concentration as a fraction of the total dry weight of the bed material. It is observed that the slope of the curve, i.e., the erosion rate, decreased with time and became nearly zero at the end of the test. This observation is in agreement with the erosion test results of Partheniades (13) with a bed composed of natural, flocculated, silty-clay from the San Francisco Bay and deposited in an open flume at low velocity. The predominant clay mineral of that sediment was montmorillonite with some illite.

Figure 4 shows an erosion test for a uniform bed under a shear stress of 0.413 Nm^{-2}. Two additional tests were carried out at shear stresses of 0.445 and 0.483 Nm^{-2}. The results were similar to those shown in Fig. 4. Inasmuch as four sample taps at four different elevations were used and since a vertical concentration gradient was generally present in the suspension, a spread of data is observed during certain times. The solid line represents the mean curve. After a relatively short period, the slope of the line, and, therefore, the rate of erosion, became constant. The same was true of the two other tests. The corresponding erosion rates, ε, were 2.03×10^{-6}, 2.64×10^{-6} and 2.92×10^{-6} g cm^{-2} min^{-1}. These rates, when appropriately non-dimensionalized and plotted against the corresponding bed shear stress also in the non-dimensional form, agreed with the earlier results of Partheniades (7, 13).

Two important observations may be made: 1) with reference to the results of the experiment with the uniform bed (Fig. 4), the observed constancy of the rate of erosion implies that the eroded material did not redeposit, since simultaneous erosion and deposition would ultimately result in a state of equilibrium in which the rates of erosion and deposition are equal, and the suspended sediment concentration attains a constant value (6, 13, 14). The absence of exchange of material between the fluid and the bed during erosion under a constant bed shear stress was noted previously by Partheniades (13). In this context it may be noted that flow turbulence varies in the vertical direction from the bed to the surface. Close to the bed a zone of high shear prevails. In the remainder of the flow the shear is relatively much lower. Depending upon the size and the strength of a settling floc at a given instant and the corresponding instantaneous value of the near-bed shear, the floc may deposit, i.e. stick to the bed, or may rupture, with the pieces re-entrained above the near-bed zone. Absence of exchange precludes deposition but not the process of settling and re-entrainment. 2) in the absence of exchange, the attainment of a constant value of the concentration in the case of the stratified bed may be explained by noting that constancy of the concentration occurs when bed erosion is arrested. This is the case because the shear strength increases with depth below the initial bed surface so that no erosion will occur below the depth at which the bed shear stress equals the shear strength.

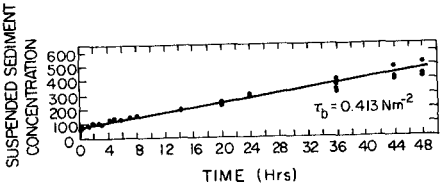

Fig. 4. Suspended Sediment Concentration, C, against Time, t, for a Uniform Bed using Kaolinite in Distilled Water at τ_b = 0.413 Nm^{-2}.

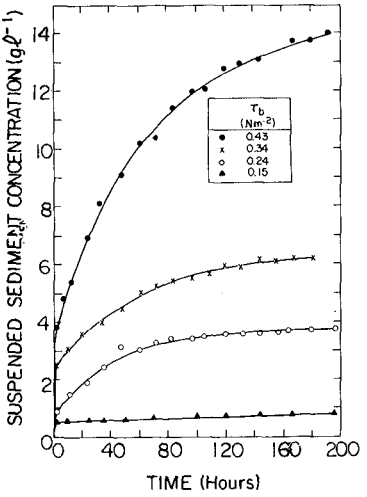

Fig. 5. Suspended Sediment Concentration, C, against Time, t, for a Deposited (Stratified) Bed using Kaolinite in Salt Water at Four Values of τ_b.

Series 2 Experiments

In these experiments, kaolinite in distilled water as well as in salt water was used in the annular flume (16). Stratified beds were prepared in a manner similar to that noted under Series 1 experiments. An example of the results from tests using distilled water is shown in Fig. 5. At the beginning of each test, an almost instantaneous and significant rise in the suspended sediment concentration was noted. It was concluded that this was partly due to mass erosion resulting from a sudden movement of the flume at start. In later experimental series, this problem was obviated by starting the flume more slowly. After nearly 200 hours, whether or not the suspended sediment concentration, C, attained a constant value is observed to have been dependent upon the magnitude of τ_b. In the test with τ_b = 0.15 Nm^{-2}, C became constant within the first few hours. In the test with τ_b = 0.24 Nm^{-2}, C became constant after approximately 140 hours. In the test with τ_b = 0.34 Nm^{-2}, C appears to have approached a constant value after 180 hours. Finally, in the test with τ_b = 0.43 Nm^{-2}, C was increasing with time at a slow rate even after 190 hours. In general, at any instant after test initiation both the magnitude of C and dC/dt (and therefore ε) are observed to vary with τ_b.

Selecting C_s as the asymptotic value of C which was close to the value of C extrapolated to 200 hours, it was found that most of the time-concentration data, after accounting approximately for the mass erosion effect, agreed with the following relationship:

$$C = C_s(1 - e^{-\beta t}) \tag{3}$$

where β is an empirical coefficient whose value was found to be within a relatively narrow range of 0.013 to 0.028 hr^{-1}, particularly for comparatively high values of τ_b. An example of the agreement between Eq. 3 and the experimental values is shown in Fig. 6 for the tests corresponding to Fig. 5. Tests using kaolinite in salt water confirmed these trends. Further tests using a natural mud in salt water also agreed with Eq. 3. The clay mineral constituents of this mud were kaolinite, montmorillonite and illite.

The observed variation of the asymptotic value of C with τ_b may be examined qualitatively with reference to the descriptive relationship between the shear strength, τ_s, and the depth z below the bed surface shown in Fig. 7. As confirmed by experimental evidence presented later, τ_s in a stratified bed increases with z, beginning with a small but finite value close to the surface. This increase is more significant in the top layer of perhaps a few millimeter thickness than in lower layers, where, infact, τ_s may approach a constant value or, atleast, the variation of τ_s with z becomes relatively small. For a given sediment-fluid mixture, the nature of the $\tau_s(z)$ distribution is determined by the flow conditions during deposition, the degree of consolidation of the bed and thixotropic rearrangement of the interparticle floc network (7). Given such a distribution of $\tau_s(z)$, under a bed shear stress τ_{bA} the bed will erode to a depth z_A at which point $\tau_{bA} = \tau_{sA}$. The rate of erosion therefore depends on the "excess" shear stress $\tau_b - \tau_s$. Similarly, if the shear stress is

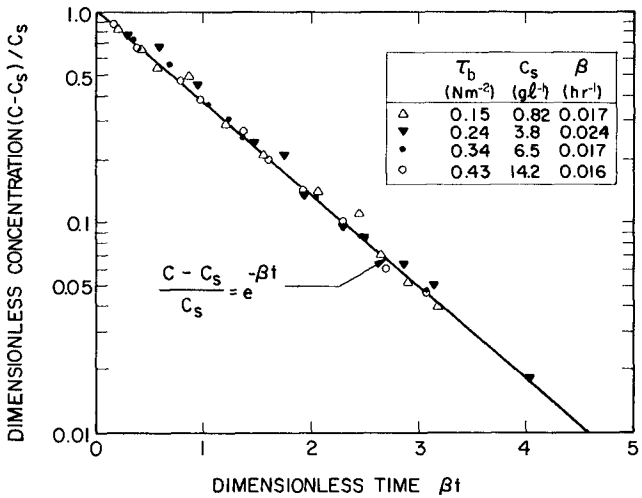

Fig. 6. Normalized Concentration, C_S-C(t)/C_S, against Normalized Time, βt. Equation 3 is Compared with Data from Tests Corresponding to Fig. 5.

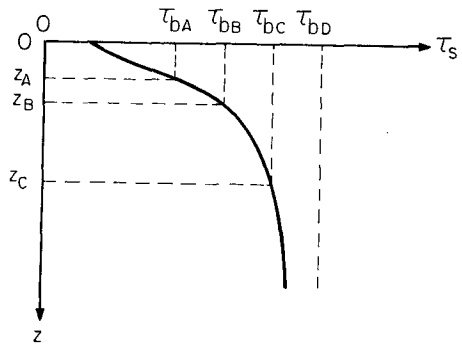

Fig. 7. Descriptive Relationship between Cohesive Bed Shear Strength with Respect to Erosion, τ_S, and Depth, z, below Bed Surface.

τ_{bB} or τ_{bC}, the corresponding depths of erosion will be z_B or z_C. Integrating Eq. 2 yields

$$C = \frac{1}{h} \int_0^z \rho(z)dz \qquad (4)$$

provided h is assumed to be constant. Since ρ also increases with z, the difference between C_C and C_B will be much greater than the difference between C_B and C_A. This aspect is further noted later. Finally, for a shear stress τ_{bD}, the bed will continue to erode indefinitely, atleast in principle, since the condition $\tau_{bD} = \tau_{sD}$ can not be attained. In a test conducted by Krone (4) using a silty-clay from San Francisco Bay, erosion continued even after 500 hours.

Series 3 Experiments

These experiments were conducted in the annular flume using kaolinite in salt water. A schematic description of the manner in which the bed shear stress was varied with time during the tests is shown in Fig. 8. Such a variation results in three phases of sediment transport. Phase I is a mixing stage in which a sediment of concentration C_0 is mixed at a shear stress τ_m for a period T_m. The shear stress τ_m must be large enough to prevent any deposition of the suspended material. In Phase II the flow is reduced to yield a comparatively lower shear stress τ_{d1}, which is maintained for a duration T_{d1}. Deposition will occur in this phase. Given a sufficient duration T_{d1} and shear stress $\tau_{d1} < \tau_{bmin}$, the entire amount of sediment will deposit and the flow will be clarified. On the other hand, if $\tau_{d1} > \tau_{bmin}$, a certain fraction C_{eq}^* of C_0 will remain in suspension indefinitely (6). In the latter case, a second lowering of the shear stress to $\tau_{d2} (< \tau_{bmin})$ for a period T_{d2} will clarify the suspension. The last sequence in Phase II is a period T_{dc} with no flow. During this period the remaining small fraction of the sediment in suspension will deposit rapidly and the bed will consolidate. Phases I and II together define the pre-erosion stress history of the bed, which is characterized by C_0, τ_m, τ_{d1}, τ_{d2}, T_m, T_{d1}, T_{d2} and T_{dc}. In order to investigate the influence of consolidation on the rate of erosion, T_{dc} was varied while maintaining all other parameters nearly constant.

Resuspension will occur in Phase III in which a series of shear stresses τ_{b1}, τ_{b2} etc., of increasing magnitudes are applied over corresponding durations (time-steps) T_1, T_2 and so on. In choosing the magnitudes of τ_{b1}, τ_{b2} etc., it is convenient to select the normalized differential shear stress $\Delta\hat{\tau}_{bi} = (\tau_{bi+1} - \tau_{bi})/\tau_{bi}$, where i = 1, 2, etc., as an experimental parameter. The selection of $\Delta\hat{\tau}_{bi}$ and the corresponding period T_i is an important factor in experimental design (11).

As an example of the results, the time-concentration relationship obtained during a test is shown in Fig. 9. Values of the various parameters selected for the test are given in the figure. The shear stress τ_{d1}, was less than τ_{bmin} (= 0.15 Nm^{-2}). During each time-step

i, the rate of erosion decreased from an initially high value, as noted in the previous two experimental series. This trend was found to be qualitatively similar to that suggested by Eq. 3. An important difference between the profiles in steps i = 1 through 7 and steps i = 8, 9 is that in the former (which will be referred to as Type I), the concentration appears to have approached a constant magnitude, whereas in the latter (Type II), the concentration did not attain a constant value at the end of the time-step. This difference between Type I and Type II profiles is also apparent from Fig. 10, in which $C(T_i)$, the concentration at the end of the time-step, i, is plotted against τ_{bi}, for consolidation times T_{dc} = 24, 40 and 135 hrs. In general it appears to be possible to represent the $C(T_i)$ - τ_{bi} curve by two straight lines meeting at a point where $\tau_{bi} = \tau_{ch}$, a characteristic value of the bed shear stress (11). When $\tau_{bi} > \tau_{ch}$, $C(T_i)$ increases more rapidly with τ_{bi} than in the case when $\tau_{bi} < \tau_{ch}$. The value τ_{ch} also increases with T_{dc}. Similar trends can be discerned from the data presented in Fig. 5 as well as from the results of a number of previous investigations (2). The significance of these trends can be recognized with reference to Fig. 7. In qualitative terms, τ_{bA} and τ_{bB} are both less than τ_{ch}, while τ_{bC} and τ_{bD} are greater than τ_{ch}. The value τ_{ch} lies somewhere between τ_{bB} and τ_{bC}, and the corresponding depth of erosion is between z_B and z_C. Since the increase in the shear strength, τ_s, with z is more significant in the range of $\tau_b < \tau_{ch}$ in comparison with the range of $\tau_b > \tau_{ch}$, if erosion is allowed to proceed for a constant duration T_i under a given bed shear stress, the amount of bed scour will be much greater when $\tau_b > \tau_{ch}$ than when $\tau_b < \tau_{ch}$. Consequently, the rate of change of $C(T_i)$ with τ_b will be much more pronounced in the range of $\tau_b > \tau_{ch}$ in comparison with the range of $\tau_b < \tau_{ch}$.

The above explanation can be used to examine the difference between Type I and II time-concentration profiles in Fig. 9. As long as the condition represented by the shear stress τ_{b0} in Fig. 7 is not attained, i.e. as long as the shear strength $\tau_s < \tau_b$ at some depth z, it is possible to obtain Type I profiles. This may be achieved by increasing T_i, i.e. the time allowed for erosion under a constant bed shear stress. Type II profiles result because T_i is insufficient for the bed to scour to a depth where $\tau_b = \tau_s$.

For Type I profiles, since the condition $\tau_b = \tau_s$ is attained, the depth-variation of τ_s can be determined, provided the depth z of erosion at the end of each time-step i (when $\tau_b = \tau_s$ for that time-step) is known. This can be done using Eq. 2 if $\rho(z)$ is known. The variation of the bed density with depth at the end of Phase II, i.e. just prior to resuspension, was determined for various periods, T_{dc}, with the help of a specially designed 2.5 cm diameter metal tube in which the bed core samples were frozen in situ, using a mixture of alcohol and dry ice (11). These tests were carried out in a separate series in which conditions in Phases I and II were identical to those for the resuspension tests. Figs. 11a,b present the density profile and the corresponding variation of τ_s with depth for the test shown in Fig. 9. The $\tau_s(z)$ distribution is qualitatively similar to the description of Fig. 7. The value of τ_s at z = 0 corresponds to the minimum value of the bed shear stress required to initiate erosion in

the flume. Indeed as noted further in the following, τ_s obtained in this way is, in general, also equal to the critical shear stress for erosion at the corresponding depth.

Series 4 Experiments

These experiments were similar to those conducted under Series 3. Kaolinite in tap water was used in the recirculating flume (1). Test characterizing parameters were: C_o = 21.7-24.1 gl^{-1}, h = 23 cm, τ_m = 0.46 Nm^{-2}, T_m = 4 hr, τ_{d1} = 0.026 Nm^{-2} (which was less than τ_{bmin} = 0.18 Nm^{-2}), T_{d1} = 12 hr, τ_{d2} = 0 Nm^{-2}, T_{d2} = 1 hr, $\Delta\hat{\tau}_{bi}$ = 0.52 and T_i = 1 hr. Nine tests with values of T_{dc} = 2, 5, 11, 24, 48, 72, 96, 144 and 240 hr were conducted.

Figures 12a,b are normalized plots of bed density variation with depth. After T_{dc} = 48 hr, the variation seems to conform to the dimensionless relationship (1, 9):

$$\frac{\rho}{\bar{\rho}} = \zeta \left(\frac{z'}{H}\right)^{-\xi} \tag{5}$$

where z' = H-z, H = bed thickness, $\bar{\rho}$ = value of ρ averaged over H, ζ = 0.794 and ξ = 0.288. It is observed that H decreased and $\bar{\rho}$ increased with increasing T_{dc}. Equation 5 is in agreement with the reanalyzed data of Owen (10) and of Thorn and Parsons (15) for four natural muds which gave ζ = 0.660 and ξ = 0.347 (1).

The time-concentration data were found to exhibit a trend which was qualitatively similar to that shown in Fig. 9. These data were analyzed as follows: 1) it was assumed, as noted before, that at the end of time-step i of the Type I profile, the bed shear stress $\tau_b = \tau_c = \tau_s$, where τ_c is defined as the critical shear stress for erosion. 2) using this assumption the variation of τ_c with z was obtained as in Fig. 11b. 3) a relationship between the rate of erosion, ε, and the normalized excess shear stress $(\tau_b-\tau_c)/\tau_c$ was empirically derived from the time-concentration variation for each time-step of the Type I profiles. In obtaining this relationship, ε was calculated using Eq. 1 for each value of dC/dt. The corresponding value of τ_c was obtained using Eq. 2 together with the $\rho(z)$ distribution (Figs. 12a,b or Eq. 5 for T_{dc} > 48 hr) and $\tau_c(z)$ distribution (e.g. Fig. 11b). Finally, 4) it was assumed that the rate expression was applicable over the entire depth of erosion. The time-concentration data of Type II profiles were then used, together with representative depth-mean values of the coefficients (ε_o and α as noted below) of the rate expression based on Type I profiles, to determine the variation of τ_c with depth z below the depth where this information could not be obtained from Type I profiles. The erosion rate expression was found to be:

$$\frac{\varepsilon}{\varepsilon_o} = \exp\left[\alpha \frac{\tau_b-\tau_c}{\tau_c}\right] \tag{6}$$

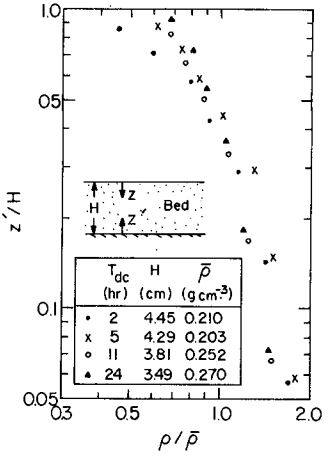

Fig. 12a). Normalized Bed Density, $\rho/\bar{\rho}$, against Normalized Depth, z'/H, for Kaolinite in Tap Water with T_{dc} < 48 hr (9).

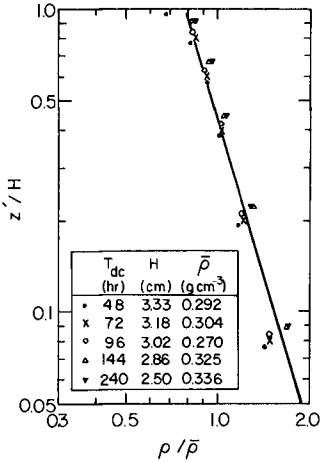

Fig. 12b). Normalized Bed Density, $\rho/\bar{\rho}$, against Normalized Depth, z'/H, for Kaolinite in Tap Water with $T_{dc} \geq 48$ hr (9).

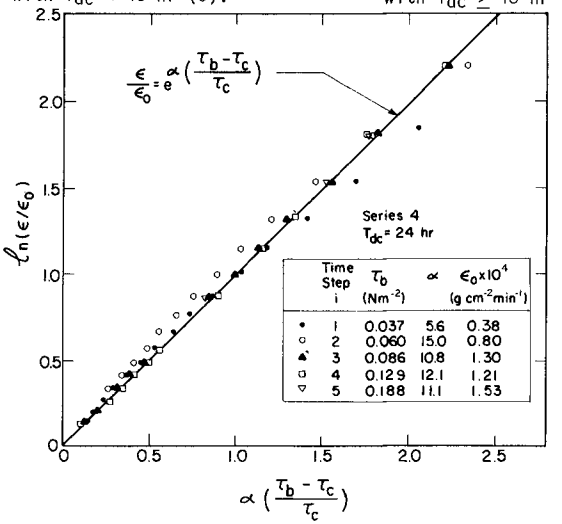

Fig. 13. ϵ/ϵ_0 against $\alpha(\tau_b-\tau_c)/\tau_c$ for a Test using Kaolinite in Tap Water with T_{dc} = 24 hr.

where ε_o and α are empirical coefficients. In Eq. 6, τ_c is a function z and, therefore varies with time t. With increasing time, τ_c increases and approaches τ_b in such a manner that the ratio $(\tau_b-\tau_c)/\tau_c$ decreases and, therefore, ε decreases. As an example, in Fig. 13 Eq. 6 has been compared with test results corresponding to T_{dc} = 24 hr. The value of α ranged from 5.6 to 15.0 and ε_o from 0.38×10^{-4} to 1.53×10^{-4} g cm^{-2} min^{-1}. Similar results from tests with T_{dc} = 48 and 240 hr are shown in Figs. 14 and 15. In Fig. 16, reanalyzed data from the test shown in Fig. 9 under Series 3 experiments are plotted in the same manner. In this case, α ranged from 5.5 to 8.4, and ε_o from 0.04×10^{-4} to 0.30×10^{-4} g cm^{-2} min^{-1}. It was, in general, found that in each test, ε_o and α appeared to vary somewhat with the time-step, and therefore with depth z below the bed surface, in a systematic manner. Further investigations are required for elucidating the precise nature of the dependence of ε_o and α on z. In general it was noted that ε_o and α became nearly independent of z for depths greater than a few millimeters. These two coefficients were also found to be independent of consolidation time, T_{dc}. In Fig. 17, the depth-average value $\bar{\varepsilon}_o$ of ε_o from each test is plotted against the corresponding T_{dc}. Results from Series 3 (kaolinite in salt water) as well as Series 4 (kaolinite in tap water) are included. In Fig. 18 a similar plot is given for α. Overall mean values of ε_o and α are: 7.9×10^{-5} g cm^{-2} min^{-1} and 9.3, respectively, for kaolinite in tap water (Series 4) and 4.0×10^{-5} g cm^{-2} min^{-1} and 5.9, respectively, for kaolinite in salt water (Series 3). The mean ε_o and α for kaolinite in tap water are higher than for kaolinite in salt water. These differences imply that kaolinite is resuspended with greater facility in tap water than in salt water. This trend appears to be consistent with the flocculation characteristics of kaolinite in the two fluids (5, 6, 9).

As an example of the variation of τ_c with depth z, Fig. 19 shows results from four tests with T_{dc} = 2, 11, 48 and 144 hr. In general, τ_c increased with T_{dc} for all $z > 0$. The value of τ_c remained practically invariant at the surface. This observation is in agreement with a similar observation made by Partheniades (13). As a result of the exponential form of Eq. 6, the significance of the variation of τ_c with T_{dc} is that the rate of erosion, ε, decreases measurably with increasing value of T_{dc}.

The form of Eq. 6 has been predicted previously from a reinterpretation of the rate process theory of chemical reactions (1, 3, 12). This theory involves the activation energy concept according to which a "threshold" energy barrier must be crossed for the conversion of reactants to products. As Paaswell (12) has noted, Eq. 6 makes possible the understanding of erosion as an internal energy/external energy system, where ε is a measure of the work done on the system (reflected in τ_b) and τ_c, α and ε_o represent measures of internal energy, and therefore the resistance to the erosion of the deposit.

CONCLUSIONS

1. The rate of surface erosion of stratified, deposited beds continuously decreases with time and can even become zero as the

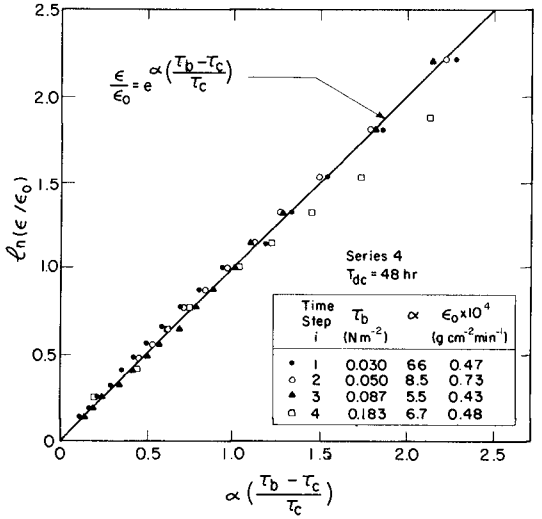

Fig. 14. ϵ/ϵ_0 against $\alpha(\tau_b-\tau_c)/\tau_c$ for a Test using Kaolinite in Tap Water with T_{dc} = 48 hr.

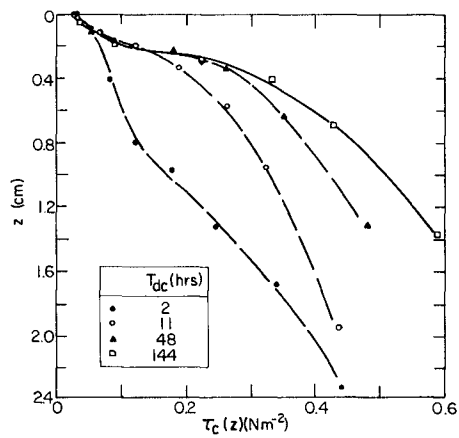

Fig. 19. Variation of τ_c with z from Tests using Kaolinite in Tap Water with T_{dc} = 2, 11, 48 and 144 hr.

depth of erosion increases. On the other hand, the erosion rate of uniform beds remains practically invariant.

2. The decrease in the erosion rate of stratified beds occurs because the cohesive shear strength with respect to erosion of the bed increases with depth. Ouring erosion flocs are detached from the bed and entrained, but redeposition of the entrained sediment does not occur. Erosion is arrested at a depth where the bed shear stress, τ_b, equals the bed shear strength. This value of τ_b is equal to the critical shear stress, τ_c, of the bed at that depth.

3. An expression for the rate of surface erosion is found. The rate varies exponentially with the normalized excess shear stress, $(\tau_b-\tau_c)/\tau_c$.

4. The critical shear stress in general increases with depth below the initial bed surface and also increases with bed consolidation time. As a result the rate of erosion decreases with increasing consolidation time.

BED LOAD TRANSPORT OF FINE SAND BY LAMINAR AND TURBULENT FLOW

by

Anthony J.Grass* and Ragaei N.M.Ayoub**

ABSTRACT

An experimental study is described in which the rate of transport of fine sand over a flat bed was measured as a function of the shear stress exerted on the bed by both laminar and turbulent flows, for a range of water temperatures. The results confirm the great sensitivity of the transport rate to changes in both shear stress and temperature over the test range. The hypothesis is propounded that in certain specified circumstances, the net rate of local bed load transport generated by an arbitrary unsteady flow, can be estimated by integration, using the measured steady laminar flow transport relationships in conjunction with the time history or probability distribution of the fluctuating bed shear stress. The concept has been tested using the measured data with encouraging results. It is suggested that this method of linking the characteristics of the near bed flow field to the local induced rates of sediment transport could be productively applied in a range of studies including the initiation and development of bed sand ripples by the action of various combinations of waves and steady currents.

1. INTRODUCTION

Over the past decade, considerable progress has been made in developing instrumentation such as the laser doppler anemometer for flow velocity measurement and also numerical mathematical modelling techniques for predicting flow behaviour. These advances coupled with significant improvements in digital data processing methods, have led to a rapidly expanding knowledge and understanding of the complex turbulence and other near bed flow charactertistics in both steady and unsteady boundary layers and separated flows. (See for example Grass(1971,1982), Kemp and Simons (1982), and Etheridge and Kemp (1979)).

As in the past, progress in sediment transport research has lagged very much behind due to the formidible theoretical and experimental difficulties. In order to fully exploit the new fluid mechanics information in the study of coastal and other sediment processes, including for example, the formation of bed ripples by

* Lecturer, Department of Civil and Municipal Engineering, University College London, England
** Senior Engineer, Ministry of Electricity and Water, Kuwait

waves and currents, it will be necessary to establish improved links between the measured or computed characteristics of the fluctuating driving flow and the corresponding response of the bed sediment.

A primary objective of the present investigation was to derive one such linking relationship for the case of bed load transport of fine grained sand.

2. BED LOAD SEDIMENT TRANSPORT

Consider an arbitrary, unsteady fluid flow inducing transport on a flat bed of non-cohesive sediment. Then, for a particular fluid viscosity, physical reasoning suggests that there will be a close correlation between the instantaneous flow velocity immediately adjacent to the bed and the simultaneous local shear stress acting on the bed and hence the induced instantaneous rate of local bed load sediment transport. Experimental evidence supporting this postulation has been previously presented and discussed by Grass (1970,1971) based on photographically recorded observations of the response of fine bed sand to the rapid fluctuations in bed shear stress generated by a turbulent boundary layer flow.

For fine grained sediment producing an hydraulically smooth boundary condition in typical water flows, the fluid forces are transferred to the bed sediment primarily by viscous shear. The hypothesis is advanced that under these conditions the instantaneous local bed load transport rate produced by a particular instantaneous value of viscous bed shear stress, τ, can be represented by the transport rate, $q_{s\ell}(\tau)$, induced by a steady laminar flow with the same bed shear stress and fluid viscosity.

In a situation where the fluctuating bed shear stress is a known function of time, t, as for example in the case of an oscillatory laminar boundary layer, then the net mean sediment transport rate, q_{st}, over a time interval T, can be calculated using the following equation:

$$q_{st} = \frac{1}{T}\int_{o}^{T} q_{s\ell}(t)dt \qquad (1)$$

If however, the fluctuating bed shear stress is random and unpredictable as in the case of turbulent boundary layer flows induced by a random wave spectrum, then the following alternative equation can be used to estimate the net be load transport rate:

$$q_{st} = \int_{\tau_{min}}^{\tau_{max}} q_{s\ell}(\tau)p(\tau)d\tau \qquad (2)$$

where $p(\tau)$ is the probability density function of the fluctuating bed shear stress τ.

The hypothesis expressed in equations (1) and (2) was tested in the present investigation by comparing the measured values of bed load sediment transport produced by a steady unidirectional turbulent boundary layer flow with the corresponding values calculated using equation (2) substituting $q_{s\ell}(\tau)$ values provided by corresponding measurements in a steady laminar flow. This procedure circumvents severe difficulties in attempting to measure the instantaneous fluctuations in bed load sediment transport rate directly.

3. EXPERIMENTAL TECHNIQUES

A fine 140 micron quartz sand from the Mersey Estuary was used in the present experiments as in the earlier study of initial movement of bed sand grains by Grass (1970). The bed load sediment transport rate was measured as a function of mean bed shear stress and water temperature ($4^0C, 17^0C, 30^0C$) under laminar and fluctuating turbulent flow conditions. Novel experimental apparatus and techniques were employed which have been described in detail by Ayoub (1977). These tests broke new ground in that they were designed to obtain strictly flat bed transport rates for bed shear stress values ranging up to 25 times the critical shear stress for initial sediment movement. This was achieved by measuring over short sample times prior to the formation of flow disturbing sand ripples.

The laminar flow experiments were carried out using the specially designed apparatus illustrated in Figure 1. A low Reynolds number, high bed shear stress laminar flow was produced between two closely spaced parallel plates 2 millimetres apart and 1 metre long and 0.4 metres wide. The carefully levelled flat sand bed was contained in a recessed pit 0.4 metres long and 0.25 metres wide located at the downstream end of the lower plate. Water was supplied to the test section from a constant head tank and the bed shear stress was determined by monitoring the streamwise pressure gradient. The sediment transport rate was measured by collecting and weighing sand samples over a know time interval using the sliding box arrangement shown in Figure 1. Very short and accurately measured sampling times were achieved using a sliding plate inlet valve and an automatic timing device attached to the sampling box. Sampling times were reduced with increasing bed shear stress down to periods as low as 1 second in the case of the higher bed stress values in order to avoidsignificant erosion of the sand bed surface. Repeated tests at the same bed shear stress indicated good reproducibility of the individual measured values of bed load sediment transport rate.

The turbulent flow was generated on a flat plate 1.5 metres long and 0.3 metres wide which was supported on a carriage and towed through still water as shown in figure 2. A sand bed 0.4 metres long and 0.2 metres wide was located at the downstream end of the plate.The plate boundary layer was tripped by means of a wire close to the leading edge and achieved a steady stable state very soon after the plate had been rapidly accelerated to its constant terminal velocity. Once again, the bed load sand transport rate was measured by weighing the sand collected in a specially partitioned box located under the downstream end of the sand bed.Differences in the weights of two sand samples collected from two experimental runs in which the bed plate

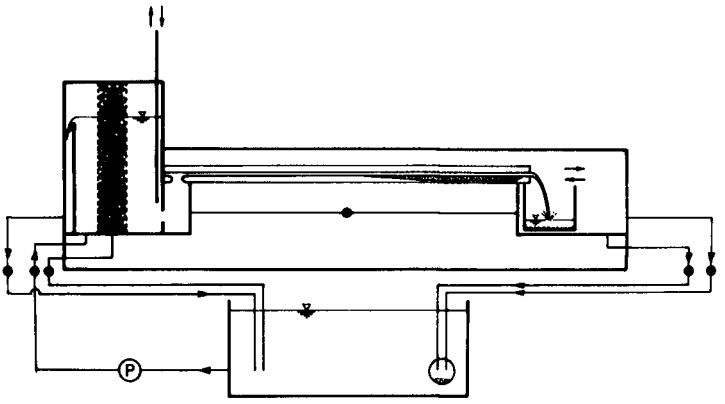

FIGURE 1. Laminar flow channel used to measure bed load sediment transport induced by a laminar boundary layer formed between closely spaced parallel plates.

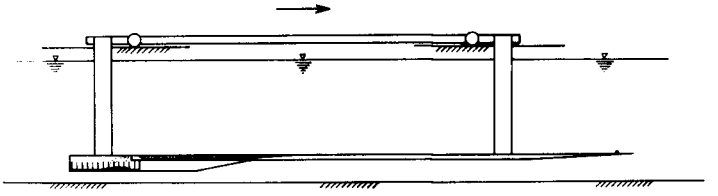

FIGURE 2. Apparatus used to measure bed load sediment transport induced by a turbulent boundary layer formed on a flat plate towed through still water.

underwent identical acceleration and deceleration phases but travelled different known intermediate distances at a common constant velocity, were used in these bed load calculations in order to eliminate end effects. Sampling times, which were simply and accurately determined from the travel distance and the known carriage velocity, were again kept very short (down to 1.5 seconds for the highest bed shear stress) in order to avoid bed erosion and also the formation of nascent sand ripples on the bed surface. Mean bed shear stresses were obtained from velocity profile measurements using a carefully calibrated hot film anemometer. This instrument was also used to record the velocity fluctuations in the viscous sublayer at the downstream end of the bed plate. The probability density functions of the fluctuating bed shear stress were calculated from these measurements. Tests were repeated four times for each of the lower values of mean bed shear stress and twice for the remainder in order to obtain closely reproducible values of the average bed load transport rates.

4. RESULTS AND DISCUSSION

The measured sediment transport rates are shown plotted in terms of the relevant non-dimensional variables in Figure 3 in which u_* is the bed shear velocity, d is the sand diameter, ρ_s and ρ are the sediment and fluid densities respectively. The slope of the fitted linear regression lines indicates that over the central experimental range the bed transport rate varies as approximately the fourth power of the bed shear stress for both the laminar and turbulent flows.

Consistent with the results obtained by Taylor and Vanoni (1972), the sediment transport rate also shows considerable sensitivity to changes in bed particle Reynolds number, R_*. Between 4^0C and 30^0C the water viscosity, ν, is halved which gives rise to a threefold increase in the bed load transport rate.

It is interesting to note that for a particular constant low value of bed transport rate, defining the initial movement stage of the bed particles, the optimized data correlation presented in Figure 3 indicates that Shields parameter, τ_{c*}, will be proportional to $R_*^{-0.64}$. This result is in good agreement with the criteria for initial motion of fine bed sand previously suggested by Grass(1970) for the same range of bed particle Reynolds numbers.

The use of equation (2) in calculating the net mean rate of bed load sediment transport from the laminar flow transport function and the probability density function of the fluctuating bed shear stress produced by a steady turbulent boundary layer flow, is illustrated in Figure 4. The particular probability distribution shown in Figure 4 and used throughout the present study, is a smoothed curve fitted to data measured in the present tests and in experiments reported by Grass (1970), Ecklemann and Reichardt (1972), and by Blinco and Simons (1974). When the various probability distributions which cover a wide range of flow Reynolds numbers and different types of steady unidirectional flow, are plotted in standard form in terms of the fluctuations in bed shear stress scaled by their standard deviation about the mean, it is found that they can be accurately summarised by a single unique curve. This takes the form of the positive skew

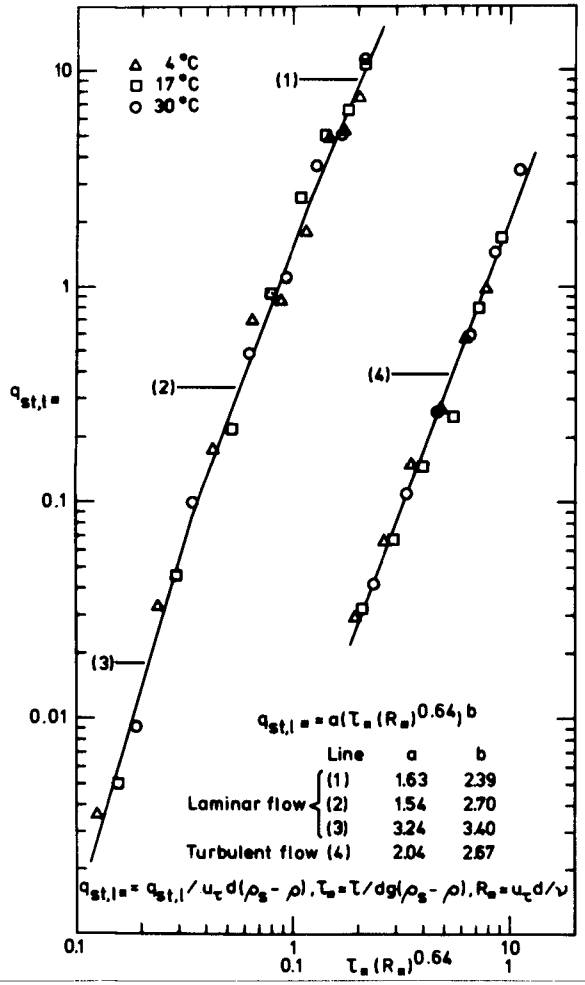

FIGURE 3. Optimized correlation of measured bed load sediment transport rates induced by laminar and turbulent flows.

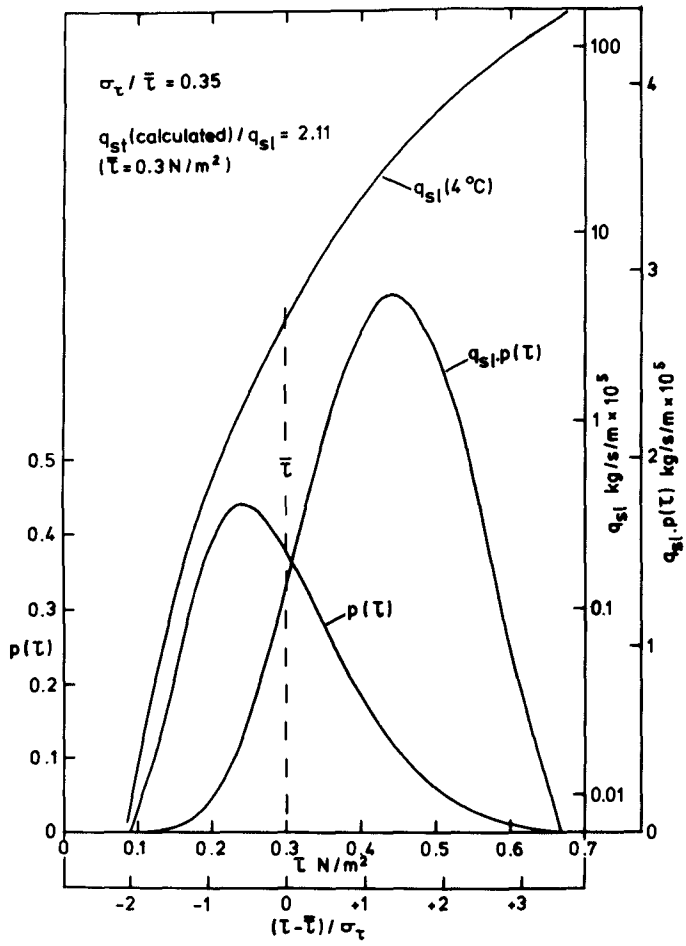

FIGURE 4. Sample illustration of the method of calculating bed load transport rate produced by a turbulent flow, q_{st}, at a particular mean bed shear stress $\bar{\tau}$ of 0.3N/m^2, from the laminar flow transport relationship, q_{sl}, and the probability distribution, $p(\tau)$, of the fluctuating bed shear stress, τ, induced by the turbulent flow.

distribution reproduced in Figure 4.

The calculation illustrated in Figure 4 is for a mean bed shear stress of $0.3N/m^2$. As can be seen, the fluctuations in instantaneous shear stress range between approximately $0.1N/m^2$ and $0.7N/m^2$. The corresponding induced rate of instantaneous bed load transport increases by four orders of magnitude over the shear stress range. For the lower instantaneous shear stresses there is negligible transport over the bed surface whilst the higher shear stress fluctuations produce very large instantaneous transport rates. This is in close accord with the evidence from direct observations of the fluctuating sand transport behaviour reported by Grass (1970).

The strong non-linearity in the sediment transport rate with increasing bed shear stress, produces maximum contributions to the next bed load transport rate at instantaneous shear stress values greatly in excess of the mean shear stress of $0.3N/m^2$, in spite ofthe rapid reduction in $p(\tau)$, as indicated by the location of the peak in the $q_{sl}.p(\tau)$ curve. In the particular example presented in figure 4, the calculated value of net mean sediment transport rate produced by the turbulent boundary layer flow with a mean applied bed shear of 0.3 N/m^2, is in excess of twice the corresponding laminar flow transport rate with the same bed shear stress.

A comparison between the experimental and calculated equation (2) values of the ratio between the turbulent and laminar flow transport rates is shown in figure 5. The experimental results are seen to lie satisfactorily in a zone bounded by the values calculated using bed shear stress standard deviation to mean bed shear stress ratios, $\sigma/\bar{\tau}$ of 0.25 and 0.35. These $\sigma/\bar{\tau}$, magnitudes correspond to the range of values measured in the present tests with both fixed and mobile beds and also to the measurements reported by Mitchell and Hanratty (1966) and by Eckelmann (1974).

The relatively rapid decreasing trend in the magnitude of the transport ratio from approximately 2 to 1.3 over the bed shear stress range from $0.3N/m^2$ to $0.9N/m^2$, the approximate observed the threshold shear stress for intial sediment suspension, suggests a possible decrease in the effective $\sigma/\bar{\tau}$ ratio with increaing flow Reynolds number. This is consistent with trends in data obtained in the present investigation and by Laufer (1951) and by Blinco and Simons (1974).

The rapid increase in the transport ratio at the lower end of the bed shear stress range indicated in Figure 5 is due to the fact that as the shear stress approaches the critical value for intial sand grain movement under laminar flow conditions, the laminar flow transport rate tends to zero. However, the corresponding transport rate, at thesame mean bed shear stress, under turbulent flow conditions remains finite and the transport ratio therefore increases asymptotically to infinity.

The detailed physics and charactistics of the two phase flow in the mobile sand layer and its interaction with the driving flow are in reality extremely complex. These effects are inevitably only partially allowed for in the proposed simple bed load transport model. Bearing

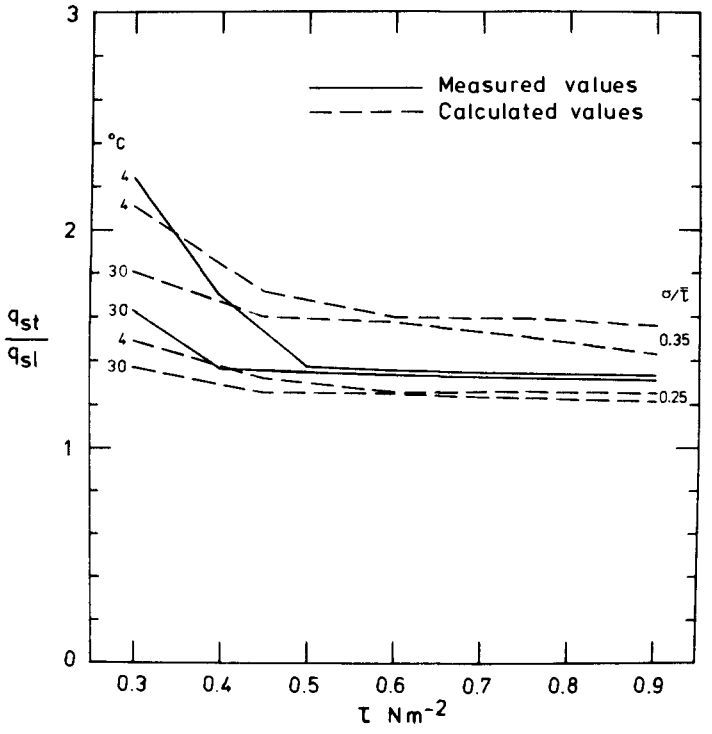

FIGURE 5. Comparison between the calculated and measured ratios of bed load transport rates, q_{st}, and q_{sl}, induced respectively by turbulent and laminar flows, as a function of mean bed shear stress.

these facts in mind, the levei of agreement between the experimentai and calcuiated results in Figure 5 is very encouraging.

5.CONCLUSIONS

a.The investigation was successful in providing completely new bed load sediment transport reiationships for strictly fiat bed conditions.
b. The test resuits confirmed the great sensitivity of the bed load sediment transport rate to changes in both bed shear stess and water temperature over the experimental range considered.
c. Under hydraulically smooth bed conditions with fine sands, the measured laminar flow transport relationship appears, on the evidence of the present results, to provide a satisfactory link function oetween instantaneous bed shear stress and the local simuitaneously induced bed load transport rate.
d. The general validity of the proposed method for caicuiating local net rates of bed load transport under arbitary unsteady flow conditions is thus confirmed as are the basic concepts on which the method is based.
e. There are several areas of study where the type of approach outiined might be productiveiy appiied in both steady and unsteady flow situations. These include quantitative mathematicai modeiling of the instability of the sand bed interface involving the initiai formation of ripples on fiat beds and their subsequent deveiopment and the prediction of their equilibrium height. The relevance in this context is demonstrated by the recent work of Sleath (1982) and Ruiter (1982). The proposed relationship between the iocal flow characteristics and the induced bed load transport can also be applied in modelling certain types of locai scour problems. Further tests will need to be carried out however in order to assess the infiuence of local bed siope on the laminar fiow transport function.

SURVEY TECHNIQUES/PROCEDURES AND DATA PROCESSING FOR MONITORING NEARSHORE SEDIMENT TRANSPORT

by

J ZACKS

1. INTRODUCTION

The cost of many coastal projects is often increased by the expensive beach repair and maintenance required to remedy the destabilising effects of structures on the adjoining coastline. Physical and/or mathematical models have been developed for use in planning these projects in order to *predict* and *quantify* the effects of marine sediment transport on the coastal topography.

Such models need to be calibrated against prototype data and one method of gauging volumetric sediment movement is by successive bathymetric/topographic *profiling surveys* which are performed seasonally and annually. Since large quantities of sediment are related to small changes in bed elevation it is clear that this profiling needs to be done with the utmost *precision*.

The areas most affected extend from the beach through the surf zone to water depths of about 25 metres. The surf zone in particular is a dynamic and hostile area which falls outside the traditional activities of both the hydrographic and land surveyors. Consequently innovative methods, deficient in sound survey principle and practice, have often been pursued in this area without any attempt being made to assess the tolerance on the data.

This paper attempts to show that it is possible to produce reliable and verifiable results to the required accuracy by using *conventional* survey equipment and techniques, also by taking the necessary precautions against the many possible sources of survey error. The procedures and techniques described have evolved from NRIO's involvement over the past decade in major projects at Richards Bay, Durban, Koeberg and in False Bay. The results of a recent verification investigation are fully reported in this paper.

2. METHODOLOGY

In principle the method is to survey a number of *parallel profiles* orthogonal to the coastline and extending across the beach, tidal and surf zones. Staff/polling methods are used from the beach to as far into the water as an operator can walk (or use a dinghy). A skiboat fitted with precision echosounder is used to work from behind the surf, and through the surf zone, towards the beach.

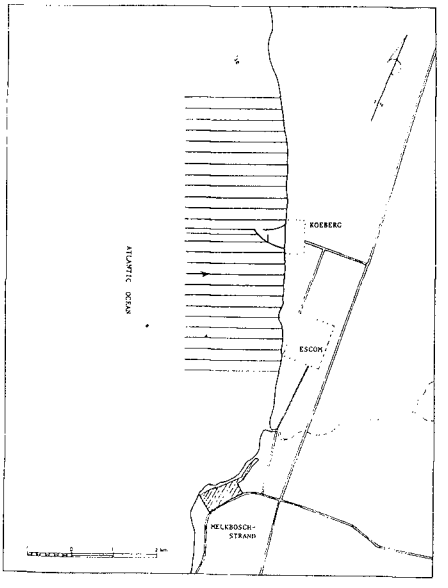

FIG. 1 KOEBERG SURVEY LOCATION

By regulating the work to span the low and high *spring tides*, a degree of overlap can be achieved between these two independent methods which permits verification of the data. By repeating certain profiles along the same lines (very exactly) further verification of the accuracy can be obtained.

The problem of precisely repeating the same echosounder footprint and the corrections required (for boat squat, wave profile, tides, etc) are dealt with in the following sections in which procedures are described for eliminating *random* errors and minimising *systematic* errors.

3. POSITION AND HEIGHTING

The profiling surveys are always preceded by a control survey to establish or replace substantial *reference beacons* erected along the coastline, based on the national trigonometrical co-ordinate and benchmark systems as datums for position and heighting. These beacons provide a reference for all measurements along a profile and for precise relocation of profiles during successive surveys. The location of the beacons should ensure unrestricted visibility, also security against erosion and wilful disturbance or removal.

3.1 Equipment

The use of electronic instrumentation is limited by the high initial cost, expensive maintenance (in the coastal environment) and the logistic requirements for recharging DC power supplies in the field. Optical/mechanical survey instrumentation is robust, portable, easily replaceable and is also required for the control survey. The close proximity of the survey area to the shore facilitates the use of conventional optical survey instrumentation with a resolution of 5 mm/km.

The basic instrumentation requirements are:

(a) Electronic distance measuring (EDM) equipment for control survey (and beacon replacement) measurements.

(b) Three precise (single-second) theodolites for accurate measurements over distances up to about 5 km.

(c) Two sounding poles consisting of aluminium tubing of 5 m length, 63 mm diameter, fitted with a flat base of 200 mm diameter and clearly marked in lengths of precisely 1 metre (painted white/black alternately).

(d) Four (plus back-up) radio transceivers (operating on VHF/HF frequencies) to synchronise observations and for general communication.

(e) Three measuring tapes to determine the elevations of theodolites above the beacons.

(f) One levelling staff.

(g) A lightweight dinghy (roof-top) powered by an outboard motor, for pole soundings in calm conditions (waves $\leq$ 0,5 m).

3.2 Procedure

The field party of *five* consists of three trained survey technicians, who undertake all optical measurements, and two others (boat/echo-sounder operators) who assist in the control survey and beach profiling (as pole carriers).

The reference beacons are linked by a closed traverse between two fixed survey stations (triangulated or Trig beacons) with orientation rays (full arc) being observed at each beacon. The levelling is connected to a benchmark at each end of the traverse, differences in elevation being determined from simultaneous reciprocal vertical observations (observed on both faces) between two theodolites and the measured heights of instruments above the beacons. The observers advance alternately (leap-frog) for successive measurements.

Position and heighting along a profile are both determined by indirect measurement from *synchronised* optical observations. Theodolite intersection techniques are used to determine accurately, relative to the survey beacons, the positions and corresponding elevations of targets (either stationary or moving) as they progress along the profile line at regularly incremented distances.

For beach profiling the traditional tachymetric survey method is discarded in favour of simultaneous observations by two (or three) theodolite observers to the *pole* which is held upright on the beach (at regular intervals) as the carrier progresses down the beach and as far as possible into the sea (to -2,00 MSL during 3 hours spanning low spring tide). The pole observations can be extended seaward to -6,00 MSL using the dinghy. The advantages of this method are:

(a) Economy of observations, three readings per pointing instead of five required for tachy, resulting in less pressure on the observer and more rapid progress. With good coordination a team of three observers and two carriers can complete nine beach profiles per hour.

(b) Greater length of beach profile can be covered since no fine staff graduations need be distinguished for the observation.

(c) Greater reliability and accuracy of the data (due to accurate distance, ± 5-10 cm) especially in the surf where the base of the staff is rapidly eroded during the observation.

For bathymetric profiling two theodolites are set up at suitable beacons, to fulfil the geometric requirements for accurate intersection, while the third instrument is set up at each intermediate beacon (in rotation) in order to position and continuously guide the boat by radio communication.

The boat traverses a fixed path (within two meters laterally), corresponding to the *exact bearing* of the profile sections, while theodolite observations are made at regular intervals of about 30 seconds. The boat operator assists in maintaining a straight track by visually aligning transit marks (topographic features) situated inland. For subsequent surveys the respective profiles are exactly relocated from the beacons.

The observations are made at regular intervals of about 30 seconds to a target mounted on the boat. These consist of *simultaneous* determinations of vertical and horizontal angle measurements, synchronised by the echosounder operator by radio, which are manually recorded, together with annotation of date, time, line and "fix" numbers.

3.3 Error Reductions

By maintaining a high degree of accuracy in the control survey (± 1 cm in elevation and position) it is possible to determine when beacons have been tampered with or replaced by unauthorised/unqualified persons. Affected or missing beacons are accurately replaced and verified by independent measurements from *both* the adjoining beacons.

Systematic errors in heighting, due to incorrect measurement of instrument elevation, are eliminated by *routinely* observing vertical angles to both the adjoining beacons (or instruments) prior to profiling. This also serves to verify the data of the control beacons which are used in further calculations.

Orientation errors in the intersection positions are eliminated by observing the known orientations to two distant beacons at the start and at the end of the observations for each profile.

The effects of random errors in observations of reciprocal vertical angles can be eliminated (and accuracy increased) by observing to both the instrument and the top of the beacon.

Instrumental error is eliminated by determining the corrections to be applied to the observations and by avoiding "creep" in the clamping/tracking mechanisms of the instrument. The index error (for correction to vertical observations) is determined by observations on both faces of the circle while the telescope is pointed at a distant object, correction = $\frac{1}{2}$ x index error (i.e. <360°>). The slow-motion tangent screws should always be turned against the spring to avoid creep.

Refraction and curvature corrections, to be applied to heighting over distances longer than 500 metres, can be verified by the index error observations if the distant object is a survey beacon.

Vertical accuracy in indirect heighting is increased by the accurate measurement of distance, from which the height is derived, or by reducing the elevation between the beacon and the target.

Observation and/or data processing errors are identified in the intersection method by comparison of the independently calculated elevations. A third observation enables an independent evaluation of accuracy to be made and allows the elimination of errors without loss of data. The conventional tachy method produces unchecked data.

The use of a theodolite for heighting, in preference to a level, enables the heighting error, due to the tilt of the staff, to be eliminated by sighting to a mark near to the base.

The accuracy of observations, when tracking a moving target, is dependent on the relative motion of the object. By maintaining a minimum distance of about 700-1000 metres from the boat, the movement can be followed accurately using the clamp and tangent screws of the theodolites.

The comparative accuracy attained in past surveys are 0,1 to 0,4 metres in position and 0,01 to 0,08 m in elevation for distances up to 3 km. Typical results for beach profiling are illustrated in Table 1. Similar pole soundings were previously made from a dinghy, to -3,0 MSL during neap tide, and a vertical accuracy of 2-3 cm (probable error) was obtained. It is estimated that a probable error of <0,10 m is possible for pole soundings at 5 m depths.

4. ECHO SOUNDING

The short period fluctuations in the elevation of the echosounder, resulting from waves or swells, are mirrored accurately in the continuous record of the depth profile provided that the sea bed is a flat sediment surface with regular changes of slope. For an irregular rocky

bottom along the profile, the effects of water level fluctuations and topographic undulations are combined to produce a confusing echo trace which cannot be resolved with sufficient accuracy.

4.1 Equipment

A 5,6 m skiboat, powered by twin outboard motors to ensure high manoeuvrability and safety in the surf zone, is used as a platform for the echosounder. A cabin houses the essential electronic instrumentation and provides protection and shelter to the crew. A spherical target (120 mm diameter) is fitted, for theodolite observation, to a mast projecting above the cabin.

The survey echosounder can operate on single/dual frequencies of 30 kHz and 210 kHz, the latter for greater accuracy in profiling and calibration, and has facilities for recording analog and/or digital depth data. The analog facility has an expandable depth scale producing a maximum resolution of 5 m/200 mm chart width, providing a resolution of about 1 cm, for accuracy in the calibration of the instrument and recording depths in calm sea conditions. Both transducers are mounted *inboard* in a well which is moulded onto the centre of the hull, and operate effectively through the hull with little loss of power provided that the well is filled with water (no splashing) and that *no air* is entrapped in the laminations of the hull.

A calibration bar is used to physically calibrate the echosounder during the survey. The bar consists of a 1,8 m length of open galvanised steel pipe, 125 mm in diameter, with a 14-metre length of light chain welded to each end. Tags are attached to the short links of both chains at predetermined distances from the pipe and exactly 1 metre apart.

An accurate tide gauge must be installed to record the sea level continuously throughout the survey. The resulting tide data are used to relate the recorded depth profiles to the vertical datum of the benchmarks (and beacons).

Radio communications are used to coordinate the operation of the echosounder with the theodolite observations.

4.2 Survey Procedure

The marine operation is performed by two operators (the crew) who can interchange their respective duties. The surveyors complete the manpower requirements for launching/recovering the boat from the beach when necessary.

The following relationships must be determined accurately for each survey boat:

1 The elevation of the transducer face relative to the reference target which is mounted on the mast.

2 The elevation of the transducer face relative to the gunwales, to

the deck and also relative to the sea level while the boat is stationary in the water.

3 The squat (settling in the water) of the boat while it is moving at various survey speeds ranging from 4 to 7 ms^{-1}.

These specifications are determined in a sheltered harbour under calm sea conditions with the aid of a theodolite, used as a level, and a levelling staff. The theodolite is set up at a slipway, near to the water level and aimed at the staff to measure the elevation of the various parameters. The respective rev-counter readings are noted at the various constant speeds.

Calibrations of the echosounder are performed *twice daily* in the work area. Instrument controls (for adjustment), which are initially set by the echosounder operator, include switches for the channel (frequency) selection, chart calibration settings and the attenuation of signal strength and stylus voltage in order to produce an optimum trace of the seabed at the maximum profile depth.

The boat is *anchored* and the calibration bar is then suspended below the boat by both chains so that the pipe hangs horizontally in a vertical plane through the transducers and directly below, the corresponding tags of each chain being held exactly on the edges of the gunwales while the top surface of the pipe is precisely 12 metres (or more) below the transducer faces. Further settings of the recorder controls are made for vertical scale expansion (set to maximum), the transducer depth below sea level (set accurately below zero line) and the "sound velocity" is finally adjusted to correct the recorded depth of the bar to the exact value. The depth of the bar is now decreased, in stages of 2 m (or 1 metre) throughout the depth range, while the measured depths are recorded and checked (should be exact). The bar is taken aboard. No further adjustments are necessary (or permissible) other than depth phasing, scale expansion and paper speed.

On completion of the day's depth profiling, a second calibration is performed as before.

The bottom trace is recorded (at anchor) for three minutes, using the event marker, in order to measure the dominant wave period and wave height for determining the relationship between wave form and water depth.

The survey boat traverses the profile line continuously from a predetermined depth to a least depth of 1,5 metres, thereby obtaining bathymetric data (to about -0,70 MSL) during a period of 1½ hours spanning spring high tide, while position fixes are coordinated by the echosounder operator for the theodolite observations.

The boat speed is regulated so as to be overtaken by 5 to 6 swells per minute (confirmed by the echo trace), a requirement for accurately eliminating the wave action from the depth profile. A *constant* speed must be maintained between position fixes to permit interpolation of intermediate positions, speed changes should coincide with the fixes. The boat must also maintain its position between the breakers, hanging back while

avoiding aeration in the water which will strongly attenuate the transducer signal. Repeated runs may have to be made in the surf in order to obtain the required profile coverage. The decision, to terminate the profile, rests with the skiboat operator who is advised by the echo-sounder operator on the clearance beneath the boat.

The observed position fixes coincide with the manually activated event marks which are on the analog depth trace. These marks must be fully and correctly annotated for time, date, line and fix numbers.

All profile lines are run *inshore* only. Previous attempts at running the lines in alternate directions produced a consistent difference of about 0,2 metres in the respective depths recorded (in/out), presumably due to the greater vertical acceleration resulting from a higher frequency of wave-crossings on the outward track.

Twelve profile lines (length 1,5 to 3 km) are normally surveyed in 3 hours each day and the survey may extend over several days because of delays resulting from poor sea conditions. Selected control profile lines (2 or 3) are therefore surveyed repeatedly, once each day, in order to verify the consistency of the data by comparison of the profile sections.

The recorded bathymetric depth data, measured from sea level, are related to the benchmark level datum by *accurate* tide data which are recorded continuously for the duration of the survey. The tide data are regularly

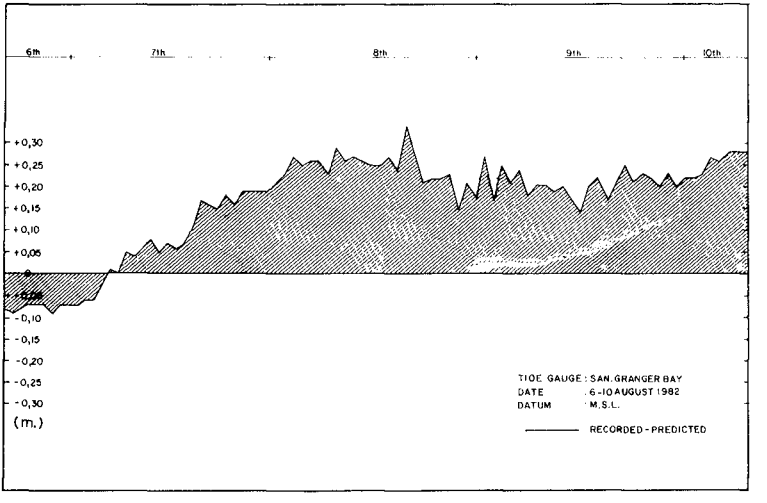

FIG.2 RECORDED VS. PREDICTED TIDE LEVELS

verified by direct observation and measurement, preferably with the aid of a stilling well or other sheltered and damped sea surface, or by comparison with similar data recorded independently nearby. The chart recordings must be meticulously *annotated* with reference to time, date and location.

Suitable tide-gauges, infrequently calibrated due to shortage of staff, are operated at various South African ports by the Hydrographer of the Navy and these data are freely available.

4.3 Error Reduction

Differences of about 300 mm (or more) often occur in elevation between recorded prototype tide data and predicted data, as prepared by the S A Navy and published in the TIDE PREDICTION TABLES, largely due to the effects of fluctuating meteorological parameters (see Figure 2) and therefore the *predicted data are totally unacceptable* for sediment profiling.

Inaccuracies in the time-scale of recorded tide data are a common cause of systematic error in the reduced bathymetric depth profile. By surveying only for a limited period spanning high tide, when the rate of change in elevation is small, the effects on individual profiles are reduced while the cumulative effect on the survey is eliminated.

Localised areas of rock outcrops along the profile *must* be identified and excluded from the comparisons. Large areas of rock may totally disqualify the location as being unsuitable for monitoring.

Temperature profiling should be carried out at random in the work area to ensure a consistent propagation (speed) of sound for all profiles.

The second calibration (each day) verifies the initial one and ensures that no "drift" in the electronics of the echosounder has taken place. The data are discarded and the profiles *resurveyed* if the calibrations differ.

When surveying in the vicinity of river estuaries during periods of flood or heavy run-off, the 30 kHz facility is used simultaneously with the 210 kHz as a precaution against the presence of dense layers of sediment (in the water column) which could mask the seabed and cause a false bottom to be recorded.

The boat speed is calculated between fixes to verify the squat correction (which is applied with the tide level correction). Squat varies in relation to the boat speed, from 10 - 11 cm at 4 ms^{-1} to 3 - 4 cm at 6 ms^{-1}. Care must also be taken to note changes in the buoyancy of the boat due to leakage of the hull and varying content of the 240 litre inboard fuel tanks.

The elevation of the boat is determined from theodolite observations to the target in order to verify the effects of wave set-down/set-up in shallow water. Observations beyond the breakers serve to further verify the tide data for gross errors.

The profile data is abstracted directly from the echo trace and tabulated together with the range distances for determining profile section and areas. The necessary precautions have been taken to ensure *direct profile comparisons* by the precise relocation of all profiles. In no circumstances need profile data be interpolated from contour plans.

5 DATA PROCESSING (GENERAL)

The processing of survey data requires a special awareness of the potential survey inaccuracies and the need to personally scrutinise the many outputs of comparative data at different stages of the work.

Independent checks are systematically applied during each phase of processing the data which is first validated before being further applied. Sufficient observations are made to verify and correct any errors which had been made in the measurements.

Much of the data is processed manually and this also requires specialised experience and a knowledge of local conditions. To increase consistency in reducing the data of successive surveys, the manual reductions are always undertaken by the same persons (to reduce the effects of personal error) in successive surveys and scrutinised by a second party.

5.1 Equipment

Portable calculators are used in the field for processing the essential control survey data while an on-line mainframe computer is available for the processing of the resultant statistical data (profile section areas, etc) at headquarters. Printers are used (with the calculators) to reduce the probability of transcription errors being made in the data.

5.2 Procedure

The processing of all survey data is performed, both in the field and at headquarters, by the survey technicians of the field party.

All data relating to the control survey are processed manually and fully validated before the profiling survey is commenced. During periods of unfavourable weather or sea conditions, the available time is utilised by processing the other survey observations. All calibration data are immediately validated by inspection and comparison. Independent checks are systematically applied to all the survey data.

A graphical comparison is made of the recorded and predicted tide data, and with independently recorded data, in order to check for anomalies (such as errors in the time-scale).

The effects of swell and waves on the analog recording of the profile are reduced graphically, prior to applying the tide corrections, by applying an established theory to relate wave form to water depth (see Figure 3). The reduction graph is based on the VOCOIDAL WAVE THEORY (Swart 1977) defining the relationship (Nc) of the mean water level (WL) to the crest and trough of a design wave relative to water depth. The parameters of

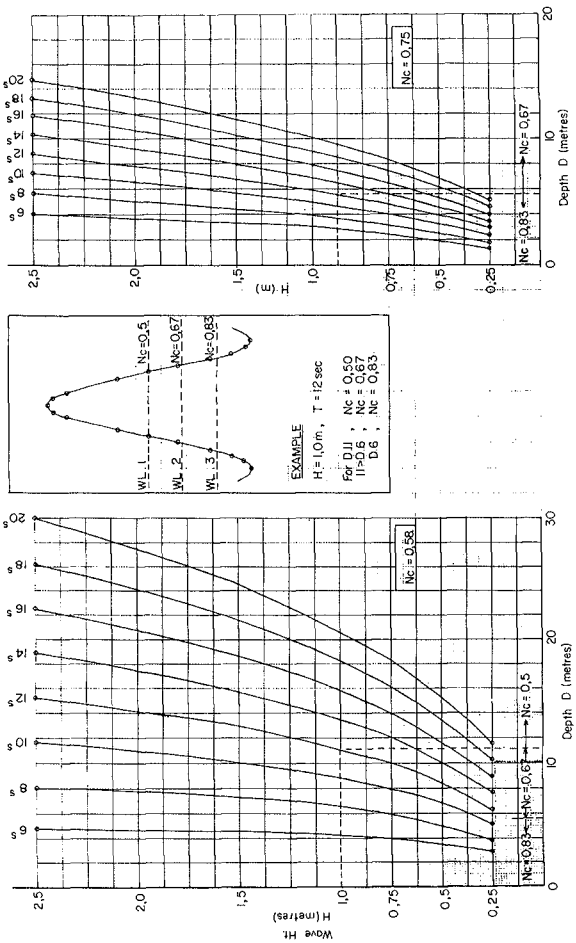

FIG. 3 WAVE REDUCTION GRAPH

wave height and wave period are derived from the initial calibration record of each day and critical depth values for Nc = 0,5 and Nc = 0,67 (also Nc = 0,83) are determined from the graph.

The inverted wave crests on the echo trace are all joined by straight lines, as are the inverted troughs. The corrected WL image is then reconstructed in accordance with the Nc/depth relationship and smoothed. This is regarded as the true image of the sediment bed. All intermediate changes in slope are annotated and their proportional range distances are derived from the calculated "fix" positions. Tide (and squat, etc) corrections are then applied to all the recorded depths of both the "fix" and annotated positions and the data are then abstracted for the determination of the profile sections.

Graphical comparisons are made of the overlap of profile data derived independently from the beach and sonic profiling.

6 RESULTS OF A VERIFICATION EXPERIMENT

During a regular profiling survey at Koeberg in September 1982, a number of additional profile sections were surveyed in order to evalulate the probable error in the depth soundings for various sectors along the profile.

Line 10 was chosen as the control profile and ten runs were made over the profile in a consistently calm/moderate sea state with swell height of about 0,5 to 0,7 metres. There were four runs on 16 September and six runs on 17 September. No overlap was obtained with the beach profile, neither were vertical intersection angles observed in this exercise. The abstracted profile data are listed in Table 2.

6.1 Sounding Error

The following methods were used to determine the values for the probable error of the soundings:

1 The *average* depth was determined for each range position at intervals of 50 metres along the profile, these values were adopted as the *correct* values and the respective errors were determined for each of the range positions throughout the profile length from range distance 300 metres to range distance 2 050 metres. These error values are plotted against the range distance, from the reference survey beacon, to indicate the error distribution (see Figure 4). The standard deviation was likewise calculated and also plotted against the range distances (see Figure 4).

The probable error of a single depth sounding in the surf zone varies from ±0,06 m to ±0,10 m while offshore the probable error of a depth sounding varies from ±0,02 m to ±0,04 m where

$$P.E. = 0,6745 \sqrt{\frac{[dd]}{(n-1)}}$$

Surf Zone — Calibration Range — Nearshore

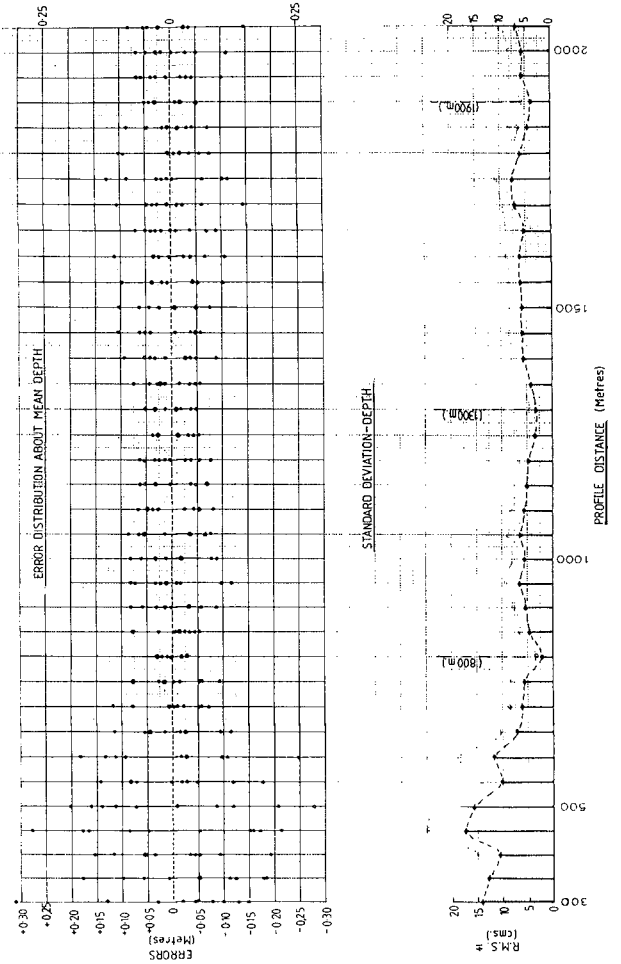

FIG. 4 EVALUATION OF ERRORS IN SONIC PROFILING

The error limits within the *95% confidence band* were found to be ±0,20 - 0,33 m in the surf zone and ±0,07 - 0,13 m offshore (for 9 degrees of freedom).

In comparing the *average* elevations of each run with the mean elevation (of all 10 runs), the differences are found to have a standard deviation of ±0,04 m.

Of special interest in Figure 4 are the apparent node points in the error distribution which recurs at regular intervals of 500-600 m apart and is apparent again at a range distance of about 2 500 m (for only three runs). These nodes indicate some tide level phenomenon, similar to a "standing wave" situation, which accounts for 50% of the probable sounding error beyond the surf zone.

The profile data listed in Table 2, under column 7/9, were recorded on 7 September during an earlier survey which was aborted because of deteriorating weather and sea conditions. A comparison of these data, with those which were acquired on 16-17 September, indicates the consistency of the profile data obtained during routine surveys.

2 No *correct* value is assumed for this analysis and the errors are derived on the basis of direct comparison between *any pair* of measurements taken, in all there are 45 possible combinations (from 10 measurements). Calculation of the probable errors of a depth sounding (as in the first method) yields values which are consistently 40% higher than previously. Within the 95% confidence limit, the errors are ±0,27 - 0,42 m in the surf zone and ±0,09 - 0,18 m in the offshore area.

Profile section *areas* were calculated for each of the 10 profile runs and the error values were determined from the mean values, a distinction being made between the surf zone, offshore and for the overall section. These results are shown in Figure 5 together with the probable error, indicated above (n = 10). For the 95% confidence band the magnitude of error value is increased by a factor of 3,35.

A second analysis was done of the section areas, as for the sounding error, and the probable errors are also indicated in Figure 5 (as n = 45) except for the overall chart where n = 36. For the 95% confidence band the magnitude of error is increased by a factor of 3.

6.2 Spacing Error

The effect of spacing error, due to the insufficient density in the profile spacing, was investigated by surveying an extra four profiles (marked A-D) which were fairly evenly spaced between the regular profiling lines 10 and 11. The section areas of profiles A-D were calculated and these values are tabulated in Table 4 and indicated graphically in Figure 6 (where comparative elevations are shown for volummetric calculations).

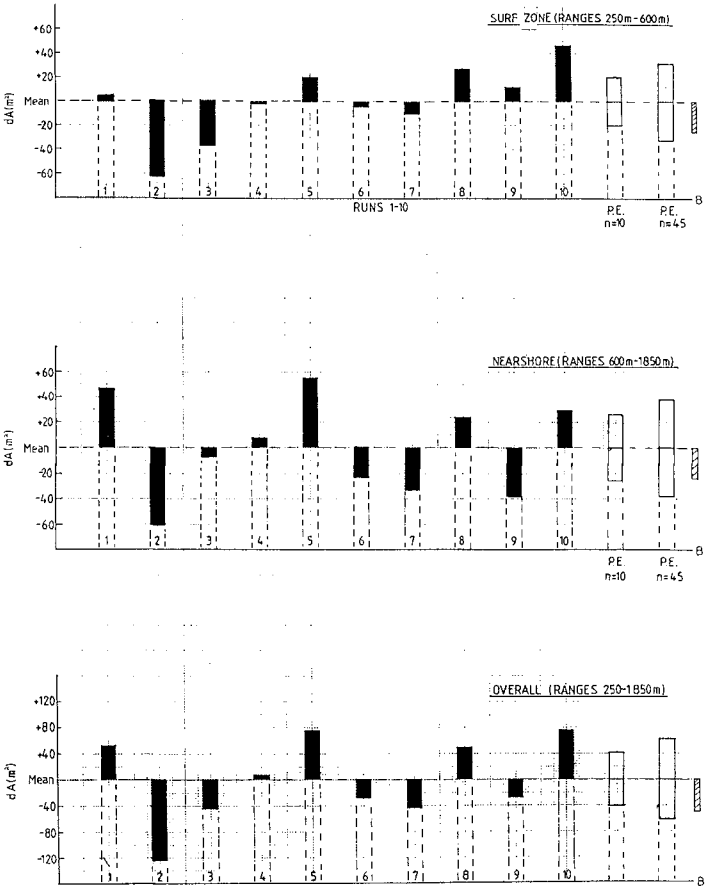

FIG. 5 ERROR DISTRIBUTION FOR PROFILE SECTION AREAS

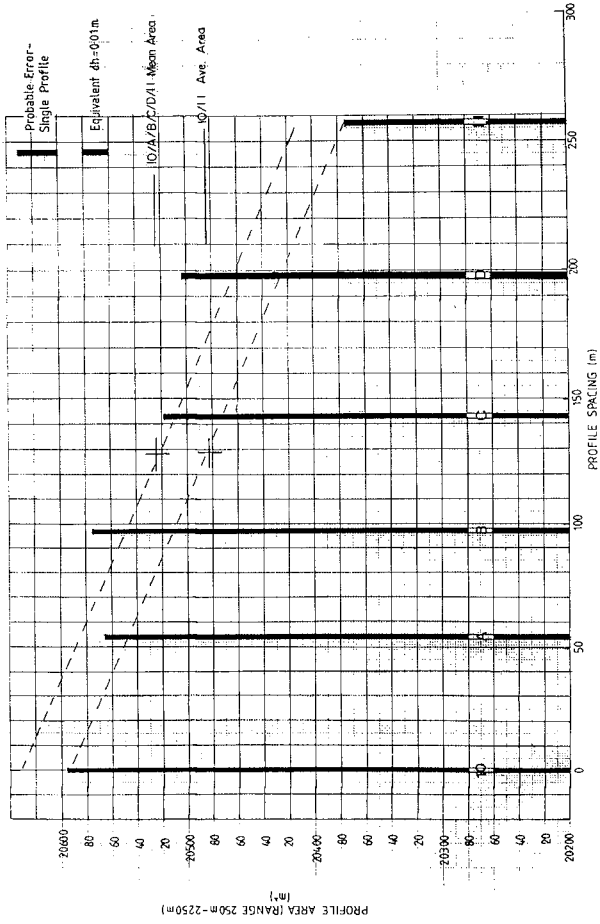

FIG. 6 SPACING ERROR FOR PROFILE DENSITY

TABLE 3 - COMPARISON OF SECTION AREAS WITH AVERAGE PROFILE

RANGE DISTANCE (m)	RUN										
	1	2	3	4	5	6	7	8	9	10	Average 1-10

600-1850 Δa_2	13164 +47	13056 -61	13110 -7	13125 +8	13172 +55	13094 -23	13084 -33	13140 +23	13078 -39	13146 +29	13117 RMS ±39
600-2250 Δa_3	19239 +89	19090 -60	19135 -15		19207 +57	19104 -46	19103 -47	19178 +28	19094 -56	19197 +47	19150 RMS ±56
250-1850 Δa_4	14520 +52	14345 -123	14424 -44	14475 +7	14543 +75	14441 -27	14425 -43	14518 +50	14441 -27	14544 +76	14468 RMS ±64
250-2250 Δa_5	20595 +95	20379 -121	20449 -51		20578 +78	20451 -49	20444 -56	20556 +56	20457 -43	20595 +95	20500 RMS ±81

Δa = Deviation from the average area (Profile OP.10)
RMS(250-600) = ±9m²/100m; RMS (600-2300) = ±3m²/100m; RMS (250-2300) = ±4m²/100m

TABLE 4 - COMPARISON OF INTERMEDIATE SECTION AREAS WITH PROPORTIONAL AREAS

PROFILE SECTION	10	A	B	C	D	11
Calculated area (m^2)	20595	20566	20574	20518	20504	20374
Proportional area (m^2)		20539	20504	20467	20422	
Δarea = (m^2)		+27	+70	+51	+82	
Profile spacing (m)	53,96	42,71	46,21	55,27	58,72	
	256,87					

The apparent result of spacing error in the volume, as calculated from the end section areas, is 10 143 m^2 which is equivalent to an average error in elevation of 0,02 m (which is well within the accuracy indicated for the probable error). From a visual comparison of the intermediate areas, A to D in Figure 6, with their assumed profile areas (indicated by the broken line from profile 10 to profile 11), it is obvious that here the disagreement is also within the limits of the sounding error.

The spacing of about 250 m between profile lines 10 and 11 is adequate for this particular section of the sea bed. Since the bathymetry of the area is very regular and the coastline is straight (see Figure 1), the profile intervals are assumed to be acceptable although further sampling of the spacing is required.

7 CONCLUSION

The results of the experiment indicate clearly that the required accuracy of measurement can be achieved under normal conditions by standard survey procedure and that the effects of systematic errors are significantly reduced. The spacing of profiles, about 250 m, is apparently acceptable in the case study.

The field operation is cost efficient in terms of capital outlay, reliability of instrumentation and optimum productivity of personnel. The required technical expertise is easily acquired without specialised training.

The survey procedure is highly efficient in the identification/elimination of random errors and the evaluation and reduction of systematic errors thereby increasing the degree of accuracy which is attained.

The precise relocation of profiles in successive surveys, together with the verification of the data, serves to confirm the validity of the resulting quantitative assessment of sediment transport.

FIELD INVESTIGATION OF LONGSHORE TRANSPORT OISTRIBUTION

by

E. P. Berek[1], A.M. ASCE and R. G. Oean[2], M. ASCE

ABSTRACT

Following a change in wave direction, the active contours in an idealized pocket beach respond by rotating such that they approach a perpendicular orientation relative to the incoming wave rays. Assuming that cross-shore sediment transport does not contribute to this contour rotation, and that the contours are in the early stages of this equilibration process, the amount of contour rotation can be interpreted as the cross-shore distribution of the longshore sediment transport.

As part of the Nearshore Sediment Transport Study, detailed nearshore profile measurements were conducted at Santa Barbara, California. Twenty-two of these profile lines were located on Leadbetter Beach, which is a quasi-pocket beach. To explore the concept described above, two of the nine intersurvey periods were selected due to their strong indications of wave direction change. Analysis of these data sets yielded two estimates of cross-shore distribution of longshore sediment transport which were compared with those presented by Komar, Fulford and Tsuchiya. Although these three distributions differ significantly, the effect of the tidal variations is to "smear" the differences in the inferred distributions as evident in the contour displacements. It was found that none of the relationships for longshore transport distribution predicted the amount of transport inferred in water depths greater than one meter. It is possible, especially for one of the intersurvey periods that the changes in contour locations were so extreme that substantial cross-shore sediment transport was induced and would be interpreted as longshore transport occurring in water depths greater than had actually occurred. The method introduced here should be useful in other field and laboratory programs to investigate the cross-shore distribution of longshore sediment transport.

INTRODUCTION

Practically all coastal engineering projects require quantitative estimates of the longshore sediment transport at the project site. This information can be derived from a variety of sources including experience at nearby structures, channels which impound sediment and computations based on local wave characteristics. Generally, even if impoundment data are available, computations are employed, partly in the interest of developing confidence in the impoundment estimates, but also because of the uncertain quality of most impoundment documentation. For example, much of the initial nearshore accumulation at jetty structures can be the result of the onshore transport of a portion of the material which formerly resided in the ebb tidal shoal. In addition to the need for estimates of total longshore sediment transport, there are a number of project/problem types that require estimates of the distribution of longshore sediment transport across the surf zone. Examples include: design of the length and elevation of the weir section of a weir jetty system, design of the length of a groin or jetty, computation of the total longshore sediment transport in cases where a portion of the surf zone is paved by beach rock or particles too coarse to yield significant amounts of transport, etc.

The Nearshore Sediment Transport Study (NSTS) was sponsored by the National Sea Grant Office of the National Oceanic and Atmospheric Administration (NOAA); the objectives of this study included the enhancement of general knowledge and understanding of nearshore hydrodynamics and sediment transport processes with an emphasis on the improvement of the capability to compute longshore sediment transport for engineering purposes (Duane and Seymour, 1978). One component of the NSTS directed specifically at this latter objective was an eighteen month measurement program carried out at Santa Barbara, California. Through measurements of volume accumulations by the near-complete trap formed by the spit in the lee of the breakwater and portions of the updrift beaches, the net longshore transport could be documented with good accuracy. The wave characteristics were provided by two S_{xy} gages located in a water depth of approximately 7 m directly off Leadbetter Beach. The initial plan did not include an attempt to determine information relating to the cross-shore distribution of longshore sediment transport. However, as the data from a number of surveys accumulated, the "rotation" of the nearshore contours resulting from shifts in the dominant wave direction suggested that some of the available data sets were well-conditioned to address the problem of longshore sediment transport distribution.

REVIEW OF RELATED WORK

The difficulties of conducting field measurements of the cross-shore distribution of longshore sediment transport have prevented the determination of any well-accepted results. Methods attempted include bed load traps by Thornton (1973) and tracer studies. Thornton estimates the efficiency of the bed load traps to be between 40 and 100 percent. He also stated that the traps appeared to be more efficient under light wave conditions and tend to bury themselves under heavy wave conditions.

Thornton (1973), Komar (1977), and Tsuchiya (1982) have developed predictive equations for the cross-shore distribution of longshore sediment transport. Thornton utilized a Bagnold (1963) model and considerations of the role of the longshore current to develop a predictive relationship for $q_y(x)$, the distribution across the surf zone of the longshore sediment transport. Thornton's results expressed $q_y(x)$ as proportional to the product of the average energy dissipation per unit bed area and the longshore current. The proportionality factors were considered to be different inside and outside of the surf zone due to the different causes of energy dissipation. The field measurements conducted by Thornton included sediment transport as determined by the bed load traps and longshore currents based on surface float trajectories or current meters. The transport proportionality factor outside the surf zone exceeded that inside the surf zone by slightly more than an order of magnitude. There is substantial uncertainty regarding the efficiency of the bed load traps. Integrating Thornton's results across the surf zone results in a proportionality factor, K, for the total transport which is approximately two orders of magnitude less than the commonly accepted value of 0.77 (Das, 1972, Figure 6).

Komar combines the sediment transport concepts of Bagnold with longshore current distributions as developed by Longuet-Higgins (1970) and modified by Komar (1976). The resulting expression for $q_y(x)$ is proportional to the product of the bottom shear stress and the longshore velocity. Results are developed in which the bottom shear stress is based on the gradient of S_{xy} (the onshore flux of the longshore component of momentum) and this gradient augmented by the longshore current. Komar finds that the magnitude of $q_y(x)$ depends on the breaker height to depth proportionality factor, a mixing parameter which controls the form of the longshore current and the friction factor for the profile. The maximum of $q_y(x)$ is predicted to be at approximately $0.8\ x/x_b$, where x_b is the offshore breaking distance. Oue to the predicted abrupt discontinuity in bottom shear stress at the surf line, q_y is also discontinuous at this location. Additionally, Komar's distribution does not include any "swash" transport, i.e. landward of the mean water line. An example is presented in Figure 1.

Tsuchiya (1982) bases his predictive relationship on an equation which appears to be appropriate only for suspended sediment transport and which does not account for the correlation, over the vertical, of the suspended sediment distribution and the longshore current distribution. Tsuchiya combines the longshore current representation by Longuet-Higgins (1970) with earlier work conducted by Tsuchiya on sediment transport by currents. In the brief 1982 abstract, Tsuchiya does not present his method in detail; however, it appears that the basic form of the longshore sediment transport is approximately proportional to the product of the longshore current distribution and the depth. An example of Tsuchiya's results is presented in Figure 1, in which the continuity of sediment transport across the surf line and lack of swash transport are evident.

Fulford (1982) determined an empirical distribution of longshore sediment transport based on a wave basin study conducted by Savage

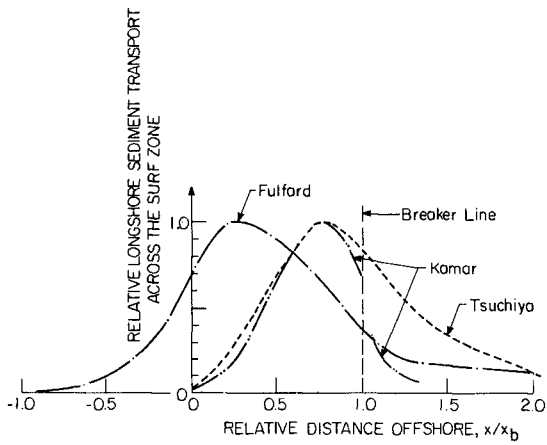

Figure 1. Illustration of Cross-Shore Distributions of Longshore Sediment Transport as Determined by Various Investigators.

(1959). In the tests utilized, Savage allowed the beach processes to equilibrate under the action of waves approaching at an angle. A long high impermeable groin was then introduced into the system. The analysis by Fulford was based on the two-dimensional equation of sand conservation

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} - \frac{\partial h}{\partial t} = 0 \tag{1}$$

in which q_x and q_y represent the local sediment transport rates per unit width in the offshore and longshore directions, respectively and h represents the local water depth. To determine the distribution of $q_y(x)$, the above equation was integrated with respect to y

$$\int_0^y \frac{\partial q_x}{\partial x}\, dy + \int_0^y \frac{\partial q_y}{\partial y}\, dy = \int_0^y \frac{\partial h}{\partial t}\, dy \tag{2}$$

with the assumption that in the early stages of accumulation by the groin, the offshore sediment transport is zero, i.e. the first term is zero and the second term can be integrated directly to yield

$$q_y(x,y) - q_y(x,0) = \int_0^y \frac{\partial h}{\partial t}\, dy \qquad (3)$$

The second term is zero if the groin is impermeable. If the integration is carried out to a sufficient distance (y value), then the unaffected transport is determined. The distribution determined by Fulford is presented in Figure 1. Note that a considerable amount of transport is located in the "swash" zone and that the maximum of Fulford's distribution is considerably landward of those in the Komar and Tsuchiya distributions.

SITE CHARACTERISTICS

Santa Barbara is located on the Southern California coast, 150 km northwest of Los Angeles and 560 km southeast of San Francisco. The beaches lie on the Santa Barbara Channel which is separated from the Pacific Ocean by the Channel Islands. Because of the origin of the waves, the sheltering influence of the offshore islands, and the refraction of the waves (O'Brien, 1950), the wave pattern at Santa Barbara is nearly the same for most of the year, with the exception of infrequent waves from southeast storms.

During 1927-28 a detached rubble-mound breakwater with a concrete cap was constructed off Point Castillo to protect the Santa Barbara harbor. The breakwater was 1425 ft. in length roughly parallel to shore, with a 400 ft. arm directed towards shore. The resulting diffraction pattern in the lee of the breakwater caused the sand normally transported along the shore to be deposited in this area. Because of this undesirable effect, the breakwater arm was connected to shore in 1930 (Figure 2).

The now L-shaped breakwater was an effective trap of the longshore transport and the area west of the breakwater soon developed into a substantial beach (Leadbetter Beach) where the present experiment took place. Leadbetter Beach is therefore bordered on the east by the breakwater which, depending on beach contour planform, can act as an effective barrier to eastward sediment transport. The western end of Leadbetter Beach, approximately 1 km from the breakwater, is bordered by a high cliff, with many rocks at its base, extending oceanward to Santa Barbara Point. This western boundary essentially precludes any sediment transport out of Leadbetter Beach to the west. Wiegel (1964) has presented an excellent summary of the Santa Barbara breakwater construction history and resulting shoreline response.

After forming Leadbetter Beach, which represented a shoreline advancement of some 300 m, the sand moved along the breakwater and eventually began infilling the harbor area. By 1935 it was necessary to begin a program of periodic harbor dredging. From 1938 to 1953, maintenance dredging was done biennially, placing most of the dredged material on the beaches to the east, which had suffered substantial erosion after the breakwater construction. In 1954 it was decided to allow part of the continuously forming sand spit at the eastern end of

the breakwater to remain as protection to the harbor from southeast storms. A wooden structure has been constructed along the axis of the spit extending almost due north from a distance of about 20 meters to about 270 meters from the centerline of the breakwater. This spit area is believed to trap all the sand being transported alongshore at Santa Barbara and was used as the major site of NSTS Task 4-C (Dean, Berek, Gable and Seymour, 1982).

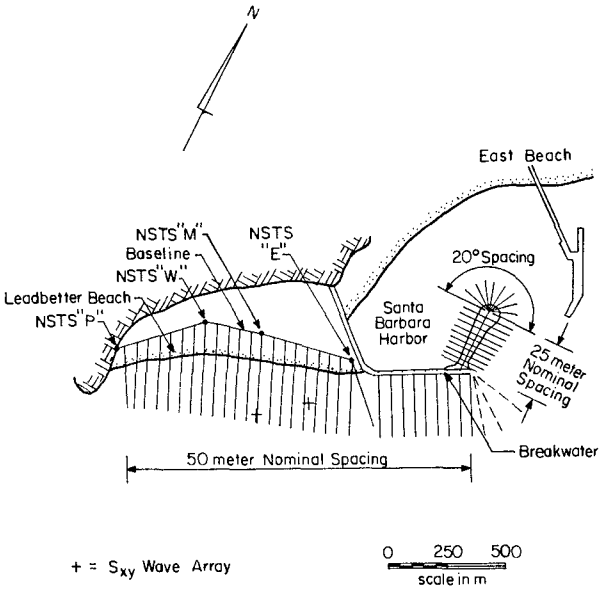

Fig. 2. Study Site, Survey Lines, and Location of the Two S_{xy} Wave Arrays

SURVEY PROCEDURES

Ten surveys were conducted at Santa Barbara from October 1979 to February 1981 (see Table I). Conventional land surveying techniques, overlapped by bathymetric surveys were utilized. Survey lines were run on the spit, on the seaward side of the breakwater and along Leadbetter Beach. A total of 22 lines were surveyed on Leadbetter Beach, two originating from the same point near the "elbow" of the breakwater, the others being at 50 m intervals along the beach, see Figure 2 for a survey plan and location of the S_{xy} gages.

The bathymetric survey was accomplished by a recording fathometer from a boat precisely located by a Cubic Autotape system. To eliminate the effects of waves, each line was surveyed three times and the depth and distance determined by averaging the values obtained over a five meter interval in the offshore direction.

Table I. Survey Oates

Survey Number	Survey Oates
1	10/18/79 to 10/22/79
2	11/30/79 to 12/04/79
3	01/20/80 to 01/25/80
4	02/25/80 to 03/01/80
5	04/10/80 to 04/13/80
6	06/03/80 to 06/09/80
7	08/25/80 to 08/28/80
8	10/22/80 to 10/25/80
9	12/16/80 to 12/20/80
10	02/26/81 to 02/28/81

Tide elevations in Santa 8arbara Harbor were documented during the bathymetric surveys to correct the fathometer data to Mean Sea Level. In addition, the surveys were checked at distances far offshore at water depths presumed sufficiently great to be outside the region of sediment transport. Fathometer calibrations were made frequently during bathymetric surveys.

In addition to the sediment data, wave information was obtained by an S_{xy} array consisting of four bottom-mounted pressure sensors as described by Seymour and Higgins (1978). In general, wave data were recorded at six-hour intervals.

8each profiling was performed during low tide periods, whereas the boat surveys took place during high tides to attempt to maximize overlap distance as much as possible. The profiles were taken with rod and level at five meter intervals, or pronounced changes in beach slope. In general, the overlap was satisfactory. The survey line locations are shown in Figure 2. A more complete description of site characteristics and survey procedures is provided by Oean, 8erek, Gable and Seymour (1982)

ANALYSIS METHOOS

Interpretation of Idealized Pocket Beach Response

The estimation of the longshore sediment transport distribution across the surf zone is based on the idealized response characteristics of a pocket beach to a change in wave direction. If no sediment flux into or out of a pocket beach can occur, and if a change in wave direction occurs, the pocket beach will respond such

that the contours will approach an orientation which is approximately perpendicular to the incident wave direction. Other contour modifications can occur due to a change in wave height and/or period. For example, it is well-known that an increase or decrease in wave steepness without a change in wave direction can cause the profile to flatten or steepen, respectively. Figure 3 summarizes the assumptions utilized in this study: that the even and odd portions of the contour displacements are due to cross-shore and alongshore sediment transport, respectively.

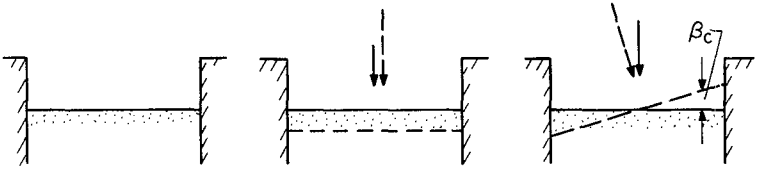

Figure 3. Representative Contour Displacement Signatures for an Idealized Pocket Beach Due to Cross-Shore (Sketch b) and Longshore (Sketch c) Sediment Transport.

The interpretation of the odd component of the beach contour displacements is as follows. Consider the contour changes shown in Figures 3b) and c) and the two dimensional equation of continuity.

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} - \frac{\partial h}{\partial t} = 0 \tag{4}$$

If the depth change effect is separated into an even component $(\frac{\partial h}{\partial t})_e$ due to the cross-shore sediment transport and an odd component $(\frac{\partial h}{\partial t})_o$ due to alongshore sediment transport, then by assumption

$$\frac{\partial q_x}{\partial x} = (\frac{\partial h}{\partial t})_e \tag{5}$$

$$\frac{\partial q_y}{\partial y} = (\frac{\partial h}{\partial t})_o \tag{6}$$

It is the odd component which will be of primary concern here. Since contour displacements, rather than depth changes are required, the transformation is introduced relating the time rate of change in depth to the time rate of displacement of a particular contour h_c, i.e.

$$\left(\frac{\partial h}{\partial t}\right)_o = \frac{\partial h_c}{\partial x}\left(\frac{\partial x_c}{\partial t}\right)_o = \frac{\partial q_y}{\partial y} \tag{7}$$

and where $\left(\frac{\partial h_c}{\partial x}\right)$ is the slope, m_c, of the beach profile at the contour of interest. Integrating from an arbitrary location y to the end of the beach compartment, $y = \ell$, where the transport, q_y is zero,

$$q_y(h_c,y) = - m_c \int_y^{\ell} \left(\frac{\partial x_c}{\partial t}\right)_o dy \tag{8}$$

which relates the longshore transport along a particular contour, h_c, to the integral of the time rate of displacement of that contour. If the location y is taken as the centerline of the pocket beach and if the contour change is approximately linear as shown in Figure 3c, with slope, β_c, then the magnitude of the longshore sediment transport rate is

$$|q_y(h_c,y)| \propto m_c \tan\beta_c \tag{9}$$

Without discussing in detail the time response of a particular contour to a change in wave direction, it is relevant to note that the initial effects are manifested at the ends of the compartment and that an odd contour change that is linear is indicative of an adjustment that has nearly achieved equilibruim under the changed wave direction. The ideal data set for establishing the transport distribution is one in which all of the contours have rotated sufficiently to allow volumes transported to be measured accurately, but a sufficiently small transport such that offshore transport has not been induced nor has equilibrium been achieved. In the general case, it would be necessary to employ Eq. (8) rather than Eq. (9).

There are three main limitations to the method described for determining the distribution of longshore sediment transport from contour rotations in pocket beaches. The first and most obvious limitation is that the pocket beach should be "sand tight" such that any alongshore transport along a contour will be manifested by a rotation of that contour rather than by being transported out of the system. The second limitation is that the method assumes that sand transported along a contour will remain on that contour. It is clear that as a result of steepening or flattening of a profile, offshore and onshore sediment transport will occur, respectively. The final limitation relates to the duration between intersurvey periods relative to the time required for the system to achieve equilibrium under the altered wave conditions. Given sufficient time, all active contours would "rotate" into the incoming wave direction and therefore it would be impossible to determine any information relating to the cross-shore distribution of longshore sediment transport. Thus the response should be documented in the early stages of the equilibration process.

Determination of Odd and Even Contour Displacement Components

For each survey, the locations of various depth contours were determined from the data by interpolation. The computer program which determined these locations also established the changes in the contour positions between consecutive surveys. These contour displacement data were then smoothed and the number of lines along Leadbetter Beach reduced to ten, resulting in a spacing of one hundred meters between lines. This smoothing was accomplished by a simple moving average filter:

$$X_1 = x_1 \tag{10}$$

$$X_i = 0.25\, x_{2i-2} + 0.50\, x_{2i-1} + 0.25\, x_{2i} \; ; \; i = 2, 10$$

where: X_i = smoothed displacements
x_i = measured displacements

To separate the contour displacements into even and odd components, the following formulas were used:

$$(f_{odd})_i = \frac{X_i - X_{(N-i)}}{2} \tag{11}$$

$$(f_{even})_i = \frac{X_i + X_{(N-i)}}{2} \tag{12}$$

where: N = total number of points (i.e., 10)

The odd parts of the contour displacements are, by definition, antisymmetric about an axis through the center of the beach planform. This axis is therefore a pivot point about which contour rotations are measured.

Wave Analysis

Wave information was obtained throughout the period of study from an S_{xy} array consisting of four bottom mounted pressure sensors, as described by Seymour and Higgins (1978). Wave recordings were normally available every six hours and spectral information summarizing the wave characteristics of each recording period was provided by R. J. Seymour and D. Castel of the Scripps Institute of Oceanography.

For longshore transport calculations the wave quantities of particular importance are the root mean square breaking wave height, H_b, and the breaker angle, α_b. A value of $P_{\ell s}$, the longshore component of wave energy flux, was calculated as

$$P_{\ell s} = C_1 (H_b)^{5/2} \sin 2\alpha_b$$

where C_1 is a proportionality factor and H_b and α_b were obtained by refraction and shoaling computations which transformed the data from the gage location to the breaker line.

Prediction of Average Longshore Transport Along a Particular Contour Including the Effect of Tidal Variations

Consider the application of a particular predictive distribution for longshore sediment transport, $q_y'(x)$. In this relationship, the origin of x is at the mean water line and the application must account for the effect of the varying tide, $\eta_T(t)$. In the approach utilized herein, the distribution with distance $q_y'(x)$ was first transformed to a distribution with depth, $q_y''(h)$, by the relationship

$$q_y''(h) = \frac{1}{m_c} q_y'(x) \tag{13}$$

in which the beach slope, m_c, was determined from the representative beach profile presented in Figure 4.

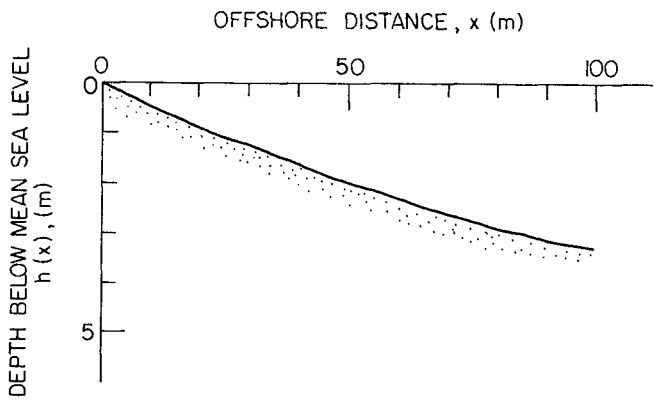

Figure 4. Representative Beach Profile.

The longshore sediment transport along a particular depth contour (h_c) then becomes

$$q_y(h_c,t) = P_{ls}(t)\, q_y''(h + \eta_T(t)) \tag{14}$$

where the distribution $q_y''(h)$ is normalized to unit area and is scaled at each time in accordance with the breaking depth $h_b(t)$ associated

with each $P_{ss}(t)$. This procedure is illustrated schematically in Figure 5. The values of $q_y(h_c,t)$ were calculated for the time-varying tide and wave characteristics at time increments of one hour. The average computed longshore transport values for each contour were determined by integrating Eq. (3) over the time interval of the intersurvey period. These computations were carried out for the distributions of Komar, Fulford and Tsuchiya as presented in Figure 1.

RESULTS

Two intersurvey periods showing significant planform rotations have been analyzed: June-August, 1980 and October-December, 1980. The character of the net beach response to the wave environment was fundamentally different in the two cases; this difference will be discussed briefly. Considering the schematic diagram of Leadbetter Beach in Figure 6, the beach contours during the June-August period rotated counterclockwise (Figure 6a), and during the October-December period the rotation was clockwise (Figure 6b). Because the breakwater does not extend sufficiently far seaward to prevent all the longshore transport, the system is "leaky" when the contours rotate clockwise. When the contours rotate counterclockwise the system is "sediment tight" or "not leaky".

Following the procedure described earlier for the determination of the odd components of the contour displacements, the survey data were analyzed and the results are presented in Figures 7a) and 7b). The odd components are of course antisymetric about the center-line of the beach compartment. Based on these figures, values for the slopes of the contour displacements, β_c, defined in Figure 1c were determined. The resulting transport is proportional to the product of tan β_c and the local beach slope, m_c,

$$q_y \propto m_c \tan \beta_c$$

It is of interest to note that for the October to December intersurvey period, the value of β_c decreases monotonically from the mean sea level contour to the deeper contours. The value of β_c for the June to August period changed in a more complex manner; first increasing slightly from the mean sea level contour to the 1.0 meter contour, followed by a decrease. This pattern leads to a very different expected profile for $q_y(x)/q_y(0)$ for the two intersurvey periods, as shown in Figure 8. The June-August period distribution shows the transport distributed over a much wider range of depths, with transport being greater than $q_y(0)$ to the 1.0 meter contour.

These two measured distributions have been compared with three predicted distributions, which are also shown in Figure 8, and are due to Komar (1977), Fulford (1982), and Tsuchiya (1982).

During the June to August intersurvey period and for depths greater than 0.5 m, all of the predicted transport distributions are less than that inferred from the measured contour displacements. Recalling the earlier discussion of the effect of large contour

Figure 8. Comparison of Predicted Relative Longshore Sediment Transport Distributions with the Distributions Inferred from Field Measurements

displacements on the inferred distribution and referring to Figure 7a and Figure 4, it appears likely that the contour displacements of approximately 17 m at the ends of the pocket beach compartment may have caused cross-shore transport. As noted, under the assumptions employed herein, the deposition resulting from cross-shore sediment transport would be interpreted as longshore sediment transport in greater water depths than had actually occurred. Moreover, the triangular distributions of the contour displacements for this intersurvey period (Figure 7a) suggest that an equilibrium planform had been achieved, at least for depths of 1 m and shallower. Although the contour displacements were in a direction such that the compartment should be sand tight, the violations of the assumptions as noted above would appear to invalidate the results of this particular intersurvey period as a basis for evaluating the cross-shore distribution of the longshore sediment transport.

The contour displacements associated with the October to December intersurvey period are clockwise and thus the pocket beach would tend to be "leaky". However, examination of these displacements in Figure 7b indicates that the other two requirements are satisfied much better than for the earlier intersurvey period: (1) the contour displacements are much smaller, and (2) the form of the displacements suggests that the equilibration process may be in the early to intermediate stages. The comparison of the distribution inferred from measurements and those based on the predictions is presented for this intersurvey period in Figure 8b. In water depths less than approximately one meter, there is good general agreement, with the Komar distribution providing the best fit. In greater depths all predicted transport values are less than the measured with Fulford results being in slightly better agreement than the other two. It appears that in water depths greater than one meter, there may be some effect of cross-shore transport induced by the contour displacements.

SUMMARY AND CONCLUSIONS

Summary

Following a change in wave direction, the active contours in an idealized pocket beach will respond by rotating such that they approach a perpendicular orientation relative to the incoming wave rays. A method has been presented for interpreting the rotation of various contours to determine the cross-shore distribution of the longshore sediment transport. The requirements for the method to be applicable are: 1) the longshore and cross-shore transport gradients result in odd and even changes in the position of a contour, respectively, (2) the pocket beach compartment should be sand tight, (3) the contour displacements should be sufficiently small that only minimal cross-shore transport is induced as a result of the perturbation of the equilibrium beach profile, and (4) the contour displacements should be documented while the equilibration process is in its initial stages.

The method has been evaluated by analyzing the NSTS Leadbetter Beach profile data from two intersurvey periods. These results are

compared with predictions based on three proposed longshore transport distributions.

Conclusions

1. The two intersurvey periods analyzed herein were for June to August, 1980 and October to Oecember, 1980. Neither of these two data sets satisfy entirely the requirements identified for determining the longshore sediment transport distribution from contour displacements. For the first period, the contour rotation was counterclockwise such that the compartment would be sand tight; however, the amount of change and duration of transport prior to documentation appear to result in an indication of excessive transport in water depths greater than one meter. For the second period, the clockwise rotation of the contours tends to result in a somewhat "leaky" system. However the character of the contour displacement indicates that little cross-shore transport was induced and that the equilibration process was in the early stages. Thus, greater confidence is assigned to the second intersurvey period.

2. Although the forms of the three trial distributions differ substantially, the effect of "tidal smearing" is to reduce these differences as manifested in predicted contour displacements and inferred distributions.

3. Although the three distributions (after tidal smearing) are not markedly different, for the second intersurvey period, which is considered to satisfy more completely the requirements of the method, the distribution of Komar provides the best agreement in depths less than one meter and that of Fulford agrees best in water depths greater than one and one-half meters.

4. To better evaluate candidate distributions, it would be desirable to apply the procedure in locations where no tide is present, such as the Great Lakes if a beach segment with proper planform controls could be identified. If applied in areas with tides, the tide range should be small compared to the representative breaking wave height.

5. It is hoped that the method will be useful in further determinations of the cross-shore distribution of longshore sediment transport, both in laboratory and field studies.

ACKNOWLEDGEMENTS

The financial support provided by the Sea Grant Program to this component of the Nearshore Sediment Transport Program is greatly appreciated. The encouragement and guidance of Dr. David Duane as Technical Monitor of that program was especially valuable as was that of Or. R. J. Seymour as Program Manager. The dedicated and professional efforts of Mr. C. G. Gable of Scripps Institute of Oceanography and personnel of Ocean Surveys, Inc. in the field surveys contributed significantly to the quality of the field data. Finally, the University of California at Santa Barbara was very helpful by

providing vessels and highly competent personnel to assist in the field efforts.

NEW FRAMEWORK FOR PREDICTION OF LONGSHORE CURRENTS

by

C A Fleming[1] and D H Swart[2]

ABSTRACT

The accuracy of prediction of longshore sediment transport depends largely on the accuracy with which the wave-driven longshore currents within the breaker zone can be predicted. Longuet-Higgins (1970) developed a formulation for longshore transport which is widely used today. In the present paper the basic theory of Longuet-Higgins is re-examined. The effect of bed roughness on the magnitude of the longshore current is quantified with the aid of over 350 individual data sets and the theory is theoretically extended to include the effect of random waves, in a similar way to Battjes (1974), and higher-order waves. For this latter purpose the Vocoidal water wave theory of Swart (1978) is used. It is shown that the use of Vocoidal theory leads to a velocity distribution which is in closer correspondence to measured data than that predicted by using linear wave theory.

1. MOTIVATION AND BACKGROUND

The magnitude and distribution of the wave-driven longshore current in the breaker zone depends on the momentum balance, which in turn depends on the underwater profile, the incident wave characteristics and the wave breaking mechanism. In 1970 Longuet-Higgins solved this momentum balance equation in the longshore direction in the shore area by making specific assumptions regarding three individual terms, namely, the driving force or radiation stress term, the bed shear and the lateral mixing, the latter two being dissipative terms.

The momentum balance in the longshore direction x as given by Longuet-Higgins is:

---

1) Sir William Halcrow and Partners, Swindon, UK

2) National Research Institute for Oceanology, CSIR, Stellenbosch, RSA

$$\frac{\partial R_{yx}}{\partial y} + B_x + \frac{\partial D_y}{\partial y} = 0 \quad \ldots \quad (1)$$

where $\frac{\partial R_{yx}}{\partial y}$ = variation in flux of x-momentum with distance y offshore;

B_x = bed shear in the direction of the longshore current; and

$\frac{\partial D_y}{\partial y}$ = exchange of momentum due to lateral mixing.

The type of solution obtained, or more specifically the variation of the current with distance offshore, depends on the assumptions made regarding these three terms.

Predicted longshore sediment transport rates are very sensitive to the **distribution** and **magnitude** of the longshore current. An error in prediction of the longshore current of 10 per cent could cause an error in the prediction of the longshore sediment transport of as high as 70 per cent.

In a laboratory study into current patterns in the vicinity of a proposed coastal structure it was observed that the longshore current velocities generated by regular waves on a very flat beach ($\approx$ 1 in 100) were between 2 and 5 times higher than predictions with the Longuet-Higgins model would tend to indicate (CSIR, 1978). This anomaly is seemingly coupled to the bed roughness.

In the shallow water region where sediment transport calculations are normally performed the waves are decidedly non-linear. Swart and Loubser (1979) have shown that linear theory does not allow for a proper representation of the time-dependent wave properties in this area. In a comparison of the applicability of 13 different wave theories they found that Vocoidal water wave theory, developed by Swart (1978), is the most applicable theory under all wave conditions tested in the shallow water region, and was significantly better than the linear theory. In addition, waves in prototype are not regular but random and do not always break as spilling breakers, as has to be assumed in order to obtain a solution for the longshore current profile.

Swart and Fleming (1980) already reported briefly on the effect of the bed roughness and the bed slope on the Longuet-Higgins solution without going into the background for the re-analysis. Subsequently more research was done into the effect of the non-linearity of the incident waves on the longshore current profile.

The objective of this paper is to report on progress made towards the understanding of the effect of the above-mentioned factors. It will deal mainly with

- the effect of bed roughness; and
- the effect of both higher-order and random waves on the type of solution obtained.

2. TREATMENT OF LINEAR, REGULAR WAVES

The theory of longshore current generation by linear, regular waves breaking, as spilling breakers, on a plane beach was covered authoritively by Longuet-Higgins (1970) and will not be repeated here. Only those points which are relevant to the present discussion will be highlighted.

Driving forces

The driving force for the longshore current is obtained by considering the variation in the flux of longshore momentum with distance y offshore.

$$\frac{\partial R_{yx}}{\partial y} = -\frac{5}{16}\gamma^2 \rho g d \tan\alpha \sin\Theta \cos\Theta \quad \ldots (2)$$

(Longuet-Higgins, 1970)

where γ = breaker index, that is, the ratio of breaking wave height H_b to corresponding water depth d_b; this index is assumed constant throughout the breaker zone;

ρ = mass density of water;

g = gravitational acceleration;

d = water depth;

α = beach slope;

Θ = angle of incidence of the waves, measured between the wave crest and the local bed contour.

Resistive forces: Bed shear

It was shown (CSIR, 1978) that the general expression for bed shear B_x in the longshore direction is:

$$B_x = \frac{2}{\pi}\rho\,(C_{LH1}\,u_o v + g v^2/C_n^2) \quad \ldots (3)$$

where C_{LH1} = a friction coefficient

$$= \left(\frac{f_w g}{2C_n^2}\right)^{0,5} \quad \text{(CSIR, 1978)} \quad \ldots \quad (4)$$

u_o = maximum value at the bed of the horizontal orbital velocity;

v = longshore current velocity at depth d;

C_n = Chezy roughness coefficient = 18 log (12d/r);

f_w = wave friction factor, as defined by Jonsson (1966).

Longuet-Higgins (1970) assumed that $v << u_o$ and obtained a simplified version of equation (3), namely,

$$B_x = \frac{2}{\pi} \rho C_{LH} u_o v \quad \ldots \quad (5)$$

In the present study the simplified equation (5) as used by Longuet-Higgins will be employed. Any approximations introduced in this manner for cases where v/u_o is not negligible, which is normally the case, will exhibit itself as a scatter in the empirical values of C_{LH}.

Resistive forces: Lateral mixing

Longuet-Higgins (1970) assumed that Dy is given by:

$$D_y = -\mu_e d \frac{\partial v}{\partial y} \quad \ldots \quad (6)$$

where μ_e = horizontal eddy viscosity

$$= N\rho y(gd)^{0,5} \text{ (Longuet-Higgins, 1970)}$$

N = dimensionless constant.

Although the eddy viscosity as defined by Longuet-Higgins increases indefinitely with distance from the shoreline, even outside the breaker zone where it would be expected to decrease markedly, the results obtained via this method are very realistic.

Solution

Using equations (2), (5) and (6) above, Longuet-Higgins obtained the longshore current profile:

$$v = v_{or} f(y,P) \quad \ldots \quad (7)$$

where v_{or} = scaling velocity at the breaker line

$$v_{or} = \frac{5\pi}{16} \frac{\gamma(gd_b)^{0,5}}{C_{LH}} \tan\alpha \sin\theta_b \cos\theta_b \quad \ldots (8)$$

P = dimensionless lateral mixing parameter; and subscript b refers to the initial breaker line.

After investigating all available data sets on longshore current, as summarised by Galvin and Nelson (1967), Longuet-Higgins (1970) found that if he neglected those data sets termed questionable by Galvin and Nelson the parameter C_{LH} varied between 0,0036 and 0,012 with a mean value of 0,0082. He therefore concluded that "C_{LH} is of order 0,01". This has subsequently been interpreted by researchers to mean that C_{LH} is a constant. Since C_{LH} is by definition a roughness coefficient this is obviously an erroneous conclusion.

Re-analysis of data

To settle this matter, the data as tabulated by Galvin and Nelson were re-analysed, along with some newer data, in an approach similar to the earlier analysis performed by Longuet-Higgins. Only the mean longshore current velocity was available for most of the data. Longuet-Higgins showed that the mean current velocity is given by:

$$\bar{v} = \frac{5\pi}{16} \beta_m \frac{\gamma^{0,5}(gH_b)^{0,5}}{C_{LH}} \tan\alpha \sin\theta_b \cos\theta_b \quad \ldots (9)$$

where β_m depends on the intensity of lateral mixing, and has a mean value of 0,33 with a possible variation of plus/minus 30 per cent.

Equation (9) can be rewritten to obtain C_{LH} in terms of a dimensionless parameter Φ_o, namely,

$$C_{LH} = \frac{5\pi}{16} \beta_m \gamma^{0,5} \Phi_o \quad \ldots (10)$$

where $$\Phi_o = \frac{(gH_b)^{0,5}}{\bar{v}} \tan\alpha \sin\theta_b \cos\theta_b \quad \ldots (11)$$

For each data set the parameter Φ_o is a function of the bed roughness and, perhaps surprisingly, of the bed slope. If one, however, keeps in mind that the bed slope influences the breaker type which in turn is strongly related to the extent of lateral mixing, it becomes apparent that Φ_o implicitly contains the effect of lateral mixing.

In this context lateral mixing is quantified by means of the lateral mixing coefficient P, which was found by Longuet-Higgins to have a theoretical upper limit of 0,4. By inspection of the available data on longshore current profiles Longuet-Higgins concluded that the data are adequately bracketed by theoretical profiles with values of P = 0,1 and P = 0,4. Furthermore, the mean value of P appeared to be P = 0,2. In the present analysis it was therefore assumed that P = 0,2 and that any effect of a different mixing coefficient would be rectified for by the value obtained for C_{LH} (or Φ_o in the present stage of the computation). Keeping the comment about β_m in mind it is then reasonable to expect that C_{LH} will also exhibit a variation of plus/minus 30 per cent, which was indeed later shown to be the case.

For a value of P = 0,2 the function f(y,P) in equation (7) becomes:

$$f(y,P) = \begin{cases} -1,74(y/y_b)^{1,61} + 2(y/y_b) & \text{for } 0 \leq y/y_b \leq 1 \\ 0,26(y/y_b)^{3,11} & \text{for } 1 < y/y_b \leq \infty \end{cases} \quad \ldots (12)$$

In analogy with the result in equation (4) it is assumed that the actual value of the roughness parameter C_{LH} is related to roughness by

$$C_{LH} = K\left(\frac{f_w g}{2C_n^2}\right)^{0,5} \quad \ldots (13)$$

Parameter K is a proportionality constant which according to Figure 1 should be a function of the bed slope.

With the aid of the data in Figure 1 and equation (10) it was found that

$$K = 25(\tan\alpha)^{0,85} \quad \ldots (14)$$

which means that

$$C_{LH} = 25\left(\frac{f_w g}{2C_n^2}\right)^{0,5} (\tan\alpha)^{0,85} \quad \ldots (15)$$

A comparison between measured and predicted values of C_{LH} is given in Figure 2.

It is interesting to note that Komar and Inman (1970) in an analysis of the same data found that

$$C_{LH} \approx 0,15 \tan\alpha \quad \ldots (16)$$

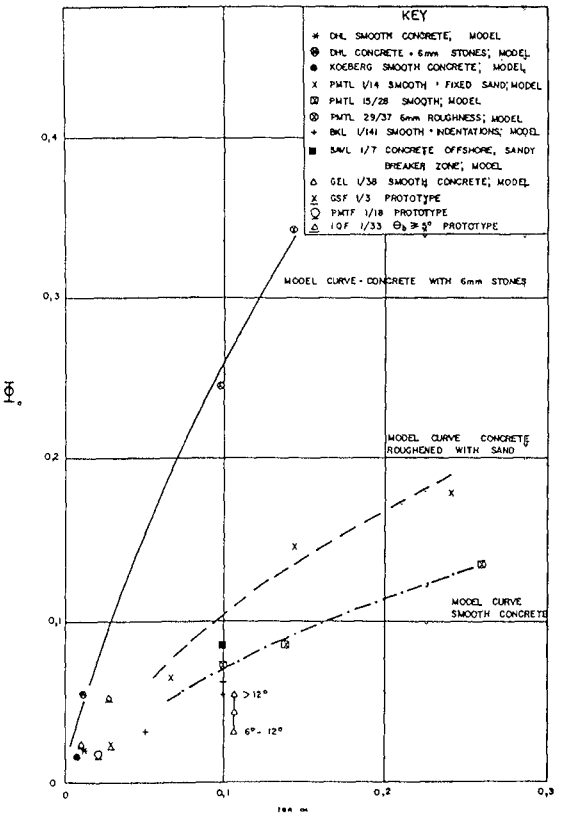

FIG. 1 RELATIONSHIP BETWEEN Φ_o, BEACH SLOPE AND BED ROUGHNESS

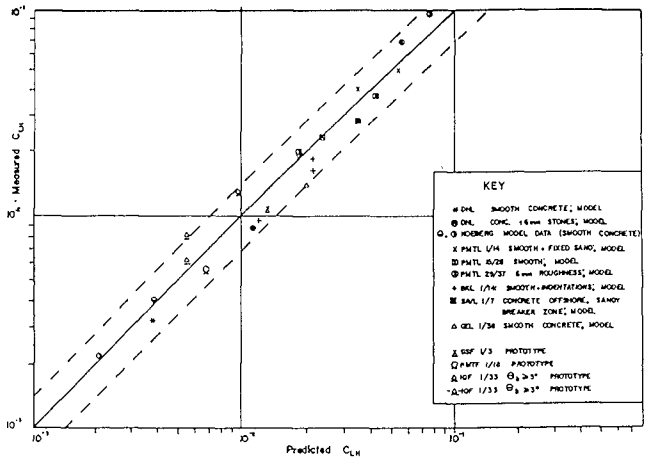

FIG. 2 RELATIONSHIP BETWEEN PREDICTED AND MEASURED C_{LH} VALUES FOR MODEL AND PROTOTYPE CONDITIONS

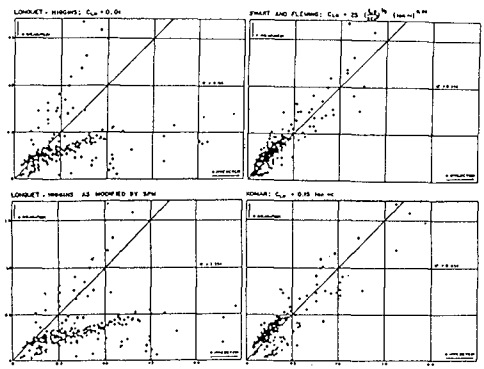

FIG. 3 PREDICTED VERSUS MEASURED LONGSHORE CURRENT VELOCITIES BY FOUR DIFFERENT METHODS

This would imply that the velocity is independent of bed slope.

Figure 3 gives a comparison of the "goodness of fit" to the data when using the present technique, Komar's method, the Longuet-Higgins method with the assumption of $C_{LH} \approx 0,01$ and a slight variation to this last approach, which also assumes a constant value for C_{LH} and which is the method recommended for use by the Shore Protection Manual (SPM, 1973). A root-mean-square error was computed for each of the four methods tested, based on the comparison between the theoretical/emprirical models tested and all 352 available data sets. The present method has a rms error of 0,248, which is only about 40 per cent of that found for the Komar method, and which is an order of magnitude better than the methods which assume a constant value for C_{LH}.

It is interesting to note that the two methods with the closest correspondence to the data, that is, the present method and Komar's method, suggest a very much lower dependence on bed slope than predicted by the classical theory. The explanation for this apparent anomaly lies in the fact, as was pointed out earlier, that the roughness coefficient contains, at least in part, the effect of the lateral mixing, which is a function of amongst other things the bed slope.

It should be borne in mind that although the method derived here is far superior to the method normally used, it is still not applicable to the case of waves breaking as plunging breakers or for waves breaking on a barred beach.

3. TREATMENT OF LINEAR, RANDOM WAVES

A theoretical framework for the prediction of longshore currents generated by random waves was developed by Battjes (1974) which yielded reliable results. It is comparable to the Longuet-Higgins approach for regular waves except that wave set-up was not neglected and for the obvious differences between regular and random waves. The method has to be applied numerically since no analytical solution was found. Battjes draws the very important conclusion that lateral mixing is not nearly as important in the determination of the velocity profile for random waves as it is in the case of regular waves.

In this section a derivation will be done for random waves at the same level of assumption as was done by Longuet-Higgins for regular waves.

Assumptions

(i) Linear wave theory is used;

(ii) Waves are random with a Rayleigh height distribution;

(iii) Waves break as spilling breakers with a constant breaker index $\gamma = H_b/d_b$ throughout the breaker zone;

(iv) The wave spectrum within the breaker zone is treated in the same way as done by Battjes (1974), that is, waves in excess of γ times the water depth are reduced to γ times the water depth;

(v) Wave set-up is initially neglected although its effect will be discussed later;

(vi) The bed slope α in the breaker zone is considered constant;

(vii) The bed roughness coefficient C_{LH} is constant over the breaker zone; and

(viii) Lateral mixing is neglected (Battjes, 1974).

Governing equations

The same momentum balance equation (equation (1)) applies as for regular waves. The assumptions outlined above lead to the following expression for the driving force term when shallow-water wave conditions are assumed:

$$\frac{\partial R_{yx}}{\partial y} = -\frac{5}{16}\rho\gamma^2(gd)\exp\left(-\frac{\gamma^2 d^2}{H_{frms}^2}\right)\sin\Theta\cos\Theta\tan\alpha \quad \ldots (17)$$

where H_{frms} = **fictitious rms wave height** at water depth d, which would have existed under the influence of shoaling, refraction and bed friction if **no wave breaking** had occurred.

When looking at the resistive forces, the bed shear is written in the simplified form of Longuet-Higgins (see equation (5)), which after substitution of shallow-water wave conditions reduces to

$$B_x = \frac{1}{\pi} C_{LH}\,\rho\left(\frac{\bar{H}}{d}\right) v(gd)^{0,5} \quad \ldots (18)$$

where $\bar{H}$ = mean wave height at depth d, after including the effect of wave breaking.

Solution

The combination of equations (17) and (18) yields an expression for the longshore current velocity at water depth d:

$$v = \frac{5\pi}{16} \frac{\gamma^2 (gd)^{0,5}}{C_{LH}} \left(\frac{d}{H}\right) \exp\left(-\frac{\gamma^2 d^2}{H^2_{frms}}\right) \tan\alpha \sin\theta \cos\theta \qquad (19)$$

If, in analogy with regular waves, one writes, with lateral mixing now being neglected

$$v = v_{oir} f(y) \qquad \ldots (20)$$

it follows that

$$v_{oir} = \frac{5\pi}{16} \frac{\gamma (g d_{bs})^{0,5}}{C_{LH}} \tan\alpha \sin\theta_{bs} \cos\theta_{bs} \qquad \ldots (21)$$

and $$f(y) = \left(\frac{d}{d_{bs}}\right) \left(\frac{d}{H}\right) \gamma \exp\left(-\frac{\gamma^2 d^2}{H^2_{frms}}\right) \qquad \ldots (22)$$

where subscript bs refers to the significant breaker line.

An example of the comparison between the velocity profiles as predicted for regular waves with lateral mixing and for random waves without lateral mixing is given in Figure 4.

In the above derivation the wave set-up was neglected. If, however, the depth d is taken to be the still-water depth plus the wave set-up, the slope $\tan\alpha$ should actually read $(\partial d/\partial y)$, then a very good first approximation of the actual effect of wave set-up is obtained. For the present equations (21) and (22) can be used together with the value of C_{LH}, as given by equation (15). However, it is deemed advisable to obtain more data on longshore currents generated by random waves, especially under controlled conditions.

Furthermore, in the case of longshore currents generated by random waves breaking as plunging breakers on a barred beach, the longshore current profile will not be as smooth as indicated by, for example, Figure 4. In this case one should for the present return to the Battjes approach. However, the effect of lateral mixing has to be included since the lateral velocity gradients, which according to equation (6) are not small any more, will lead to higher lateral mixing, especially near the breaker line.

4. TREATMENT OF REGULAR, VOCOIDAL WAVES

The only known case in the literature of a derivation for longshore currents based on a higher-order theory, is that of James (1974). James based his model on hyperbolic waves in the nearshore region and on Stokes waves further out to sea. Due to the disadvantage of coupling different wave theories at a given water depth, the limited range of applicability of the hyperbolic theory and the fact that

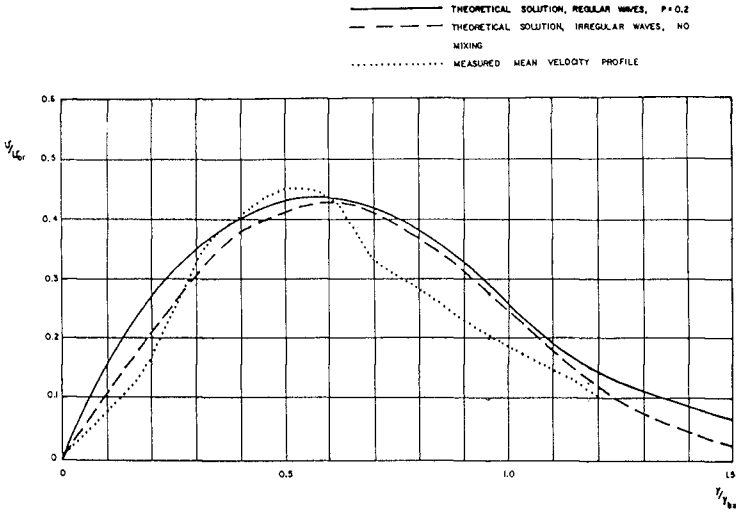

FIG. 4 COMPARISON BETWEEN THEORETICAL SOLUTION FOR REGULAR AND IRREGULAR WAVES RESPECTIVELY AND MEAN MEASURED PROFILE

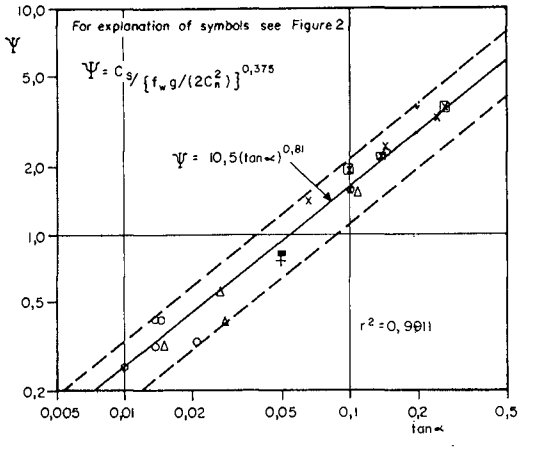

FIG. 5 RELATIONSHIP BETWEEN Ψ AND TANα

the longshore current model of James is numerical, this method is not considered further.

Swart and Loubser (1979) made a comprehensive comparison of measured wave properties with predictions from 13 different theories. The results indicate that although linear theory provides an adequate description of wave profile, wave celerity and orbital motions in deep water, the comparison deteriorates as the relative water depth becomes less. Swart and Loubser concluded that linear theory gives satisfactory results only for values of a non-linearity parameter $F_c \leq 200$ and should not be applied for $F_c > 200$. The parameter F_c is defined by

$$F = (H/d)^{0,5} \left(T(g/d)^{0,5}\right)^{2,5} \quad \ldots (23)$$

If one assumes breaking wave conditions with $H/d = 0,7$, the above restriction would imply that linear theory can only be applied for $T\sqrt{g/d}$ less than 8,9. The following table shows values of d, below which the theory should then not be applied, for different values of wave period T.

T (s)	d (m)	T (s)	d (m)
6	4,4	14	24,1
8	7,9	16	31,4
10	12,3	18	39,8
12	17,7	20	49,1

It is therefore clear that the use of the linear theory to predict breaker-line wave data is not advisable.

On the other hand, the same study by Swart and Loubser indicated that Vocoidal theory adheres well to data for all values of F_c covered by the data, which extended to $F_c = 60\ 000$. In fact, they finally concluded that Vocoidal theory is the only readily applicable analytical wave theory having a good correspondence to measured data and a good adherence to the original wave boundary value problem for the whole range of non-breaking waves. This theory therefore not only provides a good correspondence to data but also a sound framework for the derivation of expressions for the prediction of secondary wave-induced phenomena, including longshore currents.

In this section those aspects of the derivation of the longshore current as driven by Vocoidal theory will be highlighted which differ from the theory outlined in Section 2.

Driving forces

The radiation stress term R_{yx} for Vocoidal waves is given by

$$R_{yx} = 2E_{ku} \sin\theta \cos\theta \quad \ldots (24)$$

as compared to

$$R_{yx} = En \sin\theta \cos\theta \quad \ldots (25)$$

for linear waves.

In the above E_{ku} is the kinetic energy per unit surface area due to the horizontal orbital velocity, E is the total wave energy per unit surface area and n is the group velocity/celerity ratio.

In shallow water the ratio R_1 between R_{yx} as determined for the Vocoidal and linear theories respectively becomes, if one assumes for the moment that H and θ are equal for the two theories:

$$R_1 = (R_{yx})_{voc}/(R_{yx})_{lin} = 16e_{ku} \quad \ldots (26)$$

where e_{ku} is defined by $E_{ku} = e_{ku}\ \rho g H^2$.

As an example of the variation in R_1, consider the case of H/d at breaking = 0,8.

$T(g/d)^{0,5}$	R_1	$T(g/d)^{0,5}$	R_1
5	broken waves	25	0,36
10	0,74	30	0,31
15	0,56	35	0,27
20	0,44	40	0,23

It is thus apparent that the coefficient of the radiation stress term is appreciably lower for Vocoidal theory than for linear theory.

The driving force term in the momentum balance equation then becomes:

$$\frac{\partial R_{yx}}{\partial y} = -\frac{5r_{yx}}{2}\gamma^2 f_{yx}\ \rho(gd)\ \tan\alpha \sin\theta \cos\theta \quad \ldots (27a)$$

where $R_{yx} = r_{yx}\ \rho g H^2$ defines r_{yx}; and

$$f_{yx} = 1 + \frac{d}{r_{yx}} \frac{\partial r_{yx}}{\partial d} \quad \ldots (27b)$$

Resistive forces

Similarly, the bed shear as given by Vocoidal theory can be written as

$$B_x = \frac{2}{\pi} a_{voc} \rho C_s u_o v \quad \ldots (28)$$

as opposed to equation (5), where a_{voc} is the ratio between the bed shear in the longshore direction as predicted by Vocoidal and linear theory respectively and C_s is the roughness coefficient applicable to Vocoidal waves, as opposed to C_{LH} for linear waves.

Again using H/d = 0,8, one finds:

$T(g/d)^{0,5}$	10	15	20	25	30	40
a_{voc}	0,91	0,65	0,50	0,40	0,34	0,26

Solution

In setting up a momentum balance equation, the fact that the coefficient of R_{yx} is also a function of distance offshore should be kept in mind. When neglecting lateral mixing, one finds for the Vocoidal theory at the breaker line, that

$$v_{or} = \frac{5\pi}{16}(P_{reg}) \frac{\gamma(gd_b)^{0,5}}{C_s} \tan\alpha \sin\theta_b \cos\theta_b \quad \ldots (29)$$

where P_{reg} is a parameter containing the effect of the non-linearity (vocoidalness) of the waves.

The following table gives values for P_{reg} in terms of γ and T_c, where $T_c = T\sqrt{g/d}$.

T_c	Values of P_{reg}									
	γ=0,1	0,2	0,3	0,4	0,5	0,6	0,7	0,8	0,9	1,0
5	1,84	1,83	1,82	1,81	1,80	1,79	-	-	-	-
10	1,77	1,77	1,74	1,68	1,63	1,61	1,61	1,65	1,70	-
15	1,79	1,77	1,71	1,64	1,58	1,54	1,56	1,63	1,69	1,77
20	1,93	1,87	1,80	1,72	1,66	1,65	1,70	1,79	1,84	1,90
25	2,08	2,03	1,95	1,86	1,78	1,78	1,88	1,99	2,06	2,10
30	2,31	2,24	2,15	2,04	1,95	1,98	2,11	2,24	2,31	2,35
35	2,60	2,53	2,42	2,29	2,17	2,22	2,40	2,54	2,60	2,63
40	2,98	2,90	2,77	2,62	2,46	2,56	2,75	2,89	2,95	2,95

The above table shows that P_{reg} is a function of the deep-water wave steepness and the breaker index.

Equation (29) is identical to its linear theory counterpart (equation (8)) except for the inclusion in equation (29) of the parameter P_{reg}. As a first approximation to the effect of non-linear waves on the longshore current profile one can write

$$v = v_{or} \{(P_{reg})_d/(P_{reg})_{d_b}\} f(y,P) \quad \ldots (30)$$

where subscript d (or d_b) means that P_{reg} is computed at depth d (or d_b), v_{or} is given by equation (29) and $f(y,P)$ is the same function as before (equation (12)) with $P = 0,2$. The original longshore current data as compiled by Galvin and Nelson (1967) were re-analysed to obtain C_S in an analogous fashion to that described in Section 2 for the computation of C_{LH}. The equation of best fit is given by:

$$C_S = 10,5 \left(\frac{f_w g}{2C_h^2}\right)^{0,375} (\tan\alpha)^{0,81} \quad \ldots (31)$$

(see Figure 5)

A comparison of values of C_S obtained from equation (31) with those derived directly from the data resulted in a correlation coefficient $r^2 = 0,9911$. On the ohter hand, a comparison of values of C_{LH} as obtained from equation (15) with values of C_{LH} derived directly from the data yielded a correlation coefficient $r^2 = 0,9471$, that is, the correlation is not as good as that for C_S. Not only does the Vocoidal approach therefore yield a description of the current profile which is more in line with shallow-water waves than the linear theory approach, but it also yields a better estimate of the mean longshore current velocity.

More research is needed where the deep-water wave steepness is varied in a more systematic manner to improve this relationship. Nevertheless equation (31) constitutes the best estimate of C_S available at present and when used in conjunction with equation (30) it should yield better results than those predicted with the aid of the linear theory.

In the above it was implicitly assumed that the mean value of P remains 0,2 as was the case for linear waves. This assumption may not be correct, as pointed out by James (1974) and still needs to be carefully investigated with the aid of well-designed experiments.

5. TREATMENT OF RANDOM, VOCOIDAL WAVES

The same assumptions as those for the case of longshore currents generated by random, linear waves apply in the present study of random, vocoidal incident waves. The resulting shape of the longshore current profile after analogous deductions as in Sections 2 to 4 is:

$$v = \frac{5\pi}{16} P_{ran} \frac{\gamma^2}{C_s}(gd)^{0,5} \left(\frac{d}{H}\right) \exp\left(-\frac{\gamma^2 d^2}{H_{rms}^2}\right) \tan\alpha \sin\theta \cos\theta \quad \ldots (32)$$

where P_{ran} is a Vocoidal parameter known simply in terms of Vocoidal wave properties.

Equation (32) is identical to its linear, random theory couterpart, equation (19), except for the inclusion of P_{ran} in equation (32).

In the following table values of P_{ran} are given in terms of T_c and γ.

T_c	Values of P_{ran}									
	H/d=0,1	0,2	0,3	0,4	0,5	0,6	0,7	0,8	0,9	1,0
5	1,53	1,53	1,52	1,51	1,50	1,49	-	-	-	-
10	1,46	1,46	1,38	1,39	1,34	1,31	1,33	1,36	1,40	-
15	1,63	1,61	1,56	1,49	1,44	1,41	1,42	1,49	1,54	1,61
20	1,74	1,68	1,65	1,55	1,49	1,48	1,53	1,61	1,66	1,71
25	1,77	1,73	1,65	1,58	1,51	1,52	1,60	1,69	1,75	1,79
30	1,79	1,75	1,67	1,59	1,51	1,53	1,64	1,74	1,80	1,83
35	1,80	1,75	1,68	1,59	1,51	1,55	1,66	1,76	1,81	1,82
40	1,70	0,11	1,67	1,58	1,49	1,55	1,66	1,75	1,78	1,78

In analogy with linear waves a dimensionless scaling velocity v_{oir} is defined (see equation (21)):

$$v_{oir} = \frac{5\pi}{16} (P_{ran})_{bs} \frac{\gamma(gd_{bs})^{0,5}}{C_s} \tan\alpha \sin\theta_{bs} \cos\theta_{bs} \quad \ldots (33)$$

It follows that

$$v = v_{oir} f(\gamma) \quad \ldots (34)$$

where $$f(\gamma) = \left(\frac{d}{d_{bs}}\right) \left(\frac{d}{H}\right) \gamma\left[(P_{ran})_d / (P_{ran})_{d_{bs}}\right] \exp\left(-\frac{\gamma^2 d^2}{H_{rms}^2}\right) \quad \ldots (35)$$

The value of the roughness coefficient C_S for Vocoidal waves given by equation (31) applies. The same comments about wave set-up which were valid before are valid here, except that it has to be borne in mind that a new theory for the prediction of wave set-up due to random, vocoidal waves will have to be developed and tested.

6. SUMMARY AND CONCLUSIONS

The following is a summary of the main findings from the present study:

(1) The friction coefficient C_{LH} in the Longuet-Higgins model for longshore current prediction is not a constant, as was suggested previously, but varies with roughness and breaker zone beach slope. This supports earlier work by Komar and Inman.

(2) Using random incident waves a model was developed with the same approximations as for regular waves, except that lateral mixing is neglected, which gives very realistic profiles in close similarity with previous numerical work by Battjes.

(3) Using Vocoidal theory, explicit equations were derived for the longshore current profile under both regular and random wave attack. The friction coefficient is redefined and although it has a similar dependence on roughness and slope as in the linear case the actual values are higher.

(4) Although not discussed here, these four models, that is, for longshore current prediction under regular or random wave attack using linear or Vocoidal wave theory, have been extended to include the effect of mildly varying bed slope and mildly varying breaker index.

(5) Although the development of these models constitutes an appreciable advance, the models are only valid for the rare case of spilling breakers on a beach for which the water depth shows a monotonic decrease from breaker line to shore. Extensive research is still required on, for example, the non-steady nature of the longshore current, longshore currents on barred beaches and the effect of rip currents on longshore currents.

Abstract

There is a growing need for generalized numerical models for longshore currents and nearshore circulation that solve the complete equations of motion, are flexible in the formulations chosen for various terms, and can be applied to field situations at a reasonable cost. The development and application of one such model is described in this paper. The model was first tested by comparing its results to known analytic solutions and experimental data. There was good agreement. It was next applied to a field situation near Oregon Inlet, North Carolina. The results appeared to be reasonable and the computational costs were modest.

Introduction

Over the last two decades, a considerable amount of literature has been published on the computation of longshore currents and nearshore circulation due to the action of breaking waves. However, most of this literature (for example, 2, 6, 8, 10, 12) has been devoted to idealized situations such as plane beaches and periodic bathymetries. Often the analytical and numerical models used have been limited in scope. The limitations include assuming a steady state, using a linear friction, neglecting advection and/or eddy viscosity terms, etc. The development of generalized numerical models (5, 13) that can handle more complex situations is relatively recent. As of now (1982), very little work has been reported on the application of numerical current models to field situations at a reasonable cost. In view of the increasing tendency of the coastal engineering profession to employ numerical models for sediment transport in the nearshore region, there is a pressing need for generalized longshore current models. In this paper, the development and application of one such model is described.

Equations of Motion

The governing equations for the problem under consideration are obtained from the general equations of conservation of mass and momentum, after averaging over time (one wave period) and depth. They are expressed in terms of the mean horizontal velocities U, V and the mean free surface displacement $\bar{\eta}$ as follows (refer to Fig. 1):

Momentum

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + V\frac{\partial U}{\partial y} + g\frac{\partial \bar{\eta}}{\partial x} + \frac{1}{\rho d}\tau_{bx} + \frac{1}{\rho d}\left(\frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y}\right) - \frac{1}{\rho}\frac{\partial \tau_{xy}}{\partial y} = 0 \quad (1)$$

$$\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} + g\frac{\partial \bar{\eta}}{\partial y} + \frac{1}{\rho d}\tau_{by} + \frac{1}{\rho d}\left(\frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y}\right) - \frac{1}{\rho}\frac{\partial \tau_{xy}}{\partial x} = 0 \quad (2)$$

Continuity

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x}(Ud) + \frac{\partial}{\partial y}(Vd) = 0 \quad (3)$$

Here g is the acceleration due to gravity, ρ is the mass density of water, d is the total depth $= h + \bar{\eta}$, h being the local still water depth, τ_{bx} and τ_{by} are the bottom friction stresses in the x and y directions, respectively, S_{xx}, S_{xy}, and S_{yy} are radiation stresses (refer to Longuet-Higgins and Stewart (7) for their significance), and τ_{xy} is the lateral shear stress due to turbulence. For monochromatic waves, the radiation stresses are defined in terms of the local values of the wave height H, wave number k, and wave direction θ. For the numerical model under consideration, the latter variables are obtained by using a considerably modified form of the refraction program developed by Noda, et al. (9). This particular program has the advantage that H, k, and θ can be computed at the centers of the cells of a rectangular numerical grid, and wave breaking can be accounted for by a breaking index model for wave heights in the surf zone. Wave-current interactions may also be taken into account; however, this last feature was not used in the results that follow.

Bottom Friction. For the bottom friction, a linear formulation, similar to that of Longuet-Higgins (8), was used for the applications that are described here. Thus,

$$\tau_{bx} = \rho\, c\, \langle|u_{orb}|\rangle\, U \quad (4)$$

$$\tau_{by} = \rho\, c\, \langle|u_{orb}|\rangle\, V \quad (5)$$

where c is a drag coefficient (of the order of 0.01) and $\langle|u_{orb}|\rangle$ is the time average, over one wave period, of the absolute value of the wave orbital velocity. From linear wave theory,

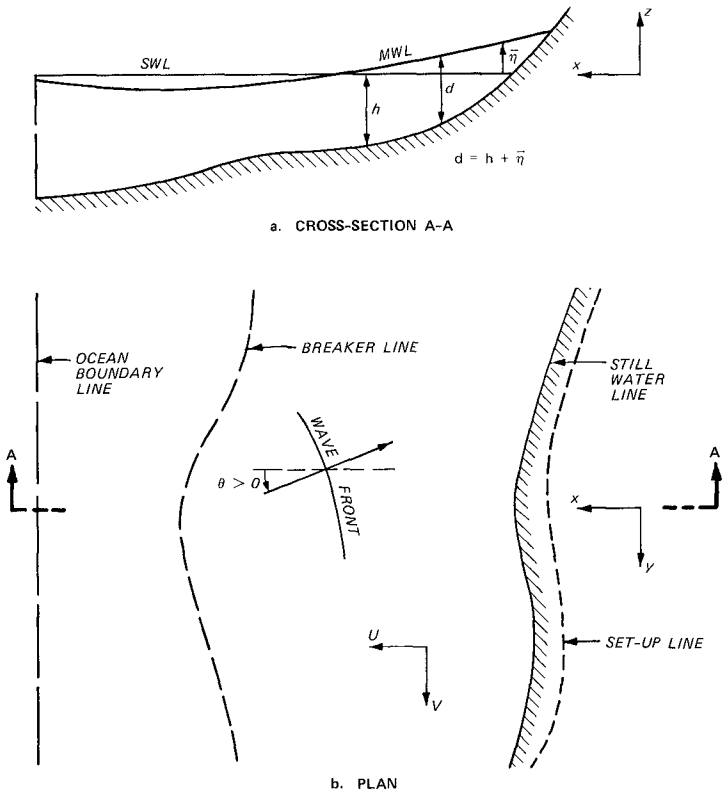

Figure 1. Definition sketch for an irregular beach

$$<|u_{orb}|> = \frac{2H}{T \sinh kh} \tag{6}$$

where T is the wave period. Eqs. 4 and 5 amount to a "weak current" assumption. The numerical model described here has the flexibility that other formulations such as a non-linear friction can be easily incorporated in the future.

Lateral Shear. In the numerical model, the coordinate scheme was chosen such that x was positive offshore and y was in the alongshore direction. An eddy viscosity formulation was chosen for the lateral shear, τ_{xy}. The eddy viscosity was assumed to be non-isotropic. Denoting ε_x and ε_y as the eddy viscosities in x and y directions, respectively, in general, ε_y was assumed to be a constant and ε_x a function of x and y. Accordingly,

$$\tau_{xy} = \rho \left(\varepsilon_y \frac{\partial U}{\partial y} + \varepsilon_x \frac{\partial V}{\partial x}\right) \tag{7}$$

For the plane beach application with lateral mixing, the eddy viscosity ε_x was assumed to vary within the surf zone in the manner suggested by Longuet-Higgins (8):

$$\varepsilon_x = N \times \sqrt{gh} \tag{8}$$

where x is the distance from the shoreline and N is an empirical coefficient. The eddy viscosity was kept constant beyond the breaker line.

For the field application, the eddy viscosity ε_x was chosen according to the relationship given by Jonsson, et al. (6). Thus,

$$\varepsilon_x = \frac{H^2 gT}{4\pi^2 h} \cos^2 \theta \tag{9}$$

This represents twice the value used by Thornton (12). It was felt that Eq. 9 represented the eddy viscosity values for the field situation more realistically than Eq. 8.

Numerical Model

Numerical Scheme. The numerical current model uses a three time level, alternating direction, implicit, finite difference scheme. The model is based on a long wave model known as WIFM (Waterways Experiment Station (WES) Implicit Flooding Model) (refer to Butler (3) for details). In view of the similarity between the equations for long waves and currents, WIFM was converted into a model for currents by the addition of radiation stress terms and modification of friction and eddy viscosity terms, etc. Because of the advection terms, a stabilizing correction

scheme was used. The numerical model has the capability that the size of the grid cells in both horizontal directions may be varied so that the grid may be made finer in regions of greater interest such as the surf zone, inlets, etc. For this purpose, a mapping function defining the mapping from real (X) space to the computational (α) space is used. The function is

$$X_i = a_i + b_i \alpha_i^{c_i} \qquad i = 1,2 \qquad (10)$$

where X_1 , X_2 correspond to x and y , respectively, and the coefficients a_i, b_i, and c_i are calculated for different regions of the grid by an interactive program. The mapping transforms the variable grid in real space to a uniform grid in computational space. Afterwards, the relevant equations are solved in the computational space.

Solution Technique. In order to apply the finite difference scheme, a rectangular grid is used to represent the region of interest. In real space, the cell dimensions in x and y directions are denoted by Δx and Δy . These dimensions may vary from cell to cell. This grid is mapped into a uniform grid with constant cell dimensions $\Delta\alpha_1$ and $\Delta\alpha_2$ in the computational space. Let m and n denote indices in the x and y directions corresponding to the center of an arbitrary cell (refer to Fig. 2). All the variables except the velocities U and V are defined at the cell centers. Velocities U and V are defined respectively at cell faces $m + 1/2$ and $n + 1/2$. The time level is indicated by a superscript k . The governing equations are written in a finite difference form. To advance the solution from a time level k to $k + 1$, an intermediate stage of the solution marked by a superscript * is introduced. The solution procedure is carried out in a two-step operation. In the first step, we sweep the grid in the x-direction. The x-momentum equation is centered about the cell face $m + 1/2$ and the continuity equation about the center of the cell (m,n) and the two equations are solved, using in the process the result $U^* = U^{k+1}$. At the end of this sweep, we know $\bar{\eta}^*$ and U^{k+1} . Next we sweep the grid in the y-direction. In this sweep, the y-momentum equation is centered about the cell face $n + 1/2$ and the continuity equation about the cell center (m,n) . Upon solving the two equations, the values $\bar{\eta}^{k+1}$ and V^{k+1} for each cell are obtained. Thus the two sweeps together complete the solution.

For each sweep, the governing equations for all the cells together with the boundary conditions can be arranged in the form of a matrix equation involving the unknown variables. Since the matrix is tri-diagonal, the solution is obtained by recursion. Finally, it should be emphasized that even though we have discussed the solution procedure in terms of (x, y) coordinates for convenience, actually the governing equations are first transformed into the (α_1, α_2) coordinate scheme and solved in the computational space.

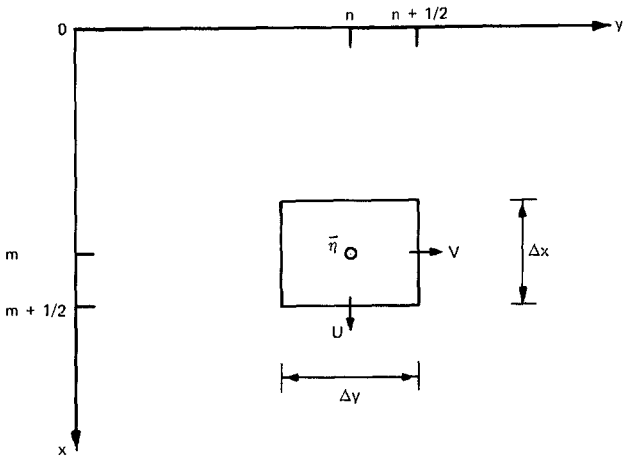

Figure 2. Notation for a cell

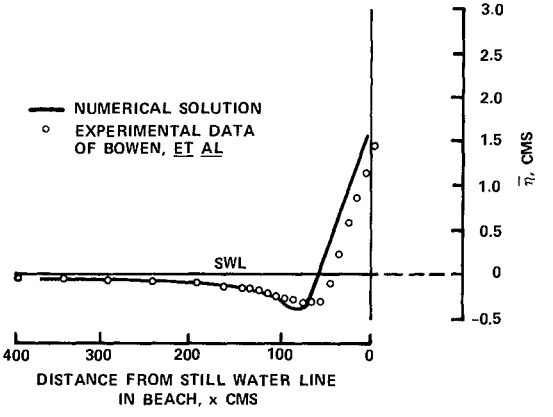

Figure 3. Comparison of the numerical solution for set-up with experimental data

Initial and Boundary Conditions. In order to solve the problem under consideration, appropriate initial and boundary conditions must be applied. For the examples reported here, an initial condition of rest was chosen so that $\bar{\eta}$, U and V are zero at the start of the calculations. To avoid shock, the radiation stress gradients were gradually built up to their full values over a number of time steps. The solution was stopped when a steady state was reached.

As for boundary conditions, along the shoreline a 'no flow' (wall) condition was assumed at the still water line. Thus, no flooding was permitted on the beach. For the lateral boundaries, a flux type boundary condition was often used. That is, the flux at a boundary cell was made equal to that at the next interior cell. It worked very well. For the offshore boundary, it is common practice to use conditions of either 'no flow' (wall) or constant elevation. However, both of these are highly reflective in nature and as a result the transients developed during the start-up of the numerical solution tend to bounce back and forth between the offshore and nearshore boundaries and take a long time to damp out. This is highly undesirable. In view of this, a radiation boundary condition of the type suggested by Orlanski (11) was selected for the offshore boundary and implemented in the numerical scheme. It worked quite well and permitted the transients to propagate out of the grid and allowed the set-down at the offshore boundary to assume an appropriate value.

Tests for Idealized Conditions

To develop confidence in the validity of the model and the accuracy of its results, several tests were run on the model and comparisons were made between model results and available laboratory data and analytic solutions. All of these tests were for plane beaches, for which the coordinate scheme is chosen such that the y-axis coincides with the still water line in beach and the x-coordinate is measured from the still water line. Note that for plane beaches, there is no variation in the alongshore (y) direction.

Plane Beach: Normal Incidence. The model was run for a case of normal incidence on a plane smooth laboratory beach, reported by Bowen, et al. (1). The conditions were as follows: T = 1.14 sec, deep water wave height H_o = 6.45 cm, and beach slope s = 1:12. To run this case on the model, a 50 x 3 variable rectangular grid with overall dimensions of approximately 40 m x 30 cm (the laboratory channel was 40 m long) was used with $\Delta\alpha_1 = \Delta\alpha_2$ = 10 cm and Δt = 0.05 sec. In this example, walls were used for the lateral boundaries as well as the offshore boundary to correspond to the laboratory situation. Since for normal incidence, the velocities U and V would be zero everywhere corresponding to the steady state, advection, eddy viscosity and friction terms were turned off in the model. The solution allowed for the effect of set-up on the wave heights in the surf zone. As the solution proceeded, since $\bar{\eta}$ changed, the wave heights for cells in the surf zone were computed afresh for each time step by using $H = \gamma(h + \bar{\eta})$, where γ is a breaking index and the radiation stresses were changed accordingly. As

suggested by Bowen, et al., a γ of 1.15 was used. A build-up time of 10 Δt was used at the start. A comparison of the steady-state set-up values from the model (after 150 Δt) with those observed by Bowen, et al. is shown in Fig. 3. As can be seen, there is excellent agreement in the offshore region. In the surf zone, the numerical model predicts higher set-ups than observed. This is not surprising since the model does not allow flooding and runup. It is to be noted that the slope of the mean water line in the surf zone is approximately the same in both cases.

Plane Beach: Oblique Incidence. For this case, a plane beach of constant bottom slope s = 1:30 was selected. A monochromatic wave with the following deep water characteristics was chosen: T = 12 sec, H_o = 10 ft, and angle of incidence in deep water, θ_∞ = 20 deg. A drag coefficient c of 0.01 and a breaking index γ of 0.82 were used in the model. A 100 x 6 uniform grid with $\Delta x = \Delta y$ = 60 ft was used for most of the runs. Uniform flux and radiation boundary conditions were used for the lateral and offshore boundaries, respectively. The build-up time varied from 15 Δt to 50 Δt, depending on the Δt used.

First the model was run without allowing for the effect of set-up on wave heights and radiation stresses. Mixing and advection were ignored. A time step Δt of 0.5 sec was used. The steady-state velocity distribution obtained (after 800 Δt) is compared to the triangular distribution of Longuet-Higgins in Fig. 4. There is good agreement. Note that for positive θ , V will be negative for our coordinate scheme. Later a finer grid ($\Delta x = \Delta y$ = 30 ft) with a Δt of 0.25 sec was used. As can be seen in Fig. 4, as the grid is made finer, the numerical solution tends to approach the analytic solution.

The effect of set-up was taken into account next. A time step Δt of 1.5 sec was used for this case. The velocity distribution from the model is compared to the corresponding analytic solution in Fig. 5. There is good agreement. Note that the numerical solution goes to zero at the still water line because a wall was assumed there. On the other hand, Longuet-Higgins' solution goes to zero at the set-up line. To plot his solution, the distance from the still water line to the set-up line was estimated by using a relation provided by Dalrymple, et al. (4).

The effect of lateral mixing was studied next, without taking the effect of set-up into account. A time step Δt of 5.0 sec was used for these runs. The mixing parameter P of Longuet-Higgins was varied between 0.01 and 0.4. Note that P is defined as

$$P = \frac{\pi}{\gamma} \frac{sN}{c} \tag{11}$$

Fig. 6 shows the effect of P on the numerical solution. As expected, the magnitude of the peak decreases, the peak moves closer to the shoreline and the velocities offshore of the breaker line increase as P increases.

Difficulties Involved in Applications to Field Situations

While it is relatively easy to apply a numerical current model to idealized cases, one must face several difficulties in applying the model to field situations. Among these is the highly irregular nature of the bathymetry, especially near inlets where channels and shoals exist. The topography must be smoothed to a certain extent in order for the wave climate and longshore current models to work properly. Yet, one must be careful not to completely change the basic features of the topography. The shoreline as well as the breaker line may be irregular and may be oblique to the grid axes. There may be more than one breaker line. There are problems connected with discretization of the shoreline and breaker line(s). Selection of appropriate values for empirical coefficients such as friction and eddy viscosity coefficients and breaking index is not easy. There are problems in connection with the wave climate model also, especially if wave-current interactions are to be taken into account.

A Particular Field Application

In order to demonstrate the applicability of the numerical model to field situations, the case of Oregon Inlet, North Carolina, was selected. Oregon Inlet is a tidal inlet in a barrier island system. Behind the inlet toward the main land is Pamlico Sound. Most of the problems mentioned in the previous paragraph had to be addressed and solved satisfactorily in this application. For purposes of the numerical simulation, a rectangular region approximately 62,400-ft long in the alongshore direction and 29,400-ft wide in the offshore direction was considered. It included a portion of Pamlico Sound. The variable grid used for the simulation is shown in Fig. 7. The grid was 77 cells wide in the alongshore direction and 54 cells wide in the offshore direction. It may be noted that the minimum cell widths in the alongshore and offshore directions were 400 and 100 ft, respectively. These widths were used near the inlet and surf zone, respectively. Note that $\Delta\alpha_1 = \Delta\alpha_2 = 100$ ft. The topography used in the simulation corresponding to this grid is shown in Fig. 8. The elevations are shown in feet and the datum is Mean Low Water (MLW). There are several points that must be mentioned about this three-dimensional perspective plot. First, the vertical dimensions are highly exaggerated compared with the horizontal. Secondly, the depths are plotted in the computational space and not the physical space. So the horizontal dimensions are distorted. The topography was somewhat modified compared to the actual topography, with respect to the depths near the offshore boundary and the land elevations on the islands. In spite of these factors, Fig. 8 helps one to visualize the irregular nature of the bathymetry. Also, the locations of the channels and shoals in the region of the inlet may be seen clearly in the figure.

A monochromatic wave with a height of 11.39 ft, period of 8.0 sec, and $\theta = 51.1$ deg in 60-ft depth of water was selected for the simulation (the depth of water at the offshore boundary of the numerical grid was 60 ft). This wave corresponded to the significant wave during a part of the Ash Wednesday storm of March 1962 at the inlet. In this case,

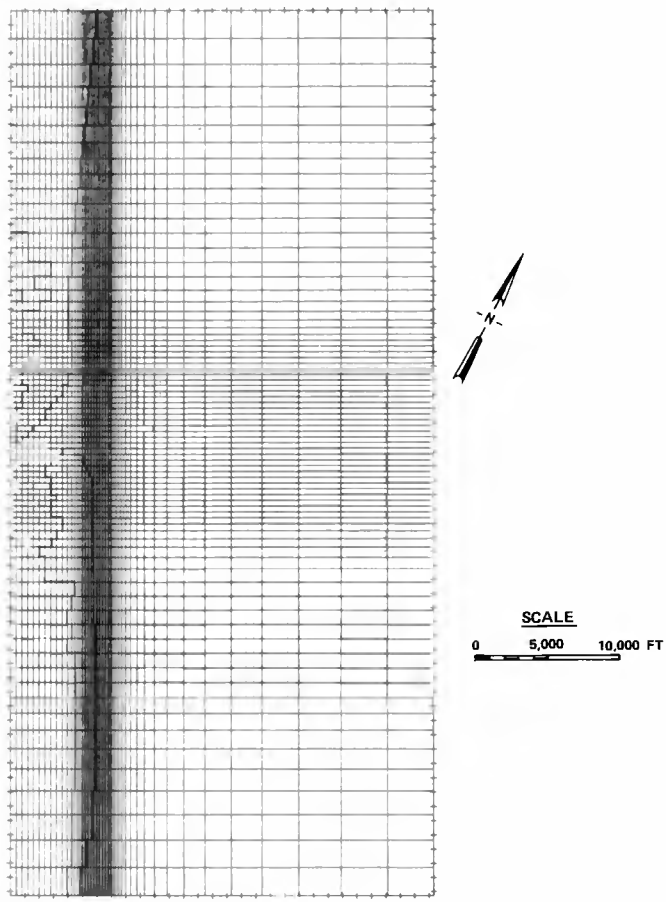

Figure 7. Numerical grid for Oregon Inlet, North Carolina

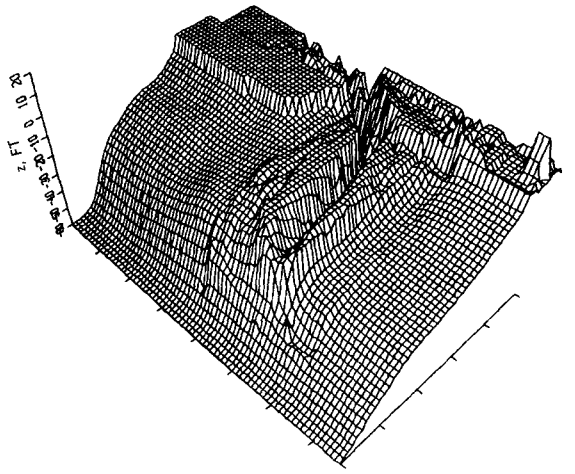

Figure 8. Topography for Oregon Inlet Numerical Model

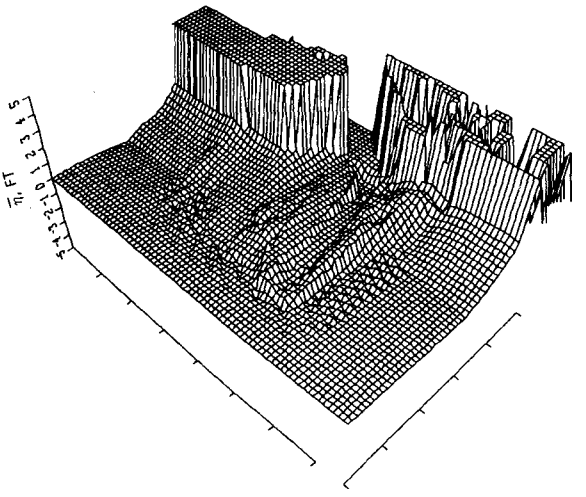

Figure 9. Surface elevation plot for Oregon Inlet

besides using 'no flow' conditions at the shoreline, a radiation boundary condition offshore and flux boundary conditions at the lateral boundaries, a flux boundary condition was used over a part of the inland side of the Sound, while the rest of the Sound was closed off. A time step Δt of 18.0 sec and a drag coefficient c of 0.01 were used in the numerical model. The breaking index γ was chosen according to the breaking criterion employed by Noda (10):

$$\frac{H_b}{L_b} \simeq 0.12 \tanh \left(\frac{2\pi d_b}{L_b}\right) \qquad (12)$$

where L corresponds to the wave length and the subscript b indicates values at breaking. A build-up time of 15 Δt was used at the start. The eddy vicosity ε_x was chosen according to Eq. 9 and the eddy viscosity ε_y was set equal to the value of ε_x at the offshore boundary. For the case under consideration, the complete equations (Eqs. 1, 2, and 3) were solved. An approximate steady-state was reached after 67 Δt. Figs. 9 and 10 represent the corresponding mean water levels and velocity vectors, plotted on the grid in the computational space. The velocity vectors are plotted for every other cell in each coordinate direction. To avoid confusion, the plotting of velocities with mangitudes less than 0.1 ft/sec is suppressed.

Referring to Figs. 8, 9, and 10, let us first consider the two portions of the beach away from the inlet. The shorelines in these regions are approximately straight and the contours are approximately straight and parallel. As we approach the shoreline from offshore, there is a small set-down followed by a set-up. The velocities are mainly alongshore and the velocity distribution is similar to that for a plane beach except that it exhibits two peaks at some locations.

The situation is more complicated in the region of the inlet (the central part of the grid). Here the breaker line is farther offshore. The depth in the main channel decreases first and increases later as we go toward the inlet. Because of these factors, the water sets up around the inlet and tends to create a flow into the inlet through the various channels, as one would naturally expect. A part of the main alongshore flow goes around the channels and shoals, to the other side.

Near the shoals, the patterns of mean water level and velocity are irregular. This is because of the fact that the waves refract around the shoals and break, creating locally set-ups and currents that do not necessarily conform to the general patterns. As the waves go toward the islands, they re-form because the depth increases.

Figs. 9 and 10 do not reflect the influence of tides and freshwater flows through the inlet. In nature, these phenomena tend to modify the patterns shown in these figures.

Computational Costs. For those interested in computational times, it should be noted that all the computations described in this paper were performed on a Cray-1 computer, which has vectorizing capabilities.

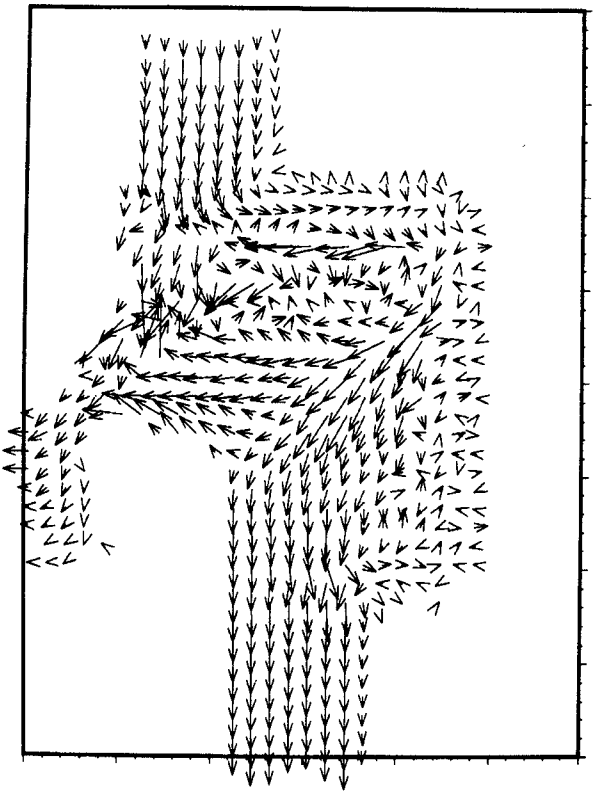

Figure 10. Velocity vector plot for Oregon Inlet

For the field application involving a 54 x 77 grid with 4,158 grid points, the Central Processor Unit (CPU) time for 67 time steps of simulation was approximately 15.5 seconds. The total cost for the job including program compilation, CPU time and data file manipulation, was approximately ten U. S. dollars. So the computational costs for the model may be considered reasonable.

Conclusions

A generalized longshore current model was developed. It retains the unsteady terms as well as advection and lateral mixing terms in the equations of motion and can be easily modified for different formulations of friction, eddy viscosity, etc.

A radiation boundary condition was successfully applied to the offshore boundary. It permits the transients due to start-up of the numerical scheme to be propagated out of the numerical grid.

Comparisons were made with known analytic solutions and experimental results. There was good agreement.

The model was applied to a complex field situation and the results obtained appeared to be reasonable. The computational costs were modest.

For the future, it is proposed to allow non-linear friction. Coordinate transformations will be used to transform the shoreline and breaker line(s) into lines parallel to the coordinate axes. It is proposed to simulate also the effect of structures such as jetties on the longshore currents and nearshore circulation.

SHORE-PARALLEL FLOWS IN A BARRED NEARSHORE

By

Brian Greenwood[1] and Douglas J. Sherman[2]

ABSTRACT

A field experiment to measure the horizontal and vertical structure of shore-parallel, nearshore currents was conducted at Wendake Beach, Georgian Bay, Canada, in 198D. Waves and currents were measured with continuous resistance wire wave staffs and bi-directional, electromagnetic current meters, respectively. Substantial variations from theoretical horizontal velocity profiles were found as an influence of small amplitude nearshore bars. Data smoothing resulted in a Longuet-Higgins type mixing parameter estimate of P=D.1B. Vertical velocity profiles analysis suggests that an estimate of mean, surf zone roughness length is of the order of $1x10^{-3}$m.

INTRODUCTION

Since the seminal work of Longuet-Higgins and Stewart (1962) on the concept of radiation stress, a strong body of theory has emerged for the prediction of depth-integrated, mean, shore-parallel flows generated by non-normally incident progressive gravity waves breaking across a planar beach slope (Longuet-Higgins, 1970a b; Dstendorf and Madsen, 1979). However, intrinsic to the modelling of fluid motion using momentum flux across the surf zone are indices describing lateral mixing and bed shear. Unfortunately, prototype experiments of a sophistication necessary to test existing theory and also provide data for determining the coefficients involved in a stress balance model of longshore currents are limited. This limitation is extreme where topographic effects-nearshore bars- introduce a potentially important modifying effect on current generation. Sonu (1972) provided a qualitative description of a spatially variable nearshore current in the presence of a bar but only very recently have more quantitative studies been undertaken (Meadows, 1977, 1978; Symonds and Huntley, 1980; Allender et al., 1979; Allender and Ditmars, 1981). This paper presents

the results of a field experiment designed specifically to examine the horizontal and vertical structure of the shore-parallel flow field across a non-tidal, barred nearshore under a wide range of incident wave conditions and to provide a dataset suitable for determining parameters describing the nearshore mixing and bed friction.

Location of Study Site

The experimental site was located at Wendake Beach, Ontario (Fig. 1): the area is a non-tidal, low-energy, storm-wave dominated coastal system with a maximum fetch of 84 km to the WNW but extremely restricted in width. Short period, steep waves that may exceed 2 m significant height with 5 to 6 second peak periods are generated during the passage of cyclonic disturbances. Wave approach angles frequently change even within a single storm in response to wind shifts in this fetch limited environment, and waves are subject to continuous forcing within the nearshore zone throughout most of the storm period.

The nearshore slope is gentle (approximately 0.015) and characterized by 3 bar-trough systems (Fig. 2); the outermost bar is highest (0.40 m) and essentially straight with a crest some 110 m offshore, while the inner two bars at distances of 65 m and 10 m from the shoreline have heights of only 0.15 m to 0.20 m and are sinuous to crescentic. The surf zone width is clearly constrained by these bars under many conditions but the general nearshore gradient is so low that breaking waves occur lakeward of the outermost bar, with a fully developed surf zone landwards, during much of the period of storm wave activity.

Experimental Design

Two types of instruments were used to monitor the fluid motions. Water surface elevation changes associated with waves were measured by surface piercing, continuous resistance wave staffs. Two or three meter long, helically wound steel wires (0.35 mm diameter) set in 18.8 mm PVC pipe (groove 0.75 mm, pitch 18.8 mm) were mounted by insulated brackets on 37.5 mm galvanized steel pipe. The latter was mounted on a two meter long base with fin to prevent rotation, and was jetted into the bed. The staffs were field calibrated individually to specific oscillator-detector circuits and were linear except for the lowermost 0.25 m. RG58A/U coaxial cable provide the shore-link. The oscillator circuit provides a 5 kHz square wave output and a simple half-wave rectifier and R-C Filter acts as a detector.

Shore-normal and shore-parallel flows were monitored using bi-axial, electromagnetic flow meters designed by Marsh-McBirney, Inc. (Model OEM 512). Based on the Faraday Principle of electromagnetic induction, they use a time constant of 0.2 s and measure flow up to 3 ms^{-1}. Considerable work on the accuracy of these meters has been undertaken (Cunningham et al., 1979; White, 1979; Huntley, 1979 etc.)

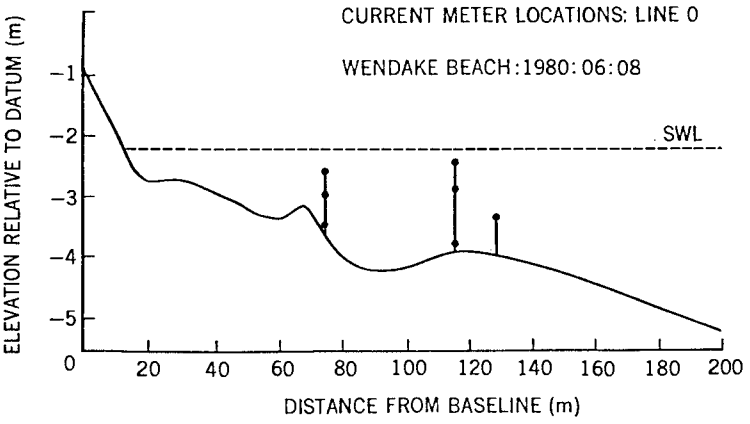

Figure 2b: Locations of current meters, 1980:06:06 to 1980:06:12.

and while some problems still exist the level of accuracy is better than 10%. The meters were mounted on a specially designed bracket (to allow rotation in both the vertical and horizontal planes), which itself was mounted on a stainless steel support. A galvanized steel pipe with fin to prevent rotation provide the base support and this again was jetted into the bed. The locations of the instruments are shown in Figures 2 and 3.

All sensors were hardwired to shore where a computer-controlled, data acquisition system (Fig. 4) provided instrument power, signal conditioning and detection, and data storage. A Hewlett-Packard 9835B mini computer with 125 K bytes of memory and real time clock controlled a high speed scanner-multiplexer (HP3495A) and digital voltmeter (HP3437A) allowing high density sampling of the current and wave sensors. Up to 40 channels could be monitored simultaneously. Record lengths varied between nine and twenty-five minutes with sampling at 2 Hz. Digital storage was on magnetic tape cartridges or flexible disc (HP9895).

Two specific plans were adopted for instrument deployment: a shore-normal array of ten wave staffs and seven flowmeters (Fig. 2a) allowed examination of the horizontal flow structure, while two sets of 3 flowmeters mounted vertically at the locations of wave wires 5 and 7 gave information on the vertical flow structure (Fig. 2b). At regular intervals during the experiments the system was activated to provide synchronous records of waves and currents at different positions across the surf zone thus giving a time series for evaluating the spatial and temporal variability of shore-parallel flows under a wide range of incident wave conditions. Specifically the datasets were used to evaluate: (i) the spectral characteristics of the incident waves; (ii) the spatial and temporal variability of shore-parallel flows; (iii) the parameters necessary to determine lateral mixing and eddy viscosity across the surf zone; (iv) the coefficients necessary to describe bed friction; (v) the influence of the non-planar slope on the above mentioned properties. Two storm events on May 30 - June 1, and June 8, 1980, will be described in this paper, with emphasis on lateral mixing and bed friction effects.

Nearshore Slope

An estimate of nearshore slope was obtained by fitting a least-squares regression line to measured profile data. R^2 values of better than 0.99 were obtained for a slope of 0.013 that intercepted the axis ($x = 0$) at -0.40 m. For a given value of water depth at the breaker line, h_b, the slope and intercept approximations were used to predict the width of the surf zone. Then an estimate of the actual slope was obtained using $s = h_b/x_b$. The process may be summarized:

$$s = 0.013\, h_b/(h_b - 0.40) \tag{1}$$

The resulting values of s ranged from 0.017 to 0.014.

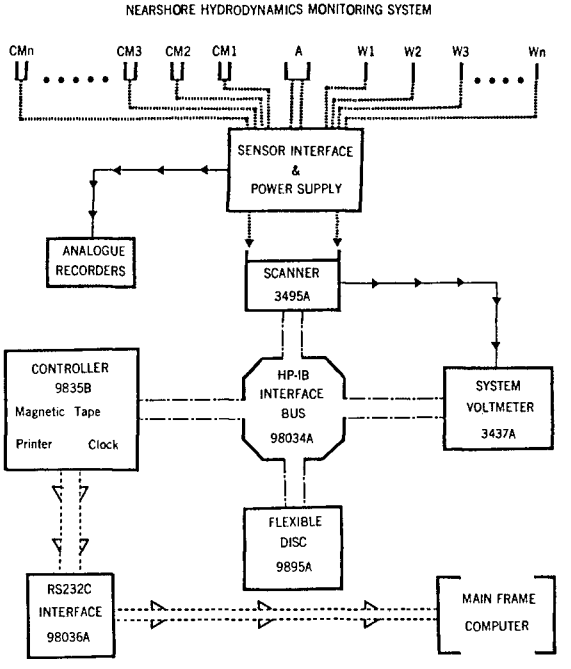

Figure 4: Schematic of the nearshore hydrodynamics monitoring system.

Storm Wave Characteristics

During the passage of depressions, waves in excess of 1.3 m mean amplitude and 5 s peak period provide the major local forcing for shore-parallel flows. Figures 5a and 5b illustrates the characteristic wave energy spectra incident to the surf zone during storms. A number of features are noteworthy:

(i) wave spectra in this continuous forcing environment exhibit large energy values over a wide range of frequencies below the peak frequency, which itself is marked by a very sharp truncation at the lower frequency end in all cases.

(ii) as expected, spectral growth (Fig. 5a) is accompanied by a consistent shift in the spectral peak to lower frequencies while there is an equally rapid increase in frequency during the decay phase (Fig. 5b). There is some evidence, however, for a dispersive effect during the decay period since at 0620 h the peak period (4.9 s) is greater than during the storm peak (4.6 s) and a broader peak at these longer periods is present.

(iii) during the most intense part of the storm, wave breaking produces a marked bimodal spectrum with the secondary peak at the frequency of the first harmonic.

(iv) in general there is very little evidence for structure in the spectra at frequencies lower than that of the incident spectrum. Some evidence is seen for a subharmonic during the early part of the storm (Fig. 5a & b) and for an oscillation at a frequency 1/4 times that of the incident wave; such structure is however, within the 95 percent confidence band for the spectra. The lack of low-frequency energy probably reflects the distance offshore of the wave staff, since under highly dissipative conditions many workers have noted the dominance of low frequency components (Huntley, 1976; Holman, 1981; Wright et al., 1982, etc.). Certainly storm conditions at Wendake Beach produce highly dissipative conditions, with the surf scaling parameter (Guza and Inman, 1975) ranging up to 192 x 10^2 (Greenwood and Sherman, 1983). Examination of the wave spectra nearer to the shoreline does indeed reveal an increase in this low frequency component.

Shore-Parallel Flows

HORIZONTAL STRUCTURE

During the storm event 1980:05:31 to 1980:06:01 fourteen records of the horizontal variability of longshore currents were obtained and Figure 6 illustrates six discrete records, from the periods of wave growth (Fig. 6a), the storm peak (Fig. 6b) and wave decay (Fig. 6c).

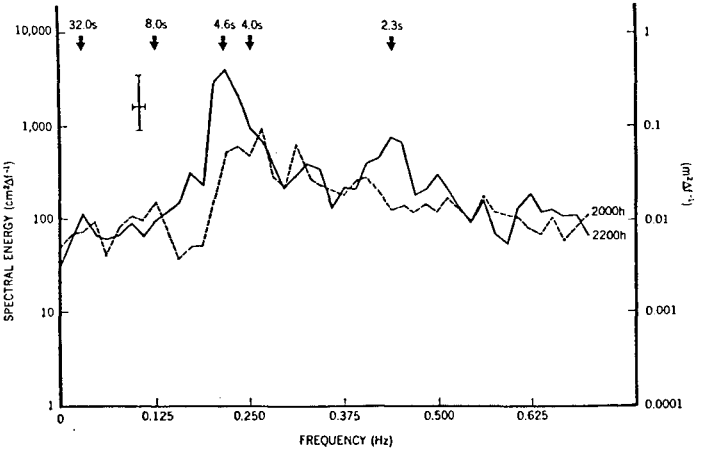

Figure 5a: Wave spectra from waxing limb of storm, WW9, 1980:05:30, 32 degrees of freedom. Vertical and horizontal crossbars indicate 95% confidence bar and unit bandwidth (0.016 Hz), respectively.

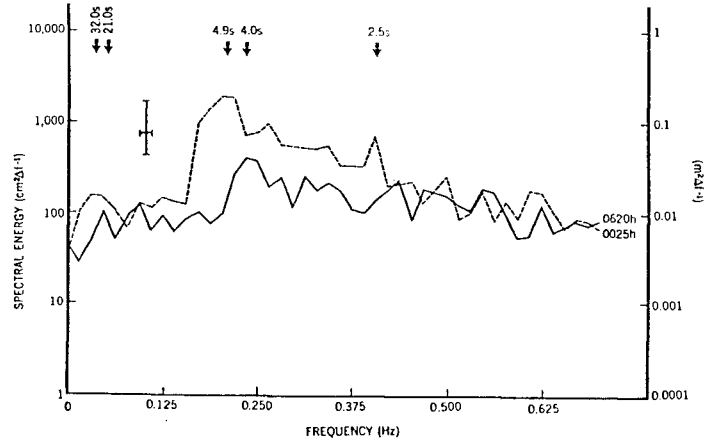

Figure 5b: Wave spectra from waning limb of storm, WW9, 1980:06:01, 32 degrees of freedom. Vertical and horizontal crossbars indicate 95% confidence bar and unit bandwidth (0.016 Hz), respectively.

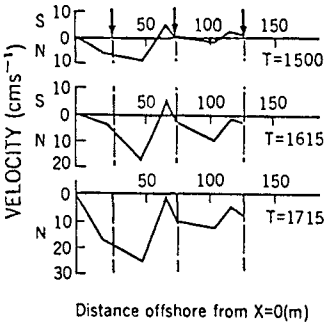

Figure 6a: Beginning of storm

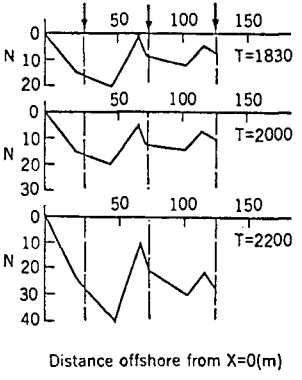

Figure 6b: Peak of storm

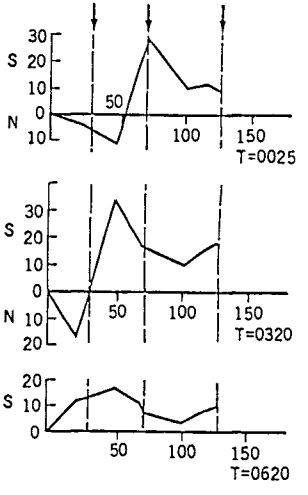

Figure 6c: End of storm

Figure 6: Time series of mean shore-parallel flows across a barred surf zone. Note the bars are located 20 m, 75 m, and 120 m, from the zero baseline.

As the storm grows flows accelerate with the increased wave driving and become more coherent up to the storm peak at 2200 h. At this time velocities reached a maximum of 40 cms^{-1}, with a maximum mean wave amplitude of 1.3 m at this time and peak period of 4.6 s.

Although bar heights are low and beach slope extremely flat in the nearshore, the topography exerts a marked influence on the horizontal structure of the flow field. Two distinct compartments of flow are associated with the outermost two bars. A marked reduction in velocity immediately landward of the bar crest should be noted with maximum flows in the trough on the landward side where water depth begins to decrease. Considerable variability in velocity is evident: excluding the zero velocity at the beach face a four-fold variation is present during the peak of the storm (2200 h). This contrasts markedly with the relative uniformity of surf zone flows across a bar-trough system claimed by Allender and Ditmars (1981). High velocities in the trough have been noted previously by Teleki et al., (1976) and ascribed to a longshore pressure gradient forcing due to wind setup.

A reversal in wind and wave direction around 2300 h produced a rapid response of the shore-parallel flows within the surf zone (Fig. 6c) in this fetch limited environment. However, an interesting feature of surf zone structure at this time was a horizontal stratification of flow reflecting a bi-directional disequilibrium response to the local wave forcing. This reversal persisted for more than 3 hours and may relate to the existence of a longshore pressure gradient (Komar, 1976, p. 196; Symonds and Huntley, 1980). However, it is important to note that between 2330 h and 0025 h the bulk of the surf zone flow was reversed and accelerated to a speed of 30 cms^{-1} in association with the change in direction of wave approach, thus implying dominance of the local forcing.

LATERAL MIXING

It is clear that a strong shore-normal variability in the average shore-parallel component of flow is evident on barred topography with the maximum velocities displaced landward of the initial break point which would occur on the bar crests. Such a pattern has long been recognized (Bowen, 1969; Longuet-Higgins, 1970 a & b) and although the shifting position of the breaker zone has been suggested as a significant control in a random wave field (Thornton, 1978) the primary control on a planar beach has been thought to be the lateral mixing associated with the horizontal Reynolds'stresses present under breaking waves. The latter tend to diffuse the local momentum flux and provide a smearing effect on the theoretical monotonic decay of currents across the surf zone (Longuet-Higgins, 1970 a & b). In an effort to compare the observations on a barred nearshore with the theory for a planar slope developed by Longuet-Higgins, estimates of his lateral mixing parameter, P, were attempted.

Dimensionless Velocity Profiles

Relative velocity values across the surf zone were calculated following Longuet-Higgins (1970b) by determining: (a) surf zone width based upon incident wave amplitudes, solitary wave breaking criterion and mean beach slope; (b) computed maximum velocity at breaking in the absence of lateral mixing, which involved a wave angle measure derived from a weighted orbital vector derived from the coherence between the surface elevation fluctuations and the measured orbital velocities; (c) a drag coefficient of the Darcy-Weisbach form assuming fully turbulent flow, a smooth boundary, and an equivalent grain roughness (following the experiments by Nikuradse).

Thus the longshore current at the breaker line, V_o (assuming no lateral mixing), is obtained from

$$V_o = \frac{5\pi}{8} \frac{\alpha S}{C} \sqrt{g h_b} \sin\theta_b \tag{2}$$

where α is a breaking criterion ($\alpha = 0.39$), C is the drag coefficient, and θ the angle of wave approach at the breaker line. Figure 7 illustrates the typical form of these profiles. Note praticularly the drop in velocity in the troughs immediately landward of the bars, and the increase to a maximum velocity in the mid trough. This shift in maximum velocities landward from the break point reflects the lateral mixing while the velocity differential from bar crest to the trough immediately landward reflects both differences in energy dissipation as a result of increasing water depths and differences in mass also as a result of increasing water depths.

Mixing Parameter P

Estimates of the Longuet-Higgins mixing parameter, P, were attempted by averaging and smoothing the relative velocities and then fitting the observed distribution to theoretical distributions based on differing mixing values (Fig. 8). The extreme values associated with non-coherent flow reversals and the local perturbations associated with the second bar have been eliminated in Figure 8 and the dimensionless velocity profiles have been averaged over the storm period and over a given interval of offshore relative distance (0.2X). It should be noted that in all cases at least six points were averaged in each interval, except for the lakeward most unit, represented by one value. The upward deflection of the curve at this location is thus less powerful an indicator of the nearshore flow.

Initial examination of the average velocity profile reveals a pattern for the whole surf zone which is very similar in its general shape to the predicted curves. The distribution is however, skewed landwards to a significant degree. To effect a best fit comparison with the Longuet-Higgins' curve the empirical-average, relative velocities were purposefully adjusted so that the measured maximum was

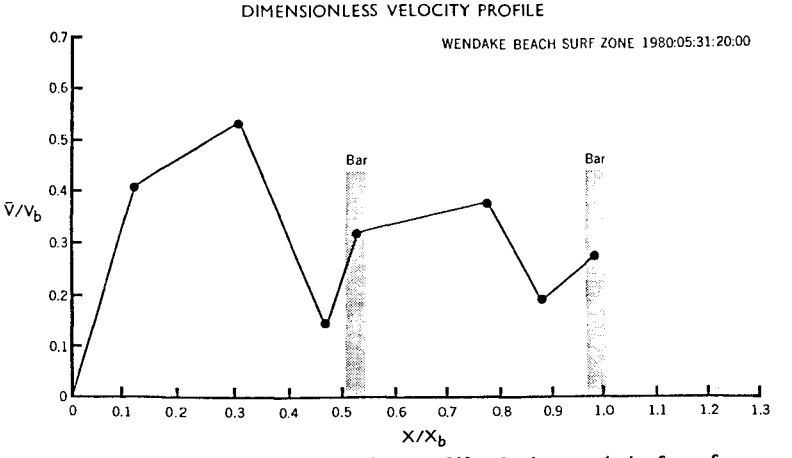

Figure 7: Dimensionless velocity profile during period of surf zone extension to outer bar.

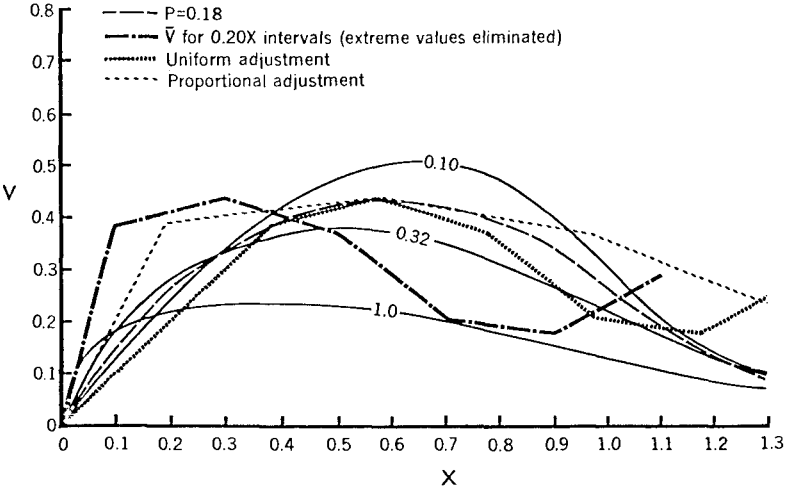

Figure 8: Theoretical and Empirical velocity profiles across the Wendake Beach surf zone.

coincident in position with the theoretical maximum. Both an absolute uniform adjustment and a proportional adjustment was applied to each value. In the former case each relative velocity is translated the same absolute distance as the maximum while in the latter case each velocity is translated a distance in the same proportion as the maximum velocity. Given the constraints of this adjustment, the best fit curve suggests a mixing parameter value of about 0.18, similar to other estimates that have been made (Longuet-Higgins, 1970b; Komar, 1975; Horikawa and Isobe, 1980; Symonds and Huntley, 1980).

VERTICAL STRUCTURE

Two sets of three current meters were used to measure the vertical structure of the longshore current (Fig. 2b). A depth-averaged, mean longshore current velocity was obtained for the storm of 1980:06:08, comprising a set of 27 observations. Mean values for specific elevations above the bed were also computed. The respective values are plotted with the overall mean as illustrated in Figure 10. For vertical arrays 1 and 2 (Fig. 9), the depth-averaged, mean velocities were 21 cms^{-1} and 28 cms^{-1}, respectively. The numbers associated with the current meter locations indicate the ratio of mean currents at that elevation to the overall mean. Note that the maximum mean variability is only about 10% of the depth-averaged flow. These findings are consistent with those of Meadows (1977), and the data suggests that the common practice of modeling longshore currents as depth-average or integrated values is not inappropriate.

Nevertheless, the form of these profiles also shows a consistent deformation of the velocity field strongly suggestive of the influence of bed friction. Assuming a logarithmic boundary layer velocity profile, and examining data from the lower two current meters in the lakeward array (VA2), estimates of boundary roughness may be obtained from

$$\ln Z_o = \frac{(V_b \cdot \ln Z_a) - (V_a \cdot \ln Z_b)}{V_b - V_a} \qquad (3)$$

where Z_o is the boundary roughness length, V is the longshore current velocity, Z is the elevation above the bed, and the subscripts $_a$ and $_b$ refer to values of the upper and lower current meters, respectively. Velocity measurements are obtained directly from the current records. Because the sand bed is moveable, however, estimates of instrument elevation must be made.

From direct measurement, the bed elevation before and after the storm is known. The maximum bed depression is also known from depth of activity rod and box core data (Greenwood et al., 1980). Other values for bed elevation are then interpolated between these three points by assuming that the magnitude of bed elevation change is directly proportional to V^2 and the total elevation changes through the storm. These estimates then provide the basis for solutions to

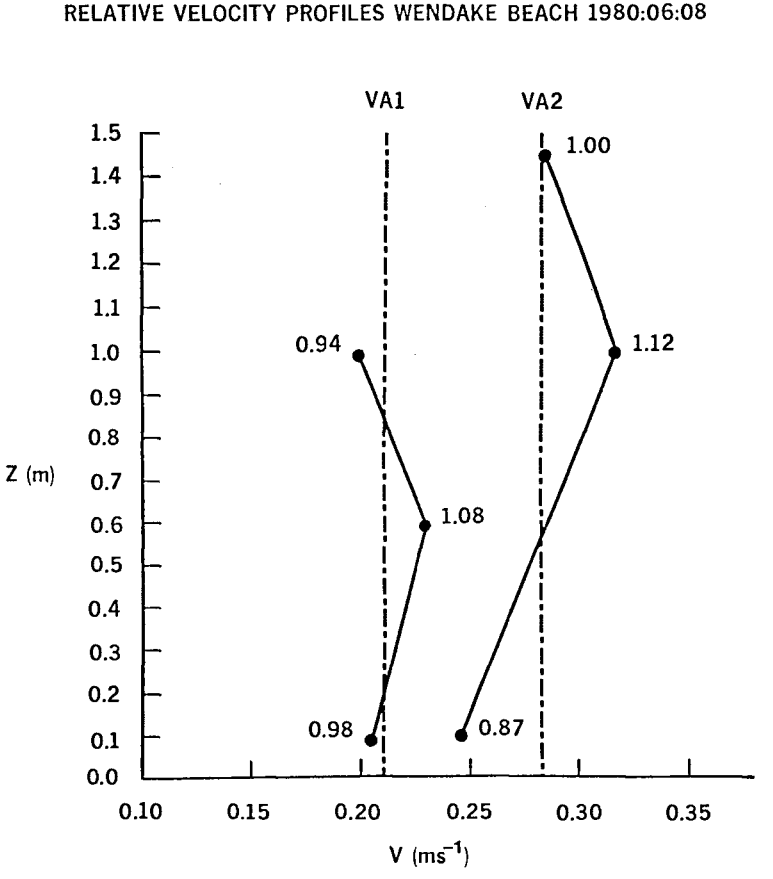

Figure 9: Mean velocity profiles from vertical current meter arrays, 1980:06:08.

equation (3). By plotting V_Z and lnZ, estimates of Z_0 may also be obtained graphically as the intercept of the line representing a logarithmic profile. Figure 10 illustrates these profiles. The dashed lines at ln 10 cm and 100 cm illustrate the values of Z that would have been used without the attempt at modeling bed elevation change. The lower dashed line represents a practical lower limit on expected values of Z_0, as determined from considerations of minimum roughness associated with skin friction on a plane bed. This relationship assumes that a Nikuradse equivalent sand grain roughness K_s, is approximated by $2D_{50}$, where D_{50} is mean grain size by weight-frequency distribution, and further, that $K_s/30 = Z_0$. It is reassuring that all of the estimates of Z_0 from the velocity profiles lie near or above this limit. This partially justifies the use of two points to determine the logarithmic profile. In terms of absolute values, the estimate of $2D_{50}/30$ obtained for the Wendake Beach data is about 0.013 mm, whereas the measured values range between about .01 mm and 3.28 mm. This variability in bed roughness over two orders of magnitude is believed to be mainly a reflection of changes in bedforms associated with wave orbital velocities, although the velocity profile measurements will also reflect changes in the wave boundary layer and internal stratification due to sediment transport. Further details concerning this analysis are presented in Sherman and Greenwood (1983).

For estimates of bed roughness effects on the deformation of the velocity field, a value for the friction (shear) velocity may be obtained from:

$$V_Z = \frac{V_*}{\kappa} \ln (Z/Z_0) \tag{4}$$

where V_* is the friction velocity and κ is Von Karman's constant (0.40). Values of V_* may further lead to estimates of boundary shear stress due to the mean current through solving

$$\tau_0 = \rho V_*^2 \tag{5}$$

where τ_0 is the boundary shear stress.

CONCLUSIONS

The data obtained during the Wendake Beach experiments allows a numerical approximation of key parameters controlling nearshore hydrodynamics. Qualitatively, the strong influences of minor nearshore relief upon the horizontal velocity structure have been demonstrated. Quantitatively, values for a lateral mixing parameter and a wave-current friction factor have been obtained for use in further modeling of the longshore flow. Specific conclusions may be summarized as follows:

1) On a "statistically" planar nearshore slope, bars of low amplitude (less than 0.4 m) exert strong control on longshore current development, particularly the horizontal structure .

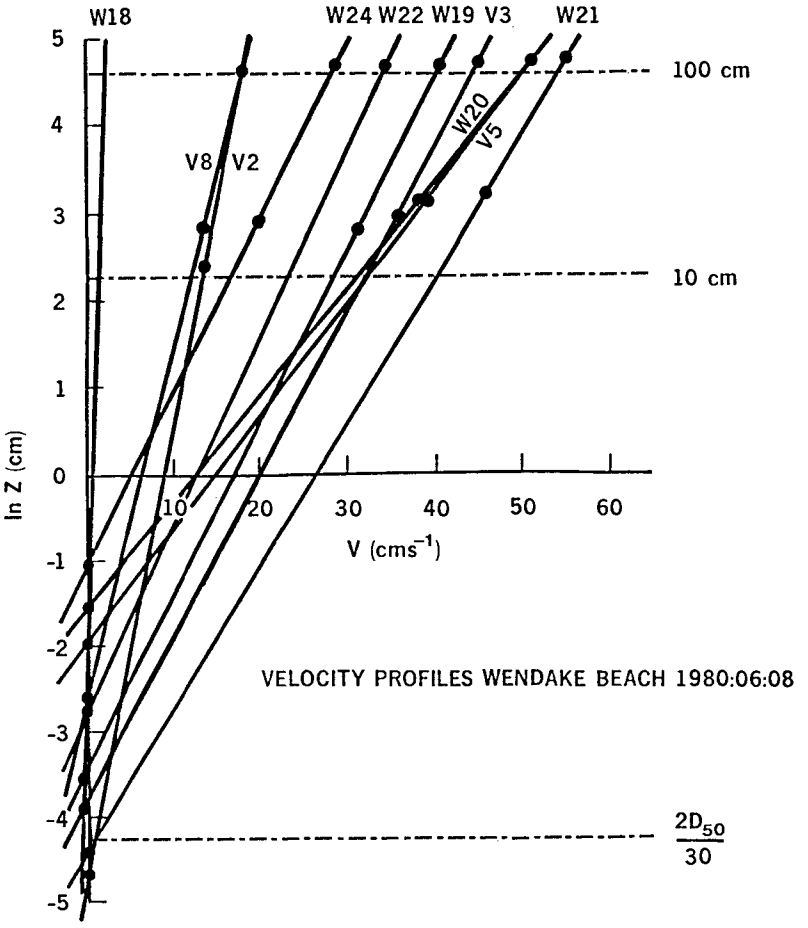

Figure 10: Graphical estimation of boundary roughness length from measurements of average longshore current velocity and estimated elevations above the bed. V and W are file designators here. V files are of 18-20 min. duration and W files of 9 minute length.

2) By discounting localized topographic effects, averaging methods yield an empirically derived, horizontal current structure in good agreement with the theoretical predictions of Longuet-Higgins (1970 b).

3) An estimate of the lateral mixing parameter, P, was found to be approximately 0.18 for the Wendake Beach nearshore.

4) Based upon assumptions of a logarithmic vertical velocity profile an average boundary roughness length of $Z_0 \simeq 1$ mm is obtained from this data set.

5) Estimates of Z_0 vary over two orders of magnitude, presumably reflecting changes in bedform configuration and sediment transport.

ACKNOWLEDGEMENTS

This study forms a part of a continuing research programme at Scarborough College in Nearshore Hydrodynamics and Sedimentation supported by both capital (E3921B, E6614) and operating grants (A7956) from the Natural Sciences and Engineering Research Council of Canada awarded to B.G. University of Toronto Open Fellowships and an Ontario Graduate Scholarship are acknowledged by D.J.S. Assistance with computer costs was given by both Scarborough College and the Department of Geography, University of Toronto. The Academic Workshops at Scarborough College assisted with instrument design and construction, while the Graphics and Photography Division of the College produced the illustrations. We gratefully acknowledge field and laboratory assistance from M. Rollingson, P. Christilaw and R. Sutherland, Scarborough College and R.G.D. Davidson-Arnott and D. Randall, Department of Geography, University of Guelph. Gretchen McManamin, Woods Hole Oceanographic Institution, typed the manuscript. The results and interpretations presented in this paper are, however, the sole responsibility of the authors.

Richards Bay South breakwater

PART III
COASTAL STRUCTURES AND RELATED PROBLEMS

Waves breaking over Gans Bay breakwater

FORCES INDUCED BY BREAKERS ON PILES

by

Robert L. Wiegel, F. ASCE*

ABSTRACT

This paper consists of three parts. The first part presents a method for analyzing the forces exerted by breaking waves on a cirular pile. The force consists of two components, a slowly varying force and a much larger but very short duration quasi-impact force (probably of the order of 1/100 of a second). The second part is concerned with breaker characteristics, with emphasis being given to the few field data that have been measured. The third part consists of a presentation of some available data on surf zone bottom profile variations with time.

Information on all three of these parts is needed for the proper design of a pile supported structure in the surf zone. If the bottom along the site of a proposed pier is sand, an estimate of the variability with time of the profile must be made. The effect of bottom depth and configuration on the height of waves moving shoreward, and the effect of this, in turn, on the wave loading is important in the calculations of wave-induced moments about the bottom. The ability of the structure to withstand these horizontal loads depends in part upon the depth of penetration of the piles. If the bottom varies with time, then calculations of wave characteristics and wave-induced loads on the piles should be made for appropriate bottom configurations.

INTRODUCTION

A large number of pile-supported structures have been built that extend from a beach through the surf zone (Simison, Leslie and Noble, 1978), and many more will be built in the future. The forces exerted on the piles and the ability of the structure to withstand these forces depend upon a number of factors such as pile shape and material, structure configuration, breaker type, beach configuration, tides, currents, and wave climate. The beach configuration changes with changing wave conditions, which further complicates the problem, as there is a relatively strong interaction between breaker characteristics and bottom configuration. Much work has been done in regard to the "design wave," but almost no work is available to the practicing engineer on the "design bottom profile." Both are needed for a well designed structure. In addition, the effect of possible local scouring at the piles or along the entire pier, must also be considered (U.S.

*Professor of Civil Engineering, University of California, Berkeley, CA

Army, Corps of Engineers, Coastal Engineering Research Center, 1982).

BREAKER FORCES ON PILES

Only a few measurements are available of the forces exerted by breaking waves on piles located in the surf zone. These measurements show a slowly varying force similar to that exerted by a nonbreaking wave, together with a very short duration rather large force that occurs just as the wave breaks at the pile, Figure 1. Some field measurements of forces induced on a circular pile by breaking waves in the surf zone are given in papers by Snodgrass, Rice, and Hall, 1951; Morison, Johnson and O'Brien, 1953; Miller, Leverette, O'Sullivan, Tochko and Theriault, 1974. Results of laboratory studies have been given by Hall, 1957; Goda, Haranaka and Kitahata, 1966; Watanaba and Horikawa, 1974. It is difficult to measure this "impact" force reliably owing to its very short duration combined with the dynamic characteristics of the test system.

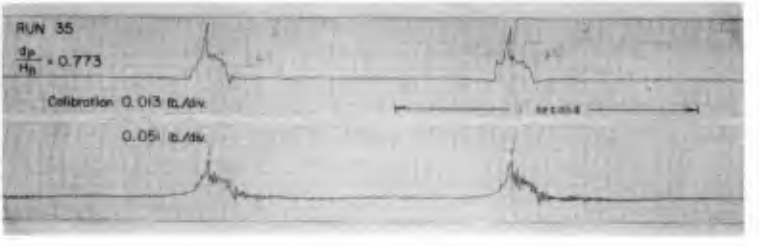

Figure 1. Force Record (From Hall, 1957)

The cause of the "impact" force can be understood by considering the analogy of the wave loading of a horizontal circular cylinder that is alternately in the air and then immersed by a passing wave crest (Kaplan and Silbert, 1976; Faltinsen, Kjaerland, Nottveit and Vinje, 1977; Sarpkaya, 1978). In this problem, one force term is $\dot{\eta}(\partial m_y/\partial t)$, where $\dot{\eta}$ is the time rate of change of the water surface in the vertical direction, and m_y is the vertical component of added mass. $\dot{\eta}(\partial m_y/\partial t$ can be given by

$$\dot{\eta}(\partial m_y/\partial t) = \dot{\eta}^2(\partial m_y/\partial y) \qquad (1)$$

Here, $\partial m_y/\partial_y$ is the change in the vertical component of added mass with with immersion by the wave of the horizontal structural member. This term has been calculated by Kaplan and Silbert (1976) and is shown in Fig. 2 as a function of the relative immersion z/r, where r is the radius of the circular cylinder and z is the immersion, and ρ is the mass density of the fluid. Note for z/r = 0, just as the circular cylinder is first immersed, the coefficient has the value of π and then decreases rapidly.

Additional papers of interest in regard to the problem described above are Attfield, 1975, Dalton and Nash, 1976, and Kjeldsen and Myrhaug, 1979.

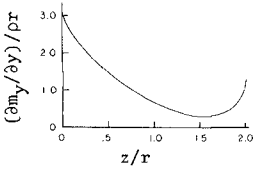

Fig. 2. $(\partial m_y/\partial y)/\rho r$ vs. z/r (From Kaplan and Silbert, 1976)

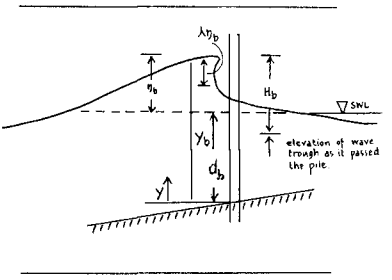

Fig. 3. Definition Sketch

The approach described above can be used to calculate the force due to a breaking wave acting on a vertical circular pile, using $\partial m_x/\partial x$ in place of $\partial m_y/\partial y$, where x is the horizontal coordinate and $\partial m_x/\partial x$ is the change in the horizontal component of added mass with immersion of the vertical pile by the breaking wave (Wiegel, 1979). One can calculate the horizontal component of the slowly varying wave-induced force using the Morison equation from y = 0 to $y = y_b - \lambda\eta_b$ (see Fig. 3). Then, one can compute the "impact" force on the section of the pile that is struck by the vertical or nearly vertical portion of the breaking wave (or, "foam" line or bore), $\lambda\eta_b$. (See the variation of dynamic pressure measurements with distance beneath the surface by Miller, et al., 1974 for the reason that this can be done).

$$F_s \approx \dot{\eta}^2(\partial m_x/\partial x) \approx \frac{1}{2}\rho C_s D C_b^2 \qquad (2a),(2b)$$

Here, the maximum value of $C_s = \pi$, D is the diameter of the pile, C_b is the velocity at which the breaking wave crest moves, and F_s is the "impact" force per unit length of the pile subject to this force, $\lambda\eta_b$. This equation is of the same form as the one developed by Goda, Haranaka and Kitahata, 1966. (See, also, Watanabe and Horikawa, 1974). λ is a function of the

type of breaker. For the range of wave steepnesses used in these tests and bottom slopes of 1/100 and 1/30, λ was less than 0.1. These were for spilling breakers. For plunging breakers on a steep slope(1/10), λ was as great as 0.5. These values of λ were obtained indirectly, and the original papers should be consulted for details. Analysis of some field data by the writer showed that η_b/H_b ranged from 0.55 to 0.95.

The interval of time during which C_s is about at its highest value is very short, with C_s decreasing from this value. Consider a design breaking wave height of 10 m, and a 1.0 m diameter pile. From other studies $C_b = 1.12\ (2g \times 10)^{\frac{1}{2}} = 15.7$ m/sec. The time it would take for the breaker to immerse completely the $\lambda\eta_b$ section of the pile would be 1/15.7 sec (about 0.06 sec). The value of C_s would be decreasing from the initial value of π during this time. Thus, the "impact" force would occur during a short time, substantially less than 0.06 sec., probably of the order of 1/100 sec. The more slowly varying wave-induced force and moment from y=0 to y=y_b calculated using the Morison equation would probably be used by most design engineers to control the design. However, the effect of the large loadings of short duration on the fatigue life of the pile must be taken into consideration (see Attfield, 1975 for a discussion of a similar problem).

It appears from the work of Snodgrass, et al, 1951; Hall, 1957, 1958; and Watababe and Horikawa, 1974, that the Morison equation is adequate for waves that have not yet broken, insofar as any individual pile is concerned. A wave breaking in the plunging manner at a pile induces a greater force in the $\lambda\eta_b$ portion of crest (see Miller et al, 1974). "Foam lines" (bores) resulting from plunging breakers exert a very large force on a pile in the same manner, Figure 4. Sketches are given in Fig. 5, which show the various types of breakers designated in Fig. 4. An example of breaking waves passing the test structure taken from the individual frames of a motion picture film is given in Fig. 6. Similar results were found in the field tests of Miller et al, 1974, for a vertical flat plate of small width and thickness.

BREAKER CHARACTERISTICS

Values of breaker characteristics are needed for the calculation of wave-induced forces on a pile. These are η_b, λ, H_b, d_b, and C_b (forward speed of the wave at time of breaking, or bore speed after breaking), together with the water particle velocities and accelerations within the wave.

One important parameter used in predicting breaker characteristics is the relationship between the type of breaker that occurs and the two primary factors; deep water wave steepness and the slope of the beach (Patrick and Wiegel). They observed this relationship during an extensive field study, followed by a hydraulic laboratory study. For later laboratory studies, see, for example, Galvin, 1968, Weggel, 1972, Battjes, 1974, Singamsetti and Wind, 1980. The most important factor has been found to be the ratio of beach slope to the deep water wave steepness:

$$\xi = \tan\theta/(H_o/L_o)^{1/2} \qquad (3)$$

where θ is the angle between a plane beach and the horizontal, H_o is the deep water wave height, and L_o is the deep water wave length. This ratio has been given the name "surf similarity parameter." It is sometimes

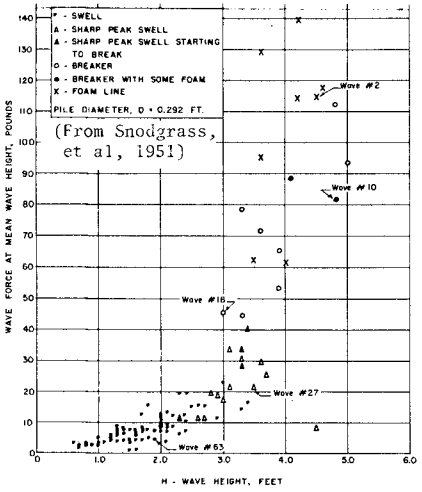

FIGURE 4. WAVE FORCE AT MEAN WAVE HEIGHT VS. WAVE HEIGHT

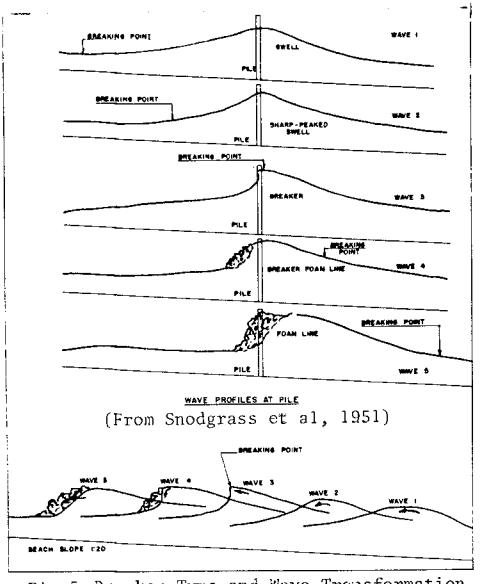

Fig.5. Breaker Type and Wave Transformation

FIGURE 6. – WAVE NO. 2 – FOAM LINE (From Chappelear et al.)

designated the "Irabarren Number," when used in regard to breaker types at a rubblemound breakwater. Numerical values of this ratio and their relationship to breaker type have been reported for plane rigid impervious beaches. A set of calculations has been made to show this relationship, and the results are presented in Table 1.

TABLE 1

		Surging Breakers	Plunging Breakers						Spilling Breakers		

*Breaker classes shown are based upon the following assumption.

Surging Breaker	$\tan\theta/\sqrt{H_0/L_0} > 2.0$
Plunging Breaker	0.4 to 2.0
Spilling Breaker	< 0.4

Many laboratory measurements have been made of breaker characteristics, nearly all for simple plane bottoms, rather than for the more complex bathymetry of natural beaches. The design engineer needs data on more realistic models of bottom configuration, with tests being made with wave spectra as the input. An even greater need, however, is for field data of the type obtained by Suhayda, 1974, Thornton, 1979, and Wright, et al, 1979, 1982.

In nature, sand beaches are not plane, nor are they impervious,

nor are they uniform in the direction along the beach; in addition, the bottom configuration changes with changing wave conditions and tide range. In general, the combination of steep beaches and relatively flat waves (swell) result in a relatively highly reflecting wave condition (called a surging breaker). The combination of steep waves (local storm waves) and a relatively flat beach result in spilling breakers. Plunging breakers occur for intermediate values of the parameter.

As mentioned above, for the combination of a very steep beach and waves of relatively small steepness, much of the wave energy is reflected. The surging type of breaker is of this type, and the runup of the waves on the beach is relatively great, and the drawdown is fast. Often, edge waves are formed under these conditions, and these appear to be associated with the formation of cusps along the beach. For flat beaches and steep waves, the waves spill over a wide surf zone. Most of the wave energy is dissipated in this process, and the wave runup on the beach is rather small. Through a complicated process there is a set-down at and just seaward of the region of breaking, and a setup of the water level within the surf zone, landward of the breakers (for example, see Saville, 1962; Longuet-Higgins, 1970; Komar and Guaghan, 1972; Battjes, 1974; Jonsson and Buhelt, 1978; van Dorn, 1978). On ocean beaches this serup varies with time, exhibiting long-period oscillations known os surf beat (most commonly in the 60 to 150 second period range). Rip currents exist, as a part of a complicated littoral current system created by the breaking waves. Between these two types of breakers are the plunging breakers, which occur for intermediate combinations of beach slopes and wave steepnesses. Strong rip currents are also observed under these conditions. Owing to the complexity of natural beaches with one or more bars present, breakers which have plunged often run as a bore in water which is somewhat deeper landward of the location at which the wave breaks, with the bore dissipating most of its energy before finally moving up a small amount onto the beach face.

Three equations sometimes used to calculate breaker speeds, C_b, needed in Eq. 2 are:

$$C_b = K_1(2g\eta_b)^{1/2}, \quad K_2(gy_b)^{1/2}, \quad \text{or } K_3(2gH_b)^{1/2} \qquad (4)$$

The writer analyzed the field measurements made by Snodgrass, et al, 1951. In these field tests a marker pole was set 6.04 m seaward of the test pile. The wave crest velocity was determined by counting the number of frames of the motion picture film for the wave crest to pass from the marker pole to the test pile (see Fig. 6). The film speed (in frames per second) was determined from a clock which appeared in the film. During the tests thirty-one waves broke at the test pile, or were foam lines (bores) or sharply peaked swell (these broke just landward of the test pile). The average value of the ratio of the measured wave crest velocity to $(2gH_b)^{1/2}$ was 1.12. The average value of the ratio of the measured wave crest velocity to $(gy_b)^{1/2}$ was 1.14. Here, both H_b and y_b were measured values at the test pile, obtained from the motion picture film. y_b may be calculated for some beaches using the equation

$$y_b = d_b + \eta_b \qquad (5)$$

where d_b is the water depth at breaking and η_b is the height of the

crest of the breaking wave above the still water level. η_b was found to be approximately equal to $0.8H_b$ from another set of field measurements, Figure 7. The average value of η_b/H_b is in agreement with the laboratory data of Wiegel and Beebe, 1956, and van Dorn, 1978. Values of η_b are needed in Eq. 5, in the first of Eqs. 4, and in the application of Eq. 2 (to calculate $\lambda\eta_b$).

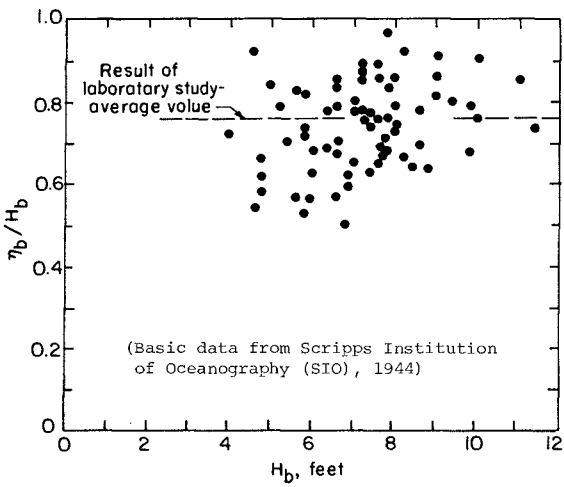

Fig. 7. η_b/H_b, Field Data, SIO Pier, CA.

The relationships among beach slopes, breaker heights, and the the water depths in which the waves break have been studied in the laboratory by a number of piople, each of whom has developed a slightly different semi-empirical equation. The general forms of the equations used to predict breaker heights and the depth of water in which waves break are

$$H_b/H_o = A(\tan\theta)^B(H_o/L_o)^C \qquad (6)$$

$$H_b/d_b = \gamma_b = D(\tan\theta)^E(H_o/L_o)^F \qquad (7)$$

Here, d_b is the mean water depth at breaking (including setdown) and A,B,C,D,E and F are empirically determined coefficients. These, and other formulae have been compared by Singamsetti and Wind, 1980, for several beach slopes. They suggest the use of

$$H_b/H_o = 0.575\ (\tan\theta)^{0.031}\ (H_o/L_o)^{-0.254} \qquad (8)$$

with the range of validity being $0.02<H_o/L_o<0.065$ and $1/40<\tan\theta<1/5$. This curve is the "best fit" curve by Singamsetti and Wind through the other suggested curves. Note the relatively insensitivity to beach slope, except for very steep beaches [$(\tan\theta)^{0.031}$ is 0.93 for $\tan\theta=1/10$, 0.91 for $\tan\theta=1/20$, 0.89 for $\tan\theta=1/40$, and 0.87 for $\tan\theta=1/100$].

The formula for H_b/d_b recommended by Singamsetti and Wind is

$$H_b/d_b = 0.937\ (\tan\theta)^{0.155}\ (H_o/L_o)^{-0.130} \qquad (9)$$

with the range of validity being $0.02< H_o/L_o<0.06$, and $1/40 \leq \tan\theta \leq 1/5$. They state that the results for the 1/5 slope differ considerably from this, and that the following formula is a better approximation for the flatter slopes

$$H_b/d_b = 0.568\ (\tan\theta)^{0.107}\ (H_o/L_o)^{-0.237} \qquad (10)$$

with the range of validity being $1/40 < \tan\theta < 1/10$. A formula similar to the one presented above (due to J.A. Battjes) is

$$H_b/d_b = 1.16\ [\tan\theta/(H_o/L_o)^{1/2}]^{0.22} \qquad (11)$$

Some measurements have been made of the breaker "bore heights as the bores (also called "foam lines") move shoreward over the bottom which has a rather flat slope. These measurements were made over the shoreward 150 meters of a wide surf zone (about 400 to 500 meters) at a beach just west of the entrance to The Coorong in South Australia (east of Adilaide). The beach is composed of fine sand (mean diameter of 0.13 mm), with the bottom slope of the 150 meter wide section where the studies were being made, of about 1/100. The beach is exposed to long high-energy southwesterly swell. During the experiment the significant breaker height was about 3 meters and the wave period in the range of 12-15 seconds (hence, ξ -see Eq. 3- in the range of 0.085 to 0.11). The average spring tide range is only 0.8 meter and the neap tide range is only 0.4 meter. No rip cells or beach cusps were present during the experiment. The measurements of the bore heights (i.e., "foam lines" after breaking) were made in the shoreside 150 meter wide portion the the surf zone. The relationship between significant bore heights and local water depth, d, was measured and the data presented in the report. The average value of γ (H_{bore}/d) was found to be only 0.42.

Van Dorn discovered a rather simple equation for the horizontal component of water particle velocity, u, along a vertical line directly under the crest of a wave just as it starts to break. It appears to be reasonably reliable for beaches flatter than 1/25. This equation is

$$u/C_b = 0.2 + \frac{0.10(y/y_b)}{1.125 - (y/y_b)} \qquad (12)$$

A reasonable approximation for calculating C_b is either

$$C_b = 1.12(2gH_b)^{\frac{1}{2}} \quad (13a) \quad \text{or} \quad C_b = 1.14(gy_b)^{\frac{1}{2}} \quad (13b)$$

where H_b is the breaker height. y_b nay be cakcukated fir sime beaches by Equation 5.

Much work has been done in the laboratory on the water particle velocity (see, for example, Hedges and Kirkgoz, 1981) and acceleration fields in breaking waves, while little field data are available (see, for example, Miller and Ziegler, 1964; Thornton, 1979; Stive, 1980). Space limitations prevent going into this problem in detail herein.

The main difficulty in applying the several equations presented above for breakers is that they have not been checked sufficiently by measurements of ocean waves with the variable bottom slopes that exist on ocean beaches. Furthermore, the laboratory studies have nearly all been for plane rigid impervious beaches, and these are not a good representation of natural beaches.

A very useful study is that of the field data measured at the Scripps Institution of Oceanography pier (Scripps Institution of Oceanography, May 1944 and October 1944; U.S. Navy Hydrographic Office, 1944). A number of characteristics of breakers (such as H_b/d_b, the ratio of the breaker height to the "still water depth" at the point of breaking) were found to depend upon the configuration of the bottom. In the report on field measurements it is stated that during the period that observations were made, two types of nearshore underwater slopes occurred: Type 1, which was a reasonably plane bottom with a slope of about 1/40; Type 2, which has an outer portion with a slope or about 1/25, then a bar, with a slight trough shoreward of this, called the middle portion. The breakers were classed into two groups: Group 1, those that broke over the outer portion, and Group 2, those that broke over the middle portion. Values of H_b/d_b were considerably smaller for the Group 2 waves breaking on the Type 2 bottom configuration than for the other three combinations.

BOTTOM CONFIGURATION

Sand is moved along a beach by the action of waves breaking at an angle to the beach, by the movement of water rushing up and down the beach in a zig-zag motion, and by the longshore currents generated in the surf zone by the breaking waves. The littoral currents are often three dimensional, with rip currents moving out to sea at intervals along a beach, with a number of "cells" existing along a beach (Shepard and Inman, 1952; Sonu, 1972; Sasaki, Horikawa and Hotta, 1976; Mei and Liu, 1977). Sand is moved up and down the beach, and in and out of the surf zone in an onshore-offshore direction by wave action (Wiegel, 1964) and by the currents generated gy winds blowing onshore, with return currents near the bottom flowing towards the offshore (King, 1959; Kraai, 1969; Sonu and van Beek, 1971; Sonu, 1972). Neglecting the wind generated currents, anc their effects, there is evidence that the parameters that describes the direction of the net motion of sand is (Hattori and Kawamata, 1980):

$$(H_o/L_o) \tan\theta / (w_s/gT) \begin{cases} < \\ = \\ > \end{cases} \begin{matrix} \text{(onshore transport, accretive)} \\ 0.5 \text{(neutral, equilibrium profile)} \\ \text{(offshore transport, erosive profile)} \end{matrix} \quad (14)$$

where w_s is the fall velocity of the median diameter sand grains. It can be seen from this, that it is difficult to apply this to actual beaches owing to the variation of sand size along a profile.

Relatively steep waves cause a net motion of sand off a beach face into the surf zone, often forming a bar. Waves of low steepness generally move sand from the bar and other portions of the surf zone onto the beach. These mass movements of sand onto and off the beach cause a modification in the characteristics of the breaking waves, the runup and rundown of the waves on the beach face, and the littoral currents, as mentioned previously. There is a strong relationship between the type of breakers and the beach slope (Patrick and Wiegel, 1955; Wiegel, 1964; Sonu, 1972; Wright, Chappell, Thom, Bradshaw and Cowell, 1979).

In planning the installation of a pier (or a pipeline) across a beach and through the surf zone, one must consider that the action of waves, currents, and winds continuously change the beach configuration, both on the shore and in the nearshore region. In calculating the bending moments exerted on piles by waves during the "design storm" one must consider the associated problem of the actual water depth along the section of a pier in the surf zone during the design storm (Wiegel, 1979), as well as the waves. An example of the variation of the bottom profile of a beach subject to heavy wave activity is shown in Figure 8. An extremely difficult problem is that of estimating where the bottom will be under various conditions (Wiegel, 1980). One must estimate the "design bottom profile."

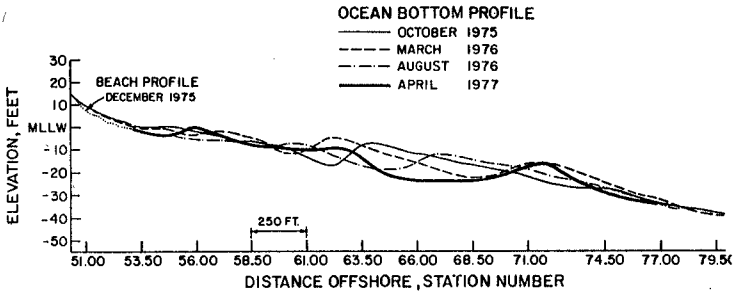

FIGURE 8. BEACH AND NEARSHORE PROFILES, SAMOA, CALIFORNIA, OCTOBER 1975-APRIL 1977 (FROM WINZLER & KELLY, 1976).

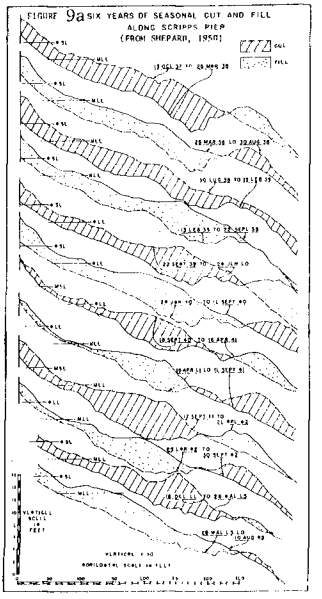
There is no simple answer to the question of how much change can be expected to occur as a result of a severe storm. It depends upon the recent past histories of the waves, tides (i.e., spring tide, neap tide, etc.) and beach profile of the particular site in question.

One of the longest set of records of beach and nearshore profiles is that obtained by Shepard,1950. He made measurements from a pier at La Jolla, California. His data are summarized in Fig. 9. This region is not as greatly exposed to waves as are many other regions, such as the northern California coast or the southeast coast of Australia.



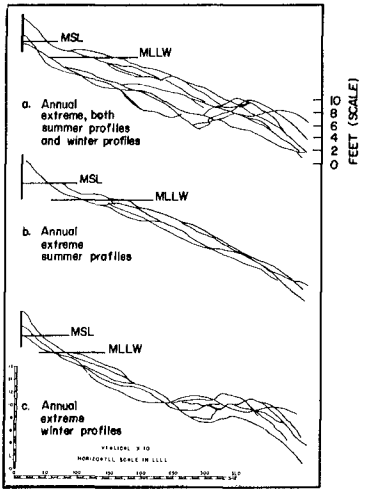


FIGURE 9b — ANNUAL EXTREME PROFILE CONDITIONS FOR 6 YEARS, DATA FROM SHEPARD (JULY, 1950) SCRIPPS PIER.

Shepard studied in detail the bar crest depths (bar depth) and bar trough depths (trough depths). It was found that the bar at the pier seemed to disappear on some occasions. Whether the bar did disappear, or was simply missing along the pier was not determined. Bars are not continuous along a beach, and there are gaps in them. That this is so can be seen by observing waves breaking on a beach where a bar is present offshore. A line of breakers (breaking over a bar) can be followed for some distance, separated by a gap, follow-by another line of breakers. The waves move in through the gap (where the water is deeper, likely about the same depth as the trough) and break closer to shore. In considering the data given by Shepard, note that the ratio of bar depth to trough depth for the large bars measured at very exposed locations along the Oregon and Washington coast is about 2 or so, rather than the smaller values at other locations, Figure 10.

Much additional work is needed on the variations of bars with wave conditions. These appear to be pertubations about some mean bottom profile on sand beaches. Dean, 1977, has found that a mean bottom profile curve can be approximated by the following formula, neg;ecting bars:

$$h = Ax^{0.67} \qquad (15)$$

Here, h is the vertical distance below the mean low water level, x is

the horizontal distance out from the origin (taken as the intersection of the beach with mean low water), and A is a coefficient to be determined empirically. As an example, consider one profile across Ninety-mile Beach, Victoria, Australia, Figure 11. Using the survey data, and an average value through the survey, it was found that $A = 0.235\ ft^{1/3}$. It is important to note that Dean found 70% of the values calculated for 502 beach profiles were between 0.1 and 0.2, and that another 18% were between 0.2 and 0.3.

GANSBAAI FISHING HARBOUR - THE DESIGN AND CONSTRUCTION OF A BREAKWATER ON A HOSTILE COAST

by

W S van Dijk * A P M Vonk ** G de F Retief ***

ABSTRACT

This paper describes the design and construction of a fishing harbour on a rocky coastline exposed to the prevailing south westerly swell of the South Atlantic and to severe westerly gales.

Because of economic pressure the first phase of the development was undertaken without adequate knowledge of the wave regime or the topography of the sea-bed in the area and resulted in a virtually unusable harbour.

The second phase of construction was therefore only embarked upon after extensive hydrographic surveys, wave recording and analyses, and probably the most exhaustive series of model tests ever undertaken for such a small project.

These investigations and the good co-operation between research staff, engineers and contractors resulted in the elimination of most of the initial problems and the creation of a functional fishing harbour.

INTRODUCTION

Gansbaai is a small fishing village situated 170 km south east of Cape Town as shown in figure 1, and only a few kilometres from Danger Point, scene of the tragic wreck of the Birkenhead in 1852. When this ship went aground more than 400 soldiers *en route* to the eastern frontier of the Cape Colony perished.

This coastline near the southern tip of the African Continent is exposed to the prevailing south westerly swell of the South Atlantic and the full force of westerly gales.

A landing place for fishing vessels developed at Gansbaai because a deep channel in line with the direction of the waves provided an approach route relatively free from breaking waves.

Although the fishing village has been in existence since the late 19th century, the first noteworthy harbour works were constructed in 1939-1942 when breakwaters were built from the northern and southern shores to enclose an area of approximately 4 hectares, of which less that 1 hectare was deeper than 3 metres at low water ordinary spring tide. Unfortunately the northern breakwater cuts across the deep entrance channel forcing boats entering the harbour to deviate from the channel towards the less safe shoaling bottom south of the channel (see figure 2).

Rapid expansion of the pelagic fishing industry in the late 1950's created a demand for improved facilities at Gansbaai as at other fishing harbours, particularly on the west coast of South Africa.

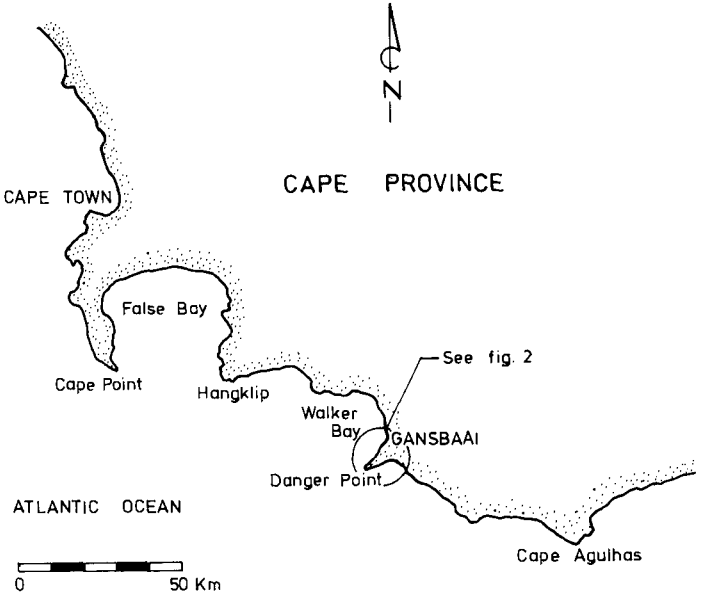

Fig 1. Location Plan

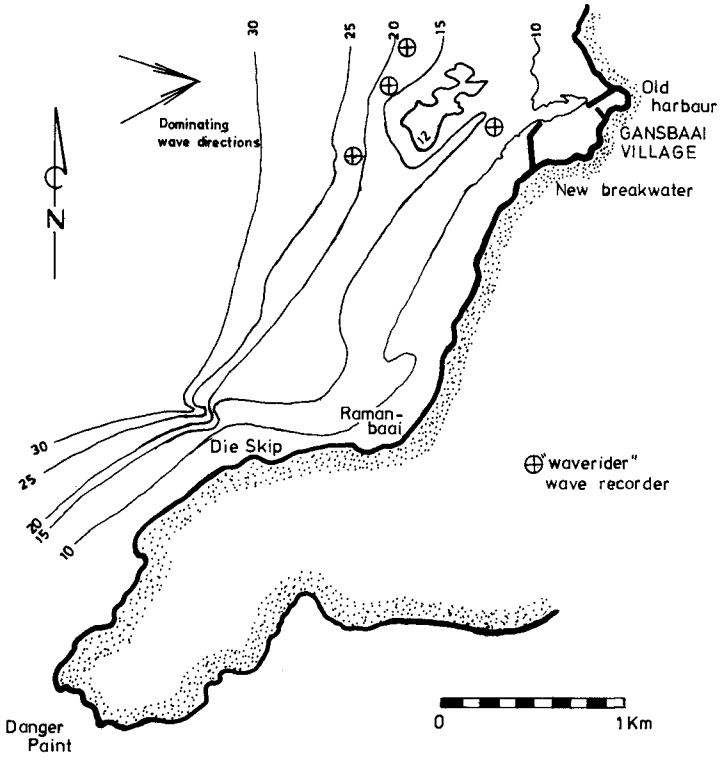

Fig 2. Coastline around Gansbaai

As no obvious solution for the improvement of the existing harbour presented itself, other sites in the vicinity notably Roman Bay and "The Ship" on the north western shore of the Danger Point Peninsula (see figure 2) were investigated. These options were discarded because of the high cost of breakwaters in the deep water at these two sites and the additional cost of a road from the existing village and it was decided to construct a new breakwater south west of the existing harbour at Gansbaai.

FIRST PHASE OF DEVELOPMENT

The new breakwater was to serve a two-fold purpose, viz to protect the entrance to the existing harbour and to provide additional mooring space which could be developed into a fully fledged fishing harbour at a later stage.

The alignment of a breakwater required to effectively protect the entrance to the old harbour, presented difficulties because it would have to extend into or across the deep channel, as shown in figure 3. Such a breakwater would be expensive and could create the same problem as that caused by the existing northern breakwater, i.e. forcing incoming boats into the shoaling water on the opposite site of the channel. Reflection of wave energy by the new breakwater could also create turbulent conditions in the entrance channel.

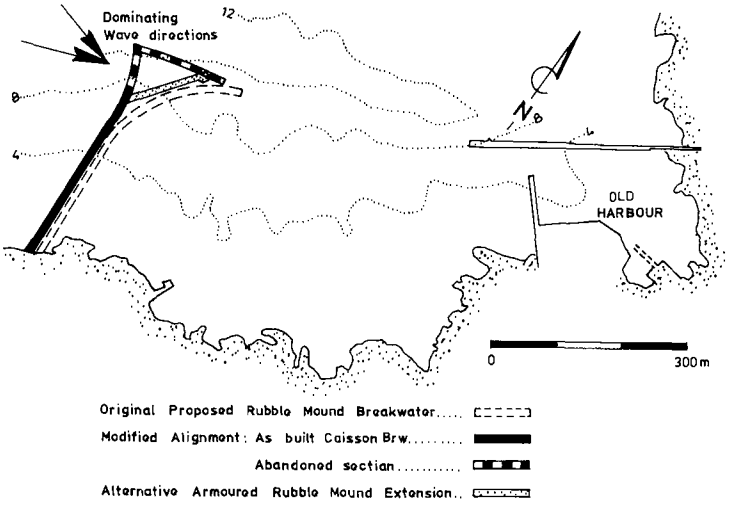

Fig 3. Layout of Breakwaters - Phase I

In 1964 the South African Council for Scientific and Industrial Research (CSIR) was requested to carry out a model study to determine the most suitable alignment for the new breakwater. A fixed bed model was constructed in an existing tank in Pretoria at a scale of 1 in 100.

The study was to be based on hydrographic and other information supplied by the Fisheries Development Corporation of SA Ltd. Unfortunately the urgency of the project precluded the collection of adequate wave data. From the deepsea wave recordings of the fisheries research vessel Africana II in 1962/63 (ref 1) it was concluded that wave heights of 6,1 m from the west and 5,5 m from the south west occurred in the area about 10 times a year for a duration of 6 hours.

Experienced fishermen in the area maintained that deepsea waves exceeding about 6 m in height would break on a series of reefs situated about 1 to 1,5 km west and south west of the harbour (see figure 2). Under storm conditions this break was continuous right across the bay making the harbour inaccessible. It was therefore concluded that even the highest waves, on reforming, would not exceed 6 m in height at or near the proposed breakwater. (Later wave recordings proved this assumption to be incorrect because of the focussing effect of the reefs.)

The hydrographic survey of the area was also inadequate. The original survey was carried out in a small dinghy with position fixing by theodolites on shore. The high swells and the distance from shore led to inaccuracies and an inadequate coverage of the area seaward of the proposed harbour. Consequently the modelling of the sea-bed was not sufficiently accurate and did not extend far enough out to sea to ensure correct reproduction of the waves in the vicinity of the proposed breakwater. It was not realised at the time that the outlying reefs resulted in marked focussing of waves at certain frequencies on to the line of the proposed new breakwater as shown in figure 6.

Before completion of the model study the pressure for the provision of additional harbour facilities became so great that a contract based on an armoured rubble mound breakwater was advertised on the assumption that minor deviations in the alignment of the breakwater indicated by the model study could be accommodated in the course of the work.

The lowest tender for the work was based on an alternative design by an international construction company for a vertical wall consisting of concrete caissons anchored to the sea-bed with post-tensioned cables. Although a vertical wall was not favoured and it was realised that the seaward face might ultimately require some form of energy absorber, it was argued that the cost of such absorber would be offset by the advantage of a quay on the inside face of the wall.

Considerable doubts had also arisen as to the practicability of obtaining suitable large rubble from the highly fractured quartzitic sandstone in the local quarry. The contract was therefore awarded in 1965 on the basis of the alternative design. Details of the original caisson structure are shown in figure 4 together with the modifications which later proved to be necessry.

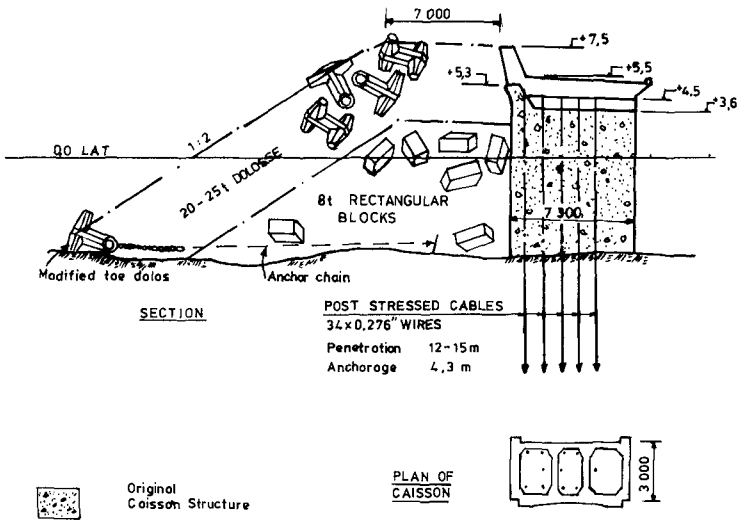

Fig 4. Caisson Breakwater (with armouring added later)

The wall, 6 m wide in shallow water and 7,3 m wide in deeper water, was constructed in open reinforced caissons 3 m long in the direction of the wall and divided into 3 cells with 300 to 400 mm thick walls. The units, approximately 3 m high, were stacked one on top of the other on a bed of broken stone and filled with concrete to within ± 400 mm of the top.

The deck was cast to a level of 3,6 m above low water and 90 mm diameter holes for the installation of the anchor cables drilled to a depth of 12 to 15 m below sea-bed level. The holes were pressure grouted to seal off fissures in the bedrock, interstices in the broken stone bed and construction joints in the concrete structure, and re-drilled. The wires were grouted in over a length of 4 to 5 m at the bottom of the hole, stressed and finally grouted in up to the level of the deck.

During construction of the wall, sea conditions were found to be more severe than anticipated. Placing of caissons was only possible when the wave height was less than about 1,5 metres. Overtopping hampered the work to such a degree that the level of the deck had to be raised from 3,6 m to 4,5 m above low water and the splash wall had to be re-designed at a very early stage of the work.

Fig 5. Wave attack on vertical breakwater

During storms the gantry crane which was specially built for the work and ran on rails concreted into the deck had to be moved back onto land. The crane was washed off the breakwater twice during the course of the work. It also became apparent that it would not be possible to use the wall as a quay and that boats would not even be able to moor near the wall because of the excessive overtopping.

The rock formation on the sea-bed proved to be highly fractured which made sealing of the holes for the stressing cables very difficult. The grouting and redrilling often had to be repeated several times before the hole could be considered watertight. (This method eventually proved to be ineffective in protecting the cables against corrosion. This was proved by ultrasonic tests on the stressed cables in 1977 and confirmed when a portion of the wall was demolished during a subsequent contract.)

When the caisson wall was incorporated in the model the excessive overtopping of the wall and the reflection of waves from the vertical face was clearly demonstrated. It was evident that the reflection of waves from west north west and north west off the last section of the breakwater would result in extremely rough conditions in the access channel to the old harbour. Various remedial measures were considered but eventually a revised alignment was proposed whereby the wall would initially curve westwards and then at chainage 360, bend sharply eastwards so that the first section would reflect waves to the south western shore and the second section would be almost parallel to the direction of the waves (see figure 3).

The adoption of this unusual alignment was unfortunate because it moved the breakwater towards deeper water and a concentration of wave energy near the proposed bend. Refraction diagrams based on more extensive hydrographic surveys carried out later confirmed this focussing effect. An example is shown in figure 6.

As the construction of the wall approached the proposed bend, sea conditions became more severe and the contractor became more and more concerned about the prospect of not being able to retrieve the crane during stormy weather via the sharp bend in the new alignment of the breakwater.

Doubts as to the efficacy of the stressing system increased as the water depth increased and the sea-bed became more highly fractured. Eventually it was decided to abandon the idea of a sharp bend in the breakwater at 360 metres, and to end the vertical wall at 300 metres. The remainder of the breakwater would be constructed as an armoured rubble mound as shown in figure 7 which would reflect less energy into the approach channel.

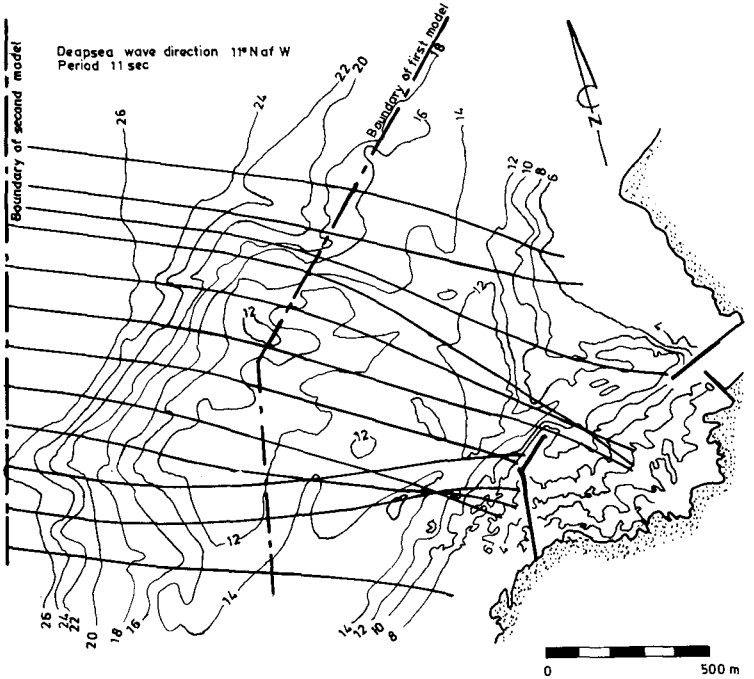

Fig 6. Wave Refraction

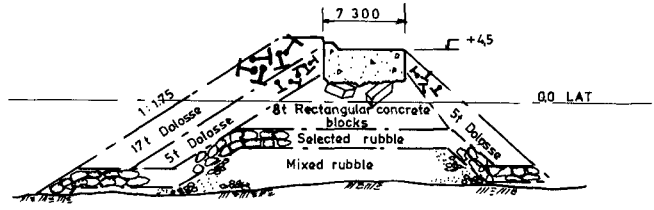
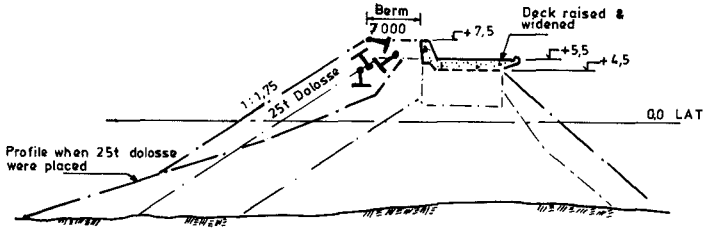


ORIGINAL PROFILE



MODIFIED PROFILE

Fig 7. Armoured Rubble Mound Breakwater

Construction of this rubble mound extension of the breakwater proved to be no less difficult than construction of the caisson wall. The fractured quartzitic sandstone available for rubble in the core contained a high percentage of fines of which large quantities were washed away. Due to the shortage of the specified selected rubble a layer of 5 ton dolosse was initially placed over the rubble core. Later 8 ton rectangular blocks were used for this purpose. These units helped to prevent the immediate loss of core material but allowed considerable quantities of fine material to be leached out with the passage of time. This loss of core material combined with the structural weakness of the 5 ton dolosse, resulted in marked settlement of the deck over several sections. One section of the deck had to be demolished and rebuilt in order to fill the large cavity which had developed under the deck.

Wave recordings which had commenced in 1968 at a depth of 15 m on a position inside the reefs as shown in figure 2, had indicated that waves up to 8 metres could be expected at the breakwater. Further model tests had shown that the 17 ton dolosse used for the armouring might not be adequate. The contractor's plant, however, did not allow for the placing of heavier units at the distances required and the design could therefore not be altered without prohibitive additional costs.

The weakest section of the rubble mound breakwater was found to be at the interface with the vertical wall. This was probably due to the focussing of waves on to this section of breakwater and the lack of interlock between the vertical wall and the rubble mound breakwater. The deflection of wave energy off the flat end of the caisson wall could also have contributed to the damage which occurred repeatedly to the breakwater along this section. Several unsuccessful attempts were made to reproduce this damage in a wave flume and in a later 3 dimensional model study. The damage was probably aggravated by fracturing of the 5 ton dolosse between the core and the deck or the overlying 17 ton dolos layer and possibly by low packing density of the dolosse.

The leeward slope of the rubble mound breakwater which was protected with 5 ton and later 12 ton dolosse also suffered considerable damage in the first year after completion because of heavy overtopping and because of the penetration of wave energy through the highly permeable 5 ton dolos layers underlying the deck. Reasonably successful attempts were made to repair the erosion of the inner face by sealing the cavities with concrete pumped into filter cloth bags and providing a steeper leeward slope so that overtopping waves could expend their energy into the enclosed basin.

It was feared that the roundhead at the end of the breakwater would be particularly vulnerable but it suffered relatively little damage possibly because the armour units were chained together above the low water level.

Although at this stage the objectives of the scheme (i.e. to provide safe mooring space for additional and larger fishing vessels and to improve the entrance conditions at the old harbour where the factory was still situated) had not been achieved, the completion of the rubble mound breakwater in 1969 marked the end of the first phase of attempts to improve facilities at Gansbaai. The fishing industry had by this time entered into a period of decline and additional funds for further development were not readily available.

SECOND PHASE OF DEVELOPMENT

Although the urgency for further development of the harbour had abated, a number of questions regarding the durability of the completed portions of the work had to be resolved. The overall stability of the rubble mound breakwater was a matter for concern because of the quality of the rubble and the inadequate mass of the armouring of 17 ton dollosse. (This concern was proved to be justified when a section was destroyed in 1979 shortly before it could be reinforced with 25 ton dollosse.)

An even more serious problem was the uncertainty regarding the stability of the caisson wall. This wall which had originally been designed with a factor of safety against overturning of 1,5, had subsequently been raised from an effective height of 3,6 metres above low water to 4,5 metres above low water and was also being subjected to attack from waves higher than the original design wave height. New calculations had shown that the factor of safety was lower than originally intended. Factors such as the force taken up by the higher splash wall, an occasional higher still water level due to set up and transverse resonance (recorded locally and confirmed by a mathematical analysis by the Danish Hydraulic Institute) were taken into account. The higher SWL also accounted for higher overtopping than expected.

A series of two dimensional tests confirmed that the factor of safety was nearer 1,0 and in some sections of the wall probably less than 1,0. The 2 dimensional tests which were being conducted to investigate the caisson stability were extended to explore various ways of reducing the overtopping of the wall (such as different shapes of splash wall and a lower splash wall on the seaward side with a secondary splash wall on the leeward side).

Serious doubts had also arisen regarding the soundness of the stressing cables which supplied the major proportion of the moment of resistance against overturning. Ultrasonic tests conducted in 1977 (ref FDC report F92-2) revealed that these wires were in fact seriously corroded especially at the interfaces between the caissons and the sea-bed and the caissons and the deck slab. The continued stability of the wall could probably be ascribed to the angle of wave attack which resulted in the forces on the wall only reaching maximum values over very short sections of wall at any given instant and the transfer of these forces to adjacent caissons through the deck and the keys between the caissons.

In order to solve the many problems which had by now been identified, i.e. stability and excessive overtopping of the completed new breakwater, and also provide design guidelines for the completion of the harbour works preferably as one combined larger harbour, a second 3 dimensional model study was commissioned in 1975. Again the FDC would be responsible for the field work while the CSIR would carry out the model study.

An intensive study of the wave regime was carried out between July 1975 and September 1978. To obviate the mistakes which had occurred in the first model a series of three "Waverider" recorders were installed seaward of the reefs and one waverider nearer the breakwater. As the direction of wave attack on the breakwaters had proved to be critical, a wave direction recorder (DOSO) developed by the FDC was installed seaward of the reef close to the central waverider. The effect of the reefs on wave refraction could therefore be accurately determined. The positions of the recorders are shown in figure 2.

More detailed hydrographic surveys were also carried out (including side scan surveys to determine the shape and nature of the rock strata). Accurate refraction diagrams, verified by numerous aerial photographs under the complete spectrum of wave attack, as recorded by the 4 waveriders and DOSO were used to calibrate the wave reproduction in the model. The model was constructed on a scale of 1 in 80 over a much larger area than for the previous model in order to reproduce the wave regime as accurately as possible.

The result of the 2 dimensional tests on stability of the caisson wall were verified in the 3 dimensional model by constructing the caisson wall of 100 mm wide hinged box sections fitted with strain gauges at several elevations. The forces and overturning moments were determined and the results compared well with those of the previous 2 dimensional models.

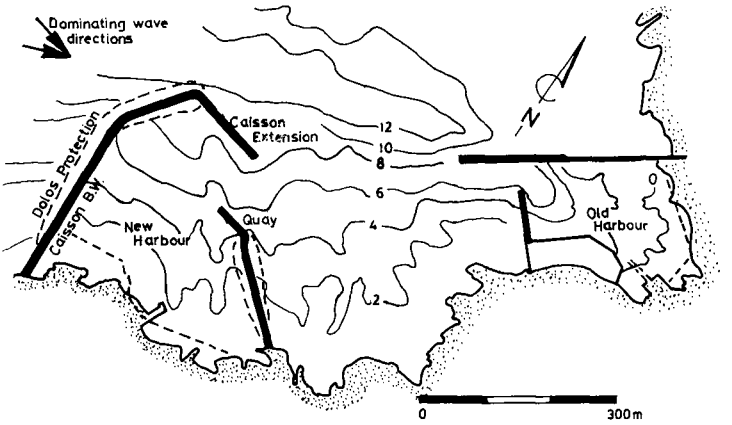


Fig 8. Revised layout of new harbour

Many different alignments, sections of breakwaters and absorbing structures seaward of the caisson wall were tested under all recorded wave directions, heights and periods, as small variations in these parameters affected the focussing of waves along the breakwaters considerably. A solution was found for the safeguarding of the existing new breakwater and an extension of this breakwater to create satisfactory entrance and mooring conditions in the "new" harbour was successfully tested. No really successfull solution was found for the combination of the old and new harbours because of the distance between the ends of the main breakwaters of the two harbours. One layout tested involved the construction of a T-breakwater halfway between the two harbours. The cost of this scheme, however, rendered it unacceptable. Even the most favoured scheme involving the extension of the north breakwater of the old harbour was not justifiable. The main part of the model study was completed in 1978 but additional tests involving mainly construction techniques continued up till 1981.

In 1978 it was decided to proceed with a scheme involving the safeguarding of the existing caisson and rubble mound breakwaters, the extensions of the rubble mound breakwater and the construction of a quay and approach mound from the southern shore. This would enclose a protected water area of approximately 7 hectares of which 3 hectares would have a water depth exceeding 4 metres at low tide.

The measures adopted to protect the existing caisson and rubble mound breakwaters took into account the variation in design wave height along the length of the wall in the design of deck and splash wall height, mass of armour units and width of berm at the top of the armoured layer. The final deck height was 5,5 m above low water and the top of the splash wall varied from 6,5 to 7,5 m.

20 and 25 t dolosse placed to a slope of 1:2 on a core of 8 t corrugated rectangular blocks were used on the outside of the caisson wall as shown in figure 4 and 25 t dolosse placed to a slope of approximately 1:1,75, were used to protect the rubble mound breakwater as shown in figure 7. A horizontal 7 m wide berm at splash wall level (7,5 m) was used for additional absorbtion of wave energy.

Specific attention had to be given to the stability of the toe of the dolos layers because of the relatively smooth sea-bed seawards of the caisson wall coupled with reflected wave energy from the wall. Model tests indicated that the toe line of dolosse would move out of position at relatively low wave heights (1,5 m). A special reinforced "toe dolos" was developed with a lowered centre of gravity to prevent overturning and with two projections on the ends of the lower fluke to prevent rocking (see figure 9). To prevent sliding these dolosse were tied back into the mound with heavy chain and a rudimentary anchor.

Fig 9. Reinforcing of toe dolos

Fig 10. Storm damage to rubble mound breakwater

The contract for the above work was awarded at the beginning of 1979, but in August of the same year, before any remedial work could be carried out, a major storm breached the existing rubble mound breakwater. Other storms followed and eventually almost 60 m of the breakwater was destroyed as shown in figure 10. Model studies were again carried out to determine the most effective way of repairing the breach, and a construction method using 8 t corrugated concrete blocks as a core with a double layer of 25 t dolosse as armouring was eventually successfully used. During the repairs to the breach the junction between the vertical wall and the rubble mound breakwater was reconstructed. The section of the vertical wall extending beyond the rubble mound breakwater was eliminated and a smooth curve introduced. Fortunately no severe storms occurred during these critical stages of the work.

The extension of the main breakwater by means of another vertical wall more or less parallel to the direction of the waves and the construction of a secondary breakwater with caisson quay from the eastern shore were also completed without serious problems.

CONCLUDING REMARKS

The construction of the extension to the Gansbaai fishing harbour has been successfully concluded but only after a disproportionate volume of model testing and other investigations. The project was carried out over a span of almost 20 years which coincided with a period of rapid development in the science of coastal engineering.

The initial mistakes were due to inadequate field data, a lack of appreciation of the effect of distant topographical features of the sea-bed on the wave regime, the adoption of an untried design without model testing and the commencement of construction before completion of the model tests.

The project has highlighted the need for closer co-operation between research personnel, designers and contractors.

REPAIR TO A DOLOS ARMOURED BREAKWATER

1. Introduction

In recent international experience several breakwaters armoured with concrete units have failed shortly after or during construction of the structure. Although investigators have not necessarily agreed on the causes of these failures, it has been generally implied that there is a relationship to breakwater construction in deep water with large units and severe wave conditions (4,9). However, the damaged sections of the dolos armoured breakwater that is the subject of the paper, are in water depths of 6 to 8m with depth limited wave conditions.

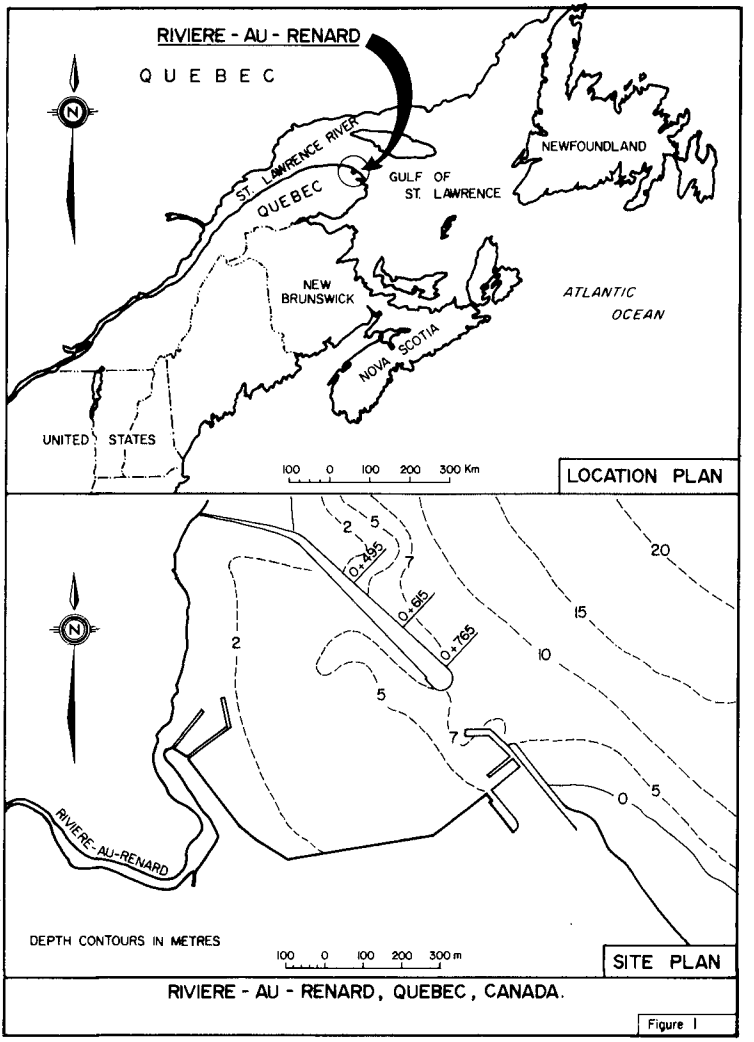
The original design parameters for selecting the dolos weight appear to have been reasonably accurate by current estimates. The recent hydraulic model tests indicate that the breaking wave conditions and overtopping of the breakwater have combined with the breakage of dolosse in the resulting failure.

The recommended repair work which was the primary objective of the study, consisted of armouring the crest of the damaged section with large stone (20t) and leaving the damaged front layer of dolos below low water level. It was judged that the further use of concrete dolosse was not economically justifiable and that there did not exist a satisfactory procedure to design dolos armour within the scope of the study.

2. Site and Damage Descriptions

2.1 Location and Breakwater

Rivière-au-Renard is located on the eastern end of the Gaspé Peninsula on the Gulf of St. Lawrence in Québec, Canada. The main breakwater is about 785m in length and encloses a natural bay to protect a fishing harbour facility. The breakwater construction was completed in 1972 (see Figure 1).



RIVIERE - AU - RENARD, QUEBEC, CANADA.

Figure 1

The outer portion of the structure of about 350m in length, was armoured with concrete dolos units of two sizes. Units at the head are 12.7t and extend back about 30m on both front and back slopes in water depths of 7 to 8m. Dolosse in the trunk are 4.5t and cover the crest and front slope only in depths of 4 to 7m. Typical cross-sections are shown in Figure 2. Unit placement was in double layer random in the densities estimated from the S.P.M. (1)

The design crest elevation of the breakwater varied from 5.3 to 8.0m over the concrete armoured section of the structure.

2.2 Construction

Some problems were encountered during construction which may have had a bearing on the subsequent damage.

Initially the contractor had some difficulties obtaining the required strength specification of 31 MPa at 28 days. An unspecified number of units near the time of the job completion were placed after a striking time of about 12 hours.

The contractor was also allowed to cover sections of the crest filter layer with quarry run material to permit equipment access. This finer material was not removed from the filter layer.

2.3 Damage Surveys and Inspections

Rivière-au-Renard has been cited in previous publications as an example of a successful dolos installation (7). It can no longer be considered as such.

In 1978 it was visually observed that the crest elevations in sections of the main trunk had decreased. Storms in the fall of 1980 eventually opened a major breach at one location and severely damaged another section, both in the 4.5t units.

Field inspections in 1981 revealed the following:

- There was a high percentage of broken dolosse along the full length of the structure including the 12.7t head section. Estimates for broken units on the front slopes above and below mean water level ranged from 10 to 50% not including the areas of the breaches.

- The major breach extended for a length of about 50m and a typical section is shown in Figure 3 (i.e. Section +615). Estimates of broken dolosse in the breach are about 30% on the front below low water, 90% on the crest and front above low water and 65% on the back.

- The secondary breach was in deeper water but extended only 10m in length and was not as extensively damaged. However, dolosse were also piled at the back side of the breakwater (section not shown).

Figure 2

- Overall the slopes were very steep on the landward side of the structure in the area above mean water level. It appeared as if the dolosse in the crest area had been pushed back en masse (see Figure 3 of Section +495), however it is not known whether the original placement met specifications. Seaward side slopes were varied and irregular but showed some tendency to form an 'S'-shape.

- The 12.7t dolosse at the breakwater head showed unusual and steep slopes that could not be accounted for without assuming significant deviations from the design specifications (see Figure 4 of Section +765).

- Over most of the breakwater crest the visible filter layer material appeared to be composed of or filled with much smaller core type stone.

- Most of the rock berm protecting the front toe was either damaged or missing and in areas where the structure resided on sand there was a small trough in place of the berm.

3. Original Design Parameters

Although details of the original design calculations are not available at the time, the Hudson stability formula was used with the K_D, or stability coefficient probably of the order of 15 to 22 for the breakwater head and trunk respectively in breaking waves on a 1 to 2 slope. Assuming a K_D of 22 for the trunk on Rivière-au-Renard, the 4.5t dolos were designed for a wave height H = 5.1m; similarly for the 12.7t dolos with K_D of 15 the H = 6.3m (Note: slope was 1 to 1.5 vertical to horizontal).

The design crest elevation of the dolos section ranges from 5.3 to 8.0m above datum and high water large tides are 2.44m. At the time of the design and even to date, there are very limited data available for estimating wave runup and overtopping and the effects on the breakwater stability (8). However, it would appear the breakwater was intended to be overtopped especially in the initial sections of the 4.5t units. In fact, economic considerations likely dictated minimizing material quantities.

To verify the original design data, wave conditions were hindcast from wind data over an 11 year period by a system of computer programs based on the S.M.B. technique (2). The system produces hourly values of significant wave height and peak period by deep water compass directions. Within this period of data, the largest significant wave heights are of the order of 6.5m with an associated peak period of 12 to 14s. The deep water wave directions for these conditions are almost perpendicular to the breakwater alignment. The wave climate in 1980 reaches similar levels to the previous 10 years, however, the occurrences of the high conditions are greater than the average year.

Figure 3

No detailed refraction analyses were undertaken for this study. The bathymetric contours are reasonably uniform and parallel to the breakwater and the higher waves approach such that there would only be a slight reduction in height due to refraction. The depths and slopes in the approaches are such that larger waves are depth limited and break offshore and in front of the breakwater.

It appears that the original 'design wave' data used were of the correct order of magnitude with the possible exception being the selection of the height for the 4.5 t dolos. It is noted that significant damage has occurred in the larger units as well. The design is complicated by other factors such as overtopping and breaking of waves, however the resultant level of damage indicates that the analysis procedure for stability is not adequate for concrete dolosse.

4. Hydraulic Model Study

4.1 Background

The primary objective of the test program was to recommend remedial works to the breached sections of the breakwater with the 4.5t dolos. Consideration was given to replacing the lost armour material with concrete units of different types or sizes and with large armour stone.

The model test facility available at the time was the 1.8m wide wave flume at the National Research Council Canada in Ottawa. The flume is approximately 1.25m deep by 67m deep and has the capability of generating and measuring irregular waves. Model dolosse were available in two sizes in a sulphur concrete material that gives the units correct specific gravity and dimensions but does not scale concrete strength (i.e. units are not breakable in model loading conditions).

The model scale chosen was 1 to 35 linear such that weight and volume were proportional to the cube of the length scale. Preliminary calculations had indicated that much heavier armour material would be needed but it was also required to model the existing failure as well as possible in the 4.5t units. This presented a conflicting requirement as only one scale could be used within the time allotted. The result was that the smaller lab units were modelled as 12.8t in prototype and these units were in fact used in the 4.5t breached section. This did not represent a gross inaccuracy since the prototype dolosse in the breach were essentially all broken pieces and tests were not intended to totally recreate the whole failure process. The approach slopes in the flume were modelled out to a prototype distance of 800m and depth of about 30m and the modelled section was .9m in width.

Wave conditions generated by each test were for irregular sea states (6). The measurement system in the flume consisted of three wave probes at locations along its length. The wave conditions generated for the tests were selected combinations of deep water significant wave height and peak period, as listed in the following prototype parameters: 2.5m and 6s; 4.0m and 8s; 5.1m and 10s; 6.2m and 12s; 6.8m and 14s.

4.2 Test Series

In general, the wave conditions were run on a test section by starting at low levels and increasing to the maximum with a constant water level (usually at high tide). Each wave condition was run for 15 to 30 minutes in model time (note: time scale approximately 1 to 6 for model to prototype).

4.2.1 Damaged Section +615

Section +615 was chosen as the model section that was typical of the main breach. Two tests were run on this section before remedial works were undertaken. The section was constructed with deliberately broken dolos pieces in the percentages indicated from surveys and diving inspections. The purpose of testing this section was to observe the wave-structure interaction at this stage of damage and to devise repair work accordingly.

The following are observations of the hydraulic tests and describe the progression of the failure at this stage:

- Dolos pieces were rocking and displacing at low wave heights (i.e. 4.2m).
- Overtopping occurred for 4m waves or larger and was quite severe at higher levels.
- Units and pieces below low water on the front became packed after initial movements and remain stable.
- Dolos pieces at the leading edge (i.e. front at crest) were pushed across the top and piled up at the back of the crest.
- Dolos units and pieces were progressively pushed over and rolled down the back slope.
- The crest was eventually stripped level to the core.
- The core became dished out behind the leading edge of the armour allowing more pieces to move across the top.
- Continued wave attack piled a mixture of all the materials behind the back slope.

It was concluded that heavier armour material would be required on the crest to prevent units from being rolled down the back from wave overtopping. Given the excessive movements of modelled dolosse and the evidence of breakage even in the 12.7t prototype units, it was assumed that a small increase in dolos weight would not be an adequate remedial measure. However, a large increase would not be economical especially since there were no available methods to estimate the structural loadings and behaviour of dolosse.

4.2.2 20 t Armour Stone

Three remedial test series were undertaken using 20t stone to fill the breach of Section +615. These included a single layer of armour stone, a double layer and a double layer with additional filter stone added (i.e. each section elevation was progressively increased).

The single layer was built directly over a tested section and run through a complete wave series at mean water level. The section was severely overtopped but remained stable. One or two stones were displaced near the front.

The double layer section was constructed by placing more armour on the previous test section. The section was run at mean water level for the 6m wave conditions. Overtopping was still occurring, but the section remained stable with no armour stone displacements.

The third test was constructed on a rebuilt damaged section and included 1 to 5t filter stone beneath the double layer of armour such that the original design height was achieved. The section remained stable with no armour displacements though it was still overtopping at higher wave conditions.

4.2.3 15 to 11 t Armour Stone

A series of tests using a double layer of smaller armour stone to repair the breach were undertaken in response to initial indications that sufficient 20t stone might not be available. The two test series were constructed over the damaged section and included 1 to 5t filter stone. The heavier armour (15 to 13t) was placed at the front of the crest and the lighter (13 to 11t) to the back of the crest.

The first test section was constructed to the original breakwater height and run at mean then high water level. The armour on the front experienced some initial rocking with no displacement while several stones were displaced down the back at the 6m wave conditions. During the high water level conditions one stone was displaced at the front, two or three more at the back and the overtopping was severe. The section remained stable but sustained significant damage on the back of the crest.

The crest elevation was raised by about 1.5m in the second test section with the increase provided by adding core material in the centre of the breach. At mean water level the section initially resisted overtopping but the 13 to 11t stone began to be rolled down the back with 5m waves. After continued testing at higher wave conditions and high water level, the elevation of the front crest was decreased by 2m and the back by 3m. The severe overtopping eventually stripped the back of the crest down to the core material.

4.2.4 12.8 t Dolos

Two test series were undertaken using 12.8t dolosse in the cross-section configuration of the original trunk design to provide a limited assessment of the stability of the units and the causes of the failure.

The first test used all intact units and appropriate filter layers. These tests began at mean water level and indicated rocking of several dolossse on the front crest near still water level for 4m waves and greater. The rocking was quite severe at higher wave conditions and at high water level there was a major displacement of units down the back. Further testing could not properly simulate the failure at Rivière-au-Renard as the dolosse in the model were not breakable.

The test was repeated with broken pieces introduced in the front of the crest down to low water level (i.e. about 30% broken units). The section went through the stages of: units and pieces rocking at the front then displacing down the front; gaps opening in the front; several units being rolled over the back; units and pieces at front below low water stabilizing; the top of the crest being eaten down to core with material piled over the back. The results appeared to be similar to the damaged section at the site.

4.3 Summary Comments

Under the severest of wave and water level conditions, the 20 t armour stone remained stable. The 15t stone indicated adequate stability with only a minor displacement, however lighter units experienced significant displacement.

The tests with dolosse demonstrated the necessity to account for the breakage of units in hydraulic modelling though the techniques used here cannot readily be proposed for other applications.

5. Conclusions

5.1 Hydraulic Tests

Within the limitations of the test procedures, the model appeared to give a reasonably accurate scenario of the intermediate stages of the failure. Sections in the model were shaped in a similar manner to those in the breach and materials were damaged or displaced in the same areas.

The model did not account fully for the structural behaviour of the dolosse even with pieces artificially injected and it may be subsequently argued that their performance in all the test series is not valid.

The model was not used in a predictive manner to estimate number of storms vs degree of damage and it is not possible to accurately estimate the time frame for the survivability of the existing breakwater. However, it would appear that the remainder of the breakwater is susceptible to a similar mode of failure at any location (probably in 4.5t section first).

5.2 Causes of Failure

It is not clear that any one specific factor has resulted in the extensive damage to the breakwater at Riviere-au-Renard. It may be more broadly attributed to the design procedures recommended for concrete dolos units.

The breakage of the dolosse at the front and crest appears to precipitate an almost total destruction of the units in a particular area. The breakage appears to be related to the potential for rocking or displacement of individual dolos and the unit's inability to resist the resultant loadings (3). The model tests indicate that the breached sections would not have failed in the observed manner if the units had remained intact. However, this is not conclusive in that heavier units were used in the hydraulic testing compared to the prototype dolosse in the breached sections.

The hydraulic testing and prototype surveys (even for the heavier dolos) demonstrated a mode of failure due to overtopping that could not be accounted for in the original design procedure. The severity of the overtopping was capable of displacing units from the back of the crest and down the slope. This phenomenon is related to a number of factors such as the height of the breakwater, the breaking wave conditions at this particular site and the degree of absorptivity of the filter layers beneath the dolos armour.

5.3 Remedial Works

Based on the hydraulic studies and the performance of the existing dolosse, the recommended remedial work consisted of filling the breaches with a double layer of 20t armour stone (17t minimum) and filter material of 3 to 5t. Dolosse were not recommended as there was no satisfactory design process to ensure that an increased size or a reinforced unit could withstand the loadings in the breakwater. The selection of a heavier concrete dolos (i.e. above the 12.4t) would not have proved economical or have provided any guarantee of the unit's structural integrity.

It was assumed from observation of the model tests that the existing dolos armour on the front slope below low water would remain stable. However, it is recommended that regular inspections of this area are undertaken to assess this assumption.

The repair was undertaken in the fall of 1981 and the breakwater was inspected in the summer of 1982. The remedial work had remained stable though a new breach appears to be in the process of opening between the two rearmoured sections. It appears that a long term solution will be required to maintain the remainder of the breakwater.

6. Acknowledgements

Special thanks are due the staff of the National Research Council Canada under the direction of Mr. J. Ploeg for assistance in the construction and operation of the model at the hydraulic laboratory facility in Ottawa.

ZEEBRUGGE'S MAIN BREAKWATERS

ir. L.V. Van Damme*

ABSTRACT

The design scheme of the Zeebrugge Outer Harbour, Belgium, consists mainly of two breakwaters protruding into the sea as far as 1,750 m beyond the existing môle or 3.000 m out from the coastline. The west outer breakwater is 4,450 m long, the east breakwater runs 4,300 m out from the seafront. The east outer harbour will accommodate terminals for liquid bulk products such as LNG. The west outer harbour will provide space to install two harbour bassins to suit general cargo, hazardous cargo, container and ferry traffic.

In the paper emphasis is put on the environmental design conditions (wave height, wave period, water depth), the development of preliminary designs and the final design. Some design features such as dimensions, wave breaking carpet, armour units, workable limits in respect to rock grade, etc ... are discussed.

By developing the design the rubble-mound breakwater has been judged to be the only viable alternative versus the caisson type breakwater, taking into account costs, technical risks, construction problems and flexibility under changing environmental conditions.

The main feature of the breakwaters is that a huge concrete parapet will have been avoided. A so called flat semi-cube armour unit has been developed. The main advantage lies in the substantial economic benefit whilst maintaining the same stability performance as a concrete cube armour unit.

* Principal Engineer, Ministry of Public Works, Ostend, Belgium

1. INTRODUCTION

The construction of the existing port of Zeebrugge has been a royal decision, pronounced by H.M. King Leopold II in 1881. A few years later the construction started and in 1907 the port has been inaugurated.

Almost a century later, in 1970, the Belgian Government decided to the extension of the port complex. Prior to this decision the port has been adapted to the prevailing traffic demands whilst remaining within the boundaries set by its initial development scheme of 1907. The annual throughput has been some 10 million tons in 1971 and 15 million tons in 1981.

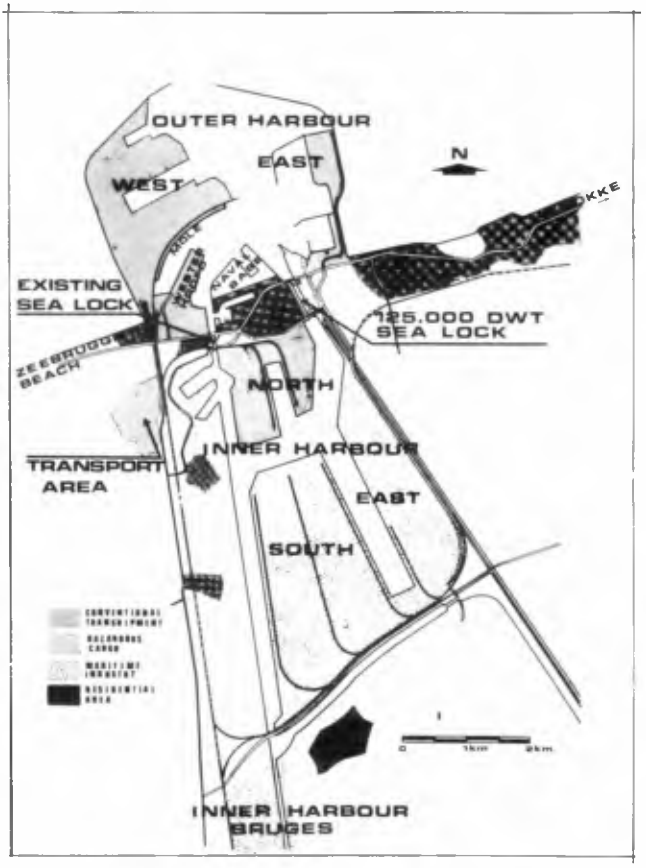

Fig. 1 : General layout of the Zeebrugge Port Extension Scheme

The master plan finally adopted provides 3,370 ha sub-divided (fig. 1) as follows :

- Outer harbour, including the existing outerport and naval base 1,165 ha
- Inner harbour 1,705 ha
- Port area of Bruges 450 ha
- Transport area 50 ha

The design scheme of the outer harbour consists mainly of two breakwaters protruding into the sea as far as 1,750 m beyond the existing môle. The west outer harbour breakwater is 4,450 m long. The east breakwater runs 4,300 m out from the seafront (fig. 2). The east outer harbour will accommodate terminals for liquid bulk product such as LNG. The west outer harbour will provide space to install two harbour basins to suit general cargo, hazardous cargo, container and ferry traffic.

2. PLANNING

The first phase of the east outer port sets up a newly built work harbour as the existing outer port is congested and no space is available to install the necessary harbour facilities and construction site yards.

Only the mound type has been retained for the service-port breakwaters. The sand-asphalt mound with open stone asphalt revetment has been selected against the rubble mound design by balancing construction costs, design and construction risks and practical construction aspects.

The southern east breakwater has been conceived as a sandfilled peninsula of ca. 36 ha. in order to install the land-based LNG-terminal facilities. The perimeter and sea defence of this peninsula are provided by rubble-mound breakwaters of ca. 1,360 m long to the west ca. 1,200 m long to the east and a north closure of ca. 500 m long.

The armour layers and inner slopes have been adapted to wave conditions and exposure time. The west slope (1:2) with 20 T cubic concrete blocks in single layer, the east slope (1:2) in quarry rock 3/6 ton grade and the north slope (1:1,5) in double layer 25 T cubic concrete blocks. The inner slopes vary from 2/300 kg quarry run to quarry rock 1/3 ton grade in double layers. Several design alternatives following different construction schemes and methods have been contemplated. Special attention has been paid to the filter construction between the rubble cores and the hydraulic sand-fill. (fig. 3)

The LNG-harbour proper will be completed by a semi-curved 975 m long, low crested rubble mound, the so called LNG-breakwater. The layout, planning and design of the LNG-terminal harbour works have been finally adopted to satisfy the stringent and draconic time schedule of the LNG-terminal project as a whole. (fig. 2)

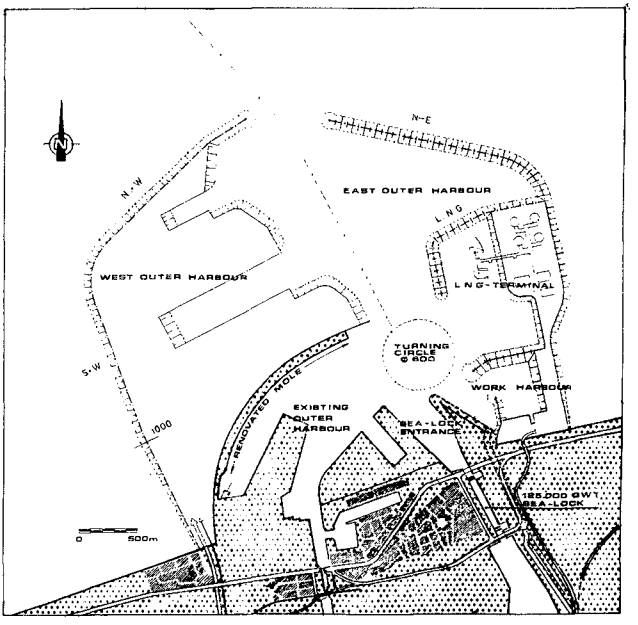

Fig. 2 : Layout Masterplan Zeebrugge Outer Harbour

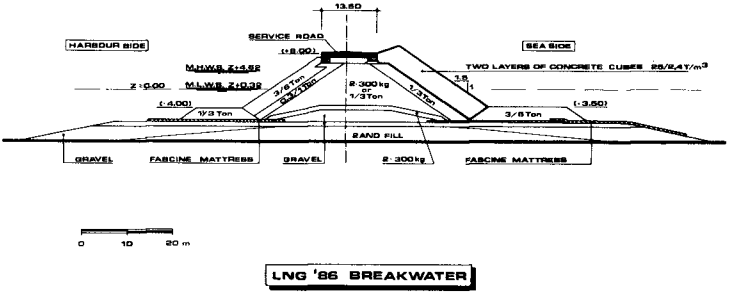

Fig. 3 : Typical cross section LNG '86 - breakwater

The northern section of the east breakwater is ca. 2,000 m in length. The west breakwater will be 4,400 m long. Up to 1,000 m out from the shore, the area between this breakwater root-section and the ancient môle has been hydraulically filled with seasand to create a secondary work and marshalling yard for the quarry rock to be worked up by truck dumper and crawler crane into the west breakwater. Because of the adjoining sandy beaches of the holiday resorts, this breakwater section has been conceived with due regard to the environmental visual impact.

In general the design up to the Z-4.00 bottom contour line (ca. 1,000 m out of the seafront) consists of a core built successively in sand, brick debris and quarry run with a concrete open pavement revetment on sublayers of crushed gravel and quarry rock of grade of 2/300 kg to 1/3 tons.

3. ENVIRONMENTAL DESIGN CONDITIONS

3.1. The **bottom** depth in the alignment of the outer harbour breakwaters ranges fairly between Z-5.00 and Z-7.00 (chart datum Z = mean low water spring + 0.08).

3.2. The **tide** is semi-diurnal with levels ranging from amplitudes of 4.40 m at mean spring tide to 2.80 m at mean neap tide. The **meteorological** set-up is up to 2.45 m in the defined design period and probability of exceedance.
The **tidal currents** at the final breakwater alignment will be (at surface) 1.2 m/s to 2.00 m/s at spring flood tide and 1.0 m/s to 1.6 m/s at spring ebb tide.

3.3. The **soil conditions** in the Zeebrugge area are rather difficult. A comprehensive geotechnical survey was undertaken with boreholes, static cone penetration tests and continuous seismic profiling.

The synthetically recorded geological profile is presented in fig. 4. The striking point is the rather pronounced accidental surface separating the tertiary sediments and the quaternary coverlayers. With as main feature the cuesta of the Bartonian clay formation with dips up to 30 % .

The less resistant bottom "sandwichlayers" consisting of alternate thin layers of soft clay and sand, mainly ca. 4 to 6 m in thickness, cover in the wester breakwater alignment, a considerable deposit of fairly dense to densely packed quaternary sand. In the eastern-alignment the deposit of quaternary sand is up to 15 m thick upon the tertiary Bartonian clay deposit. This tertiary layer rises towards the sandwich voverlayer at the head eastern breakwater.

4. DESIGN WAVE CONDITIONS

4.1. Design wave height

From 1958 to 1971 waves are systematically measured by shipborne wave recorders at the WESTHINDER lightship more than 40 km from Zeebrugge. Since 1977 wave riders record steadly at several locations in the vicinity of Zeebrugge. The measured data transmitted is analysed and synthesized by computer to statistical profiles of several relevant wave parameters.

The preliminary and final designs are based on the wave climate derived from the WESTHINDER data by refraction analyses. This analysis being carried out for different approaches, wave periods and waterlevels. The analysis showed that the existing seabed gives areas of wave concentration at the northern west and east breakwater with coefficients from 1.4 up to 1.9. The channel Pas van 't Zand / Ribzand dissipates wave energy, the coefficient at the planned harbourmouth can be 0.5.

The detailed designs are based on the more long-term wave data (1958-1971) compared and correlated with the more short-term measurements from the wave-rider buoys. In the graphs 5 and 6 the results of the comparison with the wave rider data of January '78 to December '80 is explained. Summarized :

- For the same probability of exceedance the originally established wave heights (H_S) are, compared with the wave rider values, over-estimated by :

  0.40 to 1.40 m at the N.E. - breakwater
  0.40 to 0.70 m at the W - breakwater
  0.10 to 0.50 m at the harbour entrance

- The design wave height of the outer harbour breakwater $H_S = 6{,}10$ m needs not to be changed as it is still defined by the limiting waterdepth.

- The design wave height of the LNG-breakwater and other breakwater sections defined by an average annual exceedance of 10 % (short-term risks of less than 5 years of exposure time) can be changed from $H_S = 5.75$ to 4.90 m.

- The workability defined on the $H_S = 1.00$ m and $H_S = 2.00$ m threshold values has been underestimated by roughly 7 to 8 % .

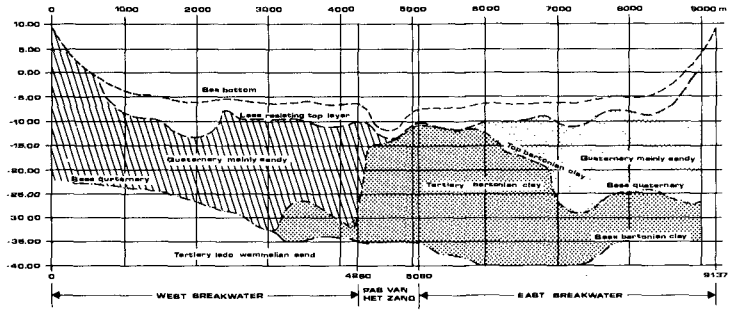

Fig. 4 : Geological profile outer harbour breakwater alignment

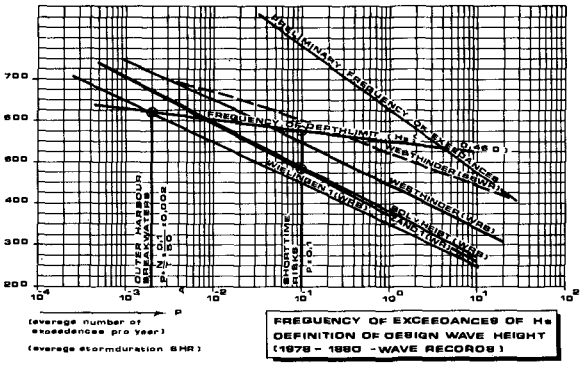

Fig. 5 : Wave height distribution - re-iteration and comparison procedure (wave rider measurements '78 - '80)

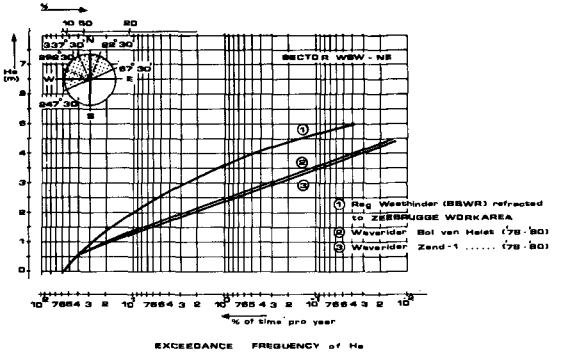

Fig. 6 : Wave climate at the Zeebrugge worksite

4.2. Design wave periods

From the Westhinder wave measurements and from the 1977 recorded wave-rider data the following conclusions can be made :

- the maximum mean period : 7 sec.
- the maximum mean peak period : 9 sec.
- the highest peak period measured : 10 to 11 sec.

As in the wave flume and wave tank studies performed by the LCHF at Maisons-Alfort, wave-trains are applied, the 9 sec. period is used finally for stability research and the 10 to 11 sec. period for research of phenomena during overtopping at maximum uprush.

4.3. Summary of design wave height conditions

The design wave height conditions, amended on the basis of the '78 - '80 wave records, are summarized in following table (fig. 7). By defining these conditions, the risk of exceedance of the design wave height has been fixed at 10 % in the design life or exposure time. For short wave risks (max. 3 to 5 years of exposure time) an average yearly frequency of 10 % has been taken. This results in the adopted design wave heights and risks levels reported in the table.

	Workharbour Northern breakwater	Southern East breakwater			LNG breakwater	Outer harbour breakwater		
		East	North	West		SW	NW/NE	Mouth
Design wave height H_s (m)	4.00	3.00	5.75	5.75	4.90	5 à 6	6.10	6.10
Design see level (m)	Z + 5.20	Z + 6.85	Z + 6.00	Z + 6.00	Z + 6.00	Z + 6.85	Z + 6.85	Z + 6.85
Accepted damage (%)	-	0-5	0-5	5-10	0-5	0-5	0-5	0-5
Probability of exceedance (%)	40	10	40	25	40	10	10	10
Lifetime or exposure time (year)	5	50	5	3	5	50	50	50

Chart datum Z = mean low low water spring + 0.08

Fig. 7 : Table : Summary of design wave height conditions

5. DEVELOPMENT OF DESIGN

5.1. For the LNG-breakwater and outer harbour breakwaters two main alternatives have been contemplated in the project definition and pre-project design stage :

- Rubble mound breakwaters
  designed according to different construction methods e.g.
  - mounds worked up over the constructed core by truck dumpers in combination with or without hydraulic dumped sand-fill. (fig. 8 and 9)
  - mounds with rubble cores and armour revetments worked up by purpose-built barges.

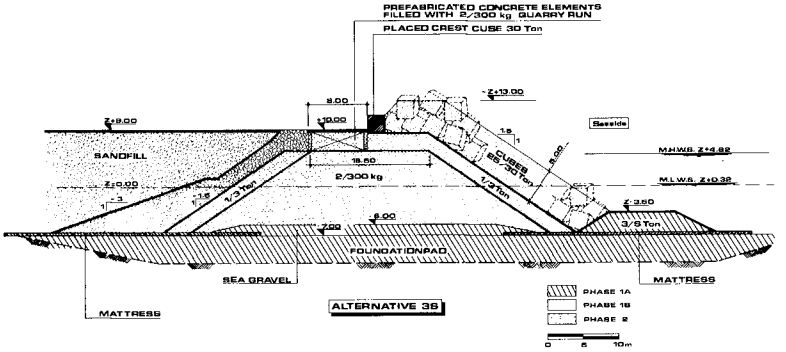

Fig. 8 : Development of design : rubble-mound breakwater alternative 3 b - core built by dumping over the head

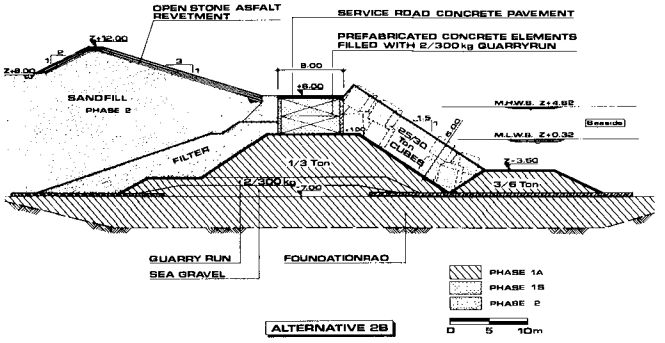

Fig. 9 : Development of design : rubble-mound breakwater alternative 2b - core built by dumping barges

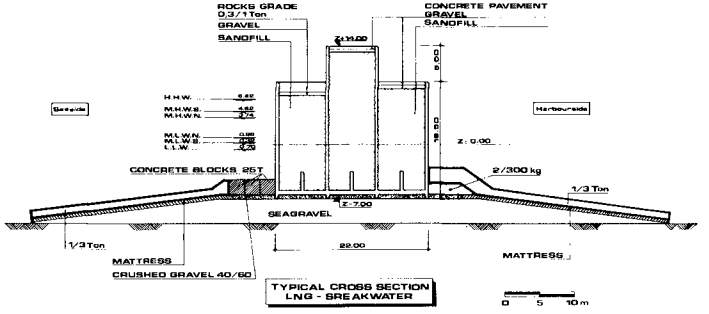

Fig. 10 : Development of design : caisson type breakwater (typical section at LNG-breakwater site)

Caisson breakwaters
prefabricated and floating caissons sunk on a prepaired foundation bed. Fig. 10 shows the conceptual design for the LNG-breakwaters.

After balancing the criteria of costs, risks, technical equivalence and construction aspects the hydraulic sandfill independent rubble breakwater type has been selected (3b).

The latter being amended for the southern west breakwater. As these sections are designed finally with an inner sand-beach, constructed simultaneously with the breakwater core.

5.2. The caisson type breakwater was judged to be unfeasible for the outer harbour breakwaters due to the unadequate soil conditions.

This initial conclusion should be amended. Indeed, the caisson type breakwater should be feasible as for almost all breakwater sections, now under construction, the detailed design specifies a foundation pad realized by a soil improvement by replacement of the soft layers with coarse dumped seasand.

As a matter of fact by the conceptual design of the breakwaters, in 1977/78, the seaworthy cutter-suction dredgers needed for such a foundation concept in unprotected waters, were not available. It was only later, during the construction of the northern service port breakwater and the LNG-terminal peninsula, that this soil improvement technique was successfully developped.

However the introduction and development of the soil improvement technique by replacement in open sea with dumped sand highlights once again the flexibility proper to the rubble mound design concept !

Indeed the soil amelioration technique has been assessed by evaluating the alternative of a mound laid directly on the existing seabed, where the overall stability is given by equilibrium embankments at both sides. Even in the instances of allmost equal costs, the soil improvement profile still offers a more controlled construction and a foundation bed with a higher quality level.

However, when choosing between rubble mound and caisson type breakwaters the other criteria are still valid.

- flexibility : the rubble mound offers more possibilities not only through adaption to local soil conditions, but also to the specific hydraulic conditions at the site (currents, waves, sedimentation, erosion, etc...).
- costs : compared with the rubble mound, the technical equivalent caisson type costs ca. 33 % more.
- construction risks : the construction problems on a site as Zeebrugge, exposed to waves, currents and siltation are of paramount importance by caisson type breakwaters.

6. FINAL DESIGN

The final design on the retained concept, the 3b-alternative, was finished in June '81. It consists mainly of (fig. 11) :

- *A foundation pad*

  A soil improvement by replacement with dumped sand is executed for all outer harbour breakwater sections. Seaworthy self propelled cutter suction dredgers with floating discharge hose remove the soft soil layers. The dumping of sea-sand is executed by trailing suction hopper dredgers. In general no extra densification has been revealed necessary after systematic controlling by static cone penetration tests of the performed works.

- *Bottom protections*

  Simultaneously with the sanddumping operations the sandlayers are covered by sea gravel layers of 0.60 m to 1.00 m thick placed by trailing suction hopper dredgers or splitbarges. Only a fortnight differ the sanddumping and sea-gravel carpet operations to avoid and excess of erosion of sand.

  Fascine mattresses, ballasted from 0.6 t/m² up to 1 t/m² by quarry run 2/80 kg and 80/300 kg grade by deck shovel barges, are covering the previous laid gravel layers.

  Where possible a 1.5 m thick core gravellayer is placed between the fascine mattresses.

  Gravel layers between fascine mattresses are covered by quarry rock 2/300 kg grade filterlayer.

  Erosion of sand and gravel between operations is detected by systematic surveys and echo-soundings. When necessary the eroded sand and gravel layers are refilled.

  To avoid an excess of materiallosses in the breakwater alignment these foundation works with bottom protection works have to be planned and executed well in advance of the core construction.

  A toe protection

  Provided by a large ca. 35.00 m wide wave breaking carpet on level Z-7.00 with fascine mattresses and quarry stone embankments of grade 3-6 ton up to a maximum level of Z-2,50 m with a gentle slope facing the seaside. The seaward 3/6 - ton and harbour side 1/3 - ton grade embankments are placed by dumpbarges or deck shovel barges.

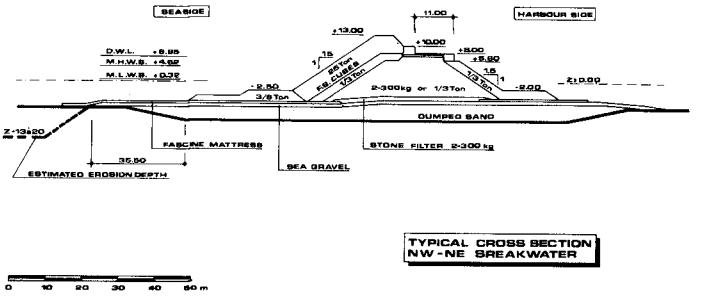

Fig. 11 : Typical cross-section NW-NE breakwater

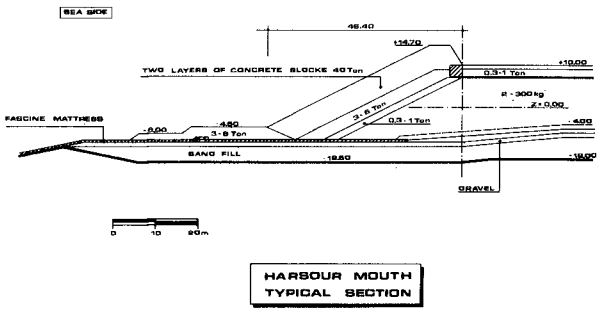

Fig. 12 : Typical cross-section (axis) at harbour mouth

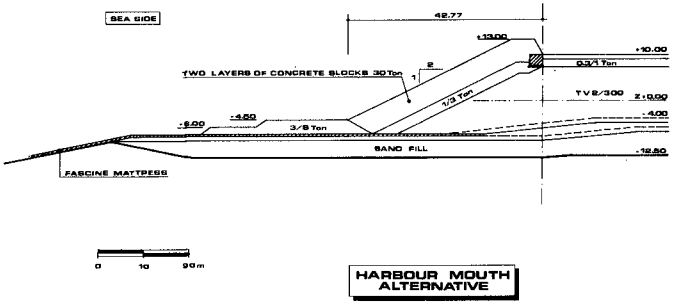

Fig. 13 : Typical cross-section (axis) - Design alternative harbour mouth (under construction)

- *A breakwater core*

  In quarry run 2/300 kg or 1/3 ton quarry rock with filterlayers 1/3 - ton grade. The armour revetment is realized by concrete cubes of 25 ton / 2,4 t/m³ density on a slope of 1:1,5 in the running profile. The head of the breakwaters (figs. 12, 13) at the harbour mouth dips 1:2 with concrete cube units of 40 T and 2,4 t/m³ on a 3/6 ton filter layer. The worklevel for the 40 ton grade truck dumpers, crawler crane, hydraulic cranes and bulldozers, working up the material, is Z + 6.80 m. This level guaranties in average a workability of minimum 90 % of the time.

- *A crest levelled to ca. Z + 13.00*

  As in the future the adjacent harbour area will be equipped with tidal basins and storage areas, no major overtopping will be allowed below the design wave conditions. The crest is finished by placing 30 t crest cubes outward and inward and a 1.00 m thick concrete pavement.

The southern west breakwater design differs slightly from the typical outer harbour design (fig. 14). The hydraulic sandfill of the protecting inner beach will progress simultaneously with the mound construction. The inner beach provides protection of the 1:1,5 innerslope in 1/3 - ton grade quarry rock against NW and N oblique wave attack as construction is running.

7. DESIGN FEATURES

7.1. Dimensions of breakwater

The width of the breakwater core is defined by following considerations (fig. 15):

- The structure is designed in such a way that the construction from core to finished crest goes continuous. The worklength e.g. the distance from the construction front to the finished crest is at maximum 200 to 300 m for the SW breakwater and 125 m up to 200 m for the NW/NE - sections.

- The serviceroad on level Z + 8.00 : min. 9.00 m wide, to assure maintenance works.

- The temporary workroads on levels Z + 6.80 to Z + 8.00 are 10.00 m wide : dubble track road for 40 - ton rockdumpers.

- The level of the construction front is defined on Z + 6.80 by 13.70 m wide (including the top of the 1/3 ton grade filterlayers. It assures a workability of min. 80 % and the manoevrability of crawler crane and one track for dumpers.

7.2. Crest of breakwater

To obtain a continuous progress in construction a parapet wall has been avoided (figs. 11, 14, 15). This has showed to be profitable both for the stability of the armour by better wave energy absorption and limited uprush. Force measurements in the wave flume concrete pavement with rather limited thickness, showed clairly that the overpressures in the core are limited and there is no risk for a resulting uplift force.

7.3. Wave breaking carpet

The sedimentological study conducted both on physical and mathematical models ascertain the possibility of huge erosion pits in front of the SW/NW - breakwater section (from Z - 13 up to Z - 20.00). The NW - breakwater (up to Z - 6.00) and the W harbour head section (Z - 14.00).

The aim of the designed carpet is to limit the wave action on the armour to the design wave height defined by the existing seabottom on Z - 7.00. Flume and wave tanks tests have demonstrated that a carpet of 35.00 m out of the 3/6 - ton grade toe protection on level Z - 7.00 will provide this limited wave action independent from the final erosion depth (Z - 13.00 and Z - 20.00 are tested). However the final erosion depth plays a significant part in the wave stability of the ballast of the fascine mattress. For the applied design conditions $H_S = 6.10$, $T = 9$ to 11 sec : an adequat ballast is found by :

Z - 13.00 : 1 T/m² 2/80 and 80/300 kg - grade
+ 0.75 T/m² 0.3 to 1 ton grade

Z - 20.00 : 1 T/m² 2/80 and 80/300 grade
+ 2,1 T/m² 1/3 ton grade

The performance of the 25 T/2.4 T/m³ - armour has been the same in both test series.

It should be noted that the judgment on damage of the mattresses ballast has been rather severe as the function of the carpet is essential to the breakwater safety and survey of damage detection and maintenance will be very difficult.

7.4. Armour units

For the main breakwater the groved concrete cubic block has been choosen as armour unit. However a rather interesting cost optimization was possible. The fig. 16 shows all different cubic and semi-cubic bloc types in use by the construction. All these cube types were cast in only three different forms (8,7; 10,42 and 12,5 m³) as for the harbour mouth the alternative 30,6 Ton will be choosen.

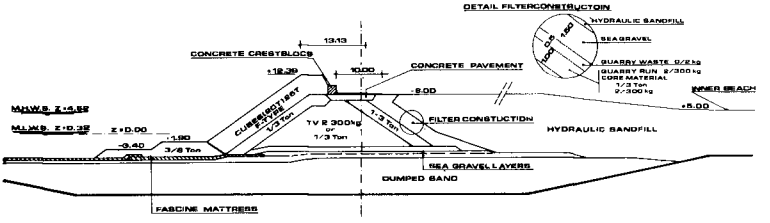

Fig. 14 : Typical cross-section - Design alternative at harbour mouth (Chainagepoints P1795 - P2150)

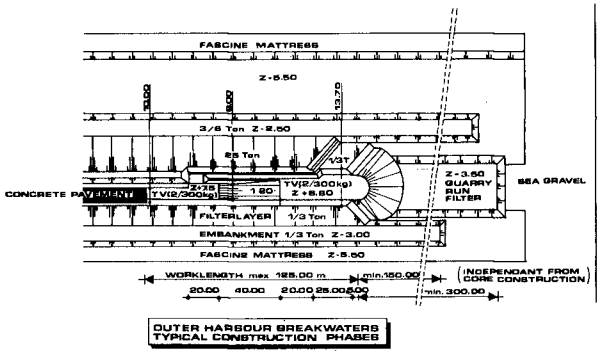

Fig. 15 : Breakwater construction in progress Worklength - typical construction phases

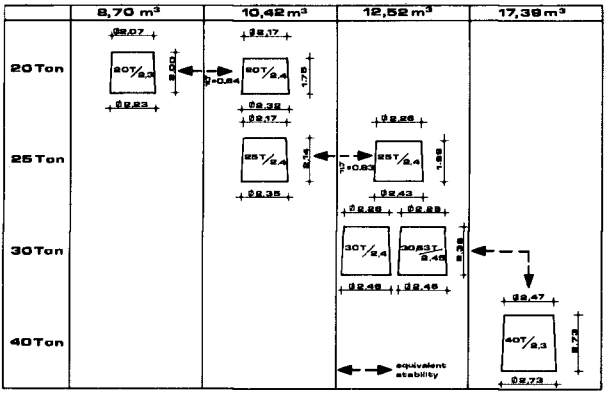

Fig. 16 : Summary of cubic or flat semi-cubic armour bloss applied or considered for the Zeebrugge breakwaters

Flume tests and wave tanks revealed that 25 T/2,3 t/m³ - cubes were necessary at the SW/NW bend section. However cost calculations show that armour layers of 25 T/2,3 t/m³, 25 T/2,4 t/m³ and 30 T/2,4 t/m³ differ only in marginal terms of max. 3% . In counterpart the safety margin for the 30 T layer yields up to 13 % of the significant design wave height.

By the same optimization process so called flat semi-cubes (F.S. - cube) were tested in the flume and wave tank. The maximum "flatness index" has been $h.r^{-1} \geqslant 0.8$ (h = height, r = bottom measure). The tests revealed no significant difference in stability between the cubic unit and the F.S. - cubic unit of equal weight. Costwise the difference is more substantial : 5 to 6 % of the armour cost in favour of the F.S. - cubes.

The choice of the groved cube for the armour is placed in evidence by comparing with a typical dolosse breakwater. The conceptual design is showed on fig. 17. By this concept two sizes of dolos-armour are compared with the cubes.

Type I : 12 T / 5,22 m³ : slight or no damage by design conditions but rocking could be considerable ($K_D \geqslant 15$).

Type II : 19,55 T / 8,5 m³ : beginning of movement (rocking) by design conditions $K_D = 10$. By 1,35 x H_{SO},slight damage can occur ($K_D > 23$).

Costwise the dolos armour revealed to be uneconomical compared with the cubes-armour-elements (tens of percent higher).

7.5. Core material

The core of the breakwater consists of rock material grade 2/300 kg or 1/3 ton. The stability of these quarry grade were tested with the construction phase of the breakwaters (fig. 15) both stationnary (static) and in progress (dynamic). The main results are (fig. 18) :

1) Construction in progress limits
   - upper threshold value for use of quarry rock grade 2/300 kg : $H_S = 1.00$ m
   - for 1.00 m > H_S > 2.00 to 2.50 m quarry rock grade 1/3 ton is to be used
   - by $H_S > 2.50$ m construction will be stopped and a provisional head with quarry rock grade 3-6 ton is to be constructed

2) Construction stopped at night and weekends

   by exceeding 0.80 m to 2.00 m significant wave height, a 1/3 ton provisional breakwater head is to be constructed. On the basis of this information the principal and contractor decided to stop every weekend from September to April with a provisional breakwater head in 1-3 ton grade quarry stone.

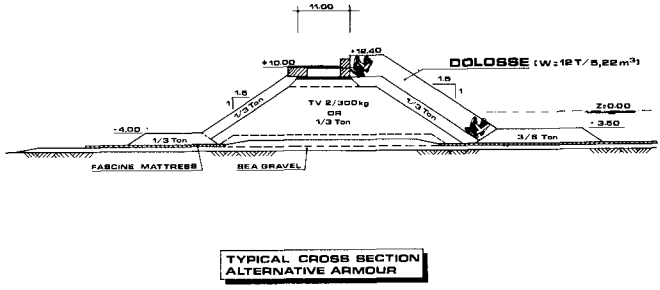

Fig. 17 : Typical cross-section NW/NE-breakwater with dolosse armour revetment

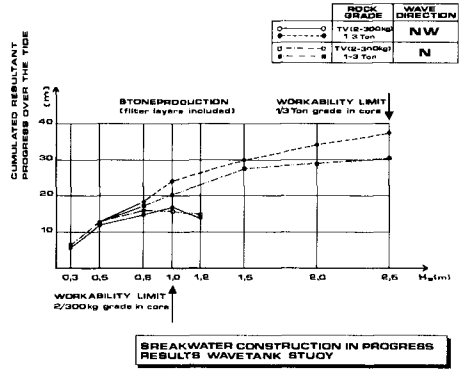

Fig. 18 : Breakwater construction in progress
Limits of 2/300 kg and 1/3 ton rubble grade

3) Detailed information has been becoming available concerning allowed protrusions of breakwater core versus armour revetment and damage to be accepted by special construction stages of breakwater e.g. by the inner slopes of the southern east peripherical breakwaters. This kind of study has been executed also for the west and east core of the LNG-terminal peninsula and the LNG'86 - breakwater. The results of all these studies differ only slightly despite the different locations and wave directions. A predominant factor is the average stone production into the core. In Zeebrugge the design production is 250 T/Hr.

7.6. Meteorological forecasting services

In order to maximise the exploitation of the information achieved by the flume tests, the principal of the works, the Ministry of Public Works - Coastal Service at Ostend - in cooperation with the Meteo Wing of the Belgian Air Force, has set up a special on site Meteorological Forecasting Service.

Twice a day a weather forecast is released with a correlated wave forecast. Directional windforce/wave-height correlation graphs have been established by the consultant on the basis of wave and wind data measured in prototype.

On this 24 hour-forecast the contractor's site managers and principal's site surveyors can judge work limitations in forthcoming shifts on breakwater constructions.

The meteo service is also equiped with an on-line wave analysis computer system, hard-ware programmed. This system is analysing on site wave data received from the wave rider buoy posted at the construction front. This is supplying sufficient information to forecasters and construction site managers about wave growth and height correlated to windforce and direction.

Besides the construction front wave-rider four to five other buoys are operational. The analysed wave data can become available if necessary within one week. In this way any damage can be correlated to the observed wave action.

These measures are only a part of a comprehensively established survey programme with analysis of data and evaluation of measures piloting the construction works.

7.7. Placement pattern of armour cubes

Once more this pattern is revealed of paramount importance. Two kinds of practical patterns are studied thoroughly. The first has been used on the LNG-terminal breakwaters,the second at the LNG '86 breakwater and outer harbour sections. The two differ only by the number of required positions of the crawler crane. By testing both patterns the first revealed a rather high risk to jam up by reaching the design conditions. The second pattern has better blocking properties.

8. STATE OF CONSTRUCTION BEGIN NOVEMBER '82

The present status of the Zeebrugge outer port extension scheme is summarized (fig. 2) :

- Project-planning and design : finalised July '81.
- Southern East-peninsula : commissioned to LNG - terminal operator at 1 September '81.
- Northern - East - breakwater : foundation works and gravellayers finished, fascine mattresses and quarry-run filter layers construction is still going but almost finished.
- Western - breakwater :
  - . breakwater construction : chainagepoint P 1750 is reached by the core up to Z + 6.80.
  - . the foundation works covered by gravellayers is finished to P 3900. The fascine mattresses with quarry-run gravellayer are finished up to ca. P 2200.

More than 50 % of the total deployed length of breakwater works is finished at present.

9. CONCLUSIONS

1. By developping the design, the rubble mound breakwater has been judged to be the only viable alternative taking in to account costs, technical risks, construction problems and flexibility by changing environmental conditions.

2. The wave breaking carpet has shown to be an adequate solution in order to limit wave action on the armour.

3. A huge concrete parapet wall can be avoided and is not necessary for an economical design of breakwaters in the Zeebrugge conditions.

4. It is of paramount importance to check and analyse both the geotechnical stability of the rubble mound on the foundation bed and the internal stability of the mound under wave action. In this connection outer and even inner slopes of 1:1,5 show marginal stability with an inadequate safety facts in some specific cases.

5. Concrete cubes as armour units have been revealed for this case to be more economical and justified. A security margin of a 13 % can be obtained and approximately no costs when upgrading up to 30 T the in the flume and wave tank tests found cube of 25 T. Semi cubes flattened to index $h/r \geqslant 0.80$ reveals to be 5 to 6 % more economical than the cube of the same weight. By tests no significant stability difference was observed.

6. A proper planned placement pattern is demonstrated, once again, necessary.

7. A meteorological forecasting service equipped with wave rider buoys gives adequate information in order to construct in a controlled manner a rubble mound structure and to avoid excessive damage during construction hardly to repair.

ACKNOWLEDGMENTS

The author is grateful to ir. D.J. VANDENBOSSCHE, Director of Haecon, Ghent, Belgium, the Consulting Engineers of the Zeebrugge Outer Port Extension Project. Indeed, his suggestions and support by preparing and editing the paper is highly appreciated.

The Contractor for the outer port extension is the joint venture Zeebouw-Zeezand, Knokke-Heist, Belgium.

CONSTRUCTION SEQUENCE MODELLING FOR HARBOUR BREAKWATER

ROGER W HENORY* Pr Eng BSc MICE MSAICE

Abstract

Gansbaai fishing and pleasure craft harbour is situated approximately 160km east of Cape Town. Modifications and extensions were required to the existing breakwater as well as construction of an internal access mound. An investigation was commissioned into alternative construction methods and construction sequences for the modifications and extensions.

The aim of the study forming the subject of the paper was to establish as accurately as possible the optimum sequence of construction for the various phases of the work and to establish the optimum construction methods to be adopted so that any damage to the work was minimised as construction proceeded. By means of a three dimensional hydraulic model, alternative construction methods and sequences were investigated under varying wave heights and sea conditions. Minimum wave heights and the sea direction causing damage or localised displacement of the elements of construction were studied.

1.0 INTROOUCTION

1.1 General

Gansbaai fishing and pleasure craft harbour is situated approximately 160km east of Cape Town. Modifications and extensions were required to the existing breakwater as well as construction of an internal access mound. The contractor awarded with the contract for the work to be carried out commissioned an investigation into alternative construction methods and construction sequences for the modifications and extensions. The investigation was to be undertaken by means of a three dimensional hydraulic model. Various construction methods and construction sequences were to be studied under certain wave heights and sea conditions for the modifications and extensions to the new harbour.

*Principal-in-Charge in Oames & Moore Consulting Engineers

Certain construction phases were to be modelled, varying the sequence of operations, during which time the minimum wave height parameters were to be established which would result in damage or localised displacement of the elements used in the construction. Simultaneously the extent of the damages would be assessed and possible protective measures to be taken would be studied.

1.2 Model Availability

The National Rsearch Institute for Oceanology (NRIO) at Stellenbosch was commissioned by the Fisheries Development Corporation to make available to Oames & Moore the model of the New Harbour at Gansbaai which had been used during the design stage model analysis (Ref 1). Personnel for the operation of the model and for building the additional model facets required for the tests were supplied by NRIO.

2.0 CONSTRUCTION SEQUENCE

Various methods of construction and possible construction phase sequences which were envisaged as being viable during prototype construction were considered during the planning of the construction sequence modelling. The various construction sequence alternatives would require to be analysed on the model under varying sea conditions. A diagrammatic representation of the harbour is shown in Figure 1.

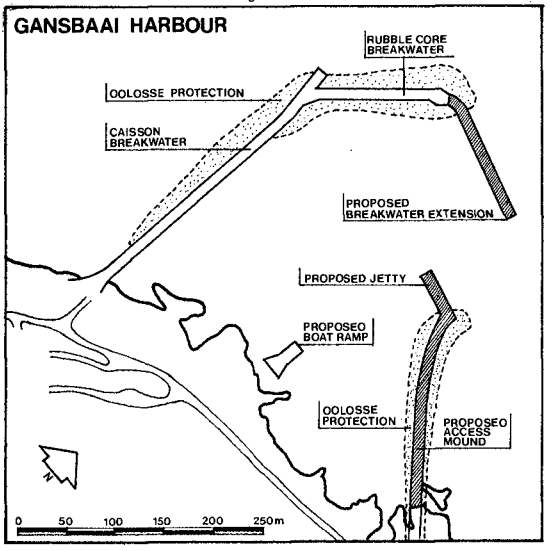

Fig. 1 Gansbaai Harbour

The information required from the model analysis may be summarised as follows:

2.1 Rubble Access Mound

It was required to establish sea and wave height parameters under which the construction of the rubble access mound could proceed.

The rubble access mound was to be modelled to two different lengths representing two stages of construction. At each of the two construction stages the access mound would be subjected to a range of wave height conditions from the direction 11° north of west.

During the test series the proposed caisson breakwater extension would be varied in length from its fully completed length to approximately 1/3 of its length.

2.2 Caisson Extension to Rubble Core Breakwater

It was required to examine the effect of various sea and wave height parameters on the construction of the caisson extension to the rubble core breakwater.

The hollow caissons to be used during construction were to be modelled to the appropriate mass and dimensions. Various placing sequences and stacking permutations were to be modelled with both hollow and concrete filled caissons. As the caissons were to be placed in various sequences, they were to be subjected to a wide range of sea and wave conditions.

2.3 Modifications to Existing Caisson Breakwater

It was required to examine the effect of varying wave heights, particularly storm conditions, on an advancing construction stage of the modifications to the existing caisson breakwater. It was assumed that 8t fluted concrete blocks would be used in the core underneath the dolosse armouring. The blocks were to be modelled and installed at a particular chainage. The advancing face of the blocks would be left exposed and the dolosse armouring would be completed to a distance of some 10 metres (in the prototype) behind the advancing face.

This construction stage was to be subjected to a range of wave height conditions.

3.0 MODEL FACILITIES

The scale of the model was 1:80. Wave height and period input to the model were based on records obtained from a prototype wave rider situated approximately 1,4km west of the harbour.

The two wave directions used during the model analysis were 11° north of west and due west. The period of the waves from both directions was 13 secs and the sea was considered to be at Mean Sea Level (MSL).

Apart from the basic model layout at NR10 the construction sequence modelling required certain additional features for incorporation in the model during testing. The main items which were to be used in the model testing programme and which were constructed for the model are as follows:

Dolosse	20t and 25t
Caissons	20t (approximately)
Rubble	50-500kg
	1, 2 and 3t
Concrete blocks (fluted)	8t
Concrete blocks (plain)	25t
	40t (for experimental purposes only)
Chain mesh	10t

4.0 MODEL TESTING

4.1 Test programme

For various reasons, some concerning the time required for the manufacture of certain items of construction to be incorporated in the model, it was decided that the order in which the major aspects of the contract would be studied, would be as indicated below.

1 Rubble Access Mound to the jetty
2 Caisson Extension to Rubble Core Breakwater
3 Modifications to Existing Caisson Breakwater

4.2 Model Testing Sequence

The following table, Table 1, contains the sequence of testing carried out during the study of the three aspects of the test programme.

TABLE 1 4.2.1 Rubble Access Mound

Rubble Access Mound	Caisson Extension	Sea Conditions
Full construction length (Ch190)	Full construction length (Ch125)	Wave spectrum 1-6,7m Wave direction 11° North of West
" " "	2/3 construction length (Ch93)	Wave spectrum 1-7,1m Wave direction 11° North of West
" " "	1/3 construction length (Ch40)	Wave spectrum 1-7,1m Wave direction 11° North of West

4.2.2 Caisson Extension to Rubble Core Breakwater

Caisson Placing System	Sea Conditions
Horizontal : 1 to 7 layers Caissons not concrete filled	Wave spectrum 1-4m Wave direction west
Stepped : 1 to 7 layers Caissons not concrete filled	Wave spectrum 1-3m Wave direction west
Vertical (single column) : 1 to 7 layers Caissons not concrete filled	Wave spectrum 1-2m Wave direction west
Vertical (single to multiple columns): 1 to 7 layers Caissons concrete filled	Wave spectrum 1-5m Wave direction west
Vertical and Stepped multiple columns Caissons concrete filled	Wave spectrum 1-6m Wave direction west

4.2.3 Modifications to Existing Caisson Breakwater

Exposed advancing face of 8t block core beneath dolosse	Sea Conditions
No protection	Wave spectrum 1-3m Wave direction 11° north of west
Protection : 4 strings of 3 blocks each fixed to breakwater	Wave spectrum 1-3m Wave direction 11° north of west

Exposed advancing face of 8t block core beneath dolosse	Sea Conditions
Protection : 40t blocks along toe of advancing face	Wave height 3m Wave direction 11° north of west
Protection : 25t blocks along toe of advancing face and chained to breakwater	Wave spectrum 3-7m Wave direction 11° north of west
Protection : Chain mesh approximately 10t	Wave height 4m Wave direction 11° north of west

5.0 RESULTS AND OBSERVATIONS OF MODEL TESTING

The model testing was carried out in the sequence shown in Section 4.2. Photographs were taken prior to the commencement of any test sequence and following each test performed.

5.1 Construction of Rubble Access Mound

The construction of the rubble access mound was modelled at two construction stages:

(i) Full construction length
(ii) Approximately 2/3 construction length

During the testing of the rubble access mound at both of these stages in construction, the caisson extension to the existing rubble mound breakwater was varied from a fully constructed length to 1/3 of the proposed construction length.

The layout of the breakwater model showing the rubble access mound and the caisson extension to full construction lengths is shown in Figure 2.

Each test was run for 10 minutes in the model representing a time of approximately 1½ hours in the prototype. The wave direction was set at 11° North of West at a period of 13 sec. The level of the sea was set at mean sea level (MSL) and the heights of the waves were varied, all waves being as measured at the prototype wave rider buoy west of the harbour.

The results of the testing at the various stages of construction of both rubble access mound and the caisson extension to the breakwater are summarised in Table 2.

Fig. 2 Model layout of Gansbaai Harbour

TABLE 2

Deep Sea Direction	Wave Height	Duration (prototype)	Observation
RUBBLE ACCESS MOUND FULL CONSTRUCTION LENGTH CAISSON BREAKWATER FULL CONSTRUCTION LENGTH			
11° N of W at 13 sec	1,0m - 2,0m	1½ hrs	No damage
"	3,2	1½ "	Slight movement of 2t rock on seaward slope
"	4,2	1½ "	Increased movement of 2t rock
"	5,4 - 6,0	1½ "	Appears calmer at entrance. No further damage
"	6,7	1½ "	No further damage

TABLE 2 (contd)

Deep Sea Direction	Wave Height	Duration (prototype)	Observation
RUBBLE ACCESS MOUND FULL CONSTRUCTION LENGTH CAISSON BREAKWATER 2/3 CONSTRUCTION LENGTH			
11° N of W at 13 sec	1,0m - 3,8m	1½ hrs	No damage
"	5,0	1½ "	50-500kg rubble movement. 1,2&3t rock movement. Damage becoming severe
"	5,9	1½ "	Severe damage
"	7,1	1½ "	" "
RUBBLE ACCESS MOUND FULL CONSTRUCTION LENGTH CAISSON BREAKWATER 1/3 CONSTRUCTION LENGTH			
11° N of W at 13 sec	1,0m - 1,5m	1½ "	No damage
"	1,8	1½ "	Slight rock movement
"	2,8	1½ "	Rock movement increasing
"	4,0	1½ "	Damage becoming severe
"	4,8 - 7,1	1½ "	Severe damage
RUBBLE ACCESS MOUND 2/3 COMPLETE CAISSON BREAKWATER 1/3 CONSTRUCTION LENGTH			
11° N of W at 13 sec	1,0	1½ "	Slight rock movement
"	2,0	1½ "	Severe damage. Advancing face destroyed
CONSTRUCTION OF ACCESS MOUND 2/3 COMPLETE CAISSON BREAKWATER AT 2/3 CONSTRUCTION LENGTH			
11° N of W at 13 sec	1,1m	1½ "	No damage
"	2,0	1½ "	Severe damage to advancing face

TABLE 2 (contd)

Deep Sea Direction	Wave Height	Duration (prototype)	Observation
CONSTRUCTION OF ACCESS MOUND 2/3 COMPLETE CAISSON BREAKWATER AT FULL CONSTRUCTION LENGTH			
110° N of W at 13 sec	1,0m	1½ "	No damage
"	2,0	1½ "	Fairly severe damage
"	3,0	1½ "	Severe damage advancing face demolished

The effect of a wave causing severe damage to the advancing face of the rubble access mound is illustrated in Figure 3. This shows a typical erosion and mixing of rubble to the leeward and seaward sides of the mound. Rubble is also tossed up onto the capping as the whole of the mound ahead of capping becomes eroded.

Fig. 3 Damage caused to advancing construction by 3m wave

5.2 Construction of the Caisson Extension to the Rubble Core Breakwater

The caissons to be used in the prototype construction are shown in Figure 4.

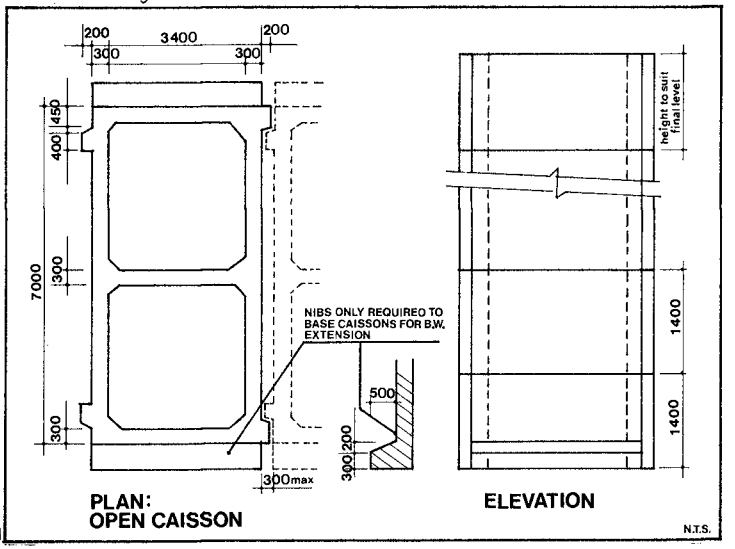

Fig. 4 Caisson design for extension to breakwater

These were modelled using polyester resin and barium sulphate.

In the prototype the caissons were to be placed in position singly and empty. Once in position, they were to be concrete-filled. During this phase of the model testing, an attempt was made to establish the optimum placing and concrete filling sequence, so that in the prototype under all likely sea conditions, the caissons would remain stable immediately after placing prior to and after concrete filling.

Filling the empty caissons in position in the model was simulated by pouring sand and a fine gravelly material into the caissons. This was found to be relatively successful although when the caissons reached the level of the surface of the water, the gravel tended to be washed out of the upper caissons by the wave action, and had to be continually topped up.

The proposed plant to be used during construction was also taken into account during the modelling. It was envisaged that a block/dolosse placing rig would be used on the breakwater with

a maximum load carrying capacity of 25t at a radius of 35m. Taking the parameters of this equipment into account and the dimensions of the caissons, it was assumed that the maximum number of caissons which could be placed on one level in line would be 7. On this basis the model analysis went ahead and within this range various placing sequences were modelled. The wave direction was adjusted from that used in the access mound testing described in Section 5.1, to try and simulate the most arduous conditions which might be experienced on the caisson extension. To give the worst conditions which might be expected at the harbour entrance the wave was therefore set at a direction west at a period of 13 sec. The duration of each test was approximately 10 minutes on the model simulating an hour and a half in the prototype. Occasionally the test run was shortened to approximately 1 hour in the prototype.

Figure 5 shows a typical layout of caissons in five horizontal layers and seven per layer.

Fig. 5 Typical layout 5 caissons high in 7 columns

Figure 6 illustrates the type of damage which could be expected after a particular wave had acted on the structure for a specific length of time.

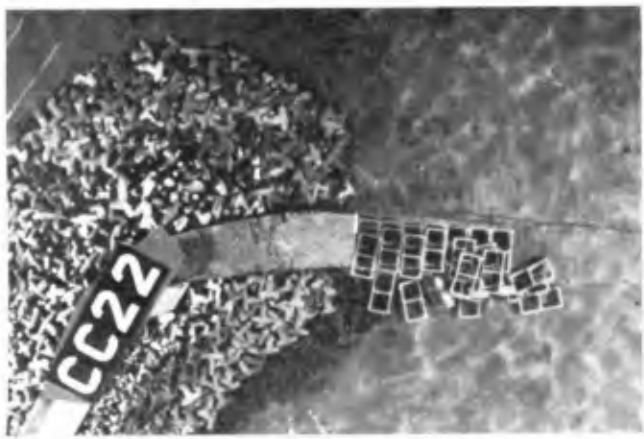

Fig. 6 Displacement by 2,0m wave of 6 layers, 7 columns placed empty

The results of the testing with various block placing combinations and sequences are summarised in Table 3.

Figure 7 shows a typical 3 column construction without strapping.

Fig. 7 Typical 7 layers placed in 3 columns unstrapped filled with gravel (simulating concrete)

In Figure 7 all caissons have been concreted to a level approximately 1,5m above MSL. The caissons are not strapped together. Figure 8 shows the same group of caissons after a 4,9m wave has impacted it for 45 minutes. After 35 minutes the outside column began to sway and move away from the second column. After 45 minutes the upper three caissons on the outside column toppled forwards.

Fig. 8 Model damage to structure in Figure 7 after prototype 4,9m wave impact

Figure 9 shows a typical layout of caissons in 7-stepped arrangement. All caissons are filled with concrete except for top caisson in each column. The arrangement represents 7 caissons recently placed in stepped construction on top of previously placed and concreted caissons.

Fig. 9 Stepped arrangement in 7 columns

5.3 Modifications to Existing Caisson Breakwater

The first phase of construction during the modifications and extensions to the Gansbaai Harbour will be the modifications to the existing Caisson Breakwater.

It was decided therefore, based on the previous model analysis by NRIO, that the area subjected to the worst sea conditions was in the vicinity of chainage 280 to 300 on the existing caisson breakwater. The modification to the existing caisson breakwater required a core consisting of 8t fluted concrete blocks placed along the outside of the breakwater to be protected by 20t dolosse which included toe dolosse held in position by means of connecting chains. The chains fixed to the toe dolosse were held in position by the core blocks. A typical section through the caisson breakwater is shown in Figure 10.

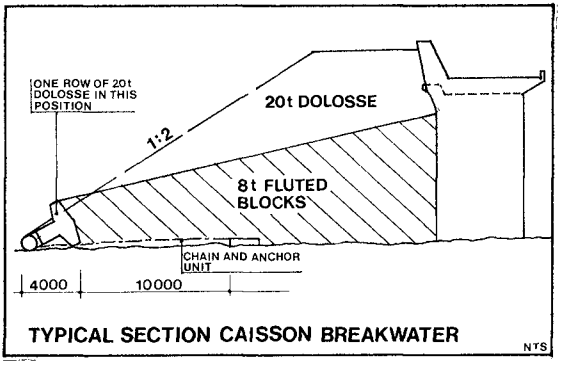

Fig. 10 Typical section of caisson breakwater as modelled

The model of the completed cross section of the modifications was constructed up to chainage 280. From Ch280 to Ch290 the density of dolosse was reduced and from Ch290 to Ch300 the 8t concrete blocks were exposed and constructed in a slope from a level of +1 GMSL to the sea bed. Toe dolosse anchored back underneath the concrete blocks over this section were also constructed. The advancing face of exposed construction is shown modelled in Figure 11.

Fig. 11 Advancing face of breakwater protection

During this series of tests the advancing face of the construction was protected in various ways and subjected to waves varying in height from 1m to 6,2m. The following methods of protection were studied:

(i) Protection by chaining exposed 8t blocks together
(ii) Protection to exposed toe of advancing construction using 25t blocks chained to breakwater
(iii) Protection to the 8t block core by means of a chain mesh

The test was also carried out with no protection at all to the advancing core and dolosse construction.

To prevent the advancing face of the core blocks from being displaced parallel to the breakwater and seaward and thus releasing the holding chains of the toe dolosse, the most effective method proved to be by means of 25t toe anchor blocks tied back across the advancing face and fixed to the breakwater. A recorded wave height of 6,2m at the wave rider failed to dislodge the 25t protective blocks. The importance of keeping the dolosse armouring as close as possible to the advancing face was clearly illustrated during the tests.

Figure 12 shows the damage resulting from a wave 11° N of W at an height of 2,8m lasting for 1½ hours. The unprotected 8t core blocks washed away from the core mass towards the sea. Others bunched up against the caisson wall. Toe dolosse broke free when the anchor chains became exposed.

Fig. 12 Damage to advancing face of breakwater protection by 2,8m wave

6.0 CONCLUSIONS

Some of the basic essentials for carrying out the contract under the sea conditions prevailing in the Gansbaai area were established. The model study indicated in specific areas the most advantageous sequences of prototype construction when adopting certain methods. Within the bounds of model error wave heights at the wave rider were established above which construction would not be possible without protective measures against damagement and displacement.

It was not possible to simulate meaningfully the actual placing of the caissons and dolosse through the waves and the tests were therefore directed at the stability of the elements once these had been lowered into position.

6.1 Rubble Access Mound

On completion of the above series of model tests, it was felt that within the bounds of experimental error and scale model limitations, a considerable amount of useful information was gathered regarding construction sequence and protection measures to be adopted.

From the tests carried out at the intermediate construction stage (approximately 2/3 of full length), it became clearly apparent that only in relatively calm seas, i.e. when the wave height as

recorded at the Waverider B registered less than 1m to 2m would construction of the rubble access mound be possible, without first considerably advancing the construction of the caisson extension to the rubble core breakwater. As continuous calm conditions do not exist, particularly in the vicinity of the proposed works, it was apparent that no construction could be commenced on the rubble access mound until construction of the caisson extension to the rubble core breakwater had been constructed at least ¾ of its length.

During prototype construction, this conclusion from the model testing was observed and only one small washaway was experienced with a wave height of 6m recorded at the wave rider buoy. Protection by means of 1, 2 and 3t rock was kept close to the advancing face.

6.2 Caisson Extension to Breakwater

Least damage to the caissons was experienced when these were advanced in stepped fashion (Figure 9). However caissons placed in this manner which had not been concreted became unstable when placed to within 2,5m of MSL when a wave height exceeding 1,5m was recorded. Nearer the surface the caissons became unstable in waves of 1m height. A form of fixing the caissons to each other using temporary tiebacks increased their resistance against sliding and toppling forwards. The stability of caissons filled with concrete is considerably higher than empty ones in the same position in the construction. For example, a filled caisson showed no tendency to slide laterally or forwards within 2,5m of MSL when the wave height was increased to 6,0m. An empty one became displaced in a wave height of 1,0m at this position. However there was a tendency for consecutive rows or columns of concreted caissons to open up under severe wave conditions. For example, caisson construction (concreted) to the level of the underside of the capping, i.e. above water level but not fixed together in any way, remained stable in wave heights up to about 4m. An increase over this wave height however caused the outside rows or columns to start moving apart. It was therefore concluded that when the construction height of the concreted caissons reached to within a metre or so of MSL, a form of linking the rows or columns of caissons together should be introduced. This would safeguard against the outer column moving away from the remainder as construction advanced. The tendency of the completed columns of caissons to part in high wave conditions decreased as construction moved further from the end of the rubble core breakwater.

During prototype construction placing of caissons commenced in steps as suggested by the model. However as with the model, the wave pattern parallel to the breakwater tended to suck out the concrete from the recently filled caissons. The method of placing caissons was therefore changed to a rapid placement of caissons in column formation. In addition, nibs were cast into the top of

each caisson which would fit into slots cast in the bottom of each succeeding caisson. Caissons were placed empty one at a time until the column had reached a height of one caisson above water level. The whole column was then cast. Protection against the removal of concrete through a sucking action of the passing wave was afforded by the top caisson which was approximately 1,5m above MSL. The tendency for the front column to move forwards as demonstrated by the model was pre-empted by strapping the exposed column to the previously cast columns until such time as the column was filled and the concrete set. The straps used for this purpose in the prototype were highly stressed by the wave action on the foremost column of caissons proving their absolute necessity.

6.3 Modifications to Existing Caisson Breakwater

It was established during the model study that either protection would be needed if construction was discontinued for a spell or a continuous operation and good luck would be required. Tests performed on this section of the construction proved conclusively that the advancing face of the 8t block core would require protection if left unattended in a storm. However there appeared little danger of the dolosse immediately behind the 8t concrete blocks becoming seriously displaced.

The most effective method established during the model testing of preventing movement and thus protecting the core block mass, was by means of 25t toe anchor blocks tied back across the advancing mass face and fixed to the breakwater. As the mass of blocks tends to shift the anchor blocks prevent forward movement and the chains holding back the blocks become very taut. These tieback chains fixed to the breakwater in turn assist in holding the mass of core blocks preventing them from vertical and lateral displacement. The chains and toe blocks are easily removed enabling further construction to continue. However during prototype construction the practicalities of constructing placing and anchoring 25t blocks were not considered feasible. Rather a continuous operation was carried out until the construction was past the critical area on the breakwater. The dolosse protection was kept close behind the core blocks and the toe dolosse were held back by chains on top of which the concrete blocks were placed. A wave height of 8m was experienced during one stage of construction and the concrete core blocks and toe dolosse behaved precisely as predicted by the model. There was a tendency for the blocks to move away from the breakwater and the toe dolosse to move seawards. Figure 12 illustrates this in the model.

DESIGN AND CONSTRUCTION OF HAOERA OFFSHORE COAL UNLOADING TERMINAL

by

S.L. Yaron[1], J. Shimoni[1], C. Tzachar[2], D. Zwemmer[3]

INTRODUCTION

A new coal fired power plant constructed by the Israel Electric Corporation on the Mediterranean coast off Hadera, Israel, requires the import of 3.3 million tons of coal per year.

As there is no port on the Israeli Mediterranean coast capable of handling the 60,000 to 140,000 DWT bulk carriers required for transferring of coal, several studies were conducted in order to decide on the most feasible facility for mooring and unloading these boats.

Rather than expand existing ports or build a new protected port, a decision was finally taken to construct an unprotected offshore terminal at the power plant site.

The terminal was designed to accommodate bulk carriers of up to 140,000 DWT in the first stage, and up to 170,000 DWT with future expansion.

The design of the coal unloading terminal in an unprotected environment created the need to develop design criteria as well as operational and structural systems that will respond to problems arising from unloading bulk in the open sea. As there was no known precedent of an unprotected unloading terminal, the criteria was based on experience in existing offshore loading terminals, laboratory tests and engineering judgement.

The construction of an unprotected offshore terminal, at a cost of $60 million (excluding mechanical equipment), represents a considerable saving of time and money in comparison to the expansion of existing ports or construction of a new protected facility.

PRELIMINARY CONSIDERATIONS

Initial studies were conducted for development of the existing Haifa port. This port, situated 50 km north of the Hadera power plant is in the bay of Haifa, and can presently accommodate boats of up to 35,000 DWT. It is not suitable for handling bulk carriers of the designated size without a substantial investment in port expansion and land transportation systems.

This investment was estimated to be twice as high as the cost of building the unprotected facility in Hadera.

Other options for building a new protected port at the power plant site in Hadera were investigated as well. These options included several harbour layouts with breakwater protection. The various layouts and types of breakwaters (Fig. 1) were tested in a marine laboratory in order to find the feasibility and efficiency of the proposed harbours.

Laboratory tests showed that placing a breakwater in the open sea did not provide sufficient protection against heavy storms and did not provide sufficient berth availability for the ships. Capital investments in each of these solutions was also very substantial, as costs and risks of building breakwaters at water depths of 24 to 27 meters are very large.

In addition, soil investigations performed at that time showed that the soil does not provide a good foundation for the various types of breakwaters. The soil found at the site is characterized by a 5 meter top layer of loose sand, overlying a 5 meter layer of soft clay which can develop circular shear failure modes under breakwater loads. The soil in general was more suitable to pile foundations than other methods of load transfer.

These considerations led to the belief that a "finger" type, pile supported pier, connected to the shore by a pile trestle (Fig. 2), will provide the sufficient berth availability needed for unloading the required quantity of coal and at much lower costs.

Operational analyses were conducted in order to estimate the required berth occupancy for importing 3.3 million tons of coal annually. These analyses, which used as parameters various possibilities of unloading equipment and various sizes of bulk carrying boats, showed that a 50% berth occupancy when unloading operation is continuous, or 65% if no unloading is performed Saturdays and holidays, would be sufficient for unloading the necessary amount of coal.

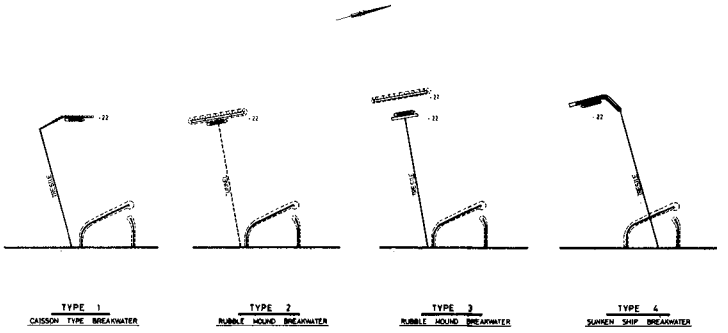

Fig. 1. Layout of Protected Harbours

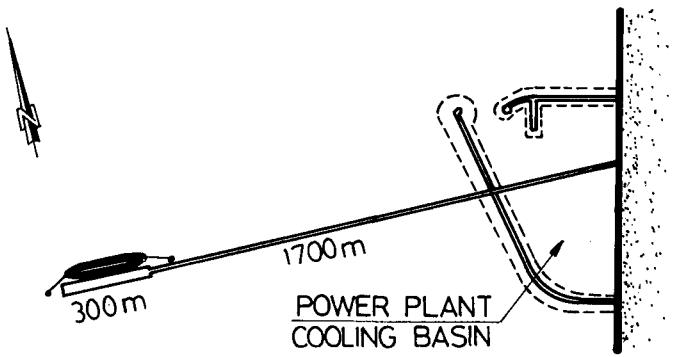

Fig. 2. Unprotected Pier

MODEL TESTS:

In order to test the berth availability of the "finger" pier, operational criteria had to be established. Limiting criteria were set for boat movements at the pier, for safe berthing and mooring and for maneuvering procedures at approach and departure of boats (see Ref. 1).

These criteria were established by consulting with ship captains and unloading equipment operators, as well as by comparing accelerations and velocities of ship movements with those of the unloader bucket movements.

Model tests were conducted on two ship models, a 60,000 DWT and 120,000 DWT. Each boat was tested in full load and in light ballast conditions.

The model tests indicated the optimum mooring fendering system that provides maximum berth availability and berth operability at the existing sea states in the location of the terminal.

These tests showed that the expected yearly unloading operability will be about 80% to 90%, depending on ship size and load. The expected yearly average berth availability will be 80% to 85%.

TERMINAL DESCRIPTION

The pier is a 300x24 meters structure, heading due west into the main direction of the waves. It is a pile supported open structure which absorbs very little impact from the waves and causes little or no reflection of waves between the pier and the boats moored along its side. The boats are moored against dolphins adjacent to the pier, bow heading into the main direction of the waves (Fig. 3). Mooring lines are connected to a quick release hook system placed on the mooring and breasting dolphins. Breastlines can be tied either to near breasting dolphins, or under the pier deck to far breasting dolphins (Figs. 3 & 4).

The pier is located at water depths of 20 to 40 meters and is connected to shore by a 1700 meters long 12 meters wide approach jetty. The approach jetty is built of 200 meters long sections.

The approach jetty deck is a composite construction of prefabricated concrete slabs on steel girders, supported on pile bents placed every 40 meters. Typical pile bents have two battered piles that provide the transverse stability. Longitudinal stability is provided by fixed points, with four battered piles, placed at the middle of the 200 meters trestle sections.

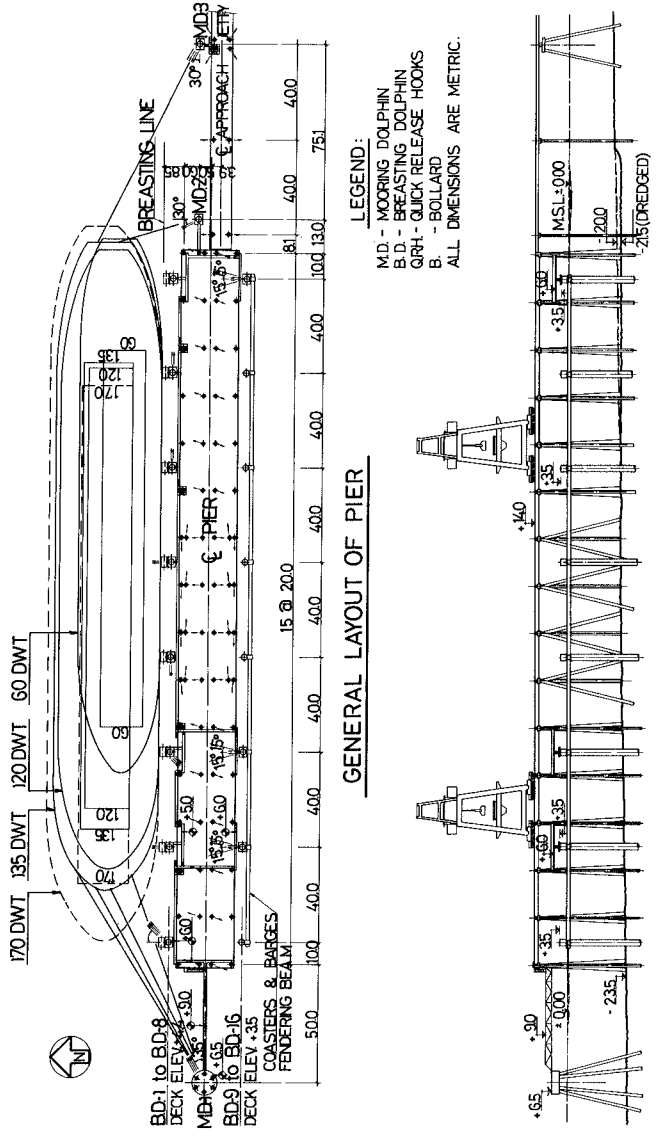

Fig. 3. General Layout of Pier

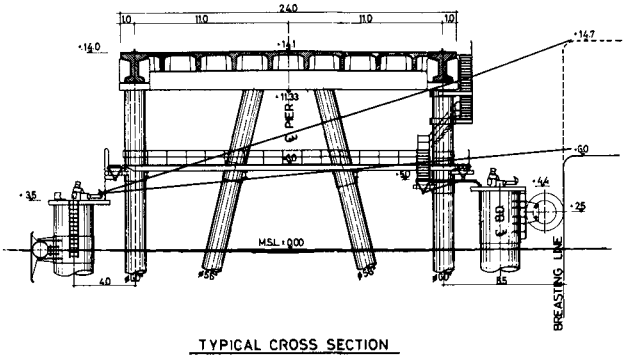

Fig. 4. Typical Cross Section

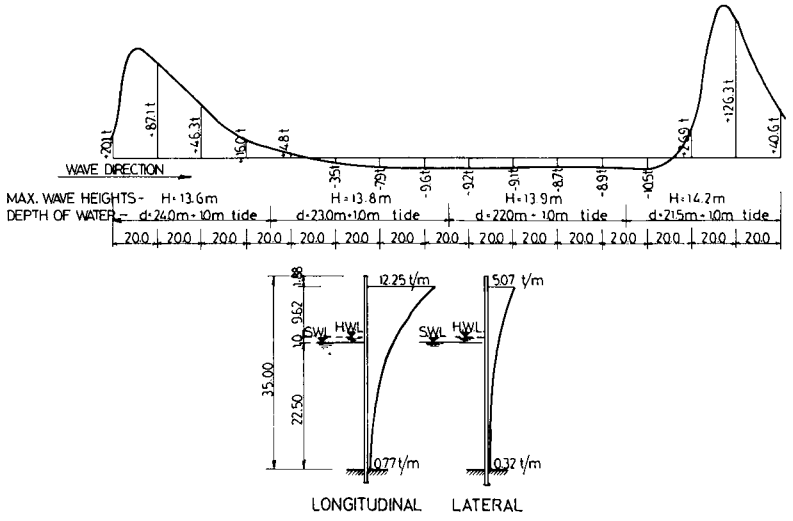

Fig. 5 Wave Shape and Forces on Pier Piles

Pier and approach jetty deck are at +14.0 meters above M.S.L.

SEA STATE AND DESIGN CONSIDERATIONS

Two groups of sea states are essentially considered in the design of the terminal. The lower sea state is the state at which the pier is operable. In this sea state the boats can be moored and unloaded, and the general layout is based on behaviour of the boats at this sea state.

Model tests, as well as the short experience accumulated to date, show that the pier is operable at wave heights of up to 4.0 to 4.5 meters max. (2.5 meters significant waves). These waves are generally 9 to 12 seconds waves, and as such are shorter than the design ship lengths, and cause ship movements that are smaller than those set by the limiting criteria.

This sea state exists over 300 days per year. The other sea state considered is the high, 1:100 year sea state, which governs the structural design and stability of the facility. At this state no boats are moored at the pier and the maximum design waves act on the structure. The 1:100 year deep water design wave at the pier is an 8.7 meters significant wave with a respective maximum wave of 14.5 meters. In general, these waves have return periods of approximately 15 seconds. The maximum wave height at the pier location (water depths of 20 to 24 meters) corresponding to the deep water design wave, is 13.7 meters. The shape of the wave at this location is cnoidal (Fig. 5) with a crest height of approximately 9.5 meters above H.W.L. or 10.5 meters above M.S.L. Pier deck elevation was set at +14.0 meters above M.S.L. so that the underside of the deck will be above the crest line.

The maximum waves breaking zone is located in the approach jetty region approximately 100 to 400 meters east of the pier (1300 m. to 1600 m.from shore) at water depths of approximately 18 meters. The maximum wave at the breaking zone is best represented by a Modified Solitary wave shape with a crest level of approximately 11.4 meters above H.W.L. This crest level is app. 1.0 meter higher than the bottom of the pile cap beams and acts with a slamming force on the structure (Fig. 6). Lenghts of approach jetty sections were set so that each section will absorb the impact of no more than one crest of the higher waves. Accordingly the sections of the approach jetty are 200 meters long with one or two fixed points for longitudinal stability. The fixed points at maximum waves breaking zone are also designed to absorb the slamming forces on the pile cap beams.

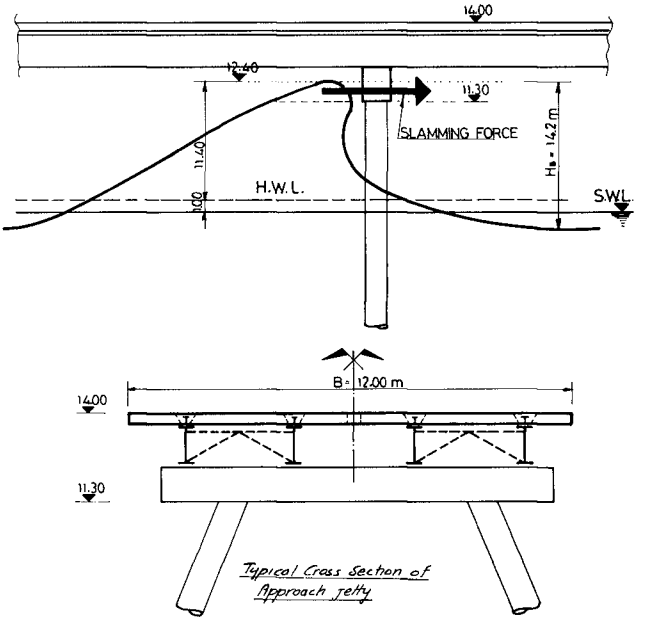

Fig. 6. Wave Forces on Approach Jetty Piles

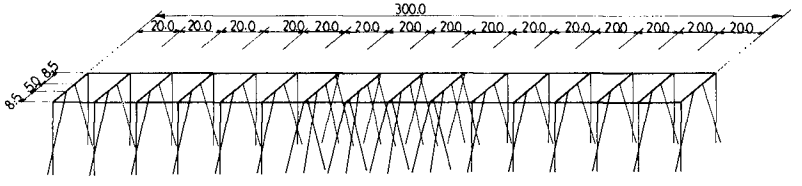

Fig. 7. Structural System of Pier

The design of the structural systems of the pier and approach jetty is based on a space frame analysis fully continuous in all directions with nonlinear soil-pile interaction (Fig. 7).

The structural design was based on a combination of the following codes - DNV (Det Norske Veritas), "Rules for Design Construction and Inspection of Offshore Structures", API-RP2A, "Recommended Practice for Design, Construction and Inspection of Fixed Offshore Structures", Israeli Codes for design of concrete and prestressed concrete structures and AISC specifications for steel design. Some of those codes are based on Ultimate Limit State (ULS) and some on serviceability Limit State (SLS). To enable the combined use of these codes, modifications had to be introduced.

All parts of the structure were designed for the 1:100 year wave loads with the exception of the walkway system under the pier deck. These walkways, at elevation +6.0, were designed for 25 year return period waves and are expected to be repaired periodically.

The supporting piles were designed for the following load combinations:

1.3P + 1.3L + 1.0D + 0.7E (ordinary)
1.0P + 1.0L + 1.0D + 1.3E (extreme)

where P - Permanent loads
L - Live loads
D - Deformation loads
E - Environmental loads

The piles were designed with a factor of safety of 1.5 for both the ordinary and extreme load combinations, which allowed for a total factor of safety of 2.0 for the "theoretical working" loads. A reduction of 20% of the factor of safety was permitted in a few piles at the approach jetty fixed points when loaded by the extreme slamming forces caused by the maximum breaking waves.

SOIL CONDITIONS AND FOUNDATIONS

Extensive soil investigations were performed at the site. Over 30 borings were performed in order to enable the preliminary studies of the various alternative layouts. Of these more than 20 were directly on the pier and trestle alignment. The borings were performed in water depths of up to 26 meters, and generally to 40 meters penetration in the soil. Several additional borings were performed during construction to penetration of up to 100 meters in the sea bed.

The soil formation at the site is characterized by three different layers, a top layer of fine sand, approximately 5.0 meters thick, overlying a second layer of very soft clay, app. 4.0 to 6.0 meters thick, overlying medium to dense sand alternating with calcareous sandstone layers. The bottom layer showed high S.P.T. values, ranging from 40 to 100. Based on these soil investigations, the piles selected for the pier were 56" diameter, 7/8" thick, steel pipe piles and the piles selected for the approach jetty were 48" diameter, 3/4" thick steel pipe piles. The required ultimate capacity of the 56" pier piles was 1000 tons, and for the 48" diameter approach jetty piles - 600 tons. The contractor proposed a change in the vertical pier piles, using a single, 60" diameter, 1 1/8" thick steel pipe pile, with ultimate capacity of 1800 tons, instead of two 56" diameter piles used in the basic design put out for tender.

A load test was performed on the 60" pile with 31 meters penetration. The test pile failed at approximately 1100 tons instead of the required 1800 tons.

As changes in the design were impractical at this stage of construction, the contractor proposed to drive the piles until the required resistance was met. This was achieved at a penetration of approximately 70 meters and at very great costs. Since the construction was delayed at that time due to heavy damages to the contractor's equipment caused by a storm, time was available to find alternative solutions for increasing the pile capacities.

Analysis of the 60" test pile failure has shown the pile has not formed a sufficient soil plug, and has cut through the sand and calcareous layers like a "cooky cutter" through batter. In order to avoid this the piles were driven to approximately 35 meters penetration, the soil inside the pile was removed by a rotary drill, and a concrete plug was cast inside the pile (Fig. 8). When concrete has reached sufficient strength, the pile was redriven to the required resistance. Redriving the piles has increased the resistance from 8 to 10 blows/10 cm to 50 to 90 blows/10 cm over an additional penetration length of 50 to 70 cms, much more than the required resistance, which was calculated to be 35 blows/10 cm when using a menck 2500 pile driving hammer (delivering 31 ton meters energy) (see Fig. 9).

The concrete plug and redrive method could not be adopted easily to the 56" diameter battered piles used in the pier. These piles with ultimate capacities of up to 1350 tons, had also to be driven to 70 meters penetration in order to develop the required resistance. In order to reduce the penetration to approximately 35 meters, a steel annulus ring was welded into the pipe approximately 15 meters from the bottom tip (see Fig. 8). The introduction of this annulus ring assisted in forming a better soil plug and develop additional bearing

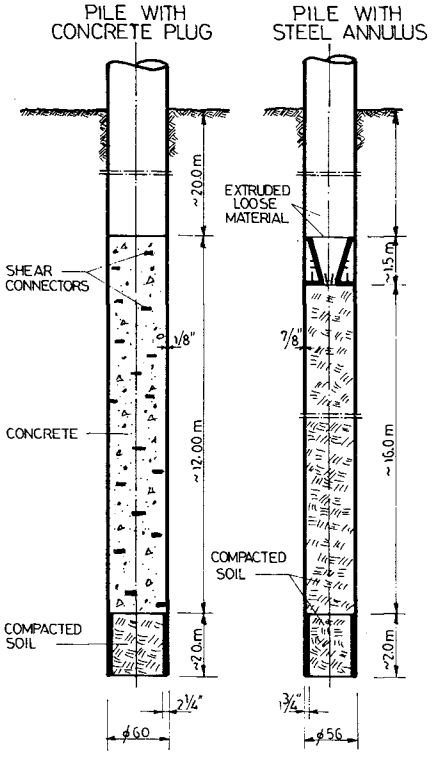

Fig. 8. Piles with Concrete and Steel Plugs

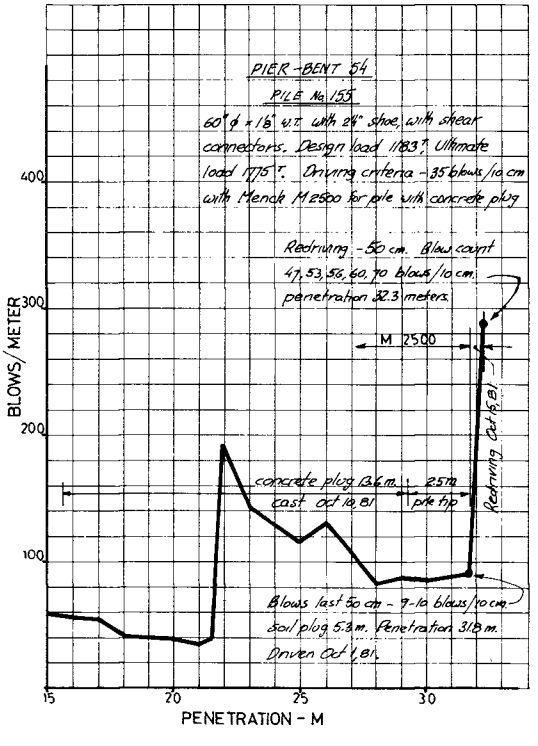

Fig. 9. Driving Record of a 60" Diameter Vertical Pile Before and After, Concrete Plug Installation

surface. The piles driven in that manner reached the required resistance at the expected penetration (Fig. 10).

These alternative solutions proved to be far less expensive than driving the piles to 70 meters penetration.

DOLPHINS

An important feature of the design is that the bulk carrying boats be berthed and moored to dolphins which are separated from the pier structure. These dolphins are designed to absorb the energy of the boats at approach and departure conditions, and take the forces of the mooring lines when the boats are moored.

For this purpose, the dolphins are designed as flexible cantilevered piles with large rubber fenders which help absorb the energy without developing large forces.

The tender documents called for a system of dolphin piles interconnected by hinged struts. The contractor has chosen to use single pile dolphins of 2600 mm. and 2800 mm. diameters with wall thickness ranging from 34 to 70 mm. The fenders used are "Vredestein" jumbo type fenders, 2700 mm outside dia., 1350 inside dia. and 4000 mm long.

The dolphins are designed to absorb the impact of 170,000 DWT boats approaching at a maximum docking speed of 20 cm/sec.

CONSTRUCTION

Construction of the terminal began in March 1980 and was scheduled for completion January 1982. The contractor was permitted to make certain changes in the design that were more adaptable to his equipment and experience, provided that they do not influence the basic concept and layout of the terminal. The contractor was also required to perform the detailed design of these changes according to the design criteria that was specified in the contract documents.

Damages that were caused to the contractor's equipment by the severe storm mentioned above as well as the problems encountered with the piles that were proposed by the contractor, delayed the final completion of the terminal. Construction of the pier and dolphins was completed in January 1982 and construction of the approach jetty was completed in August 1982.

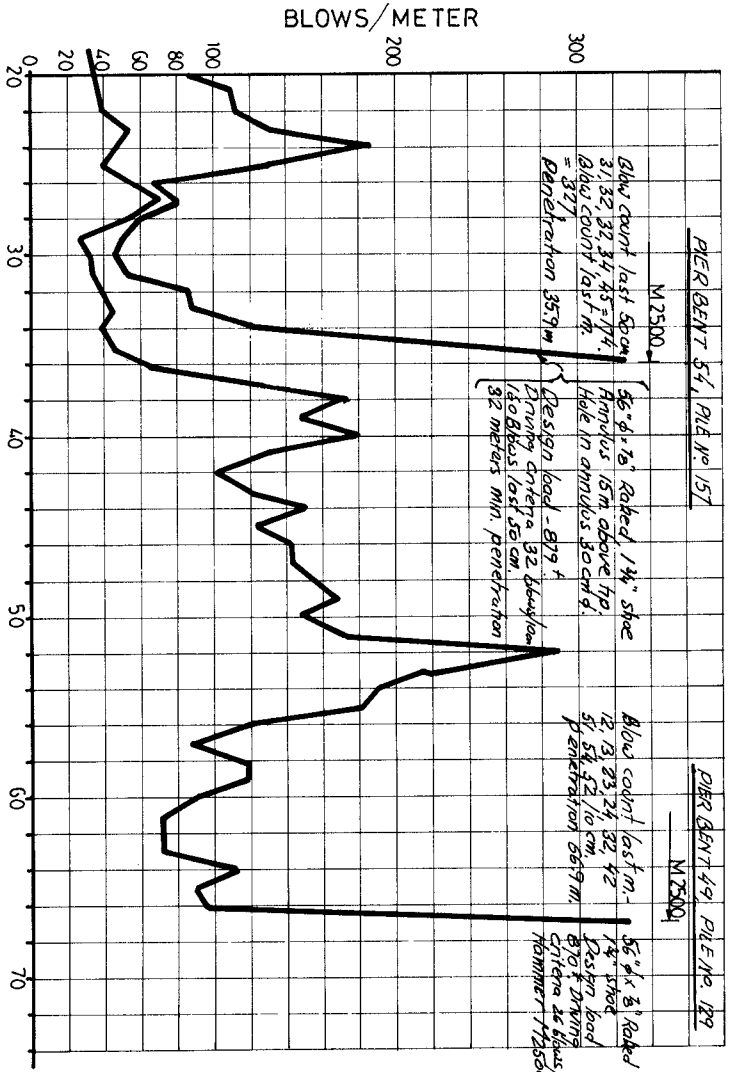

Fig. 10. Driving Records of Similarly Loaded 56" Diameter Piles With, and Without, Annulus

The first boat was unloaded at the pier in August 1982 into 500 DWT coasters that were moored at the opposite side of the pier and which delivered the coal to shore. With the completion of the approach jetty, the coal was temporarily unloaded to trucks running from the pier to shore. This will continue until the conveyor belt system is complete. To date, the behaviour of the boats at the pier was very much as expected from the model tests, with little interference from winter waves.

Wave Forces on Piles of Variable Diameter

Bernard LeMehaute[1] Ph.D., M. ASCE

SUMMARY

A method of calculating nonlinear wave induced forces and moments on piles of variable diameter is presented. The method is based on the Morrison equation and the linear wave theory with correction parameters to account for convective inertial effects in the wave field. These corrections are based on the stream function wave theory by Dean (1974). The method permits one to take into account the added wave force due to marine growth in the intertidal zone or due to a protective jacket, and can also be used to calculate forces on braces and an array of piles.

INTRODUCTION

Design of coastal structures such as piers requires calculation of wave induced forces on piles. The basic methodology is based on the application of the Airy theory in the Morrison equation. This has been a very useful tool, but the Airy theory does not account for many of the nonlinear dynamic and kinematic effects which finite amplitude waves exhibit. Several investigators have used various nonlinear wave theories and corrections to linear theory. The stream function wave theory by Dean (1965) has been determined to be one of the most originally accurate theories (LeMehaute and Dean, 1970). It has been used by Dean (1974) to determine wave forces on piles. Dean has also used stream function theory to develop a number of simple graphs which give the total wave force and moment about the mudline on pile of uniform diameter (SPM, 1977).

Many coastal engineering applications require calculation of the wave loading distribution on the pile. On a pier, the top of the pile is in some cases fixed and therefore the moment about the mudline is not a useful parameter, the designer requires the load distribution. Furthermore, the geometry of many marine structures are complicated by

Photograph 1. Pile of Variable Diameter.

the presence of marine fouling. Barnacles, mussels and other marine organisms can significantly increase the diameter of a pile in the intertidal zone as shown in Photograph 1. Wooden piles are often protected by, or their useful life extended by, a jacket wrapped around the pile. Both marine growth and protective jackets introduce a variable diameter pile near the water surface. Because the diameter is increased near the free surface, wave forces are increased for a given wave condition. Figure 1 schematically shows a pile of three diameters which could represent the situation of marine growth on a protective jacket on a pile.

The objective of this paper is to present a methodology for the coastal engineer to readily calculate the nonlinear, wave-induced loadings on piles of variable diameter. Considering the large number of parameters, it is not possible to present an exact solution to the problem in the form of a few graphs. Therefore an approximate method has been developed in which the velocity and acceleration fields, and forces and moments are initially obtained at the pile location from the linear wave theory. These parameters are integrated from the sea floor into an arbitrary elevation, z_i, which can be the free surface. The free surface is given by the nonlinear wave theory of Dean (1974). Then correction coefficients are introduced to account for the nonlinear convective inertial forces on the velocity and acceleration fields. By so doing the method is, with a few approximations, amenable to description by a limited number of graphs. The graphs reduce by an order of magnitude the interpolations required and permits the engineer to calculate the load distribution to a high degree of accuracy with a minimal effort. Furthermore, the pile can comprise multiple diameters.

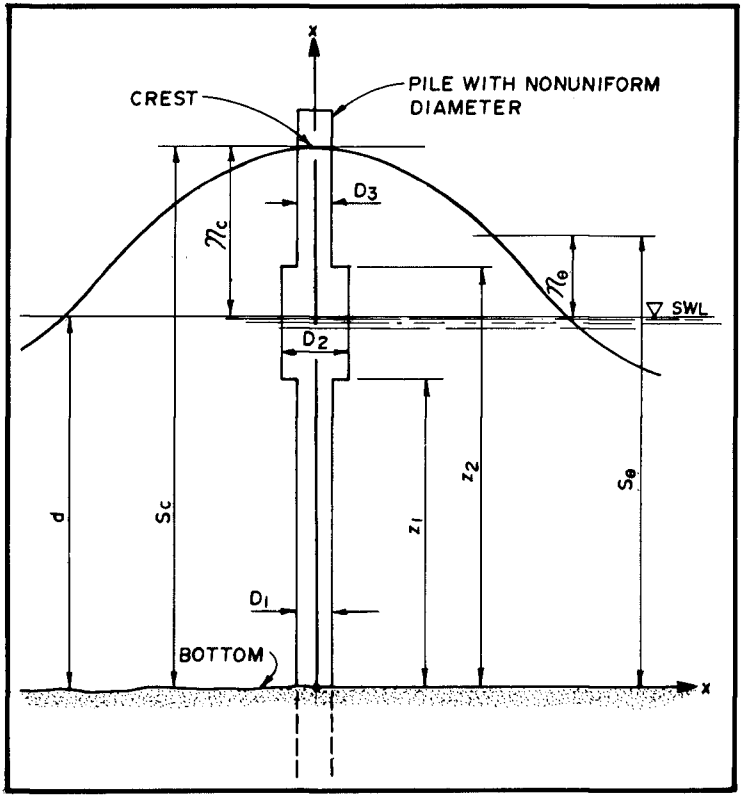

Figure 1. Definition Sketch for a Pile with Three Diameters.

The force on an array of piles can be determined by calculating the forces at various phase angles.

The methodology therefore permits the engineer to calculate wave forces on piles taking into account many of the physical properties of waves observed in nature and the laboratory as well as special circumstances which must be addressed in practical design problems. The force and moment correction factors are primarilly greater than unity and therefore will yield forces and moment which are greater than those calculated by linear theory. Where force and moment correction factors are less than unity, the correction was retained as unity for the sake of conservatism.

FORCES ON CYLINDRICAL PILES: BASIC FORMULATION

A cylindrical vertical pile subjected to a time dependent horizontal velocity, u(t), has a force, f, per unit length of cylinder which is the sum of a drag force, f_D, and an inertia force, f_I:

$$f = f_D + f_I = \tfrac{1}{2} \rho C_D u|u| + \rho C_m \frac{\pi D^2}{4} \frac{du}{dt} \qquad (1)$$

where ρ is the density of sea water, D is the pile diameter, u is the particle velocity, $\frac{du}{dt}$ is the particle acceleration, C_D is the drag coefficient, and C_m is the inertia coefficient.

When a cylindrical pile is subjected to a water wave, one considers that these equations hold true, provided u(t) is the horizontal component of the velocity field at the pile location as if the pile did not exist. The deformation of the velocity field by the pile, wave diffraction, the effect of the vertical velocity component, the vertical acceleration component and the elasticity of the pile are neglected. The equation is commonly called "Morrison's equation".

The total force, F_T, on the pile is determined by integrating the unit forces from the sea floor to the water surface, S_θ.

$$F_T = \int_0^{S_\theta} f \, dz \qquad (2)$$

where subscript θ refers to phase angle.

Forces due to nonlinear waves over piles of variable diameter, D_i, can be calculated using equations (1) and (2) using expressions for u and du/dt from the linear wave theory and adjusting them according to results obtained from the nonlinear wave theory. Nonlinear corrections are taken from the stream function theory as presented by Dean (1974). Two basic corrections are made: the asymmetric free surface correction and the nonlinear correction to the wave field.

Figure 1 shows a pile of three diameters, D_1, D_2 and D_3. The total force, F_T, acting from the sea bottom (z=0) to the elevation of the free surface ($z=S_\theta$) is given by:

$$F_T = \int_0^{z_1} f(D_1)\, dz + \int_{z_1}^{z_2} f(D_2)\, dz + \int_{z_2}^{S_\theta} f(D_3)\, dz \qquad (3)$$

where F_T = total force on the pile and $f(D_i)$ = total force per unit length acting on pile diameter D_i.

Graphs can be constructed which integrate unit force and moment from the sea floor to an elevation z_i. Then equation (3) can be written.

$$F_T = \int_0^{z_1} f(D_1)\, dz + \int_0^{z_2} f(D_2)\, dz - \int_0^{z_1} f(D_2)\, dz + \int_0^{S_\theta} f(D_3)\, dz - \int_0^{z_2} f(D_3)\, dz \qquad (4)$$

This expression can be written:

$$F_T = F(D_1)|_{z_1} + F(D_2)|_{z_2} - F(D_2)|_{z_1} + F(D_3)|_{S_\theta} - F(D_3)|_{z_2} \qquad (5)$$

where $F(D_i)|_{z_i}$ = wave force acting on a pile of diameter D_i from the sea bottom to a level z_i.

Use of equation (5) requires evaluation of the force $F(D_i)|_{z_i}$ on a pile of arbitrary diameter, D_i, and elevation above the bottom, z_i. This is done using the linear wave theory with the appropriate correction coefficients in order to account for the effects due to the nonlinear wave theory. This gives:

$$F(D_i) = \tfrac{1}{2}\, \rho\, C_D\, D_i\, \frac{H^2}{T^2}\, d\, K_D|_{z_i}\, \phi_D + \rho\, C_m\, \frac{\pi D_i^2}{4}\, d\, \frac{H}{T^2}\, K_I|_{z_i}\, \phi_I \qquad (6)$$

where H = wave height, T = wave period, and d = water depth. $K_D|_{z_i}$, and $K_I|_{z_i}$, are dimensionless drag and inertial coefficients respectively, obtained by integration from the mudline to an elevation z_i, and ϕ_D and ϕ_I are correction factors to the forces obtained by the linear theory. ϕ_D is the correction relating to u^2 and ϕ_I is the correction relating to du/dt.

According to linear theory:

$$K_D|_{z_i} = K_{DM}|_{z_i}\, \cos\theta|\cos\theta| \qquad (7)$$

$$K_I|_{z_i} = K_{IM}|_{z_i}\, \sin\theta \qquad (8)$$

The maximum values $K_{DM}|_{zi}$ and $K_{IM}|_{zi}$ integrated from the mudline to an elevation z_i are:

$$K_{DM}|_{z_i} = \frac{1}{8}\frac{gT^2}{d}\left[1 + \frac{2kz_i}{\sinh 2kz_i}\right]\frac{\sinh 2kz_i}{\sinh 2kd} \quad (9)$$

$$K_{IM}\, z_i = \tfrac{1}{2}\frac{gT^2}{d}\frac{\sinh 2kz_i}{\cosh kd} \quad (10)$$

where k = wave number = $2\pi/L$ and L = wavelength. $K_{DM}|_{z_i}$ and $K_{IM}|_{z_i}$ are given by figures 2 and 3, respectively, as a function of z/d and d/L_o.

NONLINEAR FREE SURFACE

$F(D_3)|_{z_i}$ at $z_i = S_\theta$ requires the knowledge of the free surface elevation S_θ as function of phase angle, θ. This is done by applying the free surface given by the stream function wave theory by Dean (1974). The results are presented in the form of S_θ/d as a function of H/H_b, d/L_o and θ, in figure 4. H_b is the limit wave height as defined by Dean (1974).

The use of figure 4 is illustrated by an example. Given d/L_o = .033, θ = 20° and H/H_b = .75 enter figure 4 vertically with a value of d/L_o = .033. As indicated by the arrow in the figure, one proceeds downward until the line of H/H_b = .75 is intersected. A line is then drawn horizontally towards the right until the θ = 20° line is intersected. Now move vertically downward to read S_θ/d = 1.256.

CORRECTIONS FOR NONLINEAR WAVE KINEMATICS

The second correction to linear theory is due to the nonlinear wave particle velocity and acceleration fields. The correction coefficients ϕ_D and ϕ_I incorporate a number of nonlinear effects, most notably due to the convective acceleration terms. These nonlinear effects are a complex function of relative depth, d/L_o, wave phase angle, θ, the ratio of the local height to breaking height, H/H_b, and the ratio of elevation to water depth, z/d. These are given by the ratio of the forces obtained by using the values obtained by a nonlinear wave theory to the corresponding value given by linear theory. To incorporate all of these variables at each z would require a large number of nomographs. Therefore a conservative approach was adopted where the nonlinear correction factors at the free surface were applied over the water column. While the nonlinear effects actually vary with z/d and θ, the most important corrections are near the free surface. Therefore only a global nonlinear correction is applied over the entire pile length, from the sea bottom to the nonlinear free surface. Also the phase variations given by $\cos\theta$ and $\sin\theta$ respectively, are retained in the general equation. The error resulting from this simplification is that forces are generally over-predicted by a few percent at levels below the free surface. Figures 5 and 6 present the nonlinear correction factors ϕ_D and ϕ_I as a function of phase angle, θ, H/H_b and d/L_o. Note that the corrections approach unity for θ = 30° and 50° for drag and inertia respectively. For greater θ, corrections are less than unity, but a conservative design procedure would be to use the correction at unity for $\theta > 30°$ for drag forces and $\theta > 50°$ for inertia forces.

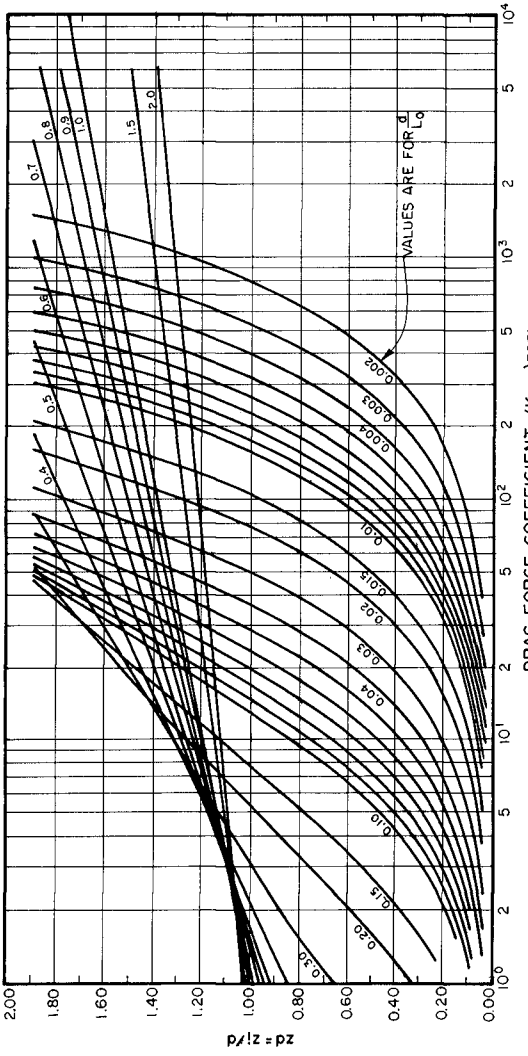

Figure 2. Drag Force Coefficient.

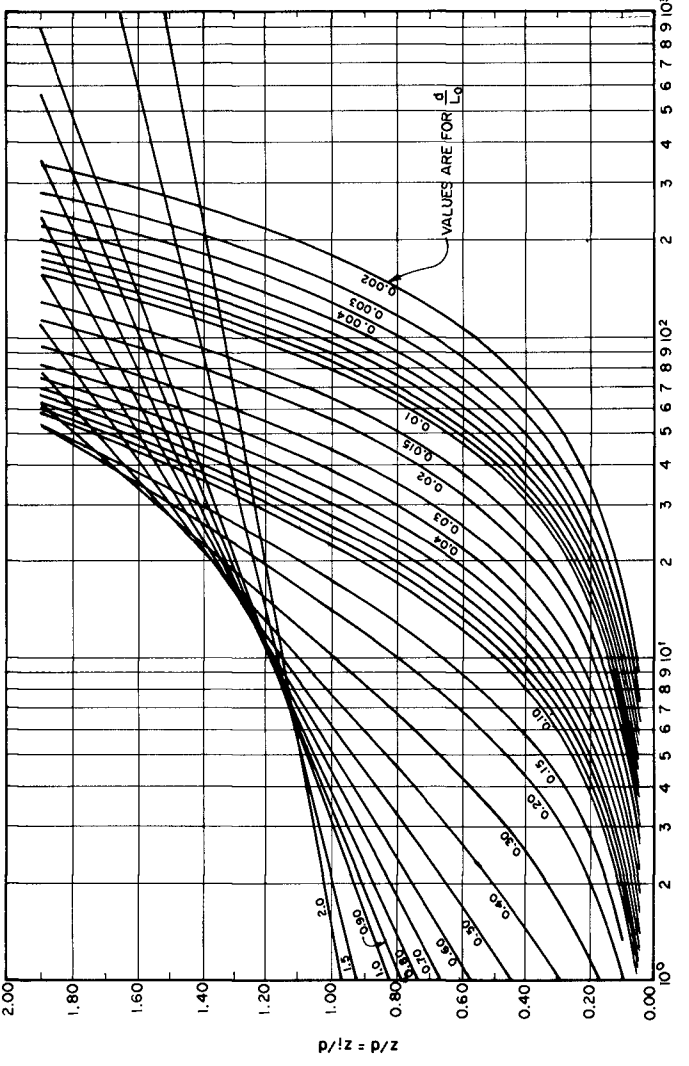

Figure 3. Inertial Force Coefficient.

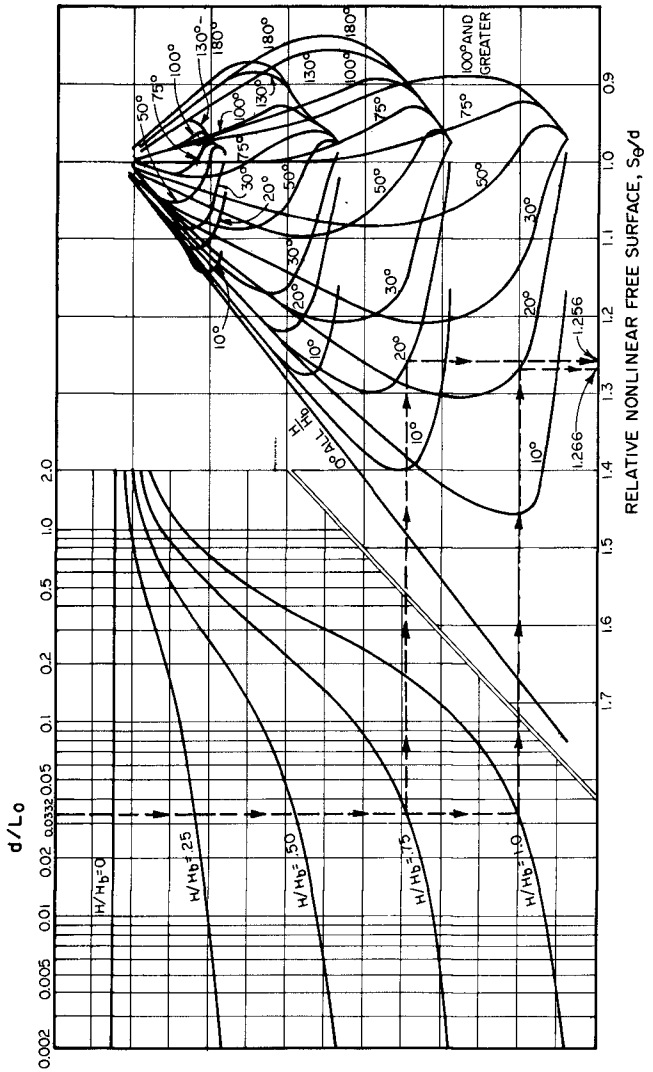

Figure 4. Nonlinear Free Surface.

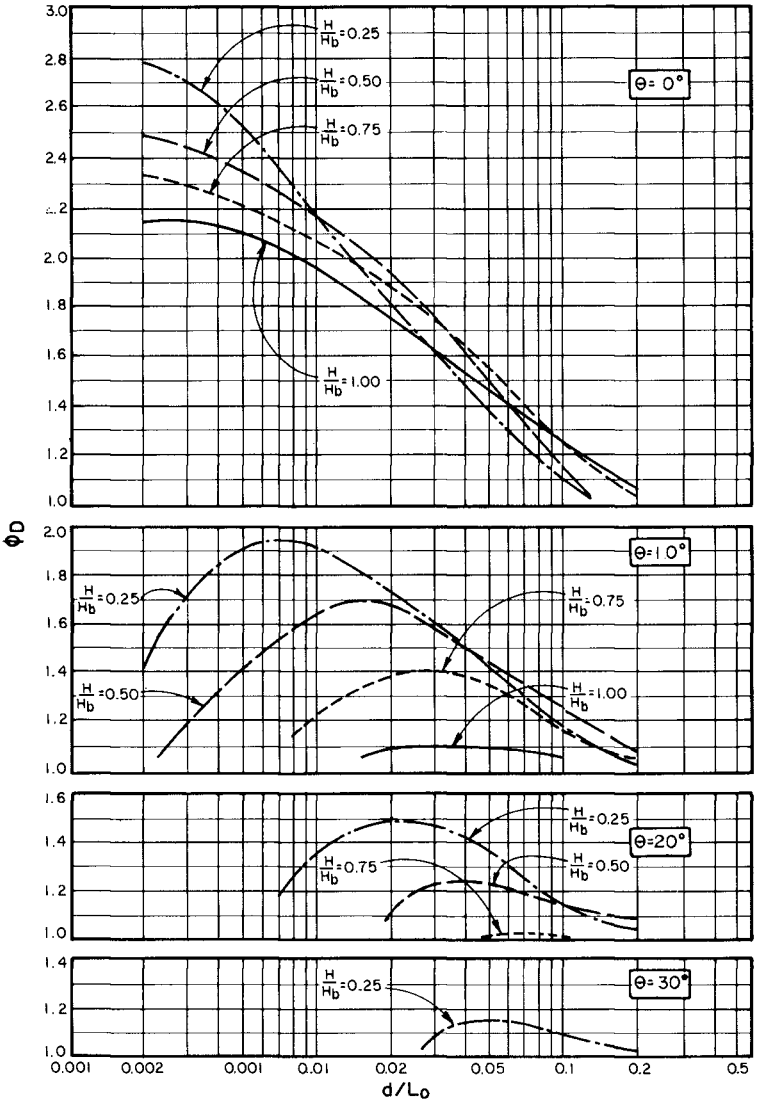

Figure 5. Nonlinear Drag Force Correction Factor.

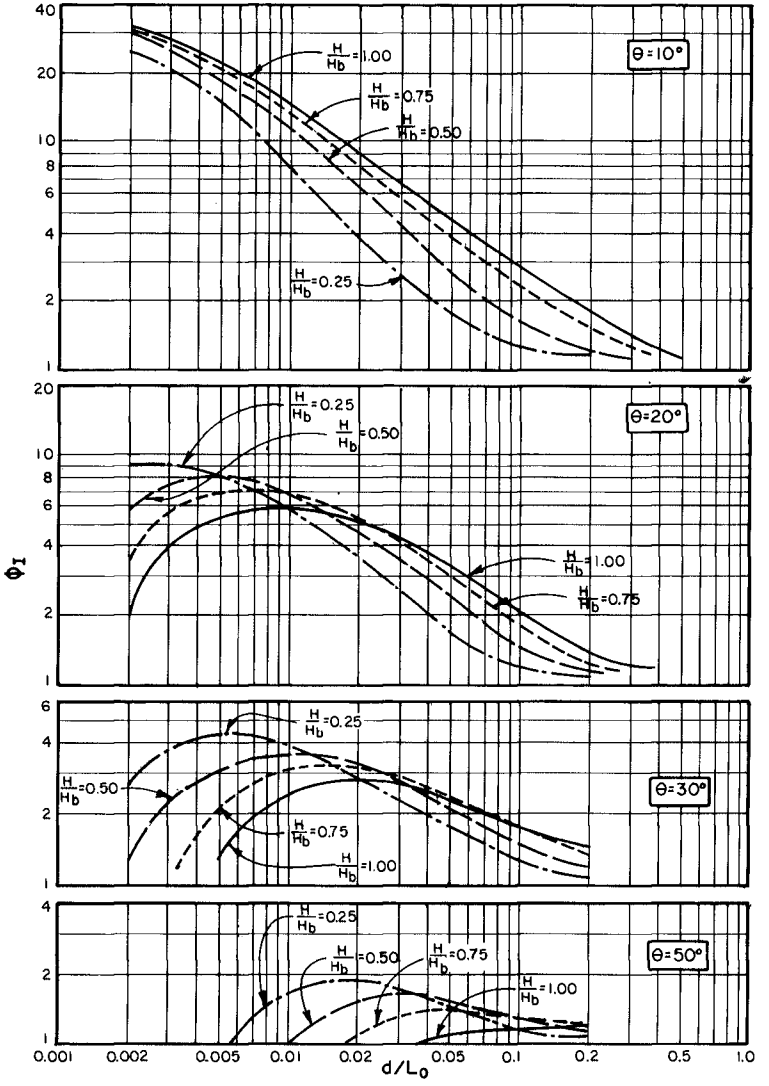

Figure 6. Nonlinear Inertial Force Correction Factor.

TOTAL FORCE ON PILE OF VARIABLE DIAMETER

Based on these assumptions the total force on a pile of three diameters can now be written:

$$F_T = F_D + F_I \tag{11}$$

$$F_D = \tfrac{1}{2}\,\rho\, C_D \frac{H^2}{T^2} d \left[K_{DM}\big|_{z_1} (D_1 - D_2) + K_{DM}\big|_{z_2} (D_2 - D_3) + K_{DM}\big|_{S_\theta} (D_3)\right] \phi_D \cos\theta|\cos\theta| \tag{12}$$

$$F_I = \rho\, C_M \frac{\pi d}{4} \frac{H}{T^2} \left[K_{IM}\big|_{z_1} (D_1^2 - D_2^2) + K_{IM}\big|_{z_2} (D_2^2 - D_3^2) + K_{IM}\big|_{S_\theta} (D_3^2)\right] \phi_I \sin\theta \tag{13}$$

MOMENT CALCULATIONS

Expressions analogous to the above force equations are presented for calculation of the wave moment on a pile of diameter, D_i, at an elevation acting about the sea bottom. The moment expression is:

$$M_T = \int_0^{S_\theta} f\, z\, dz \tag{14}$$

Referring to figure 1 and using a similar approach, the total moment, M_T, acting about the sea bottom can be written as:

$$M_T = M(D_1)\big|_{z_1} + M(D_2)\big|_{z_2} - M(D_2)\big|_{z_1} + M(D_3)\big|_{S_\theta} - M(D_3)\big|_{z_2} \tag{15}$$

where M_T = total moment acting about the sea bottom; $M(D_i)\big|_{z_i}$ = wave moment acting on a pile of diameter D_i about the sea bottom to a level z_i. Equations for $M(D_i)\big|_{z_i}$ are given:

$$M(D_i)\big|_{z_i} = \tfrac{1}{2}\,\rho\, C_D \frac{H^2}{T^2} d^2\, \Gamma_D(D_i)\big|_{z_i}\, \Psi_D + \rho\, C_M \frac{\pi D_i^2}{4} \frac{H}{T^2} d^2 \Gamma_I(D_i)\big|_{z_i}\, \Psi_I \tag{16}$$

where: $$\Gamma_D(D_i)\big|_{z_i} = \Gamma_{DM}(D_i)\big|_{z_i} \cos\theta|\cos\theta| \tag{17}$$

$$\Gamma_I(D_i)\big|_{z_i} = \Gamma_{IM}(D_i)\big|_{z_i} \sin\theta \tag{18}$$

$$\Gamma_{DM}(D_i)\Big|_{z_i} = \tfrac{1}{2}\frac{g^2T^4}{g^2}\frac{1}{(8\pi)^2}\frac{1}{\cosh^2 kd}\left[1 + 2(kz_i)^2 + 2kz_i \sinh 2kz_i - \cosh 2kz_i\right] \quad (19)$$

$$\Gamma_{IM}(D_i)\Big|_{z_i} = \frac{1}{8\pi^2}\frac{g^2T^4}{d^2}\frac{\sinh kd}{\cosh kd}\left[1 + kz_i \sinh kz_i - \cosh kz_i\right] \quad (20)$$

$\Gamma_{DM}(D_i)\Big|_{z_i}$ and $\Gamma_{IM}(D_i)\Big|_{z_i}$ are given as functions of z/d and d/L_o in figures 7 and 8 respectively and can be evaluated up to the free surface elevation given by figure 4. Ψ_D is the drag moment correction for the velocity field and Ψ_I is the inertial moment correction for the acceleration field. Other variables are as previously defined. The nonlinear moment correction factors, Ψ_D and Ψ_I, are given in figures 9 and 10, respectively, as functions of d/L_o, θ, and H/H_b.

MAXIMUM VALUES - EFFECT OF PHASE ANGLE

The total maximum force and total moment phase angle cannot be readily determined for a pile of variable diameter. The drag force is maximum at $\theta = 0$, and for small diameter piles, the maximum value is near $\theta = 0$; but as the diameter increases the inertial force becomes more prevalent and shifts the location of the maximum total force toward $\theta = 90°$. The maximum inertial force occurs at some unknown angle, but its maximum value can be determined as a function of H/H_b and d/L_o only by application of formula (13) in which one takes $z_3 = d$ and one replaces $\phi_I \sin\theta$ by ϕ_{IM} given by figure 11. A similar method applies to calculate the maximum moment due to inertia. The correction factor, Ψ_{IM}, is then given by figure 12.

CONCLUSION

The preceding outlines the methodology for determining nonlinear wave forces on piles of variable diameters. The methodology greatly simplifies the interpolation required in using stream function theory and permits one to estimate wave forces and force distribution over the pile column. The method presented is for a general case. The US Navy Manual DM26.2 (1982) describes other cases in more detail to simplify the wave force and moment calculation for special cases.

By considering θ as a variable, the time history of the total force and moments on piles of varying diameter can be determined. Therefore the method is amenable to determine the total wave forces on structures supported by a number of piles.

PROTOTYPE TESTS ON RIPRAP UNDER RANDOM WAVE ATTACK

J.D. Pitt and P. Ackers (Member ASCE)*

ABSTRACT

This paper describes the performance of test panels of riprap on an offshore island in the Wash estuary, UK, for the first 2½ years after their construction, by which time all but one had failed. It outlines the methods used in obtaining and analysing data on stone size, wind, tides and waves. The techniques used in surveying the test panels for damage and the reduction of the survey data to yield quantitative estimates of damage are described.

Comparisons are made between the damage to the riprap panels and what might have been estimated using laboratory data. Results do not support any scale effect causing riprap sized on laboratory data to be larger than necessary, and this conclusion is supported by the outcome of model tests carried out retrospectively by the Hydraulics Research Station (now HRS Ltd) at Wallingford, UK.

Slope protection is sensitive not only to wave height and stone size but also to construction methods and, bearing in mind possible departures from the desired specification, a cautious approach to the design of riprap protection is advisable.

1. INTRODUCTION

1.1 Use of Riprap for Slope Protection

In the context of this Report riprap is a graded quarry-stone layer on the sloping surface of an embankment protecting it from erosion by the action of wind generated waves. To prevent leaching of the embankment material through the riprap layer, one or more sub-layers (Filter layers) of smaller graded stone may be necessary. This method of slope protection is an alternative to continuous paving, interlocking slabs or precast concrete armour units. Because the cost of the slope protection can be a significant proportion of the total cost of a project, the reliability of available design information is important.

1.2 Limitations of Model Testing

Most design methods for riprap are based on results of hydraulic model tests, and their validity depends on the reproduction of all the characteristics of the prototype. It is seldom possible to meet this requirement fully, and errors arising from such limitations are referred to here as 'model effects'. The behaviour of riprap under wave attack depends on so many factors that some model effects are almost certain to be present (e.g. it is very difficult to ensure that the stone shape used in the prototype is reproduced in a model).

Even if the model accurately resembles the prototype, the forces are not necessarily reproduced exactly to scale, because all the

* Senior Engineer and Hydraulics Consultant, Binnie and Partners, London, ENGLAND.

requirements for dynamic similarity can not be met. Errors arising from this difficulty depend on the scale of the model, and are therefore known as 'scale effects'. Scale effects in laboratory tests of riprap were highlighted by work in the USA(1) which suggested that the use of small scale models could result in costly overdesign.

1.3 Background to the Study

Many of the early investigations into the behaviour of riprap and other forms of slope protection were based on model tests using regular waves. In that type of test, a significant 'model effect' is inevitable as real waves are irregular in height, frequency and direction. One of the first attempts to relate results of tests using regular waves to those using irregular waves is described in a U.K. Construction Industry Research and Information Association (CIRIA, formerly CERA) publication(2) on laboratory tests sponsored at the U.K. Hydraulics Research Station (HRS).

Research on the subject continued at HRS, in collaboration with CIRIA, with paddle-generated irregular waves, culminating in the publication of CIRIA Report 61 in 1976.(3). This comprehensive Report reviewed current practice under the headings of wave prediction, design procedure, design wave height, size, grade and shape of riprap, placing and thickness, filter design and run-up. Design curves and procedures based on these new measurements were presented.

1.4 The need for Field Tests

An important conclusion reached in CIRIA Report 61 was that, contrary to the American findings, no allowance for scale effects could be recommended when using these laboratory results with irregular waves for riprap design. The implication of this conclusion is demonstrated by reference to a possible Wash water storage Scheme(4) where riprap slope protection for bunded reservoirs in an intertidal zone was estimated to cost £38 m (1975 prices), about 65% of the total reservoir cost. Allowance for scale effects to reduce the size of riprap would have reduced the costs by about 30%.

With this in mind, field tests were proposed as the best method of establishing whether or not scale effects are indeed significant. An opportunity to carry out such tests arose during the construction of an offshore trial embankment in the Wash estuary, which formed part of the study of the feasibility of the water Storage Scheme.

2. OBJECTIVES AND SCOPE

The principal objective of the field trials was to compare observed behaviour at full scale with results predicted from small scale laboratory tests: hence to establish whether scale effects are significant and the scope, if any, for reducing costs of slope protection.

The field tests also provided a valuable opportunity to study practical aspects of handling and placing riprap, of checking the grading of both riprap and filter layers and of surveying the extent of the damage.

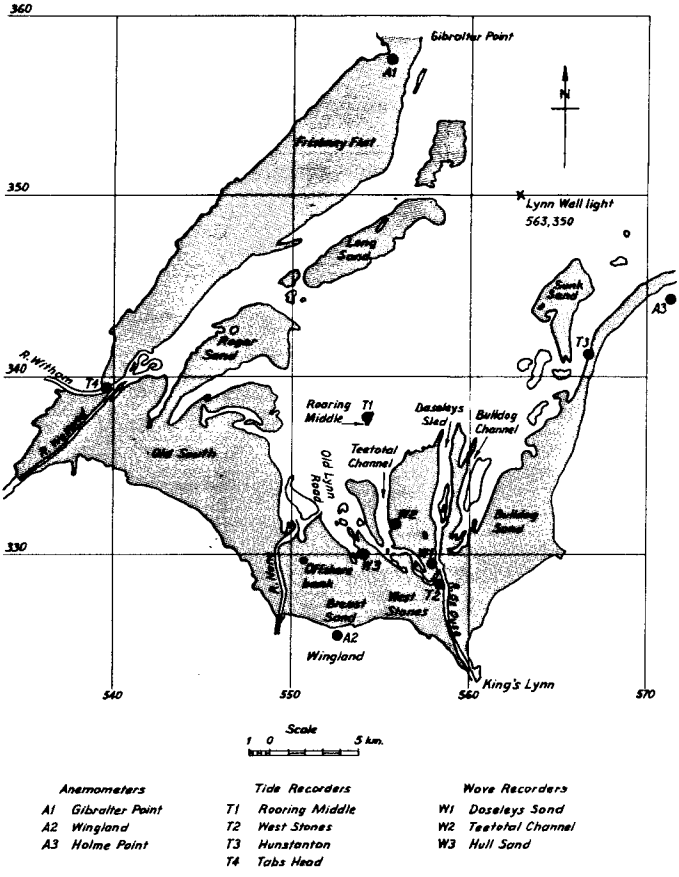

FIG. 1. LOCATION OF EXPERIMENTAL SITE AND DATA AQUISITION STATIONS.

The field study has since been rounded off by retrospective model tests, in which the test panels and wave and tide conditions that actually caused the main damage were reproduced at laboratory scale.

This paper concentrates on the field trials, but quotes the conclusions of the retrospective model tests. Details of these studies have recently been published[5],[6] and a further report[7] by CIRIA reviews both the laboratory and field tests.

3. DESCRIPTION OF THE FIELD TRIALS

3.1 Design of the Test Panels

The site in the Wash estuary is shown in Figure 1. The main trial embankment was circular in plan (Figure 2) and was constructed from hydraulically placed sand fill to a height of about 15 m above the sea bed. The large tidal range of the site (about 8 m at spring tides) was such that the foreshore was dry for about half the tidal cycle but some part of the lower half of the slopes was exposed to wave action for the other half of the cycle. The outside face of the main embankment was protected by heavy riprap (designated HRR) which was designed to withstand severe wave attack whether or not scale effects existed.

Four special riprap test panels were constructed, each 6 m wide and approximately 26.5 m long, on top of the main surface protection. Design of these panels was difficult because, for positive results, measurable damage (and perhaps failure) was desirable within a reasonable time scale. In view of the uncertainties over scale effects and in forecasting wave action, a range of sizes was selected so that the smallest riprap would almost certainly fail within a year or two with lesser damage (or none) expected to occur on the largest size. A fifth test section was selected from the adjacent permanent slope protection (HRR) which was also monitored.

3.2 Riprap grading

The specification called for riprap with the grading characteristics shown in Table 1, each size having a median diameter within a stated band, no stones exceeding a particular size, shape being such that the longest dimension was not more than three times the shortest dimension, and the small end of the grading defined by a minimum figure for the lower percentile (D_{15}).

TABLE 1 DIMENSIONS OF RIPRAP AND FILTER LAYERS

	Panel 1	Panel 2	Panel 3	Panel 4	Panel 5 (HRR)

It will be appreciated that checking the grading of riprap is not easy. Sieving is out of the question, yet, in most laboratory researches at small scale materials have been defined by sieve size. Samples in the field have to be treated as individual stones, most of which are so heavy that mechanical handling is needed. This not only poses problems on site, it also means that it is impracticable to expect a quarry to select and deliver riprap complying with a close specification.

After delivery of the material to the offshore bank site, a representative sample (about 15%) of the three smaller sizes was taken. Samples were also taken from Panels 4 and the HRR, although these samples were a smaller percentage of the total volume of stone delivered in these sizes. Every effort was made to ensure that the samples were representative of the bulk of material, but the procedure was necessarily subjective.

The material in each sample was graded by weighing on a spring balance while for every fifth stone in each sample three orthogonal dimensions were measured. The methods of weighing and measuring are described in reference 4.

The mass grading curves obtained were converted to dimensional grading curves (figure 3) using the relationship suggested in Reference 3:

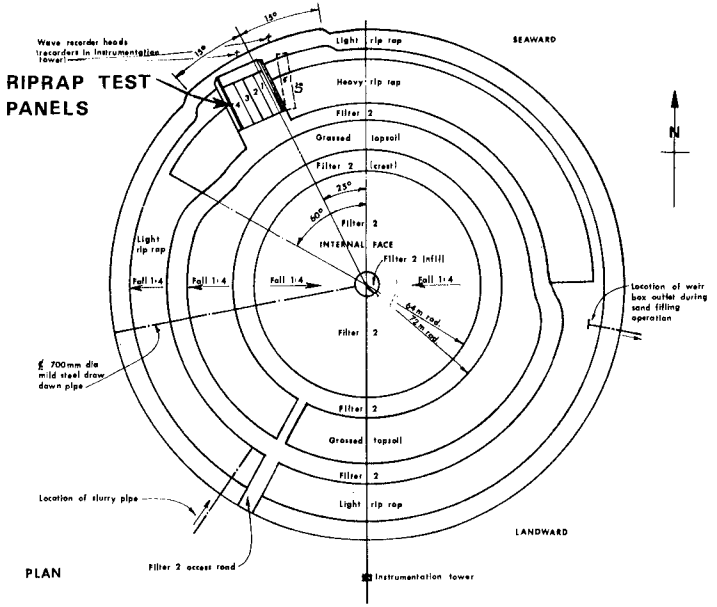

FIG. 2. LOCATION OF TEST PANELS ON OFFSHORE BANK.

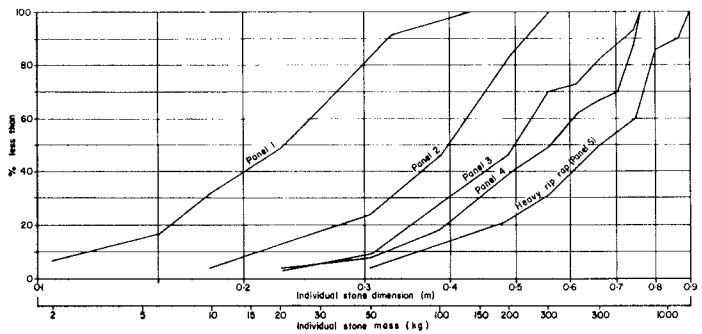

FIG. 3. GRADING CURVES FOR RIP RAP.

$$M = 0.65 \varrho D_S^3$$

which is based on conversion of sieve gradings, where D_S is sieve size, to individual stone mass, M. This relationship was implicit in the original specification of the riprap grading. The conversion showed that the materials for Panels 2 and 3 were outside the tolerance specified, being somewhat oversize.

3.3 Construction

The first stage of constructing the four test panels was to blind the selected area of main riprap protection with a layer of filter material to ensure that no settlement of the test panels would occur through the filling of voids beneath them. A fabric sandwich, consisting of two layers of a non-woven sand-tight fabric separated by a sheet of PVC, was placed on the blinded surface to make the test panel foundation impervious, in an attempt to match the previous laboratory arrangement. A layer of filter was placed over the fabric on which the stone forming the test panels was laid, with the panel containing the smallest stone (Panel 1) at the eastern edge of the test area, each panel being flanked on its western edge by the panel containing the next larger size of stone. The location and arrangement of the panels on the embankment is shown in Figure 2, and a longitudinal section through one of the panels is shown in Figure 4.

Proposals for strengthening the edges of the panels, so that if one panel failed completely the adjacent panel would not be weakened were considered. However, any method of edge strengthening would then form an upstanding edge, which could cause undesirable wave reflections interfering with the performance of the riprap or could itself be washed away. Bearing in mind the cost and uncertain performance of any such arrangement, no special edge treatment was incorporated.

The area of the main bank protection selected as Panel 5 lay immediately to the east of the special test section. No special provisions were made in placing this riprap or in placing the two filter layers separating the permanent riprap from the sandfill of the embankment.

The stone was imported by sea from quarries in Belgium. It was then brought from offshore stockpiles by barge and placed direct in position by floating crane using a 4 tonne cactus grab.

Segregation is a problem with riprap and is made worse by multiple handling, as necessarily occurred with the construction techniques employed offshore in the Wash. It also increases with widely graded stone. Despite efforts on site to control the work so as to minimise segregation generally, and particularly in the test panels, it was not practicable to correct segregation other than marginally once it occurred.

For the test panels, control of the placing operation was strict and the quality of the finished slope protection is probably better than would normally be found using this method of placing. Nevertheless,

visual inspection revealed that the riprap surface was rough and fairly open, with occasional holes through which the surface of the filter layer could be seen, this being particularly noticeable on Panel 4. The mean thicknesses of the riprap are listed in Table 1 which also shows that in all panels except Panel 1 the relative layer thickness ratio, t/D_{50}, was less than 2.0, the value recommended on the basis of laboratory research.

Three factors tended to reduce the relative layer thickness below the intended value:

1. Penetration of the riprap into the filter layer material.
2. Loss of material in transport and handling, which could not be made good at the time.
3. Because the stone tended to be oversized, the given coverage in terms of mass per unit area yielded a lower ratio of t/D_{50}.

The derivation of mean layer thickness is not always defined in earlier work but the problems of controlling this parameter are considered in Reference 5. Discrepancies must be expected in difficult field conditions.

3.4 Data Collection

There were two principle components of data collection: wave climate and damage to riprap. Measurement and analysis of wave action was a major task and only an outline of the methods adopted can be presented here (details are given in reference 5).

Waves were measured by two pressure transducer wave recorders mounted near the seabed in front of the trial panels, and data on wave heights and periods were obtained at approximately hourly intervals through the high tide period under control from a lunar clock. Water levels were measured continuously in order to identify the level at which wave attack was concentrated. The direction of wave attack was deduced from wind data obtained from an anemometer set up on the coast, about 1.5 km away.

Damage to the riprap panels was measured at regular intervals so that it could be related to the wave action. The method of surveying damage was based on the procedure used previously in the laboratory, and involved measuring profiles along the riprap surface in relation to a fixed framework.

Five survey lines for each panel were fixed by stretching piano wire tagged at the required intervals, from a frame at the toe of the panels to a pulley fixed to a second frame at the top of the panels. The level at each plan position was obtained by measuring down from the tags on the piano wire, using a vertical scale fitted with a spirit level and having a hemispherical foot. The diameter of the hemisphere was equal to half the average of the specified median stone size limits of the panel being surveyed, and thus a different foot was required for each panel.

In addition to the levelling survey, each panel was photographed from a fixed point whenever a survey visit was made.

A total of 17 surveys were carried out over the 2½ years period of study.

3.5 Damage Analysis

The survey data were analysed by computer to give a quantitative description of the damage sustained by each panel and a surface profile plot of each line surveyed.

The definition of damage was that used in the HRS laboratory studies reported by CIRIA(3) : the volume removed, expressed as an equivalent number of D_{50} - size spherical stones for a $9D_{50}$ width of panel, considering only downward movements of the surveyed profiles (reductions in thickness). In the laboratory tests, these movements occurred in a fairly well-defined area about the still-water level. Positive movements (accretion of displaced stone) generally occurring in the region below the eroded area were ignored, since these are not of interest when considering the ability of the riprap layer to withstand damage (Figure 5).

The volumes of material eroded from each panel since the beginning of the study, and also since the previous survey, were obtained by differencing the relevant profiles. The eroded volumes were then converted to the mass of stone removed and then to the equivalent number of D_{50} size spheres over a 9 D_{50} width.

Some statistical analysis of the individual survey measurements was made to give measures of the mean movement of the surface in each section, the roughness of the surface, and changes in individual measurements between surveys.

4. RESULTS

4.1 Wave events and General Damage History

It was unfortunate that large waves (H_S just over 1 m) occurred with high water levels very early in the project, during the gale lasting from 16 to 18 November 1975, within days of laying the test riprap. The main effect was the total failure of Panel 1 (Figure 6). The riprap and the underlying filter were completely washed away from the central section of the panel, part being deposited in the lower section of the panel and part being completely lost. The upper limit of damage, about 6 m from the top of the panel, was marked by a near vertical face exposing the riprap and filter layers. The failure of Panel 1 had been expected to occur during the course of the first winter, but the occurrence of a severe storm so early meant that no results on progressive damage were available for this panel.

Erosion damage on Panel 2 was also serious on this occasion, being assessed at 112 D_{50} stones. Damage was concentrated on the side

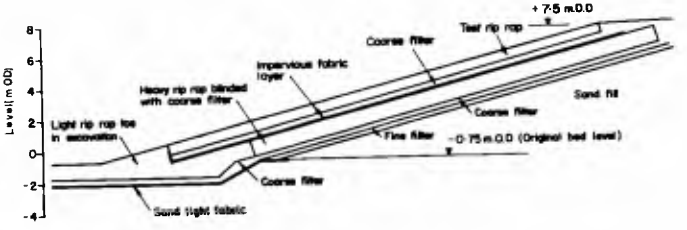

FIG. 4. SECTION THROUGH TEST PANEL.

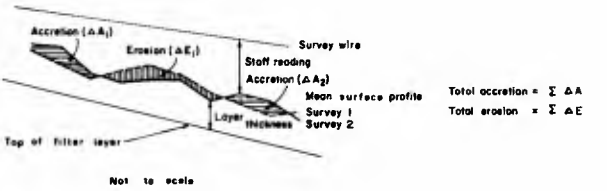

FIG. 5. ILLUSTRATION OF DAMAGE ANALYSIS.

FIG. 6. FAILURE OF PANEL 1, NOVEMBER 1975.

closest to Panel 1, and a considerable part was undoubtedly because of the loss of edge support resulting from the total loss of riprap and underlying filter from the central part of Panel 1. Table 2 lists the survey dates and the damage status.

During December 1975 three wave events were recorded, one of which included waves with H_S nearly 0.9 m. The two most severe events occurred with winds orthogonal to the panels, but tide levels were in general low at the time and so there was little additional damage to the panels. The next severe gale occurred on 3 January 1976, when winds of up to 40 m/s (90 mile/h) were recorded. Waves on this occasion were not very large, partly because the wind did not reach its peak until some time after high water and partly because it was blowing from the west with a very restricted fetch. Tide levels were high, however, and waves at high water were large enough to cause further erosion at the top of Panel 1, as filter material was washed out from the foot of the vertical cliff marking the upper limit of earlier damage. Over the next week, this caused the area of Panel 2 affected by loss of edge support to extend up the slope.

Three events with waves of about 0.75 m occurred between mid-January and mid-February 1976. Only the first event was with winds directly in line with the test panels, the second and third events being with winds from the east and northeast respectively. However, damage to Panel 3 and 4 as well as further damage to Panel 2 was noted.

The period to April 1977 covering the next winter, was relatively calm: the maximum significant wave height recorded was 0.83 m, but on this occasion the wind was further from the northeast (70° from orthogonal). Only minor drainage was observed, comparable to the probable maximum error in measuring damage, so was not significant.

Data collection in the Spring of 1977 was marred by the loss of wave records from 19 March to 8 May, a period when northerly and north-easterly winds were dominant. However, hindcasting of wave events demonstrated that particularly severe wave attacks (H_S = 1.4 m) occurred immediately after surveys on 5/6 April. Waves were directly orthogonal to the bank and, being the severest to date, some damage was to be expected to most of the panels, although no further survey was carried out until August 1977.

Immediately following the August survey there was further severe wave action (4 days with H_S up to 1 m at high tide). Winds were primarily from the north east, though they backed to north north west and resulted in the total failure of Panel 2 (see table 2, survey on 12.10.77) and further damage to Panels 3, 4 and 5.

One further event, with waves nearly 1.0 m high, was recorded in December 1977, but the wind was from the west and no damage was observed.

Waves recorded in the event of 11/12 January 1978, the third winter of observation, when winds were from the north, were far in

excess of the previous maximum (H_S = 2 m) and resulted in the total failure of Panels 3 and 4 (Figure 7) (see Table 2, survey of 9.3.78). Panel 5, the permanent riprap, suffered very little damage. This was a very rare combination of wave attack and high tide: the tide level exceeded the calamitous 1953 storm surge in fact.

4.2 Damage calculated from Laboratory results

Results of the laboratory study[3] were used with the recorded wave data to hindcast the damage sustained by the test panels. The method used is a variation of that set out as Method 2 in CIRIA report 61(3), making the appropriate allowance for the different water densities in the laboratory and fieldwork. The data contained in that Report were used to prepare Figure 8, in which damage is related to number of waves incident on the panel and the ratio H_S/D_{50}. The total damage expected was obtained by summing the damage arising from waves of each height, i.e. as if they were attacking an undamaged surface.

The laboratory work showed that a damage level of about 115 stones removed corresponds to the level of failure at which the filter layer could be touched with the survey probe. However, the differences between field and laboratory conditions (Section 3.1) reduce the significance of this value. The lower ratio of thickness to stone size used on the test panels suggests that failure might occur with fewer stones being removed. On the other hand, varying water levels would cause damage over a larger area than in the laboratory tests, suggesting that a greater level of damage could be tolerated before local failure is reached.

4.3 Comparison between measured and hindcast damage

Table 2 summarises the comparison between damage to the test panels as measured by field surveys and that hindcast on the basis of laboratory tests. The general impression is that measured damage is rather greater than that calculated except in the case of panel 5, where measured and calculated damage are comparable (but small in absolute terms and only of the order of possible survey error).

In interpretting the results of this comparison, it should be remembered that the conditions of the field study inevitably differed from those in the previous generalised, somewhat idealised, laboratory research in the following respects:

1. The presence of tides causing the water level to vary continuously from below to about three quarters of the way up the test panels.

2. The variability of the wave events.

3. The sequential action of waves at different elevations and with differing heights.

4. The range of directions from which the waves approached the test panels.

FIG. 7. FAILURE OF PANELS 3 AND 4, JANUARY 1978.

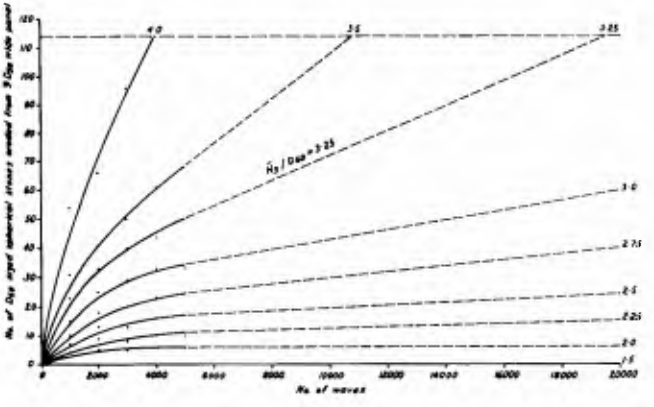

FIG. 8. DAMAGE FROM WAVE ATTACK, BASED ON HRS RESULTS (REF. 3)

5. The very large number of waves involved.

6. A different ratio of filter-size to riprap size.

7. The thickness of the panels ($2D_{50}$ in the laboratory work: but considerably less than that in Panels 2, 3 and 4 in the field trials).

8. Different methods of placing the riprap, involving some degree of segregation and differing bulk density of the finished layer.

9. Problems of measuring stone size and differences in the grading and shape of the riprap.

10. The very different sizes of the stone in the laboratory and site situation and the consequential scale effects.

Some or all of these differences between field and laboratory conditions undoubtedly account for discrepancy between observed and calculated damage, based on scaling up the laboratory work, and could perhaps obscure scale effects if they existed. Nevertheless, the clear conclusion is that using laboratory research results for riprap design, omitting any allowance for scale effects, does not result in an over-conservative design.

4.4 Retrospective Model Tests

The overall impression was that agreement between earlier laboratory tests and field trials was fair and that there was no evidence of major scale effects. Nevertheless, further evidence was sought from specific model tests in which the conditions actually observed during the field trials were reproduced as far as possible. These retrospective model tests were undertaken by HRS in 1981 and results have now been published(6). These small scale (1:17) laboratory tests satisfactorily reproduced the damage behaviour observed in the field tests, thus adding weight to the conclusion on the absence of significant scale effects.

5. CONCLUSIONS AND RECOMMENDATIONS

5.1 Evidence for Scale Effects

In general, the amount of damage sustained by the test panels was slightly greater than that calculated from laboratory research results. The exception was Panel 5 which, in the most severe event, suffered slightly less damage than predicted, though the difference is within the survey and other tolerances. The discrepancies between observed and hindcast damage can be explained by inevitable differences between laboratory and field conditions. Retrospective model tests in which the field conditions were more realistically represented than in previous basic research showed good agreement between model and full scale results.

This study has thus not confirmed the CERC findings(1) concerning scale effects, namely that small scale model results tend to overestimate the size of riprap needed to provide protection against waves of a particular height.

5.2 Practical Aspects of Riprap Design and Construction

The field trials, which were undertaken under close supervision, demonstrated the problems of laying riprap to meet specified gradings, mean size and layer thickness.

Procedures developed for monitoring and analysing progressive damage to riprap involved considerable effort but were successful and are recommended for any future full scale study.

Whilst the general guidelines for riprap design given in CIRIA report 61 have been validated by results of field tests, gaps remain in our knowledge of the behaviour of riprap. These include the effect of varying water level, the effect of oblique attack, the influence of non-uniformity arising from segregation of graded stone, the importance of layer thickness and grading of both filter layer and of the riprap itself, and the modes of progressive failure resulting from locally damaged areas.

5.3 Recommendation for Design

Results of small scale hydraulic model tests on riprap should be adopted without making allowance for "scale effects" which might justify smaller sizes. If model tests are not conducted specifically for the slope protection in question, then the design procedures given in CIRIA report 61 are recommended.

Designers should be aware of the practical difficulties in meeting specifications for riprap. If the consequences of damage to riprap are not acceptable than a cautious approach to design should be adopted.

6. ACKNOWLEDGEMENT

The field trials described in this paper were funded through the Construction Industry Research and Information Association, London (CIRIA). Their permission to publish the results obtained is gratefully acknowledged. The collaboration of R.M. Shuttler of the Hydraulics Research Station and many other authorities and individuals has been much appreciated.

OFFSHORE ARTIFICIAL STRUCTURES AND THEIR INFLUENCE ON THE ISRAEL AND SINAI MEDITERRANEAN BEACHES

by
Yaacov Nir
Geological Survey of Israel,
Marine Geology and Geomathematics Division,
30, Malkhei Israel St., Jerusalem 95501, ISRAEL.

INTRODUCTION

The Israel Mediterranean shore forms a gentle curve from an almost easterly direction in north Sinai to an almost northerly direction in Israel. This shore forms the southeastern corner of the Levantine Basin which itself forms the extreme eastern part of the Mediterranean Sea. The length of the Israel shoreline from Rosh Haniqra near the Lebanese border to northern Sinai in the south is about 230 km, while the Sinai coast from Rafah to Port Said (Fig. 1), is almost 200 km long. The coastline region consists largely of Quaternary carbonate cemented quartz sandstone, known by local name "kurkar". Recent faulting is responsible for the shape and, to a certain extent, for the morphology of large parts of the central coastline, which is characterized by kurkar cliffs (Neev et al., 1973 & 1978). Wide sandy beaches are found in the southern parts, while an abraded rocky platforms occur mainly in the central and northern parts, where the beaches are narrow having kurkar cliffs at their backshore side.

Four different morphological sections can be found in the Israel Mediterranean shore, (Nir, 1982). These differ in their beach and inland morphology on one hand, and in their sedimentological properties on the other. The four different sections from north to south are:

1) Rosh Haniqra to Akko. A sedimentologically isolated region, bounded on both the south and north. Beach sediments are mostly of local calcareous material of marine origin. Akko promontory is the most northern limit of Nile derived sands and plays as the recent edge of the Nile sedimentary cell (Nir, 1980). 2) Haifa Bay. Wide sandy beaches, bounded on the north by the Akko promontory, and by the Carmel "nose" on the south. 3) Mount Carmel coastal plain, is sedimentologically somewhat isolated region with relatively narrow beaches and small kurkar cliffs. Sediments consist of both local and imported components. 4) The kurkar cliffs and sandy beaches from Caesarea to Rafah. Beaches of differing width having quite uniform petrographic components, mostly quartz grains originating from the Nile river and transported along the Sinai beaches to the Israeli beaches. Some of the present beach components are derivated from the abraded kurkar cliff.

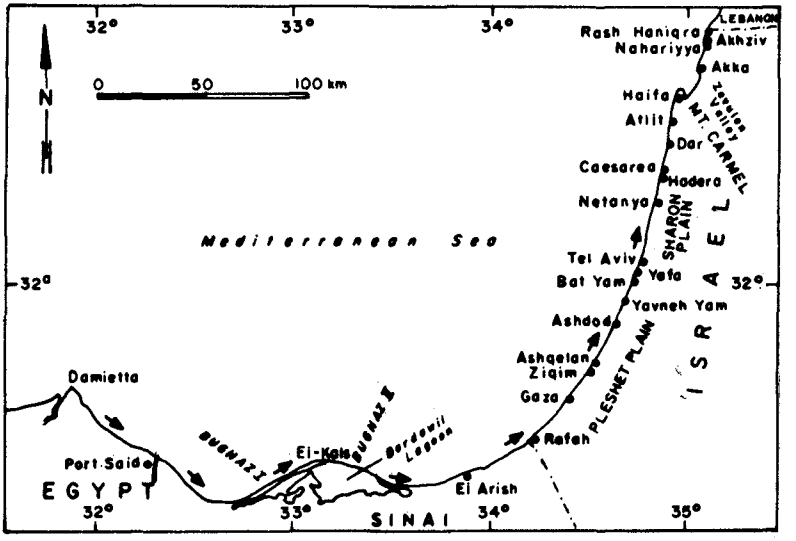

Fig. 1. Northern Sinai and Israel Mediterranean beaches, location map.

THE BEACHES

The Israel Mediterranean beaches are mostly sandy, with a few exceptions where local kurkar or limestone pebbles are found. The sands are light in colour, white to light yellow, and are mostly composed of quartz grains. The beaches between Rosh Haniqra and Akko and some parts of the Carmel Coastal Plain are exceptional in that the sands are of local origin and mostly composed of skeletal material, mostly algae and molluskal debris. Kurkar cliffs constitute a very distinct morphological feature along the shores. Most of the cliffs are 20–40 m high and are very strongly abraded by the sea at the foot of the cliff, and by rainwater along its slopes (Fig. 2).

The following scheme shows the qualitative budget of sand along the North Sinai and Israel Mediterranean beaches, showing both onshore and offshore sand sources and sinks: 1) Offshore Losses – by sand mining and dredging in harbours, accumulation of sand in and around harbours and artificial objects. 2) Seaside contribution – Nile sands transported along the beaches, destruction of beaches in the Nile delta and northern Sinai, and organic production mostly of pelecypod shells. 3) Onshore losses – sand mining (up to 1964), use of beach and artificial tombolo areas, wind blown sand and dune formation. 4) Landside contribution – erosion and abrasion of the kurkar cliffs, river alluvium, and sand dunes.

Quartz sand dunes cover relatively large areas of the nearshore regions of the Coastal Plain of Israel. The majority of the dunes are located in the southern part, connected with the north Sinai enormous sand dune sea. The origin of their quartz grains, which make up the primary component of the beach, has been investigated mineralogically (Shukri and Philip, 1960; Pomerancblum, 1966; and Nir, 1973 & 1982). Certain conclusions can be drawn: 1) Nile-derived sediments are transported along the beaches of the Nile Delta, Sinai and Israel by waves and wave generated longshore currents and the counterclockwise East Mediterranean current. 2) A relatively minor amount of sandy sediments are also introduced by local rivers (wadis), which are active only during winter floods.

Fig. 2b. Kurkar cliff near Hadera. Most of the cliff is composed of soft friable red loam ("Hamra") and sand. Landslides are typical on these cliffs, causing talus of huge blocks at their base.

Fig. 2a. Steep kurkar cliff south of Netanya. The beaches are narrow, but show maximum development in this photo.

In the cliff regions, beaches are very narrow, reaching a width of only 10-20 m and much less during winter time (Fig. 2a). The sandy beaches are relatively wide in regions where kurkar cliffs are absent, in some parts reaching widths of 60-80 meters.

Large quantities of beach-sand were quarried until 1964, at an estimated annual rate some 10 to 20 times larger than the naturally occuring annual sand replenishment. This quarrying produced a sand deficit along many beaches, causing an accelerated erosion of the beaches and nearby cliffs.

SEDIMENT TRANSPORT ALONG THE BEACHES

Artificial constructions such as groins, breakwaters, barges, etc. found along the Sinai and Israeli shores trap some of the longshore sand drift, causing damage downstream and sometimes enabling us to ascertain the qualitative and even quantitative net sand drift at a certain point.

These shores on a whole belong to the large sedimentary cell which starts at the two Nile Delta outlets at Rosetta and Damietta, and extends along the Sinai shores as far north as Akko in Israel (Nir, 1980). Zenkovich (1971) shows a very clear easterly directed sediment transport along most of the Nile Delta beaches.

Two channels ("Bughaz") were dug in the outer Bardawil bar in order to maintain its water connection with the open sea. Groins were constructed to keep the channels from silting up. As a result, sand accumulated on the western side of these groins and Inman and Harris (1970) estimated the yearly net easterly sand transport at the western outlet (Boughaz 1) to be on the order of 300-800,000 m3/year.

The El Kals temporary harbour and sand mining close and west of El Arish caused severe erosion to nearby dunes and summer houses respectivelly (Fig. 3).

Wadi El Arish drains practically all of northern and central Sinai. The beach near the outlet of this ephermal wadi is straight and usually conforms with the regular shoreline. In a very short period of time, at the end of February 1975, a voluminous flood transported several hundred million cubic meters of water and sediment to the sea. These clastic sediments formed a large new delta more than 400 m offshore with a large submarine extention. This new delta partially dammed the sand drift, resulting in a sediment accumulation on the delta's western flank, on the one hand and a very effective abrasion on the down-drift shores east of the outlet on the other (Fig. 4). The sediments of this delta were transported eastwards quite quickly and the delta changed shape, reaching an almost straight and regular shoreline (Fig. 5).

All the obstacles east of El Arish up to Rafah show a clear net easterly drift, while those northwards almost up to Tel Aviv show a northern drift. These obstacles are: a barge east of El Arish (Fig. 6), two groins and the wreck between them in Gaza Harbour (Fig. 7), a harbour with two groins on its southern and northern sides at Ziqim (Fig. 8), and the huge Ashdod Harbour, whose main breakwater reaches 18 m water depth. This last structure impedes sand transport and accumulates sand in large

quantities in the offshore at relatively great depths (Dornhelm, 1972; Kran, 1980; and Finkelstein, 1981).

Fig. 3. Summer houses at El Arish, N. Sinai. The collapse was a result of the sand deficit caused by quarrying of beach sand ("Zifzif") nearby.

Fig. 4. Roots of palm groves were exposed to wave action east of El Arish as a result of the provisional damming of the regular eastward sand transport by the delta of Wadi El Arish in Feb. 1975.

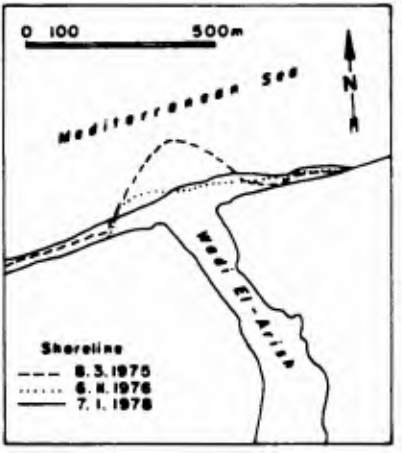

Fig. 6. A barge at N. Sinai beach east of El Arish accumulates sand on its western side, thus clearly illustrating the easterly sand transport.

Fig. 5. Schematic map of Wadi El-Arish Delta , drawn from aerial photographs, showing its different development and disapearing stages.

Dornhelm (1972), and Kran (1980) who reanalysed Dornhelm's charts show that the Ashdod Harbour's main breakwater interrupted about 80% of the annual northward transport of sand. Finkelstein (1981) also shows a

tremendous offshore sand accumulation during 13 years which reaches perhaps 4 million cubic meters at the main breakwater and westwards. Northwards he shows accumulation close to the lee breakwater and a large area of erosion farther north. By and large this agrees with the main trend of northerly drift. He also estimated the net annual northerly transport at Ashdod to be on the order of 560,000 m3, which is a very high value.

Fig. 7a. Aerial photo showing Gaza Harbour, which is made of two groins, about 120 m long and about 500 m apart.

Fig. 7b. The southern groin of Gaza Harbour, showing accumulation of a large volume of sand south of the groin, causing heavy damage to the beach structures further north.

Fig. 8. A map of Ziqim Harbour, drawn from an aerial photograph. Note the extreme widening of the beaches to the north. These are now almost totally exposed of their sand cover yearround. Prior to harbour construction beaches to the north had normal sand quantities and normal widths even during severe winter storms.

The old site of Yavneh Yam show northerly drift in the form of a large retreat of the seashore which has caused damage to the old site (Fig. 9).

Northwards from Tel Aviv the net transport decreases significantly, and at the Carmel Head transport is to the east and to the south, and the region between here and Atlit is to a certain extent isolated.

Fig. 9. The beach north of Tel Yavneh-Yam ("Minnet Rubin"), suffers from heavy abrasion due to the sand deficit and the protruding promontory of the Tel. Beaches here have withdrawn about 50 m during the last 50 years. In Early British Mandatory topographic maps almost no promontory was shown here.

Emery and Neev (1960), assumed a northerly sand transport for the southern Israel beaches and a southerly one for the central and northern beaches. A northerly directed offshore current and sediment transport of mostly fine grained sediments was also suggested. This transport is responsible for most of the present influx of fine sand to Haifa Bay.

On the basis of theoretical studies Migniot (1974), Sauzy et al., (1974) and Manoujian and Migniot (1975) show that the annual resultant sediment transport is always directed to the north and reaches about 400,000 m3 at Gaza, 215,000 m3 at Ashdod, 100-150,000 m3 at Hadera and only 80,000 m3 at Atlit.

Goldsmith and Golik (1978) summarized the Israel Mediterranean wave climate and constructed a longshore sediment transport model for these beaches. In general they support the conclusions of the earlier studies regarding sediment transport.

OFFSHORE STRUCTURES OF THE ISRAEL MEDITERRANEAN SHORELINE

Prior to 1960 with the exception of a few ancient harbour sites such as Akko, Haifa, Caesarea and Yafo (Jaffa), the Israel Mediterranean shore did not have any large offshore structures (Kravitsky, 1966).

The main stage of offshore construction for recreational purposes took place in the late sixties and the early seventies when 25 structures (15 breakwaters and 10 groins) were built along the beaches from Gaza in the south to Akhziv in the north (Fig. 1). The environmental impact of these structures were studied in the field, by succesive aerial photos, and by bathymetric and topographic maps of the sites and their vicinity. They were also studied with regard to their engineering characteristics (Fried, 1975 & 1976; Tauman, 1975 & 1976). Vajda (1975) investigated their sedimentological development in the laboratory in order to limit as much as possible their erosional effect. Nir (1976) gives a

detailed description of the different offshore structures with their sedimentological characteristics and their relationships to the nearby beaches. Spar (1976), and Sofer and Sass (1982) studied in detail the sedimentology of the Netanya twin breakwaters.

Most of the structures have developed a tombolo at their "shaded" landward side. These tombolos typically have a trapezoidal shape (Figs. 10 & 11). They reach a mature stage (at which significant size changes cease) about 5 years after the end of construction (Fig. 12). The sand accumulated in these tombolos comes mostly from the nearby beaches and shallow sea. In most cases these beaches have therefore suffered severe erosion during the first 3-4 years after the construction, while in some cases this erosion even continues beyond maturity.

Many of the detached breakwaters and groins were built in very populated areas in order to increase the amount of beachfront and to calm the relatively rough seas occuring during the bathing season in July and August. These problems were partially solved by the tombolo which was formed in the shaded area of the breakwater and by the attendent of areas of quiet water.

These breakwaters were mostly constructed about 200 m offshore of the original shoreline, mostly on a submarine exposed rocky strip in about 3-4 m water depth. This rocky strip (Fig. 13) was chosen for the practical economic purpose of reducing foundation costs. As their length almost equals their distance offshore, huge tombolos started to grow out from shore which later joined with the breakwater. Figure 12 and the following table show the aerial development with time of these tombolos, following their completion. Most of these tombolos reached almost one half of their final size within a period of one or two years. There is a sharp decrease in the rate of expasion of the sand area in the second year after the end of the construction.

Site	Time (years) for tombolo volume to go from 0-50%	50-100%	Total years
Carmel Beach	3.23	2.60	5.83
Netanya (south)	1.06	3.52	4.58
Netanya (north)	1.56	2.10	3.66
Tel Aviv 1	1.50	4.07	5.57
Tel Aviv 2	3.15	2.66	5.81

Table 1. Time needed (yrs)for tombolo volume to develop from 0-50% and from 50-100%. The averages show that the tombolo reaches its half volume in about two years and that it takes another 3 years to reach the mature stage.

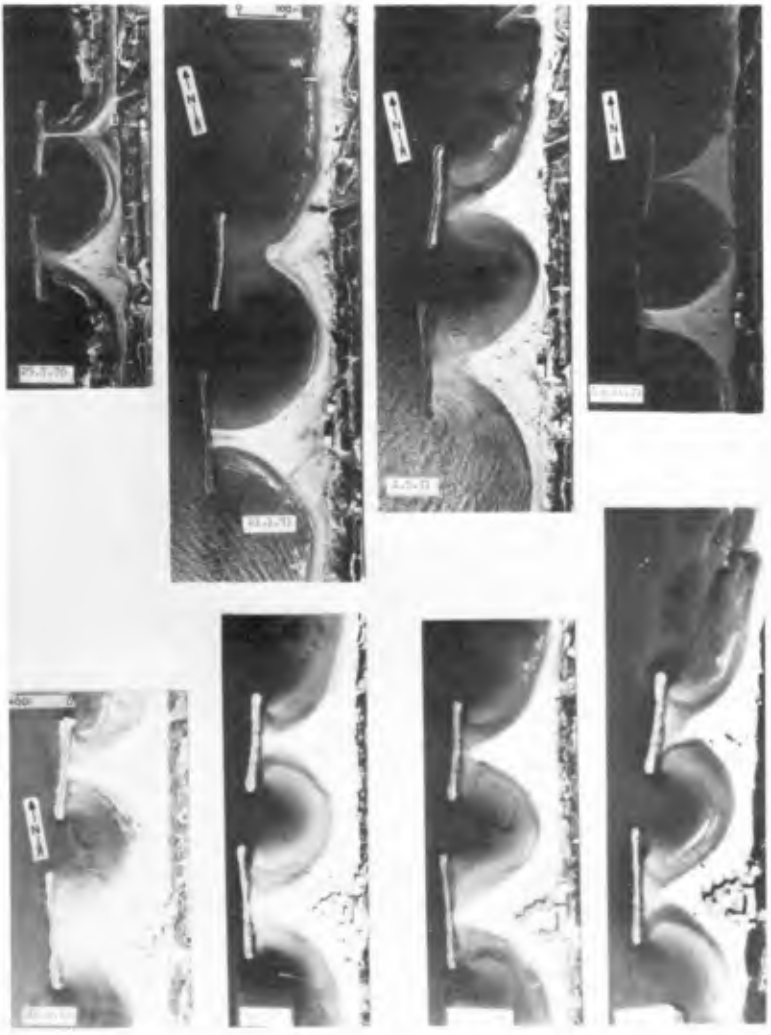

Fig. 10. The twelve year history of the twin tombolos off the Netanya beaches. The tombolos reached their first maximal stage at the end of 1973, and since then they show seasonal fluctuations. Winter storms usually open a channel between the tombolo and the breakwater.

This slowing in sand accumulation is primarily because the nearby beaches, which are the main suppliers of sand to the tombolos, have already suffered an enormous sand deficit due to sand capture by the newly built structure, and also because of the increase in water depth around the tombolo. In sites where two structures were built, the tombolo of the most recently built structure reached its 50% sand volume in a much longer time than the first structure. In Netanya, this time difference is about 50% while in Tel Aviv it required more than twice as long to reach the 50% sand volume stage, this probably due to the general deficit of sand in the Tel Aviv beaches. The Netanya case on the other hand, at the second stage of its development, shows faster accumulation at the northern structure which is the younger, with probably preferred southerly directed longshore transport.

Most tombolos reached their mature size between the 5th and the 6th year after construction. Thereafter the only changes are seasonal with maximum tombolo size at the end of summer, or more precisely just before the first storm at the end of autumn. Some decrease in size occurs during winter and early spring (Fig. 10). This fits very well with the regular winter to summer variations in beach width. In his study of the shallow Ma'agan Mikhael beach Eitam (1975) also found that the accretion period extends over the autumn.

Aerial photographs of the different sites where one or more detached breakwaters were constructed, taken before, during, and after construction, show the different stages of tombolo growth on the one hand and the fast erosion of the nearby beaches on the other (Fig. 15). At the Carmel Beach site the nearby beaches were almost totally stripped of their sands. A large beach area, just next to and south of the tombolo, disappeared 12 years ago and has not been rebuilt (Fig. 14). The Carmel Beach structure was chosen to represent a single breakwater tombolo while the Netanya structures typify twin tombolos. Fig. 10 illustrates the different stages of tombolo growth as they attain their mature stage in 4–5 years time.

In Netanya tombolos began to grow during the construction activities, and about 70,000 m3 of sand were attracted from the nearby beaches and shallow sea in 3–4 years time. Prior to construction, Netanya's beaches were already in very bad shape and waves were reaching the base of the steep kurkar cliffs. This was among other morphological and stratigraphic reasons due to the enormous quantities of sand being quarried all along Israel's Mediterranean beaches up to 1964; for example, Emery (1963) estimated that about 1/3 of the beach sand reserves had by that time already been quarried. Following formation of these tombolos, abrasion in the

nearby kurkar cliffs was accelerated, so that measures had to be taken to protect the cliff. Recently Ron (1982) has proved enormous cliff retreat in the region of Netanya during the last 35 years.

Table 2 summarizes the sand quantities that accumulated in the aerial parts of the seven first built tombolos at the different sites. These account for about 270,000 m3 of sand. It is assumed that about the same quantity or more of sand was deposited underwater in the vicinity of the tombolos. Therefore, altogether these offshore structures (with the exception of the huge quantity deposited near Ashdod Harbour), captured about 600,000 m3 of sand in a period of 4–5 years. This volume is much larger than the actual sand available from the annual import from the Sinai beaches. The volume of sand at each separate site was calculated using the following formula (derived by John K. Hall):

volume of sand $V = dc(2a+b)/3$; where:

2a – is the length (in m) of the tombolo's offshore edge (taken parallel to the shoreline).

b – is 1/2 of the length of the base of tombolo (in m).

c – is the distance between the base and the seaward edge of the tombolo(in m).

d – water depth (m) at the seaside edge of tombolo.

Site	Quantity of accumulated sand (in m3)
Nahariyya	20,000*
Shavey Zion	5,000–18,000
Carmel Beach	55,000
Netanya (north)	34,000
Netanya (south)	38,000
Tel Baruch	15,000
Tel Aviv 1	45,000
Tel Aviv 2	20,000
Bat Yam	26,000
Total	258,000–271,000 m3

Table 2. Sand quantities which were accumulated at the different offshore structures along the Mediterranean coasts of Israel (including only the subaerial sand bodies within the tombolos).
* Some sand was quarried from the tombolo.

Figures 10, 12 and 14 show the developments that occurred around the twin detached breakwaters in Netanya. The different shorelines were drawn from aerial photos of the site, taken at various time intervals. Comparison between the areas of the successive tombolos and the quantities of accumulated sand shows that one of the main

Fig. 11. The different stages of tombolo development for the Carmel beach structure, from the very early stages of construction(11a), to the formation of an enormous tombolo (11d) some 5 years later.

factors affecting the sand quantity is the ratio between the length of the breakwater and its distance from the original shoreline. The smaller the ratio – the smaller the tombolo that develops.

Empirical study shows that there is a direct relationship between a structure's distance from shore and its length (or its projection onto the shoreline): the larger this ratio the smaller the sand volume accumulated in the tombolo. Accretion is very little, or does not occur at all, if this ratio has a value of 2 or more (Fig. 16) This value is somewhat smaller than that of Inman and Frautschy (1966), who studied the Californian beaches showing that non-depositional conditions prevail only when this ratio reaches a value of 3: "pronounced accretion does not occur if the structure is situated offshore a distance equal to or greater than 3 to 6 times the length of the detached breakwater". Although there are no structures in Israel with these high ratios, it is apparent that no accretion occurs here if the ratio is smaller.

The area of the mature tombolo ranges between 40 and 75% of the rectangular area between the breakwater and the original shoreline. Beach area for that particular section of shoreline has been increased, but on the other hand the protected bathing area has been commensurately decreased; among other reasons are dead algae accumulations at the protected areas. The regions of turbulent water around the edges of the breakwater are dangerous for bathers and present another major problem resulting from the construction.

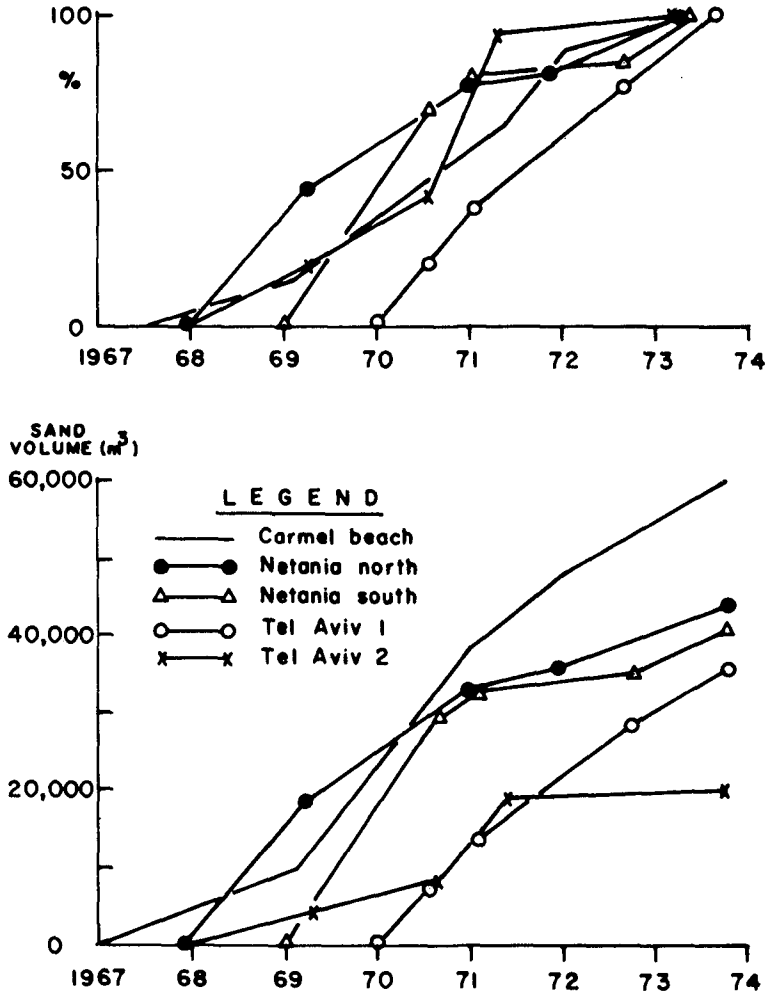

Fig. 12. Tombolo development at the different sites: Carmel beach, Netanya and Tel Aviv. The upper graph shows the cumulative percentage of the tombolo's area while the lower one shows cumulativesand volume both show the relatively quick sand accumulation at the early life stages of the structures.

Fig. 15. Severe beach erosion near offshore structures. Fig. 15a. Heavy destruction on the beaches south of Tel Baruch structure (16/6/80). Fig. 15b. Shore buildings north of the Gaza Harbour groins have suffered heavy damage. Small nearshore structures parallel to the beach were erected here to prevent further collapses. Fig. 15c. Exposed beach basement at Bat Yam, after a severe storm (19/4/71). Damage was greater here because marine construction on a half closed pool in shallow water caused buildup of water during storms. Fig. 15d. Small bay north of King Herod's ancient harbour in Caesarea. While in operation this now submerged harbour caused heavy damage to the Roman aquaduct and therefore measures should have been taken to protect the aquaduct whose broken remnants appear in the foreground.

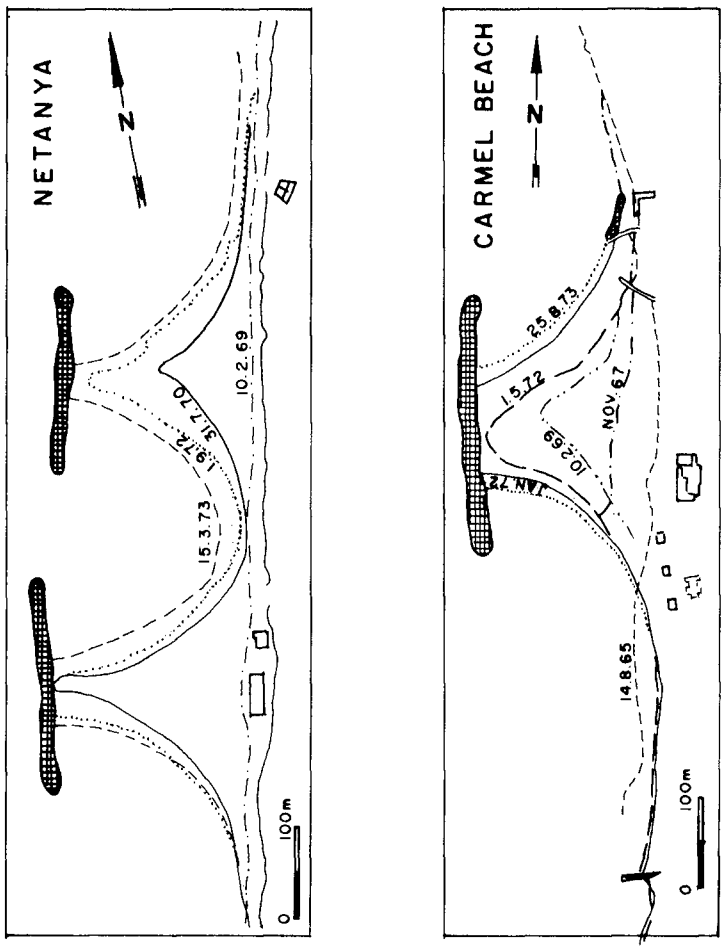

Fig. 14a. A map of Netanya's twin breakwaters and tombolos, showing the "step by step" growth of the twin tombolos and the formation in the internal of a new small bay between them. In the first few years the cliff at the backshore by the space between the tombolos suffered serious abrasion.

Fig. 14b. Map of Carmel Beach tombolo development from its early stages to mautrity. Note the original shoreline of August 1965, south of the tombolo, which shows the missing beach which has not since recovered.

Site	Distance from shore (m)	Length of breakwater (m)	Distance / Length
Nahariyya	70	180	0.38
Carmel Beach	200	280	0.71
Netanya (north)	200	207	0.97
Netanya (south)	216	240	0.90
Tel Baruch	100	200	0.50
Tel Aviv 1	200	310	0.64
Tel Aviv 2	200	240	0.83

Table 3. Dimensions, distance to length ratio, and the average sand layer thickness for the different sites.

The data given in Table 3 above was used to determine the relationship between the distance to the length ratio and the average tombolo sand layer thickness. The graph in Fig. 16 shows that the sand layer equals zero (i.e. that there is no sand accumulation at all) when the distance to length ratio is somewhat larger than 2.

The equation for the least squares straight line through the data in Fig. 16 is:

$$Y = 1.786 - 0.809\,x$$

where: Y is the average sand layer thickness of the tombolo (in m), and
X is the distance to length ratio.

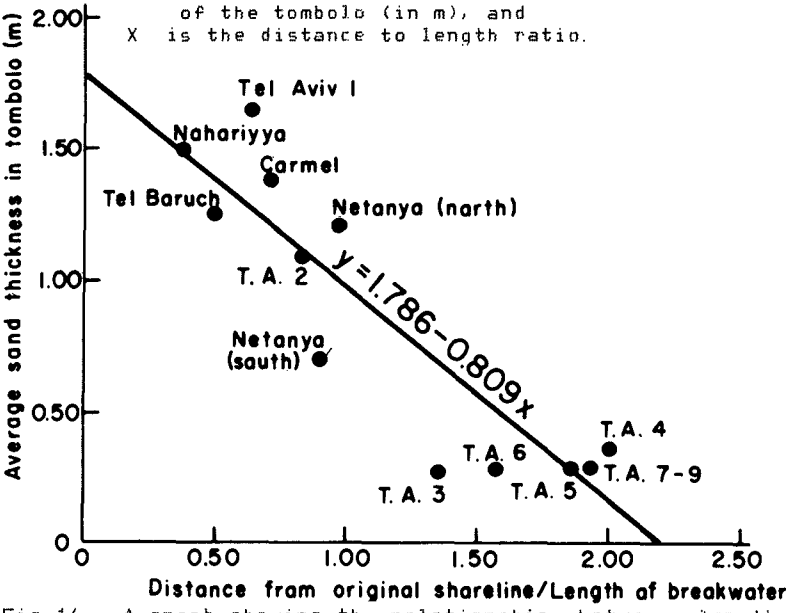

Fig. 16. A graph showing the relationship between length of the breakwater, its distance from the original shoreline and sand accumulation in the different tombolos.

This empirical formula is supported by the latest measurements of the size and quantity of sand accumulated in the tombolos developed in the more recently built breakwaters (Nos. 3-9) in Tel Aviv. These new breakwaters' dimenstions and distance offshore came from laboratory model studies by Vajda (1975). The ratio of distance from shore to breakwater length was enlarged to 1.85 and more, with the result that tombolo sizes were much smaller than the ones developed on the original structures (Fig. 17). Extrapolating the sand quantities accumulated in the modeled structures, excellent agreement was found with the above formula. It should be noted that the model studies hypothesized an unlimited sand supply to the sites, which perhaps is not the case at present in the Tel Aviv beaches.

Fig. 17. Offshore structures at the Tel Aviv beaches. The northern (right) are long and relatively close to the shoreline, so that huge tombolos developed. The chain of 7 breakwaters south of the marina (left) have shorter lengths than the northern ones, and are found at somewhat larger distances offshore so that the sand accumulation in their "shadows" is much smaller.

SUMMARY AND CONCLUSIONS

A very large number of detached breakwaters, groins, harbours and other marine structures were constructed along the Israeli Mediterranean shore during the late sixties and up to the mid-seventies.

Sand accumulated rapidly in the "shaded" areas and up-current, causing heavy damage to the nearby and downcurrent beaches. This erosional sand deficit was in addition to the large deficit caused by the heavy mining of sand for construction purposes up to 1964.

As most of the detached breakwaters were constructed relatively close to the shoreline, large tombolos have developed. It was found here that accretion is very small or negligible when the distance of the breakwater from the original shoreline is more than twice the breakwater length.

The southern beaches provide an excellent demonstration of downcurrent erosion; beaches north of structures were heavily damaged, with their sand cover almost totally removed and the backshore cliff starting to collapse (Fig. 8).

As there was almost no distinctive sand accumulation south of the main breakwater of Ashdod harbour, it appeared as if this gigantic structure did not interfere with the longshore sand transport. Recently Finkelstein (1981) showed that huge amounts of sand are being accumulated next to and off the deep parts of the main breakwater. This accumulation is equal to the transport of many years which is removed from the cycle, and the beaches north of Ashdod thereby suffer from increased erosion.

Due to the heavy damage and other environmental problems that these structures create, measures should be taken to minimize downcurrent erosion as much as possible, mainly by a continuing artificial replenishment to the affected beaches. On the other hand, if beach conditions are bad then offshore structures should be either improved or not permitted.

ACKNOWLEDGEMENTS

The author is very grateful to Dr. John K. Hall, Head of the Marine Geology and Geomathematics Division, for his thorough work in editing and reviewing the manuscript, and to Prof. D. L. Inman and Mr. I. Perath for reviewing the manuscript and last but not least to Mrs. Dina Ashkenazi of the Division for her careful typing of the text, and to the GSI Graphics Unit for preparing the artwork.

With just one exception, the aerial photographs were obtained by the Survey of Israel, Ministry of Labour, and are reproduced with their kind permission.

This work was carried out under Project No. 20677 with the Israel Ministry of Energy and Infrastructure.

COASTAL PROTECTION DEVICES - A REVIEW**

D.N. Foster, M.I.E. Aust., M.A.S.C.E.*

ABSTRACT

Coastal protection devices include, but are not limited to, dune stabilization, seawalls, groynes, detached breakwaters, sand bypassing and beach nourishment. These are the "tools". The "rules" for their use comes from a knowledge of the beach processes which in many instances are site specific. Systems which work satisfactorily at one location may not necessarily work at another. A plan is made for authors to give more information on these processes when describing case histories.

The variability of the physical conditions and the non-linear nature of many of the coastal processes often dictates how coastal protection works will behave; a fact which is not always taken into account by the designer.

For coastal protection devices to be developed to their full potential requires improved instrumentation and data bases and a greater knowledge of the coastal processes than is available at the present time.

1. INTRODUCTION

This paper was prepared as an introduction to the poster session on coastal protection devices at which seven papers were presented. (Reference 1-7). These varied between the use of low cost protection measures such as car tyres, sandbags, oil drums and other devices in the U.S.A. to the use of sand filled Longard tubes as groynes and seawalls in N.W. Canada, massive boulder seawalls in Australia, groynes in Portugal, large scale sand nourishment and bypassing operations in South Africa and detached breakwaters in Japan and Israel. The common denominator in these and other studies is, I believe, in the functional design based on a knowledge of the coastal processes.

It is not uncommon to think of coastal protection in terms of dune stabilization, seawalls, groynes, detached breakwaters, sand bypassing, beach nourishment and so on. Whilst extensions to this array and an improved understanding of accepted techniques is most important, this does not represent today's "State of the Art" in coastal defense. These are simply the "tools" and not the "rules". The "rules" come from a

knowledge of the coastal processes. Today's art lies more with the capability to understand the relative significance of the various natural forces which make defense necessary and the ability of the engineer to use this understanding to determine the optimum defense strategy making the most appropriate use of all the devices available.

2. COASTAL PLANNING

The first coastal protection device that should always be considered is that of coastal planning. Within this context the question can be aptly asked as to why coastal protection is necessary at all? Inevitably the answer will be that man wants to use the land which nature wants to take away for purposes such as:

- Recreation
- Housing
- Industry
- Airports
- Harbours
- Reclamation

This more often than not, means that man is in conflict with nature right from the very beginning. In comparison to other forms of development the coastal region tends to be different in that the highest valued land is commonly in the area of highest risk (Plate 1).

This is in contrast to flood plain land for example which tends to have the opposite trend with property values decreasing with the increased risk of being flooded. However in some respects the two have much in common.

- A certain level of protection can be justified by the reduced damages that it will provide
- Reduction of risk encourages further development
- Further development results in increased damages which justifies a higher level of protection.

This type of development in the past has ended up with the need for massive expenditure of funds to fight a never ending battle against erosion. More careful planning by our forefathers in many instances would have avoided or reduced the problems and the associated cost.

It could be argued both then and even today that many of the mistakes have been made because of our lack of understanding of the coastal processes involved. However examples of poor engineering practice in the management of the coastal zone are still evident in almost all

PLATE 1: - HIGH VALUE DEVELOPMENT IN AREA OF HIGH RISK

PLATE 2: - DAMAGE FROM NATURAL LONG TERM EROSION

countries throughout the world and all too often it is a case of trying to provide coastal protection to a problem which could have been avoided by more careful initial planning. Much of the blame must be laid on the inability of the engineer to convince the public and the legislators of the need for such planning and the long term benefits which would eventuate.

3. THE DIFFERENTIAL LITTORAL DRIFT COASTLINE

One of the most difficult coastal erosion problems is that pertaining to the differential littoral drift coastline resulting from a change to the littoral supply (Reference 1,5) or because of the natural configuration of the coast as exemplified by the Byron Bay embayment in northern N.S.W., Australia (Reference 8). At Byron Bay the littoral input is 15,000 m^3/year whilst the output is 200,000 m^3/year. As a result the whole of the embayment is eroding at rates between 1 to 5 m/year, except where the coastline is held by retaining structures such as groynes, seawalls or training walls. The end result of a small village built in the path of the sea is shown in Plate 2. The long term fight against erosion has been lost with seawalls gradually being outflanked and finally succumbing to the forces of the sea.

The owners of these homes undoubtably agree with the second demand for coastal protection suggested by Per Bruun (Reference 9) "Thou shall protect it against the evils of erosion". However, on further thought is erosion all that evil? Most modern day coastal protection strategies start with a statement of the sediment budget relating sand supply to and sand losses from a coastal region; and are aimed at reducing losses (by the use of groynes, detached breakwaters, dune stabilization, or bypassing plants for example) or by increasing the supply (by beach nourishment and sand bypassing for example). When we look at the sediment budget on an eroding coast one of the major supply terms is the coastal erosion itself which implies that if an eroding section of the coastline is protected by any method other than beach nourishment accelerated downdrift erosion will result. It is for this reason that it is difficult to simultaneously satisfy Per Bruun's second demand for coastal protection as set out above with the seventh "Thou shalt not steal thy neighbour's property, neither shalt thou cause damage to his property by thy own protection".

How do you provide protection to a shoreline such as Byron Bay?

- By beach nourishment provided there is an unlimited quantity of sand available which there isn't
- By seawalls or dykes provided you are happy to convert a sandy recreational beach into an artificial rocky coast which you are not
- By use of structures such as groynes, detached breakwaters, artificial headlands designed to equalise the littoral drift over the entire physiographic unit provided you can afford the cost which you can't.

In practice the cost of any of these options is often prohibitive, except in very densely populated areas or where they are associated with major harbour and port development.

A lower cost solution (particularly for relatively undeveloped sections of the coast) would be to provide protection to some sections of the coastline and accept accelerated erosion at others. This requires the acceptance by government and the public to changes in the configuration of the coastline. Under present legislation and the land rights of private individuals this is not easy to achieve. This cause has not been helped by the tendency for engineers in describing coastal protection case histories to give so little detail of what has or will happen outside of the area of immediate protection.

4. NATURE AS A SCALE MODEL

Nature provides many examples of coastal protection and coastal erosion. It is common to use small scale hydraulic models to assess the effect of large scale engineering works (Reference 7). Sometimes it is forgotten that a model does not have to be smaller than the prototype as the powerful principals of similarity and dimensional analysis are completely reversible. For Froudian scaling the length scale is proportional to period squared and consequently laboratory and nature provides a wide range of examples which can be scaled both up or down. Consequently the model studies of detached breakwaters undertaken by Rosen and Vajda (Reference 7) have much in common with the studies undertaken by Edge (Reference 2) in bays and lakes and those of Toyoshima (Reference 1) for the Pacific Ocean.

Consider the tidal inlet. In Australia such inlets at coastal lagoons, creeks and river systems are often closed off by the longshore transport under wave action, only to later break out during high fresh water or flood flows. From the study of the effect of artificially opening of the entrance of a small tidal lagoon at Dee Why, (Reference 10), Gordon was able to identify and to quantify a rather unusual cause of beach erosion at a much larger scale which can be typified by the conditions at Tathra in southern N.S.W. (Reference 11) as shown schematically in Figure 1.

This beach is a relatively small pocket beach contained between two major headlands. The Bega river, which is known to supply sand to the coast, enters the system at the northern end. As for most Australian rivers, daily flows in the Bega River vary from zero to very high flood flows. During relatively low river flows a plug of sand is moved from the beach resulting in shoaling of the mouth. During major floods this plug of sand is flushed far out to sea to form a shoal of mixed marine and fluvial sand. In the post flood period much of this sand bypasses the Tathra system under the predominant southerly wave climate. During the same period beach sands are moved in to reform the shoals at the entrance. As a result rapid erosion of the beach results after each flood event which slows down as the shoals are re-established.

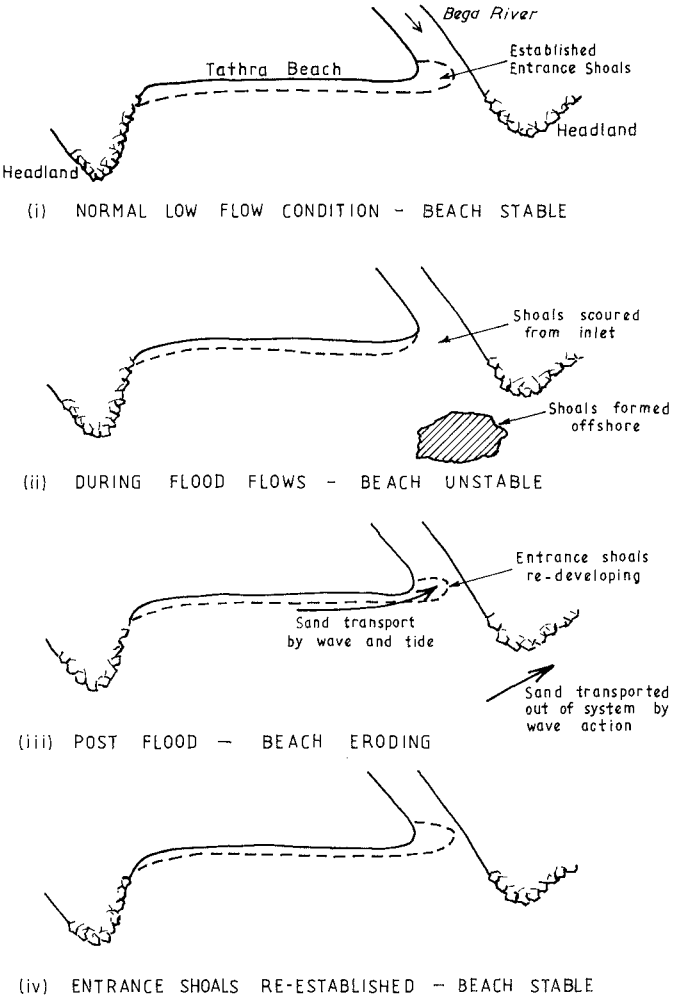

FIGURE 1: EROSION OF TATHRA BEACH AS A RESULT OF FLOOD FLOWS
(SCHEMATIC ONLY)

If it is accepted that nature provides us with many examples of both coastal erosion and protection it is surprising that not more use is made of this model, and to use conditions in bays and lakes to make quantitative predictions of what will occur in the ocean or vice versa. This technique was used by the author with some success to transfer the known behaviour of the sand bypassing system at Channel Island (Reference 12) to a less exposed region in Western Australia (Reference 13).

One of the reasons the technique is not used more often is, I believe, because many papers on case histories do not give sufficient detail of the physical parameters such as wave climate and its variability, local currents, tides, sediment characteristics to enable such scaling to be undertaken with confidence.

5. VARIABILITY OF COASTAL PROCESSES

The variability of the coastal processes often means that coastal protection is site specific. One form of protection which may work effectively at one location may be totally ineffective at another. Per Bruun (Reference 9) noted that when the techniques of the successful Dutch groynes were transferred to Denmark they did not work and large scale downdrift erosion resulted. It was suggested that this was because the Dutch groynes were supplied with sand by tidal currents whilst the Danish groynes were not.

This point can be further illustrated by the behaviour of the coastline adjacent to three natural detached breakwaters formed by offshore islands in Australia as shown schematically in Figures 2-4.

The first example is at Palm Beach near Sydney in N.S.W. (Reference 14). The coastline has a near zero net littoral drift. Because of the wave protection provided by an offshore island a shore connected tombola has developed. The tombola is of sufficient height and width not to be breached by even the largest storm and it forms a natural sand breakwater to a recreational harbour in its lee. Aside from normal changes in the beach profile resulting from rough and calm weather conditions the beach system is relatively stable.

The second example is on the Warilla-Perkins beach system to the south of Sydney (Reference 15). The total beach system is bounded by two major headlands which inhibit any significant movement of sediments into or out of the embayment. An offshore island within the embayment separates Warilla beach from Perkins beach. During calm weather sand is moved from both beaches into the lee of offshore island to form a tombola which eventually becomes connected to the island to form a groyne which inhibits further sand movement. During storms, which are dominantly from the south, the tombola is breached and the sand (some of which originated from Warilla) is transported northwards onto Perkins. The process then repeats itself. Consequently Warilla beach is suffering continuous erosion whilst Perkins is continuously accreting. The offshore island, which is acting as a detached breakwater, is obviously the cause of the erosion of Warilla beach.

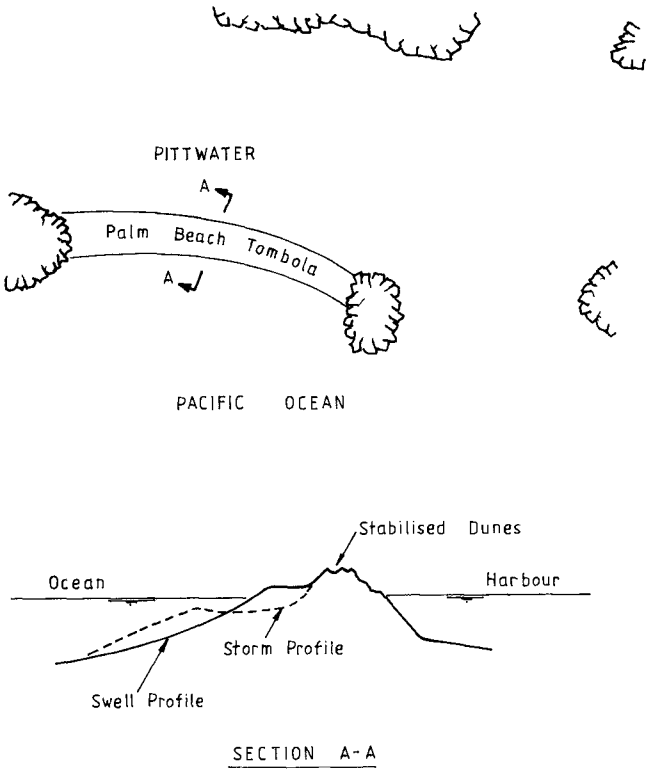

FIGURE 2: PALM BEACH N.S.W
(SCHEMATIC ONLY)

(iii) CONDITIONS DURING A MAJOR STORM

FIGURE 3: WARILLA/PERKINS BEACH SYSTEM
(SCHEMATIC ONLY)

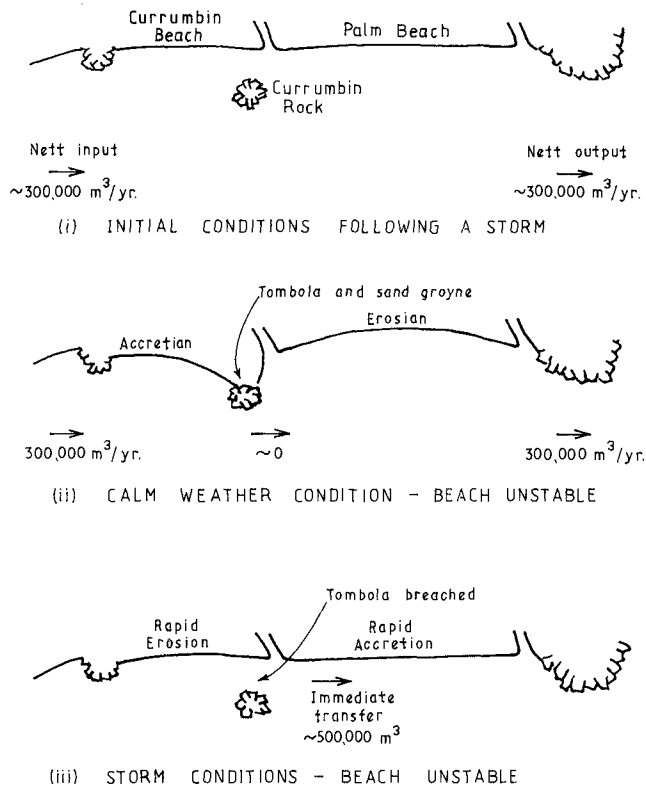

FIGURE 4: CURRUMBIN/PALM BEACH SYSTEM QUEENSLAND. (SCHEMATIC ONLY)

The third example is at Currumbin on the Queensland Gold Coast (Reference 17,18). The situation is similar to the previous example in that an offshore island which acts as a detached breakwater separates the beaches of Currumbin and Palm Beach (Queensland) and basically behaves in a similar way. During calm weather a tombola is formed in the lee of the breakwater eventually becoming connected to the island after which it acts as a groyne. During storms, which are again predominantly from the south, the tombola is breached and sand is transferred northwards. The basic difference between the Warilla/Perkins and Currumbin systems is that for the latter there is a net littoral drift of some 300,000 m^3/year (Reference 19). Surveys (Reference 17-18), have shown that during calmer weather practically the whole of the littoral drift over a period of years may be stored on the beaches to the south only to be transferred to the north within days during a storm. As a result the beaches to the north tend to erode during calm weather and build up during and following a storm, a paradox to that normally expected.

A further consequence of this action is that the sand is supplied to the coast in slugs. Tracer measurements by Chapman and Smith (Reference 20) indicate that these slugs maintain their identity over a substantial period of time and over long distances. Consequently at any given time some sections of the coastline tend to be under-nourished whilst others are over-nourished.

Plate 3 shows the end result of two houses at Wamberal on the N.S.W. central coast which were unlucky enough to be sited opposite a rip current on an under-nourished section of the coastline when a moderate storm occurred. Some weeks later the system had moved some 200 m to the north as indicated by the undermining of a flexible gabion mattress placed as toe protection in front of a Seabee seawall (Plate 4). The importance of toe protection, the desirability of flexibility of toe armour and the need to allow for the variability of the physical processes in seawall design (Reference 4) is obvious.

As coastal processes differ from site to site, no all embracing rules can be set down for the design and use of coastal protection devices. It is important that papers describing case histories of coastal protection give sufficient detail of the coastal processes to adequately assess their use in other areas.

6. NON-LINEARITY OF COASTAL PROCESSES

Closely related to the variability of coastal processes is the highly non-linear nature of these processes. The C.E.R.C. equation indicates that longshore transport is proportional to wave height squared. Einstein's equation indicates that bed load transport in rivers is proportional to discharge squared and velocity to the fourth power. In other formulae the power may differ but it is always substantially greater than unity. Consequently the larger events play a major role in the movement of sediment to and along the coast. For example a flood with a flow of 10 times the average can carry 100 times the sediment load of the average flow.

PLATE 3: - DAMAGE RESULTING FROM SHORT TERM CHANGES

PLATE 4: - SCOUR BLANKET PROTECTING SEAWALL AGAINST SHORT TERM VARIATIONS

Currents induced at coastal protection works will obviously have a very significant effect on how these protective works behave.

An exampie of using the non-iinearity of coastai processes to advantage is at Durban (Reference 21) where an artificial offshore sand bar was constructed to protect the beaches. The sand was obtained from dredging of the nearby harbour. Small to moderate waves pass over the bar with little change to the natural surfing and recreationai use of the beach. Under storm conditions the sand bar acts as a submerged breakwater forcing the waves to break and dissipate a proportion of their energy. As sediment transport is approximateiy proportionai to wave height squared there should be a rapid response to the reduced wave height.

The non-linear nature of many of the coastal processes and the variability that this produces is not always taken into sufficient account in the design or the description of coastal protective works.

7. THE FUTURE

More initiative and iaterai thinking is needed in the design of coastal protection works if the engineer is to be more successful than he has been in the past. Dune stabilization, seawalls, groynes, breakwaters and artificial nourishment will continue to be important toois. However this shouid not blind the engineer to other methods which might be equally or more effective.

If erosion is accepted as an aiiy as well as an enemy restructuring the shape of the coastline by providing sacraficial land has much to commend it.

At Port Botany (Reference 22) and Phiiip Point (Reference 23) configuration dredging has been used to change the wave refraction pattern and redistribute the wave climate to that more suitable for port operations. If configuration dredging has been successfuiiy used in these two exampies, it can obviousiy be considered in association with offshore beach nourishment programmes to defiect wave energy onto headlands or rocky sections of the coast whiist reducing wave energy or changing wave direction along the sandy beaches.

As the relationship between sediment transport and velocity is highly non-linear methods aimed at breaking up destructive currents whether they be rip, flood, tidal currents, or currents induced by coastal protection works must potentialiy be a very powerful tool.

Coastai protection devices need to be extended beneath the sea surface. At Coiiaroy in Sydney coastai process studies have indicated that a major cause of the beach erosion is the result of gaps in a natural offshore protective reef, (Reference 24) which if ciosed wouid go a long way towards eliminating the probiem.

Seawaiis do not have to be immobile. A sand breakwater has been constructed at Saiamander Bay South Africa (Reference 25) whilst a

breakwater of run of the quarry rock has been constructed at King Island Australia (Reference 26). Beach nourishment is a seawall of sand and shingle beaches serve the same purpose. There would appear to be a wide range of options within these limits awaiting future development.

It is now possible by the use of chemicals to turn sand into beach rock at relative low cost (Reference 27) which opens up many possibilities for the future.

These are but a few of the options which are or may become available in the future.

8. CONCLUSIONS

I would reiterate my introductory remarks. Coastal protection devices are simply the tools, the rules for the use of these tools came from a knowledge of the local coastal processes pertaining to each specific site. It is only when these processes are known will the engineer be able to develop coastal protection devices to their full potential. Much work and improved instrumentation and data bases are needed to refine the knowledge in this area.

9. ACKNOWLEDGEMENTS

Messrs. M. Geary and A.D. Gordon are co-authors of this paper. Both are engineers with the Coastal Branch of the Department of Public Works, New South Wales, Australia. Many of the examples referred to in the paper are taken directly from coastal process studies with which they have been associated. Their assistance and that of the Department of Public Works is gratefully acknowledged.

VARIATION OF FORESHORE DUE TO DETACHED BREAKWATERS

by

Osamu TOYOSHIMA

1. INTRODUCTION

As coastal areas are very valuable for mountainious Japan, many countermeasures against beach erosion have been taken. The length of seawalls for beach erosion amounts to 5,600 kilometers, which is much longer than the length of seadikes for flood tide, which is 2,900 kilometers. In addition, 10,000 groins and 2,300 detached breakwaters have already been constructed for beach erosion. Especially, we used many detached breakwaters for the last ten years.

Fig.1 showes the increase of total length of seawalls and seadikes for the last twenty years.

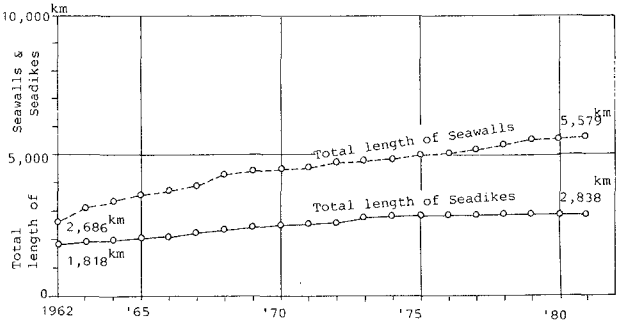

Fig.1 Increase of seawalls and seadikes in Japan.

The rate of the increase of seawalls and seadikes are as follows respectively.

seawalls : 5,579 km / 2,686 km = 2.08

seadikes : 2,838 km / 1,818 km = 1.56

Professor, Faculty of Marine Science and Technology, TOKAI University, 1000, Orido, Shimizu-shi 424 Japan

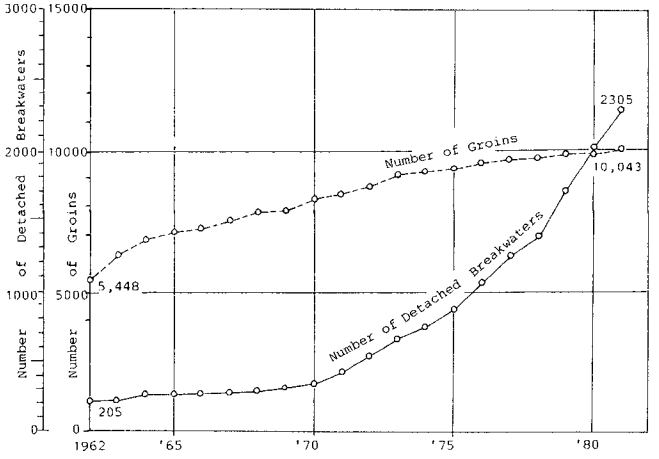

Fig. 2 Increase of groins and detached breakwaters.

Fig.2 showes the increase of number of groins and detached breakwaters for the last twenty years. The rate of the increase of groins and detached breakwaters are as followes respectively.

groins : 10,043 / 5,448 = 1.84

detached breakwaters : 2,305 / 205 =11.24

It was in the year 1966, that the author proposed a new detached breakwater system as a new countermeasure against beach erosion. After the year 1970, number of detached breakwaters showes sharp increase in contrast with that of groins in Fig.2.

Here, I take the Kaike coast as an example of the detached breakwater system, and show the variation of the tombolo and sea bed in the foreshore due to the detached breakwaters.

2.OUTLINE OF THE KAIKE COAST

Kaike coast locates on the root of the Yumiga-hama Peninsula which is believed to be a sand spit formed by sand deposition discharged from the Hino River that fed sand to this coast.

Huge waves from the east-northeast are refracted in Miho Bay as shown in Fig.3. These refracted waves give rise to the longshore current in the western direction along the Yumiga-hama Peninsula.

In the 1910's, the shoreline of the Kaike coast was advancing offshoreward year by year, and at that time, Kaike coast had sandy beach of width of more than 200 meters.

About 1920, iron sand collecting for Japanese traditional steel making was abondaned in the upper reaches of the Hino River. In addition to this, a number of Sabo dams and agricultural weirs were constructed

along the Hino River. These facts brought a remarkable reduction in sediment supply from the Hino River, and the advancing tendency of the Kaike coast turned into the receding one. The shoreline at Kaike has receded more than 200 meters during the last half century.

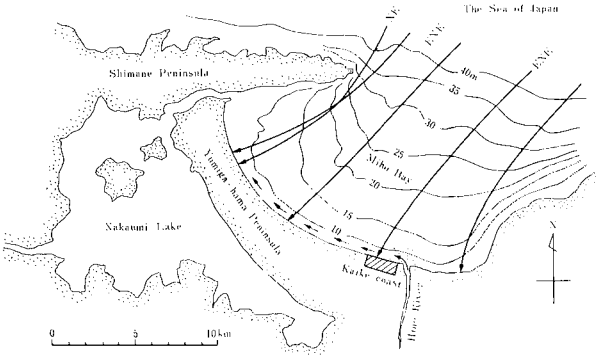

Fig. 3 Kaike coast and longshore current.

In 1947, after the War, the first experimental groin composed of rubble stones was constructed. Between 1949 and 1954, thirteen groins composed of large scale concrete blocks were constructed. As seen in Fig.4, the function of groin system gave satisfactory effect in 1954. In 1955, the Kaike coast was heavily eroded by giant waves caused by a typhoon and shoreline was in full retreat.

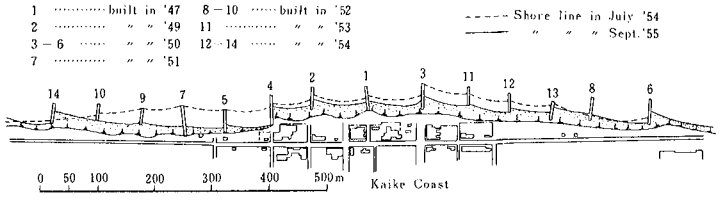

Fig. 4 After completion of groin system, Kaike was eroded.

After the heavy erosion due to a typhoon, seawalls along the shoreline were constructed. Based on the technical consideration in those days, concrete stepped face seawalls illustrated in Fig.5 have been adopted as suitable prevention structures against beach erosion in Japan. The construction of seawalls was made between 1955 and 1961. For several years after the completion of the seawalls, the Kaike coast looked like a stable beach, where very wide sandy beach extended in front of the seawalls.

Even when the Kaike coast seemed to be stable, a large amount of beach sediment was carried offshoreward with every attack of severe wind

waves in winter. After a lull in beach retrogression, Kaike coast began to retreat again in the early 1960's. Incident waves directly struck and overtopped seawalls. In order to reduce wave overtopping, wave defence works composed of artificial concrete blocks were constructed in front of the seawalls.

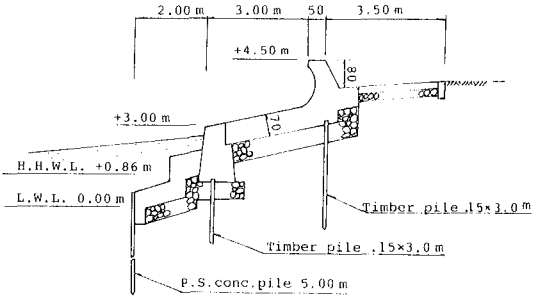

Fig. 5 Concrete stepped face seawalls was adopted.

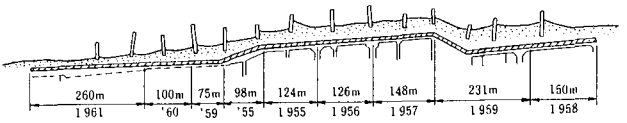

Fig. 6 Seawalls were constructed between 1955 and 1961.

As severe waves have repeatedly hit the Kaike coast, the combination system of groins and seawalls with wave defence works has shown its inadeqacy in the protection function against beach erosion. When incident waves approach normally to the shoreline, some portions of incident wave energy are reflected from the seawalls. This wave reflection results in considerable scour in front of seawalls and receding waves take away beach sediment offshoreward. Due to these unfavourable effects by the seawalls, groins and wave defence works settled and scattered. In the early 1970's, the Kaike coast was severely eroded again.

3. PROPOSAL OF A DETACHED BREAKWATER SYSTEM

Countermeasures against beach erosion in Japan was studied on a trial-and-error basis until the recent years. Many prevention works, such as seawalls and groins, have been constructed during the past thirty years. However, as the results of field investigations, it has become clear that, seawalls and groins have not been necessarily useful for beach erosion prevention, and adversely, in some cases they have promoted the beach erosion. Then, the author proposed a detached breakwater system as a new measure.

The first experimental work of this system was carried out on Isizaki coast, Hokkaido Prefecture, under the direction of the author in 1966. Soon after the completion of the work, the tombolo was formed behind the breakwater, and the system was effective in the restoration of shoreline. Generally, of cause, construction work of the detached breakwaters is not easy and maintenance cost is also high, when they are constructed on steep and deep sea bed.

The detached breakwater system at Kaike coast was proposed by the author as a new countermeasure against the beach erosion. However, the planning position of the breakwaters had considerably deeper depth than those where the previous experimental breakwaters were constructed. Therefore, the adoption and positioning were determined after long series of field surveys and researches.

4. CONSTRUCTION OF THE DETACHED BREAKWATER SYSTEM IN KAIKE COAST

In June 1971, the construction of the first breakwater in Kaike was commenced, and was completed in September of the same year. The breakwater with the length of 150 meters was constructed 110 meters offshoreward from the seawall where the water depth was about 5 meters. The breakwater as seen in Fig.7 was composed of rubble stones and armoured by tetrapods.

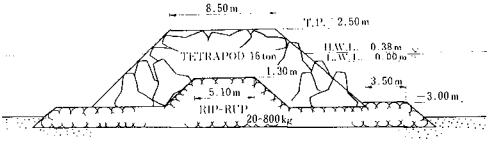

Fig. 7 Cross-section of the breakwater in Kaike

The breakwater has been quite effective in trapping sand transported from offshore zone and in forming a large scale tombolo behind it. The thickness of deposited sand was about 4 meters at the apex of the tombolo, and about 2 meters in front of the seawall.

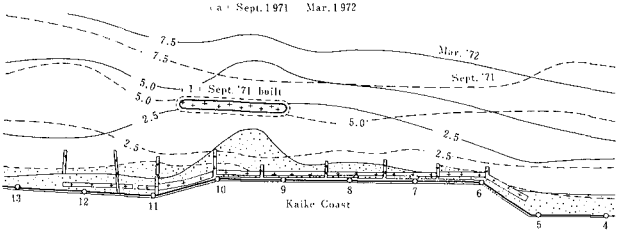

Fig. 8 The first breakwater was constructed in 1971.

Encouraged by the successful result of the first experimental detached breakwater, three more breakwaters were constructed as planned in the following three years.
The breakwaters, whose lengths were 150 meters, were positioned at equall space of 50 meters. The No.1 breakwater was constructed in downdrift zone of the longshore current along the Kaike coast, and the No.2 was constructed on the updrift side of the No.1 breakwater.
In progress of the No.2 breakwater construction, beach retrogression in the downdrift zone of the No.1 breakwater was observed.
To eliminate the undesirable effects by the Nos.1 and 2 breakwaters, the No.3 breakwater was sited on the downdrift side of the No.1 breakwater. The No.4 was in the updrift side of the No.2 in order to increase the covering area.

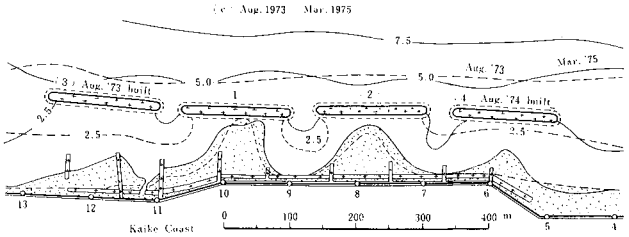

Fig.9 The No.4 breakwater was constructed in 1974.

During the later seven years, seven breakwaters were constructed annually, one breakwater every year respectively. In 1981, the detached breakwater system in the Kaike coast has completed with eleven breakwaters construction.

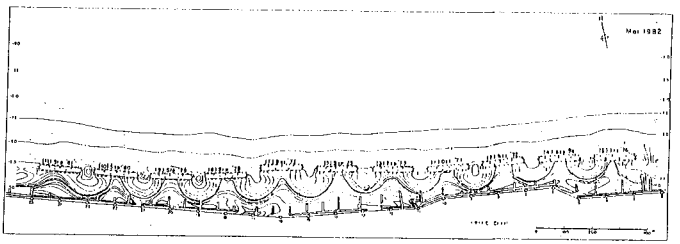

Fig. 10 The detached breakwater system has completed in 1981.

5. TRANSFORMATION OF SEA BED

Before the construction of the breakwaters, there were considerable transformation in the sea bed configuration. However, after the construction, the transformation of the sea bed have become very little. Fig.11 and Fig.12 are typical example of survey results for profile line No.8 which is located at the center of the No.2 breakwater.

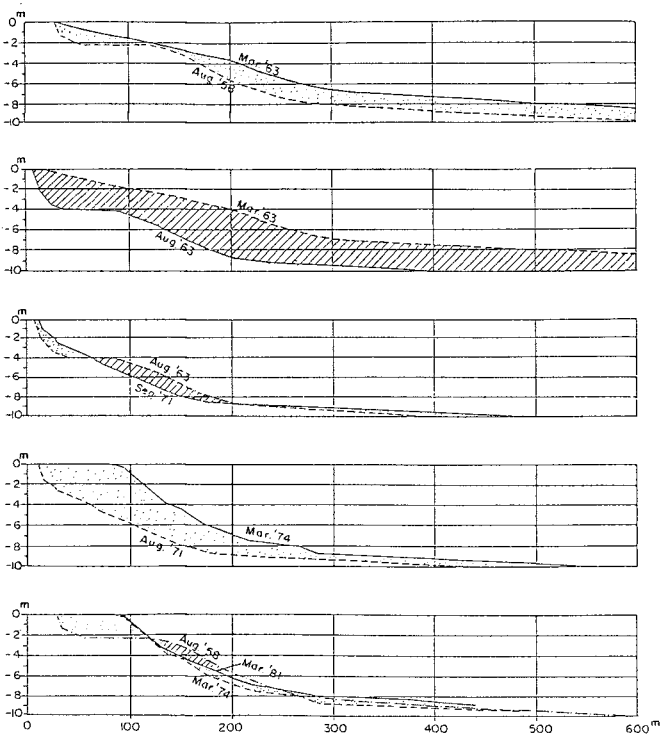

Fig. 11 Transformation of sea bed on the section No.8

The survey have been executed twice a year, spring and autumn. Fig.11 shows some striking transformations of the sea bed extracted from the annual survey results.

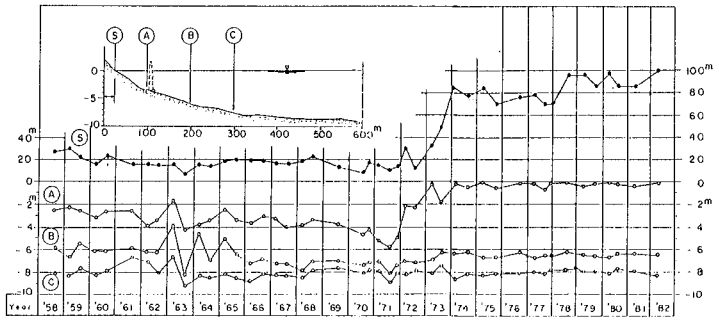

Fig. 12 Annual transformation of shoreline and sea bed on No.8

The greatest transformation of the sea bed configuration came about during March and Autumn in 1963. Maximum erosion of the sea bed amounts to about five meters in depth on the point 200 meters distant from the seawall.

In Fig.12, (S) represent the horizontal distance of shoreline from the seawall, and (A), (B) and (C) the water depth from the still sea water level at the points of 100, 200 and 300 meters distant from the seawall. The No.2 breakwater was constructed in front of the section No.8 in August 1972. Right after its construction, the sea bed at the point (A) indicated a remarkable shoaling, and the shoreline (S) greatly advanced. Since then the shoreline and sea bed have been very stable in contrast with that before the construction of the breakwater.

6. VARIATION OF SHORELINE AND EQUI-DEPTH LINE

Figs.13 to 20 show the variation of shoreline and equi-depth line before and after the construction of the detached breakwaters. Before the construction, there was considerable variation in the shore line and equi-depth line. However, since the construction, the variations of sea bed have become very little, and a lot of sand were transported from the offshore zone to the nearby areas of the breakwaters not only onshore side but also offshore side of the breakwaters.

Still more strange to say that, the equi-depth line at the offshore sea bed has become very smooth, uniform and paralleled to the line of the row of detached breakwaters.

We can not explain the reason of this flat and plane sea bed even now.

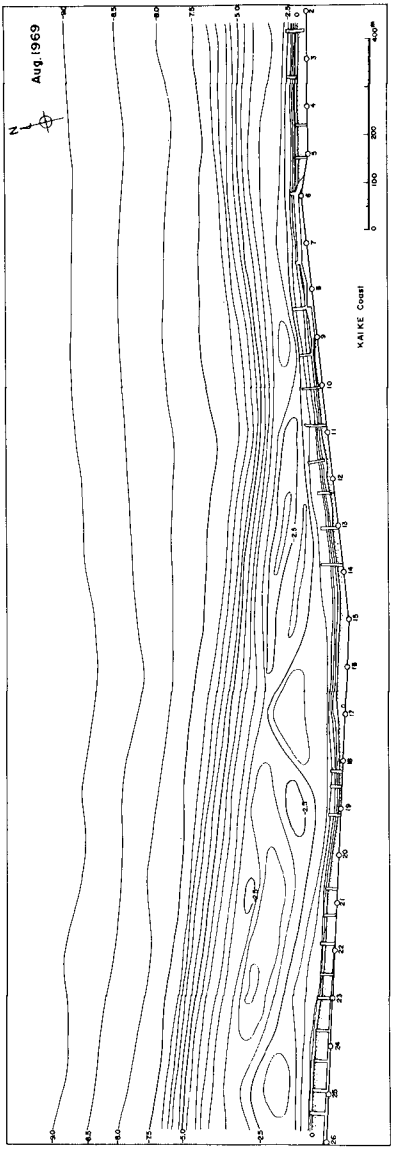

Fig. 13 Sea bed before the construction of the detached breakwater system in Kaike coast. There were many bars and troughs in the foreshore zone. These bars and troughs moved about every time the surveys had been executed.

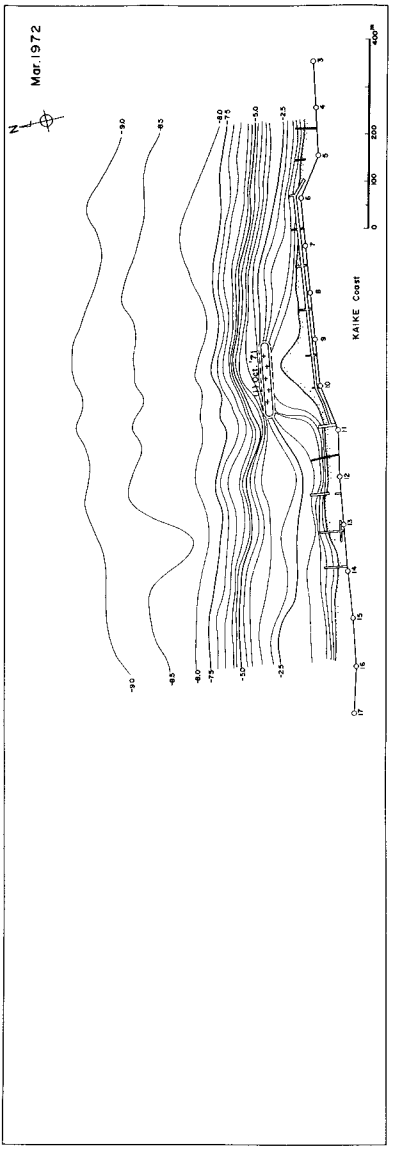

Fig. 14 The sea bed six months after the construction of the No.1 detached breakwater. A large tombolo developed behind the breakwater, and the shoreline in front of the station Nos.11 to 16 advanced offshoreward.

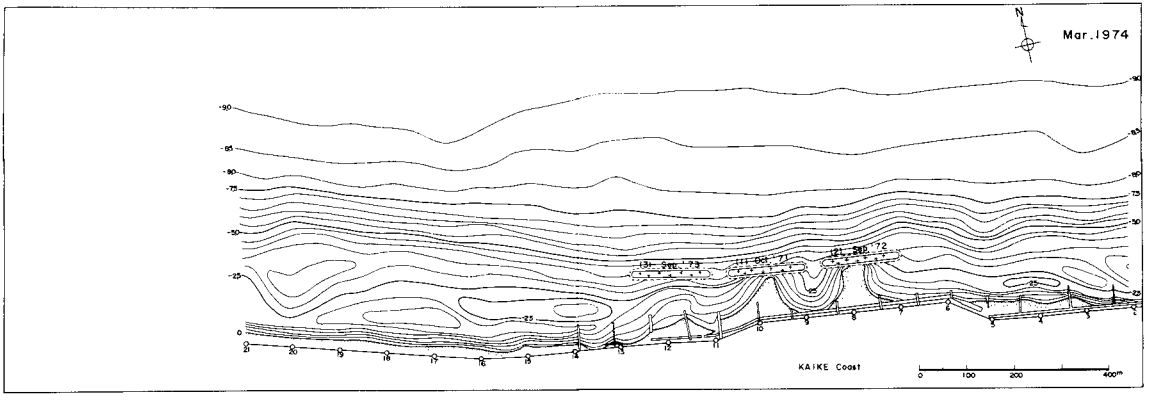

Fig. 15 Two years after the Fig.14. Three breakwaters are constructed, and there are three tombolos behind the each breakwaters. The left breakwater is the latest one, and the tombolo of it is still small in contrast with another two previous tombolos. The direction of the longshore current in Kaike coast is westward as previously stated, the rightmost tombolo is usually larger than the remaining left side tombolos.

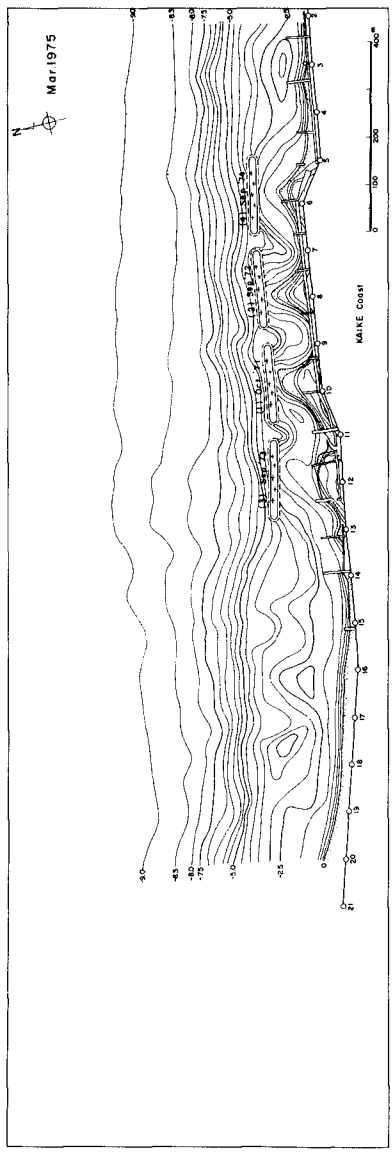

Fig. 16 One year after the former figure. No.4 breakwater was constructed six months before, and its tombolo is yet small though it is situated on the rightmost. The equi-depth line of -5 m advanced offshoreward a little in contrast with the Fig.13, before the construction of detached breakwaters.

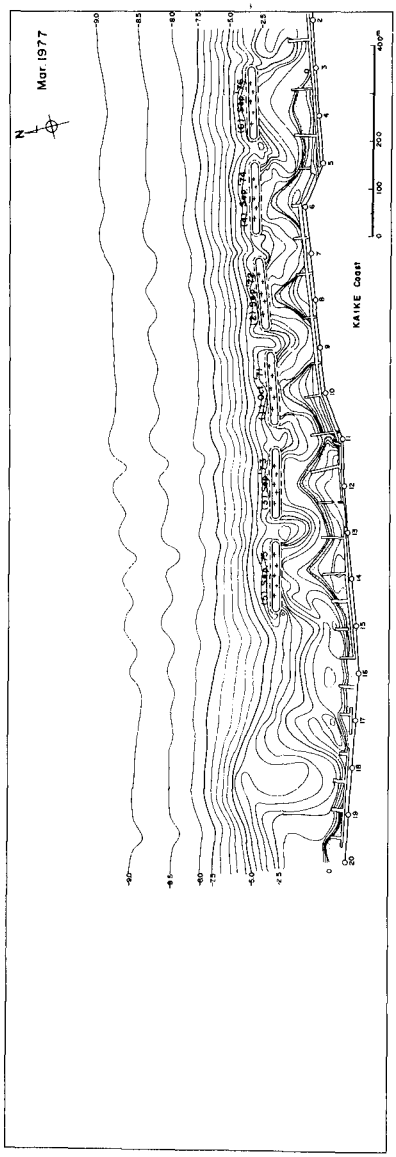

Fig. 17 Two years after the former figure, and the No.5 and No.6 breakwater were constructed during the two years. The tombolos developed respectively except the latest No.6's one. The equi-depth lines from -5m to -9m have become smooth and parallel gradually. However, the foreshore in front of station Nos.15 to 20 are left unstable.

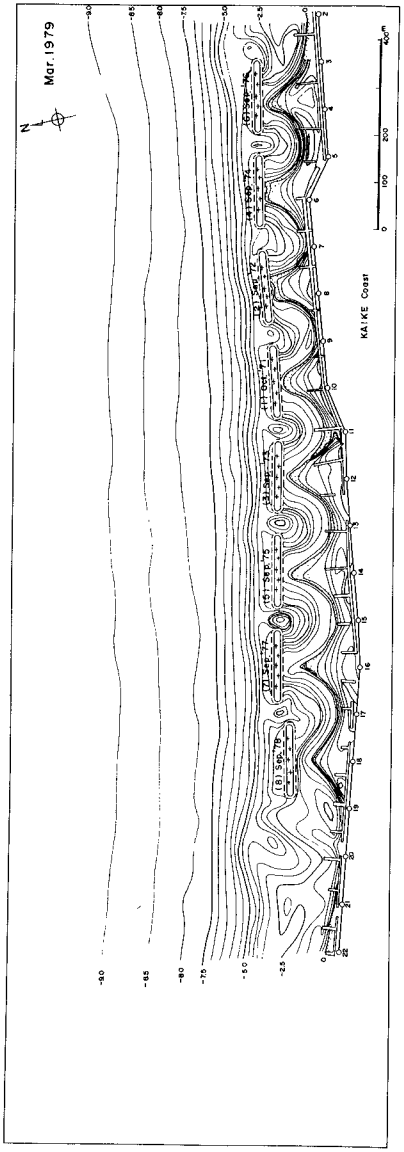

Fig. 18 Further two years after the former figure. Nos.7 and 8 breakwaters are constructed, and they have good-sized tombolos respectively. The equi-depth lines of the offshore zone have become smooth in succession.

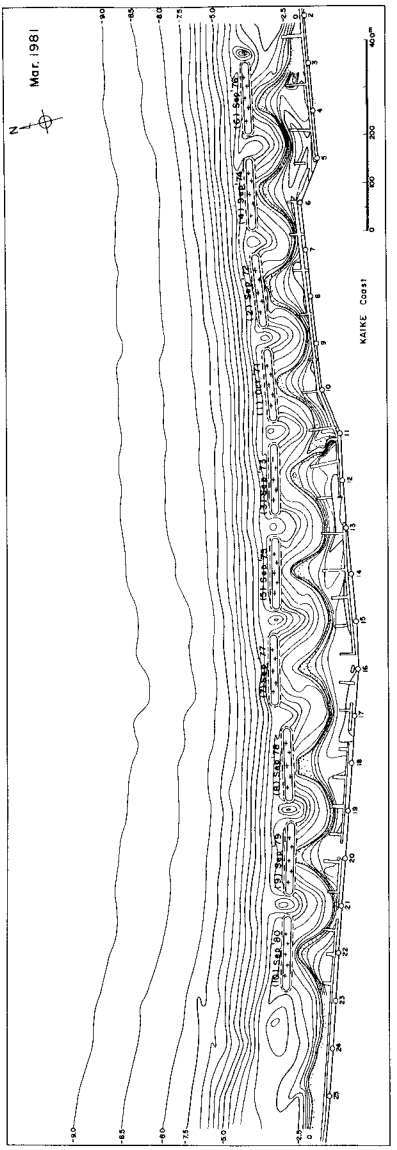

Fig.19 Ten breakwaters were constructed until 1980. Each breakwater has a good sized tombolo respectively, and the offshore sea bed has become stable and smooth.

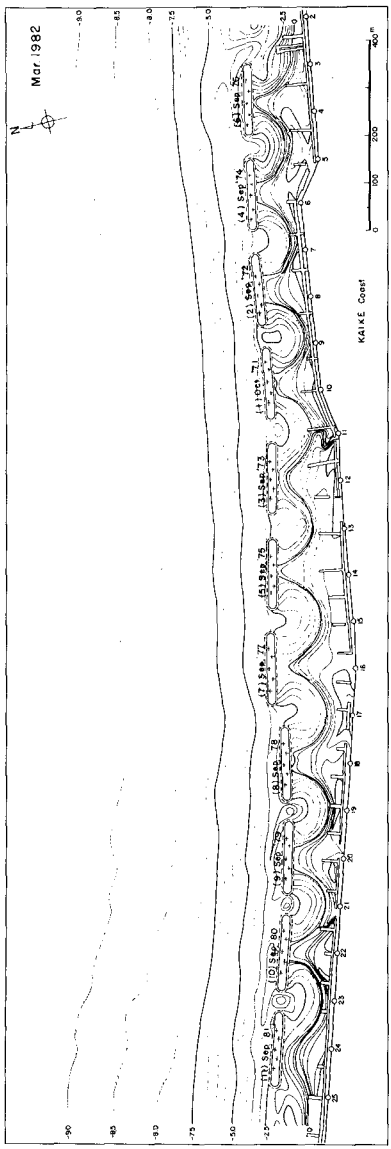

Fig.20 The Detached Breakwater System in Kaike Coast has completed in 1981. Eleven breakwaters are constructed, and all of them are successful. Each breakwater has a great tombolo behind it and all of these tombolos are very stable in spite of the every winter's huge waves. The equi-depth line in the offshore zone have become more smooth, uniform and paralleled to the line of row of detached breakwaters.

7. VOLUMETRIC CHANGES IN THE SEA BED

Table 1 shows volumetric changes in the beach profiles calculated from the survey results during the period from September 1971, before the construction, to March 1982, after the construction of the eleventh breakwater.

Table 1 Volumetric changes in the sea bed after the construction of the detached breakwaters.

Number of breakwater	Onshore side of breakwater	Offshore side of breakwater	Total volume
No. 1 breakwater zone	+ 35,800 m³	+ 86,100 m³	+121,900 m³
No. 2 breakwater zone	+ 48,800	+ 89,200	+138,000
No. 3 breakwater zone	+ 18,300	+ 49,200	+ 67,500
No. 4 breakwater zone	+ 45,000	+ 84,200	+129,200
No. 5 breakwater zone	+ 18,900	+ 21,800	+ 40,700
No. 6 breakwater zone	+ 28,900	+ 95,400	+124,300
No. 7 breakwater zone	+ 24,800	- 19,500	+ 5,300
No. 8 breakwater zone	+ 15,300	- 43,700	- 28,400
No. 9 breakwater zone	+ 13,400	- 31,600	- 18,200
No.10 breakwater zone	+ 28,300	- 41,100	- 12,800
No.11 breakwater zone	+ 7,400	- 68,700	- 61,300
Total	+284,900 m³	+221,300 m³	+506,200 m³

It is noticed from this table that a considerable volume of sand has been deposited on the sea bed in the onshore and offshore zones of the breakwaters since the construction schme of detached breakwaters commenced. However, there are some erosion in the offshore zone of station Nos.7 to 11. These areas correspond to down drift of the littoral transport in Kaike coast.

Now, Kaike coast has gained a stable sea bed and shoreline by virtue of this detached breakwater system.

Photo 1 The aerial view of the Kaike coast and four detached breakwaters on Octover 1974.

Photo 2 The detached breakwater system in Kaike Coast has completed in 1981. The photograph shows the Kaike coast just after the eleventh breakwater construction,on Octover 15th 1981.

8. OTHERS

Although the detached breakwaters are very effective in the shoreline protection, some problems involved in this system still remain to be solved. The most important problem is subsidence of the breakwaters. Up to now, the subsidence of the breakwaters in Kaike coast is fortunately considered to be moderate, but it is urgently needed to develop methods by which the speed of subsidence can be minimized.

Hereupon, our efforts must be continued without a break, so that the re-created beach may not be lost again.

(END)

RESULTS OF SHORELINE EROSION DEMONSTRATION PROGRAM

B. L. Edge[1] M. ASCE and J. G. Housley[2] M. ASCE

1. Introduction

Very little has been done in the United States to assist the private landowner when his property has been threatened by coastal erosion. Primarily, efforts have been concentrated on large scale shoreline protection efforts which cover municipalities or large regions. These efforts have been basically Federal or large state projects. Between 1974 and 1980, the United States government conducted a national program to fill this void by demonstrating a low cost technology for shoreline defense. The objective of this paper is to report on the program itself and its results.

2. The Section 54 Program

The United States Congress in 1974 authorized in Section 54 of Public Law 93-251, 93rd Congress, a program to develop and demonstrate low cost methods of shore protection. Further the Act specified that the Chief of the U.S. Army Corps of Engineers was to conduct this program and appoint a Shoreline Erosion Advisory Panel (SEAP) to advise him on its execution. Members of the Panel represented various geographic areas, professional disciplines, employers, and environmental groups. All of the members however, had knowledge and experience in some aspect of shoreline erosion and protection. The legislation specifically stated that the program would include a minimum of sixteen sites from around the shoreline of the United States. Six of these sites were to be in Delaware Bay, as mandated by the legislation, and the other ten sites were to be selected based upon the criteria provided by the SEAP. The selection of devices or systems of devices to be demonstrated at the specific sites was made by the Chief of Engineers, based on the recommendation of the Panel.

[1]President, Cubit Engineering Limited, P.O. Box 1271, Clemson SC 29631

[2]Office of the Chief of Engineers, HQ(DAEN-CWP-F), Washington DC 20314

Additionally the Act allowed that non-Federal lands could be used for demonstration sites as long as the non-Federal owner had a sponsor which was willing to pay at least 25% of the construction cost. Also as a part of the program, a number of low cost, shore protection systems, already installed at other sites, were included in the monitoring program. Including these additional sites allowed observation and evaluation of a greater number of devices and environmental conditions than would have been possible with only the sixteen mandated sites.

Another important feature of the legislation was that the effectiveness of vegetation was to be demonstrated wherever it could be employed. Often it was necessary to employ vegetation in conjunction with a protective structure until it was able to sustain itself under the environmental conditions. The Soil Conservation Service of the Department of Agriculture was involved in much of the vegetative work, selecting indigenous vegetative species, assisting to plant the materials, and in evaluating the response of the plants to the environmental conditions.

Each of the sites was monitored intensively by the Corps of Engineers. Monitoring included wind, wave and current data on a daily basis as well as bathymetric surveys, ground photographs and aerial photography flown at about three-month intervals. Sediment samples were collected from the beach and offshore. A Corps engineer would visit a site at least monthly to report on its status. A special monitoring program was used for the vegetative aspects of each site. The monitoring program was very comprehensive although few quantitative measurements were taken. The results of the monitoring were assimilated and analyzed by the Coastal Engineering Research Center.

3. Results

Originally the program was to have continued for five years, however, few projects were tested for more than two years. Thus interpretation of the performance of these structures is limited by the short life of the program. A summary, by generic system, of the performance of the devices that were installed and monitored under this program is included in Table I. Those that were "possibly successful" are devices which did not fully succeed at the particular installation that was monitored, but the devices could have succeeded if they were either in a more appropriate environmental location or had minor changes to the initially designed structure. Table II gives specific comments on the modifications which could be made to make some devices successful.

TABLE I

PERFORMANCE OF SYSTEMS INVESTIGATED

Type of System	Successful	Could be successful*	Failed
A. Bulkheads and Seawalls	Treated timber, Steel and timber, Concrete sheetpile	Rubber tire and piles, Longard tube, Earth-filled concrete pipe, Rubber tire stack, Untreated timber	Welded-wire fence and sand bags, Concrete and timber
B. Revetments	Stone riprap, Sand-cement bags	Concrete blocks, Gabions, Concrete rubble, Steel barrels	Concrete slabs, Sandfilled-bags, Fabric, Tires and fabric
C. Breakwaters and Sills	Stone riprap, Timber sheet piles, Rubber tires on piles, Sand-cement bags	Floating tire, Longard tube, Gabions, Concrete bags, Z-wall Surgebreaker, Sandgrabber	Sta-pods, Sand-filled bags, Brush dike
D. Groins	Timber, Timber and stone, Riprap, Concrete rubble, Sand-cement bags, Corrugated steel pipe, Rock with asphaltmastic	Longard tube, Gabions, Steel fuel barrels	Sandfilled bags
E. Nonstructural	Perched beach, Beach fill	Vegetation, Vegetation with protective structure	

*These could be made successful with minor changes or use in a more appropriate environment than used in the program

TABLE II

MODIFICATIONS REQUIRED FOR CERTAIN DEVICES

Type of System	Device	Comments
A. Bulkheads and Seawalls	Rubber tire and piles	Fair performance; needs good filter; tire fill material washed out; good way to dispose of used tires
	Longard tube	Tube must be away from bluff to prevent displacement by slides; sand-epoxy coating helps protect against vandal and debris damage
	Earthfilled concrete pipe	Fair performance; some pipes tipped over; needs stock pile of used pipe
	Rubber tire stack	Fair performance, but fasteners failed; system needs improvement; good way to dispose of used tires
	Untreated timber logs	System failed due to filter wash out; useful where logs are plentiful; boring insects could be a problem; needs good filter system
B. Revetments	Concrete blocks	Good performance when blocks are sized and shaped to match wave environment; easy to install, but subgrade must remain even; good small project system
	Gabions	Good performance, but broken basket wires may be a problem; needs proper sized stone fill; good substitute for stone riprap on small projects
	Concrete rubble	Good performance but failed where improperly designed; good way to dispose of large amounts of rubble

TABLE II (continued)

MODIFICATIONS REQUIRED FOR CERTAIN DEVICES

Type of System	Device	Comments
C. Breakwaters and Sills	Floating tires	Fair performance, but some systems pull apart; better interconnections needed; good way to dispose of used tires; use limited to short-period wave climate
	Longard tubes	Good performance if tubes are not damaged; requires special equipment; vandalism of tubes made demonstrations inconclusive
	Gabions	Good performance, but structural failure seemed imminent at demonstration site
	Concrete boxes	Fair performance, but requires special equipment; covers needed to keep sandfill in boxes
	Z-wall	Good performance, but structure deteriorated; system not recommended until hinging of modules is improved
	Sandgrabber	System locally effective but depletes downdrift beaches; structures deteriorated; probably could be improved, but other shore protection systems are available that perform better
D. Groins	Longard tubes	Good performance until structure failure; vandalism and debris damage is a problem
	Gabions	Good performance, but deterioration of outer ends exposed to high waves is a problem
	Steel fuel barrels	Good performance, but use is limited to Arctic regions

Of the materials tested in the program, it was found that quarry stone rubble performed well and survived longer than any other type of device. However, it was seldom one of the lowest cost devices employed. On the other hand, concrete rubble was only satisfactory when used with adequate filter material and shaped appropriately to eliminate flat and elongated pieces. In areas of the country where timber was an abundant material, it proved to be very successful because of its cost and the ease with which it could be shaped and fastened together. In the Alaskan environment, the steel drum proved to be one of the most effective and lowest cost devices available. Although these would ordinarily not be the first choice for shore protection, because of the abundance in that area, they have proved to be quite useful. Gorrosion was a problem however, whenever they were used south of the Arctic Circle.

Generally only those Gabion structures which were filled with stone larger than four inches in diameter proved useful in sites exposed to even moderate wave energy. The Gabion basket is a low cost device which is easy to install and will perform well functionally. Many baskets, however, were ripped open either from vandals, floating debris or movement of stone inside the baskets during wave action. Similarly Longard tubes were effective functionally as breakwaters, bulkheads, revetments and groins. However, at every site they were badly damaged by vandals or floating debris. When built in the dry, the Longard tubes could be coated with a sand-epoxy coating which would help to minimize damage. However, when the structures were installed in the water, no protective coating proved successful. Sand bags proved very effective functionally, but they were subject to the same damages by vandals and debris as the Longard tubes. Bags filled with a sand-cement mixture hardened into concrete modules that generally hold their shape together well after the fabric deteriorates.

In practically every demonstration project, a device was built with and without filter cloth to illustrate the importance of a filter. Although it is quite common knowledge among the coastal engineering community that a filter material is necessary, it was important that this should be emphasized.

Used rubber tires were successfully employed in several structures, although they were somewhat unsuccessful in others. In general they functioned very well as floating breakwaters, but did not function well as a revetment even when filled with concrete. Although the tires were never aesthetically pleasing, they tended to be both functionally and structurally successful on many occasions.

Vegetation was used primarily as a shore protection device only in very low wave energy environments when the underlying soil was adequate for their growth. Often the vegetation was employed in conjunction with another type of device which would provide appropriate shelter for the plant material to begin growth. Best results occurred when an underlying layer of loam or peat existed beneath a veneer of sand. Vegetation varied considerably around the country according to the locally available and adequate species. In all regions efforts were made to employ intertidal, supertidal and upland plant materials wherever appropriate.

4. Dissemination

One of the important aspects of the program was the dissemination of the results to the public. A dissemination program was planned by a team of SEAP members, Corps representatives and a private contractor. The basic document which summarized the entire project including all devices at each site was that prepared for the U.S. Congress (2). That publication has a history and compilation of all data at each site.

The basic components of the dissemination program which were prepared for the public are:

Low Cost Shore Protection: A Property Owners Guide - This report is intended for owners of property who face the decisions of dealing with their erosion problems. It contains information on the shoreline processes, explains available alternatives, reviews the decision process leading to a choice among solution options, and identifies sources of additional help.

Low Cost Shore Protection: A Guide for Engineers and Contractors - This report was prepared to familiarize engineers and contractors with established methods of low cost protection. It is written for those familiar with traditional civil engineering design and construction but who are not specialists in coastal engineering or shoreline protection.

Low Cost Shore Protection: A Guide for Local Government Officials - This report was prepared to assist and inform those government officials who have some involvement in shoreline erosion control through planning, permitting regulation or other function. The report includes a description of shoreline processes, devices available for use as solutions, guidance for selection from alternatives, permitting

requirements and a directory of information sources.

These three volumes provide the basic information for non-specialists to understand the erosion process, protection techniques and available devices. Although these references are oriented to low wave energy environments, the information is useful for all waterfront property owners. Each of these documents are available by contacting J. G. Housley, Office of the Chief of Engineers, HQ(DAEN-CWP-F), Washington DC 20314.

The program also developed brochures describing each demonstration site for those who could visit the area. At the conclusion of the program four regional workshops were held to acquaint the Corps district offices and state and local government officials with the results of the program. A 50-minute slide presentation is also available to present the results of the program to local groups. It presents a summary of coastal processes, available alternatives, and requirements for a successful project. The slide presentation can be obtained by contacting a Corps of Engineers district office or through the address given above.

5. Conclusions

Although low cost shore protection is amenable to only select sites, it certainly is a concept that has to be explored for the thousands of miles of eroding shoreline which are in the hands of private citizens. The results of this program will be helpful to the landowner in identifying the type of solution which he may employ and how to go about designing those solutions for his own particular problem.

PERFORMANCE OF SAND-FILLED TUBE SHORE PROTECTION TUKTOYAKTUK, NORTH WEST TERRITORIES, CANADA

V.K. SHAH, M. Sc., C. Eng., M.I.C.E., P. Eng.
PUBLIC WORKS CANADA, OTTAWA, CANADA

1. INTRODUCTION

Seawalls, revetments and groynes designed to protect shorelines require normally timber, natural stone or concrete for their construction. In Tuktoyaktuk, none of these materials is available and to avoid excessive costs, an alternative form of construction, using long sausage shaped tubes filled with sand, was devised on an experimental basis.

Tuktoyaktuk is situated on the eastern side of Kugmallit Bay in the Western Arctic at north latitude of 69 deg. 27' and west longitude of 133 deg. 02'. It is approximately 90 miles north of Inuvik and 1450 miles northwest of Edmonton (figure 1). The area is mainly comprised of a long, narrow, boot-shaped peninsula oriented in approximately north-south direction, a complex lagoon, which has been developed as a harbour, east of the peninsula and an island straddling the mouth of the lagoon (figure 2). Certain dwellings exist at the southern and southeasterly shores of Tuktoyaktuk Harbour. A large majority of the inhabitants reside in settlements developed on the peninsula and the southern area linking the peninsula with the mainland. Tuktoyaktuk is used as a transfer point linking the Mackenzie River barge transport with coastwide shipping serving the western arctic seaboard and inland settlements and bases. As a result of this the TUK settlement has grown to be the largest of the western arctic coast settlements.

Tuktoyaktuk is receiving further prominence owing to the recent oil explorations in the Beaufort Sea and if oil is discovered in the area, Tuktoyaktuk will see considerably increased activity and prominence. Dome Petroleum and Gulf Canada have already committed large investments in administrative support facilities at Tuktoyaktuk and Exxon is moving its northern offices there. Tuktoyaktuk is thus likely to become the Beaufort Sea administrative support center for the oil and gas industry.

Tuktoyaktuk is generally flat. Its shoreline is demarcated by steep cliffs. The Tuktoyaktuk peninsula is approximately 4,400 feet long and 1,400 ft. to 300 feet wide. It is 5 to 25 feet above the sea level and covers an area of approximately 16 acres. The Tuktoyaktuk Island is approximately one mile long, and on an average 600 feet wide. The island is characterized by its flat top which is approximately 30 feet above the sea level and cliffs steeply plunging to the sea. The harbour runs inland in a southwesterly direction and is approximately 7 miles long. The terrain around the harbour is flat and contains numerous lakes.

The whole shoreline at Tuktoyaktuk has been receding at considerable rates. Reports indicate that similar erosion is occurring along much of the adjoining coastlines. The length of shoreline of immediate concern was the shoreline at the settlement peninsula where several buildings including a local school were under threat of being undermined. There were no precedents of shore protection works in the arctics where the erosion regimes are different from those in the south, and a decision was made to protect the school building as a prototype experiment to learn from and develop a design to protect the whole settlement peninsula.

2. COASTAL GEOMORPHOLOGY

2.1 General

The coast of Tuktoyaktuk can be described as a shallow, embayed and receding coast. It is generally flat and contains narrow beaches and steep cliffs. The area is mostly underlain by fluvial sands and silts and fine grained deltaic sands. These deposits are capped by a thin layer of a mixture of sands, peat lacustrine deposits, gravel and clayey till like deposits. The subsurface includes permafrost and lenses and sheets of massive ice.

2.2. Subsurface

The analysis of test borehole samples and thermistor readings indicates that generally the subsurface can be divided into two zones. These zones are: (1) an active zone which is frozen in the winter and thaws out in the summer and (2) a permanently frozen zone below the active zone. The active zone consists of sands, silts and gravel, in places covered by peat or organic material. In areas where there is a cover of peat the thickness of the active zone as measured was small, varying from 1 to 2 feet. In the inorganic soils, the thicknesses of the active zones measured were relatively large, varying from 4 to 16 feet. The permanently frozen zone consists of layers of sands, silts and gravel together with ice crystals, lenses of ice and sheets of massive ice. The thickness of the permafrost zone was not determined. It is, however, known to extend from above to below the sea level, or in other words it straddles the sea level (figure 3).

3. EROSION REGIME

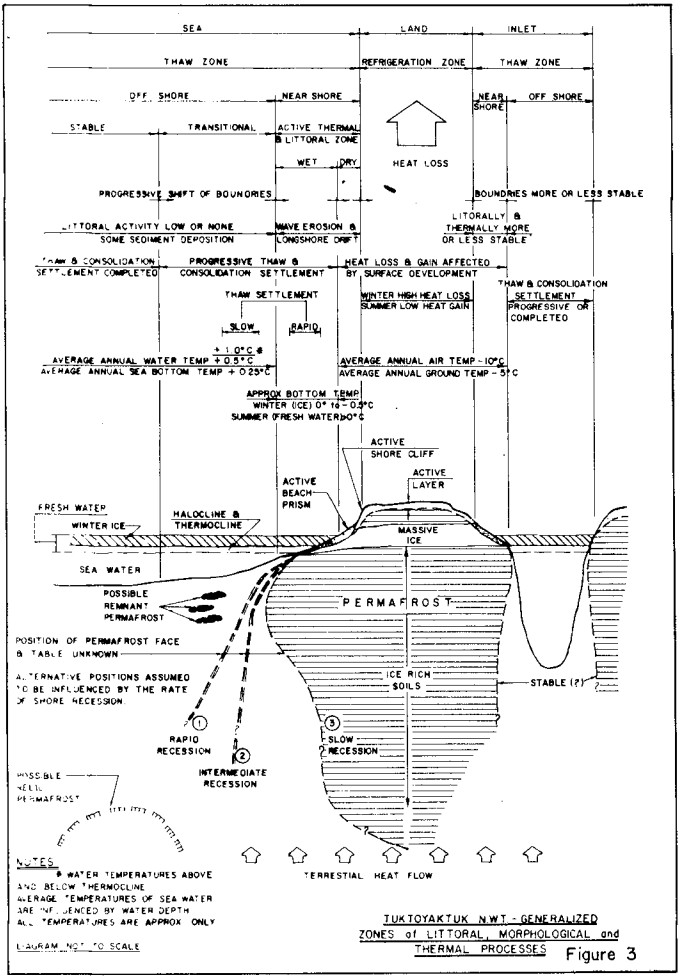
3.1 General

There are two major causes of the erosion occurring at Tuktoyaktuk. In the warm regions of the world the usual cause of erosion is the physical force of the waves. In the arctics, where ice rich soils and massive ice abound within the soil, thawing caused by the warmer temperatures in the summer and warmer sea water can be a major cause of shore recession and an accelerating factor in shore erosion. Both of these phenomena impinge on the Tuktoyaktuk coast.

3.2 Erosion by Waves

The erosion of Tuktoyaktuk shore, attributable to the physical forces of waves, can be seen to be taking place in two distinct ways depending upon the shore topography. In places where high cliffs exist, the cliffs are degraded by undermining and removal of slices from them. In areas where dunes occur, the dunes are shifted landward in varying alignments depending upon the direction of storms. The importance of these two shore erosion factors compared with the factors of thermal erosion discussed in the following section, cannot be precisely established.

The shore material transport rates calculated using a method known as the wave energy flux method do not reconcile with the large coastal recession rates of Tuktoyaktuk given by aerial photographs and surveys.



TUKTOYAKTUK N.W.T. - GENERALIZED ZONES of LITTORAL, MORPHOLOGICAL and THERMAL PROCESSES Figure 3

3.3 Thermal Erosion
Thermal erosion is considered to be the major contributory cause of the coastal recession occuring at Tuktoyaktuk. There are two ways in which the thermal action is affecting the Tuktoyaktuk coast. These are (1) the melting of the ice present in the coastal land by warm water waves at high storm water levels and (2) thawing of the permafrost and ice contained in the beach and underwater soils, by the warm summer environment (figure 4).

4. DESIGN
As discussed in the preceding section, the erosion occurring at Tuktoyaktuk is mainly as a result of an inadequate cover over the ice and permafrost present in the ground at the site. Direct solar heat and thermal action of warm water waves are the main agents that cause the erosion at Tuktoyaktuk. During normal weather conditions the water levels are low and the waves do not impinge upon the coast. In storm weather situations, high water levels occur and the beach and the coastal areas are rendered liable to direct thermal action of warm water and thermal and physical action of waves. To protect the beach and the coast from the thermal action, an insulating cover is required over the area. To abate the wave action a barrier is needed. The insulating cover and the barrier must be of flexible type to accommodate any initial and long term settlement.

The design wave length considered ranged from 60 feet to 100 feet. The design wave height (storm maximum wave height) adopted was 8 feet. The cover required to protect the permafrost and ice was estimated to be 7 feet.

Construction materials available locally are confined to sand and gravel. The materials ocur in offshore regions, along the coast and inland. While there are adequate supplies of sand and gravel within short distances from Tuktoyaktuk, there are no sites in the vicinity of the area for any rock. Experienced contractors and heavy construction equipment similarly do not exist in the area. To obtain the required materials other than sand and gravel, construction services and equipment, Inuvik and areas as far as Edmonton have to be relied upon. The logistics are further complicated by the inaccessibility of Tuktoyaktuk by land. Because of this, all the requisites must be either transported by water or flown by air.

Various alternative forms of construction were considered for the test installation, including a rock revetment, rubblemound bulkhead, steel sheet pile wall, timber crib wall, and certain patented steel wire gabions. A product known as the "Longard" tube was at that time being introduced into the North American market. The "Longard" tubes which are sausage shaped, merely require sand to fill them and had been found to be functioning well in Europe and in certain ice covered environments. The use of the "Longard" tubes as shore protection work units showed good possiblities and a decision was made to proceed with the test program using these.

Figure 4.

The test design devised utilised one metre diameter Longard tubes, Longard and Terrafix filter mats and Dura bags as sand bags. Basically, the design consisted of a bulkhead at the bottom of the cliff, another bulkhead lower down on the beach and four main groynes separated by three shorter intermediate groynes, at right angles to the bulkheads. The cliffside bulkhead consisted of a double tube. The beachside bulkhead and the groynes were built with single tubes. The bulkhead tubes were laid on filter mats held down during construction by sand bags. Originally the compartments formed by the groynes and the bulkheads were to be filled with beach material. Owing to lack of funding the compartments between the groynes and the bulkhead were left unfilled. Due to construction difficulties also the groynes were constructed without the filter mats. The length of the installation was approximately 360 feet (figures 5 and 6).

5. PERFORMANCE

The principal objectives of the test were to provide protection to the local school which was under threat of being undermined by the sea and to gain experience to develop a full scale system to protect the whole settlement peninsula of Tuktoyaktuk. Imperative in these objectives was longevity of the test installation. While the test installaton has protected the school as envisaged and provided considerable information on how we may proceed with further shore protection works in Tuktoyaktuk, the installation has been subject to an incredible amount of willful damage. The Longard tubes can withstand heavy pressures required to fill them with sand under pressure and adequately resist the natural environment. In their exposed condition they cannot, however, withstand vandalism. The groynes have been practically slashed open by vandalism. The beachside bulkhead has also suffered from deliberate cuts. The cliffside bulkhead, which was backfilled and has been covered has, however, survived.

Technically, the installation has performed as envisaged. Erosion at the school has been completely halted. There has been, in actuality, accumulation of material between the bulkheads and between the groynes. There has been a greater accretion of material on the north end of the installation confirming littoral drift to be from north to south. Because of the lack of supply of material from the north, as would be anticipated, certain erosion has occurred of the southern end of the installation.

The performance of the test installation suggests that certain modifications can be made in the geometry of any full scale shore protection work in the area. The short intermediate groynes have been virtually ineffective in trapping material and can be eliminated. The long groynes have been allowing bypassing of material to occur and can be extended to deeper water. The cliffside bulkhead has remained virtually undisturbed and if an adequate bulkhead can be built at the beachside with backfill to the cliff, the cliffside bulkhead can be eliminated except at certain locations.

Means are now available to protect the tubes against vandalism.

Basically, there are two steps that can be taken to make the design resistant to vandalism. These include coating the tubes with a hard shell and backfilling the installation with granular fill, covering the tubes to the top. The coating material available consists of an epoxy resin glue applied by painting rollers and sand which is either sprinkled manually or dumped onto the wet glue mechanically with dump trucks. The backfilling of the installation was a design requirement not accomplished in the test installation. Its purpose was to provide a blanket on the beach to protect the permafrost underneath from destabilization by the sea and the warm summer temperatures. In the final design the backfill will in addition protect the Longard tubes from damage from vandalism and from any sharp floating debris that can otherwise strike and damage the tubes with wave action.

To investigate the coating a length of one meter diameter Longard tube was obtained and assembled at the National Research Council of Canada for certain tests. Five different combinations of coating were applied to the tube. These were:

(1) uncoated
(2) one coat of epoxy glue, followed by sand
(3) two coats of epoxy glue followed by sand
(4) one coat of epoxy glue followed by sand and a second coat of epoxy glue followed by sand
(5) one coat of pre-mixed epoxy glue with sand

Several different types of tests were carried out on each section. These included resistance to slashing by hand, resistance to puncture by a knife with a proctor-needle assembly, flexure and bending tests at -40 deg.C and burning with a propane torch.

Hand slashing tests were carried out using a hunting knife. The uncoated tube offered very little resistance to hand slashing. Among the coated sections of the tube the double coating type 4 (glue - sand/glue - sand) offered the most resistance to slashing. Another advantage of coating observed during these tests was that the cuts made in the coated sections remained simply as closed cuts while the cuts made in the uncoated sections opened out allowing the sand-fill to run out.

PROTOTYPE TESTING OF SAND COATED TUBES USING A HUNTING KNIFE

PROTOTYPE TESTING OF SAND COATED TUBES FOR RESISTANCE AGAINST FIRES

Figure 7

The results of the penetration tests carried out using the hunting knife and Proctor Needle Assembly are tabulated below (figure 7).

Type of Coating	(1)	(2)	(3)	(4)	(5)
	65	69	48	90	63
	62	63	53	100	77
Pounds of Force for	50	56	58	93	77
Knife Penetration	43	57	63	120	
	62	62	59	96	
	45	61	64	89	
Average	55	61	58	98	72

The fire resistance tests with a propane torch showed the following results (figure 7).

Type of Coating	(1)	(2)	(3)	(4)	(5)
Time in seconds required to burn through coating	5	100	45	120	-

Flexure and blending tests were performed using samples from sections with type 2, 3 and 4 coating.

Relative comparisons of the results showed type (4) coating to be the most superior, both at room temperature as well as at -40deg.C.

The test results show the section with a double coating (one coat of glue followed by sand and a second coat of glue followed by sand) to be the most effective section and the final design for Tuktoyaktuk will include this double coating.

6. CONCLUSIONS

In remote areas of the Canadian north, sand filled tubes offer an attractive alternative compared with traditional materials in the design of flexible type shore protection works. The tubes in their uncoated form are vulnerable to vandalism. Techniques now exist to protect the tubes against damage and this feature should prove invaluable to guard against vandalism that can occur in remote areas.

THE BEHAVIOUR OF PROTOTYPE BOULDER REVETMENT WALLS

By A.W. Smith * & D.M. Chapman **

1. lntroduction

This paper reports the results of on-site observations of coastal revetment structures under extreme storm conditions on the Gold Coast of Australia. The Gold Coast is located at approximately Lat. 27° S on the East Coast of Australia facing the Tasman sea behind a narrow continental shelf and exposed to a relatively high energy wave climate as depicted in Fig 1. Tropical cyclones generate the highest storm activity on the Gold Coast with Ho values commonly exceeding 10m with the resultant onshore wave i.e. either the second or third wave reformed breaks within the range of 2.5 to 3.5m. Storm wave periods are usually between 8 to 18 seconds. The ocean beach on the Gold Coast, some 30km long has been receding since the early forties and this has resulted in the construction of nearly 20km of revetment walls to "protect" the rear beach. Whilst some walls in particularly erosion-prone areas were constructed in the 1920 decade, most have been constructed since 1967 which represented a particularly high cyclone prone year. Since the latter period the walls have been exposed to three further periods of high cyclone energy attack in 1972, 1974 and 1976. Nearly all revetment walls demonstrated at least some settlement and damage but over the three storm periods at least 0.8km of wall was completely destroyed. Most wall failures were monitored on site and whilst the construction of the walls varied in quality the observational results might well be classified as full scale prototype performance tests.

2. Boulder Walls

Over 90% of all Gold Coast revetments are boulder walls constructed from natural stone with a filter layer of well weathered quarry overburden material that effectively consists of a natural mixture of weathered gravel and clay.. All boulder revetments are founded at Mean Sea Level because below this the beach resists excavation by going "quick" and cofferdamming costs are prohibitive. Local philosophy has always been to found walls at M.S.L. and merely top them up in response to settlement and storm damage. The typical form of Gold Coast boulder walls is shown in Fig 2(a) and the official design standard in Fig 12(a).

The collapse mode of boulder walls is set out diagrammatically in Fig 2 starting with the as-built wall and finishing with the wall completely vanished and buried beneath the eroded beach profile. The initial failure has always been triggered by subsidence of the toe, this has then caused the face armour to rattle down until the wall's freeboard has been reduced enough to allow overtopping. As soon as the overtopping has become practically continuous the erosion of filter material became extremely rapid with the rump of the wall finally collapsing landwards into the

* Gold Coast, Queensland, Australia
** University of Sydney, Australia

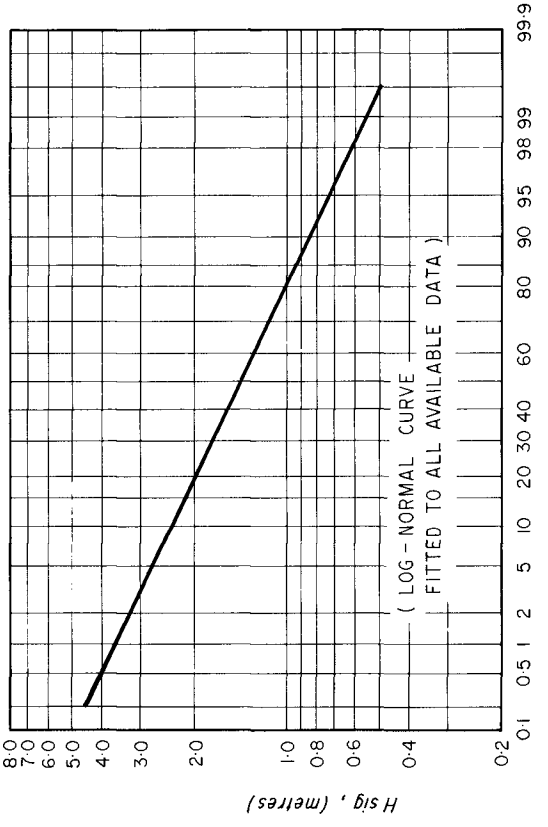

FIG. 1 WAVE HEIGHTS, GOLD COAST
PROBABILITY of EXCEEDANCE

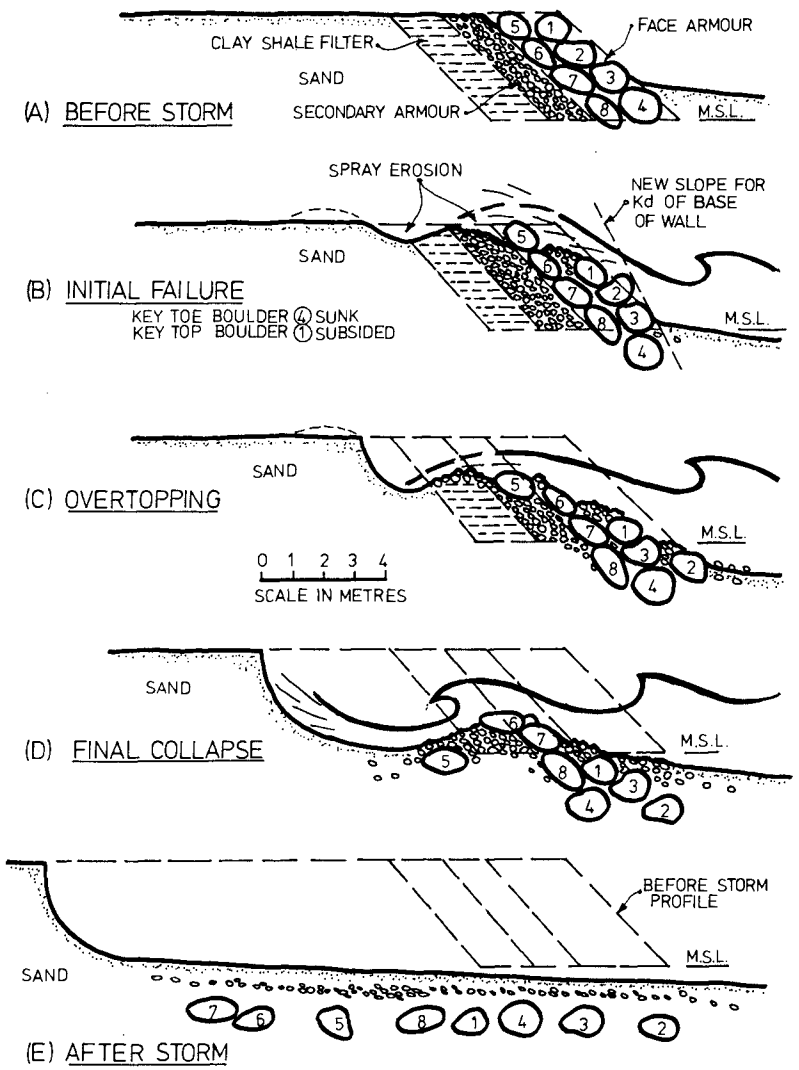

FIGURE 2:— COLLAPSE MODE OF BOULDER REVETMENT.

eroded space. The full sequence of events as shown has been observed to occur within less than 20 minutes for walls over 5m. high. The initial step by step and final positions of the numbered boulders shown in Fig 2 is typical of observed wall collapses, but it is naturally not universal, the shapes of boulders provide highly variable interlocking, some boulders bounce out of the wall during the rattle-down sequence, and small boulders (particularly in position 5) are readily plucked off the top of the wall and rolled landwards.

The initiation of toe failure has always followed the generation of semi-fluid or quicksand conditions in the beach under the toe as the lower end of the wave's trailing edge passes this zone. Once the sand becomes periodically fluidised the very low specific surface of the boulders ensures that they sink very rapidly step by step under each wave. Five tonne boulders have been observed to completely disappear in less than 150 seconds, or only 8 to 10 waves. Back-wash scour is not the mechanism of boulder settlement, as the filter layer erodes and the wall ruptures, overtopping generates a full work prism in the sand under the wall and the wall debris settles within the fluidised zone in proportion to the particle specific surface as shown in Fig 2(e) and confirmed by subsequent excavation of the beach. It might thus be observed that the practice of testing revetment walls of the class herein reported in "hard-bottom" flumes, i.e. without a sand underlay would be unlikely to reproduce the observed collapse mode of these prototypes.

From Fig 2(b) it may be noted that as the toe of the wall subsides the slope of the near toe boulders increases, thus the stability of the wall i.e. its Kd value decreases. Continued wave attack may then extend wall damage at an increasing rate, even with a constant or declining wave energy input.

3. The Role of Key Boulders

As can be seen from Fig 2 the two key elements of wall stability are the leading toe boulder (No. 4 in the diagram) and the top face boulder (No. 1 in the diagram). If neither of these boulders move the wall may maintain a capacity to resist in the short term very high hydraulic overloads.

Early efforts locally to increase the stability of the toe led to the use of the largest boulders as the key toe units. This approach was a complete failure, the bigger boulders had a lower specific surface and thus sank into the fluidised beach more easily and more quickly than standard boulders. Indeed some very large toe units sank into the beach during comparatively mild wave conditions and the walls supported by them had become dislocated before the arrival of the first storm. An alternative approach of bedding the toe boulders on secondary armour and filter material has to date also been only partially effective, since toe stability cannot be assured until the key toe unit is founded at the bottom of the work prism fluidised during a storm. Without the expedient of cofferdamming therefore it has had to be accepted that the full design capacity of the local walls cannot be attained until they have been "tempered" by one or several storm attacks and the walls topped up to accommodate the essential toe settlement.

The use of heavier boulders for the key top units has, however, proven rather more successful. In order for the key top unit to hold a Kd value equal to the other face units it should be larger in any case, the top boulder has no gravity surcharge and the least interlocking with its neighbours. It is thus the unit most susceptible to uprush and backwash forces. It is difficult however to place large top boulders flush with their surrounding armour, their size alone tends to result in them standing proud of their neighbours and leaving large gaps in between them. In this position they are very prone to rolling landwards under wave uprush and in one case a 15 tonne key unit was rolled 4 metres inland by an overtopping rush of white water only about a metre deep. The best solution seems to lie in using the largest high aspect boulders available laid flat in the top zone of the wall with their smallest face exposed to the sea and extend the top of the wall with extra top armour as shown in Fig 12(b).

An extremely effective expedient adopted on the Gold Coast for existing walls during high storm activity has been the provision of temporary top armour in the form of a single layer of sandbags laid flat and touching as shown in Fig 3. Such temporary armour however must be continually maintained by manual replacement and repair as it becomes damaged and as it distorts in response to settlement of the wall.

4. Timber Walls

At various times many segments of timber seawalls have existed on the Gold Coast with the earliest constructed circa 1920. All however have failed at one time or another and been replaced or faced seawards with boulder walls. The failure mode of a typical timber wall as shown in Fig. 4 is characterised by initial toe scour and undercutting accellerated by a lack of filter backing and the inability of the wall to settle. After a storm the partial skeleton of a timber wall may usually be seen well seaward of the erosion scarp it has failed to halt and the only reinforced masonry block wall constructed locally suffered the same fate in the same manner.

5. Grouted Walls

At one stage grouted walls became quite popular on the Gold Coast, these walls consisted of ordinary boulder walls where the Owner placed concrete in the voids between the rocks. The storm performance of these walls however has been very poor and they have always failed more rapidly than the standard walls. Ordinary face boulders absorb a great deal of wave energy by rocking and impacting on their neighbours; all boulder walls can be heard to "growl" under heavy wave attack and vibrations and movements within the armour can be felt by merely standing on top of them. Grouted armour cannot respond in this manner and the smoother more impervious face of grouted walls results in much larger uprush and overtopping volumes which lead to extensive early soil erosion behind them. It is practically impossible to effectively grout boulders in a semi submerged toe zone so once toe failure is initiated and the toe boulders settle the mass of the wall is left suspended until it collapses in a single shattering event as shown in Fig 5.

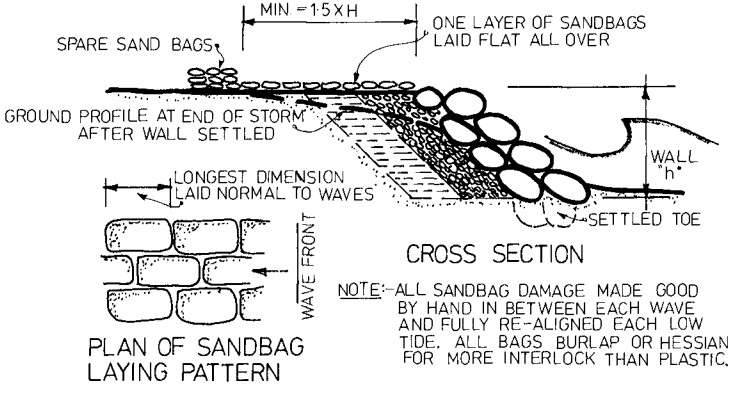

FIGURE 3:- GOLD COAST TEMPORARY TOP ARMOUR FOR REVETMENT WALLS.

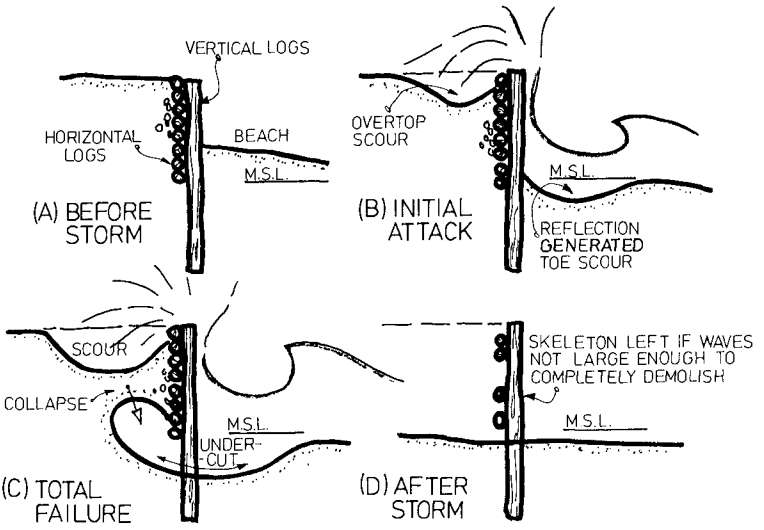

FIGURE 4:- FAILURE MODE OF LOG WALL

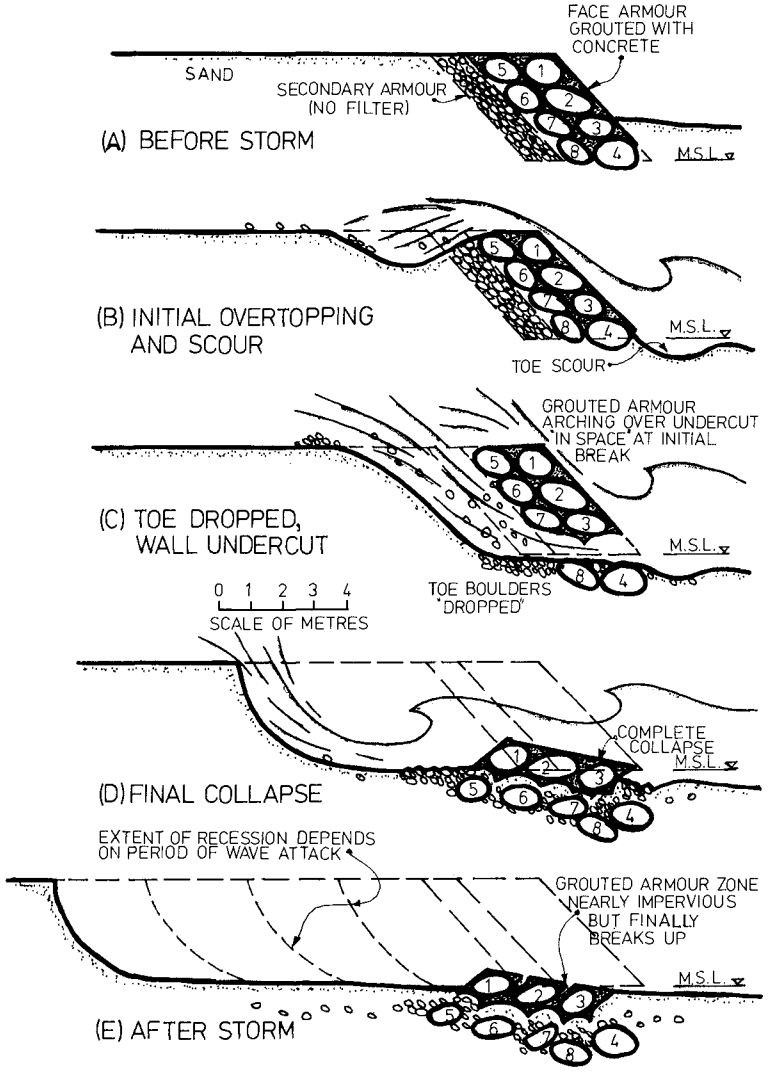

FIGURE 5:- COLLAPSE MODE OF GROUTED WALL

6. Double Waves

Of all the natural phenomena that may be included in a tropical cyclone event on the Gold Coast, the most frightening by far is the development of double waves. At least three times, in 1967, 1972 and 1974 during major storms this phenomenon has generated at least one short train of super waves, usually limited to four but sometimes reaching six in number. During a lull or low period in the incoming wave train the beach immediately in front of the revetment wall has been left nearly "dry", but this lull has been followed by a sequence of relatively large long period waves. The celerity of the first of these waves is retarded as it runs up the beach as a bore, usualy only some 2 metres deep; but the next waves celerity is not affected so it runs over the top to produce a double wave with a combined amplitude which may reach 5 metres and sometimes much more. Once the first double wave is generated the next three or four waves then also ride over the local high set-up which has been formed and the doubling phenomenon continues until the temporary set-up initiated by the first wave double drains away, and a normal wave train is re-established.

Such double waves however can do immense damage. On natural beaches such waves may overtop the highest dunes and as been observed, cause nearly seven metres recession of an erosion scarp for each double in a train. They also overtop local revetment walls with nearly two metres of green water, smashing into houses and washing away cars and other movable objects. On the Gold Coast their frequency to date has been about three major wave doubles on the beach per 8000 deep water peak storm waves per storm event but their probability remains unknown. Locally the phenomenon occurs often enough however to ensure that it will be inevitable that all revetment walls during their life-time must and will be exposed somewhere to very massive overtopping. Fortunately this process has always tended to be localised, the maximum length of beach observed affected has not exceeded a kilometer and has usually been only a third of this. Double waves can, and do, pop 5 tonne boulders out of revetment walls like champagne corks, a sight never to be forgotten once seen.

7. Gravity Forces

In the design of coastal structures it is easy to proportion the armour size and geometry for wave resistance properties alone. In addition to absorbing wave energy these structures must also maintain the capacity to hold themselves up; clearly any structure which is at its limit under body, or gravity forces alone, cannot be expected to hold any useful reserve to accept additional hydraulic forces. The local boulder revetments constructed at a slope of $1\frac{1}{2}$:1 have a factor of safety under gravity of only 1.06, a very sobering thought. It would not be surprising that for any sea wall near to its own self weight capacity, then the first element to fail should be the leading edge toe boulders, they are the most heavily stressed of all. Any seabed toe liquifaction can then only guarantee an initial failure and settlement.

8. Wave Set-Up Surge

Most coastal design texts e.g. the S.P.M. (C.E.R.C., 1977) provide ample tools for estimating surge levels due to barometric drop and wind set-up but the estimation of a realistic wave set-up appears to be a rather more

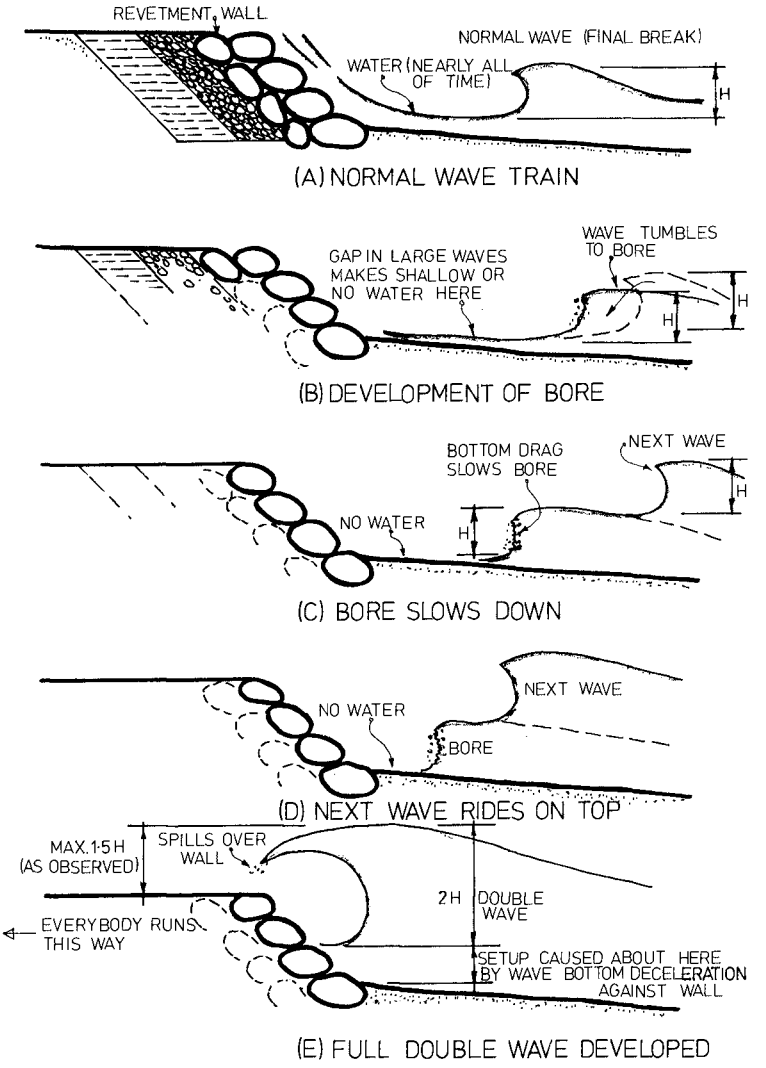

FIGURE 6:– DEVELOPMENT OF DOUBLE WAVES

intractable problem.

On the local coast during storm wave trains with Hsig exceeding 7 metre there are at least three main wave break zones with the waves reforming between each break and breaking again progressively as the water shallows up to the beach. For wave trains with Hsig generally 6 metres or less only two breaks are generated and for 3 metres or less there is usually only one significant breaking zone. Ten years observations of storms have indicated that each time a wave breaks it generates a wave set-up but that each set-up is localised to lie almost completely within the zone that the waves peak-up, break and then reform. As such for all offshore break zones each break set-up results in a local hump in the mean sea level that drains away on both sides of the breaking zone and it is only the final wave break on the beach itself that generates any set-up directly connected with the shore. The general resultant variations in mean sea level are shown diagrammatically in Fig. 7. Long term observations that the peak wave set-up within each breaking zone is approximately 25% of the breaking height seem to agree with Foster's estimates (pers. com.) but they do not support the assumption that any fixed percentage of Ho persists as a surge from the initial offshore break right onto the beach itself.

Elsewhere after great storms much evidence has been reported of apparantly unprecedented penetration by the sea to remarkable distances inland, and to such heights on dunes and local ground elevations that investigators have been led to postulate great surge levels to explain the evidence. It is quite likely however that much of this evidence has merely been the result of wave doubling. For example, eyewitness accounts record signs of wave attack levels over 13 metres above M.S.L. at Bathurst Bay in Australia in 1899 due to Cyclone "Mahina". Subsequent analyses by Silvester & Mitchell (1977) would predict a simple surge level of only 6.5 metres, but such a large cyclone must have generated many thousand waves much higher than 7 metres and it would require only one final shoaling wave of double height to reach the recorded water damage level on the shore itself, or indeed only one wave of 7 metres to ride over the beach surge, if it could penetrate that far, to attain the same result.

9. Revetment Wall Toe Exposure

The estimation of the likely water depth in front of a revetment wall at the time that it is likely to be exposed to a major storm is unfortunately rather a probabilistic exercise. A revetment wall is fixed in position but sandy ocean beaches are highly mobile with short term variations often completely masking long term recession or accretion, see for example Chapman and Smith (1981). The likely level of the beach in front of the wall, excluding localised toe scour will depend entirely upon where it is positioned within the overall swept prism of the beach (See Fig. 8). The swept prism represents the total mobile volume of the beach in response to all wave climates and sediment changes on the beach but the temporary response to great events, particularly in the offshore-onshore mode may be so large that long term trends are quite infinitesimal by comparison. Nevertheless some estimate of the probable limits of the swept prism must be made before the potential variations in shore level in front of the structure can be considered (See Fig. 9). Once a "hard" structure is constructed within the swept prism, that structure must be exposed to the same energy that would have been absorbed by the natural

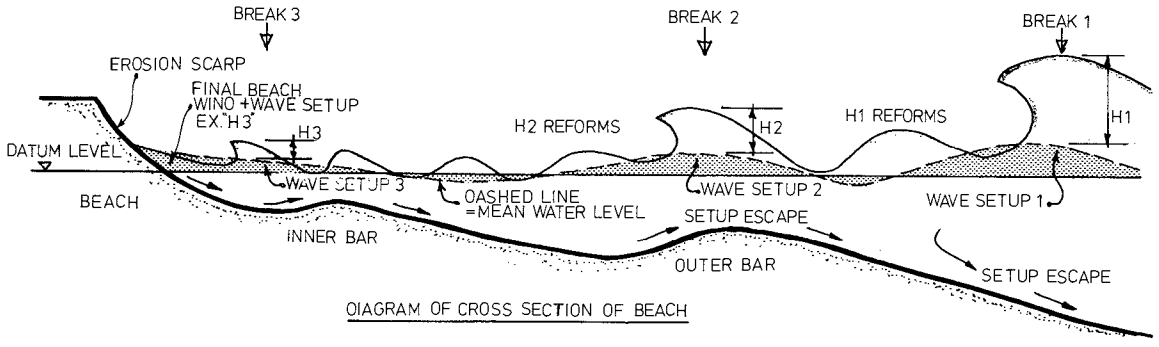

DIAGRAM OF CROSS SECTION OF BEACH

NOTES:— VISUAL OBSERVATIONS OF BEACHES INDICATE:—

(1) EACH WAVE BREAK REFORMS AND BREAKS AGAIN ABOUT HALF PREVIOUS "H"

(2) WAVE BREAK SETUP IS APPROX. 25% OF BREAKING WAVE HEIGHT AND IS LOCALISED WITHIN ACTUAL WAVE BREAK ZONE. WIND SETUP APPEARS CONCENTRATED MAINLY AT FINAL BEACH BREAK.

(3) GOLD COAST FINAL WAVE BREAK IS ALMOST NEVER ABOVE 3METRES SO THIRD OFFSHORE BREAK DOES NOT OCCUR UNTIL Ho EXCEEDS 7METRES.

(4) WAVE TROUGHS ARE NEARLY FLAT IN ALL WAVE BREAK ZONES BETWEEN INDIVIDUAL WAVES SO Ho SINE CURVE STRUCTURE BELOW LEVEL DATUM HAS BEEN SUPPRESSED AT OR BEFORE FIRST OFFSHORE BREAK.

FIGURE 11:— DESIGN HYDRAULIC EXPOSURE

beach volume now cut off from the waves by the structure itself. This it usually does in two ways - firstly by direct absorption of breaking energy by the face armour and secondly by reflecting the waves or part thereof again. Observations on the Gold Coast suggest that the reflected wave energy is then absorbed by two further concurrent processes; part of the outgoing wave energy is absorbed by the sediments themselves which adopt a "negative" beach slope in response, and the rest is absorbed by collision with the incoming waves. The total process is shown diagramatically in Fig. 10. The result is a sea-bed hollow in front of the revetment locally known as "toe scour".

Unfortunately little data have ever been collected on accurate toe scour depths but on the Gold Coast one section of boulder revetment wall during a short term beach starvation period was exposed to the ocean such that initially there was about 30 cm. of water at the toe at mean tide. Within two years the toe scour, depth "S" in Fig 11, reached 3m. at low tide and the wall had to be topped up twice, all during a calm period with the waves striking the wall seldom exceeding 1m. high. Many more observations have however been made of the magnitude of the waves reflected by boulder walls. With small waves striking rock walls reflection co-efficients of over 60% have been observed but during storms with well air entrained breaking waves (i.e. 2nd or 3rd storm breaks) the reflection co-efficient has varied between 25% and 50%. For design purposes locally the 50% factor is adopted for reasonable conservatism and the likely depths of water in front of a revetment at the beginning of a storm would be calculated as shown in Fig. 11, with depth "D" adopted for the maximum exposure at the peak of the storm.

10. Conclusions

On prototype revetment walls observations tend to suggest that many unexpected events occur in Nature that may seldom or never be detected in conventional flume tests on models. The most important results of local long term observations have been discussed and some of the resultant recommendations are set out below. Although the Gold Coast revetments represent only once class of such structures - that is a revetment sited with beach sediment all around it, i.e. in front, under and behind it; it is at least hoped that the "real time" observations may be of interest to some hydraulic structure designers.

11. Recommendations

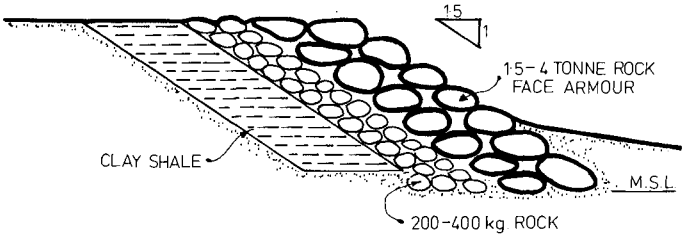
For the design of boulder revetment walls of the simple class adopted on the Gold Coast similar to the details shown in Fig 12(a) it is recommended:-

(a) Special attention should be applied to extra toe scour delay features and additional top armour as shown in Fig. 12(b).

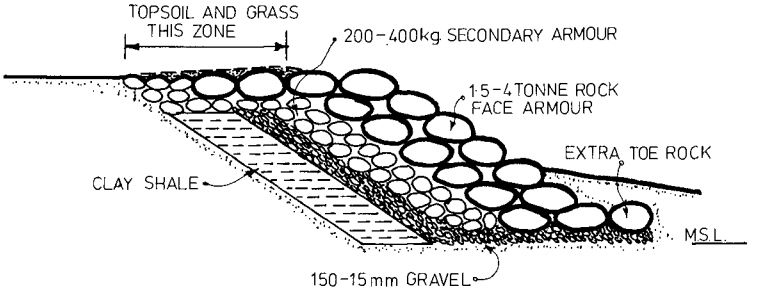
(b) Design wave set-up calculations should include consideration of Fig. 7.

(c) Design exposure water depths in front of revetments should include consideration of Figs. 8, 9 and 11.

(d) Wave testing of Gold Coast type revetments should be conducted in "soft bottom" tanks large enough to contain a compatible section of swept prism.



(A) GOLD COAST STANDARD



(B) RECOMMENDED REVISIONS

FIGURE 12:- BOULDER WALL DESIGNS

(e) There is nothing original in the concept of a "design storm" yet the basic armour and revetment stability factors might well merit the consideration of a "design event" say a cyclone or hurricane attacking the revetment for say 3 high tides of each 4 hours duration or say 3000 waves in total.

(f) Such a design wave climate might then well be simulated in the laboratory by a wave train of the form

(i) 1000 waves amplitude = 0.6D period = 10_s
(ii) 500 waves amplitude = D period = 15_s
(iii) 10 waves amplitude = 2D period = 20_s
(iv) 500 waves amplitude = D period = 15_s
(v) 1000 waves amplitude = 0.6 D period = 10_s

Such a design wave climate is highly arbitary but it does hold some resemblence to what at least local prototypes must be expected to withstand during a 1 in 50 and a 1 in 100 year event.

SEDIMENTOLOGICAL INFLUENCES OF DETACHED BREAKWATERS

by
Dov Sergiu Rosen[1], M. ASCE and Michael Vajda[2], M.IAHR

ABSTRACT

Wave diffraction and refraction in the surroundings of a new detached breakwater induce currents strong enough to cause substantial local sediment transport and consequently morphologic changes, the main feature of which are sand spits or tombolos.

As shown by field studies the morphologic changes cause an equilibrium state with some minor fluctuations due to changing wave climate. Model studies have also proved the existance of such an equilibrium state for any given geometry and sea state

The present paper treats mainly this equilibrium state, but also attempts to explain the mechanism of sand transport characterizing the initial and transitional states. According to observations by the authors in small scale models, the transporting mechanism in the transitional state involves sea bottom erosion, especially near the breakwater heads outside the protected area, and transport of sand towards the shore of the sheltered area in the form of small migrating sand bars, which finally join the shore line and widen it. Results of experimental investigations conducted by the authors, for the particular case of high impervious breakwaters attacked by waves of normal incidence, as well as results of field and model studies given by others, are used to define relationships among the factors determining the equilibrium state and to base a new hypothesis regarding the equilibrium state. This hypothesis states that a morphologic and sedimentologic equilibrium is reached behind a detached breakwater, when the shape of the contour lines becomes such, that along the sheltered beach the diffracted waves have components of momentum opposed to the gradients of the mean sea level induced by radiation stress due to non uniform wave heights along the wave fronts approaching from both sides of the breakwater. The significant parameters characterizing the dimensions of the spit or tombolo in the equilibrium state are shown to be the relative length of the breakwater (compared to its distance from the original shore line), the relative distance from the original shore line (compared to the position of the breakers' line) and the relative height of the breakwater crest (above M.S.L, compared to the incident wave height).

INTRODUCTION

Offshore detached breakwaters are used worldwide for four engineering purposes; to shelter water bodies from waves, to protect beaches against erosion, to prevent silting of harbour entrances and to facilitate shore accretion for reclamation. The achievement of these goals

can be accomplished by diminishing the wave heights inside the area protected by the breakwater, mainly due to wave diffraction, and by trapping sand inside this area in the shape of a spit, which in certain circumstances becomes attached to the breakwater and then it is called tombolo.

In the past the construction of these breakwaters was based on field experience and on empirical rules. Lately, there have been certain attempts to treat the complex hydraulic and sedimentologic phenomena and processes related to the presence of such an artificial obstacle in a wavy sea by theoretical methods and by laboratory investigations on reduced scale models.

The hydraulic and morphologic processes induced by the construction of a detached breakwater may be characterized by three stages of development as follows:

a - initial state
b - transitional state
c - equilibrium

Following the construction of a detached breakwater the current pattern in its surroundings changes immediately. In this initial state a circulatory current cell develops on each side of the axis of symmetry in the sheltered area as observed in the field by Johnson (1919), viewed in small scale model by Sauvage et al. (1954) and proved theoretically by Liu et al. (1974). These currents are directed near the shore towards the sheltered area and are generated by lateral gradients in the mean sea level in the zone of diffraction, due to the effect of radiation stresses in a non uniform wave field, as explained best by Gourlay (1974, 1976).

In the transitional state, the above mentioned currents transport sand and deposit it in the sheltered area, building a new morphological land shape named spit, or if this becomes attached to the breakwater, tombolo.

In the field this state has been studied by a number of researchers by different methods. Ingle (1966), used granulometric analysis to check the change of the mean sand grain size on the foreshore apex of the sheltered area of the Santa Monica breakwater with time (1940-1962). He found that the mean grain size at the spit apex became thinner as time passed. The explanation brought by him was that while the spit apex progressed towards the breakwater due to continuous sand deposit, regions with less and less wave energy were reached, where only small grains could be transported. U.S. Engineer Office (1939), Johnson (1940, 1949), Handing et al (1950), Wiegel (1966), Nir (1976) and Toyoshima (1976) have used differential bathymetric maps or control profiles to study the transitional state. These indicated accretion of the shore line and decrease of water depths in all sheltered area. No one succeeded to confirm whether the origin of sand deposited in the sheltered area was from the neighbouring shore or mainly from the area opposite the breakwater heads or else. However, Nir indicates (for breakwaters built inside the dominant surf zone) that the sand trapped in the whole sheltered area in the first year reached about 50 percent of the total sand trapped in the final state. In the second year the sand accretion rate regressed significantly but increased again in the following one to three years by the end of which it stopped and

and morphologic equilibrium was achieved. To Nir's opinion, the regression in the second year was due to the temporary diminution of sand sources in the area surrounding the breakwater. Furthermore, according to his opinion the main sand source was sand from the neighbouring beaches, which consequently suffered erosion in the first years.

The transitional state was studied also by means of small scale models. Sauvage et al. (1954) applied on a shore parallel detached breakwater normal waves and also waves of equal oblicity from both sides of the breakwater, while continuously supplying sand (artificial) in the surf zone outside the sheltered area. In both cases they found that the shore line progressed parallel to its original shape towards the breakwater with only a small spit formation until the distance from the breakwater reached a critical value beyond which a tombolo developed. According to their opinion, sediment deposit was best facilitated along the axis of symmetry in the sheltered area because of two reasons: a) collision of the two opposite currents developed, b) turbulence decrease due to diminished wave height on the center line. However, in certain cases they found that the main sand deposit occurred as two spits which developed opposite each breakwater head. This phenomenon was explained by wave diffraction. Their main conclusion was that the process of tombolo formation depends on the wave characteristics and on the breakwater geometry. Additional information was brought by Shinohara et al. (1966) who studied in a small scale model with natural sand the process of sand deposit behind shore parallel detached breakwaters under the action of waves of normal incidence. Two wave steepnesses representing summer waves (H_o/L_o = 0.019) and winter waves (H_o/L_o = 0.046) were applied on a breakwater model of fixed length but located alternately at different distances from the original shore line such that the relative distance X_B/Y_B was 0.5; 1.0; 1.75; 2.5. They studied mainly the change of the water line with time, giving a few other contour lines only for the final state.
Currents were not measured. Regarding the development process the main fact which may be observed from the data brought by these authors is that in almost all the tests the spit development started with the formation of two small spits each one opposite one of the breakwater heads. Furthermore, the transitional state ended with the formation of a spit of stable morphologic state but tombolo formation never occurred. for these testing conditions.

Finally, numerical models have been developed which forecast the shore (water) line in the sheltered area of a detached breakwater, all being based on the differential equations developed originally by Pelnard-Considere (1956). Results of numerical models developed by Hashimoto (1974), Sasaki (1976) and Perlin (1979) show considerable progress in the representation of the transitional state, forecasting shore line accretion with one or two spits. However, when compared with small scale model results, it comes out that the numerical results are mainly of a qualitative nature and differ considerably in forecasting the quantitative values. The accuracy of the numerical model results is limited because of problems related to accurate solution of combined refraction, diffraction and reflection in water of changing depths, non-linear wave-wave effects, correct solution of two phase (water-sediment) flow, problems related to numerical modelling methods, etc.
The equilibrium state was studied by a number of researchers by field observations and in small scale models.

Many field observations indicated that the new land formed by sand deposit behind a detached breakwater reaches finally a relatively stable shape, which fluctuates around an average state due to changing wave climate (Johnson (1952), Spataru (1963), Inman et al. (1966), Silvester (1972), Toyoshima (1974), Nir (1976) and Noble et al. (1978)). The conclusion reached by Inman et al. (1966) was that tombolo formation would take place if the ratio X_B/Y_B is less than a third, but if this ratio is larger than six the size of the spit formed would be very small. Toyoshima (1974) observed that the final quantity of sand trapped by the detached breakwater is influenced by position of the breakwater relative to the position of the breakers line. (Nir (1976), found for detached breakwater built inside the predominant surf zone that the area of the new land reclaimed reached from 25 to 75 percent of the sheltered area (X_B/Y_B) and that the morphologic equilibrium state was achieved in three to five years from the construction. Dean (1978) found from field surveys of the shores of the Atlantic and those of the Gulf of Mexico that the shape of the shore line behind two headlands or two detached breakwaters (in equilibrium state of tombolo)could be approximated by an ellipse and that the change in the depths on the median between the two breakwaters is a function of the relative distance of the breakwaters from the initial shore line at the power 2/3. As one can see, the quantity of information gathered from field observations is quite limited.

Studies of the equilibrium state in small scale models brought further information regarding the equilibrium state. Sauvage et al. (1954) brought a most important evidence for the understanding of the equilibrium state. This is presented in a picture which showed the shape of the water line of a tombolo in equilibrium state. It may be observed that this shape is elliptical and not circular, as one might assume by analogy to the shape of diffracted wave fronts.

The results of a model study by Shinohara et al. (1966) proved again that a morphological equilibrium state is achieved behind a detached breakwater and from a limited number of tests in which the wave period and the breakwater length were kept equal and constant,concluded that the equilibrium state is influenced by the wave steepness and by the relative distance from the initial shore line. However, one could observe that the actual influence was due to the different wave heights and therefore the different relative positions of the breakwater with respect to the breakers' line. These results indicated that a maximum sand deposit occurs in the sheltered area for the case when $X_B/Y_B = 1$. Silvester (1970, 1974) studied the equilibrium state of the shore lines of tombolos formed between adjacent detached breakwaters or headlands. Using the findings of Yasso (1965) which showed that the natural water line between adjacent headlands is stable in nature and can be described by a section of a logarithmic spiral, Silvester described the equilibrium water line between two adjacent breakwaters as being formed by a section of a logarithmic spiral and a straight section tangent, to this spiral section. Furthermore, the hypothesis used by him to describe the equilibrium state was, that it occurs when no more sediment is moved in the sheltered area due to the development of contour lines parallel to the diffracted wave fronts. This, according to him would lead to zero oblicity of the wave fronts with the contour lines and hence to zero longshore sediment transport. Further information regarding the equilibrium state was brought by

Gourlay (1974, 1976). Though his study purpose was to prove other things, its results can be used to prove that the hypothesis brought by Silvester and generally accepted since then (Komar (1978)) is wrong. Gourlay (1976) measured the currents developing in the sheltered area of a detached breakwater model. The bottom's contourlines were casted in concrete so that outside the sheltered area they were straight and parallel to the breakwater but in the sheltered area they were made as concentric circular sections reproducing a tombolo shape and the breakwater was attacked by waves of normal incidence. Thus, the contour lines were parallel to the incident wave fronts both outside and inside the sheltered area. This however did not prevent the generation of currents in the surf zone of the sheltered area which had in this model speeds larger (0.4 m/sec) than the incipient natural sand transport velocity. The study showed that they were generated by a gradient in the mean sea level between the unsheltered area and the sheltered area due to non uniform wave heights (and hence different radiation stresses) in two regions. Therefore the general hypothesis used until now to describe the equilibrium state is erroneous.

PARAMETRIC DESCRIPTION OF THE EQUILIBRIUM STATE

The significant physical parameters influencing the morphologic equilibrium resulting by the implantation of a detached breakwater are as follows:

- Y_B - the length of the breakwater
- X_B - the breakwater's distance from the initial shoreline
- S - the elevation of the breakwater's crest above MSL.
- K - the porosity of the breakwater
- D_B - depth at centerline of the breakwater
- $\beta(x)$- local bottom slope
- H_o - deep water wave height
- T - wave period
- α - wave approach angle

In addition some parameters pertaining to the local sediment may be mentioned , like:

- ρ_s - the specific density of the sediment
- d_{50} - median grain diameter
- θ_r - repose angle
- σ_ϕ - skewness factor of grain size distribution
- S.F.- shape factor of the grains

However, all this features may be summarized by the most significant property of the sediment from the point of view of the transport process, it is the characteristic fall velocity (V_f).

In the particular case of tombolo or spit formation induced by a shore parallel, impermeable and high breakwater (not overtopped by waves) the following dimensionless relationships can be deduced from the list of the relevant significant physical parameters:

- When only a spit is formed then

$$(1)\quad \frac{X_A}{X_B} = \phi \left(\frac{Y_B}{X_B}, \frac{X_{br}}{X_B}, \frac{H_o}{V_f \cdot T}, \frac{H_o}{L_o}\right)$$

where the parameter X_A represents the distance from the land spit at its apex measured from the original (equilibrium)shore line,

- In the case of a complete tombolo, the characteristic dependent variables are Y_T, A_T and V_T. Consequently the dimensionless relationships may be written as:

$$(2)\quad \frac{Y_B - Y_T}{2X_B} = \phi_2 \left(\frac{Y_B}{X_B}, \frac{H_o}{V_f T}, \frac{H_o}{L_o}\right)$$

$$(3)\quad \frac{A_T}{X_B Y_B} = \phi_3 \left(\frac{Y_B}{X_B}, \frac{H_o}{V_f \cdot T}, \frac{H_o}{L_o}\right)$$

$$(4)\quad \frac{V_T}{Y_B X_B^2 \tan\beta} = \phi_4 \frac{Y_B}{X_B}, \frac{H_o}{V_f \cdot T}, \frac{H_o}{L_o}$$

where:

Y_T - the attachment width at the breakwater

A_T - the accreted sand area

V_T - the total volume of sand trapped in this protected area

The expressions indicate the dependence of the geometric parameters characterizing the sedimentologic development caused by a detached breakwater on the parameters of the waves, of the sediments and of the beach profile.

SMALL SCALE MODEL STUDY

A series of tests were carried out in a small scale moveable bed model with a high impervious detached breakwater parallel to the shore line attacked by waves of normal incidence. The model study was conducted in a wave tank. A beach was built of artificial sand (coarse bakelite, $\rho_s = 1.42$ gr/cm^3, $d_{50} = 0.64$ mm, $V_f = 2.9$ cm/sec)see slopes

in fig. 1. The beach was 7 m long, the depth near the wave generator was 40 cm and the water line was located at about 9 m from the wave generator.

Three groups of tests were performed for three deepwater wave steepnesses (H_o/L_o) of 0.015, 0.025 and 0.040. For each wave steepness only one wave height H and one wave period were used. For each group of tests the breakwater length Y_B and its distance from the original shore line (X_B) varied (see table 1) to cover different conditions.

For each group of wave steepness the beach was initially brought to a natural equilibrium state, taking care that the equilibrium state would not be influenced by the initial beach slope using Dalrymple et al. (1976) conclusions. Then for such an equilibrium beach a detached breakwater with the smallest length (Y_B = 0.5 m) was implanted at a distance X_B from the new equilibrium water line and attacked by the same waves.

When morphological equilibrium state was attained, the breakwater was lengthened to Y_B = 1.0 m attacked further with the same waves until a new equilibrium was attained and then the process was repeated with Y_B = 2.0 m. At the end of these tests the initial beach slope was rebuilt, brough again to equilibrium by the same waves and the small breakwater was then built at a new distance X_B from the natural(equilibrium) water line. Then the process of breakwater lengthening was carried out as explained above.

During each test the transitional state was monitored by eye observation, by pictures, by marking with small sticks the progressing water line and by measuring control profiles by means of a point gauge installed on a carriage moving above the model area.

Morphological equilibrium was indicated by the stability of the water line, and by the practical identity of three consequitive outcomes of control profile measurements which also served as a basis for the contour charts.

SEDIMENT TRANSPORT IN THE TRANSITIONAL STATE

The process of sand deposit in the sheltered area was continously observed during the development stage. Current patterns were visualized using fluorescent dye. The observed phenomena are described below:

a) After the implantation of the detached breakwater, two circulatory currents as described theoretically by Liu et al. (1971) were observed. In some cases the dye indicated currents returning to the unprotected side of the breakwater around the heads (kind of fluctuating rip current).

b) Sand was observed to be transported from area outside the sheltered zone towards the sheltered zone and towards the shore line. Inside the sheltered area the sand accumulated around the axis of symmetry (perpendicular to the shore line) in such a way, that the resulting bathymetry was saddle - like due to concentration of sand deposit near the original shore line and near the breakwater.

c) From time to time, the formation of submerged sand bars was observed in the inshore area, opposite each one of the breakwater heads.

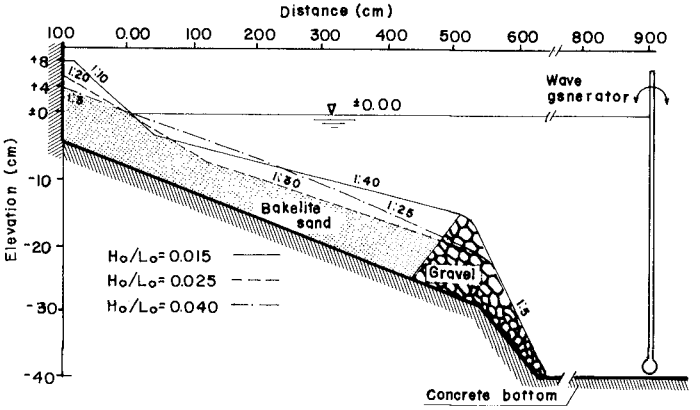

Fig.1- INITIAL BEACH SLOPES FOR THE THREE SERIES OF TESTS PERFORMED

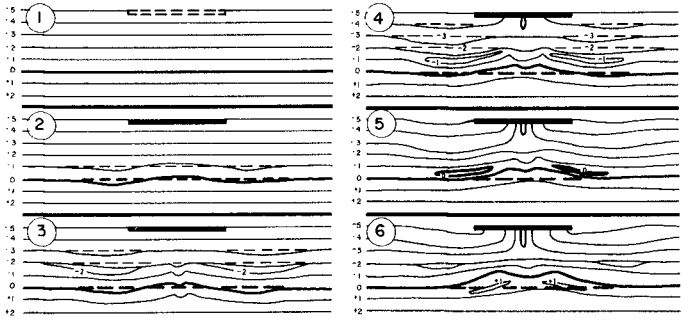

Fig. 2- TRANSITION STATE

DEVELOPMENT OF THE SAND SPIT BEHIND A DETACHED BREAKWATER

On these bars the sand moved with the waves and also with the circulatory current.

The slope of the bar was relatively moderate in the direction of wave progress but terminated with a steep slope (almost vertical) on its shoreward end (see fig. 2). The typical height of the sand bars was about 5 mm. The sand bars migrated towards the shore from both sides of the breakwater and towards each other. When they were close to the foreshore, they created with the shore line a kind of troughs. On the symmetry axis the two troughs joined and formed a channel near the water line. In the two troughs relatively high velocities were observed, but the sand was transported mainly near the edges of the troughs. The transporting speed was also high in the channel formed on the axis of symmetry of the sheltered area, but sand was transported mainly as bed load towards the ridge of the "saddle" area described previously, were most of the sand settled. The rest moved further towards the breakwater heads, parallel to the breakwater.

d) After some time, the migrating bars joined the shore creating two small spits. With time other sand bars joined them and also the area between the two spits filled with sand so finally in most cases a single spit was formed.

ANALYSIS OF THE TESTING RESULTS

The beach morphology in the equilibrium state was analyzed by comparing the change in the beach profile at control sections (fig.3), and by comparison of the final water lines obtained in each test (see figs. 4,5 and 6).

It was considered that the sand deposit in the sheltered area can be well represented by the value of X_A, i.e. the size of the sand spit at its apex measured from the initial (equilibrium) water line. Using the beach profiles the influence of the breakwater length (Y_B), its distance from the shore line (X_B), and of the wave steepness (H_o/L_o) on the size of the spit were studied. The main results of these analyses are presented in the following lines:

Influence of the breakwater length (Y_B)

The lengthening of the breakwater in a given wave regime lead usually to sand deposit in the sheltered area. The amount of sand deposited decreases from the axis of symmetry towards the unsheltered area.

Near the breakwater in the sheltered area a channel parallel to the breakwater is formed. Its dimensions grow with increasing breakwater length, especially when the breakwater was relatively far from the original water.

In the front of the breakwater, a series of sand bars develop with their length of the same approximate size like that of the breakwater. This is clearly due to wave reflection.

Influence of the distance of the breakwater from the shore line(X_B)

The closer the breakwater is placed to the shore line, the larger the sand deposit in the sheltered area and the bigger the chance that the spit would become a tombolo.

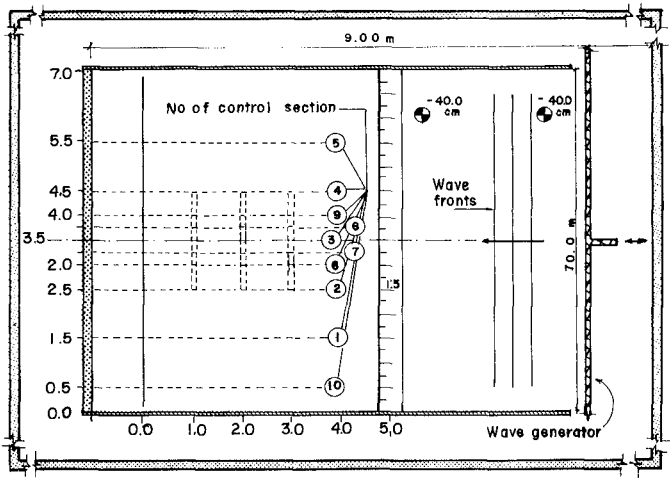

Fig. 3 - LAY OUT OF THE MODEL IN THE WAVE TANK AND LOCATION OF THE BREAKWATERS AND OF THE CONTROL PROFILES.

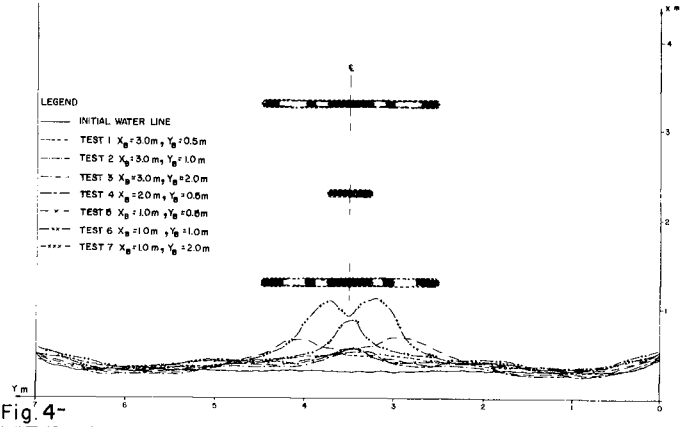

Fig. 4- WATER LINES IN EQUILIBRIUM STATE FOR TESTS SERIES H_o/L_o= 0.015

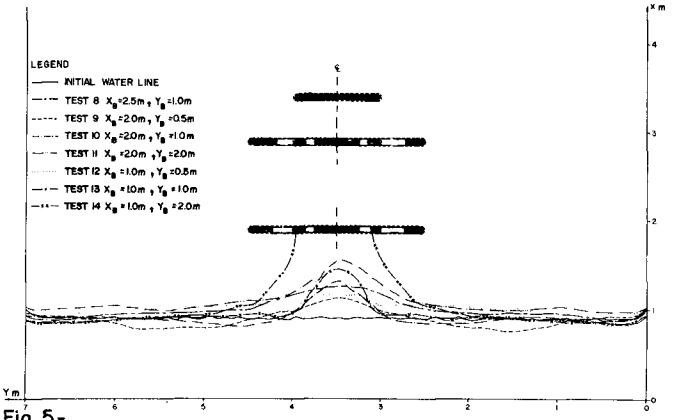

Fig. 5-
WATER LINES IN EQUILIBRIUM STATE FOR TESTS SERIES H_o/L_o=0.025

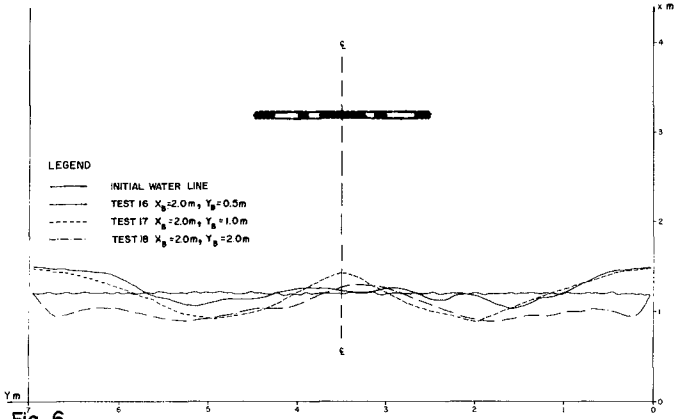

Fig. 6-
WATER LINES IN EQUILIBRIUM STATE FOR TESTS SERIES H_o/L_o=0.040

When the breakwater is placed close to the shore line the channel which develops near the breakwater, when it is far from the shore line, disappears.

Influence of the non dimensional parameter Y_B/X_B

Regarding the influence of both Y_B and X_B, and considering the outcome of the dimensional analysis it was concluded that the actual independent variable on which the geometry of the sand spit depends is the relative length of the breakwater Y_B/X_B. This served, as a matter of fact for the preparation of fig. 7, in which the dependence of the spit geometry on this factor is clearly demonstrated.

This analysis included also results from nature and from other model studies which are summarized in tables 2 and 3.

Further, for the cases when a tombolo was formed (X_A/X_B=1.0) another analysis was made and the outcome is presented in fig. 8.

For points in fig. 7, indicating tombolos formed in nature, the distance of the breakwater relative to the breaker line (X_B/X_{br}) is not specified because it is variable, usually including cases with $X_B/X_{br}<1$.

Influence of the wave steepness (H_o/L_o)

It was found that the general equilibrium beach profile differred considerably for wave steepness 0.015 which was of a "summer" type, relative to the general beach profile obtained for the other two steepnesses(0.025 and 0.040), which were of similar "winter" type. This result corresponds well to the ones obtained by Johnson (1952), but also to the ones of Dean (1973) which concluded that the fall velocity parameter $H_o/V_{f.T}$ determines the type of beach profile, the critical value for transition from summer profile to winter profile being 0.85 (see table 1).

ANALYSIS OF THE EQUILIBRIUM STATE

The existence of a morphologic equilibrium in the surroundings of a detached breakwater under the influence of a certain incoming wave was proved by the present study. Additional information obtained from actual observations in the nature shows, that this statement can be extended for the average morphology developing under the influence of a certain wave climate.

There are various hypothesis how this equilibrium state is reached and how can the stability of the new configuration be physically explained or characterized by the relevant mechanism of sediment transport.

The attempts to find such an explanation led to the following assumptions:

a) Due to bathymetric changes the longshore current in the sheltered area fades completely or becomes so weak that the longshore sediment transport stops.

b) The longshore transport does not stop in the sheltered zone (along the tombolo beach) but continuity is maintained by recirculation of sand.

TABLE 3: - Data regarding spits and tombolos in nature

Silvester (1970, 1974) explained hypothesis a) by assuming that the bottom contour lines become parallel to the diffracted wave fronts. Model tests carried out by Gourlay (1976) indicate, that this may not be the case, because such a morphology involves strong currents capable of causing intensive sediment transport along the sheltered beach. Consequently, hypothesis a) should be discarded. The condition for hypothesis b) clearly must be the existence of a circulatory current strong enough to maintain longshore transport along the equilibrium spit or tombolo beach. However, continuity considerations show, that such a strong current may not exist in the vicinity of a detached breakwater because the current at the breakwater heads would be much weaker than that at the shore, facilitating there sediment deposit which would mean that equilibrium was not reached. This was also indicated by the model tests of Gourlay (1976). Therefore, this conclusion leads back to hypothesis a) which had to be given another physical explanation.

DISCUSSION OF A NEW EQUILIBRIUM HYPOTHESIS

The authors observed in the model and then in nature that the morphological equilibrium was reached when the shape of the contour lines was not completely parallel to the diffracted and refracted wave fronts (see fig. 9 and 10). The present hypothesis states that a morphologic and sedimentologic equilibrium is reached when the shape of the contour lines is such that along the sheltered beach the diffracted waves have a component of momentum opposed to the gradient of the mean sea level induced by radiation stress due to non uniform wave height along the wave fronts. This explains the fading of the currents which caused sediment transport during the earlier stages of development.

Fading of the currents does not mean a complete absence of them, but rather indicates a state of lack of longshore sediment transport, due either to the weakness of the remaining currents, or to the combined influence of diffracted waves and weak currents, which cause only local oscillation of sediments.

As a matter of fact, weak currents may be observed along tombolo beaches in spite of their apparent state of equilibrium.

In model tests carried out in our laboratory involving detached breakwaters the weakening of the circulatory currents towards the end of the development process of tombolos was clearly observed.

In the same state sand movement along the tombolo beach could not be detected. This also confirms our hypothesis concerning the dynamic conditions required for the establishment of equilibrium in the process of tombolo development.

ACKNOWLEDGEMENTS

The present paper is based on a thesis prepared by the first author under the supervision of the second author for partial fulfillment of requirements for a M.Sc. degree in Civil Engineering, submitted to the Technion-Israel Institute of Technology.

LITTORAL PROBLEMS IN THE PORTUGUESE WEST COAST

I.B. Mota Oliveira[1], A.J.S.F. Valle[2], F.C.C. Miranda[3]

ABSTRACT

This paper summarizes a study recently concluded of a sandy coastal reach, 110 km long, on the portuguese west coast. The final objective of that study was the design of a sea defense master plan covering all the stretch, to be built at a long term. That coastal reach has been under a strong erosion process for a long time. The history of the problem and its present situation were thoroughly analysed. Different techniques, related to different aspects of the general problem (wave climate, littoral transport, sand bypassing, long term evolution under accretion or erosion conditions, groin field, spiral beaches, etc.)were used. In what concerns littoral transport and sand bypassing the improvement of currently available methods was tried. The need of an accurately defined wave climate was felt; some rather disappointing results can surely be related to the lack of accurate wave data.

1 - INTRODUCTION

The study deals with a coastal stretch 110 km long on the Portuguese west coast, limited to the north by the Leixões harbor and to the south by the Cape Mondego - FIG. 1. The stretch faces the North Atlantic Ocean, withstanding a severe wave climate. The Douro river, joining the sea just south of the town of Oporto, and the Aveiro lagoon entrance are the main geographical features of this coast.

From a geological point of view the stretch can be divided in three zones. The northern zone, only 4 km long, between the Leixões harbor and the Douro river, has a predominantly rocky nature. The second,15km long, presents a series of rocky outcrops defining a series of sandy beaches of high recreational value due to their proximity to important urban areas. The third one, to the south of Espinho, is a long and almost straight sandy stretch of 90 km.

Some centuries ago this stretch suffered a period of alluvial over feeding. The lagoon of Aveiro was formed in that period, as a result of the southward growing of a sand spit - FIG 2. Concerning this subject , a very interesting paper (The History of a Tidal Lagoon Inlet and its

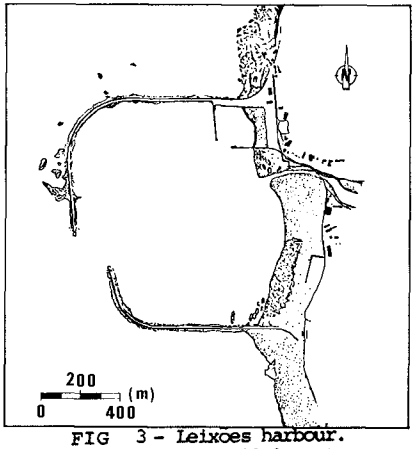

FIG 3 - Leixoes harbour. The 1892 layout

Improvement - the Case of Aveiro, Portugal) was presented by Abecasis , C.K. at the 5th Conference on Coastal Engineering, Grenoble, 1954.

In that paper a close relation between the above-mentioned phenomenon and the Douro river as an alluvial source is established. It has to be said that the phenomenon is not specific of this coastal stretch; in fact, one could refer to other cases of the same historical period around the Iberic Peninsula and even in the Portuguese coast, clearly demonstrating a situation of strong alluvial feeding. Although very interesting, the purpose of this paper is not the discussion of the causes which determined that situation.

The first records concerning the erosion process are 120 years old and concern Espinho and Furadouro which were, at that time, very small fishing villages in the northern area of the stretch - FIG 1. One is almost sure that the erosion process began earlier; however, human presence along the littoral area was almost null and the problem was not reported.

In 1892 the two long breakwaters of the Leixões harbor were completed - FIG 3. By those days the erosion process in Espinho had already begun at least 20 years ago. Even so, many people related and some people keep on relating the problems of Espinho with the construction of the port of Leixões.

The today town of Espinho has a long history of damages caused by the sea. Figure 4 registers the evolution of the water-line position (distance to a fixed point) in Espinho. We can see that from 1885 to 1910 (25 years) the coast receded 225 m (9 m/year). Even more striking is Figure 5, showing that the old village center was almost completely "swallowed" by the sea between 1880 and 1912. A historical photo taken on the 20th Dec. 1904 - FIG 6 - registers the falling down instant of the tower of Nª. Srª. da Ajuda church (see location on FIG 5).

From 1912 till 1929 the sandy coast recovered a lot, by reasons not clearly understood, although it had been related to the construction of three groins between 1911 and 1918, the first protection works ever built in the Portuguese west coast. Since then several improvements and extensions of the earlier protection scheme were performed: new groins, a sea-wall, etc. Although the town of Espinho had become really protected, the protection scheme couldn't avoid the withering of the sandy beach; by 1980 it had almost disappeared in front of the town.

A few other places along the stretch also have their historical evolution fairly well documented.

The zone just south of the Leixões harbor lost its only alluvial source, that is, the coast to the north, when the two breakwaters were built (1982). In fact, the retention effect upon the southward directed littoral transport and the dredging of the harbor entrance removed almost completely the sediment feeding of the stretch between the harbor and the Douro river mouth - FIG 1. The result has been the loss of some sandy beaches which, in the first decades of the century, were preferred by people of the northern area of the country.

The adjacent urban area remains naturally protected by the rocky coast; the landscape remains highly appreciated; but its recreational value is no longer the same as in the old days. At present, we begin

thinking on the possibility of establishing artificial beaches taking advantage of natural rocky outcrops to be improved as littoral barriers , and doing some artificial sand filling.

Taking into account the history of a disappeared little church in Furadouro - FIG 1 - it seems that the coast receded some hundred meters , between 300 and 400 m, since the last decades of the 18th century till 1930.

Quite recently (1959) the construction of two jetties in the Aveiro lagoon entrance has caused important changes on the local littoral regimen, with a strong accretion in the northern stretch and strong erosions in the southern stretch - FIG 7.

It can be said that, at present, only the last southern 30 kilometers of the whole stretch do not present any erosion problem. That is the result of the retention effect on the Cape Mondego, acting like a big natural groin. But one can be sure that the problems will "propagate" to the south as time goes by.

Erosion is particularly threatning just south of Espinho and south of the Aveiro lagoon entrance.

Until now protection works have been built separately, at different points of the coast, whenever the risk of destruction of a particular urban area occurs, without a rational plan. A study was undertaken with the final objective of establishing a long term sea defense master plan covering the whole stretch.

2 - RECENT EVOLUTION. PRESENT SITUATION

2.1 - General characterization

By "recent evolution" one means after 1950. What differentiates this period from the previous one is the existence of data, namely topo-hydrographical surveys and aerial photos adequate to a quantitative evaluation of the coastal evolution.

Topo-hydrographical surveys concern only some places or some limited coastal stretches where erosion problems are relevant on account of the patrimonial or social importance of the littoral areas; the greater this importance, the better the data of this type.

For the whole coastal stretch, the best data we could afford were aerial photos, at different times. It was possible to analyse data of this type at intervals of more or less one decade, since 1947.

Initial fears about the accuracy of this approach were not confirmed. Some difficulties had been antecipated: the correct identification of the water-line on the beach slope; the correct identification of fixed references in remote and densely wooded littoral areas; and mainly the inaccuracy resulting from a changing tidal level (one photo taken during high-water over a beach of normal slope can display an "erosion" of some 30-50 m or even more when compared with another one taken during low-water, if the tide is 3-4 m high).

Nevertheless, the result was very coherent and encouraging. Figure 8 displays the coastal evolution south of Espinho and the Aveiro lagoon

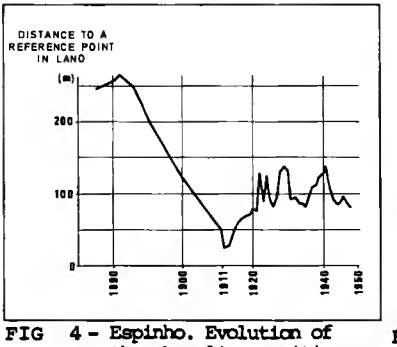

FIG 4 - Espinho. Evolution of the shoreline position

FIG 6 - Espinho, 1904. A church goes to ruins

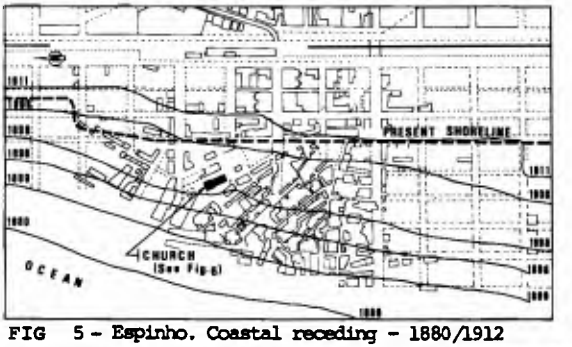

FIG 5 - Espinho. Coastal receding - 1880/1912

FIG 7 - The Aveiro lagoon inlet

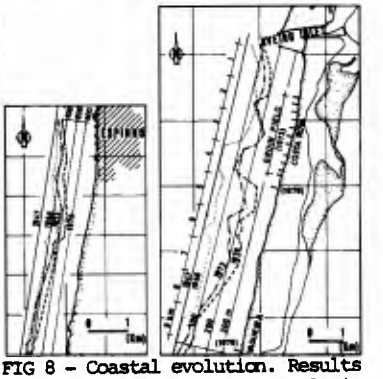

FIG 8 - Coastal evolution. Results from aerial photography analysis

inlet (FIG 1) between 1947 and 1978, as obtained from aerial photo analysis.

Both places present maximum erosion rates of 8 meters per year (temporal mean values) during that period of 30 years; erosion was particularly severe in the periods 1947/58, south of Espinho, and 1958/73, south of Aveiro (following the construction of the jetties), with local rates higher than 10 m/year.

The results of some analysis show the erosion "propagating" to the south with time; during the seventies erosion problems were present along a distance of some 20 km to the south, with mean erosion rates of several meters per year.

2.2 - Specific Cases

2.2.1 - Introduction

Some specific cases have been deserving special attention since a long time, owing to the urban value of littoral areas affected by the coastal receding phenomenon or by some other reasons (e.g. Espinho, Aveiro lagoon inlet). Therefore, data are relatively abundant, specially in what concerns hydrographical surveys, which allowed the quantitative (volumetric) evaluation of the erosion process.

Nevertheless, some difficulties were encountered as a result of data deficiencies. By far, the most important one is related to the lack of information below the zero hydrographical level. In fact, most hydrographical surveys cover the areas above that level only, in practice above low water level. So, the volumetric evaluation of the specific coastal erosion cases concerns only the zone of the beach above datum level.

The evaluation was accomplished according to the following approach:
- beach profiles, with a 200 m spacing, were drawn;
- the corresponding areas (A) above zero datum level were evaluated;
- curves A (s) for each available survey were drawn, s being the abscissa along the beach;
- areas under those curves, representing sand volumes above zero level [$V = \int A(s)ds$] were measured;
- a curve V (t) was drawn, t being the time variable (years).

The evolution of the Aveiro lagoon outer bar was evaluated by comparing the hypsometric curves characterizing the global morphology of the bar in each date.

Some comments on the results obtained in two exemplifying cases (Espinho and Aveiro lagoon bar and adjacent littoral stretches) are added.

2.2.2 - The beach of Espinho

The beach of Espinho was divided into three stretches: A (375 m), to the north of the sea defense scheme; B (1500 m), corresponding to the sea defense scheme, which comprised a sea-wall and several short groins; C (625 m) to the south (downdrift) of that scheme. Figure 9 shows the evolution curves of stretches B and C.

Curve B displays an almost regular erosion rate of 18,500 m^3/km.year above zero datum level. On the contrary, curve C displays two different

evolution periods: before and after middle sixties; the mean erosion rate raised from 19,500 m^3/km.year, in the first period, to 70,000m^3/km.year, in the second; in linear terms, coastal receding in this stretch raised from 2.3m/year to 9.2 m/year between the two periods; it should be noticed that in a period of 13 years (1964-1977) the coast receded 120 m in this stretch.

2.2.3 - Aveiro lagoon inlet area

The construction of the outer jetties of the Aveiro lagoon inlet (1950-58) determined important morphological changes in the surrounding areas: updrift and downdrift beaches and outer bar. Those changes were intensively analysed; we can only summarize here the most relevant results - FIG 10.

Nowadays, the accretion updrift zone is 8 km long. The weakening of the littoral transport and the intense extraction of sand for the construction industry led to the conclusion that the length of the above-mentioned zone may have stabilized.

The available hydrographical surveys cover a length of 3.5km and concern only the area above zero datum level. Therefore, for the evaluation of the accretion rates along the whole zone, some assumptions had to be considered.

Erosion problems in the downdrift (southward) beaches began even during the construction of the outer jetties. By the end of the sixties coastal receding had begun endangering the summer resorts of Barra and Costa Nova. From 1972 to 1973, a groin field (11 groins), protecting a beach length of 2,400 m, was built; of course, the erosion process continued very active to the south. In 1979, two long groins (250 m) were built, one just south of the village of Vagueira, the other as a complement of the previous groin field. Nowadays, erosion problems are felt south of Vagueira, in a coastal length of several kilometers.

The construction of the outer jetties also induced important changes, both on the outer bar and the lagoon channels.

Curves on Figure 10 characterize some of the main effects of the morphological evolution of those three zones: updrift and downdrift beaches and outer bar.

The accretion rate in the updrift zone above datum level displays strong interannual irregularities. Nevertheless , since the end of the sixties it shows a regular decreasing trend, which can be related to the position of the low-water line vis-à-vis the north jetty head. In the first three years the rate was particularly high: 800,000 m^3/year. Such a value led us to think, for the first time, that the mean annual littoral transport could overpass the value of 10^6 m^3, usually accepted for this coastal stretch.

Taking into account the storage under the zero datum level, a mean storage rate of 600,000 m^3/year, for the whole period (1950-1978) was found; if one also considers the sand extracted for the construction industry, it means that a volume of about 20 million m^3 has been subtracted form the natural littoral process, since the beginning of the construction of the jetties (1950). This event fully explains the erosion problems felt in the downdrift beaches.

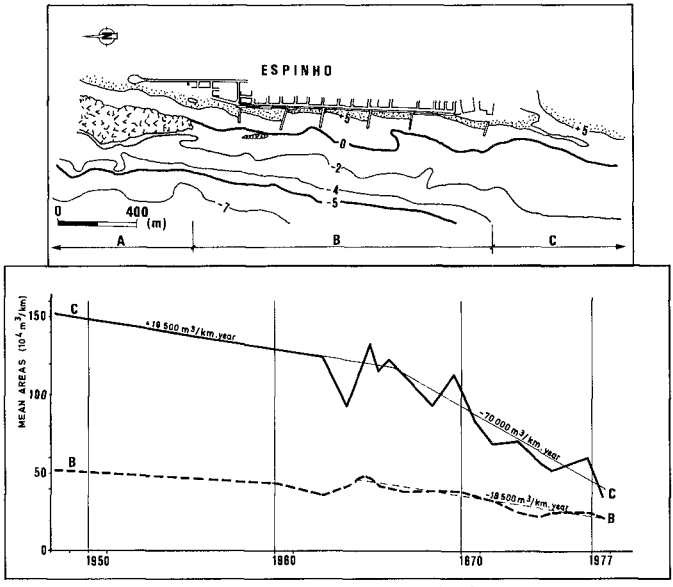

FIG 9 - Espinho beach. Evolution after 1950

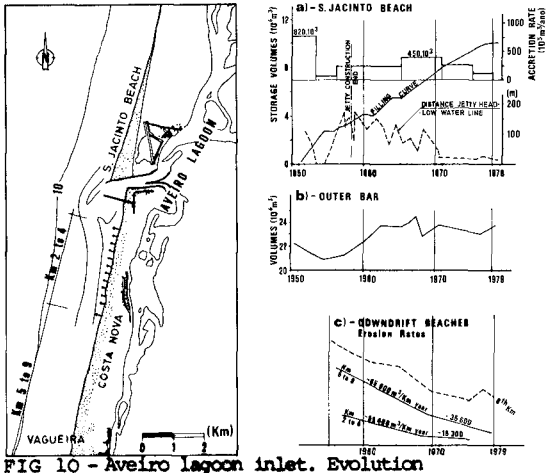

FIG 10 - Aveiro lagoon inlet. Evolution of the surrounding areas after 1950

The volumetric evolution of the outer bar displays a first withering phase (4 years) followed by recovering and stabilizing periods. This situation can be related to the advance of the northern jetty during the construction phase and to the rate of bypassing of this structure. Qualitatively, the stabilization of the outer bar and the decreasing of the accretion rate in the updrift zone can be correlated.

The erosion process in the downdrift beaches was analysed in detail, taking into account stretches 1 km long, afterwards combined into larger stretches with a particular physical meaning (e.g., stretch protected by the groin field, stretch influenced by the outer bar). The volumetric evolution presents irregularities throughout the years, as exemplified on Figure 10 with the 8th km curve. Nevertheless, one can clearly distinguish two periods concerning erosion rates above zero datum level. Curves on Figure 10 pertain to the stretch which is more directly influenced by the outer bar (from kms 2 up to 4), as well as to the downdrift stretch (from kms 5 up to 9). Erosion rates on the former has always been smaller than on the latter. That can be related to the known trap effect exerted by a big outer bar; nevertheless, any of them displays a clear reduction of the erosion rate in the last years. Again, one can correlate this erosion rate reduction, the stabilization of the outer bar and the decreasing of the accretion rate on the updrift zone.

Some other relevant results can be presented as follows:
- in the period from 1954 to 1978 (24 years), the mean coastal receding along the whole stretch (9 km) amounted to 150 m;
- during a period of two years after the construction of the groin field, the adjacent southward stretch (1750 m) receded 50 m;
- during a period of 15 years (1954-1969), the stretch south of the groin field (from kms 5 up to 9) lost 5 million m^3 of sand above the zero datum level.

3 - LITTORAL PROCESS

3.1 - Introduction

Several studies concerning the littoral process of the Portuguese west coast were carried out, namely the evaluation of the strength of alluvial sources, the evaluation of the littoral transport, the mathematical modelling of coastal morphological changes and the determination of the equilibrium beach line orientation.

3.2 - Alluvial sources

The almost exclusive alluvial sources of the coastal stretch between Leixões and Cape Mondego have been the coast north of Leixões and the Douro river. For a coast in a dynamic equilibrium state, the evaluation of the strength of those sources would be equivalent to the evaluation of the littoral transport.

The coast north of Leixões harbour is fed by several rivers. River Minho is the most important one. It constitutes border between Portugal and Spain (FIG 11). Surely the sediments carried by these rivers are transported to the south. Before the last decade of the 19th century, when the breakwaters of Leixões harbor were built, those sediments ente

red the stretch under analysis; since then they have been dredged at the entrance of that harbour.

Taking advantage of the long dredging record available, and discarding the fine fraction of the dredged material (normally absent from the littoral drift), it was possible to conclude that the littoral transport coming from the north coast would have been of the order of 150,000-180,000 m^3/year.

In what concerns the Douro river, two approaches were used. The first one took into account the above result and the areas of the catchment basins geologically suitable for the "production" of sand. A detailed survey of the available geological charts was made in order to identify those areas in the Douro river catchment and in the river basins tributaries of the coastal stretch north of Leixões. In this approach some assumptions were made: over the several basins, the mean rainfall regimen, the forest and agricultural occupation and the mean orographical (sloping) conditions are nearly the same.

Considering these assumptions, the strength of the updrift coast, as an alluvial source, would have been, previous to any human interference, of the order of 15 to 20% of that of the Douro river. Taking into account the littoral transport concerning the coast north of Leixões (150,000-180,000 m^3/year), it was concluded that the Douro river would have produced, in natural conditions, a mean annual volume of beach material of 0.75 to 1.2 million m^3. This means that a total mean annual volume of 0.9 to 1.4 million m^3 entered the stretch under analysis. This result fits quite well the currently accepted mean annual value of the littoral transport in this zone of the Portuguese west coast ($10^6 m^3$).

However, another approach for the evaluation of the Douro river strength as an alluvial source produced a much higher result. Four different theoretical bed load formulas (Dubois, Meyer Peter-Müller, Einstein-Brown and Engelund-Hansen) were used together with three different mean annual hydrological regimens: the natural, previous to the first important dams (before 1930), the present and the future one, when the plan for development of the Douro river basin will be fully implemented.

As usual, the scattering of the results is considerable. For instance, for the natural hydrological regimen the results were as follows:

	($10^6 m^3$/year)
Dubois	1.4
Meyer Peter-Müller	0.7
Einstein-Brown	3.5
Engelund-Hansen	1.8

In any case the Einstein-Brown value was much higher than the others. Besides, it exceeds largely the commonly accepted value for the littoral transport (10^6 m^3/year); therefore, it was discarded. Taking into account the average value of the remaining three formulas, the following results were obtained (10^6 m^3/year):

* natural regimen 1.8
* present situation 1.3
* after the conclusion of the Crestuma dam, under construction near the upstream limit of the Douro estuary 0.25

Considering the above natural regimen results and the littoral drift coming from the updrift coast, one gets a value of the order of 2×10^6 m^3/year. This rises the idea that the potential transport capacity of the wave climate is significantly higher than it is commonly accepted.

The coastal alluvial feeding is directly influenced by the extrac - tion of sand for the building industry; its importance is even higher than initially suspected. It's rather difficult to assess correctly the importance of this activity, owing to the more or less uncontrolled way under which it was exerted during a long period. Direct inquires along the lower reach of the Douro river were made and the scarce records were searched and analysed.

Since 1980, this activity is generally forbidden along the Portuguese coasts, with the exception of a few very specific places. One of these places is the accretion zone updrift of the jetties of the Aveiro lagoon inlet (S. Jacinto beach - FIG 10); in the last years the extraction rate increased considerably in this area, amounting to 400,000 m^3, in 1980.

Nowadays, along the lower 50 km reach of the Douro river, including its estuary, sand and gravel extraction seems to be of the order of 1.5×10^6 m^3/year.

3.3 - Littoral transport

3.3.1 - Sediment budget concept

For the evaluation of the littoral transport two approaches were used: the sediment budget concept in successive cells from north to south and the CERC littoral transport formula, using the available wave climate.

To apply the first approach, the coast between Espinho and Cape Mondego was divided into 5 cells. In this analysis the stretch Leixões--Espinho, with a predominantly rocky nature, and therefore in a sedimentary equilibrium state, was discarded.

A lot of work had to be done in order to evaluate the erosion (or accretion) inside each cell, since 1950. Some specific places have been morphologically surveyed quite regularly but, most of the time, above the zero datum level only. In those places assumptions for the relation between the erosion cross-section areas above and under datum level had to be made.

Nevertheless, for most of the stretch Espinho-Cape Mondego only the successive positions of the beach line, as registered by aerial photography, were known. At this point, an important step of the study was to establish an erosion profile. A mixed type profile was adopted: rectangular above, trianguler under the zero datum level - FIG 12. Site inspection and topographical data allowed the knowledge of the upper level of the erosion profile, i.e., the level of the littoral dunes under erosion (FIG 12, dimension A). On the other hand, taking into account some available hydrographical surveys extending to underwater areas, the lower level of the erosion profile could be established (FIG 12, dimension B). B values varying from 7.5 m up to 9.5 m between Espinho and Cabo Mondego were adopted.

Wind action is surely irrelevant in the littoral process of this particular case. Sand losses to deeper areas, due to transversal movements, were also discarded.

Boundary conditions concerning the littoral drift flowing through the cross-section of Espinho (X m^3/year) had to be established. Taking into account the results concerning the alluvial sources, the following values were assigned to the X variable

Period	X(m^3/year)
1950/59	800,000
1960/64	600,000
1965/69	400,000
1970/74	250,000
1975/78	100,000

Figure 12 presents the final result of this approach concerning two sections: one at the updrift limit of the accretion zone of the Aveiro lagoon inlet; the other at Cape Mondego. This figure warrants the conclusion that the potential littoral transport capacity of the wave climate seems to be of the order of 2×10^6 m^3/year. The littoral drift flowing through the section of Espinho being much smaller, the wave climate "nourishes" itself with the sand deposits (beaches) of the southward stretch; nevertheless, the stretch Espinho-Torreira doesn't seem big enough to saturate the potential transport capacity of the wave climate; in fact, the mean value of the littoral drift flowing through the cross-section of Torreira seems to be of the order of 1.5×10^6 m^3/year. Another interesting result of this approach concerns the natural bypassing of the Aveiro lagoon inlet. It seems that, nowadays, it remains of the order of several hundred thousand m^3/year, despite the storage on the updrift accretion zone, the extraction of sand in that zone and the weakening of the alluvial sources.

3.3.2 - Theoretical evaluation

The CERC littoral transport formula was used. Despite the amount of work developed in this analysis, the results were quite disappointing. In the next paragraphs the studies developed are summarized.

With some well-known assumptions concerning the breaking region, the CERC formula may be written as follows:

$$Q_s = 750\, H_b^{5/2} \sin 2\alpha_b \qquad (1)$$

Q_s being evaluated in m^3/hour and H_b being the root mean square breaking height.

The available wave climate data were recorded in a 6 year period (1954-60) in Figueira da Foz, a summer resort located just south of Cape Mondego. Based on this data, the mean annual deepwater wave conditions can be characterized in terms of frequence distributions of directions, periods and heights. Considering the results of some previous studies based on these data, some difficulties were expected since the beginning.

For the discretization of the wave climate, seven directions (from SSW to NNW), eleven heights (from 0.75 up to 10.5 m) and three periods (8, 11 and 14 s) were considered; that formed a set of 231 "waves" (7 x 11 x 3) characterizing the mean annual wave conditions. A computer program was prepared for the evaluation of the gross and net transport

capacities of these "waves".

Another computer program performed refraction diagrams between deep water and the (-5.00 m) contour line. Shoaling (K_S) and refraction (K_r) coefficients and directions (α) at the (-5.00 m) contour were assigned to each "wave" as input of the littoral transport program. To apply Equation (1) breaking values (H_b, α_b) area needed; however, only some particular "waves" will break at a (-5.00 m) position.

The smaller the wave height, the nearer to the beach it will break and, therefore, the greater the refraction effect. This means that the period (T) and the deep water wave direction (α_0) are not sufficient to define α_b, K_S and K_r at the breakers, the problem being of an implicit type: α_b and H_b depend on the refraction effects but, on the other hand, these effects also depend on the wave height.

To solve this problem, the following approach was used:

- Snell's law was considered valid between the (-5.00 m) contour line and the breaker line

$$\frac{\sin\alpha_b}{C_b} = \frac{\sin\alpha_5}{C_5} \quad (2); \qquad Kr_{5-b} = \sqrt{\frac{\cos\alpha_5}{\cos\alpha_b}} \quad (3)$$

- Phase velocity follows the solitary wave theory

$$C = \sqrt{g(d + H)} \quad (4)$$

- Breaking criterium: $H_b = d_b$ (5)

- Wave shoaling: as given by the linear wave theory for shallow water

$$Ks \simeq 0.5 \cdot \frac{\sqrt{T}}{\sqrt[4]{d}} \quad (6)$$

Applying Eq. (6) at the (-5.00 m) position and on the breakerline, the shoaling effect between them will be

$$Ks_{5-b} = \sqrt[4]{\frac{d_5}{H_b}} \quad (7)$$

Combining Equations (2), (3), (4), (5) and (7) we get

$$\alpha_b = \arcsin\left(\sqrt{\frac{2H_b}{d_5 + H_5}} \cdot \sin\alpha_5\right) \quad (8)$$

$$H_b = \sqrt{\frac{\cos\alpha_5}{\cos\alpha_b}} \cdot \sqrt[4]{\frac{d_5}{H_b}} \cdot H_5 \quad (9)$$

In these equations d_5 equals 5 m plus the tidal level. Equations (8) and (9) are solved iteratively. For the starting step, to obtain a first approximation of α_b and H_b, H_b takes the value of H_5.

Example: with a 2 m tidal level, d_5 = 7 m; let us consider three waves with $\alpha_5 = 10^o$ and H_5 = 5 m; 3 m; 1 m; according to this approach, breaking heights and directions would be

H_5 (m)	5	3	1
H_b (m)	5.36	3.56	1.49
α_b	9.4^o	8.4^o	6^o

The first results obtained with the littoral transport computer program were absolutely unacceptable. In fact, a northward net littoral drift of 1.1×10^6 m^3 was obtained, and it's known for sure that the net littoral drift is southward directed.

Such a result seems to mean that the available wave climate is southward biased, i.e., the true wave climate must be richer in waves coming from the north-west quadrant. Therefore, several tryings were made aiming to "construct" a more likely wave climate; this was accomplished by transferring occurence percentage values, for instance, from W to NNW.

Two measures of its likeliness were available:

- the wave climate has to produce a southward net littoral drift;
- the same wave climate, acting over a coastline making an angle of some degrees with the true coastline, would produce a zero net littoral drift (according to the studies presented in item 3.5, in the area of Aveiro this equilibrium angle would be of the order of 4^o to 6^o).

Eight wave climates were "constructed" this way; Figure 13 presents two wave roses, one concerning the original wave climate (Cl_0) and the other one related to the northmost biased wave climate (Cl_8). Four coastline directions were considered: the true coastline and three others making angles of 2^o, 4^o and 6^o with the real one (in these tryings the beach was "rotated" above the (-5.00 m) level, only). For each wave climate and for each coastline direction, the gross and the net littoral drift were evaluated.

Despite the amount of work developed, the results were inconclusive. For instance, for an intermediate wave climate, labeled Cl_4, one got (values in $10^6 m^3$/year):

	True coastline	Beach angle with the true coastline direction		
		2^o	4^o	6^o
Gross littoral drift	13.1	12.0	11.6	11.6
Net littoral drift	-4.4	-0.6	+3.2	+7.1

(minus signal means "southward directed").

We recall that the true wave climate would produce a zero net littoral drift for an angle of 4 to 6 degrees. According to the above results the Cl_4 vanishing angle would be 2.3^o only; nevertheless, the same Cl_4, acting over the true coastline, produced an unacceptable high value for the net littoral drift.

We notice that the "rotation" of the coastline produces a minor effect over the gross littoral drift; on the other hand, the net littoral drift displays a great sensitiveness to that "rotation".

It seems unquestionable that these difficulties result mainly of inaccuracies of the available wave climate data. But one also has to

keep in mind that "even with exact wave data, it is believed that the longshore transport can only be predicted within approximately -67% to +200%" (Dean, 1978).

3.4 - Mathematical modelling of morphological changes

A mathematical model was prepared with two main objectives: the study of the coastal evolution in the stretch south of Espinho and the foreseeing of the expected changes of S. Jacinto beach, as a result of another extension of the length of the north jetty of the Aveiro lagoon inlet; if the model had proved well, it would have been used in the planning of the sea defense scheme. However, the results were not satisfactory, mainly on account of inaccuracies of the wave data.

Basically, the mathematical model uses the approach of Willis and Price (1975). Two complementary devices were added: one takes into account the influence of the morphological changes on wave refraction effects; the other aims to simulate the bypassing process around a littoral sediment barrier.

One knows that a short term accretion or erosion will only affect the beach profile above a relatively high level in a shallow water region. Therefore, wave refraction effects will change only in a relatively narrow strip, adjacent to the shoreline; thus, it is not worthwhile to elaborate again all the refraction diagrams, specially when dealing with a more or less straight shoreline, in order to account for those changing effects.

The objective of the proposed approach is the evaluation of the breaking angle α_b at the modified shoreline. For that purpose, an equation of the following type is currently used

$$\alpha = \alpha_o - \arctan \frac{\partial y}{\partial x} \qquad (10)$$

α_o being the angle relative to the initial undisturbed shoreline.

The starting data for the proposed approach are the breaking wave height and the angle (H_b, α_b); they are available as output of the computer program described in item 3.3.2. In the region affected by the morphological changes the validity of equations (2), (4) and (5) is again assumed.

Knowing the breaking values of H and α, one goes back to an undisturbed depth, that is, a depth not affected by the short term morphological changes (for instance, d = 8 m under the reference level). Combining equations (2), (4) and (5) it is found

$$\alpha_{d.o} = \arcsin \left(\sqrt{\frac{d + H_b}{2H_b}} \cdot \sin\alpha_{b.o} \right) \qquad (11)$$

$\alpha_{b.o}$ being the breaking angle relative to the initial shoreline, and $\alpha_{d.o}$ the corresponding value at an undisturbed depth (d). In this approach the wave height variation was neglected.

"Rotating" the shoreline

$$\alpha_d = \alpha_{d.o} - \arctan \frac{\partial y}{\partial x} \qquad (12)$$

being α_d the wave angle relative to the "rotated" shoreline, at an undis-

turbed depth (d).

Reversing equation (11), the angle at breaking position can be found

$$\alpha_b = \text{arc sin} \left(\sqrt{\frac{2H_b}{d+H_b}} \cdot \sin \alpha_d \right) \qquad (13)$$

Summarizing, in the proposed approach equation (10) is replaced by equations (11), (12) and (13). Let us consider a breaking wave 2 m high, with $\alpha_{b.o} = 5^o$; if the shoreline rotates 2^o, as a consequence of an accretion process, equation (10) will give $\alpha_b = 3^o$ while the sequence of equations (11), (12) and (13) will give $\alpha_b = 3.67^o$ (considering d = 7 m as the undisturbed depth).

To simulate the bypassing process another device was used: it relates the bypassing rate with the position of the surf zone vis-à-vis the head of the littoral barrier - FIG 14.

For the distribution of the littoral transport capacity across the surf zone, a triangular type law was assumed, with its maximum value at the breaker line. Equation (5) was again adopted as the "breaking criterium". The width of the surf zone (B) for the used assumptions depends on the breaker depth (d_b) and on the bottom slope. Therefore, a bottom profile had to be assigned to the breaker region in each specific case; in the case of the Portuguese west coast one of the mixed type was adopted-FIG14.

When the wave breaks landward of the littoral barrier head, bypassing doesn't occur ($Q_{bp} = 0$); if it breaks seaward, the bypassing rate will be a fraction of the littoral drift arriving at the barrier (Q), that fraction corresponding to the part of the triangular transport diagram which is not intercepted by the littoral barrier. That is (FIG 14)

$$Q_{bp} = \left[1 - \left(\frac{X}{B}\right)^2\right] . Q \qquad (14)$$

X being the distance from the waterline to the head of the littoral barrier.

Some difficulties were encountered in defining a Q with a physical meaning (the littoral drift arriving at the barrier). For instance, if Q is related to the orientation of the shoreline in the adjacent stretch, and if this stretch is a fixed number of integration steps Δ s long, then the bypassing rate depends on the integration step Δs. Finally, Q was related to the orientation of an adjacent stretch with a fixed length exceeding the surf zone width of the highest waves (for instance, 400m).

Difficulties of another type were risen when the accretion-erosion effects reached the limits of the mathematical model stretch; boundary conditions such as Y = const or Q_s = const were no longer valid. Besides, in the present case accretion caused by an artificial barrier occurs over a shoreline under a general erosion process. It seems that, in such a case, the best approach would be, like in other fields, to obtain the boundary conditions as output of another far-field model, covering a much longer coastal stretch.

To test this model the accretion process of S. Jacinto beach (2.2.3) was simulated between 1950 and 1978. The results were not satisfactory.

One should be reminded of the presumed inaccuracies of the mean annual wave climate used in the whole study. However, the accretion process

Sea defense plan.
Some typical structures

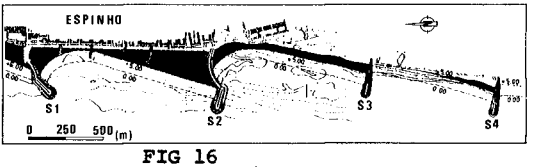

FIG 16
Beaches of Espinho.
Proposed protection plan

to be tested has been the result of wave conditions changing year after year. In fact, the true wave conditions that determined the accretion process of S. Jacinto beach are unknown. Besides, the accretion process reached the updrift model boundary much faster than in the prototype. These may be some of the reasons of the above-mentioned difficulties.

3.5 - Equilibrium beachline orientations

It will be seen further on that the sea defense master plan was designed for a zero net littoral drift condition. Therefore, the assumed beaches that will be formed between coastal protection works, will present shapes and positions corresponding to an equilibrium state. When foreseeing those beach forms, the evaluation of the equilibrium orientation of some existing beaches was very helpful. Such an approach assumes the existence of a dominant deep water wave direction characterizing the whole stretch. If that existed, one could determine the equilibrium orientation of any beach along the stretch.

Three beaches were selected for this study (FIG 1): Leça, just north of the breakwaters of Leixões, Espinho and S. Jacinto.

The first one can be considered almost in a equilibrium state, due to the relatively weak littoral drift arriving from the north. Taking into account two available hydrographic surveys, one determined a mean value $\theta_b \simeq 13.5^o$, θ_b being the beach angle with the north-south direction.

The beach of Espinho has not surely been in a equilibrium state. Surveys made at 14 different times were carefully analysed. Two particular stretches of the beach were considered, each one on the updrift side of old groins. Based on this analysis a value $\theta_b = 17.5^o$ was adopted.

Nowadays, the S. Jacinto beach is 8 km long and it is not in an equilibrium state for sure. For the evaluation of the equilibrium angle, only the 500 m long stretch, adjacent to the north jetty of the Aveiro lagoon inlet, was considered. Hydrographic surveys were analysed at 37 different times. A value $\theta_b \simeq 22^o$ was adopted.

Considering the results of the refraction diagrams, the following dominant deepwater wave directions θ_o were obtained (when wave periods of 10 to 12 s are considered):

Angles with N - S direction

	b	o
Leça	13.5^o	$37^o - 45^o$
Espinho	17.5^o	$38^o - 50^o$
S. Jacinto	22.0^o	$43^o - 50^o$

The results agree fairly well with one another, despite the fact that the stretch Leça-S.Jacinto is 60 km long. Therefore, a deepwater dominant direction $\theta = 50^o$, with a wave period T = 12 s, was adopted for the whole stretch. The corresponding θ_b equilibrium values along the stretch, necessary for the sea defense planning, were determined using the results of the refraction diagrams.

4 - SEA DEFENSE PLAN

The plan includes more than 60 structures, almost exclusively of the groin type.

In the northern zone, between Leixões and Espinho, the spacing and the length of the coastal structures are quite variable. This results from the occurence of many granitic outcrops that ought to be used to anchor the groins. In this northern zone the coastal structures will have an almost unique objective which consists of improving the existing beaches. In fact, the defense of the coast is insured by its rocky nature.

A sandy coast extends to the south of Espinho with long reaches of dunes, sometimes bordering pine forests, other times facing little towns and villages. Wherever the littoral areas have a low patrimonial value, the spacing between coastal structures is relatively large (2 km and even more). This means that some additional erosion, in some specific points of the coast, will have to be accepted; on the other hand, the number of coastal structures, always very expensive, becomes quite reduced. Figure 15 displays the proposed solution for a stretch of beach located between Aveiro and Mira. In such a case the plan took advantage of the spiral beach concept, studied by Silvester (1972) and others.

Wherever the coastal receding had to be stopped, on account of the high patrimonial value of the littoral areas, the plan used the groin field concept, in which the accretion zone of a groin reaches the updrift one. The results of experimental studies carried out at LNEC (Civil Engineering National Laboratory, Lisbon) were used. According to Barcelo' (1969) the ratio D/C varies with α as follows

α	D/C
20^{o}	2.5
15^{o}	3.5
5^{o}	4.0

D being the groin spacing, C its lenght and α the angle between the crest of the dominant wave and the shoreline.

In order to reduce the number of coastal structures a large spacing (D) was adopted; current values for D and C have been D = 875 m, C=250m.

Figure 16 presents four structures protecting a coastal length of 3 km. They have been the first sea defenses of the whole plan to be built; presently (summer, 1982) its construction is about to be concluded. The objectives of the structures labeled S1 and S2 are twofold: to defend the town of Espinho and to restore its old importance as a summer resort. This explains the length of the groins S1 and S2. They were planned to trap a "spiral beach" 1,200 m long. During the last year more than half a million m^3 of sand was naturally accumulated between S1 and S2.

5 - CONCLUSIONS

Coastal erosion became a major problem of almost every coast. The main reason for such a situation is the weakening of the alluvial sources, due to the improvement of the river basins. Human activity along the coasts often aggravates the situation by diverting the natural path of the littoral sediments. Therefore, in many instances, it seems advi-

sable to consider the long term vanishing of the littoral transport when planning a sea defense scheme.

Mathematical modelling of littoral evolution requires two main work bases: accurate wave data and a dependable littoral transport formula. If wave conditions are very variable in what concerns either heights, directions or periods, the difficulties faced when defining accurately a wave climate may be higher than those of elaborating a mathematical model. In such a case, a mathematical model seems to be a too sophisticated tool, leading to disappointing results. That has been the case on the studies undertaken concerning the littoral problems of the Portuguese west coast.

DURBAN BEACHES RECLAMATION : PRACTICAL ASPECTS

K.A. Barnett, B.Sc (Eng.) *

1 INTRODUCTION

Much controversy has revolved around the stability of Durban's beaches over the years and in its concern for this valuable tourist asset, the Durban City Council commissioned several studies culminating in a commission in 1961, jointly with the South African Transport Services, with the Council for Scientific and Industrial Research in which they were required to investigate the possibilities of maintaining the harbour entrance channel at certain depths and to find some means to stabilise and improve the Durban beaches.

1.1 Early History

In the period 1851-1903 harbour entrance channel works initiated disturbance to the beach equilibruim, causing the beaches to progress generally seawards. It was thought that this was the result of greater protection against swells from the south.

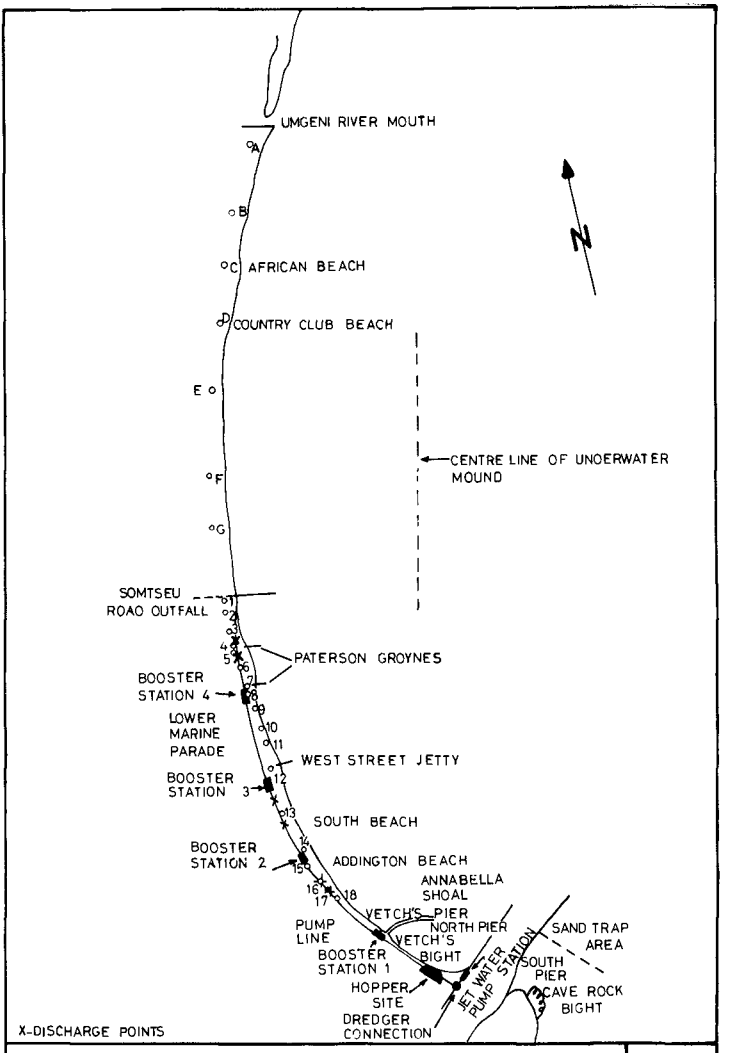
However, increase in the harbour channel depth over the period 1903--1926 caused beach losses north of Vetch's Bight, whilst in that Bight itself further deposition took place. (See Fig. 1). From 1905 onwards sand has been dredged from a sand trap to the south of the harbour entrance (Cave Rock Bight) and since 1925 the dredging rate has been relatively constant at about 600 000 m^3 per annum. Subsequent to 1926 more deposition occurred in Vetch's Bight but the general beaches continued to erode and in 1935 the Council commissioned the first sand pumping scheme with a view to nourishing the South and Central Beaches.

Sand was delivered by the South African Transport Services (S.A.T.S.) dredgers from the mooring at the North Pier to the Vetch's Pier area from where it was re-dredged by the Council scheme and pumped northwards as far as the present day South Beach.

1.2 Post-War Period

Erosion of the northern beaches continued and in the period 1950-1953 sand was pumped directly to Vetch's Bight from an area to the south of the South Pier by means of a submarine pipeline across the harbour entrance. Owing to insufficient sand collection within reach of the dredging plant, the original system with the S.A.T.S. dredgers pumping sand from the North Pier was resumed.

* Principal Engineer, City Engineer's Department, Durban, Republic of South Africa.



BEACH RENOURISHMENT IN THE SOUTHERN AREA — FIG 1

The two Paterson Groynes were built between 1954-1956 in the hopes of stabilising the Central Beaches but this was not realised.

Over ths yeare most of the material dredged by the S.A.T.S. has been dumped in a specific area at sea, called the "Dump" and it has besn found that this tends to focus wave energy, under certain conditions, near the Paterson Groynes.

1.3 Recent Developments

As was stated previously, the C.S.I.R. was commiesioned in 1961 to investigate, in depth, Durban's beach problems and several recommendations were made after extensive field and model studies. However, a further C.S.I.R. report was submitted to the Council in 1964 recommending that an underwater, offshore mound be constructed using S.A.T.S. dredgings. It was considered that the mound would offer good protection to the beaches by reducing incoming wave energy and it was thought that the beaches would improvs as a result of the presence of the mound. The mound was constructed between 1966 and 1974 but could not be raised to its full design height mainly because of the draught requirements of the dredgers.

However, further studies showed that the mound was not as effective as first thought and the littoral drift continued. The area to the eouth of Somtseu Road was subject to long term erosion at the rate of 70 000 m^3 per annum and the area to the north of Somtseu Road was in a long term state of equilibruim.

After correlation of the voluminous previous reports and findings, and of the considerable field data which had been collected as part of the monitoring programme, the C.S.I.R. submitted in 1977 a report outlining firm recommendations for a beach restoration scheme. Basically these were as follows:-

(i) The mound should not be completed to its design dimensions.

(ii) Establish a controlled zone covering the area 40 m landward of the 1977 highwater line throughout the Bight area; permit no building within this zone; and provide a stockpile of suitable renourishment material for use during storm conditions to protect critical areas.

(iii) Provide an initial beachfill to the area south of the Paterson groynes to restore these beaches to a more acceptable width.

(iv) 90 000m^3 of Cave Rock Bight material should be dumped annually on the beaches south of Somtseu Road, i.e. 60 000 $m^3/yr.$ on Addington and South Beach and 30 000 $m^3/yr.$ on North Beach.

(v) The Paterson groynes should be replaced by two low level structures. Subsequently, it can be decided whether further such structures should be constructed.

1.4 Action Taken by Council

The Council accepted (i) above and immediately put into effect (ii). It was decided in princple that (iv) should be handled by a conventional by-pass sand pumping scheme utilising the S.A.T.S. dredgers, as in the past. The technical feasibility of the construction of low level groynes is being investigated by a private firm commissioned by the Council.

Some 600 000 m^3 of beachfill was supplied by contract dredger to the Addington and South Beach areas during August and September 1982. This contract was negotiated with an overseas consortium working in Richards Bay at the time and the cost to the Council was about R2,3 m. This involved a trailer cutter suction dredger dredging material from an area seawards of the sand trap and pumping it ashore along a temporary pipeline from the S.A.T.S. dredger connection. Work was on a round-the-clock basis and usual output was about 20 000 m^3/day.

1.5 Programme for the Sand Pumping Scheme

The general conceptual design of the Durban beaches sand pumping scheme was finalised early in 1980 and immediately thereafter the detailed design work started. Tenders for the supply and installation of the mechanical/electrial equipment were invited in early 1981 and in April 1981 this contract was awarded on a "design and construct" basis, the City Engineer's Department having set out the technical concept of the scheme, the required output, concentrations, etc.

Shortly thereafter the civil and architectural contracts were put in hand and the commissioning of Stage I took place during August/September 1982. Commissioning of Stage II will take place in mid 1983.

2 Description of Scheme

2.1 Overall Concept and Modus Operandi

The focal point of the scheme is the hopper/administration site which lies near the North Pier. In this site are the tastefully designed administrative building which also houses the first booster station and the semi-circular reinforced concrete hopper which will receive and temporarily store sand from the S.A.T.S. dredgers. As stated previously the S.A.T.S. dredgers carry out maintenance dredging in the sand trap immediately to the south of the South Pier, generally dumping this material out to sea in a depth greater than 60 m. Alternatively, the vessel may tie up at the dredger connection at the North Pier and pump the sand through the "short line" to discharge into the Council's hopper.

Against the historical backdrop of the problem an agreement has been concluded with the S.A.T.S. in which they have undertaken to furnish 50 000 m^3 of sand per annum, free of charge. Any sand pumped in excess of this will be charged for at a rate of about R2,00/m^3.

Initial Beach Fill : Southern Beaches - Before

Initial Beach Fill : Southern Beaches - After

General View of Hopper/Administration Site.

Jet Water Station in Harbour Entrance.

The sand will then be re-dredged from the hopper by means of equipment housed on a mobile bridge by the injection of water pumped from the nearby jet water station, and delivered to the first booster station. From there the sand/water mixture will be boosted to four further stations with the final discharge point being near the Somtseu Road stormwater outfall. Sand can be discharged onto the beaches at a number of intermediate sites. The C.S.I.R. recommended that a minimum of 70 000-100 000 m^3 of sand is required on the beaches south of Somtseu Road annually to maintain the status quo and the scheme is designed to provide this quantity plus an anticipated 100 000 m^3 per annum to build up the beaches.

Booster stations are about 700 m apart to ensure unformity of equipment and the pumping main is a H.D.P.E. (high density polyethylene) pipe of 400 mm O.D., Class 6,3. The system has been designed to deliver a maximum concentration of 30% by volume. Total length of the pumping main is some 3,5 km and it should be noted that the entire scheme is automated and will be controlled from the hopper site. The power and signal cables run along the beach on the same route as the pumping main. The S.A.T.S. dredgers will deliver about 2000 m^3 of sand into the hopper at a time (total capacity 4 000 m^3), and this material will then be pumped onto the beaches (where required) at some 300 m^3 per hour in an 8 hour shift.

Total cost of the scheme, including the first two low level groynes and the initial fill is expected to be in the region of R10 000 000.

2.2 Mechanical and Electrical Equipment

2.2.1 Electrical supply and criteria

The supply in the area from the electrical grid is 11 kV and considering the stringent specification in relation to noise levels in residential areas it was decided to lay down that all motors were electric. The 11 kV supply is stepped down at the hopper site to 6,6 kV for the main booster station motor and to 400 V for the jet water pump motor, the dredge pump and other ancilliary equipment, for example drainage pumps, ventilation fan motors, etc. The remaining booster stations are all fed by landline from the hopper site (6,6 kV) with the respective ancilliaries at each station being catered for by separate 400 V feed.

Control of the scheme is by electrical signal transmitted by means of a "hard wire" system.

2.2.2 Mechanical data

2.2.2.1 Jet water station

The jet water pump is a vertical industrial turbine pump, the motor being rated at 150 kW and capable of delivering 1 800 m^3 of sea water per hour at a head of 18 m at 985 r.p.m. This is a mixed flow pump (nominal size 450 mm) and the impeller is manufactured from a special cast iron alloy known as Ni-resist. Other elements of the

View of Bridge Showing Control Cabin and Underslung Dredge Pump.

Jetting and Dredging Nozzles.

pump are also selected to resist corrosion, e.g. the column is Ni-resist, shaft stainless steel.

This pump station, as with all the other stations of the scheme, is force ventilated to dissipate heat generated.

2.2.2.2 Dredge pump unit

The dredge pump is underslung on the mobile bridge to ensure proper operation and is a centrifugal type slurry pump driven by a motor developing 185 kW, delivering 1 750 m^3 of sand/water mixture per hour at a head of 10-11 m at 390 r.p.m. The pump is belt driven and is identical to the main booster pumps.

2.2.2.3 Booster pump stations

The booster units (total of five) all consist of a centrifugal type slurry pump coupled to a motor rated at 450 kW, also delivering 1 750 m^3 of sand/water mixture per hour at a head of 30-35 m at 585 r.p.m. Here the motors drive the pumps through poly-vee drive belts. Nominal size of the pumps is 350 mm and materials of interest are:-

Impeller and casing - "MYTAK 1001"
Shaft - EN 8

Figure 2 shows a typical internal plan of a booster station.

3 DESIGN ASPECTS

3.1 Hydraulic Design

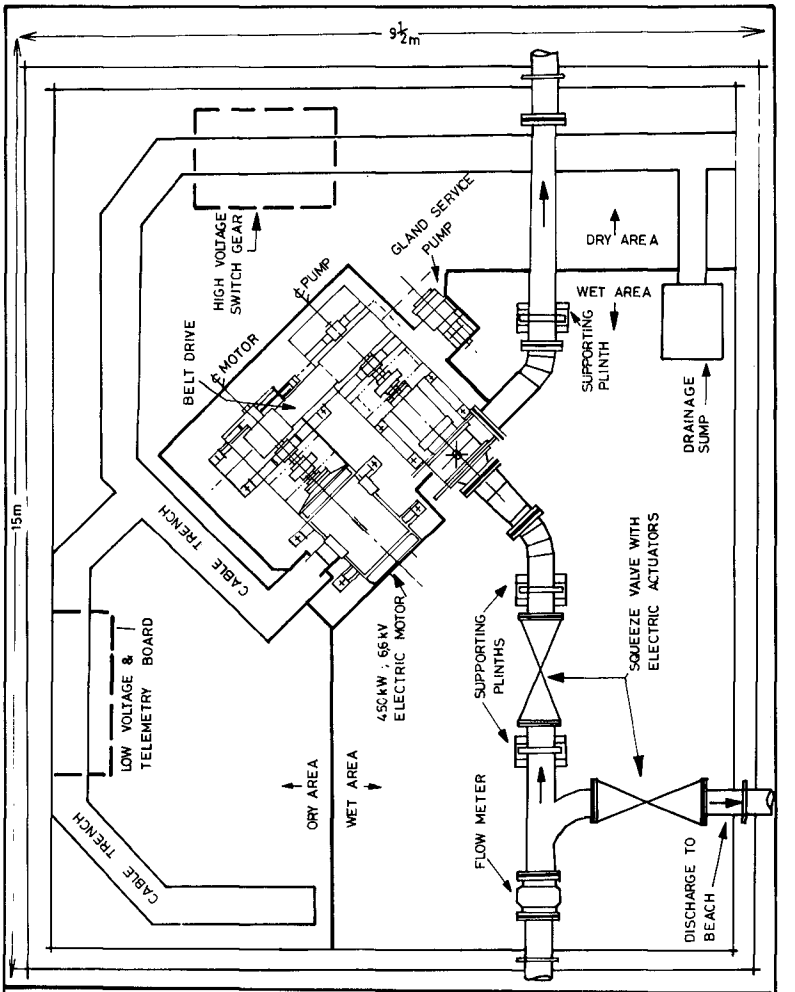
The design of the scheme is based on the calculation of critical velocity using the formula derived by Durand and the various parameters involved are dependent on the sand particle size and grading, the concentration to be pumped, the specific gravities of the solids and transporting fluids and the pipe diameter. The formula takes the following form:-

$$Vc = Fl\sqrt{2gD\,\frac{(S-Sl)}{(Sl)}}$$

where Vc = critical pipeline velocity.
Fl = factor dependent on particle size and concentration.
g = acceleration due to gravity.
D = pipe diameter.
S = S.G. of solids.
Sl = S.G. of transporting fluid.

The power requirement was then derived taking into consideration the various losses and safety margins.

In calling for tenders for the supply and installation of the mechanical and electrical plant, the City Engineer's Department specified broadly the criteria to be met by the scheme, amongst



TYPICAL INTERNAL PLAN OF A BOOSTER STATION

FIG 2

View of Panel in Control Cabin.

Typical Booster Motor and Pump Set.

others that it should be capable of pumping concentrations of slurry from 0% to 30% of sand of volume. It was therefore the successful tenderer's responsibility to ensure that these criteria were met and that the scheme operated as designed.

3.2 Selection of Pipe Material

At the outset it was decided that the pipeline should be made of a material which had the following properties:-

(i) Extremely resistant to abrasion.
(ii) Robust.
(iii) Easy to handle.
(iv) Good cost/benefit.
(v) Resistant to corrosion.
(vi) Easily jointed.
(vii) Locally manufactured (availability).
(viii) Flexibility.

After an extensive literature survey and a study of a system already in operation at Richards Bay the choice of high density polyethylene was made. H.D.P.E. pipe scored high in all the above properties and although more expensive than, say, plain steel, was not by any means the most expensive material available and by all accounts appeared to have at least equivalent resistance to internal abrasion.

The valves on the line are all the squeeze type with butyl-type rubber sleeves with helicoil wire reinforcing and have remotely controlled, electrically driven actuators.

The pipe was generally heat welded into 39 m lengths which were then joined by means of stub ends and galvanised steel backing flanges. Stainless steel studs (grade 316) are used throughout for bolting the line together. The long term resistnce to corrosion of this jointing system in the beach environment will be closely monitored.

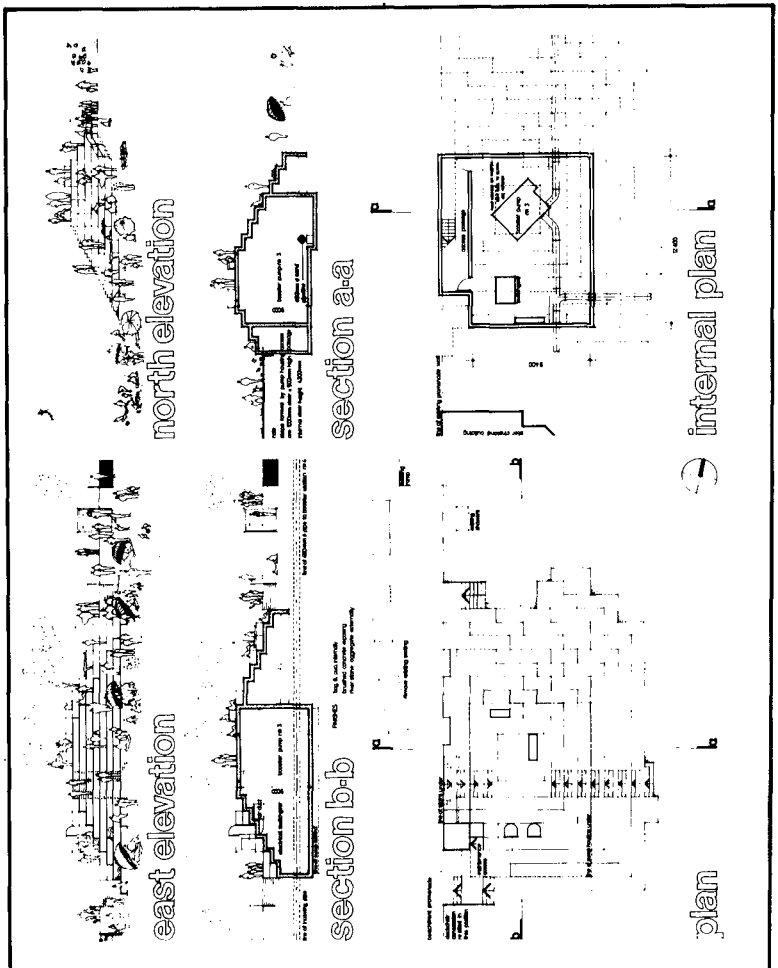
3.3 Architectural Treatment

Each of the buildings relevant to the scheme were handled separately and were designed to blend in with their individual surroundings. All were designed by the Architectural Branch of the City Engineer's Department except the hopper site building which was conceptually designed by the in-house architects, but owing to volume of work, a firm of private architects was commissioned to bring the project to completion.

Great care had to be taken with these structures to ensure that they would complement the Durban Beachfront Development Plan which is in the process of finalisation. The photographs of booster stations 1 and 2 and the figures 3 and 4 of booster stations 3 and 4 show the designs. Of particular importance was the choice of external finishes which had to combine ruggedness with an aesthetically pleasing product. Of interest is the architectural treatment of the outer wall of the hopper which sports abstract scenes painted with a highly resistant epoxy compound.

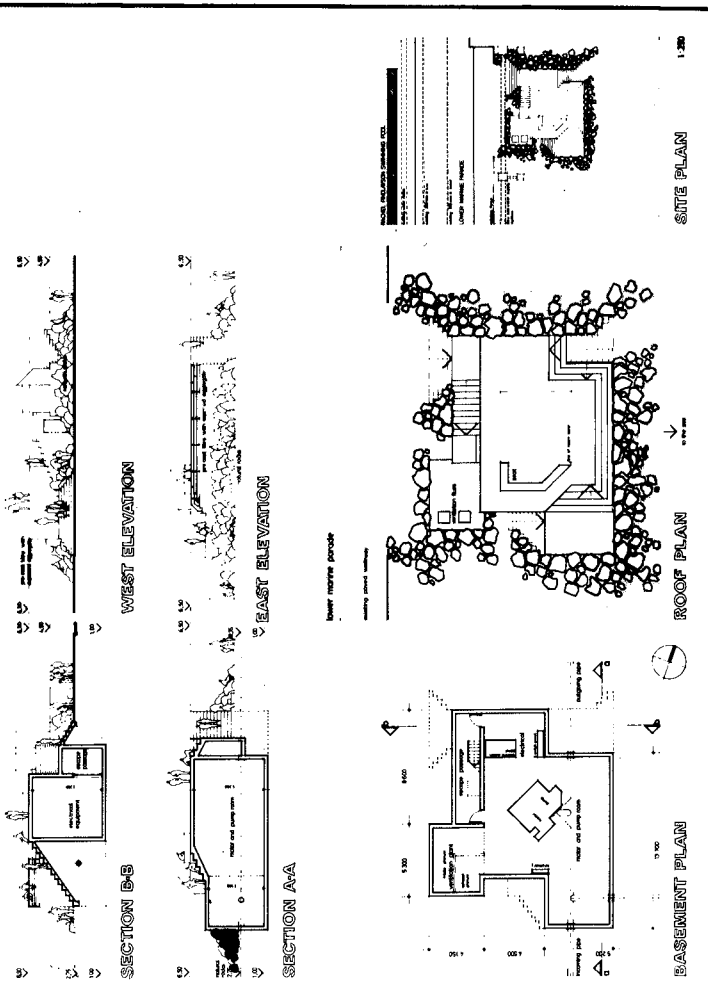
View of Booster Station No. 1

View of Booster Station No. 2



SKETCH PLAN OF BOOSTER STATION NO. 3

FIG 3



SKETCH PLAN OF BOOSTER STATION NO. 4

FIG 4

Special attention was paid to sound attenuation techniques as most of the etructures are in a seneitive locality being a combination of residential, hospital and recreational areas. It was also decided to make an attempt to reduce the transmission of vibration from the motor sets to the outer walls and roofs of the booster stations by providing completely separate foundations for the motor sets. Each motor pump base slab is on a separate pile group and the slab itself ie ieolated from the reet of the station floor slab. Noise levels were limited to 60 dB at 2 m from the structures.

To help reduce the noise levels outside the stations, walls and roofs are of reinforced concrete, solid wooden double doors are used and the ventilation inlets and outlets all pase through special muffler boxes to attenuate sound.

3.4 Civil Engineering Structures and Related Activities

The civil side of the booster stations and the hopper site building was handled by the Materials and Structures Division of the Roads Branch of the Depratment and included all reinforced concrete design as well as the requisite piling designs. The pile system of each building was designed to withstand a certain depth of scour resulting from abnormal sea attack, even though this is unlikely to occur.

The reinforced concrete sand storage hopper and the jet water station were implemented by "design and construct" contracts and had to match in with the architectural and/or mechanical/electrical requirements. The laying of the HDPE pipe and cables was handled Departmentally.

3.4.1 Sand storage hopper

This structure has a rectangular cross-section and is roughly a semi-circular annulus eubtending 152o at its centre. Centre line length of the hopper ie 109 m, depth ie 5,5 m, width 13 m and inside radius 34,15 m. The hopper can accommodate two loads from the SATS dredgers representing some 4 000 m^3 of material. Invert level of the hopper is at - 2,1 m msl and to resist buoyancy a system of tension piles was employed. In drastic instances of scour these piles can also easily double as normal compression piles to support the hopper. Static water level in the hopper is +2,4 m msl.

The hopper is simply filled by one inlet pipe at the one end, this being the discharge directly from the dredger. At full capacity the sand lies at a gradient of about 1/20 along the length of the hopper. The overflow is at the other end of the hopper and this is contained in a channel which routes the water directly back into the sea. Adequate scour protection is provided at the seaward end of the overflow channel.

Along the inner curve of the hopper is a water proof trough of 3,7m depth to accommodate the dredge pump which is mounted slung under the bridge. The top of the inner hopper wall is finished with an epoxy aggregate grout to a close tolerance to allow the bridge

wheels of bonded rubber to run smoothly and to give good operational life.

3.4.2 Jet water station

The conceptual design of this station was to give the effect of a submarine conning tower. The superstructure itself presented no problems but the founding on the North Pier was difficult as the pier was constructed some considerable tims ago and basically consists of a rubble core and loose stone pitched side slopes.

Finally, a portion of the side slope was fully grouted (under water) and the vertical column to house the pump was pre-casted and grouted into position. The superstructure was then cast on top of the column and fixed to the pier by means of grouted bars.

3.4.3 Pipe laying

To tie in with Phase I of the scheme, the jet water line from the jet water station to the hopper site (H.D.P.E., 450 mm, Class 4) and the pumping line (H.D.P.E., 400 mm, Class 6,3) from the hopper site to the West Street Jetty area was laid. Because of the high number of Contractors and sub-contractors already on site it was decided to lay the pipeline using Departmental labour. The gangs and equipment were more amenable to a "stop-start" work situation which resulted from tie-in to booster stations, beach area availability, etc.

By and large the pipe was laid in the highest part of the beach prism with approximately 600 mm to 800 mm of cover. The jointing system has been described under section 3.2. The supply Contractor welded the pipes into the 39 m lengths on site and these were then taken over in batches by the Department, and transported along the beach to the required laying area.

The laying operation was generally easy. It had been decided to lay the 6,6 kV main feed cable and the signal cable at the same time as the pumping main and in the same trench. After the trench was excavated (some 2 m bottom width) the services were merely laid at the requisite centres and the backfilling operation followed immdiately to ensure as little open trench as possible remained overnight on the beach. A laying rate of up to 100 m/day was commonly achieved. Finally the laid pipe was hydraulically tested to 1,5 times working pressure.

3.5 Control Systsm

The entire scheme is controlled by one man from the control cabin and is started merely by initiating one signal. Each booster station is started on flow, i.e. as it is recorded that there is flow just on the upstream side of a station, it starts. There is an intsrlocking system within each booster station which allows it to start up in a definite sequence as follows:-

(i) Inlet ventilation fan.
(ii) Extract ventilation fan.

(iii) Gland water pump.
(iv) Main motor.

Pressure starting devices were not used because of instrument sensitivity problems.

If any component breaks down the system shuts down automatically and if an overload should result an audible alarm sounds in the cabin. To stop the system the Superintendant only has to cancel the original signal.

4 MONITORING

4.1 History of Monitoring

Monitoring of the beaches was initiated by the C.S.I.R. in the early sixties and included the usual facets of this operation. The C.S.I.R. continued to organise and control all monitoring up until 1976 when their Coastal Engineering staff in Durban were transferred to Stellenbosch. It was considered logical, therefore, at the time, to hand over all monitoring functions to the City Engineer's Department as it was apparent that the City Council would be taking over control of the whole beach aspect progressively in the ensuing period.

Since 1976 virtually all monitoring functions have been controlled and organised by the Department and the scope of the programme has been widened considerably. A brief description of each aspect follows.

4.2 Visible Beach Survey

This is carried out each month by a firm of private surveyors. A total of 32 sections is surveyed and visible beach volume is calculated and recorded. Each section is defined by a co-ordinated beacon generally fixed at the upper part of the beach, the readings being taken from these beacons down to at least Chart Datum. The 32 sections cover the beaches from Addington to the mouth of ths Umgeni River. A plot of these volumes shows a long term degradation of the visible beaches.

Recently it was decided to establish six more sections north of the Umgeni mouth covering the beaches up to the northern City boundary. These sections are very widely spaced and are only read every 2 months at this stage to keep an overall check on the beaches there.

4.3 Nearshore Hydrographic Survey

Every month, between section 2 and 12 a shallow water survey is done covering from Chart Datum (approximately) to about 5 m of water. The survey team consists of the same private surveyors as above assisted by Departmental technicians and a motorised rubber dingy manned by 2 lifesavers from the Parks, Recreation and Beaches Department.

Soundings are taken by hand line and as all parties concerned are in radio contact, a simultaneous fix can be made. Rssults are plotted on a format, which, at a glance, shows the relative movsment of any particular contour.

Although this is a rather unsophisticated method and has only been done for about 2 years, practice and good teamwork has ensured acceptabls accuracy.

4.4 Offshore Hydrographic Survey

This survey basically covers the area from the surf zone to just seaward of the offshore mound. Originally these surveys were initiated by the construction of the mound and were all dons by the C.S.I.R., at first at frequent intervals but latterly every year only. In early 1981 this function was taken over by the Departmsnt and at pressnt the survey is being carried out quarterly again, partially to consolidate the team and also to satisfy all parties concerned of accuracy and consistency.

The Natal Anti-Shark Msasures Board hire the Dspartmsnt one of their boats and crew for the "water" side and once again the shore team consists of ths surveyors and Departmental Technicians. A sophisticated echo sounder is mounted in the boat and a continuous trace is produced on every run which co-incide with the sections mentioned in 4.2 (excluding those to the north of the Umgeni). Again, all are in radio contact and simultaneous fixes can easily be made. Additional sections are run over the northern end of the mound to assist the C.S.I.R. in their latest refraction studiss.

At this stage it is fslt that accuracy is within 250 mm either way and as this is improved so will the frequency of survey be dscreased, initially down to twice a year and possibly evsntually to once a year. The results are plotted as a contoured bathymstric chart.

4.5 Beach Sand Size Sampling

Sand samples are taken from the inter-tidal zone every month at each of the sections betwsen Addington and the Umgeni mouth. Four samplss are taken at each location, one from the high water mark, one from the low water mark and two from the third points (approximately) in between. These are not mixed together, but are analyssd separatsly, at present by a local soils laboratory, undsr annual contract.

It may be dscidsd in the future to mix the samplss from each section as there appears to be a trend towards this. Furthermore, the process will be speeded up by the use of a vsrtical tubs typs (water filled) rapid sand grader.

4.6 Wave characteristics Recording

For many years the C.S.I.R. had a clinomster set up south of the harbour entrance to measure wave direction, height and period. This instrument was read by a private person who was trained for the work. When the Department took over the monitoring function this system was not interfered with and recently a second clinometer was installed in a tall hotel on the beachfront roughly oppoeite section 3.

The clinometer is a relatively simple instrument produced by the C.S.I.R. and is read 3 times a day. Although not the most accurate of instruments, it does provide a good and reliable insight into and data of wave direction, height and period.

In the middle of 1981, a wave rider bought by the University of Natal, Durban, was installed on the landward side of the mound. The monitoring side of this is handled by the Department whose staff make daily checks on the instruments and change and forward the magnetic and paper tapes to the relevant authorities. Periodically, checks on the wave rider itself are carried out from a boat and of course, every nine months it is uplifted for cleaning, checking, battery change, etc.

4.7 Deep Sea Sand Sampling

This operation will run hand in hand with the tracer sand aspect and samples will be taken on a grid pattern, initially every 3 months. It is thought that a grab-type sampler will be best and that a sea bed surface sample will be sufficient. However this may have to be modified in the light of experience when the schsme is undsr way.

4.8 Wave Refraction Analyses

Since the early sixties, the C.S.I.R. have done numerous wave refraction studies of the Durban Bight. Because of the techniques involved, the past studies were probably relatively "coarse" and recently the C.S.I.R. have developed, it is hoped, a much more reliable programme to handle areas such as Durban.

Previous studies showed that the old SATS dump helped to concentrate wave energy in the vicinity of the Paterson Groynes. The new study may confirm this and it may give pointers as to which are the best localities for dumping sand with the sand pumping echeme. Of particular interest will be the wave patterns around the northern end of the offshore mound as it is thought that certain wave directions will be so refracted as to give rise to undeeirable concentrations of energy on parts of the northern beaches.

4.9 Current Surveys

Attempts have been made to establish current patterns in the sea area landward of the mound. Floats with drogues some 4 m below the surface have been used but to date no significant results can be pressnted as the drogue movemente have not shown a sufficiently

reliable pattern. It has been proposed that the SATS dredgers dump material in the area landward of the mound but any peculiarities in current velocity here must be known beforehand.

4.10 Tracer Sand

At this point in time it is thought that the injection of 1 m^3 of tracer sand per load of 2 000 m^3 will be sufficient. A traditional paint-coated sand will be used but results of finds will have to be treated on a strictly qualitative basis. Depending on the results, a different type of tracer may have to be employed in the future.

5 RESULTS

At present, commissioning of Phase I is taking place. A few small problems have arisen but these are being rectified by the relevant Contractor or Sub-Contractor and it is expected that Phase I will shortly be taken over by the Department. The operation of the scheme appears to be very easy and maintaining a steady concentration presents no problems. Unfortunately, therefore, no results can be presented at this stage.

6 CONCLUSION

No conclusions or recommendations can be offered until the scheme has been operating for some time.

7 ACKNOWLEDGEMENTS

The author wishes to thank the City Engineer of Durban, Mr D.C. Macleod, for permission to publish this paper.

Thanks are also due to various members of the General Section of the Hydraulics Branch of the Department for their unflagging assistance, and especially to Mr R.B. Wicks who has worked "at the face" for more than 2 years now and who has been involved in every detail of the scheme, virtually from start to finish.

FLOATING TYRE BREAKWATERS - A CASE HISTORY

ROBERT C. McGREGOR* and COLIN H.G. GILBERT**

1. INTRODUCTION

The problem of achieving a system of coastal protection which is cheap, effective and reliable has stimulated the minds of researchers and innovators for many years.

Although floating breakwaters have been written about since the 1840s, interest in them has increased rapidly in recent years. Over the last decade or so floating tyre breakwaters (FTBs) have received considerable attention. Several different designs have been proposed. Candle (1974) proposed what may be considered a nearly rigid mat of tyres where neighbouring tyres move relatively little with respect to one another whereas Noble (1976), Harms (1978) and Kowalski (1974,76) use breakwater flexibility in their wave-maze, PT and modular designs respectively. The breakwater described in this case history used the Kowalski or Goodyear design, which is made up of modules of eighteen tyres which are connected up to form a flexible mat (See Fig.1).

* Lecturer in Naval Architecture and Ocean Engineering, University of Glasgow, United Kingdom.
** Senior Engineer, Land Reclamation and Development Consultants, Haslemere, United Kingdom.

There is now an intense demand for increased recreational boating and the numbers of fish farms are growing rapidly. In both cases suitable sheltered water is scare and the mooring pontoons or fish cages require some protection to make marginal areas usable.

The FTB is a contender in these cases. An assessment needs to be made as to whether its advantages, or plus points, namely,

1. lower capital cost - since the main item the tyres themselves are scrap they are widely available in large numbers (e.g. in Britain alone 25 million tyres are discarded annually and only a small fraction are recycled) at very low unit cost,
2. simple and quick to build using unskilled labour (except for supervision) and a minimum of mechanical equipment - similarly mooring and any repairs are easily achieved with minimum interruption to the protection afforded,
3. adaptable to changing needs - the breakwater may be lengthened or broadened to provide more protection over a greater area if the needs of the site change, in addition the breakwater could be towed to another site and reformed to meet the different conditions,
4. ecologically safe with respect to
   i) toxicity - tyres are completely non-toxic in seawater and do in fact attract marine life to the extent that they have been used as submerged reefs and fishing islands,
   ii) impedance of of tidal currents which control sedimentation patterns and the regime of estuaries etc.
5. minimal hazards to boats because tyres are relatively soft in a collision,
6. not liable to catastrophic failure - failures within the module do not free part of the structure to float off to wreck boats or cages since the tyre, while it can be constrained to float vertically is bistable and will, if released, topple over and sink without causing damage or becoming a hazard; failures of moorings will lead to the situation where the breakwater wraps itself like a blanket around pontoons or cages and continues to afford some protection, and finally,
7. little wave reflection - the breakwater works by dissipating energy rather than by redirecting it and consequently undesirable standing wave conditions are not created in the access to the harbour,

outweigh the disadvantages of

1. higher maintenance cost - the breakwater is a dynamic structure and its composite parts are subject to abrasion and wear and so attention must be paid to the state of ties, moorings, buoyancy etc. at frequent intervals (to be discussed more fully later),

2. wave attenuation is partial - floating breakwaters act like filters absorbing the high frequency waves more efficiently than the larger ones but some wave energy will be transmitted or generated by the movement of the breakwater itself,
3. occupies more space - wave attenuation is linked to size of the breakwater, in particular the beam of the breakwater should be a substantial fraction of the wavelength of the waves which must be reduced,
4. relatively short service life - the materials used in the original construction will deteriorate over a few years and a point will be reached where maintenance is better achieved by a reconstruction, and
5. vulnerability to ice on lee side - this is a problem encountered mainly in fresh water sites in high latitudes but can be serious because the moorings may be overloaded.

The object of the design is to develop the situation where the disadvantages are reduced relative to the advantages. Essentially the breakwater is designed to have an adequate level of wave attenuation such that the risk of the damage is reduced to an acceptable level. If this can be achieved within the space limitations (and ice is not present) then the financial balance is the main consideration. Typically the annual maintenance cost is of the order of one third of the first cost. This is a high percentage but the first cost could be as low as 3% to 5% of that of a conventional breakwater, so the maintenance cost is less than servicing the capital involved in such a breakwater. Even with a reconstruction (costing 60% to 80% of the first cost) every three years (which is pessimistic) the life cycle costs compare favourably.

In the case under consideration there was plenty of room and wave conditions were such that an adequate design was possible within the bounds of existing FTB experience. However it is this experience which is rarely published, even though it may be communicated privately, that is presented here to justify the claim that FTBs are not only cheap and effective but can with proper handling be reliable.

2. BACKGROUND

Lothian Regional Council took over the former Royal Navy minesweeper base at Port Edgar on the south side of the Firth of Forth, Scotland.* The harbour at Port Edgar was well designed for its original purpose. Minesweepers are not troubled by waves of 0.6m or so. However yachts are. Consequently Lothian Region engaged Land Reclamation and Development Consultants (LRDC), a subsidiary of Grontmij, to review possible floating breakwaters with a view to establishing a marina as quickly as possible. LRDC recommended a floating breakwater and in association with the Department of Naval Architecture and Ocean Engineering at University of Glasgow** designed a breakwater which would provide

*The site lies in the shadow of the Forth Road Bridge and the Forth Rail Bridge is close by.

**This design service is now a function of Ostec Ltd.

adequate wave attenuation, planned its moorings, prepared detailed design documents and drawings and supervised the construction. The breakwater was made up from 3000 truck tyres and was completed in April 1979 within 5 weeks of the decision to proceed.

3. DESIGN

3.1 Site Assessment

The location of Port Edgar may be seen in Fig. 1. Fetches were measured for each of the relevant bearings and corrected for the effects of width of fetch. A shallow water correction was not considered appropriate.

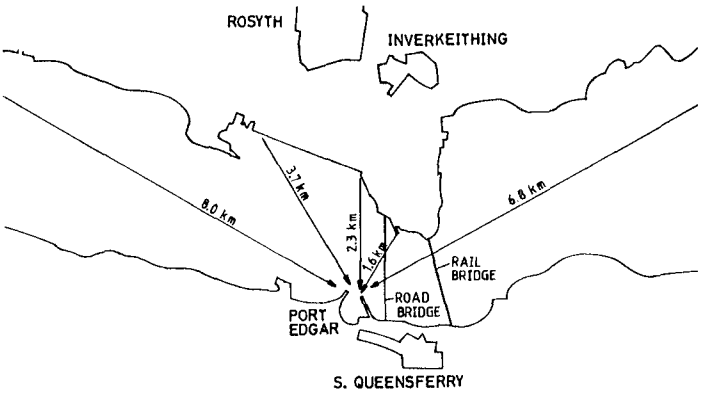

Fig. 2 - Firth of Forth near Port Edgar

Wind data was available from the Meteorological Office for a 20 year period and the mean hourly wind speeds which would have a return period of 10 years from each bearing were predicted.

Over short fetches the sea is quickly aroused to its full potential and the significant wave heights and periods were evaluated using a Bretschneider Chart (US Army, CERC, 1977). (Other methods were examined.) This predicted the sea conditions outside the harbour but in some cases diffraction by the piers of the existing harbour significantly reduces the height of the waves which would penetrate to the breakwater site. This leaves the bearings of 330° and 0° as those producing the only waves of sufficient height to justify attenuation. (In addition wave conditions from other headings are greatly ameliorated.)

This assessment is summarised in Table 1.

TABLE 1: Fetches, Wind and Wave Conditions near Entrance to Existing Harbour.

Bearing (Degrees)	275	285	330	0	30	60
Fetch (km)	7.4	16.7	3.7	2.3	1.5	6.8
Fetch (km)	5.0	7.4	3.7	2.3	1.5	5.1*
Wind Speed (ms^{-1})	26.8	17.4	14.3	14.3	14.3	14.3
Significant Wave Height (m)	1.60	1.15	0.70	0.55	0.45	0.75
Period(s)	4.4	4.0	3.0	2.7	2.4	3.3
Post Diffraction Height (m)	0.25	0.30	0.70	0.55	0.25	0.20

*Further reduced by effect of bridges.

3.2 Wave Attenuation

Extensive data on the performance of FTBs had been collected from experiments conducted on quarter scale car tyres in the Hydrodynamics Laboratory of the Department of Naval Architecture and Ocean Engineering at the University of Glasgow. This tank is 77m long, 4.6m wide and 2.4m deep and has a parabolic plunger wavemaker at one end which at that time could be programmed to generate a pseudo-random sea with wave heights up to 0.4m.

Twenty-five breakwaters fabricated of basic (Fig. 1) and deep modules were constructed and tested for wave attenuation and catenary mooring loads (McGregor 1978, McGregor and Miller 1978). In contrast with other tests on FTBs the breakwaters were tested in a broad band spectrum and analysis was by means of FFTs to generate the transmission function

$$C_T(f) = \left[\frac{S_A(f)}{S_F(f)}\right]^{\frac{1}{2}}$$

where $S_A(f)$ and $S_F(f)$ are the measured wave spectra aft and forward of the breakwater respectively. Sufficient runs were made to reduce the error in the spectral values to 4%.

Other tests described in Giles and Sorenson (1978), Harms and Bender (1978) and Kowalski (1976) have used monochromatic waves and achieved a transmission factor

$$\overline{C_T} = \left[\frac{\int_0^\infty S_A(f)\,df}{\int_0^\infty S_F(f)\,df}\right]^{\frac{1}{2}}$$

which is not useful in design.)

This different method of experimentation lead to different methods of

design. The monochromatic approach by establishing dependence on steepness implies the wave attenuation is non-linear which means that the storm sea spectrum must be idealised to a design wave. The spectral approach assumes wave attenuation can be approximated by a linear system employing a transfer function but can realistically represent the sea in spectral form.

Clearly neither of these approaches has a monopoly of truth but the authors believe that more useful information is ahcieved from a design calculation based on spectral methods. (This discussion is a superficial summary of a complex situation which merits further investigation.)

In this design study it was assumed that the sea could be represented by an ISSC spectrum. (The use of another form such as a modified JONSWAP would change the calculated values but not sufficiently to alter the design.) The evidence of the model tests was that the primary characteristic of a wave was its wavelength and so the transmission function was applied in the form $C_T(\lambda)$ (or even $C_T(^B/\lambda)$).

3.3 Breakwater Design

Figs. 3 and 4 show the predicted performance of a 3 row breakwater of truck tyres aligned east-west encountering waves from bearings of 330^o and 0^o respectively showing the difference in performance at high and low water.

From analysis of several beams and orientations this size of breakwater and orientation was judged to be satisfactory and is shown in Fig. 5. The orientation is a compromise between the extra wave attentuation available if the breakwaters western end is moved northwards and the shorter breakwater length achieved if it were moved south.

The breakwater length is determined by

a) the clearance between the breakwater and the boat moorings,
b) diffraction effects and the area to be protected, and
c) siltation problems.

The clearance was chosen to be 40m but the length is not sensitive to this value and after trying to avoid siltation problems near the east pier by as small a margin as possible it was seen that the diffraction considerations were most significant. The breakwater was designed to be 180m long.

3.4 Moorings

The peak pull on the moorings was calculated from a design wave analysis and was confirmed from extreme value statistics of the model mooring experiments (McGregor 1978) with appropriate scaling for tyre size and wave dimensions. The two methods were substantially in agreement in suggesting a probable maximum of 44 tonnes. The mooring arrangement is shown in Fig. 6.

4. CONSTRUCTION

4.1 Timescale

One of the most attractive features of FTBs is that they can be assembled and installed very quickly. In this case following the initial order in February 1979 the breakwater was tendered for during March and the initial building phase took three weeks. An extension to the originally ordered length to provide protection for an increased area took a further two weeks and the breakwater was completed and operational by mid-April in good time for the marina to be in service and earning during that year's boating season.

Although there were some problems (see maintenance) the breakwater was a successful wave attenuator and the expected life was revised to five years. This coupled with growing suspicion of the status of many of the ties and the level of regular maintenance entailed by the decision that the original breakwater was constructed without additional buoyancy* led to a reconstruction in February and March 1980 carried out on a section by section basis thus maintaining complete protection.

A summary of key dates in the history of the Port Edgar Marina Breakwater are given in Table 2.

TABLE 2: History of Breakwater

1978	December	FTB proposal and design quotation.
1979	January	Report evaluating wave conditions and designing the breakwater was commissioned.
	February	Breakwater ordered as a temporary solution with an expected life of two years.
	March	Request for, assessment of and acceptance of tender Breakwater built to original specification within 3 weeks and then extended.
	April	Breakwater completed and marina becomes operable Some modules ground on silt and are held down.
	October	Breakwater partially sinks because of lack of maintenance but is refloated within 24 hours.
1980	Feb. & March	Breakwater is overhauled and fitted buoyancy since the expected life is increased to 5 years.
1982	November	Further FTB under consideration as means of enlarging marina.

* This was done to minimise first cost in the belief that maintenance over the 2 years of expected life would give a smaller life cost.

4.2 Materials

The main construction material is of course tyres. The choice lay between car and truck/tractor tyres. In this case truck tyres were chosen for the reasons below.

a) Scaling - although appreciable quantities of experimental data exist for tyres of different sizes the precise mechanism of wave attenuation is not certain and consequently appreciable uncertainty exists on the scaling laws. For the environment at Port Edgar truck tyres scaled relative to the model tyres in much the same way as the waves thus giving the two scaling factors a similar value and facilitating the scaling problem.
b) Constructional - the number of truck tyre modules required for comparable wave attenuation was very much less than would have been needed with car tyres.
c) Size - The truck tyre breakwater was less beamy than a car tyre design.

A significant price was paid for these advantages.

d) Buoyancy - most truck tyres are tubed and lack the butyl or chlorobutyl lining which is built into car tyres. This means air can leak through the tyre causing the tyre to sink lower in the water. Fig. 7 shows how this effects the breakwater.
e) Handling - truck tyres and truck tyre modules are appreciably heavier than their car tyre counterparts and this increases handling problems. This is offset to a degree by having fewer module connections to make in the water.
f) Abrasion - the extra steel in the beading of truck tyres makes them more abrasive to conveyor belting.

Although the tyre composition factors (d) and (f) were not appreciated prior to the original construction the choice of truck tyres was sound.

Plausible tying materials include nylon, dacron, polypropelene and (stainless steel) wire ropes, open or closed link chain and conveyor belting. All the ropes have overwhelming disadvantages and the choice lies between chain which is heavy and will wear inside the links and conveyor belting which is made of a material similar to the tyres and may be obtained as scrap. Conveyor belting was recommended by Davis (1977) and was chosen for the original breakwater. Belting was cut from used conveyor belts which were scrapped rather than edging of new belting which appears to have been available in America. Three makes of belting were used and two of them exhibited failures within six months. The remaining type appeared unscathed but in the reconstruction a complete transition to chain was made.

The choice of fastenings is determined by the typing material e.g. knots, splices or crimps for ropes, shackles or closing links for chain and stainless steel or black nylon bolts for conveyor belting. Initially stainless steel bolts were used with the belting and these were satisfactory. Later high tensile shackles were used in the reconstruction. A waterproof salt resistant grease is invaluable for use with the shackles when maintenance is necessary.

Fig. 7a - New section (with buoyancy) ready for installation

Fig. 7b - Modules with and without buoyance during refurbishing of breakwater

Rope, chain and belting have all been used alone or in combination for moorings. In this case nylon rope with spliced hard eyes and black chain were used.

The mooring loads are not in general very high and depending on the bed composition and the anchor handling capability available either small(ish) anchors or concrete blocks may be used. With a silt bed concrete blocks cast in half 50 gallon oil drums were used. The blocks buried well and gave no problems.

It is useful to provide a large number of buoys around the breakwater to provide mooring attachment points which have significant buoyancy to help support the mooring and mark the breakwater. The breakwater was also provided with low intensity intermittent battery powered lights.

(The materials available including floatation aids are discussed at length by Bishop (1980)).

5. MAINTENANCE

5.1 Basic Need

It is important in the context of FTB to appreciate that maintenance is an essential feature of the operation. The very low initial cost is to an extent offset by maintenance costs which will be high relative to the first cost, although only moderate in absolute terms.

Being a dynamic structure the FTB will inevitably be subject to wear and deterioration. It must therefore be inspected regularly and frequently as well as after each storm. It is recommended that at the time of initial construction the appointment of a maintenance contractor, with clearly defined responsibilities, should be considered. Any such contractor should attend to unscheduled maintenance or damage repair without delay. All maintenance should be carefully recorded.

5.2 Maintenance Problems

Several problems were experienced with the initial design which as has already been stated involved no additional buoyancy and relied on maintenance to ensure it floated with a reasonable freeboard. These problems are listed below.

a) Loss of buoyancy from tyres which was not replaced naturally by storms - buoyancy may be lost because of

   i) air dissolving - but seawater is fully saturated with gases and will dissolve no more,
   ii) air leaking through rubber (See 4.2),
   iii) air leaking through tyre faults - any local lightening will migrate to the top,
   iv) marine growth - weeds and crustacians,
   v) flotsam - small weight addition when beached on breakwater.

Once buoyancy is being lost reasons for lack of replenishment become important. These may include

i) shape of the tyre beading,
ii) tightness of the module - in a loosely fastened module individual tyres could heave sufficiently but loose modules are undesirable for other reasons,
iii) inertia of module to wave action - truck tyres with their higher virtual mass are less likely than car tyres to be lifted sufficiently,
iv) lack of freeboard caused by loss of buoyancy makes replenishment progressively more difficult.

Initially this difficulty was to have been tackled with an air line (operated from a boat) which although quite feasible is labour intensive. In addition during a period when there was a temporary lack of maintenance through staff leave an appreciable part of the breakwater sank. A wind of force 5 or 6 blew while the breakwater was down and some considerable damage was experienced. The breakwater was refloated within 24 hours by divers with an air hose. This led to the assessment of permanent floatation. The choice lay between sealed plastic containers for which various sources give evidence of cracking, crushing, escaping or leaking (Bushell (1978)) and foams. The foam may be moulded, rods or mixed in the tyre. The foam should be high density, resistant to crushing, abrasion and pollutants. Although polystyrene cannot be recommended both polyurethane and polyethylene appear to have been used successfull. In this case polyethylene rod was chosen.

Problems created by the belting chafing on the tyre beading were solved as stated by changing to chain.

Port Edgar proved to be an area with three other potential problems.

i) Silt - early in the breakwater's life modules near the east pier grounded at low spring tides and were held down by suction. They were refloated and the breakwater moved a little to the west.
ii) Biological and Zoological Growth - a prodigous growth of kelps (laminaria saccherina and laminaria digitata) which are indigenous to the area developed. These fruit in the coldest months i.e. December and January and should be cleared just before that period removing even the roots to avoid their own ecosystems being established. Mussels were the other major growth. These settle in April and should be cleared then.
iii) Accidental and malicious damage - although this could be serious observation, maintenance and responsible boat owners kept it to a minimum.

6. CONCLUSION

The breakwater has proved hydrodynamically successful in that no damage to boats at the moorings was experienced even when the winds reached

force 11 and waves up to 1.25m high were encountered. Without the breakwater, moorings could be untenable at wind forces as low as force 5 or 6. Early constructional problems have been overcome and develop ing biological problems contained by improved understanding of their causes. This has enabled the maintenance programme to be made more timely and more cost effective.

Overall acceptance is illustrated by the consideration of another FTB to provide further protection to the marina which is being extended.

7. ACKNOWLEDGEMENT

The authors are grateful to Lothian Regional Council and its servants for their co-operation, and to colleagues in LRDC and the University for helpful discussions.

NON-LINEAR WAVE FORCES ON FLOATING BREAKWATERS

by C.T. Niwinski[1] and M. de St. Q. Isaacson[2], M. ASCE

ABSTRACT

A non-linear numerical method for calculating wave forces on floating bodies has been developed by Isaacson (1981). The time stepping procedure is programmed for a computer solution, and an incident wave train is time stepped past a fixed two-dimensional rectangular breakwater. The influence of various input parameters on the accuracy of results is investigated, and optimal values of the parameters are determined. The optimal numerical parameters are used to generate force and transmission coefficient results, which are compared to the results of other published studies. The method is shown to compare favorably with other results, with the non-linear nature of the method being clearly demonstrated by the different force curves produced by varying the wave height.

1. INTRODUCTION

The forces generated by waves on floating breakwaters or floating bridges are generally predicted on the basis of linearized potential theory. A nonlinear method for calculating the wave forces for the case of a fixed body has been developed by Isaacson (1981) and subsequently extended to floating bodies undergoing motions (Isaacson, 1982). The method employs the second form of Green's theorem, together with the usual governing equations, to time step an incident wave train past the body. In order to test the validity and range of the method, only the fixed body case is tested here. Although the method has been used on three-dimensional bodies, we apply it to the two-dimensional case and exploit that simplification to conduct a study of the incident wave conditions and numerical parameters used in the method. A comparison is made between force and transmission coefficient results generated by the method and those available from previously published studies.

2. GENERAL DESCRIPTION OF METHOD

For the two-dimensional case examined here, a body of rectangular cross-section with beam B and draught D is floating in water of uniform depth d. An x-z coordinate system is defined with x measured horizontally in the direction of incident wave propagation and z measured vertically upward from the still water level. The origin is located at the still water level midway along the beam of the body. Let η denote the free surface elevation above the still water level. A definition sketch is shown in Figure 1.

With the usual assumptions of an incompressible fluid and irrotational flow, the fluid motion is represented by the velocity potential ϕ which must safisfy the Laplace equation within the fluid region,

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial z^2} = 0 . \qquad (1)$$

Assuming an impermeable seabed and body surface, the flow will be subject to the following boundary conditions,

$$\frac{\partial\phi}{\partial z} = 0 \qquad \text{at} \quad z = -d \qquad (2)$$

$$\frac{\partial\phi}{\partial n} = 0 \qquad \text{on} \quad S_b \qquad (3)$$

$$\frac{\partial\phi}{\partial n} = \frac{\partial\eta}{\partial t} n_z \qquad \text{on} \quad S_f \qquad (4)$$

$$\frac{\partial\phi}{\partial t} + g\eta + (\nabla\phi)^2 = \text{constant on} \quad S_f . \qquad (5)$$

Here, S_f and S_b are the free and body surfaces respectively, n is the direction normal to the surface, t is time, n_z is the direction cosine in the z direction of the vector $\underline{n}$, and g is the acceleration due to gravity. The equations given by (4) and (5)

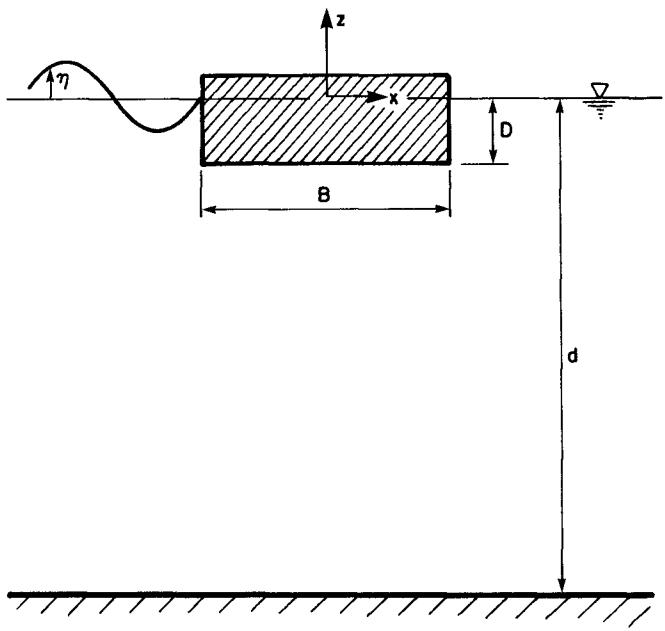

FIG. 1: DEFINITION SKETCH.

are the kinematic and dynamic free surface boundary conditions, with (4) being a form used by Isaacson (1981, 1982).

The second form of Green's theorem provides values of ϕ at any point $\underline{x} = (x,z)$ on the closed boundary in terms of ϕ and its normal derivative on the boundary:

$$\phi(\underline{x}) = -\frac{1}{\pi}\int_S \left[G(\underline{x},\underline{\xi})\frac{\partial\phi}{\partial n}(\underline{\xi}) - \phi(\underline{\xi})\frac{\partial G}{\partial n}(\underline{x},\underline{\xi})\right] dS \ . \qquad (6)$$

The point $\underline{\xi} = (\xi,\rho)$ is a point on the closed boundary in the x-z plane over which the integration is performed, dS is measured along the closed boundary, and G is an appropriate Green's function.

In order to consider a closed boundary over which the Green's identity can be integrated, vertical control surfaces extending from the free surface to the seabed are set at a chosen distance to either side of the body. The closed surface consists of the body surface, the free surface, and the control surfaces all reflected about the seabed. The control surfaces are set sufficiently distant so that the scattered potential due to the wave interaction with the fixed body will not reach the control surfaces throughout the time stepping procedure.

The closed surface on each side of the seabed is divided into N_b body segments, N_f free surface segments, and N_c control surface segments. This is shown in Figure 2. Values of ϕ and $\partial\phi/\partial n$ are assumed to be constant over each segment, and initial values of ϕ, $\partial\phi/\partial n$, and η are assigned to the midpoint of each segment according to a chosen wave theory defining the incident wave. The initial conditions require zero flow in the immediate vicinity of the body.

At a given time t, time stepping equations obtained from (4) and (5) are used to get N_f values of η and ϕ at $t+\Delta t$. A numerical integration of (6) at each body and free surface segment gives $N = N_f+N_b$ equations in N unknowns (N_b values of ϕ and N_f values of $\partial\phi/\partial n$), which are solved on the computer using conventional matrix solution techniques. Values of φ and $\partial\phi/\partial n$ on S_c are given at all times by the chosen incident wave theory. Thus, all values of ϕ, $\partial\phi/\partial n$, and η are obtained at $t+\Delta t$, and the process can be repeated as many times as necessary for the desired flow development.

With the velocity potential ϕ obtained for each segment at each time step, we can obtain the pressure distribution on the body surface using the unsteady Bernoulli equation,

$$p = -\rho\left[\frac{\partial\phi}{\partial t} + \frac{1}{2}(\nabla\phi)^2\right] . \qquad (7)$$

A numerical integration of Eq. (7) over the body surface yields the forces on the body at each time step. The numerical procedure described above is readily programmed for computer solution. The flow chart for such a solution is shown in Figure 3. A more complete

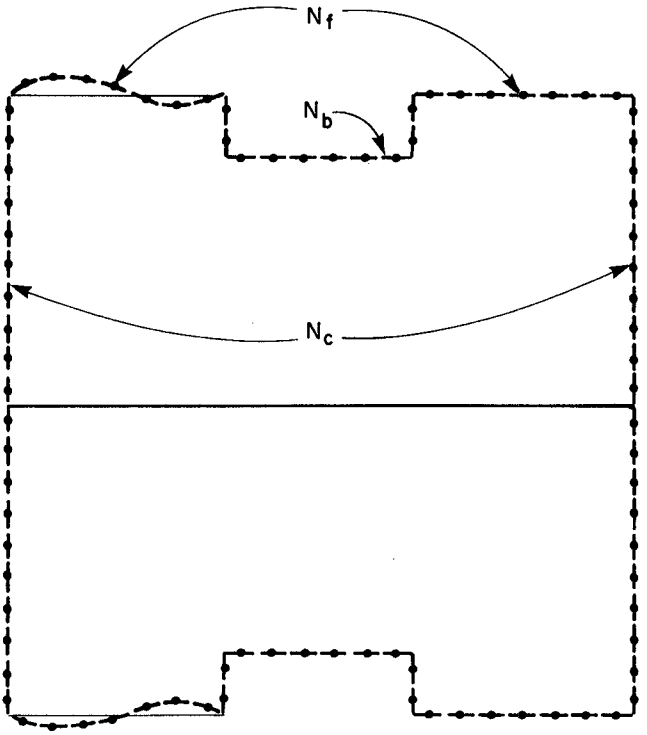

FIG. 2: SEGMENT GRID.

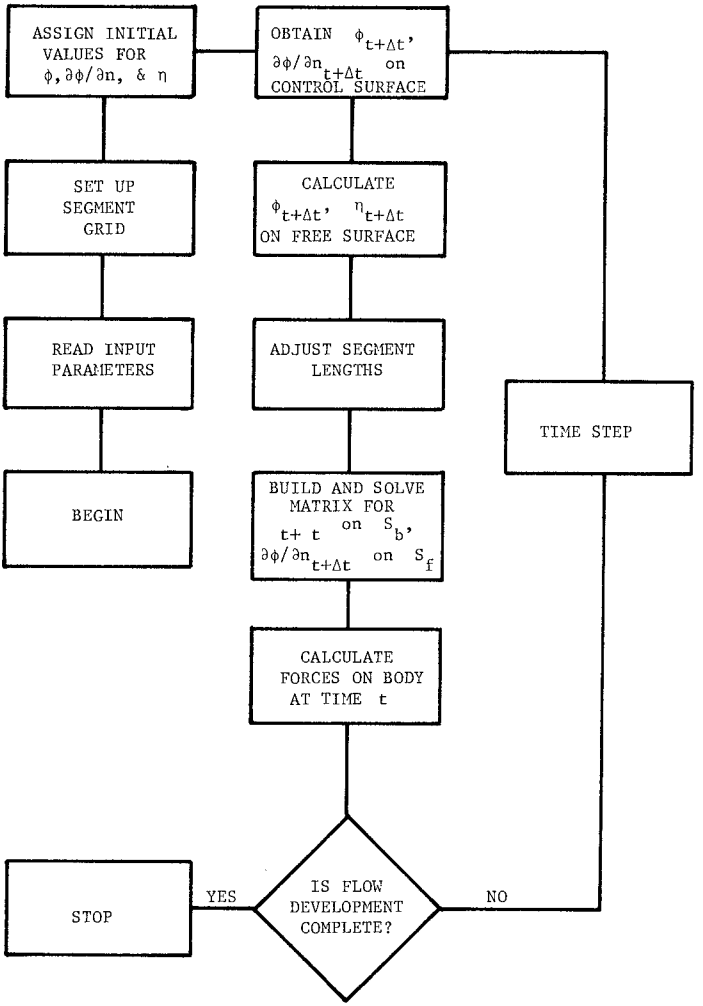

FIG. 3: FLOW CHART FOR COMPUTER SOLUTION.

derivation of the theory and numerical procedure is given by Isaacson (1981, 1982).

3. INCIDENT WAVE CONDITIONS

3.1. Incident Wave Decay Length

A harmonic wave predicted by either linear or Stokes's fifth order wave theory is used to prescribe the incident wave. To satisfy the condition that there initially be zero flow in the vicinity of the body, the incident flow is attenuated over a given decay length, L_d, as shown in Figure 4. When considering computing effort, a short decay length is desirable in order to reduce the length of the free surface and hence the number of segments needed on the free surface. A long decay length is expected to give smoother, more accurate flow development at the expense of much larger computing effort.

The program developed for this study is run with values of L_d varying from 0.25 up to 1.75 wavelengths, and the maximum forces on the body generated by the first fully developed wave to interact with the body are recorded. The results, shown in Figure 5, indicate that a decay length of about 0.75 wavelengths and less yields somewhat unreliable results, while a decay length of 1.25 and greater does not change the results significantly. A value of $L_d = 1.25$ or 1.50 is recommended for accurate results.

3.2. Group Velocity

Depending on the order of the time stepping procedure (see 4.2), the initial conditions along the entire boundary are specified at two or more time steps according to a chosen wave theory. The modulation envelope of the incident harmonic wave train travels at the group velocity c_g. For linear wave theory, c_g is given explicitly by

$$c_g = \frac{c}{2}\left[1 + \frac{2kd}{\sinh(2kd)}\right] . \qquad (8)$$

However, when using Stokes' fifth order wave theory, a reasonable value for the group velocity must be assumed since no explict expression for c_g exists.

To examine the effect of specifying different values of c_g, the program was run twice with an incident wave given by linear wave theory, the first time letting c_g equal its linear theory predicted value given by (8), and the second time setting c_g equal to the wave speed, c, which is about twice the predicted value of the group velocity. It was expected that specifying a value for c_g higher than that predicted by linear wave theory might lead to quicker flow development. However, the flow development results are found to differ only for the first few time steps, with subsequent flow development and force results being almost identical for both runs.

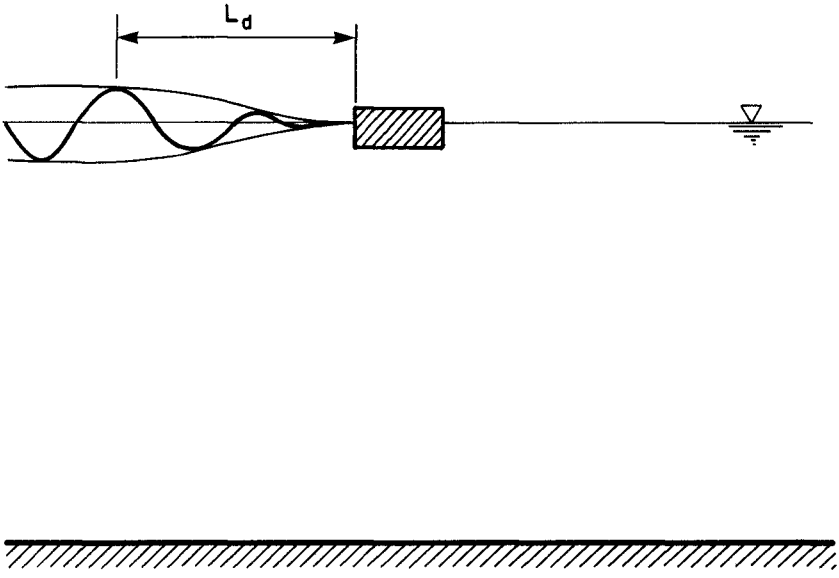

FIG.4: INCIDENT WAVE PROFILE.

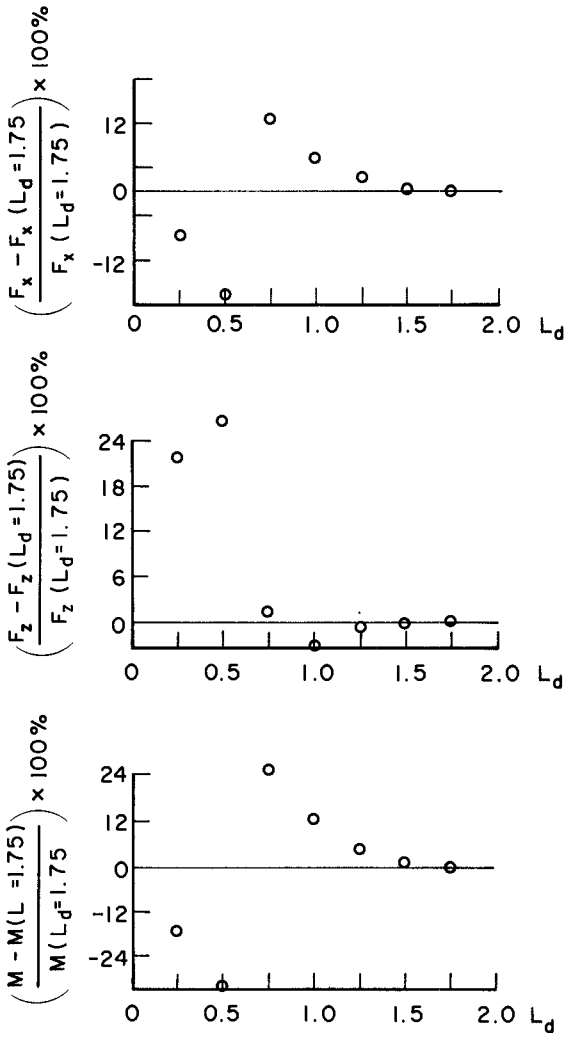

FIG. 5: EFFECT OF VARYING DECAY LENGTH, L_d.

We conclude that the method itself with its physical constraints expressed by the boundary conditions and the Green's identify very strongly defines the flow development and overrides any attempt to force a faster flow development in the vicinity of the body by setting the group velocity to a higher value.

When using Stokes' fifth order wave theory for the incident wave, the group velocity is now set equal to that predicted by linear wave theory.

4. NUMERICAL PARAMETERS

4.1. Time Step Size and Segment Length

Both the time step size and the segment length are required to be as large as possible in order to minimize the computing effort for the time stepping procedure. The time step parameter $\Delta t/T$ determines the number of cycles of the procedure for each wavelength, while the segment length parameter $\Delta S/L$ controls the size of the matrix that is solved at each time step. Here, Δt is the time step size, T is the incident wave period, ΔS is the segment length, and L is the wavelength.

If one considers the cyclical motion of the fluid particles over a wave period, it is readily apparent that the time step Δt must be sufficiently small to ensure that the motion of the particles is small compared to the segment length, and hence that $\Delta t/T$ should be less than $\Delta S/L$ for accurate flow development. Thus, for a given value of $\Delta t/T$, $\Delta S/L$ must be small enough to yield accurate results while being large enough to remain greater than the given $\Delta t/T$.

Since the body dimensions are significantly smaller than the wavelength for waves of longer period, the segment length parameter $\Delta S/L$ found to be appropriate on the free surface may not be very useful on the body surface if only one or two segments are needed to meet the specified global $\Delta S/L$ requirement. Recalling that ϕ and $\partial\phi/\partial n$ (and hence p) are constant over each segment, a minimum number of segments are needed on the body surface to adequately describe the pressure distribution over the body surface. The moment acting on the body is most likely to be sensitive to this consideration. For purposes of the body segments we define a parameter $\Delta S_b/L_b$, where ΔS_b is the body surface segment length, and L_b is the dimension of the body along which the segment lies (in our example, B or D).

Optimal values for $\Delta t/T$, $\Delta S/L$, and $\Delta S_b/L_b$ have been determined by letting each vary in turn while holding all other parameters constant and recording the force results.

It is found that as $\Delta t/T$ is decreased, the force results quickly converge to uniform values. Little increase in accuracy is gained by setting $\Delta t/T$ to values less than 0.05, and for $\Delta t/T = 0.04$ the results obtained are within 3% of the converged values.

The segment length parameter $\Delta S/L$ was set to values ranging from 0.05 to 0.25. The earlier discussion concerning upper and lower limits for $\Delta S/L$ is confirmed as the results remain relatively consistent when $\Delta S/L$ is in the vicinity of 0.1, diverging as $\Delta S/L$ is increased or decreased beyond a limited range. When $\Delta S/L$ is set to a value less than approximately twice the value of $\Delta t/T$, the results diverge to the point where the computer solution is unable to continue. It is concluded that $\Delta S/L$ should be at least two or three times greater than $\Delta t/T$, and that a value of 0.1 for $\Delta S/L$ will yield good results.

As previously discussed, a global limit on $\Delta S/L$ may not provide enough body segments to calculate the force results accurately. One should also check that the segment lengths on the body surface as defined by $\Delta S_b/L_b$ fall within the global constraints on $\Delta S/L$ determined above. Values of $\Delta S_b/L_b$ ranging from 0.1 to 0.25 have been tested. As with the global segment length parameter $\Delta S/L$, $\Delta S_b/L_b$ is found to be constrained by upper and lower bounds. A maximum value of $\Delta S_b/L_b = 0.2$ (five segments along each body dimension) is found to be necessary to adequately describe the pressure distribution on the body. More segments on the body, while desirable to define the pressure distribution more accurately, would potentially conflict with the requirement that $\Delta S/L$ be larger than $\Delta t/T$. It is recommended that for a particular body shape, a minimum of five segments be used along each body dimension and that the relationship of $\Delta S_b/L_b$ to $\Delta S/L$ and $\Delta t/T$ be checked to ensure that it falls within the required range.

4.2. Time Stepping Equation

As mentioned in Section 2, the time stepping equations for η and ϕ on the free surface are obtained from (4) and (5). Applying a central difference approximation to (4), we obtain

$$\eta_{t+\Delta t} = \eta_{t-\Delta t} + 2\Delta t \frac{1}{n_z}\left(\frac{\partial \phi}{\partial t}\right)_t .$$

A similar expression can be obtained for $\phi_{t+\Delta t}$ on S_f using (5).

For better accuracy, higher order time stepping methods are desirable. For our purposes, the Adams-Bashforth multistep methods are useful. These are described by Burden, Faire and Reynolds (1978).

The central difference method and the Adams-Bashforth two, three, four, and five step methods have each been tested with the same input parameters, and the forces at each time step recorded for each method. The plotted results are shown in Figure 6. It is found that the central difference method produces a slightly uneven plot, particularly for the first few time steps. The two, three, and four step methods give smoother results. The five step method produces highly erratic results which sawtooth about values coincident with the other plots.

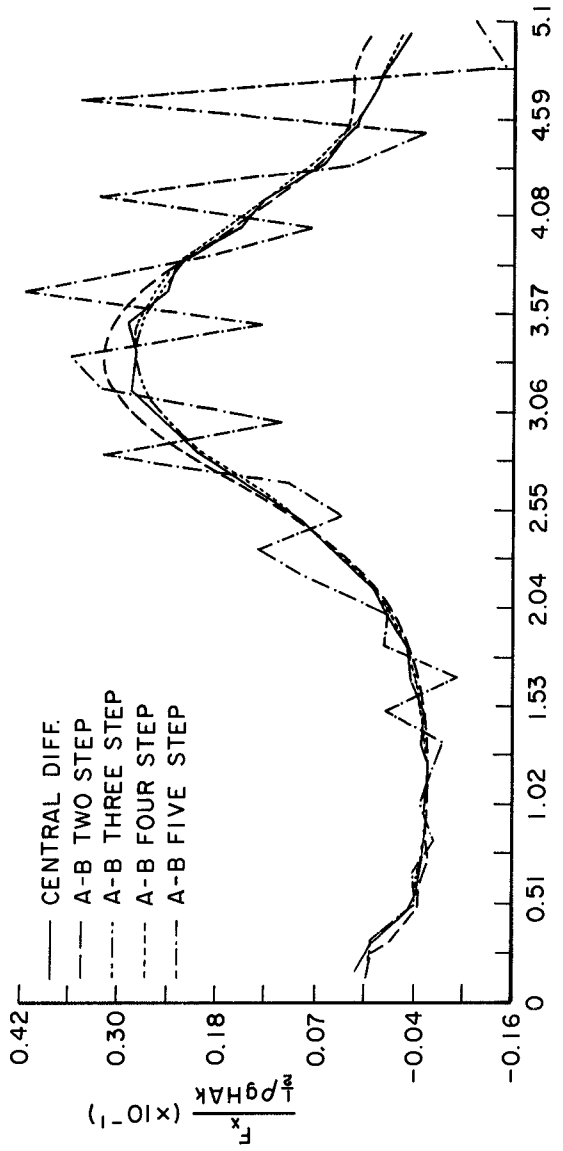

FIG.6: EFFECT OF VARYING TIME STEPPING METHODS.

The sawtoothed results of the five step method are probably caused by small perturbatlons from smooth results belng magnified by the fitting of a fifth order polynomial to previous points when projecting forward at each time step to values at $t+\Delta t$. Anticlpating that the same effect could occur for the four step method, the Adams-Bashforth two and three step methods have been adopted as the preferred time stepping techniques.

The program developed for this investlgation was also tested without a body present, using the optimal vaiues of the numerical parameters as determined above. The time stepping technique yielded a wave train progressing along the free surface as expected.

5. RESULTS

5.1. Exciting Forces

Using the method described in Section 2, the exciting forces on a two-dimensional rectangular cross-section were obtained for a range of lncident wave angular frequencies ω, and for different values of wave height to water depth ratios, H/d. An incident wave decay length of 1.25 wavelengths was used, with 25 time steps per wave period, 10 segment lengths per wavelength, and 5 segments along each body dimenslon. The Adams-Bashforth three step method was used as the time steppling technique for the equivalent of (4) and (5).

The force resuits for a beam to draught ratio, $B/D = 4.0$ are plotted in Figure 7, with Vugts' (1968) deep water experimental results and Fraser's (1979) linear finite element results shown for comparison. The results of Figure 7 clearly demonstrate the non-linearity of the method, with different force curves resulting from different values of H/D. The results show that the method used here has a fairly wide range of application, and that the magnitude of most of the force results compares well to previous experimental and theoretical results. While the results for the horlzontai exciting force coincide closely with Fraser's linear results, the non-iinear method produces curves for the vertlcal force and moment that dlffer significantly in slope from the linear predictions.

5.2. Transmisslon Coefficient

An interesting byproduct of the method is the capablllty to monitor the transmission coefficient for the fixed body case. Since the fixed case is used here only as an idealization to calculate exciting forces that can be used for a subsequent analysis of the actual response of a moored breakwater, the observed transmlssion coefficients are of little or practical value, but do provide a lower limit for the transmission coefflcient of a responding body.

The program was run with the same input parameters descrlbed in Section 5.1, but for $B/D = 2.0$, 4.0, and 8.0 in turn. The results for the transmission coefficient K_d are shown ln Figure 8 together with the results of Nece and Richley (1972) for $B/D = 5.0$. The experlmental results are for an incident wave of the same steepness for a given ω as for our results.

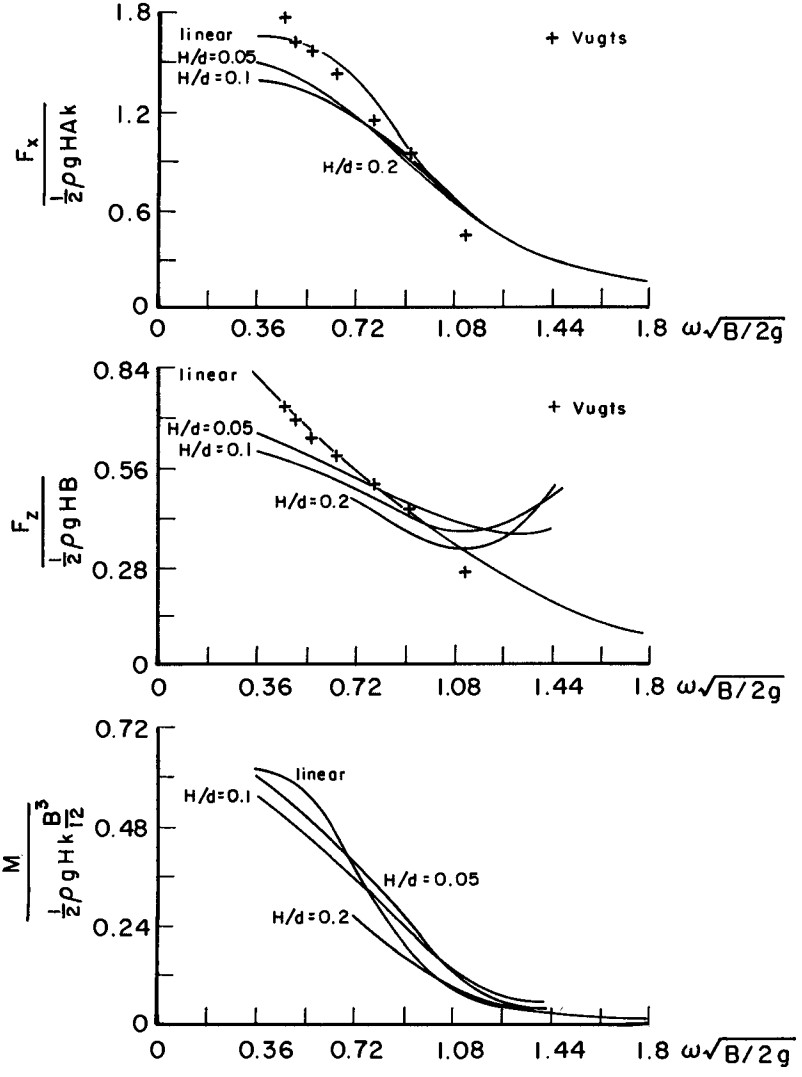

FIG. 7: FORCE RESULTS FOR B/D = 4.0 .

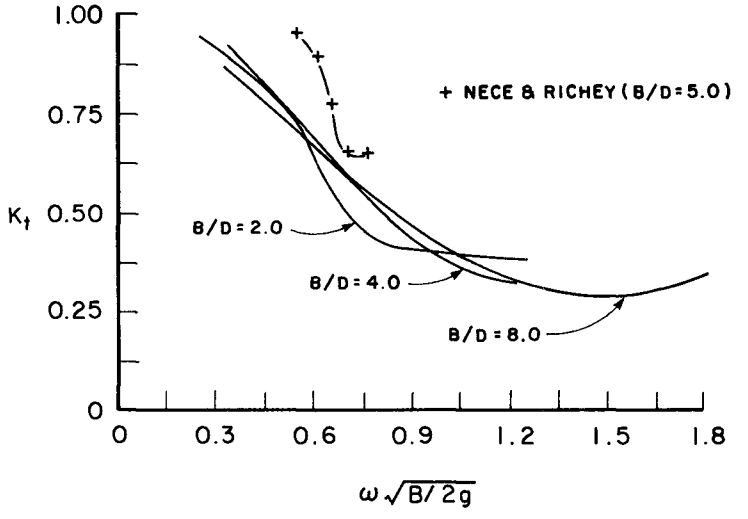

FIG.8: TRANSMISSION COEFFICIENT RESULTS.

The results obtained for the transmission coefficient are found to be relatively independent of water depth over the range tested. As expected, the present results for a fixed body give lower values for K_d than Nece and Richey's experimental results for a responding cable moored body, and thus appear to provide a reliable lower limit for K_d.

6. CONCLUSIONS

By testing a computer program based on the nonlinear numerical method described here, optimal values of the numerical parameters were determined. It was found that 25 or more time steps per wave period and at least 10 segments per wavelength were needed to obtain accurate flow development. There should also be at least 2 to 3 times as many time steps as segment lengths per wavelength. The decay length of the initial incident wave profile should be 1.25 or more wavelengths.

The method itself as defined by the physical conditions and boundary integral determines the group velocity of the flow development, and specifying a different value of the group velocity for the initial time steps changes the flow development of only the first few time steps.

Using a central difference time stepping equation produced a slight sawtooth effect in the force results, while using a four or five step method occasionally produced a divergent instability, probably due to the fitting of a higher order polynomial to the values at previous time steps. The recommended time stepping procedure is a two or three step Adams-Bashforth method.

Force results from the program were plotted in the appropriate dimensionless form over a range of frequencies. The results produced different force curves for different values of the wave height to water depth ratio, thus verifying the nonlinearity of the method. The force curves obtained compared well in magnitude to previous numerical and experimental results, although the slopes of the curves varied significantly. The transmission coefficient for the fixed rectangular breakwater over the range of frequencies tested appeared to provide a reliable lower bound for the transmission coefficient of responding bodies. It is concluded that the nonlinear method used here has a significant potential for improved accuracy in the prediction of forces on floating bodies and their transmission coefficients.

DOLOS STABILITY
EFFECT OF BLOCK DENSITY AND WAIST THICKNESS

by

D J P Scholtz, J A Zwamborn and M van Niekerk*

ABSTRACT

Model tests were done with dolosse having the same shape and volume, but with different **block densities,** to determine the effect of block density on stability and to check whether the theoretical third-power relationship between block volume and relative block density is valid.

From these tests it can be concluded that the higher the density of the block material the greater the stability becomes. Although the individual scatter is appreciable, the average results indicate that the stability of dolosse is inversely proportional to a power of about 2,3 of the relative density, which is significantly less than the theoretical power of 3.

Model tests were also carried out on dolosse having the same mass and volume but with different **waist-to-height ratios** to determine the effect of waist-to-height ratio on the stability of a dolos armour.

From the results of these tests it can be concluded that the stability of the armour decreases with increasing waist thickness, particularly for relatively high waist ratios.

1. INTRODUCTION

The dolos armour unit has been used widely for harbour and shore protection works in various parts of the world (Zwamborn et al., 1980). Dolosse appear to provide an effective and economic means for protecting many small and medium-sized coastal structures, but, as these units are being used for increasingly larger projects in greater water depths and in more severe wave climates, serious doubts have emerged especially on, amongst other factors,

---

* Coastal Engineering and Hydraulics, National Research Institute for Oceanology, CSIR, Stellenbosch, Republic of South Africa

the structural behaviour of the units. The obvious answer to the more severe wave climates is to increase the unit size or mass. However, when the size of the dolos is increased, tensile stresses also increase which may result in breakages.

There are two possible solutions to this problem, namely, (1) reinforcing and (2) increasing the waist-to-height ratio of the units. This paper deals with model tests carried out to determine the effect on the stability of the dolos of increased waist thickness.

According to theoretical stability formulae, the mass of the armour block is inversely proportional to the third power of the relative block density (PIANC, 1976). It is, therefore, attractive and, in certain cases imperative (Standish-White and Zwamborn, 1978), to use a higher than normal block density. Some doubt has been expressed, however, about the validity of this proportionality as applied to dolosse (Zwamborn and Beute, 1972) and tests with regular non-breaking waves were, therefore, done to determine the effect of relative block density on the stability of dolosse (Zwambron, 1978 and 1980 and Zwamborn and Van Niekerk, 1982).

It is generally accepted that when the linear dimensions of a dolos block are increased to obtain a heavier block with better stability, the stresses in the block will increase if the shape of the block remains the same. To overcome this increase in stress the waist of a dolos must be thickened if reinforcing is not used. Zwamborn and Beute (1972) suggested that the following waist ratio for a dolos with a mass W be used:

$$r = 0{,}34 \sqrt[6]{W/20}$$

It was, however, uncertain what the effect of an increase in waist ratio would be on the stability of the armour; it was decided, therefore, to do tests to determine this effect.

2. TEST FACILITIES

Tests on both the block density and the waist thickness of the dolos were done in the 160 m long (effective length), 3 m wide and 1,1 m deep wind-wave flume in Stellenbosch (Figure 1). Only regular waves which were produced by a translatory wave board were used. Waves were recorded with temperature-compensated probes and wave height meters connected to standard chart recorders and/or an electronic microprocessor which processed the outputs from the probes to yield the heights of the incident and reflected waves and the reflection coefficient. During the wave calibration stage, the waves were measured at the place at which

the model slope would be positioned in the stability tests. During the actual tests, the waves were measured from a moving trolley in front of the model.

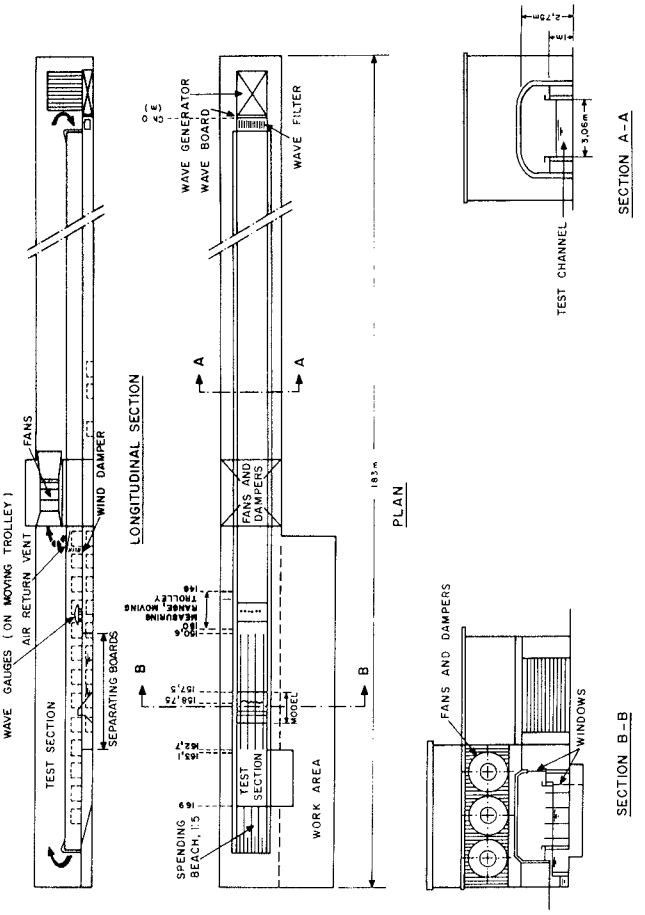

Figure 1 General layout of wind wave flume

3. MODEL LAYOUT

The flume was divided into three 0,75 m test sections leaving a dummy channel of about half that width on either side of the sections (Figures 2 and 3). The breakwater core was built of loose bricks and clean 6 mm stone. The underlayer consisted of 16,5 g sorted stone and the layer thickness was 43 mm. The top armour layer consisted of dolosse with a volume of about $35 \times 10^{-6} m^3$ during the block density tests and dolosse with a mass of about 81 g during the waist ratio tests. In both test series a 'mean' packing, $\phi = 1,00$ was used where (Zwamborn, 1980):

$$N_n = \phi_n V^{-2/3}$$

with N = number of dolosse per unit area
V = block volume
n = number of 'layers'.

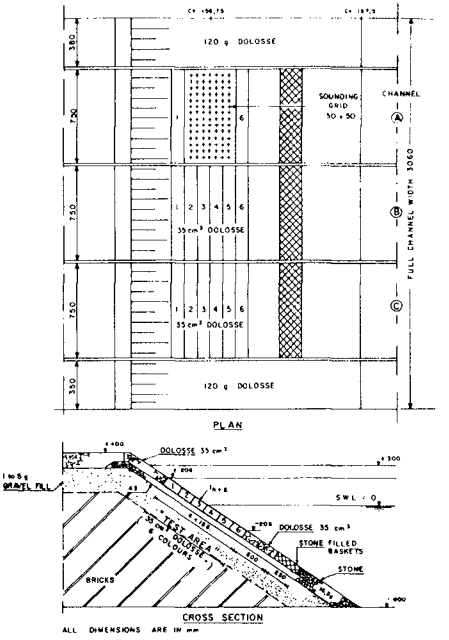

Figure 2 Model layout

Figure 3 General model view

The slope of the model was 1:1,5 and the depth of water was 0,8 m.

The test areas were 750 × 750 mm and the model dolosse were placed in six 125 mm (about 2 h, where h is the dolos height) wide bands of different colours, three above and three below still-water level, that is, 208 mm below to 208 mm above water (about 1,5 H_d, where H_d is the 'design wave height', Zwamborn, 1980).

4. TEST CONDITIONS AND PROCEDURES

All tests were done with regular waves of 1,75 s period, water depth of 0,80 m, and each test series consisted of 24 'bursts' of 2,5 min wave action for each wave height, namely, 49, 66, 83, 100, 117, 135, 152, 168, 185, 203, 221, 237 and 253 mm for the density tests and 75, 95, 115, 135, 146, 157, 173, 189 and 206 mm for the waist ratio tests. In the density tests the test series were repeated six to nine times and with the waist ratio tests nine repeat tests were done. During the repeat tests the test channels were alternated to eliminate the effects of the channels on the results.

With the above wave conditions the range of Ursell parameters used was 0,79 to 4,05 and of Iribarren number 2,9 to 6,6. Damage refers to the test section shown in Figure 2.

5. TEST RESULTS

5.1 Effect of Block Density

The initial tests with armour with block densities of 2,31; 2,41 and 2,57 indicated that increasing the density results in an increase in stability, but no clear relationship between dolos stability and block density could be established (Zwamborn, 1978 and 1980). Because of this, further tests were done with a much wider range of block densities, namely, γ_s = 1,81 to 3,02 (Zwamborn and Van Niekerk, 1982). The results of the latter tests will mainly be referred to in this paper.

Details of the model dolosse were as follows (based on 35 dolosse per density):

Model dolosse	W(g)	V($10^{-6}m^3$)	γ_s	h(mm)	r
Mean	62	34,2	1,81	59,6	0,32
Max deviation (%)	±1,45	±1,46	±0,83	±0,5	±1,5
Mean	83	34,8	2,39	59,2	0,33
Max deviation (%)	±3,25	±2,59	±2,15	±0,4	±5,3
Mean	106	35,1	3,02	60,1	0,32
Max deviation (%)	±2,55	±1,56	±1,10	±0,25	±1,7

The characteristics of the dolos armour for each test before wave action determined with the standard sounding technique (Zwamborn, 1978 and 1980), are given in the following table:

Test series D1,75		10	11	12	13	14	15	Mean
γ_s = 1,81	$t_{n=2}$ (mm)	75,6	68,5	72,2	70,0	68,6	71,3	71,0
	$C_{n=2}$	1,16	1,05	1,11	1,07	1,05	1,09	1,09
	P_f (%)	56,8	52,3	54,8	53,3	52,4	54,2	54,0
γ_s = 2,39	$t_{n=2}$ (mm)	73,4	69,2	68,9	71,1	66,7	70,5	70,0
	$C_{n=2}$	1,12	1,06	1,06	1,09	1,02	1,08	1,07
	P_f (%)	55,5	52,8	52,6	54,1	51,0	53,7	53,3
γ_s = 3,02	$t_{n=2}$ (mm)	71,1	73,8	67,2	71,5	67,1	70,8	70,3
	$C_{n=2}$	1,09	1,13	1,03	1,10	1,03	1,08	1,08
	P_f (%)	54,1	55,7	51,4	54,3	51,3	53,9	53,5

In the above tables:

W = dolos mass
V = dolos volume
h = dolos height
γ_s = specific block density
r = waist-to-height ratio
t_n = layer thickness
C_n = shape factor
= $\phi_n/n(1-P_f/100)$
P_f = fictitious porosity

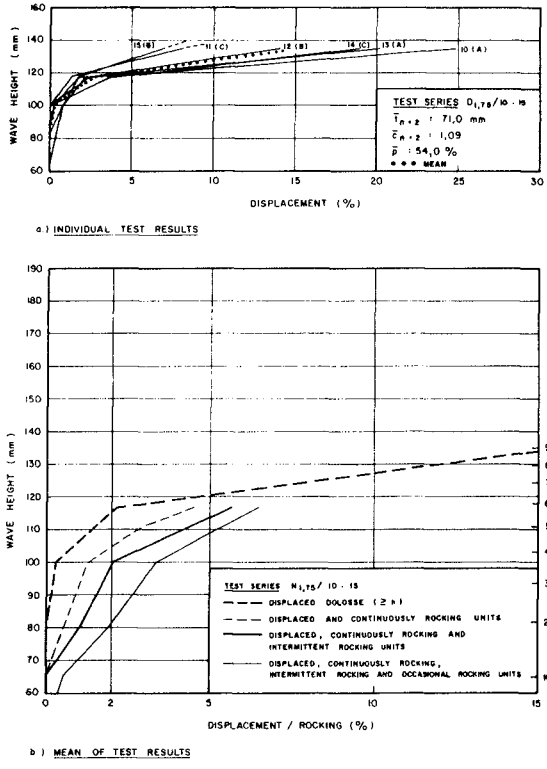

Figure 4 Test results with very light dolosse $\gamma = 1{,}81\ t/m^3$

The test results are plotted in Figures 4, 5 and 6 which show (a) the individual test results for displaced dolosse and (b) the mean results for displaced and rocking units. These figures show a considerable increase in 'damage' if the number of rocking units are included.

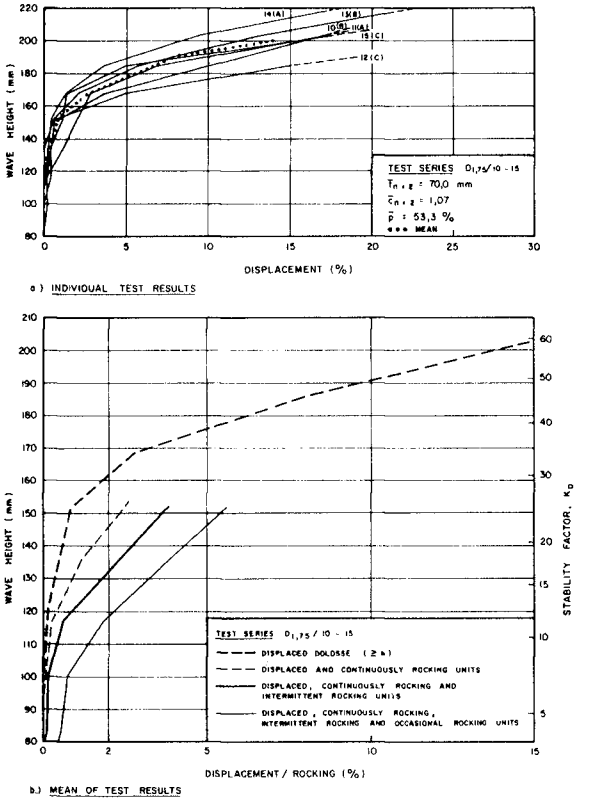

Figure 5 Test results with normal density dolosse $\gamma = 2,39\ t/m^3$

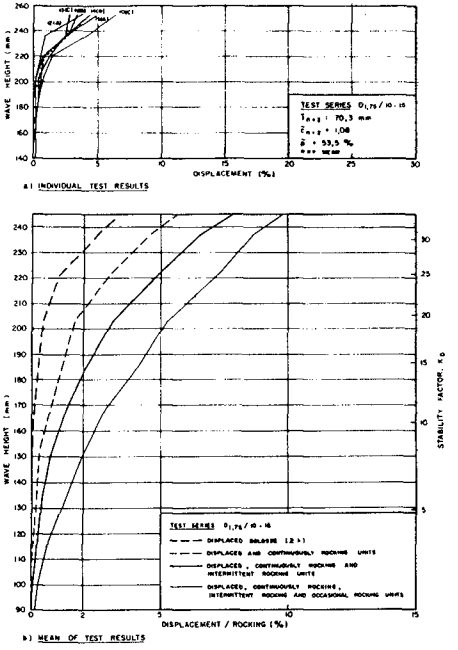

Figure 6 Test results with very heavy dolosse $\gamma = 3{,}02\ t/m^3$

The areal distribution of damage along the slopes is shown in Figure 7.

The mean and extreme values for displaced dolosse are compared in Figure 8. The mean values obtained in the initial tests are also shown in this figure from which it is clear that:

(i) initial and present test results compare reasonably well, particularly for the lower damage ranges;

(ii) there is a considerable increase in stability with increase in the density of the dolosse; and

(iii) an increase in damage from 1 to 5 per cent occurs for dolosse with

γ_s = 1,81 for a 13 per cent increase in wave height;
γ_s = 2,39 for a 15 per cent increase in wave height; and
γ_s = 3,02 for a 17 per cent increase in wave height.

The reserve stability for the heavier units is thus slightly greater but this is not considered to be very significant.

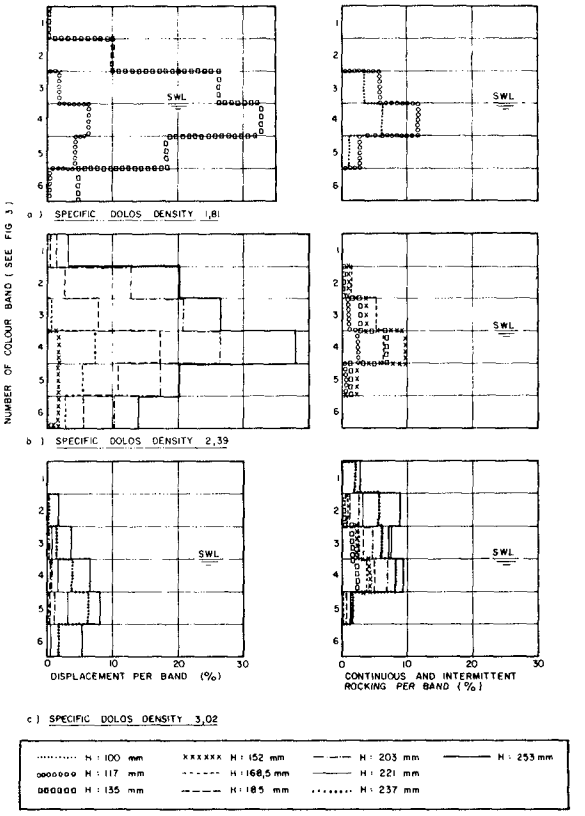

Figure 7 Block density tests - mean areal distribution of damage

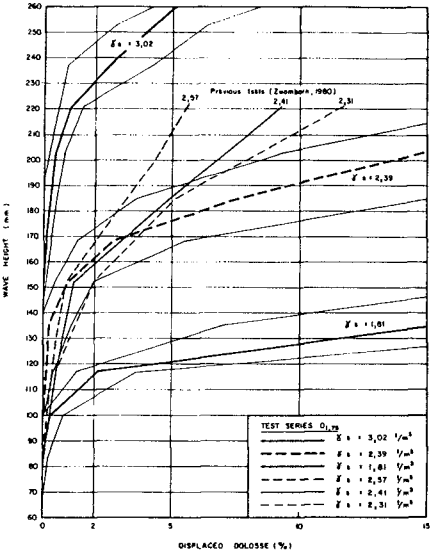

Figure 8 Comparison of mean and extreme test results for all unit densities tested

5.2 Effect of Waist to Height Ratio

Details of the model dolosse were as follows:

Model dolosse	W(g)	V($10^{-6}m^3$)	γ_s	h(mm)	r
Mean	80,9	34,50	2,34	59,3	0,33
Standard deviation	0,72	0,605	0,035	0,19	0,003
Mean	81,2	33,95	2,39	56,4	0,38
Standard deviation	2,30	0,785	0,047	0,18	0,004
Mean	80,4	33,47	2,40	52,9	0,43
Standard deviation	1,98	0,698	0,052	0,17	0,004

The characteristics of the dolos armour for each test before wave action, determined with the standard sounding technique, are given in the following table:

Test series R		1	2	3	4	5	6	7	8	9	Mean
r=0,33	$t_{n=2}$ (mm)	69,9	68,2	63,9	67,8	73,5	69,5	67,4	66,5	67,4	68,2
	$C_{n=2}$	1,07	1,05	0,98	1,04	1,13	1,07	1,03	1,02	1,03	1,05
	P_f (%)	53,4	52,3	49,0	52,0	55,7	53,2	51,7	51,0	51,7	52,2
r=0,38	$t_{n=2}$ (mm)	-	67,4	64,8	61,9	69,8	61,6	66,6	65,1	60,1	64,7
	$C_{n=2}$	-	1,04	1,00	0,96	1,08	0,95	1,03	1,00	0,93	1,00
	P_f (%)	-	52,0	50,0	47,7	53,6	47,4	51,4	50,3	46,1	49,8
r=0,43	$t_{n=2}$ (mm)	62,4	59,9	56,6	62,1	62,7	59,9	61,6	57,4	56,0	59,8
	$C_{n=2}$	0,97	0,93	0,88	0,96	0,97	0,93	0,96	0,89	0,87	0,93
	P_f (%)	48,3	46,2	43,1	48,1	48,6	46,2	47,7	43,9	42,4	46,1

The individual and mean test results of nine repeat tests for waist ratios r = 0,33; 0,38 and 0,43 are presented in Figures 9, 10 and 11.

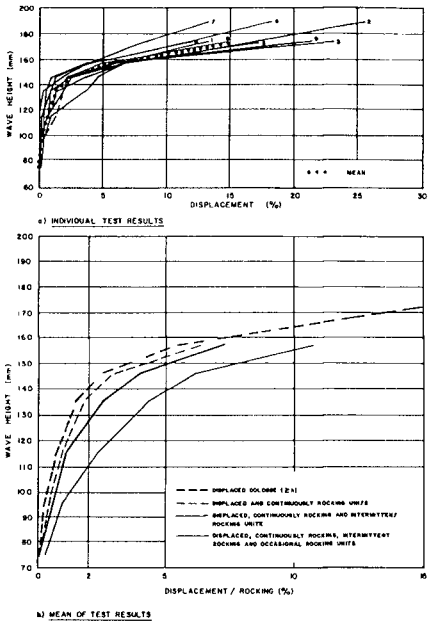

Figure 9 Test results with r = 0,33

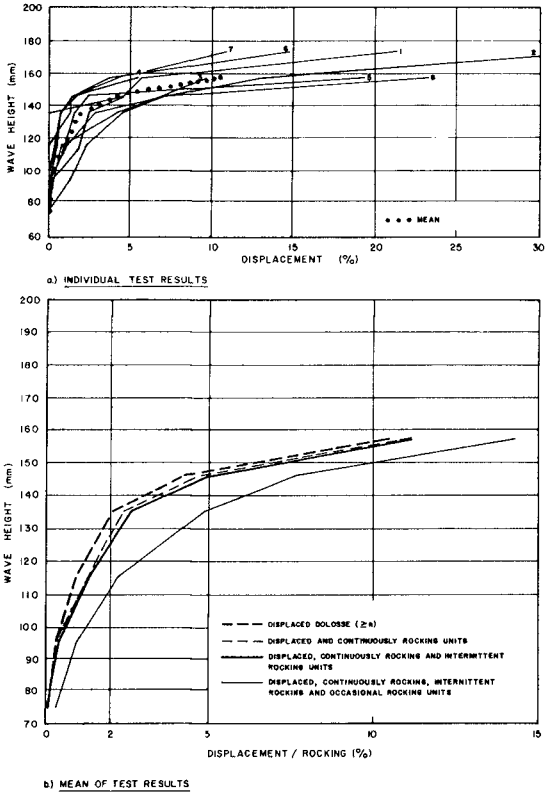

Figure 10 Test results with r = 0,38

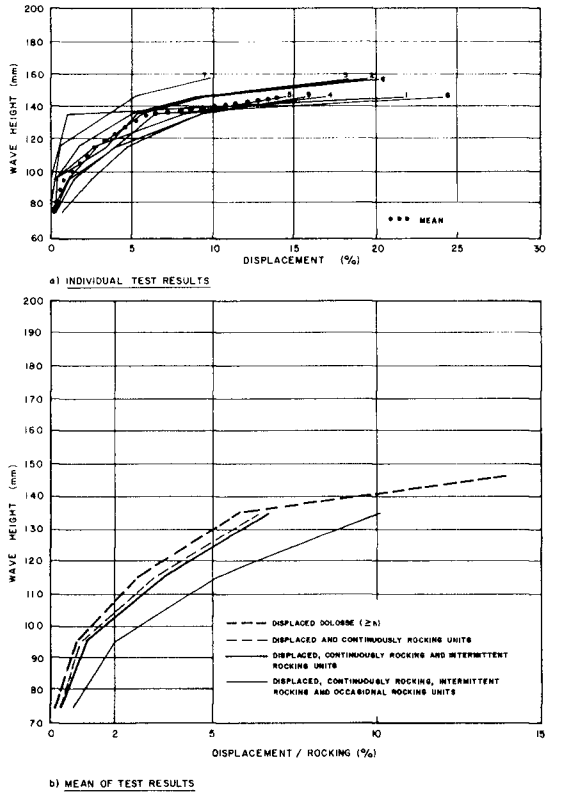

Figure 11 Test results with r = 0,43

The mean values for displaced dolosse for the three waist ratios tested are shown in Figure 12 for comparison. This figure indicates that there is a marked decrease in stability with r increased from 0,33 to 0,38 and a considerable decrease in stability with r increased from 0,38 to 0,43.

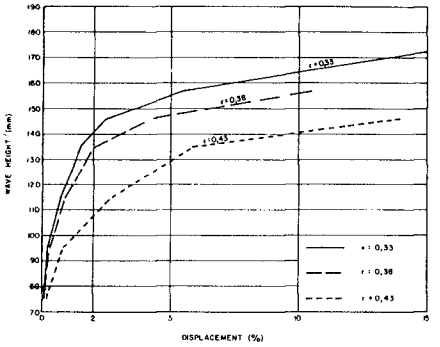

Figure 12 Comparison of mean test results for waist ratios tested

6. INTERPRETATION OF TEST RESULTS

6.1 Effect of Block Density

The basic stability equation may be written

$$\frac{V}{H^3} f(\alpha) = \frac{1}{K} \left(\frac{\gamma_s}{\gamma} - 1\right)^x = \frac{\Delta^x}{K} \quad \text{(Zwamborn, 1978 and 1980)}$$

This equation converts into the Hudson stability formula when $f(\alpha) = \cot \alpha$, $V = W/\gamma_s$, $x = -3$ and the constant $K = K_D$.

Since in the model tests the breakwater slope was always 1 in 1,5 ($\tan \alpha$), the effect of the slope, α, cannot be checked. By disregarding $f(\alpha)$ in the above equation, the tests with different γ_s values make it possible, however, to check the correctness of the remainder of the formula. Figure 13 shows the results of the initial tests (Zwamborn, 1978 and 1980) and of the new tests (Zwamborn and Van Niekerk, 1982) plotted as $V/H^3 \cot \alpha$ as function of $\gamma_s/\gamma - 1$ for 1, 2, 5 and 10 per cent damage (displaced dolosse).

Initially, curves were drawn through the test results excluding those for $\gamma_s = 1{,}81$ and these curves appeared to support the theoretical third power relationship, that is, $x \simeq -3$, for $\gamma_s > 2{,}3$ t/m^3 (Zwamborn and Van Niekerk, 1982). However, a statistical analysis of the test results showed that a significantly better fit was possible when

all test results are included, with the following resulting values for x and K (Figure 13):

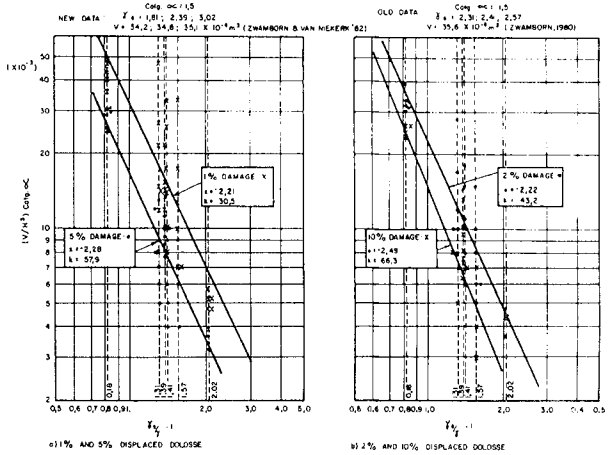

Figure 13 Relative dolos volumes versus relative density

Statistical values	Dolos displacements (%)			
	1	2	5	10
$-\bar{x}$	2,21	2,22	2,28	2,49
95% conf. lim.	1,18 to 3,24	1,78 to 2,66	1,92 to 2,64	1,87 to 3,11
$\bar{K}$	30,5	43,2	57,9	66,3

The mean value of the power x is therefore -2,30 (95% confidence limits 1,89 to 2,71) and not -3,0 and it thus appears that the theoretical equations (PIANC, 1976) and also Hudson's stability equation does not hold for dolosse, with respect to the effect of block density.

A comparison of earlier dolos tests (Zwamborn and Beute, 1972) also indicated a higher value of the power of the relative density (x > -3). Moreover, comprehensive tests on natural stone by Kydland and Sodefjed (Zwamborn, 1978) gave the following results (1 in 1,5 slope):

Power	Kydland		Sodefjed
	1% damage	4% damage	1% damage
-x	2,00	2,08	2,40

Thus the mean value for dolosse, $\underline{x = -2,30}$, compares reasonably well with the values for natural stone and it appears from this that the theoretical and Hudson's formulae **generally** overestimate the effect on stability of increased block density.

If the Hudson formula is adjusted for dolosse according to the above results, to determine the density effect, namely,

$$W = \frac{\gamma_s H^3}{K\Delta^{2,3} \cot \alpha}$$

corresponding values for K must be used and **not** the previous K_D values based on the Hudson formula. Values for K have been calculated for the test results and are plotted in Figure 14 as function of damage (per cent displacement). The data points for the different densities tested are all seen to fall in a relatively narrow band and the mean values can be used as first estimates for the 'stability factor', K.

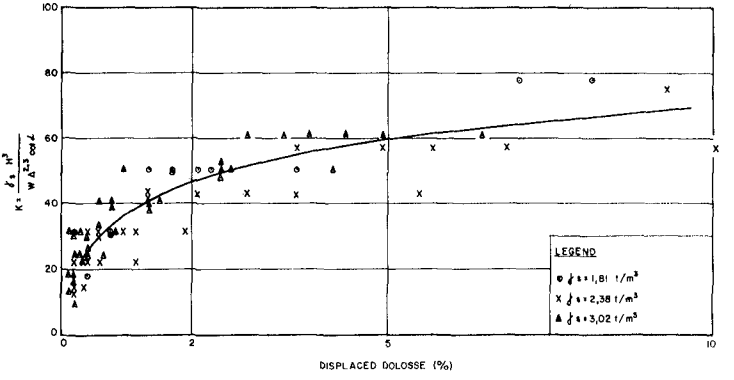

Figure 14 Comparison of stability factors, K, for different unit densities

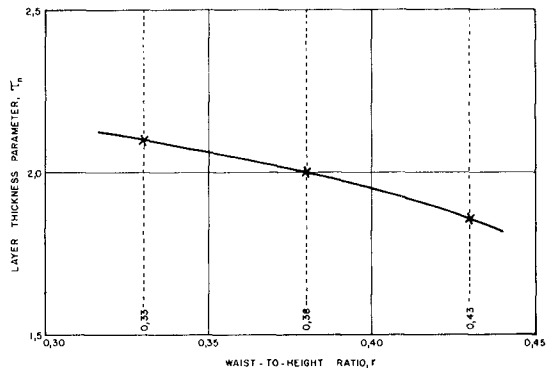
6.2 Effect of Waist-to-height Ratio

The test results show two effects of an increase in waist ratio, first, on the layer thickness and porosity and, second, on the stability of the dolosse. The layer thickness, shape factor and fictitious porosity are seen to decrease slightly with an increase in waist ratio from 0,33 to 0,43 (see Section 5.2). Since all dolosse had the same volume, this reduction was expected. The layer thickness is defined by:

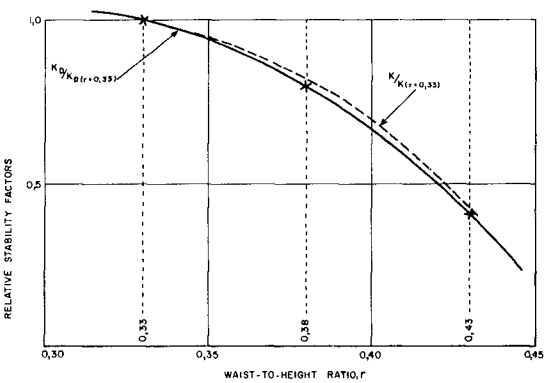
$$t_n = \tau_n V^{1/3}$$

where $\tau_n = nC_n$ = layer thickness for n layers. The following average values were found (see Figure 15a):

Waist-to-height ratio r	P_f (%)	$C_{n=2}$	$\tau_{n=2}$
0,33	52,2	1,05	2,10
0,38	49,8	1,00	2,00
0,43	46,1	0,93	1,86



a.) LAYER THICKNESS PARAMETER.



b) RELATIVE STABILITY FACTOR

Figure 15 Effect of increased waist ratio

Based on the test results, the relationship between the waist ratio (r) and the stability factors K_D and K are shown in Figure 15b. A marked decrease in stability occurs, especially when the waist ratio is increased to above 0,38. The reduction in stability is probably due to the loss in the interlocking ability of the units because of the thicker waist. If the waist ratio is increased further, the block will lose more of its interlocking ability and will ultimately resemble a cube which is totally dependent on its mass for stability.

Wave heights causing 2 per cent displacement in the model were converted to prototype values by adopting the waist ratio,

$$r = 0{,}34 \sqrt[6]{W/20}$$

suggested by Zwamborn and Beute (1972) and assuming γ_S = 2,40 and γ = 1,025. These results, presented in Figure 16, show that increasing the mass of dolosse above 40 t is much less effective in increasing stability then increasing the mass of dolosse below 40 t. It is also clear from this figure that the present data is insufficient to define the relationship between H and W and no attempt was therefore made to fit a curve through the data. To establish this relationship further tests will have to be done on dolosse with waist ratios of about 0,36 and 0,41.

Thus, when it is considered to use dolosse heavier than, say, about 40 tonnes it may well be more economical to use dolosse with reinforced thinner waists with correspondingly higher stability instead of a thick waist with lower stability. It must be stressed that Figure 16 is based on the relationship

$$r = 0{,}34 \sqrt[6]{W/20}$$

which was derived by accepting from prototype observations that 20-tonne dolosse with a waist ratio of 0,34 are strong enough to withstand stresses due to normal handling and design wave conditions. If, however, this would not be the case, for instance, a 15-ton dolos should rather have a 0,34 waist ratio, the W-H curve in Figure 16 will become lower.

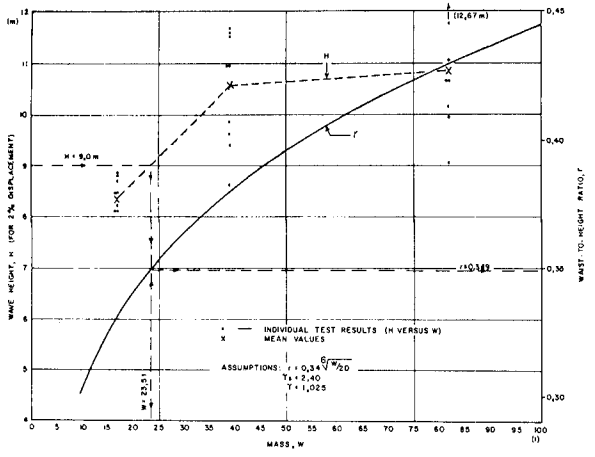


Figure 16 Relationship between H, W and r

7. CONCLUSIONS AND RECOMMENDATIONS

The initial tests with dolos armour with block densities of 2,31; 2,41 and 2,57 gave no conclusive results and further tests with dolosse with a larger range in block densities, namely, 1,81; 2,39 and 3,02 were done. These new test results showed clearly the effect of block density on the armour stability. The classic third-power relationship with regard to block density seems to over-estimate the effect of block density and a power of 2,3 was found to represent the test data better. The lower power agrees approximately with previous test results on natural stones and the theoretical stability equations, therefore, do not appear to represent the density effect correctly.

When high-density dolosse are used, care must be taken that they are at least as strong as the dolosse of normal density which can be achieved by increasing the waist-to-height ratio accordingly.

Test results showed that the stability of dolosse decreases as the waist ratio increases. Tests were done with dolosse with r = 0,33; 0,38 and 0,43 and K_D and K values for the latter two were found to be 20 and 60 per cent, respectively, smaller than the K_D value for dolosse with r = 0,33.

Further tests with waist ratios of about 0,36 and 0,41 would be needed to determine the reduction of stability more accurately.

Thus, when model tests are performed for a certain project, dolosse with the correct waist ratio must be used in the tests. If such dolosse are not available, the test results must be adapted to allow for the change in stability due to a different waist ratio tested.

To compensate for the larger tensile stresses in the heavier dolosse it has been suggested that the dolos waist ratio be increased according to the formula

$$r = 0{,}34 \sqrt[6]{W/20}$$

Because the stability decreases for the higher waist ratios, however, it was found that the stability of dolosse, designed accordng to this formula, increases very little when the mass exceeds about 40 t.

IMPROVEMENTS IN MODELLING RUBBLE-MOUND BREAKWATERS

G.W. Timco and E.P.D. Mansard*

ABSTRACT

Physical modelling is a technique which is commonly used in the design procedure of rubble-mound breakwaters. For reliable results it is necessary that the model tests accurately represent the prototype situation. In this paper, two significant improvements in modelling of breakwaters are presented. They are the generation of realistic sea states at the test site, and the simulation of the breakage of the armour units by using units which have mechanical properties properly scaled from the prototype units. These techniques have been used to study the recent breakwater failure at Rivière-au-Renard, Canada.

1.0 INTRODUCTION

A common method of protecting harbours and in dissipating wave energy in both inland and ocean ports is by the use of rubble-mound breakwaters. These structures are built up from the sea floor with specific profiles and material layers. Usually the uppermost armour layer consists of large quarry stones or specially designed concrete units. Depending upon the wave climate at the site, armour units can weigh as much as 100 tons. Recently there have been a number of breakwater failures causing enormous financial and environmental losses. Some of these breakwaters failed due to the breaking of individual concrete armour units during storm conditions with an eventual collapse of the structure as a whole. The design of a stable breakwater is a challenging engineering problem.

Physical modelling is a method frequently used to aid an engineer in the design of a rubble-mound breakwater. For this, a model of the proposed breakwater is geometrically scaled in a laboratory flume and subjected to similarly scaled wave conditions. In order to obtain reliable information from these types of tests, it is necessary that certain scaling laws are met. In particular, it is important that geometric (linear), kinematic (velocities) and dynamic (forces) similitude be preserved. This entails maintaining in the model test system, the relative importance of each of the independent forces acting in the prototype system. If all forces are in the same ratio, then the equations of motion will be the same everywhere in the model and prototype. The model and prototype will behave, therefore, in the same dynamical fashion. In early model tests of breakwaters, a regular wave

*Hydraulics Laboratory, National Research Council, Ottawa, Ont. K1A 0R6 Canada

train was propagated onto a scale model of the breakwater and before-and-after profiles were used to define the stability of the structure. In recent years, several important improvements in the modelling techniques have been developed including the use of "random" waves simulating the variance spectral density, damage criterion in terms of the rocking motion of the armour units, and careful selection of materials which influence the hydraulic stability of the breakwater. Although these improvements have contributed to better model-prototype conformity, there still remains a number of important parameters to be considered.

This paper addresses itself to two important improvements achieved by the Hydraulics Laboratory of the National Research Council of Canada in the techniques of physically modelling breakwaters. They are:

(1) the generation of realistic sea states at the test section of the flume, and

(2) the simulation of the breakage of armour units by using a material which has properties scaled from those of prototype concrete units.

In this paper, the details and significance of these two improvements are discussed. In addition, these modelling techniques are applied to a model test study at a 1:25 scale of the dolosse-armoured breakwater at Rivière-au-Renard, Quebec, Canada.

2.0 REALISTIC SEA STATES

Most hydraulic laboratories now have the capability of generating irregular waves for their experimental investigations. The normal practice has been, however, to describe the sea state solely by a variance spectral density and then to reproduce it in the model. Recent studies [Johnson et al (1978), Burcharth (1979)] have shown that simulating just the spectrum is not sufficient because a certain sequence of high waves occurring as a wave group can induce greater damage on the structure than equally high waves occurring individually in a wave train. The large number of high waves present as a sequence in the grouped wave train cause a continuous rocking and eventual displacement or breakage of armour units. Because of this effect it is desirable that the frequency as well as the time domain characteristics of the natural sea states are reproduced in the model whenever possible.

The phenomenon of wave grouping is well known to the oceanographers since prototype waves often exhibit distinct wave group patterns in their records. Considerable research has therefore been carried out in the past particularly to relate the broadness of the spectrum to the wave group characteristics. In fact, the traditional concept of representing the sea state by just its variance spectral density was based on the assumption that the spectral width is an indication of the degree of grouping such that a narrow spectrum corresponded to higher grouping. However, in a recent study Funke and Mansard (1980) showed that there is no apparent relationship between the shape of the spec-

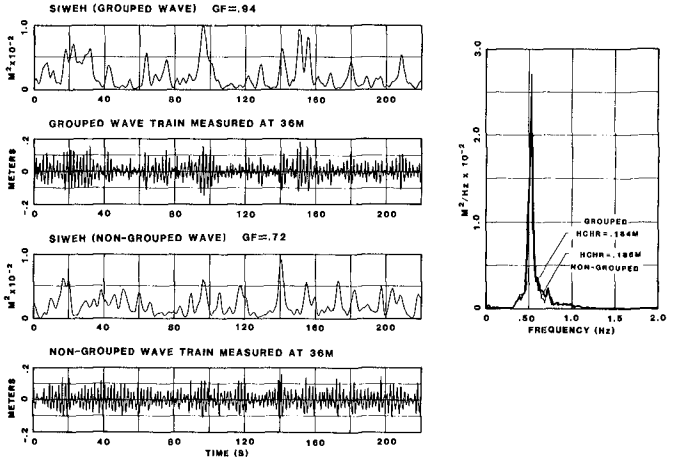

FIG.1 COMPARISON OF THE GROUPED AND NON-GROUPED WAVE TRAINS

trum and the amount of grouping in the wave train. Figure 1 presents two wave trains having a common variance spectral density but different degrees of grouping.

In order to have a physically meaningful description of wave group activity in a sea state, this Laboratory has developed the concepts of a Smoothed Instantaneous Wave Energy History (SIWEH) and a Groupiness Factor (GF). Both the SIWEH and the GF can be easily derived from the water surface elevations of the wave record (Funke and Mansard 1980). As illustrated in Figure 1, this SIWEH E(t) function, which represents the distribution of wave energy in the time axis, effectively describes the wave groups in a time series.

The concept of Groupiness Factor, developed as a tool to measure the degree of grouping in a sea state, is a dimensionless factor, describing the standard deviation of the SIWEH about its mean and normalized with respect to this mean.

The amount of wave grouping increases with increasing Groupiness Factor. Values of GF in the vicinity of 0.9 indicate highly grouped waves.

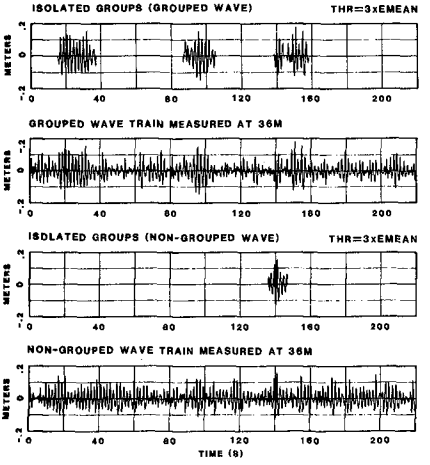

FIG.2 ISOLATION OF WAVE GROUPS

The SIWEH function can serve also as an effective tool to isolate wave groups in the time series. The groups shown in Figure 2 were isolated using a concept of threshold for the SIWEH. Any wave sequence which caused the SIWEH to exceed a given threshold (3*E in this case) was defined as a wave group event.

Because it is often not possible to obtain prototype wave records for a desired location of interest, this Laboratory has developed a synthesis technique to generate realistic sea states which include wave grouping. This technique, illustrated in Figure 3, provides the necessary tools for testing the stability of the various structures (be floating or fixed) for the wave grouping effects. The SIWEH spectral density shown in Figure 3 is a theoretical model often encountered in the linear dynamic system analysis. The expression for this SIWEH model is:

$$\varepsilon(\lambda) = \frac{1}{\sqrt{(1-\lambda^2)^2 + 4\zeta^2\lambda^2}} \cdot \frac{\lambda}{\sqrt{(1+\lambda^2)}}$$

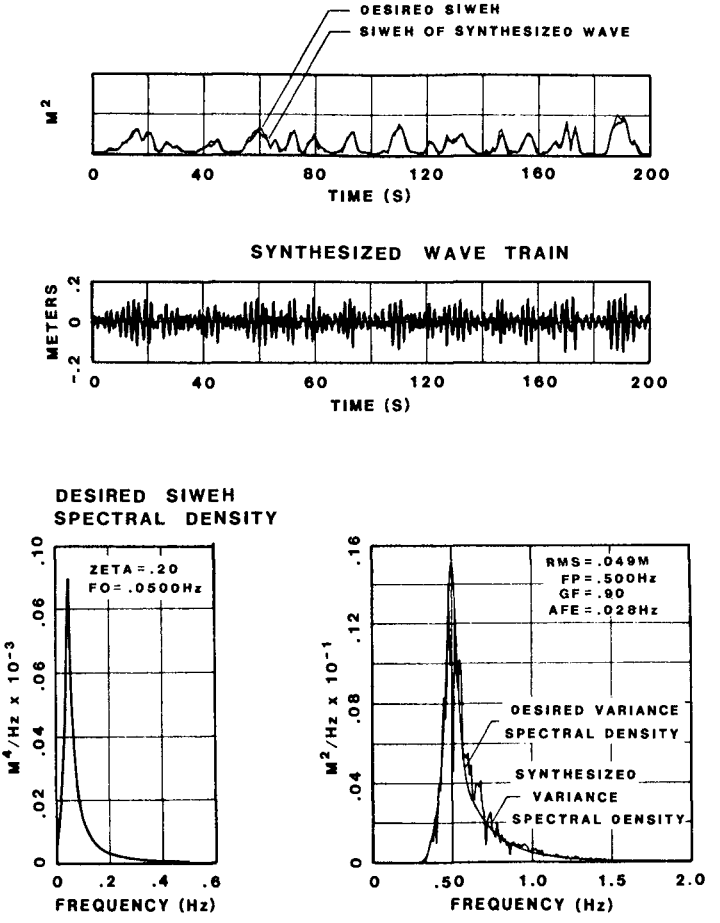

FIG.3 SYNTHESIS OF A GROUPED WAVE TRAIN

where $\varepsilon(\lambda)$ = SIWEH spectral density
λ = normalized frequency f/f_0
ζ = damping factor which controls the width of the spectral peak which occurs in the vicinity of $\lambda=1$. The smaller is ζ, the narrower is the spectral peak
f_0 = peak freguency for $\zeta=0$

The time history of SIWEH is derived from this spectral density through an Inverse Fourier Transform using random phases.

In the absence of prototype information on wave groups, this model could be used to synthesize time series with different grouping characteristics (GF) while maintaining a constant variance spectral density. The period of the groups can be changed by varying the peak frequency of this spectrum. The wave train shown in Figure 3 satisfies both the frequency domain characteristics of the desired spectrum and the time domain characteristics defined by the SIWEH function. This technique is well documented in Funke and Mansard (1980).

2.1 Reproduction of Wave Trains at the Test Section

When a time series (derived either from a prototype wave record or by synthesis technigue) is to be reproduced in the flume, it is necessary that it is realized at the test section rather than at the wave paddle. But in deep and intermediate water depths the various freguency components present in the sea state travel with their own celerities resulting in continually changing seguences of waves during propagation. However, it is found that these celerities can satisfactorily be described by the linear dispersion relationship. Hence, in order to achieve the desired time domain characteristics near the test section (which may be 30 to 50 m from the wave paddle), the inverse dispersion relationship is applied to the wave train, in order to account for the wave propagation. In addition to the propagation, it is found that important phase changes can occur in the various wave machinery components such as the servo hydraulics, wave paddle, analog filter, etc. Complex transfer functions (which include both the amplitude and phase compensations) are therefore applied to these various components while preparing the driving signal. This technique has been found to be quite successful in reproducing various sea states and even extreme waves in the Laboratory.

Figure 4 compares a prototype wave record with a wave record measured at 36 m from the wave paddle in the model. The severe seguencing of prototype waves has been well preserved in this reproduction of this time series in the wave flume.

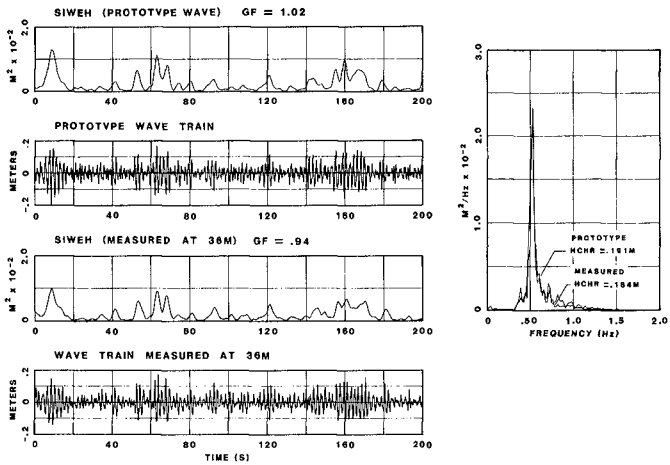

FIG.4 REPRODUCTION OF WAVE TRAIN IN THE FLUME

3.0 SIMULATION OF CONCRETE STRENGTH

In model testing of breakwaters, the interpretation of the results is very subjective. In early tests, the stability of a particular design was usually determined by a comparison of before-and-after storm profiles of a section of the structure. More recently, the stability has been defined subjectively as the onset of rocking of the armour layer. Neither of these techniques is satisfactory. This is so because a common failure mode of prototype breakwaters occurs through a deterioration of individual armour units with pieces breaking off and hammering against other larger units. In addition, the constant slight flexing and continual motion of the units during a storm result in a reduction in strength (and ultimately failure) due to slow propagation

of cracks. These two failure modes, although undoubtedly important in the prototype system, are not considered at all in geometrically scaled model tests. In order to simulate these conditions in a model test, it is important that some of the physical properties of the armour units scale by the linear scale factor (λ). In particular, the strength and strain modulus must be scaled whereas the density, Poisson's ratio and frictional factors must not. To date, this has not been done due to the lack of a material which would simulate homogeneously these properties of concrete on a reduced scale. Because of the many advantages of using strength-reduced armour units in model tests, a project was initiated to develop a material which would simulate the properties of concrete for this type of model testing. In this section, the development and properties of this material are briefly discussed.

3.1 Modelling Laws

The first step in developing the model material is to define the appropriate scaling laws and to define representative concrete (i.e. prototype) mechanical properties to which the scaling laws are applied. This defines the properties of the model material.

In model tests, the forces of interest are the gravity (weight), inertial, elastic and frictional (viscous). In order to maintain the relative importance of each of these in the model regime, it is necessary to maintain the Froude number (inertial forces/gravity forces), the Cauchy number (inertial forces/elastic forces), and the Reynolds number (inertial forces/viscous forces). Since it is not possible to simultaneously satisfy all three of these numbers, a compromise is made and the model tests are scaled according to Froude similitude. This is done since gravity and inertial forces predominate. As a consequence of this, the physical properties of the model armour units must meet certain well-defined requirements. In particular, the properties of the model (m) material must scale from the prototype (p) concrete values as

mass	$m_m = m_p/\lambda^3$
density	$\rho_m = \rho_p$
flexural strength	$\sigma_{fm} = \sigma_{fp}/\lambda$
tensile strength	$\sigma_{tm} = \sigma_{tp}/\lambda$
compressive strength	$\sigma_{cm} = \sigma_{cp}/\lambda$
elastic (Young's) modulus	$E_m = E_p/\lambda$
fracture toughness	$K_m = K_p/\lambda^{3/2}$
Poisson's ratio	$\mu_m = \mu_p$
friction	$f_m = f_p$

where λ is the scale factor of the test. For proper results in the model regime, the properties of the armour units must meet these requirements.

3.2 Mechanical Properties of Concrete: Prototype Values

Before it is possible to model the properties of concrete, representative values of the properties must be defined. However, concrete is a complex mixture of calcium silicates and aluminates cement, sand, stone and water. As such, by altering the relative proportions of each of these constituents, the properties of concrete can be varied over a wide range. Moreover, the properties of concrete are known to be affected by temperature, loading rate, moisture content, sample size, etc. This does not allow unique, unambiguous values to be defined. However, since the variation of the properties is reasonably systematic, such that conditions which lead to high compressive strength (say), also lead to high flexural and tensile strengths, representative values can be defined in this way. In the prototype system, usually high quality (35 MPa minimum compressive strength) concrete is used. Assuming a high quality concrete, the relevant properties of concrete, as determined from surveying the literature (Gonnerman and Shuman, 1928; Neville, 1977; Jayatilaka, 1979) as well as the required properties of the model material for two scale factors (λ=20 and λ=40) are

	Concrete	λ=20	λ=40
compressive strength (MPa)	31-38	1.6-1.9	.78-.95
flexural strength (MPa)	4.1- 4.7	.21-.24	.10-.12
tensile strength (MPa)	2.4-3.0	.12-.15	.06-.08
density (g/cc)	2.2-2.5	2.2-2.5	2.2-2.5
elastic modulus (static) (GPa)	29-32	1.5-1.6	.73-.80
elastic modulus (dynamic) (GPa)	43-47	2.2-2.4	1.1-1.2
fracture toughness (MPa-$m^{1/2}$)	.45-1.4	.005-.016	.002-.006
Poisson's ratio	.11-.21	.11-.21	.11-.21

3.3 General Consideration for Producing Strength-Reduced Armour Units

As a further restriction in defining the properties of model armour units, it would seem that in addition to the physical properties which the material must have, it must meet the following conditions:

(1) The material should be macroscopically homogeneous throughout.

(2) The material must be readily mouldable since armour units may have unusual shapes.

(3) The material must be able to be removed from the mould without breaking.

(4) The units made from the material should be relatively quick and easy to make since a large number would be required for a breakwater study.

(5) The material should be reasonably economical.

(6) The material should be non-toxic, non-corrosive and not break up into uncleanable debris.

(7) Since the tests are performed in water, the material must have relative stability in water over a reasonable time span.

In reviewing the properties which model armour units must have, it is clear that no "standard" material has these properties. Usually, for example, relatively weak materials have relatively low densities. As such, it was decided to try to develop a material which would meet as many of the properties as possible. Since one wants a structurally weak, yet dense material, this suggests that a reasonable approach to take would be to choose a binder (matrix) material which is filled with cohesionless inclusions. In this case, the strength of the material would be proportional to the volume porosity of the binder, i.e.

$$\sigma = \sigma_0 \ (1 - \psi)^n$$

where σ = strength of the material, σ_0 = strength of matrix material, ψ = volume of cohesionless material, and n is some exponent. In this way, the strength of the overall material can be decreased by decreasing the amount of matrix material, whereas the density of the overall material can be increased by increasing the density of the filler (inclusions) material. If the particle sizes are small enough, this will result in a homogeneous mix. Such an approach should allow enough flexibility for proper scaling of some strengths and density over a range of scaling factors.

In choosing a binder material for these tests, the general properties of the material (as discussed above) were considered. Although it is possible to choose any number of binder materials (such as waxes, cement, sulphur based binders, etc.), it was decided that a matrix of gypsum plaster ($CaSO_4 \cdot 1/2\ H_2O$) would best meet the requirements for a suitable matrix. This is so since it is economical, easily mouldable, fast setting, requires minimal equipment, etc. With regard to the filler, sand was chosen as a reasonable material to start with.

In setting up these experiments, it was decided that the density and flexural strength were two properties which were essential to scale properly. Clearly, if the density is incorrectly scaled, the armour units will not respond to the incident waves as they should. In observing failures of prototype armour units, it would seem that although there are undoubtedly several failure modes, crack propagation due to flexure (tensile) stresses is a predominate failure mode. This suggests that this failure mechanism must be properly scaled. To this end, a series of experiments were performed to measure the density and flexural strength of a number of different mixtures of plaster, sand, water and several other constitutents. This was done by weighing out the proper amount of each of the ingredients and mixing them to form a creamy paste. This paste was then poured into bar-shaped moulds 2.5 x 2.5 x 30 cm made out of aluminum and allowed to set overnight. A thin film of light oil was used as a parting agent. The bars were then removed from the mould and both the flexural strength and density of the bars were determined. In these tests, it was found that by decreasing

the amount of plaster in the mix, the strength of the resulting material could be reduced to the desired range; whereas by increasing the density of the aggregate mix (by adding iron ore ρ = 5.0 g/cm^3), the density could be increased to the proper range for concrete. Unfortunately, due to limitations in space, the complete details of the development and the variation of the properties of the model material with changes in constituent proportions, cannot be reported here. However, the recipe and complete information on the behaviour of the model material can be obtained from the senior author (Timco, 1981a).

3.4 Properties of Model Material

Before using this model concrete material in breakwater tests, it was necessary to know all of its mechanical properties. However, because of the mechanically weak nature of the material, testing of its mechanical properties is quite tricky. For example, at λ=50, a bar of this material 2.5 cm x 2.5 cm x 6 cm, if held at one of the square ends, would not support its own weight. In order to determine the properties, a series of tests were performed similar to those used to document the properties of "model ice" (Timco, 1981b). The full details and results of the tests on the model concrete will not be reported here. They can be found in Timco (1981a). Instead, only the salient features will be presented. In brief, for scale factors of $40>\lambda>20$, the properties of the model material can be summarized as follows:

Density - By properly choosing the ingredients in the mix, the density scales correctly for any scale factor.

Flexural Strength - Since the flexural strength is directly defined by the scale factor, it scales correctly for any scale factor.

Tensile Strength - The tensile strength is related to the flexural strength, and in testing using the ring-tensile test, it scales well for any scale factor.

Compressive Strength - Tests of the compressive strength were performed at two loading rates. In general, it is strain-rate independent and overscales (i.e. is too low) over the whole range of scale factors.

Elastic (strain) Modulus - Tests of the modulus were also performed at two loading rates. At very high rates (ultrasonic), the elastic modulus underscales; whereas at lower rates, the strain modulus overscales over the whole range of scale factors.

Fracture Toughness - The fracture toughness (i.e. resistance to fracture by crack propagation) scales correctly over the whole range of scale factors.

Frictional Properties - The frictional properties scale well over the range of scale factors.

Erosion - Because the amount of binder in the material is necessarily low (in order to produce the low strength), the material does not have good resistance to erosion. This limits the time span in which a model test can be performed (usually less than one hour).

Pourability - In the fluid state, before setting, the material has a low viscosity and can be cast in any shape (see Figure 5).

FIG.5 PHOTOGRAPH OF STRENGTH-SIMULATED MODEL DOLOS , CUBE D'ANTIFER AND TETRAPOD

Setting Time - The material has its initial set within 15 minutes of pouring. After this time, the unit can be removed from the mould.

Cost - The cost of the basic ingredients for these model armour units is extremely low (≈$0.10 each). However, the labour charge and non-reusability of the units significantly increases the overall cost of production.

Shelf-life - After making the armour units, they can be stored on the shelf for at least four months before testing in the flume.

In total, this material has all of the important mechanical properties correctly scaled. As such, if it is used conscientiously in

model testing of rubble-mound breakwaters, it should significantly improve the model results. Failures due to tensile cracking and flexing of the armour units due to both static and dynamic loads should be well simulated if the proper scale factor is chosen. The use of this material in model testing is a definite improvement in the physical modelling of rubble-mound breakwaters. Model tests using this material in the armour layer should give good insight into the structural stability of any proposed breakwater design.

4.0 RIVIERE-AU-RENARD BREAKWATER STUDY

In order to apply these two new modelling techniques to breakwater studies, a test was performed on a 1:25 scale of the breakwater at Rivière-au-Renard, Quebec, Canada. This breakwater was chosen since it has recently failed and new designs are currently being tested for its repair (Glodowski et al 1982). This breakwater is 0.5 km long with an armour layer primarily composed of 5 tonne dolos units. In failure, many of the dolosse have broken especially near the mean water level (MWL) resulting in a slumping of the structure in several locations. The water depth at the breakwater site is 6 m which represents a depth limited situation. Many wave spectra typical of that location were tested. Since it was a depth limited situation, there was considerable wave breaking near the structure. The results presented below correspond to a JONSWAP spectrum having a peak period of 11.6 s and a characteristic wave height of 4.9 m. In performing the tests, two different test set-ups were used. For the first test, a cross-section of the breakwater was built using regular (i.e. not strength-reduced) dolosse. During the storm conditions, there was some rocking of several of the dolos units. At the end of the storm, however, there was no change in the initial cross-section of the structure. Assuming that some rocking of these low mass dolos units is allowable without causing breakage, this test would suggest that this was a stable breakwater design. For the second test, the breakwater was rebuilt using the strength-reduced units. During the storm conditions in this test, there was a number of dolosse which were rocking and hammering on other units without intially breaking. As the storm progressed, as a result of the constant hammering, first one, and then a second unit, broke in the area of the centre of the flume. These breakages started an "unlocking" of the units such that at the end of the test, there were numerous broken units in this region and a large area of the underlayer was exposed (see Figure 6). After the storm, there were five features of the model test which were in agreement with the prototype: (1) the dolosse at the top were mostly intact and slightly pushed back; (2) there was dolosse breakage at the MWL; (3) the dolosse were pulled out of that region resulting in some exposure of the underlayer; (4) the units well below the MWL were intact without substantial movement from their original position; and (5) there was a general slumping of the breakwater as a whole. In addition to this, however, in some cases there were compression-type failures of the units evident which were not observed in the prototype. This results from an unavoidable overscaling of the compressive strength of the model material. The results of this test clearly showed the rapid deterioration of the breakwater as a whole once the individual dolos started to break due to the rocking under wave attack. Once breakage of the units occurred,

the stability and usefulness of the breakwater was substantially reduced. This test indicated that, as originally designed, the breakwater would fail under the severe storm conditions encountered in that region.

5.0 SUMMARY AND CONCLUSIONS

Two improvements in the techniques of modelling rubble-mound breakwaters have been discussed and applied to the study of a model of a dolosse-armoured breakwater. These improvements, the simulation of both realistic sea states and breakage of the armour units, if used conscientiously in model testing of rubble-mound breakwaters, should significantly improve the accuracy of the model test results.

PROTOTYPE TESTING OF DOLOSSE TO DESTRUCTION

T. Terao[1], K. Terauchi[2], S. Ushida[3]
N. Shiraishi[4], K. Kobayashi[5], H. Gahara[6]

ABSTRACT

The Dolos, a type of armor unit, has been used widely for breakwater and shore protection works in the world. However, it has been reported that the armor layers of several breakwaters have been damaged by wave action, and it is probable that the breakage of Dolos has been the cause of that failure.

In this paper, static and dynamic tests using Dolosse units are described. 4t reinforced units and 4t, 0.4t and 0.04t unreinforced units were used.

In these tests, concrete surface and reinforcing bar stress of Dolos, and impact load were measured.

The results of these tests were as follows:
(1) From the both tests i.e. the static load test and the drop test, stress was greatest in the corner between the chamfer and the stem. Cracks occurred at this point.
(2) In the static load test, comparing the results of both units with reinforced and unreinforced chamfer, it became clear that the reinforcement of the chamfer could reduce the magnitude of the stress concentration.
(3) In the drop test, the drop height which made cracks was almost constantly independent of the weights of the units. And it could be considered that there was little influence of increasing the concrete strength as to the breakage of Dolos

1. INTRODUCTION

used at many port and harbor locations (1, 2). However, recently, it has been reported that the armor layers of several breakwaters have been damaged by wave action (3), and it has been considered that the breakage of Dolos is one probable cause of this damage. Consequently, the problem related to the structual strength of Dolos has been discussed. O.J. Lillevang and W.E. Nickola (4) examined the stress distribution of Dolos model with some shapes of chamfers under static load by using the three-dimensional photoelastic stress analysis, and suggested the shape of the chamfer to reduce the concentration of the tention stress. H.F. Burcharth (5) did the drop and pendulum tests using 1.5t to 20t Dolosse, and proposed a method for the design of impact loaded Dolosse. C. Galvin and D.F. Alexander (6) proposed a theoretical relationship between wave height and concrete strength of armor units. And there were some papers of tests related to the breakage of Dolosse prior to using them to breakwaters, for example, S. Barab and D. Hanson, C.A. Walter and D.R. Clark (7, 8).

In the case of a composite type breakwater with armor layer which are filled completely with armor units of the same size, it is considered that the lowest units will be subject to the static load caused by the dead weight and the units of the exposed side will suffer from the impact load resulting from rocking.

As armor units in these two situations are prone to some damage, we made static load and drop tests using Dolosse and also measured the stresses in some parts of units.

2. TEST CONDITIONS AND PROCEDURE

Assuming the load conditions, two different types of tests were performed. The static load test was performed to simulate the condition of a dead load of units caused by settlement, and the drop test was instigated to simulate the impact resulting from rocking under wave action. Fig. 1 shows the test methods.

4t reinforced and 4t, 0.4t and 0.04t unreinforced units were used in these tests. The waist ratio was constant at 0.32. Table 1 shows the test program, Fig. 2 shows the geometry of units, and Table 2 shows the mix proportions of concrete. Tensil strength test results of steel bars and bar arrangement drawing are given in Table 3 and Fig. 3, respectively.

In the static load test, the vertical fluke of the unit was fixed by a support equipment. There were two different loading conditions. One was imposed on the mid point of the horizontal fluke and the other was on the tip point. A hydraulic jack was used for loading. Photo. 1 shows the

situation of the static load test.

In the case of the drop test, the horizontal fluke was supported in a way to keep the stem level. Then, the vertical fluke was lifted up to a predetermined height and dropped onto a concrete slab of 1 meter thickness by use of a quick release device. Drop height started at 2 cm and increased every 2 cm. Some of the drop test units were provided with load cells at the bottom of the vertical fluke to measure the impact load. Photo. 2 shows the situation of the drop test.

In both tests, several strain gauges were placed on the reinforcing bar and the concrete surfaces of each test unit in order to measure the strain.

3. TEST RESULTS

3-1 Static load test

3-1-1 In the case of imposing a load on the mid point of the horizontal fluke

Stress concentrated on the corner between the chamfer and the stem due to the bending force. Cracks occurred at this point. Photo. 3 shows the breakage of Dolos. From the results of unreinforced units shown in Table 4, it is considered that the ultimate imposed load which caused cracks increased slightly as the compressive strength of concrete increased. Fig. 4 shows the relationship between the concrete surface stress and static load.

In the case of reinforced units, cracks appeared in that corner under the static load which was almost as large as the results of unreinforced units. Fig. 5 and 6 show the stress distribution of the reinforcing bar using the units with the chamfer reinforced and unreinforced, respectively. Stress concentrated on the corner revealing themselves as corresponding cracks.

In the case where the chamfer was not reinforced, the reinforcing bars placed at the stem yielded under a smaller imposed load compared to that of the reinforced chamfer. It is apparent that reinforcement of the chamfer is effective.

3-1-2 In the case of imposing a load on the tip point of the horizontal fluke

The results of cracking were different between 92 kg/m^3 and 151 kg/m^3 reinforcement units.

In the case of the 92 kg/m^3 reinforcement unit, cracks occurred in the corner between the chamfer and the stem, and

Weight (t)	Design compressive strength (MPa)	cracking static load (kN)	Breaking static load (kN)
4	20.6	61.7	73.5
	29.4	71.5	80.4
	39.2	80.4	93.2

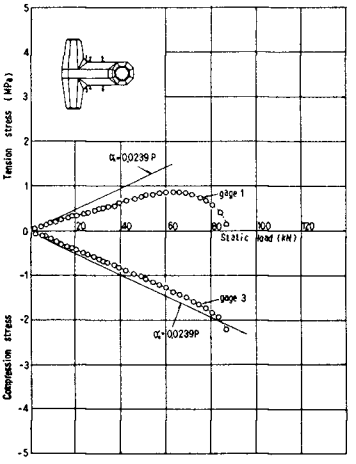

Figure 4 Relationship between concrete surface stress and static load

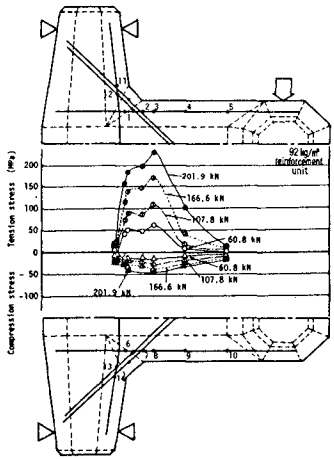

Figure 5 STRESS DISTRIBUTION OF REINFORCEMENT
(Imposed on the mid point of the horizontal fluke)

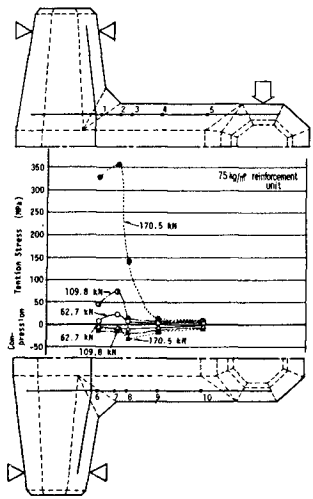

Figure 6 STRESS DISTRIBUTION OF REINFORCEMENT
(Imposed on the mid point of the horizontal fluke)

progressed toward the stem at 45°. Ultimate breakage was identified as shear rupture due to bending and torsion forces. Photo. 4 shows the cracks of the stem. Fig. 7 shows the stress distribution of the reinforcing bar. From the result of the relationship between the reinforcing bar and static load shown in Fig. 8, the stem and chamfer bars placed at the corner section ultimately yielded at about 170 KN.

While in the case of 151 kg/m^3 unit, cracks appeared in the corner with a small imposed load, and thereafter new cracks occurred and progressed inthe stem at 45°. Ultimate breakage was identified as sheer rupture due to tortion force. Fig. 9 and 10 show the stress distribution of the reinforcing and static load, respectively.

3-2 Drop test

Cracks occurred in the corner between the chamfer and the stem identical with the results of static load test.

From the results of unreinforced units shown in Table 5, it is considered that the drop height which crack occurs is almost constant independent of the weight of the units and concrete strength. Photo. 5 shows the broken unit.

In the case of the reinforced units, stress concentrated on the corner and cracks occurred at this point, too. But the units didn't separate into two pieces. The stress distribution of the reinforcing bar is shown in Fig. 11.

Impact load and impact time were also measured by using load cells. Fig. 12 shows the relationship between the impact time of the load and the drop height. Fig. 13 shows the relationship between the impact time of the load and the weight of the unit. From these results, it can be assumed that the impact time of the load is almost constant independent of the drop height while using the same weight of the unit, and the ratio of the impact times is almost equal to the ratio of their characteristic length i.e. Dolos height.

From the results of the relationship between the maximum impact load and drop height shown in Fig. 14, it is considered that the impact load is proportional to the square root of the drop height and the ratio of the impact loads is equal to the square of the ratio of their characteristic lengths under conditions of the same drop height.

As the ratio of the concrete surface strain is almost equal to the square of the reciprocal of the ratio of their characteristic lengths under conditions of the same impact

load, the maximum strain on the concrete surface is proportional to the square root of the drop height as shown in Fig. 15. This results in the stress of the concrete surface being constant independent of the weight of the unit under conditions of the same drop height.

4. CONCLUSIONS

Stress distribution, the influence of the concrete strength and weight of unit for the breakage of Dolos, and impact load were obtained through these static load and drop tests.

The result of these tests were as follows:
(1) From the both tests, i.e., the static load test and the drop test, stress was greatest in the corner between the chamfer and the stem. Cracks occurred at this point.
(2) In the static load test, comparing the results of both units with reinforced and unreinforced chamfers, it became clear that the reinforcement of the chamfer could reduce the magnitude of the stress concentration.
(3) In the drop test, the drop height which made cracks was almost constant independent of the weights of the units. And it could be considered that there was little influence of increasing the concrete strength as to the breakage of Dolos.

A NUMERICAL MODEL OF WAVE/BREAKWATER INTERACTIONS

D. Ian Austin, AM, ASCE*
Roger S. Schlueter*

Abstract

A numerical model has been developed to simulate breakwater response to wave impacts with special reference to armor unit behavior and breakwater stability. The model uses a finite difference hydrodynamic code to follow the wave impacts and determine wave forces upon the breakwater components. A discrete element code models the breakwater response and motions. The model rationale and numerical basis are followed by three examples used in this, the concept validation, stage of model development.

1. Introduction

Failures of rubble-mound breakwaters, particularly those built with artificial armor units, have been occurring over the last decade. The much publicized major breakwater failure at Sines, Portugal (Edge and Magoon, 1979) has highlighted the problem. Damage assessment of the Sines event (PSID, 1979) funded by the National Science Foundation demonstrated that the design methods and philosophies which were used may have been inadequate. These methods have included use of the empirical Hudson's stability formula which links the slope of the breakwater face with the weight and stability coefficient of the armor units.

With introduction of artificial breakwater armor shapes, in particular the dolos unit (Merrifield and Zwamborn, 1966), much lighter armor units than the equivalent quarried rock armor have been used. The artificial units have dramatically increased interlocking abilities and hence larger stability coefficients. Thus, for a given design wave, Hudson's formula predicts a lighter unit than if a low stability coefficient typical of natural rock had been used. However, recent studies have concluded that artificial armor units are particularly susceptible to dynamic motions imparted by the inertial and drag forces of waves impinging upon a breakwater structure. Specification of artificial armor units for breakwater design demands better understanding of the structural loading phenomena on individual elements and the limitations imposed by the concrete and reinforcing properties.

* Dames & Moore, Suite 1000, 1100 Glendon Avenue, Los Angeles, California 90024.

This paper presents a numerical technique for studying both the behavior and overall breakwater stability under a variety of wave loadings and the behavior of individual armor units. A discussion of the numerical approach is followed by examples using simplified armor unit shapes and breakwater geometries. While the ultimate aim of this line of research is to be able to model, in three dimensions, breakwaters constructed using both existing and proposed armor units, the object of this paper is to show the feasibility of the adopted approach using two-dimensional examples. The computer model is structured in a modular fashion which allows additions and enhancements to be included as they are developed.

2. Numerical Approach

Consider a generalized breakwater cross section consisting of a wave breaking on a multilayered armored breakwater (Figure 1). The wave breaking process is highly non-linear, consisting of inertial and viscosity induced forces. A complex energy dissipation and force reversal process follows in the armor unit, filter layer and core regions. The armor units are designed to resist the forces but they will rock and possibly break if overstressed or improperly positioned. Such breakages aid or initiate larger failures.

Rather than attempt to model the complete wave/breakwater interaction with one computer code, an approach has been adopted which is believed will allow both theoretical and numerical developments in wave breaking analysis to be incorporated with a minimum of program restructuring. The wave/breakwater interaction is modeled by two distinct codes, one describing the wave action and forces, the second describing the armor unit behavior. At this stage of concept development, it is being assumed that the interactions can be decoupled for time periods on the order of the time between subsequent wave impacts. This assumption implies that the short term response of the armor units does not significantly alter the wave force field within these intervals. For non-catastrophic failure, the assumption is valid as armor movement is on the order of centimeters. In failure situations, the assumption is no longer valid. However, the decoupling assumption reduced computation time considerably during this concept validation stage of the model development. As model development progresses, full coupling will be introduced.

In formulating an numerical approximation to the physical system it was realized that a complete description of the wave forces does not exist. However, simplified numerical approximations to the wave breaking process can be made. The classical equations describing stress within a structural unit are well known and have been applied in a number of studies of breakwater armor units (e.g., Lillevang and Nichola, 1976).

2.1 Wave Forces

The wave forces resulting from impacts upon a breakwater type structure are calculated using a version of the finite difference

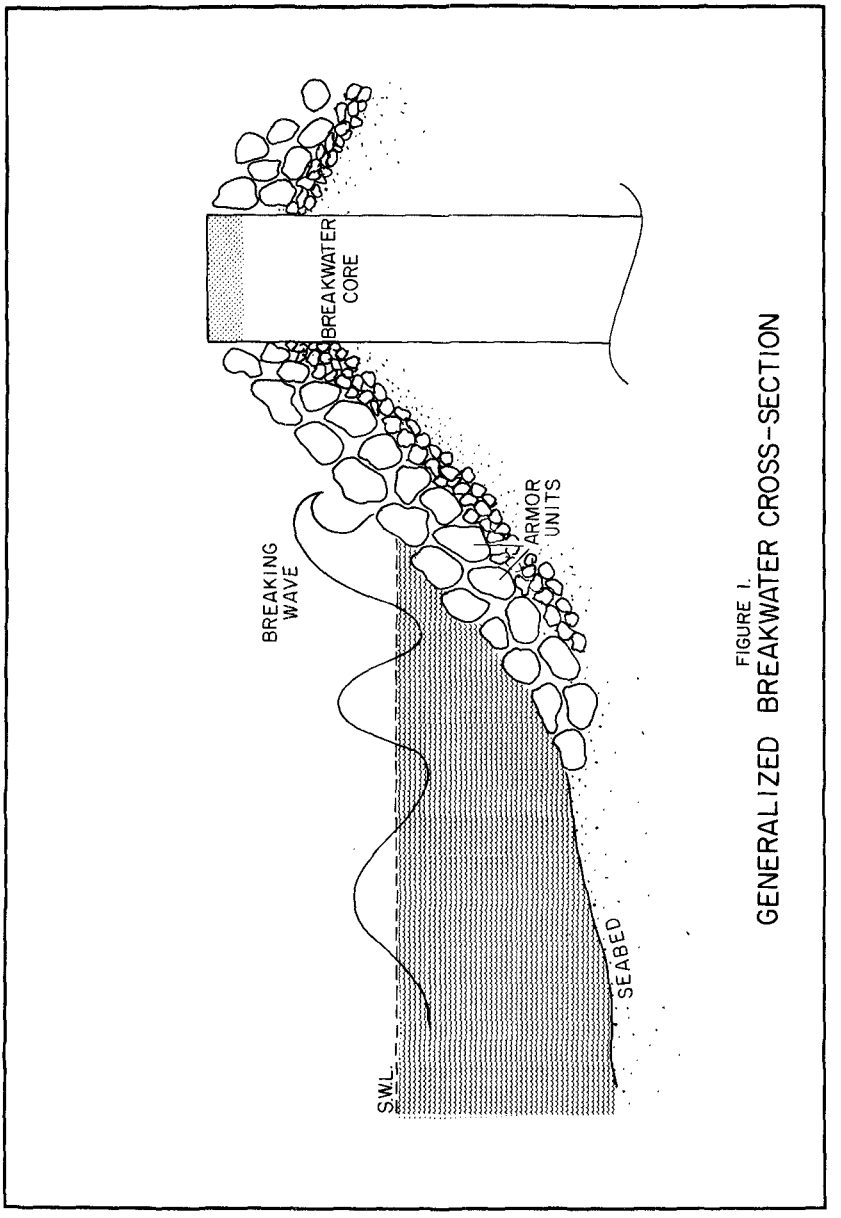

FIGURE 1.
GENERALIZED BREAKWATER CROSS-SECTION

computer code, SOLA-VOF, developed at Los Alamos Scientific Laboratories for solving transient fluid flow problems with multiple free boundaries (Nicholas et al., 1980). The constitutive equations used in the code are the Navier-Stokes equations and a form of the continuity equation which includes limited fluid compressibility (Figure 2). The feature of the program which makes it particularly useful in this application is the concept of the fractional volume of fluid (VOF). The "F" equation (see Figure 2) is used to describe the existence and position of a free surface within a finite difference cell. The value of F is zero in an empty cell and one in a full cell. A cell with a value between these limits indicates that a free surface (or boundary surface) exists in that cell. Because the free surface is defined in a cell by cell manner, multiple free surfaces can exist within a modeled region. As no a priori assumptions are necessary regarding the position of the free surfaces as it varies spatially or temporally, free surfaces can pass over or through a mound of obstacles.

At the current stage of development, obstacles to the water movement such as armor units are included as rigid zones within the modeling area. For non-failure conditions this approximation is reasonable. However in order to study the effects of rocking and failure, a more general movable description of the obstacles will be necessary. Forces on the obstacles are calculated by integrating the pressures around an obstacle. This method allows inertial effects to be included directly.

Wave loadings can be specified by a number of methods. In the examples to be shown, an initial water surface was defined with and without initial velocities. Alternatively, a pressure field can be used to initiate a wave response or a full description of internal velocities and surface elevations could be input. A random sea could be defined by the last method.

A simplified diagram of the program's operation is shown on Figure 3. The finite difference approximations to the momentum equations are first solved using the previous timestep values of velocity and pressure in the appropriate terms. After application of the boundary conditions, the continuity equation is solved in an iterative manner to obtain the new timestep values of velocity and pressure. Finally the F equation is solved for all cells. More explicit details of the scheme have been published previously (Nicholas et al., 1980).

2.2 Armor Units

The response and behavior of the breakwater armor units are modeled using a discrete element model originally developed for simulating jointed rock behavior (Cundall, 1980; Dames & Moore, 1981). The model calculates the individual armor unit (i.e., element) response to both the applied fores and the constraints of the surrounding units. The internal block stresses and inter-block fluid pressures can be calculated at each step in the armor unit

Navier-Stokes

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + g_x + \nu\left[\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right]$$

Continuity

$$\frac{1}{\rho c^2}\frac{\partial p}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$$

Volume of Fluid

$$\frac{\partial F}{\partial t} + u\frac{\partial F}{\partial x} + v\frac{\partial F}{\partial y} = 0$$

FIGURE 2. EQUATIONS USED IN FLUID CODE

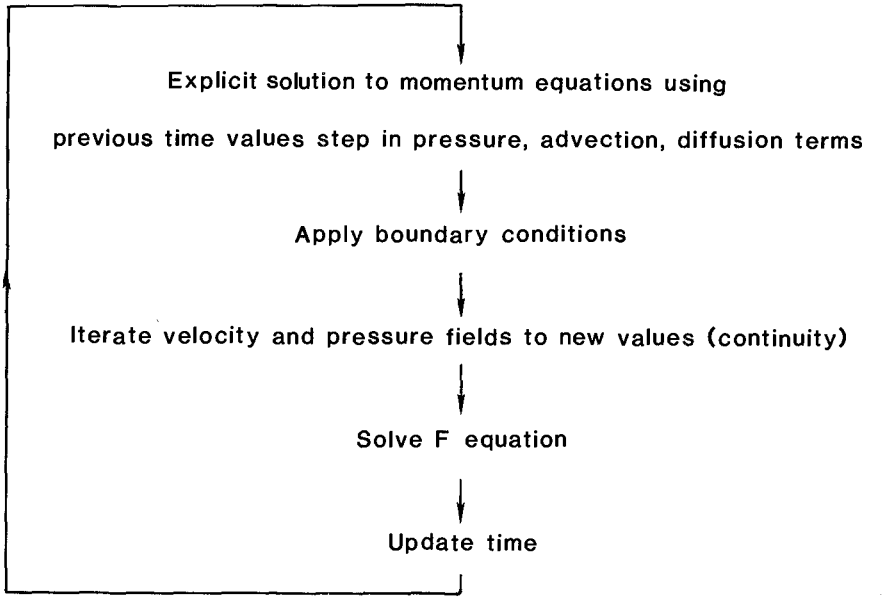

FIGURE 3. SIMPLIFIED CALCULATION CYCLE: SOLA-VOF

code. Joints between the units and corner-to-edge or corner-to-corner contacts are treated as boundary conditions between the units. Therefore the corner locking and frictional forces associated with breakwater unit interactions can be modeled correctly. By including fracturing and splitting within the discrete elements, failure of the armor units and/or the overall breakwater can simulated. The code uses a fully dynamic explicit scheme to solve the equations of motion thus allowing the true response of the units and the interactions to be followed. The basis calculation cycle is shown on Figure 4.

At the present stage of program development, armor unit shapes from discs to rectangles can be modeled. The discs are simulated by increasing the corner rounding, which is used to prevent elements "locking up", until a disc results. Further developments of the jointing or shaping aspects of the program, by which joints and hence blocks are defined, will allow more sophisticated armor shapes to be modeled.

3. Examples

Three examples of the current program configuration follow. The first two are essential revetment problems as a fully reflective boundary is assumed at the centerline of the "breakwater". In the third example, a breakwater is constructed by adding a "harbor" side to the revetment grid. In all cases, artificial spacing of the armor blocks in the fluid program is required to allow forces to develop around the blocks. The space is the result of modeling a three-dimensional problem in two dimensions. The breakwater geometries are extremely simplified - more so than the programs will allow - as these examples were aimed at concept validation rather than quantitative validation.

3.1 Revetment Example

The grid used in the fluid modeling is shown on Figure 5. The armor blocks are defined as rigid obstacles as is the revetment core. The armor units are 1.6 meters square. A wave loading is approximately by a 2.6-meter high "block" of water released in a manner similar to a dam break. One of the many verification cases of the fluid code included the reproduction of a laboratory dam break test. A no-flow boundary condition is used on all boundaries. As previously mentioned, the armor units are separated to allow fluid flow between the blocks. Snapshots of the fluid behavior are shown on Figure 6. This figure shows the initial block of water collapsing to form a "surging" wave.

The forces on the armor blocks developed during the wave impact and reversal are shown on Figure 7. Comparison of the force histories on Blocks 1 and 2 shows the expected force reduction on the second layer block afforded by the first layer block. A similar pattern can be seen in the force histories of Blocks 3 and 4. Blocks 1 through 4 show a smooth increase and decrease of forces as would be expected from submerged blocks. Blocks 5 through 7 show

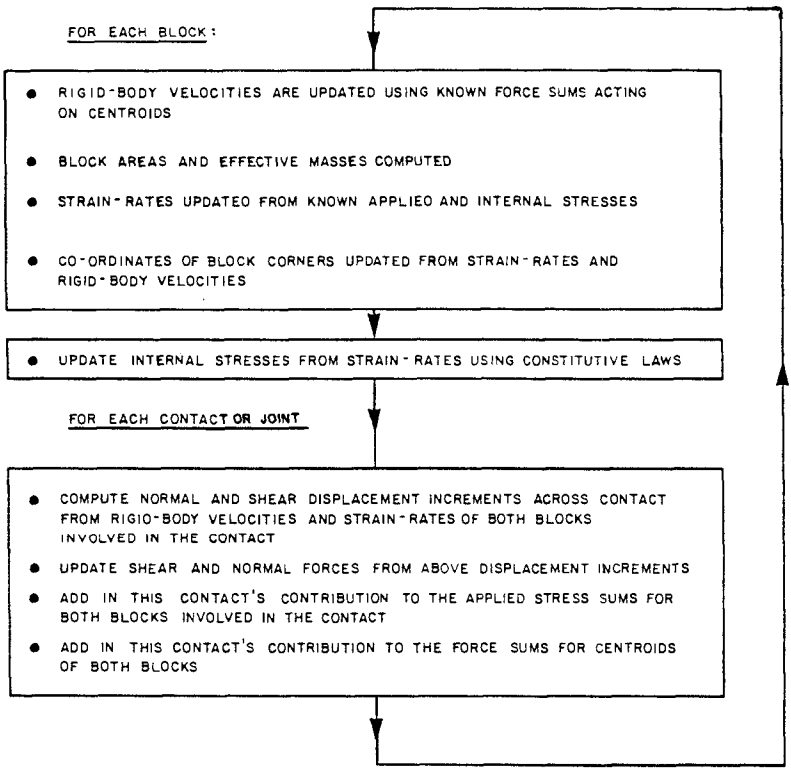

FIGURE 4. SIMPLIFIED CALCULATION CYCLE: RAGE

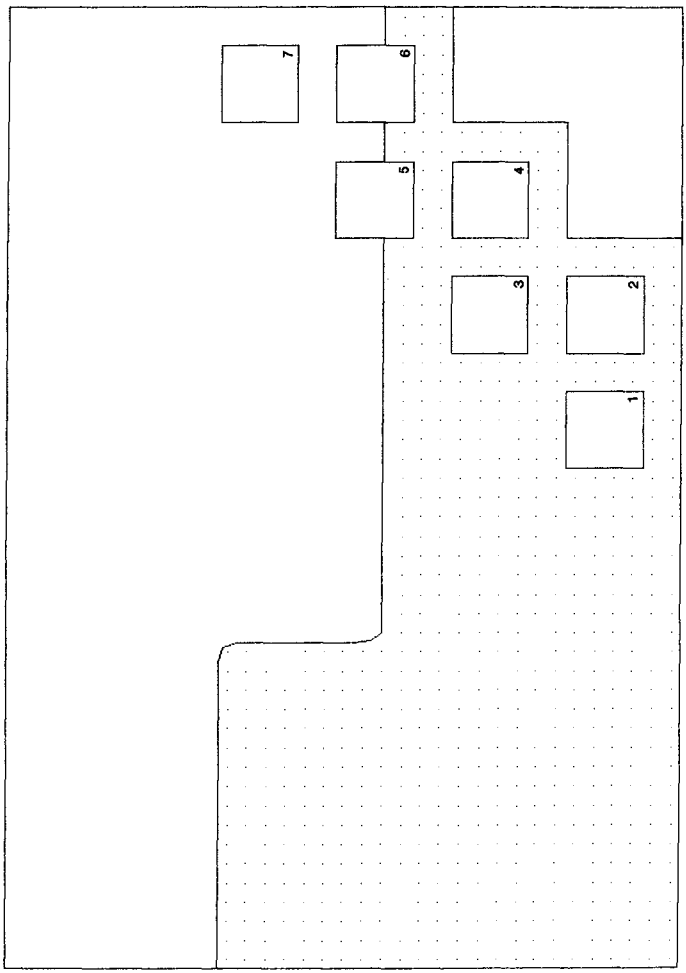

FIGURE 5. EXAMPLE 1: INITIAL WATER SURFACE

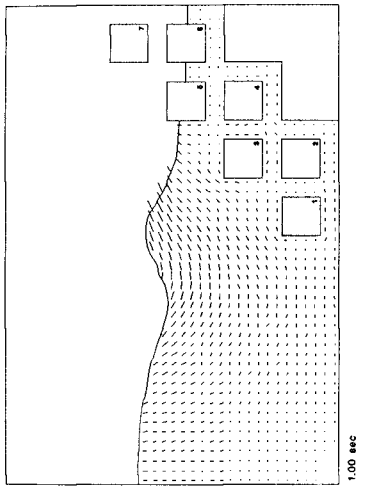

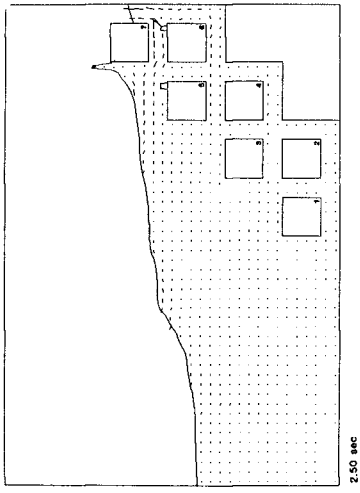

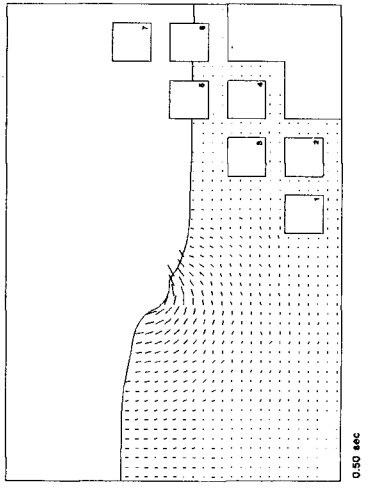

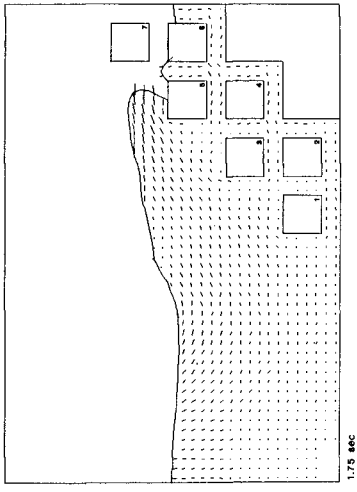

FIGURE 6. EXAMPLE 1: WAVE IMPACT

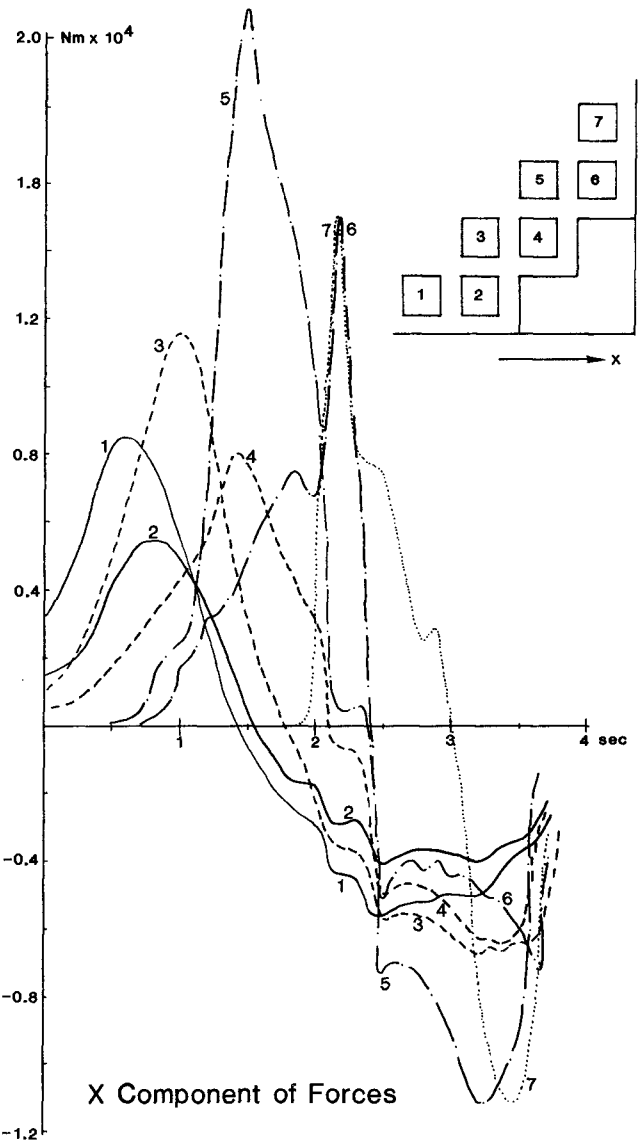

FIGURE 7. EXAMPLE 1: FORCES ON BLOCKS

much sharper peaks resulting from impacts upon the semi-submerged and free blocks. Block 5 shadows Block 6 as in the case of the submerged blocks.

The discrete element block model setup is shown on Figure 8.a. As the forces are applied at the block centers, no artificial spacing between the blocks is required or could be maintained as the blocks are free to move and are subjected to gravitational accelerations. The block movements resulting when the force histories are used is shown on Figures 8.a through 8.e. The displacements are exaggerated as the actual movements are very small (on the order of millimeters). The incoming wave (Figures 8.a, 8.b) has very little effect while the backwash (Figures 8.c, 8.d) causes the blocks to rock and hence the toe block to move outwards. Figures 8.e and 8.f show the return rocking of the blocks and the final pattern when the forces are removed. Reapplication of the same force history to the displaced blocks caused retightning during the incoming wave portion of the force history and redisplacing during the backwash. Repeated applications of the wave history did not cause a failure.

3.2 Revetment Modifications Example

The fluid grid was modified to include a "filter layer" of smaller blocks and four cases were run modifying the spacing between the blocks and the wave loading. Case 1 is the above "surging wave" example run again with the new grid, Case 2 is the same grid with the interblock spacing reduced from two grid cells to one grid cell. In the second two cases, a wave shaped block of water was defined with an initial velocity to form a "plunging" wave. Again, interblock spacings of two and one cells were used.

The histories of forces acting upon the small filter block marked with an X on Figure 9 are shown on Figure 10. As expected, the surging wave produces less force on the filter unit than the plunging wave. The larger spacings allow greater forces to develop in the interior of the breakwater.

3.3 Breakwater Example

To investigate the effect of replacing the revetment in the first example with a true breakwater, the grid was extended as shown on Figure 11. The figure shows snapshots of the wave passing through and over the breakwater. It is interesting to note that jetting through the breakwater (Figure 11.c) induces waves on the harbor side (right) of the breakwater. This jetting has been observed in real breakwaters.

In this example a "surging" type of wave was applied as in the first example. The x component of forces on two blocks are compared with the forces on the equivalent two blocks in the previous example, Case 2. Figure 12 shows the forces histories on the exposed Blocks 3 and 5. Block 3 is a submerged block, while Block 5 is initially only partially submerged. The impact histories for the blocks are identical with the exception that in the breakwater case

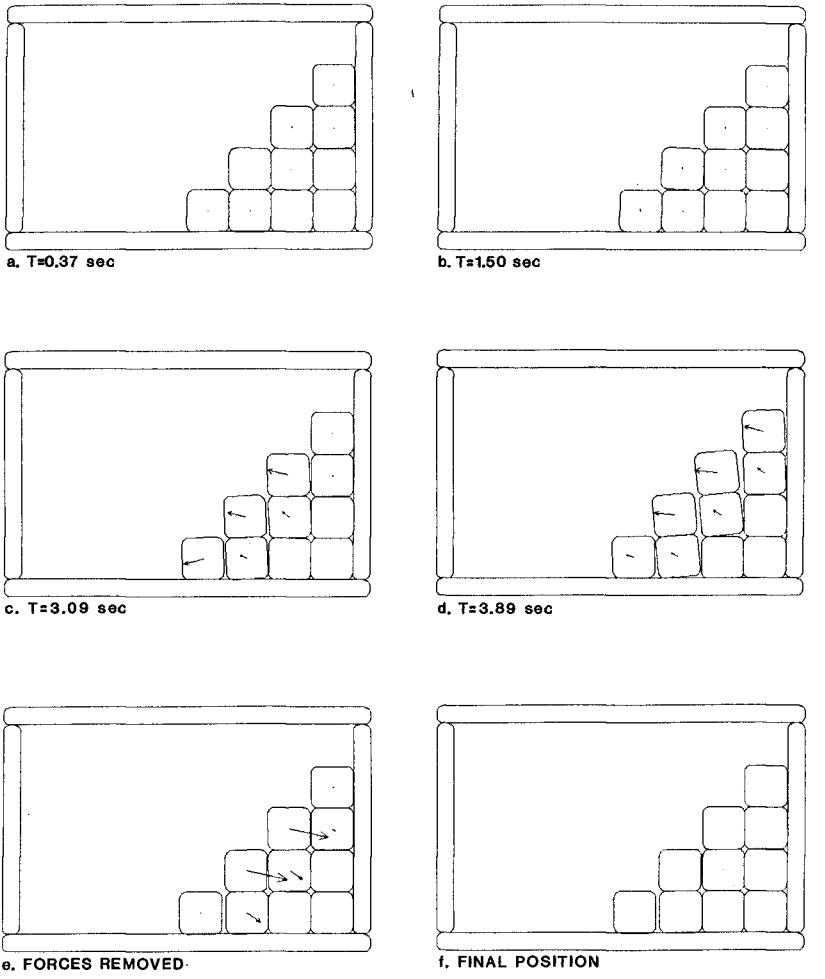

FIGURE 8. EXAMPLE 1: BLOCK MOVEMENTS

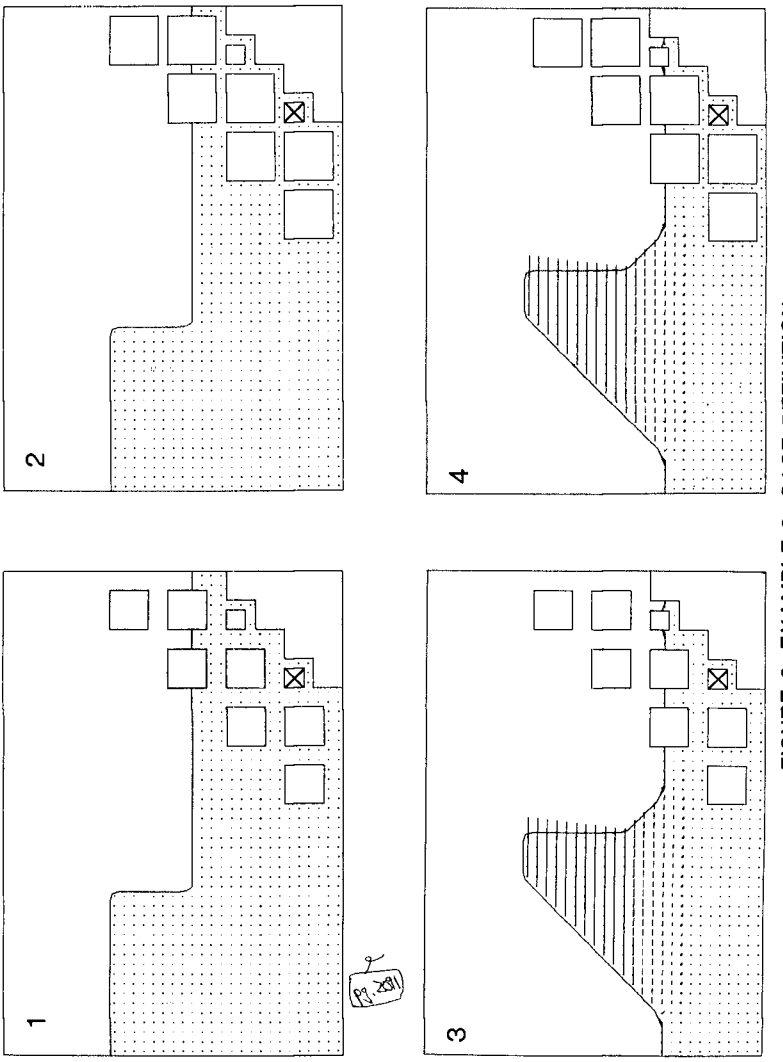

FIGURE 9. EXAMPLE 2: CASE DEFINITION

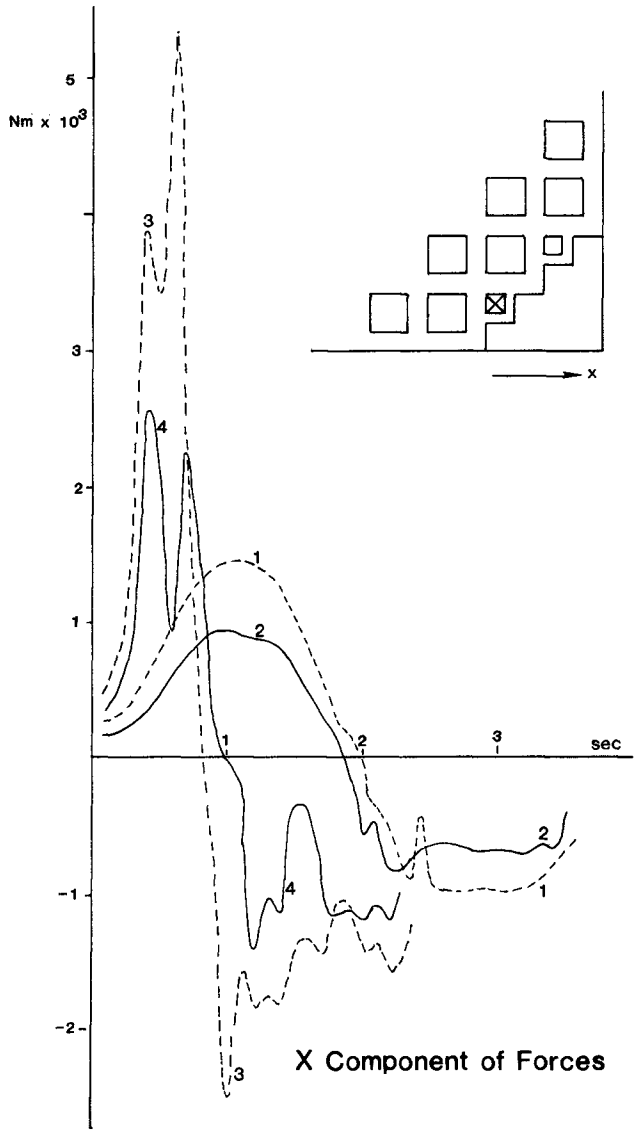

FIGURE 10. EXAMPLE 2: FORCES ON FILTER BLOCK

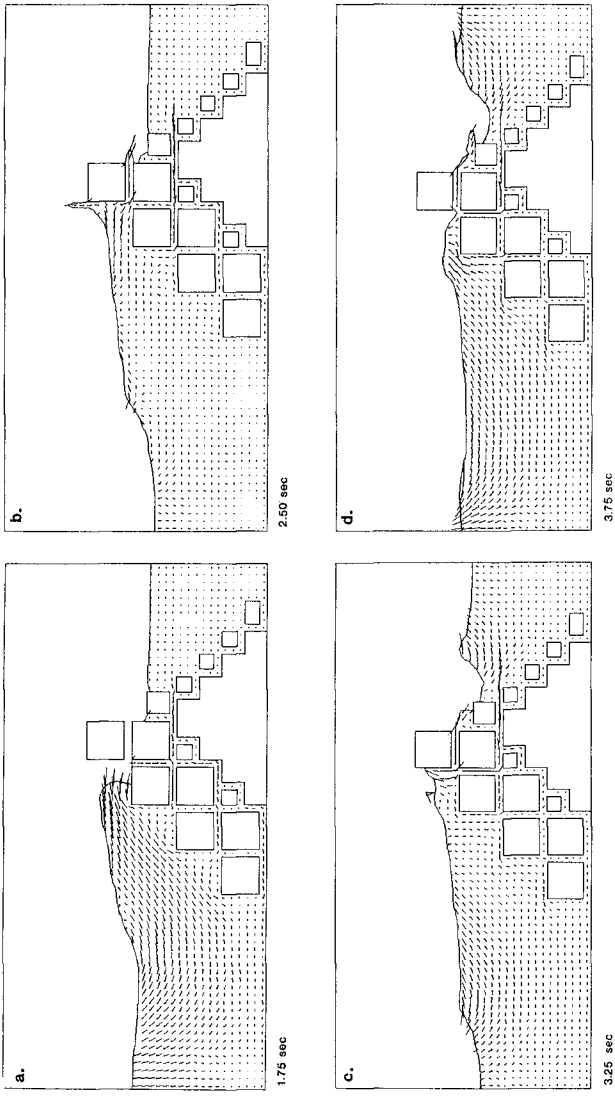

FIGURE 11. WAVE IMPACT ON BREAKWATER

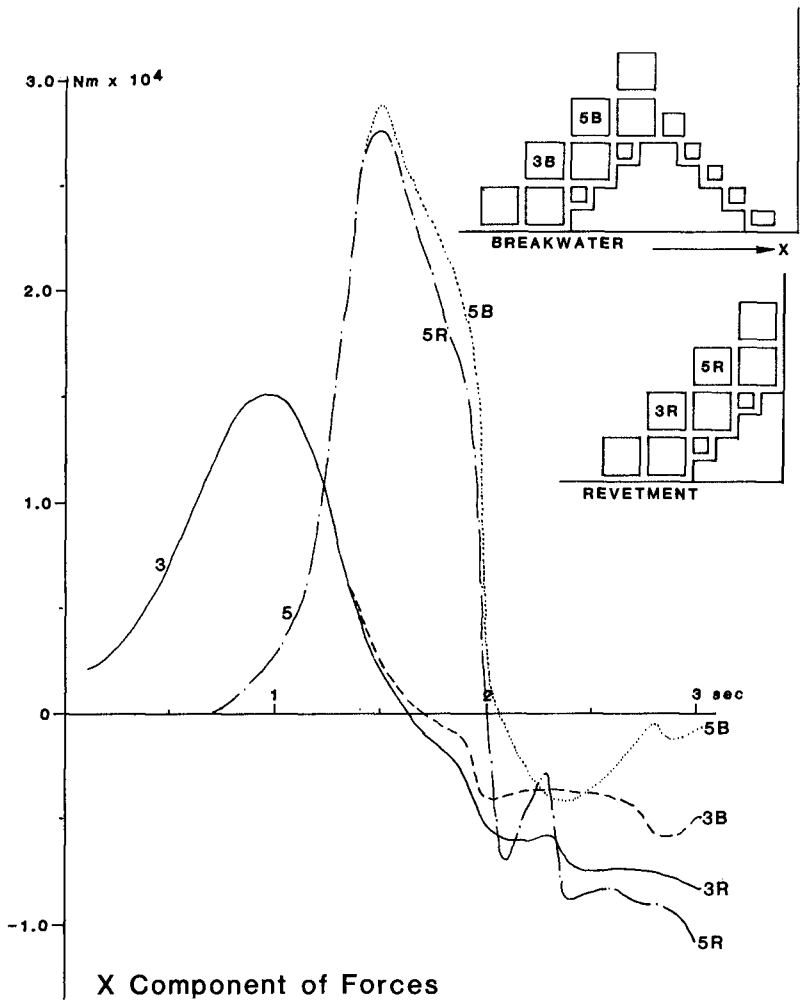

FIGURE 12. EXAMPLE 3: FORCES ON BLOCKS

a slightly greater maximum force is experienced on Block 5. This may be due to a reduction in the amount of water traveling up through the gap between Block 5 and its neighbor to the right in the breakwater case because of jetting through the breakwater. Consequently, an increase in the net impact force acting on the front face will result.

The backwash forces on both blocks are less in the breakwater case than those in the revetment case due to the flow through the breakwater. Block 5 shows a breater reduction than Block 3. This is probably because the backwash experienced by Block 5 in the revetment case is primarily due to wave runup caused by the revetment wall. The backwash experienced by the submerged Block 3 is due in greater part to the effects of the blocks to its right.

4. Conclusions

The results described above are encouraging and indicate the feasibility of the adopted approach. Considerable work needs to be done, such as introducing movement to units in the fluid program and conduting calibration tests, before the model can be used as a predictive tool. However, even in this relatively crude form, useful calculations can be made. Eventually, random placing of units matching that used in breakwater construction will be achieved by simulating the placing and settling processes.

Although the present model is two-dimensional, it is envisioned that in this form the model will provide a useful function in the design and stability analyses of present and future breakwaters. The jump from the current two-dimensional model to the three-dimensional model will eventually be made though at this time the additonal costs and complexity are not justifiable.

Acknowledgments

The authors are grateful for the help of Tony Hirt, Peter Cundall and Peter Carpenter in coaxing the model to its present state.

ABSTRACT

This paper proposes to improve the safety of breakwaters by two important changes in the philosophy of design. When hydraulic model testing is used as a design tool the authors propose to reduce the specific gravity of the model breakwater to introduce a factor of safety in the prototype. They also recommend that the concept of testing for stability with the once in 50 year or once in 100 year wave should be replaced by a more rigorous statistical analysis to determine a design wave which has a probability of exceedence of no more than 5% in the lifetime of the structure.

INTRODUCTION

Severe damage to several breakwaters in recent years has focussed attention on current design methods, which appear in some circumstances to be unreliable. Most designers are aware of the inadequacy of present design formulae, and they therefore rely heavily upon hydraulic model tests. The use of conventional hydraulic models to check the design provides at best an uncertain safety margin against failure. The authors' view is that this is a major factor in the large number of breakwaters which fail.

Parallels are drawn from the design of building structures in which partial factors of safety are applied to the forces and to the properties of constructional materials in order to analyse the design of its ultimate limit state.

The introduction of quantified partial factors of safety in the design process for breakwaters is proposed, not only in theoretical analyses but also in hydraulic model testing procedures.

DAMAGE TO BREAKWATERS

During the winters of 1978, 1979 and 1980 several rubble mound breakwaters on the western seaboard of Europe and on the North African coast were severely damaged.

Possible causes of damage have been discussed by Brunn (1). Damage to caisson type breakwaters, used most frequently in the Far East, has also occurred in the past and has been summarised by Goda (2). Because of the bad record in service of large breakwaters, both of rubble mound construction and caisson construction, this paper has been prepared to consider improvements to our design philosophy with these two forms of construction chiefly in mind.

PRESENT DESIGN METHODS

The limitations of present design methods have been discussed in a previous paper (3). Present practice for the design of rubble mound breakwaters of the type shown in Fig. 1 is to prepare an outline design using Hudson's formula (4) and then test the cross-section in a hydraulic flume. The design is modified during the testing programme until predetermined damage criteria are satisfied.

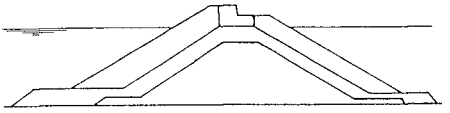

Figure 1 Rubble mound breakwater

In the case of natural rock armour the criterion may be expressed as a percentage loss of armour units over the exposed face, perhaps 1%. This is an inexact definition as "exposed" may have various conflicting meanings and for the same wave climate breakwaters at shallow and deep water sites have very different superficial areas of armour. Because the Hudson formula was developed for rock armour where breakage of units is not normally a problem, loss of armour in the model may have correctly represented the importance of damage in the prototype. Provided that it is relatively easy to mobilise the equipment to reposition armour stones (or provide extra armour) repair is not difficult but if plant is not available the problem of repair can be much more serious than is represented by the percentage of armour lost.

Although the Hudson formula is not strictly applicable to artificial armour units which depend for their stability on interlock, it is often used to obtain a first estimate of unit mass which is then checked by carrying out

flume tests. The acceptance criterion is the degree of rocking or movement of individual units. In cases where excessive movement leads to fracture of armour units, repair of damaged sections is quite a different matter from merely repositioning rock armour units.

Interpretation of the model test results should reflect this difference but there is no agreement on how to do this.

Irregular waves are now used in flume testing, except in laboratories which lack up-to-date wave making equipment and sophisticated control systems. The wave spectrum is usually based on JONSWAP or other spectra derived from instrumental recordings. The flume model is tested in stages by increasing the wave height until the armour layer becomes unstable, which gives an indication of the margin against failure.

Although vertical faced caisson type breakwaters of the type shown in Fig. 2 can be designed without tests by using wave pressure theory, it is usual to carry out hydraulic model tests in a flume to check the stability of the design. Failure can occur by either sliding or overturning, but Japanese experience (2) shows that sliding is the most common type of failure.

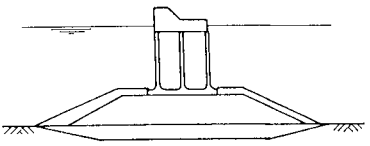

Figure 2 Caisson breakwater

The chief weakness of existing design and hydraulic model testing procedures is that there is no commonly agreed method of introducing a factor of safety against failure (however defined) for either type of breakwater nor is there an accepted set of definitions on which quantitive criteria and measurements are based.

The easiest way of providing a safety margin against failure of any type of breakwater is to increase the height of the design wave. Doing this increases the forces which the structure has to resist. For example in the case of Jubail east breakwater (5) completed in 1979, wave records were inadequate and the 1 in 100 year design wave height was assessed from wind records at 4.5m. Because no direct wave observations were available and because it was considered essential to provide a maintenance free

structure the consultants increased the design wave height to 6.5m. This represents a factor of 1.4 on the 1 in 100 year wave height.

For rubble mound breakwaters another simple way of increasing the margin of stability of the armoured slope is to use heavier armour in the prototype than the model tests, or calculations, indicate is required. If artificial armour units are used this does not necessarily lead to a corresponding increase in total volume of concrete used in the armour layer and it normally reduces the number of individual units to be placed. However, the feasibility and costs of producing and handling larger sized armour have to be taken into account. The increase in stability is not as great as it might appear as the wave height which can be resisted is in proportion to the cube root of the weight of armour unit. Doubling the weight of armour units therefore introduces a factor of about 1.26.

Measures such as these give a margin of safety but are purely arbitrary, and there is no generally accepted philosophy to guide the designer in applying them. When this lack of guidance is compared with the extensive use of codes of practice for the design of other types of structure the contrast is quite remarkable.

MODERN BUILDING DESIGN CODES

Consider, for example, the procedures for designing a building structure, in which (in contrast to breakwaters) the applied loads are reasonably known, the properties of the construction materials are strictly controlled and the workmanship is open to inspection at all stages. What is more the different phenomena such as bending, shear, bond etc., can be easily analysed separately; this is not at present the case with armour design, although the authors believe that further research would enable this point to be reached (3). There are however some useful concepts on factors of safety which could be applied to the design of breakwaters.

In the past, building structures have been designed on a "working stress" basis in which it is confirmed that the actual applied loads can be carried without exceeding allowable stresses. The allowable stresses are chosen to provide a margin of safety on stresses which would cause failure. This well established method is still used in many countries but it has weaknesses which have led to the introduction of a different method of design. The most serious weakness arises when the stability of a structure depends partly on its mass and partly on the strength of its members. Working stress analysis provides a margin of safety on the latter but not the former. Consider for example a quay wall design in which a relieving platform is supported on raking piles. The combined factor of safety against failure due to variations in applied load is not equal to the ratio between ultimate strength and working stress. To achieve this requires a different method of analysis.

The present design concept in UK, which was introduced for reinforced concrete structures by a code of practice published in 1972 (6) and is being introduced for other types of construction, is based on analysis of conditions at failure. The analysis, known as the limit state method of design, applies factors both to the values of the applied loads and to the strength of concrete and steel reinforcement. These factors, known as

partial safety factors, are chosen to ensure that when its stability has been analysed with appropriate partial factors of safety applied to loads and materials the structure will not become unfit for the use for which it is required, i.e. that it will not reach a limit state in service. In preparing the code of practice the drafting committee state that insufficient statistical data was available to enable a design method to be developed which is in complete accord with probability theory. The choice of partial factors of safety is admitted to be arbitrary but the intention is that as new knowledge of loads and strengths becomes available they can be amended. The factors applied will then vary according to the quality of data on loadings available to the designer, the accuracy of knowledge about material properties and the acceptable probability of failure.

The order of probability of failure which might be considered to be acceptable in the design of a building structure is 1 in 200,000 of failure leading to fatality during the working life of the building (7). This is achieved by adopting characteristic strengths of materials which have a 5% probability of being exceeded, and loadings which are intended to have a similar probability of being exceeded. The safety of the final structure depends upon the combination of events of low probability of occurence.

LIMIT STATE DESIGN OF BREAKWATERS

When designing breakwaters there are many areas of uncertainty where use of a partial safety factor would lead to a more logical design process.

These are:

(i) loadings

- wave heights
- wave periods
- wave form and grouping
- storm duration
- effects of wave refraction and diffraction

(ii) structure

- strength of materials
- specific gravity or bulk density of materials
- interlock achieved (for rubble mound breakwaters)
- accuracy of construction and general standard of workmanship
- breakage of elements

(iii) miscellaneous effects

- scale of model
- foundation settlement
- effectiveness of scour protection

Our present state of knowledge on breakwater design does not permit us to assign a partial safety factor to each of the variables outlined above. The two variables which are generally of the most importance are wave conditions and stability of armour layers or of caissons. Let us therefore consider the possible application of partial factors of safety to these two variables.

Wave conditions are usually assessed using graphical statistical methods to predict (for example) the once in 10, 20, 50 or 100 year wave height. Recorded data seldom fits the probability graph exactly and a judgement has to be made on precisely how the line on the graph should be extended to give the extreme wave heights, or which type of probability graph paper to use for this purpose.

If we then use one of these values for design of a breakwater, there is a high probability of thc design value being exceeded. Even if we know exactly what the once in 100 year wave is there would still be a 63 percent probability of it occurring or being exceeded once in 100 years, so this would not be a safe basis for design of a structure which we wish to have a 100 year life. But in fact our data and our methods of analysing it are far from perfect so the probabilities of exceedance may be much greater than 63%.

There is a strong case for adopting a more conservative design wave and also applying a partial factor of safety to the design.

A major consideration in applying factors of safety to wave heights is the length and type of records which determine the quality of our knowledge of the conditions. Perhaps the simplest case is when wave heights are depth limited. Before the concept of irregular waves was introduced it might have been argued that the maximum height of breaking wave was known, depending only on maximum depth of water (or highest water level), but we now know that combinations of waves of different periods are capable of producing "freak" waves even in shallow water. These cannot be predicted mathematically and even when they are reproduced in a hydraulic model we cannot be certain that there is not a more severe combination in nature. Some factor of safety is required to cover this uncertainty. When a final design depends upon model tests it will not be practicable in the depth limited case to provide this safety margin by increasing wave heights and it must be done in some other way. This is discussed later, but we should first consider the case when waves are not depth limited.

If wave heights are not depth limited it is logical to introduce a partial factor of safety by increasing the applied wave height.

By analogy with structural design we should be designing the breakwater to resist the most severe waves which have only a small probability of occurrence in the life time of the structure after making full allowance for the inadequacy of our basic data. It is common to use as a design wave the best estimates of the 1 in 50 year wave - or once in 100 year wave. As Tucker and Fortnum (8) have shown for Seven Stones Light Vessel there is a 63% probability that the 1 in 50 year wave height will be exceeded in a 50 year period. Clearly this is a much higher probability of exceedence than would be accepted in structural loadings. They also showed that there would be a 10% chance that the highest wave in 50 years would be more than 16% higher than the 1 in 50 year wave.

Another problem arises from the relatively short periods of observations which we have to use for projecting long term probabilities. All too often engineers have had to design breakwaters using significant wave heights

derived from only one or two years relevant wave records. Variations between individual years can be considerable; at Seven Stones light vessel the maximum 50 year wave height predicted from 12 months records in 1969 was 24.4m and from 12 months records in 1973/4 was 28.8m (8). Assuming a cubic relationship for armour weight, this represents an increase of 64% in weight of armour unit.

These relations depend upon local wave climate and require careful satistical analysis of specific records. The authors propose that statistical analysis to predict the wave height which has no more than 5% (or at most 10%) probability of exceedence during the life time of the structure should replace the use of once in 50 year or once in 100 year design waves.

As wave records are normally not available at the exact site of the structure, and wave heights may be affected by the presence of the structure, it would still be necessary to consider, as carefully as possible, the effects of refraction and diffraction on wave heights at the breakwater and to use increased waves to allow for these effects in the hydraulic model. The quality and duration of base data is also very important in assessing the possible range of variation in wave heights at the structure. Taking all aspects into consideration one would estimate the design wave heights which would have an acceptably low probability of being exceeded within the life time of any particular structure. These could then be used in theoretical analysis or in tests in a hydraulic flume.

We must also make allowance for uncertainties regarding the accuracy of hydraulic modelling of the wave spectrum and of the representation in a model of the true prototype stability.

Whether we are considering armouring of a rubble mound structure, a concrete capping on a rubble mound, or a deep caisson structure on a rubble base, the main disturbing force results from water pressure and the main stabilising forces derived from the weight of armouring, capping or caisson. In theoretical analysis using limit state design a factor of safety would be introduced by increasing the applied loads calculated from the design wave. In theory the same margin of safety could be achieved in model tests by increasing the specific gravity of the fluid used in the flume. This is however not a practicable method to usc in a hydraulic model; water is the only convcnient choice of fluid. The authors therefore propose instead that these uncertainties should be dealt with by a simple reduction in the specific gravity (in the model) of the main elements of construction. This has the same effect as increasing the wave forces.

Current modelling technique is based on the concept of reproducing the prototype as accurately as possible, and the main effort has been devoted to getting weights (specific gravities) correct. Precise reproduction of the prototype is no doubt an cxcellent aim in pure research intended to advance knowledge, say, of the type of collapse which can occur (or to reproduce a failure which has occurred) but in using hydraulic modelling as a design tool it would be much more helpful to the designer to model the structure deliberately with reduced specific gravities so as to incorporate a factor of safety in the prototype. In all the most

important failure conditions the critical masses are submerged. The factor of safety introduced by reducing specific gravity would therefore be in the ratio of submerged specific gravities in prototype and model.

A great advantage of doing this, rather than arbitrarily increasing the design wave height used in tests or altering the dimensions of, say, the armour units by testing for one size and building another larger size is that the geometry of the model and prototype would be the same. The hydraulic advantages of this will be obvious but correct geometrical relationship of the disturbing (wave) forces and stabilising (gravity) forces is no less important. Concentration in recent years on "correct" modelling of specific gravity has led to the use of armour units made from plastics rather than mortar. As a result it has not been possible to reproduce the coefficient of friction between units correctly and the geometry of the forces between units has also been wrong.

When modelling with reduced specific gravity, sand-cement mortar will again be a practical solution and it should be easier to produce units with surface friction close to prototype values.

Table 1 shows the effect on model specific gravities of introducing factors of safety of 1.2, 1.5 and 2.0 into tests of concrete armour units.

TABLE 1 - EFFECTS OF FACTOR OF SAFETY ON MODEL SPECIFIC GRAVITY

Factor of safety required	1.2	1.5	2.0
Specific gravity of prototype concrete	2.40	2.40	2.40
Prototype submerged specific gravity (sea water SG = 1.025)	1.38	1.38	1.38
Model submerged SG	1.15	0.92	0.69
Model SG in dry	2.18	1.95	1.72

A great advantage of introducing this concept of reducing specific gravities of breakwater units so as to provide a partial factor of safety in the prototype compared to the model is that in most types of breakwater, and in many different elements of, say, a rubble mound or caisson structure, weight in the final analysis provides all the stabilising forces. Even with interlocking units which derive stability partly from contact with their neighbours it is in the end the weight of a group of units which provides the stability of the structure. This method can therefore be applied consistently to a wide range of different forms of construction.

The exact choice of factor safety to be introduced in this way must be the subject of further research and therefore, another paper, but the authors would strongly advocate the adoption of partial factors of safety in

breakwater design and suggest the use of values in the above range in the meantime. The lower value of 1.2 might be adopted for rubble mound breakwaters armoured with rock, or with very robust concrete armour units such as cubes, where substantial movements can be accepted with no risk of breakage. A value of 1.5 might be adapted for caisson structures and for concrete armour units which are liable to break under excessive movement. A factor of 2.0 may be appropriate only where heavy loss of life could result from a failure. Factors of safety below 1.2 could be used for example, in rubble mound designs where the main armour is rock and where equipment could always be mobilised quickly for repair.

Conclusion

The authors' conclusion is that the large numbers of failures of breakwaters can and should be reduced in future by introducing the concept of partial factors of safety into the design philosophy.

When we have reliable mathematical methods of analysis we will be able to do this in exactly the same way as in limit state structural design codes.

Until then we much rely upon the use of hydraulic models to test and develop modifications to our ideas. Factor of safety can be provided by a deliberate reduction in the specific gravity of the elements of construction being tested. This would be the only way of introducing a factor of safety where waves are depth limited.

Where waves are not depth limited it is recommended that the use of design waves based upon return periods of once in 50 years or once in 100 years should be replaced by a more rigorous statistical analysis to determine the wave conditions which are likely to have a probability of occurence of not more than 5 percent during the intended lifetime of the structure.

If the authors' proposals are adopted they believe that there would be a long overdue improvement in the performance of breakwaters. Our choice between different design options would also be made on a more rational basis.

BREAKWATER STABILITY - BREAKING WAVE DATA

by

Robert D. Carver[1], M. ASCE, and D. Donald Davidson[2]

Abstract

The objective of the research presented is to furnish design information for stone and dolos armor on non-overtopping breakwater trunks that are subjected to severe depth-limited breaking waves. Since it would be a mammoth task to comprehensively investigate all the different types of existing armor, this particular research effort concentrated on stone, which is a natural and economical protection when it is of sufficient size and quality to meet design constraints, and on the dolos, which according to nonbreaking wave data is the best hydraulically stable concrete armor unit.

Introduction

A proposed rubble-mound breakwater may necessarily be designed for either nonbreaking or breaking waves depending on positioning of the breakwater and severity of anticipated wave action during its economic life. Some local wave conditions may be of such magnitude that the protective cover layer must consist of specially shaped concrete armor units in order to provide economic construction of a stable breakwater; however, many local design requirements are most advantageously met by quarry-stone armor. This paper addresses the use of quarry-stone and dolos armor on breakwater trunks subjected to breaking waves.

Previous investigations have yielded a significant quantity of design information for quarrystone (Hudson, 1958 and Carver, 1980) tetrapods, quadripods, tribars, modified cubes, hexapods, and modified tetrahedrons (Jackson, 1968), dolos (Carver and Davidson, 1977), and toskane (Carver, 1978). However, the studies conducted by Hudson, Jackson, Davidson, and Carver were limited in that test waves were always nonbreaking and the relative wave height (H/d) varied over a very limited range.

[1]Research Hydraulic Engineer, U. S. Army Engineer Waterways Experiment Station, Vicksburg, Mississippi 39180.

[2]Chief, Wave Research Branch, U. S. Army Engineer Waterways Experiment Station, Vicksburg, Mississippi 39180.

Purpose of Study

The purpose of the present investigation was to obtain design information for stone and dolos armor used on breakwater trunks and subjected to breaking waves. More specifically, it was desired to determine the minimum weight of individual armor units (with given specific weights) required for stability as a function of:

a. Type of armor unit.

b. The sea-side slope of the structure.

c. Wave period.

d. Wave height.

e. Water depth.

f. The sea-bottom slope on which the breakwater is constructed.

Dimensional Analysis

When short-period waves attack rubble-mound breakwaters, the interaction of the dislodging forces induced by the water motion and the resistive action of the armor units produces a complex dynamic phenomenon. Previous attempts to analyze this phenomenon to ascertain the magnitude of the dynamic forces involved by theoretical analyses have not been successful; however, hydraulic scale models of breakwaters can yield accurate design information that relates the required weight of individual armor units to breakwater geometry, local bathymetry, wave characteristics, etc.

An attempt will be made through the use of dimensional analysis to develop functional relationships between the primary variables affecting armor stability. The Buckingham Pi Theorem can be used to determine the number of dimensionless and independent quantities (Pi terms) required to express a relationship among the variables in any phenomenon. Dimensional analysis may then be used to obtain a suitable set of Pi terms.

Definitions and characteristic dimensions in terms of Force (F), Length (L), and Time (T) of the primary variables affecting armor stability are as follows:

γ_a = specific weight of an armor unit, F/L^3

W_a = weight of an armor unit, F

Δ = shape factor of the armor unit, dimensionless

γ_w = specific weight of water, F/L^3

H = wave height, L

L = wave length, L

d = water depth, L

g = acceleration due to gravity, L/T^2

h = height of breakwater crown, L

β = angle of wave attack, dimensionless

ν = kinematic viscosity, L^2/T

α = angle between the horizontal and the seaward face of the breakwater, dimensionless

θ = angle between the horizontal and the sea-bottom on which the breakwater is constructed, dimensionless

PT = technique used to place armor units in the cover layer, dimensionless

D = damage parameter, dimensionless

The present investigation addresses only waves normal to nonovertopping breakwater sections. Therefore, the variables, β and h, are eliminated. Also, since α is directly related to the seaward slope of the breakwater, this variable can be replaced by cot α where cot α is the reciprocal of breakwater slope. With these considerations, the list of variables is reduced to 13.

With 13 variables and 3 basic dimensions involved, the Buckingham Pi Theorem predicts that armor stability should be a function of 10 dimensionless Pi terms. One possible set of Pi terms is

$$\pi_1 = \frac{\gamma_a^{1/3} H}{(\frac{\gamma_a}{\gamma_w} - 1) W_a^{1/3}} \tag{1}$$

$$\pi_2 = H/d \tag{2}$$

$$\pi_3 = H/L \tag{3}$$

$$\pi_4 = L^2 H/d^3 \tag{4}$$

$$\pi_5 = \cot \alpha \tag{5}$$

$$\pi_6 = \Delta \tag{6}$$

$$\pi_7 = \theta \tag{7}$$

$$\pi_8 = \frac{(gH)^{1/2}\, \ell_a}{\nu} \tag{8}$$

$$\pi_9 = PT \tag{9}$$

$$\pi_{10} = D \tag{10}$$

Correlation of the test data will be attempted by the functional relationship

$$\pi_1 = f\,(\pi_2, \pi_3, \pi_4, \pi_5, \pi_6, \pi_7, \pi_8, \pi_9, \pi_{10}) \tag{11}$$

or

$$\frac{\gamma_a^{1/3} H}{\left(\frac{\gamma_a}{\gamma_w} - 1\right) W_a^{1/3}} = f\,(H/d,\ H/L,\ L^2H/d^3,\ \cot\alpha,\ \theta,\ \Delta,\ (gH)^{1/2}\, \ell_a/\nu,\ PT,\ D) \tag{12}$$

Stability Scale Effects

If the absolute sizes of breakwater materials and wave dimensions become too small, flow around the armor units enters the laminar regime; and the induced drag forces become a direct function of the Reynolds Number. Under these circumstances, prototype phenomena are not properly simulated and stability scale effects are induced. Hudson (1975) presents a detailed discussion of the design requirements necessary to ensure the preclusion of stability scale effects in small-scale breakwater models (critical $R_N = 3 \times 10^4$). For all tests reported herein, the sizes of model armor and wave dimensions were selected such that scale effects were insignificant (i.e., R_N was greater than 3×10^4).

Selection of Test Conditions

In planning a stability investigation, it is not possible to preselect exact values of H/L and H/d since the design-wave heights are unknown at the outset of the study. However, the widest possible range of these parameters can be insured by using various armor weights that range from just above the scale-effect regime at the lower limit up to the maximum weights that the test facility is capable of displacing. For the present investigation, armor weights ranged from 106 to 322 grams.

The wave flume was calibrated for depths from 12.2 cm to 29.0 cm in 1.5-cm increments at d/L values of 0.04, 0.06, 0.08, 0.10, 0.12, and 0.14. This range of depths and, consequently, breaking wave heights proved to be compatible with the selected armor weights and sea-side breakwater slopes.

All stability tests were conducted on sections of the type shown in Figures 1-3. Sea-side slopes of 1:1.5, 1:2, and 1:3 were investigated while the beach-side slope was held constant at 1:1.5. Structure heights of 30 to 50 cm were used. The height necessary to prevent wave overtopping was determined by the combination of structure slope, armor type and weight, and water depth being investigated.

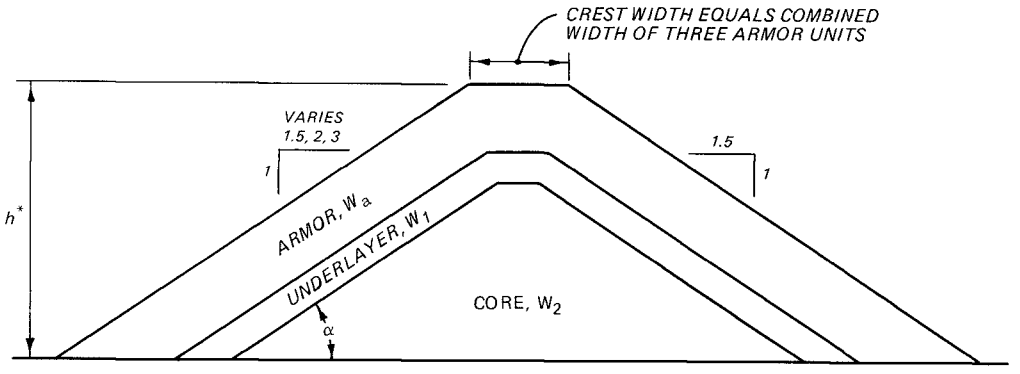
Method of Constructing Test Sections

All model breakwater sections were constructed to reproduce as closely as possible results of the usual methods of constructing prototype breakwaters. The core material was dampened as it was dumped by bucket or shovel into the flume and was compacted with hand trowels to simulate natural consolidation resulting from wave action during construction of the prototype structure. Once the core material was in place, it was sprayed with a low-velocity water hose to ensure adequate compaction of the material. The underlayer stone was then added by shovel and smoothed to grade by hand or with trowels. No excessive pressure or compaction was applied during placement of the underlayer stone. Armor units used in the cover layers were placed in a random manner corresponding to work performed by a general coastal contractor, i.e., they are individually placed but are laid down without special orientation or fitting. After each test, the armor stones were removed from the breakwater, all of the underlayer stones were replaced to the grade of the original test section, and the armor units were replaced.

Test Equipment and Materials

All wave-action tests were conducted in a 1.5-m-wide, 1.2-m-deep, and 36.3-m-long concrete wave flume with test sections installed about 27.4 m from a vertical displacement wave generator. The first 3.0 m of flume bottom, immediately seaward of the test sections, was molded on a 1:10 slope while the remaining 24.4 m was flat. The generator was capable of producing sinusoidal waves of various periods and heights. Test waves of the required characteristics were generated by varying the frequency and amplitude of the plunger motion. Changes in water-surface elevation as a function of time (wave heights) were measured by electrical wave-height gages in the vicinity of where the toe of the test sections was to be placed and recorded on chart paper by an electrically-operated oscillograph. The electrical output of the wave gages was directly proportional to their submergence depth.

Rough hand shaped granitic stone (W_a) with an average length of approximately two times its width, average weights of 173 gr ($\pm$9 gr), 250 gr ($\pm$11 gr), and 322 gr ($\pm$14 gr), and a specific weight of 2.68 gr/cc was used to armor the stone sections. Dolos sections were armored with the following sizes of units.



MATERIAL WEIGHTS, GRAMS

W_a	W_1	W_2	ARMOR TYPE
173	17	0.04 - 0.86	STONE
250	25	0.06 - 1.27	STONE
322	32	0.08 - 1.63	STONE
106	21	0.02 - 0.54	DOLOS
125	25	0.03 - 0.63	DOLOS
267	53	0.06 - 1.32	DOLOS

* TOTAL STRUCTURE HEIGHT (h) VARIED FROM 0.3 m TO 0.5 m DEPENDING ON THE COMBINATION OF STRUCTURE SLOPE, ARMOR WEIGHT, AND WATER DEPTH BEING INVESTIGATED.

Figure 1. General breakwater cross-section.

Figure 2. Cross-sectional view of typical stone section.

Figure 3. Cross-sectional view of typical dolos section.

W_a, gr	γ_a, gr/cc
106	2.21
125	2.28
267	2.26

Sieve-sized limestone (2.64 gr/cc) was used for the underlayer (W_1) and core (W_2) of both armor types.

Test Procedures

For a given wave period and water depth, the most detrimental breaking wave (i.e., the most damaging wave) was determined by increasing the stroke adjustment on the wave generator in small increments and observing which wave produced the most severe breaking wave condition on the model structures. Wave heights of lower amplitude did not form the critical breaking wave and wave heights of larger amplitude would break seaward of the test structures and dissipate their energy so that they were less damaging than the critically tuned wave.

A typical stability test consisted of subjecting the test section to attack by waves of a given height and period until stability was achieved. Test sections were subjected to wave attack in approximately 30-sec intervals between which the wave generator was stopped and the waves allowed to decay to zero height. This procedure was necessary to prevent the structures from being subjected to an undefined wave system created by reflections from the model breakwater and wave generator. Newly built test sections were subjected to a short duration (five or six 30-sec intervals) of shakedown using a wave equal in height to about one-half of the estimated no-damage wave. This procedure provided a means of allowing consolidation and armor unit seating that would normally occur during prototype construction.

Test Results

Breaking wave stability test results for stone and dolos armor are summarized in Tables 1 and 2, respectively. Presented therein are experimentally determined design wave heights, wave steepness, relative wave height, Ursell Number, and breakwater slope. All stability test results presented in Tables 1 and 2 were verified by at least one repeat test. Sea-side breakwater slopes of 1:1.5, 1:2, and 1:3 were used for both armor types. The following ranges of armor weights, water depths, wave periods and heights, relative depths, wave steepness, Ursell Numbers, and relative wave heights were investigated.

Variable	Range for Indicated Type of Armor	
	Stone	Dolos
armor weight, gr	173-322	106-267
water depth, cm	12.2-22.9	13.7-29.0

Variable	Range for Indicated Type of Armor	
	Stone	Dolos
wave period, sec	1.04-2.82	1.30-2.32
wave height, cm	10.1-16.8	13.7-23.5
relative depth	0.04-0.14	0.06-0.14
wave steepness	0.042-0.099	0.058-0.094
relative wave height	0.64-1.05	0.64-1.02
Ursell Number	34.0-655.7	33.7-283.9

The number of armor units per given surface area, A, was $N = 1.45\ \forall^{-2/3}$ and $N = 0.83\ \forall^{-2/3}$ for the stone and dolos, respectively. The variable, $\forall$, is defined as the volume of an individual armor unit. Figures 4 and 5 show typical after testing views of selected test sections.

As previously discussed, it was hoped that stability test results could be analyzed by the following functional relation for the stability number, N_s, where

$$N_s = \frac{\gamma_a^{1/3} H}{(S_a-1) W_a^{1/3}} = f(H/d,\ H/L,\ L^2H/d^3,\ \cot\alpha,\ \theta,\ \Delta,\ (gH)^{1/2}\ell_a/\nu,\ PT,\ D) \qquad (13)$$

For tests described herein θ, PT, and D were held constant; therefore, Equation 13 reduces to

$$N_s = f(H/d,\ H/L,\ L^2H/d^3,\ \cot\alpha,\ \Delta,\ (gH)^{1/2}\ell_a/\nu) \qquad (14)$$

Also, the sizes of model armor units and wave dimensions were selected such that turbulent flow was always obtained: therefore N_s was independent of Reynolds Number $[(gH)^{1/2}\ell_a/\nu]$ and Equation 14 becomes

$$N_s = f(H/d,\ H/L,\ L^2H/d^3,\ \cot\alpha,\ \Delta)$$

Plots of N_s versus H/d, H/L, and L^2H/d^3 are presented in Figures 6, 7, and 8, respectively. These data show a functional dependence of N_s on H/d, H/L, and the Ursell Number (L^2H/d^3) with the dependence being more pronounced for dolos armor. For both armor types it generally appears that minimum stability occurs for the larger values of H/d and L^2H/d^3 and for the intermediate range of H/L ($0.07 \leq H/L \leq 0.085$). Results of previous tests conducted on quarrystone by Hudson (1958) and

Figure 4. Typical sea-side view of stone section after wave attack.

Figure 5. Typical sea-side view of dolos section after wave attack.

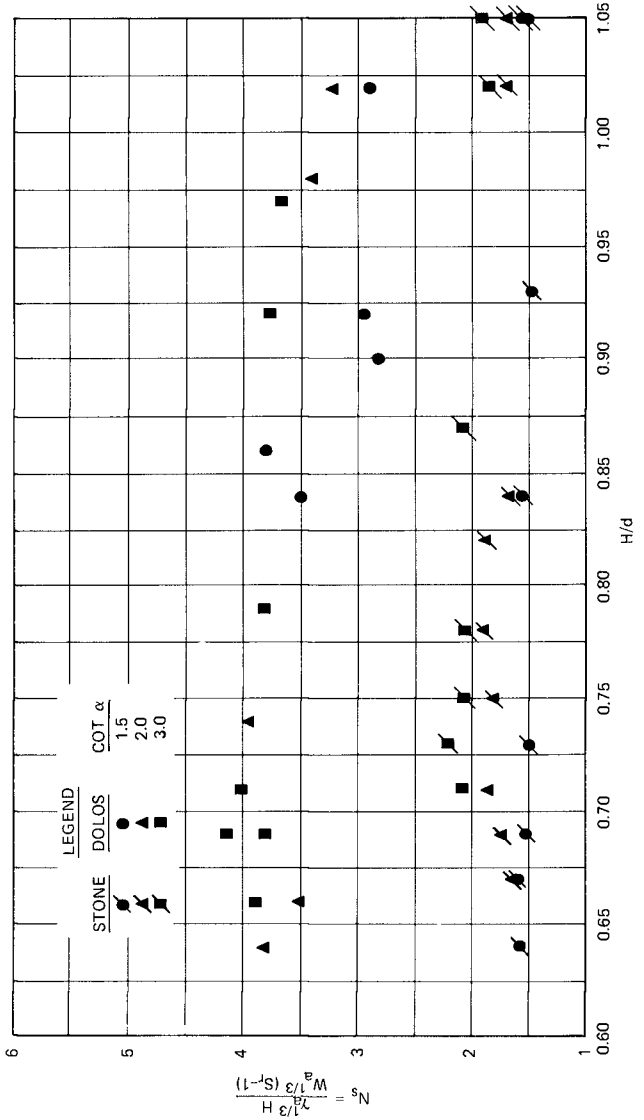

Figure 6. Stability number versus H/d.

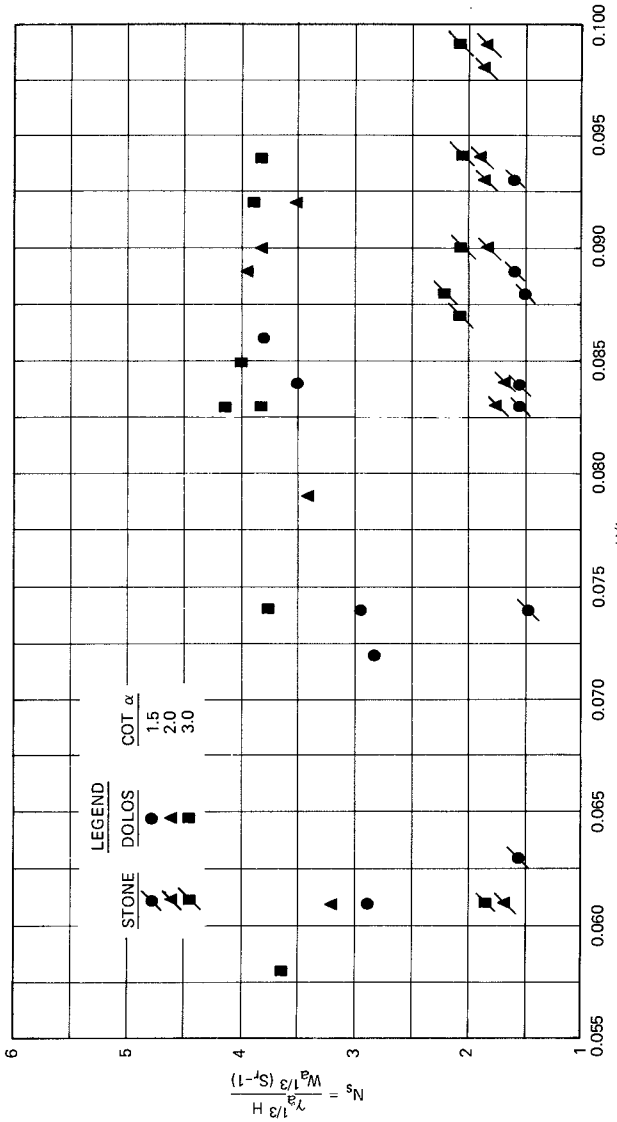

Figure 7. Stability number versus H/L.

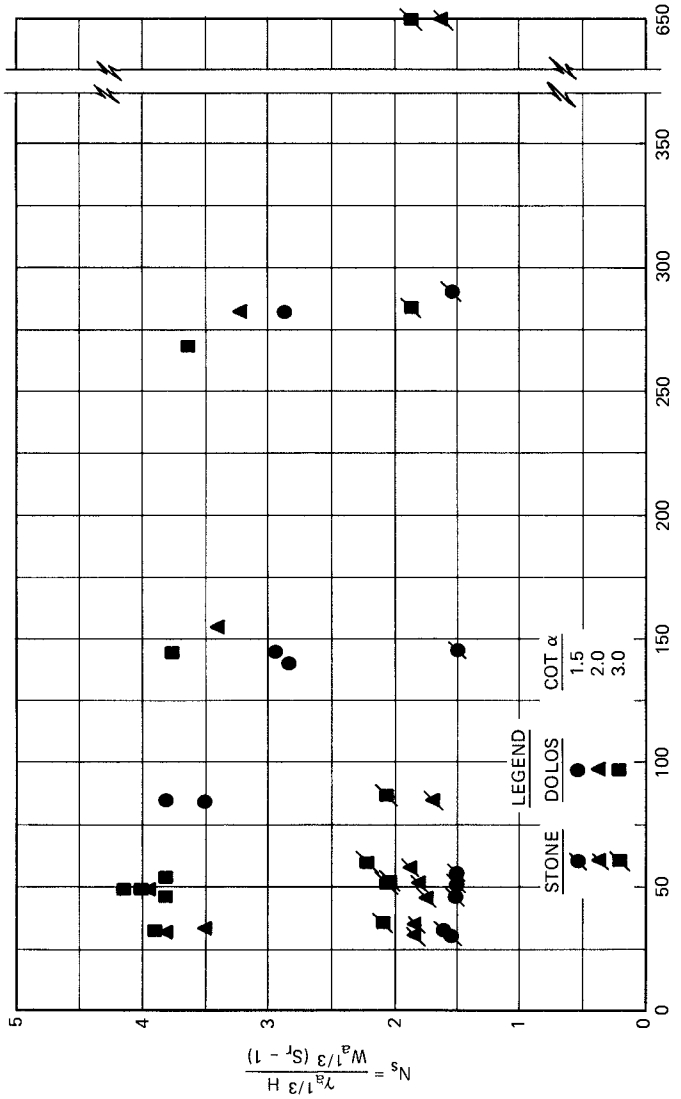

Figure 8. Stability number versus Ursell Number.

Carver (1980) for nonbreaking waves, $H/d \leq 0.32$, and $0.03 \leq H/L \leq 0.08$, do not show these trends. Also the trends are absent from earlier nonbreaking wave tests on dolosse (Carver and Davidson, 1977). The tests of Carver and Davidson were conducted with $H/d \leq 0.37$ and $0.031 \leq H/L \leq 0.083$.

Figure 9 presents a log-log plot of N_s versus cot α. Average and lower limit linear fits of the Hudson type, i.e., 1:3 slope linear fits, are also shown. Even though there is some data spread for each distinct value of cot α (due to variations of H/d, H/L, and L^2H/d^3) the linear fits generally give a reasonable approximation of N_s as a function of cot α, especially for the stone armor.

Conclusions

Based on the tests and results described herein, in which stone and dolos armor are used on breakwater trunks and subjected to breaking waves with a direction of approach of 90 deg, it is concluded that:

a. Armor stability is influenced by wave steepness (H/L), Ursell Number (L^2H/d^3) relative wave height (H/d), and breakwater slope.

b. Effects of H/d, L^2H/d^3, and H/L are more pronounced for dolos armor.

c. In general, minimum stability for each armor type occurred for the larger values of H/d ($H/d > 0.90$), intermediate values of H/L ($0.06 \leq H/L \leq 0.085$), and larger values of L^2H/d^3.

d. Linear Hudson-type data fits generally give a reasonable approximation of N_s as a function of cot α; however, the influences of H/d, H/L, and L^2H/d^3 are strong enough to merit their consideration in final selection of armor unit weight.

Acknowledgements

The data presented in this paper were extracted from model tests described in the Waterways Experiment Station (WES), Technical Report HL-83-____ , entitled "Stability of Stone- and Dolos-Armored, Rubble-mound Breakwater Trunks Subjected to Breaking Waves with No Overtopping," which is being reviewed for publication. The comprehensive study was conducted at WES for the Office, Chief of Engineers under the Corps of Engineers Civil Works Research and Development Program.

Grateful acknowledgement is extended to the Office, Chief of Engineers for granting permission to publish this paper.

STABILITY ANALYSIS FOR A RUBBLE-MOUND FOUNDATION THROUGH IRREGULAR WAVE TEST

by

Masato Yamamoto* and Tsutomu Asakawa**

ABSTRACT

Irregular wave tests have been conducted to research into the stability characteristics of armor units for a rubble foundation of a composite breakwater.

A cover layer to protect the rubble foundation from erosion had two layers of tetrapods. Waves higher than $H_{1/10}$ (the average height of the highest 10% of all waves) caused damage to armor units at the point of critical stability. This suggested that wave height changes in the surf zone should be taken into consideration for design purpose.

1. INTRODUCTION

In Japan, composite breakwaters with superstructures resting directly on rubble foundations have been designed to be used even in areas of deep water. This is due to the fact that construction schedules of breakwaters can be shortened by adopting concrete caissons as a superstructure and damages during construction can be avoided. Many damages to breakwaters occur before completion of the construction.

These composite breakwaters are exposed to high design waves in areas of deep water and very large armor units are required to protect their rubble-mound foundations. Design wave heights sometimes exceed 10 meters in the southern districts of Japan e.g. Okinawa and Kogashima prefectures. Stones as foundations of composite breakwaters are unstable in such districts, especially in the surf zone. In such cases engineers have to use armor blocks like tetrapods to protect the foundations.

Stability analysis of vertical-faced superstructures such as concrete caissons have progressed remarkably. One example is Goda's (1974). To our knowledge some studies on rubble foundations have been reported but they are mostly based on regular wave test results.

---

* Engineer, Assistant Manager, Hydraulic Laboratory, Nippon Tetrapod Co., Ltd.

** Engineer, Manager, Hydraulic Laboratory, Nippon Tetrapod Co., Ltd.

The results using stones based on regular wave tests by Brebner and Donnelly (1963) have been very useful design criteria. But caution should be paid in selecting the design wave heights because of the irregularity of waves, especially in deep water areas and against high design waves.

This paper deals with model tests on the stability of rubble foundations to irregular waves and two layers of tetrapods as an armor layer were used.

2. TEST EQUIPMENT AND TEST PROCEDURE

2-1. Test equipment

The tests on rubble-mound foundations were carried out in a wave tank, 49.0 m long, 1.0 m wide and 1.0 m deep as shown in Figure 1 at the Hydraulic Laboratory, Nippon Tetrapod Co., Ltd.

The wave generator consisted of a flap type paddle which was operated by a hydraulic piston enabling it to make random waves.

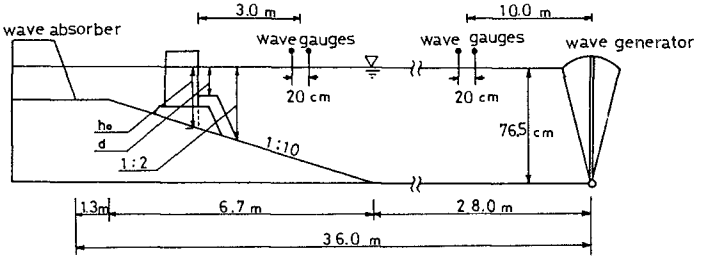

Figure 1 Wave tank and allocation of model

2-2. Test procedure

A simplified sketch of the allocation of model studies is also shown in Figure 1. The bottom slope was 1 in 10. Two pairs of wave gauges at a distance between them of 20 cm were set up at distances 10 m from the paddle of the wave machine and 3.0 m seaward from the model breakwater in order to separate incident and reflected wave heights using Goda's method (1976).

The test wave height was 10.8 cm at a point where the model breakwater was to be constructed. The wave periods were 1.3 sec and 1.8 sec in the model. These irregular waves of Bretschneider-Mitsuyasu spectrum presented by the following equation were simulated.

$$S(f)=0.257\ H_{1/3}^{2}T_{1/3}(T_{1/3}f)^{-5}\exp(-1.03(T_{1/3}f)^{-4})\text{---}(1)$$

where
S(f); power spectrum density function
$H_{1/3}$; significant wave height
$T_{1/3}$; significant wave period
f ; frequency

Two layers of tetrapods as armor blocks were used. The range of model tetrapod weight was from 14.7 g to 190.0 g.

A section of the model breakwater is shown in figure 2.

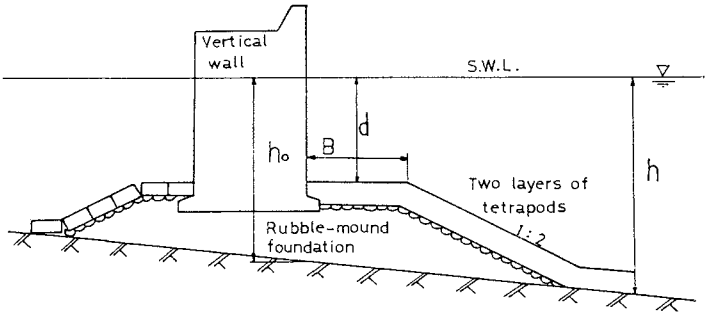

Figure 2 Sketch of cross section of model breakwater

where
h; water depth at the toe of breakwater
h_o; water depth at the structure site
d; depth at the crest of rubble-mound foundation
B; berm width of rubble-mound

B was fixed constant 15.0 cm. d values were 9.0 cm, 13.0 cm and 16.0 cm below the still water level in the cases where h_o=-28.0 cm and 9.0 cm, 11.0 cm and 14.0 cm were the d values in the case where h_o=-23.0 cm.

Wave duration time was 30 minutes in each case in the model.

3. TEST RESULT AND DISCUSSION

The conditions were classified. Three categories were decided on:

(1) Stable condition where the number of armor units which moved was zero and the number of rocking blocks was less than three.
(2) Unstable condition where more than two unis were moved by wave forces while more than four rocking units were discernable.
(3) Critical condition which is an intermediate state between the stable and unstable conditions.

The stability test results are shown in Figure 3 and 4. These figures show the relation between d/h and weights of tetrapods used. In these two figures black represents unstable, white is stable and black and white is the critical state respectively.

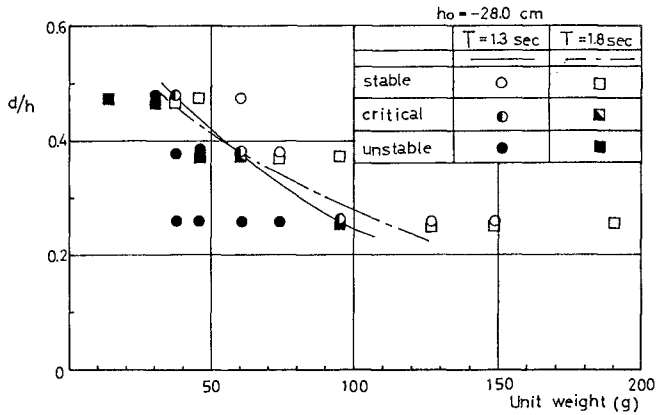

Figure 3 Test results (h_o=-28.0 cm)

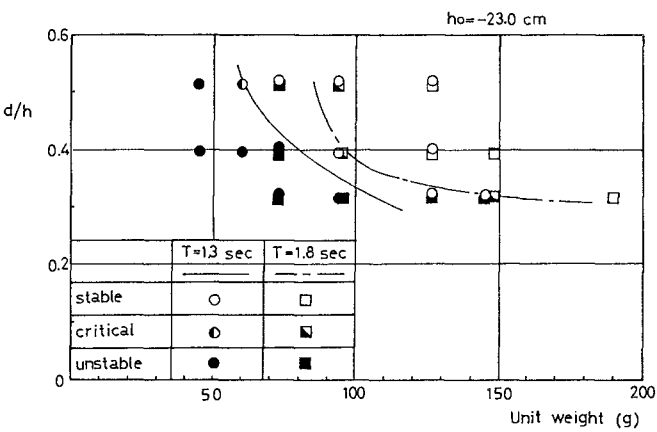

Figure 4 Test results (h_o=-23.0 cm)

Lines show the critical relation between d/h and the unit weight. As shown in Figure 3 and 4 the critical weights increase rapidly as d/h decreases indicating that d is smaller, the critical weight is required to be heavier if h is constant. In addition, it can also be seen that the critical weight is influenced by the wave period, especially in the case where h_o=-28.0 cm, the effects of the wave period are not so apparent. However as the water depth at the breakwater (h_o) increases, it becomes less apparent that the critical weight increases as the wave period increases.

Observation during the tests

In order to investigate how armor units had been damaged by a certain wave in the wave train, the wave action in front of the vertical wall and the movement of tetrapods were filmed by means of a video camera with a rotary shutter. The speed of the shutter was 1/60 seconds.

From this observation, as shown in Figure 5, armor unit suffered an up-lift force and rose up just after a large wave hit the site.

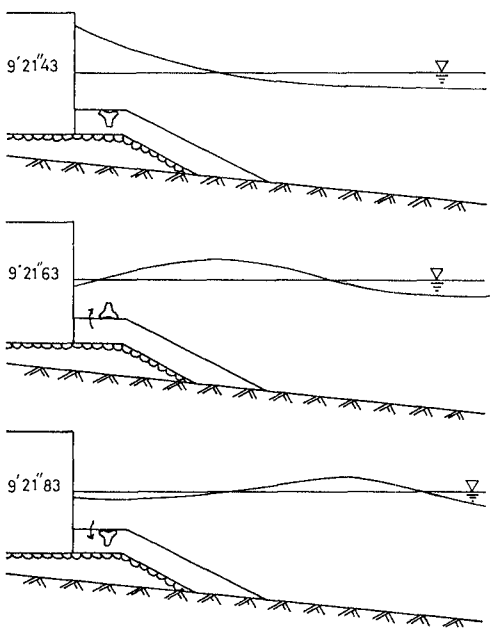

Figure 5 (a) Movement of tetrapod resulting from wave action

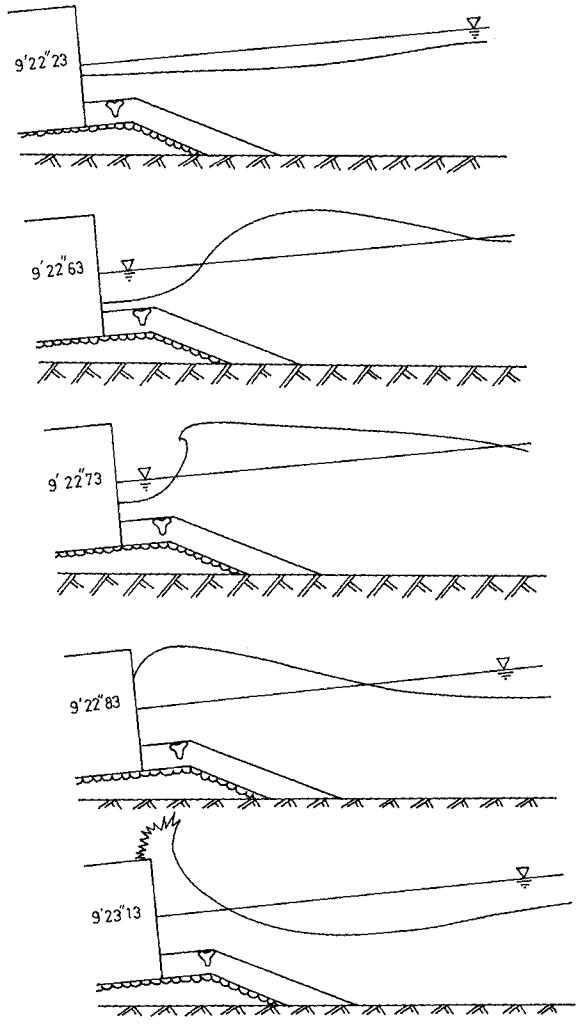

Figure 5 (b) Movement of tetrapod resulting from wave action

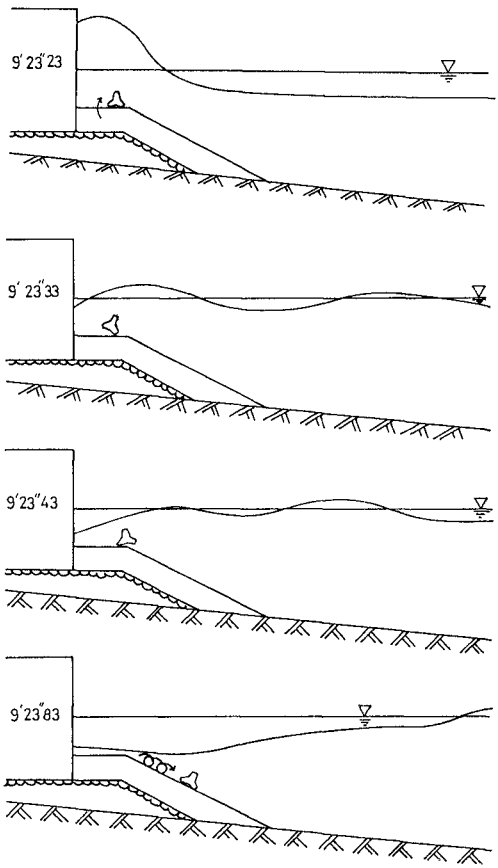

Figure 5 (c) Movement of tetrapod resulting from wave action

Subsequent run-down washed the units seaward. It could be seen that waves breaking on the mound were influenced by the previous run-down. It can be assumed that the magnitude of the lift force was influenced by the previous run-down meeting an incoming wave resulting in damage of the units. Damage in rubble foundations was observed to depend on how much of the top of the foundation was exposed above the water, especially when the troughs of waves near Hmax hit vertical faced structures.

Figure 6 shows an example of a surface elevation measured at a station at a distance of one wave length away from the site whereas Figure 7 shows a record of the waves without the breakwater measured at the point where the model breakwater was to be set up.

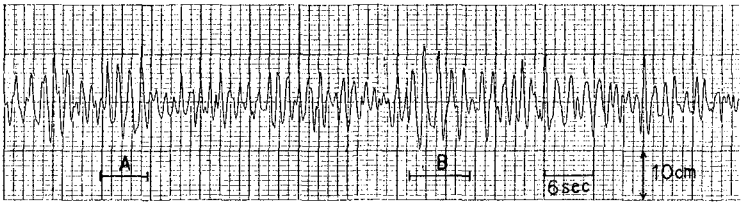

Figure 6 An example of a wave record at a distance of one wave length from the breakwater

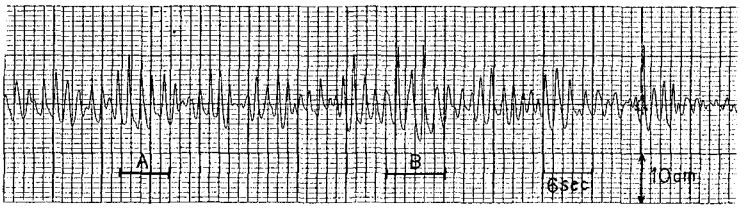

Figure 7 An example of a wave record at the breakwater

A few tetrapods moved due to waves in sections A and B (Figure 6 and 7).

Waves except those in sections A and B caused no movement to armor units. The damage of the armor units by waves in B section was greater than that in A. The maximum wave in this train appeared in section B and several large waves occured successively. These subsequent waves including the maximum wave struck the breakwater damaging the armor units. The consequtive wave heights including sections A and B are shown in Figure 8. The significant wave height and the one-tenth maximum wave height are illustrated in the same figure.

From the investigation using the video film, in critical cases, the movement of tetrapods was caused by those wave groups in sections A and B. Waves exceeding the one-tenth maximum wave height damaged the armor layer. Waves included in B section caused damage more sever than that in A section. Although the only maximum wave can damage, a group of waves exceeding the critical wave height (Hc) is more destructive.

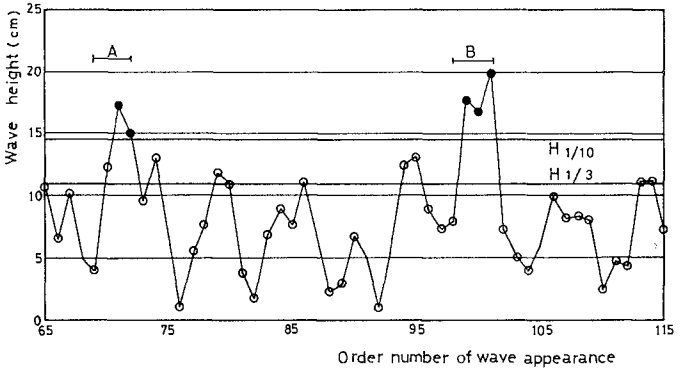

Figure 8 An example of wave group

Stability Number

Stability Number is presented by the following equation.

$$Ns = \frac{\gamma^{1/3} H}{W^{1/3} (Sr - 1)} \qquad \text{--------} \qquad (2)$$

where

Ns ; Stability Number
γ ; specific gravity of armor unit
W ; average weight of armor unit
Sr ; specific gravity of armor unit relative to water
H ; wave height

The relationships between d/h and Ns calculated by equation (2) using significant wave heights measured in the tests are shown in Figure 9 and 10.

Figure 9 shows the results in the case where h_o=-28.0 cm and Figure 10 is the results where h_o=-23.0 cm. In order to compare the test results with those obtained by Brebner and Donnelly(1963), their values of Ns are included using dashed lines in Figure 9 and 10. As it is not possible to compare directly with the results of Brebner and Donnelly(1963), their values of Ns were roughly revised using Kd values of quarry stones and tetrapods. Solid and dotted lines show the results of the cases where T=1.3 sec and T=1.8 sec respectively.

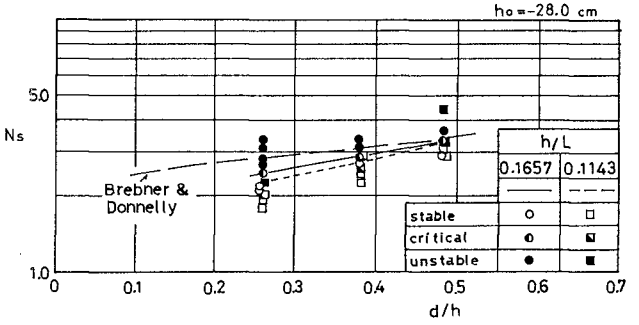

Figure 9 Stability Number as d/h ($H_{1/3}$ as H)

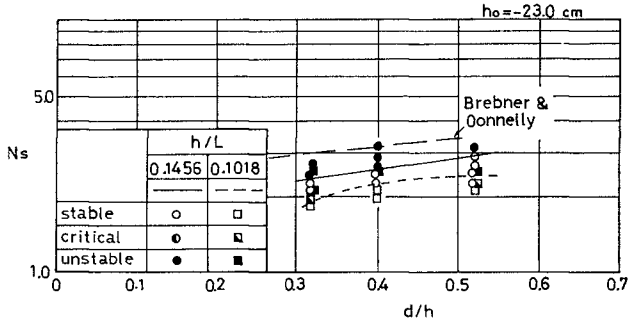

Figure 10 Stability Number as d/h ($H_{1/3}$ as H)

Stability Numbers show a tendency to increase as d/h increases. The rate of increase become smaller in the case where h_o=-23.0 cm.

Where h_o=-23.0 cm, if the wave period was 1.3 sec, the Stability Number is slightly smaller than that where T=1.8 sec. Hence the Stability Number seemed to be affected by the wave period.

The revised Stability number of Brebner and Donnelly(1963) dashed lines) is greater than that found in these test results which were obtained by substituting $H_{1/3}$ measured into equation(2).

Figure 11 and 12 show the Stability Number which was calculated using $H_{1/10}$ measured at the point of a site without a breakwater. In these figures the revised Ns found by Brebner and Donnelly(1963) is also included(by dashed lines). As shown in these figures, Their revised Ns has almost the same value as our results.

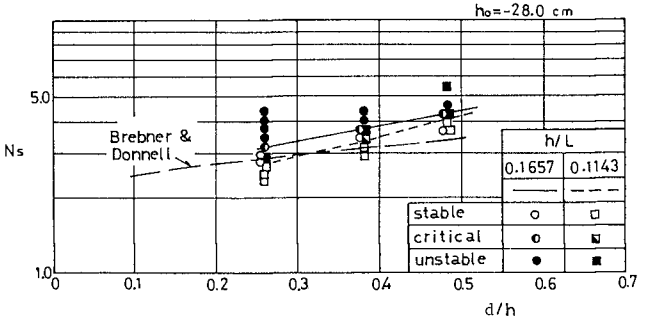

Figure 11 Stability Number as d/h ($H_{1/10}$ as H)

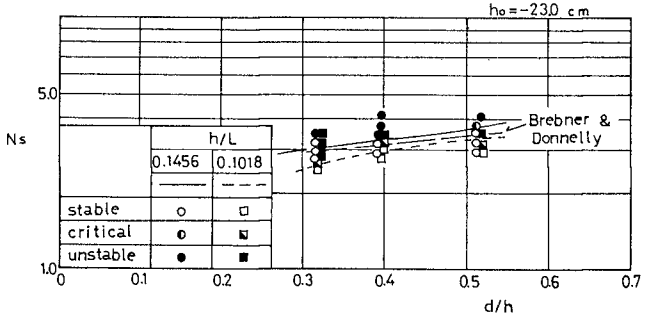

Figure 12 Stability Number as d/h ($H_{1/10}$ as H)

As mentioned above, if $H_{1/3}$ is used in the estimation of a critical unit weight using the revised Ns when the weight calculated is lighter than the required weight.

When the results obtained though regular wave tests are applied to evaluate a required weight of armor units, it seems that the one-tenth maximum wave height as a design wave height is appropriate.

There are no formulae for estimation of weights of armor units, like tetrapods, which protect the rubble-mound at present. Engineers have estimated the stable weight of the armor units as foundations referring to the results of Brebner and Donnelly(1963). However they have to select the design wave height with caution.

Critical weight

From the test results, the critical weight seemed to be a function as d/H where H is a representative wave height,e.g. $H_{1/3}$ and $H_{1/10}$, measured at a point on the site without a breakwater. The relationship between $Wc/w_oH_{1/3}^3$ (w_o: unit weight of water) and $d/H_{1/3}$ are shown in Figure 13 and 14.
Figure 13 shows the results of two cases where h_o=-28.0 cm and h_o=-23 cm at the fixed period of T=1.3 sec. Figure 14 shows similar results where the wave period was 1.8 sec.

From each figure, the boundaries of each case between stable and unstable results can be separated using one straight line, independent of the water depth at the site (h_o), on semilogarithmic graph paper.

Critical relationships are obtained as following equation in each case where T=1.3 sec and T=1.8 sec as a result of the lines drawn.

$$W/w_oH_{1/3}^3 = 0.284 \times 4.58^{-(d/H_{1/3})} \quad \text{(at T=1.3 sec)-----(3)}$$

$$W/w_oH_{1/3}^3 = 0.695 \times 6.55^{-(d/H_{1/3})} \quad \text{(at T=1.8 sec)-----(4)}$$

These two equations show the effect of the wave period.

Engineers have problems in making decisions about what wave height to use ($H_{1/3}$, $H_{1/10}$, Hmax) as design wave heights.

As mentioned before, the armor units were damaged by waves of heights exceeding the one-tenth maximum wave height under critical conditions. In addition, if the depth at the breakwater and the gradient of sea bottom change, the ratio $H_{1/10}$ to $H_{1/3}$ also changes. Then critical conditions would be presented more directly by $H_{1/10}$ than the significant wave height.

The relationship between $W/w_oH_{1/10}^3$ and $d/H_{1/10}$ is shown in Figure 15 and 16.

The empirical equations of the critical relationship are obtained as follows.

$$W/w_oH_{1/10}^3 = 0.125 \times 6.72^{-(d/H_{1/10})} \quad \text{(at T=1.3 sec)-----(5)}$$

$$W/w_oH_{1/10}^3 = 0.187 \times 7.56^{-(d/H_{1/10})} \quad \text{(at T=1.8 sec)-----(6)}$$

These results seem to have an application in estimation of the critical unit weight as suggested by Inagaki et al (1971). When these equations are applied, attention should be paid to the effects of the wave period because the wave with longer period are more destructive than those of shorter periods.

However, these equations were obtained through tests under conditions of a constant wave height, two values of wave period and a constant gradient sea bottom. The effects of these are not yet apparent. Some additional test will be tried.

The test wave height was not so longer in the model, therefore there still remains the problem of the scale effect.

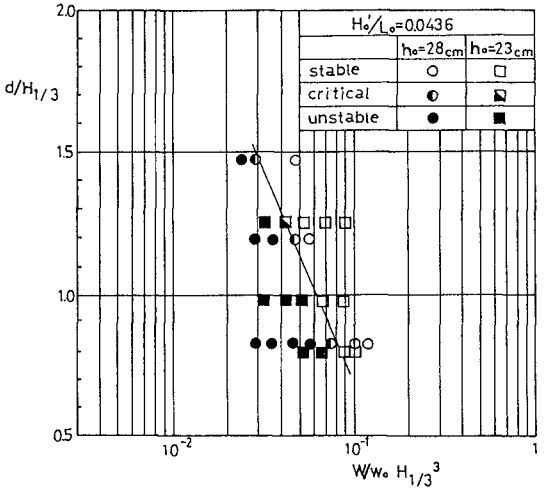

Figure 13 Critical weight as $d/H_{1/3}$ (T=1.3 sec)

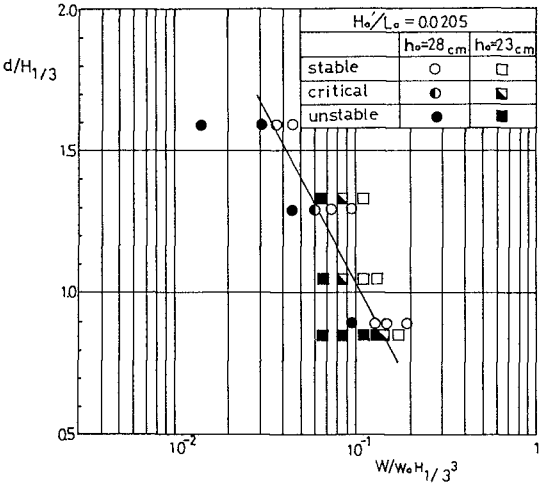

Figure 14 Critical weight as $d/H_{1/3}$ (T=1.8 sec)

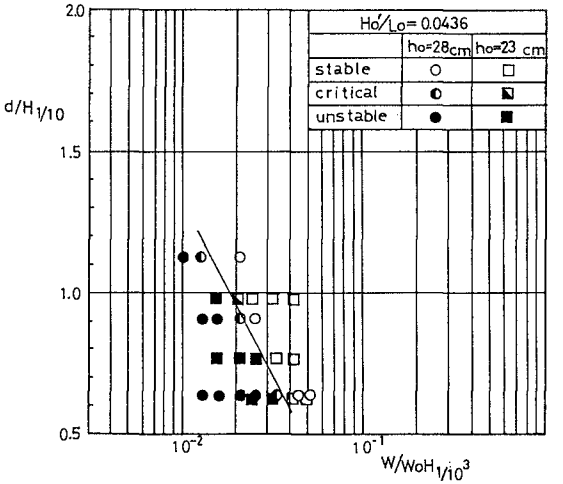

Figure 15 Critical weight as $d/H_{1/10}$ (T=1.3 sec)

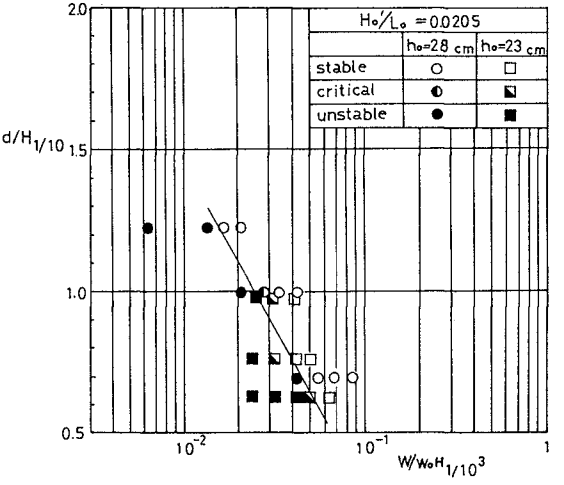

Figure 16 Critical weight as $d/H_{1/10}$ (T=1.8 sec)

Design wave heights are often greater than 7 m and 8 m in the southern area of Japan and the depths of foundations are around -10 m in many cases and as concrete armor units are used to protect such foundations. Figure 13 to 16 could be utilized when faced with this situation.

4. CONCLUSIONS

The conclusions obtained by the tests are summarized as follows.

1. The waves with longer periods were more destructive than shorter waves when h_o was small.
2. Under critical conditions, the tetrapods as a protection of the rubble-mound received damage by waves of height exceeding $H_{1\ 10}$.
3. The stability of the armor unit was affected by the wave group.
4. Critical weight was a function of d/H (H: representative wave height) and increased as the wave period became longer in our range of d/H. It is recommended to use $H_{1/10}$ for design, especially in the surf zone.

IRREGULAR WAVE TESTS FOR COMPOSITE BREAKWATER FOUNDATIONS

Katsutoshi Tanimoto*, Tadahiko Yagyu**, Yoshimi Goda***

ABSTRACT

The stability of armor units for the rubble mound foundations of composite breakwaters has been investigated under the action of irregular waves. The tests establish that irregular waves are more destructive than regular waves, when the height of regular waves is set equal to the significant wave height.

The stability number, defined by Hudson, for quarry stones and concrete blocks with simple shapes is formulated on the basis of irregular wave tests. The stability number is expressed by two parameters of $h'/H_{1/3}$ and κ, where h' is the crest depth of the rubble mound foundation, $H_{1/3}$ is the design significant wave height, and κ is a parameter for the combined effects of the relative water depth and the relative berm width of the rubble mound foundation to the wavelength.

The design mass of armor units can be calculated by the stability equation with the stability number. The application of the proposed method to the results of the irregular wave tests demonstrates that the damage percent for the quarry stones is at most 3.5% at the design condition and the damage progresses rather gradually for the action of higher waves. On the other hand, the damage of the concrete blocks almost jumps beyond the design wave height. In particular, the drastic damage is often caused in the case of high rubble mound foundations. The proposed method is confirmed, however, to be applicable for the ordinary low mound foundations with a sufficient safety.

INTRODUCTION

Composite type breakwaters which are composed of upright sections and rubble mound foundations have several advantages over rubble mound breakwaters. They are more stable, faster in construction, and less in wave transmission than rubble mound breakwaters. Because of these advantages, they have been built in great length of extension in Japan without major mishaps in several scores of years in the past.

** Deputy Director, Planning Division, Overseas Coastal Area Development Institute of Japan

*** Director, Hydraulic Engineering Division, Port and Harbour Research Institute, Ministry of Transport

Design practices of this type of breakwaters also have been improved continuously through theoretical, laboratory and field studies. In particular, much efforts have been maid to study wave forces on the upright sections. As a result of those studies, a general formula to calculate the design wave forces due to nonbreaking to postbreaking waves has been established by Goda (1974). This formula is being successfully applied to the design of composite breakwaters (Bureau of Ports and Harbours, 1980).

On the other hand, the armor layer of the foundation mounds are being designed on the basis of egineer's experiences, supplemented by informations obtained from laboratory studies: e.g. Brebner and Donnelly (1962). Those previous studies, however, were based on the regular wave tests and little information on the irregular wave attacks is available until now, although a number of studies on the stability of armor units for rubble mound breakwaters have been conducted using irregular waves. Consequently, design engineers are always puzzled how the results by regular wave tests should be applied to the actual action of irregular waves. A possible solution for this question is undoubtedly to investigate the stability of armor units for foundation mounds of composite breakwaters by irregular wave tests.

The authors have carried out the irregular wave tests for the stability of armor units in order to get better knowledges for the design of composite breakwaters. The present paper describes the results of the irregular wave tests and discusses the stability number, defined by Hudson (1959), to formulate it on the basis of test results. The study in the present paper is of two-dimensional and limitted to the action of waves of normal incidence to breakwaters.

STABILITY EQUATION

Figure 1 illustrates the typical cross section of the composite breakwaters and defines the symbols used in the present paper;

h : water depth at the structure site

h' : depth at the crest of rubble mound foundation excluding the armor layer

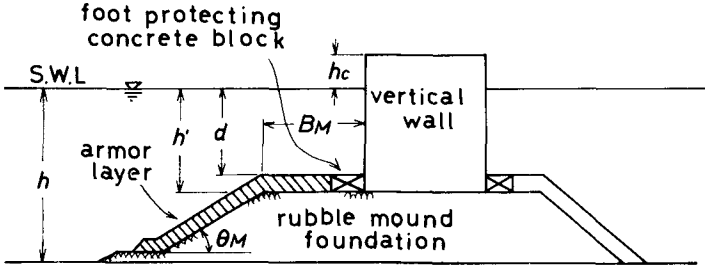

Figure 1 Definition sketch of cross section of composite breakwater

d : depth at the crest of rubble mound foundation
B_M : berm width of rubble mound foundation
θ_M : angle of the front slope measure from the horizontal plane
h_c : crest height of vertical wall above the still water level

Because these dimensions associated with the structure and the water depth as well as wave conditions influence on the stability of armor units for the rubble mound foundation, the problem is very complicated and inherently contains a number of parameters. In the present study, a simplified analytical consideration is made at first in order to find the principal parameters governing the stability of armor units.

In the ordinary conditions, the most critical position of the armor layer being subject to the initial damage may be assumed to be around the top of the slope or the seaward end of the berm crest. For this reason, the composite breakwater is replaced by the vertical breakwater on a hypothetical horizontal bottom having the water depth of h' and the stability of single rubble unit, which is placed at the position with the distance of B_M from the vertical wall, is considered under the action of standing waves as shown in Figure 2.

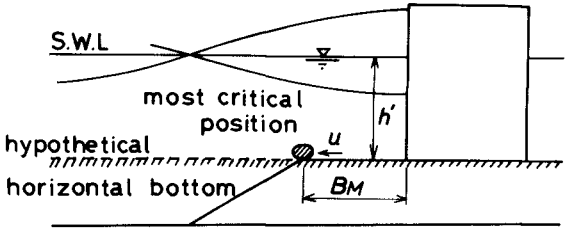

Figure 2 Simplified model for analytical consideration

As to wave forces on the unit, it is assumed that the drag forces predominate over the inertia forces. Then, the horizontal force (drag force, F_D) and the vertical force (lift force, F_L) on the unit are given by the following expressions:

$$F_D = \frac{\rho_w}{2} C_D u_{max}^2 k_A a^2 \quad (1)$$

$$F_L = \frac{\rho_w}{2} C_L u_{max}^2 k_A a^2 \quad (2)$$

where ρ_w is the density of fluid, C_D and C_L are the drag and the lift coefficients, u_{max} is the maximum horizontal velocity, a is the characteristic linear dimension of the unit such that the projected area of the unit perpendicular to the velocity is $k_A a^2$ and the volume of the unit is $k_V a^3$.

On the other hand, the mass of the unit, W, is expressed

$$W = \rho_r k_V a^3 \tag{3}$$

where ρ_r is the density of the unit. Then, the condition of limiting equilibrium against the horizontal displacement of the unit is

$$\mu\{g(\rho_r - \rho_w)k_V a - F_L\} = F_D \tag{4}$$

where μ is the friction coefficient, g is the acceleration of gravity. When Eqs.(1) and (2) are substituted into the above Eq.(4), the following relation is obtained:

$$a = \frac{1}{2g}\frac{k_A}{k_V}\frac{C_D/\mu + C_L}{S_r - 1}u_{max}^2 \tag{5}$$

where

$$S_r = \rho_r/\rho_w \tag{6}$$

Using Eq.(3), Eq.(5) is written as:

$$W = \{\frac{1}{2g}\frac{k_A}{k_V^{2/3}}(\frac{C_D}{\mu} + C_L)\}^3 \frac{\rho_r}{(S_r - 1)^3} u_{max}^6 \tag{7}$$

This relation indicates that the critical mass against the horizontal displacement is proportional to six powers of the maximum horizontal velocity.

When standing waves are formed in front of the vertical wall, the maximum horizontal velocity at the bottom can be expressed by the following equations according to the small amplitude wave theory:

$$u_{max} = \{\kappa \frac{H_I'}{h'} g H_I'\}^{1/2} \tag{8}$$

$$\kappa = \frac{4\pi h'/L'}{\sinh(4\pi h'/L')} \sin^2(2\pi B_M/L') \tag{9}$$

where H_I' is the incident wave height, L' is the wavelength at the depth of h'. The parameter κ represents the combined effects of the relative water depth and the relative distance from the vertical wall on the maximum horizontal velocity at the bottom.

Substituting Eq.(8) to Eq.(7), we get

$$W = \frac{\rho_r}{N_s^3 (S_r - 1)^3} H_I'^3 \tag{10}$$

$$N_s = \frac{2k_V^{2/3}}{k_A (C_D/\mu + C_L)} \frac{1}{\kappa} \frac{h'}{H_I'} \tag{11}$$

Eq.(10) is written in the form of the stability equation which was derived by Hudson (1959) for the armor units of rubble mound breakwaters and N_s is called as the stability number. According to Eq.(11), the stability number is in proportion to h'/H_I' and in inverse proportion to κ.

Because there are many assumptions in the above-mentioned derivation,

the relation given by Eq.(11) is not directly applicable to the armor units for the rubble mound foundations of composite breakwaters. For example, waves are deformed by the existence of the rubble mound foundation and breaking waves also act on the structure when incident waves are high enough. Therefore, in the present study, h'/H_I and K are simply considered as principal parameters governing the stability number, although the stability equation in the form of Eq.(10) is adopted as the basic equation. The wave height of progressive waves in the depth of h is applied to the wave height in the stability equation, and for the action of irregular waves the significant wave height, $H_{1/3}$, is selected as a representative wave height. Thus, the stability equation is defined by the following relation:

$$W = \frac{\rho_r}{N_s^3 (S_r - 1)^3} H_{1/3}^3 \qquad (12)$$

and the effect of the irregularity of individual waves becomes to be contained in the evaluation of the stability number.

The stability number may be expressed as:

$$N_s = f\left(\frac{h'}{H_{1/3}}, K ; \text{shape and placing method of armor units} \right) \qquad (13)$$

where f( ) indicates "function of". The parameter K is calculated for given values of h'/L' and B_M/L'. Figure 3 shows the K-value against B_M/L' when the value of B_M/h' is fixed. For the irregular waves, the wavelength corresponding to the significant wave period, $T_{1/3}$, is applied to L' in the calculation of K-value.

TEST CONDITIONS

Tests have been carried out in the wave flume of 163 m long, 1.0 m wide, and 1.5 m deep as sketched in Figure 4. The wave generator consists of a wave paddle of piston type driven by a linear electric motor with low inertia, the movement of which is controlled by an electric signal from a sine-wave generator (regular waves) or a magnetic tape (irregular waves). In front of the wave generator is a wave filter which absorbs, to some extent, waves reflected from the model structure. The bottom of the wave flume is mostly horizontal, but the test section is the sloping bottom formed as a fixed bed. In front of the model structure, a vertically sliding wall is prepared to avoid the unfavorable effect of transient waves which are caused in the wave flume when the motion of wave paddle is stopped. Glass windows are equipped in a side wall at the test site so that visual observation of the stability of armor units can be made from the side.

The water depth, h, at the site of model structure was selected to be 40 to 50 cm and the model of the composite breakwater was set up for four different thicknesses of the rubble mound foundation in the range of h'/h from 0.3 to 0.9. The front slope of the rubble mound was fixed to be constant at cot $\theta_M = 2$ for all the test cases. The relative berm width to the water depth, B_M/h, was fixed mostly to be 0.6, but, in case

of h'/h = 0.6, it was changed in the range from 0.4 to 1.4.

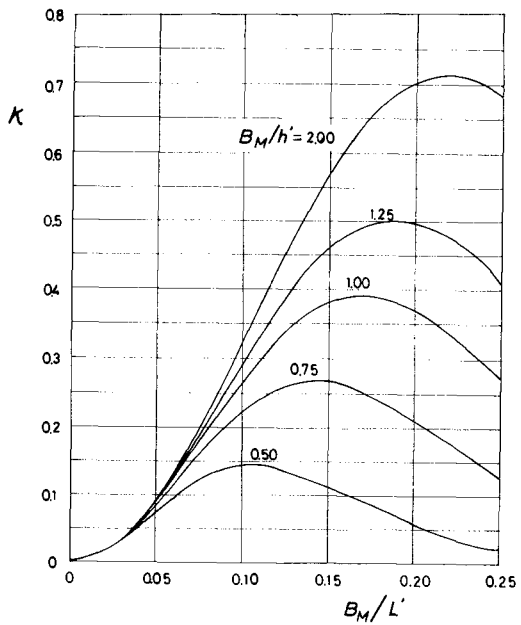

Figure 3 Value of K

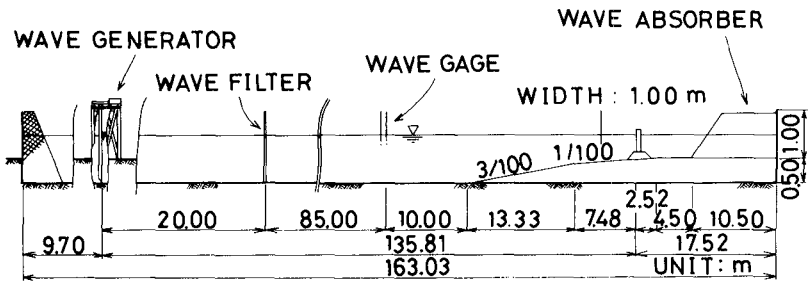

Figure 4 Wave flume

Quarry stones having five different graded sizes as shown Table 1 were tested. They were placed in two layers on the front slope and the crest berm of the rubble mound foundation. The foot of the vertical wall, however, was protected from scouring by placing concrete blocks of the rectangular solid with a sufficient mass.

Table 1 Mass and density of quarry stone

Grade	Mass W (g)		Density ρ_r (g/cm^3)
	average	standard deviation	
I	15.0	2.05	2.60
II	29.9	3.51	2.59
III	57.3	5.99	2.62
IV	105.5	12.5	2.64
V	250.0	27.9	2.75

The concrete block with a vertical hole as shown in Figure 5 was tested as well as the basic shape without a hole. Their masses are from 36.9 to 147.1 g for the basic shape and from 34.1 to 208.7 g for the shape with a hole. The densities are from 2.21 to 2.33 depending on the shape and the size. They were placed regularly in single layer on the rubble mound foundation.

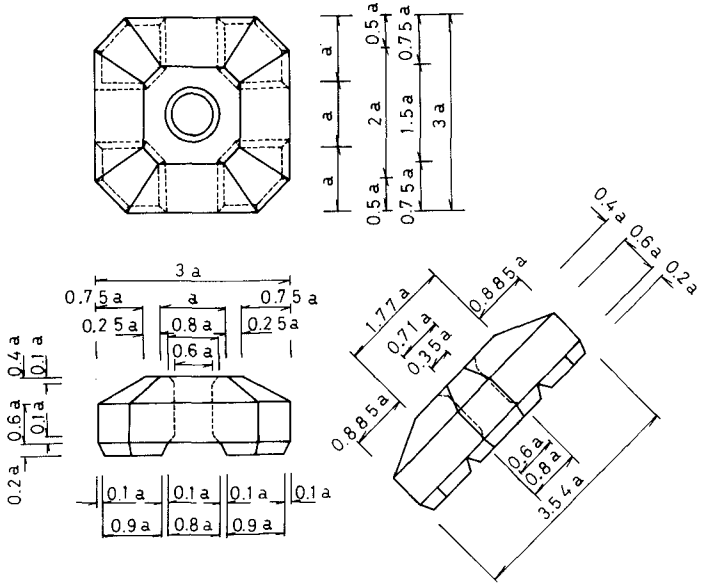

Figure 5 Concrete block with a vertical hole

Irregular waves having the following spectrum of Bretchneider type were simulated:

$$S(f) = 0.257 \ H_{1/3}^2 \ T_{1/3} \ (T_{1/3}f)^{-5} \exp\left[-1.03(T_{1/3}f)^{-6}\right] \quad (14)$$

where $S(f)$ is the spectrum density, and f is the frequency. The significant wave period was changed to give the range of relative water depth from 0.075 to 0.143. The effective duration of irregular waves was selected to be 900 seconds in most cases, but for the tests of the concrete blocks having a vertical hole it was determined so that about 500 zero-up cross waves act on the structure. During the tests, waves were recorded at two adjacent locations in the offshore, and the progressive wave height toward the structure was obtained by the resolution technique of incident and reflected waves from the composite waves (see Goda and Suzuki, 1976). Then, the incident wave height at the test section was estimated from the relation between the wave height at the offshore and the wave height at the test section, which had been measured preliminary without the model structure. The test range of relative wave height, $H_{1/3}/h$, is from 0.16 to 0.44 for the quarry stones and from0.14 to 0.61 for the concrete block having a vetical hole.

The crest height of the vertical wall, h_c, was changed according to the incident wave height so that the relative crest height, $h_c/H_{1/3}$, is kept to be constant value of 0.6. Therefore, the condition is that some extent of wave overtopping is caused for the all test cases.

TEST RESULTS AND DISCUSSIONS

Stability of quarry stones

Armor units of respective masses were tested for given conditions of h'/h, B_M/h and h/L by increasing wave heights, and the relationship between the average mass of armor units and the incident wave height at the equilibrium state between stable and unstable conditions was determined in order to evaluate the stability number. The typical results for the quarry stones are shown in Figure 6. The critical line between stable and unstable conditions is drawn so as to represent one percent damage on the distribution of damage percents which are defined as the percentage of armor units removed from the original position to the total number of armor units in the cover layer. When the critical wave height, Hc, for the respective average mass is determined, the stability number is evaluated by the relation of Eq.(12).

The stability number of quarry stones obtained by the above-mentioned procedure is plotted against $h'/H_{1/3}$ in Figure 7, in which the data are distinguished by the parameters h/L and h'/h, and linked by lines for the same conditions of them. The data indicate that the stability number is increased as $h'/H_{1/3}$ becomes large. It is also seen that the stability number is variated by the other parameters as h/L, and shorter waves are more destructive than longer waves if the value of $h'/H_{1/3}$ is the same. In particular, this tendency is apparently noticed, when the value of $h'/H_{1/3}$ is relatively large. These results establish, as predicted by the analytical considerations, that the stability of armor units for the composite breakwater foundations is greatly effected

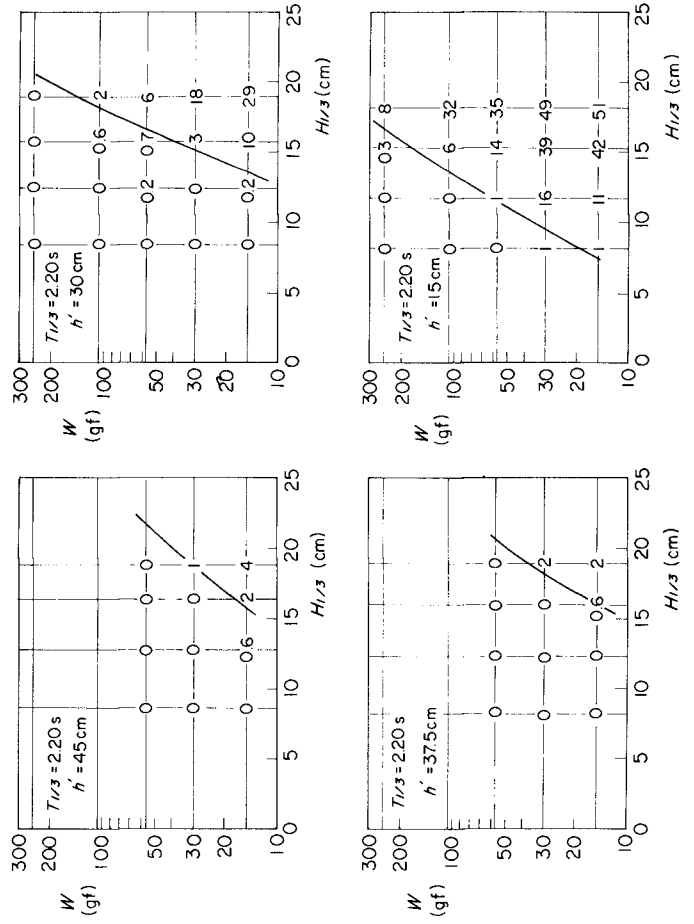

Figure 6 Example of test results for quarry stones (h = 50 cm, B_M = 30 cm)

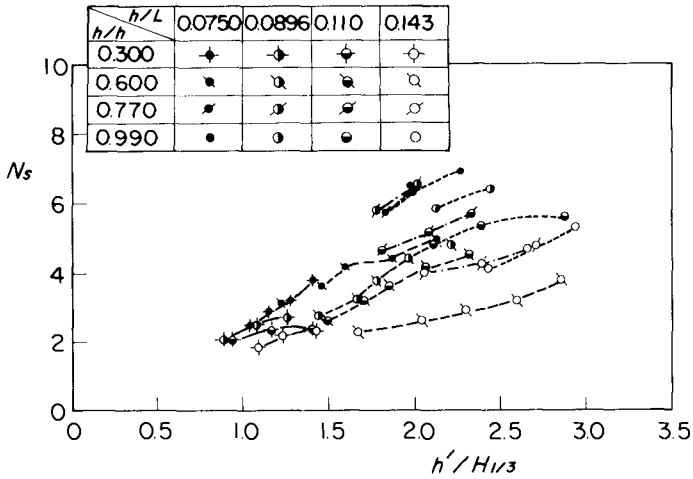

Figure 7 Effect of the crest depth and wave conditions (B_M/h = 0.6)

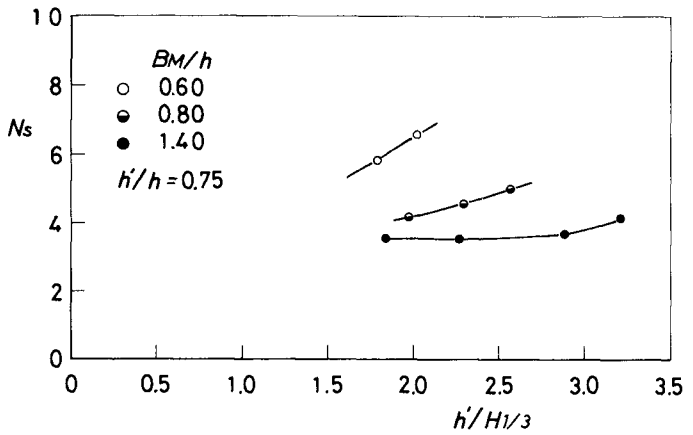

Figure 8 Effect of berm width (h'/h = 0.75)

by the wave height and the period, when the crest depth of the rubble mound becomes deep and standing waves are formed in front of the vertical wall. It is also observed that the stability number has a tendency to converge to a constant value when the value of $h'/H_{1/3}$ becomes small. This constant value must be the stability number of armor units for rubble mound breakwaters, since the extreme state of $h'/H_{1/3} = 0$ corresponds to the rubble mound breakwaters.

On the other hand, Figure 8 shows the stability number when the condition of B_M/h is changed. No data for the condition of $B_M/h = 0.4$ is plotted in the figure, because any damage was not caused at that condition. The results demonstrate that the stability number decreases as the value of B_M/h becomes large. This means that the armor units for the rubble mound foundation with a wide berm width are more subjected to damage than those for the rubble mound foundation with a narrow berm width.

Previous considerations based on the simplified model suggest that these effects of the wave period and the berm width on the stability number may be represented by the parameter K given by Eq.(9). For this reason, the data classified in the appropriate range of K-value are replotted in Figure 9. From these results the following remarks are pointed out:

(1) The stability number for the same rank of K-value increases almost linearly with $h'/H_{1/3}$, although the data are scattered.

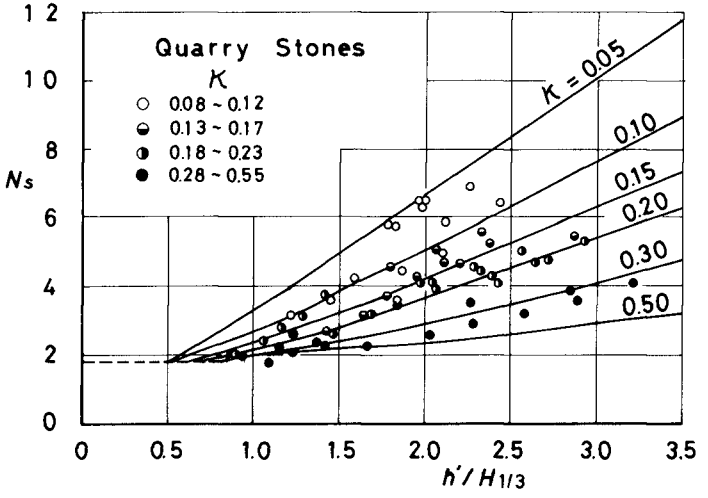

Figure 9 Stability number of quarry stones

(2) As the value of κ becomes large the stability number becomes small, but the difference is not large when the κ-value is larger than 0.3.
(3) When the value of $h'/H_{1/3}$ becomes small the stability number is not much different by the κ-value and has a tendency to converge to a constant value.

Thus, the stability number, N_s, may be formulated by a function of $h'/H_{1/3}$ and κ, so that $N_s = N_{s0}$ at $h'/H_{1/3}$ and N_s is increased in proportion to $h'/H_{1/3}$ when it is sufficiently large. In the present study, N_s is expressed as a sum of two terms as shown in Figure 10, the one is the term which increases linearly in proportion to $h'/H_{1/3}$ and the other is the term which decreases from the value of N_{s0} to infinitesimal at the large value of $h'/H_{1/3}$. After several trials, the following expression was selected:

$$N_s = A \frac{1-\kappa}{\kappa^m} \frac{h'}{H_{1/3}} + N_{s0} \exp\left[-B \frac{(1-\kappa)^2}{\kappa^m} \frac{h'}{H_{1/3}}\right] \qquad (15)$$

The constants of N_{s0}, A, B, m in the above equation are determined so that calculated results agree with test results as closely as possible. The following values were determined for the quarry stones:

$$N_{s0} = 1.8,\ A = 1.3,\ B = 1.5,\ m = 1/3$$

The stability number of $N_{s0} = 1.8$ corresponds to the K_D-value of 2.9 in the Hudson's formula for rubble mound breakwaters, when the value of $\cot\theta_M$ is set equal to 2.

However, Eq.(15) has a minimum value slightly less than N_{s0} at the

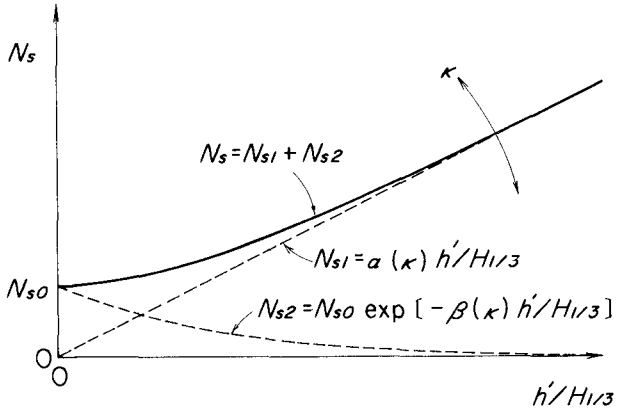

Figure 10 Formulation of stability number

small value of $h'/H_{1/3}$. Finally, the following empirical equation to calculate the stability number of quarry stones is proposed:

$$N_s = \max \{1.8,\ 1.3\ \frac{1-\kappa}{\kappa^{1/3}}\ \frac{h'}{H_{1/3}} + 1.8 \exp\left[-1.5\ \frac{(1-\kappa)^2}{\kappa^{1/3}}\ \frac{h'}{H_{1/3}}\right]\} \tag{16}$$

where max $\{a, b\}$ indicates the larger one of a or b. The curves in Figure 9 indicate the relationships between $h'/H_{1/3}$ and N_s which are calculated for the representative κ-values. It is seen that the calculated relations represent considerably well the tendency of test results.

The design mass of quarry stones can be calculated by applying the stability number obtained from Eq.(16) to the stability equation (12). The calculations were made for the all test conditions in order to compare with test results of damage percent. In Figure 11, the data of the damage percent realized in the tests are plotted against W/W_c. Here W is the average mass of quarry stones which were tested and W_c is the mass calculated by the above-mentioned method for the test conditions. In the theory, $W/W_c = 1.0$ indicates the equilibrium state between stable and unstable conditions, and the damage percent should be about one percent. Such ideal results, however, can not be expected, becuase the behaviours of armor units under the action of waves are essentially changeable due to the slight variations of conditions. The results shown in Figure 11 are satisfactory, although they are considerably scattered. It is also pointed out that the damge of quarry stones progresses rather gradually.

Stability of concrete blocks

Figures 12 and 13 show the test results of N_s for the concrete blocks with and without a vertical hole. The stability numbers for these concrete blocks are also formulated by two parameters of $h'/H_{1/3}$ and κ in the same way as the quarry stones. The curves in the figures indicate the relationships calculated for the appropriate κ-values. The constants in the empirical equation are as follows:

For the concrete block without a hole,

$N_{so} = 1.4$, $A = 1.0$, $B = 1.2$, $m = 1/3$

For the concrete block with a hole,

$N_{so} = 1.6$, $A = 0.82$, $B = 0.9$, $m = 1/2$

The stability number of concrete blocks having a vertical hole is generally higher than that of concrete blocks without a hole. Particularly, the advantages of having a vertical hole is noticed when the κ-value is relatively small.

The tests demonstrate that the damage of concrete blocks placed in single layer progresses drastically when the incident wave height exceeds the critical wave height. Therefore, it should be noted that slight overestimation in the stability number sometimes results in the serious damage. In particular, the drastic damage is often caused in the case of high rubble mound foundations. The results presented in Figure 14 show

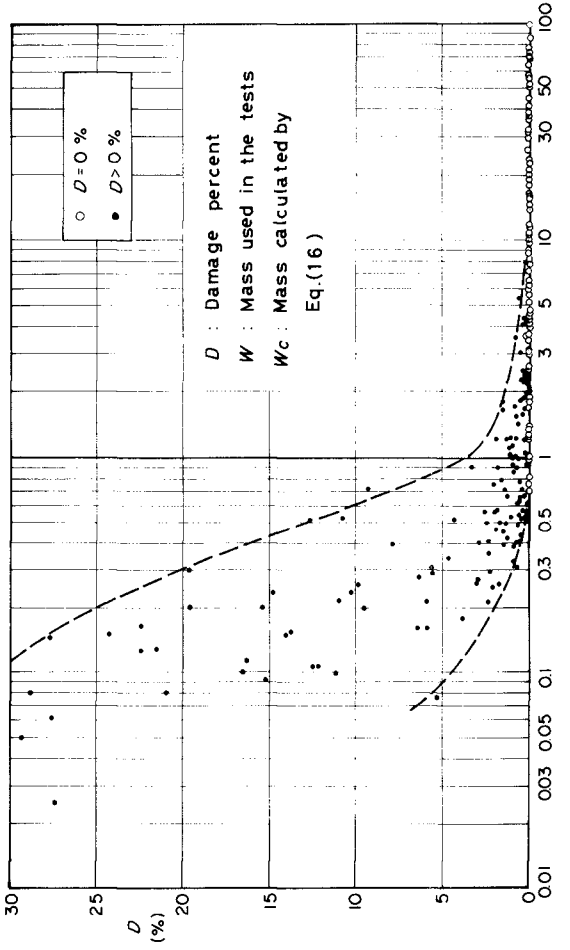

Figure 11 Damage percent of quarry stones

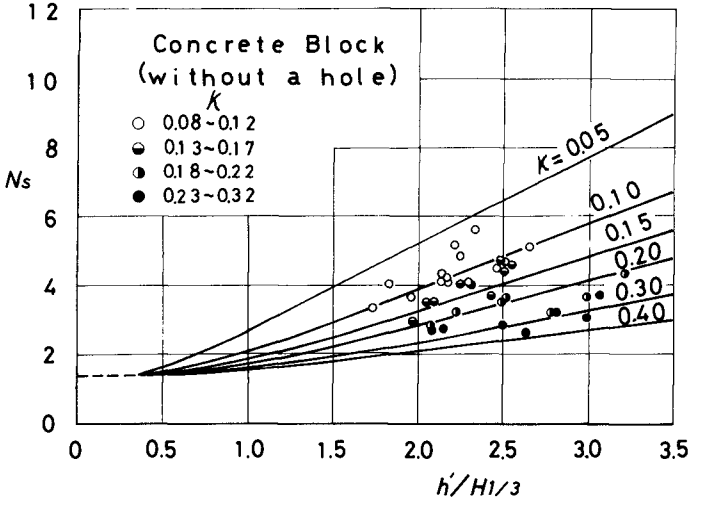

Figure 12 Stability number of concrete block without a hole

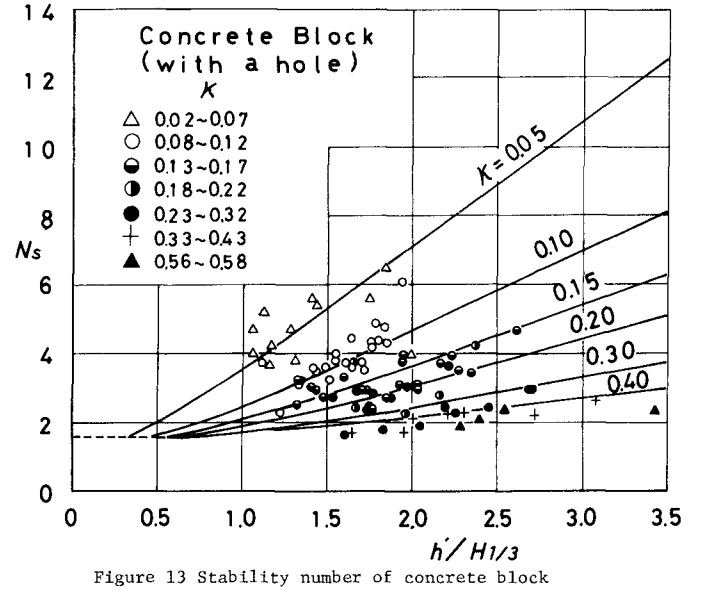

Figure 13 Stability number of concrete block with a vertical hole

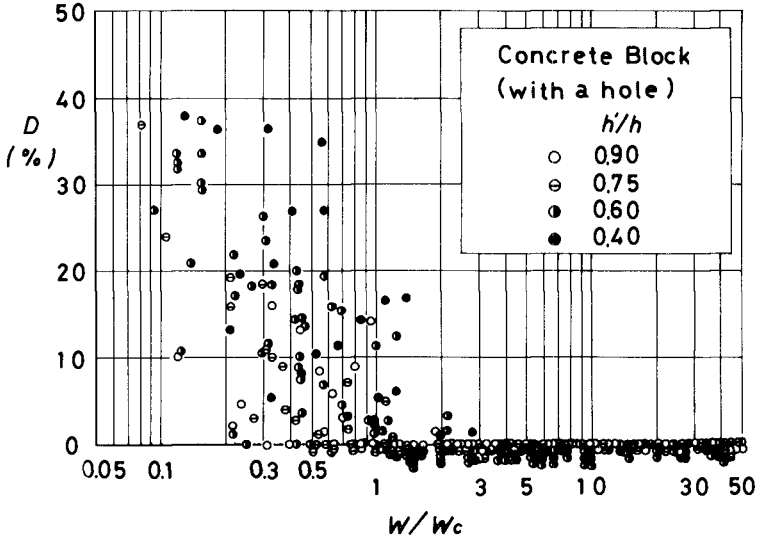

Figure 14 Damage percent of concrete block with a vertical hole

that the damage percent almost jumps beyond the critical conditions and the largest damage percent at W/W_c = 1.0 comes up to about 20 %. However, most data, which indicate the damage in the condition of $W/W_c \geqq 1.0$, are the cases of high rubble mound foundations of $h'/h \leqq 0.6$. For the ordinary low rubble mound foundations, the present method would be applicable with a sufficient safety.

Comparison with results of regular wave tests

Regular wave tests for the concrete block without a hole were carried out in order to make direct comparison with the results by irregular wave tests. The period of regular waves was selected so as to be equal to the significant wave period of irregular waves. The total duration of regular waves with a wave height of certain level, however, was shortened to one third of the duration of irregular waves and it was divided into several short runs so that no re-reflected waves from the wave paddle act on the structure. The tests were carried out by three different conditions of h'/h = 0.60, 0.75, and 0.90, but within the test range of wave heights no damage was caused by the action of regular waves for the case of h'/h = 0.90.

The tests establish that irregular waves are more destructive than regular waves, if the regular wave height is set equal to the significant wave height. Figure 15 shows the relation between the critical wave height of regular waves, H_{creg}, and the critical significant wave height of irregular waves, H_{cirreg}, at the equilibrium state. According to the

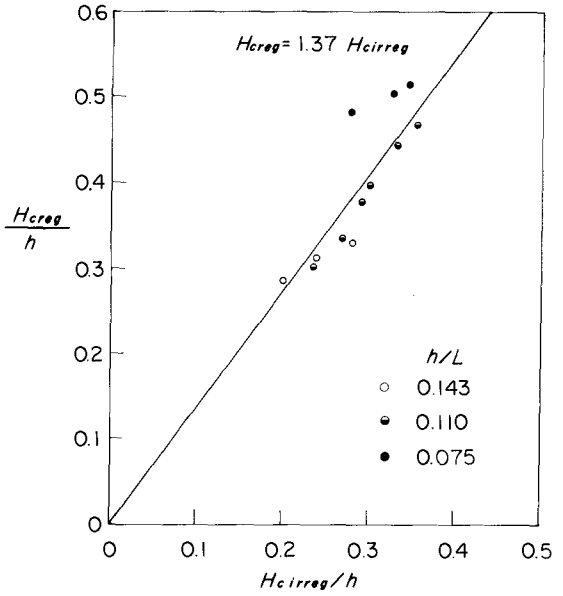

Figure 15 Relation between the critical significant wave height and the critical wave height of regular waves

results, the action of regular waves almost equivalent to that of irregular waves, when the height of regular waves is set equal to 1.37 times of the significant wave height on an average.

Examples of calculations

Examples of calculations of design mass of quarry stones will be given together with the results by two previous studies.

Brebner and Donnelly (1962) proposed the design curve of minimum stability number as a function of d/h. Although thier results were based on regular wave tests, they suggested that the design wave height used in the stability equation should be twice or one and half times of the expected significant wave height depenging on the importance of the structures. In the present calculations, however, the average wave height of the highest one percent of all waves, $H_{1/100}$ (= 1.67 $H_{1/3}$), and the average wave height of the highest of one tenth, $H_{1/10}$ (= 1.27 $H_{1/3}$), are applied according to the recommendation by CERC (1973). The regular wave height equivalent to the action of irregular waves, which was obtained for concrete blocks in the present study, corresponds to the average

wave height of highest one sixteenth, $H_{1/16}$, between $H_{1/10}$ and $H_{1/100}$.

The other previous study is made by Inagaki and Katayama (1971). They investigated the field data of damaged and non-damaged cases of armor stones and proposed the following empirical formula:

$$W = 0.08 \frac{1}{5^{d/H_{1/3}}} H_{1/3}^{3}$$

The conditions for calculations are as follows:

h = 20 m, h' = 15 m, B_M = 10 m

Wave conditions are selected so as to be $H_{1/3}/L$ = 0.045 for the range of the significant wave period from 8 to 16 seconds. Here, L is the wavelength corresponding to the significant wave period at the water depth of 20 meters. The cover layer for the rubble mound foundations is supposed to have a thickness of two armor units and densities of the rubble unit and the sea water are given to be 2.65 t/m^3 and 1.03 t/m^3, respectively.

The results are very different by the mothods as shown in Figure 16, where the absissa is taken as the significant wave height. Generally, the method by Brebner and Donnelly for the rubble mound as foundation results in a very large mass. On the other hand, the method by Inagaki and Katayama gives the minimum mass. The mass calculated by the authors' method is between them and close to the latter rather than the former. The calculated masses for the rubble mound as toe protection by Brebner and Donnelly are also shown in the figure. In this example, the results are very close to those by authors' method, when $H_{1/10}$ is applied. However, such relative relations by the different methods will be changed by the conditions of water depth and the configuration of the rubble mound foundation, since the parameters involved in the methods are different.

CONCLUDING REMARKS

The results of this study provide the design informations of armor units for rubble mound foundations of composite breakwaters. The stability number of the armor units are greatly influenced by the configuration of rubble mound foundation and wave conditions. The stability numbers for quarry stones and concrete blocks were formulated by two parameters of $h'/H_{1/3}$ and K on the basis of irregular wave tests. Generally, the damage of quarry stones placed in two armor layers progresses rather gradually. The application of the proposed method to the test results demonstrates that the damage percent of quarry stones is at most 3.5 % at the design condition. On the other hand, the damage of the concrete blocks placed regularly in single layer progresses drastically in the case of high rubble mound foundations. Therefore, it is not recommended to apply the concrete blocks in single layer to high rubble mound foundations.

THE MONITORING OF RUBBLE MOUND BREAKWATER STABILITY USING A PHOTOGRAPHIC SURVEY METHOD

by

J W J Kluger*

ABSTRACT

A method of surveying the above-water slope of breakwaters by means of photography has been developed at the National Research Institute for Oceanology. The method is simple and inexpensive and yet capable of detecting movement or displacement of a single armour unit on a breakwater.

This poster paper describes the method and presents some examples of its application in the field.

1. INTRODUCTION

The long-term stability of, and the intermittent storm damage to, rubble mound breakwaters are of considerable interest to the designers, builders and authorities responsible for maintenance. A major disaster will obviously be noted immediately, whereas a gradual deterioration, settlement or breakage and movement of individual armour units can often pass unnoticed until major damage occurs. Early detection of cases of potential damage is therefore essential. Full breakwater surveys can become costly and time-consuming and often do not detect the finer details of damage.

A simple yet effective photographic method of surveying the above-water part of a rubble mound breakwater has been developed at NRIO to monitor effectively the movement, displacement and breakage of armour units on the slope. Since this method only records the above-water part of a breakwater it cannot reveal its overall condition, however, it will nevertheless give a reasonable indication of the condition of a breakwater since it is able to record damage in the above-water part of the zone where damage normally commences, that is, the zone with boundaries just above and below still water level (Zwamborn, 1980).

* Coastal Engineering Structures Division, National Research Institute for Oceanology, Council for Scientific and Industrial Research, Stellenbosch, Republic of South Africa

To determine the overall stability of a breakwater this method of survey should obviously be supplemented with an under-water survey method.

2. THE METHOD OF SURVEYING

The technique involves photographing the breakwater in sections from a distance such that individual armour units on the breakwater can be identified easily. A picture of the whole length of the breakwater is obtained by joining the photographs. The sections of the breakwater and the positions from which the photographs are taken are recorded so that subsequent photographs, taken of these sections from the set positions, when compared with the earlier photographs, permit damage to the breakwater to be detected and estimated.

The horizontal photographs taken at sea level can be complemented by photographs taken vertically from the air e.g. aerial survey photographs enlarged to the same scale as the horizontal photographs. These provide means for even closer examination of the condition of the breakwater.

The success of the method depends largely on the accuracy with which it is possible to identify and fix the positions from which the photographs are taken of the breakwater sections. However, no sophisticated position-fixing equipment is used in the surveys and the method is as follows:

Two large beacons are erected on shore to provide a fixed reference line parallel to the breakwater. By sighting and keeping the two beacons in line, the survey boat from which the photographs are taken can maintain a course parallel to, and at the required distance from, the breakwater.

Each breakwater section is identified by two marks painted on the breakwater, one on the top of the splash wall and the other on the land side of the breakwater deck. The line connecting these two marks is perpendicuar to face of breakwater. During a survey a large board with the number of the breakwater section and with a flag at its top is placed over the mark on the splash wall. A long staff, also with a flag at its top, is placed over the corresponding mark on the land side of the breakwater. These two markers, clearly visible from the survey boat, thus provided a reference line of sight to the breakwater section. The positioning of the survey lines and of breakwater sections is shown diagrammatically in Figure 1.

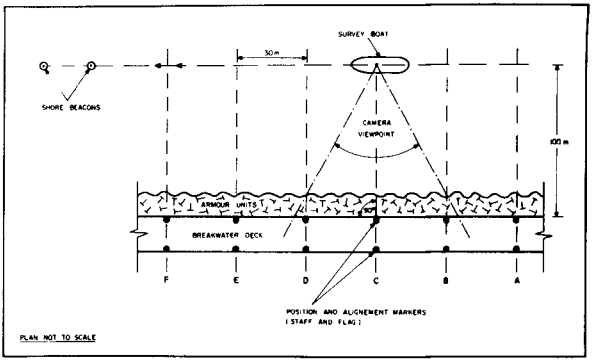

Figure 1 Method of photographic survey (diagrammatic)

The procedure for the survey is as follows:

The survey boat, using the two shore beacons as references, takes up a position on the line parallel to the breakwater, at a fixed distance from the breakwater section to be photographed. The identity board and the flagstaff are placed over the corresponding marks on the breakwater section. The survey boat then moves along the reference line and when the two markers on the breakwater coincide in the centre of the camera viewfinder the photograph is taken. In this way, the position from which the photograph is taken is fixed. This procedure is repeated at each section.

The camera used for the survey is a 6 × 7 single-lens reflex with a 90 mm focal length lens. Each photograph taken from a distance of 100 m provides a 74 m horizontal coverage of the breakwater.

Since the breakwater survey sections are normally marked at 30 m spacings each photograph covers more than two sections. This large overlap provides for the possibility of three-dimensional viewing under a stereoscope.

There are several ways in which the photographs can be analysed.

As mentioned earlier, the photographs can be viewed in pairs under a stereoscope to provide a three-dimensional image of the breakwater section.

For initial comparison of any two surveys, photographs of corresponding breakwater sections are enlarged to the same scale, usually 1:250, and the two photographs examined to detect any changes in the breakwater.

If any changes are noted, and if a closer inspection is needed, the photographs can be enlarged to a much higher degree. The photograph of the first survey (A) is printed in the normal way on photographic paper while the corresponding photograph from the second survey (B) is printed on a positive transparency sheet film. Changes in the positions of dolosse on the breakwater can be detected accurately when the transparency B is placed over the photograph A. If even more detailed analysis is warranted the photographs of only the damaged section can be enlarged further. Since lighting conditions, shadows, etc., are not likely to be the same in any two surveys, the outline of each dolos in the damaged section can be traced onto a film sheet to make the comparison easier. The two tracings overlaid can then be examined dolos by dolos.

When only one or two dolosse have been noted to have moved, the change in dolos position can be shown sufficiently well on an enlargement of the photograph of the relevant breakwater section.

Since damage to an armour slope normally occurs in a zone with boundaries just below and above still water level it is important to do the photographic survey during low water spring tide so that as much as possible of this zone is recorded.

3. SOME RESULTS OF SURVEYS

To date, the method has been used to monitor the stability of breakwaters at three sites, the western breakwater of the Table Bay harbour, the cooling water intake basin at the Koeberg power station and the harbour entrance breakwater at Richards Bay.

Table Bay harbour western breakwater is an old structure which in the course of time has been extended and modified. Because of this there are different types of construction and armour units along its length of about 1 km. These range from caissons to concrete blocks to dolosse. The breakwater is subjected to severe breaking wave action during the winter storms and some parts of the breakwater occasionally require repairs. Photographic surveys are

Figure 2 Loss of dolosse at section P10

used there to monitor the effectiveness of the repairs as well as the general stability of the breakwater. Examples of photographs of damage on the breakwater are shown in Figure 2.

The two breakwaters of the cooling water intake at Koeberg were completed recently (1980). Both breakwaters are rubble mound constructions overlaid with dolos armour units. Regular breakwater surveys have been undertaken as part of the post-construction monitoring programme. Very limited settlement of a few individual dolosse has been recorded on the two breakwaters. An example of settlement (two dolosse) on the head of the breakwater is shown in Figure 3.

Figure 3 Dolos settlement at section S2

Richards Bay harbour breakwaters, both of rubble mound construction with dolosse as the armour unit, were surveyed prior to the proposed improvements. Further surveys are planned to monitor the long-term stability of the breakwaters.

4. CONCLUSIONS

The method of photographic surveying of the above-water part of breakwaters has been found capable of detecting the movement and displacement of individual armour units on a breakwater slope. In spite of the fact that it can only record the above-water part of the zone about the still water level where damage normally commences it can be most valuable as far as giving an early warning of damage in that zone. The method is simple and inexpensive, involving a few people and a boat. A survey takes an average of

about one hour for a 1 km length breakwater. The time required for the analysis of results depends on the extent of change or damage on the breakwater recorded during the survey.

5. ACKNOWLEDGEMENTS

The development of the method was done as a basic research project of the National Research Institute for Oceanology. The assistance by South African Transport Services in the field trials and their permission as well as that of the Electricity Supply Commission to publish the field data is hereby acknowledged.

COMBINED WAVE-CURRENT FORCES ON HORIZONTAL CYLINDERS

by

B.D. Chandler[1] and J.B. Hinwood[2]

ABSTRACT

Some early results are reported from an investigation of the forces exerted on horizontal cylinders by waves and currents. It appears that the values of the inertia coefficients decrease as U/u_o increases, and the drag coefficients decrease also, for values of U/u_o up to 0.7. Comparisons with measured data show that linear theory and the stream function theory satisfactorily describe the wave motion for the conditions investigated, and that velocity superposition can be used with either of these theories to describe conditions involving waves plus currents, with reasonable accuracy.

1. INTRODUCTION

There have been many theoretical and experimental investigations of the hydrodynamic forces that are exerted on submerged cylinders by wave action. Most have been aimed at deriving accurate values for the drag and inertia coefficients for use in the Morison force equation. The forces acting on a cylinder in a steady flow situation have also been investigated extensively, much of this work having been undertaken in wind tunnels. There has, however, been very little investigation of the forces that are exerted when there is a current present in addition to the waves.

Tung and Huang (1973) studied the importance of the presence of the current and the effects of wave-current interactions on the probability function, spectrum and peak distribution of the fluid loading on a cylinder. Since they were interested primarily in the effects of the current upon these statistical properties of the fluid

force, rather than in predicting actual force values for given situations, they assumed values for the Morison force coefficients. Dalrymple (1975) investigated the effects of combined waves and currents using field data obtained in the "Wave Project II" exercise. He concluded that the presence of a current must be taken into account in order to obtain accurate drag force coefficients. Knoll and Herbich (1980) conducted an experimental investigation of the simultaneous wave and current forces acting on a submerged pipeline. They found that the drag coefficients obtained from simultaneous measurement of the force and the velocity were less than those obtained when the velocity was computed by adding the wave velocity from Airy and Stokes third order wave theories to the current velocity. Recently, Kemp and Simons (1982) have undertaken an extensive experimental investigation of the wave/current kinematics. They found that the thickness of the steady flow boundary layer was reduced by the superposition of waves propagating with the current.

The purpose of the present study is to investigate the interaction that occurs between a known wave pattern and a known current; to determine the effects that this interaction has upon the hydrodynamic loading on a submerged, horizontal circular cylinder; and to relate the changes in loading to the detected flow pattern around the cylinder. Measurements were made of the water particle velocities in a combined wave-current flow condition. The wave-current interaction was investigated by comparing these measured values with the velocities obtained by vector addition of the individual wave and current components. One could thereby determine the accuracy achieved by representing the overall velocity field as the sum of the individual components. Measurements were also made of the forces acting on the cylinder; and these, together with the simultaneous velocity measurements, were used to calculate the force coefficients.

2. THEORY

2.1 Wave Theory

In this report, the principle of superposition is used for the theoretical prediction of fluid motion for conditions involving waves plus currents. The horizontal orbital velocities are therefore expressed as the sum of the current velocity and the orbital velocity predicted by the particular wave theory. For these calculations, the wave period used is the one measured in a frame of reference moving with the current. This period, denoted by T', is defined as:

$$T' = T\left(\frac{V}{V - U}\right) , \qquad (1)$$

where T = wave period in stationary frame
V = speed of propagation of wave crest in the flowing water
U = current velocity (the average value over the cross-section of the channel).

The measurements will be compared with the predicted results of two wave theories: the Airy linear theory, and the stream function

theory. The stream function results are obtained from the tables prepared by Dean (1974). Linear interpolation is used to correct for the small departure of the wave parameters from the tabulated results.

2.2 Force Equation

The Morison (1950) equation is normally used for determining the hydrodynamic forces acting on a submerged cylinder due to wave action. In this equation, the force is expressed as the sum of a velocity-dependent drag force and an acceleration-dependent inertia force, as follows:

$$F = C_d \frac{1}{2} \rho D u \left| (u^2 + v^2)^{1/2} \right| + C_m \rho \frac{\pi D^2}{4} \dot{u} \qquad (2)$$

where F = horizontal force per unit length
ρ = density of fluid
D = diameter of cylinder
u = horizontal wave-induced water particle velocity
v = vertical wave-induced water particle velocity
$\dot{u}$ = horizontal wave-induced water particle acceleration
C_d = drag coefficient
C_m = inertia coefficient.

The drag force term is commonly expressed as being proportional to $u|u|$; that is, independent of the vertical velocity. The definition given in eqn (2), however, more correctly describes the horizontal component of the total drag force acting on a horizontal cylinder.

Numerous investigations since 1950 have been aimed at determining the correct values to use for the drag and inertia coefficients. The results of these investigations show a considerable scatter in the derived values for the coefficients, and the coefficients have been shown to be dependent upon parameters such as the Reynolds number, the Keulegan-Carpenter period parameter, the surface roughness of the cylinder, and the vertical to horizontal velocity ratio, v/u .

The design codes (e.g. British Standards Institution (1978)) recommend that the velocities and accelerations be determined by using one of the commonly-used wave theories, such as the linear theory, the Stokes fifth order wave theory, or the stream function theory. The appropriate theory to use will depend upon the particular conditions at the site.

2.3 Force Equation for Simultaneous Waves Plus Current

For conditions involving waves as well as a current, the design codes recommend that the drag force term in the Morison equation be based upon the sum of the current velocity and the wave velocity which would be present in the absence of the current. For horizontal cylinders, the Morison equation should more accurately be written as follows:

$$F = C_d \frac{1}{2} \rho D(u + U)\left|((u + U)^2 + v^2)^{1/2}\right| + C_m \rho \frac{\pi D^2}{4} \dot{u} \qquad (3)$$

where U = current velocity at the depth at which u and $\dot{u}$ are being determined.

For the experimental analysis in this investigation, the term $(u + U)$ is replaced by the total, measured, horizontal velocity. Note that in eqn (3), F, u, v and $\dot{u}$ are functions of time, varying over the wave period.

3. EXPERIMENTAL PROGRAMME

3.1 Equipment

The tests were conducted in a wave channel measuring 15 m in length, 0.60 m in width, and 0.30 m in depth. The waves were generated using a paddle driven by a variable speed electric motor. Openings in and under the paddle permitted the current to flow through it. A specially designed beach was used which satisfactorily dissipated the wave energy, while at the same time allowing water to flow through it. The beach face consisted of parallel wooden slats, with gaps between the slats equal to about 25% of the slat width. A layer of nylon filter material was placed over the upper surface of the slats. The slope of the beach was approximately 1 in 10.

The aluminium test cylinders were 400 mm long, with phosphor bronze end plates fitted to each end. Two different cylinders were used; one having a diameter of 12.7 mm, and the other having a diameter of 25.4 mm. The hydrodynamic forces acting on the cylinder were measured with load-cell devices attached to each end of the cylinder. The load-cells employed semiconductor strain gauges arranged in a Wheatstone Bridge configuration, which had the advantages of increasing the signal output as well as rendering the devices insensitive to small temperature fluctuations. The load cells were tested and found to have negligible drift over a typical recording period of a few hours. Both the vertical and the horizontal forces acting on the cylinder could be measured and recorded simultaneously. To avoid possible errors, no mechanical damping was incorporated into the load cells. They were therefore vulnerable to external mechanical vibrations. To overcome this problem, a very rigid support was constructed for the test assembly, and the support was isolated from the parts of the laboratory building which could transmit vibrations.

A 2 W Argon-Ion laser-Doppler velocimeter was used to measured the water particle velocities. This enabled the horizontal and vertical velocity components to be measured simultaneously, at a point at the same relative depth as the test cylinder.

Two capacitance-type wave gauges were used to measure the water surface elevation directly above the velocity measurement point and above the test cylinder.

The laboratory's constant head tank was used to supply the water for the experiments requiring a current. The head tank was connected, via a control valve, to a reservoir behind the paddle. After flowing through the paddle, along the channel and through the beach, the water passed over a control weir into a weighing tank. It then flowed into the laboratory's sump, from which it was pumped back up to the head tank. The weighing tank was used to obtain an accurate measure of the mass flow rate of the current, from which one could easily determine the current velocity, averaged over the cross-section of the channel.

3.2 Procedure

The still water depth for all tests was 220 mm. The horizontal test cylinders were positioned at three different levels, namely 60, 100 and 150 mm above the floor of the channel. The lowest level was therefore 2.4 cylinder diameters above the floor of the channel, whilst the upper level was nearly 3 diameters beneath the still water level. These levels were set to ensure that no interference effects would occur as a result of the proximity of these boundaries.

The experiments involved generating waves of the same height and period on four different current velocities, ranging from 0 to approximately 100 mm/s. The experiments were repeated for waves of different heights and periods. Four different periods were used, ranging from 0.72 to 1.25 s, with two different heights, ranging from 40 to 74 mm, for each period.

In each experiment, six channels of data were recorded simultaneously. These were the horizontal and vertical forces acting on the cylinder; the horizontal and vertical velocities being measured by the laser-Doppler; and the water levels directly above the cylinder and the velocity measurement point. The velocity measurement point was normally about 150 mm upstream from the cylinder.

A sampling rate of 1000 Hz was used to record the six channels of data, and so each variable was sampled at approximately 167 Hz. The minimum number of measurements for each wave cycle was therefore 120. Data were sampled for approximately 30 seconds, corresponding to 24 to 43 successive wave cycles per sample. All measurements were immediately digitised and stored on magnetic disc for subsequent analysis on an HP21MX computer. The resolution of the analog to digital converter was 5 mV, which was satisfactory in view of the fact that the signal inputs were all of the order of a few volts.

Measurements were made of the time taken for the waves to travel 7.8 m along the channel. From this, one could determine the wave celerity, the wavelength (from knowing the period), and also the phase shift between the locations of the velocity measurement point and the test cylinder.

The load cells were calibrated each day, with the cylinder set up in the configuration being used for that day's experiments. The

calibration of the laser-Doppler was checked on several occasions throughout the course of the experiments; and the wave gauges were calibrated several times at the end of the experiments. No significant changes in the calibration factors were observed for any of the instruments.

3.3 Range of Parameters

The ranges of wave heights and periods, and the current velocities, have already been given in Section 3.2. The still water depth and the steady flow depth was 220 mm for all experiments.

The experiments covered the following ranges of dimensionless parameters:

$\frac{U}{u_o}$: 0 to 1.2

K : 2.1 to 14.2

Re : 9×10^2 to 5×10^3

$\frac{v_o}{u_o}$: 0.23 to 0.86

$\frac{H}{L_o}$: 0.015 to 0.069

$\frac{h}{L_o}$: 0.080 to 0.272

$\frac{H}{H_b}$: 0.23 to 0.43

where h = still water depth
H = wave height
H_b = breaker height = 0.78 h
u_o = horizontal velocity amplitude
v_o = vertical velocity amplitude
K = Keulegan-Carpenter number = u_oT/D
L_o = deep water wavelength
Re = Reynolds number (based on u_o).

3.4 Data Reduction

The drag and inertia coefficients, as defined in eqn (3), were determined by least squares curve-fitting over one whole wave cycle. The average values of the drag and inertia coefficients for each flow condition were obtained in two different ways. One method involved calculating the coefficients for each wave cycle sampled, and determining the average value of these 20 to 40 coefficients. The other method involved averaging the velocity, acceleration and force

data from the 20 to 40 wave cycles sampled, to obtain one representative cycle for each variable, for that particular flow condition. The drag and inertia coefficients were then determined from these averaged cycles of the velocity, acceleration and force. As would be expected, no significant differences were found between the values of the coefficients calculated by these two different methods. These averaged cycles of data were also used for all comparisons of profiles, velocities and accelerations with the wave theories.

4. RESULTS

4.1 Forces

One of the aims of this study is to investigate the effects that the introduction of a steady flow velocity component has upon the values of the drag and inertia coefficients. Figs. 1 and 2 show some of the results obtained by plotting the force coefficients against the current/wave velocity ratio U/u_o . The points lying on each series of lines have approximately the same values of K and v_o/u_o . The results shown are for the 25 mm diameter cylinder, for the levels 98 mm and 148 mm above the floor of the channel. The results for the 12.7 mm diameter cylinder showed similar trends to the larger cylinder, but there were unexpected inconsistencies between the three different levels. These experiments are presently being repeated, and so no results are yet available.

It can be seen in Fig. 1 that the values of C_m decrease steadily as U/u_o increases, such that when $U/u_o = 1.0$, the values of C_m are about 0.4 less than for $U/u_o = 0$. The values of K range from 2.3 to 7.6, and v_o/u_o ranges from 0.35 to 0.82. Both of these parameters appear to have had little influence on the value of C_m , over the ranges quoted.

In Fig. 2, the values of C_d decrease rapidly as U/u_o increases from 0 to about 0.7. Then the values increase rapidly as U/u_o increases from 0.7 to 1.1. The reasons for this dramatic change are not clear. It was observed, however, that, for conditions in which U/u_o was approximately 1.0, the force records displayed a periodic behaviour whose period was twice that of the wave period. This may have been caused by a regular, asymmetric vortex shedding pattern, and it is proposed to investigate this further with the assistance of hydrogen bubble flow visualisation. If a vortex shedding pattern is causing the two-period variation in the force records as well as the change in the C_d values, then it is surprising that it appears to have had negligible effect upon the values of C_m .

The ranges of K and v_o/u_o for the results shown in Fig. 2 are the same as those for Fig. 1, and once again these two parameters appear to have had little effect on the value of C_d .

The values obtained for both coefficients were compared with those reported by others for conditions involving waves alone. They

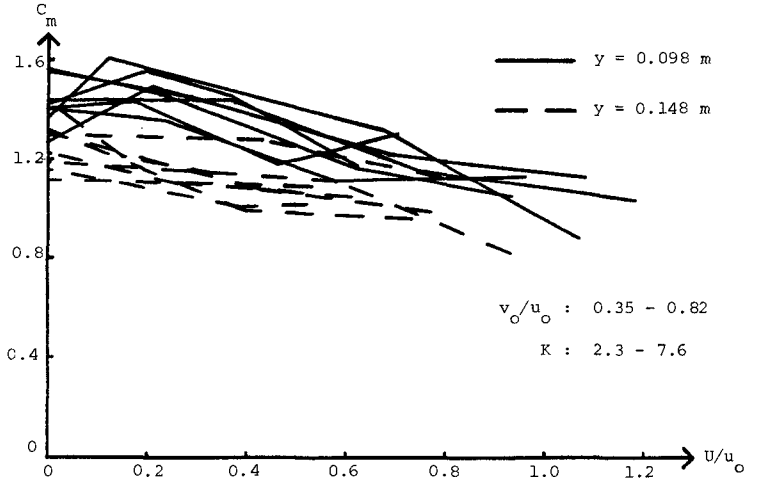

Fig. 1 C_m vs. U/u_o

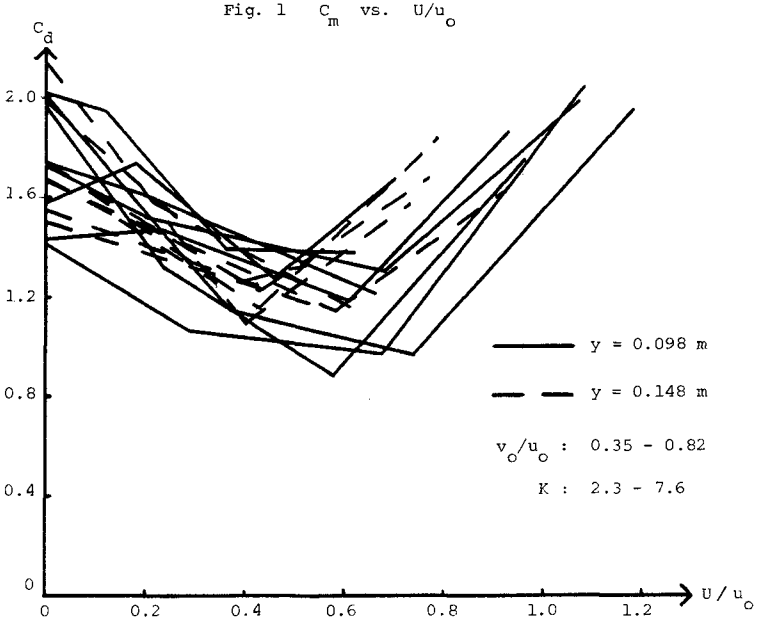

Fig. 2 C_d vs. U/u_o

were generally within the range bounded by the results obtained by Ramberg and Niedzwecki (1980), and the planar flow water tunnel results obtained by Sarpkaya, as reported by the previous authors. There was a slight tendency for the coefficients obtained for high values of U/u_o to be closer to Sarpkaya's results.

The error analysis technique developed by Dean (1976), and modified by Chandler and Hinwood (1981) to apply to conditions involving waves plus a current, was used to determine the suitability of the experimental data for determining the drag and inertia coefficients. Generally, the experiments involving waves alone were better suited for determining the inertia coefficients. As the current velocity was increased, the drag force became more dominant until, for the maximum current speeds investigated, the data had become better conditioned for determining C_d than C_m.

4.2 Wave Motion

4.2.1 Description of Wave Data

All of the experimental results presented in this section are averaged results, obtained by averaging the data from at least ten successive wave cycles. For the comparisons of experimental results with theoretical results, the phase-matching of the different curves was done subjectively to achieve the best general fit over the whole cycle, rather than just matching the curves at, for instance, the crests.

The same basic wave pattern was used for all of the comparisons presented. The main features of this wave pattern are as follows: $H = 0.073$ m ; $h = 0.220$ m ; $T = 0.83$ s (measured in the stationary reference frame); $L = 0.968$ m ; $C = 1.166$ m/s ; $h/L_o = 0.205$; $H/L_o = 0.068$; $H/H_b = 0.43$. For these conditions, Dean (1974) suggests that Stokes V would be the analytical theory providing the best fit to the dynamic free surface boundary condition, but that the stream function V theory would be the best theory overall. For the conditions involving waves plus current, the average current velocity across the channel was 101 mm/s for Figs. 3 and 4, and 61 mm/s for Figs. 5 to 8.

Similar comparisons have been done for a wave pattern with $H = 0.047$ m , $T = 1.03$ s and $L = 1.310$ m . The results are not shown in this report, but the observed trends and wave theory comparisons were found to be similar to those presented.

For the linear theory predictions for waves plus current, the calculations were based on the measured wave height, the measured wavelength, and the period measured in the frame of reference moving with the current, as described in eqn (1). The average current velocity (61 mm/s) was added to the calculated horizontal orbital velocity.

For the stream function predictions of waves plus current, the wave conditions were determined from the appropriate values of h/L_o

and H/L_o, where L_o was set equal to the speed of propagation of the wave in deep water multiplied by the period measured in the stationary reference frame. The speed of propagation was calculated as the sum of the deep water wave celerity for the wave period measured in the moving reference frame, and the average current velocity. Once again, the average current velocity (61 mm/s) was added to the calculated horizontal orbital velocity.

The measured velocities were all measured at a point 100 mm in from the side wall of the channel, and approximately 100 mm above the floor of the channel. The velocities were also measured 300 mm in from the wall, which is effectively in the middle of the channel, but these measurements were not used here since the laser-Doppler signals had higher noise levels than those obtained nearer the wall. Comparisons were made between data measured at these two locations, and it was found that there was no significant difference between them.

For the data presented in this report, the positive direction for the horizontal velocities is the direction of wave propagation. For the vertical velocities, positive is taken as being upwards. The surface elevations are also positive upwards.

4.2.2 Wave Profiles

Fig. 3 shows a comparison of the wave profiles for waves of identical height and period (measured in the stationary frame), one being for waves alone, and the other being for waves plus a current of 101 mm/s. The introduction of the current lowered the levels of both the trough and the crest by about 6% of the wave height, and the trough was not as flat and shallow as for the zero flow case. The current also made the leading face of the wave flatter, and the trailing face slightly steeper.

Figs. 5 and 6 show comparisons of the measured profiles with the linear theory and stream function theory profiles, for conditions involving waves alone and waves plus a current of 61 mm/s. For both flow conditions, the measured crests and troughs laid well above the linear theory predictions. For the zero flow case, the differences were about 8% of the wave height, while for waves plus current the differences were about 6%. The measured profiles had flatter troughs, and narrower, steeper crests than the sinusoidal profiles.

For waves alone, the stream function profile compared extremely well with the measured profile. The measured crest and trough were about 1% below the predicted levels, and the general shape of the wave was almost identical. For the wave plus current condition, the measured crest and trough were about 4% below the stream function levels, and there was still reasonably good agreement between the shapes of the two profiles.

The stream function profiles provided better predictions of the extreme water levels and water surface slopes than did the linear theory profiles, although the linear ones were still only about 8% to

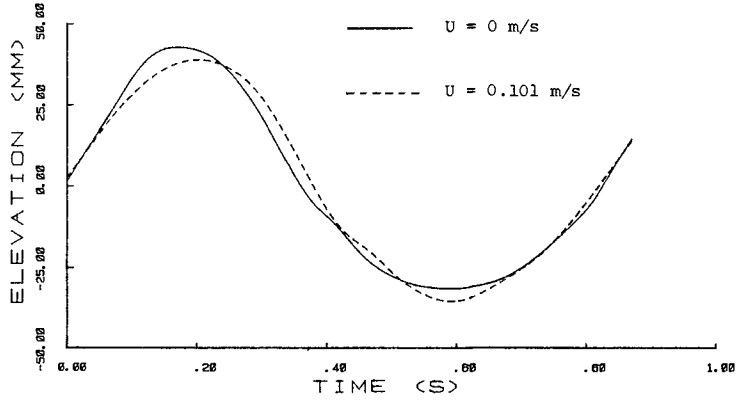

Fig. 3 Comparison of measured wave profiles
(H = 0.074 m, T = 0.83 s, y = 0.098 m)

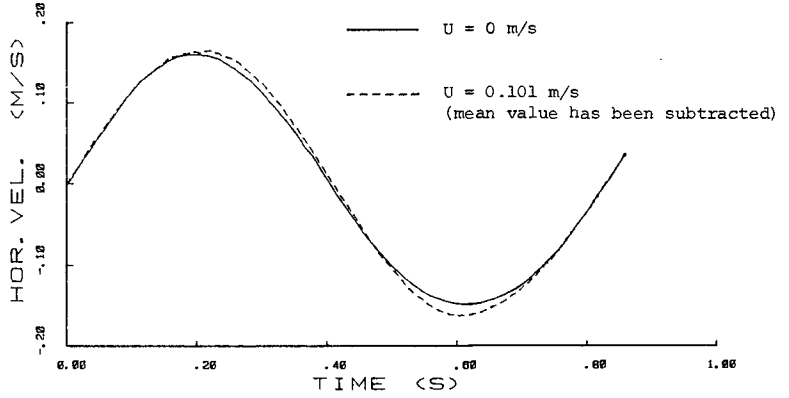

Fig. 4 Comparison of measured horizontal velocities
(H = 0.074 m, T = 0.83 s, y = 0.098 m)

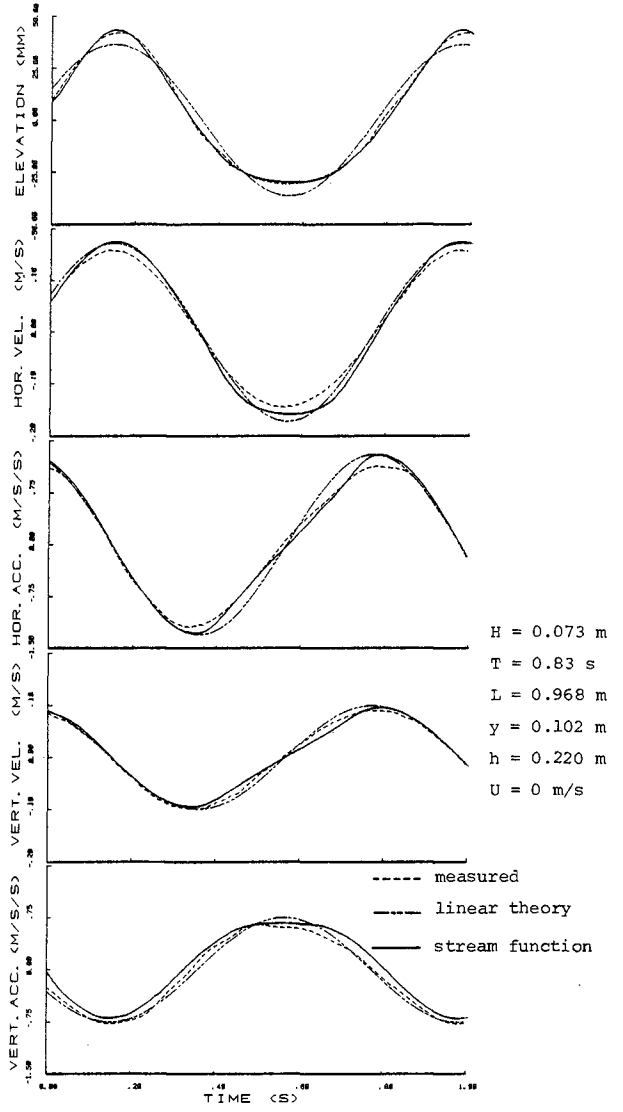

Fig. 5 Comparisons of measured and predicted values for waves alone

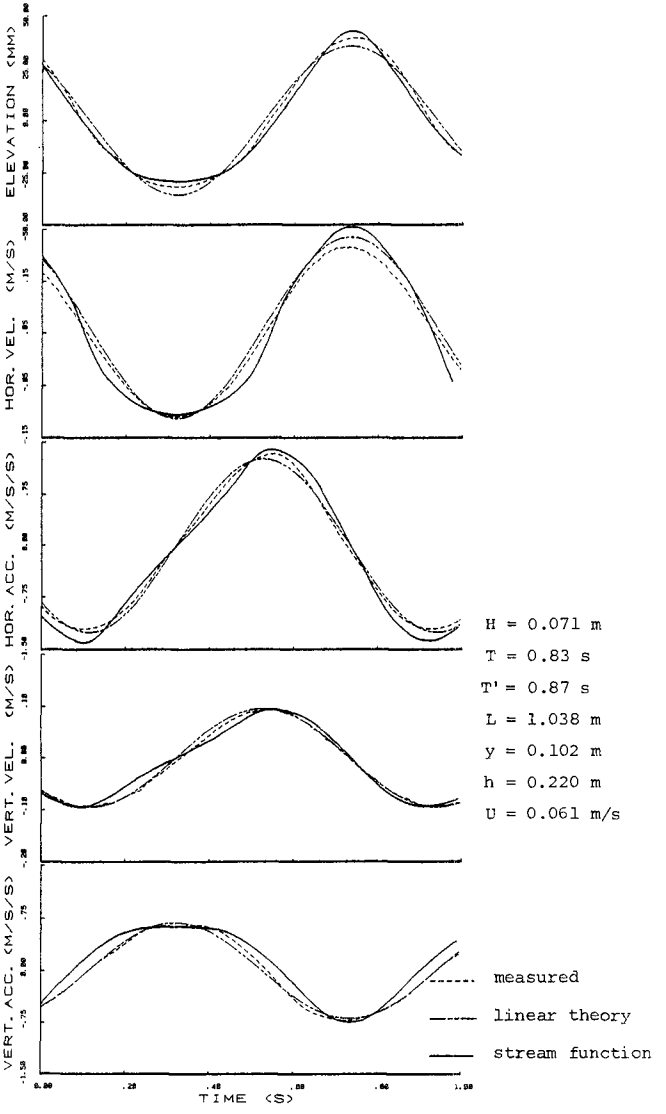

Fig. 6 Comparisons of measured and predicted values for waves plus current

10% of the wave height in error. The linear theory improved slightly for the waves plus current condition, whereas the stream function became slightly worse.

4.2.3 Velocities

Fig. 4 shows a comparison of the measured horizontal velocities for waves alone and for waves plus current. The average current over the cross-section of the channel was 101 mm/s, and the wave celerity for the zero flow condition was 1161 mm/s. The mean velocity over one cycle for the waves plus current condition at the point of measurement was 99 mm/s, and this has been subtracted from the velocities so that both curves have zero mean. The shapes of the two curves are very similar, but the waves plus current curve has a range about 6% greater than the waves only case. However, if linear theory corrections are applied to correct for the period measured in the moving reference frame and also the longer wavelengths of the waves on the current, then this reduces the waves plus current velocities by 6%, making the amplitudes of the two curves almost identical.

Figs. 5 and 6 show comparisons of the measured horizontal velocities with linear theory and stream function predictions. For waves alone, both theories gave similar velocity curves, and they both overestimated the peak velocities. The stream function theory overestimated the velocity range by about 10%, whilst the linear theory overestimated it by about 13%. For the waves plus current conditions, the stream function overestimated the range by about 10%, whereas the linear theory was only about 7% too great.

Figs. 7 and 8 show the variation with depth of the peak horizontal velocity, for y/h varying from 0 to 0.7, where y is the height above the floor of the channel. Due to limitations of the laser-Doppler traversing rig, velocity measurements could not conveniently be obtained at levels higher than $y/h = 0.7$. Fig. 7 indicates that for waves alone, both theories overestimated the velocity range, over most of the depth, by about 5% to 12%, with the stream function theory being generally slightly better. For the waves plus current conditions in Fig. 8, the mean values of the measured results became less than the average mean of 61 mm/s, as y/h increased. This suggests that there may have been a net circulation or drift set up in the channel, in addition to the steady flow. Looking at the velocity range, however, both theories once again overestimated the range by 5% to 15%. In this case the linear theory appears to have provided the better overall estimate.

Figs. 5 and 6 also show comparisons of measured vertical velocities with the theoretical estimates. Generally the agreement is very good. For waves alone, the peak downward velocities were predicted to within a few percent by both theories, and the peak upward velocities were overestimated by both theories, by up to about 5% for the linear theory. Overall, the stream function provided a better estimate. For waves plus current, the two predicted ranges were virtually the same as the measured range. The linear theory provided a slightly better fit at points between the peaks.

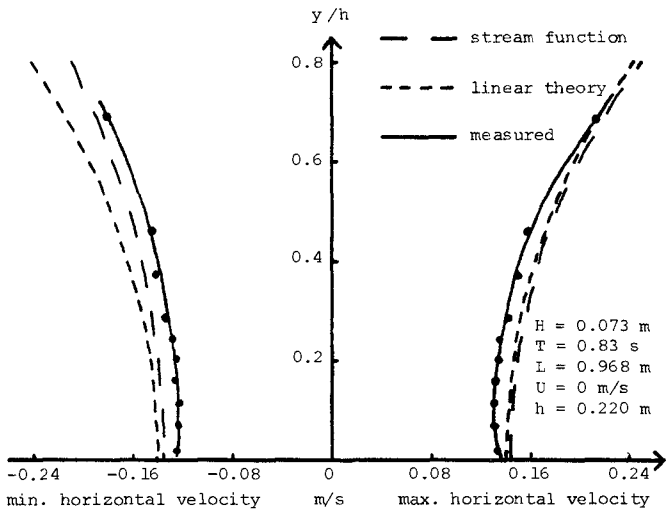

Fig. 7 Variation with Depth of Peak Horizontal Velocity - Waves Alone

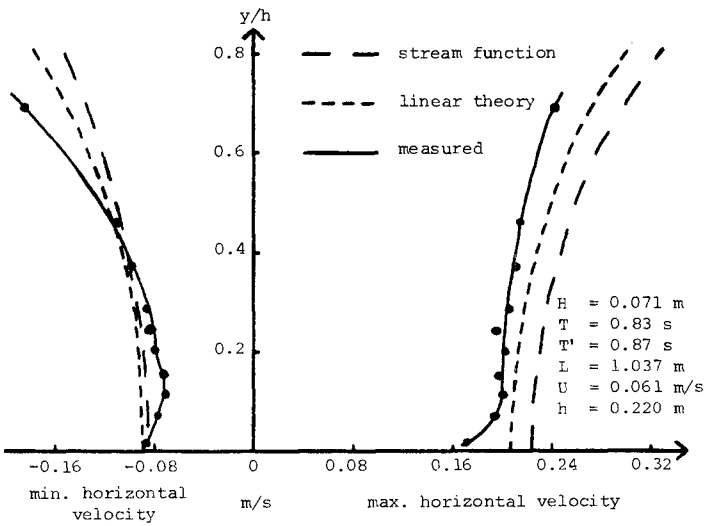

Fig. 8 Variation with Depth of Peak Horizontal Velocity - Waves Plus Current

4.2.4 Accelerations

Figs. 5 and 6 show comparisons of measured and predicted horizontal and vertical accelerations, for waves alone and waves plus current. In Fig. 5, for waves alone, both theories overestimated the peak horizontal accelerations. The linear theory overestimated the range by about 12%, and the stream function theory was about 10% too great. The stream function generally provided the better estimate.

For the case of waves plus current, (Fig. 6), the linear theory slightly overestimated the negative horizontal acceleration peak and underestimated the positive peak, so that its estimated range was only about 1% less than the measured range. The stream function theory overestimated the negative peak appreciably, and slightly overestimated the positive peak, so that its estimated range was about 9% greater than the measured range.

The linear theory's prediction of the vertical acceleration, for waves alone, slightly underestimated the downward accelerations at the wave crest, and overestimated the upward accelerations at the trough by about 7%. This is consistent with the fact that the measured wave profiles had wider, flatter troughs than the sinusoidal profile. The stream function slightly underestimated the crest accelerations, and overestimated the trough accelerations, such that its estimated range was approximately the same as the measured range.

For the vertical acceleration for waves plus current, both theories estimated the peaks and the range to within a few percent. The linear theory, however, provided the better estimate of the general shape of the acceleration curve.

5. CONCLUSION

This paper reports some of the early results obtained from a continuing investigation of the forces exerted on submerged horizontal cylinders by wave and current action. The range and conditions of the experiments were limited, with Keulegan-Carpenter numbers ranging from 2 to 14 and Reynolds numbers ranging from 900 to 5000, based on the orbital velocities. Due to the small scale of the experiments, it cannot be hoped to be able to use the experimental results to recommend coefficient values for prototype conditions. However, it is hoped to be able to provide a greater understanding of the forces exerted by interacting waves and currents, and in particular how these forces and the force coefficients compare with those for waves alone.

Early results from the force data analysis suggest that the values of the inertia coefficient decrease as the current velocity ratio U/u_o increases. Typically, the coefficients decrease from a value of about 1.4, at $U/u_o = 0$, to about 1.0 at $U/u_o = 1.0$. The drag coefficients initially decrease as U/u_o increases to about 0.7, and then they increase again, as U/u_o goes from 0.7 to 1.1. As already discussed, this change in behaviour may be attributable to a dominant vortex shedding phenomenon.

The measured water surface elevations, water particle velocities and accelerations for conditions involving waves alone and also waves plus current have been compared with the results predicted by the Airy linear theory and the fifth order stream function theory. The wave conditions, which extend to $H/H_b = 0.43$, are such that the linear theory would not be expected to be very accurate. It is found that the stream function theory provides better estimates of the elevation, velocities and accelerations, for conditions involving waves alone. Often, it is only marginally better than the linear theory, and the maximum errors associated with the linear theory are only about 10%. For conditions involving waves plus current, the linear theory generally provides a better estimate of the velocities and accelerations than does the stream function. The maximum errors for either theory are still normally less than 10% of the measured value. Both theories can therefore be used with reasonable accuracy for the types of wave conditions investigated here. It would also appear that velocity superposition is valid for both theories, for describing wave plus current conditions.

DISSIPATION OF WAVE ENERGY IN A SEAWATER OUTFALL CHANNEL

K.G. WITTHAUS[1], G. DE F. RETIEF[2], G.K. PRESTEDGE[3]
AND L.R. HUSKINS[4]

ABSTRACT

This paper describes the investigation of means of reducing wave action reaching the shoreward end of a power station cooling water outfall channel without resulting in significant head loss to the outflowing water. A variety of conceptual methods of reducing wave action in the outfall channel was examined. A physical model of the outfall was constructed. It was found that a rubble mound wave energy dissipator located in the outfall channel dramatically reduced wave action at the discharge seal pit.

1. INTRODUCTION

South Africa's first nuclear power station is located on the south west coast and will use seawater as a coolant. Up to 86 cumecs of seawater will be abstracted via an intake basin comprising two rubble mound breakwaters. The intake basin has an area of about 4 ha in which suspended sediments drawn into the basin through its 900 m offshore, 9 m deep entrance will settle before removal by maintenance dredging.

The warm return water will be discharged through a shallow outfall channel into the surf zone south of the intake basin.

The cooling water system is designed to operate as a syphon to minimise pumping costs. At the outfall, four low level 3 m diameter pipes discharge into a seal pit, over a weir and into a tapered concrete channel through the beach. The weir crest is 40 m long with a level of 0,0 m G.M.S.L. (Geodetic Mean Sea Level). The 150 m long outfall channel is curved in plan and tapers to 20 m at the seaward end. The level of the concrete floor is - 2,0 m. The capping beams to the concrete sheet piled walls have a top level of + 2,2 m. Mean sea level is at + 0,15 m G.M.S.L., Mean High Water Springs at 0,86 m and Mean Low Water Springs at - 0,56 m.

The outfall structure was designed to resist full wave action, but after construction of the outfall, the Electricity Supply Commission (ESCOM) requested the designers to investigate means of reducing wave action in the outfall channel. This decision was taken for several reasons but generally it was ESCOM's intention to research any improvements that might add to operating efficiency and safety of the station and thereby maintain the very high standard set by ESCOM for this project.

This paper describes the investigation of means of reducing wave action reaching the shoreward end of the outfall channel without resulting in significant head loss to the outflowing cooling water.

2. PHYSICAL MODEL

A variety of conceptual methods of reducing wave action in the outfall channel was examined. It was decided to construct a physical model of the outfall and foreshore in the vicinity of the outfall to examine wave action and to develop and test methods by which wave action could be reduced.

A fixed bed, 1:30 scale Froude model was built in the hydraulics laboratory of the University of Stellenbosch.

A general view of the modelled outfall and surrounding shoreline is shown on Photograph 1.

The seabed over the prototype distance of 150 m from the end of the channel was constructed at a level equivalent to - 2,0 m GMSL. Further offshore the water depth was gradually increased to provide the depth required for the mechanical generator.

PHOTOGRAPHS

1: GENERAL VIEW OF MODEL

2: CLOSE-UP VIEW OF MODEL OUTFALL STRUCTURE

In the prototype, jet action of the water discharged from the outfall is likely to scour the sandy bed in front of the channel exit, but further seaward, an offshore bar is likely to form. The sea bed level at the offshore bar is unlikely to be lower than the chosen fixed bed level in the model (- 2,0 m) and hence the resulting depth limited waves entering the channel in the model were considered to be a reasonable simulation of prototype conditions.

Regular waves generated in the model were controlled to approach the breaking limit close to the channel entrance in order to maximise the wave energy entering the channel. Wave periods between 6 and 16 seconds were used in the model. It was found that 10 second waves produced effects as severe as any other periods in the model.

This period, which is typical of a large proportion of waves recorded at the site was therefore used in the majority of tests.

Photograph 2 shows the model of the outfall structure with the modelled pipe transitions between the outfall structure and straight lengths of 3 m diameter (prototype) pipes connecting the structure to a reservoir. Water was pumped from the model into the reservoir (via a V-notch weir) to simulate the cooling water flow through the outfall. By means of varying the recirculating flow and capping off the pipes leading to the model C.W. structure, variable flows through any combination of the four C.W. ducts could be simulated. Model tests included no-flow, 40 cumec and 80 cumec flow conditions. Forty cumec flow conditions simulated the closure of either Reactor 1 or Reactor 2 by directing the flow through the northern (left hand side on photograph 2) or the southern pair of ducts respectively. The model C.W. outfall structure had removable perspex slabs to represent the temporary stoplogs. Various still water levels ranging from - 1,5 m to + 2,1 m were used in the model. Most of the tests were carried out with the S.W.L. at + 1,6 m as this was considered to be a realistic normal upper design condition and corresponded approximately to an event with a recurrence interval of 5 years. An extreme still water level of + 2,1 m was also tested. It had been calculated that the recurrence interval of this event, based on an extrapolation of the available records of water level fluctuations due to tide, surge plus long period (50 s to 300 s) wave action, will be in excess of 50 years. (This is the minimum recurrence interval resulting from the most pessimistic of the data using a Weibull population distribution.)

In order to record wave induced pressure surges in the pipes, manometer tubes were fitted to each of the four perspex pipe transitions entering the rear of the seal pit. In addition, pressure transducers were fitted diametrically opposite the manometers on the northern and southern ducts and linked to an analogue recorder.

Wave heights at the closed stoplogs were also measured.

The wave direction used in the model was 247,5 degrees (true bearing of wave orthogonal). This corresponded to the mode of the winter wave directional spectrum, (1,25 degrees north of the mode of the summer spectrum), was normal to the seabed contours between - 5 m

and - 10 m and was 9 degrees north of the C.W. channel centreline at its seaward end.

3. MODEL TESTS OF THE UNMODIFIED C.W. OUTFALL

3.1 No-Flow Conditions

A full range of tests was carried out to study the behaviour of the C.W. outfall without modification when subjected to various discharge flow rates and wave conditions.

Wave induced pressure surges in the ducts under no-flow and various flow conditions were measured and in addition, observations were made of the height to which the waves rose against the closed stoplogs. General wave action in the channel and over-topping of the channel walls was noted.

Model tests were carried out over a range of conditions including various wave periods, water depths, stoplog closure and flow rate conditions.

Photograph 3 shows the general pattern of wave action in the channel under conditions of no-flow. The waves which enter the seaward end of the channel are generally compressed against the southern wall of the outfall channel due to the curvature of the channel, resulting in a variation of wave height across the width of the outfall structure, with larger waves at the southern end.

Waves reflected off the vertical face of the stoplogs and walls of the structure were observed travelling seawards, resulting in increased wave height where the waves interact.

For still water levels higher than about + 1,6 m, an increasing proportion of wave crest overtopped the channel walls and hence wave action due to standing waves caused by the interaction of incident and reflected waves was reduced.

Photograph 4 shows a test carried out with the waterlevel at + 1,6 m and wave period of 10 seconds. During this test the wave height at the stoplogs on the most southern side of the structure was such that a spout of water was projected through the gap between the overhead bridge (+ 5,0 m) and the stoplogs. These test observations appeared to correspond closely with the observations on site and corresponded to the most severe conditions observed in the model.

Pressure surges in the ducts for the no-flow conditions and stoplogs removed were also recorded.

3.2 Half and Full Flow Conditions

Flow of cooling water in the channel resulted in reduced wave action in the channel and hence reduced pressure surges in the

3: TYPICAL WAVE ACTION IN CHANNEL
(SWL +1,6 m GMSL)

4: WAVE ACTION ON STOPLOGS-SOUTH BAY
(SWL +1,6 m GMSL)

ducts, as compared with the no-flow condition. The degree of reduction depends on flow velocity in the channel and therefore is greatest for large flow rates and shallow depths, (i.e. at low tide levels).

As a result of the variation of wave height across the outfall structure, (increasing from north to south i.e. left to right in photograph 4), a corresponding variation of pressure surges was recorded in the ducts.

Surges in the most southern duct, for the case of an extreme S.W.L. of + 2,1 m and 40 cumecs flow in the northern ducts was found to be 1,5 m.

Tests carried out under 40 cumec flow showed that wave action in front of the no-flow half of the structure and pressure surges in the corresponding no-flow ducts with the stoplogs removed were slightly less severe than for the complete shut-down condition.

4. POSSIBLE MEANS OF REDUCING WAVE PENETRATION

To reduce wave action at the outfall structure, a number of structural alterations or additions were considered. These fall into two basic categories, those than sought to prevent waves reaching the seaward end of the outfall and those that modified wave action within the outfall channel.

From preliminary evaluations of the various schemes that were considered, the following conclusions were reached. Some qualitative model testing was used to support conclusions drawn.

Offshore Structures

In this category an offshore rubble mound breakwater constructed either linked to or isolated from the southern breakwater of the intake basin was considered. Its position, orientation and length would have needed careful study but in any case it would have been very expensive. However, it would also have had potential disadvantages in its deflections of the discharge plume and the changes it would have imposed on siltation which may have been encouraged in its shadow.

Such a breakwater for a somewhat lower cost could have been attached to the north side of the channel thus retaining the continuity of the discharge jet, although the jet would have been deflected to the south with a potential loss of cooling efficiency. Scour at the base of the structure would have been a problem.

To retain the jet discharge direction two rubble mound breakwater arms could have been built on either side of the outfall, with spending beaches each side of the present outfall. This solution would also have been expensive, but it was nevertheless tried in the model. The brief trial indicated that very little protection

was afforded and that the outflow currents reduced the spending effects.

Despite the advantage that offshore structures could have been constructed during operation of the outfall, it was concluded that offshore structures would be investigated further only if high cost were justified and all other options were relatively unsuccessful. They were not therefore considered further and it was decided that solutions inshore of the sea end of the outfall should be persued as more likely to meet the requirements.

Outfall Channel Modifications

- Moveable Devices

  Moveable devices were considered as a possibility for insertion or operation during extreme wave conditions or under particular operating or shut down conditions. Such devices included for example gated structures, floating breakwaters or caissons but in all cases would have been attended by maintenance problems. Disadvantages would have varied with the particular arrangement and operating conditions but would have included problems of moving, maintenance, disruption of flow and flow back-up. It was concluded also that periodic floating-in or launching a structure would have been impracticable in this coastal environment. These solutions were therefore rejected.

- Reduction in channel entrance width

  Reduction of the outfall end width appeared attractive but of course higher discharge velocities at low levels would have caused flow back-up and consequent scour problems would have resulted. Nevertheless a trial was made on the model which indicated that significant wave action still penetrated the outfall channel.

- Increased roughness and/or canalising flow

  The addition of increased roughness to the sides and bottom of the outfall channel was mathematically investigated and found to have little effect. Even the use of a number of splitter walls with artificial roughness was found to offer only a modest reduction in wave height. It would, in any case, have been very difficult to construct such splitter walls.

  One new wall down the centre of the outfall channel was able to concentrate the 40 cumec flow over half the channel to equal the velocities of 80 cumec over the whole channel but did not reduce wave penetration in the no-flow condition. This solution would also have been somewhat difficult structurally and expensive to build.

- Change in Channel plan geometry

  More fundamental changes to the plan geometry of the outfall channel

were then considered. Resonator basins could have been used to damp out wave action travelling along the walls, particularly on the south side. Each resonator needed to be designed for a narrow band of wave period and a number would have been needed to cover sufficient of the wave spectrum.

Fairly fine tuning of the group would have been needed to optimise the result and hence they would have been less efficient when non-designed conditions occurred. Construction would have involved cutting down substantial lengths of the outfall piles and driving a longer indented length at high cost.

A simpler constructional approach would have been to build a combination of deflectors and wave breakers in the channel. A typical solution on these lines was modelled and showed that benefits might be obtained from the absorption but that the deflectors were less effective. Structural problems would have been similar to the central walls and probably expensive to overcome. An advance on the wave absorption theme could have been to cut off some of the side piling and produce a spending beach just outside the channel. The cut off level would have needed to be low, only the outer ends of waves would have been affected, and outflow would have been distorted.

To avoid expensive removal and reconstruction in the channel, isolated wave absorbing devices could have been placed in the channel, for example, shaped perforated blocks. These were tried in the model but the wave period was too long for their effect to be noticeable. These would, of course, have caused a restriction to outflow.

Many of the above solutions were found to have inherent cost or effectiveness disadvantages, however two promising solutions were a long slab spanning the entire width of the outfall at a relatively low level, and a rubble mound wave energy dissipator (WED) constructed inside the channel.

The first of these was sufficiently interesting to seek a degree of optimisation by model tests, from which it was concluded that, located near the downstream end of the channel and spanning 20 metres across it, an unbroken slab extending over about 18 metres length of the channel was needed. The level of the slab soffit had to be set at about 0,0 GMSL to prevent the passage of wave energy whilst allowing outflow of 80 cumecs beneath it. Large wave forces were involved, however, and the slab needed to be heavy. Its weight required separate support outside the sheet piling, which was not designed to support such loads.

There was sufficient head loss in the cooling water outflow across the slab (approximately 600 mm under the worst conditions). Wave resonance between the outfall structure and slab occurred under certain conditions which required the introduction into the channel of simple anti-resonance devices. The slab cut out wave overtopping at the inshore end of the channel and would have been virtually maintenance free. However, there could have been problems of

stability during construction and a lengthy model study would have been needed to optimise the design. The cost was estimated to be 50% more than the WED mound and therefore this alternative was carried no further.

The wave energy dissipator (WED) mound comprises a periphery of heavy precast concrete blocks in the centre of the outfall commencing at a point 25 m seaward of the crest of the seal pit weir and extending about half way down the channel. Inside the blocks, a rubble mound is constructed up to a peak level of + 3,0 m GMSL in the centre of the channel. The layout tested is shown in photographs 5 and 6.

During the course of testing the possibility of splitting the mound into two parts, one along each side wall of the channel, (for easier construction) was examined, but the result was far less effective hydraulically. Only the centre channel mound was therefore evaluated during the remaining model tests.

It quickly became apparent that the WED was not very sensitive to detailed adjustments in design, it was effective over a wide range of wave periods, and it eliminated resonance.

It achieved a significant reduction in wave action at the outfall structure under no-flow conditions and substantially reduced surge in the pipes when flow was present. It produced an insignificant loss in head in cooling water outflow.

The effectiveness of the WED in reducing wave penetration is due to three basic hydraulic phenomena:

(i) As a wave travels up the outfall it moves between the channel walls and the sloping rock bank. The latter causes wave refraction, so bending the wave front at that end and allowing its energy to be partly spent in the top of the rubble mound.

(ii) As the shoreward end of wave diffracts around the round head of the WED and the energy which remains is spread over a greater width of channel before reaching the outfall structure leading to a reduction in wave height.

(iii) During the half flow condition, the WED concentrates almost all the flow down one side of the channel, which effectively results in the same wave energy exclusion by current in that side of the channel as in the full flow condition over the full channel. The wave energy reaching the operating side of the outfall is thus further reduced.

The WED had one potential problem, namely how to construct it taking account of wave action and whilst still permitting outflow up to 40 cumecs in the channel. Further consideration, however, led to the conclusion that suitable temporary works could be devised to make the scheme entirely practicable.

5: MODELLED WAVE ENERGY DISSIPATOR (SWL -0,5 m GMSL, flow 80 cumecs)

6: MODELLED WAVE ENERGY DISSIPATOR (SWL +1,0 m GMSL, flow 80 cumecs)

5. MODEL TESTING OF THE RUBBLE MOUND WAVE ENERGY DISSIPATOR

Various preliminary tests were carried out to finalise the general arrangements of the WED concept and these included tests on a series of tall blocks projecting above the water surface around the perimeter of the mound to 'deflect' the wave towards the mound, additional V-walls along the length of the mound and a pier connecting the outfall structure with the shoreward end of the mound. These were found to have nominal benefit with respect to reducing the wave activity at the structure in relation to the cost of providing such refinements. A definite reduction in wave energy dissipation was noted for a reduced mound length.

Model testing of the WED has shown that it is capable of dissipating a large proportion of the incoming wave energy. There was also a significant reduction in wave activity and pressure surges on the no flow side of the structure under half flow conditions.

For the + 1,6 m design water level the maximum wave height recorded at the stoplogs was found to be 1,2 m for the no flow condition with all stoplogs in place - photograph 7.

It was found necessary to have 'toe' blocks to the rubble mound in order to ensure the stability of the rock in the mound under extreme low tide conditions when the velocity in the channel resulting from an average discharge of 86 cumec was greatest. An extreme low water level test equivalent to a water level of - 1,5 m (recurrence interval in excess of 1000 years) showed flow conditions to be acceptable and that the toe blocks would be stable.

Tests at the extreme high still water level of + 2,1 m indicated that the surge in the southern duct would be 0,6 m for the 40 cumec flow condition. The WED rock mound was also noted to be stable for the + 2,1 m water level and no flow condition.

6. APPLICABILITY OF MODEL RESULTS TO PROTOTYPE

Comparison of the roughness in the model channel with that in the prototype indicated that the model was marginally rougher than the prototype. For the 80 cumec flow and still water level at + 1,6 m the additional friction in the model could be expressed as an additional 10 mm of prototype head backup in the outfall chamber. The additional friction would result in very slightly lower channel velocities and correspondingly less wave reduction in the model, leading to conservative observations of surge.

With the WED in place the relative roughness of prototype and model are comparable.

The use of regular waves of equal height in the model represents the fairly severe condition of the wave train of maximum wave heights compared with a normal wave spectrum which would include a spread of wave height and wave periods.

(c.f. photograph No. 4)
(SWL +1,6 m GMSL)

8: TEMPORARY WEIR IN OUTFALL CHANNEL

9: COMPLETED WAVE ENERGY DISSIPATOR IN SERVICE

7. CONSTRUCTION

The WED was designed in such a manner that it could be constructed with minimum interference with the operation of the power station contractor. This was particularly important since cooling water pumping tests (40 cumecs) were scheduled to commence prior to completion of construction. Furthermore, these tests were likely to be intermittent and of unspecified duration.

A temporary weir (Photograph 8) had been built in the outfall channel ahead of construction of the WED to minimise C.W. flow velocities in the construction area and as far as possible to reduce the return of sand removed from the construction area of the channel. The weir would also afford a degree of wave exclusion.

The weir consisted of tubes made from anchovy fish net filled with 58 mm aggregate. Each tube had a mass of about 2 tonnes. This design successfully accommodated large settlements into the sand infill on which part of it was constructed and facilitated easy removal.

The rock mound consists of a 1 metre deep underlayer of 0 to 1 tonne quarry run rock placed within the precast concrete toe blocks and the remainder of rock is 1 to 3 tonne mass.

The completed structure is shown in Photograph 9.

8. CONCLUSION

It was found that a rubble mound wave energy dissipator located in the outfall channel dramatically reduced wave action at the discharge seal pit. Under maximum discharge the additional head loss in the channel due to the WED was found to be negligible. The authors believe that the rubble mound wave energy dissipator provides an economical and highly effective means of suppressing wave action in an outfall channel without creating impediment or head loss to the cooling water discharge.

TIDAL EROSIONAL EFFECTS ON A BULKHEAD SYSTEM

by
Ronald M. Noble[1], M. ASCE, Wolfgang H. Roth[2], M.ASCE
and Uday K. Patil[3], M.ASCE

ABSTRACT

In the design and construction of waterfront bulkhead systems, it is essential to consider the coastal effects of tides, waves, boat wakes, currents, bottom sediment movement and bottom scour. Many improperly designed bulkhead systems experience severe loss of backfill and toe materials with the bulkhead eventually failing if it is not corrected in time. Inadequate drainage, joint connections, and/or inadequate toe protection are typically the causes of failure.

This paper describes an investigation of a bulkhead system supporting a large waterfront development in southern California which was experiencing widespread sinkhole development in the bulkhead's backfill and was on the verge of losing toe material. The objective of this investigation was to determine the extent and cause of ongoing subsurface erosion, to evaluate its effect on the bulkhead stability, and to recommend and design mitigative measures. The cause of the erosion was determined to be piping of fine grained soils due to inadequate backfill drainage. A remedial drainage scheme was designed and field-tested, and several structural repair schemes were suggested for portions of the bulkhead where accumulated damage affected the integrity of the structure.

INTRODUCTION

The Channel Islands waterfront development in southern California consists of approximately 585 lots adjacent to artificial waterways connected to the Pacific Ocean. The lots are supported by concrete retaining walls or bulkheads completed in 1970. Two types of pile-supported bulkhead designs were used in this development: an L-shaped retaining wall without tie-back anchors and a precast panel and pilaster system with tie-back anchors. The latter was used for 231 lots and is the subject of this paper.

---

[1]President, R.M. Noble & Associates

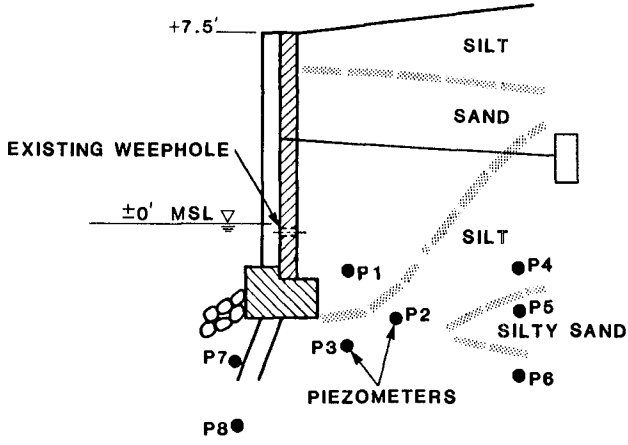
[2]Associate, Dames & Moore

[3]Project Engineer, Dames & Moore, Los Angeles, CA

Within a period of 2 to 4 years after the completion of construction, several sinkholes and areas of subsidence were observed in various lots. The purpose of this investigation was to inspect the bulkheads and to assess their safety and stability. Following the initial assessment, the physical causes of the observed defects were investigated and, where necessary, recommendations for remedial measures were made.

BULKHEAD STRUCTURE

A typical cross section of the bulkhead is shown on Figure 1. The bulkhead is 9.5 feet high and consists of precast concrete panels, which are supported by precast concrete columns, 11 feet on center. The columns are tied back by anchors to a continuous concrete deadman and rest on a continuous 4-foot-wide by 2.5-foot-high poured-in-place footing which is supported by one row of batter timber piles. Two weepholes per panel, with wire mesh screens, are provided for drainage of the sand backfill.



Note: MSL = Mean Sea Level

Figure 1. BULKHEAD CROSS SECTION

The waterway channel is dredged to a depth of approximately 6 feet below the bottom of the bulkhead footing. The underwater slope of 2(h):1(v) is protected by filter cloth and riprap. The elevation of the original ground surface was about 2 to 3 feet below the bulkhead top elevation. The construction of the waterfront development proceeded in three major steps: (1) excavation of channels with berms for bulkhead footing and concrete deadman; (2) construction of bulkhead; and (3) backfilling to existing grade, final grading and placing of slope protection.

INVESTIGATION

At the time of this investigation, approximately 50 percent of the waterfront lots were unimproved and accessible, while the rest were built on, and thus were not inspected. The investigation consisted of a visual inspection of all accessible lots, an exploratory drilling program on a few selected lots, a diving survey of selected underwater slopes, and a field testing program involving the installation of pore water pressure gauges on two selected lots for the purpose of measuring hydraulic gradients due to tidal movements within the backfill. Finally, one of the instrumented lots was selected to field-test remedial drainage measures.

Visual Inspection

During the visual inspection, numerous sinkholes measuring approximately 0.5 to 2 feet in diameter and 1 to 3 feet in depth were encountered immediately behind the wall. Such sinkholes were found mainly at the joints between the columns and wall panels and in a few cases at the locations of the weepholes in the center sections of the panels. In addition to the sinkholes, several areas (approximately 10 by 10 feet) with a subsidence on the order of 2 to 4 inches were encountered, usually at convex bulkhead corners.

Subsurface Investigation

Subsurface conditions were explored by drilling at least two borings each on seven selected lots, ranging in depth from 9 to 17 feet below the ground surface. Undisturbed soil samples were obtained at intervals of aproximately 2 feet. The emphasis of the laboratory testing program focused on grain-size analysis and determination of dry density, both considered to render data for evaluating the soil's potential for subsurface erosion (piping).

A typical subsurface profile in the immediate vicinity of the bulkhead is shown on Figure 1. A backfilled wedge of loose fine sand extends down to the footing base, which is underlain by soft natural sandy to clayey silts. The loose sand backfill is generally covered by a stiff silt layer of 3 to 4 feet in thickness. The soils behind the backfill wedge range from loose silty fine sands to dense sandy silts.

Underwater Slopes

The upper, riprap-covered portion of the underwater slope extends from an elevation of 1 foot below the top of the footing to 4 feet below the top, and slopes 2(h):1(v). After having reviewed preliminary data from the Phase I investigation and results of the bathymetric survey, several locations were explored qualitatively by divers. Generally, sandy silt deposits up to 8 inches in thickness were encountered on top of the footings, as well as on the riprap-covered slope extending downwards from the toe of the wall.

Judging qualitatively, the underwater slopes, seemed to be intact with the exception of the slopes at the convex corners of two lots. At one of these lots, the top of the slope had settled extensively, and a gap had developed between the footing base and soil. The gap was up to 17 inches high, and up to 4 feet deep. At the other lot, the top of the slope seemed to have settled also, however, without exposing a gap.

Pore Pressure Measurements

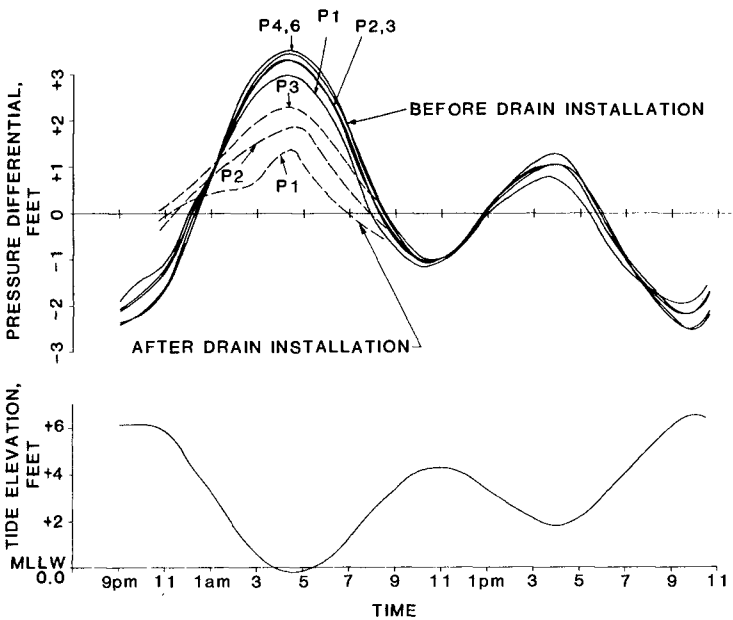
Pore pressures were measured in order to evaluate pressure gradients resulting from seepage toward the channel at low tide. Figure 1 shows the layout of the installed piezometers which consisted of instant-responding pneumatic pore pressure probes. After allowing a minimum of 7 days for stabilization of seepage conditions after installation, the piezometers were read hourly during one 24-hour cycle of extreme tidal movements. Relating the measured pore pressures to the free water level in the channel, it was possible to construct flow nets indicating areas of high hydraulic gradients in the backfill and bulkhead foundation which are especially endangered by piping.

The general trend of seepage gradients versus time in the backfill is shown graphically on Figure 2. The upper portion of the figure shows the pore pressure differentials, with reference to the free water level in the channel, at the locations of the installed piezometers. For instance, a pore pressure differential of +2 feet at a particular location and time would mean that the ground water in a hypothetical stand pipe installed at this location would rise 2 feet above the water table in the channel. The ground water seepage would thus be directed towards the water channel. From the standpoint of piping, the most severe conditions exist at the peak of positive pore pressure differentials. The lower portion of Figure 2 is a plot of the corresponding tide elevations versus time.

Flow nets were constructed at several critical times, making simplified assumptions, such as homogeneous soil conditions and two-dimensional flow conditions. The flow nets shown on Figure 3 represent two "snapshots" of a constantly changing flow pattern in the backfill. The indicated times (1 a.m. and 3 a.m.) for which the flow patterns are depicted correspond to the time scale of the graph on Figure 2.

The flow net at 1:00 a.m. indicates a zone of flow reversal moving away from the wall as the free water level in the channel moves down. The fact that this flow reversal condition, involving very small relative pressure differentials, could consistently be derived from actual pore pressure measurements increased confidence in the piezometer data.

The most critical flow condition in terms of underground erosion (piping) is demonstrated with the flow net at 3:00 a.m. The flow lines in this and subsequent "snapshot" flow nets (not shown here) suggest that the bulk of the seepage water escapes through the vertical panel/column joints above the footing.

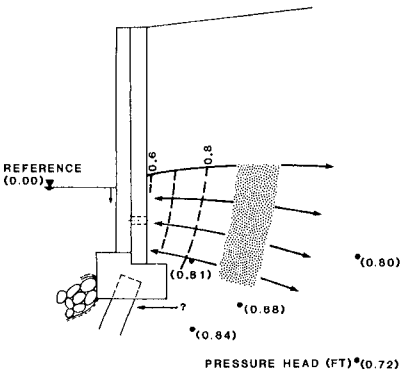


Note: MLLW = Mean Lower Low Water = -2.8' MSL

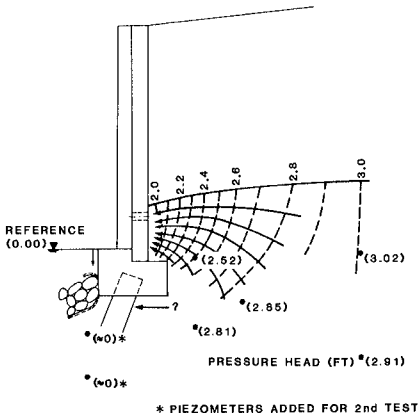
Figure 2. PORE PRESSURE MEASUREMENTS

Although the test results did not indicate significant seepage underneath the footing, a second test was performed with two additional piezometers (P-7 and P-8 in Figures 1 and 3) inserted on the waterside beneath the footing, with the objective to study the seepage in the foundation soils. It was observed that these two additional piezometers essentially fluctuate in phase with the free water level

a) 1:00 A.M.



b) 3:00 A.M.



* PIEZOMETERS ADDED FOR 2nd TEST

Figure 3. FLOWNETS

in the channel. This indicates minimal seepage in the lower portions of the subsoil beneath the footing. However, it does not exclude the possibility of concentrated seepage through a gap or thin soil layer just beneath the footing base.

CONCLUSIONS

The primary cause for the development of sinkholes and subsided areas behind the bulkhead is loss of sand backfill through the panel joints caused by seepage forces (piping). Sinkholes and subsidence are initially of only cosmetic consequences. However, if such conditions were neglected for long periods, progressive failure involving the bulkhead footings and/or deterioration of the underwater slope could develop. Such conditions were actually encountered at some locations as described above.

Piping underneath the footing base does not appear to be a primary cause for loss of material. However, once a gap has developed between footing base and subsoil, migration of the sandy backfill progressively accelerates underneath the footing. Because the bulkhead rests on piles, the soil tends to settle away from the footing due to minor creep movements of the underwater slope. such creep movements are believed to have caused the slumping of the slope at some locations observed by the underwater survey.

Summarizing, there is evidence that cyclic seepage forces (piping) mainly due to tidal action, are responsible for existing subsidence, sinkholes and gaps. Therefore, the main objective of remedial measures discussed in the following sections is the reduction of these seepage forces. In addition, at selected locations where progressive undermining of the footings is already taking place, repair schemes for foundation and/or underwater slope will be discussed.

REMEDIAL MEASURES

Backfill Drainage

Consideration was given to various kinds of drainage systems, including vertical sand (or wick) drains, gravel drainage trenches, inclined wick drains, and horizontal well-point drains. A desk study narrowed the alternatives down to two: the inclined wick-drain system and the horizontal well-point system.

The schematic of the inclined wick-drain system is shown on Figure 4. A typical wick drain is 3 to 4 inches wide and consists of a corrugated plastic core wrapped in filter fabric. These drains are installed with a mandrill pushed into the ground with the wick drain attached to its point. Upon withdrawal of the mandrill, the drain stays in the ground acting as an effective drainage channel. The drains would be installed from the land side, aiming at a center location just above the footing. After installation of the drains, a gravel-filled filter-cloth pouch would be inserted, from the water side, through a hole drilled in the concrete panel.

Because access from the land side was judged to be quite difficult for the majority of the waterfront properties, the drainage method involving horizontal well-points (installed from the water side) was finally selected for a field test. No. 7 well points (0.007-inch-wide slots) 3/4-inch in diameter were used for this test.

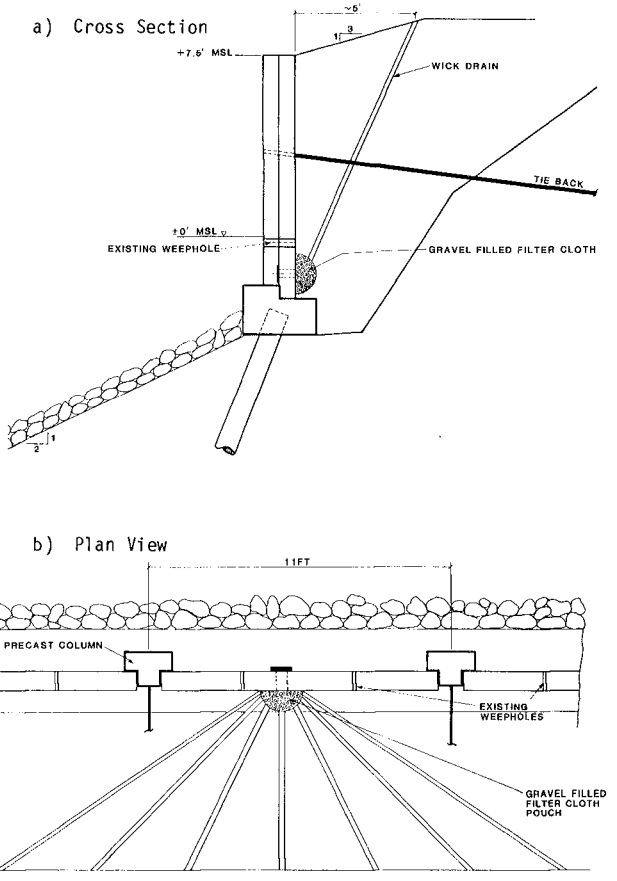


Figure 4. INCLINED WICK-DRAIN SYSTEM

The grain size distribution of the backfill material indicated that approximately 10 to 15 percent would pass the 0.007-inch sieve. While initially small amounts of the fine soils might pass through the well screens, rearrangement of the grains around the well screen will eventually develop a natural filter preventing further material loss. The field test was conducted at the location which was previously instrumented with piezometers, in order to compare hydraulic gradients before and after installation of the drainage system. Figure 5 shows the layout of the field test.

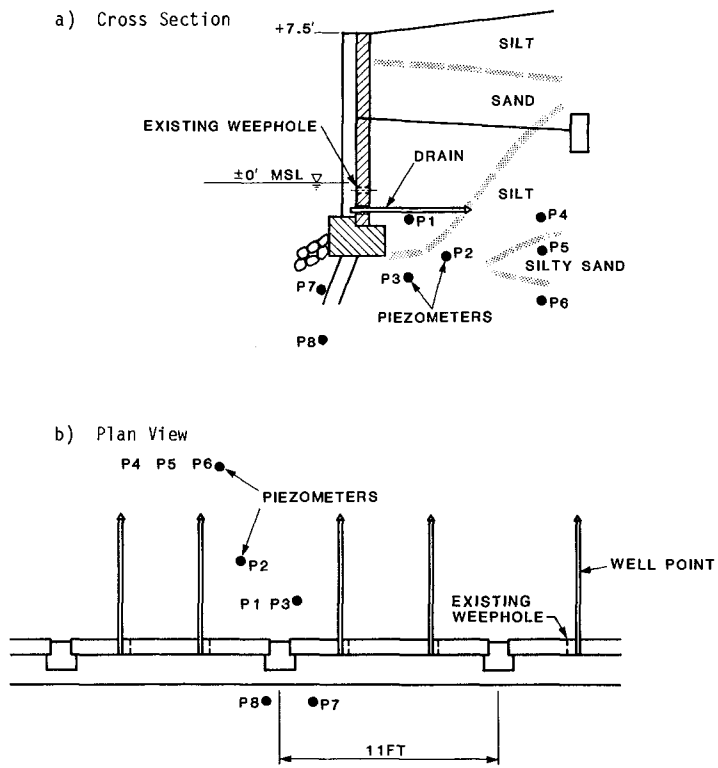

Figure 5. HORIZONTAL WELL-POINT SYSTEM

Based on experience with dewatering in similar soils, two drains per panel were estimated to be sufficient for significant drawdown of the water table in the backfill between the drains. A total of six horizontal drains, two per panel, were installed for the field test. Two well points are of plastic (PVC) and four are of stainless steel. While the material is insignificant for the functioning of the drains, it was found that the stainless steel well points were installed more conveniently than the plastic ones. The latter had to be driven with a mandrill acting on the pointed tip, and care had to be taken not to separate the tips during the driving procedure.

The evaluation of the drains' effectiveness relied on pore pressure measurements in the backfill before and after the installation. Figure 2 shows the pore pressure differential towards the free water level, measured during a critical tidal cycle before the drain installation, and during a similar cycle after the installation. Plotted pressure potentials (after installation) are those of locations P-1 through P-3, represented by the piezometers closest to the wall. Any potential piping which could lead to development of a gap would occur through seepage from the loose backfill at the footing/subsoil interface rather than through deeper zones of the underlying silty soils. The most important piezometer location is P-1 since it represents the conditions in the loose backfill just above the footing base. P-2 and P-3, on the other hand, were expected to record higher pore pressure differentials than P-1, because of the time lag caused by slower drainage of the natural silts in which they are embedded.

Piezometer P-1 shows a rather large reduction, due to the drains, of the maximum pressure potential towards the free water level (from 3 to 1.4 feet). The well points are approximately 1 foot higher than the minimum water level of the tidal cycle under consideration. Therefore, at the time of minimum water level, the ground water behind the wall forms a pool whose water table remains roughly at the well point outlet. Thus, the recorded pressure differential can not be smaller than 1 foot, even under perfect drainage conditions. Hence, the field test with horizontal well points was considered successful and this drainage system was recommended for remedial measure of the entire bulkhead system.

For the locations where apparent gaps beneath the footing base have already developed, repair measures for the footing and/or underwater slope protection were designed as described in the subsequent section.

Foundation Repair and Slope Protection

For lots where apparent gaps beneath the footing base had already developed, it was recommended that the gaps should be closed by grouting with provisions for proper formwork to retain the grout. The slope protection on these corner lots was to be upgraded to resist future erosion. Two schemes were developed for the foundation repair work. One scheme was to allow visual pile inspection at the pile-footing connection in case of marine borer attack on the piling. The potential for marine borers reaching exposed piling during extreme low

tides was considerable in areas with large gaps beneath the bulkhead footing. The second scheme only differed from the first in that it did not easily allow for visual pile inspection.

The two schemes are shown in Figures 6a and 6b. These schemes called for driving sheet piling several feet into the bottom in front of the bulkhead footing. The sheet piling would be secured to the footing and act as a protective curtain wall from bottom scour (erosion) exposing the pile-footing connection. The space between the footing and sheet pile wall would then be filled with concrete, and a grout pipe would be inserted behind the bulkhead to the base of footing to grout all void areas beneath the footing.

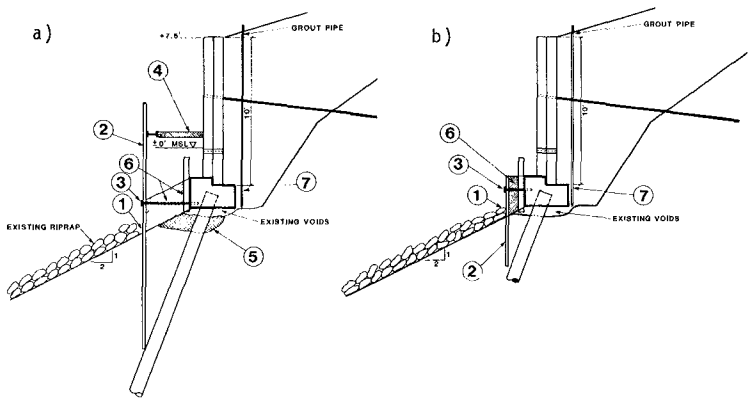

Figure 6. FOUNDATION REPAIR SCHEMES

(1) Remove rock slope protection.

(2) Drive sheet piles.

(3) Secure sheet piles to concrete footing.

*(4) Install support members and dewater.

*(5) Excavate and inspect pile.

(6) Fill with concrete and insert 4" pipes 3-5 feet on center, extending into the cavity (5).

(7) Pressure grout until grout extrudes from PVC pipe (6) (alternatively, pressure grout through PVC pipe).

(8) Cut off sheet pile at top elevation on concrete.

Note: Applies for Figure 6(a) only.

It was recommended that the slope protection for the corner lots be upgraded by use of either rock riprap and filter cloth or a concrete mattress and filter cloth as shown in Figures 7a and 7b. In addition, concentrated seepage of surface water into the backfill immediately behind the bulkhead was to be prevented by appropriate surface drainage.

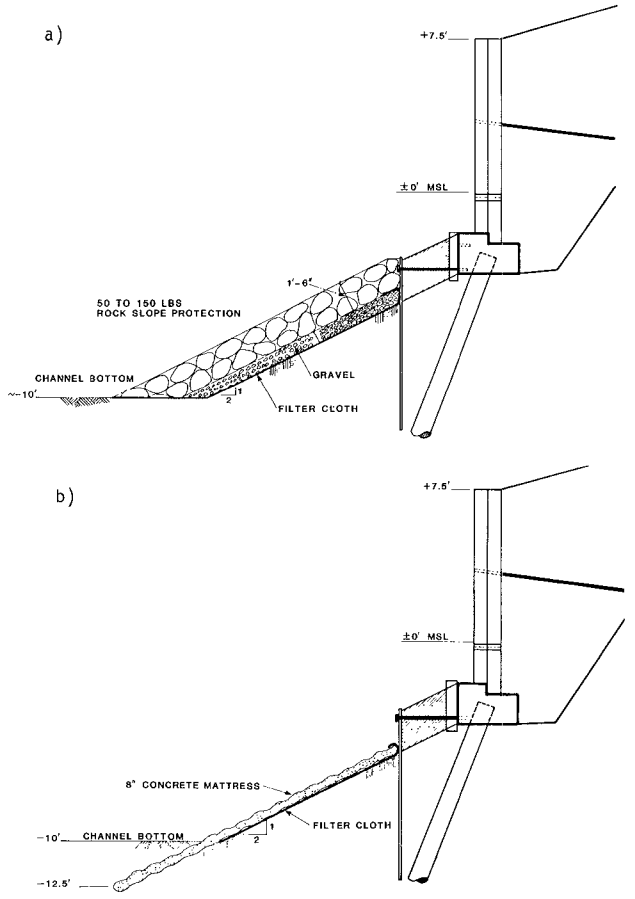

Figure 7. SLOPE PROTECTION

BREAKAGE OF CONCRETE ARMOR UNITS

by

Dennis G. Markle,[1] M. ASCE, and D. D. Davidson[2]

Abstract

A survey of existing Corps breakwaters with concrete armor units and hydraulic model tests of rubble-mound breakwater trunk sections protected with dolosse were conducted to determine the effects of broken armor units on breakwater stability and to establish some criteria by which decisions can be made as to when maintenance and rehabilitation work should be initiated on damaged concrete armor unit cover layers. The survey revealed that where good engineering designs were used, prototype breakage has been random and has not exceeded about 3 percent of the total number of units placed. The model tests, conducted with both breaking and nonbreaking waves with no overtopping, revealed the percent breakage can be quite a bit higher than 3 percent before the overall functional integrity of dolos cover layers is affected.

Introduction

In the past few years, the amount of breakage and the effect that broken concrete armor units have on breakwater stability have caused serious concern to designers and field engineers that are responsible for safe and reliable structures. Although concrete armor units have been and continue to be used extensively throughout the United States and the world (SPM, 1977), very little field performance data (Lillevang and Nickola, 1976; Zwamborn and Van Neikerk, 1981) and/or laboratory research (Davidson and Markle, 1976) are provided on the effect such breakage has on the stability of coastal structures. The need to determine prototype experience and to supplement these data with engineering research is of utmost importance.

Objectivies and Techniques

A field data survey (Markle and Davidson, 1982a) and experimental research investigation (Markle and Davidson, 1982b) were conducted to provide past prototype experience and to determine the effect broken

[1]Research Hydraulic Engineer, U. S. Army Engineer Waterways Experiment Station, Vicksburg, Mississippi 39180.

[2]Chief, Wave Research Branch, U. S. Army Engineer Waterways Experiment Station, Vicksburg, Mississippi 39180.

armor units have on breakwater stability against wave attack. This work consisted of both a survey of armor unit breakage that has occurred on existing Corps structures protected with concrete armor units and experimental model tests of rubble-mound breakwater trunk sections protected with dolosse. The survey of existing Corps structures was accomplished by field trips, letters, conferences, telephone conversations and a questionnaire to all Corps Districts and Divisions. The survey was restricted to Corps structures because preparation of plans and specifications, construction techniques and quality control are generally more uniform than non-Corps projects and access to more detailed cause-and-effect data was available. While data from non-Corps projects are important for learning purposes, it was surmized the efforts of collecting first-hand world-wide data and the uncertainies involved were not sufficiently warrented under this study. The experimental model tests involved various degrees of random and cluster breakage exposed to both nonbreaking and breaking wave conditions with no overtopping.

Prototype Case Histories

Crescent City Harbor, California, is located on the Pacific Coast about 17 miles (27.4 kilometres) south of the Oregon-California border, Figure 1. The existing outer breakwater is 4,670 ft (1,423.4 m) in length. The main stem and dogleg of the breakwater are approximately 3,670 (1,118.6 m) and 1,000 ft (304.8 m) in length, respectively. The original project did not call for the dogleg but intended for the main stem of the breakwater to extend out to Round Rock. The main stem of the original breakwater, beyond Sta 37+00, accrued severe damage and was reconstructed on two occasions. Finally, this portion of the main stem was abandoned and the 1,000-ft (304.8 m) dogleg, referred to above, was added. Two dimensional stability tests were conducted of the tetrapod breakwater designs proposed for the trunk portion of the 1,000-ft (304.8 m) dogleg (Hudson and Jackson, 1955 and 1956). In 1957, 1,836 25-ton (222,441 newtons), unreinforced tetrapods were placed on the sea-side slope from Sta 41+20 to the end of the dogleg (Sta 46+70) and 140 tetrapods (25 ton (222,441 newtons), unreinforced) were stockpiled on the sea-side slope of the first 200 ft (61 m) of the dogleg, adjacent to the main stem (Sta 37+00 to Sta 39+00). Model tests were not conducted for the severe breaking wave action that occurs around the elbow of the breakwater and, as of 1975, approximately 70 tetrapods placed in this area had been broken. To date, only 3 tetrapods placed on the last 550 ft (167.6 m) (Sta 41+20 to Sta 46+70) of the dogleg have been reported broken. In 1974, 246 40-ton (355,858 newtons), unreinforced dolosse were placed on the sea-side slope of the last 230 ft (70.1 m) of the breakwater's main stem (Sta 34+70 to Sta 37+00). Although there is some controversy as to the exact number of dolosse broken (reported values range from 38 to 70) a maximum number of 70 units has been reported. Of this number, it is certain that 22 were broken during placement and/or during storm conditions that occurred while construction was being completed. These units were not removed from the structure. Various portions of the breakwater were repaired with armor stone in 1979. With the completion of the latest repair work (1979), the breakwater is in relatively good repair and no major stability problems have been noted.

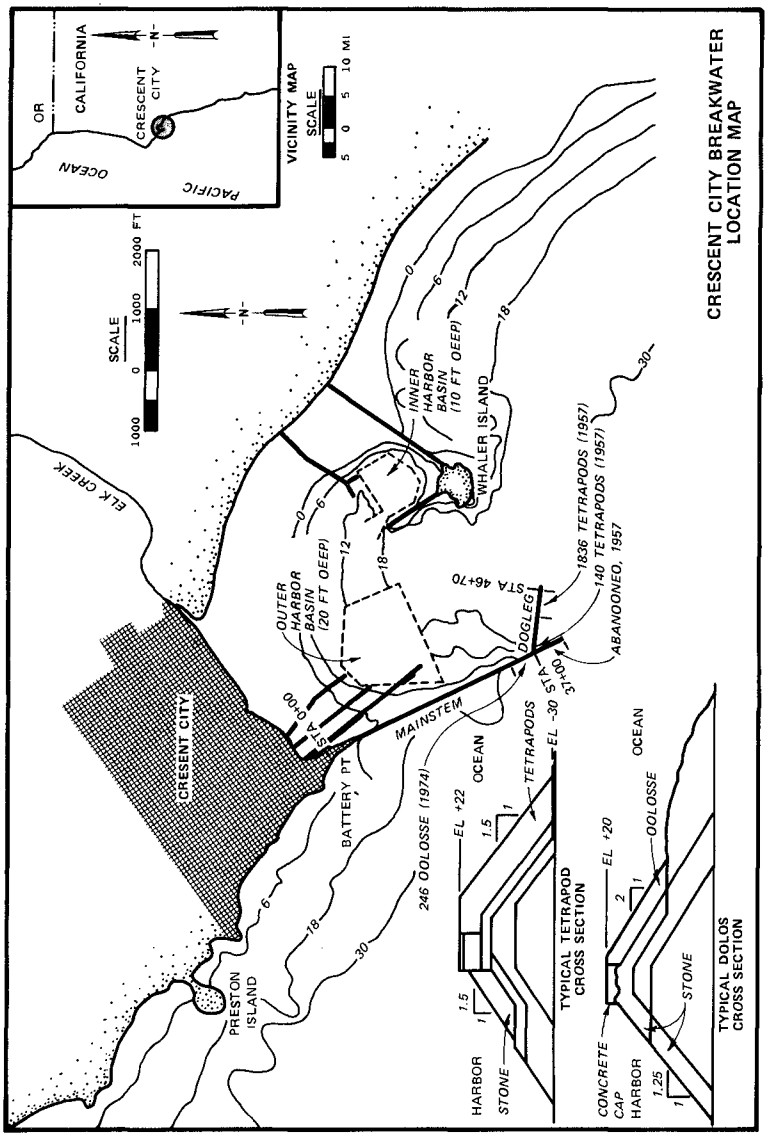

Figure 1. Location and vicinity maps of Crescent City Breakwater

Humboldt Bay is located on the Pacific Coast of northern California. The city of Eureka, about 280 miles (450.6 kilometres) north of San Francisco and about 80 miles (128.7 kilometres) south of Crescent City, California, is located on the northwest shore of Humboldt Bay, Figure 2. The Humboldt Bay entrance channel is protected by two rubble-mound jetties. Construction of the parallel north and south jetties, 4500- (1,371.6 m) and 5,100-ft (1,554.5 m) long, respectively, was initiated in 1889 and completed in 1899. The original jetty construction was rubble-mound armor stone. Severe damage to the heads and portions of the trunks has required numerous rehabilitations and reconstructions of both jetties. Between 1911 and 1970, parapet walls, concrete caps, 20- (177,929 newtons) and 100-ton (889,644 newtons) concrete blocks, concrete monoliths, armor stone, and 12-ton (106,757 newtons) tetrahedrons have been utilized on both jetties in an effort to stabilize the structures. The latest rehabilitation work, 1971 to 1972, consisted of rebuilding the concrete monoliths on both the north and south jetty heads. In addition to this, two layers of dolosse were placed around the heads and tapered into the trunks of both jetties approximately 400 ft (121.9 m) behind the heads. This repair work was model tested (Davidson, 1971). To date, 12 dolosse have been reported broken on the north jetty and 22 broken on the south jetty. About 5 of the total number of dolosse broken were supposedly left on the structure during construction. In any case, almost all of the breakage reported occurred in the first year after construction. At this time, the only noted effect is some settlement of the 42-ton (373,650 newtons) dolosse placed around the heads, but the structure does not appear to have any serious stability problems.

Santa Cruz Harbor is located on the northern end of Monterey Bay at the city of Santa Cruz, California. This area lies about 65 miles (104.6 kilometres) south of the entrance to San Francisco Bay, Figure 3. The 850-ft (259.1 m) and 1,125-ft (342.9 m) east and west jetties, respectively, were constructed in 1963 to protect the entrance channel and harbor from storm waves. The outer 400 ft (121.9 m) of the west jetty was constructed with 28-ton (249,100 newtons), unreinforced quadripods while the remainder of the jetties were constructed using armor stone. Based on available data, the structure has not as yet been exposed to the design storm conditions and no stability problems or breakage of armor units has occurred.

Pohoiki Bay is located on the southeast coast of the island of Hawaii, about 25 miles (40.2 kilometres) southeast of Hilo, Hawaii, Figure 4. In 1979 a 90-ft (27.4 m) breakwater was constructed to protect an existing boat launching ramp. The breakwater slopes and head were protected with two layers of 6-ton (53,379 newtons), unreinforced dolosse. The dolosse were placed from the toe of the structure to the concrete rib cap. Out of the 210 dolosse placed, 5 were broken and left on the structure during construction. Since its completion, the breakwater has been exposed to the design storm conditions on several occasions, and no dolos breakage or damage to the structure has been observed.

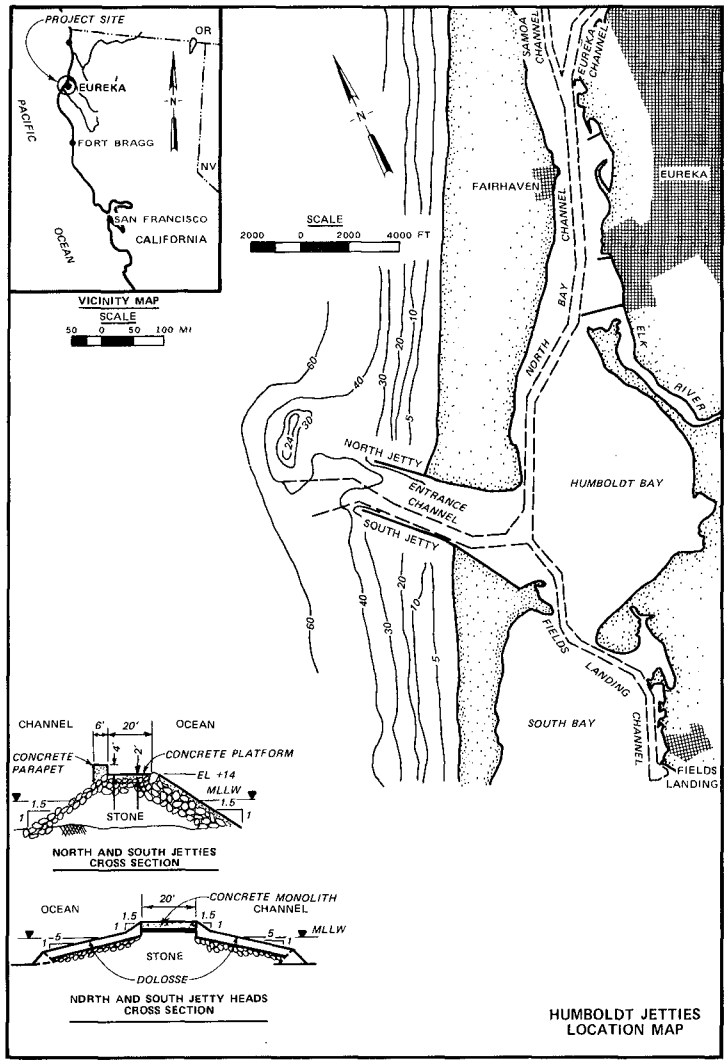

Figure 2. Location and vicinity maps of Humboldt Jetties

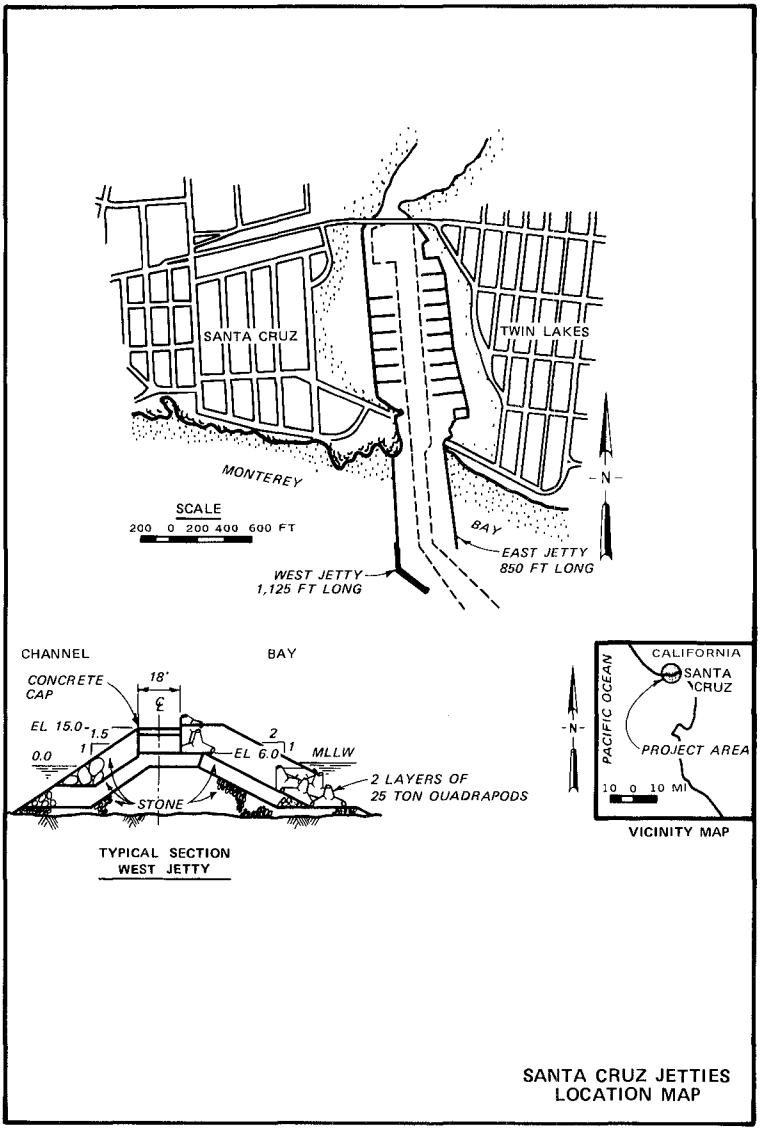

Figure 3. Location and vicinity maps of Santa Cruz Jetties

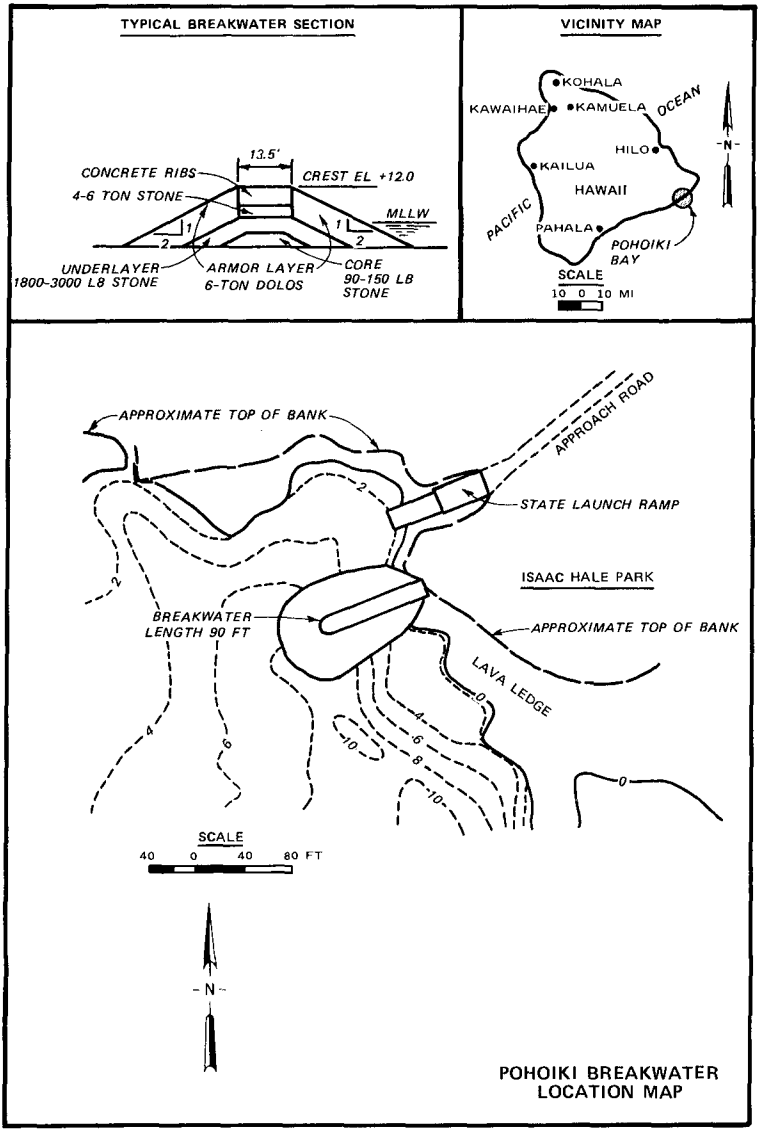

Figure 4. Location and vicinity maps of Pohoiki Breakwater

Kahului Harbor is located on the north coast of the island of Maui, Figure 5. Kahului, Hawaii is about 94 miles (151.3 kilometres) southeast of Honolulu, Oahu, Hawaii. The harbor is protected by two rubble-mound breakwaters. The 2,766- (843.1 m) and 2,315-ft (705.6 m) east and west breakwaters, respectively, were completed in 1931. The heads of both breakwaters were severely damaged by storm waves in 1947, 1952, and 1954. In 1956 the breakwater heads were repaired by casting concrete monoliths on the crowns. The slopes of both heads and 250 ft (76.2 m) of the west breakwater trunk (sea side only) were protected with a double layer of 33-ton (293,583 newtons), unreinforced tetrapods. A total of 400 units were placed. A major storm of 1958, approximately 34-ft (10.4 m) breaking waves at the breakwater heads, breeched the trunk of the east breakwater and caused major damage on both heads. Seven of the 33-ton (293,583 newtons) tetrapods were broken; 3 on the sea-side slope of the west breakwater trunk and 4 were among the 30 units that were displaced off the inside quadrant of the west breakwater head. A few units were also displaced off the east breakwater head, but no breakage of these units was observed. After the 1958 storm, emergency repairs were made on the east breakwater trunk using basalt-armor stones, and model tests were initiated at WES (Jackson, 1964) to determine the best methods of stabilizing the breakwaters. In 1966 a partial repair of the breakwaters was completed using 35 (311,375 newtons) and 50 ton (444,822 newtons), reinforced tribars. It is known that at least two units were broken and left on the structure during the 1966 repair work. Also during the 1966 repair, a concrete rib cap was added to the crest of the east breakwater trunk. In 1969, 260 19-ton (169,032 newtons), reinforced tribars and a concrete rib cap were added to the west breakwater trunk. This repair work was shoreward of the 33-ton (293,583 newtons) tetrapod area. This provided a partial repair of damages accrued by the structure during the storm of December 1967. None of the 19-ton (169,032 newtons) tribars used in the 1969 repair were broken during construction. In November 1970, high storm waves dislodged 25 of the shoreward end 19-ton (169,032 newtons) tribars and moved them toward the root of the west breakwater. Three units were reported broken during this event. Repair of the west breakwater trunk was initiated again in 1973 using 19- (169,032 newtons) and 35-ton (311,375 newtons) reinforced tribars: no construction breakage occurred. It was noted in the 1975 aerial photos that a total of 9 and 4, 33-ton (293,583 newtons) tetrapods were broken on the west and east breakwaters, respectively. A 1977 repair of the west breakwater included placing 30- (266,893 newtons) and 20-ton (177,929 newtons), reinforced dolosse over the damaged 33-ton (293,583 newtons) tetrapods areas. One of the 2 dolosse units broken during construction was left in place. Thirty, (266,893 newtons) 20- (177,929 newtons) and 6-ton (53,379 newtons) dolosse were used in the 1977 rehabilitation of the east breakwater. The 6-ton (53,379 newtons) dolosse were the only unreinforced units used in the repair work. During transporting and placement of the 6-ton (53,379 newtons) dolos units, 5 units were broken. This was the only construction breakage that occurred in the 1977 repair of the east breakwater and these units were either not used or were removed from the structure. On 28 March 1979 a survey was made of the east and west breakwaters to determine the amount of observable breakage. Table 1 lists all observed armor unit breakage to date. This breakage has not had an adverse effect on the functional integrity of the structure.

Waianae Small Boat Harbor is located at the town of Waianae on the west coast of the island of Oahu, approximately 30 miles (48.3 kilometres) west of Honolulu, Hawaii, Figure 6. Model tests of the harbor geometry and stability of the 1,690 ft (515.1 m) main breakwater were conducted (Bottin, Chatham and Carver, 1976) and prototype construction was completed in January 1979. The first 350 ft (106.7 m) of the breakwater was constructed using armor stone only. The remainder of the structure was constructed with a double layer of 2-ton (17,793 newtons) unreinforced dolosse on the sea-side slope and around the breakwater head. Forty-seven of the 6,633 dolosse placed were broken and left on the structure during construction. To date, a total of 170 dolosse (including the 47 mentioned above) have been found broken and remain on the structure. Most of the post construction breakage occurred in the year following construction. During a field inspection of the breakwater in June 1980, it appeared that an unusually large number of the first layer dolosse had been placed with their vertical fluke downslope. Extensive stability tests conducted with dolos armor units (Carver, 1977) have indicated that pattern placement tends to reduce the stability of dolosse. Also several areas of the sea-side slope on the Waianae breakwater appear to be considerably steeper than the 1V:2H slope for which the structure was originally designed. These two

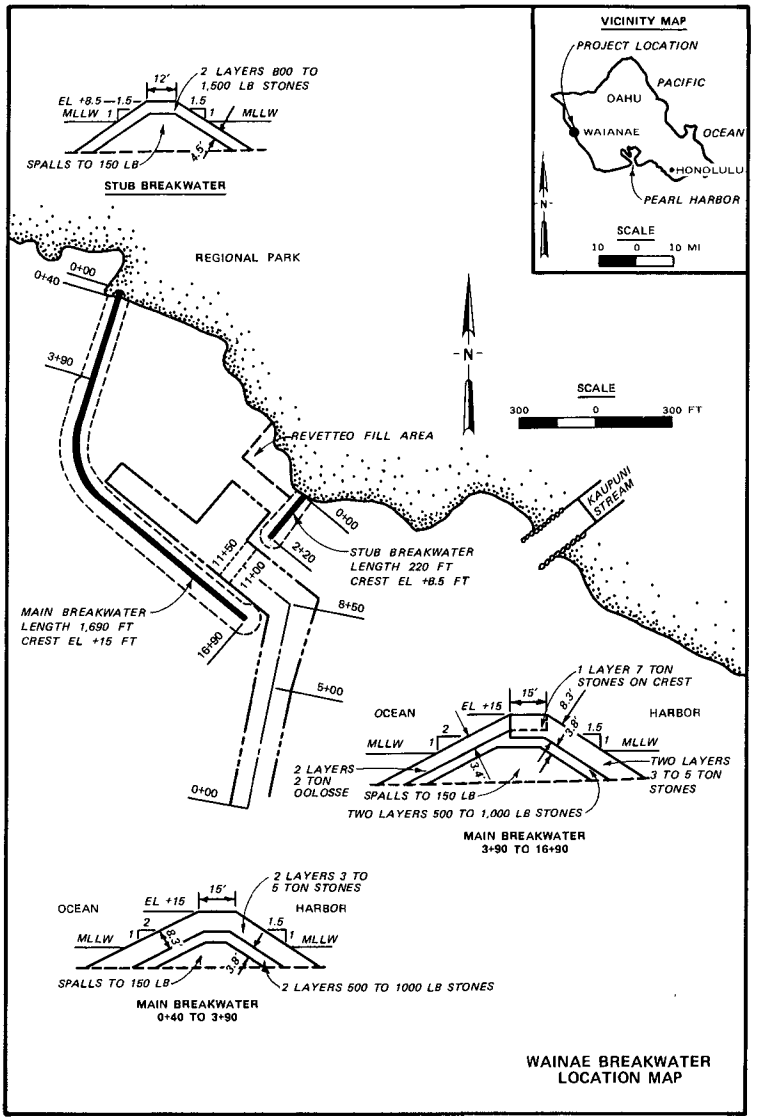

Figure 6. Location and vicinity maps of Waianae Breakwater

factors may have played a significant role in the dolos breakage that has occurred since the construction was completed. The breakage has caused no obvious stability problem to date but it is hoped the structure will be closely observed to see the long term effects of the existing or future breakage that may occur.

Nawiliwili Harbor is located on the southeast coast of the island of Kauai, about 100 nautical miles (185.2 kilometres) northwest of Honolulu, Hawaii, Figure 7. Construction of the 2,150 ft (655.3 m), rubble-mound breakwater was completed in 1930. Severe storms in 1954, 1956 and 1957 severly damaged the breakwater and model tests were conducted in 1958 (Jackson, Hudson, and Housley, 1960) to determine the best method of rebuilding the head and strengthening about 500 ft (152.4 m) of the seaward end of the breakwater. In 1959 the head and seaward 500 ft (152.4 m) of the sea-side slope of the trunk were rehabilitated with 17.8-ton (158,357 newtons) tribars and a concrete cap was poured on the crest of the breakwater. Of the 598 tribars placed, 351 were reinforced. One layer of tribars was uniformly placed on the trunk while a double layer of random placed tribars was used on the sea-side slope of the head. A survey of the breakwater in 1975 found major deterioration of about 1,000 ft (304.8 m) of the armor stone trunk and several slumped areas in the uniform placed tribars. Further inspection revealed that several of the tribar units (approximately 98) were broken and at that time model tests were initiated to determine the best method of rehabilitating the structure (Davidson, 1978). The rehabilitation work was completed in October of 1977. The one layer tribars were overlaid with 2 layers of 11-ton (97,861 newtons) unreinforced dolosse (485 dolosse). The dolos coverage extended from the toe of the slope to approximately +5.0 ft (+1.5 m) mllw. For 300 ft (91.4 m) shoreward of the tribar area, the sea-side slope of the trunk was rehabilitated with two layers of the 11-ton (97,861 newtons) dolosse. Four hundred forty-nine dolosse were placed in this area from the toe to the crown of the structure. Thirteen of the dolosse were broken during placement, but these were removed from the structure. No further stability problems or breakage have been observed since the 1977 rehabilitation work and the overall functional integrity of the breakwater appears to be good.

Manasquan Inlet is located on the Atlantic coast of New Jersey about 26 miles (41.8 kilometres) south of Sandy Hook in the boroughs of Manasquan and Point Pleasant Beach, Figure 8. The inlet forms the mouth of the Manasquan River and the northern most end of the New Jersey Intracoastal Waterway. In 1880, the previously unnavigable inlet was dredged to provide access to a safe harbor for small vessels navigating along the coast. At the same time, sand filled timber jetties were constructed out to 120 ft (36.6 m) beyond the low water line. The jetties proved to be ineffective in maintaining an open channel and no maintenance was provided. By 1887 the inlet was totally blocked by sand. In 1930 a 1,230-ft (374.9 m) North Jetty and a 1,030-ft (313.9 m) South Jetty were authorized. Both jetties were of riprap (rock) construction. Although the size of stone used is uncertain, the maintenance history (details not available) shows that the original and all subsequent repair and replacement stone have been inadequate. A reconnaissance in early 1977 found that the outer portion of both jetties had been destroyed and the sand accumulation in the inlet was accelerating

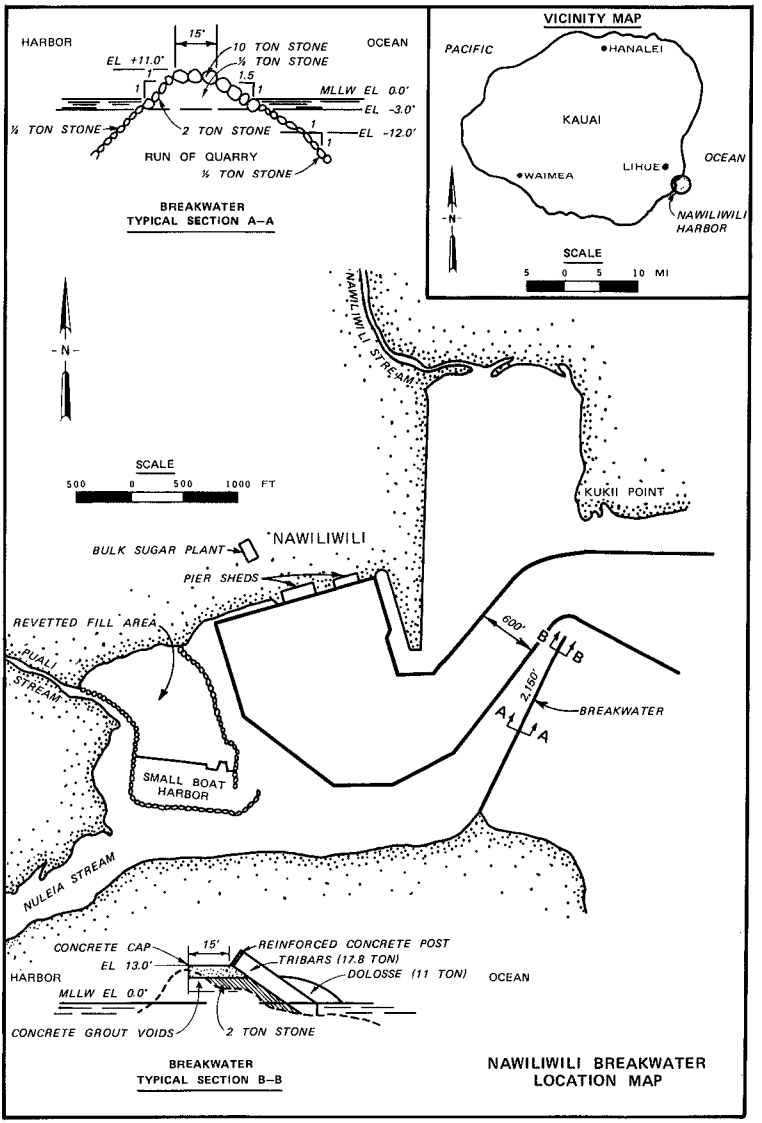

Figure 7. Location and vicinity maps of Nawiliwili Breakwater

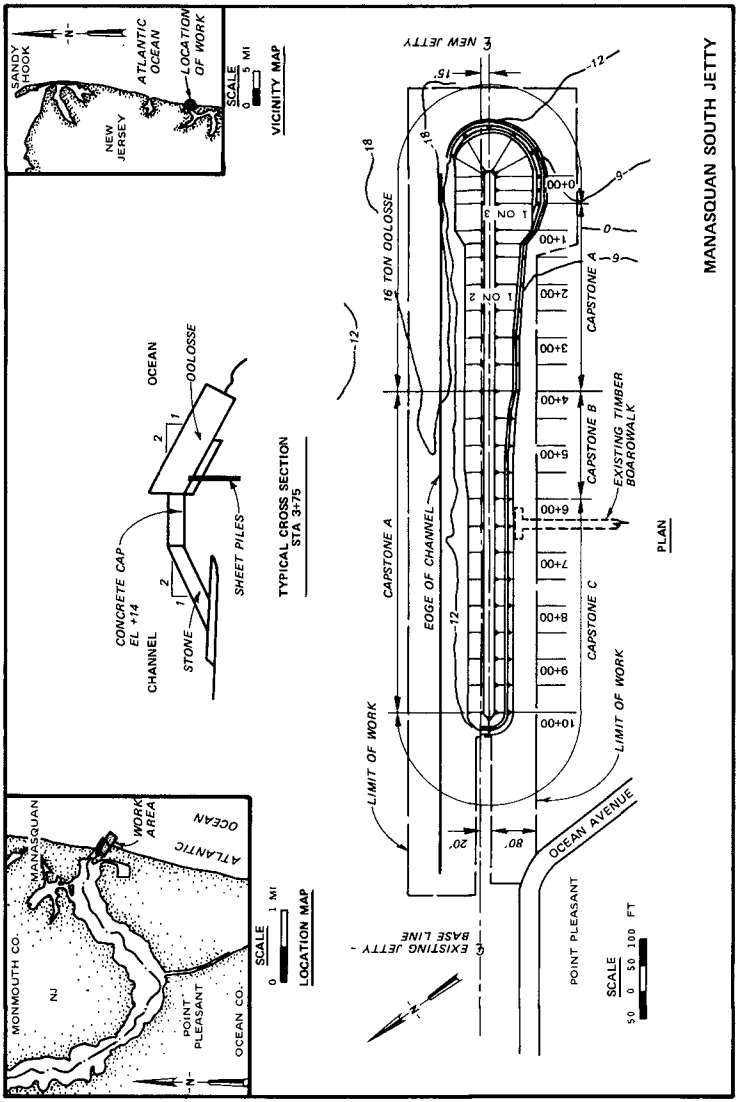

Figure 8. Location and Vicinity maps of Manasquan South Jetty

due to the damage accrued by the South Jetty. A rehabilitation of the South Jetty was carried out in 1980. A portion of the rehabilitation used reinforced, 16-ton (142,343 newtons) dolos armor units. One or two dolosse were broken during construction, but these units were removed. The structure has not been exposed to the design storm conditions and no dolos breakage has been observed since the rehabilitation was completed.

Cleveland Harbor is located on the southern shore of Lake Erie at Cleveland, Ohio, Figure 9. Cleveland is located about 110 miles (177 kilometres) east of Toledo, Ohio, and about 191 miles (307.4 kilometres) west of Buffalo, New York. The harbor is protected by a 20,970-ft (6,391.7 m) East Breakwater, 6,048-ft (1,843.4 m) West Breakwater and two 1,250-ft (381 m) arrowhead breakwaters. The arrowhead breakwaters are connected to the East and West Breakwaters at the main entrance to the harbor. The westerly 3,000 ft (914.4 m) of the East Breakwater is composed of a timber crib, constructed from 1887-1900, and a stone superstructure, constructed from 1917-1926. The remaining 17,970 ft (5,472.3 m) of the East Breakwater was constructed from 1903-1915. This portion of the breakwater is a rubble-mound structure with a keyed and fitted system of special shaped armor stone. Using construction similar to the original work, repairs were made on the East Breakwater in the years 1927, 1928, 1930, 1932-40 and 1946-78. During 1980, the eastern 4,400 ft (1,341.1 m) of the East Breakwater was rehabilitated. Two thicknesses of 2-ton (17,793 newtons) unreinforced dolosse were placed on the lakeside of the trunk, Figure 10, and around the head, Figure 11. Twenty-nine thousand seven-hundred dolosse were placed with a concentration of 161 dolosse per 25 linear ft (7.6 m) of the breakwater. Breakage of several dolosse occurred during the construction period and it was suspected that many of these were due to poor quality concrete and/or incorrect curing. Prior to completion of construction, but on a completed portion of the rehab, twenty two units (randomly located on the structure) were broken during a June 1980 storm. All units that were found broken after the 1980 storm were removed from the structure. Final construction on the dolos section was completed in November 1980, at which time a formal monitoring program to show armor unit movement and breakage on the rehab portion of the project was initiated. During the next year (primary period of consolidation and adjustment) ramdomly located breakage continued until by November 1981 the total number of broken dolosse observed was 329 (1.1 percent of the units placed). No adverse effect on the functional stability of the structure was noted during this time. On 6 April 1982, a particularly severe storm (hindcast waves of 12 ft (3.7 m) in height) occurred simultaneously with the highest lake level (+6.1 ft (+1.9 m) low water datum) ever recorded and caused damage to the rehabilitated dolos section. Although there was some displacement of dolosse over the crest of the trunk section, the primary damage was localized on the tip of the head section where a hole about 20 ft (6.1 m) in diameter at the armor surface penetrated to the underlayer stone. The exact cause of this localized damage is not known, but it is surmized by the authors that the combination of high water level, high wave action, and reflective characteristics of the Coast Guard tower monolith played a major role in the armor displacement. The number of units broken due to displacement from the damage hole was not available, but total breakage on the entire dolos section after the April 1982 storm was reported as 487 or 1.6 percent of the units placed.

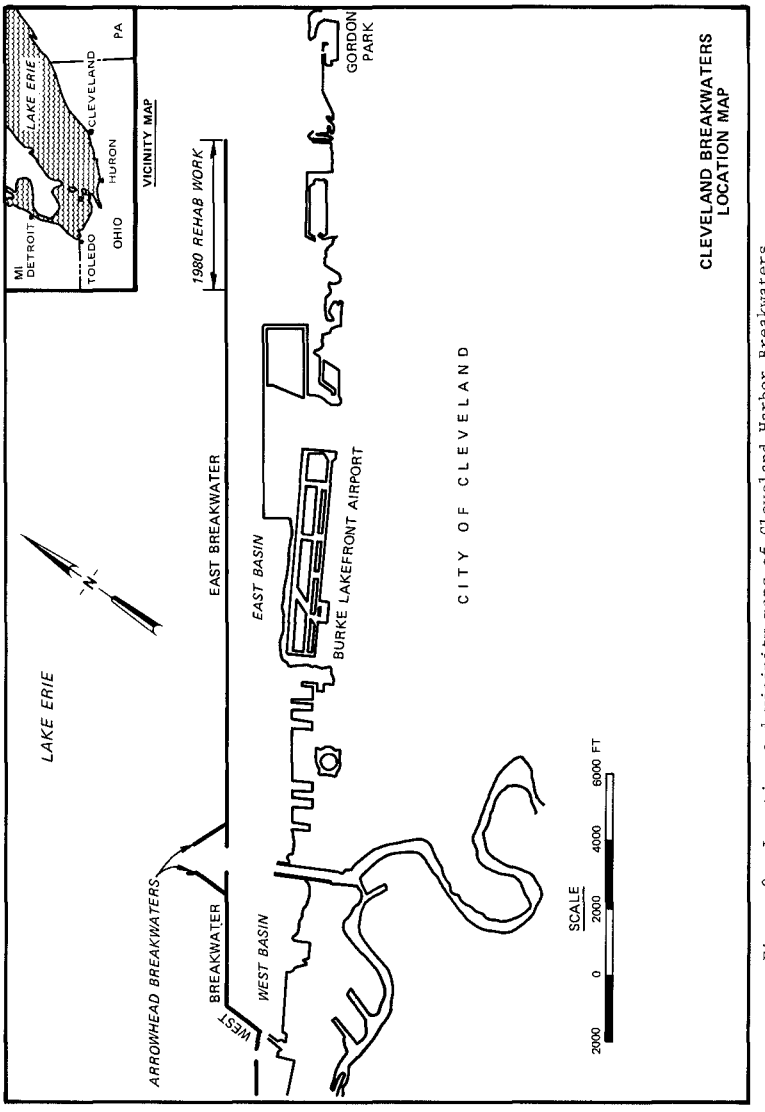

Figure 9. Location and vicinity maps of Cleveland Harbor Breakwaters

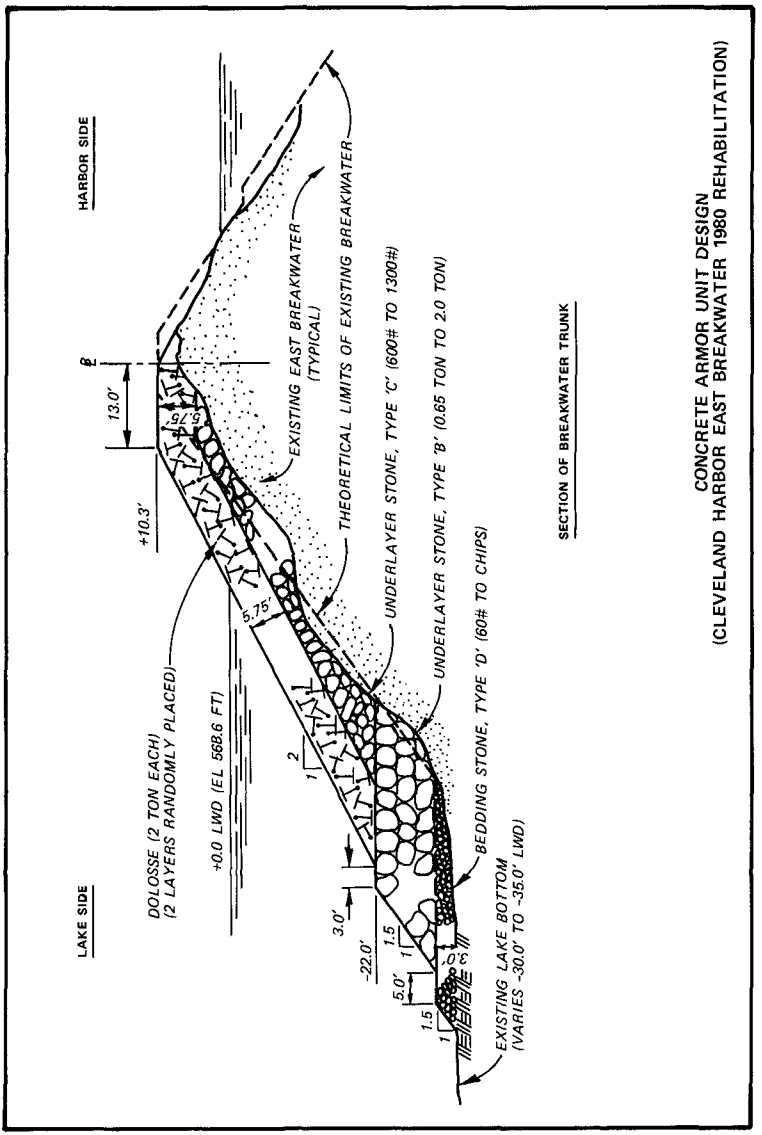

Figure 10. Cross section of Cleveland Harbor Breakwater Trunk

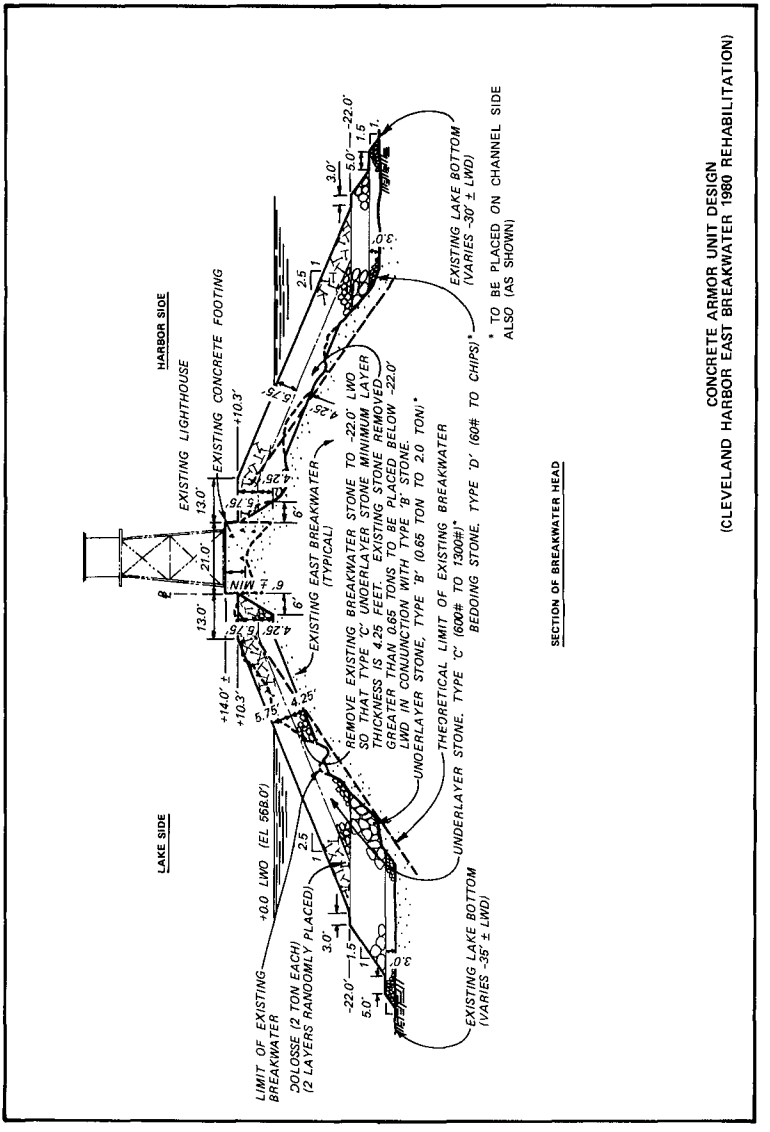

Figure 11. Cross section of Cleveland Harbor Breakwater Head

Diver's survey indicated that the broken dolosse are generally in a zone 4 (1.2 m) to 6 ft (1.8 m) above and below the water level. The head section is being repaired by placing approximately 200 dolosse in the localized damage area. The trunk section is not being repaired and does not appear to have any serious stability problems.

Discussion

Only 3 of the 9 existing Corps structures with concrete armor units were originally constructed using these units (Santa Cruz, Pohoiki and Waianae). The other 6 structures are old armor stone breakwaters or jetties that have been rehabilitated with one or more sizes or types of concrete armor units. Of the 9 structures discussed, only 2 have accrued any significant amount of known armor unit breakage and even these appear to have valid reasons for the breakage. All of the projects incurred breakage for one reason or another, but most of the breakage was <3 percent and has not had any adverse effect on the stability of the structures. Table 2 presents a summary of the breakage on each project. One of the two projects with significant breakage had been model tested for hydraulic characteristics (Nawiliwili) and one had not (Crescent City - the main tetrapod portion of this breakwater was model tested, but the areas where subsequent dolos and tetrapod breakage occurred was not).

When the initial model tests (Jackson, 1960) were conducted for the tribar rehabilitation portion of the Nawiliwili Breakwater, it was recommended that a row of large armor stone be placed along the breakwater toe to serve as a buttress for the tribars. Based on POD records this was not done during the prototype rehabilitation. It can not be stated conclusively, but this very well could have been part of the reason for the slippage and breakage that occurred in the one layer tribar area.

During addition of the 1,000-ft (304.8 m) dogleg at Crescent City in 1957, 140 tetrapods were not needed to complete the construction on the outer portion of the dogleg. Since it was already evident that the elbow area was receiving severe wave action due to remnants of the damaged breakwater extention toward Round Rock, the excess units were stockpiled in an incoherent manner on the sea-side slope of the dogleg adjacent to the main stem (about Sta 37+00 to Sta 39+00). Unlike the end of the dogleg, model tests were not conducted to check the adequacy of the 25-ton (222,411 newtons) tetrapods to withstand the severe breaking wave action that occurs in this area, thus it is not surprising that the tetrapods in this area have been subjected to high displacement and movement which would result in significant breakage and erosion.

As for the dolosse breakage at Crescent City, it has already been brought out that there is some controversy as to how many are broken. To date the numbers range from 38 to 70. It is fairly definite 22 were broken prior to completion of construction. Sixteen of the units were broken in a storm that occurred during construction when two rows of individual toe units had been placed ahead of the main body of dolosse. Six additional dolosse were reported broken immediately after construction was completed (1974-75 winter) and 6 units were reported broken

TABLE 2

Summary of Armor Unit Breakage
Reported on Prototype Survey

Location	Type of Unit and Date of Placement	Armor Unit Size (tons)	Was Reinforcement Used	Total No. of units Placed	Units Broken To Date No.	Units Broken To Date %

during the winter of 1978-79. A survey conducted in mid-1982 indicated that total breakage could be as high as 70 units. More importantly, the fact that the original breakage was not removed and that the dolos section only extends to just below low water and is frequently subjected to very high depth limited breaking waves adds to the potential instability.

In summarizing the prototye experience that has been presented, it is generally found that where sound professional engineering practices were followed, prototype breakage has been random and has not exceeded about 3 percent of the total number of units placed. This amount of breakage does not appear to have had adverse effects on the overall functional and structural integrities of the breakwaters and jetties.

Experimental Tests

Previously conducted model tests to determine the number of dolosse which could be broken without having a detrimental effect on stability are reported by Davidson and Markle (1976). These tests were limited in scope in that it was a site specific project with limited wave conditions and the breakage investigated was limited to uniformly distributed units broken in the top layer or to specific sets of cluster breakage through both layers of units. Results of this study indicated that as long as the uniformly distributed breakage does not exceed 15 percent of the number of dolosse in the top layer and the cluster breakage does not exceed three dolosse, the functional stability of the breakwater would not be seriously affected.

More recent model tests by Markle and Davidson, (1982b) cover a much wider range of dolos breakage conditions and encompass both breaking and non-breaking wave conditions that produce little or no wave overtopping. Using a dolos armored no-damage trunk section (1V:1.5H slope) of unbroken units as a base condition, various degrees of uniformly distributed and cluster breakage were investigated. Wave conditions included a range of relative depths (d/L, where d denotes depth and L denotes wave length) from 0.08 to 0.25 and relative wave steepnesses (H/L, where H denotes wave height) ranged from 0.031 to 0.075. Dolos breakage conditions consisted of (1) uniform breakage in the top layer, (2) uniform breakage in the bottom layer, (3) uniform breakage in both layers, and (4) cluster breakage of both layers positioned at, above, and below the still water level. Results obtained from these tests were similar to the earlier work in that any one of the following breakage conditions can exist without having a detrimental effect on the functional stability of dolos armor layers. These conditions are: (1) 15 percent uniform breakage of either the top or bottom layer, (2) 7.5 percent uniform breakage of each layer, and (3) clusters of five broken units.

Conclusions

No firm guidance is available as to when, how much and what type of reinforcement, if any, should be used in concrete armor units. The survey showed that as a result of this lack of guidance, sporadic use of both normal and fiber steel reinforcement has occurred. This random

usage of reinforcement and the mixing of reinforced and nonreinforced units make it impossible to draw any definite conclusions as to possible benefits or problems derived from its use. Where sound professional engineering practices were followed, prototype breakage has been random and has not exceeded about 3 percent of the total number of units placed. This amount of breakage does not appear to have had adverse effects on the overall functional integrity of the breakwaters and jetties. Model tests substantiate that, depending on the type and location of dolos breakage, a significant amount of breakage can be tolerated without detriment to the overall stability of the structure.

Acknowledgements

The survey and model tests reported herein were extracted from parts of the Waterways Experiment Station (WES) Miscellaneous Paper HL-83-___, entitled "Breakage of Concrete Armor Units, Survey of Existing Corps Structures," and WES Technical Report HL-83-___, entitled "Effects of Dolos Breakage on Stability of Rubble-Mound Breakwater Trunks, Subjected to Breaking and Nonbreaking Waves With No Over-Topping," which are in the publication review stage. The comprehensive study was conducted by WES for the Office, Chief of Engineers under the Corps of Engineers Civil Works Research and Development Program.

Grateful acknowledgement is extended to the Office, Chief of Engineers for granting permission to publish this paper.

ABSTRACT

The rising sea level issue affecting U.S. coastal policy is reviewed, and the U. S. Army Corps of Engineers coastal role is summarized. Three case studies are provided to demonstrate the successful application of several structural devices available to solve different coastal problems. The coastal engineer, and other scientists, should contribute significantly to the information upon which society bases its decisions on use of the shoreline.

INTRODUCTION

The coastal zone represents the most rapidly growing region in the United States in terms of population and wealth. Forty-two percent of the population lives in this zone (U.S. Dept. Comm., 1978). Twelve of the 13 largest cities are located in the 30 coastal states. Increasing pressures of population and development are evident in the competition for use of the shoreline and coastal zone. Pressure is exerted for public access and use of the shore: for development of private residences and high-rise apartments; for construction of facilities for commercial, industrial, and transportation purposes; and for the preservation of aesthetic and natural values of shore and marsh areas (HD No. 93-121, 1973).

Prior to the mid-1800's, the sea usually provided the most convenient and economic means of transportation and communication, and cities grew in the vicinity of the ports. Industrialization and improved inland transportation brought increased population density to the coastal centers. Accommodating the expanding urbanization and the accompanying essential services required additional use of the estuaries and adjacent ocean shores. Harbor entrances and channels were improved and facilities to dispose of industrial and urban waste were constructed. However, very little of the outer coast was developed until the automobile and the airplane, together with a great increase in leisure time, made all coasts accessible and increased the demand for space.

PRESSURES TO ABANDON THE SHORELINE

Many U.S. Citizens (individuals and groups) are lobbying publicly for abandonment of the shores and barrier islands of the United States. They reason that rising sea levels, an overly large government support system for protection, utility and transportation subsidies, and the potential devastation of development by coastal storms combine to justify this position. They explain that the barrier islands are transitory and that construction of permanent structures in such environments is futile. They conclude that the obvious solution is abandonment, to be achieved by prohibiting future development and circumscribing rehabilitation of damage. This stance is promoted through the media and through some elements of the scientific community as the only sensible means of saving our shorelines.

What has been overlooked in the debate regarding development in the coastal zone is that the desire for the enjoyment and habitation of the shore seems to be deeply ingrained in the nature of people. Furthermore, the satisfaction of this desire is now within the means of a large segment of the United States populace. The demand for space at the shore will likely be met, eventually, despite temporary obstruction by regulations, policies, or laws. Our objective should be to satisfy this demand without harming those features which make the coast attractive and without so limiting the available sandy shoreline as to make it economically unavailable to lower income families. Laws and policies which prohibit or strongly deter any increase in the shore areas open to development and public use will undoubtedly lead to an increase of land values in the already available coastal areas. Concomitant increases in the price of the facilities and services economically appropriate to those land values will increasingly restrict the number of people who can afford such recreation or who can afford to live there. Overcrowding and unacceptable environmental stress in the areas remaining open and easily accessible to the general public will soon lead to extension of restrictions to these areas. Clearly, some mechanism is required to determine the proper balance between development and preservation.

RISING SEA LEVELS

A basic rationale used to support the move to abandon the barrier islands and shores of the United States is that of rising sea level. The reasoning is that the sea level has been rising and will continue to do so in the near and long term. With the increasing sea level, the barrier islands are migrating, rolling over themselves like a caterpillar tractor tread, toward shore. All of man's efforts to stem or counter such eventualities are claimed to be futile and a waste of resources. Eustatic changes in sea level are a result of worldwide events which cause changes in either the capacity of the ocean basins or the volume of the ocean waters (Hands, 1977). The direct cause of this change is veiled in the passage of time, and only recently has man developed the technology and data with which to speculate as to the root cause or causes.

Various measurements indicate that sea level has been fairly stable over the past 2,000 years, probably within a range of about one meter

(O'Brien, 1982). Over the period of 1940 to 1975, tide gage data around the US. coast indicate a eustatic rise in the mean level of 1.15 dynamic mm per year (0.115 meter per century) (Hicks, 1978). This effect is frequently linked to melting of the polar ice caps, but also includes such factors as plate tectonics, changes in ocean temperatures and densities, climatic changes, underground withdrawal of liquids and gases, compaction, and other phenomena. The magnitude of long term mean sea level change due to various causes, observed at selected locations, is as follows.

Land Subsidence Due to Glacioisostatic Causes (Hands '77)

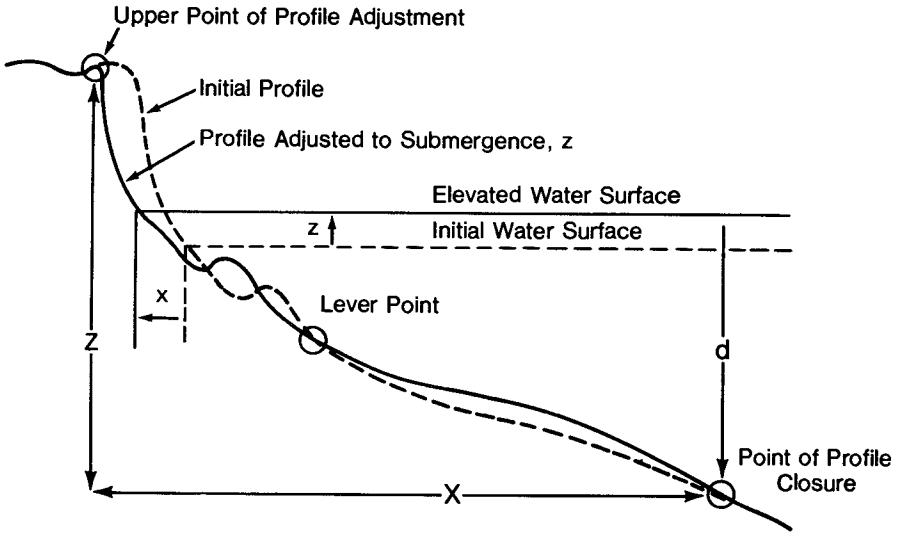
Location	Subsidence Rate (CM/YR)	Period	Reference
Netherlands	3-4	1880-1930's	Edelman '57
Great Lakes, US.	0.3	1878-1977	Hands '77

Subsidence can occure quite rapidly, as was the case at the Cook Inlet, Kodiak Island, Kenai Peninsula, Alaska, where the March 1964 earthquake lowered about 100,000 square kilometers about 1 meter (Stanley '68). On the Great Lakes, long term climatic cycles (10-30 yrs) can effect a relative subsidence of the land beneath the water (Hands '77). These areas of relatively rapid change require special attention for coastal activities.

A search of recent literature did not reveal that any of the investigations of mean sea level change have ventured a forecast of probable change during the next century (Keehn,1982). Considering the uncertainty associated with past eustatic sea level changes and the scientific uncertainty as to the predominant cause of change, it seems wiser to base public policy on the assumption that mean eustatic sea level will continue to rise during the next century at the same rate experienced over the past century. When more reliable predictive models exist, then public policy can be revisited.

While the physical consequences of mean sea level rise on sandy shores exposed to the open ocean may be significant, storms and their consequences are still the primary concern. Figure 1 illustrates the nature of shore change due to sea level rise and its caption explains the derivation of the formula, known as the Brunn rule (Brunn, 1962). Generally, the landward retreat of the shore (X), is many times the amount of the rise Z. The disproportionality of X to Z will vary from beach to beach, normally ranging hetween 10:1 and 100:1. The concept underlying the Brunn rule seems sound from the standpoint of the processes involved; measurements in the Great Lakes have confirmed this quantitative relationship.

Figure 2, showing profiles of the beach near the U.S. Army Corps of Engineers research pier at Duck, North Carolina during the year 1981, illustrates the difficulty of obtaining a direct measurement of the shore changes attributed to changes in mean sea level. The combined effects of waves and tides during the year were a horizontal movement of the high water line of 39.6 meters and a maximum change of profile elevation of 2.5 meters. Tide gages at Portsmouth, Virginia, north of the pier, and Charleston, South Carolina, south of the pier, had recorded a trend of mean sea level rise of about 3.9 mm per year (Hicks,1978). The Brunn rule indicates an average annual shoreline retreat of 0.15 meters per year. Although this change is unidentifiable in such a short period measurement, the effect, if continued over a



Use of Bruun Rule (Bruun, 1962). Sketch of Profile Measurements Required to Predict Shore Adjustment to a Change in Water Level Elevation. Providing There Is no Net Gain or Loss Outside the Control Volume, Constancy of Profile Shape Requires That the Ultimate Shore Retreat x Be Equal to zX/Z

FIGURE NO. 1

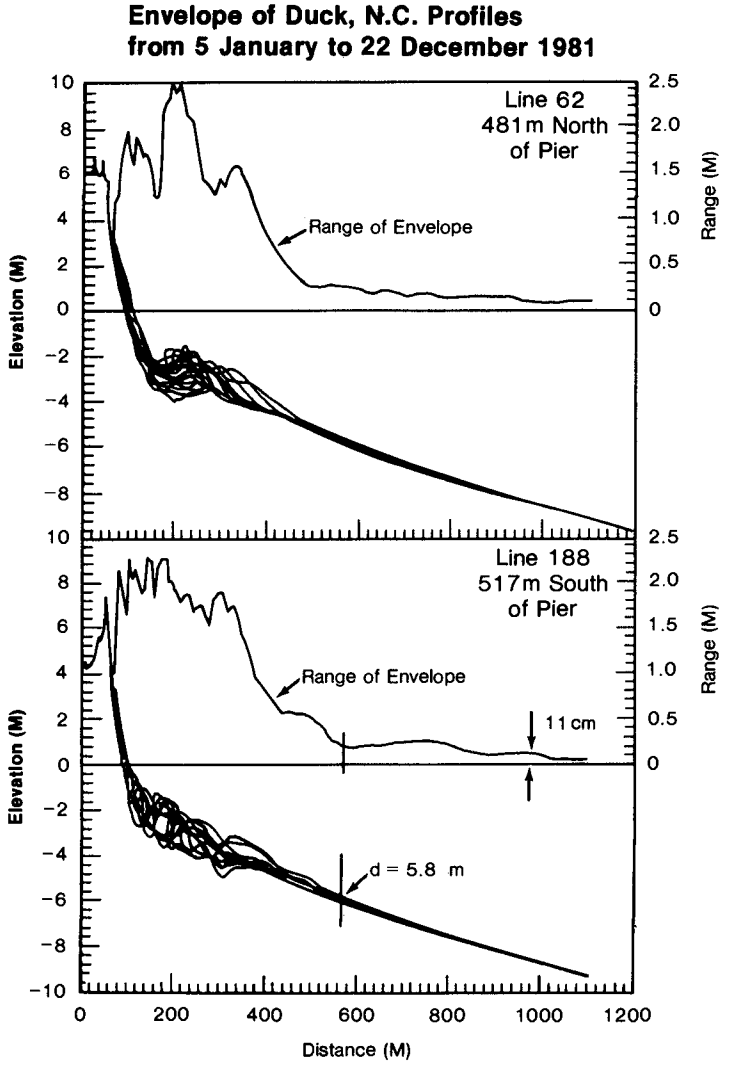


FIGURE NO. 2

(William A. Birkmeier Personal Correspondence, June, 1982)

century, is 15 meters of shoreline retreat. Shoreline change studies on Bodie Island south of the pier for the period 1937-1975 and on Hatteras Island for the period 1852-1946 indicate that actual shoreline retreat rates are 2 to 5 times greater than the 0.15 meter per year which may be attributed to sea level rise.

A trend noted in the comparison of the 1852 and 1946 maps of Hatteras Island was a general decrease in the total subaerial land mass of the barrier island, which indicated erosion on both the ocean and bay sides. In addition, the portion of the island that was marsh increased from approximately 26.6% in 1852 to 35.1% in 1946. This increase in marsh area occurred primarily as a result of seaward propagation of the marsh into low areas that were classified as upland in 1852. Overwash and aeolian processes were evident along the marsh line, but their effects on the island characteristics were minor compared to the ocean and bay shoreline erosion and marsh grass propagation seaward over the barrier island. These changes do not support the generalized theory of barrier island migration, at least within the time frame of several generations. (US Army Corps of Engineers, Wilmington, N.C. 1980)

The question at issue is not whether a rising sea level would cause erosion, hut rather what the prohahle course of sea level change will be over the next century. So far no one has been willing to make such a prediction. The National Academy of Sciences, through its Marine Board, has established a blue ribbon committee, chaired by Professor Rohert G. Dean of the University of Florida, to investigate the sea level change phenomena and to determine the efficacy of forecasting such changes.

RESOURCES MANAGEMENT

As indicated above, the growing population and growing demands for coastal vacations are providing for increased development pressure along our coastlines. The mechanisms used to balance these demands for coastal resources and to manage the utilization of coastal areas are incorporated within the governmental systems at all levels. As example, at the local level, zoning ordinances are used to regulate the type and density of development; at the state level, highway and bridge construction determines the accessability of coastal areas; and at the national level, significant historical, ecological, and scenic areas are preserved through acquisition and management or by withholding national subsidies. A law prohibiting the Federal Government from funding commercial and residential growth on undeveloped barrier beaches and islands was signed by the President on October 18, 1982. More than 190 pieces of land stretching through 16 states, incompasing 700 miles of coastal property are affected. The law specifies which portions of those islands should no longer receive Federal flood insurance or money for water and sewer systems.

The influence exerted on these barrier systems by changes in sea level will depend on the magnitude and direction (higher or lower) of future projected trends and the confidence in the projections exhibited by the scientific community and conveyed to the government decision makers. The shoreline and water level changes which accompany seasonal storms and variations in the along-shore littoral sand supply, as influenced hy nature and man, are normally much greater than the effects of mean sea

level change. These changes, and the attendant environmental consequences have influenced coastal resources management up to now. It is these changes, with the exception of some local areas such as those listed previously, rather than mean sea level changes, that cause the primary adverse effects with which rescue of the shore areas must deal.

THE CORPS ROLE

Nearly 100 years ago, the United States government, recognizing the need to maintain navigable waterways, gave the U.S. Army Corps of Engineers the mandate to develop and protect the Nation's waterways. At that time, the interests of navigation were considered paramount. Many of the affected beach areas were then undeveloped, and there had been little systematic study of the littoral processes involved.

The 1930 River and Harbor Act enacted by Congress provided a broader Federal role in shore protection. The Corps of Engineers was empowered to make studies of beach erosion problems at the request of, and in cooperation with, cities, counties, or states. In 1946, Federal contributions to construction costs were permitted when projects protected publicly-owned shores, or if such protection would result in public benefits. The Corps mission was expanded to include hurricane flood protection in 1955. Contained within the 1968 Federal legislation was the mission to prevent or mitigate shore damage attributable to Federal navigation works. An objective evaluation of the cost of Federal shoreline programs administered by the U.S. Army Corps of Engineers will show that a conscientious effort has been made to insure that public benefits substantially outweigh the public cost.

COASTAL STRUCTURES

Shoreline restoration and stabilization structures built with the assistance of Federal dollars and by the Corps of Engineers are tested by: (1) an economic analysis which indicates the benefit-to-cost ratio is greater than one; (2) an engineering analysis and an environmental assessment based on current technology, which has had the benefit of at least one and often two levels of review, usually including that of the Coastal Engineering Research Center; (3) a cost-sharing policy which reduces the Federal share--normally 50 percent--by the ratio of private to total benefits; and (4) a policy which requires public beach access and public beach use as a condition for Federal aid.

EFFECTIVENESS OF COASTAL STRUCTURES

The Corps of Engineers has constructed more than 800 jetties, breakwaters, and coastal groins. More than 80 beach fill projects have been constructed. Early coastal structures were mostly breakwaters to protect anchorages from wave action, jetties to stabilize the location of entrance channels, and sea walls to protect exposed port or urban areas. Most of these were built in support of navigation, and many have performed their intended functions for nearly a century. Structures to protect or stabilize sections of the open coast (groins, revetments, seawalls, and beach fills) are generally of more recent origin. Examples of long terms of effective service are understandably more limited. However, the record of coastal structures is generally one of

overall success, rather than of failure. It is, of course, true that coastal processes have become better understood in recent years and design techniques have improved correspondingly.

We have referred above to a large number of projects. If we had a huge number of failures, then we would have a national disaster. To list and comment on even the 100 or so projects constructed prior to 1900 is impractical for this presentation. We will instead focus on only three projects. One was an almost immediate success, one has evolved into a very successful project, and one is a recent project, which promises considerable success. The three projects perform different functions and illustrate a relatively wide variety of coastal structures.

GALVESTON, TEXAS, SEAWALL

At the turn of the century, Galveston, Texas, had a population of about 38,000. The first floors of residents and businesses were elevated as a safeguard against storm-induced flooding, which the city occasionally suffered. On September 8, 1900, a hurricane struck Galveston with a storm surge of 4.6 meters msl, accompanied by winds of up to 40.7 meters per second. The storm left in its wake 3,600 demolished buildings and about 6,000 people dead. The city rebuilt and protected itself with a seawall (See Figure 3). On August 16-17, 1915, another severe hurricane swept across Galveston. The winds exceeded 26.8 meters per second for over 19 hours and exceeded 31.3 meters per second for over 9 hours. By comparison the September 1900 hurricane winds had exceeded 26.8 meters per second for only about 7 hours, and its surge height was 8.9 centimeters less than the 1915 storm surge. In striking contrast to the less severe hurricane of 1900, there was comparatively small damage and few casualties (12) within the city in 1915. There was considerable scour along the toe of the seawall and the apron was undermined in places. However, the concrete section of the wall suffered no major damage. The seawall undeniably paid for itself during this one storm (Davis, 1961).

SANTA BARBARA HARBOR, CALIFORNIA

During the 1920's, the beaches of Santa Barbara, California, (Figure 4) and the communities to the east were developed with expensive public improvements and private beach homes. There was a demand for a protected harbor for small boats because severe storms and the open coastline made the Santa Barbara roadstead unusable as a safe moorage. During 1927-29, the city constructed a breakwater offshore to protect a harbor area of about 34 hectares. The breakwater was about 550 meters long and had a short arm at its western end which curved landward. A 183-meter gap to permit an unobstructed flow of sand along the beach was left between this arm of the breakwater and land.

On completion of the offshore section, the breakwater cast a "wave shadow" which caused the littoral transport to be deposited and sand began to shoal the harbor. Complete filling of the harbor was feared, and the breakwater gap was closed. Figure 5 shows the harbor shortly afterwards in 1930. By 1933, the beach had accreted to the bend in the breakwater and a shoal was building into the harbor from the eastern end of the breakwater. At the same time, the beaches to the east of the

FIGURE 7. Santa Barbara Harbor, California - 1970

harbor began to erode. Riprap walls and groins were constructed to protect the eroding areas. Ultimately, erosion proceeded eastward some 21 kilometers. In 1935, approximately 154,000 cubic meters of material were removed from the shoal by hopper dredge and placed as close to shore as possible. It was hoped that the sand would move shoreward and help replace the beach. The sand was placed in 6.1 meters of water, and very little, if any, reached shore. Years afterwards it was still possible to identify the disposal area when soundings were taken. Figure 6 is a 1938 photograph of the harbor. Initiation of periodic pipeline dredging of the shoal followed shortly thereafter. The material is placed east of the harbor beyond the wave shadow of the breakwater and the eastern beaches have recovered. Besides providing about 700 boat berths in an area of increasing demand (see Figure 7), the project has restored beach property values far in excess of expenditures and is now considered successful (Penfield, 1960).

This project was a first in "sand bypass" engineering. The processes involved were not as clear then as they are today, some 50 years later. The shoreline at Santa Barbara is shielded by the Channel Islands which shelter approximately 40 kilometers of the coast. Normal wave action enters the Santa Barbara Channel from the west and induces an eastward littoral transport through most of the year. However, storms may occasionally reverse the littoral transport for short periods. This situation was not clear when the breakwater was designed. Due to the limited wave exposure behind the Channnel Islands, the littoral drift at Santa Barbara is almost uni-directional and sand bypassing presents a relatively simple challenge. In other situations, where the littoral drift reverses over extended periods, as often is the case, the gross littoral transport quantity may be many times the net littoral transport quantity and the problems of designing a sand bypass system are an order of magnitude more difficult than the problems at Santa Barbara.

DADE COUNTY, FLORIDA

The beach erosion control and hurricane surge protection project for Dade County, Florida, provides a good example of the recent technology in beach fills.

Responding to public concern, the State of Florida, Dade County, and the Corps of Engineers cooperated in constructing the Dade County project, which is designed to withstand a hurricane similar to the 1926 hurricane, the maximum recorded at Miami, Florida. The project provides beach erosion control and hurricane surge protection by the initial placement of 10.7 million cubic meters of sand to form a protective and recreational beach and protective dune for 16.9 kilometers of Miami Beach shore. The project provides for a dune 6.1 meters wide at the crown at an elevation 3.5 meters above mean low water and a level berm 15.2 meters wide at an elevation of 2.7 meters above mean low water with a natural seaward slope (see Figure 8). The beach would be nourished, as needed, to compensate for erosion losses estimated at an annual rate of 161,000 cubic meters. All project fill came from borrow areas 1,800 to 3,700 meters offshore. The fill material was pumped ashore through a submerged discharge line hy a floating hydraulic dredge (US Army Corps of Engineers, Jacksonville, 1980).

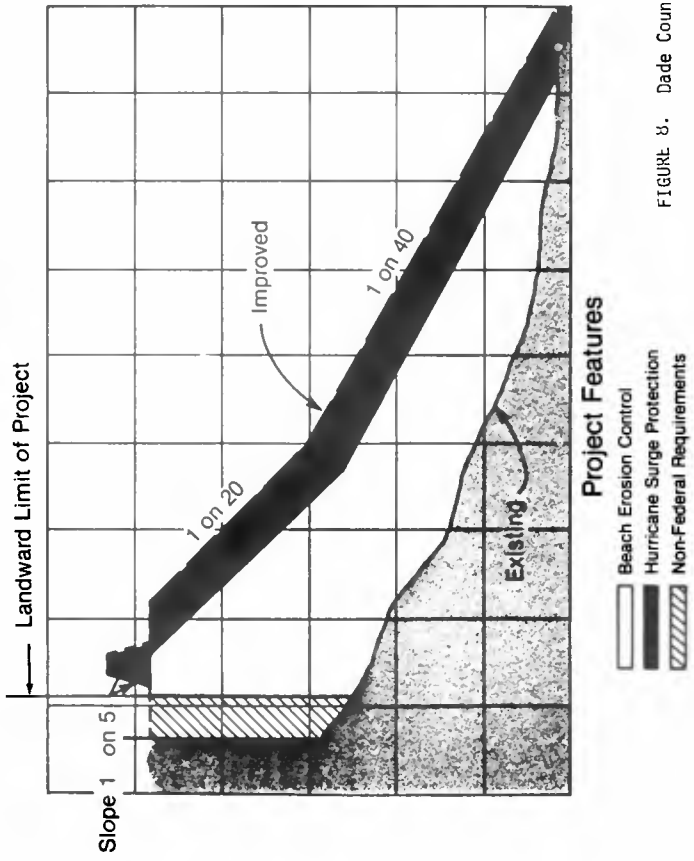

FIGURE 8. Dade County, Florida

FIGURE 9. Miami Beach, Dade County, Florida. Storm Wave Attack before project construction.

FIGURE 10. Miami Beach, Dade County, Florida, before project construction

FIGURE 11. Miami Beach, Dade County, Florida, after project construction.

What is the public receiving for the investment? To begin with, the beach (see Figures 9, 10 and 11), at a cost to date of $2.4 million per kilometer, is protecting property valued at $146 million per kilometer. Protection inherently enhances property by increasing its value on the market, by optimizing its income potential, and by increasing its tax contribution to government. Over one million international tourists visited the beach in 1980 and spent over $200 million, and combined with domestic tourist spending, this amount grows to $500 million, or $29.6 million per kilometer per year. All these factors account for a benefit to the public of $23.1 million per year. Miami Beach represents an excellent example of the merging of governmental functions, private investment, disparate interests, and puhlic demands in providing a high degree of protection and a recreation resource for the maximum use and enjoyment by the greatest number of people. By duplicating nature's own process, the beach fill remains in reasonable harmony with nature while protecting property and enhancing recreational opportunities (Adams, 1981).

This brief review illustrates that coastal erosion and catastrophic flooding can, in fact, be controlled. With proper mitigating actions, the coastal area can be utilized commercially and recreationally. Where circumstances warrant, the beach can be restored and maintained. The Corps of Engineers procedures insure that such efforts are only undertaken in cases that will produce greater economic efficiency than relocation, "no action," or other alternatives. Eurther, 1980's decision-making insures that social and environmental impacts are within acceptable limits. With almost 13,000 kilometers of the United States shoreline experiencing significant erosion, there are numerous areas where rescue of the shore is not only possible, but economically desirable (HD No.93-121,1973). At the same time, today's improved understanding of coastal processes makes it unlikely that costly mistakes will be made.

CONCLUSIONS

The processes active at the ocean's shores range in scale from granular to global and from seconds to centuries. Our planning, design, and construction in the coastal zone improves with an ever increasing understanding of this very dynamic environment. Society, through governmental, benevolent, and market-place mechanisms, makes the decisions on how the coasts will be used. Coastal engineers and other scientists must maintain a continuous, objective pursuit of factual information and make it available in an unbiased way for the judgment of society in arriving at the decisions that must be made. By supporting research and investigative efforts focused on better understanding the dynamic and wide range of processes present at the shore, and by utilizing this knowledge in guiding our activities, we can better plan and design to save our shores for ourselves and future generations.

ACKNOWLEDGEMENT

The authors wish to thank Dean M. P. O'Brien for his generous assistance and many helpful suggestions. We also wish to thank the other Corps of Engineers employees for their efforts in typing, editing, and illustrating the paper. Many constructive comments were provided by the

staff of the South Pacific Division, Galveston District, Jacksonville District, the Waterways Experiment Station, and the Coastal Engineering Research Center. The views expressed in the paper are our own and should not be construed as reflecting official U.S. Army Corps of Engineers policy.

ENVIRONMENT IN COASTAL ENGINEERING: DEFINITIONS AND EXAMPLES**

Cyril Galvin, M. ASCE*

ABSTRACT

In current usage, environmental aspects of coastal engineering design include aspects of ecology and aesthetics, as well as environment. In practice, the aspect of environment is a limited one, considering man's surroundings, with the works of man left out. The increased consideration of environmental aspects over the past 15 years has brought real benefits to the coastal engineering profession, as well as obvious problems. One problem is a mythology of coastal processes that has become widely accepted. Priorities in coastal engineering design remain a structure that will last a useful lifetime and perform its intended function without creating new problems. After satisfying these fundamental requirements, the structure should minimize ecological change, and fit pleasingly in its setting.

INTRODUCTION

Design and THE Environment. A coastal structure must remain standing when hit by the most severe waves, currents, and winds that can reasonably be expected during its intended lifetime. Waves, currents, and winds are basic elements of the physical environment. In this structural sense, good coastal engineering is always sensitive to the environment.

But the designer who creates a structure that doesn't fall down has not necessarily solved a coastal problem. The structure must also perform a function, without creating significant new problems. It must reduce beach erosion, prevent flooding, maintain a channel, provide a quiet anchorage, convey liquids across the shore, or serve other functions. There are groins standing out at sea after the beach has eroded away; jetties exist that enclose a deposit of sand rather than a navigable waterway; some seawalls are regularly overtopped by moderate seas; water intakes are silted in.

*Principal Coastal Engineer, Cyril Galvin, Coastal Engineer, Box 623, Springfield, Virginia 22150, USA.

** This paper is an overview of the papers discussed in the poster session on Environmental Aspects in Coastal Engineering Design. The papers discussed are presented in Chapters 136-137.

These functional failures are no less costly than structural failures. To design a structure to function as intended requires a thorough knowledge of the coastal processes affecting the site. These coastal processes are basic elements of the environment. So in the functional sense also, good coastal engineering is always sensitive to the environment.

But physical factors of the environment (waves, currents, sediment transport, etc.) are not the principal factors of THE environment, as that word is now used in discussing environmental aspects of coastal engineering. "Protect the Environment" does not mean protect the design wave height. Rather, "Protect the Environment" means protect a complex of factors including fish and wildlife, wetlands, scenic views, water quality, odors and sounds, low population density, and even the subjective imaginings of people who will never see the sight.

Intent of this Paper. This paper is about the relation between coastal engineering and the environment in the above contemporary sense. The occasion of the paper was a poster session "Environmental Aspects in Coastal Engineering Design" held on 15 November 1982 in Cape Town as a part of the 18th International Conference on Coastal Engineering. A poster session provides for the individual authors to publish abstracts of their papers and to display key illustrations from their papers at the meeting hall during the conference. The chairman of the session discusses the authors' papers and the general subject, and puts his ideas in a paper. This is the chairman's paper for the poster session on "Environmental Aspects in Coastal Engineering Design."

Given the occasion of this paper, it should serve two functions: review the work of the individual authors taking part in the session, and comment on the subject matter in general. There are 4 papers eligible for review, that is, 4 papers whose abstracts were published in the conference abstract volume and whose authors displayed their results at the conference. These are the works of Perry (1982), Clark (1982), Hoffman, Mussalli, and Taft (1982), and Geldenhuys (1982).

The next section of this paper defines and distinguishes the meanings of environment as they apply to this paper. Following these definitions, four sections review each of the poster papers. The final section presents opinions of the writer on environmental considerations in coastal engineering design.

DEFINITIONS

To a large extent, words mean whatever their users think they mean. This has been especially the case in discussing environmental questions. Nevertheless, it is useful to review the accepted meanings of key words that are a part of the discussion. There are three words particularly relevant here: Environment, Ecology, and Aesthetics.

The authoritative sources of meanings are dictionaries, and the most authoritative dictionary for the English language is the Oxford English Dictionary (OED), issued in corrected form in 1933 with later supplements. A more contemporary and concise dictionary is the Oxford American Dictionary (1980). These two dictionaries (the OED and the OAD) are the sources of the following definitions.

Environment. Environment, according to the 1933 OED, comes from a French word meaning to encircle. Two definitions are given, the first and most general being "the object or regions surrounding anything." The second definition is "the conditions under which any person or thing lives or is developed; the sum-total of influences which modify and determine the development of life or character." The 1980 OAD defines environment as "surroundings, especially those affecting people's lives."

The coastal engineer developing a design wave height for a structure considers the environment in the first sense of these dictionary definitions. Once it is built, the structure itself becomes part of the coastal environment in this sense. But the environment, as used in the phrase "Protect the Environment", implies a slightly different definition; environment in this usage corresponds roughly to animals, plants, and the natural landscape, with the works of man removed. As used in this environmental sense, the meaning approaches that of 'ecology'.

Ecology. The word, 'Ecology', as such, does not appear in the 1933 OED. At that time the accepted spelling was 'oecology', which is defined as "The science of the economy of animals and plants; that branch of biology which deals with the relations of living organisms to their surroundings, their habits and modes of life, etc." (The 1972 Supplement to the OED now accepts 'ecology' as the more usual spelling.)

The 1980 OAD shows the evolution in meaning of ecology that has accompanied recent usage. The first OAD definition of ecology is a concise restatement of the 1933 OED definition: "The scientific study of living things in relation to each other and to their environment". The second definition is simply "this relationship", i.e., the study of relationship among organisms which was the original meaning of ecology is now coming to be replaced by the relationship itself. The OAD editors also add a postscript to their definition: "Note that ecology does not mean environment."

Relationships among native species and their environment, i.e., the ecology, may be affected by coastal engineering works, and the works themselves may be affected by the ecology. As an example, improving an inlet to make it more navigable may also increase the tidal prism, and thus change the salinity of the bay waters. Changed salinity could increase or decrease the productivity of oyster beds in the bay, an effect of a structure on the ecology. It could also change the abundance of marine borers infesting timber piles and bulkheads in the bay, an effect of the ecology on those timber structures. Depending on the circumstances, the net effect of the changes may be beneficial or harmful, although the doubt is usually in favor of maintaining the status quo, since the individuals whose livelihood is most threatened by such changes often hold a potential veto over the approval of the project.

The practical effect of these considerations is the development of a new functional design requirement for a coastal structure: the structure should not cause any significant change in the existing ecology, except for changes (such as improved water quality) that are not strongly opposed by any element of the affected population.

Aesthetics. 'Environment' and 'ecology' are words that have become commonplace. Their meaning may be vague, and one is often confused with the other, but these two words undoubtedly connote good things that people are in favor of. It has been the writer's experience, however, that regulatory decisions made in the name of the environment or ecology are often based, not on ecological principles, but on the personal philosophy of the regulator about what is right, i.e., what contributes to beauty in the situation. Often, in fact, the regulator has relatively little ecological data to base a decision on.

In these decisions, personal aesthetics and not the environment or ecology, determines the outcome. Aesthetics is defined (1933 OED) as "The philosophy or theory of taste,

or of the perception of the beautiful in nature and art." The 1980 OAD defines aesthetics as "a branch of philosopohy dealing with the principles of beauty in art."

Few people, of course, formally sit down and write out their personal theory of what is pleasing and beautiful in nature, and then make decisions consciously following this formulation. It is more intuitive than that. Some things fit and others do not. Given the choice, wilderness is more appealing than development; clear water is preferred to turbid water; dunes are more natural than seawalls; and so on. Often it seems that these aesthetic judgements, with which almost everyone would agree, are made first and the ecological reasons to support the decision are brought up later. The net benefit of the structure to society runs a distant second in consideration.

Thus, while protecting the environment or the ecology may be the slogan, the practical application is often based on personal aesthetics. Aesthetic judgements are important and must be given weight. They are often intuitively correct. As an example, the selection of the site for the Field Research Facility of the Coastal Engineering Research Center located at Duck, North Carolina, was determined by a regulatory decision based on aesthetics. The site originally favored for that facility was Assateague Island, part of a National Seashore. The principal cogent objection to the facility at Assateague was the visual incompatibility of the pier superstructure with the setting. As a result of this objection, plans for the Assateague site were abandoned and the present site at Duck, North Carolina, was selected, a fortunate selection in the writer's view.

Sometimes, the basis for aesthetic decisions appears to automatically assume greater attractiveness of natural conditions. But the natural condition is not necessarily the most pleasing one, despite a strong predilection to assume so. The writer has had black California beach sand pointed out to him as evidence of oil spills. The sands in question were indeed visually unpleasing, but the blackness was entirely natural, due to naturally occurring dark minerals of the region.

In previous paragraphs, this section of the paper attempts to define and distinguish three terms applicable to what is called the environmental aspect of coastal engineering. The next sections get down to four concrete cases that were included in the poster session on Environmental Aspects of Coastal Engineering Design. These four cases are, in effect, a random sample of current coastal studies bearing on environmental aspects of design.

CLASSIFICATION OF NATAL ESTUARIES

Reference. The Estuaries of Natal: A Method of Classification, J.E. Perry, Abstracts volume, 18th International Conference on Coastal Engineering, Paper No. 17, pp. 33-34. (This abstract has been supplemented by selected data reports supplied by Mrs. Perry.)

Natal Estuaries. This report concerns the classification of 72 estuaries in Natal, South Africa. Classification is based on 6 sets of air photos covering the period from 1937 to 1980. Most of these photos were taken during the southern hemisphere winter. The photos are converted to a common 1:10,000 scale and landmarks used to locate changing features. A large number of measurements are made, most of which describe the geometry of the river and adjacent areas. Perhaps only 20% of these measurements concern coastal features directly, these being features associated with the river mouth. Table 1 identifies only the river mouth features measured in the classification.

The mouths of these estuaries often have spits from one or both sides, which frequently seal off the river mouth entirely. Rocks commonly occur in the vicinity of the mouth, and roads or rail bridges are also common. Data from the work of G.W. Begg (1978) and additional data supplied by J.E. Perry (received Dec 1982), show the following: The estuaries can be conveniently divided into north and south sets, with Natal Bay as the approximate dividing line (approximately $29^{o}53'$ south latitude). The majority of Natal estuaries are south of Natal Bay and most of these are usually closed. Spits commonly grow north to south in the south and south to north in the north. In the south about 43 of 53 estuary mouths have noticeable rocks in the vicinity, but in the north only 8 of 21 show rocks in the vicinity. The estuaries in the south commonly are crossed by road and/or rail bridges near the mouth, but in the north this is the case at only 4 estuaries.

In their present state, these data are still being tabulated and interpreted, but as indicated in the previous paragraph, they offer interesting information, for example, on longshore transport directions. Mrs. Perry reports that particularly for the coast north of the river Tugela ($29^{o}13'$ south latitude), there are long northward-directed spits. Some of these shores show prominent accretion, as shown by the shoreline changes in Figure 1, reduced from a supplement to the report by Selby and Perry (1982).

**measured from MSL

Opinion. This study illustrates a necessary fundamental step in any proper environmental study: the description of what actually exists in the field. The use of aerial photos is ideal for this purpose, since they provide a uniform source of morphologic data at identifiable times in the past. Once finished, the availability of such a set of data will put future analysis and policy decisions on a much surer basis. The wider possibilities of these data are illustrated by the shoreline change information of Figure 1.

FLORIDA COASTAL CONSTRUCTION GUIDELINES

Reference. Coastal Construction Building Code Guidelines, Ralph R. Clark, P.E., editor, Florida Department of Natural Resources, Bureau of Beaches and Shores, Technical Report TR 80-1, Nov 1980, 52 pp.

Purpose. As explained in its introduction, this document is a product of the evolving state coastal management program in Florida. Since 1957, the Florida Department of Natural Resources (DNR) has held regulatory authority over building setback lines and coastal construction in the state. In recent years, Florida state legislation has encouraged delegation of this authority to the particular municipalities and counties, provided that the municipalities and counties have appropriate procedures to control coastal construction. The purpose of TR 80-1 is to provide local Florida governments with guidelines for a coastal construction building code.

(This delegation of regulatory authority to lower levels of government is an example of a nationwide trend. A similar effort in state coastal zone management is that taking place in California. Much of the permit jurisdiction formerly held by the California Coastal Commission is being assumed by the particular cities and counties within that state following completion of their local coastal programs.)

Building Code. This document (TR 80-1) consists of a one-page introduction, followed by two, nearly-identical modifications to existing building codes of approximately 24 pages each, and ending with 5 pages of references.

The body of the report (pages 1 thru 47) presents the building code guidelines recommended by DNR. These are in the form of supplements to the existing South Florida Building Code (pages 1 thru 23) and the existing Standard Building Code (pages 24 thru 47). The principal difference between the two supplements is the terminology used to subdivide and identify specific paragraphs.

As indicated by Clark (1982), three major concepts of coastal engineering design are incorporated into these building code guidelines:

a. Identification of a zone where major coastal construction is permitted, but where special coastal design criteria apply. The zone is three-dimensional, that is, it has both landward and seaward limits in plan, and vertical constraints in elevation.

b. Requirement that foundation design anticipate erosion occurring during the 100-year storm surge, or its cumulative equivalent.

c. Requirement that the structure be designed for loading expected during the 100-year storm surge.

Both supplements contain identical sections on definitions. The zone subject to these recommended building code supplements is defined as the Coastal Construction Building Zone. This zone is bounded on the seaward side by the Coastal Construction Conservation Zone, which is approximately the dunes and the beach as far as the mean high water line. Major structures cannot be constructed within the Conservation Zone. On the landward side, the Construction Zone is bounded by the Coastal Construction Control Line. This control line is defined by statute and plotted on official maps. It is intended to mark a landward limit to the effect of the storm surge with a 1% chance of occurrence in any year (the 100-year surge) or of a number of lesser storms which cumulatively have the same probability of occurrence. (The zoning is generalized for the purpose of this paper as Figure 2, drawn in part from the FEMA (1981) Coastal Construction Manual.)

Two types of erosion are distinguished under 'erosion' in the definitions: Horizontal Recession and Scour, based on whether or not the storm surge inundates the profile. This distinction appears unsatisfactory to the writer, because both horizontal recession and vertical scour can occur in the absence of storm surge, and because it appears to imply erosion due to onshore-offshore transport when much erosion is due to longshore transport. It would be better to define erosion within the concept of littoral sediment budget, erosion being the result when more sand is carried out of the area than is carried in by waves, currents, winds, and other processes.

The general load requirement is for all habitable buildings to be designed to withstand the forces accompanying the 100-year storm. These forces are defined to be "waves, hydrostatic, hydrodynamic, and wind loads". Wave loads are specified to be those required by appropriate Navy or Army Corps of Engineers Manuals (NAVFAC DM-26 or Shore Protection Manual, Volume II). Hydrostatic loads are given as the pressure resulting from the equivalent height of water. Hydrodynamic loads are given a lengthy discussion in the definitions section, but are discussed only briefly and in general terms under required loads. The wind load is

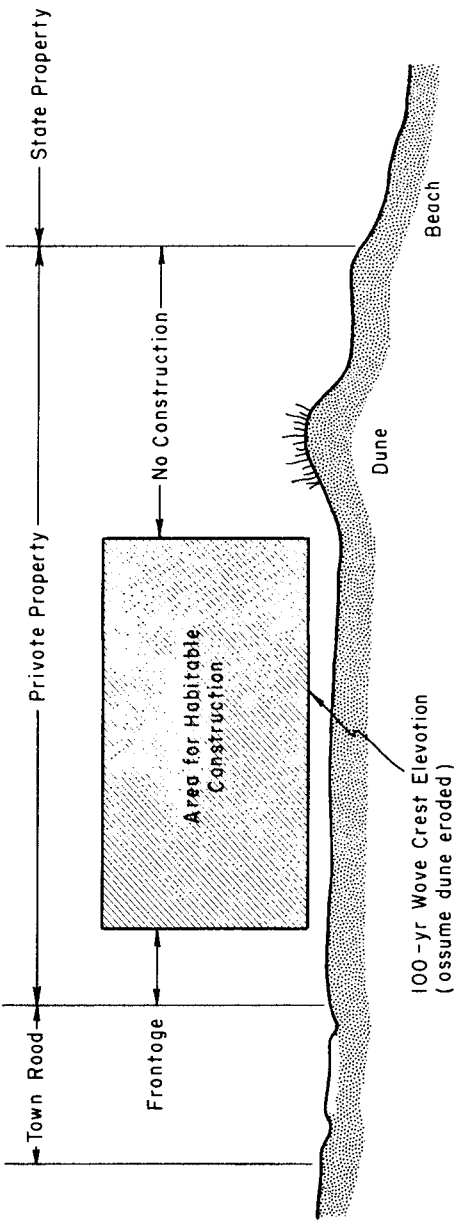

Figure 2. TYPICAL COASTAL CONSTRUCTION ZONE

specified by a table developed from the 2/7 power of elevation above grade, based on an assumed 140 mile per hour wind.

Although habitable structures must be designed for the 100-year storm, shore protection structures may have shorter design lifetimes, down to 10 years for bulkheads. Shore protection structures must be "designed for the minimum wave loads which are applicable for the design storm conditions which justify the structure."

Excavation in the Coastal Construction Building Zone is not recommended but is permitted, provided that excavated beach material is replaced or used elsewhere in the zone and provided that the excavation does not present potential danger during the 100-year storm design conditions.

The first floor must be above the expected wave crest elevation during the 100-year storm. This elevation is the higher of those determined by the DNR or the Federal Emergency Management Agency (FEMA), and is subject to revision.

A pile foundation is recommended for habitable structures, although soil-bearing foundations are permitted, if allowance is made for localized scour during the 100-year storm. The pile foundation is to have pile caps below the expected erosion surface during the 100-year storm. The pile foundation above grade is to have adequate spacing, defined as 8 feet or 8 times the pile diameter, which ever is greater.

Bibliography. The document contains a useful list of 65 references, almost all of which are not specifically listed in the building code guidelines. These 65 references identify about 13 national, county, and local building codes; 13 text books on a variety of subjects; 5 manuals; 6 reports related to FEMA's coastal flood insurance mapping; and at least 11 articles that might be called construction guidelines. The remaining 17 references deal mostly with coastal processes, sediment transport, and waves.

Opinion. Construction codes concern criteria based on the physical environment. The ecology of the environment is considered in the earlier steps defining the construction zone and granting the building permit. These Florida guidelines systematically reduce coastal engineering practice to terms applicable to the work of the building contractor, without overspecifying the criteria. The engineer still has to determine for the specific site the probable ground level during the 100-year surge and the forces exerted by this surge. Among the tougher questions to be determined is

whether the dune, which is usually pictured seaward of the construction zone (Figure 2), will survive the 100 year surge. The 5-page bibliography is a most useful addendum to the guidelines.

EXCLUDING ORGANISMS FROM COASTAL WATER INTAKES

Reference. Environmental Considerations in Designing Coastal Water Intakes, P. Hofmann, Y.G. Mussalli, and E.P. Taft, unpublished draft report, Stone & Webster Engineering Corporation, 1982, 14 pp. including 7 figures.

Fish Transfer Systems. Cooling water intakes to power plants may entrain organisms, resulting in high mortality to the entrained organisms and possible damage to the cooling water system. The problem of excluding organisms from the water intake without killing them is a sophisticated extension of the problem of excluding trash, which has occupied engineers for a longer time (Linsley and Franzini, 1979, p. 233). Design of a water intake usually requires consideration of a trash rack; exclusion of organisms from coastal water intakes adds to this standard design requirement the effect of a living organism capable of independent reaction to the environment, and the complications imposed by coastal processes. The authors describe solutions to the problem of organism entrainment which they have studied. Additional related studies are found in Taft and Mussalli (1978).

Physical constraints of the site usually will determine the overall plan of the cooling water system. Modifications to that system are then made to minimize organism entrainment. The principal modification recommended by the authors, based on their studies, is the use of screens angled at about 25° to the centerline of the upstream channel. Fish swept downstream sense these screens and in avoiding them, they are shunted into a bypass from which they are returned safely to open water. (The fish do not 'see' the screens, which are usually in the dark. Even if in a lighted conduit, the fish approach the screens tail first, so the sensing of the screens is presumably a reaction to the turbulent eddies shed by the screens.)

Louvers have been used for fish diversion in hydroelectric plant intakes, but the authors' studies show that the net efficiency, considering the cooling water system and fish mortality, makes screens the better choice. Mortality rates for fish vary considerably with the species tested. The 25° angle of the screen is an empirical result of their tests with live fish.

The use of these screens is further modified to minimize pumping requirements for the fish bypass system. To reduce this cost it is desirable to minimize the flow in the bypass. This is accomplished by making each screen a vertical conveyor belt with fish buckets which lift fish to a smaller return trough (Figure 3). The conveyor belts are equipped with low pressure sprays to transfer the fish into the fish trough and a high pressure spray to remove trash.

There is a further complication in one Florida power plant imposed by the requirement to remove small organisms from the flow. This requires reducing the screen mesh from the normal 9.5 mm to 0.5 mm, which results in unique operational and reliability problems.

Opinion. These modified solutions to the problem of avoiding organism entrainment appear to be still in the development stage. It will be useful to see statistics on their operational reliability after several years. Statistics concerning the net effect of the cooling water system on the local ecology would be useful in justifying the cost of the traveling screens. Presumably, the heat discharge and turbulent energy accompanying the operation of the cooling system contribute benefits, as well as losses, to the local ecology.

RICHARDS BAY OUTFALL

Reference. Richards Bay Marine Effluent Pipeline - Environmental Aspects, N.D. Geldenhuys, Abstracts volume, 18th International Conference on Coastal Engineering, Paper No. 20, Nov. 1982, p. 39.

Discussion. This abstract identifies salient factors of the outfall at Richards Bay, South Africa, intended to handle effluent resulting from future industrial and population growth. The pipeline is a 1 meter diameter plastic pipe which is to extend 4 to 5 kilometers out to sea. Buoyant effluent will be discharged at a depth of 28 meters; dense effluent at a depth of 25 meters. The effluent consists of 3 principal substances: dense waste from a phosphoric acid factory, including gypsum, fluorides, and heavy metals; buoyant paper and pulp mill effluent; and buoyant municipal sewerage.

The volume of effluent is expected to rise from 64,000 m^3/day in 1984 to 176,000 m^3/day by 2013. The volume of dense waste will be a relatively low percentage of the total initial discharge and will remain relatively constant in

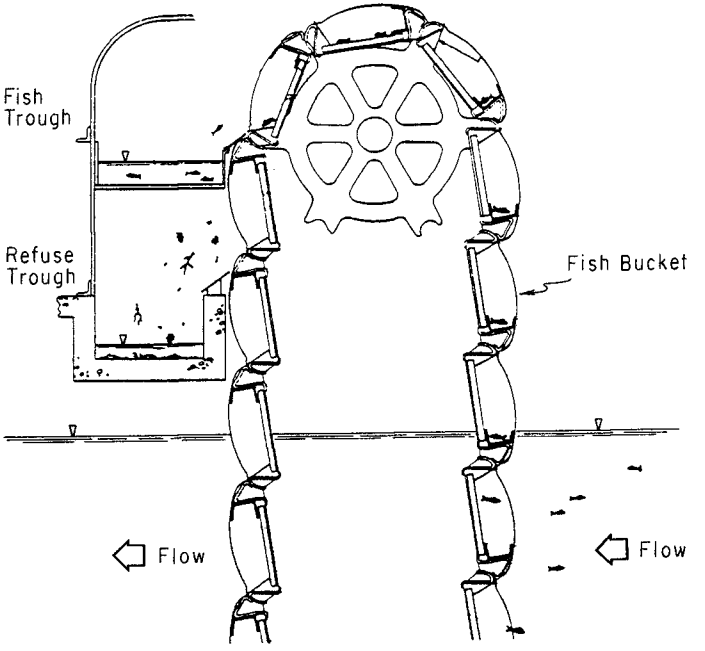

Figure 3. MODIFIED TRAVELING SCREEN WITH FISH BUCKETS (HOFMANN, MUSSALLI, AND TAFT, 1982)

absolute terms. The volume of buoyant waste is a large percentage of the initial total, and is expected to grow in absolute terms.

Some environmental deterioration is expected in the vicinity of the diffuser, particularly from deposition of the gypsum slurry which will eventually cover 4 square kilometers of bottom. Adverse effects may be reduced by inplant treatment, by searching for alternative use of the material, and by monitoring.

Bottom currents are estimated to be slight with median values between 7 and 10 cm/sec. Wave action is moderately severe with 90% of all wave heights between 0.5 and 2.0 meters. The available information does not provide data on the design criteria leading to the selected pipeline lengths, discharge point, and diameter. The design of outfalls based on physical and ecological criteria is discussed in detail by Grace (1978).

SELECTED ASPECTS OF ENVIRONMENT IN DESIGN

The previous sections of this paper indicate the range of environmentally related studies that now occupy coastal engineers and scientists, from basic description of the environment (Table 1) to design and testing of highly specialized fish handling mechanisms (Figure 3). The environmental concern that led to these studies has had a number of effects on coastal engineering design, some of them for the good. In this final section of this paper, three effects on the profession are discussed:

a. Benefits to coastal engineering practice
b. Fostering of coastal myths
c. Design priorities

Benefits of Environmental Concern. The environmental movement is blamed for delay and cancellation of projects; perversion of technical data; exaggerated concern over improbable outcomes; and many other errors of commission and omission. Most practicing coastal engineers will have their share of stories to tell, so they will not be reviewed here. Despite these real difficulties, however, the environmental movement has benefited the coastal engineering profession in significant ways.

On an economic level, environmental requirements have generated a lot of work for coastal engineers. On a technical level, environmental studies have significantly improved the profession's capacity to design for new environments.

The work done in planning for the Atlantic Generating Station in New Jersey provided much work for the profession and advanced its technical understanding considerably. There have been many other projects of smaller scope.

Preliminary studies required to satisfy environmental regulations probably have reduced net project costs in many cases by eliminating some of the uncertainty that faces a contractor in making up his bid. An Engineering News Record article ("Outfall bid $10 million under estimate", 9 Apr 1981) credits the low bid on the Southwest Ocean Outfall in San Francisco to preliminary studies which reduced the size of contingency allowances added to the bids.

Environmental requirements have forced coastal engineers to recognize the costs of unwanted ecological change. Although engineers retain strong suspicions that the ecological data on which these costs are calculated are often questionable, the requirement to consider the question has widened the view of the engineers, to the benefit of the profession.

The activity of coastal engineers on these environmental questions has also partially educated the regulators. There is now grudging recognition among environmentalists that some coastal engineers know what they are doing.

Myths. The environmental movement has fostered a pervasive mythology about coastal processes. These myths include logical impossibilities, highly improbable assertions, and dubious hypotheses. These are reviewed in reports and editorials published in Shore and Beach (see Adams, 1982; O'Brien, 1982; O'Brien, 1980) and in Proceedings of Coastal Zone '80 (see O'Brien and Johnson, 1982, Olsen, 1982). The following paragraphs start off with a brief statement of a myth, followed by a statement believed to more accurately represent the facts.

a. *All structures cause erosion.* Well designed structures retard or prevent erosion. As pointed out by O'Brien and others, few people would go to the expense of building a structure if erosion did not already exist at the site. Since many structures are separated from the water by a sand beach when they are built, this supposed causal action implies that waves are equipped with some sort of remote-sensing ability to perceive the structure behind the berm. To really evaluate the effect of the structure, compare the condition after construction with what would have been the condition had no structure been built.

b. *Seawalls cause unacceptable scour.* It has not been demonstrated that wave action at a seawall results in worse conditions than no seawall at all. Well designed seawalls are effective structures in sites that require them.

c. *Sea level rise is the cause of erosion.* The net effect of even rapid sea level rise is small compared to the effects of other coastal processes contributing to erosion (Galvin, 1983).

d. *The world's beaches are eroding almost everywhere.* Erosion probably does dominate, but accretion is not negligible. The writer believes that this myth is partly an artifact of the reporting system. The beaches most justifying study (and thus being reported) are those that are eroding. Accretion, such as that shown in Figure 1, gets noticed and reported only by accident. It is also true that both environmentalists and engineers may stand to gain from reports of widespread erosion, and this can subconsciously affect the reported prevalence of erosion.

e. *Erosion is inevitable.* Erosion is preventable, often by modest engineering efforts. A large sand fill at Ocean Beach, San Francisco, was maintained on the Pacific Ocean for half a century prior to current construction. A sand dike at the entrance to Fire Island Inlet, New York, has remained exposed to the Atlantic Ocean for over 20 years.

f. *Barrier islands are fragile.* Barrier islands have evolved in a tough environment, and they persist there. Barrier islands pictured on 18th century charts of the U.S. Atlantic coast are still in place, along with most of the important inlets between them. The seawall at Galveston, on a low barrier island in an area of subsiding land levels, is now about 80 years old and still functioning. Lighthouses from the 19th century and earlier exist today on Atlantic coast barrier islands.

Priorities in Coastal Engineering Design. It is difficult to design a structure that will last a useful lifetime and perform its intended function without introducing new coastal problems. The pressure of environmental concern tends to displace these design priorities. The ecological and aesthetic requirements of the design must be subordinate to these primary requirements. A suggested list of priorities for the responsible engineer are as follows:

a. Know the environment of the structure under design. This must be personal knowledge, adequate to establish the physical design criteria with confidence. This is a first requirement, before design can begin.

b. Design the structure to last a useful lifetime under the expectable extremes of the environment. This is the primary requirement of the design.

c. Design the structure to perform its intended function without introducing significant new problems. If this functional requirement is not satisfied, the structure will still be a failure, even if it lasts its intended design life.

d. Design the structure to minimize environmental change, particularly those aspects of the environment which are critical to the existing ecology. As indicated above, approval of the project may depend on this.

e. Within the constraints of the preceding priorities, make the structure fit the landscape in a pleasing way. A structure that is both physically adequate and functional is usually aesthetically pleasing as well.

STRUCTURAL DESIGN ASPECTS OF A COASTAL BUILDING CODE

by
Ralph R. Clark[1]

1 INTRODUCTION

Since 1957, the State of Florida, U.S.A., has witnessed the evolution of coastal regulatory concepts based upon coastal engineering design guidance. In 1978, the Florida Legislature encouraged counties and municipalities to adopt coastal construction zoning and building codes to supplement the existing minimum codes which include the Standard Building Code, the National Building Code and the South Florida Building Code. Subsequently, coastal building code guidelines were developed to provide statewide uniformity in the adoption of supplemental codes by coastal counties and municipalities.

It is the intent of this paper to present the structural design aspects required in a coastal building code using the code guidelines developed for and specifically applicable to Florida's coastal communities. These same design aspects and code guidance are applicable to most other state's or nation's developable sand shorelines which are subjected to coastal storm damage.

The purpose of a coastal building code in Florida communities is to supplement the existing minimum code by providing the structural design standards for construction within that portion of the beach and dune system which is subject to substantial scour, erosion, flooding, and loads accompanying the impact of a major hurricane. A coastal building code includes structural design standards for the construction of residential structures, enclosed commercial structures, coastal and shore protection structures, and other substantial structures of a semi-permanent nature. Although the few minimum codes currently in effect in the coastal communities are comprehensive for conventional construction, they do not adequately address the special structural design considerations identified for the Florida coast. Along a developable coast, special design considerations are necessary for the preservation of the beach and dune systems, as well as, for the structural adequacy of the construction.

The major concepts of coastal engineering design which are necessary in a coastal building code include:

1. Zone identification (horizontal and vertical).
2. Foundation design for erosion and scour.
3. Storm loading (including wind, waves, hydrostatic, and hydrodynamic loads).

---

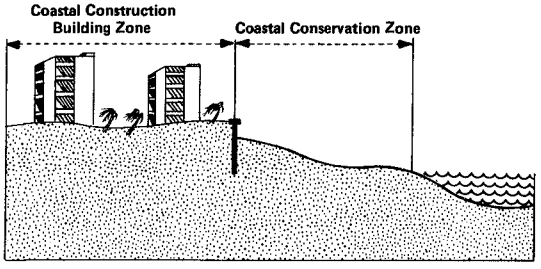
[1] P.E., P.L.S., Chief of Bureau of Coastal Engineering and Regulation, Division of Beaches and Shores, Florida Department of Natural Resources.

2 ZONES

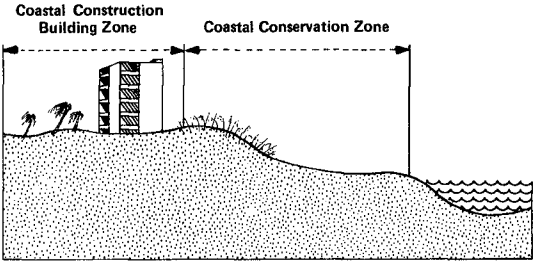
A coastal building code should identify the zone within which major construction should be designed for the physical environmental conditions accompanying a major storm event. The standard adopted by law in Florida is the zone of impact of a 100-year storm surge or of a number of lesser storms which cumulatively have an equivalent probability of occurrence. For coastal areas which are predicted to be flooded by the storm surge of a 100-year storm, a zone of impact is identified by the possible existence of breaking waves which are significantly large to cause structural damage. For coastal areas not overtopped by a predictable 100-year storm surge, the impact zone is identified by the wave runup and the erosion limits of that storm or of storms having impact with an equivalent cumulative probability.

Seaward of a coastal construction building zone, a coastal conservation zone should be identified within which no major habitable structures should be erected. The inland limits of this coastal conservation zone would coincide with the seaward limits of the coastal construction building zone and would identify the seaward-most dune and beach area in need of preservation from the impact associated with the construction of major habitable structures. Identification of the line of demarcation between a coastal construction building zone and a coastal conservation zone would have to result from a consideration of the existence and degree of existing development, as well as the predictable beach and dune response to high frequency (less than 20-year) storm events.

For developed coastal areas within which there exists a reasonably continuous line of rigid coastal protection structures, regardless of the design adequacy of these coastal protection structures, such a line should define the seaward limits of the coastal construction building zone. (See the following illustration.)



For developed and undeveloped coastal areas where there does not exist a line of rigid coastal protection structures, the dune system itself should be identified as a flexible coastal protection structure. Although guidance and rationale would vary in different locales, it is suggested that the inland limits of the coastal conservation zone be defined by the dune erosion limits of a 20-year storm event or the dune erosion which would be expected resulting from storms with an equivalent cumulative probability. (See the following illustration.)



Although horizontal zonation, that is identification of the coastal construction building zone and coastal conservation zone, is of primary importance, vertical zonation should be included by identifying the elevation above which major habitable structures should be constructed. The standard adopted by the State of Florida is the requirement to elevate the habitable structure such that the structural soffit or the underside of the lowest supporting structural member, excluding the foundation piles, is above the design breaking wave crests or wave uprush as superimposed on the storm surge of a 100-year storm.

3 FOUNDATION DESIGN

Foundation design within the coastal construction building zone should consider the topographic changes which may be expected over the design life of the structure. Foundation design should consider the erosion, scour, and loads accompanying a 100-year storm event.

Soil bearing foundations are discouraged within the coastal construction building zone and should be prohibited above the design grade. The elevation of the soil surface to be used in the calculation of bearing capacities should not be higher than that which would result from the erosion of a design storm. Calculation of the design grade should account for localized scour due to the presence of structural components. The maximum elevation of a soil bearing foundation should be set below the design grade resulting from the erosion (including scour) of a 100-year storm event. Erosion computations for foundation design should account for all vertical and lateral erosion and scour producing forces.

All habitable structures within the coastal construction building zone are recommended to be elevated on and securely anchored to an adequate pile

foundation. The structure should be anchored in such a manner as to prevent flotation, collapse or lateral displacement. A pile foundation should be designed to withstand all anticipated loads resulting from a 100-year storm event including wave, hydrostatic, hydrodynamic, and wind loads acting simultaneously with live and dead loads.

Design ratio of pile spacing to pile diameter is not recommended to be less than 8:1 for individual piles; however, this would not apply to pile clusters located below the design grade. Pile caps should be set below the design grade (which includes localized scour), while the piles should be driven to a penetration which achieves adequate bearing capacity taking into consideration the anticipated loss of soil above the design grade.

In addition to normal foundation analysis, pile foundation analysis should consider piles in column action from the bottom of the supported structure to the design grade. Consideration should also be given to the degree of exposure to wave attack and the resulting impact loads on lateral or diagonal bracing between piles. Lateral bracing should be designed to minimize resistance to flow and to the entrapment of floating debris.

Within the coastal construction building zone, substantial walls and partitions constructed below the level of the first finished floor should be prohibited. It is recommended that such a prohibition exempt stairways, utilities, shearwalls perpendicular to breaking waves, wind/sand screens, light open wood lattice partitions, elevator shafts, and breakaway or frangible walls designed to collapse under wave forces. Any construction within the vertical zone of design storm wave impact should be designed in such a manner so as to minimize the release of destructive hydrodynamic missiles.

4 STORM LOADS

A coastal building code should require that all habitable major structures be designed for the loads accompanying a 100-year storm event, including wind, wave, hydrostatic, and hydrodynamic loads. Within the coastal construction building zone and the coastal conservation zone, minor structures need not meet specific structural requirements for wind and wave forces, but they should be designed to minimize the potential for generating aerodynamically or hydrodynamically propelled missiles. Minor structures should also be designed to produce a minimum adverse impact on the beach or dune system.

The wind load requirements of a coastal building code need to be established considering historical records of storm generated wind velocities over water in the specific region. The problem with the wind requirements of the existing minimum codes in Florida was the inland location of the data from which the wind requirements were derived. Following recommendations of the National Hurricane Center, the University of Florida, and the Florida Department of Natural Resources, the State of Florida increased the required wind velocity for load computations to a minimum of 140 mph (225 kilometers per hour) at a height of 30 feet (9 meters) above the ground. The designer of a habitable major structure

should be aware, however, that localized wind forces under design hurricane conditions may exceed this minimum wind load requirement.

The coastal building code should be flexible to invite a detailed analysis of structures whose dynamic properties allow for wind sensitivity. In designing for hurricane generated winds, consideration should be given to the frictional effects and induced vortices due to the influence of topographic roughness and other existing structures. Consideration should also be given to the internal pressures on interior walls, ceilings, and floors resulting from damaged windows or doors.

The water related loads accompanying a design coastal incident storm event provide a major area of deficiency in most building codes, with wind generated waves producing the most analytically complex yet the most critical of forces to which the coast and its structures are subjected. The coastal building code should require that major habitable structures be designed in consideration of the expected shore-propagating wave conditions upon the surge of a 100-year storm event. Breaking, broken, and non-breaking waves should be considered as applicable. Design wave loading analysis should consider vertical uplift pressures and all lateral pressures to include impact, as well as, dynamic loading and the harmonic intensification resulting from repetitive waves. Recommended sources from which to base minimum criteria and methodology in design wave computations are the Department of Navy, Naval Facilities Engineering Command Design Manual NAVFAC DM-26, the Department of the Army Corps of Engineers Shore Protection Manual, Volume II, Department of the Army Coastal Engineering Research Center Technical Papers and Reports, and Florida Department of Natural Resources, Division of Beaches and Shores Technical and Design Memoranda.

In addition to the wind and wave loads, a coastal building code should require that all major habitable structures be designed for the hydrostatic and hydrodynamic loads which would be expected under the conditions of maximum inundation associated with a 100-year storm event. Calculations for hydrostatic loads should consider the maximum water pressure resulting from a peaked breaking wave superimposed on the storm surge of a 100-year storm event. Both free and confined hydrostatic loads should be considered, while confined hydrostatic loads should be determined using the maximum elevation to which the confined water would freely rise if unconfined.

Vertical hydrostatic loads should be considered as forces acting both vertically downward and upward on horizontal or inclined surfaces of major structures (e.g. floors, slabs, roofs, walls). Lateral hydrostatic loads should be considered as forces acting horizontally above and below grade on vertical or inclined surfaces of major structures and coastal or shore protection structures. Hydrostatic loads on irregular or curving geometric surfaces may be determined in consideration of separate vertical and horizontal components acting simultaneously under the distribution of the hydrostatic pressures.

Calculations for hydrodynamic loads should consider the maximum water pressures resulting from the motion of the water mass associated with a

100-year storm event. A more detailed discussion of these loads may be found in the definitions which follow.

When considering water related loads, specialized loads of importance to the coastal building code are battering loads. Habitable major structures including the foundation should be designed to resist the battering loads which may reasonably be anticipated resulting from isolated floating or suspended objects during a 100-year storm event.

5 EXCAVATIONS

A major consideration of a coastal building code, excavation is generally not recommended within the coastal construction building zone and should be prohibited within the coastal conservation zone. Any proposed excavation design should consider the coastal topographic changes accompanying a 100-year storm event and those anticipated topographic changes which have an equivalent probability of occurrence. Upon consideration of these topographic changes, any excavation within the coastal construction building zone which have the potential for a negative impact or would accelerate erosion should be prohibited. Excavation associated with the construction of a major structure within the coastal construction building zone should be limited to that incidental to the construction of the foundation and necessary for utilities. Excavation required for swimming pool construction within the coastal construction building zone should be minimized, located as far inland as possible, and not result in a net loss of sediment in the immediate area. All beach compatible excavated material or an equivalent volume of beach compatible material should be used as fill to be placed generally seaward of the excavation.

6 COASTAL AND SHORE PROTECTION STRUCTURES

The coastal building code should address coastal and shore protection structures as a separate classification for design. In general, the construction or rehabilitation of flexible coastal and shore protection structures such as beach nourishment, dune construction and stabilization, and sand fencing should be encouraged over the construction of rigid coastal and shore protection structures (seawalls, bulkheads, revetments, rubble mounds, groins, etc.) if such beach and dune restoration activity is of acceptable coastal engineering design and is compatible with the existing coastal systems. The construction of isolated rigid coastal or shore protection structures on undeveloped property is not recommended nor should such structures be designed primarily to protect minor structures.

Seawalls and other rigid coastal protection structures are intended to protect upland structures and property and not to protect the beach. In fact, rigid coastal protection structures usually may be expected to have a long term adverse effect on the adjacent beach. In those instances in which a rigid coastal or shore protection structure is the only feasible means of protecting existing upland structures and property, then that rigid

coastal or shore protection structure should be located as far landward as possible, consistent with design and construction requirements. Any seawall or other rigid coastal protection structure should be designed to minimize its erosion impact. Sloping rock revetments, rubble mound structures, and toe-scour protection with rock in front of vertical bulkheads and seawalls are recommended over vertical or sloping solid walls which due to their reflective surface cause substantially greater erosion losses to the adjacent beach.

The major design considerations for coastal and shore protection structures should include structural siting, foundation (e.g. geotextiles), crest (or cap) elevation, toe elevation, structural slope(s), components as impacted by waves superimposed upon the design storm surge, expected scour, impact on the beach and dune system, and impact on the adjacent properties. Coastal and shore protection structures should be designed for the minimum wave loads which are applicable for the design storm conditions which justify the structures. Seawalls, revetments, and rubble mound structures are generally designed for a 20 to 50-year storm event. Recommended sources from which to base minimum criteria and methodology in the design of coastal and shore protection structures are the Department of the Army Corps of Engineers Shore Protection Manual, the Department of the Army Coastal Engineering Research Center Technical Papers and Reports, the Department of Navy, Naval Facilities Engineering Command Design Manual NAVFAC DM-26 and DM-7, and Florida Department of Natural Resources, Division of Beaches and Shores Technical and Design Memoranda.

The coastal building code should also address those cases where development is proposed upland of an existing seawall or other rigid coastal protection structure. Such development should be located a sufficient distance upland from the coastal protection structure to allow for the containment of partial failures and to provide adequate room for routine maintenance and future repair to the coastal protection structure. Wave and runoff induced seepage in fill behind coastal protection structures should be considered to avoid partial or complete failure due to piping of fill material under the structures.

7 CODE DEFINITIONS

The following definitions are recommended for inclusion within the coastal building code, in order to clarify the coastal engineering and construction terminology adopted.

BEACH: The zone of unconsolidated material that extends landward from the low water line to the place where there is marked change in material or physiographic form, or to the line of permanent vegetation. Unless otherwise specified, the seaward limit of a beach is the mean low water line. Beach is alternatively termed the "shore."

BREAK-AWAY WALL or FRANGIBLE WALL: A partition independent of supporting structural members that will withstand design wind forces but will fail under hydrostatic, wave and runup forces associated with the

design storm surge. Under such conditions, the wall should fail in such a manner that it dissolves or breaks up into components that will not act as potentially damaging missiles.

COASTAL AND SHORE PROTECTION STRUCTURES: Shore hardening structures, such as seawalls, bulkheads, revetments, rubble mound structures; groins and breakwaters; aggregates of materials other than beach sand used for shoreline protection; beach and dune restoration; and other structures which are intended to prevent erosion or protect other structures from wave and hydrodynamic forces. Coastal protection structures are intended for the protection of upland properties and structures, whereas, shore protection structures are intended for the protection of the beach or shoreline.

COLUMN ACTION: The elastic instability in piles or columns resulting from stresses due to axial and/or lateral loads.

DUNE: A mound or ridge of loose sediment, usually sand-sized, lying upland of the beach or shore, and deposited by any natural or artifical mechanism (e.g., a dune may also include a beach ridge, dune ridge, chenier, etc.).

EROSION: The wearing away of land or the removal of beach or dune material by wave action, tidal currents or deflation. Erosion includes but is not limited to:

(a) Horizontal recession, which is where the storm surge intersects but does not inundate the profile and where horizontal littoral activity due to waves, currents and runup erodes the profile.
(b) Scour, which is where the topography is completely inundated by the storm surge, and where wave and current forces erode the profile in the vertical direction.

EXCAVATION: Any mechanical removal of rock or unconsolidated material.

HYDRODYNAMIC LOADS: Those forces resulting from a mass of water in motion, e.g., the flow accompanying a storm surge. Hydrodynamic loads are generally lateral forces, but also include effects of the turbulence resulting from the interaction of the flowing water mass with a rigid structure. Hydrodynamic load computations for construction consider all predominant forcing functions responsible for the motion of the aquatic mass, which are the astronomical tide and the storm waves (including the orbital particle transport, longshore mass transport, and shore-normal mass transport), as well as the storm surge. Gravity and forced flow resulting from the inundation accompanying the storm surge of a 100-year storm event are considered. Hydrodynamic load computations consider the processes of mass transport, heat transport, and momentum transport, along with the corresponding natural laws which are the conservation of matter, the conservation of energy (first law of thermodynamics), and Newton's second law (the equation of motion). Hydrodynamic load computations also consider the various flow forms including forms referring to spatial variation (uniform and non-uniform flow), forms referring to variation in time (steady, quasi-steady, and non-steady flow), forms referring to the

nature of flow (laminar and turbulent flow), and forms referring to the type of flow energy (subcritical, critical, and supercritical flow). In addition, hydrodynamic load computations include the transformation of flow energy form from supercritical flow to subcritical flow, and vice versa, including all classifications of hydraulic jump. Hydrodynamic load computations consider hydraulic flow across both a fixed bed and a movable bed where applicable.

HYDROSTATIC LOADS: Those lateral and vertical (including uplift) forces resulting from a mass of water standing either above or below the soil surface. These loads are equal to the product of the water pressure at the centroid of the plane surface area on which the pressure acts times the area of that surface. The hydrostatic pressure is equal to the product of the unit weight of the water times the elevation of the water above the point of measurement. Hydrostatic loads which are confined may be determined using the elevation to which the confined water would freely rise if unconfined. Hydrostatic pressures at any point are equal in all directions and act normal to the applied surface and are passive in nature.

INUNDATE: To cover or overflow as with a flood.

MAJOR STRUCTURES: Houses, mobile homes, apartment buildings, condominiums, motels, hotels, restaurants, other types of residential or commercial buildings, towers, swimming pools, piers, pipelines, and other projects having the potential for substantial impact on the beach and dune systems. Major structures include any structure which is neither a "minor structure" nor a "coastal or shore protection structure."

MINOR STRUCTURES: Elevated dune and beach walkover structures, beach access ramps and walkways, stairways, pile-supported elevated viewing platforms, gazebos, boardwalks, lifeguard support structures, pile supported or cantilevered decks or porches on new or existing structures, slab patios, sidewalks, driveways, and other uncovered paved areas (e.g., parking areas, shuffleboard courts, tennis courts, etc.), earth retaining walls, sand fences, privacy fences, ornamental walls, ornamental garden structures, aviaries, subgrade utilities (e.g., wells, septic tanks, and drain fields) which require material alteration and restoration of topography, and ornamental projects. Usage is not the only criterion used to classify structures as minor. It is a characteristic of minor structures that they are considered to be expendable under wind and wave forces.

ONE-HUNDRED-YEAR STORM: A shore-incident hurricane or any other storm with accompanying wind and wave intensity having a one-percent chance of being equaled or exceeded in any given year during a 100-year interval.

PILE FOUNDATION: A system of piles providing the support of a structure, including those piles terminating below grade at pile caps and those piles extending above grade to superelevate a structure.

STORM SURGE: The rise above normal water level on the open coast due to a number of factors, including the action of wind stress on the water surface and the rise in level due to atmospheric pressure reduction.

UPLIFT PRESSURE: Any upward hydrostatic, hydrodynamic, or wind pressure on the soffit, base, deck or floor of a structure.

WAVE: A ridge, deformation, or undulation of the surface of a liquid. Storm generated ocean waves shore-propagating upon the storm surge are considered for design purposes. The wave forces are dependent upon the type of wave considered (i.e., unbroken, broken or breaking).

8 CONCLUSION

Special design standards are needed specifically for the construction of structures fronting on the open coast exposed to extreme storm events. Predicting waves, flooding, erosion and scour is a necessary requirement for the proper design of ocean front construction. By systematically identifying the special design aspects for coastal construction, a coastal building code may be developed to supplement the minimum design standards set forth in the current building codes.

THE ESTUARIES OF NATAL: A METHOD OF CLASSIFICATION

by

J E Perry

ABSTRACT

This poster paper describes a hydrological/hydraulic classification of the estuaries of Natal, based upon aerial photography. The modus operandi is outlined and although the study is in its early stages, some key factors (natural and man-made) are indicated together with the method by which they are quantified.

1. INTRODUCTION

A hydrological/hydraulic study, aimed at acquiring an understanding of the long-term functioning of the estuaries of Natal is being done by NRIO (CSIR) for the Natal Town and Regional Planning Commission. Special emphasis is given to the influence of man on the natural river régime. The investigation falls into three phases, namely, evaluation of available data, classification of the estuaries and examination of specific problems in particular estuaries. This poster paper is concerned with phase two, classification of the estuaries. As hydrological data are scarce, a method of study has been devised to make the maximum use of the main data source available which is aerial photography dating back to 1937.

2. PROCEDURE

2.1 Basis

For each of the 72 estuaries, a suitable reach of the river is selected to include at least the known estuarine area. The upstream limit is usually a road or railway bridge which provides a good control position but occasionally a river confluence has to be chosen. This reach is then identified on enlargements of six vertical aerial photographs from 1937 to 1980 and re-photographed. Prints are

* Sediment Dynamics Division, National Research Institute for Oceanology, CSIR, RSA

then made on a scale of 1:10 000 using tracings of permanent features from 1:10 000 orthophotos to obtain the best possible fit. The orthophoto itself is often used as one of the six photographs selected for study. Tracings of the river courses for the six years are made on transparent film (one for each year) and used to compile an envelope of mobility of the river. Within this envelope of mobility, lines of measurement are marked at regular 250 m to 300 m intervals from the upstream limit of the reach to the mouth together with a suitable datum line for measuring sand-spit lengths and directions. These items are transposed onto the six river course tracings together with an outline of the flood plain area (if present) which is assessed from the orthophoto. The remaining areas within the flood plain to be traced onto the six master river course film tracings are sand deposits, swamps and cultivation (from the 1:10 000 photographs).

2.2 Direct Observations and Measurements

The six aerial photographs are studied in detail with respect to:

(i) terrain above the valley,
(ii) valley characteristics,
(iii) river mouth,
(iv) flood plain, and
(v) the river course and its channel.

Several of the observations made are of a general descriptive and qualitative nature (e.g. terrain, land-use, settlement, relation of channel to valley bottom and sides, description of the river mouth, river pattern, lateral channel activity and man-made factors). Other observations require measurements. Some are done manually with a steel ruler or an opisometer, direct from the photographs: amongst these are vegetation and land-use on the valley sides and riverine vegetation. The remaining linear, areal and angular measurements are made using a flat-bed digitizer. These may be made direct from the photograph in the case of an orthophoto. Otherwise, for greater accuracy, they are made from the master film tracings - compilation of which is described in 2.1 above. Such linear and angular items measured include mid-valley lengths, thalwegs, valley widths, flood plain lengths and widths, wetted perimeters and sand-spit lengths, widths and directions. Areas measured on the digitizer include the flood plain, swamps, sand deposits, cultivation, open water and bars.

2.3 Indirect Measurements and Calculations

River widths are measured, averaged and the standard deviation calculated. If the channel widths (in this

context synonomous with bank-full conditions) are markedly different from the river widths and clearly seen on the aerial photographs, these are also measured (across the same lines of measurement, marked at 250 m to 300 m intervals). The sinuosity for the whole reach is calculated. In order to quantify the lateral stability, distances are measured from the maximum left bank position to mid-river (along the selected lines of measurement on the six master film tracings). From these measurements, an average lateral displacement and an average coefficient of lateral stability is calculated for the time period under review.

2.4 Recording of Data

A table has been compiled (Table I) to facilitate the observation and recording of salient points. The basic idea for this tabular classification was taken from Kellerhals et al. (1976). Modifications were made to the initial table as the study progressed to include:

(a) local features of Natal rivers,

(b) estuarine conditions (e.g. river mouth characteristics), and

(c) particular needs of the study (e.g. man-made influences).

Data reports are prepared for each estuary. These contain the basic tabular classification forms for each photograph studied and tables showing river widths and lateral stability. Thalweg displacement is graphed. Other features selected for graphing vary from estuary to estuary, depending upon what is found to be pertinent. These may include open water areas (often found to be decreasing with time), thalweg changes, sinuosity changes and bar areas. Copies of the photographs used for classification are reproduced in the data reports together with a most recent aerial photograph onto which is superimposed the 1937 river course. The latter give a good visual indication of changes occurring in the estuaries over a period of approximately 40 years. Brief notes and an abstract of results are also prepared for each estuary. Data will be codified later and stored on computer for further analyses.

3. BACK-UP DATA

Hydrological data are scarce but simulated run-off is now available for tertiary catchments in Natal (H.R.U. Report 9/81). These data are an invaluable aid to interpreting the aerial photographs because wet and dry phases together with antecedent soil moisture conditions can be defined.

TABLE I — CLASSIFICATION OF THE LOWER REACHES OF NATAL RIVERS — NRIO No 41

RIVER LOVU, 24 % ESTUARINE, REACH from Sugar Mill Bridge to Mouth, 3,8 km from mouth. REF. DEA 4 700 a

RIVER VALLEY AND RIVER MOUTH FEATURES

General Description of the Terrain above the Valley

Terrain	*Vegetation*	*Land-Use*
mountainous	✓ almost none	none
✓ hilly	grass	scattered cultivation
undulating	sparsely forested (0-25%)	partly cultivated
plains	moderately forested (25-75%)	✓ mainly cultivated
	heavily forested (75-100%)	scattered settlement
	swamp/bog	✓ partly built-up *
		urbanised

Valley Sides (~~Not~~ Well-defined)

Slumping	*Vegetation and Land-use*	*Left*	*Right*
✓ none	none		
occasional	grass	NIL	NIL %
frequent	trees	11	12 %
	cultivated	89	88 %
	built-up	NIL	NIL %

Comments * near coast

Valley Characteristics

Measurements	*Terraces*	*Relation of Channel to Valley Bottom (Vertical)*	*Relation of Channel to Valley Sides or Resistant Terraces (Lateral)*	*Surface Geology*
valley length 3600 m	none	not applicable	✓ not applicable (no valley or free)	bedrock
bottom width(av.) 880 m	indefinite	not obviously degrading	occasionally confined	lacustrine deposits
valley slope ± 1:900	✓ fragmentary	partly entrenched	frequently confined	✓ fluvial deposits
height at head	continuous	entrenched	entrenched	aeolian
of reach 4 m to MSL approx.		✓ aggrading		sand covered NIL % area

Comments

River Mouth

Characteristics	*Measurements*	
✓ open/~~closed~~	right bank breakwater length	m
✓ natural/~~artificial~~	left bank breakwater length	m
canalized	rock sill level	m to MSL
✓ sandy	cliffs on right bank: height	m to MSL
✓ rocks on right bank	cliffs on left bank: height	m to MSL
rocks on left bank	spit/~~bar~~: direction of growth 205	°
outer bar	length of spit/~~bar~~ 640	m
silt plume (fluvial)	length stabilized 510	m
✓ suspended sediment (marine)	width 110	m

Comments

FLOOD PLAIN AND CHANNEL FEATURES

Description of Flood Plain

Presence	*Extent*	*Vegetation*	*Forest Type*	*Land-Use*
none	none	almost none	not known/applicable	✓ ~~not cultivated~~, not built-up
indefinite	average width 735 m	grass	riverine:	✓ cultivated 53 % area
fragmentary	maximum width 1300 m	reed swamp 19 % area	main channel	✓ crop/s sugar cane
✓ continuous	aerial length 3419 m	sparsely forested	tributaries	partly built-up
	area 246 ha	moderately forested	✓ coastal dune/evergreen	mainly built-up
		heavily forested	mangroves	

Comments

Channel Description N.B. Estimate of flow stage: ~~LOW/NEAR LOW/~~MEAN/HIGH **

Pattern	*Measurements*		*Islands/Shoals*	*Type of Flow*	*Bar Type*
straight	thalweg	3817 m	none	stagnant/still	none
sinuous	*sinuosity	1,12	occasional	✓ uniform water surface	channel side bars
irregular	*open water area	15,7 ha	frequent	uniform with rapid in reach	✓ point bars
regular meanders	perimeter	9159 m	split	irregular	channel junction bars
✓ irregular meanders	lake/lagoon area	____ ha	braided	pool & riffle sequence	mid-channel bars
tortuous meanders	✓ river X-sections available				diamond bars
bifurcated	channel slope	____			diagonal bars
lake/s	channel width x	____ m	s = ____ m		sand waves/large dunes
lagoon	river slope	≈ 1:1388			
	river width x	37,4 m	s * 4,75 m		

Comments *whole reach

Obstructions/Constructions

Natural	*Degree*
✓ none	none
logs	minor
boulders	major
vegetation	

Comments

Man-made	*Degree of Obstruction/Constriction for Each*	*Position (from head of reach)*
✓ road bridge/s	Sugar Mill + Naval Rd (NA) bridges	R. confined Head + 3km
✓ rail bridge/s		R. confined 3,8 km
✓ causeway	remains of 1959 causeway ? obstruction	± 3 km
weir/dam		
fish traps		
✓ embankment/s	(2) for NR + Hwy bridges	across L. flood plain
groynes		
✓ canal/s	making whole flow	0 - 1,2 km
✓ drainage furrows		widespread
✓ others		

Lateral Channel Activity

Lateral Activity	*Nature of Banks*	*Bank Vegetation*	*Lateral Stability*
not detectable	✓ alluvium (silt/sand)	none	stable
downstream progression	natural levées	✓ weak	slightly unstable
✓ progression & cut-offs	rock/boulders	good	✓ moderately unstable
mainly cut-offs	protected/stabilized	very strong	highly unstable
entrenched loop development	✓ cultivation to	left bank 8 %	
irregular lateral activity	channel edge	right bank NIL %	
avulsion			

Comments

Rainfall analyses of wet and dry periods, using exponentially filtered monthly rainfall data (Zucchini, 1975) are also very valuable - especially for smaller catchments for which no run-off data are available. When available, topographical surveys (for river gradients and cross-sections), physical model studies (for river flood behaviour), land-use studies for the whole catchment and archival data (old maps and cross-sections) are used to aid the study. For example, archival data has been used in one estuary to quantify river aggradation, making it possible to extend the period for which changes in the average river bed level could be calculated. At 21 estuaries, daily observations are made as to whether the mouth is open or closed. Water level stations are being established at 26 of the estuaries.

4. RIVER MOUTH AND SHORELINE FEATURES

Although this classification method highlights fluvial features which are dominant in the case of Natal's estuaries, the true quantitative picture of change is only revealed when viewed in conjunction with land-use and river mouth features. Table II gives a brief review of four important river mouth features:

(i) Mouth opening and closure is a dominant feature.

(ii) Rocks, rocky headlands and sills are very important because rocks to the south of an estuary afford protection from the dominant swell and allow a southerly extending spit to form where the general littoral drift is to the north.

(iii) Spits have an important effect on siltation. The prograding coastline north of the Tugela is dominated by long, northeasterly-extending spits causing river capture in one case and generally altering the courses of the rivers near the coast. For example the spit at Siaya has extended by 727 m in 40 years. South of the Tugela estuary the spits are generally southerly-extending.

(iv) Several man-made influences are apparent. Groynes affect littoral drift and the stabilization of spits inhibits the natural flood flows.

5. RESULTS

It has been found that major floods, riverine vegetation, swamp areas and sand-spits/bars at the mouth are the main natural factors influencing the behaviour of the estuaries. Man's influence is marked in land-use on the flood plain

TABLE II: SUMMARY OF MOUTH FEATURES

	Open/Closed			Rocks			Spit			Artificial
	Mostly									Including groynes, pipes, canals and spit stabilization
North Natal	O	C	O/C	→S	→N	N&S	→S	→N	Variable	
	10	7	3	7	0	1	8	7*	4	4
							* one shows spit →S after major floods			
South Natal	12	36	4	34	3	6	41**	7	3	36***
							** six - maybe more show spit →N after major floods			*** 30 of these have road/rail bridge embankments - often involving spit stabilization

The above table gives the number of estuaries to the north and south of Durban showing the features as itemized. It is based upon "The Estuaries of Natal" by G W Begg (1978) and a study of aerial photographs.

and in the whole catchment area, the construction of embankments and bridges, groynes and breakwaters, dams in the catchment, the drainage of swamps, the removal of riverine vegetation, canalization and the stabilization of formerly mobile sand-spit and bar areas. Instability is clearly shown by sinuosity index fluctuations, large lateral thalweg displacements with a high coefficient of variation and longer thalwegs (behind prograding sand-spits). The converse may not mean stability, however. "Apparently stable" estuaries often show marked deterioration through decreased open water areas, narrowing river widths, increased bar areas and general aggradation. Some examples of lateral stability are given below:

Estuary	Av. lateral displacement (m)	$\overline{V}$%	Notes
Mtamvuna	19	11	Stable
Mzumbe	122	40	Unstable
Mahlongwa	4	12	*Apparently stable
Mkomazi	22	17	*Apparently stable
Lovu	95	42	Unstable
Mgeni	53	16	*Apparently stable
Mdloti	62	42	Unstable
Tongati	30	35	Unstable
Zinkwasi	7	8	*Apparently stable
Siaya	14	47	Unstable (esp. 1953+)
Mhlatuze (Richards Bay)	1 255	66	Unstable

* These estuaries show instability in other ways e.g.

(i) loss of open water areas
(ii) aggradation with loss of tidal influence.

6. CONCLUSION

This interpretation of fluvial features, based upon aerial photographs over a period of 40 years, is expected to provide a key to the natural functioning of the estuaries of Natal and the estuarine responses to human influences. Thereby, this study will also facilitate conservation measures and/or planned development of estuarine resources by the Town and Regional Planning Commission, Natal.

7. FOOTNOTE

Readers are invited to contact the author direct for further information on specific estuaries.

ACKNOWLEDGEMENT

The author wishes to thank the Chief Planner, Natal Town and Regional Planning Commission, for permission to publish this paper.

INTRODUCTION

Water intakes developed for coastal use often require special design considerations to ensure the incorporation of engineering features which are compatible with environmental protection. Due to the severity of the coastal zone environment, cooling water intakes for power generating facilities typically incorporate one of two possible designs:

1. A shoreline (surface) intake which could incorporate jetties, breakwaters, or inlet channels for wave protection and, when necessary, for retardation of sedimentary processes, or

2. An offshore, submerged intake connected via tunnel or pipeline to an onshore screen/pumphouse.

Naturally, protection of structural integrity is of primary concern in designing and locating such intakes. Therefore, physical or hydraulic conditions are required to enhance plant reliability which may be adverse from an environmental viewpoint. As a result, it is often necessary to integrate additional provisions into intake designs which will mitigate potential adverse impacts resulting from plant operation.

During the mid to late 1960s, as the size and number of power plants began to dramatically increase in the United States, various agencies responsible for protecting fish and wildlife were becoming increasingly alarmed that sport and commercial fisheries were being adversely affected by thermal discharges (Krenkel and Parker 1969). In response to this concern, various state and Federal regulations were promulgated to limit the effects of thermal discharges on aquatic biota. Various engineering options were developed to limit thermal effects. These options ranged from simply limiting the rise across the condenser, and therefore the ultimate temperature at the point of discharge, to employing various means of closed-cycle cooling, particularly at sites where water availability was limited (Parker and Krenkel 1969).

It became apparent in the early 1970s that, in addition to addressing the effects of thermal discharges on aquatic biota, consideration would have to be given to limiting the effects associated with withdrawing large quantities of water in cooling water intakes. In 1972, the Federal Water Pollution Control Act Amendments established requirements to ensure that large water withdrawals would not have significant impacts on various fish and invertebrate lifestages (e.g. eggs, larvae, and juveniles). Mortality of these organisms in circulating water systems may occur as a result of entrapment in intake structures, impingement (of larger lifestages) on screening equipment designed for condenser protection, or entrainment (of smaller life stages) through the system. Regulatory concern over the past decade has led to extensive research efforts in an attempt to resolve these problems. As a result, a variety of innovative technologies have been developed which can be integrated into the design of coastal intakes for organism protection without jeopardizing plant reliability (ASCE 1982). Three such designs are described in this paper.

INTAKE DESIGNS

The design of a coastal intake is largely dictated by site-specific physical, hydrologic, and environmental conditions. In areas of limited water depth, wave action, and littoral sediment transport, dredged canals protected by parallel jetties are often used to ensure an adequate water flow while minimizing problems resulting from sedimentation and wave forces. Where deeper water is available in near-shore areas, submerged intake structures connected to a shoreline pumping station via tunnels or pipes can offer protection from wave action and icing problems. In both cases, embayment areas are created which can cause mortality among aquatic organisms. Therefore, protection systems may be required to minimize organism losses.

Canal Intakes with Jetties

Engineering Design

A nuclear power plant in New York withdraws approximately 37 m^3s^{-1} from Long Island Sound for cooling and service water purposes. Initially, two alternatives were available for withdrawing water from Long Island Sound; a submerged offshore intake structure connected by pipeline to an onshore screenwell or an onshore intake structure.

For the offshore alternative, two locations were evaluated; 457 m and 1707 m offshore. These locations were selected on the basis of bottom topography and the fact that recirculation from an offshore discharge diffuser would be minimized. Based on a comparison of the offshore alternatives to an onshore location, the offshore locations were not selected. The offshore alternative operational and maintenance costs were substantially greater than an onshore location. Biofouling control in the long submerged inlet pipes would necessitate the use of large quantities of chlorine or a flow reversal scheme to elevate temperatures in the inlet pipe to 46°C for extended periods of time. It was deemed that utilization of these biofouling control methods for either of the offshore locations would present problems in complying

with environmental criteria. Another disadvantage of the offshore intake schemes is the inability to easily retrofit fish protection facilities to the system should an increased level of protection be required in the future.

On the basis of this evaluation, an onshore intake system was selected and is shown in Figure 1. It consists of the following:

(a) A 488 m long canal, 122 m of which extends beyond the mean low water (MLW) shoreline, with a 24 m bottom width at elevation -3.7 m MLW. It was not possible to select an onshore intake without a canal because of the rise and fall of the tide. It was also necessary to protect the canal with jetties to avoid the almost continuous dredging that would be necessary to prevent it from becoming filled with sand. The jetties are constructed to an elevation of 3 m MLW. The jetties were constructed of irregularly-shaped core stone blocks weighing from 1.8 to 7.2 MT. The canal sides are covered by a 0.8 m layer of core stone but the bottom consists of the naturally occuring sand, which will allow periodic dredging to remove accumulated sand.

    The canal has been designed to discourage fish entrapment by keeping the average velocity less than 0.3 ms^{-1} at MLW and 0.15 ms^{-1} at MHL.

(b) A screenwell, as shown in Figure 2, which is divided into four bays, with each bay supplying water to a service water (0.55 m^3s^{-1}) and a circulating water (9 m^3s^{-1}) pump. The flow passes through trash racks and traveling water screens which are designed for fish protection.

Organism Protection

Due to the need for jetties at this Long Island Sound site, an embayment resulted between open water and the cooling water intake screenhouse. The presence of this embayment raised regulatory concern that fish might become entrapped in the intake screenhouse and impinge on the traveling screens, a process which results in mortality unless protective measures are taken. For this reason, a novel fish collection system was incorporated into the screenwell design to allow for the safe removal and return of impinged fish to the Sound.

As shown in Figure 3, the collection system consists of a series of vertical, traveling water screens modified from the conventional design to include fish lifting buckets and a low-pressure spraywash to gently rinse collected fish into a trough for return to the Sound. The screens have the capacity to operate continuously to minimize the time of impingement, collection and removal.

Fish which enter the intake screenwell and impinge on a screen are carried by the screen to the water surface. At this point, they drop into a fish-lifting bucket containing approximately 5.0 cm of water. These buckets are attached to each screen panel at 0.61 m intervals.

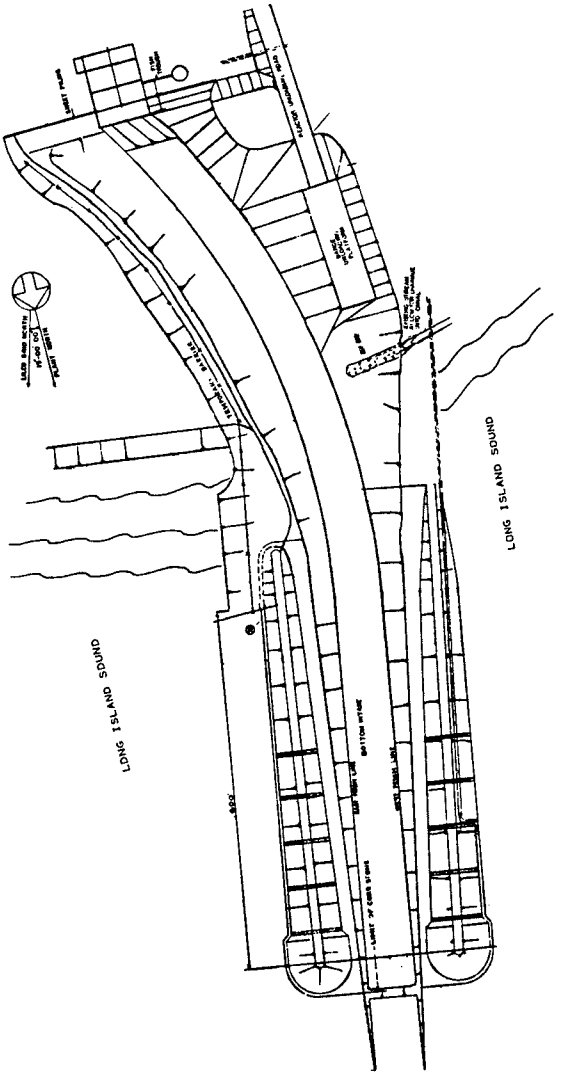

FIGURE 1 ONSHORE INTAKE SYSTEM WITH JETTIES

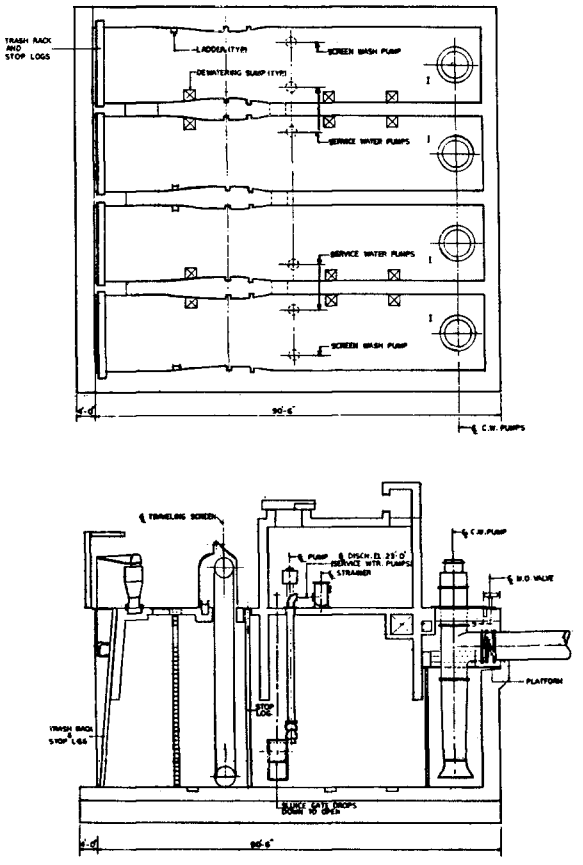

FIGURE 2 INTAKE SCREENWELL WITH MODIFIED, FISH PROTECTION SCREEN

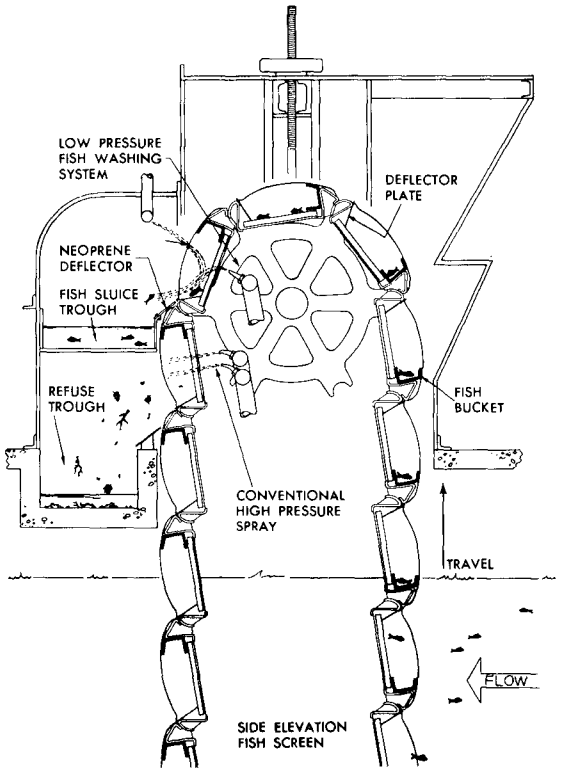

FIGURE 3 MODIFIED THROUGH-FLOW TRAVELING SCREEN WITH FISH BUCKETS

Containing the fish in water prevents them from flipping off the screen and becoming reimpinged on the submerged screen area.

At the operating deck level, a low-pressure spray (less than 1.4 kg cm^{-2}) rinses the contents of the lifting bucket into a return trough. A high-pressure spray is located above the low-pressure spray to rinse remaining debris from the screen mesh into a separate debris trough.

The fish trough transports recovered fish back to Long Island Sound at a suitable distance from the intake to minimize recirculation.

This system has only recently become operational and fish survival data is, unavailable at this time. However, other power plants incorporating this system have been in operation for several years. The biological data obtained at these sites clearly demonstrates the effectiveness of the modified screen concept.

The first collection screen system installed in the U.S. is at Virginia Electric Power Company's Surry Nuclear Station in Virginia. An 18 month biological evaluation of this system showed that the average initial survival of 58 species of fish after recovery from the screen was about 93 percent (White and Brehmer 1976).

Similar studies were conducted with a fish collection screen at Boston Edison Company's Mystic Station (Stone & Webster 1981). In these studies, all fish recovered from the screen were held for 96 hours after collection for observation of latent effects resulting from the collection and removal process. Initial survival rates were similar to those observed at the Surry Station for fish species common to both sites. However, latent survival varied by species, as expected. For example, the relatively hardy flounder showed nearly 100 percent survival under all conditions tested. On the other hand, fragile species, such as herring and smelt, displayed survival rates under optimal condition in the range of approximately 50 to 65 percent.

These studies, along with other studies conducted at power plants throughout the United States, indicate that the modified fish collection screen system is a viable and effective means of protecting fish entering intake screenwells.

Offshore, Submerged Intakes

Engineering Design

At a power plant on Lake Ontario, wave action and severe icing conditions that result in ice packing along the shore necessitated the withdrawal of cooling water (20.5 m^3s^{-1}) from a submerged (9.1 m) intake structure connected to an onshore screenhouse in a 305 m long tunnel.

As a result of regulatory requirements, provisions had to be incorporated into the design of this system to protect fish which may be drawn into the intake. In this case, the species of concern were fragile and could not survive collection on a screen. Therefore, an

innovative fish diversion system was incorporated into the design of the screenhouse. The design consists of primary and secondary fish diversion and pumping systems which together act to divert fish into a small bypass flow which ultimately returns the fish to Lake Ontario via a pipeline.

Figures 4 and 5 illustrate the screenwell arrangement incorporating angled flush mounted screens leading to the bypass. Fish entering the screenwell pass through 7.6 cm spaced trashracks and guide along the angled screens into a 15.2 cm wide bypass. Each bay is equipped with two 3 m wide screens angled 25° to the direction of the flow. The screens are separated by 1 m wide concrete piers and have been modified so that the screen baskets are flush with the piers and opening of the bypass to allow fish to easily guide along the face of the structure. Upon entering the bypass, fish are carried to a secondary angled screen and diverted to a pipeline which returns them to the lake.

Although debris loading tends to be low, the bypass was designed so that it can be manually cleaned by raking or, if necessary, flow can be reversed to free any material which passes through the trashracks and becomes lodged in the bypass. Bypass flow is designed such that the ratio of the screenwell approach velocity to the bypass entrance velocity is 1:1, a condition that yields high fish diversion efficiencies. Approach and bypass velocity is approximately 0.3 ms^{-1}, resulting in a 0.15 ms^{-1} velocity at the screenface. A jet pump provides the energy to induce the required bypass flow and return fish back to the lake in a submerged pipeline.

Organism Protection

The design of this system for fish protection was developed as a result of several years of investigation in the laboratory. (Taft and Mussalli 1978). These laboratory studies demonstrated that the angled screen system is 100 percent effective in diverting a wide variety of fish species to bypasses. Subsequent to diversion, test fish were held for 96 hrs for observation of delayed mortality. In all cases, mortality was low (less than 5 percent), thus yielding overall system efficiency values in excess of 95 percent.

The full-scale angled screen system on Lake Ontario has been in operation for over two years. Although published results are not presently available, ongoing studies indicate that diversion efficiencies are generally high for all fish entering the plant including species which had not previously been evaluated.

Intakes with Fine Screening

Organism Protection

In the previous two examples of coastal intake designs, engineering design requirements dictated the need for biological protection. At a power plant on the coast of Florida, the need for organism protection necessitated an engineering design study to develop an organism handling system. Due to regulatory concern over the loss of small

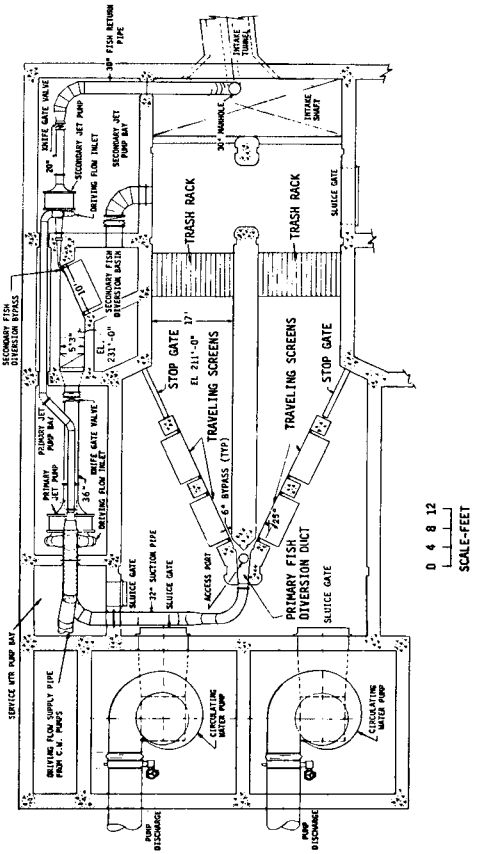

FIGURE 4 ANGLED TRAVELING SCREENS AT LAKE ONTARIO POWER PLANT

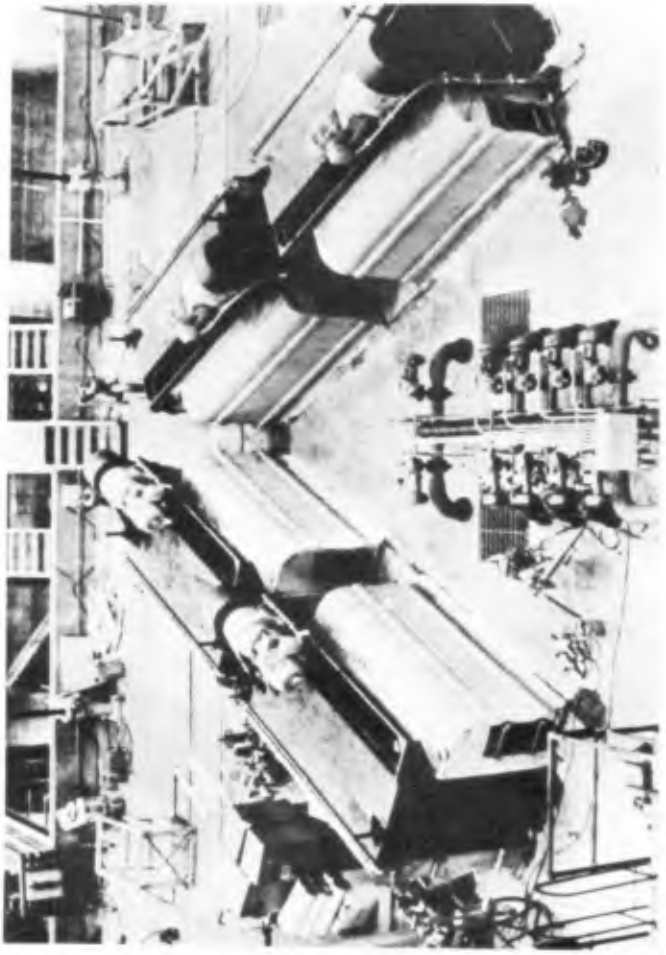

FIGURE 5
OSWEGO STEAM STATION - UNIT 6 ANGLED SCREEN INTAKE
DESIGNED AND CONSTRUCTED BY STONE & WEBSTER

organisms (the earliest life stages of various fish and invertebrate species) at this station, a major research program was conducted to optimize the design and operation of a unique collection screen system.

A full-scale, prototype system was constructed on site to permit both engineering and biological evaluations. The system consisted of a dual-flow (no-well) traveling screen, modified to incorporate 0.5 mm screen mesh (Figure 6) to exclude small life forms, special organism lifting lips and a very low-pressure spraywash system for rinsing collected organisms into a trough. Screens were also operated continuously to minimize the time that organsims would be impinged on the mesh.

Two years of research was conducted with the fine-mesh prototype screen. Results of biological studies indicated high survival rates for many of the organisms of concern at this site. For example, crab and shrimp larvae generally showed latent survival rates in excess of 85 percent, with many approaching 95 to 100 percent. Similarly, fish eggs collected from the screen showed hatching rates generally greater than 90 percent and subsequent, 48-hr larval survival rates ranging from about 82 to 100 percent (Taft, Horst, and Downing 1981).

Engineering Design

The field studies demonstrated a high biological efficiency of this organism collection system. As a result, two generating units are being equipped with fine-mesh screens (Figure 7). Each unit will be equipped with 3 screens to handle 15.3 m^3s^{-1}. The stringent design criteria required for organism protection (very small mesh size, continuous screen operations) necessitated detailed engineering design evaluations and studies to ensure reliable operation.

Due to the requirement for fine screening at this site, unique operation and reliability questions arose which had not previously been addressed. A major concern and focus of the developmental studies was the potential for greatly increased clogging due to the use of 0.5 mm mesh, and subsequently pressure drop, over that experienced with conventional 9.5 mm mesh. Consequently, a head loss monitoring program was conducted as part of the overall prototype system evaluation. The results of this program showed that, even under conditions of moderate loadings of jellyfish (ctenophores), head losses could be maintained at levels less than 10 cm.

In order to ensure reliable screen operation in actual application, features were incorporated to prevent clogging, including continuous operation capabilities and screen spray systems. The screens will be equipped with variable speed motors to accommodate various debris loadings and will be completely sealed to minimize organisms losses (Mussalli, et al 1981).

PLAN

FIGURE 7 FLORIDA FINE-MESH SCREEN INTAKE

CONCLUSIONS

The selection of a design for a coastal water intake depends on several factors. Consideration has to be given to the topography and geology at the site, severity of wave action and potential for icing, the types and quantities of debris that may be encountered, and regulatory concern as to the types of aquatic organisms that have to be protected.

These three cases demonstrate how environmental concerns related to the engineering of cooling water systems in coastal zones can be addressed and resolved through careful study and the development of innovative design concepts.

COASTAL ENGINEERINC IN SOUTH AFRICA

by

K S RUSSELL

1. INTRODUCTION

The paper presents a review of the historical movement of ships around the South African coastline, traces the evolution and development of the harbours of South Africa, describes the development of coastal engineering and summarises the organisations and their activities in both basic and applied research projects contributing towards coastal works.

2. HISTORICAL

The coastal currents and winds have played a major role in the historic exploration of the African coast. The earliest reference to a circum-navigation of Africa, although unconfirmed, was that by Herodotus who, in about 600 B.C. wrote that the Pharaoh Necho (Neco), then at war with the Syrians and wishing to combine his Mediterranean and Red Sea fleets, caused a fleet of ships manned by Phoenicians to sail from the Erythraean (Red) Sea and return through the Pillars of Hercules (Straits of Cibraltar). The journey is reputed to have taken three years; wind and currents make such a voyage in square-rigged boats a possibility.

Fig.1. Ocean currents in the Southern hemisphere. The Restless Seas.

Fig.2. The earliest navigations around Africa. Southern Land. A.R.Wilcox.

National Research Institute for Oceanology, Stellenbosch, South Africa

Accounts exist of voyages on the west coast by Hanno (c.500BC) who, with a fleet of 60 ships, explored as far as Cape Palmas (Liberia), and of Sataspes (c.475BC) who, in an attempt to sail around Libya (Africa) on the west and return by the Arabian Gulf (Red Sea), reached a similar destination. The limit to these voyages was dictated, no doubt, by the square-rigged ships which could not tack against the wind, and the extent of the NE trade winds off the West African coast, the doldrums being encountered at about latitude 5^{o} north.

Fig.3. Reconstruction of an ocean going Phoenician ship. Southern Land. A.R. Wilcox.

The Portuguese navigator Bartholomew Diaz in January 1488 rounded the Cape out of sight of land and subsequently landed at Mossel Bay. Because of his rough passage around the cape, Diaz named it "The Cape of Storms". On his return to Portugal it was renamed "The Cape of Good Hope" since it promised a sea route to the East Indies, so long a goal of the earlier explorers.

Fig.4. Diogo Cão caravel - 1483 AD. Southern Land. A.R. Wilcox.

The voyages of Diaz were followed by those of Da Gama (1497) and De Saldanha (1503), while the coast of Southern Africa was first surveyed by Perestrello (1576). On 18 July 1580, Sir Francis Drake rounded the Cape homeward bound on his circumnavigation of the world. The opening of this sea route led to extensive trade with the east coast of Africa and the Far East, but it was not until after the formation of the Dutch East India Company in the first half of the 17th century that a serious attempt was made to establish a permanent port of call at the Cape for the replenishment of supplies and repair of ships in preparation for the voyage to the Far East or return to Europe.

3. HARBOURS

The numerous bays and inlets along South Africa's 3 000 km of coastline provided convenient refuge for Portuguese, Dutch, English, French and Scandinavian vessels. Locations offering the best natural protection together with the opportunity to replenish water and food gradually emerged as potential harbours. These were Table Bay, Port Elizabeth, East London, Durban and Walvis Bay. Saldanha Bay, while providing ideal protection for anchorage, was without fresh water.

Numerous other shallow-draft harbours, most of which were located in river mouths, also developed along the coastline: Port Alfred, Port St. Johns, Port Shepstone and Port Nolloth. These harbours were important in the coaster trade active up to the 1930s until improvements in road and rail connections and the continuing increase in the size of freighters caused their gradual decline.

Major harbours developed at those locations which offered the maximum natural benefits and all have subsequently been improved by the construction of breakwaters and by dredging.

There are six major harbours along the coastline: Durban (the second largest port in Africa in terms of cargo handled), Richards Bay (190 km north of Durban, built especially to export coal but likely to become the country's biggest commercial port), East London (South Africa's only river port), Port Elizabeth (major mineral ore export harbour), Table Bay, Cape Town (its Sturrock "graving dock" is the largest in the southern hemisphere) and Saldanha Bay (110 km north of Cape Town, built especially to

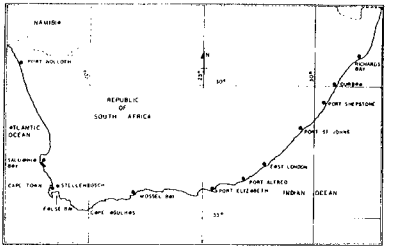

Fig.5. Location of South African Harbours.

export iron ore). Less significant are Mossel Bay (on the Cape south coast) and Walvis Bay (a South African enclave into South West Africa/ Namibia). These ports, administered by the South African Transport Services, annually handle 70 M tons of cargo and 12 500 ships with a gross tonnage of more than 300 M.

The fishing fleet consisting of 6 300 vessels of various sizes continues to utilise the several shallow draft harbours which are controlled by the Fisheries Corporation.

TABLE BAY - "TAVERN OF THE SEAS"

Fig.6. Aerial photograph of Table Bay Harbour and Cape Peninsula.

It was on 6th April 1652 that Jan van Riebeeck landed on the shores of Table Bay to set up a transit station for ships of the Dutch East India Company. The voyage - one way - from Holland to the Indies averaged about 6 months with appalling loss of men and ships. Although a number of jetties, dating from 1656, were originally built, the first significant coastal structure in South Africa was an uncompleted rubble mound breakwater. This breakwater, financed by taxing farmers delivering produce to the town through the use of their wagons to haul stone from the quarry to the breakwater, was started in 1743 but soon abandoned. Construction of a 546 m-long breakwater and excavation of a dock was inaugurated by H R H Prince Alfred on 17th September 1860. The dock, now Alfred Basin, was opened in 1870. Following the discovery of gold in the Transvaal, the breakwater was extended and the Victoria Basin was completed in 1905, with a water area of 27 hectares catering for ships up to 13 500 tons. No further development took place until after the First World War although ships of 18 500 tons were rounding the Cape regularly. In 1929 new quays were constructed which form part of Duncan Dock. Duncan Dock, developed between 1937 and 1945, provided an additional 195 hectares of water area 12 m deep and a total of 1 830 m of quay wall. A tanker basin was added in 1965, and by 1972, seven additional deepwater berths had been added. Construction of the Ben Schoeman Basin commenced in 1969 and it became fully operational in 1978.

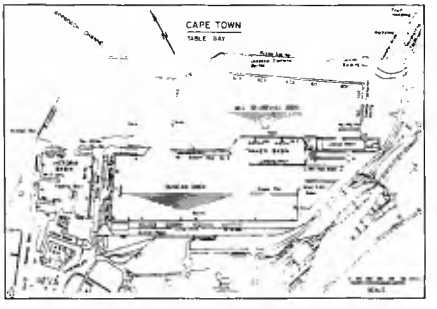

Fig.7. Lay-out of Table Bay Harbour.

DURBAN HARBOUR - "PORT NATAL"

Vasco da Gama sighted the coast, which he named Natal on Christmas Day, 1497. The Portuguese made no attempt to establish a settlement in Natal and there are many accounts by survivors of the many ships which foundered on the desolate coast and of their perilous journey to Lourenco Marques. In the later seventeenth century, survivors from the "Good Hope", together with survivors from the "Bonaventure" and "Stavinesse" built a boat and sailed to the Cape in 12 days. From descriptions of the bay and the rich trade in ivory the Dutch East India Company decided to develop the bay but changed their decision, as recorded in the Cape Town Archives.

"The East India Company would have taken possession of this fertile land (terra de Natal) years past, but for at the mouth of the port, a reef or sandbank that no galliot could get over without touching".

It was not until 1824 that the port began to develop; at that time the brig "Salisbury" was blown over the bar and grounded on what is now Salisbury Island. The first survey of the entrance was undertaken by Haure in 1831. Records of this and of subsequent surveys are still available in the Africana Museum.

In 1850, the first harbour engineer began to build two breakwaters designed to force the flow of the water down the channel and to scour the entrance. By 1854, a survey showed a depth of 6,4 m, but this was no permanent solution; in 1868 the depth had decreased to 3 m and by 1882 was reported to be 1,8 m. Sir John Coode in 1877 published a detailed description of the stability of the tidal entrance indicating the two opposing forces, the waves due to wind piling up sand in the entrance and the tidal currents and river flow scouring the entrance. He undertook an "estimate" of the tidal prism (quoting the tidal volume to be 18 794 737 yds^3) and by comparison with the entrance areas at Dunkirk, Calais, le Havre, Madras and Algiers suggested that the entrance width be reduced from 800 ft to 600 ft with a flow area between 1 300-1 400 yds^2 to produce a stable entrance. Many alternative schemes were proposed. In 1882 a new attempt at construction of piers was launched under a joint Milne and Coode scheme. Dredgers were purchased in 1889. By 1892 the sand bar was dredged to 4,4 m and the southern training wall extended by 474 m and by 1900 the depth of the bar had been increased to 5,9 m. Dredging thus far had been confined to the removal of obstructions after gales, in 1902 systematic dredging of the entrance and to provide a sand trap at Cave Rock updrift of the breakwater commenced.

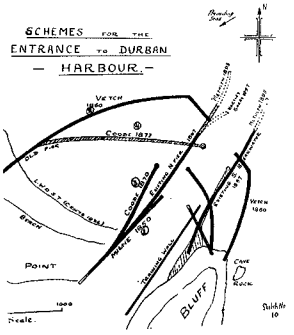

Fig.8. The numerous schemes suggested for the entrance to Durban Harbour.

This virtually solved the bar problem and by 1906 there was a depth of 10 m in the entrance. An average of 700 000 m^3/year

has been dredged in the entrance and sand trap since the early 1900s. Interception of this south to north sediment transport and development of the beach eventually led to severe erosion on the premier bathing beaches north of the harbour. In 1938 a sand by-passing scheme was introduced by which sand dredged from Cave Rock bight was transported by the dredger to a dolphin inside the entrance and pumped via a booster station onto the north beaches. In 1949, two pipes were laid under the harbour entrance through which sand, dredged from a jetty in Cave Rock bight, was syphoned directly to the booster station. This scheme was abandoned in 1954 and the scheme using the dredger re-introduced. At present some 100 000 m^3/year of dredged material is pumped from the dredger into a storage hopper loaded north of the north breakwater, for discharge at a number of intermediate sites along the beach.

The breakwaters have been considerably strengthened and improved over the years, the taper in the North Pier, due to Hartley and Barry, was removed during 1941 as it was considered to be a danger to shipping.

PORT ELIZABETH HARBOUR - "SETTLERS PORT"

Although visited by Diaz in 1488, Algoa Bay was little used since it provided scant shelter and little trade for ships. The 1820 settlers landed in Port Elizabeth by surf boat and sailing barges brought up to a warp secured to the beach. It was not until 1837 that the first jetty was begun using the remains of the wreck, as support for the deck of the jetty. This jetty, completed in 1841, measuring 147 m of timber jetty and 63 m of masonry approach, was totally destroyed in 1843 during a south-east storm. In the 1860s a 400 m-long solid breakwater was built at the mouth of the Bakens River; the work was a complete failure due to build-up of sand to the south of the structure and eventual shoaling in the lee.

The main breakwater was commenced in 1922 and completed in 1933. This breakwater was constructed from the top of an existing open piled Dom Pedro jetty which was filled with quarry material only after completion of the breakwater. A further expansion of the port commenced in 1975 included a 335 m curved extension of the breakwater and a 3 km-long approach channel 900 m wide, with a dredged depth of 14,5 m for the deeper-draught bulk carriers and container ships.

Fig.9. Buffalo River and East London Harbour.

EAST LONDON HARBOUR - "PIONEER PORT"

East London is the only South African river port and is located on the Buffalo River. A survey party, sent in 1689 by Simon van der Stel to explore from Table Bay to Delagoa Bay, found that the mouth of the Buffalo River formed a natural harbour but extensive

sandbars were located in the entrance - thus for centuries development of the port was prevented.

The town of East London was established in 1848.

By 1893 dredging had sufficiently deepened the entrance to allow ships of up to 8 000 tons to enter the port. In 1927 construction commenced of the present turning basin which was completed by 1937 and subsequently enlarged between 1959 and 1961.

RICHARDS BAY HARBOUR

Richards Bay is named after Rear Admiral Sir Frederick Richards who in 1879 landed troops during the Zulu War. During the early 1900s the British undertook hydrographic surveys along the coast to locate a possible bunker station, (to be linked by rail to an inland coal course) for the Royal Navy. In 1902, Richards Bay was surveyed by Cathcart Methven, the harbour engineer for Durban, who rated the bay to have more development potential than Durban Harbour. Methven proceeded to design and provide a cost estimate for the harbour at slightly more than £1M. The scheme was, however, never realised. Richards Bay was the first new South African harbour to be constructed since Union, at a total capital investment for the harbour works of some R200M.

Fig.10. Aerial photograph of Richards Bay Harbour.

The entrance channel, dredged on the alignment of an old submerged gorge, presently provides depths required for the handling of 150 000 t bulk carriers. The approach channel has a length of 3,5 km, width 400 m and depth -24m outside the breakwaters and 6,1 km, width 300 m and depths 24 m to 19 m inside the breakwaters. The main south breakwater extends 1,3 km offshore and the north breakwater 0,6 km offshore. The breakwaters are rubble-mound structures protected by dolos blocks. Dolos sizes range from 5 to 30 tons and a total of 42 200 blocks were used in the construction. Dredging of the entrance channel and harbour area involved a total volume of 160M m^3 of spoil material and a further 35M of dredge material used for reclamation.

As at Durban, the south to north sediment drift of 800 000 m^3/year is intercepted by a sand trap located adjacent to the south breakwater; some 400 000 m^3/year is by-passed by the dredger by being pumped onto the north beach while the remainder is dumped at sea. At present some 28M t of coal are exported per year and this is expected to increase to 44M t by 1987. Additional coal berths are presently under construction.

SALDANHA BAY

Saldanha Bay was named after Antonio de Saldanha - although he never visited it. The name was originally given by de Saldanha in 1503 to what is now Table Bay; the Dutch subsequently gave the name to the present Saldanha Bay.

Saldanha Bay provided the best natural anchorage along the entire coastline but was not developed since it totally lacked fresh water. The bay was the scene of major conflict between the Dutch/French and English exploiting the numerous seals and later guano (used as fertilizer). One report records that during August 1844 some 300 ships were concentrated in Saldanha Bay to mine guano and that Skaap Island had been divided into segments "like a cake" to avoid fighting between the different nationalities.

Saldanha Bay later became the centre for fishing and whaling along the productive west coast. The present harbour, developed for the export of iron ore, was constructed during the period 1973-76. Construction included an ore-loading jetty inside the bay protected from wave penetration from the open sea behind a sand breakwater linking an island (Marcus Island), with a headland (Hoedjies Punt). The entrance channel, located south of the island, can accommodate VLCs up to 250 000 tons although the jetties have been built to accommodate 350 000 ton vessels.

COASTAL ENGINEERING

Early harbour development in South Africa fell under the jurisdiction of the Colonial Office, with the result that the majority of the design and planning aspects were undertaken in England and local harbour engineers were responsible only for construction.

Coastal engineering is historically and essentially a branch of civil engineering and it was only following the creation, in 1919, of a department of civil engineering at the *University of Cape Town* that local expertise developed. An early staff member, Mr G Stewart in 1941 built what was probably the first coastal model in South Africa to study range action or harbour resonance in South Africa. Mr Basil Wilson continued the pioneering studies, and during the period 1941 to 1946 he extensively studied range action and the proposed harbour extension for Table Bay Harbour. The small 12 m by 15 m model built in the Cape Town docks was later replaced by a much larger model built by the South African Railways at Langlaagte (Johannesburg). Wilson also extended these studies to investigate mooring forces related to range action.

At the *University of Stellenbosch*, coastal engineering research was started in 1957 with a series of investigations on small-craft harbours and especially fishing harbours carried out in conjunction with the Fisheries Development Corporation of South Africa. Expansion of the hydraulic model facilities and in 1976 the formation of an Ocean Engineering Research Group has led to further work on armour units, breakwater stability, ocean dredging, devices for extraction of wave energy and the design of oil deflection booms.

Both the Universities of Stellenbosch and Cape Town offer study courses at postgraduate level towards a M.Eng. degree in Civil Engineering. The *University of Natal* (Durban) over the past few years has offered a specialist course in civil engineering as an honours thesis towards a B.Eng. degree.

The *Fisheries Development Corporation* is a State sponsored organisation responsible for the planning, construction and maintenance of fishing harbours. Model studies for proposed new fishing harbours or improvements to existing harbours are normally carried out in conjunction with the National Research Institute for Oceanology of the CSIR or with the University of Stellenbosch. Because of its requirements with regard to precise survey for demarcation of harbour boundaries, navigational aids, and hydrographic survey the Corporation's survey branch has developed expertise in seismic and side-scan surveys and aerial photography of the coastline.

The *Coastal Engineering and Hydraulics Division* of NRIO originated from a small Hydrodynamics Division established in 1956 as part of the National Mechanical Engineering Research Institute at Pretoria. The need for applied research in the field of coastal engineering increased rapidly, particularly because of the proposed construction of major harbours at Richards Bay and Saldanha Bay. The need for a suitable laboratory to house the usually large hydraulic models and the formation of a specialist group to undertake the studies became essential. These new buildings and facilities were created in Stellenbosch adjacent to the Faculty of Engineering to permit a close liaison with the University, and in 1969 the Hydraulic Research Unit was established.

The National Research Institute for Oceanology (NRIO) was formed in 1974 to take over and merge the ongoing CSIR activities in marine science and technology. The Institute now comprises four coastal engineering and hydraulic divisions, four marine science divisions, various service divisions, administrative back-up and the South African Data Centre for Oceanology. The staff numbers 165 (in 1982).

The Coastal Engineering and Hydraulics Divisions undertake basic and applied research (some 50 per cent of the projects are of an applied nature undertaken on a contract basis) required for the optimum design and operation of coastal works including major and 'small-craft' harbours, beach and estuary improvement and marine disposal works. A further objective is to develop and provide specialised expertise and consultancy services in coastal engineering with special reference to the needs in South Africa.

SUMMARY

Despite a long history of shipping and considerable harbour construction along the coastline it was not until the early 1900s that "coastal engineering" emerged in South Africa. Prior to the Union of South Africa in 1910 all harbour development was under the jurisdiction of the Colonial Office and planning and design referred overseas. The establishment of a civil engineering department at the Univesity of Cape Town in 1919 provided a nucleus for gradual development of coastal engineering, which spread to the other universities with the formation of civil engineering faculties and particularly departments of hydraulic engineering. In the 1960s the proposed construction of major harbours at Richards Bay and Saldanha Bay dramatically emphasised the need for applied research in the field of coastal engineering and directly contributed to the development of the research facilities at the University of Stellenbosch and Coastal Engineering and Hydraulic Divisions of NRIO. The scope of work undertaken by the various organisations involved in coastal and ocean engineering research has expanded and now includes wave energy research, ocean outfalls and coastal management.

YACHT HARBOURS IN THE UNITED KINGDOM

ABSTRACT

The authors describe the introduction and development of commercial yacht harbours in the United Kingdom. In the case of the south and west coasts where there is a high mean spring tidal range of up to 8 metres, this has resulted in the provision of enclosed basins, provided with either some form of gate or sill to retain the water. These are described, with typical examples. Recent developments in the design of sector gates are reviewed.

INTRODUCTION

In this paper a yacht harbour means a harbour designed for yachts, and a marina means a yacht harbour combined with an integrated residential development, although these distinctions are not always observed. Yachts, in accordance with the PIANC definition, are taken to mean pleasure craft, either sale or powered, over 8 metres in length. Taken overall, about two thirds in U.K. are sailing yachts and one third are power boats. Few craft in U.K. exceed 12m to 15m overall length.

A yacht harbour provides protection from wave action, permanent access to berths and to adjacent deep water sailing or cruising areas, either the sea or a river/canal with sufficient navigable depth at all times. This is an ideal which is not always attainable because the costs involved may be unacceptable.

"Dry" yacht harbours, which provide land storage and launching facilities for small pleasure craft, are not discussed.

DEVELOPMENT OF YACHT HARBOURS

About twenty years ago the growth in recreational sailing led to a shortage of moorings in popular sailing areas along the south coast of England and the development of commercial yacht harbours. Fig. 1 shows that in 1966/7 there were 17 commercial yacht harbours with access to tidal waters, concentrated in the south-east of England. In 1979 there were 63, the locations being shown in Fig.2.

Fig.1 Yacht Harbour locations, 1966/7

Fig.2 Yacht Harbour locations, 1979

Yacht harbours tend to be located in the south-east of England, within reach of the London conurbation. Popular sailing areas along the south coast are shown in Fig. 3.

Some sheltered rivers, for example the Hamble River, are so crowded with moorings that the navigation authority has put a limit on numbers. Few berths are vacant in the yacht harbours shown in Fig. 3 and most have waiting lists. In other, less popular areas, this is not the case and occasionally berths are advertised as being vacant.

The number of berths in a yacht harbour averages about 250, except for the two biggest harbours at Chichester and Brighton, which provide about 1,000 and 2,000 berths respectively.

With the introduction of low maintenance, glass reinforced plastics (G.R.P.) hulls it is no longer essential for yachts to be taken ashore for winter

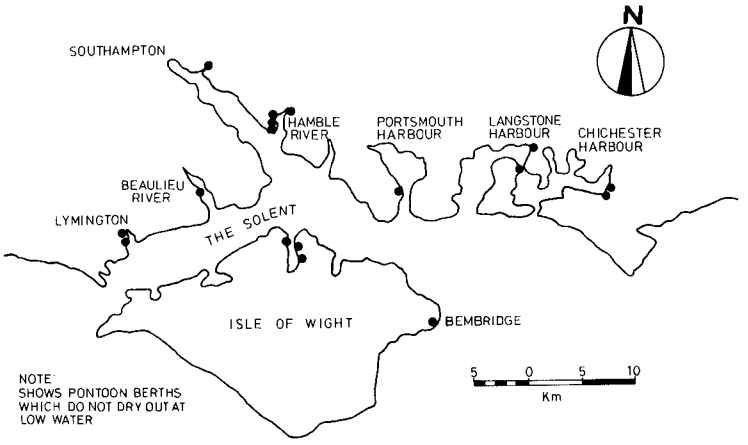

Fig. 4 Popular sailing areas - south coast

storage and most are kept afloat all year, apart from a scrub and application of anti-fouling in the spring.

BERTH CHARGES

There is no standard method of charging the yachtsman for his berth in a yacht harbour. In most cases the cost is expressed in pounds sterling per metre length per annum, on the assumption that the owner will keep his yacht in the marina all year. Typical rates, current in May 1982, are given in Table 1.

TABLE 1

TYPICAL BERTH CHARGES, MAY 1982

Location	Charge per metre
R. Hamble, Hampshire	£119
R. Thames, London	£53 to £66
R. Medway, Kent	£68
R. Crouch, Essex	£49 to £54
R. Orwell, Suffolk	£63
Poole Harbour, Dorset	£108
Falmouth, Cornwall	£75

COASTAL ENGINEERING ASPECTS

The first yacht harbours involved providing pontoons in a river, which replaced trot moorings, or mud berths, and gave sufficient depth for yachts to remain afloat at all stages of the tide.

When the river sites had been fully developed in popular sailing areas, it was necessary to look at coastal sites without natural wave protection. These can be developed either as tidal basins with surrounding breakwaters or as enclosed basins provided with a sill or a lock. All these solutions are expensive as they involve substantial civil engineering works as well as the basic pontoon accommodation provided at river sites; only a handful of yacht harbours come under this category at present because of cost constraints. They represent a challenge to the civil engineer because they present the same engineering problems as commercial ports but the investment is limited to a tenth (or less) of the cost. There are examples at Brighton and Poole, which have surrounding breakwaters with no entry restrictions, and at Chichester Yacht Basin and Ramsgate, which each have a locked entrance.

BREAKWATERS

Until recently the cost of infrastructure items, such as breakwaters, had to be borne by the developer. Grant aid is now available from EEC funds and from the British government for schemes in defined areas of Scotland. Two harbours have floating breakwaters but only one has been successful (1); the remaining few have fixed breakwaters. Examples from two ends of the scale are shown in Fig. 4. Fig. 4(a) is the breakwater at Brighton Marina, which is fully exposed to storm waves in the English Channel, whereas Fig. 4(b) is the one at Poole Harbour Yacht Club Marina, drawn to the same scale, which is in a relatively protected location.

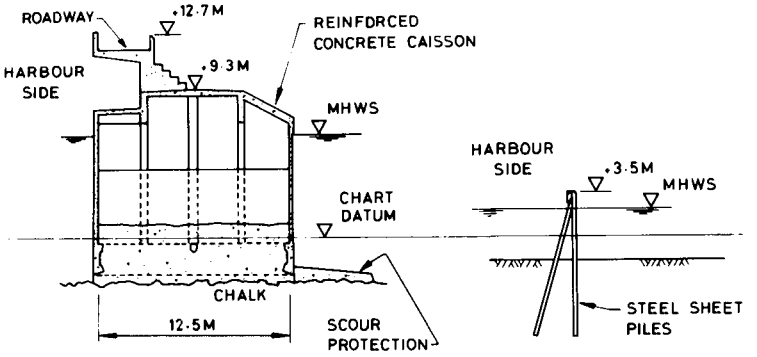

Fig. 4a Brighton Marina

4b Poole Harbour Yacht Club Marina

Fig. 4. Types of breakwater

The Brighton Marina breakwater, designed for about 5m waves, uses circular concrete caissons of the type used for Hanstholm harbour in Denmark. This type of construction was selected because the giant crane used for transporting and placing the caissons in Denmark was up for sale. The breakwater design was tailored to enable the crane to be reused at Brighton.

The Poole Marine breakwater, designed by the authors' firm, represents the other end of the scale. Although Poole Harbour is fully enclosed and land locked, apart from a narrow entrance from the sea, it is one of the largest natural harbours in the world. Wave action within the harbour from local fetches produces waves during the winter months approaching 1m, depending on the location. At the marina site the breakwater, which has a vertical face of continuous light steel sheet piling, was designed for a 50 year maximum wave height of 1.2m. Horizontal wave forces are resisted by inclined steel tube piles which are bonded to the sheet piling by means of a continuous reinforced concrete capping beam.

ENCLOSED BASINS

The need for enclosed basins arises from problems with tidal range and/or suspended silt load in the water. In the U.K. a mean spring range of about 4m can be considered as low, with 8m as a high value. This is not the highest; in the Channel Isles it reaches about 10m.

At coastal sites with a high tidal range the volume of material to be excavated or dredged to provide a basin is considerable. Capital costs can be reduced by partial or full control of water level in the basin. Set against this is the disadvantage that yachts do not have free access to the basin at all stages of the tide. There are however various means by which this disadvantage can be minimised and these are discussed below.

BASINS WITH FIXED SILLS

Partial control of water level can be achieved by providing a fixed sill around the basin so as to retain enough water at low tide to prevent yachts from grounding. Passage over the sill is only possible for an hour or two on each side of high water depending upon the tidal range. The principle is illustrated in Fig.5.

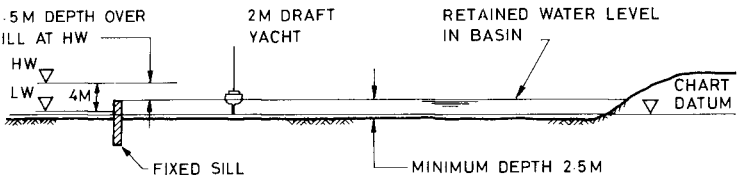

Fig.5. Basin with fixed sill

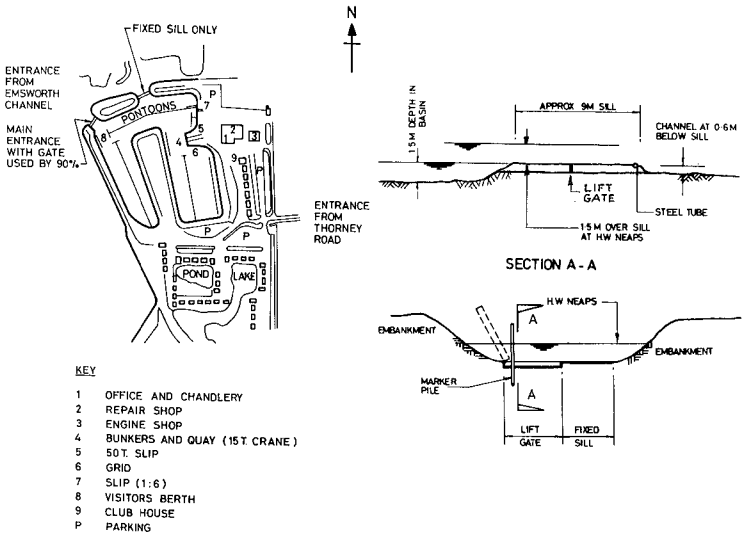
Where wave protection is needed the basin can be enclosed by an embankment with a gap in which the sill is installed. Emsworth Yacht Harbour with 250 berths is a typical example; its layout is shown in Fig. 6 (a). The basin is enclosed by banks of dredged spoil, the sill consisting of undisturbed material. Puddled clay is used as a watertight lining to the sill, which is shown in cross-section in Fig. 6 (b).



6a Layout 6b Sill Detail

Fig. 6 Emsworth Yacht Harbour

As the lifting gate, shown in Fig. 6 (b) is not working now, all the sill is fixed. The impounded depth is 1.5m.

The sill level was chosen to give 1.5m depth over the sill at lowest (i.e. neap) high water. Craft drawing only 0.9m can cross the sill for $2\frac{1}{2}$ hours each side of high water.

Another example, this time of a natural rock sill, is in Guernsey, at the Channel Islands Yacht Marina. The yacht harbour, which has pontoon berths for 150 craft, was made from a former 18m deep stone quarry by blasting a channel to the sea. The sill is undisturbed rock, and is shown in Fig. 7. The sill level has been chosen so that there is 2.8m of water at half tide, which gives a good duration of access. This is a consequence of the very high tidal range in the Channel, which accounts for use of basins with sills in several French yacht harbours in the area.

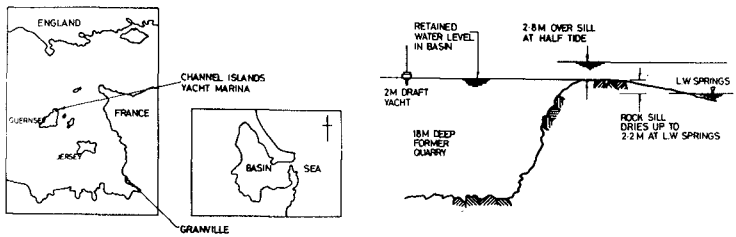


Fig. 7 Channel Islands Yacht Marina

This limitation leads to a fairly recent development - the use of a moveable sill - which goes some way to solving the problem. This arrangement is described below.

BASINS WITH MOVEABLE SILLS

Fig. 8 illustrates the principle of the moveable sill. When the level of the rising tide equals that of the retained water in the basin, the gate is lowered to give an immediate increase in depth. Movement of the sill is controlled automatically by a float system which responds to changes in tide level.

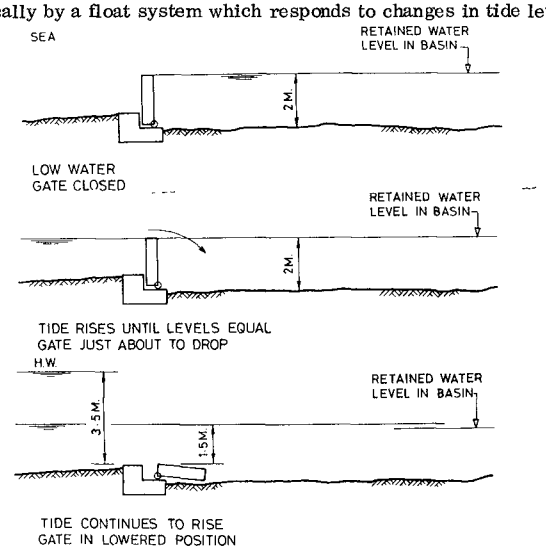

Fig. 8 Moveable Sill

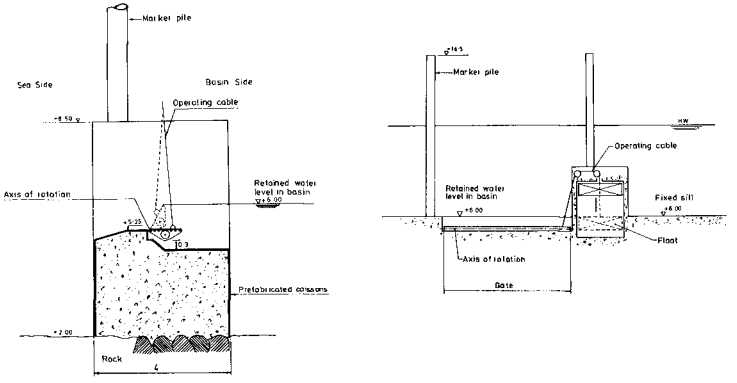
Moveable sills represent a most useful facility for sites with high tidal ranges as they extend the time during which yachts can enter or leave the basin. They are cheaper than a lock and provided the resulting restrictions on yacht movements at mid tide and below are accepted, they should find further application in the U. K.

The first U. K. installation has been constructed at St. Helier Marina in the Channel Isles. An earlier example, but this time on the French coast, is at Granville (location shown in Fig. 7). The principle of the operating mechanism is shown in Fig. 9.



9 (a) Gate detail

9 (b) Operating principle

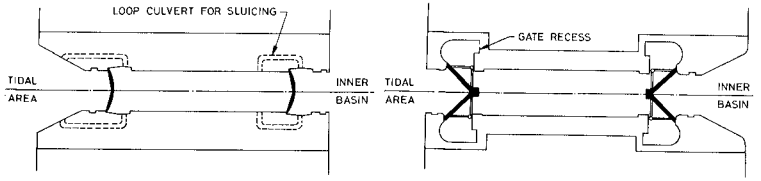
Fig. 9 Moveable sill - Operating Mechanism

BASINS WITH TIDAL GATES

There are a few yacht harbours, usually conversions of commercial docks, which have single gates which can be opened for an hour or so each side of high water. Although inconvenient this restriction is accepted. Ramsgate Yacht Marina in Kent, with 500 berths, is a good example. It is popular with yachtsmen because it gives the shortest crossing to France.

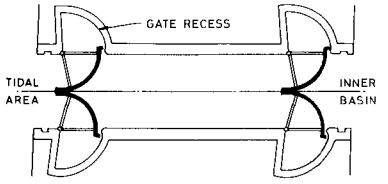
BASINS WITH LOCKS

A few former commercial docks with conventional lock access have been adapted for recreational use. The locks are of the mitre gate type illustrated in Fig. 10 (a), which are much longer than are needed for pleasure craft and slow to operate. The sector type of gate, illustrated in Figs. 10 (b) and 10 (c), has been developed in U. K. to reduce delays.



10 (a) Mitre gates

10 (c) Delta sector gates



10 (b) Curved sector gate

Fig. 10 Types of Entrance Lock

DEVELOPMENT OF THE SECTOR TYPE LOCK GATE

At sites where the installation of a lock cannot be avoided, the provision of sector type lock gates gives rapid lock cycle times and, at suitable sites, a free-flow period when both sets of gates remain open. The first installation in U.K. was at Chichester Yacht Basin (1,000 berths) in 1966, shown in Fig. 10 (b), followed by Brighton Marina (2,000 berths) in 1978 shown in Fig. 10 (c).

Both installations were the responsibility of the authors' firm. The development of the cheaper flat faced "delta" gate from the curved type used at Chichester was carried out with the help of hydraulic model tests.

PONTOON LAYOUT AND CONSTRUCTION

Floating berths using pontoons are normal in U.K. Yacht harbours where craft moor end-on to a quay (i.e. Mediterranean fashion) are rare owing to tidal variations. Main piers are normally provided with "fingers", as illustrated in Fig. 11.

In the earlier marinas pontoons were constructed on a "do-it-yourself" basis using timber superstructures supported on oil drums or steel tanks. Current U.K. practice is to use expanded polystyrene as the buoyancy medium, in association with steel, timber or concrete superstructures.

Pontoons are located in position generally with vertical piles, but some are secured by chain moorings.

Increasing sophistication of services has meant that the provision of space for pipes and cables has come to dictate the design of pontoons. Electrical

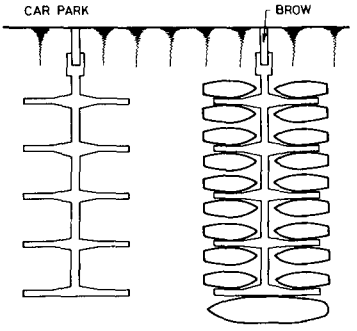


Fig. 11 Berth Layout

power outlets are a usual requirement in most new yacht harbours, as well as water and sometimes telephone services. Provision of firefighting equipment is extremely important.

Until recently no provision has been made for discharging sewage from holding tanks aboard. The first installation in U.K. was completed recently and with recent stricter legislation on pollution, more yacht harbours in U.K. will be providing this service.

THERMAL IMPACT STUDIES

FOR FRENCH COASTAL NUCLEAR SITES

by

Y. COEFFE (1), P.M. CLIQUE (2), and B. MANOHA (2).

ABSTRACT :

The paper presents the different stages of the environmental studies performed at the Laboratoire National d'Hydraulique concerning some of the French coastal nuclear power plants using a once - through cooling system, and the different means used, in function of the proper caracteristics of the site, to come to an optimum inlet-outlet configuration leading to a minimum thermal impact and to a minimum recirculation of the heated waters at the intake.
The paper particularly describes the original studies performed for the Flamanville power plant where a special computer controlled tank has been used.

1. INTRODUCTION

The setting up of a coastal nuclear power plant using a once - through cooling system requires many environmental studies because of the importance of the coastal works leading to an important impact on the marine environment. For example the last generation of french coastal nuclear power plants (Paluel, Flamanville, Penly) are made of four units of 1300 MWe each, needing an intake and discharge flow of 180 m^3/s (corresponding to the average annual flow of the river Seine in Paris), with a discharge temperature elevation of 15°C.

So the thermal studies are particularly important as to :

- minimize the effect on the marine environment
- minimize the recirculation of the heated waters at the intake as to optimize the efficiency of the plant.

2 HOURS AFTER HIGH TIDE AT BREST

TIDAL CURRENTS COMPUTED ON THE FRENCH COAST

Fig.1

These two problems are of course closely connected and can be solved by way of numerical and physical models calibrated on many field measurements which are essential for a good knowledge of the medium where the calories will be diluted.

The paper presents the different stages of the studies performed at the Laboratoire National d'Hydraulique concerning some of the French coastal nuclear power plants, and the different means used, in function of the proper characteristics of the site, to come to an optimum inlet-outlet configuration leading to a minimum thermal impact and to a minimum recirculation of the heated waters at the intake.

The paper particularly describes the original studies made for the Flamanville power plant where a special computer controlled tank has been used.

2. DIFFERENT MEANS USED

2.1. Field measurements

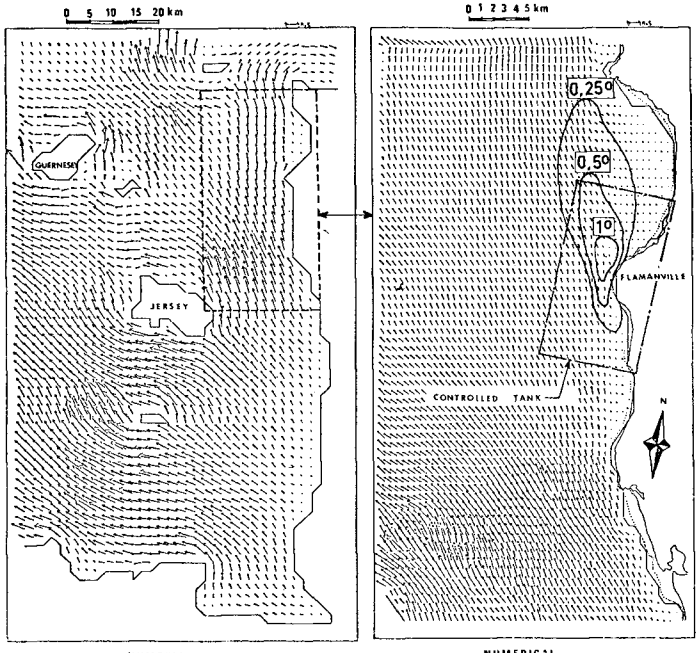
The studies of the impact on the marine environment of the warm waters discharged by a nuclear power plant as Flamanville (4 x 1 300 MW needs 180 m^3/s of water with a discharge temperature elevation of 15°C) require a very good knowledge of the hydrometeorological characteristics of the site, and in particular of the tidal currents which are the main factor of dilution of the calories for the different french sites chosen up to now (cf. Flamanville). Therefore many drogue trackings and punctual current measurements by currentmeters are performed around the site as to evaluate the characteristics of the marine currents, and in particular the drift and the excursion of the waters.

Many other field measurements are performed, as the meteorological conditions (wind, air and water surface temperature) which are essential to estimate the exchange coefficient with the atmosphere which is the final sink of the calories, the waves (for the protection of the discharge and intake works), the salinity, the vertical profiles of water temperature (eventual possibility of thermocline), the bathymetry of the site, etc.

All these measurements enable then to evaluate the relative effects of the different parameters as to choose the most appropriate means to be used (different types of numerical or physical models), and to calibrate them as accurately as possible.

2.2. Numerical models

Many different numerical models can be used for the evaluation of the thermal impact ; they are mostly used for the intermediate and the far field, the near field being preferably studied by way of physical models.



FLAMANVILLE
CALCULATED CURRENTS AND THERMAL IMPACT (3H AFTER HIGH WATER)

Fig. 2

2.2.1. Current models

The dilution of the calories is made by advection, diffusion and finally by exchange with the atmosphere ; different types of models can be used for the description of the current fields in which the calories will be diluted. For the nuclear power plants erected along the English Channel (ex : Flamanville), the currents are due to the tide and are nearly homogeneous along the vertical. Then bidimensional models of tidal currents, calibrated on field measurements, are used. A complete description of this type of numerical model, called CYTHERE ES, which can now take into account tidal flat flooding and drying, is presented in the ASCE paper : "New Method for Tidal Current Computation" (ASCE vol. 108, N° WW3, August 1982) ; let us just say that it is based on a fractional step method in which momentum advection is calculated using the method of characteristics, horizontal momentum diffusion is calculated using an implicit finite difference scheme, and wave propagation is calculated using an iterative alternating direction implicit algorithm. Many different zones, covering various areas, have then been studied (see figure 1) :

- "large models" (10 km gridmesh) cover the English Channel, the Bretagne, and the Atlantic coast ;

- "regional models" (2 to 2,5 km gridmesh) are then used for the far field ; their boundary conditions of flows and levels are given by the "large models" (additional calibrations and adjustments being performed if necessary) : Baie de Saint-Malo, baie de Seine, Finistère, etc.

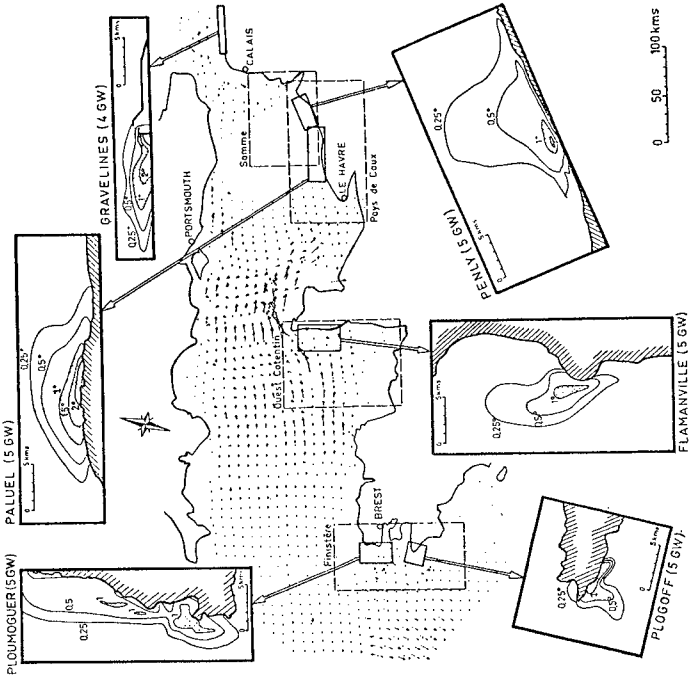
- "local models" (about 500 m gridmesh) cover then the intermediate field (boundary conditions given by the regional models) : Paluel, Flamanville, Penly, etc.(figure 1) ;

- "detail models", with small and irregular gridmeshes can also be used for a finer description of particular zones in the near field (boundary conditions given by the local models).

The figure 2 presents the example of Flamanville where regional and local models of currents were built, each model using the results of its corresponding bigger sized model as boundary conditions.

2.2.2. Thermal models

The thermal impacts and their evolution during the tide, especially in the intermediate and far field, are then computed through bidimensional numerical models using the results of the above mentioned current models, where the equations of advection diffusion and exchanges with the atmosphere have been solved ; the order of magnitude of the dispersion coefficients used in these models are generally between 0,5 m^2/s (transversal) and 5 m^2/s (longitudinal), the exchange coefficients ranging between 30 and 100 $W/m^2/°C$; the intake and discharge zones are described by a refined gridmesh enabling a more precise evaluation of the near field impact.



THERMAL IMPACTS CALCULATED FOR DIFFERENT COASTAL POWER PLANTS

Fig. 3

Some examples of results are shown on figure 3 where the thermal impacts calculated for different coastal nuclear power plants are presented :

- Gravelines : it was the first coastal nuclear plant, with an intake and an outfall made through free surface channels (intake inside the Dunkerque harbour, outfall outside the harbour).

- Paluel : as for Flamanville and Penly, the intake is erected along the shore (free surface channel), and the discharge is made through offshore submerged outfalls with high discharge velocities enabling a good initial dilution.

- Flamanville : this plant is erected on a cape with high current velocities contributing to a good dilution of the calories.

- Penly : on this site is a marine drift to the North East enabling a good renewal of the waters and thus a relatively small thermal impact.

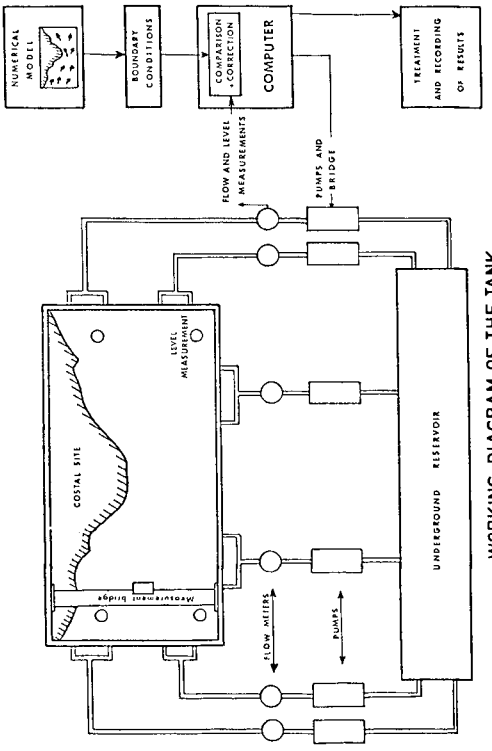
- Ploumoguer : this project was situated inside a bay enjoining to make the discharge far away from the coast as to dilute the calories in the strong currents off the bay and to avoid a too important heating of the bay ; the difficulties of this project made it abandonned.

- Plogoff : this site, finally abandonned for political and ecological reasons, was very favourable from a thermal point of view because of the existence of an important dissymmetry between the ebb and the flood, leading to a big tidal drift to the West considerably reducing the thermal impact.

2.3. Physical models

In fact other numerical models can be used for the study of the near field, especially three-dimensional models, but usually most of the near field problems are studied by way of physical models taking into account more accurately and continuously the tridimensional aspects of the dilution : topography, density effects, turbulent mixing, vertical profiles of velocities and temperatures, etc...

As the boundary conditions on classical physical models are usually very long and hard to work up, we have recently built for the environmental studies a special test stand (first used for the Flamanville power plant) which is a hybrid model reducing those difficulties by using both numerical and physical techniques, i.e. a physical model whose boundary conditions are given by the numerical current models and automatically controlled by a computer.



WORKING DIAGRAM OF THE TANK
CONTROLLED BY COMPUTER

fig.4

3. THE COMPUTER CONTROLLED TANK

3.1. Purpose of the model

The computer controlled tank developed by the L.N.H. allows to reproduce, without long manual adjustments, any configuration of non steady flow, for example tidal currents.

The large dimensions of the tank and of its whole equipment make the installation work as a testing stand allowing the study of successive sites one after the other, the only parameters to introduce being the topography and the boundary currents derived from field measurements or from a numerical model of larger area. If the boundary conditions are well known, they will be immediately reproduced whereas their reproduction with classical model equipments needs to proceed cautiously and tentatively during three months to one year, according to the complexity of the current field. If the boundary conditions are badly known, their determination by progressive adjustments in terms of the velocities obtained in the model will be possible within an iteration time of a few weeks, whereas the classical technology makes this research quite impossible because of the long iteration time. This automatic control by computer therefore induces an important gain of time.

3.2. Dimensions of the model.

The dimensions of the model are :

- Overall length : 54,50 m
- Useful length : 47,50 m
- Overall width ; 31,40 m
- Useful width : 28,40 m
- Overall depth ; 1,50 m
- Useful depth : 1,20 m

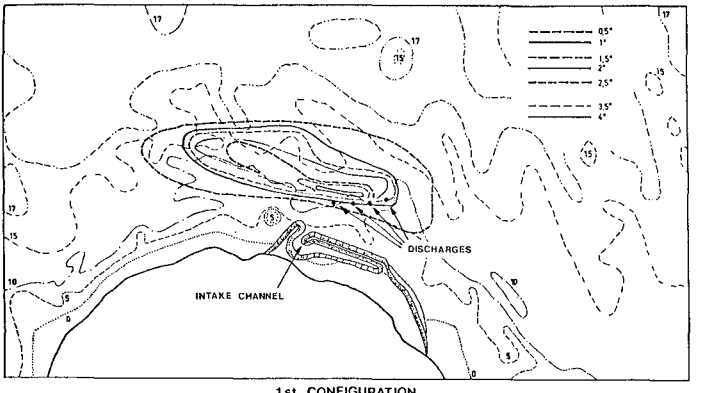
The underground associated storage capacity is about 1 200 m^3.

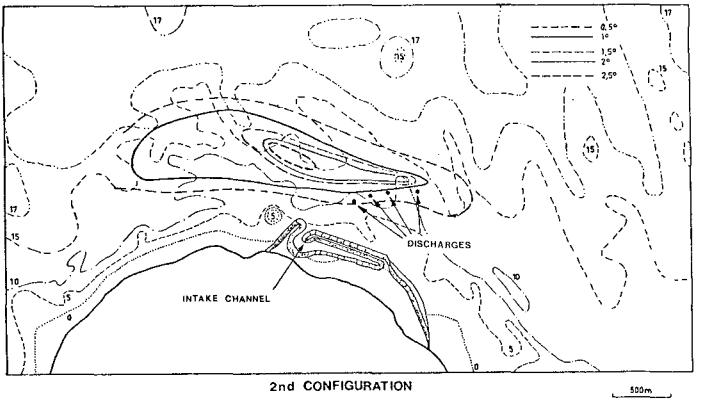
3.3 Simulation of the levels and currents

The working diagram of the tank is presented on figure 4.

The model is equipped at its three open boundaries with six water supply systems (2 for each boundary), each one being completely independent from the others and automatically controlled by a computer.

Three of them consist in reversible axial pumps dispatching the water from the underground reservoir to the model or from the model to the underground reservoir with a flow ranging between - 500 l/s (drainage of the model) and + 500 l/s (supply of the model). These pumps are equipped with direct current motors and thyristor speed variators.





FLAMANVILLE NUCLEAR POWER PLANT
$\Delta T = 15°C$; DISCHARGE FLOW = 180 m^3/s
COMPUTER CONTROLLED TANK
SURFACE TEMPERATURE ELEVATIONS AT SPRING TIDE
6 H BEFORE HIGH WATER
Fig.5

The three others consist in constant-flow centrifugal pumps associated with flow partition valves ; according to the position of the valve, a part of the 500 l/s flow of the pump is recirculated in a closed loop, the other part going either to the model or to the underground reservoir.

The flow in each of the six supply circuits is measured by an electromagnetic flowmeter with an accuracy of about $\pm$ 0,5 %.

A minicomputer HP 2 100 S 32 Kbytes memory brings under control the flows of each water supply circuit, as to reproduce at the boundaries the flows and levels stored on a magnetic tape and previously calculated by a numerical model validated by field measurements.

3.4. Bottom topography

As to allow quick transitions from a site to another, the bottom topography is represented by removable moulded plastic caissons of 1,75 m x 2,50 m easily interchangeable.

3.5. Instrumentation of the model

The tank is equipped with a system of hot water and dye injection allowing to simulate thermal or polluted discharges and to study the diffusion of different types of pollutants.

The measuring equipment is composed of thermal probes, directional propeller currentmeters, 24 x 36 cameras for chronophotographies.

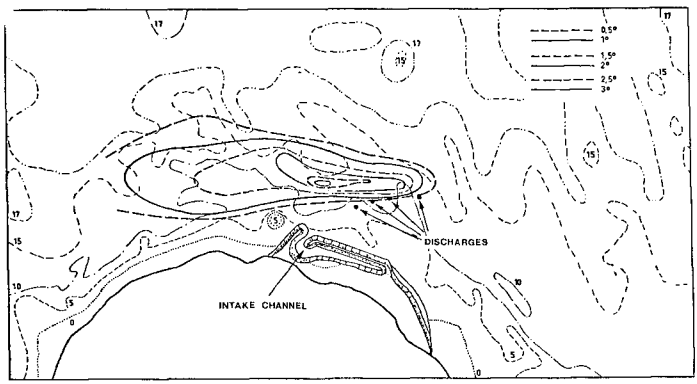
A measurement bridge, equipped with a probe holder trolley, whose movements in the three directions are controlled by the computer, allows automatic scanning of the model with temperature or current probes.

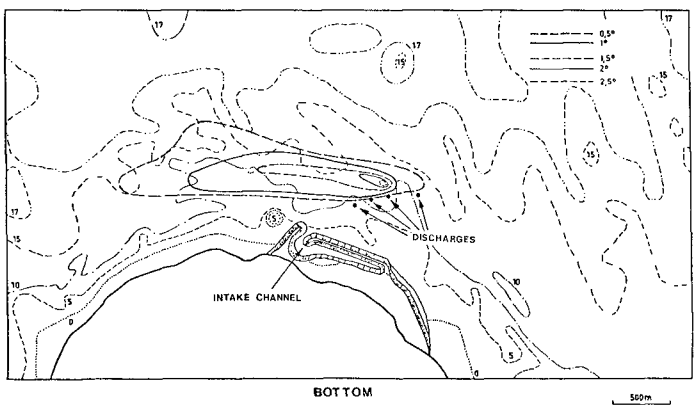
Moreover, a system of automatic treatment of float images by video camera connected to a computer is under progress for the acquisition of the current fields on the model.

3.6. Data acquisition

The acquisition of all the measurements of temperature, current velocities and directions, flows, levels, etc. is made by the HP 2 100 S computer during the experiments. All data are stored on a magnetic tape. Their treatment is made on large capacity computers equipped with quick and high-quality graphic display systems for final results edition.

3.7. - So this facility can be used to examine faster any problem involving tidal currents and diffusion processes, the dimensions and equipment of the tank allowing to treat the near field as well as the intermediate field, the far field being studied with mathematical modelling.





FLAMANVILLE NUCLEAR POWER PLANT

COMPUTER CONTROLLED TANK
TEMPERATURE ELEVATIONS AT SPRING TIDE
4 H BEFORE HIGH WATER
Fig.6 (2nd CONFIGURATION)

4. THE FLAMANVILLE POWER PLANT

The impact on the marine environment of the Flamanville nuclear power plant has been particularly studied in this model. Numerical regional and local models of currents have been first performed (figure 2). Then, they have been used for the thermal impact study in the far field by way of a numerical model (figure 3) ; this model gave, in particular, an estimation of the average area concerned by a temperature elevation of more than 1°C (about 5 km^2 during spring tide and 7 km^2 during neap tide), and an evaluation of the total recirculation peaks at the intake (maximum about 2°C during spring tide, 3°C during neap tide).

The results given by the numerical models of currents were then used for the currentological and thermal impact in the near and intermediate field by giving boundary conditions to the computer controlled tank here above described.

The model scales are 1/285e horizontal and 1/125e vertical, thus representing an area of about 15 km x 9 km ; once the bottom topography was set in place, the reproduction of the marine currents was quite immediate and showed the interest of the method which allowed to reproduce with a good accuracy the complex configuration of the currents existing North and South the Flamanville cape, which were poorly represented on the numerical model, though well known in the field and very important for the recirculation.

The study was directed on three main points :

- optimization of the positions of the four discharge outlets in order to minimize the recirculation,

- thermal impact in the near field (at different depths and in particular near the bottom),

- influence on the currents of the breakwaters protecting the intake works.

Some results of this study are presented on figures 5 to 7 :

- Figure 5 shows the effect of the relative positions of the 4 discharges (the second configuration was finally chosen) ;

- Figure 6 shows the thermal impacts measured in surface and at the bottom ;

- Figure 7 shows the effect of the tidal coefficient (neap and spring tide).

5. CONCLUSION

Different types of means are used to study the thermal impact on the marine environment of french coastal power plants using a once-through cooling system. Both numerical and physical models are used depending on the problems. New hybrid models appear, as the computer controlled tank, using the complementarity of both techniques, giving then very interesting results in a much quicker studying time.

STUDY ON SEDIMENT TRANSPORT IN A POWER STATION HARBOR BASIN

By

Kohki Maruyama*, Ryoichi Kajima**

Akio Narihiro*** and Kosuke Kondo****

ABSTRACT

Extensive field investigations were carried out over a two-year period on the process of sand deposition in the cooling water intake basin in the harbor of a power station. The trapped bed load weight and mean suspended sediment concentration were found to have good correlations with the Shields Parameter corresponding to conditions of simultaneous waves and currents. A simple numerical model was developed to estimate the total net transport rate of the bed load and suspended load. Calculated results from the model were found to give a reasonable estimate of the sand deposition in the intake basin.

INTRODUCTION

In Japan, harbors for power stations are often built on the coast because of the availability of cooling water. Sediment deposition is one of the serious problems in designing harbor facilities which house water intakes and outfalls, since deposition around the harbor entrance can pose a danger to vessels. Fleming and Hunt (1976) investigated sediment deposition in a power station basin used for the intake of cooling water, and gave a brief description of the sedimentation occurring in the basin. In order to further our basic understanding of this problem, and to provide data for development of a predictive model of the deposition, comprehensive and intensive field investigations were carried out over a two-year period at Fukushima No. 1 Nuclear Power Station, Fukushima, Japan, beginning in the summer of 1979.

In addition to the data obtained from the intensive investigations, quarterly hydrographic surveys and daily incident wave observations have been performed at the site for more than 15 years. These measurements are useful for understanding the long-term tendency of sand deposition in the intake basin.

The objectives of this study were 1) to uncover the mechanisms of sediment transport around a harbor under conditions of simultaneous waves and currents, based on the results of extensive field investigations, and 2) to construct a simple numerical model useful for estimating the volume of sand deposited in a cooling water intake basin.

FIELD INVESTIGATION PROGRAM

Fukushima No. 1 Nuclear Power Station directly faces the Pacific Ocean as shown in Fig. 1(a). The harbor consists of two breakwaters, one to the north and one to the south. The basin in the harbor is used as a landing and for cooling water intake (Fig. 1(b)). At the present time, six B.W.R. generators are in operation with a total generating capacity of 4,696 MW. The maximum rate of cooling water intake is 270 m^3/sec. The width and the annually averaged water depth of the harbor entrance are 125m and 7.4m, respectively.

The field investigation program can be summarized as follows:

1) Periodic measurements of the waves and currents at the monitoring station at the harbor entrance (4 times/day).

2) Measurements of sediment transport using bed load traps at the harbor entrance (once/week). Measurements of suspended sediment concentration using pumps at the monitoring station and at the interior substation (twice/day). Grading analysis of sampled material (once/month).

3) Hydrographic surveys around the harbor entrance (700m by 700m; once/month).

4) Samplings and grading analysis of bed materials (50 locations in and around the harbor; once/month).

5) Measurements of wave height and current distribution in the basin using pressure wave gauges and electromagnetic current meters.

6) Measurements of sand movement using fluorescent dyed sand tracer.

The locations of both the monitoring station, substation, and hydrographic survey area are indicated in Fig. 1(b).

Figure 2 is a photograph of the monitoring station at the harbor entrance. Three electromagnetic current meters and one ultrasonic wave gauge were used for measuring the waves and currents. The intakes of the three pumps were set 0.5m, 1.0m and 5.5m above the sea bed. The pumps each sampled 200 liters of water for every measurement.

RESULTS OF FIELD INVESTIGATIONS

Long Term Tendency of Sand Deposition Around the Harbor

The topography, geology and wave climate of the coast at the Fukushima No. 1 Nuclear Power Station have been described in detail by Sasaki et al. (1980). A major characteristic of the area is the existence of coastal cliffs, some 30m high, which face the Pacific Ocean. These are constantly being eroded by wave action. It is estimated that 70% of the material supplied by such erosion consists of sand with the remaining 30% being silt and clay. The greater part of the sea bottom within the area having a water depth of 10m or less is covered with a sand layer of more than 1m. There are also partially exposed rocks along the bottom.

From comparisons of the locations of the cliffs measured on aerial photographs, it is estimated that a volume of material of about 176,000 m^3/year is supplied from the eroded cliffs which exist within a range of about 5 km north and south of the harbor. An additional amount of 35,000 m^3/year is estimated to be supplied from rivers within the range (Fig. 1(a)).

The cumulative sand deposition rate around the harbor (calculated from quarterly hydrographs) and the intake flow rate of cooling water (for the past 15 years) are shown in Fig. 3. Breakwater construction was completed in October, 1969, and the cumulative sand deposition rate was set to zero at that time. The deposition rate in the harbor (area III in Fig. 3) includes the dredged sand volume. From the figure, it is seen that the cumulative deposition rates in each area (I, II and III) are almost equal, and have reached about 500,000 m^3 in the past 10 years. The annual sand deposition rate in the habor (area III) tends to increase with increase of the intake flow rate, which has recently become 60,000 to 80,000 m^3/year.

Significant deposition outside the harbor also occurs up to 1,900 m north and 1,300 m south of the site. It can be roughly estimated that the volume deposited in the calculation area (I and II in Fig. 3) contains 60 to 70% of the total amount deposited outside the harbor. Taking this into account, the total amount of material deposited inside and outside the harbor is estimated to be about 200,000 m^3/year, an amount equivalent to that supplied by the cliffs and rivers within a range of 5 km from the harbor.

Table 1 shows the change in depth at the harbor entrance. The rate of bottom rise has also become greater with increase of the intake flow rate. The depth necessary for vessels to pass the harbor entrance safely is now maintained by dredging about twice a year.

An example of the median diameter distribution of sediment inside and outside the harbor is given in Fig. 4. The bed material in the vicinity of the harbor entrance consists of relatively coarse sand grains, whereas in the interior part of the basin, fine particles with diameters less than 0.1 mm are found.

Fig. 2 Monitoring station at the harbor entrance.

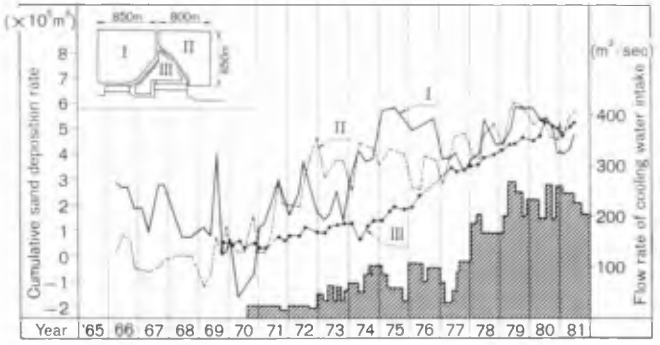

Fig. 3 Change of sand deposition rate around the harbor and flow rate of cooling water intake.

Table 1 Decrease in depth (bottom rising rate) at the harbor entrance.

Interval	Change in depth (m/year)	Average cooling water intake (m^3/sec)
1970—'74	0.5	30
'74—'76	1.0	70
'77—'78	2.0	100
'78—'79	3.0	170

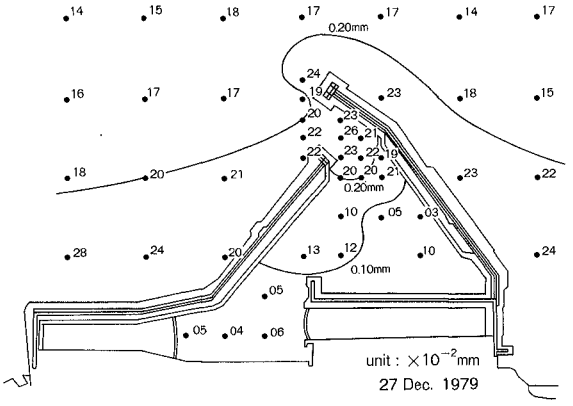

Fig. 4 Distribution of median diameters of the sediment inside and outside the harbor.

The gradings of the bed and suspended materials found at the harbor entrance are indicated in Fig. 5. Of the suspended material, more than 50% of the particles have a diameter less than 0.1 mm. Such sediment is scarce in the bed at the harbor entrance. The ratio of this fine material increases as the distance from the sea bed increases.

From the difference between levels of bottom surveys, and from the distribution of median diameters (see Fig. 4) measured every month, the total amount of sediment (from Jul. 1979 to Dec. 1980) deposited in the hydrographic survey area (see Fig. 1(b)) can be obtained for each diameter grading. The amount of suspended load for the same period entering through the harbor entrance can be estimated from the products of the cooling water intake rate and vertically averaged sediment concentration from the sea bed to the sea surface, which were measured at the monitoring station. In the calculation, the concentration at the sea bed was assumed to be three times that at the 0.5 m level above the bed, based on measurement of the vertical distribution of suspended sediment using suspended sediment traps set 0.5, 0.4, 0.3, 0.2 and 0.1 m above the bed. Moreover, the constituents by grade in the suspended load can also be calculated from the results of the monthly grading analysis, as shown in Fig. 5.

Figure 6 shows the estimated amounts of bed and suspended loads by sediment diameter step. In this figure, 'inflow rate' means the amount entering through the harbor entrance and 'net deposition rate' means the amount deposited in the hydrographic survey area. The amount for the bed load is the value obtained by subtracting the estimated net deposition rate of the suspended load from the total amount, for each sediment diameter step. From the figure, it is estimated that the contributions of each mode to the sand deposition, excluding fine material less than 0.1 mm in diameter, are about equal.

From Figs.4 to 6, it is concluded that the greater part of the fine material passes through the harbor entrance without settling, and that deposition only occurs in the interior part of the harbor where the wave height and current velocity are both low. Therefore, sand deposition just inside the harbor entrance, where the external forces decrease greatly, should depend upon the bed and suspended loads of sand grains with a diameter of more than about 0.1 mm.

Characteristics of Bottom Shear Stress Under Waves and Currents

In order to understand the characteristics of the bottom shear stress under simultaneous action of waves and currents, the bottom shear stress under waves only, τ_1 as presented by Jonsson and Carlsen (1976), and the bottom shear stress under waves and currents, τ_2 as presented by Tanaka and Shuto (1981), will be reviewed.

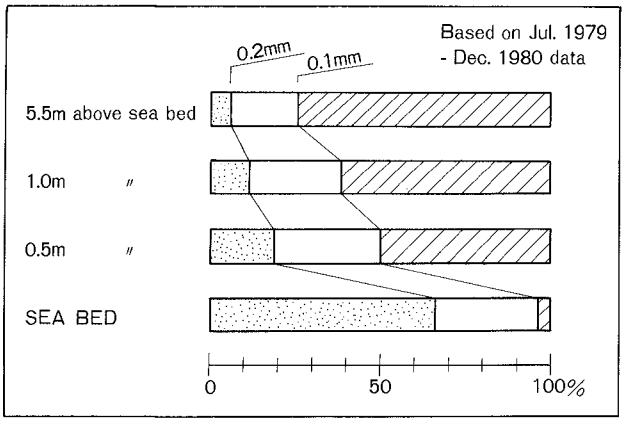

Fig. 5 Grain size constitution of the material deposited on the sea bed and the suspended load at the harbor entrance.

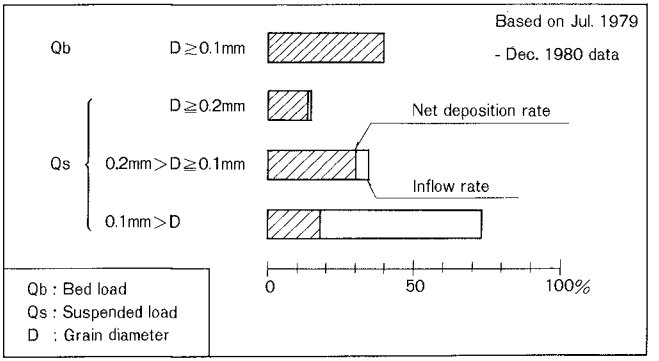

Fig. 6 Relative amounts of bed and suspended loads.

Jonsson and Carlsen gave an expression for the bottom friction factor under waves only, f_w, as follows:

$$f_w = 0.3 \qquad (a_o/z_o < 1.57)$$

$$\frac{1}{4\sqrt{f_w}} + \log \frac{1}{4\sqrt{f_w}} = 0.08 + \log \frac{a_o}{z_o} \qquad (a_o/z_o \geq 1.57) \tag{1}$$

Here a_o is the amplitude of bottom water particle movement, and z_o is the roughness length, ordinarily taken as the grain diameter, D. Using this friction coefficient, we can write the bottom shear stress under waves only, τ_1, as

$$\frac{\tau_1}{\rho} = \frac{f_w}{2} u_b^2 \mid \cos \sigma t \mid \cos \sigma t \tag{2}$$

in which ρ is the fluid density, u_b is the maximum bottom orbital velocity, and σ is the angular frequency of the waves.

On the other hand, Tanaka and Shuto introduced the following equations to express the bottom friction factor, f_{cw}, for the simultaneous existence of waves and current:

$$\frac{f_{cw}}{2} = B_1^2 \left(\frac{u_c}{u_w}\right)^2 + 2B_1C_1 \left(\frac{u_c}{u_w}\right) \cos \theta + C_1^2$$

$$B_1 = \frac{\kappa}{\ln (h/z_o) - 1}$$

$$C_1 = \frac{\kappa}{\pi} \{0.25 + 0.101 \left(-\ln \frac{u_w}{\sigma z_o} - 0.5 \ln f_{cw} + 2.42\right)^2\}^{-1/2} \qquad (50 < u_w/\sigma z_o) \tag{3}$$

and

$$C_1 = 0.728 f_{cw}^{-0.25} \left(\frac{u_w}{\sigma z_o}\right)^{-0.408} \qquad (10 < u_w/\sigma z_o \leq 50)$$

Here u_c is the current velocity, u_w is the amplitude of the bottom orbital velocity, θ is the angle between current direction and wave direction, κ is the Karman coefficient (= 0.4), h is the water depth, and z_o is the roughness length. It is noted that D/30 (D = grain diameter) must be used for the roughness length z_o in Eq. (3).

According to potential wave theory, u_w is given as

$$u_w = \frac{\pi H/L \ (L/T - u_c \cos \theta)}{\sinh (2\pi h/L)} \tag{4}$$

where H is the wave height, and L is the wavelength.

Using these equations, the bottom shear stress under waves and currents, τ_2, is given by Eq. (5), where the current direction and wave direction are assumed to be the same, i.e., $\theta = 0$.

$$\frac{\tau_2}{\rho} = (B_1 u_c + C_1 u_w) \ (B_1 u_c + C_1 u_w \cos \sigma t) \tag{5}$$

The maximum values of τ_1 and τ_2 divided by ρ, i.e., τ_{1m}/ρ and τ_{2m}/ρ, are compared in Fig. 7. In Fig. 7(a), the current velocity u_c (= 0.2 m/s) is fixed, and in (b), the wave height H (= 0.5 m) is fixed. For the calculations, it was assumed that D = 0.25 mm, h = 8m and $\theta = 0^o$, which would represent average topographical and hydrological conditions at the harbor entrance of the Fukushima No. 1 Nuclear Power Station. The two figures show the results for wave periods T of 10 sec and of 6 sec.

The distibution of current velocity u_c, i.e., the time-averaged value of the velocity measured by electromagnetic current maters, is shown in Fig. 8. The velocities 0.5 m above the sea bed are not uniform in the harbor entrance section, and the value near the north breakwater is usually 2 to 2.5 times that near the south breakwater. In addition, it was also found that the variation of the current velocity in the vertical direction is rather small, and that the current direction is almost parallel to the south breakwater. The waves diffracted by these breakwaters tend to propagate along the south breakwater; therefore, the angle θ can be regarded as zero.

It is readily seen from Fig. 7 that τ_{2m} is between 1.5 to 3 times τ_{1m} under ordinary environmental conditions at the harbor entrance of the investigation site, i.e., H = 0.5 m and u_c = 0.2 to 0.4 m/sec (see Fig. 8). It is also observed that τ_{1m} and τ_{2m} are almost equal when the wave height is about 2 m and u_c = 0.2 m/sec. However, such environmental conditions are rarely encountered at the harbor entrance.

Bed Load and Suspended Load Under Waves and Currents

A sketch and photograph of the trap used in measuring the bed load are shown in Fig. 9(a) and (b) respectively. A trap was placed at a given location for between 6 and 24 hr. Results from the traps for the area around the harbor entrance are tabulated in Table 2 with reference to sediment diameter, water depth, current velocity, and wave height and period. Figure 10 shows the relationship between trapped bed load weight, Q, and maximum Shields Parameter, ψ_m. The parameter ψ_m is

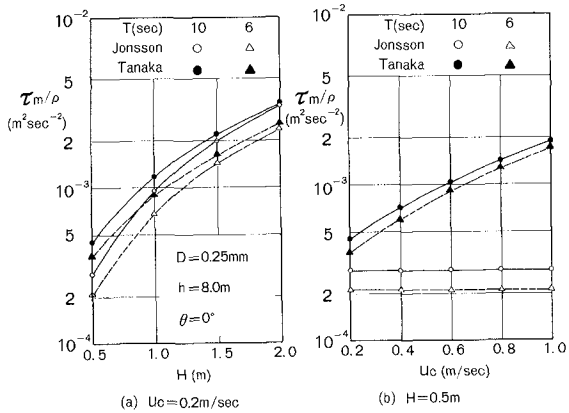

Fig. 7 Comparison between maximum bottom shear stresses; under waves only, (Jonsson and Carlsen, 1976); under simultaneous waves and currents, (Tanaka and Shuto, 1981), for D = 0.25mm, h = 8.0m, and $\theta = 0^{\circ}$. Current velocity is fixed (u_c = 0.2m/sec) in (a), and wave height is fixed (H = 0.5m) in (b).

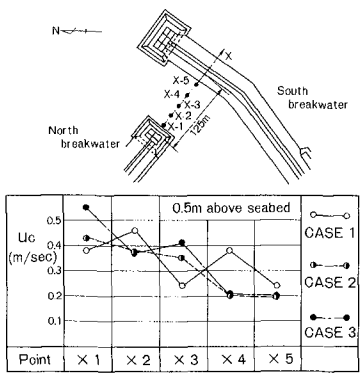

Fig. 8 Current velocity distribution at the level 0.5m above the sea bed.

defined as

$$\psi_m = \frac{\tau_m}{\rho g (s - 1) D} \tag{6}$$

in which s is the ratio of sediment density ρ_s to fluid density ρ, and g is the acceleration of gravity. The maximum shear stress τ_m was calculated from Eq. 5 for the condition of simultaneous waves and currents. Sand ripples were observed on the sea bed around the harbor entrance; however, it has been pointed out that the existence of ripples may not affect the bed load transport rate (Madsen and Grant, 1976). Therefore, the roughness length z_o in Eq. 3 was kept as D/30 even under ripple conditions.

From Fig. 10, it is seen that Q is proportional to $\psi_m^{3/2}$ for ψ_m greater than 0.1. In the region where ψ_m is smaller than 0.1, there is relatively wide scatter, and Q decreases rapidly. The critical value of the Shields Parameter is approximately 0.04. The trapped bed load weight corresponds to the to-and-fro rate of sand movement in the vicinity of the sea bed, and does not necessarily correspond to the net transport rate. Therefore, efforts to determine the functional relation between Q and ψ_m would not be fruitful as far as the net transport rate is concerned.

Examples of ten cases of measured vertical distributions of mean suspended sediment concentration, C, are shown in Fig. 11. The suspended load was measured by pumps at the monitoring station (Fig. 2) under relatively high wave conditions. The mean ratio of the concentration in the lower layer (0.5 m above the sea bed) to the concentration in the upper layer (5.5 m above the sea bed) is about 6:1. This ratio decreases as the wave height becomes smaller, and the mean ratio calculated from all data is about 3:1 (cf. Table 3, where the sediment diameter, water depth, current velocity, wave height and period are listed together with C). The mean ratio, however, is rather small compared to the estimate obtained by the well-known diffusion method (Rouse, 1937). One of the reasons for this is that fine materials, which occupy a considerable part of suspended sediment, flow into the harbor almost uniformly distributed in the water column.

The relationship between mean suspended sediment concentration 0.5 m above the sea bed, $C_{0.5}$, and ψ_m for selected representative values from Table 3 is shown in Fig. 12. It is noted that $C_{0.5}$ appears to be proportional to ψ_m over the entire region. The critical value of the Shields Parameter is not as clear as in the case of bed load.

The trapped bed load weight Q near the north breakwater, where the current velocities were comparatively large, was always greater than that near the south breakwater, whereas the suspended sediment concentration $C_{0.5}$ exhibited a rather uniform distribution at the entrance. The difference in distribution between Q and $C_{0.5}$ can be explained by the difference in terms of the coefficient of the exponent of ψ_m. That is, when the current velocity u_c varies in the harbor entrance section (Fig. 8), the deviation of $\psi_m^{3/2}$ ($\propto Q$) tends to become relatively larger than that of ψ_m ($\propto C_{0.5}$).

HARBOR SAND DEPOSITION MODEL

This model for estimating sand deposition in a harbor is based on two assumptions.

(1) There is an inexhaustable supply of sand outside the harbor.

(2) The "wash load", consisting of fine materials with a particle diameter less than 0.1 mm (and which is difficult to relate to the external forces of the waves and the currents) can be neglected.

According to the results of the analysis in the previous section, the transport rates of bed load and suspended load are evaluated separately as:

transport rate of bed load $\sim \psi_m \cdot \psi_m^{1/2} \sim \psi \cdot u$

transport rate of suspended load $\sim C \cdot u \sim \psi_m \cdot u \sim \psi \cdot u$

Since ψ and u depend on time, both transport rates at given time are assumed to be proportional to the instantaneous power ($= \tau \cdot u \simeq \psi \cdot u$) exerted by waves and currents (Bagnold, 1963).

The following equations were then used to estimate the total "net" transport rate q (apparent volume) of the two modes:

$$\frac{q}{\sigma D^2} = \frac{\alpha}{1-\epsilon} \cdot \frac{1}{\sigma D} \cdot \overline{|\psi| \cdot u} \tag{7}$$

where

$$\psi = \tau / \rho g(s-1)D \tag{8}$$

and

$$u = u_c + u_w \cos \sigma t \tag{9}$$

Here ϵ is the sediment porosity, α is an empirical coefficient, and the overbar in Eq. 7 expresses an average for one wave cycle. The bottom shear stress τ is calculated by Eq. 3, which is modified for the coexistence of both waves and current. The sand deposition rate in the harbor can then be obtained by integrating Eq. 7 along the harbor entrance.

The critical value of the Shields Parameter is not included in Eq. 7 because it could not be clearly defined for the suspended load, and also because the contributions of bed load and suspended load to the sand deposition around the harbor entrance are about the same. Komar (1977) used an expression similar to Eq. 7 in estimating the longshore sand transport rate. Approximating the right side of Eq. 7 by $\psi^{3/2}$, an expression is obtained similar to that of Sleath (1978), whose result was based on detailed experiments dealing with sediment movement under waves.

A cumulative sand deposition rate was calculated using daily data of waves and current at the harbor entrance. The results were then compared to the measured bottom change around the harbor entrance and the empirical coefficient α was obtained as 0.92. The sediment diameter was assumed to be constant and equal to 0.22 mm, the annual mean value of median diameter D_{50} of the sediment at the harbor entrance. Figure 13 shows the estimated and measured sand deposition rates around the harbor entrance from July 1979 to November 1980, allowing for a possible scatter of $\pm$ 20%. The calculation is seen to give fairly good results throughout the simulated period.

A calculation was also made using the Brown formula, $q \sim \psi^3$ (Madsen and Grant, 1976) adapting the bottom shear stress under simultaneous waves and currents. However, the result for the total sand deposition rate over the same period as above was about 1/8 of the measured value. In an attempt to eliminate the discrepancy by modifying the procedure through a coefficient of proportionality, the maximum value of the deposition rates calculated for each month in Fig. 13, were found to reach about 50 times that of the minimum value, which deviates greatly from the actual observed phenomena.

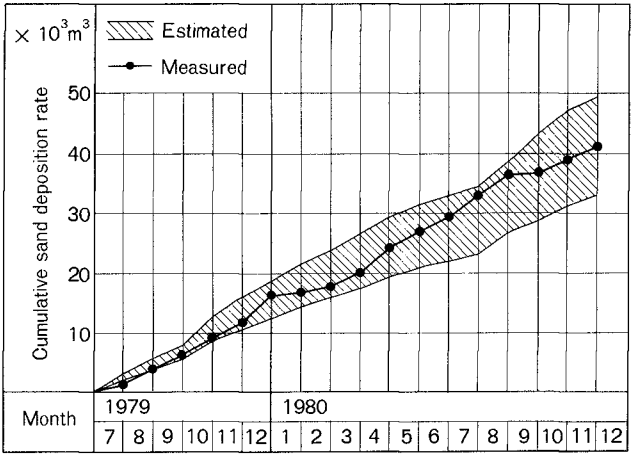

Fig. 13 Comparison between estimated and measured sand deposition rates.

CONCLUSIONS

Comprehensive field investigations were performed at the harbor of a power station, and a model for engineering use was developed to estimate the sediment transport rate based on the measurements. Calculated results of the model were found to give a reasonable estimate of sand deposition in the cooling water basin of the harbor. This model could be used in planning harbor facilities in order to minimize the dredging cost. Modification of the model is expected when the quantitative relationship between the transport rate of fine materials and external forces becomes known, on the basis of further investigations.

ACKNOWLEDGEMENTS

The authors extend their appreciation to Professor K. Horikawa, University of Tokyo, for valuable consultation and advice. We would also like to thank Dr. N. C. Kraus, Nearshore Environment Research Center, for critically reading and preparing the manuscript.

SALINITY INTRUSION INTO MULTI-PORT SEA OUTFALLS

John A. Charlton, M.Sc., Ph.D., C.Eng., M.I.C.E., M.I.W.E.S., *

ABSTRACT

Sea water intrusion into the diffuser system of a long sea outfall is likely to reduce the efficiency of the outfall. Recent surveys have revealed outfalls with a significant proportion of their diffuser blocked, and others discharging through as few as 50% of their diffuser ports. It is suspected that intrusion is the cause of these malfunctionings. Intrusion may be encouraged by the design requirement of low efflux velocities to obtain optimum dilution, or by over-design to cater for future increases in discharge. Although intrusion can only commence at low discharge velocities, when a port Densiometric Froude number falls below about 1, once it has started sea water will continue to enter the diffuser system until a state of balance is reached. Subsequently a considerably greater flow will be required to purge the outfall of all sea water. Intrusion may also be prematurely triggered by wave action, currents, or by reduced flow through a damaged port.

Hydraulic model tests at the University of Dundee are leading to an understanding of the intrusion mechanism as it affects the various diffuser systems in current use. A continuing research and site survey programme is aimed at design recommendations to eliminate intrusion or reduce its effects.

1. INTRODUCTION

Long sea outfalls are being increasingly used to convey waste effluents away from the coastline into areas of the sea where currents are able to generate conditions favourable to rapid dilution and dispersion.

Most of these outfalls terminate in some form of multi-port diffuser designed to optimise the initial dilution of the effluent. The main design criteria for a diffuser system are:-

a) that the flow through the ports should be as equal as possible over the full discharge range of the system,

b) that head losses should be kept to a minimum, and,

c) that the initial or rising plume dilution should be as great as possible.

This is generally achieved by designing for low diffuser port flow efflux velocities, the limit being that the port Densiometric Froude number should remain greater than unity. (At values less than unity saline reverse flow will occur). (Abraham 1963, Brookes 1970)

Outfalls are frequently designed to cater for future population growth and consequent future increase in discharge. By their very nature, they also have to cope with wide ranges of discharge, particularly if they carry storm water. Thus it is likely, especially in the early life of an outfall, that it will occasionally operate under low flow conditions which are favourable to sea water intrusion.

Unfortunately, out of sight, out of mind, has too frequently been the dictum of many operators of sea outfalls, and it is therefore not too surprising that reduced performance of an outfall is rarely reported. However a number of observations have recently come to hand indicating that some outfalls have not been functioning in the manner that their designers envisaged. Noticeable failure is apparently rare, but reduced performance surprisingly common. A notable example in the UK, recently reported, is that of the Hastings sea outfall (type b, fig. 1). It was discovered that, although the outfall had been discharging its full load, a substantial portion of the seaward end of the diffuser was blocked by debris and marine growth. It is now accepted that this blockage resulted from continuous sea water intrusion due to over conservative design. (Bennet 1981, 1982) A similar case has been reported in 1982. Another case concerns a large UK tunnelled outfall (type c, fig. 1) in which only half of the diffuser risers are carrying effluent at the design D.W.F.

The problem of sea water intrusion is not new, but the realisation of the problem is comparatively new. It was at the ICE Conference on Sea Outfalls in London in October 1980 that the problem was privately discussed by a number of experts. One of the main difficulties on this occasion was conceptual, in that nobody had observed the intrusion problem, and its manifestation was largely conjectural, although a number of outfall designers had proposed mechanisms for the intrusion process.

1.1 Pilot model

A thorough literature search yielded virtually no references on the subject and no record of any relevant outfall model testing. Therefore in an attempt to elucidate the problem, a pilot model of a tunnelled outfall was constructed in the hydraulics laboratory at the University of Dundee. This model, entirely constructed in perspex, had a foreshortened tunnel and only two risers. For a typical outfall its modelling scale would be about 1:20. Despite difficulties in maintaining appropriate salinity levels in its small 'sea tank', this model convincingly demonstrated some of the intrusion mechanisms, and that intrusion problems could arise in existing outfalls. The opportunity to observe the intrusion process was extremely valuable and necessary before we could attempt to quantify the process by a theoretical approach.

1.2 The Aberdeen outfall model

We were very soon able to apply the lessons learnt on the pilot model when the Grampian Region's Department of Water Services, through their consultants D. A. Donald and Wishart of Glasgow, commissioned the building and testing of a section of the Aberdeen sea outfall, which was then under construction.

The Aberdeen outfall comprises a landward shaft and a 2.5 km tunnel of 2.5 m diameter, the last 270 m of which is a diffuser section. Ten diffuser risers are connected to the tapering tunnel invert on alternate sides at 30 m centres. (type d, fig. 1) The shaft, some 40 m of tunnel and the first 100 m of the diffuser section including four risers was modelled in perspex, to a scale of 1:18.9. The risers discharged into a 6 m^3 'sea tank' maintained at a density of 1025 kg/m^3, and flow behaviour was observed with the aid of a comprehensive dye injection system.

This model has now been superseded at Dundee by a multi-purpose outfall test facility built on very similar lines to the Aberdeen outfall model. This facility has been financed by the UK Science and Engineering Research Council as part of a 3 years laboratory and site investigation into the salinity intrusion problem. (Charlton 1982).

1.3 Sea water intrusion as a design parameter

It has become evident that the traditional approach to sea outfall design needs to be modified taking into account an appreciation of the intrusion phenomenon. It will be another 3 years before an analysed description of intrusion processes can be published from the Dundee research programme, but in the interim period it is considered that a broad description of these processes as they have been observed to date would be beneficial to those currently engaged in outfall design.

While not attempting to supply the answers, the following sections of this paper describe the intrusion process, and its consequences, as a current 'state of the art' document.

2. OUTFALL DESIGN

The criteria listed in section 1.2 are generally achieved, after appropriate hydrographic and dispersion surveys (Charlton 1980), by conveying the effluent seawards through a pipeline or tunnel to a diffuser section which is designed to maximise the initial dilution. Invariably the diffuser section comprises a number of ports close to the sea bed. The number and spacing of these ports is a function of the water depth, total effluent flow and the required surface dilution. The use of the Brookes and Abraham rules results in low port efflux velocities and consequent low differential pressures between the outfall pipe and the sea, particularly at low discharges. Outfalls frequently operate over wide ranges of flow and in trying to obtain maximum dilutions over the higher flows, designers sometimes reduce port Densiometric Froude numbers very close to unity, when intrusion is likely to occur. It will be shown in later sections that intrusion under these conditions can be triggered by other factors at flows corresponding to significantly higher Densiometric Froude numbers.

Clearly, if an outfall is being designed to cater for increased loadings in later life, this problem is exacerbated.

3. OUTFALL TYPES

To list the many variations of outfall design would be superfluous, but to simplify matters we may divide outfalls with diffuser sections into four main types.

a) Sea bed outfall pipes with the diffuser section being entirely above the sea bed. In this case the diffuser ports are usually in the side of the pipe. Fig. 1 (a).

b) Shallowly buried outfall pipes, the diffuser section consisting of a number of short riser pipes. Fig. 1 (b).

c) Tunnelled outfalls where the diffuser section consists of a number of shafts connecting the soffit of the tunnel to sea bed diffuser heads. Fig. 1 (c).

d) Tunnelled outfalls where the diffuser section consists of a number of staggered shafts connecting the invert of the tunnel to sea bed diffuser heads. Fig. 1 (d).

4. THE INTRUSION CONDITION

4.1 The intrusion condition in an outfall with a diffuser section entirely above the sea bed (Fig. 2).

This type of outfall tends to be self regulating, the amount of sea water remaining in the pipe at any given time depending on the gradient of the pipe and the location of the outlet ports.

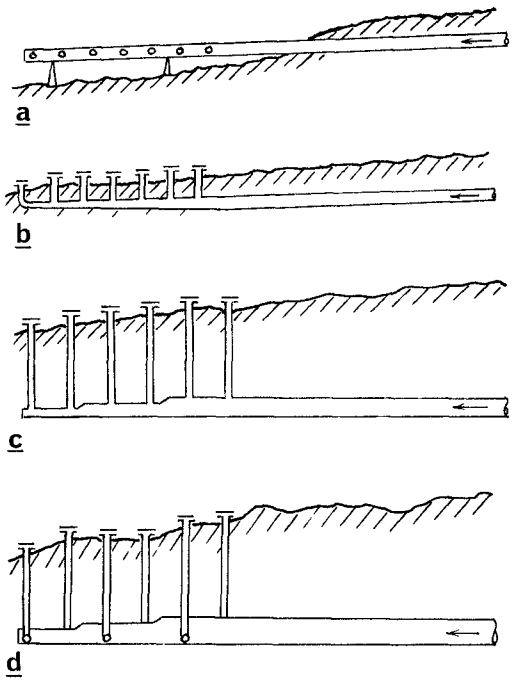

Figure 1 The four main types of outfall and diffuser configuration

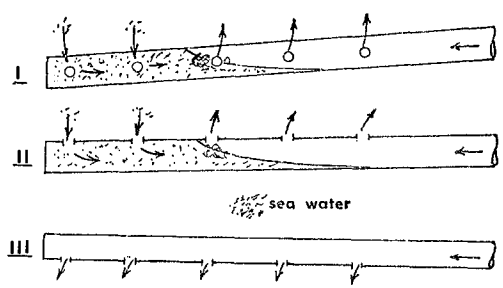

Figure 2 Intrusion processes in type *a* outfalls

Figure 2I shows how sea water intrudes into an inclined diffuser section. A similar interface configuration will occur whether the ports are on the side, top or bottom of the pipe.

The fresh-saline water interface will move downstream with increasing flow and vice-versa until an equilibrium position is reached. Mixing at the interface will be replenished by inflow through the sea water submerged ports.

As the diffuser pipe approaches a horizontal configuration there is a marked difference in performance between a diffuser with ports in the top or base of the pipe. (Figs. 2II and 2III) With top opening ports the flow patterns will be similar to case 2I, but with bottom ports there should be equal flow out of all ports at all times, particularly at low flows. (Any sea water within the pipe will be expelled with a horizontal interface inside the pipe until all sea water is cleared.)

4.2 The intrusion condition in a sea bed outfall with short vertical risers (type b), or a tunnelled outfall with longer risers (type c) both joined to the pipe/tunnel soffit.

These two cases are geometrically similar, the main difference being in the length of the riser pipes. (Fig. 3)

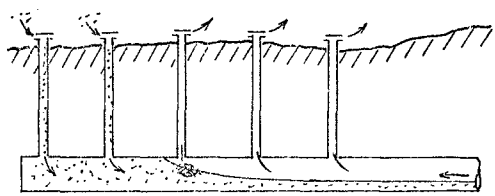

Figure 3 Intrusion process in type c outfalls

In this case the intrusive condition is very similar to that depicted in Figure 2II. However, the differential head created between a long riser full of sea water and another full of fresh water (effluent) increases with length and can generate considerable downward flow in those risers full of sea water. For equilibrium, mixing must take place at the interface as shown. Once again the interface will move to an equilibrium position.

4.3 The intrusive condition in a tunnelled outfall with invert connected risers.

This is the configuration that, to date, has been most closely studied (in the Aberdeen sea outfall model). (Fig. 4)

In this configuration the interface wedge is not so pronounced. The interface tends to form horizontally with a mixture of fresh and sea water being fed into the upward discharging risers. Under intrusive conditions some of the risers are full of sea water and flow downwards, thus maintaining the sea water layer in the tunnel.

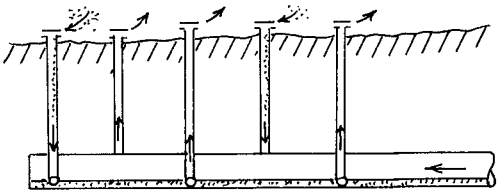

Figure 4 Intrusion process in type d outfalls

5. THE INTRUSION PROCESS

The conditions described in section 4 may be regarded as steady state conditions for a constant discharge. To arrive at this condition we may consider an outfall system full of sea water. This is a condition that would result from a cessation of effluent flow. If now a low flow of effluent commences, this flow will displace sea water with a clearly defined interface similar to that depicted in Figs. 2, 3 and 4. This interface will move downstream in types a, b and c with increasing effluent flow until the flow, and pressure differential, between the pipe and sea, is great enough to expel all the sea water. Once this condition is reached flow may be decreased again considerably before intrusion once again occurs. Intrusion will not recommence until the Densiometric Froude number of any orifice is reduced below unity. (See later for modifications to this condition.)

In the case of a type (d) outfall, with increasing flow from a fully saline start the horizontal interface in the tunnel is depressed until a mixture of sea and fresh water flows up the risers. At this stage, imbalances occur between adjacent risers and some actually go into reverse flow. This reverse flow maintains the saline layer in the tunnel and the upward flowing risers carry a mixture of fresh and saline water. With increasing effluent flow more risers come into the upward discharging state until eventually all are in this state and all sea water is expelled from the tunnel. As in the previous case intrusion cannot recommence until the outlet port Densiometric Froude Number reduces below unity. Once intrusion starts, it progresses to the full equilibrium condition described in section 4.3.

Flushing, which clears intrusive salt water with increasing fresh water flow tends to be a slow process as it depends on sea water entrainment by the fresh water, and there may be large volumes of sea water within the system.

Thus in most outfall configurations the intrusion process takes the form of a hysteresis loop, with an established intrusive condition persisting to fairly high flows, but once cleared, not starting again until a very low flow occurs. This is illustrated in Figure 5 where the total head loss through the outfall system is plotted against the total discharge. With intrusion the head required to discharge a given flow through a reduced number of ports is greater than it is without intrusion and discharge through all the ports.

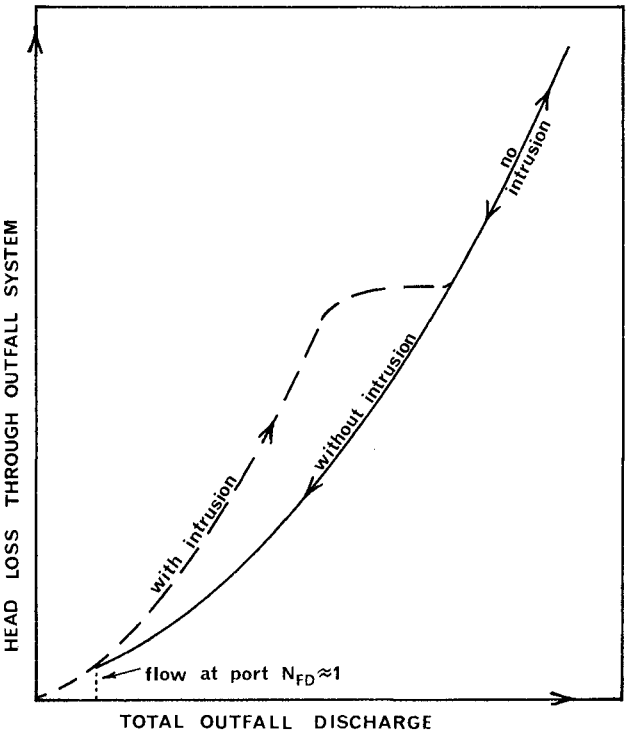

Figure 5 Diagram showing the effect of sea water intrusion on the head loss in a complete outfall system.

A number of factors may raise the commencement of intrusion above the nominal Densiometric Froude number unity condition. Wave action generating attenuated sea bed pressures will trigger this process, and varying levels of outlet port (usually due to sea bed slope) will generate unequal flows in tunnel diffuser risers at low flows. This latter condition will prematurely lower the flow in some outlets and make them vulnerable to intrusion.

6. THE SUSCEPTIBILITY OF OUTFALLS TO INTRUSION

By their very nature all outfalls are susceptible to intrusion to some degree at low flows. However some designs are more resistant than others. For example the configuration in Figure 2iii is almost proof against intrusion. Types b and c have proved to be most vulnerable as the flow needed to expel all sea water is often very close to their maximum discharge.

Outfalls which operate over a wide range of discharge can be designed to function above the intrusive condition, and outfalls which operate at high efflux velocities are naturally protected.

7. THE CONSEQUENCES OF SEA-WATER INTRUSION

If intrusion and sea water clearance take place regularly due to cyclic flow variations, little harm will come to an outfall system. It is expected that a large number of outfalls operate in this fashion. However, if the clearance condition is only occasionally reached and intrusion persists for long periods, those areas of an outfall which contain sea water may become subject to marine growth and debris collection. This can eventually lead to blockage.

Often tunnelled outfalls are driven up-hill in a seaward direction for ease of construction drainage. When working under intrusive conditions stratified sea water will migrate downhill towards the landward shaft and obstruct the stratified fresh water flow. Sedimentation will thus be encouraged in the tunnel.

8. CONCLUSION

While saline intrusion may often occur in outfall systems, it may not be persistent and by its self regulating nature may go unnoticed. However,there are many outfalls whose performance is being restricted by the phenomenon.

This paper, while not giving the remedies, does aim to describe the intrusion process, in the belief that for designers an awareness of a problem is nine tenths of the solution.

When our current research programme is completed we hope to present working design criteria and designs that will enable designers to avoid, or minimise,problems that might be caused by

saline intrusion.

Most of the observations made in this paper have come from hydraulic model investigations. While intrusion models are a new venture the principles on which they are operated are well proven, and prototype predictions based on their performance can be taken with confidence. We also have sufficient prototype case histories to back this confidence.

DRIFT CURRENTS OF CLEAN AND SLICK SEA SURFACES

Jin Wu[1]

1 INTRODUCTION

Drift currents near sea surface govern movement and dispersion of man-made discharges near the sea surface, and influence design, deployment, and stability of offshore structures. The wind-induced drift currents and the wave-induced mass transports at the sea surface are separately estimated. The total surface drift current, the sum of wind- and wave-induced components, agree well with oceanic data (Hughes, 1956).

The mass transport of waves over slick surface is greater than that over clean surface due to dynamic interactions between the surface film and waves. On the other hand, the wind-stress coefficient of slick surface is smaller than that of clean surface, resulting in a smaller wind-induced drift current over the slick surface. Available laboratory results (Alofs and Reisbig, 1972) on slick movements are reanalyzed to provide basis for estimating movements of slicks of various sizes over waves of different lengths under different wind velocities.

2 DRIFT CURRENTS OF CLEAN SURFACE

2.1 Experiments in Laboratories

A slow forward motion of water particles under surface waves was theoretically predicted by Stokes (1847). The so-called Stokes transport at the water surface, V_v, can be expressed as

$$V_v = \sigma a^2 k \tag{1}$$

where σ, a, and k are the radian frequency, amplitude, and wave number of waves, respectively. Experimental observations of (1) were provided, among others, by Lange and Hühnerfuss (1978).

Studies on drift currents in a wind-wave tank have been conducted by Wu (1975). The difference between measured total drift current and estimated Stokes transport was considered as the wind-induced current. The wind-friction velocity was suggested (Wu, 1975) as the proper parameter for correlating this wind-induced component,

$$V_n/u_* = 0.53 \tag{2}$$

where V_n is the wind-induced surface drift current, and u_* is the friction velocity of the wind.

[1]Professor of Civil Engineering and Marine Studies, University of Delaware, Newark, Delaware 19711.

2.2 Estimations for Field

The Stokes surface transports at various fetches under different wind velocities can be obtained from (1) with wave data reported in Wu (1969),

$$V_v/U_z = 0.0186\ (gL/U_z^2)^{0.03} \qquad (3)$$

where g is the gravitational acceleration, L is the fetch, and U_z is the wind velocity at the elevation z above the mean sea surface.

In the meantime, the wind-induced shear current can be obtained from (2) with empirical wind-stress (Wu, 1980) and wave-drag coefficients. Combining wind- and wave-induced components, the ratio between the total surface-drift current and the reference wind velocity (V/U_z) decreases with increasing fetch at short fetches, and is independent of fetch at long fetches. The total surface drift current is about 3.1% wind velocity at very long fetches.

2.3 Comparison with Other Results

From the equilibrium wave spectrum (Phillips, 1977), Bye (1967) obtained an expression for the Stokes surface transport. Accepting the value of the spectral coefficient suggested by Longuet-Higgins (1969) for the open sea, we obtained from Bye's expression: $V_v/U_{10} = 0.0274$. This is in fair agreement with the present estimate of the mass transport. More recently, the spectral coefficient was found to vary with both fetch and wind velocity (JONSWAP). Coupling these results with Bye's expression, the mass transport at the sea surface decreases with fetch and increases with wind velocity, having the same trend as the present estimate.

An expression similar to (3) was proposed by Kondo (1976). The surface mass transports calculated from Kondo's and the present expressions for U_{10} = 10 m/s at various fetches are shown in Table 1. In comparison with the present as well as other results, such as those discussed above, Kondo's estimate appears to provide rather low values.

Fetch (km)	10	50	100	500	1000	5000
Kondo (1976)	1.63	1.68	1.70	1.75	1.77	1.82
Equation (3)	2.29	2.40	2.45	2.57	2.63	2.95

Table 1. Ratios (%) Between Estimated Surface Mass Transport and Wind Velocity for U_{10} = 10 m/s.

The drift currents at the sea surface were measured by Hughes (1956) with plastic envelopes floating close to the water surface. He found that the water within 1 cm or so of the surface drifted parallel to the wind. The drifting speeds of plastic envelopes were about 3.1% of the wind velocity. This value coincides with the present estimate.

3 DRIFT CURRENTS OF SLICK SURFACE

3.1 Increase of Surface Mass Transport

Experiments have been conducted by Alofs and Reisbig (1972) to investigate wave-induced drifts of simulated oil slicks in a wave tank. Floats made of

thin, flexible plastic sheets of various sizes were laid on the water surface before the experiment, and were found to conform with the wavy surface. The drift of floats due to waves, verified to be very similar to that of oil lens, was measured with waves of two different lengths and various steepnesses. For each experimental condition, we obtained an equilibrium drift velocity V_{max}, at which the drift current no longer increased with the float length, ℓ. Inasmuch as the mass transport over the clean surface in Alofs and Reisbig's experiments was found to be greater than V_v, we determined the additional movement due to the presence of float from $V_{max}-V_o$, where V_o is the velocity of the "float of zero length" found by extending their results obtained with floats of various lengths to $\ell = o$.

As discussed earlier, the leeway between the transports of slick and clean surfaces increases with the film length, and the maximum leeway is produced by the film with its length approaching the wavelength. Consequently, when the ratio between the measured and the maximum leeways is plotted versus the ratio between the float and the wave lengths, the movements of floats over waves of not only various steepnesses but also various lengths can be incorporated with a nondimensional relation expressed as

$$(V_f-V_o)/(V_{max}-V_o)=1-(3/4)\ \log\ (\ell/\lambda) \quad \text{for } \ell/\lambda < 1$$
$$(V_f-V_o)/(V_{max}-V_o)=1 \quad \text{for } \ell/\lambda < 1 \qquad (4)$$

where V_f is the measured float velocity, and λ is the wavelength.

The floats of monolayers were used by Lange and Hühnerfuss (1978) in their experiments. The length of floats was longer than the length of waves tested (20 cm < λ < 70 cm). They found no streaming effects with the drift velocity of floats following very closely the Stokes surface transport.

3.2 Decrease of Wind-Induced Surface Currents

Effects of the monolayer upon the wind structure have been studied in the field by Barger et al. (1970). Vertical wind profiles were measured over clean and slick surfaces, and were verified to follow the logarithmic distribution,

$$U_z/u_* = (1/\kappa)\ \ell n\ (z/z_o) \qquad (5)$$

where κ is the Karman universal constant, and z is the roughness length. Values of z_o and u_* for both the clean and slick surfaces were obtained by Barger et al. The presence of monolayer causes damping of small waves; consequently, the roughness length was drastically reduced. The transition of the wind boundary layer, therefore, occurred at a higher wind velocity, approximately 6 m/s. Below this wind velocity, the roughness length of the slick surface is about the same as that of the clean surface. The similarity in roughness lengths for clean and slick surfaces at high wind velocities is believed to be due to disruption of the surface film by wind.

As expected, the variation of the wind-friction velocity has similar features; for the same wind velocity the friction velocity for the surface covered with monolayers is much greater than that for the surface without.

Before the disruption of the monolayer, the wind velocity for the surface covered with the monolayer is about twice that for the clean surface having the same friction velocity. Because the wind-induced drift current is proportional to the wind-induced surface drift current, the wind velocity for the slick surface is, therefore, about one-half that for the clean surface.

No similar study has been reported with wind blowing over water surface covered by oil slicks.

LOCAL WIND FORCING AND SMALL SCALE UPWELLING

Cairns A.R. BAIN*

ABSTRACT

This study characterizes some wind stress effects on a coastal site which is a focus of small scale upwelling having a scale of the order of 10 km. Two time scales are considered. Firstly the seasonal character of wind stress with the associated sea temperature fluctuations is described. Secondly individual wind events of a few days duration are characterized by extent and rate of upwelling and offshore displacement of the thermocline front. Data on the thermocline displacement is fitted to Csanady's model of coastal upwelling, which leads to the prediction of upwelling parameters for given wind events.

INTRODUCTION

The occurrence of coastal upwelling induced by favourable alongshore winds is well known off Oregon, Northwest Africa, Peru and in the Southern Benguela region, (Huyer 1974); (Barber 1977); (Walsh 1971); (Andrews 1980). These upwellings are on a scale of 100's km alongshore and several tens of kilometer offshore. Less well known are the small scale localized upwellings with a length scale of about 10 km. These small scale upwellings are the result of orographic effects and changes in coastline orientation. Such sites are often embedded in the large scale upwelling regions, and have also been studied in the Great Lakes, (Csanady 1980) and in Gulf of Lions (Mediterranean), (Millot 1979).

Airborne radiation thermometry (ART) surveys have revealed several such areas of intense upwelling along the Cape Peninsula and adjacent west coast of South Africa, (Andrews 1969); (Bain 1976). The study site is a strong focus of localized upwelling with a scale of the order of 10 km^2 just north of the Melkboschstrand headland some 30 km north of Cape Town. (Fig. 1) Eight km north of Melkbosch is the site of South Africas first nuclear power station. A considerable amount of oceanographic and meteorological data has therefore been collected for this site (Loewy 1976) over several years by the Electricity Supply Commision of South Africa (ESCOM). This data provided an essential backup to the work reported here, which forms part of a more comprehensive study of wind stress effects on oceanographic parameters at the site.

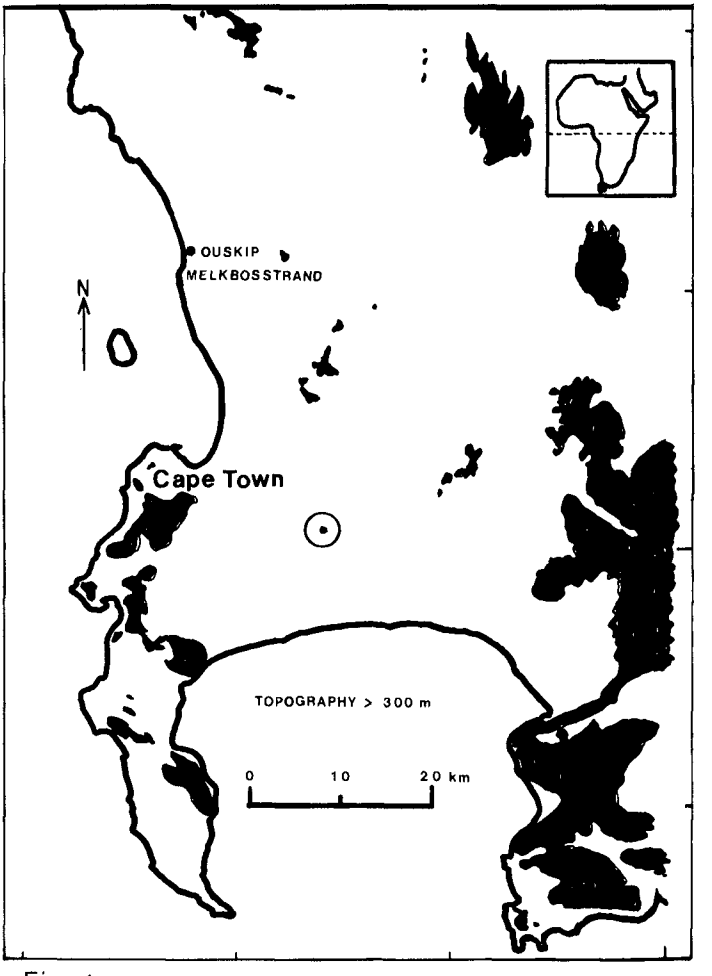

Fig. 1

In this report we discuss wind stress effects on two time scales. Firstly we characterize the seasonal wind pattern and the associated sea temperature fluctuations. Secondly we consider wind events of a few days duration, characterized by rate of upwelling and offshore displacement of the thermocline front. This displacement is compared with Csanady's model of coastal upwelling.

Factors about the site that are relevant to this report include: its position in the temperate zone which is subject to seasonal variations in the wind field as the semi-permanent south Atlantic anticyclone follows the solar incident. During summers, high pressure systems pass south of the country resulting in alongshore equatorward winds that are greatly influenced by the orography south and south east of the site. Strong thermal-diurnal mechanisms also feature at that time. In winter, low pressure systems skirt the southern corner of Africa and generate north-westerly onshore winds (Jury 1980). The temperature salinity properties of these coastal waters are such that temperature fluctuations are the main contributor to density changes and at a first approximation salinity changes can be ignored (Bang; 1973); (Gunn 1977). Temperature variations are therefore a good signature of upwelling processes in summer.

TECHNIQUES ANO OATA BASE USED

For the seasonal analysis use was made of ESCOM data. Their tabulations of hourly wind speed and direction at Ouskip (Lampbrecht anemometer situated on a tower ~ 20 m above sea level a few meters from the highwater mark) covering several years were coded for computer analysis. An ESCOM maintained sea tower one kilometer offshore in a depth of 11 meters was equipped with three temperature probes at 2 m, 5 m and 8,5 m depths. The temperature data was recorded continuously on a multipen chart recorder. A number of years of this raw chart data was digitized on an hourly basis and coded for computer analysis.

The event time scale study made use of the above data as well as bathythermograph temperature sections taken on a number of lines perpendicular to the coast and out to a distance of 6 to 10 km. The lines were run with a small ski boat with stations at 0,5 km intervals, on a number of consecutive days covering a wind event cycle.

There is a general lack of current data, particularly on a continuous time base. Lagrangian current trajectories and moored buoy current readings are available for the overall project but are not reported here.

ANALYSIS

The wind and temperature time series data were filtered with a twice applied 41 hour running mean filter (Chelton 1982) to suppress tidal and inertial oscillations and with a twice applied 23 day running mean filter (half power point of 50 days) to produce a very low passed time series. Simple statistical computations for standard deviations and

linear correlations between wind components and the different depth temperature records were computed for year long and seasonal sections of data.

The temperature section data was plotted and estimates made of the distance offshore that the thermocline intersected the surface to compare with (Csanadys 1977) model for full upwelling for a longshore wind impulse.

Assuming a two layer fluid with top layer having a thickness h_t and density ρ and the bottom layer having a thickness h_b and density ρ^1 the distance of the upwelled front from the coast is given by Csanady as:

$$Y_o = -R_i - \frac{I\, h_b}{f\, h_t\, (h_t + h_b)}$$

where $R_i = \frac{1}{f}\left(\frac{g\, \varepsilon\, h_t\, h_b}{h_t + h_b}\right)^{\frac{1}{2}}$, $\varepsilon = (\rho^1 - \rho)/\rho^1$

and I the wind impulse = $\int_o^{t_1} (\tau/\rho)dt$.

RESULTS

The study shows on a seasonal time scale that there are two major wind regimes. The southerly component dominates for on average about eight months over the spring/summer period, and the north component with a reduced amplitude dominates for about four months during winter. Fig. 2 for 1976 shows the main trends for very low passed filtered daily record but 1976 had a shorter than average winter regime and an anomously long duration northerly event at the end of November. Over a number of years the average duration of the transition between the summer and winter regime is only about 10 days; the winter to summer transition is longer about 30 days in duration.

The very low pass filtered temperature record shows a higher temperature during the winter months and generally lower temperature during the summer regime when active upwelling brings cold water to the surface. The 1976 data Fig. 3 shows this effect but also illustrates the marked rise in temperature during the anomolous onshore winds in November. In January 1976 the average monthly temperature was 10,7 ± 1,2 and 11,6 ± 1,3°C for the 8,5 m and 2 m depth probes respectively and in July 1976 the averages were 13,9 ± 0,9 and 14,1 ± 0,8°C for 8,5 and 2 m respectively. The mean annual temperatures for 1976 were 12,5 ± 2,0°C and 12,9 ± 1,9°C respectively.

The low pass filtered (41 hour running mean) time series for the wind data of 1976 Fig. 4 shows a good number of southerly wind events and only a few large northerly events. The associated temperature time series Fig. 5 shows a good correlation between temperature decreases during southerly (upwelling) events and increases during northerly or onshore winds. The temperature variability is most marked during the summer regime. A simple linear correlation between the N/S wind

component and the 2 m depth temperature low passed time series gave a correlation coefficient of 0,61 for January to April 1976 and of 0,11 for May and August. The significant correlation coefficient at the 95% confidence level is about 0,13. The explanation for the non significant correlation during winter is that the site, embedded in the larger scale Benguela upwelling region, has a more homogeneous water mass close inshore with the cold waters displaced offshore. In contrast during the summer regime, primed by the larger scale effects, stratified water comes close inshore and oscillates with the Ekman forcing of the wind event cycles.

The rapid responce of the thermocline to the onset of a wind event is shown in the bathythermograph temperature section data for 16 February 1978, Figs. 6 and 7. For the two days prior to these measurements the wind was light westerly veering to northerly causing the thermocline to be flattened. By the early hours of the 16th the wind had backed to strong SSE and veered to strong SSW at the time of the measurements. Within a few hours the 13°C isotherm is seen to be displaced a few kilometers offshore. In order to make comparisons with Csanadys model, events were chosen that had an initial sea condition approaching the ideal two layer system, followed by a wind impulse that lifted the thermocline. Table 1 shows reasonable agreement obtained between the theory and field observations.

CONCLUSIONS

The study characterizes the wind stress and sea temperature response on a seasonal and event basis for a small scale coastal site. The displacement of the thermocline front from the coast is predicted for some wind conditions by the Csanady model. In the more comprehensive project of which this report forms part other aspects of Csanadys model including double wind impulses and current response are investigated. Initial rotary spectral analysis of the time series data indicate further potentially useful information for this small scale site. Useful 'edge effect' information for correlation with the much larger scale investigation of other workers of the Benguela upwelling program is obtained. Mans impact on the ocean occurs chiefly at the coast. The results of the complete study will provide needed background for both biological studies in the nearshore environment and dispersion studies of ocean outfalls and thermal water releases from power stations.

ACKNOWLEDGEMENTS

MARINE PIPELINE PROTECTION WITH FLEXIBLE MATTRESS

Alan D. Crowhurst

Maccaferri Gabions, Inc.

Williamsport, Md. USA

Abstract

Development of oil and gas fields offshore presents new problems in the design of the civil engineering works since in many cases little is known about prevailing conditions on the bed of the sea over the considerable lengths involved. Movement of pipelines after construction, is, therefore, not uncommon and may result in the failure of the line. Consequent losses can be considerable.

Pipelines are also vulnerable to mechanical damage by anchors and by fishing activities, the latter giving rise to political problems where the pipelines are laid across existing fishing grounds. To give protection to oil and gas pipelines as well as to marine outfalls and cables a method of protection has been developed using the well known concept of rock filled wire mesh or gabions.

To adapt this method to use in underwater works another well proven material, sand mastic asphalt, has been combined with the gabion mattresses to give the required qualities of strength, durability, flexibility together with sufficient weight to restrain movement in the pipeline.

INTRODUCTION

Although pipelines have been built in the tidal zone and for short distances offshore for many years, earlier work has been largely in the sewage disposal and cooling water outfall sectors. In works of these types failures, although serious, are generally capable of repair by conventional means.

Offshore pipelines for oil and gas transmission have now been laid in much deeper water and for many miles at considerable depths. In addition, in areas such as the North Sea, work can only be carried out for a few months per year and failures therefore become extremely serious even before production losses are calculated.

Sea bed conditions over the lengths of these new pipelines are by no means uniform or consistent, nor is survey information as complete as the designers would like. Over undulating terrain pipelines laid on the surface may well bridge across many of the valleys.

Strong currents can lead to major movements of pipelines while in service, unless suitably anchored, and can also give rise to vibrations which may shorten the life of the pipes. Similar protection methods used to anchor pipelines may also be employed to protect against mechanical damage by trawls or by dragging anchors. Since pipelines may cross valuable fishing grounds it is necessary to ensure that these protective measures do not cause additional damage to the trawls and nets.

Although more familiar as a river defense system the use of wire-enclosed riprap, gabions, has been adapted to marine structures of many types. The main change is the addition of a PVC sleeve to the galvanized wire mesh to give resistance to corrosion in salt water. Gabions have been pre-filled and used for outfall protection, jetties in inshore waters and various coastal defense projects worldwide.

A method of protection and anchorage has been developed known as the Sarmac mattress which combines this ancient and well proven gabion method of construction with sand mastic asphalt grout to give a dense yet flexible mattress capable of being placed over a relatively small diameter pipe without failure. The units can be made with sufficient length on either side of the pipeline so as to give considerable protection against scour since they fold down to accommodate changes in bed levels over the service life of the pipeline.

Considerable care has to be taken in the design of the sand mastic asphalt mix since the required flexibility may have to be maintained over a large temperature range between that at the assembly yard and that at laying depth.

Methods of placing are also critical in view of the high cost of employing divers. For a recent project in the Mediterranean special lifting frames were developed by the subcontractor, Ing. Sarti Giuseppe S p A of Ravenna. This enabled placing to be carried out in deep water by remote control methods using a remote control vessel guided by television cameras. To date Sarmac mattresses have been placed satisfactorily at depths of up to 600 metres.

MATERIALS & METHODS

With the introduction of the Sarmac mattress into the offshore pipeline protection inventory there has been an interesting combination of ancient and very modern methods of construction.

Gabions are of considerable antiquity having origins in military uses several centuries ago and, it is thought, in hydraulic works in China, much, much earlier. Of course these early gabions were not made with metal but used wicker work filled with stones, soil and turf. From these origins gabions were developed using steel wire in the form of cylinders of mesh, filled with rock, used for emergency river protection. Later it was realized that it would be possible to manufacture the gabions in rectangular form thus enabling much larger and more uniform structures to be built.

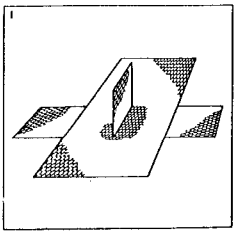
A further development came in the use of woven mesh with a double twist for added security. From these rectangular forms were developed mattresses which were simply gabions with thicknesses relatively small compared with their length and width. Galvanized wire may have a limited life expectancy in highly corrosive conditions and the addition of a PVC sleeve extruded onto galvanized wire enable the mesh to be used in coastal and offshore locations.

For use in the tidal zone investigations have been carried out on the use of PVC coated woven wire mesh mattresses used as continuous revetments by a number of researchers in Canada, Australia and elsewhere, (2), with generally favorable results. In one case design rules have been formulated giving equations for eventual failure by downslope sliding, buckling and uplift (3).

For sloping revetments wire enclosed riprap or mattresses are not normally laid at inclinations greater than IV to 2H or 26° where downrush waves limit the stone size. This has been described by Stephenson who has listed comparisons with rounded rock, angular rock and also concrete units (4).

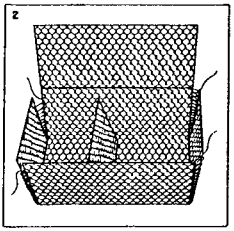
Proprietary concrete block systems have been tested in the wave zone along with other "low-cost" systems including gabions and mattresses in a comprehensive study by the U.S. Army Corps of Engineers (5).

FIGURE 1



GABION BEFORE ASSEMBLY

FIGURE 2



ASSEMBLY OF GABION

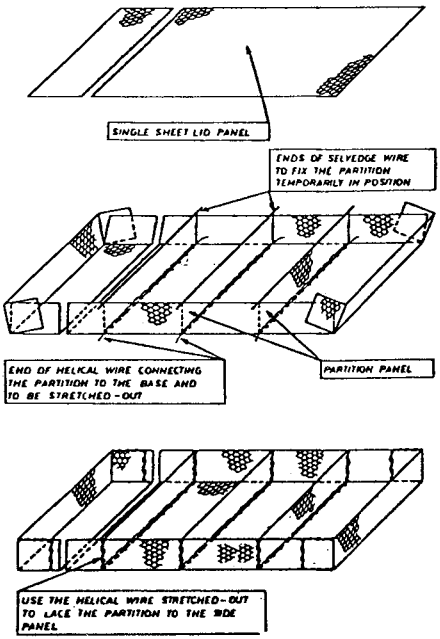


FIGURE 3 MATTRESS TYPE GABIONS

At one location, Ninilchik, in Alaska the gabions were filled by means of filter cloth bags which were themselves filled with a combination of beach gravel, cobbles and concrete rubble. However both this structure and a second at Kotzebue also in Alaska had a rock riprap toe protection which was displaced during the test period. In general this is not a good practice since the riprap can be thrown against the mesh causing damage. However the report on these trials and a third at Oak Harbor, Washington was very favorable.

Gabions and mattresses have also been used for many years to form groynes as a method of countering beach erosion in the United Kingdom, Italy and elsewhere (3). Sand mastic asphalt grouted riprap groynes have also been used with limited success in some locations but giving rise to problems when extended beyond the low water mark (6)(7).

These materials have been combined in revetments and groynes for coastal defenses and have been suggested for a number of related uses such as offshore breakwaters or headlands.

The use of pre-filled gabions for underwater structures had been developed over many years from the original use of cylindrical gabions to fill breaches in river defenses and scour holes around bridge piers and in similar emergency situations.

It was soon realized that modern rectangular gabions could be used in a similar fashion and gabions have subsequently been used pre-filled to form many types of structures (Fig.4). Examples included a large landing stage or jetty at Pula Langkawi in Malaysia, sea walls in Helsingfors Harbor, in Finland (Fig.5). A structure was built some five or six metres high to provide a quay for dhows at Ruweis in Qatar, the gabions having been pre-filled out in the desert and trucked to the site.

These structures employed cranes to place the units either from dry land or pontoons or barges but in recent years placing has even been carried out using helicopters.

However for offshore structures of some size other methods were adopted with gabions wired together into the form of a raft constructed above low water mark and subsequently floated into position using buoyancy supports of several types. Several outfall structures handling cooling water from nuclear power stations were so protected.

While methods of placement for standard gabions were being developed similar attention was being paid to enable Reno or Revet Mattresses to be pre-filled for placing underwater in river and canal projects. Although lifting frames similar to those used for placing filled gabions were employed, other methods were also initiated. These included launching from pontoons which at first were simple fixed decks (Fig. 6).

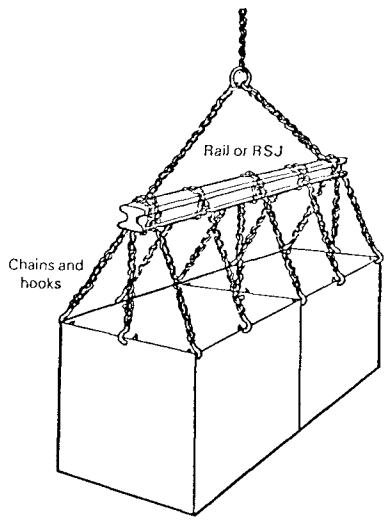

FIGURE 4
SIMPLE LIFTING METHOD

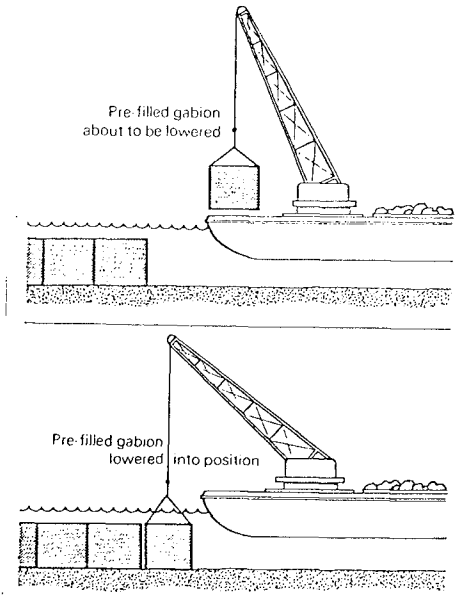

FIGURE 5
PLACING GABIONS BY CRANE

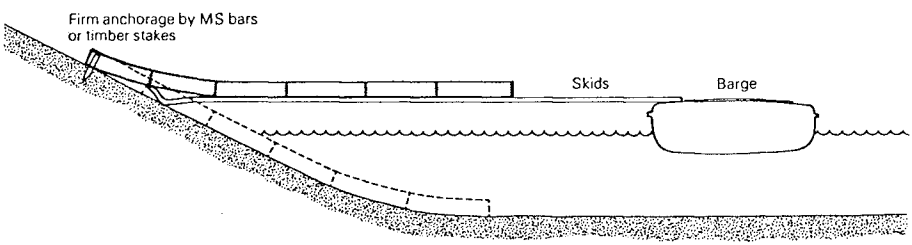

FIGURE 6

PLACING PREFILLED MATTRESSES FROM A SIMPLE PONTOON

Pontoons were then developed with tilting decks upon which mattresses could be built and then launched, the inshore ends being securely anchored to the bank.

This form of bank protection was also used in areas where impermeability was necessary. For this purpose, of course, gabion mattresses were unsuitable if used alone.

The addition of a sand mastic asphalt grout provided the necessary impermeability whilst retaining the essential flexibility of the revetments.

The use of pre-filled and grouted mattresses for underwater applications where construction in the dry was not feasible employed pontoons as developed for regular mattresses with the grouting operation actually carried out with the mattresses already in position on deck. When used with a grout the thickness employed could be reduced for some structures.

Pre-filled mattresses could also be placed by crane when grouted with sand mastic asphalt since the stone fill was held in place by the grout and not permitted to fall to the bottom of each cell as would happen if an ordinary mattress was so lifted (8)(9)(10). For offshore works gabion and Reno Mattresses had been used frequently since methods of placing were relatively expensive requiring the use of divers in many cases.

However protection was given to the cooling water outfall at a nuclear power station on the southern coast of England using a raft of Maccaferri Gabions floated into position and then lowered around the mouth of the outfall which was built in tunnel out from the power station, but this method was not applicable to most types of undwater structure.

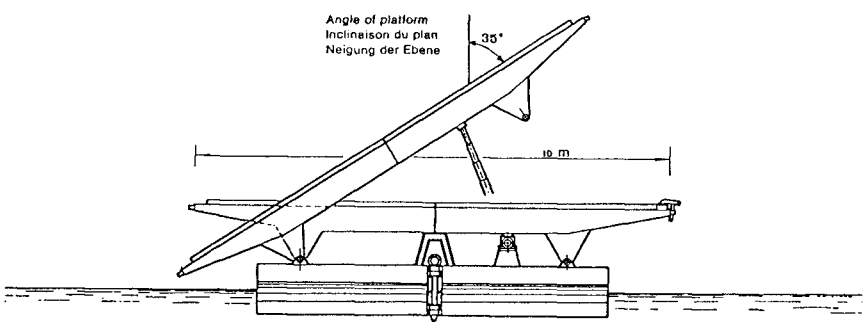

FIGURE 6

SAND MASTIC ASPHALT

Sand mastic asphalt has been used increasingly in gabion and mattress structures of various types ranging from canal linings, power station outfalls, protection of the upstream face of earth dams and for spillways. When used for canal linings the combination of the two products, gabion and sand mastic asphalt, enabled considerable reductions in thickness to be made in some cases. The design of the sand mastic asphalt mix varies according to the required design characteristics. Information on such applications is well documented (11).

TABLE 1 WEIGHTS OF GROUT

SARMAC MATTRESSES

From these origins was developed the Sarmac mattress which combined the strength and flexibility of the Reno or Revet Mattress form of construction with the addition of the weight and impermeability given by the addition of the sand mastic asphalt grout and while retaining the necessary flexibility of the mattress concept.

When used for hydraulic structures such as river and coastal defenses, dams and canals the design of the mastic asphalt mix was subject to rather less vigorous constraints than when applied to the Sarmac technique. It is only necessary that the asphalt can penetrate and flow through the gabions or riprap to the design depth and remain in place without further movement should ambient temperatures increase from those experienced during the construction period. The range of temperature during which such grouting takes place and to which the completed works are exposed is usually well documented and the range not too great to make additives necessary. When mastic grouted mattresses are placed from pontoons or by crane their thicknesses are relatively small and flexibility remains good.

With the new possibilities presented by the construction of offshore pipelines of considerable length and size, the techniques described in the preceding paragraphs were combined to give a material with the require characteristics and, as important, the ability to be placed economically at considerable depths.

At the design stage of such pipelines it has often been necessary to place reliance on climatic data and tidal information from available sources which was not always comprehensive enough for the purpose. In particular, although information might well be applicable for surface conditions, this did not apply to those existing on the sea bed where strong currents could be met. These could result in scouring around and under pipelines laid on the surface.

As a result of such scouring action pipelines may well become entirely unsupported and this can even occur where initial construction was as buried pipelines. The resulting effects arising from unsupported lengths on fatigue life have been assessed in a number of studies(1).

Experience gained in the design and construction of pipelines has resulted in the development of a method of both anchoring and protecting such pipelines. The method was also capable of use in the construction of supports under the pipes which could thus reduce the length of unsupported spans and could reduce vibratory effects.

Since the sea bed in the vicinity of the pipelines could vary considerably it was advantageous to develop the mattress used for its protection with capability to fold in service to adjust to the changing levels. Flexibility was also necessary to take up the curve of the pipe which could be as small as 500mm diameter.

Considerable weight was also called for in order to function as anchors and therefore the combination of sand mastic asphalt and gabions or mattresses already frequently used in combination in hydraulic structures of several types, was a logical development.

The Sarmac mattress was developed to address several of the problems experienced in the rapid construction of the massive net of oil and gas pipelines that now cross vast expanses of seas and oceans.

Reno or Revet Mattresses are used as the basis of a dense, flexible unit, using stone fill in the usual way but with stone size selected to permit the most suitable penetration by the sand mastic asphalt and to give the required finished weight. Choice of single or double thicknesses is made according to site conditions.

The sand asphalt mix is designed to give the required flexibility at the ambient temperatures in which it is to be placed, but at the same time must not be so soft as to deform or even flow during manufacture or transport to site. It is equally important that it should not become too hard thus losing flexibility in service and risking failure by brittleness. Since pipelines are currently being placed in conditions as diverse as the North Sea and the Indian Ocean, mix designs must be selected with care for each application.

	PENETRATION	R.& B. SOFTENINC POINT	DUCTILITY	VOLATILITY AFTER 5 HOURS AT 322° F
80/100 Pen	.314-.344	125 - 140°F	39,37 inch	0.5%
60/70	.234-.275	115 - 129°F	"	0.2%
40/50 Pen	.157-.196	124 - 136°F	"	0.2%

TABLE 2 BITUMEN SPECIFICATIONS

Having selected the correct mix design and thickness, overall dimensions are designed to suit the conditions of use, i.e. for mattresses used as protection against scour, as anchors where the pipeline is liable to move laterally, as deadweights to constrain the pipeline where it is not laid continuously on the ocean bed and as protection against mechanical damage.

For placing underwater in depths of up to 600 metres or more the use of divers to locate and place the Sarmac units may be impracticable or very expensive and methods have been developed by which the units can be located in position and released by remote control vessels whilst being monitored on close circuit television.

For such underwater structures temperature ranges are often even more restricted. Placing generally takes place during the warmer months although work was recently carried out on a project in Cumbria in North West England during a very cold period from November'81 to January '82 when the temperatures rarely rose above °Selsius and much of the grouting was carried out at much lower temperatures. This required that the temperature at the mixer was at or very near the maximum for the material in order that reasonable flows could be obtained in the very cold mattresses.

Earlier work had in fact been carried out by the French in Antartica many years ago and those experiences have been documented (12).

However initial studies were incorporated in projects sited in less intemperate areas and for the first full scale application this type of construction was used at points along the gas pipeline being built from Algeria to Italy which has 170 kilometres of its total length of 2500 kilometres on the bed of the Mediterranean. This project, which was initially proposed in 1971, was authorized in 1977 following negotiations between the Algerian authority SONATRACH and the Italian ENI company. Design work was carried out with the cooperation of both companies.

Across the Sicily Canal underwater construction was carried out by a consortium of Italian and Algerian companies under the title TMPC. However technical direction was the responsibility of SNAMPROGETTI. The depths at which pipes were laid in this sector exceeded 500 metres and the pipeline was divided into three separate lines for safety reasons.

The Sarmac units designed for this part of the project had overall dimensions of 4 metres by 3 metres. Each unit comprised two separate thicknesses of 200mm each giving an overall thickness of 400mm joined together with steel cables. Double twist mesh mattresses were used to give flexibility reinforced with steel wire ropes for lifting purposes. The units were wrapped in a non woven polyester filter cloth of weight 0.55 kilogrammes per square metre. Polyester was required as other fabrics are unable to withstand the temperatures at which the sand mastic asphalt is placed.

The total weight of the units was 12,000 kgs. or 1,000 kgs. per square metre and the specific gravity 2500 kgs. per cubic metre.

Manufacture took place at the SNAMPROGETTI yard in Trapani, Italy by the contractor, Ing. Sarti Guiseppe & Co. and then transported the short distance to the docks. Placing was made from the ship, Saipem Ragno 2, for most of the work.

The application for which the Sarmac units were required in this project was that of anchoring the pipes, by virtue of their weight, to the sea bed across areas where the bed was irregular.

A later use of Sarmac mattresses of similar size and construction but with overall thicknesses of 500mm is by Saipem in a British petroleum field in the North Sea. In this case the application is to protect one pipeline where it is crossed by new work and the total weight per unit and, of course, the specific gravity has been designed to be somewhat lower.

When the requirement is for thicker mattresses of the types used for Sarmac units, typically 40 or 50 cms thick, the composition of the mastic mix is much more difficult to design since the completed mattress must have excellent flexibility if it is to flex around small diameter pipes in deep water.

In addition the units may be manufactured in an area of fairly high ambient temperatures for placing in cold deep seas. If the required flexibility is not maintained, the unit could become brittle and not take up the required curvature in service.

To establish design criteria early experimental work was carried out in the United Kingdom by River and Sea Gabions, Ltd. but at an early stage the work was taken over by Officine Maccaferri S p A in Italy where there had been extensive work with sand mastic asphalt for a wide variety of hydraulic works.

This work proceeded jointly with Ing. Sarti Guiseppe with considerable assistance from Dr. V. Castagnetti of Industria Italiana Petroli of Genova. Much of this work was carried out simultaneously with the development of systems for use in the widening of the Suez Canal (13) (14)(15).

The experimental work not only concentrated on the design of the mix to achieve flexibility but also on completed thicknesses, density and application rates which were themselves variations on those already calculated and used in hydraulic works, see Table 1.

The Sarmac mattress concept also necessitated the development of methods to simplify lifting from the point of manufacture and transportation inland and by sea to the jobsite.

These were, of course, relatively minor problems since there was already a fund of knowledge based on previous uses of pre-filled and grouted mattresses and gabions. However placing underwater had previously involved the use of divers which was not impracticable when only a few units were to be placed in shallow seas.

For gas and oil pipelines the depths at which protection was to be carried out were such that effective diving time per shift would be very limited and costs accordingly very high. It was therefore necessary to develop underwater placing methods using remote control techniques and a lifting frame was devised which could be operated from a remote control vessel.

This has worked satisfactorily and has permitted relatively fast placing times although, unfortunately, detailed data remains confidential to the companies concerned.

A simplification of the construction technique, omitting both the filter cloth envelope and the lifting cables built into the body of the Sarmac units, has been employed for small scale pipeline protection in estuarial areas in the North Adriatic. These units, resembling the standard wire enclosed riprap mattresses used for river defenses, were grouted with a mix also being used to grout a riprap revetment several years old situated a few miles from the mixing plant. Since the application was close to normal water level, the range of temperatures under which the grouted mattresses were to be employed was very limited and the mix design was therefore not formulated specifically for that project.

It should be noted that few filter fabrics are suitable for use as envelopes for grouted mattresses since the melting point of most membranes is at or below the temperature at which the sand mastic is normally poured.

The final product, as used in offshore pipeline work, is very different to early underwater gabion structures such as that for a

nuclear power station in the United Kingdom where the gabions were assembled as a raft within Folkestone Harbor at a location between high and low water marks. The raft, supported by steel drums and fastened together by steel rails, was floated into position and sunk on top of the outfall position.

This type of simple construction has therefore evolved into a degree of sophistication not foreseen at that time but still offers a considerable scope for further development particularly in inshore areas and in the immediate vicinity of platforms where complex pipe layouts are to be found.

CONCLUSIONS

Use of these methods of construction to protect parts of the gas pipeline from Algeria to Italy and also a small application in the Magnus Project in the North Sea have shown the effectiveness of this method of construction. The experience gained in earlier underwater gabion work and in the design of sand mastic asphalt for hydraulic works has enabled challenges posed by the new applications to be met thus marrying old and very new techniques in the manufacture and use of the Sarmac Mattress.

SAN FRANCISCO'S SOUTHWEST OCEAN OUTFALL

by Y. Eisenberg[1], M.ASCE

and D. D. Treadwell[2], M.ASCE

ABSTRACT

The Southwest Ocean Outfall, with an overall length of 23,400 feet and a capacity of 450 million gallons per day, will be a major element of the Clean Water Program of the City and County of San Francisco, California, U.S.A. Offshore, the Outfall will cross one of the world's major active fault zones, the San Andreas.

Outfall construction started in 1981 and is scheduled to be completed by early 1985. The shoreward 3,000 feet is being built from a pile-supported trestle; offshore, the Outfall conduit sections will be placed using a barge designed and built specifically for the project. Oceanographic, coastal, geotechnical, and seismic conditions pertinent to design are presented along with discussions of specific Outfall design and construction features.

INTRODUCTION

The Southwest Ocean Outfall is part of an improved system of collection, transportation, treatment, and disposal of sanitary and storm wastewater flows for the City and County of San Francisco. After passing through a system of transport lines, treatment plants, and tunnels, these flows will reach the Outfall, where they will be dispersed at a diffuser section located in the Pacific Ocean approximately four miles southwest of Lake Merced (Figure 1). About 8,700 feet offshore, the Outfall will cross the San Andreas fault zone, one of the world's major active faults.

---

[1]Parsons Brinckerhoff, San Francisco, California.

[2]Woodward-Clyde Consultants, San Francisco, California.

The Outfall will be a single conduit composed of reinforced concrete pipe sections with an inside diameter of 12 feet extending about 23,000 feet offshore. The water depth at the Outfall terminus is about 80 feet. Throughout its length, the Outfall will be embedded in a trench excavated as much as 25 feet below the sea-floor. The design gravity flow rate of the Outfall system is 450 million gallons per day (about 700 cubic feet per second).

Starting in 1977, the project design team conducted various data acquisition and analysis programs (Belvedere et al, 1978; Treadwell et al, 1978; Murphy et al, 1979; Treadwell et al, 1980; Gilbert et al, 1981). The results of these studies were utilized in the planning, preliminary design, and final design efforts completed in late 1980.

The purpose of this paper is to describe the geotechnical, oceanic, coastal, and seismic conditions and their impact on the unique design features of this project. The first 18 months of Outfall construction are also described.

GEOTECHNICAL CONDITIONS

Prior to the studies and data acquisition programs associated with the Outfall project, very little information existed concerning geotechnical conditions offshore San Francisco. The offshore geotechnical investigations performed for the project included:

- surf zone borings using a truck-mounted rotary drill rig on a self-propelled shallow-water work platform

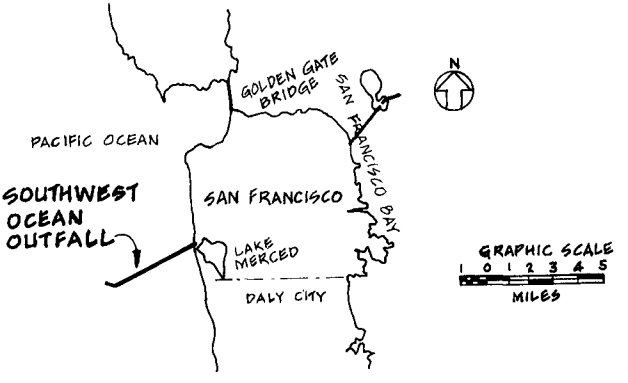

Figure 1 OUTFALL VICINITY MAP

- offshore borings, vibratory corings, and cone penetrometer tests using a specially-equipped and modified drillship
- marine geophysical surveys using an ocean survey vessel equipped with precision electronic navigation and fathometer systems as well as specialized seismic reflection, sonar, and magnetometer systems
- test pit construction and monitoring using a derrick barge clamshell dredge and an ocean survey vessel

Offshore Soil Conditions

The offshore soils along the Outfall alignment are primarily dense to very dense fine sands. Within the surf zone, extending to about 4,500 feet offshore, the seafloor generally consists of a loosely consolidated layer of sand 2 to 8 feet thick, underlain by hard clayey silts and silty clays. These cohesive soils are underlain by dense to very dense sands with occasional lenses of fine gravel.

A thin veneer of loose surface sands was encountered along the entire alignment. This layer is typically 2 to 4 feet thick, but in localized areas is as much as 6 to 8 feet thick. Beneath the surface layer, the sands increase in density with depth, from medium dense to very dense.

From about 11,000 feet offshore and westward, the surface sands are underlain by medium stiff to stiff, moderately overconsolidated silty clays which grade to clayey and sandy silts at greater depths. The top of the clays appears to vary from 15 to 35 feet below the seafloor, based on the borings and geophysical data. The relatively level surface of these cohesive soils apparently represents an ancient shoreline.

Offshore Faults

Offshore fault zones located in the project vicinity are the San Andreas, Pilarcitos, and Seal Cove (Figure 2). The latter were found to be westward of the Outfall, thus efforts were focused on defining the width and orientation of the San Andreas fault zone at the Outfall alignment.

Between the surf zone and the San Andreas fault zone is a series of tightly-folded, thinly-bedded sediments. These sediments may be correlative with similar outcrops seen on the shore. The limbs of the folds dip approximately 10 to 20 degrees; the fold axes plunge to the northwest, and the width of the geological structures decreases toward the fault.

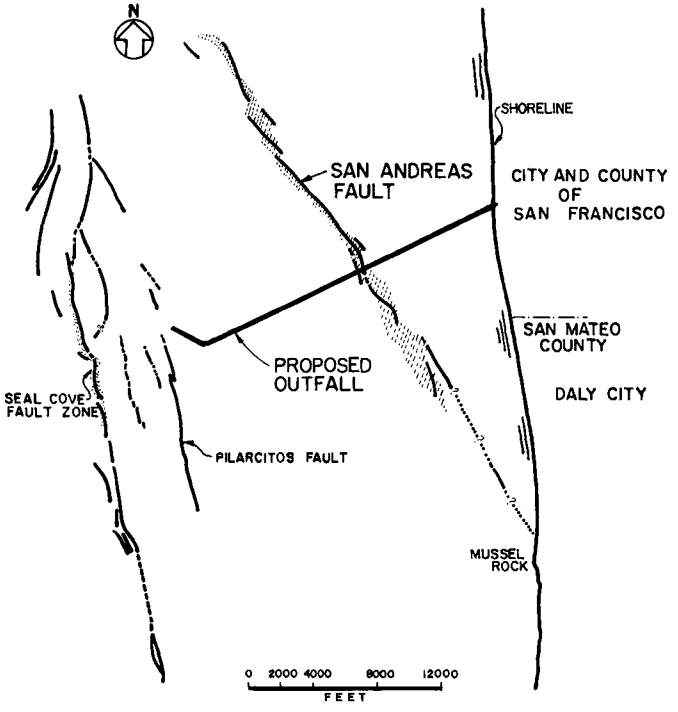

Figure 2 OFFSHORE FAULTS IN PROJECT AREA

In the vicinity of the Outfall alignment, the trace of the San Andreas fault is represented on the geophysical records by a blurred zone which does not show internal structure across the zone. This zone marks a transition between tightly-folded sediments to the east and relatively horizontally-bedded sediments to the west.

Along the Outfall centerline, the San Andreas fault zone was determined to be approximately 400 feet wide. The strike of the fault zone is approximately N39°W, which is 12 degrees west of perpendicular to the Outfall alignment.

OCEANOGRAPHIC CONDITIONS

A major factor in the design of the Outfall was the development of an understanding of the oceanographic conditions (e.g., wind, wave, current, tide, and water quality) likely to be encountered in the Gulf of the Farallones. These data were acquired and criteria developed through a variety of offshore sampling and analysis programs and reviews and evaluations of wave and storm records.

Monitoring Programs

A 13-month physical oceanographic monitoring program was conducted in 1977-78. Endeco current meters were installed and retrieved on a monthly basis from four fixed locations and two roving locations within the survey area (velocity and direction data were internally recorded every half hour by the meters). Density profiles and water quality samples were also taken on a monthly basis. In-situ measurements were taken of temperature and conductivity using an Inter-Ocean Model 513 CTD at selected depths and locations. The results of the measurements were converted to sigma-t (density) values.

Water quality samples were taken at selected locations and depths in the offshore project area. The water quality parameters analyzed were temperature, dissolved oxygen, conductivity pH, total coliforms, fecal coliforms, total suspended solids, settleable solids, turbidity, ammonia, nitrate, total phosphorous, chlorophyll, phaeophyton, and sulfide. The density profiling and water quality sampling programs were performed in cooperation with CH2M-Hill, Inc., the sanitary and hydraulic subconsultant to the design team.

On a less frequent basis, surface drifter and drogue studies were also performed. Surface drifters were plywood blocks painted a bright orange on both sides. Several drift block batches, from two to four in number (500 to 100 drift blocks each) were released in serial order during each drifter study. Ten-foot square windowshade drogues were also deployed, with releases during the three distinct

oceanic seasons, to measure current speeds and trajectories and eddy diffusivity.

Tides, Currents, and Wind

In the project area, tides vary over about an 11-foot range (about 8.05 feet above to 2.45 feet below MLLW), based on over 60 years of records at the Presidio tide gage near the Golden Gate Bridge. It is also expected that the sea level will rise about 6 inches in the 75-year design life of the Outfall.

Current velocity and direction were determined from the results of the oceanographic field data collection program. It was found that currents in the project area are dominated by the tidal influence and generally move toward the Golden Gate during a flood tide and away from the Golden Gate on an ebb. Currents greater than 1.0 knot occur less than one percent of the time.

Analyses of the current meter, drogue and drifter data indicated a net long term drift to the northwest (away from the shore). Winds are primarily from the west (toward the shore) and average 15 to 25 mph in warmer months and 10 mph in cooler months.

Waves

Determination of both normal and extreme wave conditions in the project area consisted of estimation of wave conditions offshore, in deep water, and transfer of these data to the nearshore. Extreme storm wave characteristics were developed based upon the selected design storm. The 8-hour design storm contained 3,141 waves with a significant wave period of 12 seconds; wave periods were expected to be primarily in the range of 7 to 14 seconds.

The design significant wave height at the diffuser location (80 feet of water) was predicted to be about 38 feet for the 100-year storm. For the 200-year storm, the significant wave height is expected to exceed 47 feet. The wave-induced currents at the seafloor are expected to be about 11 to 12 feet per second.

OUTFALL DESIGN

The Southwest Ocean Outfall is ultimately to be the terminus for all of San Francisco's sanitary and storm wastewater. Until recently, the existing combined wastewater disposal system caused severe pollution in San Francisco Bay and the surrounding shores. Every rainfall exceeding 0.02 inches per hour in intensity caused the system to overflow and discharge raw sewage into the Bay; on average, this used to happen about 80 times a year. The

Clean Water Program, of which the Outfall is an important part, is designed to remedy this condition.

The Outfall consists of a single 12-foot diameter pipe weighing about 3 tons per linear foot extending about 4.5 miles into the Pacific Ocean to a water depth of 80 feet. The Outfall's capacity is 450 million gallons per day by gravity; this capacity may eventually be increased to 590 million gallons per day by adding a pumping station. It is scheduled to be completed in the spring of 1985 and for the first 5 to 10 years will be utilized to only about 30 percent of its capacity, while the remainder of the system is completed.

The location of the Outfall was selected so as to carry the effluent into deeper water as quickly as possible within the otherwise relatively shallow continental-shelf. Also, the diffusers had to be placed at a sufficiently remote distance from the Golden Gate to avoid the likelihood of tidal currents carrying the effluent into San Francisco Bay.

The Outfall has been designed to resist or accommodate all environmental forces or displacements anticipated during the design life of the system. Where significant damage appears unavoidable, such as across the fault zone during a major rupture, provisions have been made to limit the extent of damage and to facilitate required repairs. Provisions have also been made to permit the operation of the Outfall system on an emergency basis during the repair period.

Seismic Design Criteria

The centerline of the Outfall lies across the San Andreas Fault, one of the world's most active and violent earthquake fault zones (Figure 2). Based on review of historical seismicity, a design Richter magnitude of 8+ was selected for the project with a peak ground acceleration of 0.6g, transient displacement of 20 inches, and a peak velocity of 30 inches per second.

Based on review of the famous 1906 event, it was concluded that the Outfall could be subjected to a relative horizontal displacement of 16 to 20 feet and a relative vertical displacement of 3 to 4 feet. Additionally, a relative fault creep movement of about 6 inches can be anticipated during the 75-year design life of the project.

Earthquake Joints

Conduit sections with special earthquake joints (Figure 3) will be placed longitudinally at 20 feet on center across the fault zone (400 feet) and the two bands on each side, a total length of 1200 feet. The earthquake joints were

designed to absorb the following anticipated transient forces and movements:

- o longitudinal pipe tension = 150 tons
- o total joint extension = 12 inches
- o total joint contraction = 5 inches
- o total joint deflection = 2.4 degrees
- o gasket pressure = 300 psi
- o internal water pressure = 10 psi

A joint consists of two neoprene gaskets sliding on teflon surfaces, the outer one being for testing purposes only. The locking device is made up of four Dywidag rods, fusion epoxy coated and encased in PVC conduit, with crushable closed cell urethane foam reinforced with nylon behind the rod washers. When the joint reaches its expansion or contraction capacity by crushing the urethane foam, it then transfers the force and movement through the pipe to the next joint, and then to the following joint(s) until the entire motion is absorbed.

Backfill Configuration

The backfill configuration (Figure 4) was designed to provide protection for the Outfall conduit for the design life of 75 years. The lowest layer of gravel (Type I) was selected to furnish proper bedding of highly pervious material providing rapid pore pressure redistribution during periods of earthquake-induced shaking and potential liquefaction. The second layer of gravel (Type II) is a graded filter course to minimize infiltration of the natural sands into the Type I backfill. The armour stone layers are for wave defense, with Type IV placed on top of Type III in the surf zone and diffuser areas only.

Diffusers and Manholes

At its outer extremity, the Outfall contains 85 diffuser units (Figure 5). Each diffuser consists of structural unit with a riser containing an 18-inch diameter conduit connecting the pipe invert to the diffuser riser cap which protrudes several feet above the seafloor. Each cap contains eight 4-inch diameter ports through which the effluent is diffused to the ocean. The risers are connected to the pipe bottom in order to minimize the likelihood of sediment accumulation and possible constriction of the pipe cross section and capacity. Surprisingly, the lateral forces caused by fishing nets dragged along the seafloor which may snag on the diffuser caps proved to be potentially far greater than the seismic

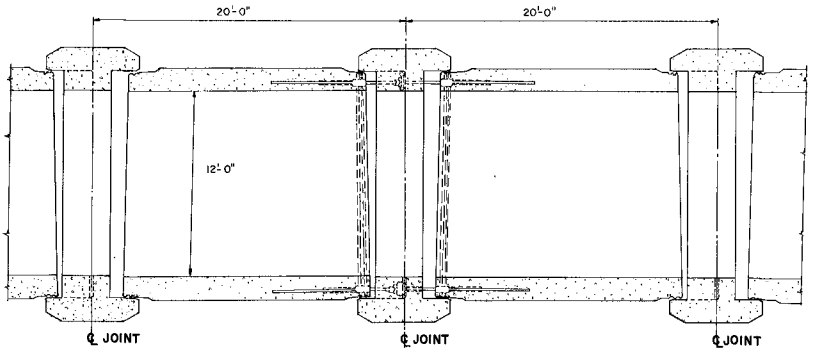

Figure 3 EARTHQUAKE JOINTS

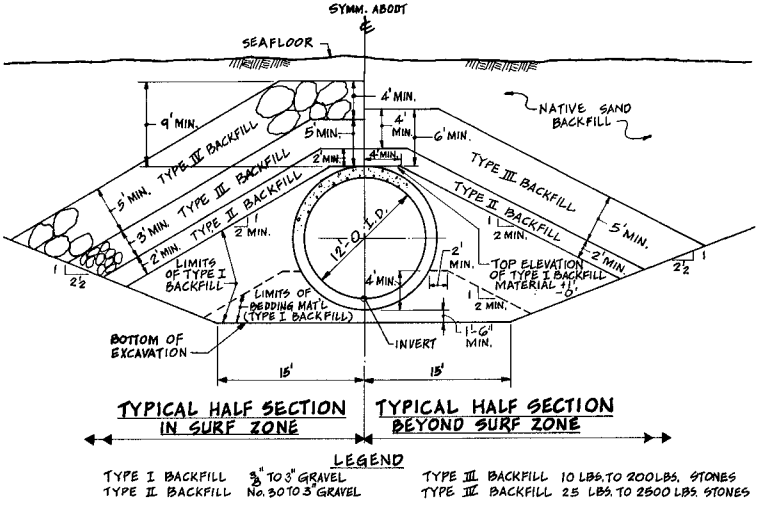

Figure 4 BACKFILL CONFIGURATION

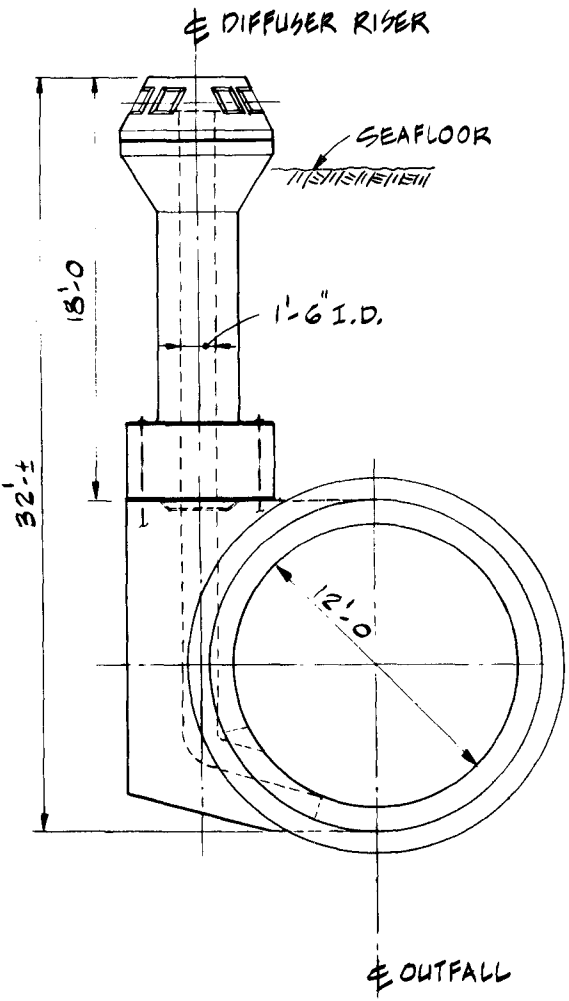

Figure 5 DIFFUSER UNIT

or wave forces and thus became the design load. Also, erosion or accretion of the seafloor in the diffuser area is not expected to exceed 3 feet in 75 years, based on historical records.

Access manholes were designed at a maximum center-to-center spacing of 500 feet. This spacing allows for the timely rescue of a tethered maintenance/repair diver inside the Outfall conduit. The manholes essentially consist of 42-inch diameter holes at the top of the Outfall pipe with reinforced concrete gasketed covers. A special marker is connected to the manhole cover and protrudes some 5 feet above the seafloor. The manhole cover is backfilled in a manner similar to the pipe itself. No access chimneys were designed to ease entry into the pipe, since it was felt that they were unlikely to survive the hostile seismic and wave environment. Access to the manholes will therefore require excavation and backfilling equipment in order to remove and later replace the backfill material above the manhole cover.

Emergency Features

Two emergency features have been incorporated into the Outfall design to respond to the possibilities of flows exceeding design capacity or a rupture of the conduit; these are the emergency overflow structure and several emergency diffuser units.

The emergency overflow structure consists of a 10-foot diameter pipe and spillway structure connecting the onshore headworks to Ocean Beach. It is anticipated that the emergency overflow structure would be used during rare periods of major flooding or in case the Outfall conduit should break near shore for any reason. The effluent discharge on the beach would continue until the flood flows abated or until repairs were completed.

Should a major slip occur along San Andreas fault zone in the project area, the Outfall conduit will almost certainly break. To mitigate the impact of this possibility, provisions have been made to excavate and expose two or more manholes on the shoreward side of the break, remove their covers, and then install emergency diffuser units (Figure 6). These units will act to diffuse the effluent about 1.5 miles offshore during the conduit repair operations.

OUTFALL CONSTRUCTION

The contractor has now (December 1982) finished the surf zone trestle (Figure 7) which extends about 3,000 feet into the ocean to a water depth of about 38 feet. The 32-foot wide deck of the trestle stands about 28 feet above the water. Its main supporting members are 24-inch diameter

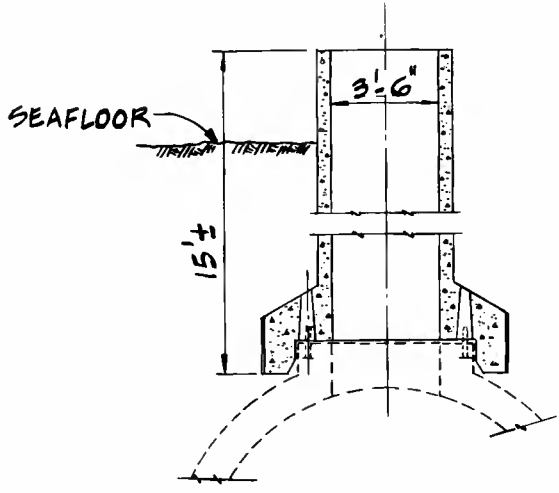

Figure 6 EMERGENCY DIFFUSER

Figure 7 SURF ZONE TRESTLE

pipe piles at 30 feet on center for the first 2,000 feet of trestle; 30-inch diameter piles were used for the outer 1,000 feet of trestle. The trestle carries tracks for movement of cranes, material carts, and a pipe laying gantry (Figure 8).

Surf Zone Construction

The Outfall pipe is presently being installed from the gantry in a protected trench (Figure 9). Ordinary interlocking sheet piles spaced 24 feet apart were used for the first four hundred feet; they were jetted and driven with some difficulty due to the hard material encountered just below the top loose sands. The contractor then employed three-legged wave barriers 20 feet long by 12 feet wide consisting of three pipes connected by steel plates with interlocking connections to the abutting wave barriers and weighing about 10 tons each (Figure 10). These are placed in position during relatively calm seas and pin piles are driven through the wave barrier piles to secure them in place. After the completion of the excavation, pipe laying, and backfilling in a given section, the pin piles are loosened and pulled and the wave barrier modules are transported to new positions (Figure 11). The present pipe laying rate is 2 to 3 units per day.

The pipe being installed from the gantry was produced in a pipe plant near the beach (Figures 12 and 13) and consisted of about 120 units weighing about 90 tons each. The other 900 or so conduit sections, including the special earthquake sections and the diffuser units, are being manufactured at Rio Vista, about 60 miles up the Sacramento River from San Francisco.

Offshore Construction

A 13,000 ton capacity barge (Figure 14) was built in Portland, Oregon specifically for this project at a cost of about U.S.$15 million. It was launched in mid-September 1982 and is presently being outfitted and rigged. It is scheduled to arrive at the site in early 1983 and to commence offshore operations beyond the end of the trestle shortly afterwards. The barge is 420 feet long, 98 feet wide and 25 feet high. It has a draft of 10 to 12 feet, depending on the weight of its cargo, and a 500-ton capacity crane with a 200-foot boom. Excavation, pipe laying, and backfilling will be performed off the barge at an anticipated rate of two pipe lengths (48 feet) during each 24 hour day.

ACKNOWLEDGEMENTS

The prime consultant for the Outfall is Parsons Brinckerhoff. Woodward-Clyde Consultants is principal subconsultant for geotechnical, seismic, coastal, and

oceanographic aspects of the project. Principal subconsultant for hydraulic and sanitary design is CH2M-Hill, Inc. Cost estimates and special studies on constructibility are provided by H. V. Anderson Engineers.

In addition to the authors, the project management team includes P. H. Gilbert and G. J. Murphy of Parsons Brinckerhoff, G. E. Hervert of Woodward-Clyde Consultants, and P. B. Hall and L. E. Hanson of CH2M-Hill, Inc. The special joint system was designed by Robert Warshaw of Parsons Brinckerhoff; the senior geotechnical engineer was the late O. H. Gilbert, Jr. of Woodward-Clyde Consultants.

Guidance concerning seismic design and constructibility of the Outfall system was provided by the Seismic Advisory Board. This panel of consultants, under the chairmanship of T. R. Kuesel of Parsons Brinckerhoff, included H. B. Seed, B. C. Gerwick, Jr., B. A. Bolt, and J. W. Johnson of the University of California, Berkeley, G. W. Housner and N. H. Brooks of the California Institute of Technology, and the late N. M. Newmark of the University of Illinois.

The contractor, Ocean Beach Outfall Constructors, is a joint venture headed by Morrison-Knudsen of Boise, Idaho. R. R. Vlach is project construction director and W. Hirvela is project construction engineer. Construction management services are being provided by Deleuw-Greeley-Hyman under the direction of George Kline.

The cooperation and assistance of L. A. Vagadori, R. T. Cockburn, A. B. Kenck, and W. Tsai of the Clean Water Program of the City and County of San Francisco was instrumental to the success of the data acquisition, engineering, and design programs. The efforts of the staff of the State of California Water Resources Control Board are also gratefully acknowledged.

SEDIMENT TRANSPORT INVESTIGATIONS IN A NEW ZEALAND TIDAL INLET

K.P. Black & T.R. Healy
Department of Earth Sciences
University of Waikato
Hamilton, N.Z.

ABSTRACT

A study of sand and shell movement under the action of tidal flow was initiated in 1980 to ascertain the suitability of Whangarei Harbour at Marsden Point, New Zealand, for a proposed timber port. The aim was to assess the effects such a development may have on the sediment fluxes and the potential shoreline and channel instability that might be induced in the sandy inlet system.

Vertical water velocity profiles were analysed to determine bed friction coefficients which were subsequently broken into two component parts: one due to form drag and the other associated with the skin friction. It was shown that the Vanoni and Hwang (1967) equation for form drag can be extrapolated to include drag under tidal flow over megaripples. The skin friction component was obtained from the speed at 1m above the bed and the D_{65} grain size, by utilising the Karman-Prandtl equation. This was applied to analysis of bedload trap yields and bedform advance rates over megaripples and good agreement with the Yalin bedload equation for plane beds was obtained.

Suspended sediment transport was found to vary with $U_1^{7.75}$ and total load rates were in general agreement with the Engelund Hansen equation but deviations occurred due partly to expected form drag components being out of phase with the flow because of bedform hysteresis. Under tidal flow, the velocity at 1m was found to be a better predictor of sediment transport than the shear stress obtained from the velocity profile, thus methods presented in this paper use the 1m speed for determination of total load transport.

1. WHANGAREI HARBOUR HYDRAULIC CONDITIONS

Whangarei Harbour (Fig. 1) at high spring tide has a surface area of 98 x $10^6 m^2$ (Millar, 1980) and a tidal prism of 186 x $10^6 m^3$. At low tide exposed banks cover an area of 46 x $10^6 m^2$. Currents in the harbour mouth, in depths which exceed 30m attain a maximum vertically-averaged mean speed of approximately 1.3 ms^{-1} during Spring tides. The channel floors are depleted of sand by these erosive flows and a shell lag lines the bed.

Two flood tidal deltas, Snake and McDonald Banks, possess a high order of stability and the former supports commercial quantities of cockle (*Chione stutchburyi*).

Mair Bank is an ebb tidal delta with several shell beds (Venus and Beazley, 1982) and much of the surficial bank sediment is discarded shell. The bank is protected from ocean wave activity by Busby Head to the east, with generally only E-SE storm waves reaching it with any significant intensity.

Wave activity inside the harbour is mostly locally-generated (fetch ~5km near the port site) although some ocean swell refracts (Black and Healy, 1981) and diffracts to reach the port vicinity (Fig. 1).

Two continuous-recording tide gauges are located in the harbour; one at Marsden Point near the mouth and the other at Port Whangarei in the upper reaches. Analysis of these records over a seven month period from June to December 1981 revealed that the ebb at the mouth has a shorter average duration of 6 hrs 9 mins compared with the flood average half cycle of 6 hrs 16 mins. Mean tidal range was 1.87m and minimum and maximum ranges were 1.17 and 2.80m respectively.

2. COMPLEMENTARY INVESTIGATIONS

General stability of the subtidal deltas and channels was revealed when bathymetric surveys along transects in the lower harbour and across the Mair Bank ebb-tidal delta in 1981 were compared with an R.N.Z.N. survey completed 20 years earlier (1959-61). A complete bathymetric survey by the R.N.Z.N. in late 1981 revealed the same trends. The region of most significant change was on the western end of Mair Bank where sand was accreting. The source for this is most likely to be Bream Bay which has been subject to erosion (Tonkin and Taylor, 1979).

As a first stage in the investigation, some 70 sea floor sites were colour photographed with a still camera (Black et al., 1981) and large areas of shell lag were revealed. Much of the shell was algae-coated signifying bed stability. The photography aided the interpretation and analysis of data collected throughout the study.

A side-scan sonar survey of the inner harbour and Mair Bank region was undertaken in early 1982 (Black and Healy, in preparation, b). The side-scan allowed identification of shell-covered areas and "active" bedload transportation zones which were evident from the megaripples and/or sandwaves on the side-scan traces. Active regions (Fig. 1) flank the main channel where it discharges into Bream Bay. Others occur at Marsden Point and north of Mair Bank; off Pt Sinclair on the south side of the main shipping channel; along the northern side of Snake Bank towards Darch Point then to the west of Reotahi Bay; and finally from the sub-tidal extension south-east of Snake Bank across towards Marsden Point. The last "pathway" runs across the proposed port dredge zone and has been studied in some detail. Other smaller and some less active zones are present. Extensive areas of the harbour bed are covered with shelly lag including a large expanse at the proposed dredge zone. A better understanding of the inter-relationship between these regions is gained in the light of 2-dimensional numerical model results (Black, in preparation).

3. MEASURED CURRENT SPEEDS

During a four year period full-tidal cycle velocity measurements were made at 54 sites. These were made at several levels above the sea bed every half hour for a 13 hour period. Sites are shown on Fig. 1 and some were measured twice. This very detailed field program provided an unusually comprehensive specification of the prototype hydraulic conditions.

Using a Braystoke BFM 010 MkII multiparameter meter, the speed, direction, salinity and temperature were recorded at each level. Distance from the sea bed was obtained with a built-in sounder and the meter was winched between levels. At some of the earlier sites, mean velocity was found over a 50s time interval, but to average out the longer period turbulent fluctuations (Dyer 1973; Heathershaw & Simpson 1978) more completely, the recording time was extended to 100 seconds after field tests revealed significant differences (10-20%) in the speeds for two consecutive 50 second intervals.

In obtaining the velocity profile, speeds were measured consecutively, e.g. the speed at an upper level was measured perhaps 15 minutes after the first level. Under normal operation the speeds were measured at each level at half hourly intervals. Parabolae fitted through three such measurements gave velocity-time curves over a 1 hour period at each level. Instantaneous velocity profiles were determined from these curves.

Without further measurements, turbulent fluctuations with periods of the same order as the measurement time can only be considered as random and as such they cannot be corrected for. Errors introduced by turbulence, which are an integral part of measuring speeds consecutively, must remain in the data. The longer measurement time reduces the scatter considerably.

4. VELOCITY PROFILES

It is well accepted that the Karman Prandtl (K-P) equation describes the velocity profile near the sea bed in the majority of cases for fully rough, turbulent tidal flow. Sternberg (1968) found that a logarithmic profile was evident 62 to 100% of the time over low topography (ripples, gravel and shell). The profile applied in the inner boundary layer, which in fully developed tidal flow is the region from the bed up to about 15-20% of the total water depth. Komar (1976) reported that the outer boundary layer can be described by a velocity defect law (UVDL) of the following form.

$$\frac{U_\infty - u}{u_*} = -8.6 \log_{10} \left(\frac{z}{d}\right) \quad \ldots\ (1)$$

U_∞ is the free stream speed, u is the velocity at distance z above the bed, u_* is the friction velocity and d is the boundary layer thickness.

The Karman Prandtl equation can be represented as

$$\frac{u}{u_*} = 5.75 \log_{10} \left(\frac{z}{z_o}\right) \quad \ldots\ (2)$$

where the constant, 5.75, includes the von Karman constant $\kappa = 0.4$ for conditions of low suspended sediment levels (Soulsby and Oyer 1981) and z_o is the roughness length. From equations (1) and (2), the friction velocity u_*, can be found by linear regression. The measured profile gradient on a semi-log plot is 8.6 u_* for the UVDL, and 5.75 u_* for the K-P.

The question arises as to whether the bed shear stress is represented in the body of the flow, under tidal flow conditions. Smith and McLean (1977) state that at great distances from the boundary the velocity field is related "to the overall boundary stress, that is to the boundary stress averaged over a large region of the bed, form drag on the topographic features thus being included". The Whangarei data strongly support this, and values of the drag coefficient are shown to be related to the bed configuration over sand boundaries with megaripples.

Many of the measured vertical profiles spanned the inner and outer boundary layers. It has been shown by Black and Healy (1982b, in prep.) that there is a measurable change in gradient from the inner to the outer boundary layer under tidal flow conditions. At several sites the velocity gradients in the inner layer (taken as 0-20% of the depth) and in the outer layer (taken as 15-100% of the depth) were determined. Although there was considerable scatter for individual profiles, over a tidal cycle the average gradients in the two layers were nearly in the ratio suggested by the UVOL and K-P law of 8.6/5.75. Programming was written to fit the K-P law to the inner layer and the UVDL to the outer layer, then to average the value of the friction velocity obtained from each. This average value was used to calculate the bed shear stress and drag coefficient.

$$\tau_o = \rho u_*^2 \quad \ldots\ (3) \qquad C_1 = \left\{\frac{u_*}{u_1}\right\}^2 \quad \ldots\ (4)$$

where u_1 is the speed measured at 1m above the bed and ρ is the water density. Data were not used if fewer than 3 speeds were recorded in either layer.

5. SEDIMENT TRANSPORT EXPERIMENTS

Six full tidal cycle sediment transport experiments were conducted at 3 locations of significance to the harbour sediment circulation (Fig. 1). Measurements were made of water velocities, and both bed and suspended load, while the sea floor was observed on an underwater video camera. A velocity profile (0.5, 1.0,

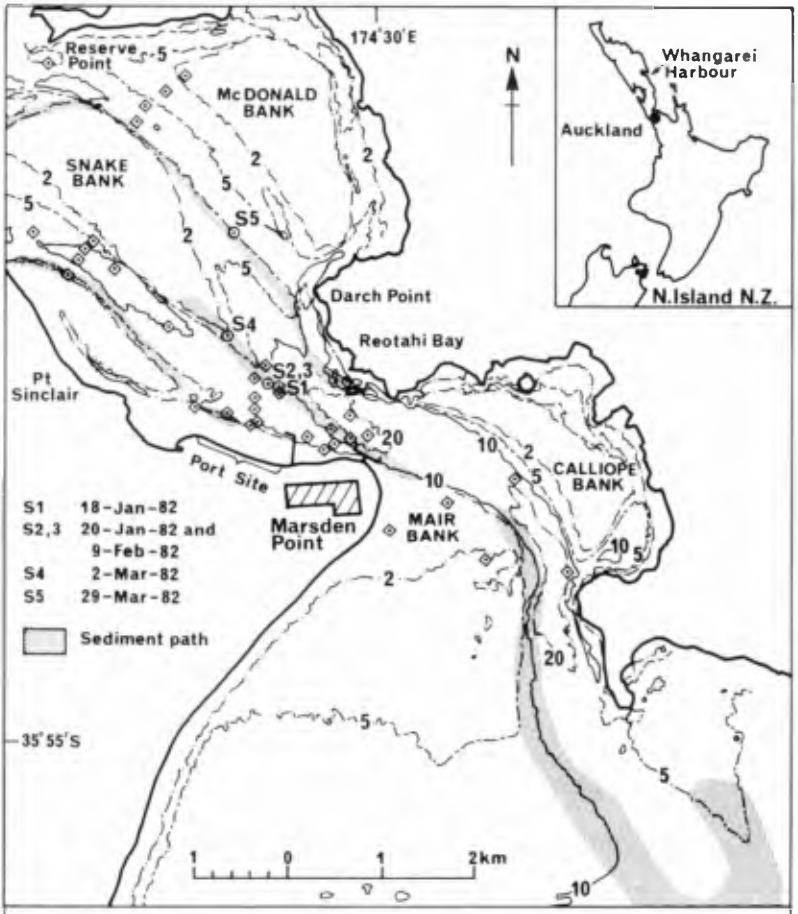

Fig. 1 Location of Whangarei Harbour, North Island, New Zealand and the field measurement sites. Active sediment transport paths are shaded.

2.0, 4.0, 6.0m above the bed) was recorded every half hour (e.g. Fig. 2). Speeds at 1m were measured every 15 minutes or more often on request during periods of interest on the video.

Bedload movement was obtained with two sediment traps of the VUV type (Graf, 1971 p. 363) and emptied every 1-2 hours. The trap is designed to be lowered by rope from the surface but experimentation revealed that a diver was needed to correctly align it on the bed, and to stabilise it in high flow on the way to the surface. Moreover to avoid sand being lost when the trap was raised, a door was fitted to the mouth which could be closed by a diver before retrieval. The traps have a rectangular mouth of size 260mm by 120mm.

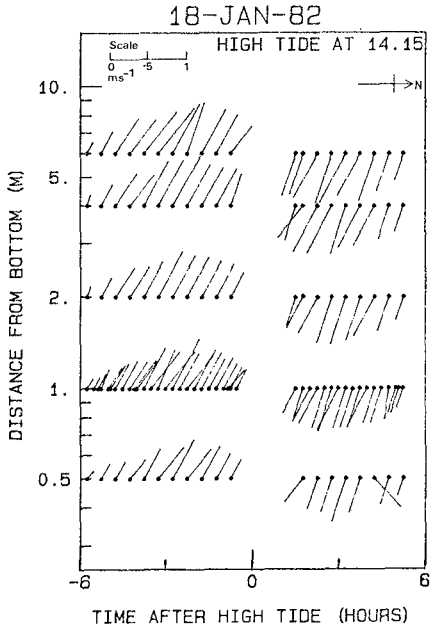

Figure 2: Velocities recorded on 18-Jan-82. True North is to the right.

During slack water, stakes were driven into the crests of 6 consecutive megaripples on the bed and crest advance was measured at the next two quiescent periods and during the tide.

Suspended load was sampled regularly at 0.1, 0.3 and 1.0m above the bed by pumping samples to the surface from nozzles mounted on a steel frame.

An underwater video camera mounted on a steel frame on the sea floor, supplied information on the sediment threshold, ripple advance rate and the behaviour of the sediment under tidal flow. Of the 6 experiments the video was used during the first two only.

6. SEDIMENT THRESHOLD

Of fundamental importance to the specification of sediment transport rates are the threshold conditions which initiate the movement of sediment. Many bedload equations use excess shear stress (Yalin 1963; Sternberg 1972; Bagnold 1963) and small errors brought about by inaccurate threshold conditions are magnified in the transport equations because of a high power dependence. For example, Gadd et al. (1978) modified the Bagnold equation to express the stream power in terms of the velocity at 1m. The bedload was assessed to be proportional to the cube of the difference between the water speed at 1m and the critical velocity.

A major difficulty associated with the determination of threshold in tidal flows is the effect of turbulent fluctuations. Sand moves in gusts, with sweeps and ejections (known as "bursting") occurring intermittently (Heathershaw 1974). When speeds are measured with an instrument such as the Braystoke to produce an average over a period of some 1-2 minutes, these high speed bursts are difficult to incorporate into the concept of a critical velocity. Grass (1970) defined a threshold by considering the overlap of the critical stress distribution associated with the placement of the grain on the bed and with the distribution of bed shear stresses due to fluid flow. Sternberg (1971) defined the threshold as a state of "general sediment movement". In tidal flow even at very low speeds there is still a chance of movement in a burst (Paintal 1971). Dyer (1980) interpreted the threshold as coinciding with the intercept of the regression line of sediment transport against water speed or friction velocity. A statistical approach is adopted in our paper.

6.1 Video Film Over a Sand Bed

The video tapes at Whangarei were analysed in a fashion similar to that undertaken by Dyer (1980). The film was viewed at 5 second intervals and a yes/no decision was made as to whether sandy sediment was moving anywhere in the frame of the camera (approximately a bed area of 12cm x 16cm). From

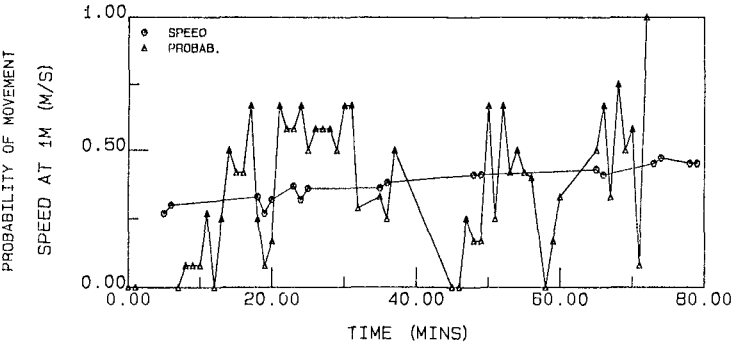

Figure 3: Sandy sediment threshold showing the probability that sand will move in a 1 minute interval with the speed at 1m, for 18-Jan-82 and based on analysis of video tapes.

12 consecutive answers a probability of movement was calculated for the one minute period.

Fig. 3 shows results for one tide during accelerating flood flow plotted with the speeds measured 1m above the bed. Initially below 0.3 ms^{-1} no movement was seen. Then firstly, as reported by Dyer (1980), shell fragments move randomly, appearing to "wobble" in the flow. These shell fragments were not considered for Fig. 3, which corresponds with the motion of sand grains only.

Grain size of the sediment viewed was found by sieving samples taken from nearby sediment traps, and off crests and troughs of the megaripples by divers. Median size D_{50} was coarsest in the troughs (0.35mm); finer in the trap (0.32mm); and finest on the crests (0.31mm). The sand in the trap was felt to best represent the population of sand that was being transported.

Initial motion - such that sand grains were moving more than 50% of the time - occurred when the speed at 1m was between 0.3 and 0.35 ms^{-1}. This was less than the corresponding threshold for grains over a plane bed (reported in Miller et al. 1977) and calculated to be 0.45 ms^{-1}.

The difficulty of assigning a threshold in tidal flow is highlighted by Fig. 3 where, after periods of activity and even with an increase in mean speed, there are still dormant times. Also the probability of movement shows no increase near time = 70 mins compared with time = 25 mins. This suggests that the threshold is increasing with increased flow velocity (Dyer 1980).

6.2 Laboratory Flume

In view of the effects on the threshold of the spread of the grain size distribution and the grain shape, experiments were conducted in a rectangular glass walled flume with sand taken from the port site at Marsden Point. The flume was 0.44m wide and 12.9m long, and shear stresses were determined by measuring vertical profiles on the centre line 9m from the top end of the flume with a mini flow meter. The impellor size was 9mms diameter. Observations of initial motion were made along the centre line and the bed was initially flattened before each run.

Grain size analyses from three sieved samples produced an average mean grain size of 0.24mm, D_{50} of 0.25mm and standard deviation of 0.41ϕ. These statistics were calculated by the moments method from the weight distribution in phi units.

The threshold obtained by curve fitting the vertical velocity measurements to the K-P equation was $u_* = 0.0148$ ms^{-1} or shear stress $\tau_o = 0.219$ N.m^{-2}. This is somewhat higher than an expected value of $u_* = 0.0133$ ms^{-1} (Yalin threshold curve modified by Miller et al. 1977) but is within the range of scatter on Fig. 3 in Miller et al. for quartz density sand of the same mean size, which includes values over the rather wide range of $0.0125 < u_* < 0.0161$ ms^{-1}.

6.3 Shell Bed

A coarse, shelly lag covers large areas of harbour floor and several experiments were conducted on the sea bed watching for the initiation of shell movement.

The difficulty encountered in these observations was due to the wide variety of shape and size of the shells. In summary, the general conclusions were that on a bed of total shell cover even in Spring tides the shells rarely move. Many of the beds have an aged appearance with the shells being covered by algae; a testimony to the stability of the sediment. Shells which were picked up by divers fell quickly to the sea bed and found a stable position with an orientation that depended on the configuration of their immediate neighbours. In contrast, on the sandy harbour floor pelecypod halves prefer to lie convex up but are more stable than surrounding sand.

7. ESTUARINE BED FRICTION ENERGY LOSSES

Tidal energy losses over a rough bed are complicated by many factors including flow accelerations and the mutual interaction of the fluid and the bed. Bedforms change with the stage of the tide, and moreover, the time-scale of bed inertia differs from that of the fluid (Allen 1973; Allen and Friend 1976; Nasner 1978). To estimate sediment transport rates under these conditions, the skin friction and form drag energy loss components must be isolated as only the former is effective in transporting sand (Einstein 1950). Whangarei velocity data were fitted by linear regression as described previously to determine the friction velocity (and the associated parameters: bed shear stress, drag coefficient and roughness length) and were then broken into component parts for application to sand transport under oscillatory tidal flow.

7.1 Average Bed Resistance

Fig. 4 shows the drag coefficient distribution for all sites (excepting sites discussed individually later) where the speed at 1m from the bed was greater than 0.3 ms^{-1}. The minimum speed limit ensures that the flow is fully rough (flow Reynolds Number greater than approximately 1.5×10^5 (Sternberg 1968)) and it is a natural cut-off being approximately the entrainment velocity for sandy sediment.

There is scatter of about 5 orders of magnitude in the flood values and 4 for the ebb. This compares with a similar spread found to occur in Chesapeake Bay by Ludwick (1975). Much of this is accounted for by variations in form drag over the wide range of bed types in Whangarei Harbour including sand bedforms, shell, gravel and marine flora.

The distribution peak during the flood lies between $1.0 \times 10^{-3} < C_1$ (flood) $< 3.2 \times 10^{-3}$ with the ebb maximum spanning a higher range $3.2 \times 10^{-3} < C_1$ (ebb) $< 1 \times 10^{-2}$. Also the correlation coefficient representing the goodness of fit of the measured profiles to the logarithmic shape was larger during the ebb than the flood (Table 1).

Ludwick (1975) noted a higher drag coefficient on the ebb using the same sort of experimental technique and Knight (1981) found that "in general the flood resistance coefficients were slightly less than the ebb values" in a tidal reach of the Conway estuary. Longitudinal density gradients may be partly responsible for the variations (McDowell and O'Connor, Fig. 1.10 1977).

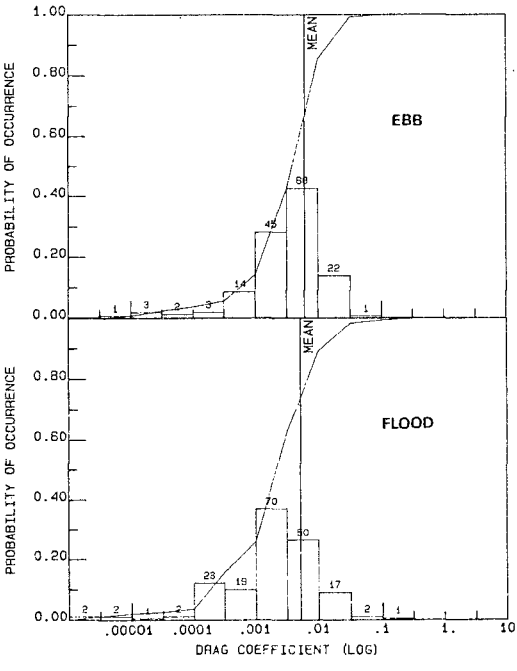

Figure 4: Distributions of ebb (upper) and flood drag coefficients for cases where $u_1 > 0.3$ m.s . Numbers above bars are the numbers of occurrences in each bin.

The shorter duration of the ebb flow and also the higher water speeds may be an influence.

Table 1 compiles mean statistics for (a) all sites, (b) sites with known shell beds and (c) sites with sand beds for all cases where the velocity at 1m exceeds 0.30 ms^{-1}. Mean and median C_1 values are supplied. Arguably, the mean is not the best statistic to describe a distribution which varies over several orders of magnitude. As with grain size analysis, the percentile sizes often represent the distribution and a physical process better than the mean; similarly median C_1 is a more stable statistic which is less affected by a few large C_1 values that may result from experimental error.

Over sand which is presumably bedformed, the increase of friction velocity due to form drag is reflected in a higher C_1 than over the shell sites. Median drag coefficients for cases where u_1 exceeds 0.3 ms^{-1} at Whangarei are then $C_1 = 3.0 \times 10^{-3}$ for all bed types

TABLE 1:

$R = \frac{u_1 z}{\nu}$, ν = kinematic viscosity, z = 1m.

Median C_1 is listed with the roughness length, z_o , calculated from the median C_1 using the K-P equation. N is the number of data points averaged.

(c.f. 3.1×10^{-3}, Sternberg 1972); $C_1 = 2.3 \times 10^{-3}$ for shell bed; and $C_1 = 3.5 \times 10^{-3}$ for non-cohesive sand bed.

By application of the Student's t test (Freund 1974), for the population correlation coefficient to be significantly different from zero, the sample correlation coefficient must exceed 0.81 for a typical case of 5 velocity measurements in the profile (0.99 for 3 levels) at the 0.05 level of significance. Only 57% of the profiles had $r_{12} > 0.8$ which is poorer correlation than that obtained by Sternberg (1968) and reflects that (i) the outer boundary layer is more subject to inertial variations than the inner layer and (ii) turbulent fluxes cannot be totally accounted for when speeds are measured sequentially.

7.2 Friction Losses Over Megaripples

Figs 5 and 6 show velocity at 1m and friction velocity for 5 of the sediment transport sites with megaripple beds. The friction velocity varies over a wider relative range than the speed at 1m. For example the friction velocity on the 9th February 1982 is about 5 times the value on the 20th January 1982. The explanation for this lies with the changing form drag, and sympathetic drag coefficient which is indicative of bed geometry. Dyer (1980) following Lettau (1969) suggests that the areal concentration of features is related to the flow roughness length as, $z_o = h.s/2S$ where h is the effective obstacle height, s is the cross-sectional area seen by the flow per unit horizontal area S.

For two dimensional megaripples, $z_o = \Delta^2/2\Lambda$, where Δ is the bedform height, and Λ is the wavelength.

Insertion of this into the K-P equation produces,

$$C_1 = 1/[5.75 \log_{10} \frac{2\Lambda}{\Delta^2}]^2 \quad \ldots.(5)$$

Average bedform heights and lengths were obtained from measurements at high and low water over 6 consecutive megaripples (Table 3). From this, the expected value of C_1 was calculated with (5) above and the median and mean values from the velocity profiles compared with it (Table 3). The agreement supports the suggestion of Smith and McLean (1977) that the profile reflects the average shear stress over a large region of the bed.

There is an overall correlation of the bedforms measured at slack water to the mean drag coefficient but the friction velocity varies widely throughout the tidal cycle. This compares with similar variations described by Dyer (1970) as "anomalously high and low", and assessed to be associated with the position relative to the megaripple crest at which the profile was measured. For the case at Whangarei where measurements were made largely in the outer boundary layer, the position of the megaripple crest is not as critical and the peak u_* is possibly related to the time when the megaripples turn around and generally occurs when the 1m speed is 0.5-0.55 ms^{-1}.

7.3 Form Drag and Skin Friction

In laboratory flumes a logarithmic relationship has been shown to exist which relates the form drag friction factor, c", to the geometry of the bed and flow depth (Vanoni and Hwang 1967; Pillai 1979).

The Vanoni and Hwang equation for a 2-dimensional bed can be written as

$$\frac{1}{\sqrt{f''}} = 3.3 \log_{10} \left[\frac{d\Lambda}{\Delta^2}\right] - 2.3 \quad \ldots. (6)$$

and $$f'' = \frac{8u_*''^2}{\bar{u}^2} = \frac{8}{c''^2} \qquad \text{i.e. } c = \frac{\bar{u}}{u_*} \quad \ldots. (7)$$

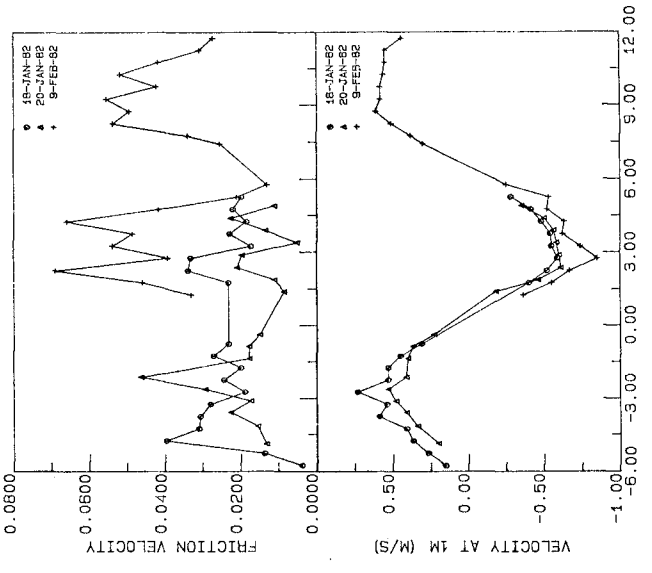

Figure 5: Friction velocity and velocity at 1m above the bed against time after high tide.

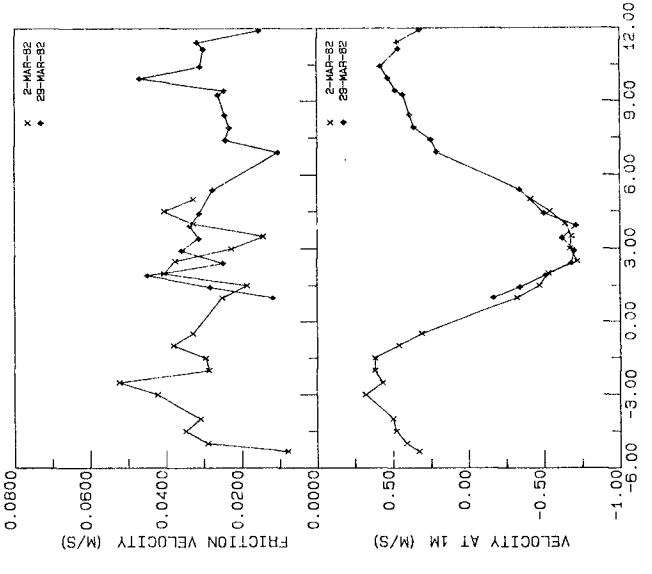

Figure 6: Friction velocity and velocity at 1m above the bed against time after high tide.

$\bar{u}$ is the mean water speed and $u_*"$ is the friction velocity associated with the form drag, and d is depth of flow.

As is usual the superscript (") will refer to form drag and the superscript (') will denote association with skin friction. Furthermore, the skin friction factor, c', may be derived using the K-P equation as

$$c' = \bar{u}/u_*' = 5.75 \log_{10} \frac{0.38d}{(k_s/30.2)} \quad \ldots\ (8)$$

where mean speed occurs at 38% of the depth, d, above the bottom and k_s is the Nikuradse roughness.

Over a moving bed, the roughness can be represented by $k_s = 2.0\ D_{65}$, where D_{65} is the grain size for which 65% is finer by weight. This assumes that the K-P equation is valid all the way to the surface, which has been shown to be strictly incorrect but will suffice for the sake of these calculations, (Mehta (1978) suggests that the K-P relationship can be used for determining mean speed in estuaries). If the total bed shear stress is partitioned in a fashion proposed by Einstein and Barbarossa (1952) such that the component due to form drag and that due to skin friction can be summed to give the total shear stress then,

$$u_*^2 = u_*'^2 + u_*"^2 \quad \ldots\ (9)$$

$$1/c^2 = 1/c'^2 + 1/c"^2 \quad \ldots.(10)$$

$$f = f' + f" \quad \ldots.(11)$$

This does not include a third component associated with energy lost by the flow when sediment is suspended (Yalin 1977).

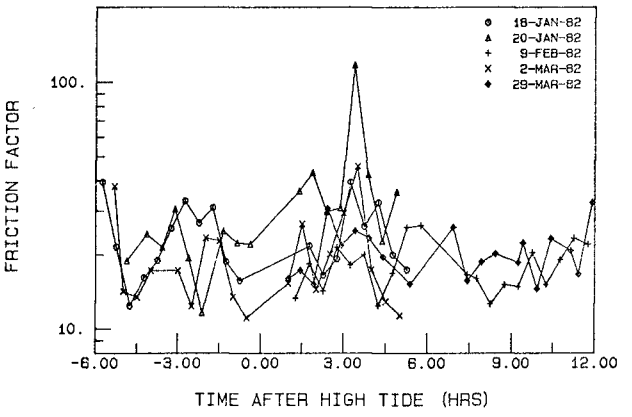

Figure 7: Friction factor ($\bar{U}/u_*$) against time after high tide.

Calculations to determine the combined friction factor from mega-ripple and grain sizes with eqns (6) and (8) respectively were compiled on Table 4 along with measured values of c (Fig. 7) found from the mean speed and friction velocity. Table 4 shows that the median measured friction factor is consistently 5-10% greater than the value obtained from the bed parameters. This consistency for average conditions is very encouraging even though several approximations were made including that (1) the bed geometry measured at slack water is representative of the bed during the tide; (2) a mean water depth taken as the depth at mid-tide is sufficient; (3) the megaripples are 2-dimensional; (4) the D_{65} grain size represents the bed grain roughness adequately; and (5) the K-P equation can be used to ascertain the skin friction. (Annambhotla et al. (1972) stated that Missouri River data were

Suspended sediment statistics: defined as Z, calculated Rouse number (eqn 16); Z_m, regressed Rouse number; x, fall velocity power; u_* (ms^{-1}) friction velocity; $C_{1.0m}$ ($kg.m^{-3} \times 10^3$) concentration of sediment as mass per unit volume at 1m; u_1, (ms^{-1}) speed at 1m; $\bar{u}$, (ms^{-1}) mean speed.

"reasonably consistent" with the Vanoni and Hwang equation for a similar range of the function $\Delta^2/(\lambda d)$).

It appears that the form drag losses can be estimated adequately with the Vanoni and Hwang equation under tidal flow. Similar calculations made with the Engelund and Hansen (1967) development, which employs Carnot's equation for sudden flow expansions, produced unrealistically high values of the form drag friction factor in depths of 8-10m.

Furthermore, the Einstein-Barbarossa (1952) division of form drag and skin friction (Fig. 6.13, Raudkivi 1976), which relies on an implicit assumption that the mean flow and the bedforms are in equilibrium, was found to be unworkable for tidal flow where the bed hysteresis introduced a complicating factor, such that the bed geometry depends on the history of the bed as much as on the present conditions. Fig. 8 presents the Einstein-Barbarossa method in a site specific format. By entering this figure with the mean speed and friction velocity, the intersection of the two curves should supply the magnitudes of u_*'' and u_*'. In many cases with Whangarei data, it was found that the u_* and u curves did not intersect and no solution was possible especially near the beginning or end of the tide.

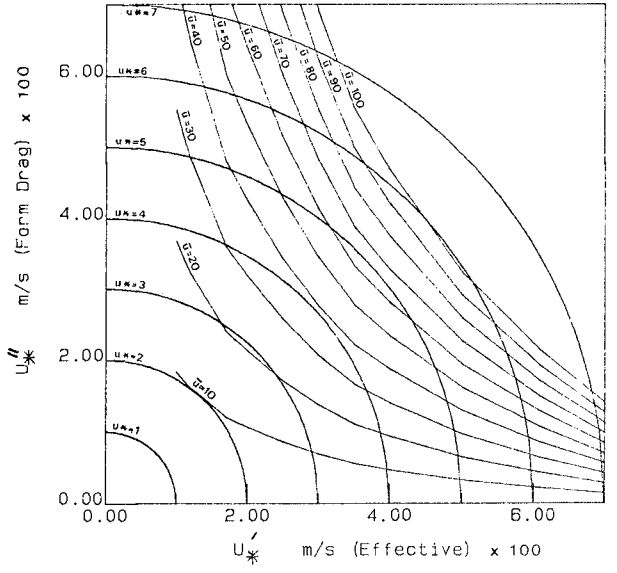

Figure 8: Einstein-Barbarossa division of form drag and skin friction for D_{35} =0.0002m, ρ_s =2650 kg.m^{-3}, ρ =1025 kg.m^{-3}.

8. BEDLOAD TRANSPORT OVER MEGARIPPLES

The bedload transport rates indicated by trap yields were compared with empirical equations derived from unidirectional flow data, to ascertain their applicability to the tidal environment in a megarippled region.

Of the six sediment transport experiments, three days were rejected (a) for wave interference or (b) because only one bedload trap was serviced. On the remaining three days, two traps were deployed simultaneously and the weights caught were averaged. This accounts in part for variations of transport rate with position on the bedform. Accepting Graf's (1970) assessment of work by Novak that VUV traps are about 70% efficient the trapped weights were scaled accordingly to compensate for systematic deficiencies.

In all cases, the bedload traps were placed for 1-2 hours and during this time both the friction velocity and 1m speed varied so that an "average" value had to be found. To do this, the area under the curves of velocity versus time was ascertained numerically by finding the area under continuously updated parabolae fitted to three values of velocity; the one nearest the time of interest

and the one before and after. Because bedload equations are non-linear in u_*, and vary as u_*^3 according to the Yalin equation, when a representative friction velocity was required, the interpolated values were cubed to ascertain the area under the cube of the function between the times that the traps were submerged. The resulting friction velocity was the cube root of the area divided by the elapsed time. With the cubed refinement, an improved correlation to the Yalin equation was obtained (Black, in preparation). By a similar method the Engelund Hansen predicted transport rate, was found from the area under the function $\overline{u^2}.u_*^3$.

It was necessary to introduce a critical friction velocity because often the traps were placed just after slack water in readiness for the next tide, and the total time that the trap was submerged included periods when the bed was dormant. The transport rates and mean friction velocities are more correctly estimated from the time that the bed was in motion. Critical skin friction velocity was found from the Yalin threshold curve (Miller et al. 1977). For cases dealing with total friction velocity, the threshold was the summation according to eqn (9) of the skin friction component from the Yalin curve and the form drag component, which in the light of the analysis in this paper, was calculated from the bedform geometry measured at slack water with the Vanoni and Hwang equation (6). The results of these calculations are compiled on Table 2. In all cases the D_{50} grain size was assumed to represent the bed sediment.

The data were compared with the Engelund Hansen total load equation for "duned" beds (Engelund and Hansen 1967). In mass per unit width of bed per unit time, q_m, this is

$$q_m = \frac{0.05\rho_s}{[g(\frac{\rho_s}{\rho} - 1)]^2} \cdot \frac{\overline{u}^2 . u_*^3}{D_{50}f} \quad \ldots.(12)$$

where ρ_s is sediment density, and g is the gravitational acceleration. After sieving sediment samples taken from the bedload traps (Table 2) the D_{50} fall velocity was obtained from the median diameter (Engelund and Hansen 1967, Table 2.2.1).

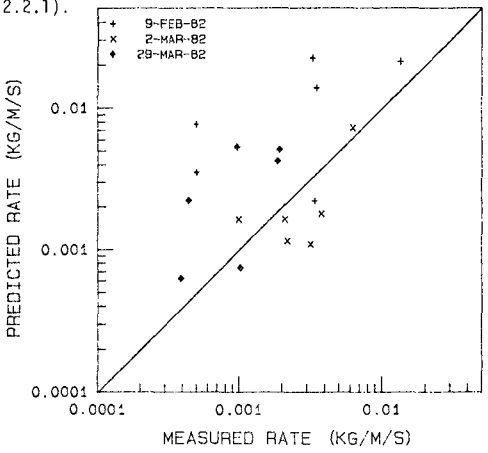

Figure 9: Transport rate according to the Engelund Hansen (1967) total load equation against the bedload trap measured rate.

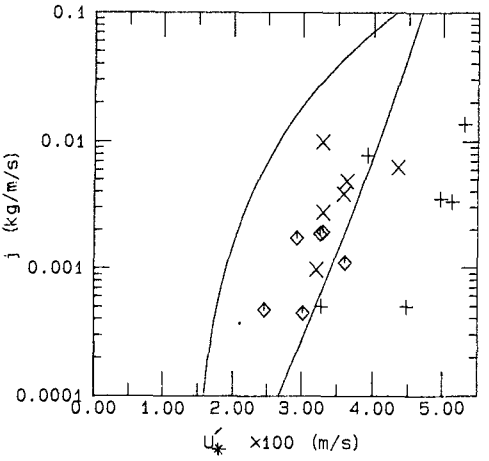
Fig. 9 shows the predicted rate against the rate determined from the bedload catches. In general, the Engelund Hansen equation overestimates the bedload rate. This would be expected for a total load equation especially at the fastest site on 9th February 1982 where suspended loads which have not been included are likely to be significant. For some cases though (2nd March 1982 especially) there were greater catches in the bedload traps alone than predicted by the total load equation. This deviation is apparently systematic.



On Fig. 10, the transport rates plotted against u_* were compared with both the Yalin (1963) equation and the Sternberg (1972) modified Bagnold equation. The Yalin equation is for a plane bed and as the friction velocity includes the form drag, which does no effective work on the sediment, the equation overestimates the transport rate in all cases. The Sternberg formula which was partly derived from field data over ripples, approximates the Whangarei data better, but there is still a considerable scatter especially for the cases of high drag coefficient on 9th February 1982.

Figure 10: Measured bedload transport rate against the friction velocity, plotted with the Yalin and Sternberg bedload equations for D=0.0003m and u'_{*c} =0.014 m.s^{-1} .

Because of bedform hysteresis and site dependent form drag components, bedload equations which use total bed shear stress are susceptible to inaccuracies in tidal flow because there can be no way of guaranteeing that the effective shear will be represented in the total friction velocity which often has an over-riding form drag component. For this reason, it is felt that a better approach is to attempt to isolate the skin friction (Vittal et al. 1973) and revert to a bedload equation such as the Yalin curve.

Nasner (1978) states that "for water depth of approximately 10m ... the dune height is governed by the ... velocity over the dune crest". The sediment transport rate is similarly motivated, and further analysis revealed that the speed at 1m showed the best correlation with the bedload catches. Returning to the K-P equation, the skin friction was calculated as

$$u_*' = u_1/5.75 \log_{10} (\frac{30.2}{k_s}) \quad \ldots.(13)$$

with the roughness selected to be $k_s = 2.0\ D_{65}$. On Fig. 11 the bedload transport rate is plotted against the derived skin friction. The result is good correlation to the Yalin bedload equation with no apparent systematic deviations related to ebb or flood, or accelerating or decelerating flow (Gordon 1975). The remaining scatter in the data could be due to:

(i) Bedload trap deficiencies and too few sampling locations on the megaripples.

(ii) Turbulence at near bed levels which varies with megaripple geometry and is not accounted for by the analysis method. Turbulence over bedforms can affect transport levels especially at the point of flow reattachment (Raudkivi 1976). Turbulence can also reduce the critical friction velocity.

(iii) Experimental errors related to long term turbulence and the position of the current meter relative to the bedform crest when speeds were measured.

The Yalin bedload equation is:

$$q_m = 0.635\rho_s D u'_* [\tau_* - \frac{1}{a} \ell n(1 + \tau_* a)] \quad \ldots.(14)$$

$$\tau_* = \frac{u'^2_*}{u^2_{*cr}} - 1, \quad a = \frac{2.45\sqrt{\theta_{cr}}}{(\rho_s/\rho)^{0.4}} \quad \theta'_{cr} = \frac{\rho u'^2_{*cr}}{(\rho_s - \rho)gD}$$

τ_* is the dimensionless excess shear stress; u'_{*cr} is the threshold friction velocity to be ascertained from the Yalin threshold curve, and θ'_{cr} is the threshold Shields entrainment function, and D is grain size. The application of this equation has advantages in that the rate of transport depends on easily measured quantities, reducing fundamentally to a determination of the speed at 1m and the D_{50} and D_{65} grain sizes to specify the bedload rate. This compares with the modification of the Bagnold equation by Sternberg (1972) and by Gadd et al. (1977), for similar reasons. The correlation to the Yalin equation suggests that in oscillatory tidal flow over the short term (1-2 hours), the bedload transport rates approximate their counterparts under unidirectional currents.

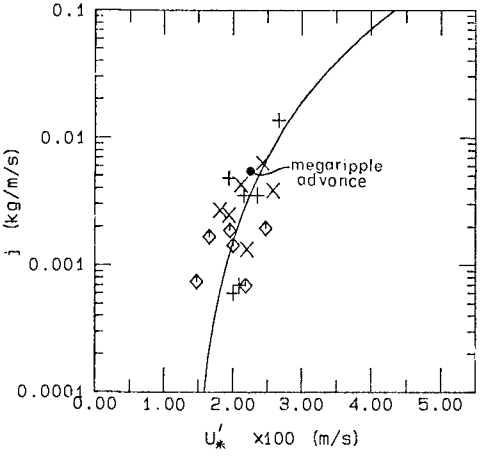


Figure 11: Measured bedload transport rate against the skin friction, plotted with the Yalin bedload equation for D=0.0003m and u'_{*c} =0.014 m.s

8.1 Megaripple Advance Rates

The experiments with staked megaripple crests were designed to measure nett bedload movement over a tidal cycle. For this reason, the crests were staked and generally measurements were taken at slack water only. It is evident that in reversing flow, it is difficult to estimate the bedload transport rate over a half cycle because when the megaripples turn around, the crest movement is often far in excess of the movement of the centre of mass of the feature, and the latter is required to specify the transport rate. A complete set of measurements over 6 megaripples were taken during the tide (i.e. after the crests had turned around) and then again at slack water when the features still faced the same way. Only this data is discussed here.

The bedload transport rate was found by application of the method with constants proposed by Engel and Lau (1981), which allows for reverse transport rates in the lee of the bedform crest, and under the assumption that the megaripples were triangular in form. The 6 megaripples (Table 2) moved an average of 0.3m in 1½ hours when the speed at 1m averaged 0.53 ms^{-1}. When plotted on Fig. 11 the megaripple advance rate compares favourably with both the Yalin bedload equation and the bedload trapping results. Skin friction was assessed with the K-P equation as described for the bedload traps.

9. SUSPENDED SEDIMENT LOAD

Suspended load concentrations have often been described by the Rouse (1937) formula

$$\frac{C}{C_a} = \left[\frac{d-y}{y} \cdot \frac{a}{d-a}\right]^z \quad \ldots.(15)$$

where C is the concentration ($kg.m^{-3}$) at y metres above the sea bed; C_a is the reference concentration at a metres; and d is the total water depth. The Rouse number z, is defined as

$$z = \frac{w}{\kappa u_*} \quad \ldots.(16)$$

where w is the fall velocity. Raudkivi (1976) suggests that for small values of z the formula gives "surprisingly" good results but for larger Rouse numbers there are deviations. Measured Rouse numbers are mostly less than the value calculated by eqn (16) (Fukuoka, Fig. 9.1 1978), signifying a more uniform sediment distribution than predicted by the Rouse formula. The formula could not be applied at Whangarei without modification to z.

Suspended sediment load was sampled at 0.1m, 0.3m, and 1.0m above the bed from three nozzles mounted on a steel frame. In megarippled regions, the definition of the zero bed level becomes important when sampling heights are comparable to the megaripple height. Also at low levels, the suspended load varies more markedly with distance from the crest. Practical difficulties prevented samples being taken along the length of the bedforms. The stand remained in place for the tidal cycle except to be turned around just after slack water to face into the next tide. For these reasons, the concentration at the highest level i.e. at 1m above the bed, was chosen as a reference.

Samples of approximately 2 litres were passed through a 70 micron filter. Material was washed to remove all fine suspended matter which was not of interest to this study. As no grain size analyses were performed, D_{35} from the samples out of the bedload traps was selected to represent the material in suspension.

With data from the three levels, the measured Rouse number, z_m, was found by linear regression, and in all cases (Table 5) it was less than the value from eqn (16), but was generally within the range of scatter in Fukuoka (1978). It was found that the observed concentrations could be predicted with the Rouse formula, when the Rouse number was redefined as,

$$z = \frac{w^x}{\kappa u_*} \quad \ldots.(17)$$

where x (Table 5) is any power. Average values of x were found to be

$\bar{x}$ = 1.31 9-Feb-82 N = 3
1.29 2-Mar-82 N = 3
1.32 29-Mar-82 N = 3

with overall mean of $\bar{x}$ = 1.31.

The suspended transport rate as mass per unit width of bed per unit time is equal to the integral over the depth of the concentration multiplied by the water speed. To evaluate this, the speeds at 0.1 and 0.3m were found from the gradient of the velocity profile and actual concentrations were used. In the upper levels where speeds had been measured, concentrations were derived from the Rouse formula with Rouse number defined by eqn (17) and x = 1.31 in all cases. The integral was evaluated from 0.12m above the bed (the height of the sediment trap mouth) up to the surface by numerical integration, assuming linear changes between measured levels.

Whereas suspended load showed scatter against u_* and $\bar{u}$, the calculated transport rate when plotted against the speed at 1m (Fig. 12) exhibited good correlation. The best fit equation was

$$q_{ss} = (2.03u_1)^{7.75} \times 10^{-3} \quad \ldots.(18)$$

where q_{ss} has units $kg.m^{-1}.s^{-1}$ and u_1 has units ms^{-1}.

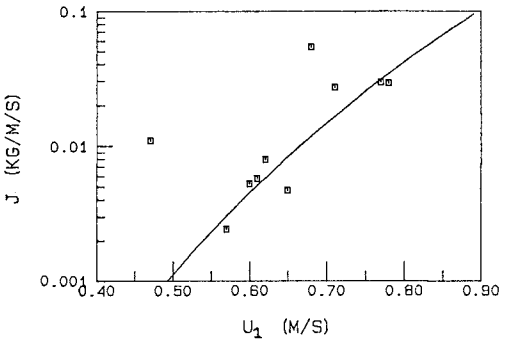

Figure 12: Suspended sediment mass transport rate against the speed at 1m with best fit curve.

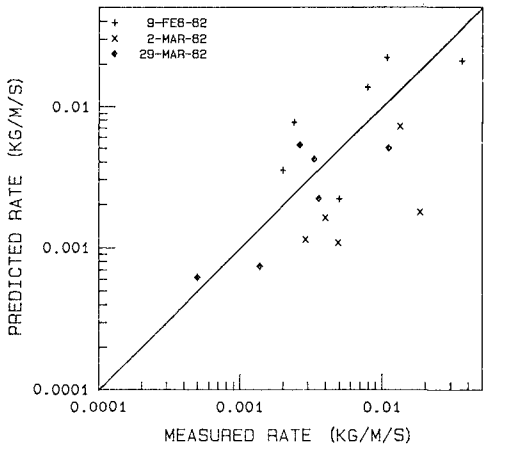

Figure 13: Predicted total load transport rate according to the Engelund Hansen equation against the measured total load transport rate.

The correlation coefficient was 0.94. This equation was obtained with 8 data points and did not include the two points furthest from the curve on Fig. 12. The high power dependence compares with a suspended transport rate proportional to the friction velocity raised to the seventh power found by Dyer (1980).

Applying error bars to the sample correlation of 0.94, with the Fisher Z transformation (Freund 1974, p. 428), the population correlation coefficient lies in the range $0.70 < R < 0.99$, at the $\alpha = 0.05$ level of significance. On the strength of this correlation, which includes data from three sites with different grain sizes, the suspended loads for the periods when the traps were on the bed were found: (1) from each measured velocity at 1m, the suspended sediment transport rate was determined with eqn (18), (2) the mean rates during the bedload trapping periods were found numerically, (3) these were added to the bedload trap rates and the total load was compared with the prediction of the Engelund Hansen equation on Fig. 13. The comparison is now adequate with data for 9-Feb-82 and 29-Mar-82 showing good correlation.

For the shallow site (2-Mar-82), there is a consistent trend for the measured rate to exceed the prediction by a factor of about 3. Raju et al. (1981) found that the Engelund Hansen equation underestimated the total load by an average factor of about 2 in unidirectional flow. At Whangarei, the deviation is associated with wide variations of friction velocity during the tidal cycle. The plotted point which deviates the most corresponds with an anomalously low friction velocity at about 3 hrs after high tide (Fig. 6). The form of Fig. 6 shows a strong resemblance to flood case (a) of Fig. 6 in Dyer (1970), which is typified by a steep peak ($u_* > 0.06$ ms^{-1}) then a sudden drop to an extremely low value of less than 0.02 ms^{-1}. Irrespective of whether these variations result from position relative to the megaripple crest or are associated with megaripple reversal, they make it more difficult to determine sediment transport with the bed shear stress obtained from the profile curvature. The

correlation of the 1m speed to the transport rates is pleasing because the former is an easier parameter to determine than either the bed shear stress or the mean velocity.

In summary, with the speed at 1m the suspended load was found from eqn (18), and the bedload with the Yalin equation (14) and skin friction from the K-P relationship (13) with $k_s = 2.0\ D_{65}$. The variation in grain size for the three sites discussed was $0.24^2 < O_{50}mm < 0.34$ with quartz density of 2650 $kg.m^{-3}$.

10. CONCLUSIONS

(1) Although the drag coefficient varies over several orders of magnitude, it centres on a peak between 0.001 and 0.01 with median value of 0.003 (c.f. 0.0031, Sternberg, 1972).

(2) In tidal estuaries, the form drag over megaripples can be described by the Vanoni and Hwang (1967) equation, and the skin friction by application of the K-P equation with the 1m speed, and the D_{65} grain size.

(3) As a result of the conclusions in (2), the bedload transport rate was estimated from the effective drag as represented by the skin friction. Bedload trap catches and megaripple advance showed good agreement with the Yalin (1963) bedload equation, which suggests a convenient way to ascertain the bedload transport rate in reversing flow.

(4) Suspended sediment transport rate varied with the 7-8th power of the speed at 1m (correlation of 0.94).

(5) The Engelund and Hansen total load equation adequately described the sediment transport over megaripples at two deeper locations but showed a systematic deviation at a shallower site. This is most likely due to megaripple hysteresis and difficulties associated with determination of effective bed shear stress from the friction velocity in tidal flow. The 1m speed showed better correlation with the transport rates. Use of the 1m speed overcomes the problems inherent in the estimation of τ_o from the velocity profile.

11. ACKNOWLEOGEMENTS

This research was undertaken on behalf of the Northland Harbour Board and their considerable assistance and logistic support is gratefully acknowledged. We are also indebted to the R.N.Z.N. for their assistance with the underwater video recording, photography and side scan sonar survey. Dr Alex Sutherland, Civil Engineering, University of Canterbury, kindly read a draft and provided helpful criticisms. A special thanks to our typist for handling a difficult manuscript.

ABSTRACT

During the flood year of 1981 the "Bot River Vlei", one of the largest lagoons in the south-western Cape of the Good Hope was opened to the sea by two artificial breachings of the sand bar which were aimed at lowering the excessively high water levels in the lagoon, and at the re-establishment of estuarine conditions.

The Coastal Engineering and Hydraulics Division of the National Research Institute for Oceanology of the CSIR surveyed and monitored the hydrological and sedimentological events in the Bot River lagoon and at the mouth channels in an attempt to formulate a future viable management policy, which had to take into account the conflicting interests of the defenders of continued artificial breachings and of those who advocate conditions of a closed estuary which will eventually change into a coastal freshwater lake.

1. INTRODUCTION

Most South African tidal inlets are small or are closed for the greater part of the year because of relatively low run-off in the river catchment and high wave action resulting in strong sand movement along the coast. During the rainy season this situation may be temporarily reversed, when riverine floods lead to natural breaching of the sand bar at the mouth and to the scouring of an estuary inlet to many times its normal size.

The study area is the Bot River Vlei, a large shallow triangular lagoon, 7 by 2 km in extent, situated in a wide valley between the coastal townships of Kleinmond and Hermanus, about 100 km SE of Cape Town (Figure 1). Historical reports from the 19th century (Koop, 1982) indicate that the Bot River Vlei once was an open estuary

which was used as a harbour for small vessels shipping grain from the fertile district of Caledon to Simonstown. At present the lagoon is separated from the sea by a massive dune belt which, because of a combination of artificial influences in the catchment as well as at the sea front, and a natural overflow system to an adjacent estuary, cannot be breached by natural forces.

At times, mainly during the rainy winter season, riverine run-off causes flooding of the Bot River Vlei which, although considered by scientists to be natural in the hydrology and ecology of such an estuary, causes concern to the users of the lagoon (property owners, yacht and fishermen and numerous visitors attracted by the recreational value of the lagoon). Reasons for this are:

(a) flooding of low-lying premises and bank erosion;

(b) desalination resulting in mass mortalities of marine and estuarine fish; and

(c) silt pollution rendering the waters and shore of the lagoon unsuitable for recreation.

To maintain its estuarine character and to augment the few natural breachings that occurred from time to time, the Bot River Vlei has been opened to the sea in the past 50 years by artificial breachings about every three years at a sufficiently deep section of the lagoon, namely, west of "Sonesta" (Figure 1). This caused the lagoon to be flushed and permitted seawater and fish to enter it, the salt water contributing at the same time to the flocculation and settling of the remaining mudload in the vlei so that clear-water conditions were re-established.

During the periods of two artificial breachings of the Bot River lagoon in 1981 the Coastal Engineering and Hydraulics Division of the National Research Institute for Oceanology of the CSIR monitored the cross-sectional variation of each of the two artificial mouths after breaching, as well as water levels, discharge and hydrological consequences of the openings on the Bot River system. The aim of this investigation was to provide hydraulic data on the behaviour of the system to be used in conjunction with biological studies, and to collect data on the post-breaching situation for application in mathematical models of estuary mouth dynamics presently being developed within the division.

2. PHYSICAL CHARACTERISTICS

2.1 General Setting, Geomorphology, Geology

Although the Bot River drains only a small catchment of about 900 km^2, which is situated in the winter rainfall area of the Cape, and has a mean annual rainfall of only 500 to 600 mm, it forms one of the largest lagoons in the south-western Cape. This is mainly due to the effective damming up of the lagoon waters by a large coastal dune belt along the sea front, 3 to 6 m high and partially vegetated, which is backed by a 100 to 200 m wide vegetated hummock dune hinterland (Figure 1).

The lagoon itself, 7 km long and 2 km wide at the seaward end, lies in a broad valley flanked by the mountains of Kleinmond to the north-west, and Hermanus in the south-west, both 450 m high on the average, and consisting of Table Mountain Sandstone (Ordovician). At the banks of the upper lagoon Bokkeveld shales (lower Carboniferous) outcrop, while the lower sections are surrounded by flats of drift sand and the above-mentioned dune belt on which shrubs grow (Koop, 1982).

2.2 Coastal Hydraulics and Sandbar Characteristics

Because it is exposed to the severe swells and storm waves of the open South Atlantic Ocean the coast at the Bot River mouth can be regarded as a **high-energy coastline.** Maximum wave heights of 8,7 m are recorded (Swart et al., 1982), while the average significant wave height is 3,5 m (Rossouw et al., 1982). As can be seen from the wave rose in Figure 1 the percentage occurrence of deep sea waves is the highest from the south-westerly sector, with a maximum of 15,4 per cent from SSW.

The wave rose in Figure 1 shows that 52,8 per cent of the incident waves arrive at the coast from the south-east. This, together with a number of visual observations such as the movement of turbid water masses flushed out of the lagoon during the artificial openings of mouth channels in 1981, indicates a **predominantly north-westerly longshore drift.**

The strong sand movement along this coastline causes relatively fast closure of any inlet openings by sand bars as soon as the fresh water flow from within the lagoon decreases, usually during the dry summer season.

In the coastal dune barrier there are two potential breaching sites which, according to cartographic evidence and local information, are opened by natural means only

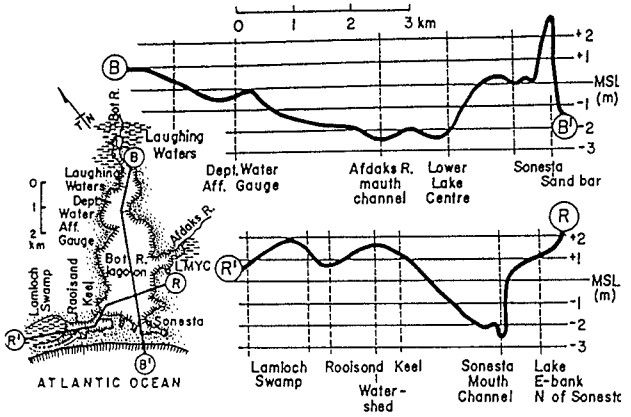

FIGURE 2: BOT RIVER LAGOON, Cross sections

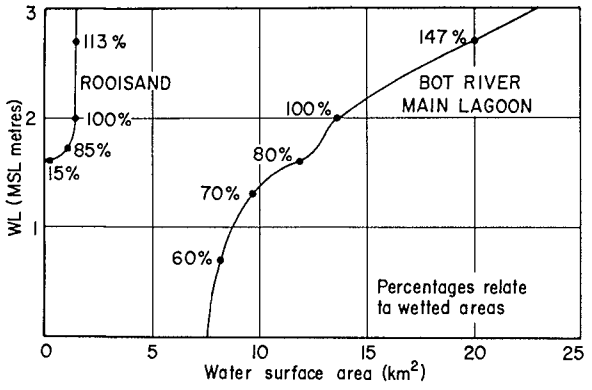

FIGURE 3: WATER LEVELS AND WETTED AREAS, Bot River main lagoon and Rooisand

every ten to twenty years, apparently under a combination of extreme conditions such as river floods and high spring tides.

The one site, at Sonesta, is indicated by a large syncline in the dune ridge, 250 to 300 m wide, and by a deep water channel leading from the shallow lagoon to the gap in the dunes (Figures 1 and 2). This has been formed by continuous, mostly artificial breachings every two to three years, but the mouth itself is usually closed a couple of months after a breaching. Conspicuous 8 to 10 m high bare transverse sand dunes are formed at the north-west bank of the breaching gaps by the strong south-easterly summer winds blowing across the large zone of unconsolidated sand produced by these breachings. From these dunes sand is also driven by wind action to an ever growing shoal at the north-westerly inner (lagoon) side of the mouth area.

In August 1981 another artificial opening was created in the Bot dune barrier at the westerly end of the shallow **"Rooisand"** lagoon, a westerly shallow side arm of the Bot River system (Figure 1). This mouth, which was about 50 m wide, was also closed by a sand bar only three months after the breaching.

There are also a number of natural, smaller transverse gaps in the dune barrier through which sea water washes occasionally. This happens only when equinox spring high tides coincide with high waves, onshore wind and a high water level in the lagoon.

2.3 Bathymetry and Hydraulics of the Lagoon

The isobaths in Figure 1 and two cross-sectional profiles in Figure 2 show that the lagoon is generally deeper along the easterly banks and that the deep-water areas are congruent with the thalweg of the ancient Bot River which existed when the valley was not yet flooded by the marine transgression to form the present lagoon ("Flandrian Transgression", about 18 000 years ago; Theron, Du Plessis and Rogers, 1981). The deepest parts of the main lagoon are at about MSL -2,5 m, but on average the lagoon bed is approximately only at MSL -1 m. The high elevation of the sandbar at Sonesta (nearly MSL +3 m) is also shown in Figure 2, cross-section BB^1. Some marginal low-lying areas of the lagoon are flooded only when the water level is high.

TABLE: RELATION WATER LEVELS AND WATER SURFACE AREAS (see Figure 3)

Water level MSL + (m)	Water surface area				Conditions
	Main lagoon		Rooisand		
	Km^2	%	Km^2	%	
2,7	20,0	147	1,44	113	Extreme high water level, July/August 1981
2,0	13,6	100	1,28	100	Average high water level
1,7	-	-	1,09	85	Elevation of Rooisand watershed
1,6	10,9	80	-	-	Water level Sep/Oct 1982
1,3	9,6	71	0	0	Water level December 1982
0,7	8,2	60	0	0	WL when lagoon is tidal (October/November 1981)

The relationship between water levels and submerged areas in the Bot River lagoon system is shown in the table above and in Figure 3. This demonstrates that a moderate decrease in water level in the range above MSL + 2 m will rapidly reduce the water surface area of the main lagoon, and vice versa; while decreases in water level below MSL + 2 m have a less radical effect on the water surface. This is due to the extensive shallow bank areas.

Because of the pan-like character of the adjacent Rooisand lagoon and a watershed elevated 1,7 m above MSL in the middle of the lagoon, the response to variations in water level is different, namely, that a slight drop in water level below MSL + 2 m will rapidly decrease the water area and cause complete depletion of the lagoon.

The above-mentioned Rooisand lagoon is of high hydraulic significance to the entire Bot system. This is because it forms an **overflow** from the main lagoon through a bottle-neck ("Keel") into the very shallow Rooisand lagoon (bottom elevation MSL + 1,7 m), and further westward through the "Lamloch swamps" into the Kleinmond estuary and, if this estuary is open, out to the sea. Comparison of cross-sections BB' with RR' (Figure 2) shows that a very high water level in the Bot River lagoon is required to overflow and breach the sand bar at Sonesta (approximately MSL + 3 m). Before this happens the flood water in the lagoon

will escape through the Rooisand-Lamloch overflow system (cross-section RR'). When the levels were very high in 1981 such excess water was even drained from the Rooisand lagoon to the Kleinmond estuary via an open channel through the slack behind the main dune ridge and the Lamloch swamps (Figure 1).

Although the Rooisand-Lamloch overflow represents a hydraulic link between the Bot River lagoon and the Kleinmond estuary it allows only a slow release of flood waters from the Bot system, while the influx of seawater from the Kleinmond estuary into the Bot lagoon is insignificant. **The Rooisand-Lamloch overflow can, thus, never fulfil the role of a fully functional tidal inlet for the Bot River lagoon.**

2.4 The Problem of Restricted Contact with the Sea

The hydraulics of the Bot River lagoon is governed by the seasonal character of the influent rivers (floods in winter, droughts in summer) and by the above-described overflow system from the main lagoon to the Kleinmond estuary (see pp 7, 8) which prevents the lagoon from breaking open naturally. This situation is aggravated by the extraction of water from the catchment for agriculture and forestry and by dune stabilization close to the potential breaching area at Sonesta.

Winter floods cause the water to rise to a very high level of about MSL + 2,7 m which is associated with a **freshening out of the lagoon water, mud pollution, exclusion of the flocculation effect** of saline water on mud-laden fresh water, and a **change from an estuarine to a fresh water lake-type of ecology** including mass mortalities of estuarine fish and increasing growth of limnetic weeds which, in turn, enhances deposition of sediment in the already shallow water body. Flooding of low-lying properties and undesirable bank erosion are other side-effects of high water levels in the lagoon.

The restricted "one-way" overflow system through the Rooisand lagoon and the Lamloch swamps to the Kleinmond estuary prevents discharge of mud-laden water from the main lagoon and the entry of seawater by tidal exchange, as well as the recruitment of fish from the sea.

3. FLOODING AND ARTIFICIAL BREACHINGS IN 1981

3.1 First Breaching at Rooisand in August 1981

After exceptionally high rainfalls in 1980 and 1981 the conditions in the Bot River Vlei became critical with regard to high water levels, mud pollution and desalination. By the end of July 1981 the water level in the Bot

River lagoon was very high at MSL + 2,69 m and the salinity was very low at 5 to 7 ppt at the beginning of August 1981 (Figure 6), while a large amount of mud was suspended in the water. In order to save low-lying properties from inundation, but also to minimize damage to the ecology of the lagoon, which apparently had already begun to adapt itself to near-freshwater conditions, the Department of Nature Conservation of the Province of the Cape of Good Hope decided on an opening at the western end of the very shallow Rooisand lagoon; this was done on 11 August 1981.

The most significant features of the breaching were:

(a) A spectacular increase of all dimensions of the initial channel cut by caterpillar within 24 hours from 11 to 12 August and the shaping of a wide flat erosion funnel into the lagoon bed by back-cutting erosion. The width of the channel increased from 5 to about 50 m, the length of the channel doubled from about 150 to 300 m, and the depth increased from 0,5 to 2,5 m. The erosion funnel was 165 m wide and 85 m long. By the end of August 1981 the scouring of the mouth appeared to have stabilized after the water level in the lagoon and the discharge through the mouth had subsided. The flow over the edge of the erosion funnel and over the steep "chute" down into the channel ceased between 8 and 9 October, the Rooisand mouth was found to have been closed on 4 November 1981 by a sandbar.

(b) A rapid increase in flow through the channel from about 1 to 40 m^3/s within the first two days after the opening and a decrease to 7,5 m^3/s on 25 August 1981. After a brief increase after heavy rainfalls to 26 m^3/s on 1 September the flow decreased steadily towards the beginning of October and ended on 9 October 1981, after which the mouth sanded up quickly from the sea side. Some typical cross-sections of the mouth channel during the breaching and a flow diagram of the Rooisand opening are shown in Figures 4 and 5.

(c) A lowering of the water level in the Bot River lagoon system as illustrated by the hydrograph in Figure 6. The maximum lowering was from MSL + 2,69 m before the opening (11 August) to MSL + 1,96 m (25 August), that is, 0,73 m. After the heavy rainfalls from the end of August to September the water level rose again to MSL + 2,15 m but fell slowly to below MSL + 2 m at the beginning of October 1981.

In contrast with the variations of water level in the main lagoon the drop in the water level at the Rooisand mouth (scour-edge) was more marked but the water level did not

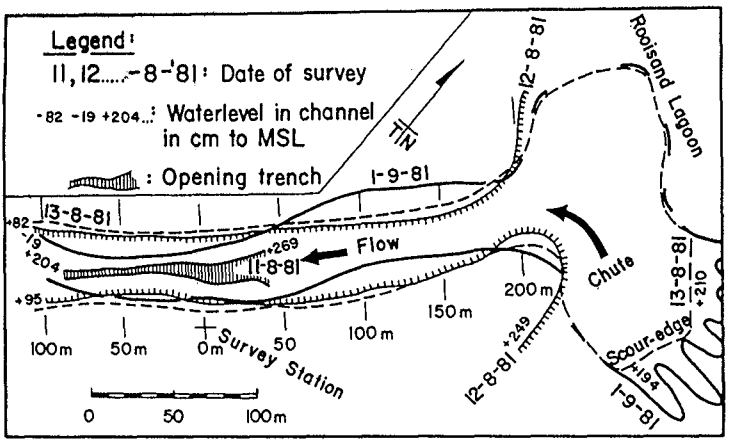

FIGURE 4: Breaching at "Rooisand", 11 August 1981

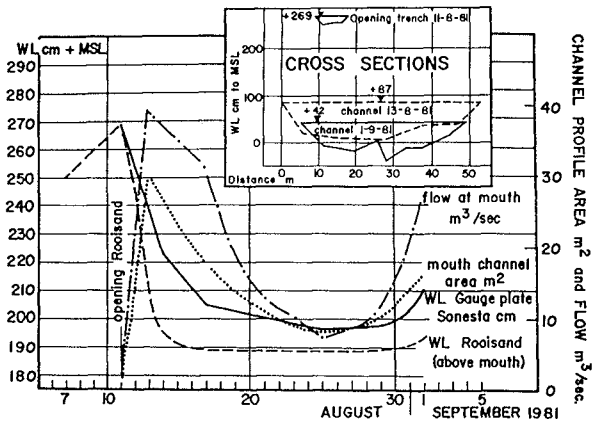

FIGURE 5: ROOISAND BREACHING, hydrograph and channel cross sections (inset)

rise after the heavy rainfalls at the same rate as it did in the main lagoon. This meant that any excess in flow into the Bot River Vlei reached the outlet at Rooisand only after being retarded considerably.

3.2 Second Breaching at Sonesta in October 1981

Although the opening at Rooisand on 11 August caused the desired lowering of the water level, no seawater could enter the main lagoon, because of the elevation of the bottom of Rooisand (MSL + 1,7 m). Subsequent to the above-mentioned rainfalls more flood water and mud entered the lagoon reducing the salinity to a mere 2 ppt and causing deterioration of the water quality. This resulted in a sudden mass mortality of adult estuarine fish at the beginning of October which necessitated a further breaching of the Bot on 10 October 1981, this time at the usual site west of Sonesta where a deep channel in the lagoon lends itself to effective breaching.

The conditions at the opening at Sonesta were different from those at Rooisand insofar as the water level had already been lowered by the Rooisand breaching. The deep water channel upstream of the Sonesta cutting, however, caused a similar behaviour of the cross-section of the mouth. The main difference was that, because of the deep water channel behind the cutting, this opening caused depletion of the lagoon from MSL + 1,88 m down to MSL + 0,7 m within one day of the breaching, that is, by 1,18 m. The lagoon became tidal immediately after the opening of the mouth, with a tidal range of about 0,15 m (see Figure 6). A side-effect of the lowering of the water level was the complete drying out of the shallow margins of the lagoon including Rooisand.

Although the mouth remained open only until 2 December 1981 this breaching can be considered as having been successful in terms of ridding the lagoon of decaying fish cadavers and of suspended mud which was flushed out to sea with every ebb tide. Also, the salinity increased to about 30 ppt, and the lagoon waters became clearer after one week. The disadvantage of the breaching was a substantial loss in water volume and water surface, the latter being reduced to about 60 per cent of the water surface prior to the Rooisand breaching; which had a severe impact on the ecology of the system, mainly because of the exposure of the shallow water habitats around the lagoon.

4. POST-BREACHING CONDITIONS IN 1982

4.1 Conditions in the Main Lagoon

The hydrograph in Figure 6 shows that the dry, hot summer season 1981-82 (December 1981 to April 1982) was marked by decreasing water levels and increasing salinities, which are typical for the summer conditions in the south-western Cape region. The lowering of the water level from the period when the lagoon had an open inlet and was tidal (October and November 1981) to the extreme low-water level in April 1982 was from MSL + 0,7 to MSL + 0,2 m, that is, 0,5 m; while the salinity increased from about 30 ppt (October/November 1981) to 36 ppt in March 1982, or even to 41 ppt at the inflow arm of Bot River Vlei at "Laughing Waters". This was caused by high evaporation rates and no inflow from the river.

The onset of the rainy winter season in April 1982 reversed this condition with the river flow increasing and the water level rising steadily in the main lagoon to a maximum of MSL + 162 cm, and an inverse proportional decrease in salinity to about 20 ppt in September 1982. With the increasing water levels most of the shallow marginal areas of the lagoon were submerged again (see table on page 7 and Figure 3).

Rainfall and run-off in 1982 were rather moderate, with low rains equally spread from April to December. Figure 6 shows that the hydrological reaction of the lagoon at the beginning of the dry summer season 1982/83 with regard to decreasing water levels and increasing salinities was mild. By the end of 1982 the water level was at MSL + 128 cm and the salinity 23 ppt (see table on page 7 and Figure 3).

4.2 Conditions at the Rooisand-Lamloch system

During the post-breaching period after October 1981 significant hydrological developments took place in the Rooisand-Lamloch-Kleinmond overflow area.

When that half of the Rooisand lagoon east of the low watershed in the centre of Rooisand (elevation MSL + 1,7 m; see Figure 1) became dry because of the Sonesta breaching, a confined little lagoon, 0,5 km long and 0,3 km wide, had formed in the westerly half of Rooisand by damming up behind the ever growing sandbar plugging the previous Rooisand inlet.

Being closed off from the saline waters of the Bot River lagoon by this watershed (which remains effective as long as the water level in the Bot River lagoon does not exceed MSL + 1,7 m), and receiving fresh water from the Lamloch

River during the winter season (2,9 m^3/s on 13 July 1982) the newly formed Rooisand-West lagoon changed into a small fresh-water lake, which showed all the attributes of a coastal fresh-water ecosystem, with regard to bird life, fish population and aquatic vegetation. The decrease in salinity in this lake was from 32 ppt in February 1982 to 18 ppt in April, 2 ppt in July and finally to zero salinity in September 1982.

Subsequently the water level in the Rooisand-West lake rose substantially so that the water started to **leak over from west to east** over the shallow watershed in the middle of Rooisand. Because the water level in the main lagoon was not able to keep pace with that in the Rooisand-West lagoon the unique situation arose in mid-winter 1982 that water from the Lamloch River freshened the water of the main lagoon (0 to 6 ppt salinity at the "Keel" in September 1982), and the usually **east-west orientated overflow** from the main lagoon into the Lamloch-Kleinmond system was **reversed** into an **overflow from west to east.** At this stage the entire Rooisand lagoon, including the extensive hummock dune area between the high sand dunes west of the previous Sonesta opening and Rooisand (Figure 1), was flooded with fresh water.

Only at the end of September and in October 1982, when the flow from the small Lamloch catchment subsided did this west-east overflow cease, while at the same time the level in the Bot River main lagoon rose to a maximum of MSL + 1,62 m, so that the "Keel" was filled rapidly with saline water (22 ppt on 28 October 1982).

Towards the end of the year, when the water level in the main lagoon decreased to about MSL + 1,3 m the water retreated from the area of the "Keel" leaving the entire Rooisand-East lagoon dry once again. At the same time, the fresh-water body at Rooisand-West had also decreased in extent and depth forming again a pool confined between the Rooisand watershed, the high sand bar at the previous Rooisand opening and the Lamloch swamp area, as happened shortly after the breaching at Sonesta during the summer of 1981/82.

5. SUMMARY AND DISCUSSION

During the present century the Bot River Vlei, having once been an open estuary (Koop, 1982), has changed character and has tended to become a coastal lake without an open connection to the sea. In such a stagnant water body increasing accretion of fluvial-terrestrial sediments will cause conversion into a marshland, similar to some marginal sections of the Bot River lagoon.

This is caused by extraction of water and soil erosion in the catchment by agriculture and forestry, and the stabilization of the barrier dune at possible sea inlet sites. A natural long-term trend of terrestrial sedimentation of low-lying coastal wetlands, together with the strong longshore sediment movement which closes inlets effectively, also contributes a great deal towards the closure of lagoon mouths and the formation of swampy fresh water lakes in estuaries.

In the case of the Bot River Vlei the local population have succeeded in counter-acting this trend by artificial breachings of the lagoon at Sonesta during winter flood conditions. Although such breachings remained open for only limited periods (up to half a year) they caused a re-establishment of estuarine conditions which lasted for periods of two to three years.

Recent (still incomplete) ecological studies have indicated that the ecosystem of the shallow water margins of the lagoon can be damaged by the abrupt drainage resulting from breachings. The argument which had arisen subsequently between ecologists and the defenders of regular artificial breachings shows the urgency of the establishment of a **scientifically supported management policy** to control the conditions in the Bot system.

The conditions in this respect were particularly critical during the flood year of 1981 because of the large extent of inundated shallow water areas during the relatively long period of more than half a year, which, after the artificial breachings in August and October 1981 were drained within hours.

It appears that the key to future decisions can be found in the bathymetry and the associated hydraulics of the lagoon (see Section 2.3). The Bot River lagoon consists of a deep-water zone in its central parts, and of marginal shallow water areas above a bottom level of approximately MLS + 1 m. These shallow water areas increase rapidly when the water rises to levels of higher than MSL + 1,6 m. Flooding with water levels of 2,7 m as recorded in 1981 will, therefore, abnormally increase the flat areas under water (see Figures 1 and 3). On the other hand, any lowering of such a high flood level must cause radical drainage of these flat areas, with an unavoidable impact on the ecology.

This suggests that from the point of view of hydraulics considerations, a viable proposal for the future management of Bot River Vlei would be **not to allow the water to flood the shallow margins of the lagoon, that is, not to rise to more than MSL + 2 m, and to breach the sand bar artificially before this happens.** In this way the establishment

of a shallow water ecology which will be destroyed by any slight or radical lowering of the water level, by artificial or natural breachings (the latter may still possibly occur!), or, by evaporation during the dry summer months, could be avoided. At the same time all the disadvantageous effects of flooding while the lagoon mouth is closed, such as mud-pollution, desalination, extermination of valuable marine/estuarine fish species and the damage to low-lying properties and bank erosion could be prevented.

The investigations on the Bot River Vlei are being continued with the aim of defining an optimum management policy based on all available information from hydraulic, hydrological, sedimentological and ecological research.

INTERFACIAL AND BED SHEAR STRESSES IN SALINE WEDGES

by

Vassilios Dermissis[1], Member, Technical Chamber of Greece

and Emmanuel Partheniades[2], Member, A.S.C.E.

ABSTRACT

The shear stresses and the associated friction coefficients at the interface and at the bed of an arrested saline wedge have been studied experimentally together with the detailed flow structure. Interfacial stresses, evaluated from hot film anemometer measurements and actual velocity profiles, agree well with those based on the integration of the equations of motion while the simplified one-dimensional analysis gave considerably higher values. It was found that both the average interfacial friction coefficient, $\bar{f}_i$ and the average bed friction factor, $\bar{f}_o$ are best correlated with the dimensionless number, $ReFr^2$, where Re and Fr are the Reynolds number and the non-densimetric Froude number of the flow respectively, and with the relative density difference, $\Delta\rho/\rho$. The results are presented in two families of curves with $\Delta\rho/\rho$ as a parameter. The scattering of data points is minimal and the agreement with the results of some previous laboratory investigations and field data is good.

1. INTRODUCTION

Shear stresses at the interface and at the bed of arrested or quasi-stationary saline wedges develop as a result of the flow pattern which is generated by the dynamic interaction of fresh and salt water. These stresses, noted by τ_i and τ_o respectively, as well as the associated coefficients, f_i and f_o, have been extensively studied in the past not only for saline wedges but also for other types of two-layered stratified flows (3). In particular, the frictional resistance at the interface and the related flow dynamics constitute two of the most intricate and most important aspects of stratified flows. A reasonable evaluation of the interfacial friction may lead

[2] Prof., Dept. of Civil Engrg., Aristoteles University of Thessaloniki, Greece; and Prof., Dept. of Engrg. Sciences, University of Florida, Gainesville, Florida, U.S.A.

to a quantitative model, since stratified flow systems are controlled by gravity, friction, and inertia forces; they can, therefore, be readily analyzed to various degrees of approximation provided that suitable expressions for the friction forces at the interface and at the solid boundary are introduced. Two typical examples of such models are the one-dimensional analyses for uniform density underflows (6) and for arrested saline wedges (13).

In an earlier paper the authors reviewed studies on stratified flows prior to 1978 (4, 10). It was found that results obtained through various theories and equations differed enormously, and that the scattering of experimental data points in certain studies was too wide for the formulation of any reliable universal law (7, 8). The discrepencies were attributed to the restricting assumptions and conditions of each study and to the limited range of variation of the governing parameters while the scattering of data points suggested either that an inadequate number of independent variables was taken into consideration or that these variables were not properly separated in the dimensionless correlation parameters for their effect on the friction coefficients to be sufficiently displayed. It, moreover, appears that turbulent exchange through the interface may take place to a degree sufficient for the generation of Reynolds stresses while the flow maintains its stratified appearance (11).

The authors, in their first attempt to derive a univeral functional relationship for the interfacial friction coefficient, conducted extensive experimental investigations in a closed rectangular duct where fresh water was flowing over a quasi-stagnant salt water layer at various salinities (4, 10). The analysis of the test data was based on a one-dimensional steady uniform flow model similar to that developed by Schijf and Schoenfeld for open channels (13). Attempts to correlate f_i with the Reynolds number, the densimetric Froude number, and the Keulegan number resulted, like in several earlier studies, in wide scattering with no consistent trend of variation. The Keulegan number is defined by the Eq.:

$$\theta = \frac{1}{V}\left(\nu\, g\, \frac{\Delta\rho}{\rho}\right)^{1/3} \qquad (1)$$

where V is the local average velocity in the moving layer, ρ is the density of the fresh water, $\Delta\rho$ is the density difference between fresh and salt water, g is the acceleration of gravity and ν is the kinematic viscosity assumed to be the same for both fluids.

The scattering was minimized and a consistent trend of variation was achieved when f_i was plotted against the parameter $ReFr^2$, where Re and Fr are the Reynolds number and the non-densimetric Froude number, with $\Delta\rho/\rho$ as an independent parameter. The family of curves, thus obtained, agrees reasonably well with reanalyzed data obtained by other investigators and with one data point from the Mississippi river. In the present study, a similar correlation was achieved for both $\overline{f}_i$ and $\overline{f}_o$ for saline wedges. The interfacial shear stresses were evaluated both directly from hot film anemometer measurements and from

an integration of the equation of motion over each layer along the same line used by Keulegan (7, 8).

2. THEORETICAL BACKGROUND

The interfacial friction coefficients, f_i, have been evaluated by the following four different approaches:

2.1 Direct Measurement Approach

This approach was based on directly measured velocity profiles and Reynolds stresses from which the interfacial shear stress was computed by the equation:

$$\tau_i = \mu \frac{du}{dy} - \rho\overline{u'v'} \tag{2}$$

In this equation, u is the local temporal mean velocity, y is the direction normal to the flow direction, x, u' and v' are the instantaneous turbulent velocity components in the x and y directions respectively, and μ is the dynamic viscosity. From Eq. 2 the local interfacial friction factor, f_i, is defined as:

$$f_i = \frac{8\tau_i}{\rho V_1^2} \tag{3}$$

where V_1 is the average fresh water velocity (Fig. 1).

2.2 Integration of the Equations of Motion

In this approach the equations of motion were integrated for each layer in the vertical and in the horizontal directions over the salinity intrusion length.

The general two-dimensional equations of motion and continuity for steady flow have the forms:

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -g\frac{dz_o}{dx} - \frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{1}{\rho}\left(\frac{\partial \tau_{zx}}{\partial z} + \frac{\partial \tau_{yx}}{\partial y}\right) \tag{4}$$

and

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{5}$$

where, refering to Fig. 1, u and v are the local temporal mean velocities in the x and y direction respectively, z is the horizontal direction normal to x-y plane, z_o is the bed elevation and τ_{zx} and τ_{yx} are the shear stresses in the direction x, acting on planes normal to z and y directions repectively.

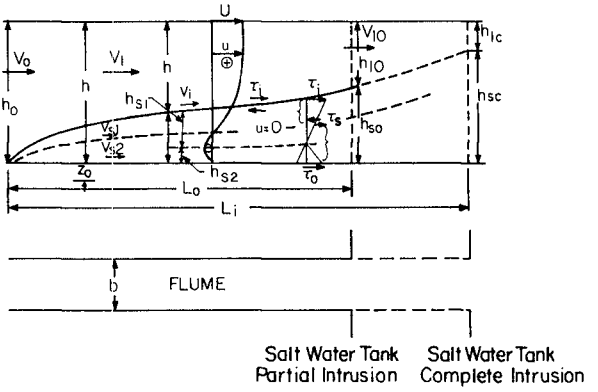

Fig. 1. Definition sketch of an arrested saline wedge.

A combinaton of Eqs. 4 and 5 leads to:

$$\frac{\partial u^2}{\partial x} + \frac{\partial (uv)}{\partial y} = -g \frac{dz_o}{dx} - \frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{1}{\rho}\left(\frac{\partial \tau_{zx}}{\partial z} + \frac{\partial \tau_{yx}}{\partial y}\right) \qquad (6)$$

The last equation is first integrated over the cross sectional area of each layer separately and subsequently over the length of intrusion. In the second integration two cases had to be considered: 1) the case where the depth near the salt water basin is critical and the salinity intrusion length attains its maximum value, L_i and 2) the case where the fresh water depth near the basin is larger than critical, whereas the intrusion length, L_o, is less than L_i. In all experiments a layer of fresh water was formed over the salt water basin. As long as the depth of that layer was smaller than the critical depth of fresh water at the channel entrance, it had no effect on the salinity intrusion which attained its maximum length, L_i; otherwise, the actual intrusion length was equal to the distance from the toe of the wedge to the point where the fresh water depth is equal to that over the basin.

2.2.1. Complete intrusion.

2.2.1.1 Fresh water layer

The pressure distribution in that layer is given by

$$p = p_o + \rho g(h - y) \quad \text{for } y \geq h_s \qquad (7)$$

where $h = h_1 + h_s$ (Fig. 1) and where the vertical direction y is measured from the bottom. Eq. 6 is next integrated over the cross sectional area bh_1. Setting:

$$\alpha V_1^2 A_1 = \iint_{A_1} u^2 dA \tag{8}$$

where α is the momentum flux correction coefficient, neglecting the velocity variation in the z direction and taking into consideration the Leibnitz rule, integration of the first term of the left hand member yields:

$$\int_{-\frac{b}{2}}^{\frac{b}{2}} dz \int_{h_s}^{h} \frac{\partial u^2}{\partial x} dy = \frac{\alpha}{2} bh_1 \frac{dV_1^2}{dx} - bU^2 \frac{dh}{dx} + bV_i^2 \frac{dh_s}{dx} \tag{9}$$

where U and V_i are the velocities at the free surface and at the interface, respectively. Likewise:

$$\int_{-\frac{b}{2}}^{\frac{b}{2}} dz \int_{h_s}^{h} \frac{\partial (uv)}{\partial y} dy = bU^2 \frac{dh}{dx} - bV_i^2 \frac{dh_s}{dx} - bV_i v_s \tag{10}$$

where v_s is the net rate of salt water entrainment. The vertical velocity at the free surface is:

$$v_h = U \frac{dh}{dx} \tag{11}$$

and the same velocity at the interface was taken as:

$$v_{hs} = V_i \frac{dh_s}{dx} + v_s \tag{12}$$

The integrated terms of the right hand member of Eq. 6 are:

$$\int_{-\frac{b}{2}}^{\frac{b}{2}} dz \int_{h_s}^{h} g \frac{dz_o}{dx} dy = bh_1 g \frac{dz_o}{dx} \tag{13}$$

$$\frac{1}{\rho} \int_{-\frac{b}{2}}^{\frac{b}{2}} dz \int_{h_s}^{h} \frac{\partial p}{\partial x} dy = bh_1 g \frac{dh}{dx} \tag{14}$$

$$\frac{1}{\rho} \int_{h_s}^{h} dy \int_{-\frac{b}{2}}^{\frac{b}{2}} \frac{\partial \tau_{zx}}{\partial z} dz = -\frac{2h_1 \tau_w}{\rho} \tag{15}$$

$$\frac{1}{\rho}\int_{-\frac{b}{2}}^{\frac{b}{2}} dz \int_{h_s}^{h} \frac{\partial \tau_{yx}}{\partial y}\, dy = -\frac{1}{\rho}\, b\tau_i \tag{16}$$

where τ_w is the shear stress at the sidewalls. Eq. 6 obtains thus the form:

$$\frac{dH}{dx} + \frac{\alpha}{2g}\frac{dV_1^2}{dx} + \frac{1}{\rho g h_1}\left(\tau_i + \frac{2\tau_w h_1}{b}\right) + \frac{V_i v_s}{g h_1} = 0 \tag{17}$$

where H is the piezometric head, $z_o + h$, and $\frac{dH}{dx}$ is, therefore, the slope of the piezometric line. The entrainment velocity is equal to:

$$v_s = \frac{q_s}{b\bar{L}_i} \tag{18}$$

where q_s is the rate of salt water entrainment over the saline wedge. The latter has been given by Keulegan (8). In the analysis of data, the term $V_i v_s/gh_1$ was found to be of minor importance with a maximum effect of 5%. Because of this reason and of the fact that entrainment takes place not continuously over the interface, but at isolated spots in the form of breaking of interfacial waves, it was neglected in the subsequent analyses. Expressing, next, τ_w by:

$$\tau_w = f_w \frac{\rho V_1^2}{8} \tag{19}$$

the following equation for τ_i is obtained:

$$\frac{\tau_i}{\rho} = -g(h - h_s)\frac{dH}{dx} - \frac{\alpha}{2}(h - h_s)\cdot\frac{dV_1^2}{dx} - \frac{f_w(h - h_s)V_1^2}{4b} \tag{20}$$

which, integrated for $-L_i$ to 0, gives:

$$\frac{T_i}{\rho V_o^2} = -g\frac{h_o}{V_o^2}\overline{\frac{dH}{dx}}\, I_1 - \frac{\alpha h_o}{2L_i} I_2 - \frac{f_{wo} h_o}{4b} I_3 \tag{21}$$

where T_i and $\overline{dH/dx}$ are the average values of τ_i and of dH/dx over the wedge and where I_1, I_2 and I_3 are the following dimensionless functions:

$$I_1 = \int_{-1}^{0} \left(\frac{h}{h_o} - \frac{h_s}{h_o}\right) d\left(\frac{x}{L_1}\right) \tag{22}$$

$$I_2 = \int_{-1}^{0} \frac{1}{V_o^2} \frac{dV_1^2}{d\left(\frac{x}{L_1}\right)} \left(\frac{h}{h_o} - \frac{h_s}{h_o}\right) d\left(\frac{x}{L_1}\right) \tag{23}$$

$$I_3 = \int_{-1}^{0} \frac{f_w}{f_{wo}} \left(\frac{V_1}{V_o}\right)^2 \left(\frac{h}{h_o} - \frac{h_s}{h_o}\right) d\left(\frac{x}{L_1}\right) \tag{24}$$

For the evaluation of these integrals, the following dimensionless equations for the interface, developed by the authors and Mehta and based on Schijf and Schoenfeld's model (11, 13), was used:

$$\frac{x}{L_1} = \frac{\left(\frac{h_s}{h_{sc}}\right)^3 \left\{\left[4 - 2\frac{h_s}{h_{sc}}\left(1-(F_o')^{2/3}\right)\right]^2 + \left[4 + \frac{h_s}{h_{sc}}\left(1-(F_o')^{2/3}\right)\right]\right\}}{6(F_o')^{4/3} + 3(F_o')^{2/3} + 1} + \\ - \frac{10\left(\frac{h_s}{h_{sc}}\right)^2 \left[(F_o')^{4/3} + (F_o')^{2/3} + 1\right]}{6(F_o')^{4/3} + 3(F_o')^{2/3} + 1} + 1 \tag{25}$$

where $F_o' = V_o\sqrt{g(\Delta\rho/\rho)h_o}$ is the densimetric Froude number with V_o and h_o defined in Fig. 1. The three integrals obtain thus the form:

$$I_1 = \frac{2\left[5(F_o')^2 + 6(F_o')^{4/3} + (F_o')^{2/3} + 1\right]}{3\left[6(F_o')^{4/3} + 3(F_o')^{2/3} + 1\right]} \tag{26}$$

$$I_2 = 2\left[(F_o')^{-2/3} - 1\right] \tag{27}$$

$$I_3 = \frac{0.29\left[5 + 255(F_o')^{13/6} - 221(F_o')^2 - 39(F_o')^{17/6}\right]}{\left[1 - (F_o')^{2/3}\right]^3 \cdot \left[6(F_o')^{4/3} + 3(F_o')^{2/3} + 1\right]} \tag{28}$$

2.2.1.2 Salt water layer

A similar integration of Eq. 6 over the cross sectional area of the wedge, $A_s = bh_s$, with the pressure this time described by the equation:

$$p = p_o + (h - h_s)\rho g + g(\rho + \Delta\rho)(h_s - y) \tag{29}$$

gives:

$$\frac{\tau_i + \tau_o}{g(\rho + \Delta\rho)h_s} = \frac{\rho}{\rho + \Delta\rho} \cdot \frac{dH}{dx} + \frac{\Delta\rho}{\rho + \Delta\rho} \cdot \frac{d(h_s + z_o)}{dx}$$

$$+ \frac{\beta}{gh_s} \frac{d(V_i^2 h_s)}{dx} + \frac{V_i v_s}{gh_s} = 0 \tag{30}$$

where β is the momentum flux correction coefficient for the lower layer given in terms of V_i by:

$$\beta V_i^2 A_s = \iint_{A_s} u^2 dA \tag{31}$$

and where the sidewall friction has been neglected since, due to the reversal of flow direction, its overall effect is expected to be negligible . Integration of Eq. 30 from $-L_i$ to 0 gives:

$$\frac{T_i}{\rho V_o^2} + \frac{T_o}{\rho V_o^2} = \frac{gh_o}{V_o^2} \frac{\overline{dH}}{dx} I_4 + \frac{g\frac{\Delta\rho}{\rho}}{2V_o^2 L_i} h_{sc}^2 + \frac{\rho \frac{\Delta\rho}{\rho} h_o}{V_o^2} \cdot \frac{\overline{dz_o}}{dx} I_4$$

$$+ \beta\left(1 + \frac{\Delta\rho}{\rho}\right) \left(\varepsilon \frac{V_{ic}}{V_o}\right)^2 \cdot \frac{h_{sc}}{L_i} \tag{32}$$

where T_o is the average bed shear stress over the length of intrusion, $\overline{dz_o}/dx = -S_o$ is the average bottom slope, $h_{ic} = h - h_{sc}$ is the critical depth of the fresh water layer, and $\varepsilon = V_i/V_o$. The term $V_i v_s/gh_s$ has again been neglected for the aforementioned reasons while the integral I_4 is:

$$I_4 = \int_{-1}^{0} \frac{h_s}{h_o} d\left(\frac{x}{L_i}\right) \tag{33}$$

which, on the basis of Eq. 25, becomes:

$$I_4 = \frac{\left[1 - (F_o')^{2/3}\right] \cdot \left[10(F_o')^{4/3} + 4(F_o')^{2/3} + 1\right]}{3\left[6(F_o')^{4/3} + 3(F_o')^{2/3} + 1\right]} \cdot \qquad (34)$$

The analysis presented so far is similar to the one used by Keulegan (7, 8) with the following differences: 1) A more detailed analytical equation for the wedge profile has been used instead of one single experimental curve and, 2) the actual measured values of α and β for each experiment were used, instead of the constant values of $\alpha = 1.028$ and $\beta = 0.146$ used by Keulegan.

2.2.2 Partial intrusion

In several experiments, the fresh water layer at the downstream basin was larger than h_{1c} - in which case the salt water depth at the downstream end of the channel, h_{so}, was smaller than h_{sc} (Fig. 1). In these cases the following simplified form of Eqs. 21 and 32 was derived and used: First, Eqs. 20 and 30 are written in the form:

$$\frac{\tau_i}{\rho V_o^2} = -\frac{gh_1}{V_o^2}\frac{dH}{dx} - \frac{\alpha h_o}{V_o}\frac{dV_1}{dx} - \frac{f_w h_1 V_1^2}{4bV_o^2} \qquad (35)$$

$$\frac{\tau_i}{\rho V_o^2} + \frac{\tau_o}{\rho V_o^2} = \frac{gh_s}{V_o^2}\frac{dH}{dx} + \frac{(\frac{\Delta\rho}{\rho})gh_s}{V_o^2} \cdot \frac{dh_s}{dx} + \frac{\beta(1+\frac{\Delta\rho}{\rho})^2 \varepsilon^2}{V_o^2} \cdot \frac{d(V_1^2 h_s)}{dx} \qquad (36)$$

where dz_o/dx in Eq. 32 has been neglected as much smaller in comparison to dh_s/dx and where the wall friction coefficient f_w has been introduced by the Blasius equation:

$$f_w = \frac{0.316}{Re^{0.25}} \qquad (37)$$

where the Reynolds number, Re is:

$$Re = \frac{4V_1 R_{h1}}{\nu} \qquad (38)$$

and

$$R_{h1} = \frac{bh_1}{(b + 2h_1)} \qquad (39)$$

Eq. 35 obtains thus the form:

$$\frac{\tau_i}{\rho V_o^2} = -\frac{gh_1}{V_o^2}\frac{dH}{dx} - \frac{\alpha h_o}{V_o}\frac{dV_1}{dx} - \frac{0.0559}{b^{1.25}} h_o^2 \left(\frac{\nu}{V_o h_o}\right)^{0.25} \left[\frac{(b + 2h_1)^{0.25}}{h_1}\right] \qquad (40)$$

Averaging of Eqs. 36 and 40 over the actual length of salinity intrusion, L_o, as in the case of full intrusion, but considering h_1 and h_s constant and equal to their average values $\bar{h}_1$ and $\bar{h}_s$, leads to the following equations:

$$\frac{T_i}{\rho V_o^2} = -\frac{g\bar{h}_1}{V_o^2}\frac{d\bar{H}}{dx} - \frac{\alpha h_o}{h_{1_o}} \cdot \frac{h_{so}}{L_o} - \frac{0.0559}{b^{1.25}} h_o \left(\frac{\nu}{V_o h_o}\right)^{0.25} \left[\frac{(b + 2h_1)^{0.25}}{h_1}\right] \tag{41}$$

and

$$\frac{T_1}{\rho V_o^2} + \frac{T_o}{\rho V_o^2} = \frac{g\bar{h}_s}{V_o^2} \cdot \frac{d\bar{H}}{dx} + \frac{\left(\frac{\Delta\rho}{\rho}\right)g}{2V_o^2} \cdot \frac{h_{so}^2}{L_o} + \frac{\beta\left(1 + \frac{\Delta\rho}{\rho}\right)\varepsilon^2 V_{1_o}^2}{V_o^2} \cdot \frac{h_{so}}{L_o} \tag{42}$$

where bars indicate average values over the length L_o. For a direct evaluation of the average stresses T_1 and T_o, given either by Eqs. 21 and 32 or by 41 and 42, a reliable measurement of the average slope of the piezometric line, $d\bar{H}/dx$, is required - as was done earlier by Keulegan (7, 8). This has been found to be very difficult, since the head loss over the effective length of the flume is of the order of a few tenths of a millimeter. Attempts to measure that head loss optically through a laser beam required an excessively long time of measurement, due primarily to the slowness of achieving equilibrium in the two static tanks, and to the very long period of oscillation of the water level in these tanks. Moreover, the above equations are quite sensitive to $d\bar{H}/dx$ so that a measurement error of the order of 10% may cause an error in T_1 of the order of 50% (5). This difficulty was bypassed by introducing a linear relationship between τ_1 and τ_o. Indeed, the shear stress distribution within the wedge is given by the equation.

$$\frac{\partial\tau}{\partial y} = \frac{\partial}{\partial x}\left[p + g(\rho + \Delta\rho)z_o + (\rho + \Delta\rho)\frac{u^2}{2}\right] \tag{43}$$

The velocity head is very small and can be neglected. Eq. 29 then, for p gives:

$$\frac{\partial\tau}{\partial y} = \rho g \frac{dH}{dx} + (\Delta\rho)g \frac{\partial(h_s + z_o)}{\partial x} \tag{44}$$

The free surface slope, dH/dx, is very small, as discussed, and can be considered as constant. Also, apart from two relatively short segments around the wedge toe and the critical section, the interface is very nearly a plane surface, and $d(h_s + z_o)/dx$ is also very nearly constant. Therefore, it is reasonable to assume linear variation of τ with y within the wedge. It follows thus from Fig. 1 that:

$$\frac{\tau_i + \tau_o}{\tau_i} = \frac{h_s}{h_{s1}} = \lambda \tag{45}$$

where h_{s1} is the distance from the interface to the point of maximum velocity in the wedge. It was assumed next that λ is constant over the wedge - in which case Eq. 45 holds also for the average stresses T_i and T_o, that is:

$$T_i + T_o = \lambda T_i \tag{46}$$

Eliminating $d\bar{H}/dx$ from Eqs. 41 and 42 and using the last relationship, the following equation is obtained:

$$\frac{T_i}{\rho V_o^2} = \left\{ \frac{\left[\left(\frac{\Delta\rho}{\rho}\right) g h_{so} + 2\beta\left(1 + \frac{\Delta\rho}{\rho}\right)\varepsilon^2 V_{1o}^2\right] h_{1o}\bar{h}_1 - 2\alpha h_o \bar{h}_s V_o^2}{2V_o^2 h_{1o}(\lambda\bar{h}_1 + \bar{h}_s)} \right\} \frac{h_{so}}{L_o} +$$

$$- \frac{0.0559}{b^{1.25}} h_o^2 \left(\frac{\nu}{V_o h_o}\right)^{0.25} \cdot \left[\frac{(b + 2h_1)^{0.25}}{h_1}\right] \cdot \frac{\bar{h}_s}{(\lambda\bar{h}_1 + \bar{h}_s)} \tag{47}$$

All the terms of the right hand member of Eq. 47 are either known or can be directly measured. The maximum measurement error of λ was estimated to be about 15% (5). With T_i computed from Eq. 47, T_o is readily evaluated from Eq. 46. $d\bar{H}/dx$ could be eliminated in the same way from Eqs. 21 and 32, valid for complete intrusion. However, after a few trials for the latter case, it was found that Eqs. 41 and 42 could be used for both partial and complete intrusion. These equations have been used for the analysis of all data.

2.3 One-dimensional Energy Equation

This equation, developed by Schijf and Schoenfeld (13), is based on the energy conservation principle applied separately to each layer and on the assumptions of one-dimensional flow, infinite width, and negligible entrainment through the interface. For zero net flow within the wedge, the average velocity is also zero and, therefore, for the one dimensional approach, τ_o has to be taken also as zero. The final form of the equation is:

$$\bar{f}_i = \frac{2h_o}{L_i}\left[\frac{1}{5(F_o')^2} - 2 + 3(F_o')^{2/3} - \frac{6}{5}(F_o')^{4/3}\right] \tag{48}$$

which gives the average interfacial friction factor if the total intrusion length is measured. If the actual intrusion length, L_o, is less than L_i, the latter can be computed graphically from Eq. 25, where h_{sc} is known and equal to $h_o[1 - (F_o')^{2/3}]$ (11).

2.4 Simplified Equations of Motion

This is a combination of the last two approaches and its main objective was to investigate the effect of the assumption of zero bed shear stress and zero wall stress, used in the one-dimensional model, on the interfacial shear. For $\tau_o = 0$, $\lambda = 1$, $f_w = 0$ and $\beta = 0$, Eq. 47 reduces to the approximate form:

$$\frac{T_i}{\rho V_o^2} = \left[\frac{(\frac{\Delta\rho}{\rho}) g \bar{h}_1 h_{so}}{2V_o^2 h_o} - \frac{\alpha \bar{h}_s}{\bar{h}_{1_o}} \right] \cdot \frac{h_{so}}{L_o} \qquad (49)$$

3. BASIC RESEARCH EQUIPMENT

The experiments were conducted in a variable slope plexiglass flume 20 m long, 46 cm wide, and 46 cm deep, constructed at the Coastal Engineering Laboratory of the University of Florida. This flume, outlined in Fig. 2, discharges into a 3 m by 1.53 m tank supported on another 3 x 3 x 0.75 m^3 tank.

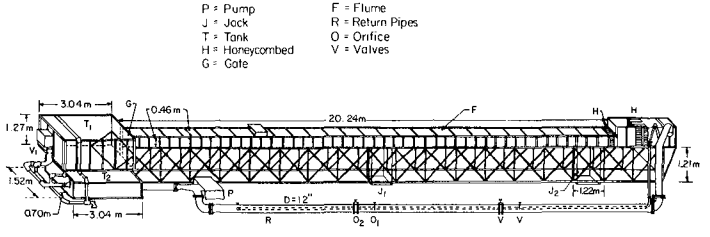

Fig. 2. Outline of basic experimental apparatus.

The channel is connected at its upstream end to a 2.31 m by 0.45 m head tank where the fresh water is pumped into from the fresh water tank and where turbulence dampens out through a honeycombed section. The water circulation system consists of an axial flow pump, of two pipes with either one or hoth in operation, depending on the required discharge, and of all the necessary orifice meters, valves, gates, pressure taps and manometers. The maximum discharge is ahout 115 l/sec.

The channel and head tank are supported on a steel frame 1.2 m high, which rests on two hydraulic jacks - one at the center and the other at the upstream end of the flume. Through a gear-chain system, the central jack could be moved up and down at a distance equal to $\frac{1}{2}$ that of the upstream jack. The $\frac{1}{2}$ -inch thich plexiglass wall of the flume forms a channel with its flanges, fortified with stiffeners, directed outwards. To this steel frame, rails have been placed on

each of the upper two flanges for the support and smooth movement of the instrument carriage. The downstream end of the channel is connected to the salt water tank through a five centimeter long thick rubber forming a flexible and waterproof hinge. A water-tight vertical plexiglass gate separates the flume from the salt water tank. That gate can be raised and lowered mechanically by a vertical threaded shaft and a circular threaded disc supported on an independently fixed frame. A second gate at the downstream end of the salt water tank regulates the water level in the latter. The outlined system of flume and tanks is supplemented with the necessary pipes and valves for proper operation and control.

The measuring instruments - that is, the hot film anemometers, a specially designed salinity probe, and the point gages - are supported on the aforementioned carriage, which is collapsable sidewise to permit its movement over the cross bars of the flume without removing the instruments.

4. EXPERIMENTAL RESULTS

After the necessary preparations and instrument calibration, each experiment was started and continued to a point where reasonable steady state conditions were established. Entrainment caused a gradual erosion of the salt water layer as a result of which salt water had to be periodically supplied from the preparation tank to the salt water basin. Space limitations do not permit a description of the detailed procedures of experimentation and calibration, which can be found in ref. (5) and in a forthcoming report. The measurements took place immediately after the steady state was achieved and lasted for about one-half hour, during which no measurable change in the flow conditions occurred. The primary measurements consisted of velocity and density profiles - with points more densely located around the interface. The instantaneous velocities were recorded on tapes from which the Reynolds stresses were subsequently computed. A total of 74 experiments were conducted with fully developed turbulent flows. The relative density difference, $\Delta\rho/(\rho + \Delta\rho)$, in these experiments ranged from 0.008 to 0.093. In such flows the velocity distribution in the neighborhood of the interface was found to be logarithmic and quite similar to that near solid boundaries. This is in general agreement with results from earlier studies (2, 9) but with major differences in certain important aspects. The velocity distribution laws and the flow structure around the interface is the subject of another forthcoming paper. It was found that the salinity distribution around the interface follows closely the law:

$$\frac{\rho_\ell - \rho}{\Delta\rho} = \frac{1}{2}\left[1 - \tanh\left(\frac{y - h_s}{\delta/2}\right)\right] \tag{50}$$

where ρ_ℓ is the local density, y is the distance from the bed, h_s is the depth of the density interface, and δ is the thickness of the interfacial zone, as defined in Fig. 3.

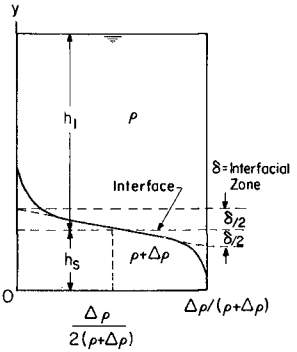

Fig. 3 Definition sketch for the interfacial zone.

As determined in an earlier study by the authors (4, 10), it was again found that the best correlation is obtained if f_i, determined by any one of the outlined four methods, is plotted against the dimensionless number $ReFr^2$ with $\Delta\rho/(\rho + \Delta\rho)$ as an independent parameter, where:

$$Re = \frac{4\overline{V}_1 R_h}{\nu}, \quad Fr^2 = \frac{V_1^2}{gR_h} \tag{51}$$

and where R_h is the hydraulic radius of the fresh water layer. The parameter $ReFr^2$ can be written in the form:

$$ReFr^2 = \frac{4\overline{V}_1^3}{g\nu} = \frac{4V_o^3 I_R}{g\nu} \tag{52}$$

where:

$$I_R = \frac{10}{\left[6(F_o')^{4/3} + 3(F_o')^{2/3} + 1\right]} \tag{53}$$

In Fig. 4 the results for four of the eight ranges of $\Delta\rho/(\rho + \Delta\rho)$ computed by all four approaches are shown with the average value of $\Delta\rho/(\rho + \Delta\rho)$ for each range indicated at the insert. The results from all four approaches can thus be compared. Here the interfacial friction coefficient is defined either as:

$$f_i = \frac{8\tau_i}{\rho\overline{V}_1^2} \tag{54}$$

or as:

$$\bar{f}_i = \frac{8T_i}{\rho \bar{V}_1^2} \tag{55}$$

with T_i computed from Eq. 47 for the second approach and from Eq. 49 for the fourth approach. In the third approach $\bar{f}_i$ was evaluated from Eq. 48. The comparison of these four sets of data leads to the following conclusions:

First, as in the earlier study by the authors (4, 10), the scattering of data points around each curve is minimal for a flow of this type. Secondly, there is a very good agreement between the data obtained from the first two approaches - that is, between the data based on direct shear stress measurements and those based on the integration of the equations of motion. These data constitute the lower family of curves. Thirdly, there is an equally good agreement between the results based on the two approximate approaches and which constitute the upper family of curves (dotted lines). Finally, a comparison of the two families of curves indicates that both approximate approaches give values of f_i considerably higher than the corresponding values obtained either by direct measurments or through the equations of motion. This difference is indicative of the effect of neglecting the bed shear stresses. It follows that $\bar{f}_i$, as determined from Eq. 48 through calibration, that is, by measuring L_i either in the laboratory or in the field (11), can be used as a convenient virtual friction coefficient for modeling purposes; it is not representative of the true shear stress at the interface, however.

The above conclusions hold also for the case of $\Delta\rho/(\rho + \Delta\rho)$ equal to 0.0225, 0.0355, 0.0485 and 0.082. For this reason the data for these cases are not reproduced in detail; instead, the summary of all eight curves based on the first and second approach is given in Fig. 5.

In Fig. 6 the curve corresponding to $\Delta\rho/(\rho + \Delta\rho) = 0.0225$ has been reploted together with reanalyzed laboratory data by Abraham and Eysink (1) and with one field data point from the Mississippi estuary (11). The agreement is quite good. This suggest that until the curves of Fig. 5 are implemented with field data, they can be tentatively extrapolated following the extrapolation of the 0.0225 curve of Fig. 6.

In Fig. 7, the results for $\Delta\rho/(\rho + \Delta\rho) = 0.0225$ are compared with resent results obtained by Powell for flow of fresh water over a semistagnant deep water layer in an open conduit and for a relative density difference close to 0.024 (12). When plotted against the Reynolds number only, these two sets of data deviate strongly (Fig. 7a); however, they appear to closely agree when they are plotted against $ReFr^2$. In fact, the drop of the curve for low values of $ReFr^2$ agrees with the trend observed in the authors' experiments. Thus, Powell's point for Re≈22000, which in his original diagram (Fig. 7a) seems to be in error, is in fact in agreement with the general law derived from this study.

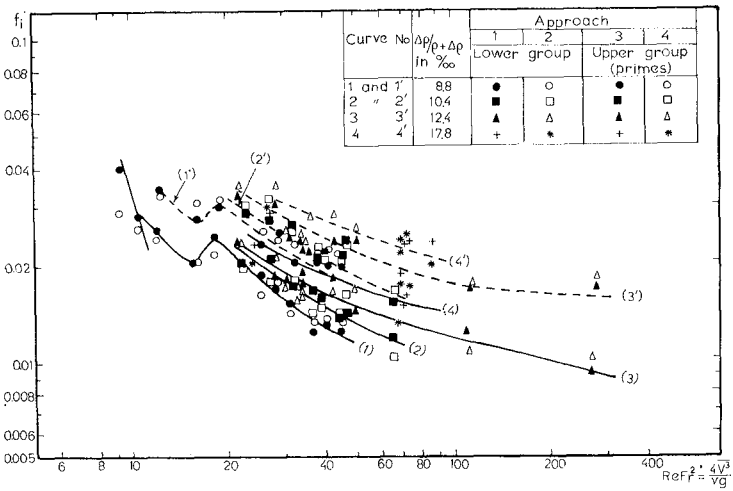

Fig. 4. Interfacial friction coefficients obtained from all four approaches.

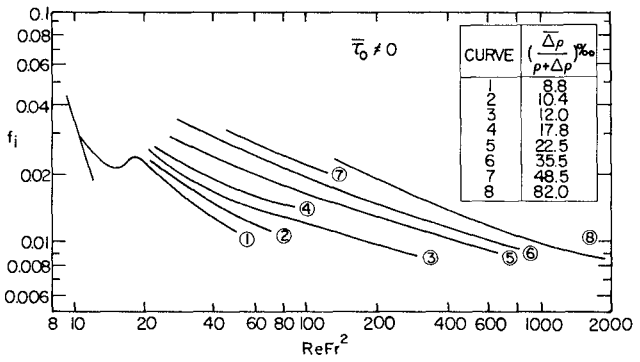

Fig. 5. Summary of interfacial friction coefficient curves based on approaches (1) and (2).

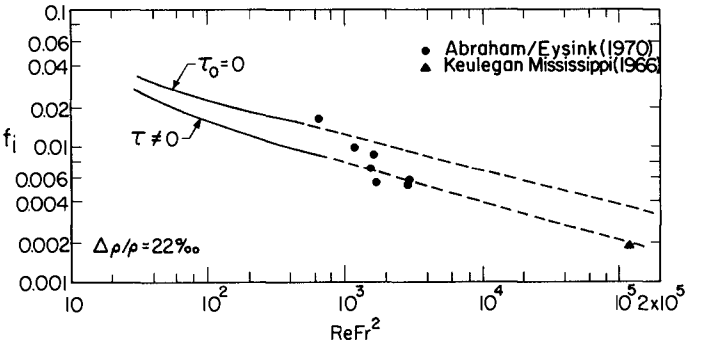

Fig. 6 Comparison of results of the present study with test data of previous studies.

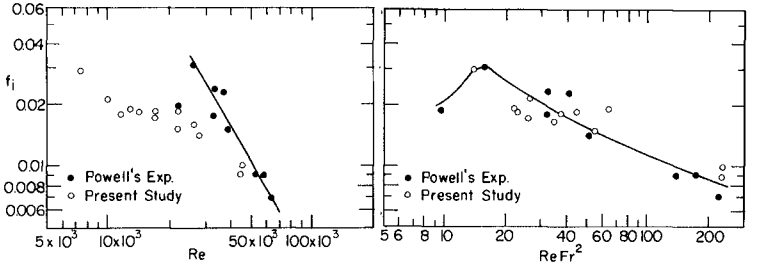

a. Plot vs Re b. Plot vs $ReFr^2$

Fig. 7 Comparison of results of present study with Powell's data (12).

The bed friction coefficient, f_o, defined as:

$$f_o = \frac{8T_o}{\rho \bar{V}_1^2} \tag{56}$$

has been determined from Eq. 46 where $T_1 = \tau_1$ was computed from Eq. 54 for values of f_1 taken from Fig. 5. The value of λ was determined for each experiment and the results are shown in Fig. 8. λ appears to be a function of the number $ReFr^2$ only while for values of the latter smaller than 100, it is essentially constant and equal to about 1.4. The results are plotted in Fig. 9 as a family of curves similar to the

one of Fig. 6. It is observed that, contrary to conclusions of earlier studies (7, 8), f_o is clearly smaller than the corresponding f_i.

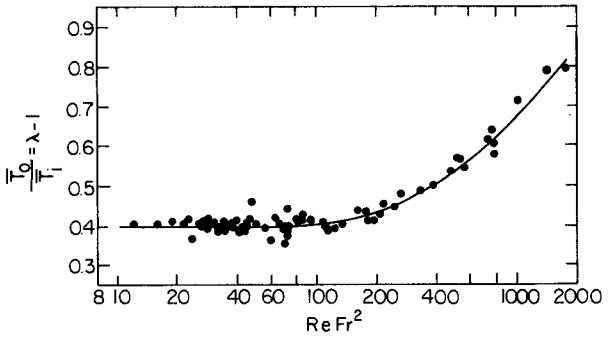

Fig. 8 Variation of $\lambda = \tau_i/\tau_o$ with $ReFr^2$.

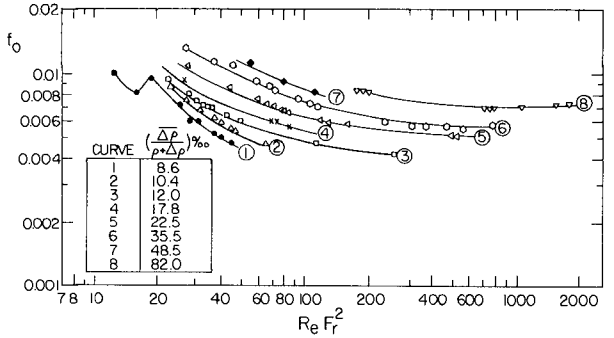

Fig. 9. Bed friction coefficients, f_o.

5. SUMMARY AND CONCLUSIONS

Laboratory experiments and theoretical analyses led to a new relationship linking the friction coefficients at the interface and at the bed of arrested saline wedges to the pertinent flow parameters and fluid properties. The relationships are presented graphically as a family of curves with $ReFr^2$ as an abscissa and the relative density difference, $\Delta\rho/(\rho + \Delta\rho)$, as an independent parameter. The scattering of data points was minimal and much lower than in earlier studies on the subject. In the present correlations the number $ReFr^2$ incorporates the friction, gravity, and inertia forces, which control the main flow, while the buoyant forces, which are responsible for the

density stratification and the asociated flow pattern have been separated and introduced through the parameter $\Delta\rho/(\rho + \Delta\rho)$.

This study indicated that values of f_i evaluated through an integration of the equations of motion closely agree with values based on measured velocity profiles and Reynolds stresses. Values of f_i obtained from the simplified and frequently used Schijf-Schoenfeld's one-dimensional analysis were shown to be higher than corresponding values based on the previous two methods.

ACKNOWLEDGEMENTS

This study has been supported by the U.S. National Science Foundation under Grant No. ENG 76-11537-A01. Travel funds were provided to the second author by the same institution under Grant No. CEE - 8214607 for presentation of this paper before the 18th International Conference on Coastal Engineering in Cape Town, South Africa. Both supports are gratefully acknowledged.

MORPHOLOGICAL REACTIONS OF TIDAL SYSTEMS DUE TO NEARSHORE CONSTRUCTION WORKS

by

R. DIECKMANN[1], H.W. PARTENSCKY[2], H. SCHWARZE[3]

1. INTRODUCTION

The nearshore region of the North German North Sea coast is characterised by a large area of tidal flats with a width of 10 to 30 km (Fig. 1).

The development of the structure of this coastal area in the past centuries was mainly determined by several severe storm surges, which have destroyed the formerly existing coastline. In its present state the coastal area is subdived into numerous tidal flats, islands and peninsulas of different size and more or less deep channels and small gullies.

Due to its historical development, this area cannot be expected to be morphologically stable. Once people learnt to build safe dikes, the coastline existing at the time was fixed whilst the islands in the shore belt were protected against flooding during storm surges.

However, the shore belt is furthermore exposed to waves and tidal currents which cause - apart from certain shiftings of gullies - extensive permanent erosion and sedimentation in parts of the shore belt with an increasing tendency in the last decades. The nearshore region at some places on the coast is extremely endangered in its function as part of the coastal protection system, consisting of the dike, the foreshore above MHW and the tidal flat area.

First attempts to achieve morphological stabilisation of the nearshore region consisted in the construction of dams normal to the coastline. However, the shore belt still remained morphologically unstable and could not yet be transformed into a stable system.

FRANZIUS-INSTITUT, University of Hannover,
Federal Republic of Germany

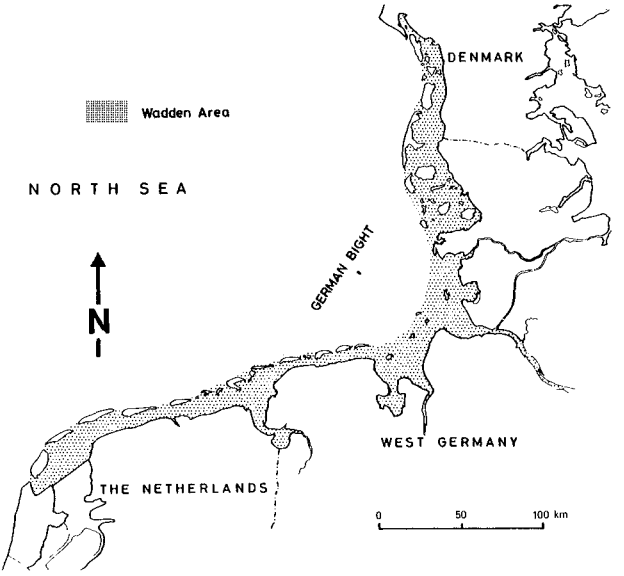

Fig. 1: Map of the North Sea with the German Bight

It was the aim of intensive investigations at the FRANZIUS-INSTITUT, together with the local authorities involved in these problems, to demonstrate the influence of artificial structures on the morphological reactions of well defined drainage areas, consisting of tidal flats and gullies, to a morphological stabilisation of the shore belt.

2. CONCEPT OF INVESTIGATIONS

On the basis of former investigations showing qualitative relationships between geometrical and hydrological parameters, investigations were performed in order to quantify morphological changes to be expected as a result of a variation of a drainage area due to dikes or reclamation works, or in other words, the artificial structures necessary to stabilise a morphologically unstable drainage area.

For instance, a stability criterion was determined for tidal systems, in which the ratio of the tidal prism upstream of a certain cross-section to the area of that cross-section at mean water level is a constant value. According to this criterion, if the tidal prism decreases, the cross-section will decrease proportionally.

In a more detailed investigation (RENGER and PARTENSCKY,1974), the evaluation of some 25 tidal systems, in which artificial constructions had not yet been carried out, showed a clear relationship between the tidal prism (water volume between Mean Low Water and Mean High Water Level) V_{TP} (in 10^6 m^3) and the corresponding drainage area E (in km^2), as follows (Fig. 2)

$$V_{TP} = 1.65 \cdot E^{1.036} \quad (1)$$

as well as between the volume of the tidal basin below Mean Low Water V_{MLW} (in 10^6 m^3) and the drainage area E (in km^2) (Fig. 3)

$$V_{MLW} = 4.39 \cdot 10^{-2} \cdot E^{1.643} \quad (2)$$

Certain scatter in the data may be explained by the fact that not all selected areas are in a true stable state.

The results of these investigations represent an important step towards solving the problem, since the possibility of generalising the results for all drainage systems has been demonstrated. However, deviations of calculated mean values from actual values for a certain drainage area using the above-mentioned equations provides only an approximate indication of the instability of the overall area. The distribution of erosion and sedimentation to be expected in different parts of the drainage area could not, however, be determined.

3. SUMMARY OF RECENT RESULTS

Recent investigations, carried out on approximately 50 tidal flat systems with different subsystems and subsubsystems along the Dutch, German and Danish coasts, have shown that the above criteria are also generally valid for parts of these basins.

Equations (1) and (2) can therefore be used in a stepwise determination of the increasing volume of the tidal basin from the origin of the main gully towards the sea.

For these evaluations, drainage areas are subdivided into portions as given by the distribution of gullies, branching more and more towards the coast line. Watersheds are determined on both sides of the gullies as boundaries of the drainage area belonging to the gullies (Fig. 4).

For each of these drainage areas, water volumes below MLW, as well as volumes of the tidal prism, are calculated and summarised for the whole drainage area.

The latter calculation results in a summation curve for the tidal volume relating to the surface area of the tidal basin. This curve describes the stable morphological and hydrological state of a drainage system.

This represents an important result of the investigations

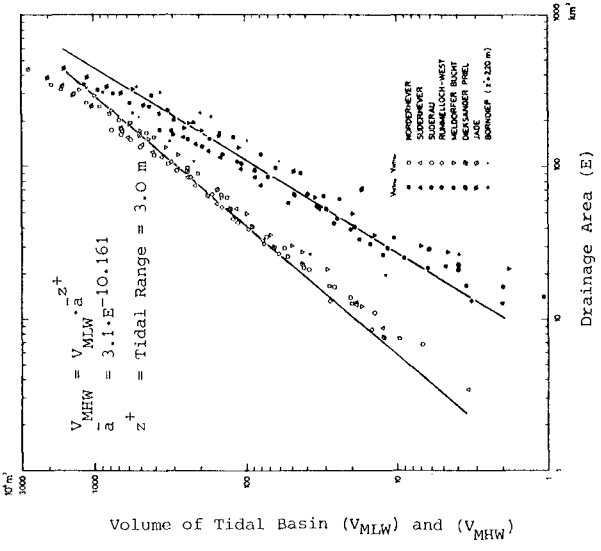

Fig. 3: Relationship between Volume below MLW/MHW and Drainage Area

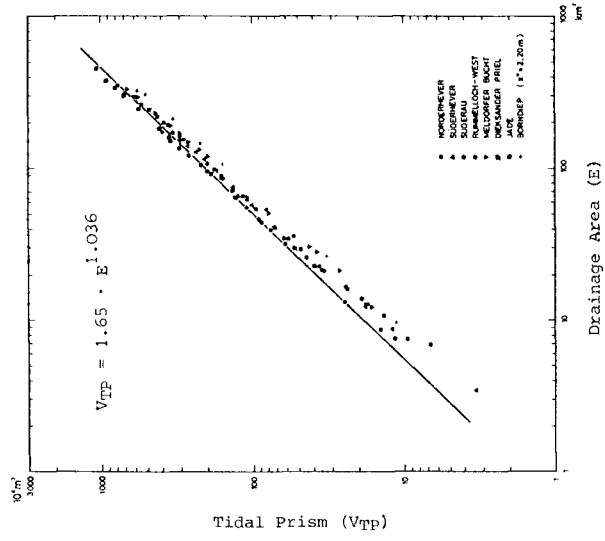

Fig. 2: Relationship between Tidal Prism V_{TP} and Drainage Area E

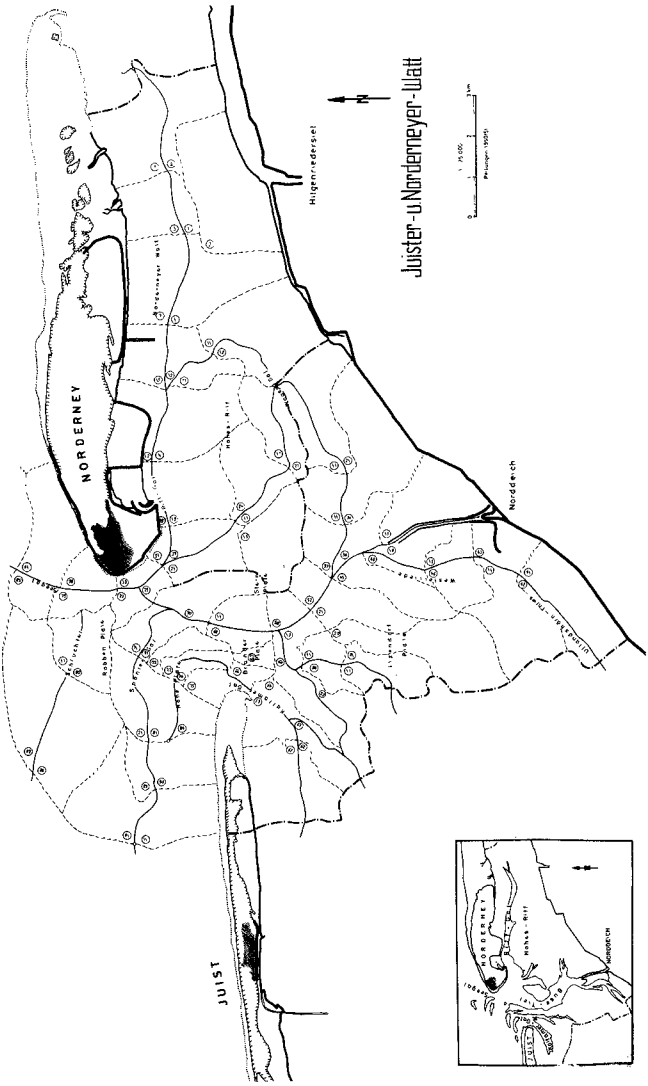

Fig. 4: Subdivision of a Drainage Area (Juister/Norderneyer Tidal Basin, Germany)

with respect to the description of the inner structure of a drainage area.

On the basis of the stability criteria for tidal systems, the stability of a certain area can be evaluated by comparing the measured tidal volume to that determined analytically from the volumetric summation curve based on equations (1) and (2). The deviation from the theoretical curve, which represents the equilibrium state, indicates the degree of instability of the tidal system and subsystems concerned.

In the case of a volumetric deficit, in which the calculated curve lies above the measured curve, erosion may be expected in the tidal basin. In the case of a surplus in tidal volume, a shrinkage of the tidal basin due to sedimentation will occur.

Fig. 5 illustrates a well-balanced tidal basin (Rummelloch-West). In Fig. 6, a tidal basin is presented in which sedimentation is present (Süderau).

The stability criteria show that a given drainage area is associated with a well-defined volume. This equilibrium can be disturbed by artificial measures such as nearshore constructions. The morphological reactions of the tidal system can be determined quantitatively from a comparison of the volumetric summation curves.

In addition, sedimentation in a nearshore region can be caused by the construction of offshore dikes and artificial dams.

Comparisons of water volumes, evaluated on the basis of hydrographic charts and soundings, with calculated volumes, have shown that some of the tidal basins on the northern coast of the Federal Republic of Germany are not in a state of equilibrium, but are rather subject to temporary erosion and sedimentation phases. The erosion of these areas significantly endangers the structural stability of the sea-dikes as well as of the islands in the vicinity of the coast.

For instance, in the last 50 years, increasing erosion has occurred in a gully between an island situated approximately 10 km from the coast and the shore line. In 1930 the water depth of this gully was only 0.5 m. Up to now the gully has deepened to nearly 12 m. The adjacent subdrainage areas are also in a state of erosion.

This problem can be overcome by constructing offshore dikes and control-dams between the mainland and the island concerned, thereby reducing the drainage area of the tidal basins. By this means, areas of erosion in a tidal basin may be influenced in such a way as to convert the deficit of volume into a surplus. Plans have been made to stabilise a coastal region of about 450 km^2 in this manner.

As an example, results of evaluations for a subsystem of the tidal system HEVER in the North Frisian shore belt are given

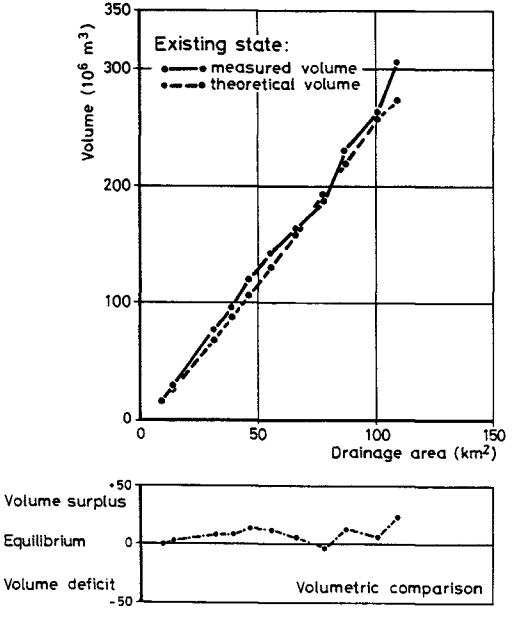

Fig. 5: Volumetric Comparison for Tidal Basin RUMMELLOCH as an Example of a well balanced Tidal Basin

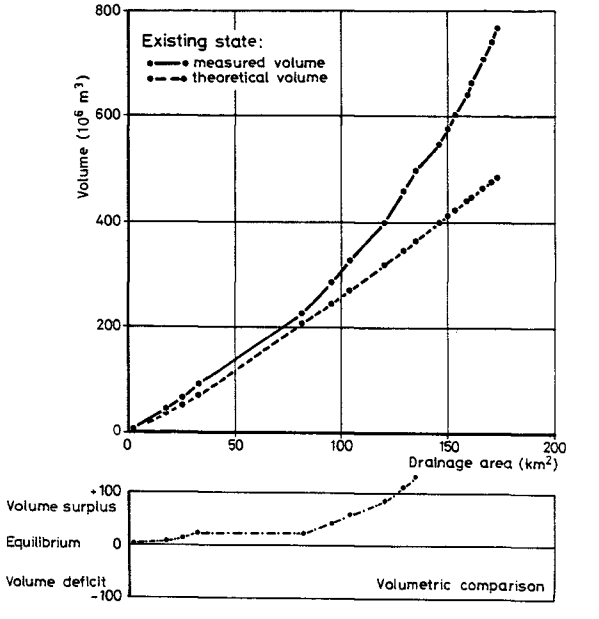

Fig. 6: Volumetric Comparison for Tidal Basin SÜDERAU as an Example of a Tidal Basin in which Sedimentation is Present

in Fig. 7. In this case, the summation curve for the water volume below MHW is plotted in relation to the length of the main gully of the subsystem HEVER. Calculations for the determination of the stability criterion were carried out using equations (1) and (2). The measured volume of water is determined on the basis of bathymetric plans.

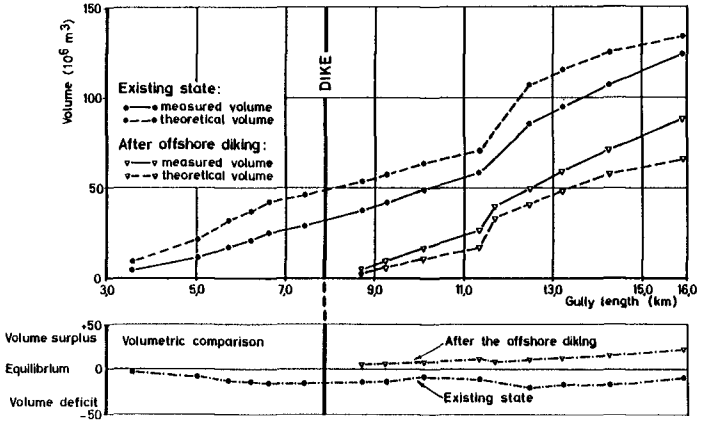

Fig. 7: Volumetric Summation Curves for Tidal Basin HOLMER FÄHRE at MHW before and after the Planned Offshore Diking Project

The comparison of both curves shows erosion throughout the entire system. The system is unstable and erosion must be prevented by an artificial construction, such as a dike, which reduces the drainage area.

By considering a certain dike, volumetric summation curves calculated both theoretically from equations (1) and (2), and evaluated on the basis of bathymetric plans for the reduced drainage area, are also plotted in Fig. 7. A comparison of the volumetric summation curves shows a change in the morphological behaviour of the system. The former volume deficit could be converted into a volume surplus, which means that sedimentation can be expected to stabilise the nearshore region in all cases.

4. APPLICATION OF THE RESULTS

Such investigations were carried out for all main drainage areas in the latter region of the German shore belt. An example of the results for one of the subareas is illustrated in Fig. 7.

On this basis of these results, a system of dams and dikes were planned in order to avoid further dangerous erosion of the nearshore flats (Fig. 8).

The conservation of the belt of foreshore and flats is vitally necessary to ensure stability of the islands distributed in the shore belt as well as the coastline. Nearshore reclamation works involving artificial groynes and trenches will be introduced in order to support and accelerate the natural morphological changes induced artificially.

The results of the investigations indicate the magnitude of volumetric changes to be expected in a tidal system until a morphologically stable state is achieved. The time dependent development of erosion or sedimentation, as well as the time necessary to establish a new final state following the construction cannot be predicted on the basis of the applied method at the present time.

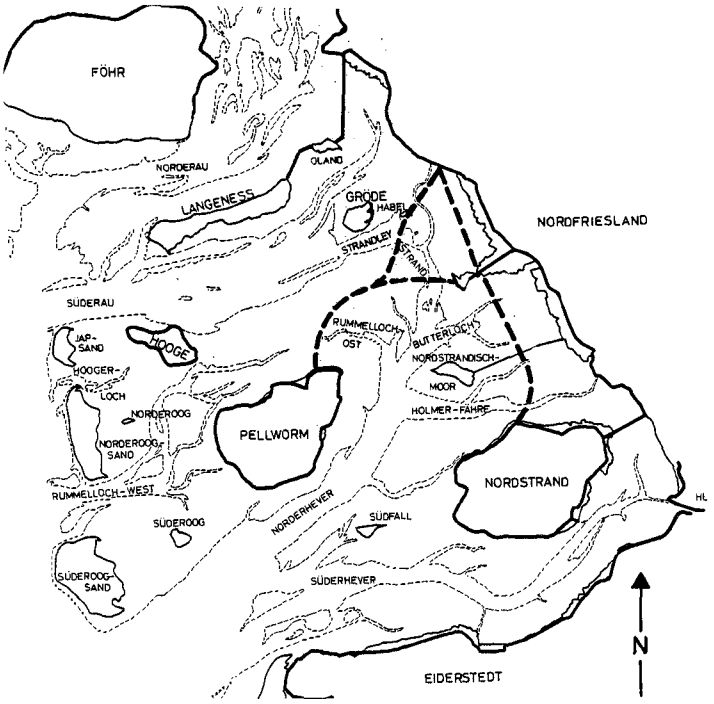

Fig. 8: Offshore Diking Project in the North Frisian Shore Belt

During the period of construction, and particularly after completing the system of dams and dikes, detailed measurements will be carried out in order to monitor morphological development. A minimum necessity is to provide confirmation of the empirically determined basis for estimating such a large impact on a tidal system.

A SURVEY OF MAN-MADE TIDAL SWIMMING POOLS ALONG THE SOUTH AFRICAN COAST

by

D E BOSMAN*, D J P SCHOLTZ**

1. INTRODUCTION

A large number of man-made tidal swimming pools (two examples are shown in Figure 1) exist along the South African coast. They are usually situated on rocky outcrops in the close vicinity of popular sandy bathing beaches to provide protected bathing conditions in these areas mainly for children and elderly people. Some tidal pools, especially along rocky coast, provide the only safe bathing facilities. Besides affording protection against waves and surfzone currents the pools provide protection from sharks. A large number of tidal pools were built during the early 1950s along the Natal South Coast after the occurrence of a relatively large number of shark attacks on bathers on that coast.

The semi-diurnal tide with a range of about 1,5 m along the South African coast makes it possible for pools to be built such that water replenishment can occur during every high-water (approximately every 12 hours) during both neap and spring tide periods.

Presently, there exists a great need for more tidal pools as part of the demand for more recreational facilities along the South African coast. However, no information on design criteria could be found in the literature.

2. OBJECTIVES

Because of the existing lack of design guidelines for tidal pools it was decided to make a detailed survey of the existing pools. Data obtained from such a survey could then contribute to the first step in identifying factors which should be considered to ensure safe swimming conditions, effective operation of pools, minimum maintenance and minimum impact on the environment.

SUNSET BEACH TIDAL POOL

STRANDFONTEIN TIDAL POOL

FIGURE 1. EXAMPLES OF TIDAL POOLS

3. METHODS USED

Information on types, physical characteristics, maintenance, operation and usage was obtained from questionnaires sent to local authorities, followed up by discussions with the authorities and by making site visits to the pools.

Detailed observations such as of rate of overtopping versus tidal level were made at 13 of these pools.

Available aerial photographs of pools were also used as a source of information on the location and environment of the pools.

4. RESULTS

4.1 General

Data for 80 tidal pools (about 90 per cent of the existing pools along the 3 000 km coast) were obtained. Most of these pools are situated in the more highly developed coastal areas i.e. the Cape Peninsula, Natal South coast, Port Elizabeth and East London areas. The distribution of tidal pools along the South African coast is shown in Figure 2. It was found that tidal pools play an important role in providing safe bathing conditions. On rocky coasts and dangerous sandy beaches tidal pools provide, in many cases, the only safe bathing conditions, and where a safe bathing beach for adults exists, a tidal pool close to it can provide in the important need of safe bathing conditions for small children.

4.2 Types

Two basic types of pools could be distinguished:

(i) Pools which are partly enclosed by walls. The landward sides of these pools consist of sandy beaches.

(ii) Pools which are fully enclosed by walls. These are either attached to the shore or can become detached from the shore during the high water.

Figure 3 illustrates schematically the different types. The pools which are partly enclosed by walls are usually situated on beaches with relatively flat slopes. (See a, Figure 3). Their walls enclave part of the beach so that the depth in the pool varies from zero at the beach to the maximum depth of the pool at the seaward side. Wall crest levels of these pools are relatively low so that they usually do not significantly interrupt the longshore sediment movement in the beach zone. The pools which are fully enclosed by walls are usually situated on beaches with relatively steeper slopes. Pool b in Figure 3 illustrates the detached type and pool d the type attached to the beach with relatively high walls which exclude the beach from the pool and reach up to the primary dune. The semi-detached type (c, Figure 3) tends to intercept the longshore sediment transport on the beach with a consequent sand build-up next to the pool. The sand build-up can be of such an extent that large quantities of sand can eventually enter the pool.

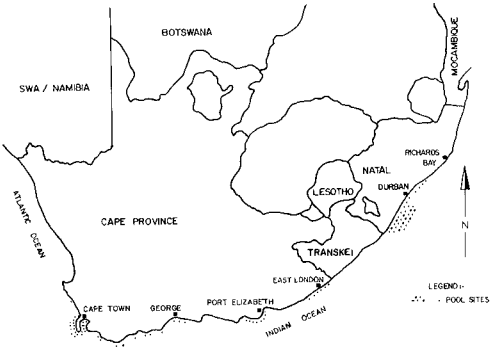

FIGURE 2: DISTRIBUTION OF TIDAL POOLS ALONG THE SOUTH AFRICAN COAST.

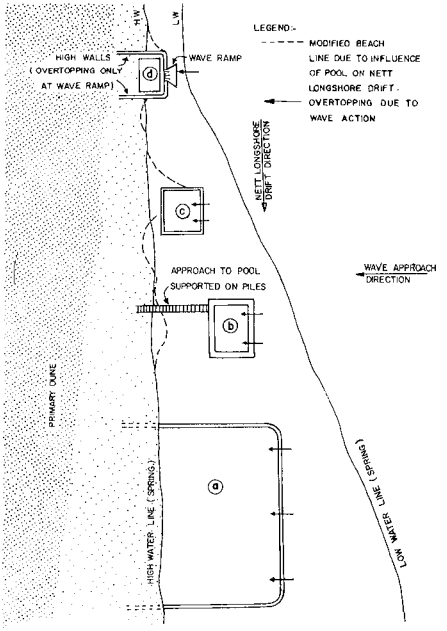

FIGURE 3: SCHEMATIZATION OF TYPES OF POOLS

4.3 Physical Characteristics

The walls of all pools (mostly of mass concrete) are founded on rock except in one case where the walls are partly founded on steel sheet piles driven 6 m into sand. (Besides serving as a foundation support to the wall the sheet piles also limit seepage of water from the pool). The foundation level of the walls are in most cases above the mean low spring tidal level.

Distributions of pool water area, wall crest level and maximum pool depth for the majority of the pools in Natal and Cape Province are shown in Figures 4, 5 and 6 respectively and the dominant ranges of these are summarized in the table below:

Parameter	Natal	Cape Province
Water area (m^2)	500 - 1 000	500 - 1 500
Wall crest level (m above mean sea level)	1,0 - 2,0	0,5 - 1,5
Maximum pool depth (m)	1,25 - 2,0	1,25 - 2,25

The wall crest levels of most of the pools are above the mean high water spring tidal level with the predominance of crest levels about 0,1 m to 0,5 m above mean high water spring level.

The majority of the pool walls facing the approaching waves have seaward slopes between 2:1 and vertical and crest widths between 0,4 m and 1,0 m.

Pool floors consist usually of either sand or rock or a combination of the two. Some pools have concrete floors.

All pools are provided with drain pipes at the lowest position in the pool to allow drainage during low water spring tides.

4.4 Operation

Detailed observations made of 13 pools showed that the rate of water inflow due to wave overtopping as well as the tidal level at which inflow commences is largely influenced by the location of the pool (namely, whether protected from wave attack by shallow rocky outcrops or whether exposed to large waves).

Other important factors influencing inflow are tidal level, wall crest level, offshore wave conditions and local wind conditions.

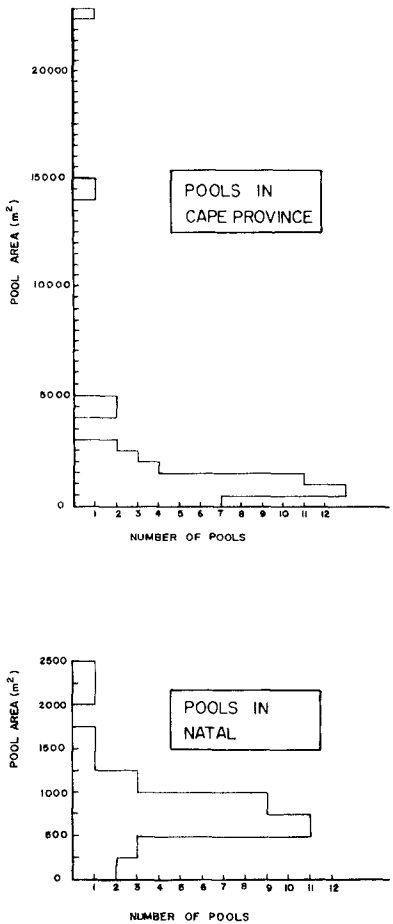

FIGURE 4: DISTRIBUTION OF POOL AREAS

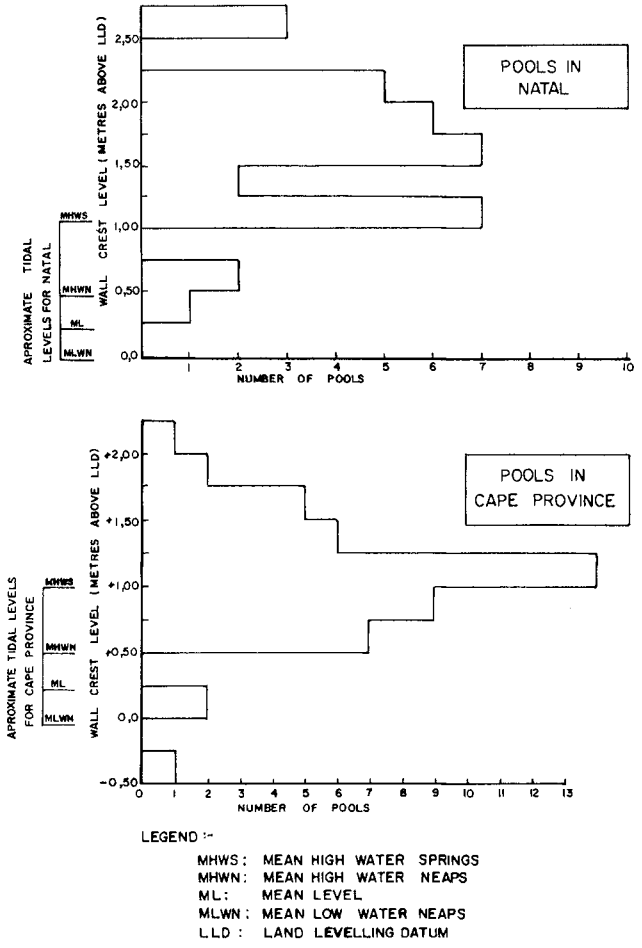

FIGURE 5: DISTRIBUTION OF WALL CREST LEVELS

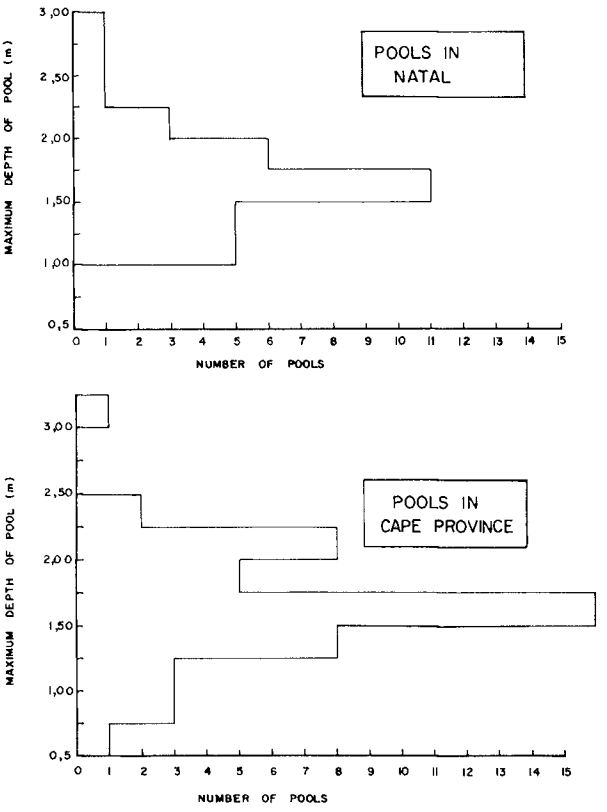

FIGURE 6: DISTRIBUTION OF MAXIMUM DEPTHS OF POOLS

Because of the above many factors, a large range in the water inflows during high water spring tide of between 20 and 650 m^3 per m length of wall was recorded.

4.5 Maintenance

A large number of pools are drained fortnightly to clean the pools, remove accumulated sand and to enable the rock and concrete surfaces to be washed with lime to control the growth of slippery algae. Other chemicals used to control algal growth are carbide and copper sulphate.

Several well-sited pools with low crest levels are self maintaining since inflow is frequent and sufficient to minimize the growth of algae and sand accumulation. These pools are usually submerged during high water spring tides.

4.6 Problems

A few pools are frequently sanded up due mainly to incorrect siting. Two of these are sanded up to such an extent that they are out of use.

Water replenishment at about eight of the pools is considered to be insufficient. This leads to stagnant water conditions and excessive algal growth.

Some of the pools are dangerous since bathers can be washed from side or back walls out to sea.

Parts of walls of three of the pools have been destroyed by waves. This was probably due to weak walls and improper bonding between wall and rock foundation.

5. DESIGN FACTORS TO BE CONSIDERED

The study indicated a number of factors which should be considered in the design of a recreational tidal swimming pool.

(a) The needs of the bathers: It should be established whether provision should be made for small children as well as adults and the type of bathing (e.g. swimming, diving, playing etc.) required by the bathers.

(b) The siting of the pool: The pool should preferably be situated so that the walls can be founded on rock where possible. Where no rock foundation is present sheet piling could be considered as a foundation for the walls. Seasonal variation of the beach profile as well as longshore sediment transport in the beach zone should be considered in the siting to prevent the pool from being sanded up.

Sufficient consideration should also be given to the aesthetic and ecological considerations to minimize the impact of the structure on the environment.

(c) Water replenishment by wave action: Sufficient quantities of

fresh sea water should enter the pool frequently enough and overflows should be situated so that adequate renewal of water throughout the pool is ensured. A general criterion for inflow would be to stipulate that inflow should occur at least during high water neap tides with dominant wave conditions. The walls should be built rather too low than too high since it will be easier to raise the walls if this is afterwards found to be necessary. The seaward slope of the wave-facing wall should be about 2 horizontally on 1 vertically or flatter since flatter slopes increase overtopping and stability.

(d) Safety: The pool floor should be even and if the pool is not of uniform depth the slopes should be gentle. Situations where overwash from walls to sea can occur which could be a danger to bathers should be prevented. Intakes of drain pipes should be covered with grids. Notice boards indicating water depths should be provided.

(e) Maintenance: The floor level of the pool should be above low water springs to allow drainage. It appears to be good practice to whitewash the walls with lime when the pool is cleaned as this apparently retards the growth of algae and shells and also gives the pool an attractive and tidy appearance.

DESIGN OF COASTAL STRUCTURES FOR RECREATIONAL PURPOSES
by G H O'CONNELL Pr Eng B.Sc C.E.

1. INTRODUCTION

1.1 Although the major aspect of this paper deals with a specific part of the South African coast line it is believed that certain fundamental parameters which emerge are applicable to the greater part of the Southern African coast line of 2954 km.

Typical of the African continent the nature of the Southern African coast line is regular and even with few bays or inlets and has long unprotected beaches subject to long- and off-shore current patterns.

The absence of barrier islands as well as the few in number of protected lagoons and inlets, requires the creation of artificial tidal enclaves or the protection of selected sections of beach to ensure safe bathing conditions where further extensions of existing areas is indicated both by an increase in the population as well as changing socio-economic conditions which place access to the coastal recreation areas, as an increasing facility, to a steadily growing number of people.

This need has been intensified in South Africa by the rapid urbanisation and socio-economic development of the rural population as well as the geographic dispersion of the population of which a high percentage lives at or near the coast.

It is unfortunately so that the need to provide additional access to the beach areas exists in such areas where maximum exploitation of the beach frontage has already taken place and where new development must take place accordingly in less favourable conditions and subject to various constraints imposed by existing development in these areas.

These constraints are inter alia the development of industrial areas right onto the beach front, urban area development on the beach front and sewage outfall works discharging raw sewage into the surf zone.

The absence of an adequate inland area contiguous to the beach, forces planners to absorb an increasing part of the primary dune area to accommodate parking areas and other facilities required for the accommodation of the mass migration to the beaches.

These very constraints imposed upon the planner as well as the capital limits to development, in itself creates a further concentration of people in the most vulnerable part of the beach environment.

1.2 The paper now laid before this congress seeks to evaluate various considerations and factors which lead to the adoption of certain design parameters which may satisfy the criteria of safety, user preference, health standards, beach stability and sympathetic environmental treatment.

The creation of a pleasing and sensible development of beach recreation areas may in turn be seen to create a need for a service infrastructure including access under peak conditions not dissimilar to those associated with a new and popular sports stadium.

The submissions made provide certain suggested standards for the service infrastructure for the accommodation of peak conditions. Notwithstanding that the objective of the submissions is to achieve a common philosophy in planning which may be applied generally, the analyses undertaken are relevant to particular sections of the coast line and are user orientated to that section of the population most likely to make use of the facilities thus created.

However, the successes attained as well as the errors incurred may hopefully stimulate sensible and responsible planning for the future.

1.3 Whereas the design of extensive coastal structures involves the complete spectrum of environmental, sociological, transport, future urbanisation and economic research, it is patently not within the terms of reference of this paper to deal with these other than in general terms when such have a direct bearing on the structure design and general arrangement being promoted.

The author expresses the opinion however that controlled and planned exploitation of selected portions of the coast to accommodate the needs of a growing and economically developing population is of greater overall environmental benefit than is a lack of planned development and a consequent concentration of human activity in the ecologically sensitive areas as an unlimited dispersion of temporary sojourners without a sense of permanent involvement.

2. USER CONSIDERATIONS AND PREFERENCES

2.1 Other than in the case of natural parkland areas where the emphasis is in the maintenance of the environment

and ecological system, the creation of artificial bathing areas is both to accommodate man and also to control his further exploitation of the coastal areas for recreation purposes.

In this regard no sensible planning can be undertaken without an indepth study of the user characteristics and preferences. User preferences vary from the east coast to the west coast over the length of the coast line of 2954 km. where the warm Mozambique-Agulhas current, which skirts the east and south coasts as far as Cape Point, is replaced by the Cold Benguela System flowing north along the west coast, with climatic conditions which vary from dominantly subtropical conditions on the North and East coast to generally cool temperate conditions of the South coast with the uninvitingly cold waters of the West.

These climatic as well as water temperature conditions determine the relative degree of emphasis on bathing or dry beach activity.

2.2 User preferences are also related to the heterogeneous character of the South African population and demographic considerations pertinent to the community involved. These in turn are affected by the degree of cultural and social heterogeniety prevalent as well as economic standards of different sections of the community.

Notwithstanding this complexity of influencing factors, man tends to adjust himself in his recreation to the circumstances and environment existing, provided such satisfies certain norms and in this regard the following is quoted from the report titled "Coastal Development Project - False Bay Coast - Cape Town". (Reference No 1).

"The relevant quality of bathing and beach enjoyment conditions, whether natural or man created, is of considerable but not sole importance, and are evaluated by the individual in terms of a number of other facets of his recreational pursuits and his decision to utilize a particular recreation area is the result of his assessment of all relevant factors in their inter-related importance, of which the accessibility of the beach area, provided that all other aspects are reasonably satisfied, may be of highest priority to the individual.

Under accessibility we consider that the actual point at which the motorcar is parked or where the bus delivers passengers, relative to the point where the individual may start 'doing his thing' is, in relative importance of equal value to the route and quality of access road from home to recreation destination.

It has been established that particularly in the case of the more affluent section of the total society, people will travel considerably further to reach a beach where they may step out of the vehicle onto the sand or where they may park their vehicle in the immediate vicinity of the beach and bathing area with good sight of beach activity and a continuous sense of involvement in the beach environment.

Throughout South Africa the significance of this aspect is revealed by the degree of preference given to those areas where parking is immediately adjacent to the beach, lagoon or bathing pool."

This inter-relationship between accessibility and quality of recreation, places an additional constraint on the selection of sites for development and requires the coastal engineer to be pleasingly creative under the most adverse physical conditions in order to create safe bathing conditions as near as practical to immediate access from motor vehicle parking areas which are served by arterial road systems.

The capital cost of the transport infrastructure synonomous with beach development schemes encourages the urban planner to create out of the area a grand terminus for all conceivable recreation as representing the optimum utilisation of capital resources.

The presence however in the vicinity of the beach area of other forms of entertainment such as park and playground development does not of necessity increase the popularity of the beach area but attracts generally a differently motivated recreation seeker whose presence in the area places a fresh complexity on the service infrastructure required and due to various factors adversely affects the comfort, safety and security of parents with young children.

The population age structure in respect of communities in the vicinity of which new beach recreation areas are being planned and which communities accordingly will be the dominant users of the facilities provided is particularly significant as will appear from the following figures applicable to the False Bay area.

Population Age Structure	
0 - 4 years	16,3 percent
0 - 9 years	32,1 percent
0 - 14 years	45,0 percent
0 - 19 years	55,5 percent
0 - 24 years	65,2 percent

For planning purposes, while giving the family factor due weight, the visitor population age structure is

likely to be :

3 - 9 years	45 percent
10 - 15 years	16 percent
16 - 24 years	14 percent
25 years and over	25 percent
Total :	100 percent

This reveals an important emphasis on the lower age group.

3. DEVELOPMENT OF DESIGN CRITERIA

3.1 All design, irrespective as to its nature, requires an evaluation of system loading and in the case of a tidal pool or bathing enclave with its related supporting infrastructure this is equally true, in as much as it is necessary to make a prediction of the visitor normal peak and the manner in which this may be accommodated in its occurence within the bathing area, on the beach, within the change rooms and ablution blocks and in terms of the transportation system.

There is no universal formula which can be applied and each particular set of circumstances requires its own evaluation based on, among others, the following factors and considerations :

1) The overall completeness and attractiveness of the beach recreation scheme and its immediate environs.

2) The relationship of parking areas and other transportation termini to the point where the individual may commence 'doing his thing'.

3) The capacity and quality of arterial road systems, their congestion factors and the distance to be travelled.

4) The socio-economic standards of the respective population.

5) The demographic structure of the relevant population.

6) The spatial relationship of urban residential areas and population densities.

3.2 In the studies and planning undertaken in the False Bay area of Cape Town the careful weighting and evaluation of the factors referred to, led to the preparation of a visitor projection graph for normal peak days of the form

$$p = k_1 - k_2 S^{\frac{1}{2}}$$

where p - resultant percentage of resident population who would visit the beach on a warm, sunny, low wind, vacation day.

k_1 - maximum effective percentage for people resident within walking distance of beach.

k_2 - spatial relationship - population dispersion factor.

S - best route travelling distance in kilometres.

The importance of the formula lies not solely in an assessment of visitor peak influx but also in the rational assignment of traffic flows to various routes and transportation modes.

The values adopted for the False Bay report are :

$K_1 = 40$; $K_2 = 5$

3.3 Notwithstanding the peak tendency, the facilities provided will have their own optimum capacity beyond which the user congestion factor acts to limit the abnormal peak and deflect the balance of visitors to other or adjoining areas.

For the planner however it is important that capacities throughout the system be consistent and compatible one with the other. In other words the overloading of the bathing enclave would be accompanied by an overload on the dry beach area, parking areas, toilet and ablution blocks, etc.

This requires the determination of a comfort level optimum capacity bearing in mind that man is gregarious in nature and beach crowding is part of the scene he loves.

Up to a water depth of 800 mm a loading of 20 people per square metres is acceptable; from 800 mm to 1500 mm the loading should not exceed 12 people per 100 square metres and over 1500 mm in depth the loading should be less than 8 persons per 100 square metres.

This would place the optimum capacity of the Strandfontein tidal pool at 5000 people whereas a peak of over 15000 has been experienced.

The probable ratio at peak hour of people in the water to people on the dry beach is 1 to 2.

3.4 A structural and geometric design philosophy for the attainment of favourable bathing conditions is functionally related to the measure of assurance of the

ordinary bather, when committing himself to the relatively strange environment, in his ability to predict changes in underwater topography as well as the dynamic forces to which he may be subjected.

In practical terms this design philosophy can be stated as ensuring that :

1) No localised changes of any serious consequence occur in the beach or tidal enclave topography in the design area.

2) The occurence of irregular and/or strong currents be eliminated.

3) That a beach gradient of good regularity and not exceeding 1 in 50 in the surf bathing zone between High Water Mark and Mean Sea Level - 3,0 metres should be aimed at.

4) That in the case of a tidal pool the floor gradient should not exceed 1 in 30.

5) That a sand area is to be preferred to a rock and sand area in the bathing zone.

3.5 Service To be Provided

The minimum number of plumbing fittings required for male and female changerooms should be in accordance with the applicable Building Regulations for places of public entertainment based on sixty percent of the assessed recreation area optimum capacity divided evenly between both sexes.

Changerooms should provide accommodation for peak usage at three percent of the optimum capacity at 2,5 square metres per person.

External showers should be provided on the ratio of ten percent of changeroom capita accommodation. An equal number of faucets is required within each changeroom block.

4. THE FALSE BAY RESEARCH AND CONSTRUCTION PROGRAMME

4.1 A report evaluating the need for development in the False Bay area and recommending further research was presented in 1979 and resulted in the construction of a tidal pool at Strandfontein Point as well as an extended research progamme in respect of protective works at Middlebank and Kapteinsklip.

4.2 The Strandfontein Tidal Pool Model Tests were carried

out at an early stage of the False Bay Model Studies and were directed at :

1) an examination of wave action under various wave conditions with a view to predicting the inflow of freshwater to the pool area for the geometric configration and full supply levels recommended by the Consultants

2) the determination of the stability of the toe armouring proposed

3) the determination of the overturning forces on the seawall due to wave action

4) a correlation between inflow and sediment transport into the pool.

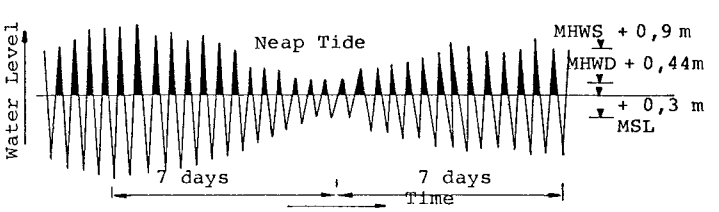
Various tests for different wave conditions and tidal levels were undertaken by the C.S.I.R. the results of which in practice after completion of construction were found to be of a high order of accuracy of prediction.

The following limiting conditions of inflow from the model studies were ascertained for proto type crest level of seawall of R.L. 1,50 m M.S.L.

1) That inflow took place only during high tide conditions and when sea levels rose above R.L. 0,30 m M.S.L.

2) That no inflow under any conditions took place for wave heights (H_S) 0,40 m and less - which condition pertains for 16 percent of the time.

3) That during 50 percent of the high tides an inflow of more than 40 000 cubic metres could be expected.



These results together with the structural stability results for armouring size and overturning moments were employed in the final design.

A good indication of sediment inflow probability was available from the correlation calculations and in all the use of the model was found to be completely

successful and fully justified and served to confirm the consultants recommendations. It is not possible in this paper to deal with the C.S.I.R. report in depth but to provide the following salient features.

Scales applicable to the model testing in accordance with the Froude laws were :

Geometrical	$1 : 15$
Velocity	$1 : 15^{\frac{1}{2}}$ (1 in 3,87)
Time	$1 : 15^{\frac{1}{2}}$ (1 in 3,87)
Force	$1 : 15^{3}$ (1 in 3375)

In view at that time of the early stage of the False Bay project research as well as the urgency of the tidal pool aspect of the research being undertaken, model calibration was based on wave directions determined from aerial photographs then available and field observations from survey rods located in accordance with the prototype geometrical configuration at 20 metre intervals.

4.3 The objective of the experimental measurements of inflow due to wave action was to optimize the height of the seawall so as to achieve a satisfactory fresh water replenishment rate without the occurrence of unduly rough conditions within the pool.

A full supply level of M.S.L. 1,50m based upon previous experience was adopted for experimental purposes and found to be the optimum level for geometric design.

The lowering of the crest level by 200 mm revealed in the experimental analysis virtually no change to the conditions of no-inflow but did affect quite appreciably the total inflow and bathing conditions.

A final crest level for construction purposes of 1,40 m M.S.L. was adopted.

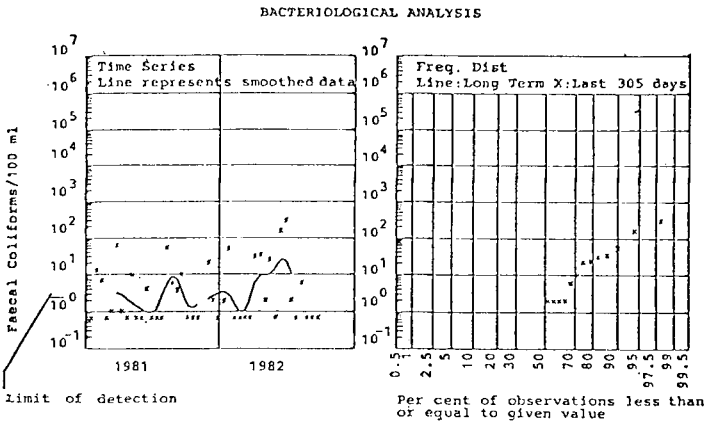
The experimental mean inflow per tide was found to be 40 000 cubic metres with a maximum at sea level 0,90 m (M.S.L) at M.H.W.S.T. of 160 000 cubic metres.

In general it was established that the best sustained inflow conditions occur during the summer months and in particular December and January when incidentally the most severe visitor loading of the tidal pool takes place.

During December 1978 the sustained period of S.W.L. below M.H.W. was two days; for the same month in 1979 on no occasion; one day in January 1978 and two days in January 1979 as acertained from the S.A. Tide Tables for 1978 and 1979.

The occurrence during the remainder of the summer season of suitable water levels for wave actuated inflow needs however to be equated within the limiting parameter of minimum significant wave height of 0,40 metres in respect of which value waves lower in height occur for 16 percent of the time. The median inflow per tide for the adopted crest level of 1,40 m M.S.L. has been assessed as being 50 000 cubic metres.

Monitoring of water quality by examination of the faecal coli count under peak conditions has been undertaken by the City Engineer and found under all conditions to comply with acceptable standards for public swimming baths thus justifying the crest level adopted and the model analyses of wave inflow.



4.4 Siting of the pool was subject to geographic, environmental and foundation constraints. The extension of the residential suburbs in an easterly direction placed emphasis on coastal recreation development within easy reach of these areas while at the same time creating a new problem of environmental control consequent to the selective exploitation for recreation purposes for several hundreds of thousand of people of a part of the coast line as yet untouched in the False Bay area.

Foundation problems as well as the type of structure limited the choice of site in as much as the least exposure of the structure to the open sea was sought in view of the economic inaccessibility of bedrock which lies upto ten metres beneath the unconsolidated sediments.

From a regional planning point of view the City Engineer of Cape Town favoured the development of three nodal points in the study area and accordingly studies were directed at the establishment of a tidal pool complex at Strandfontein Point and groyne systems at Middle Bank and Kapteinsklip to cater for larger beach crowds. This planning concept was found to be compatible with the hinterland development, forming a sensible whole.

The location as primary objective of a large tidal pool at Strandfontein Point involving the daily movement in season of scores of thousands of visitors into the area made the removal of primary dune and fynbos environment and the provision of landscaped grassed areas and parking allotments an inescapable feature of the project development.

4.5 Pursuant to the preliminary report more extensive investigations of foundation conditions were undertaken. Although general uniformity of geological conditions pertain in the study area the occurrence of an extensive, albeit soft, calcarenite shelf at Strandfontein Point offered the most protected section of the coast for a minor structure.

In this respect the author suggests that the geometric limitations of the structure and the need to create a light and pleasing arrangement required a greater need for design sensitivity than might otherwise be the case.

Geological investigations of offshore conditions both in the field as well as from aerial photographs revealed discontinuous platforms of calcarenite in the surf zone. The calcarenite rock took the form of a surface layer overlying an extensive depth of unconsolidated sands.

Sites were selected for exploratory drilling and boreholes were advanced through unconsolidated sands by washboring methods using bentonite to support the sides of the holes.

Representative samples of the unconsolidated materials being penetrated were taken at intervals of 1,5 metres.

The calcarenite beach rock was penetrated using a diamond bit and NX size cores were recovered in this consolidated material.

Standard Penetration Tests were carried out in the unconsolidated materials at intervals of 500 mm i.e. with gaps of 200 mm followed by 300 mm of penetration over which the Terzaghy N-value was recorded.

The following is an abstract from the report prepared by Dr T Partridge on the geological investigation :

"The properties of the various materials, deduced from the four exploratory boreholes, augumented by Standard Penetration Tests in one case, are as follows :

a) Surface littoral sand : ranges in thickness from 1,3 to 6,0 meres. Usually a coarse, medium and fine shelly sand of loose consistency (N-value 4-8), which would correspond with an in situ dry density of 1450-1600 kg/m^3. Maximum allowable foundation pressure 50-100 kPa (Reference 1).

b) Calcarenite : ranges in thickness from 0,35 m to about 1,0 m. Usually a moderately weathered, medium textured soft rock material which becomes slightly softer towards the base. Joints are generally infrequent. This material is lenticular in its occurrence and may thicken and lens out sporadically under the surface.

c) Clayey sand : ranges in thickness from about 0,9 m to 3,0 m. Usually a clayey medium and fine sand of firm to stiff consistency (N-value 11-27). Maximum allowable foundation pressure 100 - 200 kPa. (Reference 1) May contain channels, as reflected by water losses during drilling of up to 35 litres per minute in this material and in underlying littoral sands. The material becomes progressively less clayey with depth and grades into underlying littoral sands; precise position of lower contact therefore uncertain.

d) Littoral sand : ranges in thickness from about 2,15 m to 4,55 m, but may be thicker in places. In the uppermost two metres it is usually a coarse, medium and fine shelly sand of very loose to loose consistency (N-value 1-70, which would correspond with an in situ dry density of about 1300-1500 kg/m^3. Maximum allowable foundation pressure about 50 kPa (Reference 1). The lower levels of this material are of similar texture, but have a medium dense to dense consistency (N-value 21-48), which would correspond with an in situ dry density of about 1600-1900 kg/m^3. Maximum allowable foundation pressure 200-400 kPa (Reference 1).

Horizons e, f and g are, in general, repetitions of horizons b, c and d respectively.

It should be noted that, in the tidal channels, horizon

(c) and the upper part of horizon (d) may be absent beneath the collapsed calcarenite slabs, depending on the depth to which scour has occurred locally."

Four principal factors emerge :

1) The relatively extensive depths of the unconsolidated littoral deposits.(In certain boreholes over ten metres)

2) The occurrence of two horizons of low N-values and related high porewater pressures.

3) The identification of a zone of firm to dense and stiff consistency of clayey medium and fine sand with N-values of 11 to 27. (Generally referred to in the report as the marl layer)

4) Marked lack of uniformity of foundation conditions over the length of the proposed wall.

4.6 From a structural point of view it was patent at the outset that in view of the previously referred to localised variations in foundation conditions a monolithic structure was desirable.

A semi-circular structure presented the following advantages :

1) A good natural geometric relationship between shallow and deep water relative to bather preference.

2) The most economical wall length per unit of surface area.

3) Certain dynamic load advantages in as much as that although a particular wave train could theoretically impose a simultaneous force system over the length of the wall, the maximum force acts over a limited length of the wall. In the structure under consideration the maximum force may be considered to act over a length of 60 metres i.e. over a 14 percent section of the wall.

It is a corollary that most of the wave inflow takes place over this section.

Beyond this section of wave frontal attack there is an appreciable progressive reduction in dynamic forces due to the effect of a changing angle of wave approach which decreases from a theoretical 90° for that portion of the structure at right angles to the wave direction to 0° at the diametral point.

From the model study photographs it may be observed that progessively away from the frontal attack section

the angle of wave approach tends to increase due to wave refraction over the shallow calcarenite reef. This is however accompanied by an appreciable refractive energy loss.

Disregarding wave refraction along the length of the wall the incident angle various linearly to length of wall and by applying the equation $R^1 = R\sin^2 \alpha$ the reduction factor for dynamic force calculation along the length of the wall becomes :

1) At frontal attack section	1,00
2) At three-quarter point	0,85
3) At half point	0,50
4) At quarter point	0,15
5) At diametral point	0,00

To satisfy the condition of simultaneous dynamic forces, the forces in their adjusted value for incident angle act radially resulting in an axial ring stress with secondary moments and shear forces due to load change along the length.

From the structural analysis it became apparent that the critical design condition is represented by an internal loading system comprising a pool filled with sand and water at L.W.S.T. tide state.

From the geological investigation it became apparent that in order to secure reasonable waterholding properties it was essential that the sheetpiling as curtain membrane be taken well into the dense clay sand layer. This depth as well as the minimum section required for driving the sheetpiling resulted in a fairly rigid simple cantilever and the effect of a ring beam apportionment of load was disregarded in the factor of safety analysis. This is illustrated by the low stress analysed in the ring beam when maximum stress is developed in the sheetpile in bending.

4.7 In order to determine the axial load resistance of the proposed sheetpiling a series of sheetpile driving and load tests were carried out employing six metre piles driven 4,40 metres into the substrata. Loading using 1,08 KN units took place five days after completion of driving and the following worst deflections recorded :

1) At working load 28,5 KN per metre,settlement 0,3 mm.

2) At test load 57,1 KN per metre,total settlement from unloaded level 0,6 mm.

3) At time zero plus 24h00 pile rose 1,0 mm.

4) At time zero plus 40h00 pile settled 1,0 mm.

5) At time zero plus 66h00 pile was unloaded.

6) At time zero plus 92h00 pile level was 0,4 mm above original unloaded position.

Spring tide conditions prevailed during the test period.

The geological section on the line of the sheet pile curtain membrane dictated the use of five metre and six metre piles driven to form an interlocking diaphragm to predetermined depths in accordance with the geological findings.

The pile section adopted was a BZ12 Arbed imported from Luxemborg.

Overturning moments transferred to the sheetpile are absorbed in passive resistance by the substrata in accordance with the deformation condition imposed by the sheetpile in bending deflection.

In the analyses the pile section adopted allows for loss of 50 % of steel section due to corrosion over a 40 year period. At the point where maximum bending moment occurs it is likely that anaerobic conditions prevail and that the assumption for reduced section modulus appicable at this point are conservative.

4.8 The following design considerations apply :

1) Worst possible internal load condition is pool full of sand submerged, at tide state L.W.S.T.

2) Worst possible external load condition occurs at maximum wave forces with pool empty.

3) The submerged sand and substrata mean angle of shearing resistance $\emptyset$, employed in the calculations, is 20°.

4) The solid weight of sand comprising quartzitic and shell particles is 20 KN/m^3.

5) The well compacted sand percentage voids is 30 %.

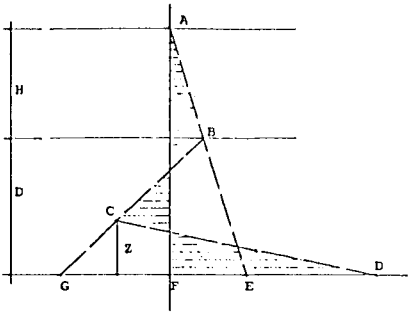
6) From the aforegoing the active pressure development factor K_p is 16,2 KN/m^2 per metre of depth.

7) The passive pressure development factor is 36,6 KN/m^2 per metre of depth.

8) Horizontal deflection of the superstructure results in a peripheral strain in the concrete section of where delta is the deflection and r the radius of the

pool.

4.9 Calculations are based on Terzaghi Theory for a Cantilever Sheetpile :



$$Z = \frac{D^2 Kp - (H + D)^2 Ka}{(H + 2D)(Kp - Ka)} \quad \ldots\ldots\ldots (1)$$

and

$$\left(\frac{D}{H}\right) + \frac{(Kp - 3Ka)}{Kp - Ka}\left(\frac{D}{H}\right)^2 - Ka\frac{(7Kp - 3Ka)}{(Kp - Ka)^2}\left(\frac{D}{H}\right)^2 - Ka\frac{(5Kp - Ka)}{(Kp - Ka)^2}\left(\frac{D}{H}\right) - \frac{KaKp}{(Kp - Ka)^2} = 0 \quad \ldots\ldots\ldots (2)$$

The following values of 'D' have been calculated compatible with the probable values of K_p and K_a.

Sand Level in Pool	Required 'D'
RL 01,40	4,86 m
RL 01,05	4,41 m
RL 00,70	3,92 m
RL 00,40	3,48 m
RL 00,00	3,13 m

'Z' for the extreme condition of 'D' = 4,86 m has been calculated to be 1,01 m, while developing a passive resistance of 55,9 KPa at a depth of 3,85 m equal to a linear rate of development of passive pressure = 14,5 KN/m^2 per metre of depth.

The 'D' value for the sheet piles installed is 5,40 m.

4.10 Seepage Losses

The substrata formation is as may be seen from the geological section complex and this together with a bedrock horizon of between four metres and eight metres below the lower limit of the sheet pile diaphragm places a low confidence level on the projection of seepage losses. Nevertheless actual observations of water loss conform well to the calculated values.

For the pool full at 01,40 m M.S.L. and tide state - 0,90 the maximum seepage hydraulic gradient is :

$$\frac{2,3}{(4,5 + 5,4)} \approx 0,23$$

and the critical gradient at which boiling displacement of the sand at L.W.S.T. on seaside can take place : $i_{cr} = \frac{\delta - \delta\omega}{\delta\omega}$

$$= \frac{20 - 9,8}{9,8} : 1,04$$

$$\text{Factor of Safety} : \frac{1,04}{0,23} : 4,52$$

Assuming the maintenance of a high pore pressure condition on the landward side of the pool which tends to stabilise water movement inland and secondly that the marl layer acts as a semi-pervious homogeneous blanket of effective thickness 1,80 metres as deduced from the geological reports, with permeability $K = 1 \times 10^{-4}$ cm/sec then the mean seepage gradient through the marl layer would be $\frac{1,4}{1,8} \approx 0,78$ and seepage rate 67 mm/day.

For a period of three days of no inflow the waterlevel would drop by a total of 200 mm.

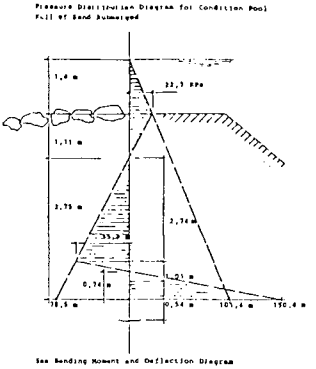
This has been largely confirmed in the field.

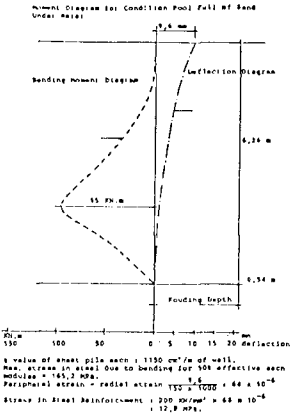
4.11 Concrete Design

The reinforced concrete pile cap was designed to be sufficiently rigid for the structure to act monolithically so as to transfer localised foundation failure conditions to the remainder of the structure while at the same time providing a minimum cover on all steel of 100 mm.

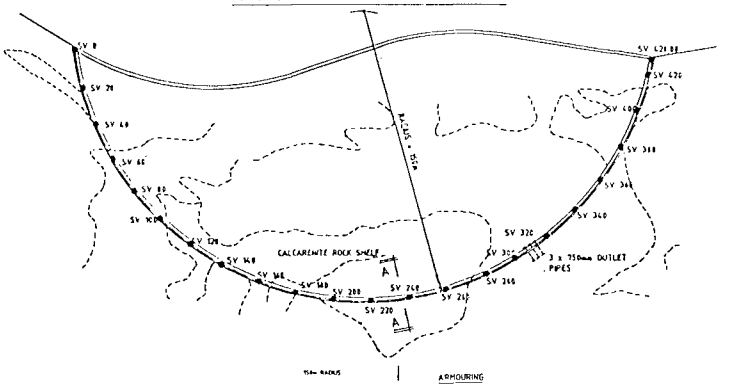
A 30 MPa concrete was employed with 0,30 percent steel reinforcement.

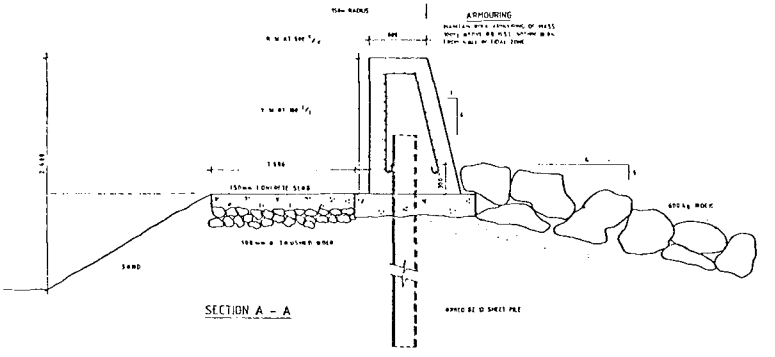
A 0,25 to 1 seaface batter was adopted for wave induced inflow, reduction in dynamic forces and for aesthetic considerations.





GEOMETRIC ARRANGEMENT OF STRANDFONTEIN TIDAL POOL





4.12 Armouring Design

It is essential to provide adequate toe armouring to prevent progressive scour in the seaface foundation area, while at the same time limiting the top reduced level of the armouring to the extent necessary to ensure retention of sufficient wave energy for wave induced inflow.

Reasonable assessments of the controlling levels based on experience were made but it is indubitably the case that the model experiments were essential to establish the adequacy of inflow.

Armouring size was determined by the Hudson Formula :

$$W = \frac{W_r H^3}{Kd(S_r - 1)^3 \cot \theta}$$

W_r = unit weight in lbs/ft³
= 156 lbs/ft³ (25 KN/m³)

H = Design wave height in feet
= 6,5 ft (2,0 m)

S_r = Specific gravity of armour unit
= 2,5

W_w = Unit weight seawater
= 64,0 lbs/ft³ (10 KN/m³)

θ = Structure slope angle in degrees
= 14°

K_D = Stability co-efficient
= 2,5

W = 1270 lbs (577 kg)

Say 600 kg.

4.13 Construction

The construction method adopted by the contractor involved the provision of a rubble mound as a sea cofferdam with a sand access road on the inside of the berm. The rubble mound was constructed to a height of 4,00 m M.S.L.

Sheet piles five to six metres in length were driven using a compressed air pile driver suspended from a 30 ton crawler crane off the access road.

The contractor successfully designed a system of driving to geometric configuration by use of steel

channel walers anchored to the previous piles and forward anchored to a transportable concrete block of some two tons mass.

A moveable shutter arrangement capable of being trimmed to the radius of curvature and hung from a gantry system on rails was a further successful innovation by the contractor.

The concrete was cast in alternate section of 7,5 metre length with continuity reinforcement but without waterstops.

On completion of construction the major portion of the rubble mound was employed to form the toe armouring.

The unavoidable inclusion in the armouring of undersize material resulted in an inflow of sharp rock fragments into the pool and future designs should provide particular attention to the temporary cofferdam in order to employ material which later may be utilized in the armouring zone.

ACKNOWLEDGEMENTS

1) The assistance of the City Engineer of Cape Town and his staff in the submission of this paper including the provision of results of pollution monitoring is gratefully acknowledged.

2) Research by the S.A. Institute of Oceanology of the S.A. Council of Scientific and Industrial Research has been fundamental to the submissions made and particular reference is made to the assistance of Dr D H Swart.

Multipurpose Gate Operation

by

Kazumasa Mizumura

Abstract

Predictions of time-varying salinity under arbitrary gate operations are presented of a tidal lake and its inlet. Particular regard is given to the modeling of salinity and gate operations and the applying the Markov process with Kalman filtering. In contrast to previous papers that predict only water levels the present paper also estimates salinity downstream the gate and of the tidal lake, simultaneously. It is postulated that present water level and salinity are expressed by the explicit linear functions of water levels, salinity, and gate operations at the other and the same positions in the past step. Using physically plausible estimate for these parameters in the functions the results of the predictions are in good agreement with observation.

Introduction

Gate operations at the inlet of tidal lakes have usually two purposes. First is to control the water surface level of the lake and second is to prevent from the intrusion of saline wedges. Considering the aspect of water quality and quantity, the existence of rice fields near the tidal lake requires precise gate operations. In this work, a method for estimating water level and salinity due to gate operations based on a combined estimation model including the Markov process and Kalman filtering theory is applied to control the gate at the inlet of Lake Kahokugata. Several applications of the Kalman filtering theory to water quality are found in (1, 2).

General

Lake Kahokugata (Fig.1) is located north of Kanazawa city and its length and width are almost 2.0 km and 1.0 km, respectively. The Ohno river connects the lake with the sea of Japan through the port of Kanazawa. A saline wedge intruded into the lake along the river before the construction of this gate. Therefore, this gate was constructed to prevent the lake from the intrusion of saline wedges and to control the water level of the lake. The simple illustration of

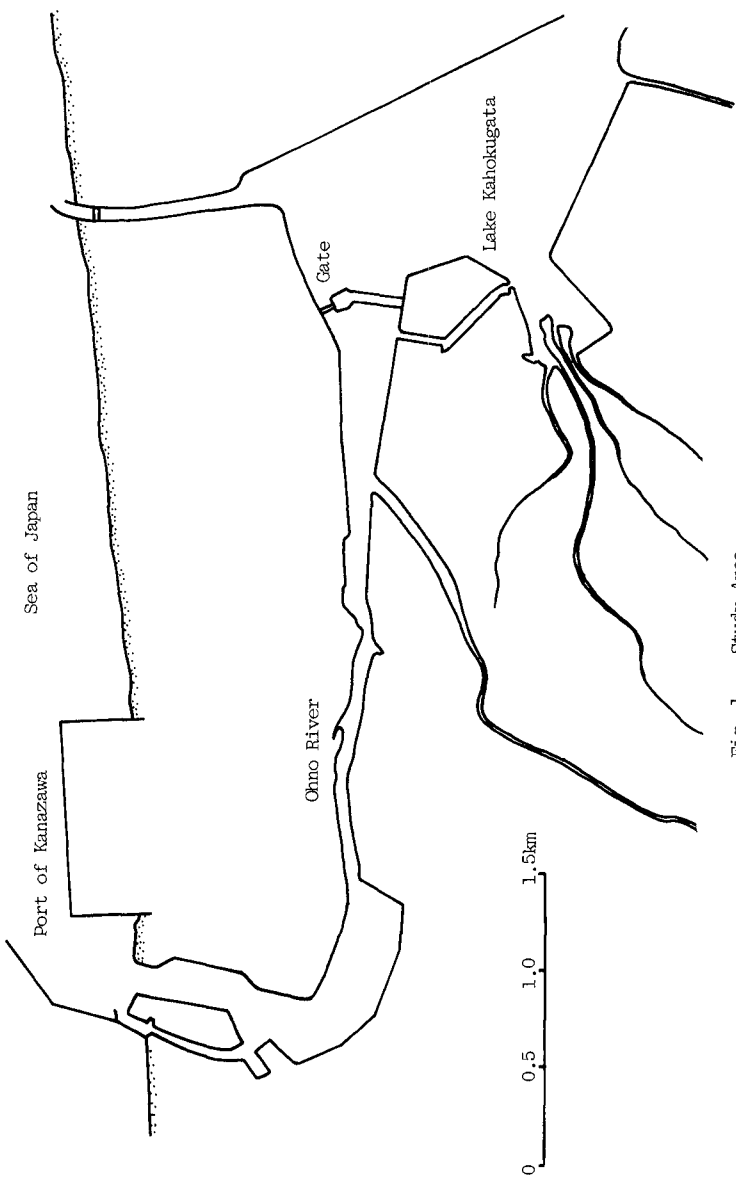

Fig. 1.— Study Area

the gate is given in Fig.2. Fig.3 represents the observed water levels at the sea, at the gate, and of the lake and the state of the gate operation every hour in May of 1980. There is another inlet and gate in this lake connecting to the sea. This gate is not considered in present study since this gate is not operated except during the typhoon season when the water level of the lake becomes remarkably high.

Prediction Techniques

For multipurpose gate operations we seek to predict the water levels and salinity at the position located downstream of the gate as a function of time. They are also considered to be the explicit functions of the sea level, the water level of the lake, and the state of the gate operation. If the sea level, the water level of the lake, and the salinity of the lake are not known, they are also predicted. Fig.4 and 5 show the effect of the gate operation on salinity at the gate and the relationship between the water level and the salinity of the lake. We consider that they may be expressed by the combination of the deterministic and the fluctuated part. That is,

$$y_k = \bar{y} + y'_k \tag{1}$$

$$T_k = \bar{T} + T'_k \tag{2}$$

$$d_k = \bar{d} + d'_k \tag{3}$$

$$c_k = \bar{c} + c'_k \tag{4}$$

$$s_k = \bar{s} + s'_k \tag{5}$$

in which k = time step, y_k = the water level at the gate, T_k = the sea level, d_k = the water level of the lake, c_k = the salinity of the lake, s_k = the salinity downstream the gate, and "–" and "'" mean the deterministic and the fluctuated part, respectively. By the physical consideration, the fluctuated parts are represented by the following forms.

$$y'_k = \alpha_1 y'_{k-1} + \alpha_2 y'_{k-2} + \cdots + \alpha_j y'_{k-j} + \beta_1 T'_{k-1} + \beta_2 T'_{k-2} + \cdots + \beta_j T'_{k-j} + \gamma_1 D_{k-1} + \gamma_2 D_{k-2} + \cdots + \gamma_j D_{k-j} + \delta_1 H_{k-1} + \delta_2 H_{k-2} + \cdots + \delta_j H_{k-j} \tag{6}$$

$$T'_k = a_1 T'_{k-1} + a_2 T'_{k-2} + \cdots + a_j T'_{k-j} \tag{7}$$

$$d'_k = b_1 d'_{k-1} + b_2 d'_{k-2} + \cdots + b_j d'_{k-j} \tag{8}$$

$$c'_k = \rho_1 c'_{k-1} + \rho_2 c'_{k-2} + \cdots + \rho_j c'_{k-j} + \sigma_1 d'_{k-1} + \sigma_2 d'_{k-2} + \cdots + \sigma_j d'_{k-j} \tag{9}$$

$$s'_k = \lambda_1 s'_{k-1} + \lambda_2 s'_{k-2} + \cdots + \lambda_j s'_{k-j} + \mu_1 T'_{k-1} + \mu_2 T'_{k-2} + \cdots + \mu_j T'_{k-j} + \nu_1 D_{k-1} + \nu_2 D_{k-2} + \cdots + \nu_j D_{k-j} + \pi_1 H_{k-1} + \pi_2 H_{k-2} + \cdots + \pi_j H_{k-j} \tag{10}$$

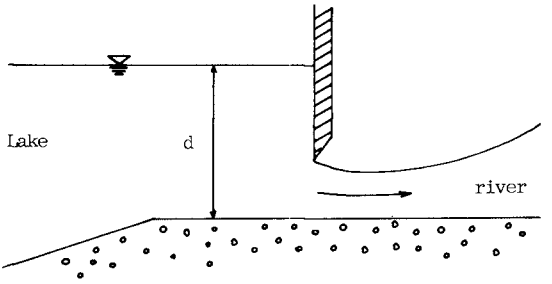

Fig. 2 (b)-- Lift Gate

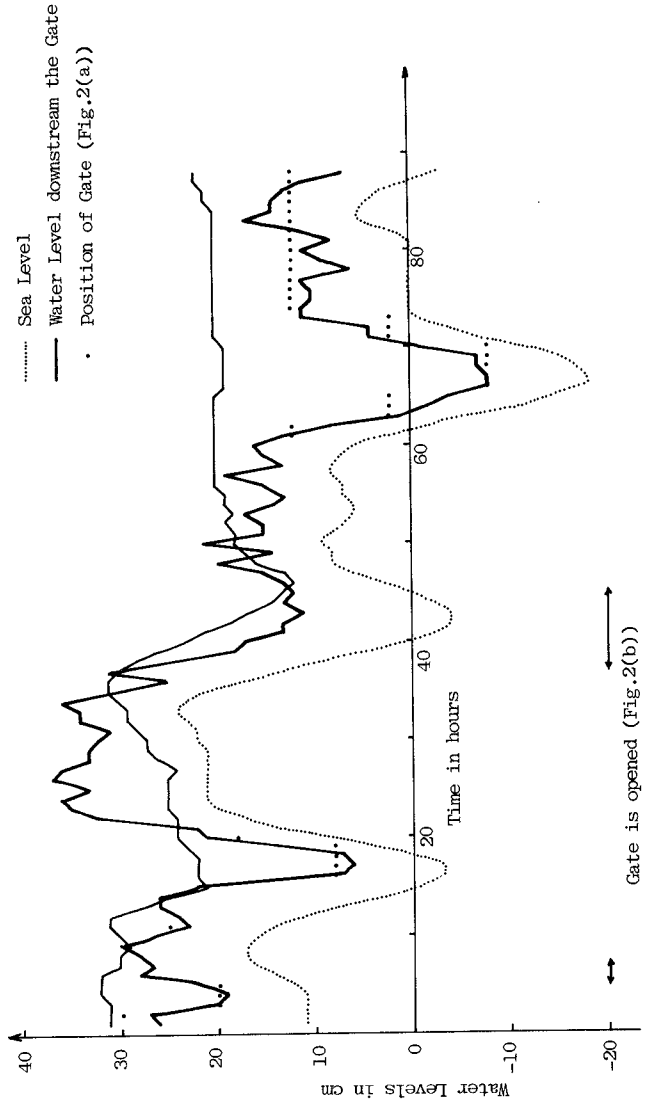

Fig. 3.— Observed water levels and gate operations

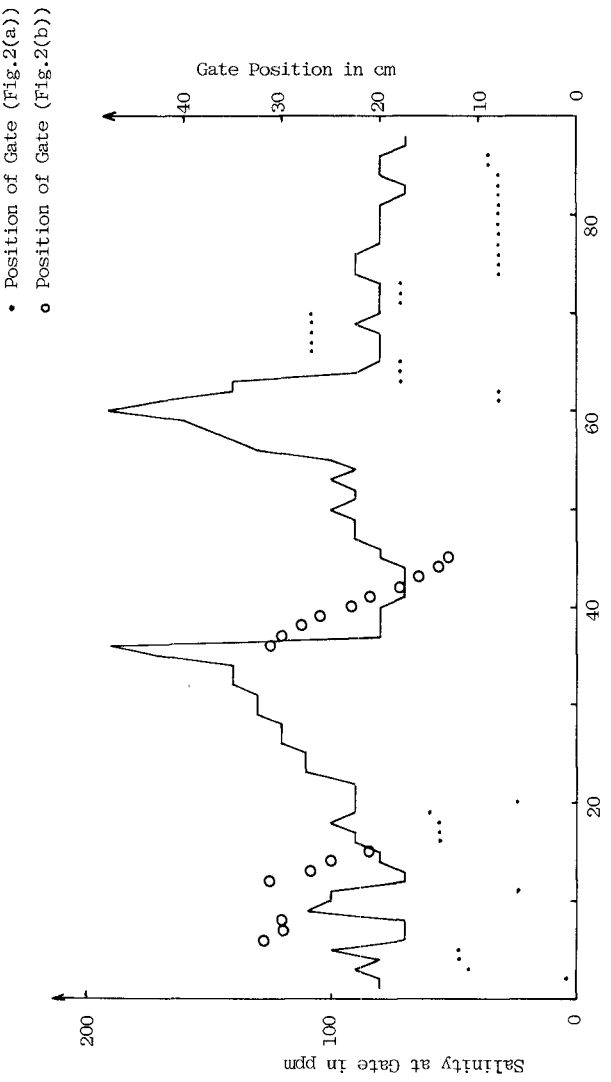

Fig. 4.— Effect of gate operation on salinity at gate

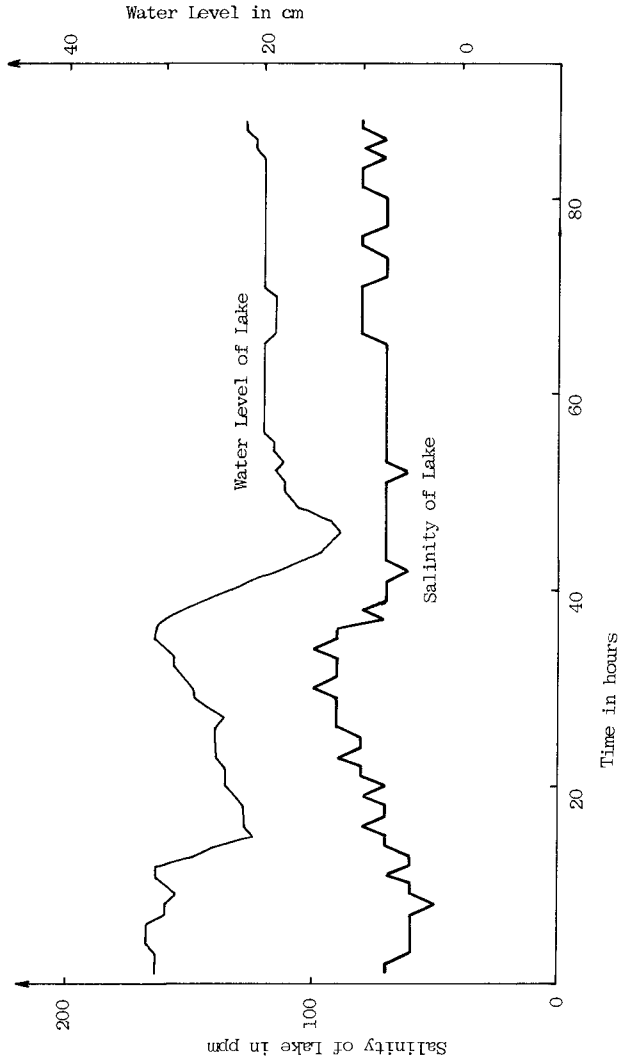

Fig. 5.— Relationship between water level and salinity of lake

in which α_i, β_i, γ_i, δ_i, a_i, b_i, ρ_i, σ_i, λ_i, μ_i, ν_i, and π_i = the constant parameters for $i = 1, 2, \cdots, j$, H_{k-j} = the water depth to determine the discharge through the gate (Fig.2(a)), and

$$D_{k-i} = \begin{cases} d_{k-j}, & \text{if the gate is opened (Fig.2(b))}, \\ 0, & \text{otherwise.} \end{cases}$$

Kalman Filtering Theory

The detailed discussion of the Kalman filtering theory is given in Gelb(3) or Sage and Melsa(6). By applying an appropriate transformation to the original formula (4, 5), the state equation for parameter identifications becomes

$$\underline{h}(k+1) = \underline{h}(k) + \underline{v}(k) \tag{11}$$

in which $\underline{h}^T = (\alpha_1, \alpha_2, \cdots, \alpha_j, \beta_1, \beta_2, \cdots, \beta_j, \gamma_1, \gamma_2, \cdots, \gamma_j, \delta_1, \delta_2, \cdots, \delta_j, a_1, a_2, \cdots, a_j, b_1, b_2, \cdots, b_j, \rho_1, \rho_2, \cdots, \rho_j, \sigma_1, \sigma_2, \cdots, \sigma_j, \lambda_1, \lambda_2, \cdots, \lambda_j, \mu_1, \mu_2, \cdots, \mu_j, \nu_1, \nu_2, \cdots, \nu_j, \pi_1, \pi_2, \cdots, \pi_j)$ and $\underline{v}$ = a noise vector (white Gaussian). The observation equation is represented by (Fig.6)

$$\underline{z}(k+1) = M(k)\,\underline{h}(k) + \underline{w}(k) \tag{12}$$

in which $\underline{z}^T(k+1) = (y'_{k+1}, T'_{k+1}, d'_{k+1}, s'_{k+1}, c'_{k+1})$, $\underline{w}(k)$ = a white Gaussian,

$$M(k) = \begin{bmatrix} \underline{m}_1^T(k) & & & & & 0 \\ & \underline{m}_2^T(k) & & & & \\ & & \underline{m}_3^T(k) & & & \\ & & & \underline{m}_4^T(k) & & \\ 0 & & & & & \underline{m}_5^T(k) \end{bmatrix}$$

$\underline{m}_1^T(k) = (y'_{k-1}, y'_{k-2}, \cdots, y'_{k-j}, T'_{k-1}, T'_{k-2}, \cdots, T'_{k-j}, D_{k-1}, D_{k-2}, \cdots, D_{k-j}, H_{k-1}, H_{k-2}, \cdots, H_{k-j})$, $\underline{m}_2^T(k) = (T'_{k-1}, T'_{k-2}, \cdots, T'_{k-j})$, $\underline{m}_3^T(k) = (d'_{k-1}, d'_{k-2}, \cdots, d'_{k-j})$, $\underline{m}_4^T(k) = (c'_{k-1}, c'_{k-2}, \cdots, c'_{k-j}, d'_{k-1}, d'_{k-2}, \cdots, d'_{k-j})$, and $\underline{m}_5^T(k) = (s'_{k-1}, s'_{k-2}, \cdots, s'_{k-j}, T'_{k-1}, T'_{k-2}, \cdots, T'_{k-j}, D_{k-1}, D_{k-2}, \cdots, D_{k-j}, H_{k-1}, H_{k-2}, \cdots, H_{k-j})$.

Illustrative Examples

By using the Kalman filtering algorithm, the water level and the salinity downstream the gate, the sea level, the water surface level

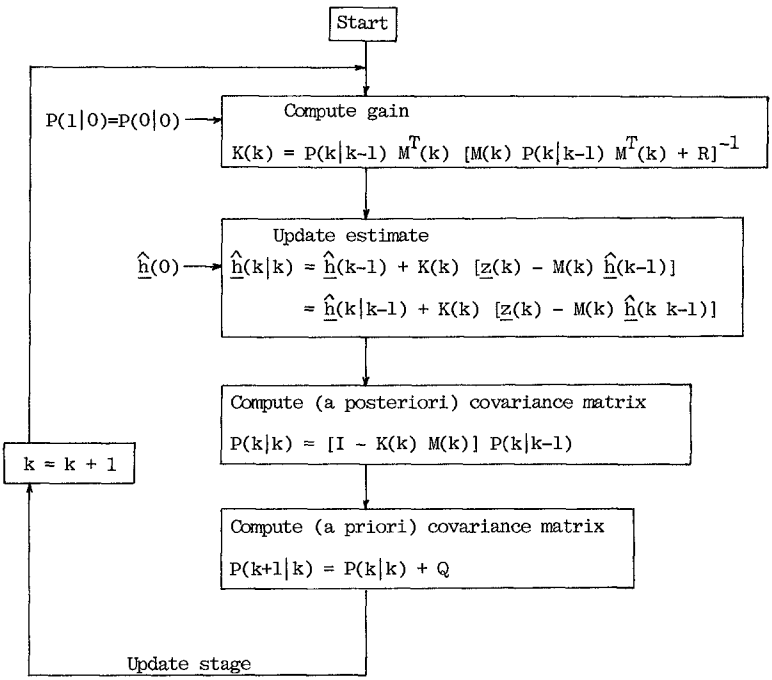

Fig. 6.— Algorithm of Kalman Filtering

and the salinity of the lake may be predicted step by step. Since we published the results on the prediction of water levels (5), we herein do not refer to them. The initial values of $\underline{h}$ and P are assumed as follows.

$$\underline{h} = \underline{0} \tag{13}$$

$$P = 0.1 \tag{14}$$

The initial values of each variable are used to represent the deterministic parts which are illustrated by "-". The predicted salinity downstream the gate an hour and three hours ahead of time is given in Fig.7 in the case of j=1. After 35 hours from the start the prediction an hour ahead of time almost coincides with the observation, but the prediction three hours ahead of time is not still in good agreement with the observation. Fig.8 shows the prediction of the salinity of the lake in the case of j=1. After 40 hours from the start the predicted salinity an hour ahead of time coincides with the observed data, but the prediction three hours ahead of time is not enough. The identified parameters by the Kalman filtering algorithm are illustrated in Fig.9. The severe fluctuations of the parameters are not found after 40 hours from the start. The time of 40 hours corresponds to the time when the reasonable prediction an hour ahead of time occurs. Fig.10 and 11 represent the predictions of the salinity downstream and of the lake during another time period which immediately follows to the period used in the previous analyses, respectively. These predictions are gradually improves as time passes. Fig.12 shows the erroes of the predicted salinity of the lake in the case of j=1 and j=2. In the early stage the prediction for j=2 is better than that for j=1. But after 40 hours the superiority decreases. That is, an appropriate prediction may be made by using the first order Markov process.

Summary and Conclusions

1. The prediction of the salinity and the water level is made by the Markov model with the Kalman filtering theory. The prediction an hour ahead of time is in good agreement with the observation.
2. To describe the phenomena in this paper the first order Markov process may be adequate, since the length of the river is short and the dimension of the lake is small. The modeling does not need to memorize much past information.
3. The prediction of future sea levels is usually calculated by the other method, but the prediction of the water level of the lake is not predictable. The limitation of the prediction model for the water level of the lake is made by using the simple Markov process (autoregressive process).

Appendix 11.- Notation

The following symbols are used in this paper:

a and b = constant parameters;
c_k = salinity of lake ($\approx c + c'_k$);
D_k = water depth, if gate is opened;
d_k = water surface level of lake ($= d + d'_k$);
H_k = vertical water depth between water surface level of lake and the upper part of gate (Fig.2(a));
$\underline{h}$ = parameter vector;
$\underline{K}$ = Kalman gain matrix;
j = order of Markov process;
k = time step;
M = observation transition matrix;
P = covariance matrix of estimation error;
Q = covariance matrix of $\underline{w}$;
R = covariance matrix of $\underline{v}$;
s_k = salinity of gate;
T_k = sea level;
$\underline{v}(k)$ = noise vector (white Gaussian);
$\underline{w}(k)$ = noise vector (white Gaussian);
$\underline{z}_k$ = observation state vector; and
α, β, γ, δ, λ, μ, ν, π, ρ, and σ = constant parameters.

THE COASTAL WIND FIELD OF THE SOUTHERN CAPE

by

Ian Tyrrell HUNTER

ABSTRACT

The coastal region of the South Cape is presented as a typical semi-developed coastal zone with a limited environmental dataset. The author places himself in the position of a coastal engineer requiring wind data for design purposes. The various sources of wind measurement are discussed. Time series are presented depicting responses at different sites to the same large-scale synoptic situation. Spatial variations, both across the coastal boundary and in the offshore region are emphasized. These variations are brought to the attention of those engineers who may have to extrapolate wind conditions to their site of interest.

1 INTRODUCTION

The Cape south coast extends from Cape Agulhas to Cape Padrone at the eastern extremity of Algoa Bay (Figure 1). The continental shelf widens considerably in this region to form the Agulhas Bank which has been chosen as the site of a multidisciplinary oceanographic research project. As part of the meteorological program for the project, existing sources of wind data were fully explored. They include:

(i) Long-term wind data from weather offices.
(ii) Synoptic reports from ships of opportunity.
(iii) Wind from offshore drilling platforms.
(iv) Estimated wind data from lighthouses.

An additional source was created in February 1982, when three automatic weather stations were erected at suitable coastal sites. A fourth station was periodically mounted on the *R V Meiring Naudé* and this provided invaluable offshore data. Figure 1 shows the distribution of the various sources of wind data along the coast.

The various types of wind observations are discussed in terms of their accuracy, representativeness and distribution. Justification for such a study, from a coastal engineering point of view, comes from the fact that a significant proportion of the wave energy on this coast is generated by the high-frequency, locally generated component.

2 WIND OBSERVATIONS AT FULLY FLEDGED WEATHER OFFICES

There are two weather offices in the study area, one at H F Verwoerd Airport, Port Elizabeth, and the other at George. Both have been

---

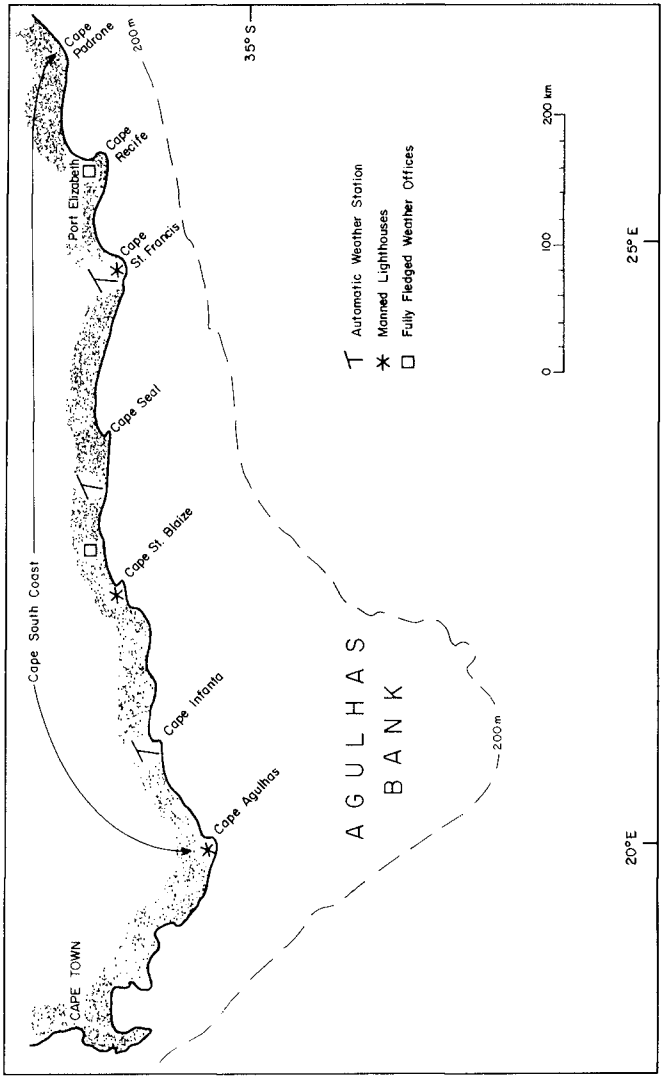

FIGURE 1: LOCATION OF WIND RECORDING STATIONS

recording hourly wind speed since 1951, using Dines pressure tube anemometers.

H F Verwoerd Airport (see inset Figure 2), is located 3 km from the coast with the anemometer at a height of 60 m a.s.l. The general terrain surrounding the airport is flat with no marked topographical features. Yet it can be shown that data collected here are not representative of coastal conditions.

During the period 1 to 3 September 1978, a series of intense low pressure systems resulted in high seas on the Agulhas Bank. In Figure 2 hourly wind data from H F Verwoerd Airport are compared with those from the oil rig Sedco-K, roughly 40 km to the south (See Section 5 for details of wind reduction to standard height).

It is evident that there was initially no coupling between air movement at the airport and that offshore. However, this situation improved as the boundary layer became more mixed, especially overnight. Nevertheless, if one compares the maximum values measured on the Sedco-K, with the 50-year return value of hourly wind speed for the airport (22,3 m/s), (South African Weather Bureau,1974), it is obvious that the airport is underestimating offshore conditions. This particular series of storms resulted in a significant wave height of 8,6 m (Shillington and Britten, 1979), at the Sedco-K site while an estimate of up to 15 m was received from a tanker within the Agulhas current further up the coast. The only other source of long-term, accurate wind data is the weather office at George. However, since this station is 221 m a.s.l. and more than 10 km from the coast it was considered to be unsuitable as a source of information on wind conditions.

Hsu (1980) has related mean monthly offshore wind conditions to those at a suitable coastal site. Unfortunately, insufficient data were available for such a study of conditions here. However, it is obvious from Figure 2 that the airport is not suitable for measuring coastal wind conditions.

3 WIND FROM OFFSHORE DRILLING PLATFORMS

The search for oil on the Agulhas Bank and the associated demand for environmental data, have provided researchers with invaluable offshore wind measurements. However, even this dataset presents problems:

(i) Although measurements began in 1978, the record is by no means continuous,
(ii) Measurements represent several well sites on the Agulhas Bank,
(iii) The anemometer is 73 m a.s.l. which poses a height reduction problem.

With regard to (ii), another drilling rig, the Sedco-708, was temporarily on the Agulhas Bank, drilling to the south of Sedco-K. While it was in a position roughly 78 km southwest of Sedco-K, wind speeds registered at Sedco-708 were significantly higher for much of the

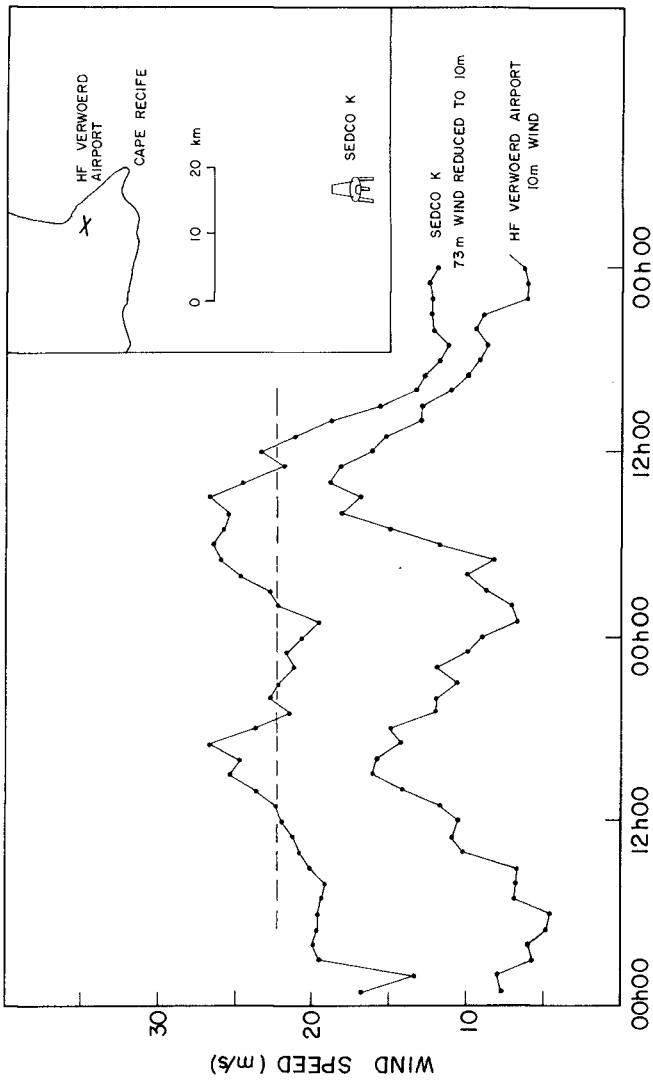

FIG. 2: VARIATION OF WIND SPEED OFFSHORE - HOURLY AVERAGES

time (Figure 3). However, the latter rig was later moved to a position roughly 74 km WSW of the Sedco-K and the comparison was greatly improved (Figure 4). It was significant that Sedco-708 was closer to the warm Agulhas Current when it was in the first position.

The reduction of wind speed from 73 m to the standard 10 m a.s.l. is a function of boundary layer stability, which may vary considerably in time and space. Whereas the wind power law has previously been applied with the exponent for a neutrally stable atmosphere, i.e.

$$U_{10} = U_{73} \cdot \left(\frac{10}{73}\right)^{,143}$$

subsequent wind measurements showed that this reduction may be too severe, especially under unstable, high-wind conditions. The hourly wind values plotted in Figure 2 were obtained using an exponent of 0,1 which effectively reduced the 73 m wind by 18%. It is felt that this reduction will, if anything, underestimate the 10 m wind, under extreme conditions.

In order to obtain a 50-year return period hourly wind for the Agulhas Bank, the method outlined by Katsiambirtas (South African Weather Bureau 1975), was followed. It should be noted that the chosen dataset of twelve months did not include the September 1978 storm (Figure 2). A value of 25,8 m/s was obtained. This value was exceeded on several occasions prior to the used dataset. This illustrates the folly of applying statistical methods to a relatively short wind record.

4 SHIPS OF OPPORTUNITY

Prior to the advent of offshore drilling operations, synoptic reports from merchant ships ('SHIP' reports) represented the only significant source of offshore wind data on the Agulhas Bank. The coastal engineer planning to utilise these data would have to bear in mind that :

1. Most vessels are 30 km or more from the coast in the region between Cape St Francis and Cape Agulhas (see Figure 5).
2. Reports are usually sent only on the main synoptic hour, i.e. every 6 hours.
3. Vessels will be trying to avoid extreme conditions if possible.
4. Observations are often neglected when the ship is within sight of land.
5. The majority of SHIP reports contain estimated wind speeds.

With regard to this last point, it must be borne in mind that most deck officers use state of sea to estimate wind speed. However, sea state is not purely a function of wind. Boundary layer stability and surface currents play an important role. Also it must be expected that wind estimates will decrease in accuracy as wind speeds increase. There is no simple solution to this problem, since an anemometer would measure relative wind speed and further errors may be introduced in the calculation of true wind speed. A height reduction problem also arises since anemometer height is not provided in the standard message and this will vary greatly from vessel to vessel.

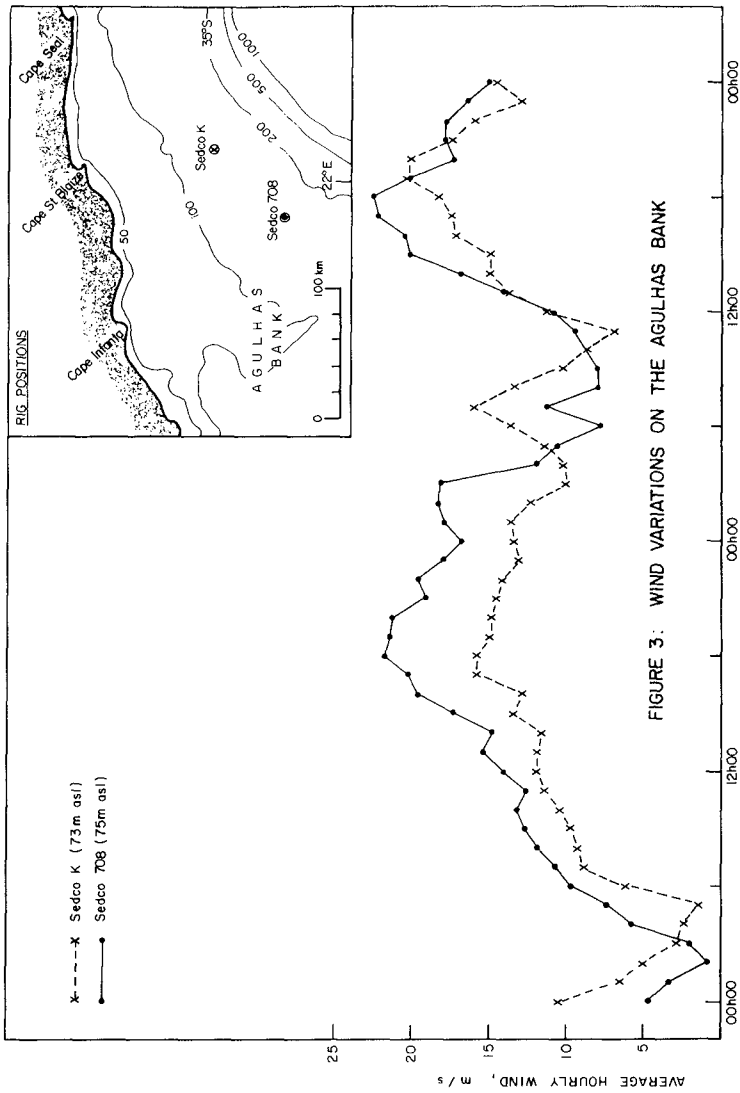

FIGURE 3: WIND VARIATIONS ON THE AGULHAS BANK

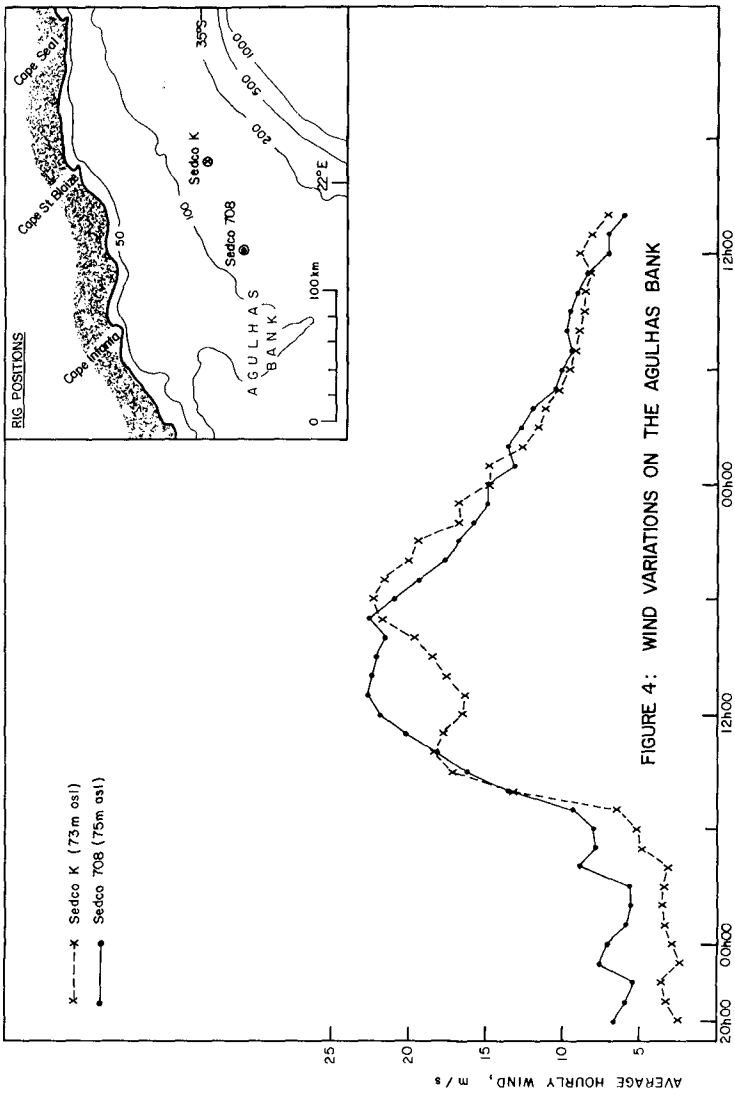

FIGURE 4: WIND VARIATIONS ON THE AGULHAS BANK

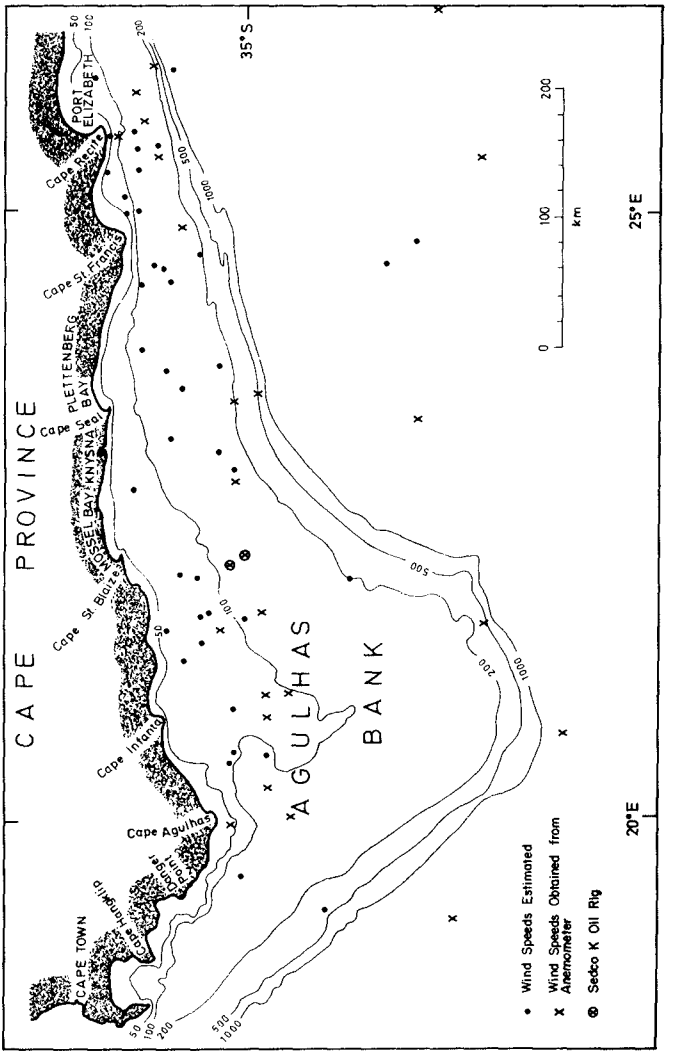

FIGURE 5: SHIPS' POSITIONS FOR MARCH AND APRIL 1982 AT 06h00 Z

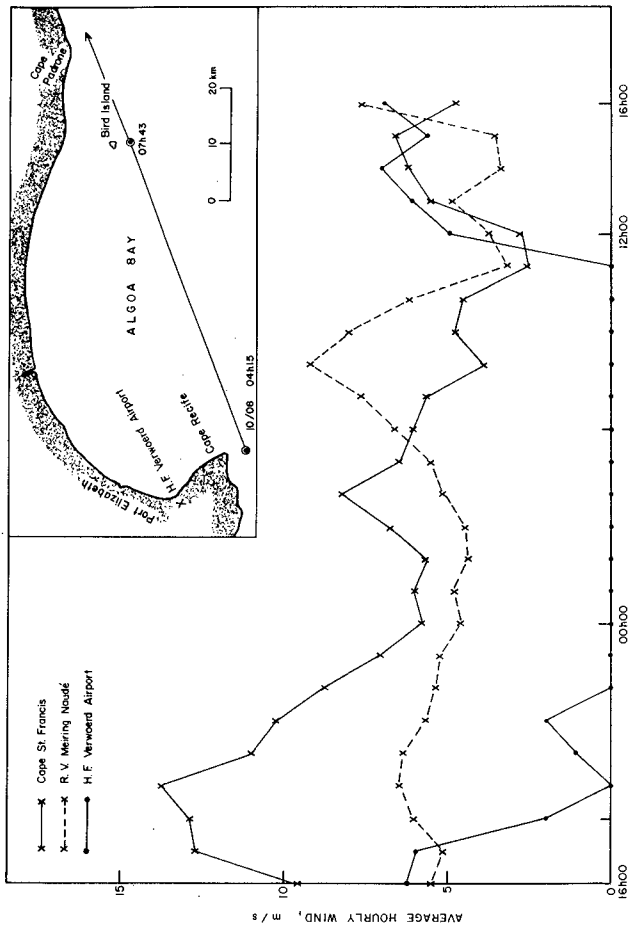

FIGURE 6: SPATIAL VARIATIONS

5 ESTIMATES OF HOURLY WIND FROM LICHTHOUSES

This represents the only source of long-term, truly coastal observations. There are now only three fully manned lighthouses on the Cape south coast (Figure 1). Of these three -

1 Cape St Francis is fitted with a pressure plate which is of no use under extreme conditions as it is almost horizontal at 15 m/s.
2 Cape St Blaize is badly positioned for wind observations, being sheltered from wind from certain directions.

Bearing in mind the limited accuracy of observations from these lighthouses, it has not been possible to determine their relationship to offshore conditions.

6 AUTOMATIC WEATHER STATIONS

Three permanent automatic weather stations were set up on the Cape south coast in February 1982. At all three sites, the prevailing winds have very limited stretches of coast to cross before reaching the anemometers. The surrounding terrain is also reasonably flat. The anemometers are all placed well above the internal boundary layer (IBL).

A fourth automatic weather station is mounted on the NRIO's research ship, R V *Meiring Naudé*, for those periods which she spends off the south coast. These wind data are invaluable in the study of offshore variation.

Figure 6 illustrates how nocturnal cooling may totally decouple the air flow on shore from that offshore. Early on 9 August, the R V *Meiring Naudé* was crossing Algoa Bay in the direction of Bird Island. A land breeze of about 5 m/s was blowing as the vessel passed within 15 km of H F Verwoerd Airport. At the latter site the establishment of the nocturnal inversion resulted in calm conditions from 22h00 until 11h00 the following day. In the vicinity of Bird Island the land breeze reached a peak of 9,2 m/s at 08h00, finally dying off at 11h00. The third curve in Figure 6 represents conditions at Cape St Francis (see Figure 1). The high wind speeds recorded there on 9 August are due to a frontal wave which was much weaker when passing the R V *Meiring Naudé* (the vessel was at that stage to the west of Cape St Francis). Note that the anemometer at Cape St Francis is above the nocturnal inversion with the land breeze there reaching a peak speed at 04h00.

7 CONCLUSIONS

This study has compared actual hourly wind averages as opposed to the comparison of long-term means. The following conclusions may be drawn:

(1) Although a simple relationship may, at times, exist between wind speed at a coastal site and one a few kilometres inland, the inland record may become completely decoupled due to excessive boundary layer stability.
Should extreme return period winds for such an inland site be applied to the coastal site, a severe underestimate may result.

(2) Extreme return period winds for an offshore site, based on a relatively short dataset (less than 10 years), may also underestimate the true condition.

(3) Offshore conditions may vary over relatively short distances (less than 100 km). This may be attributed, amongst other things, to sea surface temperature distribution and preferred locations for new synoptic developments.

8 ACKNOWLEDGEMENTS

Appreciation is expressed to the Southern Oil Exploration Corporation (Pty) Ltd., the Lighthouse Department of South African Transport Services, and the South African Weather Bureau for the valuable data which they provided.

TIDAL AND INERTIAL CURRENTS AROUND SOUTH AFRICA

by

E H SCHUMANN and L-A PERRINS

ABSTRACT

Limited information is available on currents in the semi-diurnal and diurnal frequency bands for the coastal ocean areas around Southern Africa. However, recently mooring data have become available from sites on the east, south and west coasts, and this paper analyses these results in an attempt to assess the importance of tidal and inertial currents.

It is clear that on the narrow shelf on the east coast the Agulhas Current dominates the energy spectrum, and tidal currents should be relatively unimportant at such sites. In the south on the Agulhas Bank the Current is still important, but comparable energy resides in inertial and tidal fluctuations. Modal analysis indicates the tides are primarily barotropic, with the inertial fluctuations mainly baroclinic.

In the absence of a major current on the west coast, most of the current variance occurs in the tidal and inertial bands; a complex vertical structure is also found. It is therefore clear that there are regions where such currents cannot be ignored.

1 INTRODUCTION

The most predictable forcing in the ocean is that due to the astronomical tides, with the tidal potentials associated with the various motions of the earth, moon and sun known to a high degree of accuracy. However, that does not mean that the response of the ocean to this forcing is necessarily predictable to the same degree of accuracy. Indeed, the ocean can respond in a variety of forms, dependent primarily on coastal and bottom topography, and the internal ocean structure.

The most obvious tidal motion is that of the surface of the ocean, with regular fluctuations in sea level ranging, in various parts of the world, from less than a metre to more than ten metres. Since such changes are of immediate interest to coastal communities, sea level tides have been known, studied, and predicted with various degrees of accuracy for many years. Prediction techniques have generally been

---

Physical Oceanography Division, National Research Institute for Oceanology, Council for Scientific and Industrial Research, P O Box 320, Stellenbosch, South Africa.

dependent on sea level measurements carried out over long periods at appropriate coastal sites. This is also so in South Africa, where regular tide tables are issued by the Naval Hydrographer.

By continuity, there must also be currents associated with such movements of the sea surface. The strength of the currents is dependent on topography, with the most apparent examples occurring in estuaries and on the wider continental shelf regions.

Internal tides, dependent on the density structures within the ocean, also occur. Wunsch (1975) reviewed the nature of these fluctuations, which may cause vertical deflections of 30 m or more in the constant density surfaces. As with the surface, or barotropic tides, there are also currents associated with such baroclinic motions, although phase changes take place with depth.

There are further fluctuations in ocean currents that will be discussed here, since the periods involved are in the range of the semi-diurnal and diurnal periods of the dominant tidal forcing. These are the inertial currents, the oscillations in water set in motion and then moving over a rotating earth. The major generating force is wind stress, but with the details of the motion dependent on topography and ocean density structure. The period of such inertial oscillations depends on latitude, being given approximately by the relation 12.04/ sin(latitude) hours.

Except where they are influenced by distinct coastal features such as estuaries, tidal currents around South Africa have been given little attention. To some extent this has been due to the lack of suitable measurements, but on the other hand it appears to be accepted that the effects of tidal currents should be negligible compared with currents generated by other forces. Reasons for such assumptions may be the generally straight coastlines, and the limited continental shelf areas.

This paper attempts to take a first look at tidal and inertial currents using data from moorings deployed on the east, south and west coasts of South Africa. These are distinctly different oceanic regimes, with the resulting currents also having different characteristics. It is clear that there are areas where such currents cannot be ignored, and where they may, in fact, constitute the most energetic part of the current spectrum.

2 OCCURRENCE OF TIDAL AND INERTIAL FLUCTUATIONS

The periods of astronomical tides cover a wide range, with the dominant components tending to fall into groups centered at semi-diurnal, diurnal and longer-period motions. Within these groups the frequencies are split by multiples of a cycle per fortnight, cycle per year, etc. Table 1 lists the major semi-diurnal and diurnal components of interest here.

Analyses have indicated that in many areas the tides propagate largely as Kelvin waves (e.g. Platzman, 1971; Munk, Snodgrass and Wimbush, 1970). This means that the tidal potentials can excite waves at

selected periods, and that the observed amplitudes and currents then occur as a result of the propagation of these waves. They are gravity waves modified by rotation, and propagate in the southern hemisphere with the coastline on the left in the direction of propagation.

The major portion of the tidal amplitude observed at a coastal site is generally due to a barotropic type of Kelvin wave. Such a wave does not depend on stratification, and for narrow shelf regions does not depend markedly on shelf topography. Around South Africa there are no great variations in the amplitudes of the semi-diurnal and diurnal barotropic tides, with spring tide amplitudes ranging from about 1.4 to 1.8 m, and neap tides from 0,5 to 0,6 m.

The offshore scales of the baroclinic tides are the corresponding Rossby radii of deformation, generally of the order of a few tens of kilometres or less. As such, smaller-scale topographic features on a continental shelf region can exert a considerable influence on their characteristics. Usually the buoyancy frequency due to the stratification is much less than the tidal frequencies, so that resonance does not occur. The patterns of baroclinic tides also show considerable variations with respect to the more stable barotropic tides. Thus the small wavelengths make them susceptible to Doppler shifting by more energetic currents, thereby changing the frequency with respect to a stationary observer. Moreover, if measured tidal current amplitudes are strong functions of time, it can be assumed with a fair degree of certainty that they are due to baroclinic tides.

Baines (1982) discusses the internal tide generation models, where the forcing is due to the barotropic onshore-offshore tidal currents. The analysis indicates that the amplitude of such forcing will be accentuated markedly at a shelf break; the generated internal tide should therefore be sensitive to variations in stratification in such a region.

Analyses, such as those by Torgrimson and Hickey (1979) and Huthnance and Baines (1982), indicate that the propagation of tidal signals and the associated currents are complex phenomena. If the details of their structures are to be elucidated, a knowledge of the ocean stratification, ambient currents and bottom topography is needed, not only in the region of interest, but also far enough alongshore to accommodate waves moving along the coast; this again brings with it factors such as frictional dissipation.

An important factor in tidal theory is the existence of so-called "inertial latitudes", where the inertial period at that latitude is equal to one of the tidal constituents (Wunsch, 1975). For the diurnal constituents this occurs at latitudes between 26,5° and 30°, while for the semi-diurnal constituents the inertial latitudes range between 71° and 90°. Initially it was in fact thought that inertial motions occurred primarily in resonance with tides. However, Webster (1968) reviewed existing literature on the subject and discounted the idea. In particular, it is now accepted that one of the prime generators of inertial period motions is wind stress (Wang and Mooers, 1977; Mayer, Mofjeld and Leaman, 1981).

By the nature of its dependence on the local vertical component of the earth's rotation, pure inertial motion is horizontally polarised. It is also a circular motion, with an anticlockwise rotation in the southern hemisphere.

In the South African context the inertial period is close to the diurnal tidal period, possibly giving rise to interactions and making the separation of the two motions more difficult. In particular, it is worth noting that in an earlier analysis Welsh (1964) found pronounced inertial currents on the Agulhas Bank.

3 DATA AND ANALYSIS

The current data analysed here were all recorded by Aanderaa RCM-4 meters. These utilise a Savonius rotor to give a mean value of current speed over the measuring period, while a large vane gives an instantaneous value of current direction; the size of the vane effectively eliminates high-frequency fluctuations. Water temperature was also measured.

One mooring was chosen on each of the east, south and west coasts, and Figure 1 depicts the approximate positions at which the moorings were deployed, while Table 2 gives further mooring details. The mooring off Natal formed part of the Shelf Dynamics Project, with the meter mounted on a rigid stand some 3 m off the bottom. The moorings on the Agulhas Bank and off the west coast were done as part of a contract for the Southern Oil Exploration Corporation (SOEKOR). These consisted of taut-wire moorings, with the one at site W1 deployed directly from an oil drilling platform. Four meters were included in the vertical array, although good data were obtained only from three meters at the S1 site.

The depth of the shallowest meters on all the moorings should have precluded excessive contamination of the current speed record by wave-induced motions (Halpern, 1977). The rigid stand deployment, the configurations off the oil drilling platforms, and the subsurface upper buoy deployment would also have stopped or limited "rotor pumping" caused by mooring motion (Halpern and Pillsbury, 1976). As a consequence, for present purposes the values of currents and temperatures registered will be assumed to be an accurate reflection of the conditions actually present in the ocean at the time.

For all meters the data interval was set at 15 minutes. The values of currents and temperatures thus obtained were subjected to standard processing and analysis procedures before being filtered and decimated to hourly values by the operation of a Cosine-Lanczos filter with 24 distinct weights and a half power point of 0,5 cycles/hour. The hourly values served as the basis for most of the subsequent analysis, although in some cases further filtering giving three-hourly values was also applied.

Standard spectral analysis techniques were utilised to obtain the power spectra of the measured currents and temperatures (Jenkins and Watts, 1968). The resultant of any periodic, orthogonal pair of velo-

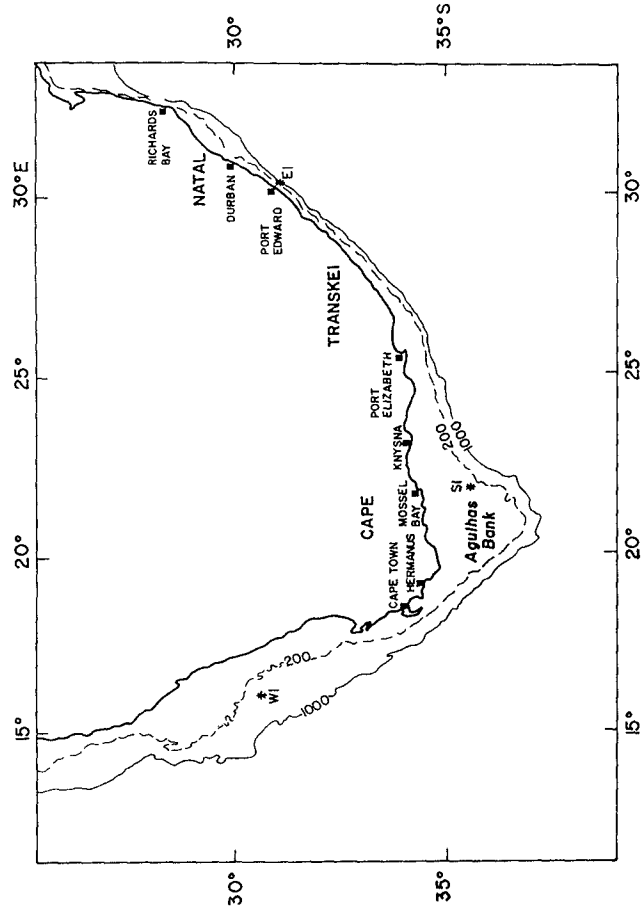

FIGURE 1. The Southern African coastline, showing bathymetry and indicating the positions of the moorings discussed in the text.

cities may also be represented as the combination of two vectors which rotate in opposite senses. Thus a velocity signal at a given frequency may be thought of as consisting of both clockwise and anti-clockwise portions. Such a decomposition can then be used to compute clockwise (S_-) and anti-clockwise (S_+) energy spectra, also referred to as rotary spectra (Gonella, 1972). The total spectrum S_t is then the sum of the two portions.

The rotary coefficient C is defined as

$$C = \frac{S_- - S_+}{S_t} = 1 - \varepsilon$$

and gives the partition of the energy S_t and the relationship with the normal ellipse eccentricity, ε. For pure circular motion the magnitude of C will be one, while it will be zero for linear fluctuations. Such an analysis is therefore important in distinguishing between inertial and Kelvin wave-type fluctuations. In the southern hemisphere inertial motion is anti-clockwise, that is, $S_+ >> S_-$, while for Kelvin waves $S_+ \sim S_-$.

Current ellipses can thus be determined at all frequencies of interest, with the orientation of the major axis giving the dominant direction for the current fluctuations.

A further parameter of importance in this analysis is the stability of orientation of the ellipse. This gives an idea of the isotropy of the wave field generated by tides and inertial motions in the ocean; in particular, the barotropic tides should be stable, with a greater variability inherent in the internal motions.

In order to obtain more information about the nature of the internal fluctuations, empirical orthogonal mode (eom) analysis can be performed (Kundu, Allen and Smith, 1975). In essence, this technique determines the subdivision of the variance of the current fluctuations into the possible modes of oscillation, as well as giving information on their depth structure. In this way it can be ascertained whether the motion was predominantly barotropic, first mode baroclinic, etc. Of course, with four meters in the vertical it is possible to investigate only the first three baroclinic modes, although even this depends on the position of the meters relative to the density structure.

The basic technique was extended by Wang and Mooers (1977) to enable modes to be determined at specified frequencies. This involves the determination of the co-spectra and quadrature spectra, and then finding the empirical modes as eigensolutions of the cross-spectrum matrix. These methods were used in the analysis of the results from moorings deployed on the south and west coasts.

4 EAST COAST - NATAL

As shown in Figure 1, the shelf here is narrow, with the off-shore region dominated by the influence of the Agulhas Current (Pearce, 1977). This is a major western boundary current flowing polewards along the coast. Schumann (1981) analysed the data from moorings deployed off Natal and concluded that markedly different regimes existed in the region. In particular, the subtidal currents measured at the site E1 were largely associated with the Agulhas Current.

Figure 2 shows the result of rotary spectral analysis at the site E1. It is clear that, at the diurnal O_1 and K_1 tidal frequencies, a fairly significant peak emerges. The stability and ellipticity are high, as would be associated with classical Kelvin wave propagation. The abrupt drop at the inertial frequency associated with a high ellipticity indicates limited inertial motion.

A peak also emerges at the M_2 semi-diurnal frequency. The ellipse stability is lower, with a lower ellipticity, indicating a more circular type of motion than that at the diurnal periods.

However, overall it is clear that the fluctuations at the diurnal and semi-diurnal periods play a relatively minor role in the energetics at the site. It is dominated by energy at much longer periods, probably associated with the Agulhas Current.

5 SOUTH COAST - AGULHAS BANK

The Agulhas Bank comprises the widest continental shelf around South Africa, with a maximum offshore extent of about 270 km (see Figure 1). The measurements to be discussed were made on the eastern side of the Bank in water depths of less than 150 m. The Agulhas Current plays an important part in the dynamics of the region, particularly in terms of the spin-off eddies on the inshore edge which can penetrate onto the Bank itself (Lutjeharms, 1981). The influence of the Current, and the variations over the shelf, is then also apparent from the results obtained at the mooring S1 (Figure 1), particularly at longer periods.

Figure 3 shows the results of rotary spectral analysis carried out at the site S1. It is clear that there are three main contributions to the current fluctuations observed there, namely, those occurring at periods longer than about three days, and then the diurnal/inertial and semi-diurnal fluctuations. Only the latter two are of interest here, although it is worthwhile noting that, at periods of longer than about ten days a clockwise rotation dominates; this is probably associated with the spin-off eddies.

A substantial, broad peak appears in the anti-clockwise spectrum covering the diurnal and inertial periods in the range from about 18,5 to 27 hours. This is not reflected in the clockwise spectrum, indicating the existence of a dominant anti-clockwise motion. This is as expected at or near the inertial frequency, and is confirmed by the relatively high ellipse stability and low ellipticity shown in Figure 3.

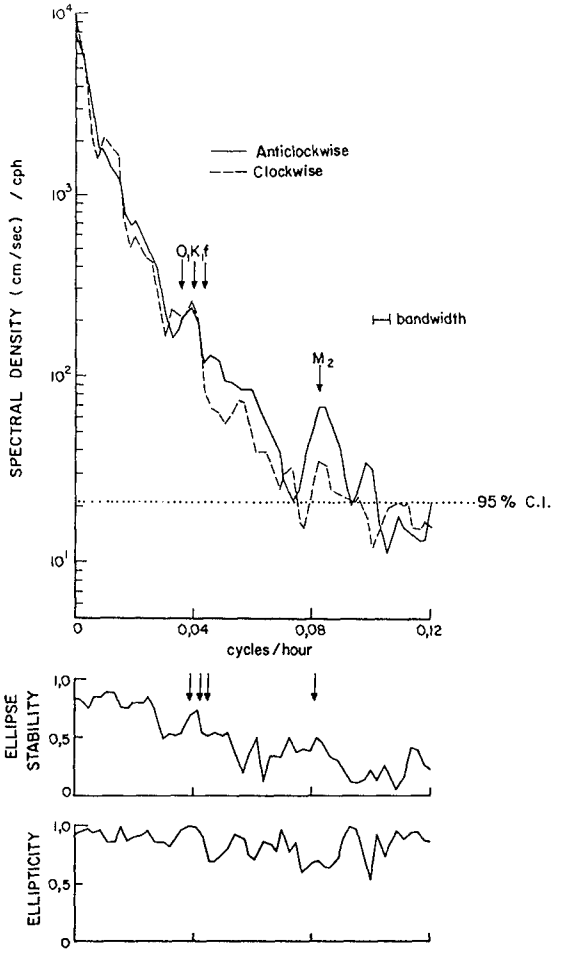

FIGURE 2. Clockwise and anticlockwise spectra for the measurements taken at site E1. Also shown are the ellipse stability and ellipticity, while the positions of the major tidal frequency bands are indicated, as well as the inertial frequency (f).

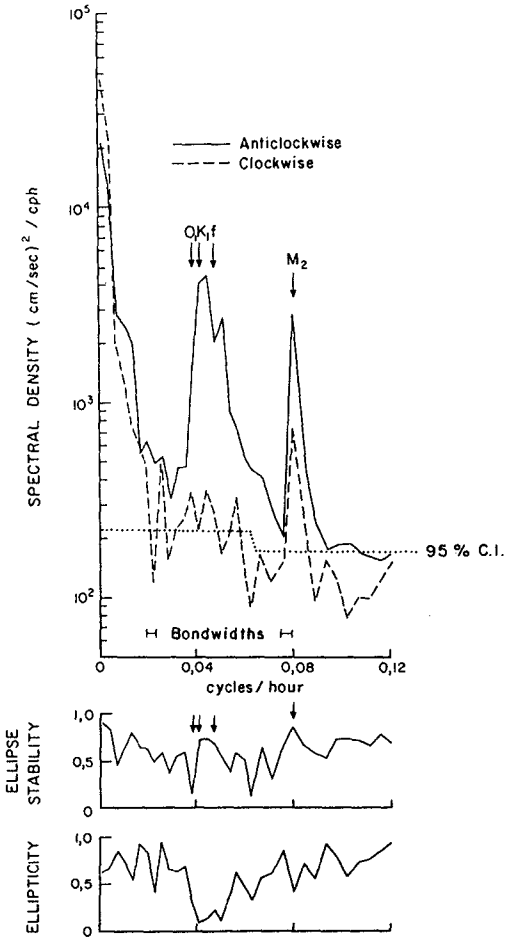

FIGURE 3. Clockwise and anticlockwise spectra and ellipse stability and ellipticity for the measurements taken at the topmost meter (depth 38m) at site S1.

A sharp, energetic peak occurs at the M_2 tidal frequency. Again the anti-clockwise spectrum dominates at this point, although there is nonetheless a substantial peak in the clockwise spectrum. A high ellipse stability is found, but with an intermediate value of the ellipticity.

The spectra determined from the measurements made at the two lower meters showed the same characteristics as those depicted in Figure 3 for the upper meter, although with slightly lower energies. However, this does not mean that the fluctuations observed were barotropic, since the analysis has merely indicated that the division of energy into the various frequency bands is similar.

Figure 4 shows the variations in coherence and phase between the east and north components of current at all three depths. It was not considered necessary to select any specific orientation for the current components, since Figure 3 did not reveal an exceptionally marked orientation for the current fluctuations.

It is clear that there is a major difference between the tidal and inertial period fluctuations. At the semi-diurnal and diurnal tidal periods a high level of coherence is found throughout the water column, with a minimal phase change with depth. At the inertial period a high level of coherence is also found, but with a phase change approaching 180° between the upper and middle meters. Calculation of the mean temperatures recorded at the three depths over the whole measuring period gives values of 16,6°C (38 m), 10,2°C (108 m) and 9,9°C (130 m). It is therefore clear that a major pycnocline existed between the upper and middle meters, giving favourable conditions for the existence of baroclinic fluctuations. On the other hand, only the inertial period fluctuations appear to respond, as indicated as well by the sharp dip in coherence between the diurnal tides and the inertial frequency in the upper meters of Figure 4.

The results of eom analysis are given in Table 3, and support the above conclusions. The vast majority of the fluctuation energy resides in the barotropic and first baroclinic modes, although there are some much smaller phase variations with depth in each of these modes; these may be associated with frictional effects or vertical propagation.

The difference between the long-period, tidal and inertial fluctuations is clear. The former are all essentially barotropic, with no more than about 10% of the energy distributed amongst the baroclinic modes. However, the inertial fluctuations are primarily dependent on the variations in density over the ocean depth, with less than 20% of the energy in the barotropic mode. This seems to be in agreement with the result that inertial oscillations in a coastal boundary or shelf region are essentially dependent on stratification (Pettigrew, 1981). It is also likely that there was considerable variability in the extent of the inertial fluctuations over the measuring period.

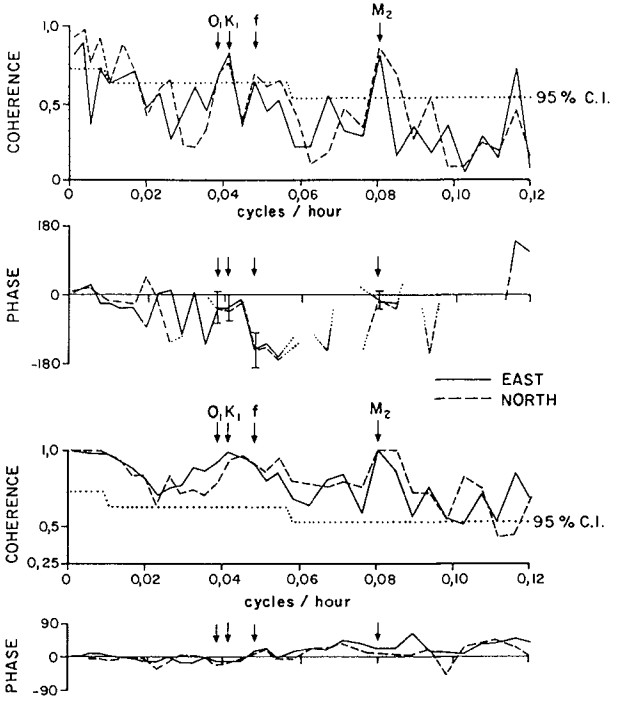

FIGURE 4. Coherence and phase between the east and north current components at site S1. The top section considers currents from the upper and middle meters (38 and 108 m), while the bottom section considers the middle and lowest meters (108 and 138 m). The 95% confidence limits are shown in the coherence, while for the upper meters the approximate error bars for phase are shown only at the indicated frequencies; for the lower meters the error in phase is less than 20°. Phase is only shown for relatively high coherence, while a positive value indicates that the lower of the two meters leads.

6 WEST COAST

The bottom topography is much more broken off this coast than either on the east or south coasts, with no well-defined shelf or slope. The Benguela Current flows northward here but should not be thought of as a well-defined current, but rather as a general movement of water northwards with eddies and current reversals.

The inertial period at this mooring is very close to the K_1 tidal period (Table 2). With the relatively short records, it was therefore not possible to resolve fluctuations at these two periods.

Figure 5 shows rotary spectral calculations at three of the four measuring depths. It is clear that the fluctuations at tidal and inertial frequencies contribute a major portion of the current energetics at the site. There is, moreover, a change with depth, with the diurnal/inertial peak highest at the upper meter, but then gradually being superseded by the semi-diurnal peak as the depth increases. However, it should be remembered that the time series at the upper meter covered only about four-fifths of that at the lower depths. The reason for the apparent emergence of a peak at about a 17-hour period is also not clear.

As expected, at the diurnal/inertial frequency the anti-clockwise peak contains most of the energy, with associated ellipticity values of less than 0,06 at all four depths. At the semi-diurnal peak the motion is also primarily anticyclonic, with ellipticity values of 0,42 at the upper meter and less than 0,28 at the deeper meters.

Figure 6 shows the coherence between adjacent meters on the mooring. Only the eastward components of the currents were considered, since again the low ellipticity values at the frequencies of interest show that any fluctuations will be reflected in all current components.

At the diurnal/inertial frequencies, there is a low coherence over the whole water column, while at the semi-diurnal M_2 frequency a very high coherence emerges. Inspection of the phase angles at the M_2 frequency shows values close to zero between all the measuring depths, that is, largely barotropic motion occurred with the semi-diurnal tidal propagation.

The eom results support these conclusions, with only the M_2 tidal fluctuations having a well-defined structure; here the barotropic mode dominated the energy partition with about 91%, with 8% in the first baroclinic mode. The long-period barotropic component comprised about 74% of that band's energy, although with more limited coherence especially near the surface. About 20% and 6% went into the first and second baroclinic modes, respectively. At the O_1, K_1 tidal and the inertial frequency bands the situation is much more confused, with little indication of barotropic motion, but with a limited vertical coherence in the baroclinic motions.

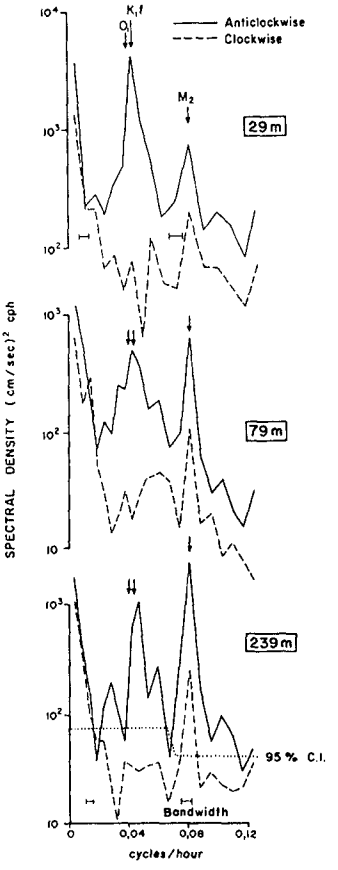

FIGURE 5. Clockwise and anticlockwise spectra from measurements at 29, 79 and 239 m depth at site W1. The 95% confidence limit shown for the bottom spectra applies to all three cases, while the bandwidths at the upper meter differ because of the shorter record.

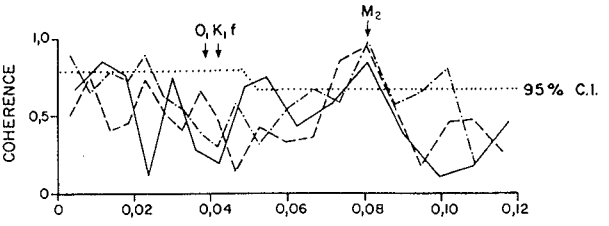

FIGURE 6. Coherence between adjacent meters on the mooring W1. Thus ———— considers the meters at 29 and 79 m, —·—·—· the meters at 79 and 159 m, while — — — — — is for 159 and 239 m depths.

7 CONCLUSIONS

The analysis that has been presented here has been limited by the small amount of current data available. As a result it was not possible to investigate the propagation of tidal and inertial signals, with only a limited analysis being possible of the vertical structure on the south and west coasts of South Africa.

Nonetheless, as a first look at the tidal and inertial currents, some very important differences between the coastal ocean regimes around South Africa have emerged. Moreover, it is clear that these currents cannot be ignored as a matter of course; indeed there are regions where they provide the dominant contribution to the total current variance.

Table 4 gives the comparison. The majority of spectra, particularly along the south and west coasts, have exhibited peaks at the semi-diurnal diurnal/inertial frequencies, as well as at the low-frequency limit. Consequently these peaks have been considered in the comparison; in some cases judging the extent of the peaks has been somewhat subjective, but in the majority of cases the error involved is small. The low frequency limit has included all frequencies less than about 0,014 cph (3 days).

On both the south and west coast sites the current ellipses at the tidal and inertial frequencies all rotate anti-clockwise. The ellipses themselves are not very eccentric, with the currents not showing the linear polarisation associated with the classic barotropic Kelvin wave. Nonetheless the indications are that at the M_2 semi-diurnal frequency the fluctuations were predominantly barotropic, also supported by the very consistent values found with depth in Table 4. Without more measurements the precise structure of the baroclinic fluctuations is not known, although the evidence for a strong first mode oscillation at the sharp thermocline at site S1 is clear.

The generation of the baroclinic fluctuation at tidal and inertial frequencies falls outside the scope of this paper, and indeed there are only limited data available to investigate this aspect. Nonetheless, given the proximity of the diurnal and inertial frequency bands, it is likely that some interaction occurred. Wind stress should also play a part, in which case a seasonal variation could be expected with the different seasonal winds. Changes in density structure would then markedly affect the response.

As a result, it is probable that considerable variability is likely to occur in the baroclinic fluctuations, that is, at times there may be minimal currents, but in order to achieve the mean values in Table 4, there must have been substantial currents at other times. Topographical variations and changes in ocean structure will also cause changes in the currents at the various frequencies; at present such variability across the shelf regions and with time is not known. It is nonetheless clear that in any construction or development in the ocean around South Africa, cognisance should be taken of the fact that tidal fluctuations may constitute the dominant portion of the currents actually encountered.

ACKNOWLEDGEMENTS

Much of the analysis presented here was done while one of us (EHS) was visiting the Woods Hole Oceanographic Institution. As such the PROSPECT series of programs were used, while Dr Bob Weller advised on aspects of the analysis. Acknowledgement is also given to Dr Ken Brink for the use of his eom programs, in addition to helping with the interpretation of results.

The data on the south and west coasts were collected under contract to the Southern Oil Exploration corporation, and acknowledgement is given here for permission to use the data in this analysis.

THE RELINING OF SAICCOR'S EFFLUENT OUTFALL

BERNSTEIN, MARK
AHRENS, HUGH P.L. (MEMBER ASCE)
SMART, MICHAEL D.

ABSTRACT

This paper describes the method employed to refurbish an existing marine outfall which was deteriorating rapidly. It reviews the repair options that were available and how each was investigated and rejected until the best solution was obtained. Finally the execution of the project is described in detail through each stage to successful completion.

1.0 INTRODUCTION

The SAICCOR rayon pulp mill at Umkomaas on the east coast of South Africa was commissioned in 1954 with an initial capacity of 100 tons of pulp per day and is currently producing 1 200 tons of pulp per day.

During 1964 and 1965, investigations into the provision of a sea outfall were carried out and in 1967, a rubber lined steel pipeline of 914 mm internal diameter designed to discharge a little over 100 000 m^3 per day of effluent at 50°C into the Indian Ocean through a diffuser system located 2500 m offshore in 20 to 25 m of water was commissioned. The outfall consisted of a landline delivering effluent from a pumping station on the south bank of the river to a sealine which was located north of the Umkomaas River mouth.

The landline was made up of three separate sections as follows:

(a) Pumphouse to bridge

This was a 117 m long section of buried pipe terminating in a 9 m high vertical leg discharging into a bend on a bridge over the Umkomaas River.

(b) Bridge section

This consisted of 8 No 25 m long self supporting pipes spanning between the existing bridge piers.

Bernstein, M. Consultant to Campbell, Bernstein & Irving
Ahrens, H. Partner of Campbell, Bernstein & Irving, Overport, South Africa
Smart, M. Engineer with Campbell, Bernstein & Irving

(c) Bridge to the sea outfall

This consisted of a 200 m length of buried pipe from the end of the bridge to a 90° bend at the beach which is the start of the sealine.

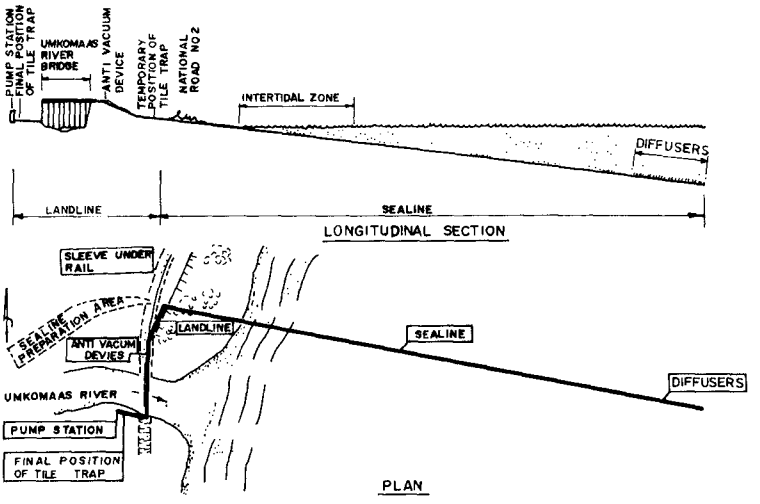

FIGURE 1

The 2000 m long sealine was made up of 97,5 m flanged lengths with a 100 mm thick concrete weightcoat. It terminated in a 300 m long diffuser section containing 48 No vertical outlets ranging in diameter between 100 mm and 137 mm.

An examination of the pipeline at the end of 1971 revealed some deterioration of the rubber at the invert and there were also signs of blistering up to 25 mm diameter under the pulp scale which had built up to a thickness of about 25 mm. It was considered that most of this deterioration was caused by the passage of heavy grit in the effluent and equipment to reduce this was installed.

Further inspections at regular intervals revealed a reduction in the rate of deterioration. Although the friction factor was building up at a rapid rate, it was decided not to attempt to remove the scale because this was undoubtedly offering protection to the lining.

An inspection in 1978 revealed that tiles from the pump station sump lining had broken away and entered the pipeline through the pumps. These 150 x 150 x 37 clay tiles accumulated at the bottom of the 9 m high riser to the bridge until they broke roughly in half and were carried up the riser and through the main pipeline.

Following reports of further deterioration and damage to the lining within the pipeline as a result of the movement of tiles, a series of shut-downs was arranged and inspections of the accessible sections of the pipe were made during early 1981.

Photographs were taken which revealed that the build-up of pulp was severe and, in certain areas, debris mainly in the form of broken tiles had built up and become cemented by the pulp. Attempts to clear away the debris mechanically proved largely ineffective because of the lack of suitable facilities to transport the debris over any distance in the time available.

Later in that year, leaks were detected on the land section of the pipe north of the bridge and these were sealed using external clamps. A further internal inspection using television equipment was made of that section of the pipe and the resulting picture was not encouraging. It was realised that the repair or replacement of the pipe was a matter of urgency and SAICCOR, working with its Consultants, pressed ahead with investigations into various alternatives.

2.0 ALTERNATIVE SOLUTION

Investigations revealed that the following were the only alternatives available:

(a) a new pipeline estimated to cost more than R10 million requiring 15-18 months for construction,

(b) relining of the existing pipeline with 800 mm OD plastic pipes estimated to cost R2,5 million but requiring only a few days to construct once pipes were available and site preparations completed.

The latter alternative which had obvious attractions also had attendant risks of blockage due to:

(i) pulp accumulated on pipe walls,
(ii) rubber lining which may have been loosened by debris passing through the pipeline,
(iii) accumulations of cemented debris which had been observed during inspections,
(iv) the configuration of the existing pipeline which was known to have been moved into a flat S-curve shortly after laying.

A study of each of these problems revealed that they were not insuperable and it was agreed that there were emergency measures which could be taken provided that a jam did not occur within the surf zone which was inaccessible to divers.

3.0 RELINING

3.1 PHILOSOPHY

A simple philosophy was evolved in which the existing pipeline would be regarded as a "hole in the ground or in the sea" which could be exploited for either the receipt of a new internal liner or as an anchor for a new pipeline if this had to be laid external to the existing pipeline in the event of a jam.

The following main factors emerged from the ensuing study:

(i) that the gap between an existing 914 mm internal diameter rubber-lined steel pipe and an 800 mm external diameter plastic pipe should be adequate to prevent jamming as a result of pulp accumulations,

(ii) that, if jamming did occur outside the surf zone, the causes could either be removed by divers who would cut holes under water in the existing pipeline or alternatively, a large hole would be cut to permit a connection to be made between the section of liner already completed and a new pipeline which would be clamped to the extension of the existing pipeline,

(iii) that an experiment would be carried out by lining the short landline section before embarking on the more formidable task of lining 2 000 m of underwater sealine.

It was obvious that the entire operation was primarily dependant upon the passage of the liner through the 500 m long surf zone which was inaccessible to divers and it was accordingly decided to carry out an inspection of this section and clear any debris before proceeding further with the project.

The hot dark coloured effluent in the surf zone section was displaced by cold seawater and divers traversed the entire surf zone in order to inspect the interior of the pipe. This was a formidable task requiring great physical endurance and courage but it was completed without incident and divers reported that there was no loose rubber or piles of debris in this section of the pipeline. It is also of interest to note that two heavy stainless steel props which had been used to secure plates internally over leaks had also disappeared having been carried away by the pumped

effluent. As a result of the favourable report by divers, it was decided to proceed with the re-lining proposal.

3.2 MATERIALS

It was apparent that only semi-rigid pipes could be used particularly in the case of the sealine where the liner had to be introduced in one continuous length of 2100 m. Jointing was therefore of prime importance because, in addition to constructional requirements, the liner could only be anchored at the shore end which would result in the full frictional force of about 20 tonnes being transmitted by tension through the joints.

Many relining materials were investigated including the following:

(i) Stainless Steel

Stainless steel had proved reliable against chemical attack but was extremely costly and inflexible so that the use of this material would be restricted to use on the land only.

(ii) Glass Reinforced Plastic (GRP)

Although this material had been successfully used in relining operations, it was considered that the jointing procedure was too slow and could not be rigidly controlled to obtain uniformity and reliability. The local cost was also somewhat high and production capacity limited.

(iii) Polypropylene (PP)

This material which was manufactured locally would have been capable of withstanding the chemical attack and could meet the temperature requirements. The wall thickness proposed by the manufacturers was however considerable and some concern was expressed regarding the reliability of welding such thick walled pipes in the field.

(iv) High Density Polyethylene (HDPE)

These pipes could also be manufactured locally but were unsuitable for the high temperature of the effluent.

(v) Ultra high molecular weight high density polyethylene (UHMWHDPE)

This material was only available from the United States of America. At that time there was only one

manufacturer with the expertise, equipment and experience of re-lining existing pipes of the size under consideration. Although more expensive than

local products, the reduced wall thickness permitted greater flexibility and the use of a proven welding technique. The supplier also offered the services of an experienced technician to carry out the fusion welding of the pipes and to supervise the handling of the pipe on site.

3.3 DIAMETER AND CAPACITY

Ultra high molecular weight high density polyethylene was therefore selected for the material of the liner and 800 mm was chosen as the outside diameter. This allowed a 57 mm annular space which would provide adequate flexibility during relining and would ensure a somewhat better capacity than the existing pipeline in its "aged" condition.

The coefficient of friction for new rubber lined steel pipes would be about 0,013 in the Manning formula but, as a result of pulp adhering to the internal surface, the existing pipeline had a measured co-efficient of 0,023.

It was considered however that a co-efficient of 0,020 could be achieved by light pigging and this figure was used for comparative calculations of capacity.

The Manning co-efficient for new plastic pipes was given as 0,007 and it was assumed that, if pulp built up on the plastic surface, it could be easily dislodged with regular pigging. It was nevertheless decided to use a conservative 0,010 for comparative calculations.

Table 1 shows comparative friction heads per 1 000 m of the existing pipeline and of a new 800 OD plastic liner for flows of 3 000, 3 500 and 4 000 m^3/h.

TABLE 1 : FRICTION HEADS PER 1000 m

TYPE OF PIPELINE	NETT INTERNAL DIAMETER	FRICTION HEAD in m per 1000 m at		
		3000 m^3/h	3500 m^3/h	4000 m^3/h
Rubber-lined steel	914 mm	4,60	6,27	8,19
Plastic Pipe 800 OD	738,8 mm	3,59	4,89	6,39

Allowing for a possible 500 m extension of the pipeline for a new diffuser at a later date, total heads for various flows would be as shown in Table 2.

TABLE 2 : TOTAL FRICTION HEADS

TYPE OF PIPELINE	TOTAL FRICTION HEAD in m at FLOWS of		
	3000 m^3/h	3500 m^3/h	4000 m^3/h
Rubber-lined steel	13,43	18,28	23,88
800 OD Plastic Pipe	10,64	14,49	18,93

It will be seen from TABLE 1 that the smaller plastic pipe has a lesser unit frictional head than the larger rubber-lined steel pipe whilst TABLE 2 shows that, even with an additional length of diffuser, the total head in the new smaller diameter plastic pipe would be less than that in the existing larger pipe because of the reduced friction.

It was concluded therefore that the lined pipeline would have a better capacity than the original pipeline.

PRESSURE DIAGRAM

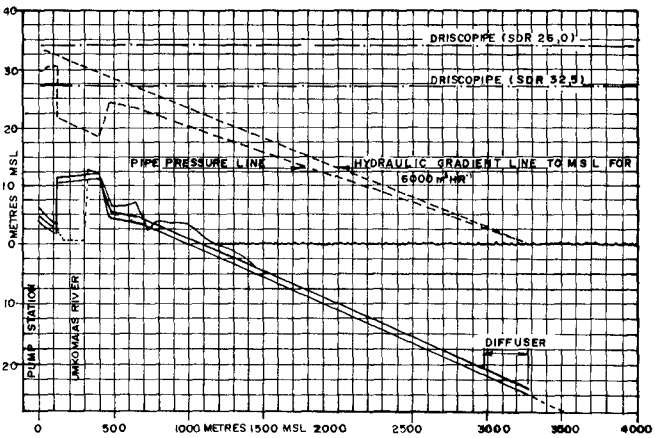

FIGURE 2

3.4 TIME FACTOR

It was important to minimise the times of stoppages because of the considerable loss of production involved and the difficulty of stopping and restarting operations at the pulpmill.

The construction work was therefore designed and planned to have stoppages of only 21 hours for the landline and 34 hours for the sealine.

4.0 CONSTRUCTION

4.1 PREPARATION FOR PROJECT

The preparatory work required in order to achieve the least possible stoppage of factory operation was a most important part of the project and required several months of intensive effort and the massing of considerable resources. Everything that could be done without causing interference with the flow of effluent was completed well in advance of the relining operations. Main items requiring special attention were as follows:-

4.1.1 The sea end of the pipeline was opened and the diffuser ports were blanked off. Pumping at maximum flow rates was then used periodically to flush debris from the pipeline. Divers made frequent inspections at the outlet and reported considerable discharges of debris and pulp.

4.1.2 Wherever relaying was possible as an alternative to relining, this work was completed well in advance of the relining operation.

4.1.3 Specials were manufactured and anchor blocks and foundations were constructed in advance.

4.1.4 Scaffolding was erected at the south end of the bridge where the lining operations would take place at a height of some 9 m above the roadway.

4.1.5 Where connections were to take place below ground level sheet piling was driven to ensure safe access.

4.1.6 A large site was prepared for the receipt and storage of the 12 m long pipes and a welding machine was set up on that site to enable the pipes to be welded into 500 m lengths in readiness for the relining operation. Arrangements were made for the welded joint between the 500 m long sections to be carried out speedily during the relining operation.

4.1.7 As this site was on the side of a main railway line away from the sea, a 2 m diameter concrete culvert was jacked under the railway in order that the stored lining could be fed into the existing sealine.

4.1.8 A system of winches mounted on tracks was set up so that the new liner could be pulled through the concrete sleeve and pushed into the pipeline.

4.1.9 Divers and fully equipped vessels were commissioned to standby during the operation in order to open the pipeline and clear any jam should this occur or alternatively, to lay the new pipes alongside the existing pipeline in the event of it not being possible to insert the entire liner. A pinger was purchased for installation in the end of the pipe to assist with location of the pipe end in the event of a jam.

4.1.10 Food kitchens, emergency power equipment, and a mass of special tools and equipment was assembled in case of need.

4.1.11 Rigid timetables and lists of duties were established in order to implement a number of alternative plans in case problems should arise.

4.1.12 Special equipment and protection was set up to cope with inclement weather.

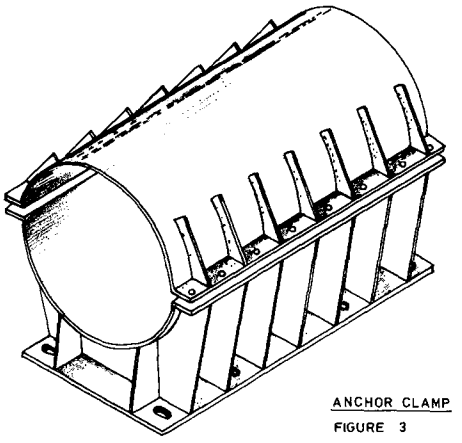
In effect, the whole exercise was planned as an emergency operation with plans to meet any contingency and it was significant that no contingency arose during the operations for which there was not a plan prepared well in advance.

4.2 PRELIMINARY WORKS

4.2.1 The section from the bridge to the sea outfall was constructed first and this involved the laying of a plastic pipe in a new position adjacent to the existing pipe. The north end of this new pipe was connected to a tile trap combined with a pig port adjacent to the 90° bend at the start of the sealine. This tile trap remained in this temporary position to trap any further debris which might find its way into the line after commissioning of this section of pipes so as to avoid further accumulations of broken tiles in the sealine.

Each end of this new pipeline was restricted by means of heavy anchor clamps. Details of the anchor clamps are shown in Figure 3 and a feature of these clamps was the arrangement provided to allow for adjustment of lengths and location should this be necessary. The holding down plate

was drilled with oversize holes and large rectangular washers were fitted. These large washers allowed reasonable movement within the bolt holes and, after final tightening of the bolts, the washers were welded in position.



ANCHOR CLAMP
FIGURE 3

The whole of this section, except for the two ends, was backfilled before the first mill shut so as to hold the pipe in place and to provide a platform on which the liner pipe could be laid out in readiness for winching into the bridge section.

At the south end of this section, provision was made for the connection to the bridge section after relining by sheetpiling a portion of the existing line which had to be removed later to provide a gap for the insertion of the liner. All necessary preparatory work for connecting the liner to the newly laid pipeline was thus prepared in advance.

4.2.2 The section of the landline from the pumphouse to the bridge was constructed between the two mill shuts. Due to the complexity of the route, part of the pipeline was replaced using a plastic pipe buried adjacent to the existing pipe with stainless steel fabricated fittings being used to tie in at the pumphouse and bridge ends. The final connections were made during the second mill shut.

4.2.3 During the landline operations, the liner for the sealine was being made up into approximately 500 m lengths ready for introduction into the sealine.

As the liner was to be pushed into the sealine by using a system of clamps and winches, preparations were made to receive a hydraulic clamp mounted on rails and two sets of winches for moving the clamp backwards and forwards.

4.3 MILL SHUT NO. 1

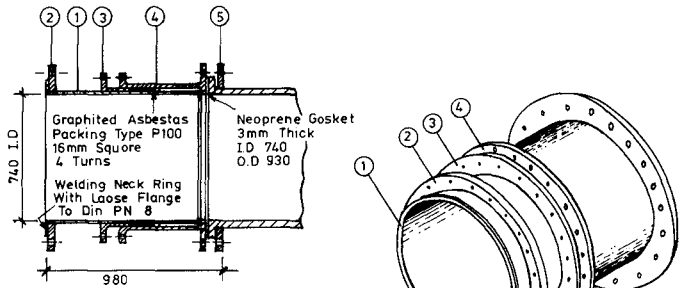
4.3.1 The bridge section was relined during the first mill shut by pulling the liner into the existing pipes which were retained as structural beams. The liner was pulled from the south end of the bridge using a system of winches which would pull against the southern most flange of the pipeline and not introduce any load on to the bridge structure itself. The liner was introduced at the north end once an existing air valve, bend and length of pipe had been removed.

A sample length of plastic pipe was pulled through as a sizing piece to confirm that the liner could negotiate a 4° bend which was known to exist in that section of the pipeline. Once this test had been cleared, the new liner was pulled into position. The actual pulling operation was completed in about 1,5 hours.

The front end of the line being pulled was notched to form a conical nose while the tail end was fitted with a stub-end and loose flange. This flange was pulled hard up against the flange of the existing steel pipe. A new flanged stainless steel air valve tee was bolted to this and was then anchored to a concrete base so that the north end of the liner was effectively locked into position.

The gap between the air valve tee and the previously laid plastic pipeline was closed with a section that comprised a length of plastic pipe, a specially designed stainless steel anti-vacuum fitting and an adjustable stainless steel closure piece to ensure an accurate fit.

This closure piece is shown in Figure 4 and comprised a temporary stuffing box which was welded up after commissioning. The anti-vacuum device consisted of a NORVAL type reflux valve with a stainless steel screen and diaphragm designed to allow air to enter the pipeline and prevent the creation of an air vacuum which could cause collapse of the plastic pipes.



ADJUSTABLE CLOSURE PIECE (FULLY CLOSED)

2. Loose carbon steel flange
3. Stainless steel packing compressor
4. Stainless steel outer sleeve
5. Loose carbon steel flange

FIGURE 4.

To achieve a seal at the south end of the bridge, the notched end of the pipe was cut off square and a specially designed sleeve was inserted and bolted between the steel pipe flanges. Once the pipe was commissioned, the plastic liner would expand and seal itself against a neoprene ring around the sleeve.

4.3.2. The divers' inspection of the 500 m surf zone section was carried out during the relining of the bridge section. Water which had been stored in a dam on the beach was pumped into the sealine via a manhole on the beach. Once the pipeline had cooled sufficiently, three divers entered the pipe and began the inspection. Only one diver traversed the full 500 metres, the other two divers stopping off en route to assist in handling the air lines, communication cable and safety lines necessary for the lead diver. This magnificent team effort was completed in about 6 hours, and the information obtained from the survey enabled the decision to proceed with the second mill shut to be made with confidence.

4.4 MILL SHUT NO. 2

4.4.1 When the time for the second mill shut arrived, it was necessary to carry out two preliminary operations before the relining could commence. First the tile trap was disconnected and physically removed from its temporary foundations. This exposed the open end of the pipe entering the sleeve under the national road.

Rails for the winch assembly designed to pull the liner pipe into the sea outfall were bolted to the concrete foundation of the tile trap so that the task of winching the pipe from the assembly yard, through the railway culvert and into the sealine, could commence. This winch assembly consisted firstly of a hydraulic clamping device which was mounted on rails and which gripped the pipe with sufficient force to transmit the winch pulling force to the pipe. The hydraulic clamp had a travel of 12 m and was pulled by two winches capable of exerting a total pull of 40 tonnes. On completion of its 12 m travel, a return winch, mounted over the culvert under the railway pulled the hydraulic clamp, which was now in the open position, back to its starting position. The clamp would then be closed and the main winches would repeat the cycle and pull the hydraulic clamp back over the 12 m track.

Next an existing bend and portion of an adjoining length of steel pipe were uplifted on the beach side of the road as the bend was too sharp for the passage of the semi-flexible liner. In order that the total anchoring force required to restrain the completed liner would not be restricted to a single flange at the beginning of the section, an additional anchor block was constructed in advance on the beach side of the main road. This was provided with a clamp to which the liner could be bolted when completed.

The first 500 m of liner moved into the pipe with ease and a speed approaching 10 m per minute was initally achieved. This rate gradually decreased and, towards the end of the operation, the speed had reduced to about 1,5 m per minute whilst the force induced by the winches had gradually increased to a maximum of 16,3 tonnes.

Including brief stoppages to weld the 500 m lengths together, the lining operation continued for 21 hours until the end flange of the liner was set against the flanged end of the existing sealine as the first anchor. The liner was then clamped to the anchor block previously provided on the beach to act as a second anchorage. The sea end of the liner was left loose to accommodate the 18 m of expansion anticipated when hot effluent was re-introduced into the pipeline.

4.4.2 Whilst the sealine was being relined, the tile trap was moved to its new and final position adjacent to the pump station and the new pipeline laid between pumphouse and the south end of the bridge was connected into the system.

The gap between the relined sea outfall and the new pipe previously laid up to the tile trap during the first mill shut was closed with a stainless steel bend anchored to the tile trap foundation and connections made by using the same adjustable closure piece described previously.

5.0 CONCLUSION

The operation was carried out with relative ease largely because of the advance planning of the exercise. Although not all precautions taken in anticipation of problems were required, they were necessary in order to minimise the heavy risks involved in a major operation of this type.

The system has been in successful operation for over 12 months and the pumps are handling the total effluent quantity effectively at a reduced pumping head.

It is believed that this is the longest large diameter pipe relining ever attempted and it was completed in a total shutdown time of less than 60 hours at a cost of about 25% of a replacement pipeline. Its success heralds opportunities for the renewal of many ageing pipelines which would otherwise require costly and disruptive replacement.

6.0 ACKNOWLEDGEMENTS

The contributions made by SAICCOR and its engineers during the project, the expertise and experience of working with large bore plastic piping provided by Maskell-Robbins Inc of Oregon USA, and the co-operation and dedication of all the staff of the main contractor, Murray and Roberts, associated with this project, are acknowledged.

The authors wish to thank SAICCOR for permission to publish this paper.

CIRCULATION OF TWO MULTIPASS ESTUARIES IN THE GULF OF MEXICO

by

Donald Steven Graham[1] A.M. ASCE

1. Introduction

An important class of estuaries which has received relatively little attention is the barrier-island-contained multi-inlet one. Cases range in scale from the tidal rivers common along the S.E. coast of the U.S.A. to the very extensive embayments found on the Gulf of Mexico. A sound knowledge of the dynamics of the type of estuary is important for enlightened management of the resource. In the Gulf of Mexico region these estuaries tend to be significant spawning areas for marine fishes, and also support important local fisheries and oyster beds. Fortunately (or not) they are also geomorphically associated with coasts underlain by nearly-horizontal sedimentary rocks which often yield petroleum. Finally, in the Gulf of Mexico area of the U.S.A. the relatively attractive setting and climate of the barrier islands induces dense human development. (Surprisingly this attraction does not seem to occur in Latin America where the Gulf Coast is relatively unpopular and sparsely populated). Petroleum extraction and residential development, and the civil appurtenances needed to support them, can pose significant threats to the water quality, and hence marine life, of these estuaries. Local economic and social impacts can be severe since the fishing economy is usually marginal and traditional (even in the U.S.), while the oil and real estate businesses are usually strongly linked to wealthier portions of the exogenous economies. Because of this, regulation is probably necessary to prevent excessive adverse impacts, and sound knowledge is required for proper and enforceable water quality regulation.

As occurs in many disciplines from time to time, Carter, Najarian et al. (1, p. 1586) pointed out that rigorous estuarine analysis has suffered from the nature of its origin in Chesapeake Bay:

> "One of the most extensive and most thoroughly analyzed set of observations for any estuary was that of Pritchard ... taken in the James River in 1950. ..Although this set of measurements and their analysis by Pritchard resulted in vastly improved understanding of estuarine physical (sic) processes, it so influenced subsequent estuarine studies that measured circulation patterns that were at variance, at least for part-

1 Assistant Professor, Dept. of Geography, Scarborough College, University of Toronto, West Hill, Ontario, Canada, M1C 1A4

> ially mixed estuaries, were viewed as measurement artifacts, which they were not rather than .... real events, which they probably were"

A particular mental constraint resulting from the notion of the classical estuary (i.e., James River, VA) was that tidally-averaged water flux equals freshwater inflow and tidally-averaged salt flux is zero, under steady state conditions. Further, tidal motion was considered to be the most important variable affecting estuarine dispersion, and the source of most of the ambient turbulence available for mixing. A review of the literature indicates these notions only came to be questioned, disproved, and then incorporated into more sophisticated models after about 1975. Two significant papers appeared around that time. Weisberg (2, also 3) showed that meteorological forcing caused a significant portion of the total turbulent energy even in a narrow tidal river. It has subsequently been realized that wind forcing can almost completely overwhelm tidal effects in broad shallow embayments of the Gulf of Mexico which has minimal tidal amplitude (of the order of a foot). (In all honesty it appears that this may have been appreciated by field biologists before coastal engineers and oceanographers).

The second significant paper was that of van de Kreeke and Dean (4) (followed later by 5, 6, 7), in which the principles of Stokes velocity, as discussed in an earlier theoretical paper by Longuet-Higgins (8), were applied to the engineering analysis of circulation of shallow bays with 2 inlets. The essence of the paper was that nonlinear flux terms resulting from periodic tidal motion do not disappear upon tidal averaging (even for single inlet estuaries(9)) and residual flows will typically occur. This will be discussed in more detail anon.

The environmental engineering and biological implications of these results are extremely significant, and, in the author's opinion, almost totally unappreciated by workers in these fields despite some efforts by van de Kreeke (5, 7) to point them out. The effect of net nontidal residual flows caused by wind or nonlinear tidal residuals is to induce an advective component which can greatly reduce the flushing time of the estuary, and change distributions of water quality parameters (7). Since coastal engineering projects can change these renewal rates (10), or at least require them to be evaluated for EIS's, it follows that they should be studied in detail so that adverse environmental impacts can be avoided wherever possible by engineers working in these estuaries.

2. Scopes of Apalachicola and Terminos Projects

Apalachicola Bay is a large (550 km^2) 4-inlet embayment on the Florida Panhandle. Laguna de Terminos, the largest (2000 km^2) estuary on the Gulf of Mexico, is a 2 inlet-embayment located at the base of the Yucatan Peninsula. See Figures 1 and 2. Both support significant local fisheries. Apalachicola is being impacted by nonpoint pollution from silvicultural activities near its head (11-15), and by residential development in St. George Island. Terminos is being affected by intensive petroleum exploration offshore in the Gulf of Campeche and by associated growth of the barrier island city of C. de Carmen. There

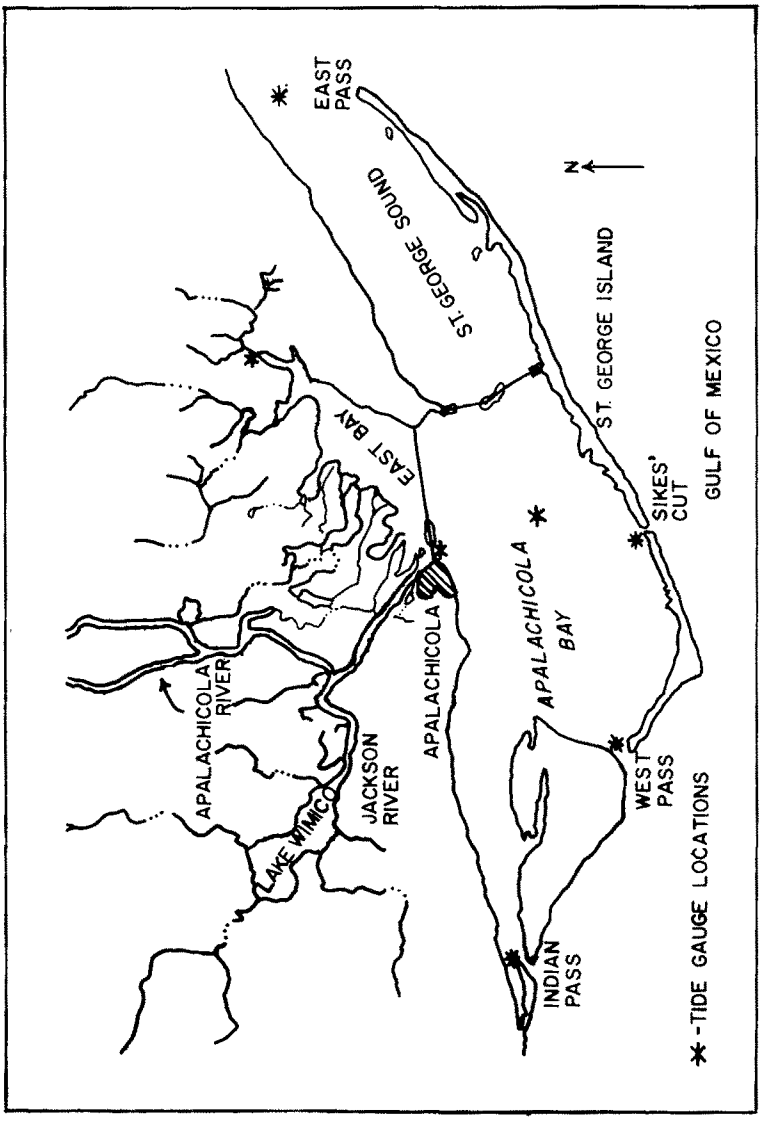

Figure 1 GEOGRAPHY OF APALACHICOLA BAY

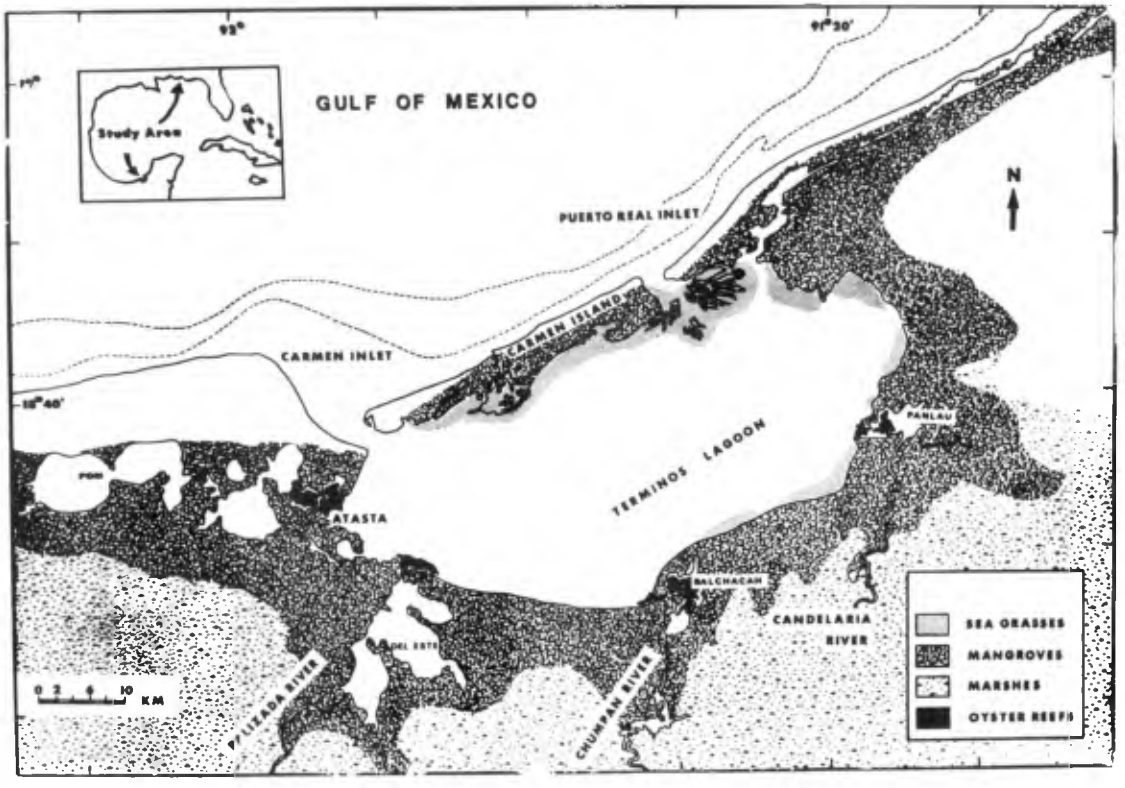

Figure 2 Geography of Laguna de Terminos, Mexico

is concern over the fate of another large oil spill or blowout. In both cases the vertically-averaged 2-dimensional real-time finite-element circulation model CAFE-1 (16) was applied to provide information about the macro-circulation features of the estuaries. Both projects were consulting jobs essentially in support of biological studies and hence were limited in scope and funding. Some field data for model verification were obtained for Apalachicola Bay, none was specifically available for Terminos. The purpose of the paper is to discuss the general results of the two model applications to geomorphologically and dynamically similar estuaries on the Gulf of Mexico, and the relate these to the comments made in the introduction. It is emphasized that these were engineering projects limited in scope and not exhaustive scientific programs.

3. Discussion of Significance of van de Kreeke's Results

Numerical model outputs for both Apalachicola Bay (10, 17) and Laguna de Terminos (18, 19, 20) both showed residual nontidal flows with windless conditions. Frankly, we thought that either the model results might be erroneous or that we had discovered something new, particularly since drowning victims and loose boats at Apalachicola were known to drift west. Dr. Tavit Najarian kindly brought van de Kreeke's work to the attention of the author. This material appears to be germane, although it does not seem to have been applied to such large systems before. It will be compared to numerical results herein.

In terms of unit discharges the equations of motion used by van de Kreeke (4, 6) were

$$\frac{\partial \eta}{\partial t} + \frac{\partial q}{\partial x} = 0 \qquad 1.$$

$$\frac{\partial q}{\partial t} + gh\frac{\partial \eta}{\partial x} + g\eta\frac{\partial \eta}{\partial x} + \frac{2}{h} q \frac{\partial q}{\partial x} + \frac{gh^2}{\rho 2} * \frac{\partial \rho}{\partial x} = - Fr \qquad 2.$$

$$\text{where } Fr = \frac{F_1 \, q \, |q|}{(h + \eta)^2} \quad \text{quadratic} \qquad 3.$$

$$\text{or} \quad Fr = \frac{F_2 q}{h} - \frac{F_2 q \eta}{h^2} \quad \text{quasi-linear to second order} \qquad 4.$$

where η - tidal were amplitude, q - unit discharge, h - mean depth, ρ - density, Fr - bottom friction term, F_1 - constant and F_2 - constant.

In comparing these with the basic equations in the CAFE-1 model (see 16, or 14, 17, 19) the primary differences are i) the dimensionality, ii) the exclusion of Coriolis and wind-stress terms, and iii) the inclusion of a baroclinic term. A 2-D analog of equations 1-4 is given by van de Kreeke in (7), but ii) still holds. The quadratic resistance relation, eq. 3, is used in CAFE, while van de Kreeke uses the quasi-linear form (4) for his illustrations. As shown in (4) the differences are great enough to warrant using full quadratic formulation, but the results are similar and of the same order. Substituting eq. 4 in

eq. 2, a tidally-averaged form of eq. 2 can be derived in which second-order terms are retained as residuals and are balanced by the net bottom stress (see 4, 5, 6, 7). Assigning boundary conditions at each inlet of the channel of

$$\eta = a_0 + a_1 \sin\sigma t \text{ and } \rho = \rho_a \text{ at } x = -L/2 \qquad 5.$$

$$\text{and } \eta = b_0 + b_1 \sin(\sigma t - \delta) \text{ and } \rho = \rho_b \text{ at } x = +L/2 \qquad 6.$$

and denoting the tidally averaged unit discharge as q_*, it is shown (4, 6) that

$$\frac{q_* T}{hL} = P\left(\frac{\lambda}{L}, \frac{F_2 L}{C_0 h}\right) \frac{a_1 b_1}{h^2} \sin\delta + Q\left(\frac{\lambda}{L}, \frac{F_2 L}{C_0 h}\right) \frac{a_1^2 - b_1^2}{h^2}$$

$$+ \frac{C_0 h \lambda}{F_2 L L} \frac{a_0 - b_0}{h} - \frac{C_0 h}{F_2 L} \frac{\lambda}{L} \frac{\rho_a - \rho_b}{\rho_0} \qquad 7.$$

where T - wave period, λ - wave length, $C_0 = \sqrt{gh}$, P and Q are functions (see 4). Eq. 7 is given in (6), while only the first two terms on the rhs appear in (4). The contributions represent, respectively, net flow induced by phase differences, amplitude differences, differences in mean water level, and baroclinic effects. The nature of the latter is reasonably well known and will not be given further consideration here. Also, $\partial\rho/\partial x$ effects are not used in CAFE. Note that terms in the rhs of eq. 7 are of order a^2/h^2, so q_* would be expected to be largest in shallow lagoons, such as Apalachicola and Terminos.

In other words, if the tidal wave at each inlet has a different amplitude and phase lag, caused by differences in offshore shelf topography, then a net nontidal flow will be set up in shallow multi-inlet estuaries. Further, if the mean sea level varies along the coast, a net-flow will be induced, as expected. The latter is not uncommon and van de Kreeke (6) found this to be the largest contribution at Marco Island, Florida. Unfortunately we did not have the capability of finding mean sea level at either Apalachicola or Terminos, although we expect there is a difference at Apalachicola since superior model results were obtained by inputting a gradient of mean sea level.

A final comment is made that van de Kreeke and Chiu (7) found similar residual currents with a 2-D finite-difference model. Residual flow eddies were also present but it could not be readily determined to what extent these were real or numerically-induced. Tee (21) claimed residual eddy currents computed for the Minas Basin, NS, were real. At the April 1980 AGU convention in Toronto van Zant and Hsueh (see 22) presented a finite difference Leendertse-type model of Apalachicola Bay which they had developed contemporaneously, but independently, from our own CAFE application. Using similar boundary conditions, but cruder boundary representation, they computed residual eddies near East and West Passes. CAFE, on the other hand did not (although a (real) residual eddy can appear near East Bay under some circumstances). Further, our field work and satellite images showed no

evidence of such eddies existing under these conditions. Consequently, residual eddies in numerical models must be viewed with skepticism until proven. As shown in (19), satellite images confirmed the existence of the central eddy in Terminos calculated by CAFE.

4. Selected Apalachicola Results

Since most of the Apalachicola and Terminos material has been published, only selected results germane to the foregoing comments will be presented. Interested readers are referred to the original papers for more details.

As shown in Figure 3, a strong east to west net nontidal velocity was calculated for windless conditions with T = 44640s; at West Pass $a_0 = 0$, $a_1 = 0.21$ m; at East Pass $b_0 = 0$, $b_1 = 0.40$ m; $\delta = 3780$ sec (see eq. 5, 6) from the tide tables. In this case then, L = 39 km, h = 3 m approximately, $C_0 = 5.4$ mps, $\delta = 30.48^0$, $\sin\delta = .507$, $\lambda = 242$ km. n = 0.018 in the model, so

$$F_1 = \frac{n^2 g}{h^{1/3}} = \frac{.018^2(9.81)}{3^{1/3}} = .00220 \qquad 8.$$

and letting $F_1 \doteq F_2$ (rather than eq. 22 in (4)) we get, from eq. 7, 9.

$$q_* = 2.62\,[P(6.21,\ 5.30)(.008)(.507) + Q(6.21,\ 5.30)(-.014)] \qquad 10.$$

$$P \doteq 1.8, \quad Q \doteq 1 \quad \text{from (4)} \qquad 11,\ 12.$$

$$\text{so } q_* \doteq 2.62\ (.007 - .014) = -.019 \qquad 13.$$

$$\text{so } v_* = q_*\, h = -0.019 * 3 = 6 \text{ cm/s westward} \qquad 14.$$

Typical values computed (10) are about 20-30 cm/s westward for 3 m depths, hence the results are reasonable and comparable, considering the approximations of eq. 9, 11, 12, lack of Coriolis terms in (4), and the suspicion that $a_0 \neq b_0$ on the average. Hence the net westward flux in Apalachicola Bay can be ascribed to nonlinear interaction of tidal waves. This net flux is surmised to be responsible for the high quality of Apalachicola Bay water, and it was demonstrated in (10) that construction of a mid-Bay island for bridge abutments had probably resulted in an increase in flushing time.

In November 1979 we placed tide gauges at each inlet to Apalachicola Bay and in the Bay center (see Figure 1). Records were correlated by superposing Doodson-filtered signals of mean surface water levels (17). The magnitude of wind-induced (5-10 kt maxima) fluctuations in amplitude and "mean" sea level in this type of estuary is evident in Figure 4. Wind forcing can readily dominate tidal motion. As shown in Figure 5, CAFE produced reasonably good results. It can be seen however that relatively long-term records are needed to establish that $a_0 = b_0$ in eq. 5 and 6.

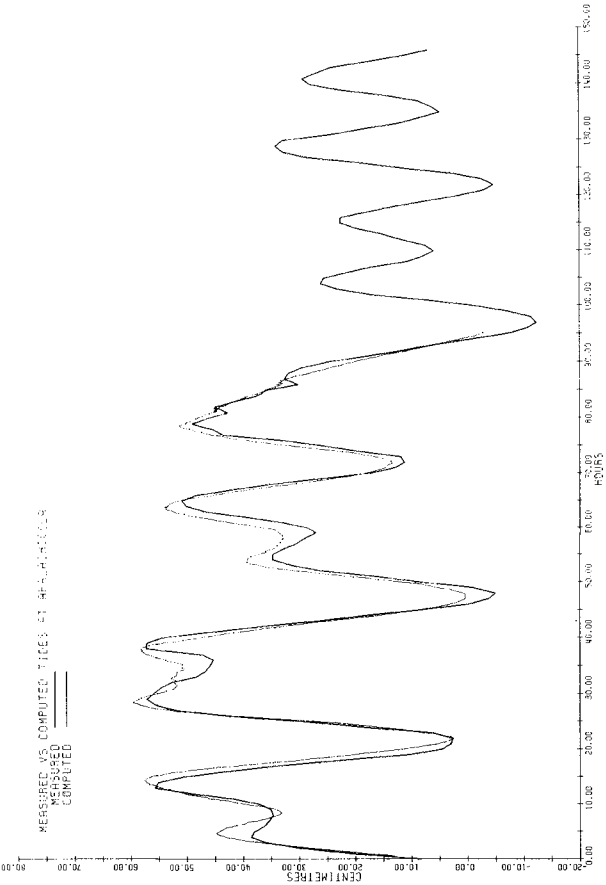

Figure 5

MEASURED VS. COMPUTED TIDES AT APALACHICOLA

5. Selected Terminos Results

Because Laguna de Terminos is morphologically and dynamically similar to Apalachicola, we were asked to apply the CAFE model to it in support of a UNAM - LSU biological assessment. No data were available to us except those in standard tide tables. A crude bathymetry of Terminos was provided by LSU. Terminos lies in Trade Wind zone so that it enjoys a constant breeze from the NE of about 2-5 mps for much of the year. This is surmised to cause the net westward flow , as discussed by Mancilla and Vargas (23), and evidenced by the prominent flood-tidal delta at Puerto Real inlet.

The cases simulated for Terminos are listed below

	Amplitude			Lag			Wind	
	E	m	W	E	s	W	Speed mps	Direction from
1	.24		.24	0		0	0	-
2	.24		.30	+120		0	0	-
3	.24		.24	0		0	5	NE
4	.24		.24	0		0	10	NW

where E - Puerto Real inlet, W - Carmen inlet. The LSU field biologist said he suspected there was no difference in tidal properties between the two inlets. The differences in Case 2 were the greatest that could be expected by interpolation and extrapolation from the few stations in Tide Tables. The results showing net velocities are depicted in Figure 6. The large eddy for Case 4 also appears in winter satellite images.(19)

Subsequent work by M. C. Julio Candela P. (24) and Crivel et al. (25) appears (to the extent the author understands the Spanish) to yield the following information on the tidal properties. According to Candela the dominant tides at Carmen are O_1(amp = 11.23 cm, period = 25.82h, phase = 317.25°), K_1 (amp. = 11.04 cm, period = 23.93 h, phase = 321.32°), and M_2 (amp = 7.51 cm, period = 12.42 h., phase = 88.58°). This results in a mixed tide with Band 1 dominant. Taking mean values of $O_1 + K_1$ of amp = 22 cm, phase = 319.3° for Carmen, the comparable values for Isla Aguda in Puerto Real are, for Band 1, amp. = 22 x 0.92 = 20.2 cm and phase = 319.3° + 6.7° = 326°. Crivel et al. (25) find the same phase difference, i.e. 6.7° or 27 minutes, to exist.

In summary the Band 1 amplitude difference is 1.8 cm and the phase difference is 27 minutes with Carmen leading. These are of the same order as those used by Craham in Case 2, but not close. An analysis using van de Kreeke and Dean's (4) eq. 7 for $a_o = b_o$ (25) with the values: T = 25h = 90000s, h = 3.5 m (24), L = 38.5 km between the inlets (24), C_o = 5.9 mps, λ = CT = 527 km, a1 = 20.2 cm, b1 = 22 cm, δ = 6.7°, sinδ = .117, F = F_2 = .0022, then

$$q_* = 1.5\,[P(13.7,\ 4.1)(.0036)(.117) + Q(13.7,\ 4.1)(-.00062)] \quad 15.$$

$$P \doteq 0.6,\ Q \doteq 1.8 \text{ from (4)} \quad 16.$$

so $q_* = 1.5\ (.00025 - .00112)$

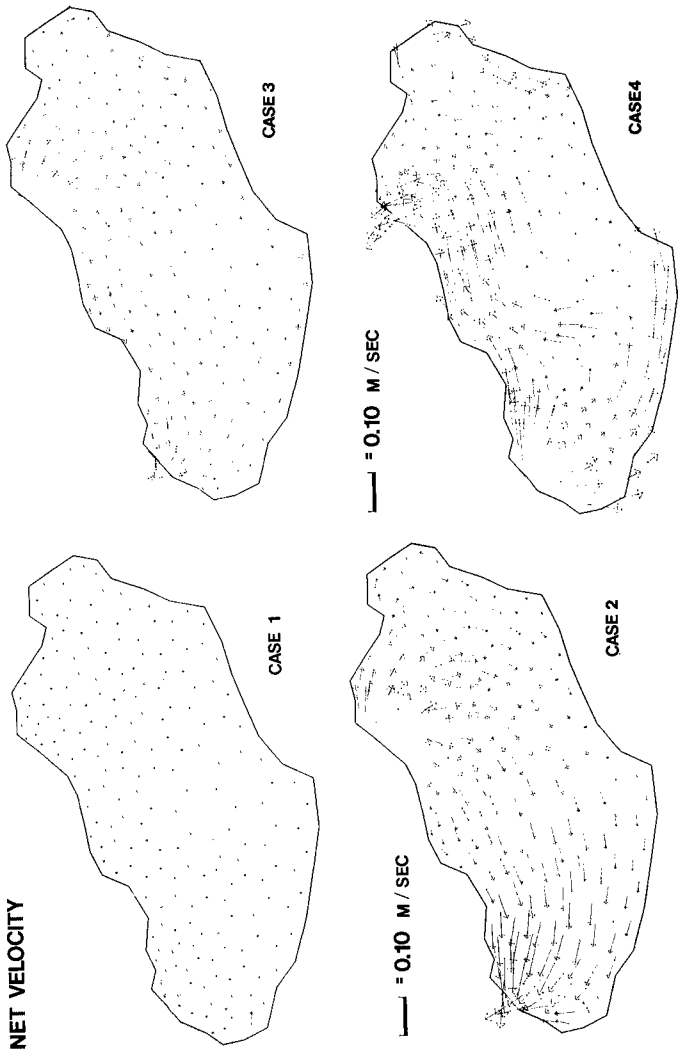

Figure 6 Net Residual Terminos Velocities

$$q_* = -.00082 \qquad 17.$$

$$\text{so} \quad V_* = q_* \, h = -.003 \text{ m/s} = -.30 \text{ cm/s} \qquad 18.$$

eastward. This does not correspond to the computed results of Figure 6 because the phase is lagged in the opposite direction. It also suffers the same caviats as mentioned earlier for Apalachicola. It may be concluded that the net westward drift in Terminos likely occurs because of the steady trade winds and in spite of the nonlinear tidal wave flux. Modification or filling of Puerto Real inlet could severely alter the flushing rate of the Laguna. Conversely, oil spills near Carmen might enter Terminos under windless conditions. It is hoped further cooperative work on Terminos can be done.

6. Summary

The flushing and water quality of shallow multi-inlet estuaries in the Gulf of Mexico appears to be dominated by nonlinear wave flux advection and wind forcing, rather than advection from river inflow and tidally enhanced dispersion. Understanding and managing these systems requires detailed knowledge of their tidal characteristics and response to wind shear. Coastal engineering works could significantly alter the properties of the circulation of these estuaries.

7. Acknowledgements

John Daniels performed much of the CAFE modeling and his assistance is gratefully acknowledged. Jack Hill supplied satellite images. Julio Candela P. furnished information on Terminos and interesting discussions. The Apalachicola work was sponsored by NOAA, Office of Sea Grant (Florida) under Grant No. 04-158-44046, and by the Engineering and Industrial Experiment Station of the University of Florida. Assistance was provided by the Departments of Environmental, Civil and Industrial Systems Engineering of UF. The Terminos work was funded through the Center for Wetland Resources, LSU by International Sea Grant, and by UNAM. The Estacion de Investigacion Oceanographica and CICESE at Ensenada provided some assistance and gracious hospitality. The University of Toronto has provided clerical support.

AUGMENTATION OF URBAN WATER BY ANTARCTIC ICEBERGS

by J.D. Lawson, M.ASCE.[1] and D.S. Russell-Head [2]

ABSTRACT

The indigenous water resources of the south west of Australia are under increasing stress. One solution to this problem may be water importation in the form of Antarctic icebergs. This possibility is discussed in this paper. To be cost effective, an iceberg water scheme needs to provide water at less than A$ 0.14 kl^{-1} from the reservoir, and at yearly volumes of the order of 10^8 m^3. A number of analyses of the selection and towing of icebergs have been given in the past but the offshore processing of icebergs has been somewhat neglected. A conceptual solution to the processing problem is given in this paper and cost estimates for the acquisition and processing of icebergs are given. Our analysis indicates that iceberg water may be a feasible and economical urban water augmentation system for yearly volumes greater than 2 x 10^8 m^3. Further work on iceberg water augmentation is warranted.

1 INTRODUCTION

The water resources, especially for urban use, in the south western region of the Australian continent are under increasing stress and augmentation alternatives and demand management strategies have been examined closely during the last decade. Serious interest in the use of icebergs for water has been shown since 1973. This paper examines the process of water supply augmentation by icebergs and focuses on the largely undiscussed problem of iceberg processing. A conceptual solution to the problem of processing icebergs in the coastal zone is offered and, as the cost of water is the most important basis of comparing various methods of augmentation, indicative iceberg water costs are given.

2 URBAN WATER COSTS

A water resources study for Metropolitan Adelaide in 1978 (Engineering and Water Supply Department, 1978) included indicative costs of water supply augmentation. Table 1 has been adapted from the report of the study.

1. Professor, Dept. of Civil Eng., University of Melbourne, Australia
2. Research Fellow, Faculty of Eng., University of Melbourne.

Method	Indicative cost cents per kilolitre
Present cost including treatment	29
Mount Lofty Ranges evaporation control	36
Adelaide groundwater basin/surface supply	37 - 42
River Murray/Mount Lofty Ranges storage	40
River Murray - direct pumping	42
Mount Lofty Ranges - new storage	51
Iceberg (cost excludes harvesting uncertainties)	71
Desalination of seawater	78
Sewage effluent re-use	78
River Murray - flood cropping	93
Water tankering	101
Urban runoff	101
Rainwater tanks	144

Table 1. Cost of water supplied to Adelaide by various methods (June 1977 A$ cost levels)

The costs in Table 1 include treatment and reticulation costs.

Cost analyses have also been carried out for Perth where particular emphasis has been placed on the utilization of extensive groundwater resources present in that region of Western Australia (Metropolitan Water Supply, Sewerage and Drainage Board, 1981). For urban Perth, the ex-reservoir price of iceberg water needs to be about A$0.14 kl^{-1} for iceberg importation to be competitive with other augmentation methods.

An alternative (or complementary) strategy to water supply augmentation is to exercise demand management and improve the efficiency of water use. Demand management tends to gain recognition by water supply authorities only in times of severe drought.

Management options considered in the Adelaide study included

- Changing community attitudes to water use. (One major area of water wastage in Australia is the watering of urban gardens. Half the annual water use in some cities is for the maintenance of exotic gardens and lawns.)
- Alternative pricing. (Higher water prices could be charged during the hot dry summer.)
- Technical changes. (Toilets could be fitted with reduced discharge flushing devices.)

It is against this background of water augmentation and management alternatives that consideration should be given to Antarctic icebergs as a source of urban water.

Figure 1. Tabular Antarctic iceberg 1200 m by 400 m by 27 m freeboard. (R. Wills)

3 ICEBERG TECHNOLOGY BASICS

There are three distinct phases to the business of getting urban water from icebergs

- iceberg selection
- iceberg towing
- iceberg processing

In this paper, we shall refer to iceberg selection and towing as iceberg "acquisition".

3.1 Iceberg Acquisition

The papers which first discussed the use of Antarctic icebergs as a source of water (Weeks and Campbell, 1973 and Hult and Ostrander, 1973) were mostly concerned with iceberg acquisition. The proceedings of two subsequent international conferences on icebergs (Husseiny, 1977 and International Glaciological Society, 1980) contain further detail on the characteristics of icebergs and methods of propulsion and protection.

At present, the general consensus seems to be that an iceberg of suitable size (Fig. 1) can be transported to southern areas of continents in the Southern Hemisphere, but protection from melting and break-up will be necessary for transportation to the Northern Hemisphere. A review paper by Schwerdtfeger (1979) gives a good overview of the acquisition phase.

3.2 Iceberg Processing

After an iceberg has been delivered, it then remains to turn it into water for urban reticulation. This is not a trivial task. When delivered, an iceberg of an economic size is likely to be of the order of 100 m draft and will ground on the continental shelf several kilometers from shore. The iceberg will melt at its base and sides at a rate of between 1 and 3 m per day (Russell-Head, 1980). The energy required to process ice by various techniques has been discussed by Weeks and Mellor (1978). DeMarle's (1980) paper is another of the relatively few to deal in some detail with the processing phase. In it, he discusses an iceberg processing scheme for Saldanha Bay in South Africa and provides subjective target estimates for the costs of implementing the scheme.

Our approach was to devise a harvesting scheme based as much as possible on existing technology, and then to cost the processing component of iceberg water using the best estimates applicable to that known technology. The total augmentation cost of iceberg water is the sum of the acquisition and processing costs. We were particularly interested to find out the relationship between iceberg size and total augmentation cost.

3.2.1 Processing techniques

The main aim of the processing phase is to land a high proportion of the iceberg mass as fresh water. Unless the iceberg is totally enclosed with an impermeable wrapping, sea water will melt ice from the berg and mix with the melt water. An important function of the harvesting scheme then is to separate melting ice from sea water.

Some of the proposed (Husseiny, 1977) processing methods are

- Skirt collection
- Mechanical cutting
  - saws
  - high pressure jets
  - dredging
  - blasting
- Electrothermal cutting
  - heated cables
  - laser beam

and these will now be briefly discussed.

Skirt entrapment of fresh water does not seem feasible (Huppert and Turner, 1978) due to the substantial mixing of saline and melt water during the iceberg melting process.

Mechanical methods of harvesting are efficient from an energy expenditure viewpoint but all suffer from the problems of the transfer of mechanical power to the cutting face. It would be undesirable to instal large equipment on an iceberg to be processed and therefore dredging and high pressure jets are not favoured methods. Blasting is energetically efficient but control and secondary processing of the blasted ice would be difficult. Sawing appears to be the most attractive of the mechanical methods. A type of bladeless chain saw that cut over the entire width of the iceberg could probably be developed.

Electrothermal methods are not as energetically efficient as mechanical ones but they do possess the ability to easily transfer power to the cutting face. Laser methods offer the possibility of transferring energy without physical contact with the iceberg, however their overall thermal efficiency is only about 10%. Cutting with heated cables is probably the processing method easiest to implement and is the one we have adopted for costing purposes in this paper.

4 ICEBERG WATER COSTS

The cost of iceberg water is the sum of the acquisition and processing costs. We shall use the results of other studies for an estimation of acquisition costs. A processing method will be described and costed.

4.1 Acquisition Costs

Weeks and Campbell (1973) have provided costs of towed ice delivered to offshore processing sites. Table 2, applying to Western Australia, was derived from their analysis.

Initial volume 10^6 m^3	Delivered volume 10^6 m^3	1972 cost cents m^{-1}	1982 cost cents m^{-1}
1200	840	0.3	2.1
600	390	0.5	3.5
300	180	0.8	5.6
150	75	1.5	10.5

Table 2. Cost in A$ of delivering icebergs to Western Australia.

The 1972 costs have been increased by a factor of seven to update to 1982 A$. Allowances have been made for inflation, increases in oil prices and, on the other hand, improvements in towing technology.

4.2 Processing Costs

The processing system that is costed here contains six functional elements:

iceberg + MOOR + SLICE + TUG + LOCK + POND = POWER + water

The moored iceberg is cut by heated electrical cables into slices which are towed into a lock. The lock serves to separate the ice from sea water and to pass it into a freshwater cooling pond used by a power station. The lower condenser temperature provided by the ice melting in the pond increases the thermal efficiency of the power station and thus provides some offset to the other costs. Table 3 provides a breakdown of the indicative costs.

The unit costs of mooring, slicing and tugging are independent of iceberg volume as is the return from power generation. The largest costs are for the provision of a lock and pond. The unit cost of locking is proportional to the throughput of ice and so it could be reduced if more than one iceberg per year were processed. The unit cost of providing a pond to accommodate the processed ice reduces with increasing volume.

Further discussion on the details of the cutting process, block sizes, locking and ponding schemes, as well as a consideration of the environmental impact of the presence of a large low-temperature heat sink, is to be the subject of a further paper.

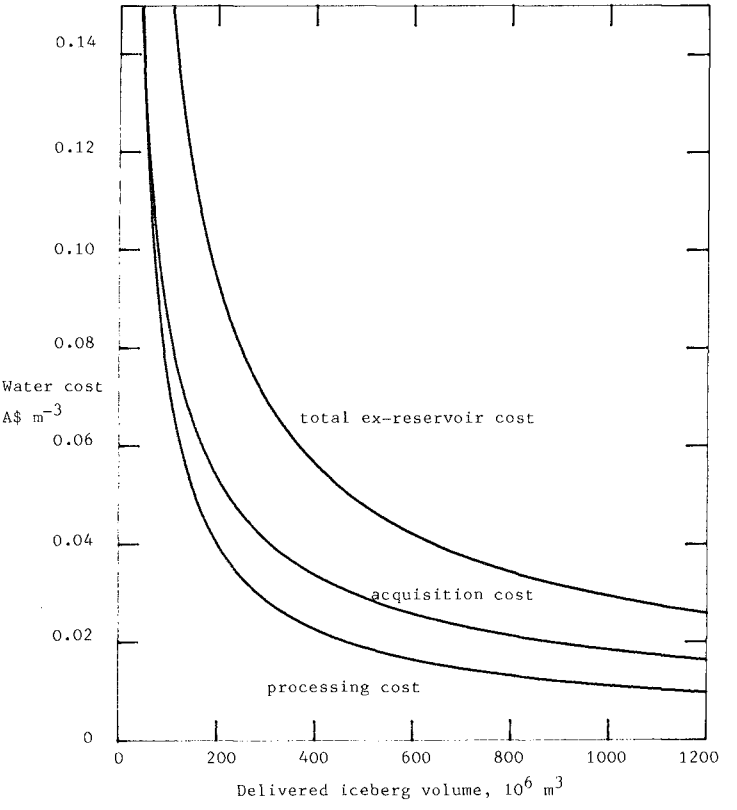

Figure 2. Ex-reservoir iceberg water costs for Western Australia.

Iceberg size 10^6 m^3	COSTS (cents kl^{-1}) Moor	Slice	Tug	Lock	Pond	Power	Water
1000	0.01	0.17	0.22	0.57	0.53	-0.45	1.0
500	0.01	0.17	0.22	1.13	0.76	-0.45	1.8
200	0.01	0.17	0.22	2.84	1.20	-0.45	4.0
100	0.01	0.17	0.22	5.67	1.69	-0.45	7.3

Table 3. Indicative costs of iceberg processing (1982 A$ prices).

4.3 Total Costs

The sum of the harvesting and processing costs are shown in Figure 2. For a yearly augmentation demand of 2 x 10^8 m^3 or more, the indicative ex-reservoir unit cost is less than 14 cents kl^{-1}.

5 CONCLUSIONS

A generalized estimate of an iceberg water augmentation scheme for the Perth region of Western Australia has been given in this paper. The costs of processing icebergs through the coastal zone appear to be about half the cost of bringing an iceberg to the offshore site. There are economies of scale applicable to both the acquisition and processing phases of iceberg water augmentation and it seems that the augmentation demand perceived by the water authorities in south western Australia may be economically fulfilled by iceberg water.

At this stage it seems that a system can be implemented using fairly conventional technology and that the cost may not be prohibitive. The use of icebergs as a supply of urban water is a concept that warrants further serious enquiry.

6 ACKNOWLEDGEMENTS

We thank the water supply authorities of both Perth and Adelaide for the availability of their reports. Professors Bill Budd and Peter Schwerdtfeger are also thanked for their discussions with us on this topic.

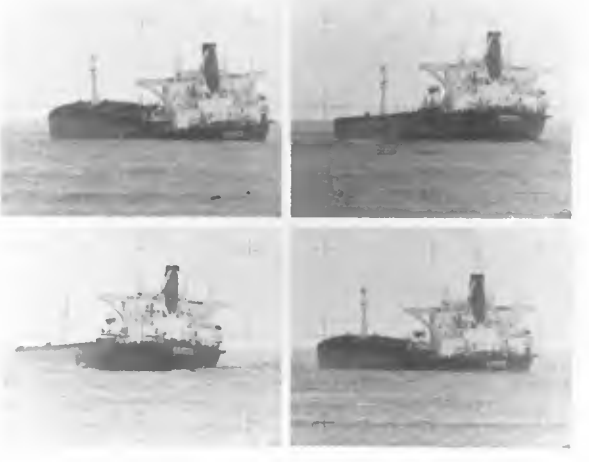
Ship Motions

Observed Ship Motions, Ship leaving Richards Bay Harbour



MOORED SHIP RESPONSE IN IRREGULAR WAVES

E.P.D. Mansard and B.D. Pratte

ABSTRACT

The traditional concept of representing a "random" sea state by just a variance spectral density has been found to be insufficient for modelling the slow drift oscillations of large moored ships. This paper illustrates, through experimental investigations, the importance of including wave grouping as an additional design parameter. A special technique called SIWEH, developed by the Hydraulics Laboratory of the National Research Council Canada, for the generation of realistic wave climates which include wave grouping, is presented. However, when generating the grouped sea state, one also has to properly create the group-bound long wave components. The effect of proper compensation for the spurious free wave components is illustrated by the test results on the moored vessel response.

1.0 INTRODUCTION

It has been observed, in physical model studies, that the response of moored vessels, in terms of motions and mooring loads, is far greater in irregular waves than in regular waves of equivalent wave height. This is due to the non-linearities found in irregular waves which give rise to slowly varying forces which over time are able to build up large oscillations of the vessel, leading to high mooring forces.

A vessel floating in regular waves experiences a steady force, while in the case of irregular waves, since the wave height is not constant, the force will vary with the wave envelope. This results in a slowly varying force on the vessel with a period equal to that of the wave groups.

The horizontal oscillations, such as surge, sway and yaw, for a large vessel have natural periods in the range of 20 seconds to a few minutes, far greater than the wind generated waves. The largest response of the vessel would be expected to occur when the period of the groups, which is often in the low frequency range, is equal to or lies in the vicinity of these natural periods. Although considerable research work has been carried out [Remery and Hermans (1972), Rye et al (1975), Van Oortmerssen (1976), Faltinsenen and Loken (1978), Pinkster (1979), Spangenberg (1980)], to investigate these slowly varying forces, there exists no suitable technique to simulate wave groups in terms of their periodicity and energy content. Recently the Hydraulics

National Research Council, Hydraulics Laboratory, Ottawa, Ontario K1A 0R6, Canada

Laboratory of the National Research Council Canada has developed a synthesis technique to generate realistic sea states which include wave grouping [Funke and Mansard (1980)]. This technique, which can generate varying amounts of grouping and group periods, was used in the present study in order to illustrate the importance of these slowly varying forces.

Longuet-Higgins and Stewart (1964), using the concept of radiation stress, have shown that in irregular waves, a set-down of mean water level (MWL) occurs under wave groups with a corresponding set-up between the groups. This results in a long wave variation of mean water level, with a period equal to that of the wave group in question, interacting with the vessel.

This variation of MWL, known as group-bound long wave or Bounded Long Wave, is of second order and therefore cannot be reproduced correctly with classical first order wave generation. Currently, many investigations are being carried out to establish the importance of these second order wave components in the assessment of the dynamics of structures (fixed or floating).

This paper will also illustrate, through experimental investigations, the importance of reproducing this MWL variation in order to have a realistic response of the vessel.

2.0 LOW FREQUENCY COMPONENTS IN IRREGULAR WAVES

Figure 1 presents a definition sketch of the frequency components present in irregular waves, which result in slow drift oscillations of the vessel. The Smoothed Instantaneous Wave Energy History (SIWEH) shown in this figure, serves as a useful tool to define the wave group characteristics present in a sea state. This function, developed at the National Research Council Canada [Funke and Mansard (1980)], can be computed from the water surface elevations by using the following equation:

$$E(t) = \frac{1}{T_p} \int_{\tau=-\infty}^{\infty} \eta^2(t+\tau) \cdot \phi_K(\tau) d\tau$$

where $E(t)$ = SIWEH function
$\eta(t)$ = water surface elevation
ϕ_k = smoothing window function
T_p = peak period of the spectrum

A measure of the wave group activity, known as the Groupiness Factor GF can be computed using the following expression:

$$GF = \sqrt{\frac{1}{T_n} \int_0^{T_n} (E(t)-\bar{E})^2 dt} \Big/ \bar{E} = \frac{\sqrt{m_{\epsilon_0}}}{m_0}$$

where T_n = length of wave record
$\bar{E}$ = mean value of E(t)
m_{ε_0} and m_0 = zeroth moments of the SIWEH and the variance spectral densities

The SIWEH describes the distribution of wave energy in the time axis while the GF represents the standard deviation of the SIWEH about its mean and normalized with respect to its mean.

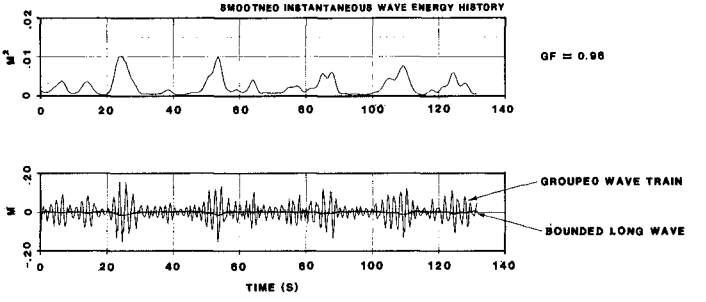


FIG.1 GROUPED WAVE TRAIN AND ITS LOW FREQUENCY COMPONENTS

Figure 1 also illustrates the long period oscillation of the MWL generated by the wave groups. This oscillation, known as Bounded Long Wave (BLW) is 180° out of phase to the SIWEH function. It can be shown that the amplitude of this oscillation is directly related to the Groupiness Factor GF.

As discussed above, the Bounded Long Wave cannot be correctly reproduced in the model by first order wave generation since the boundary condition required at the paddle to generate it cannot be satisfied directly (Ottensen-Hansen et al 1980, Bowers 1980). This results in the generation of certain spurious long wave components (shown in Figure 2), which in turn lead to a vessel response which is not realistic. The two main sources which contribute to these spurious long waves are:

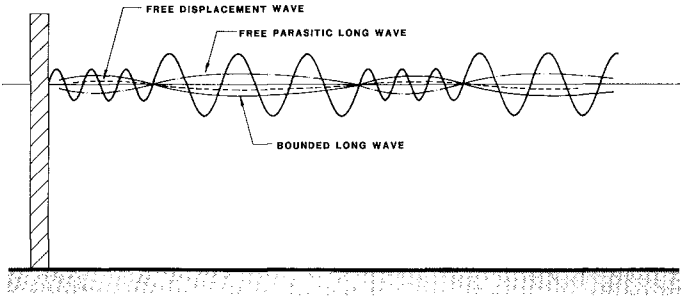

FIG.2 DEFINITION SKETCH OF LONG WAVE COMPONENTS IN A GROUPED WAVE TRAIN

1. free parasitic long wave, which is opposite in phase to the BLW, generated at the paddle since the particle motions from the group induced long waves cannot pass through the solid paddle;

2. free displacement waves generated due to the moving boundary of the paddle.

These spurious long waves are called free waves since they travel with their own celerity, while the Bounded Long Wave travels with the group velocity since it is bound to the wave groups. The free long waves can travel back and forth along the flume corrupting the incident wave system, since the reflection coefficient of these long waves is often very high (50 to 60%) even from beaches with mild slopes. However, the free long waves can be eliminated by including proper suppression terms in the wave generation. Under a cooperative program between the Danish Hydraulic Institute, the Delft Hydraulics Laboratory and the National Research Council Canada, techniques for the correct reproduction of the Bounded Long Wave were developed by verifying the various long wave terms and the effectiveness of the suppression. A joint publication by the three laboratories (Barthel et al 1983), describing the various techniques involved, is being submitted to Ocean Engineering. The present paper, therefore, only deals with the application of this technique in the assessment of the vessel response.

3.0 WAVE GENERATION TECHNIQUES

The effect of wave grouping on the dynamics of floating or fixed structures can be investigated in laboratory models by the wave synthesis technique illustrated in Figure 3. This technique, developed at the National Research Council Canada, can be used to synthesize time series with different wave grouping characteristics, keeping however the variance spectral density of the sea state constant. Because of

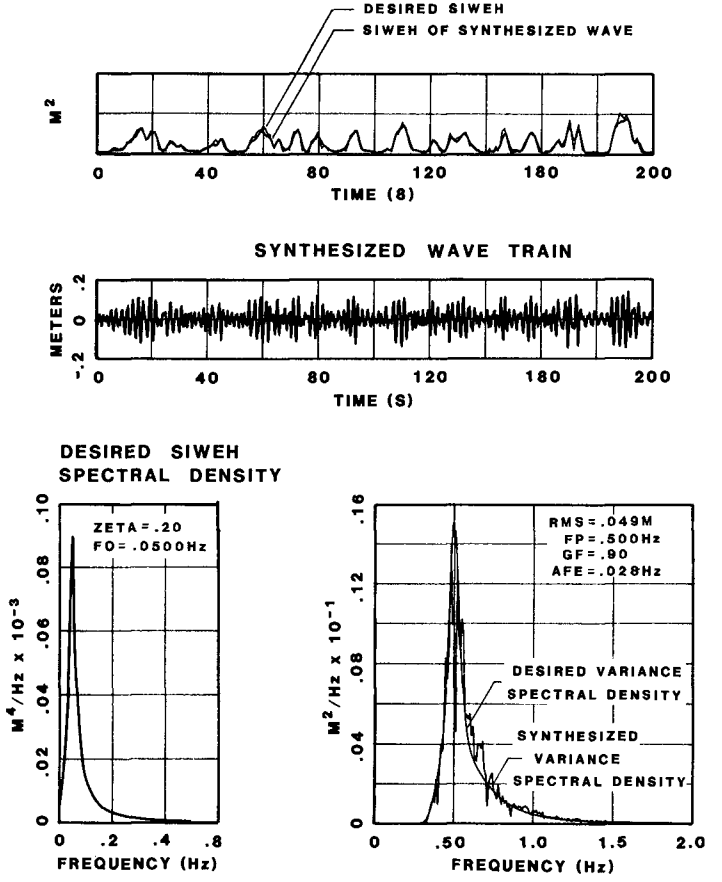

FIG.3 SYNTHESIS OF A GROUPED WAVE TRAIN

the high correlation which exists between the wave groups and the slow drift oscillations, this technique is particularly useful to evaluate their relationships in a given sea state.

In the absence of sufficient analysed prototype records of wave groups, a theoretical model of the SIWEH spectral density is used in this synthesis. The parameters of this model can effectively be varied to generate SIWEH functions having different characteristics. Since, $GF = \sqrt{m_{\varepsilon_0}}/m_0$, the area under the SIWEH spectrum, shown in Figure 3, can be varied to achieve different Groupiness Factors with the same variance spectral density. On the other hand, different period and distribution of the groups can be obtained by varying the peak frequency and the width of the spectrum.

As shown in Figure 3, the synthesized wave train satisfies the frequency domain characteristics of the desired variance spectral density as well as the time domain characteristics defined by the SIWEH function. Details of the various steps involved in this synthesis technique are well documented in Funke and Mansard (1980).

4.0 EXPERIMENTAL SET-UP

The investigations in the physical model were carried out to a scale of 1:100 using a model of a 227000 DWT tanker in a wave basin approximately 67 m long and 7.7 m wide. The flume, Figure 4, was equipped with a hydraulically-driven wave generator controlled by an on-line computer. The model tanker, located midway between the wave paddle and the beach, was moored at about a 30° angle between the bow and the incident wave direction. Greater angles could not be tested due to the relative narrowness of the flume. A mild sloped stone beach (1:25) ensured good dissipation of the incident energy.

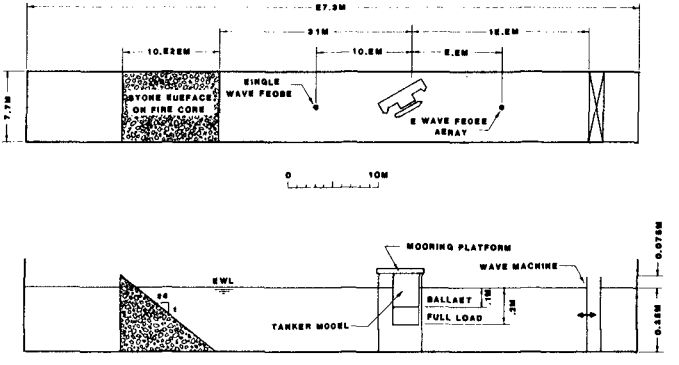

FIG.4 SHIP MOORING BASIN LAYOUT

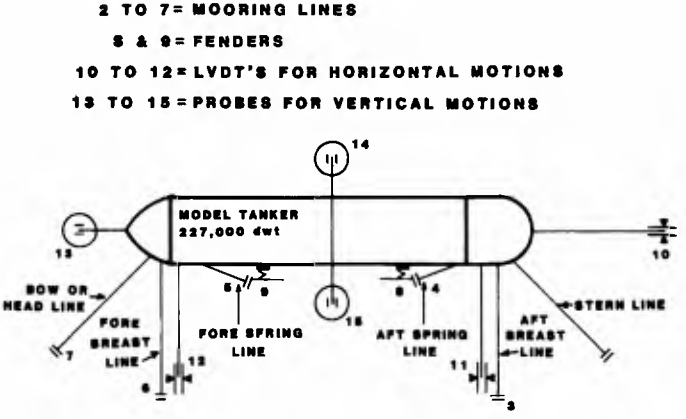

FIG.5 GENERAL LAYOUT OF MOORING CONFIGURATION

FIG.6 PHOTOGRAPH SHOWING A GENERAL VIEW OF THE PHYSICAL MODEL

The water surface elevations were monitored using twin wire capacitance probes located midway between the vessel and the wave paddle. An array of five probes was used to establish the reflection characteristics of the vessel and of the beach.

The model tanker was moored, as shown in Figures 5 and 6, by six mooring lines (representing four prototype nylon lines each with a pretension of 30 t and two steel spring lines with nylon tails with 10 t pretension). Two fenders, placed symmetrically, absorbed the impacts of the vessel on the mooring jetty. The jetty was supported on thin piles, and presented no obstruction to the waves. Since a direct measurement of the six degrees of freedom of the vessel motions (surge, sway, heave, roll, pitch and yaw) was not feasible, the approach used was to monitor the motions at the six locations (10 to 15) shown in Figure 5 and then to relate them to the six degrees of freedom. Accordingly, the vertical motions were measured by capacitance type probes while the horizontal movements were monitored by using Linear Variable Displacement Transducers (LVDT).

In model studies it is not easy to simulate the non-linear load elongation characteristics of the mooring lines by just varying their elasticity. Therefore, non-stretching mooring lines were used and the elasticity of the prototype mooring lines were simulated by the device shown in Figure 7. This simulator, developed at the Hydraulics Laboratory of the National Research Council Canada, consists of a cantilevered blade spring of rectangular cross-section mounted on a plate. The desired non-linear load-elongation characteristics of the mooring line can be achieved by varying the positions of the spring contact points so that as the spring is pulled down onto them an effective shortening of the length of the spring and consequently a stiffening effect results. Mailhot et al (1982) have recently developed a computer method for determining these contact positions.

Stainless steel is a spring material well suited for this device since it combines very low permanent deformation with high elasticity. The choice of the width and thickness of the spring can be used to vary the stiffness to a certain extent. The frequency response of this simulation was found to be high, on the order of 5 to 10 Hz.

While the elasticity of the prototype mooring line is simulated by the above device, the loads on the different lines are monitored by using Direct Current Displacement Transformers (DCDT) in a force transducer. The DCDT has a moving core, suspended from a pair of spring blades, and connected to the mooring line. As the core moves through the electromagnetic field within the DCDT windings, a voltage output is produced which is calibrated to the displacement of the core and thus to the force required to achieve that displacement.

FIG.8 PHOTOGRAPH SHOWING THE CANTILEVER SPRING, FENDER, AND MOORING FORCE TRANSDUCER

5.0 EFFECT OF LONG WAVE COMPENSATION ON VESSEL RESPONSE

In order to establish the effect of the correct reproduction of the Bounded Long Wave (BLW) on vessel response, tests were carried out using two different cases of wave generation: with and without compensation for spurious long waves. The BLW components measured in these two cases are presented in Figure 9 along with the grouped wave trains. In the same figure, a comparison between the expected (theoretical) and the measured BLW is also shown (to a larger scale) for these two cases.

The measured BLW was extracted from the total grouped wave train by applying a low pass filter whereas the expected BLW was computed by theoretical relationships, from the measured wave train using a cut-off frequency which excludes the measured long wave.

In the first case, where proper compensation accounted for the spurious long waves, the agreement between the measured and expected values of BLW is satisfactory: the set-down under each group is well reproduced and the small discrepancies found in amplitude are only in the order of millimetres in the model. On the other hand, where no compensation is done, the amplitudes and especially phases of the BLW are different from the theoretical predictions. The change in phases results in an improper set-down (or cross-over from a set-up to a set-down) under the wave groups. This is mainly due to the standing wave pattern caused by the free long waves.

The correct reproduction of the BLW can also be checked by its propagation characteristics. Figure 10 shows an example of the propagation of the Bounded Long Wave in a flume, for three distances from the waveboard. With compensation, the set-down under the groups is well maintained during propagation, while with no compensation important amplitude and phase changes can be detected. This means that, in tests where no suppression of the spurious components is made, the response of the vessel could be quite different (high or low) depending upon the position of the test structure in the flume.

The vessel response, in terms of mooring line forces and vessel movements, for the two wave trains presented in Figure 9, is summarized in Table 1.

The two wave train records had similar time and frequency domain characteristics. The peak frequency of the SIWEH spectrum and the groupiness factor were the same as well as the peak period and the characteristic wave height. The results show, that both the RMS and maximum values of the mooring line forces (in tonnes) and vessel motions (meters, radians) were generally higher when the spurious long waves were properly suppressed (WC). This is possibly due to the proper timing of the set-down, causing an increase in velocity due to the slightly shallower water conditions, resulting in a larger response of the vessel with the higher waves of the groups. With no compensation (NC) for spurious long waves, the set-down is less, resulting in less vessel response. Table 1 for motions shows that with compensation the main component excited is sway for this particular wave input and incidence angle.

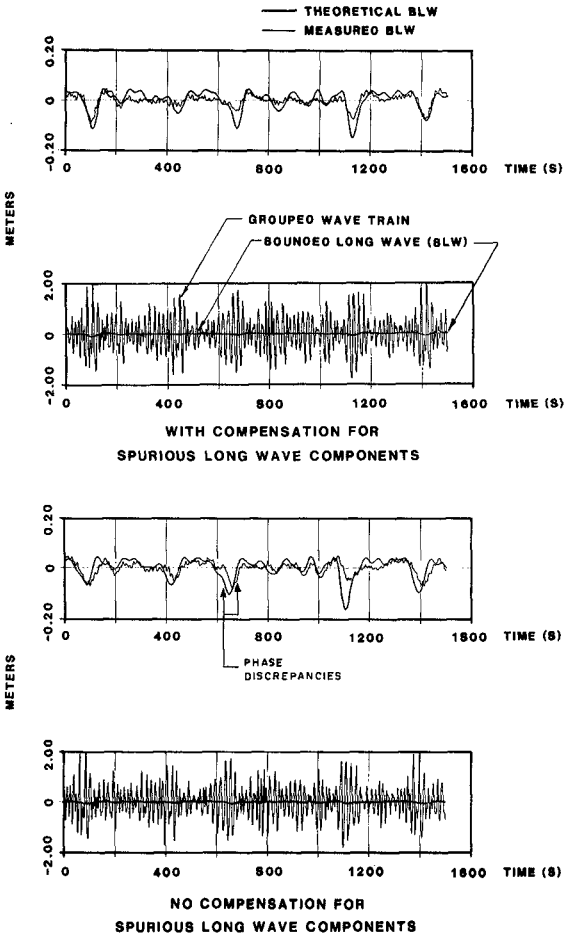

FIG.9 BOUNDED LONG WAVE COMPONENTS IN THE FLUME (WITH SHIP)

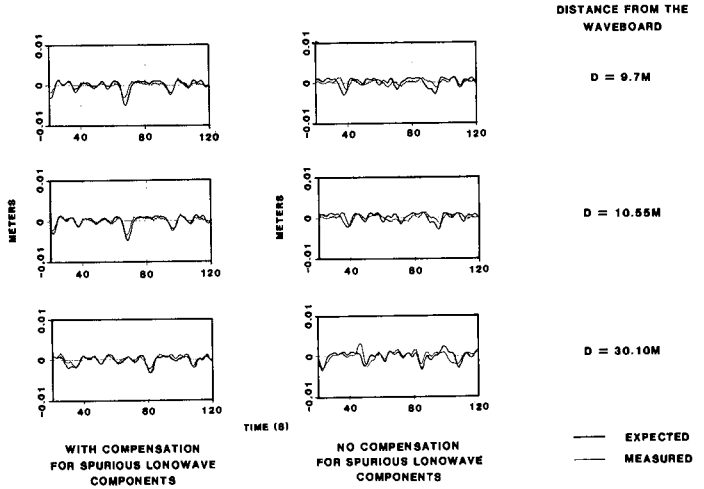

FIG.10 BOUNDED LONGWAVE COMPONENTS ALONG THE FLUME

(NO SHIP)

(MODEL UNITS)

When considering the response of a moored structure, the heave exciting force may be assumed to be:

$$F_e = \beta_1 \eta(t) + \beta_2 \eta^2(t)$$

where β_1 and β_2 are coefficients and η is the water surface elevation [NAESS (1978)]. This means that the heave motion of the vessel is related to the square of the water surface elevation $\eta^2(t)$, or in this case to the SIWEH function. This relationship is well illustrated in Figure 11 where the second order heave motion was extracted from the measured response by low pass filtering. Figure 11 also presents a comparison of the heave response between the two cases of wave generation discussed. In the first case, the long wave component of the heave response is well correlated to the SIWEH (i.e. amplification under the groups, whereas a cross-over phase shift occurs for the non-compensated free long waves. The RMS heave motions are much the same in either case.

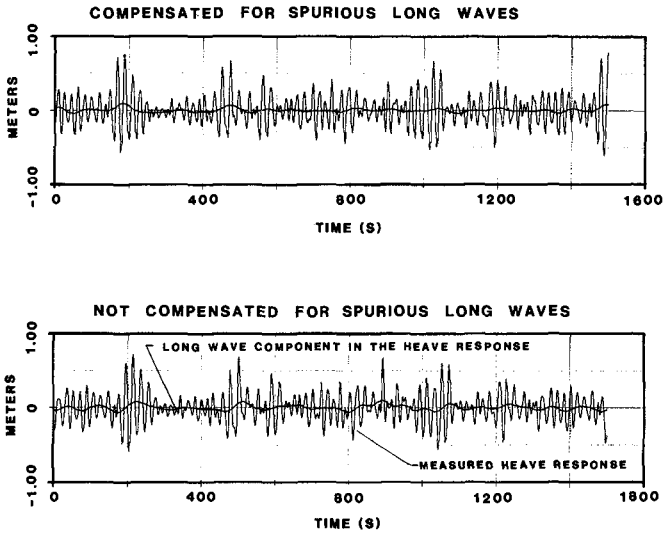

FIG.11 MEASURED HEAVE MOTION

Since the above results indicate that the response of the vessel is a function of the long wave components, it appears that proper compensation for spurious long wave components is required, in model studies, in order to determine realistic mooring line forces and vessel movements.

The results presented in the next section, on the relationship of the SIWEH to the slow drift oscillations of the vessel, were therefore investigated using proper suppression for the free long waves.

6.0 EFFECT OF WAVE GROUPING ON SLOW DRIFT OSCILLATIONS OF THE VESSEL

In order to investigate the relationship between the wave grouping present in a time series and the resulting slow drift oscillations of the vessel, three sets of wave conditions were generated in the flume using the technique previously described. These wave trains, measured in the flume, had identical variance spectral densities but different SIWEH spectra. Since the Groupiness Factor GF is directly related to the SIWEH spectrum GF = $\sqrt{m_{\epsilon_0}}/m_0$, these three wave records, shown in Figure 12, had different groupiness factors ranging from 0.46 to 1.03.

The maximum and the RMS values of the vessel movements and the resulting mooring loads, measured under the three wave conditions, are summarized in Table 2. These results indicate that the response of the vessel increases with increasing groupiness factor in spite of the fact that the characteristic wave height and the peak period of the sea state were similar. The horizontal oscillations, surge, sway and yaw, which are sensitive to excitation by long wave components, increase when the amplitude of the long waves generated by the groups increases, resulting in increased mooring line forces.

The results of these investigations are illustrated in Figures 13 and 14 in the form of spectral plots. Figure 13 presents the spectra of mooring line forces for three typical mooring lines while the spectra of horizontal motions are shown in Figure 14.

The results indicate that a distinct correlation exists between the wave grouping and the vessel response. Therefore, in model studies, a sea state cannot be represented solely by its variance spectral density, peak period and significant wave height without considering its time domain characteristics. In other words, the wave grouping is an important parameter to be taken into account in the assessment of vessel response.

It should be mentioned that the experimental results were somewhat limited due to the narrowness of the flume to small angles of heading (30°) of the vessel relative to the waves. Further work in a wider basin may well yield more dramatic response comparisons for other heading angles, under-keel clearances, and vessel loading conditions.

In a recent study, Spangenberg (1980), was able to show a similar correlation between the wave grouping and the slow drift oscillation of a semi-submersible. The synthesis technique used in that work does not, however, allow an easy control of wave grouping characteristics (well defined periods and groupiness factors). Furthermore, no compensation was done for the spurious long wave components.

The concept of SIWEH can also be used in numerical models as input excitation functions for the slow drift oscillations.

7.0 CONCLUSIONS

Representing a sea state solely by its variance spectral density has been found to be insufficient for modelling the slow drift oscillations of the vessel.

The synthesis technique, used to generate realistic sea states in the model, has successfully illustrated the correlation between the slow drift oscillations and the wave grouping.

The results show that the wave grouping, present in irregular waves, is an important parameter to be taken into account in the assessment of vessel response.

It has been shown that a correct reproduction of Bounded Long Wave Components is required, in model studies, in order to have a realistic response of the vessel.

8.0 ACKNOWLEDGEMENTS

The authors wish to thank Mr. E.R. Funke, who developed the cantilevered mooring line simulator, for his invaluable suggestions during this study. Thanks are also due to Mr. J.R. Clarke for his technical assistance.

MEASUREMENT TECHNIQUES FOR MOORED SHIP DYNAMICS

by

J Moes and S G Holroyd*

ABSTRACT

Problems arise during adverse sea conditions with ships moored to the ore loading jetty at Saldanha Bay. Under certain wave conditions moored ships undergo large motions which cause breakage of mooring lines. In order to obtain a quantitative insight into the problem an extensive measurement system was installed at Saldanha Bay. This system comprises instrumentation for the measurement of short and long waves, currents and wind, mooring line and fender forces and the motions of the moored ships. Preliminary results show that during storm conditions long waves with periods between 50 and 150 s occur at the jetty. These periods fall within the same range as the observed natural periods of horizontal oscillation of the moored ships.

1. INTRODUCTION

The increase in the size of tankers and bulk carriers during the last decades has led to a tendency to build cargo-handling jetties for these ships close to deep water in order to reduce the costs of dredging navigation channels. As a result of this development, the mooring locations are, in general, more exposed to wave action. This requires careful design and operation of the mooring equipment to assure the safety of ships and jetty structures and to reduce downtime in loading or unloading of the ships.

A loading jetty has been built in Saldanha Bay, a natural bay on South Africa's west coast, about 150 km north of Cape Town, for the export of iron ore (see Figure 1 and Photograph 1). The main harbour construction, which was completed during 1976, consists of a sand breakwater between Hoedjies Point and Marcus Island, an ore handling plant, a causeway, a jetty and a navigation channel, dredged to a depth of between -23,0 and -23,7 m CD (Chart Datum) in order to allow ships of up to 250 000 dwt to be

loaded at the jetty (see Figure 2). Since 1977 up to 18 million tons of iron ore have been exported annually.

2. MOORING PROBLEMS

At Saldanha Bay problems have arisen with moored iron ore carriers. Under certain wave conditions, the moored ships undergo large horizontal motions which have, on occasions resulted in the breaking of mooring lines. This in turn has led to interruptions of the loading of iron ore and even necessitated in some isolated instances the removal of ships from the jetty.

The South African Transport Services requested CSIR to assist in investigating these problems and to advise on possible steps to minimize or eliminate their occurrence.

3. STUDY APPROACH

In order to investigate the nature of the problems NRIO initially carried out a feasibility study. This study comprised a literature survey on possible similar problems experienced elsewhere, long-wave measurements at the jetty and discussions with the operational staff at Saldanha Bay on the characteristics of the mooring system, the behaviour of the moored ships and the environmental conditions during the occurrence of problems.

From the literature it was found that similar problems were encountered elsewhere, as reported by Wilson (1954), Keith and Murphy (1970), Bowers (1975) and Nagai *et al.* (1977). Most problems were caused by the occurrence of relatively long waves with periods between 50 and 150 s, which is in the same range as the natural periods of horizontal oscillation of the moored ships. These long waves may be penetrating into the harbour from the ocean or may be caused by harbour resonance.

During the design of the harbour Wilson was asked to investigate the occurrence of harbour resonance at Saldanha Bay. He concluded (Wilson, 1972) that the natural periods of wave oscillation in the bay would be much larger than the resonance period of the moored ships.

From discussions with the operational staff at Saldanha Bay it appeared that the mooring pattern of the ship is always rather similar, using an average of about 16 mooring lines of various materials and thicknesses (see Figure 3). The jetty consists of a concrete deck supported by caissons and is about 60 per cent open. The jetty is equipped with Yokohama pneumatic fenders with a diameter of 3,3 m and a length of 6,5 or 10,6 m. In almost all cases when problems with moored ships occurred heavy swell was reported. This

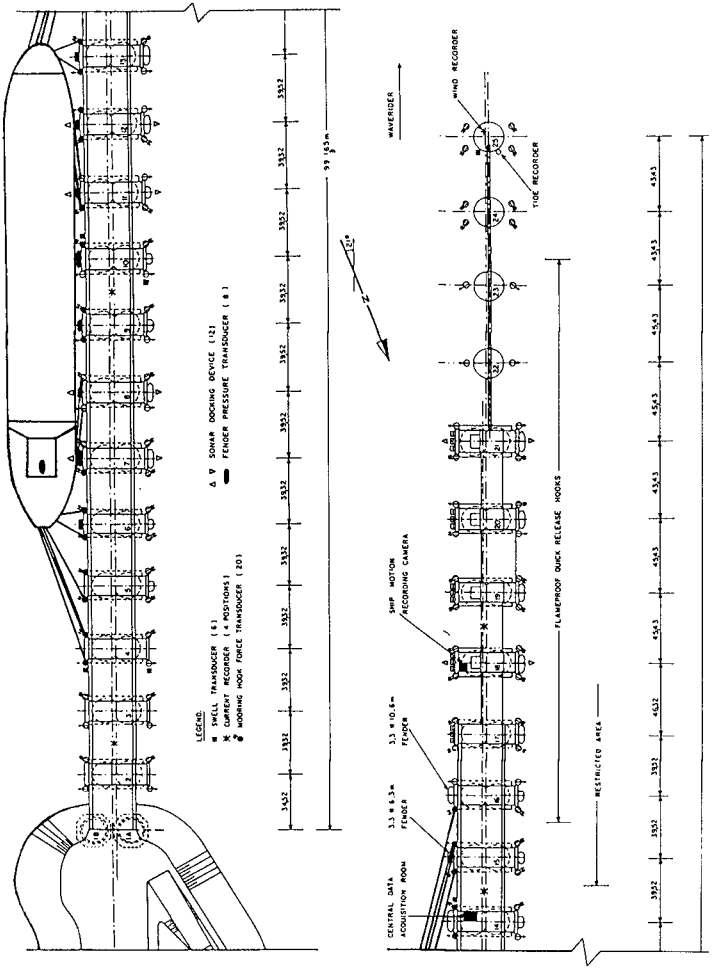

FIGURE 3: Ore jetty, position of instrumentation and typical mooring layout

was determined using a Datawell Waverider, positioned at the entrance of the navigation channel (see Figure 2).

On the basis of this information the first aim of the study was therefore to determine quantitatively the relationship between any low-frequency wave energy and the resulting ship motions and mooring forces. For this purpose an extensive measurement program was undertaken, involving a wide variety of instruments. On the basis of the results of the field measurements preliminary recommendations will be made in order to alleviate the problems. However, physical and mathematical model studies may be necessary to determine the effect of various alternative mooring conditions. These models may be calibrated with prototype data obtained from the field measurements.

4. MEASUREMENT SYSTEM

In order to collect the data required for the investigation, a data-logging system was designed to monitor and record the environmental conditions as well as the motions of the moored ship and of the forces involved. The following were therefore measured:

(a) Long swell at six points along the jetty.

(b) Two components of current from at least one point along the jetty.

(c) Forces in up to 20 mooring lines.

(d) Pressures in eight fenders. The pressure data could be processed to determine forces.

(e) Ship motions.

The above measurements are made only during the presence of a ship in adverse conditions. To obtain general historic data, the following environmental observations are made continuously:

(f) Wind speed.

(g) Wind gust speed.

(h) Wind direction.

(i) Long swell at one point along the jetty.

(j) Waves.

(k) Tides.

For the measurement of the ship motions and of the forces involved it was decided that monitoring the conditions at one of the ore berths would yield sufficient data for the study. The eastern side of the jetty was chosen (see Figure 3), since the largest ships are usually moored at this berth.

5. WAVE MEASUREMENTS

5.1 General

A waverider buoy is anchored at the entrance of the navigation channel (see Figure 2). This buoy can record waves with periods of only between about 1 and 25 s. This is below the range of wave periods expected to be critical for the moored ships, namely, 50 to 150 s. Therefore, long-wave recorders had to be installed to record the waves with periods of between 25 and 150 s.

5.2 Short Waves

To establish a possible relationship between the energies of long and short waves it was decided to use also the waverider data. To facilitate spectral analysis of the data a data logger was installed which sampled the wave-rider signal at 0,5 s intervals during a period of about 20 min., four times a day. Provision was also made to allow continuous recording during severe ship motions.

5.3 Long Waves

During the feasibility study a pressure recorder was in operation at caisson No 14, east side (see Figure 3) from August 1979 to January 1981, except during the winter months of 1980 when the transducer failed. In order to determine the variation of long-wave energy along and across the jetty it was later decided to deploy six pressure recorders, distributed along the jetty (see Figure 3). To be able to obtain a wave period resolution of between 5 and 500 s the sampling rate of the pressure recorders was set at 2 s while the recording period was about 120 min. The transducers measured the instantaneous water pressures two to five metres below the water surface, where they were fixed onto the caissons by means of stain-less steel brackets. One swell recorder (at caisson No 14) was set to record automatically twice a day, while the others could be switched on as required.

5.4 Tides and Very Long Waves

Very long waves with periods of at least 300 s could be determined from the tide recorder installed at caisson No 25 (see Figure 3).

5.5 Wave Correlations

The pressure transducer data were spectrally analysed, and a typical storm sequence is shown in Figures 4a to d.

The spectral analysis is performed for four period ranges, namely, for the wave period ranges 5 to 50 s, 30 to 100 s, 70 to 150 s and 90 to 250 s. Figures 4a to d show that low-frequency energy between 30 and 150 s occurs only during the peak of the storm (Figure 4c). Figures 5a and b show a comparison of characteristic wave heights for the specific wave period ranges. It appears that the low-frequency wave height for both the period ranges 30 to 100 s and 70 to 150 s is about 20 per cent of the wave height in the period range 5 to 50 s.

From visual inspection of the spectral plots such as Figures 4a to d, those plots showing a clear low-frequency energy content, such as in Figure 4c, were selected. These occurrences are related to the observed short-term maximum wave heights H_M at the waverider position, as shown in Figure 6. It can be seen that low-frequency wave energy almost always occurs when the observed wave height H_M at the waverider is larger than 2 m.

6. CURRENT MEASUREMENTS

The most severe motions of the moored ships were reported by the operational staff to be in a horizontal plane, namely, surge, sway and yaw. Therefore, the horizontal water motions are probably a major cause of the problems. These motions can be estimated from the heights and periods of the waves and from the local water depth. In order to provide a check for these estimates as well as to determine a possible existence of cross-currents at the jetty a current meter was installed. Initially only one current meter was used. This could be installed at various positions along the jetty (see Figure 3). In this way possible cross-currents could be measured during various wave conditions, while it was hoped that a correlation with the swell data could be established. A reported strong marine growth at Saldanha Bay prohibited the use of a propeller type current meter, while the large amounts of moving iron ore and steel structures would render an electro-magnetic current meter useless. Therefore, an ultrasonic current meter was used (see Figure 7). The instrument was suspended between two adjacent caissons by means of four stainless steel wires. Because of corrosion problems these were later replaced by polypropylene lines (see Figure 8).

7. WIND MEASUREMENTS

Because wind as well as water motions contribute to ship motions, an Aanderaa anemometer was installed at the top of

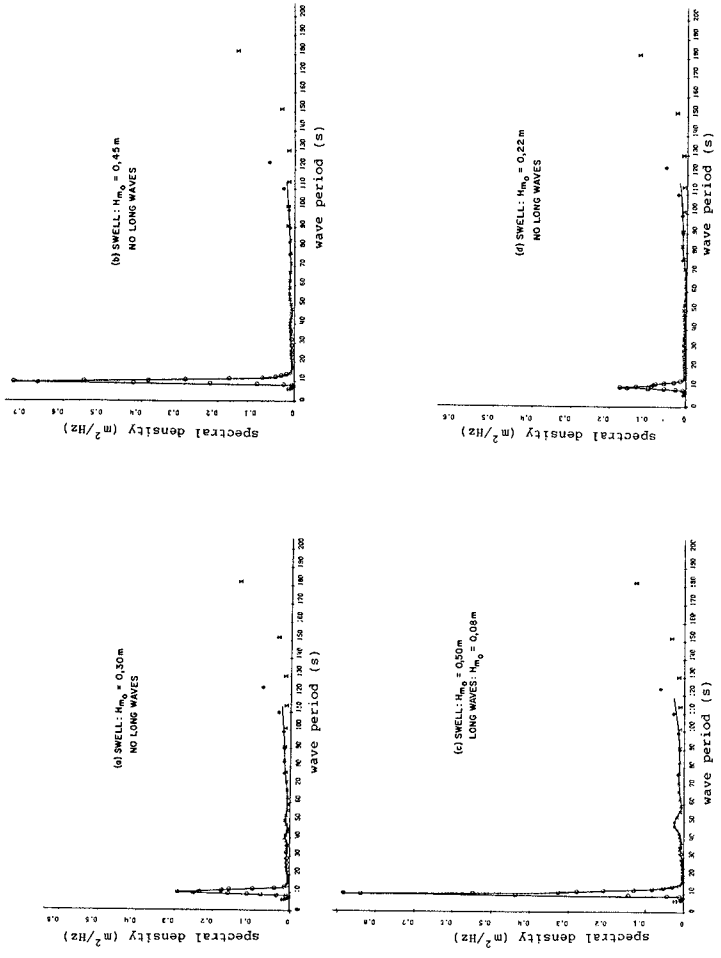

FIGURE 4: Spectral density estimates for a typical storm

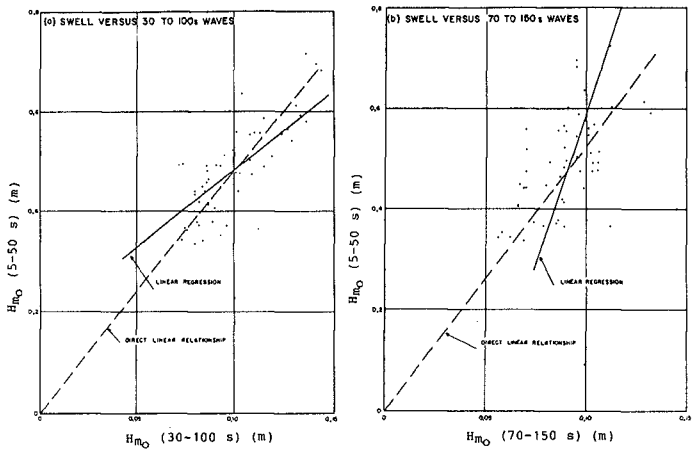

Figure 5: Relationship between characteristic wave heights based on various wave period bands

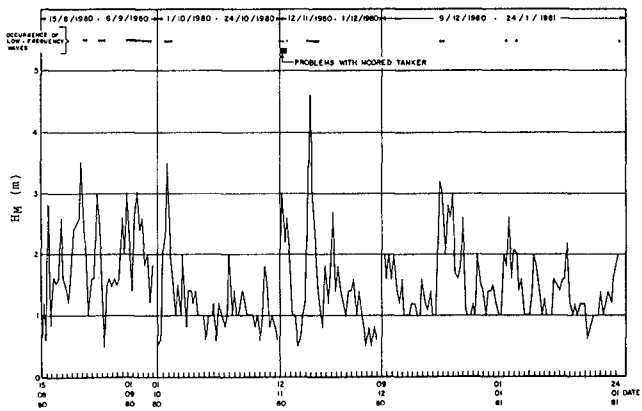

Figure 6: Relationship between short-term maximum wave height H_M and the occurrence of low-frequency waves

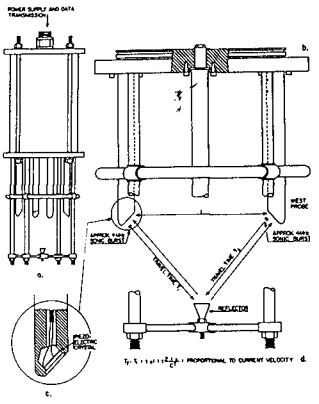

Figure 7: Simrad HC-100 ultrasonic current meter

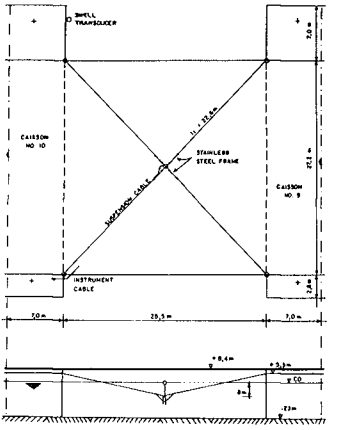

Figure 8: Typical position of current meter

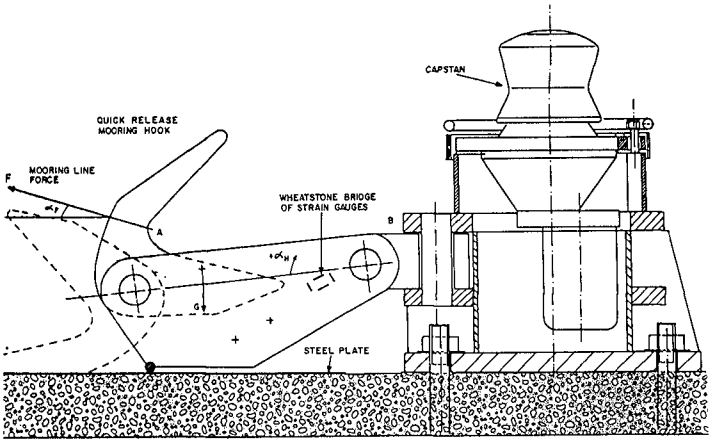

Figure 9: Mooring hook equiped with strain gauges

a light mast at caisson No 25 (see Figure 3). This anemometer monitored continuously wind speed and direction,and every 15 minutes the following data were recorded:

(a) The average wind speed during each 15 min. interval.

(b) The average wind direction during each 15 min. interval.

(c) The maximum wind gust during each 15 min. interval.

8. MOORING LINE FORCE MEASUREMENTS

Forces in the mooring lines can be determined either by monitoring the tensions in the ropes or those in the mooring hooks. Four methods of doing this were considered:

(a) Use of a load cell fitted to the mooring hook and onto which the mooring line could be hooked. The sheer mass of such a device as well as its relative complexity made this impracticable. Its use would also mean the loss of the advantages of the quick-release mechanism of the hook.

(b) Use of a mooring line "forerunner" incorporating a load cell. This offered a technically sound solution but in the given situation would have been difficult to use. The danger of loss of these forerunners, either by their being left attached to the ship's mooring lines or by their falling off the jetty into the water seemed too great to make this method feasible. Further, use of the quick-release mechanism of the hook would almost certainly have resulted in loss of the forerunner. As with method (a) this device would have had to be tested regularly to ensure that mechanical failures did not occur. Further, the long flexible electrical connections would be fairly vulnerable to damage and therefore unreliable.

(c) Monitoring strain in one of the pivot pins of the quick-release mooring hooks, using strain gauges mounted onto these pins. A disadvantage of such a system would have been the complexity of retrofitting such pins in hooks which were in regular use.

(d) Monitoring strain in the mooring hook side plates. This offered a neat solution to the problem, provided that the stability, reproducibility and system inaccuracies were within the required specifications. Also, calculations predicted that the stress in the side plates at the selected point of measurement would have been almost linear with respect to force on the hook (see Figures 9 and 10).

To investigate the feasibility of this method preliminary tests were done on one hook. Strain gauges were fitted to one side plate (see Figure 9) and the hook was taken

through a number of load cycles. This test was repeated after three weeks and again after a further two weeks. During these tests the following points were examined:

(a) Reproducibility of observations, both in the short-term and in the long-term.

(b) Temperature stability, particularly with regard to irregular heating of the hook, such as heating up of one side of the hook only by the sun.

(c) Linearity.

The results of these tests showed that the system would meet the required accuracies, namely, that the hooks could be used to monitor forces up to 800 kN (about 80 ton-force) with a resolution and accuracy of 10 kN (about 1 ton-force). Greater inaccuracies would occur at the lower forces but these could be neglected since they were not in the area of interest. At the higher forces the linearity and repeatability improved, giving adequate accuracies.

On the strength of these tests, 20 mooring hooks were instrumented using strain gauges mounted on the side plates of the hooks (see Figure 3 and Photograph 2). The strain gauges are covered with an epoxy-coated aluminium die-cast box which apart from affording protection to the gauges, also houses the local electronics and line drivers.

The hooks are calibrated by means of an hydraulic jack, together with a calibrated load cell, various attachments and spacers. The jack applies a force between the bollard and the curve of the hook (between point A and B as shown in Figure 9). By taking into account the bending moment introduced about the rear pivot axis of the hook, a sufficiently accurate calibration curve was obtained.

9. FENDER FORCE MEASUREMENTS

Since tables are available which give the relationship between pressures in, and forces applied to, the fenders, it seemed that the monitoring of pressure in the fenders would provide the simplest method of determining the forces on the fenders. Tables are also available giving the relationship between fender deflection and force against the fender. Photographic measurements of fender deflection could therefore also be correlated with pressure measurements.

The attachment of the pressure transducer was simple, as a suitable outlet plug was available on the headplate of the fender and required only the insertion of an adaptor and throttle valve. Coupling the transducer to the jetty was a greater problem as the cable had to be flexible enough to

allow for the continuous movement of the fender due to wave and swell actions as well as the movement due to tidal variations. The problem was solved by using the coiled flexible cables used between trucks and trailers. Two such lengths joined together provided a sufficient extension to cater for the movements encountered.

The pressure transducer used is a Bell and Howell type with a range of 300 kPa absolute pressure. This provided a range of close to 200 kPa above atmospheric pressure. The fenders are maintained at a pressure of about 75 kPa gauge and the safety release operates at 175 kPa. Eight fenders were equipped with these pressure transducers (see Figure 3 and Photograph 3).

A local pressure transducer amplifier and line driver is mounted on the edge of the jetty in a protective housing. This converts the pressure transducer signal into one suitable for driving down a long line to the recording station. When fenders are being serviced or replaced, it is a relatively simple matter to remove the pressure transducer and the coiled cable from one fender and install it in the replacement fender.

10. SHIP MOTION MEASUREMENTS

10.1 Photographic Technique

Various methods were considered for measuring the motions of the moored ships. This can be done mechanically by attaching an instrument onto the ship, e.g. by a set of lines connected to potentiometers (see Stammers et al., 1977). Another possibility, which was chosen for Saldanha is a remote-sensing method. In this case a camera was installed at a fixed position to take photographs of the ship at 2 s intervals.

A relatively suitable vantage point for the installation of a camera was found at the top of the chimney at caisson No 18 (see Figure 3). From this position it was possible to determine the most important sway and yaw motions of the ship accurately, as well as the vertical motions of heave, roll and pitch. Only the surge motions could not be determined accurately from this position.

It is necessary to photograph fixed points behind the ship as well as fixed points on the jetty (see Figure 11). Furthermore, the forward mast, bridge and funnel of the ship must be included as target points on the ship. To include all these points for a large ship a lens with a focal length of about 100 mm was required. The large number of photographs to be taken required a camera with a large magazine and an automatic recording system. On the basis of these considerations a Robot Motor Recorder was chosen,

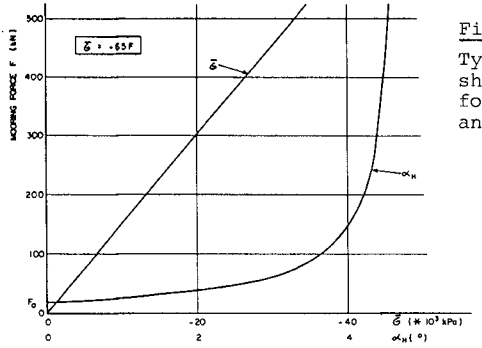

Figure 10:
Typical relationship between mooring force F, stress σ and lift angle α_H

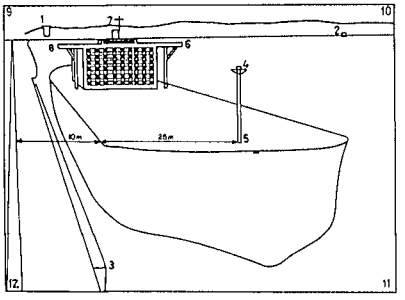

Figure 11:
Sketch of photograph of moored ship

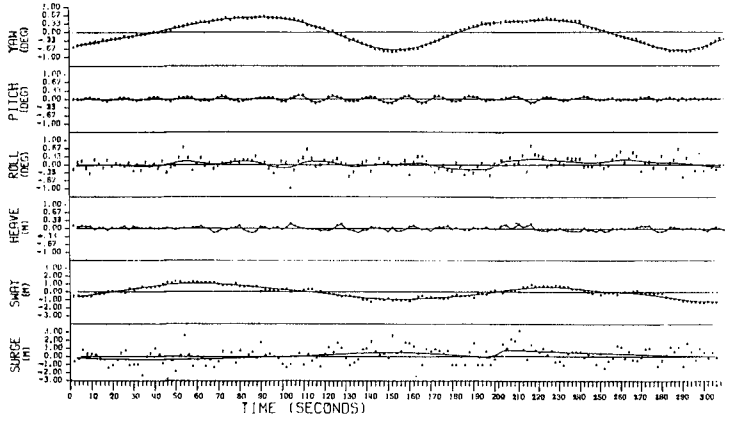

Figure 12: Results of analysis of digital moored ship photographs (run No SM003)

with a lens of 75 mm focal length and a magazine which could contain film for 1 600 frames of 18 by 24 mm.

10.2 Sonar Docking Device

The ore jetty is equipped with an Elac sonar docking device installed by the harbour authority for use by pilots during docking operations. The device makes use of two independent horizontally-looking ultrasonic echo sounders, one for the bow and the other for the stern of the ship. Each system has two transducers mounted in the water on the side of the jetty (see Figure 3). The decision as to which of the two transducers to use, was based on the size of the ship and the position of the ship alongside the jetty.

Measurements of speed of the bow and stern are made as well as of the distance of the bow and stern from the jetty. It was decided that since the device was available, its outputs should be recorded to provide some back-up for and a check on the photographic recording system.

11. DATA ACQUISITION

11.1 Central Data Acquisition System

Most data acquisition is done at the central recording station at caisson No 14 (see Figure 3). This therefore means that all signals have to be transmitted from the various sensors to the recording station. It was decided to use a frequency-modulated system for the transmission of all signals to the recording station and this therefore led to the design of a general-purpose amplifier module to interface the sensors to the cabling system. The module includes an amplifier, voltage-to-frequency convertor and line driver. The amplifier stage can be adjusted to suit the output of the particular sensor, and the voltage-to-frequency convertor is set to suit the range required. Conventional 25-pair telephone cables are installed along the length of the jetty with junction boxes at each caisson. The amplifier modules are installed as close to the sensors as possible and are connected via two-pair telephone cables to the junction boxes on the respective caissons. At the recording station all the frequency modulated signals are fed via phase-locked loops (for filtering and signal conditioning) to the recording system.

The data-acquisition system, DAS (see photograph 4), is an exact copy of the data-acquisition system used in the NRIO coastal engineering model hall (Holroyd, 1980). It is based on the NRIO microcomputer system (Holroyd, 1982) and, in line with the general approach of the Institute, uses digital cassettes as the storage medium. The DAS is split between the continuous monitoring section and the section which operates only when ship monitoring is being done.

The continuous monitor is permanently on power and automatically logs data from the wind sensors and the swell sensor at caisson No. 14. Wind data include the average wind speed, the average wind direction and the highest gust speed for each 15-minute interval. These data are accumulated in the computer's memory over a 12-hour period and are written onto the cassette at 06h00 and 18h00 as a complete data file covering the past 12 hours. At noon and midnight swell data files are recorded for a two-hour period with a two-second sampling interval.

The ship monitoring section of the DAS includes the central control unit, with keyboard and VDU, and five data logging units all connected to and controlled from the central control unit. The central control unit is used to initiate a monitoring run, insert header information, such as the ship's name, and generally acts as a communication link for commands to and prompts from the data-logging units. It was decided to use five data logger units because of the volume of data being collected during a monitoring run. This has the added advantage that the data from each group of sensors are stored on a different cassette, therefore simplifying the subsequent sorting of the data during the analysis stage. All inputs are synchronously sampled at two second intervals and a direct measurement is made of the frequency from the sensor amplifiers.

All data are stored onto digital cassettes in a properly file organised format with headers giving real-time, the type of data, the data format as well as information entered by the operator during initialization. The data are allocated to the logging units as follows:

Unit 1 - sonar docking device, bow and stern, speed and distance from jetty
Unit 2 - six long swell sensors
Unit 3 - X and Y current speed from Simrad HC100 current meter
Unit 4 - eight fender force sensors plus six mooring hook force sensors
Unit 5 - fourteen mooring hook force sensors.

The DAS includes a cassette reader and a printer which permits **in situ** checking of the system's performance. Another important built-in maintenance aid permits the display of the sensor line frequencies on the VDU, simplifying checks on sensor performance and calibration.

11.2 Other Data

It was not feasible to store all recorded data at the central data-acquisition system on Memodyne cassettes. The waverider data logger is already an automatic recording system with an accurate time base. Besides graphical

recording of the wave history, the signal is sampled every 0,5 s and the values written onto Memodyne cassette four times a day, namely, at 00h00, 06h00, 12h00 and 18h00 GMT. These tapes are spectrally analysed at NRIO using a standard FFT program.

The data from the tide recorder are recorded only graphically. However, any long period oscillations can be easily noticed. Also the actual water levels during the presence of a ship can be read off directly. Both the waverider data logger and the tide recorder are installed at the Port Administration Building (see Figure 2), where they are also used to provide normal harbour operational data.

12. DATA PROCESSING AND ANALYSES

12.1 Digital Data

The in-house data processing system has extensive facilities for reading cassette tapes. Quick look and edit programs are available for checking the data on cassettes, scaling the data according to the calibration values for each sensor and transferring the data onto nine-track magnetic tapes in a standard ASCII-coded file format.

These data are then read from the tape and stored on high-density archive tape at the CDC Cyber 170/750 computer at the Centre for Computing Services of the CSIR. The data from each channel will be spectrally analysed using programs based on the autocovariance method. Directly related spectra can be analysed further using cross-correlation techniques, while also time-history plots of the various signals may show any correlation by visual inspection.

12.2 Photographic Data

12.2.1 Digitizing technique

After the films of the moored ship have been developed, the negatives are projected onto a digitizing tablet where the coordinates of three fixed shore points, of five points on the ship and of the corners of the frame are determined and stored on cassette tape.

The coordinates of the fixed shore points (1 to 3 in Figure 11) relative to those of the corner points of the frame (9 to 12) are used to compute the orientation of the camera and a coordinate system with its origin at the camera position is defined. Also the fixed points 1 to 3 are used to compute the scale of the projection. The projected height of the forward mast (from points 4 and 5) relative to the real height is used to compute the instantaneous distance of the ship relative to the camera, which yields the surge motion of the ship after projecting the

distance to the camera to a horizontal plane. The top of the forward mast (point 4), the bridge tip (either point 6 or 8) and the top of the funnel or radar mast (point 7) are used to compute the motions of the ship relative to the camera-based coordinate system. After this system has been transformed to a horizontal coordinate system the instantaneous motions of sway, heave, roll, pitch and yaw can be determined.

The process of digitising is controlled by a Tektronix 4051 desk top calculator. After the digitizing is completed the data files on tapes are transfered to disc storage at NRIO's in-house HP 21 ME minicomputer and from there transformed into ASCII code and written onto nine-track magnetic tape. From here the data are treated in the same way as the digital data described in Section 12.1 are.

12.2.2 Analysis program and ship motion results

A computer analysis program has been developed to compute the motions of the ship in six degrees of freedom, using the coordinates determined with the digitizing tablet. A typical raw result of this analysis is shown in Figure 12. It can be seen that the surge motion has the largest scatter, while sway and yaw show a very smooth variation with periods of about 100 s and almost in phase. Heave and pitch show oscillations with periods of about 16 s, which is slightly above the dominant swell period of about 14 s.

13. PROBLEMS

A number of problems were encountered during the installation period and some are still present. As already mentioned in Section 6 it was known that very active marine growth occurs at Saldanha Bay, especially barnacles, red bait and black mussels. These animals grow so rapidly that they can choke the aperture of pressure gauges. Although copper gauze was used to protect apertures, this toxic metal proved to be ineffective and regular mechanical cleaning by divers has to be performed to keep the instruments functioning.

Another problem is strong corrosion of the metals in the sea water. Initially, copper was used in order to control the marine growth at the instruments. Stainless steel was also used because copper is not a very strong and elastic material. Therefore, initially stainless steel Hilti bolts were used to fasten clamps, brackets and instruments under water. Some instruments were made of stainless steel, such as the Simrad current meter. However, serious galvanic corrosion occurred between copper and stainless steel, as well as mutually between stainless steel when parts of the surface became active due to lack of oxygen. Even the

application of zinc anodes did not prevent galvanic corrosion.

The system of sensors along the jetty requires many long lengths of cables which carry signals to the main telephone cables or directly to the recording station. Many of these cables are in fairly vulnerable positions and can easily be damaged during normal mooring operations. Even though cable damage is less than expected, it is still necessary to inspect cables regularly for wear or damage.

Iron ore dust is everywhere and is hostile to electronic circuitry. Keeping the electronic units such as the remote amplifiers clean during installation, repair or calibration is not easy. This task is often made more difficult by unfavourable weather conditions. On some occasions the presence of strong winds, swell and sea spray make repair work impossible.

The scatter of the surge motion results is very large. Attention should be given to determining surge more accurately.

14. CONCLUSIONS

On the basis of the results obtained so far it can be concluded that the various instruments are effective in yielding the required quantitative data for the moored ship investigations. The strain-gauged mooring hooks do not show a significant drift during short periods of measurements; regular recalibration checks are, however, necessary. The flexible coiled cable has also proved to be an adequate connection between the continuously moving fenders and the caissons.

The most important motions of the moored ship, namely, sway and yaw which form the most serious problem, are effectively and accurately determined by using the Robot Motor Recorder and computer analysis system. The central data acquisition system, particularly is very useful in recording the monitored data on a mutual time base.

Preliminary results of the analysis of long-wave data and ship motion data show that wave energy is present at periods between 50 and 150 s, while natural periods of horizontal oscillations of moored ships have been shown to be in this same range. It is expected that further correlation of environmental and ship dynamics data will permit the determination of firm relationships between cause and effect of the moored ship problems, when a sufficient number of problem cases have been monitored.

SHIP MOTIONS RELATED TO DEEP DRAFT CHANNEL DESIGN

By Scott Noble, [1] A.M. ASCE

ABSTRACT: This paper discusses the investigation that the U.S. Army Corps of Engineers, Portland District undertook for possible modifications to the Columbia River entrance channel. Because of the characteristically high sea conditions at this location, wave induced ship motions were considered an important criteria to be evaluated. Phototype ship motion measurements were obtained along with wave data. The data and preliminary results are summarized. Emphasis is given to the analysis of a relationship between environmental conditions and vertical excursions, and the subsequent use of the relationship to determine a new channel depth.

INTRODUCTION

In 1972, a resolution was adopted by the Public Works Committee of the United States Senate directing the Corps of Engineers to investigate the feasibility of modifying the entrance channel to the Columbia River, especially with regard to providing deeper depths. The Columbia River Port authorities, who lobbied for the resolution, felt that a deeper channel was necessary to bring the entrance channel in-line with the river channel as well as to allow larger ships to transit the system in the future. In the early phases of the investigation it was determined that insufficient data were available to permit an accurate design of the channel. This was especially true since sea conditions in this area are notoriously rough and analytic procedures to determine channel depths where wave induced ship motions are a primary design factor are scarce. Therefore, a prototype ship motion monitoring program was initiated that was to provide the criteria with which to base the modifications. References (4,5,6) contain detailed discussions of the field work, data results and initial analyses. The present paper will discuss further analysis of the data and its application

to the determination of modified channel dimensions. Previously presented information will however be summarized.

The Columbia River rises on the west slope of the Continental Divide in British Columbia and flows approximately 1,200 miles (1,900 km) to the Pacific Ocean, approximately 745 miles (1,200 km) in the United States. As shown in Figure 1, the river also forms the natural border between the states of Oregon and Washington. The river is a major artery for the transportation of goods to domestic and international markets. An annual average of about 23 million tons (21 million m tons) are transported past the mouth of the river by roughly 2,000 vessels.

Congress has delegated to the Corps of Engineers the responsibility for construction and maintenance of Federal navigation projects. Portland District has those responsibilities for over 40 seperate projects in Oregon and Washington. The project at the entrance, shown in Figure 2, provides for a channel 48 ft (14.6m) deep, measured from the plane of mean lower low water (mllw), 2,640 ft (805 m) wide and about 5 miles (8 km) long. The channel is to be secured by two rubble-mound jetties, a spur jetty, Jetty A, on the north shore and by dredging. Maintenance dredging is primarily performed by the hopper dredge BIDDLE, which historically has averaged about 4.5 million cu yd (3.4 million m^3) annually. The deep-draft river channel then proceeds from the mouth to the Portland-Vancouver area some 102 miles (165 km). The primary dimensions of this project are 40 ft (12.2 m) deep by 600 ft (183 m) wide. Annual maintenance dredging of this project is roughly 5 million cu yd (3.8 million m^3).

DATA COLLECTION

The monitoring program involved acquiring ship motion and wave data. This was done so that a correlation between environmental conditions and ship motions could be investigated.

Ship Motion Measurements - During the periods of May - June 1978, October 1978 - March 1979, and October 1979 - March 1980 a total of 53 deep-draft vessels were monitored. The field work was accomplished through a contract with Tetra Tech, Inc. Basically, a two-man field team boarded the vessels at the point of departure and recorded measurements during the approximately half hour necessary to transit the entrance. Measurements were made of vessel vertical acceleration (heave), pitch, roll, heading, and position continuously. The data were then reduced and analyzed to generate time histories and distributions of bow, stern and side excursions, vessel

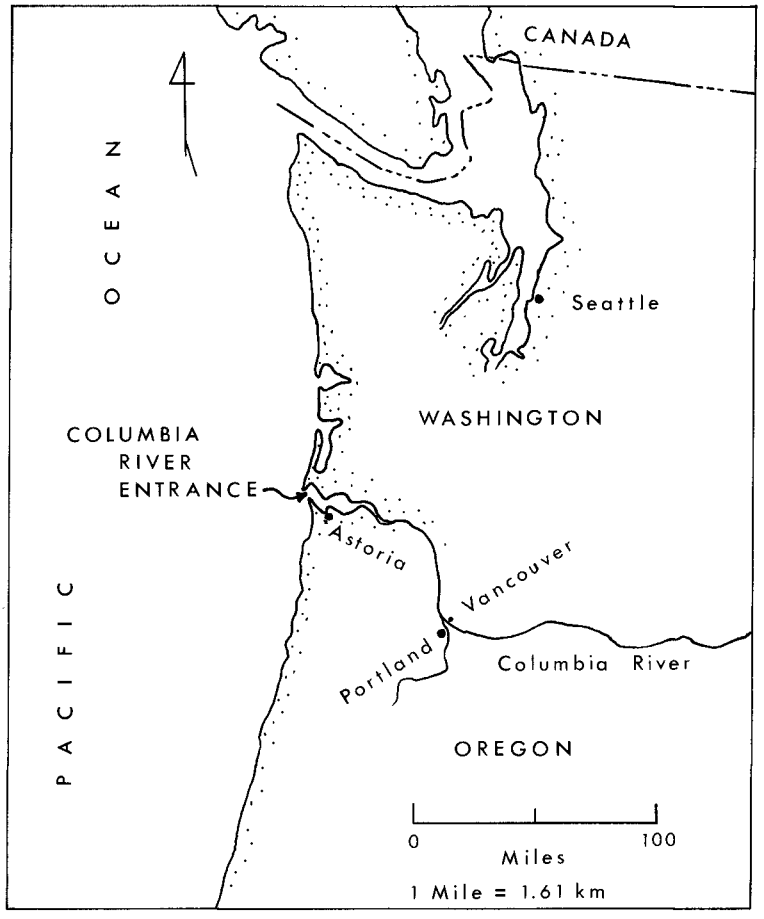

FIG. 1- VICINITY MAP

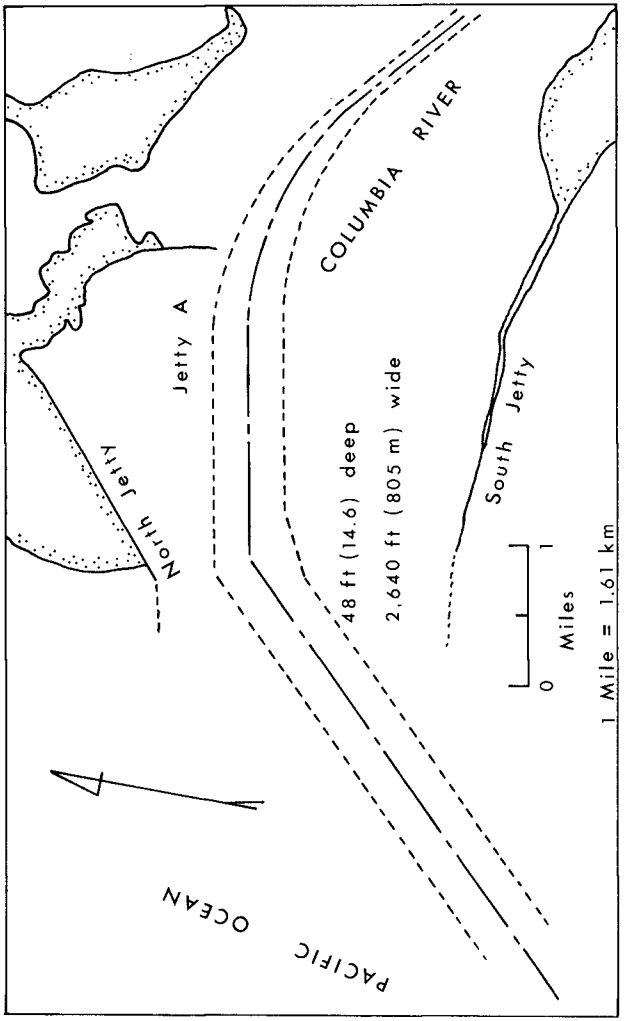

FIG. 2- COLUMBIA RIVER ENTRANCE

heading and yaw, as well as of the recorded motions. - The excusion is the vertical movement of a particular point on the vessel relative to its still water position.

With the aid of the Port of Portland, arrangements were made to monitor Chevron tankers, Weyerhaeuser bulk carriers, Japanese and Matson line container carriers, and an auto carrier. Table 1 gives the principal dimensions for the vessels monitored. The monitored vessels resemble the distribution of vessels that transit the Columbia River.

Wave Data Gathering

Under the guidance of the Corps of Engineers Coastal Engineering Research Center waverider buoys were deployed in the entrance area and offshore to measure wave height and period, and a wave imaging radar unit was used to obtain wave direction, length and transformation characteristics over a broad region. Numerous difficulties were experienced in getting the equipment operating properly and maintaining the operation. The buoys were hard to keep on station because of the rough sea conditions experienced there and the high density of commercial and pleasure craft. Other sources of data were also utilized to provide information on wave conditions throughout the monitoring period. These included visual observations of sea conditions made by the two man field crew aboard the instrumented ships; and, wave measuring instrumentation placed on the Columbia River entrance navigation buoy just outside the entrance. A comparison of the visual observations with coincidently recorded significant wave heights indicated that the observations were a reliable source of information.

DATA RESULTS

Although the study was concerned with both vertical and horizontal motions, this paper will deal with just the vertical motion results and the implication to channel depth design.

Ship Motion Results - Out of the 53 voyages monitored, 51 complete sets of vertical motions were obtained. Equipment failure occurred during two of the crossings. Table 2 is a tabulation of the cumulative percent frequency of occurrence for the average and maximum heave, roll and pitch values. The table indicates the magnitude of motion that is exceeded by a certain percentage of the crossings. For instance the table shows that 25 percent of the voyages had a maximum heave, roll and pitch value of at least 6.0 ft (1.8 m), 5.7 deg and 2.1 deg, respectively.

	Auto Carriers				
10.	WORLD WING	566	90	29	23,000

Note: 1 ft = 0.305 m; 1 ton = 1.016 Kg

The next step in the preliminary analysis was to convert the preliminary motions into vertical excursions. This was done by combining the heave and pitch to determine bow and stern excursion, and combining the heave and roll to determine side excursion. In the analysis the center-of-gravity was assumed to be the point-of-rotation. Table 3 is a tabulation of the cumulative percent frequency of occurrence for the average and maximum bow, stern and side excursions. The table shows that 25 percent of the voyages had an average bow, stern and side excursion of at least 5.3 ft (1.6 m), 2.6 ft (0.8 m) and 2.6 ft (0.8 m), respectively. Similarly, 25 percent of the voyages had a maximum bow, stern and side excursion of at least 15.0 ft (4.6 m), 7.4 ft (2.3 m) and 7.1 ft (2.2 m). The table indicates that the bow and stern excursion are the critical excursions to consider in the channel design.

Wave Data - As mentioned previously, wave data was gathered from a few sources. During the monitoring program 5 percent of the voyages had waves in excess of 15 ft (4.6 m) high. Most of the waves were however below 10 ft (3 m). Wave periods were generally 10 seconds but ranged between about 6 to 17 seconds. Wave directions near the Columbia River are predominantly from the west to northwest but storms generally come from the southwest. The wave directions observed during the monitoring program also tended to follow this pattern.

DATA ANALYSIS

After the initial data reduction and analysis, the object of the study was to relate the ship motions to the environmental conditions. If a satisfactory relationship could be obtained, then an appropriate channel depth could be determined based upon a design wave condition.

As a design procedure, we were interested in the maximum motions, although the best relationship did not occur with the maximum values. The reason for this is that the maximum motion is dependent on the wave height, length and direction at the time and location that the maximum motion occurs. Since we did not obtain this detailed wave data, nor did we attempt to, and since wave conditions at the Columbia River vary greatly throughout the entrance area, a relationship other than with the maximum motion was sought. Since basic wave conditions, as obtained during the field study, should be indicative of average conditions, a relationship between average motions and wave conditions was investigated. Then, as shown by Wang (5) the maximum motion, or a motion with some other cumulative percent frequencey of occurrence, could be determined utilizing the Rayleigh distribution. For example, the motion with a 90 percent cumulative frequency of occurrence during a particular voyage could be determined from the average

motion.

To begin the investigation into a possible relationship between average motions and environmental conditions use was made of Lundgren (1). In his general report to the 1965 PIANC Congress on the subject of ship motions due to waves, he listed 5 dimensionless parameters as principal variables. These variables were:

1. Wave height to ship draft ratio (H/D)
2. Encounter period of ship to natural response period of ship ratio (Te/Tp:Tp for the case of pitch period)
3. Relative wave length in direction of ship to ship length ratio (Lr/LOA)
4. Depth of water to ship draft ratio (d/D)
5. Wave direction relative to ship.

As the initial results showed, and later analysis clarified, the critical motions occurred at the bow or stern of the ship, and these motions were most dependent on the wave height and encounter period. The wave height, as would be expected, has the most influence on the magnitude of the motions. From the initial results, it was apparent that the outbound voyages generally exhibited greater motions than inbound voyages, indicating that shorter encounter periods cause greater bow/stern motions than longer periods. Following through with this thinking, a "best fit" relationship was determined using the independent variables wave height, natural pitch period, and encounter period of the ship. The dependent variable was the average bow or stern excursion. In the statistical analysis the greater of the 2 excursions was used. The relationship, as shown in Figure 3 is:

$$E\ (avg) = 0.57 + 0.99\ (HTp/Te)....(Ft)....(1)$$

The 95 percent confidence limits are also shown in the figure. The correlation coefficient (r^2) for the relationship is 0.86. The values used to derive the relationship are listed in table 4, with vessel type being referred back to table 1.

As the above equation shows, average excursion increases as wave height increases and/or the ratio of ship's natural pitch period to encounter period increases. While the excursion is predominantly related to wave height, the period ratio accounts for additional variance in the excursion. Of the two period variables, the encounter period has a much wider range than the natural pitch period, and thus is the dominant component of the ratio. The following

paragraphs briefly describe the independent variables.

The wave height used in the formulation of the equation was the measured significant wave height closest to the time of transit, when measurements were made. Precedence was given to channel measurements, and then to measurements made off the entrance. For the remainder of the transits visual observations by monitoring crew were used. Observations were taken as indicative of the significant wave height.

The natural pitch period is a function of vessel length, beam, and loaded condition (draft, displacement, and center of gravity). The method described in Myers (2) was used to determine the natural pitch period of the 51 vessel crossings for the regression analysis. The natural pitch period was calculated by:

$$Tp \triangleq 1.108\ Kxx/GM\ (L)^{\frac{1}{2}} \quad \ldots. \text{ (U.S. Customary Units)} \ldots. (2)$$

The position of the center of gravity (cg) needs to be known to calculate GM(L). The natural pitch period ranged between 4.6 and 6.0 seconds for the vessels monitored. In the design the distance from the center of buoyancy to the metacenter is used as an estimator of GM(L).

The encounter period is the wave period relative to the moving ship and is a function of wave period and direction, and ship speed and course. The equation to determine encounter period is,

$$Te = Tw/\ (1 - 2\ \pi\ (1.689\ VcosB)gTw). \text{(U.S. Customary Units)} (3)$$

CHANNEL DESIGN

In the case of the Columbia River most of the deep draft traffic travels the approximately 102 miles (165 Km) to the Portland-Vancouver area. The river channel is therefore an important aspect of the movement of commerce. For this reason the primary assumption in the design of the entrance channel was to determine a depth that would bring the entrance channel in-line with the river channel. In other words, the design vessel for the river channel would also be used as the design vessel for the entrance channel. Specifically, the design vessel for the entrance channel was chosen to be that vessel which could transit the river channel approximately 95 percent of the time. It was also decided to consider the largest grain vessel that could transit the river channel (grain being the greatest commodity moved on the system); and, the largest vessel that could call at the Port of Astoria, which is located near the entrance where a vessel could play the tides. Table 5

lists the dimensions of the vessels considered in the study.

TABLE 5. - Dimensions of Design Vessel and Others

Vessel (1)	Draft, in feet (2)	Length overall, in feet (3)	Beam, in feet (4)	Dead weight tonnage, in tons (5)
Design Vessel	35	650	90	40,000
Largest-Grain	39	700	100	50,000
Largest-Astoria	43	780	105	70,000

Note: 1 ft = 0.305 m; 1 ton = 1,016 kg

The basic equation used in the design of the channel depth was:

$$d + T = D + E + t + C \quad \ldots\ldots \quad (4)$$

or,

$$d = D + E + t + C - T \ldots \quad (5)$$

A few points need to be made about the equation and its specific application to the Columbia River entrance. The design of the channel was predicated on a design excursion that is exceeded only 5 percent of the time when waves are less than or equal to about 10 ft (3 m) high. The reason for this was that when waves are higher than this level other factors come into play; e.g., the pilot can slow the vessel to minimize motions, or higher tide levels can be played. Vessel squat was not specifically designated in equation (4). The 2 reasons for this are that the measurement technique indirectly accounted for squat by measuring any movement, whether long term or short term; and, the 2 mile (3.2 km) wide opening will not induce much of a squat phenomenon. The last comment is that for the design the tidal elevation was taken as 0 mean lower low water, the vessel trim was assumed to be 1 ft (.3 m), and the minimum clearance was assumed to be 2 ft (0.6 m).

As stated earlier, the distribution of excursions on an individual voyage follows the Rayleigh distribution. For the case of ship motions this distribution can be stated as:

$$p = 1 - \exp\left(- (E(p)/E(\text{rms}))^2 \right) \ldots\ldots\ldots \quad (6)$$

The equation can be rearranged to read,

$$E(p) = E(rms) (-\ln (1-p))^{\frac{1}{2}} \quad \ldots\ldots\ldots (7)$$

Since the cumulative Rayleigh distribution results in,

$$E(rms) = 1.13\ E(avg) \quad \ldots\ldots\ldots\ldots\ldots (8)$$

then,

$$E(p) = 1.13\ E(avg) (-\ln (1-p))^{\frac{1}{2}} \quad \ldots\ldots (9)$$

It was also assumed that the critical excursion for a particular voyage would be E(95) as opposed to either the average or the maximum excursion. Therefore, the critical excursion would be

$$E(95) = 1.13\ E(avg) (-\ln (1-.95))^{\frac{1}{2}} \quad \ldots (10)$$

or,

$$E(95) = 1.96\ E(avg) \quad \ldots\ldots\ldots\ldots\ldots (11)$$

The upper 95 percent confidence level was used in the determination of E(avg).

Instead of designing the channel based on a particular wave condition, it was decided to base the design on the distribution of all waves below the 10 ft value mentioned previously. The basic wave data were obtained from a National Marine Consultants (3) wave hindcast study. Use was then made of a 1978 refraction study of the Columbia River entrance performed by the Waterways Experiment Station for the Portland District. The refraction results were used to obtain a distribution of swell characteristics just outside the entrance. A comparison was then made between wave data collected in the entrance and data collected outside the entrance during the ship motion study. It was determined that on the average, waves are approximately 10 percent higher in the entrance than outside the entrance. This factor was used to modify the hindcasted annual wave distribution for the design analysis. By considering the frequencey of occurrence of each wave condition, a distribution of the critical excursion (critical excursion being the E(95) of a voyage under a particular set of conditions) was obtained for a particular vessel. Figure 4 is the resulting distribution of E(95) for the design vessel. The meaning of Figure 4, for example, is that over a long period of time 50 percent of the transits of the design vessel during the year will have an E(95) that will not exceed approximately 9.5 ft (2.9 m).

As stated previously, the channel was to be designed so that passage is available 95 percent of the time under

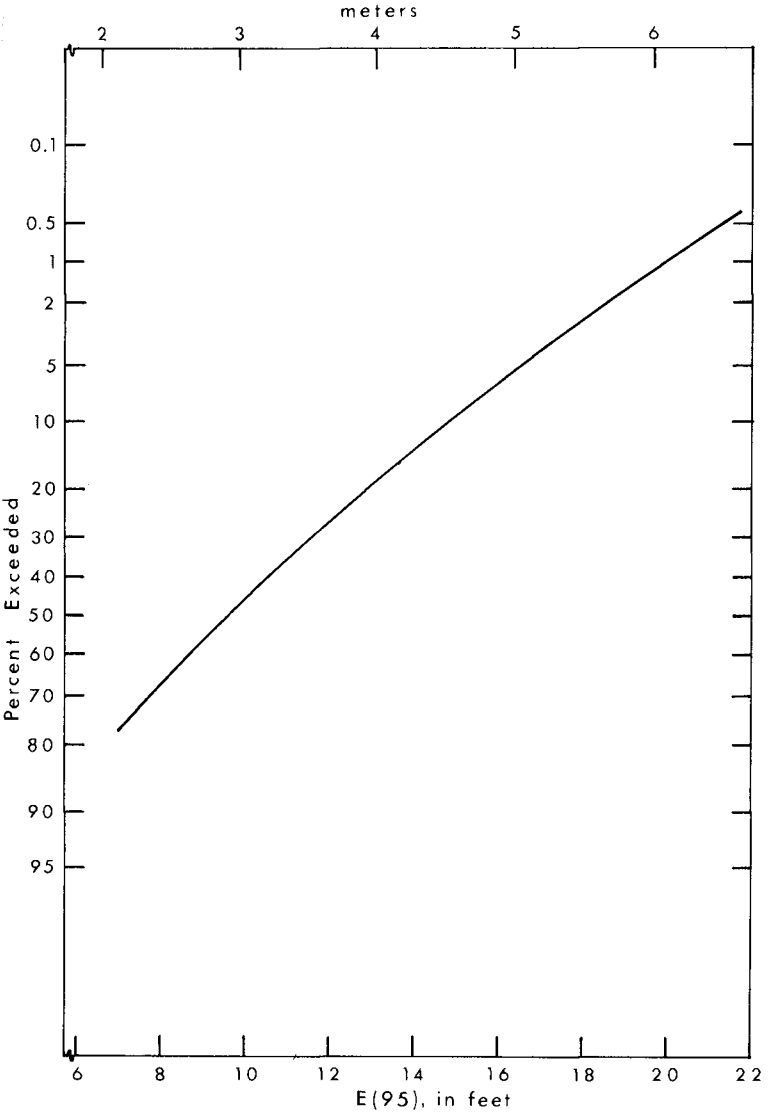

FIG. 4 - DISTRIBUTION OF E(95) FOR THE DESIGN VESSEL

certain wave and tide conditions. Therefore, from Figure 4 the design excursion (E) was determined to be 16.5 ft (5.0 m). From equation (5) the design depth is determined to be

$$d = 35.0 + 16.5 + 1.0 + 2.0 - 0 \approx 54.5 \text{ ft } (16.6 \text{ m}) \quad (12)$$

Therefore, an entrance channel of at least 54.5 ft (16.6 m) is necessary to bring the entrance channel in-line with the river channel.

The same procedure is followed to determine a depth associated with the other vessels. Table 6 is a summary of the design excursion and channel depth required for all vessels assuming a mllw tide level.

TABLE 6. - Channel Depth Requirements

Vessel (1)	Draft, in feet (2)	Excursion, in feet, (3)	Channel Depth, in feet, mllw (4)
Design Vessel	35	16.5	54.5
Largest Grain	39	16.8	58.8
Largest - Astoria	43	17.0	63.0

Note: 1 ft = 0.305 m

SUMMARY AND CONCLUSIONS

Since the completion of the ship motion study a feasibility report recommending an entrance channel depth of 55.0 ft (16.8 m) has been forwarded from Portland District Office of the Corps of Engineers. It is anticipated that this depth will provide a channel that can be utilized by the design vessel essentially all the time. Vessels larger than the design vessel, or vessels with higher motion response functions, may have to modify their operating procedures at times to transit the entrance. This may require reducing speed to minimize motions, playing the tides, or waiting for calmer conditions.

The equation (eqn 1) relating average bow or stern excursion to wave height, encounter period and natural pitch period can be utilized at other coastal entrances to aid in channel design. Other sources of information should also be consulted when ships much larger or differthan those considered in this particular study are the

primary design vessels. Hopefully in the future enough information will be analyzed from various sources to propose design guidelines bracketing all possibilities.

ACKNOWLEDGEMENTS

The work described in this paper was accomplished while the author was employed by the Portland District, Corps of Engineers. The author wishes to thank Mr. Gene Pospisil, his immediate supervisor at that time, for permission to present this material.

Tw = wave period
t = vessel trim (mean draft to bow or stern draft)
V = vessel speed

WAVE-INDUCED SHIP MOTIONS IN HARBOUR ENTRANCES - A FIELD STUDY

by

A C van Wyk*

ABSTRACT

Extensive field monitoring programmes were implemented to study the behaviour of deep-draught ships in the entrance channels to two major South African ports. These programmes form part of a study to assess the future accessibility of these ports to ships of greater draught.

This paper describes briefly the monitoring techniques and methods of data analysis used, and reviews the results with regard to the environmental conditions during the monitoring operations.

The prototype results on ship response to waves will provide valuable data for the calibration and validation of both mathematical and physical models. The results are also used to establish allowance criteria based on safe underkeel allowances for ships presently using these harbours.

1. INTRODUCTION

In 1978 the Ship Dynamics Division of the National Research Institute for Oceanology started an extensive study, on behalf of the South African Transport Services, to determine criteria for optimum use by deep-draught ships of the entrance channels to the two major South African export harbours under adverse sea conditions.

The coal harbour at Richards Bay on the east coast presently handles bulk carriers of up to 150 000 dwt (17 m draught in an outer channel depth of -24,0 m CD (Chart Datum)) while the ore harbour at Saldanha Bay on the west coast frequently accommodates vessels of up to 270 000 dwt (21 m draught in an outer channel depth of -23,7 m CD).

---

* Ship Dynamics Division, National Research Institute for Oceanology, Council for Scientific and Industrial Research, Stellenbosch, RSA

Safe use of the entrances with respect to underkeel allowance during adverse sea conditions has become a matter of considerable importance in the light of demands for handling larger ships and of the high costs involved in deepening the channels.

As part of the overall study, field monitoring programmes were implemented at these harbours to record the behaviour of the larger ships using the entrance channels under various environmental conditions. The data are needed to calibrate and validate the mathematical and physical models to be used in future studies and, also to update the provisional allowance criteria used at present which were based on limited results of earlier model studies.

This paper describes briefly the monitoring techniques and methods of data analysis (covered in detail by Zwamborn and Van Wyk, 1981) and reviews the results with regard to the wave conditions during the monitoring operations. Since the emphasis is entirely on wave-induced vertical motions, horizontal behaviour of the ship is considered only in order to determine the direction of wave approach relative to the ship.

2. FIELD MONITORING

Ship behaviour is recorded by a method of discrete time-interval photography. The monitoring technique, basically, comprises taking photographs, from a land-based station, at 2 s intervals, of each ship during her transit of the entrance channel. The photographic equipment consists of a motorized 35 mm camera fitted with a telephoto lens which enables behaviour of the ship to be monitored over a distance of roughly 2 km in the channel. Recording is therefore limited to daylight hours and when visibility is satisfactory.

The environmental conditions recorded during each event comprise the wind, the tide and, particularly, the waves. A waverider system provides, during monitoring, a continuous record of the waves in the vicinity of the entrance channel while the dominant wave direction is obtained from clinometer observations, radar wave images or pilot boat observations.

Each ship is also visited after arrival or before departure to obtain essential geometric details of the ship as well as the loading condition at the time of sailing.

Since August 1978 just over 200 different shipping events have been monitored, about 90 per cent of them at Richards Bay. These events were rated according to the severity of the wave climate as well as quality and extent of the records.

3. DATA PROCESSING AND ANALYSIS

3.1 Film Processing

To date the photographic records of the 70 top-rated events (all of which were recorded at Richards Bay) have been processed using a simple photogrammetric technique. The procedure consists of digitizing target points on the images of the ship on each film negative relative to a fixed coordinate system.

These coordinates, together with the geometry of the ship, are used to compute:

(i) the vertical motions of the target points on, and

(ii) the route, heading and speed of each ship.

The motions of the target points are used to derive:

(a) the three principal motions, namely, roll, pitch and heave, and

(b) the vertical wave-induced motions at the perpendiculars, shoulders and quarters of the ship due to roll, pitch and heave.

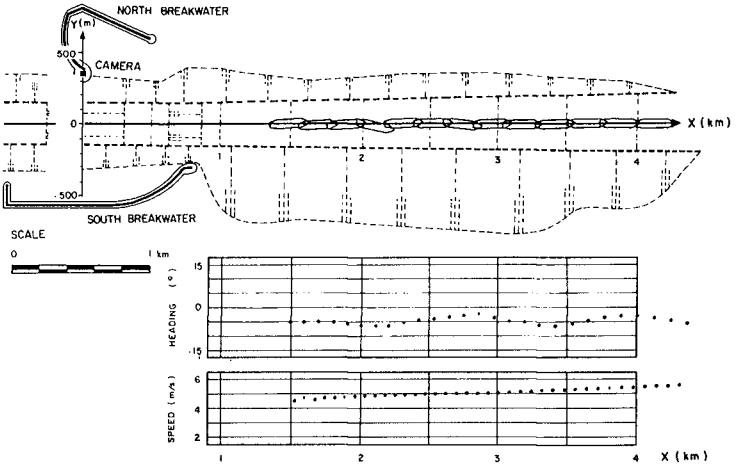

Figure 1.1 Ship trajectory for event R065

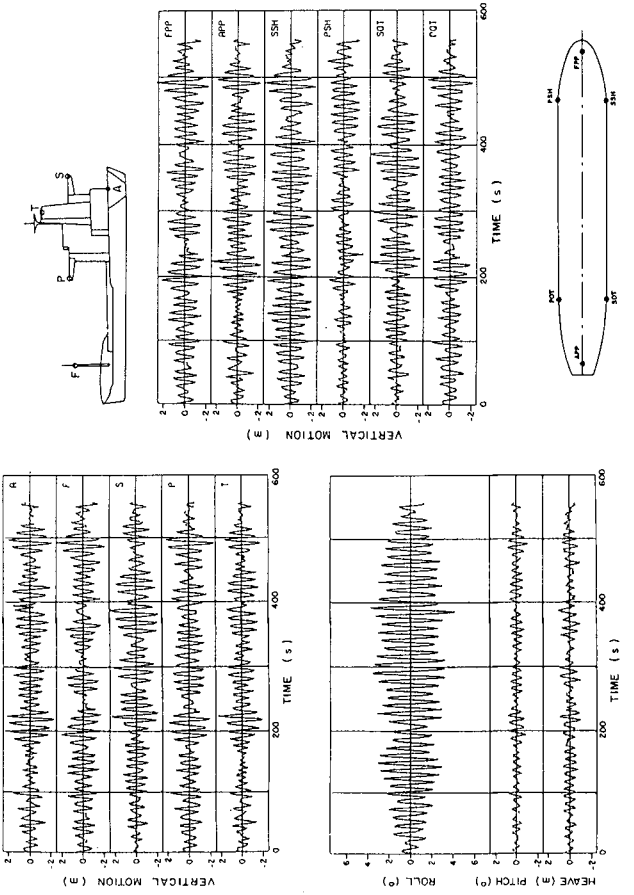

Figure 1.2 Sample motion time series for event R065

Examples of the results for a typical case study (event R065) are shown in Figures 1.1 and 1.2. Ship positioning relative to the channel coordinate system is believed to be accurate to within 50 m longitudinal and 10 m transverse. Heading angles relative to the channel orientation are accurate to about 1,5° and the speed of the ship averaged over intervals of 14 s is accurate to about 0,05 m/s. The vertical motions are subject to random measuring errors of about 0,1 m to 0,3 m depending on the distance from the camera to the ship (1 000 m to 3 000 m).

Since certain target points, particularly those chosen on the bow of departing ships, were frequently obscured from view, all three principal motions, and, consequently, the combined motions at the perpendiculars and shoulders of the ships, could not always be calculated. For the majority of the events the motions of only the port and starboard tips of the bridge superstructure and the stern of the departing ship could be obtained. The bridge motions, however, could be taken as approximately those of the ship's quarters since the bridge tips more or less coincide with the hull quarter points, the bridge width being equal to the beam of the ship.

3.2 Probabilistic Analysis

The motion time series, being, on average, of about 8 min duration, were accepted to be representative samples of a stationary random process so that the standard deviation of motion, s, could be used to characterise each record.

Normalized distributions of motion amplitude were derived for the motions at each target point and were compared with the well-known Rayleigh distribution given by

$$P(a) = \exp\left(-\tfrac{1}{2}\left(\frac{a}{s}\right)^2\right) \qquad \ldots 1$$

where a is the apparent amplitude of motion.

The calculated distributions were found to fit the Rayleigh distribution very well as is shown, for example, by the exceedence distribution of motion amplitudes at the port quarters of 70 different ships in Figure 2.

Longuet-Higgins (1952) postulated that the expected maximum amplitude, $E\{a_{max}\}$, in a given sample record with known standard deviation, s, and with Rayleigh-distributed apparent amplitudes, depends only on the record duration (number of oscillations, N) and is found from the relationship

$$E\{a_{max}\}/s = 2\left[(\ln N)^{1/2} + \tfrac{1}{2}\nu(\ln N)^{-1/2}\right] \qquad \ldots 2$$

with $\nu = 0{,}5772$ (Euler's constant).

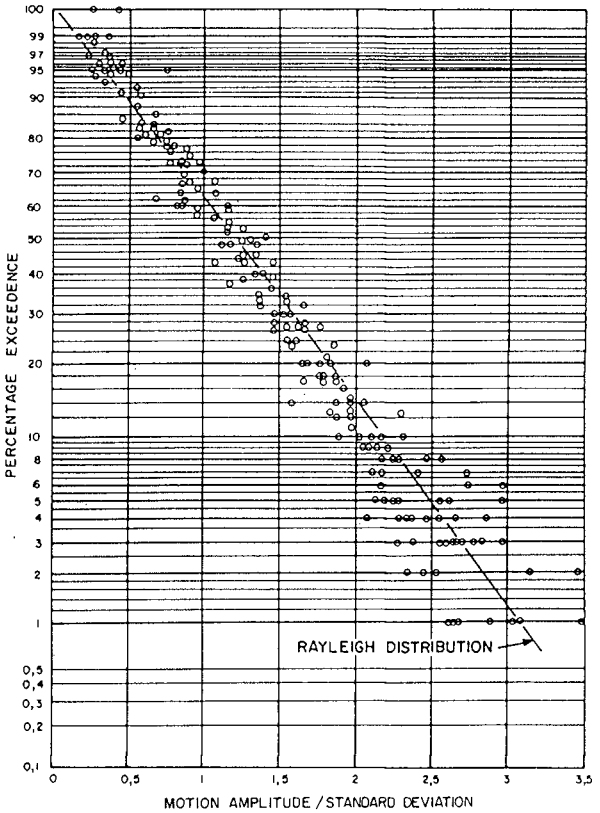

Figure 2 Distribution of motion amplitudes at port quarter

Using Equation 2, expected maximum motion amplitudes were calculated for 35 different records of from 20 to 50 oscillations and were compared with the recorded maxima as shown in Figure 3. Since Equation 2 apparently predicts the maximum motion amplitude well even for records of short length, this approach was adopted to estimate maxima from the sample standard deviations of motion and assuming that on average the ship underwent 100 oscillations for the period that she remained in the channel. Equation 2 then becomes

$$E\{a_{max}\} = 3{,}22\ s \qquad \ldots 3$$

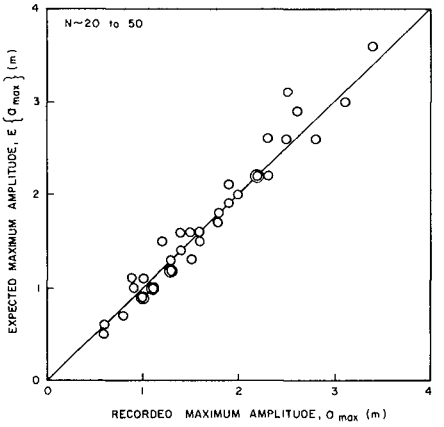

Figure 3 Expected versus recorded maximum motion amplitudes

3.3 Frequency Domain Analysis

For a selected number of events the incident wave records and ship motion records were spectrally analysed using a frequency resolution of 0,005 Hz.

The incident wave spectrum, S(f), was transformed to an apparent wave spectrum, $S_e(f_e)$ the wave spectrum encountered by the ship, using the relationships

$$S_e(f_e) = S(f) \frac{df}{df_e} \quad \ldots 4a$$

and

$$f_e = f - \frac{V}{\lambda} \cos\alpha \quad \ldots 4b$$

where V is the ship's speed, λ is the incident wavelength and α is the angle of wave incidence relative to the ship.

The incident and apparent wave spectra for event R065 are shown in Figure 4. The incident waves show a typical 1,7 m swell peaking at 15,4 s. With the dominant angle of wave incidence of 220° and taking the average speed of the ship to be 5 m/s (the ship in fact increased speed from 4,3 m/s to 5,5 m/s over a distance of roughly 2 km) the ship would have encountered the peak of the swell at about 12,2 s.

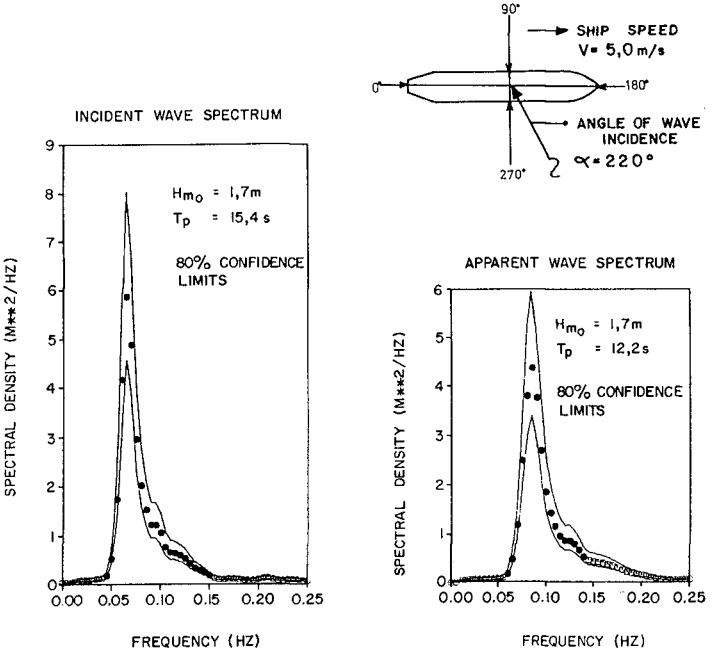

Figure 4 Incident and apparent wave spectra for event R065

Figure 5 illustrates the motion spectra of the ship, $S_S(f_e)$, for roll, pitch and heave and the combined motions were converted to translatory vertical motions at the ship's quarters.

From the assumption that a ship can be regarded as a linear system, the amplitude response function, $R(f_e)$, for each of the motions was calculated using the relationship

$$R(f_e) = [S_S(f_e)/S_e(f_e)]^{1/2} \quad \ldots 5$$

The amplitude response functions for roll, pitch and heave and for the combined vertical motions at the quarters for the ship monitored during event R065 are shown in Figure 6.

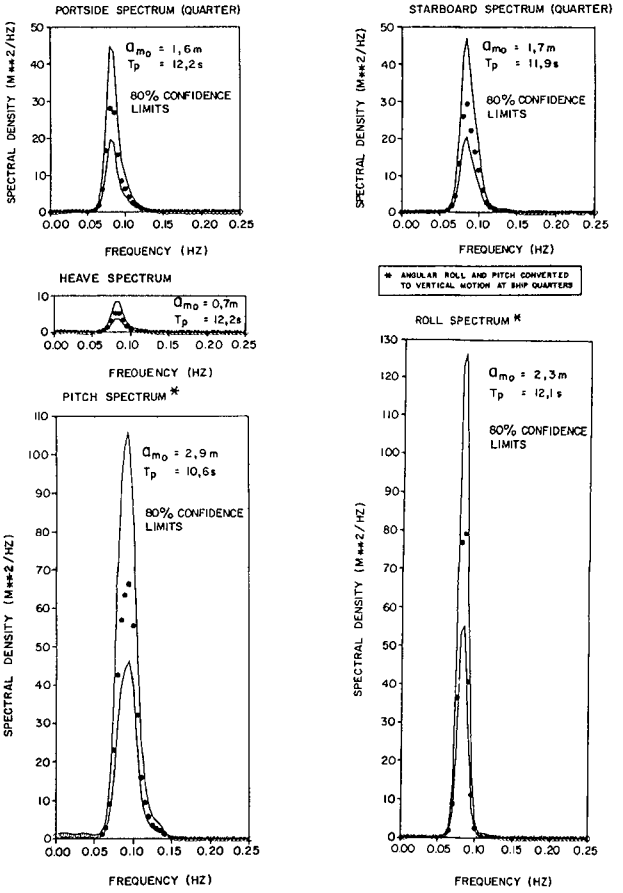

Figure 5 Sample ship motion spectra for event R065

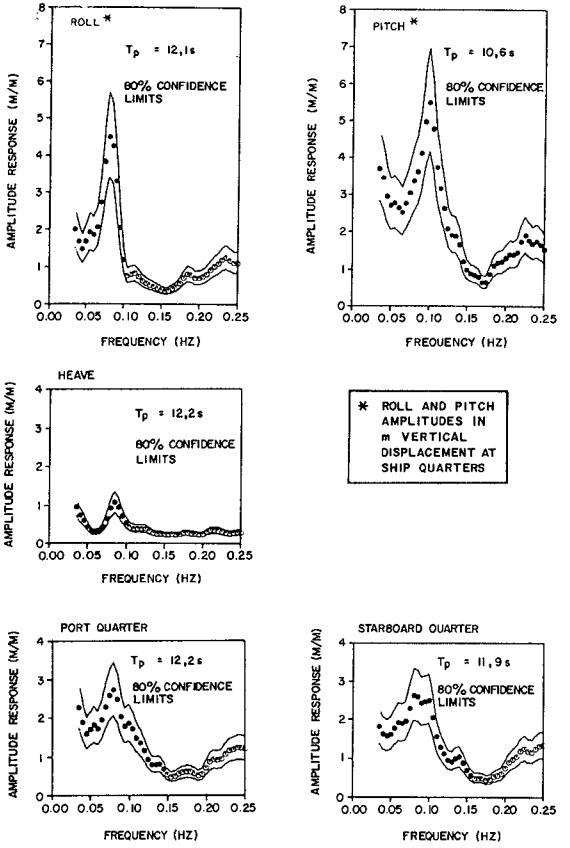

Figure 6 Sample amplitude response functions for event R065

4. DISCUSSION AND INTERPRETATION OF RESULTS

4.1 Maximum Ship Motions Versus Significant Wave Height

The expected maximum motion amplitudes calculated from the records with the largest standard deviations for each of the 70 processed events are shown plotted against significant wave height, H_{m_o} in Figure 7. The 18 events labelled with run numbers all took place under particularly adverse wave conditions.

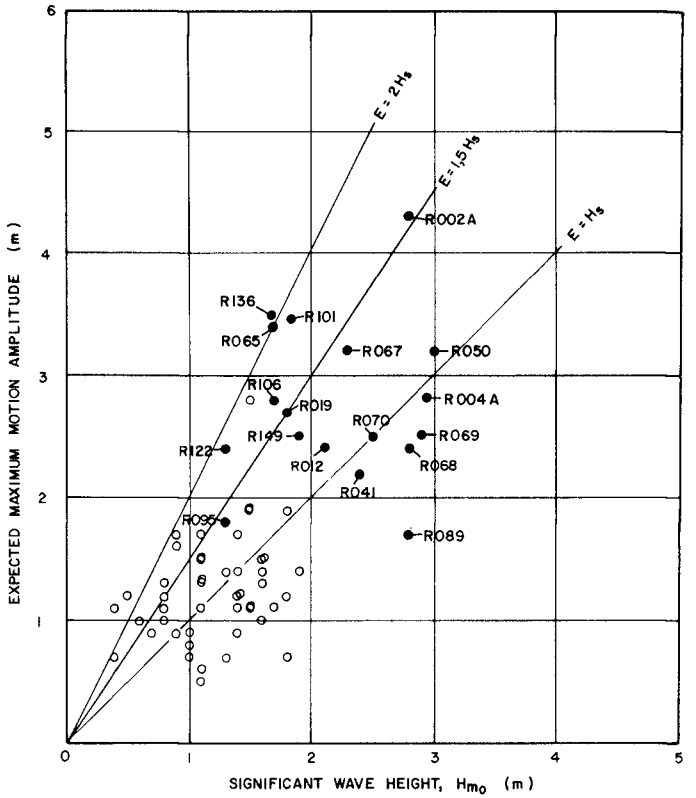

Figure 7 Maximum motion amplitude versus significant wave height

Gradients of 1:1, 3:2 and 2:1 were included showing that about 24 per cent of the data falls above the 3:2 gradient with significant wave heights generally less than 2 m. For larger wave heights the data always remained below the 3:2 gradient.

Inspection of the data enables the large variation in ship response to be attributed to a number of possible causes:

(i) **Variability of incident wave fields:** The wave spectra showed various stages of wind-generated seas and swells and were often composed of both. Swells approaching the channel varied in direction by as much as 70° and peaked at periods ranging from 11 s to well over 16 s. Heavy seas resulting from strong local winds were either beam-on or parallel to the channel line of orientation. The wind fields were, at times, of sufficient duration and strength to generate appreciable wave energy at periods of up to 12 s.

(ii) **Variations in ship's speed and heading:** Speeds ranged between 3 m/s (6 kn) and 6 m/s (12 kn) while ships, on leaving port, often increased speed by about 1 m/s to 2 m/s over a distance of 2 km. Angles of wave incidence relative to the ship also varied considerably due to variations in the ship's course. Figure 8 summarizes ship speed and angle of wave incidence for the 70 events considered in Figure 7.

(iii) **Differences in ship geometry and size:** The ships ranged in size from 95 000 dwt to 160 000 dwt and showed large variations in principal dimensions even for ships of equal displacement. Lengths between perpendiculars ranged from 240 m to 290 m and beams ranged from 37 m to 45 m.

(iv) **Differences in ship loading:** Ships leaving port were carrying from 100 000 t to just over 150 000 t of coal and had draughts ranging from 14 m to just over 17 m. The occasional entering ship was either in ballast or partly loaded.

Table I summarizes the principal ship dimensions and loading conditions for 18 of the 70 events (those numbered in Figure 7).

4.2 Hull Points of Maximum Vertical Motion

The wave-induced vertical motions at the perpendiculars, shoulders and quarters of the ships could be calculated from the measured target motions for 25 of the 70 processed events.

For these events expected maximum motion amplitudes at both starboard shoulders and starboard quarters (thus, on the weather side of the ship) were, at times, up to about 50 per cent larger than the motions at their port-side counterparts (Figures 9a and b). A comparison of the starboard motions at the quarters and shoulders of these ships (Figure 9c), however, showed no tendency for motions at one point to be consistently larger than those at the other point.

Motions at the forward perpendiculars (resulting purely from heave and pitch), moreover, were of the same order of magnitude as those at the shoulders and quarters (which also include roll), Figure 9d. This emphasizes the fact that, in the majority of cases, wave encounter was such as to also stimulate ship motions in the pitch mode.

4.3 Ship Response Functions

Ship response functions were calculated from the motion spectra and wave spectra for the 18 events identified in Figure 7. The ship particulars are listed in Table I and the wave and ship response data are summarized in Table II.

Observations of dominant wave directions were often limited to visual clinometer measurements only and could, sometimes, be very misleading, particularly with strong winds which caused very confused sea states. Thus, verification of the primary wave fields was obtained by relating incident wave spectra to meteorological conditions prior to and during these events. The synoptic weather charts were found to be useful for delineating the primary sources of wave generation and to confirm the deep-sea swell directions. These were then converted to wave directions in and around the channel by means of appropriate refraction diagrams, and the results were checked against the local observations.

The extreme swells recorded during these events can be seen to have propagated from three primary directions, these being SSW/SW'ly, S'ly and SSE'ly. The peak swell periods ranged from 11,7 s to as long as 17,8 s and significant wave heights ranged from 1,2 m to 3,0 m.

These swells were refracted considerably while approaching the channel because of the coastal bathymetry and this

resulted in channel wave directions being confined to a narrower sector ranging from 130° to 160° TN.

When allowance was made for the ship's heading relative to the channel orientation, the angles of wave incidence to the ships while leaving port ranged from about 190° to 235° (bow waves) and depended both on the directions and periods of the swells. The periods of wave encounter thus were shorter than those of the incident waves. Both ships entering port (events R041 and R070) encountered quartering waves with the resultant periods of wave encounter being much longer than those of the incident waves.

The motion amplitude response functions for the ships are characterised by the maximum amplitude response and corresponding period in Table II.

Maximum response ranged between 2,5 and 5,3 for roll at periods of wave encounter between 11 s and 12 s. Pitch and heave response could be assessed only for a limited number of these ships. Pitch resonance seemed to occur at periods between 10 s and 11 s. Maximum response factors at these periods were usually large, a value of 7 having been recorded at one occasion. Heave response, however, showed little, if any, gain at the normal periods of wave encounter.

Maximum amplitude response at the port and starboard quarters of the ships showed values of up to 4, but generally remained below 3.

Motion amplitude response due to combined roll, pitch and heave motions were much less than would have resulted from simply adding the contributions algebraically. This indicates strong phase dependence between the three principal motions.

5. CONCLUSIONS

The field monitoring programmes have been successful in providing useful data on wave-induced vertical ship motions as well as on ship speeds and ship trajectories under a variety of wave conditions.

The data, particularly the amplitude response functions, will prove valuable for the calibration of both mathematical and physical models which are presently being developed and which will be deployed to assess harbour accessibility for future deeper-draught ships. The measurements are also useful in verifying and updating existing allowance criteria based on limited earlier model tests.

Since vertical wave-induced ship motions are intrinsically narrow-banded and amplitudes are found to be Rayleigh-distributed, maxima can be estimated well by means of the Longuet-Higgins approach.

Though plots of expected maximum motion amplitude versus significant wave height showed large variations due to differences in both the wave conditions and ship characteristics, maximum amplitudes were shown to **never exceed twice the significant wave height** in magnitude.

Starboard motions were frequently **larger** than port side motions while motions at the perpendiculars of the ships were often of the same order of magnitude. It became evident that both pitch and roll contributed largely to the vertical hull motions while a strong phase dependence exists between all three principal motions.

The longer period swells (14 s to 16 s) proved to be most critical with regard to vertical ship motions for ships leaving port since these ships tended to encounter the waves at periods close to their natural resonance periods. These swells, however, would have less effect on ships entering port since the periods of wave encounter would then be far removed from their own natural periods of oscillation.

OPERATIONAL PROCEDURES RICHARDS BAY HARBOUR

by

J A Zwamborn* and P J Cox**

ABSTRACT

The new port of Richards Bay on the east coast of South Africa (Figure 1), was officially opened in April 1976 and was mainly built for the export of bituminous coal. Exports increased from an initial 2,5 million tons per annum to 26,5 million tons per annum in 1981. Extensions are now under way to increase this further to 44 million tons per annum by 1987.

Because near-beam long swells occur frequently at Richards Bay, special care was taken with the design of the entrance channel. These swells cause much greater vertical ship motions than normally occur in other ports around the world and a 24 m deep outer channel was therefore provided for the 17 m draught design ship (40 per cent underkeel allowance, based on physical model tests).

Vertical motions recorded at Richards Bay as part of a comprehensive research project into ship motions in shallow water confirmed that this large underkeel allowance is realistic. Experience with ship manoeuvring also indicated that the channel width (300 to 400 m) and the stopping length (6,1 km) are adequate, probably for ships up to about 250 000 dwt.

To assist the port operating staff in deciding whether a particular entry or departure of a loaded vessel under adverse conditions is safe, particularly with regard to underkeel clearance, a **Port Operation Manual, Mark I,** was prepared. This manual describes the procedures for collecting ship and environmental data and contains diagrams from which the limiting wave height or the minimum required tide level can be read off as function of wave direction and the ship's draught.

This manual has been in use since October 1981 and has already been found very valuable in the operation of the port. As the research into ship motions progresses, the manual will be updated.

INTRODUCTION

Richards Bay harbour was officially opened to traffic on 1 April 1976. The harbour was built for the handling of bulk cargoes, initially, mainly the export of bituminous coal. Situated on the Zululand coast between Durban and Maputo, it was the nearest suitable site to the Transvaal and the Orange Free State coal fields. Total cargo handled during 1981 was 29,4 million tons of which 26,5 million tons was coal.

A detailed description of the design and construction of the harbour was given by Campbell and Zwamborn (1977).

Layout

The overall harbour layout is shown in Figure 2. The relevant dimensions of the **entrance channel** are as follows:

length,	outer channel	~ 3,5 km
	inner channel	6,1 km (available stopping length)
width,	seaward end	400 m
	tapering to	300 m (inside breakwaters)

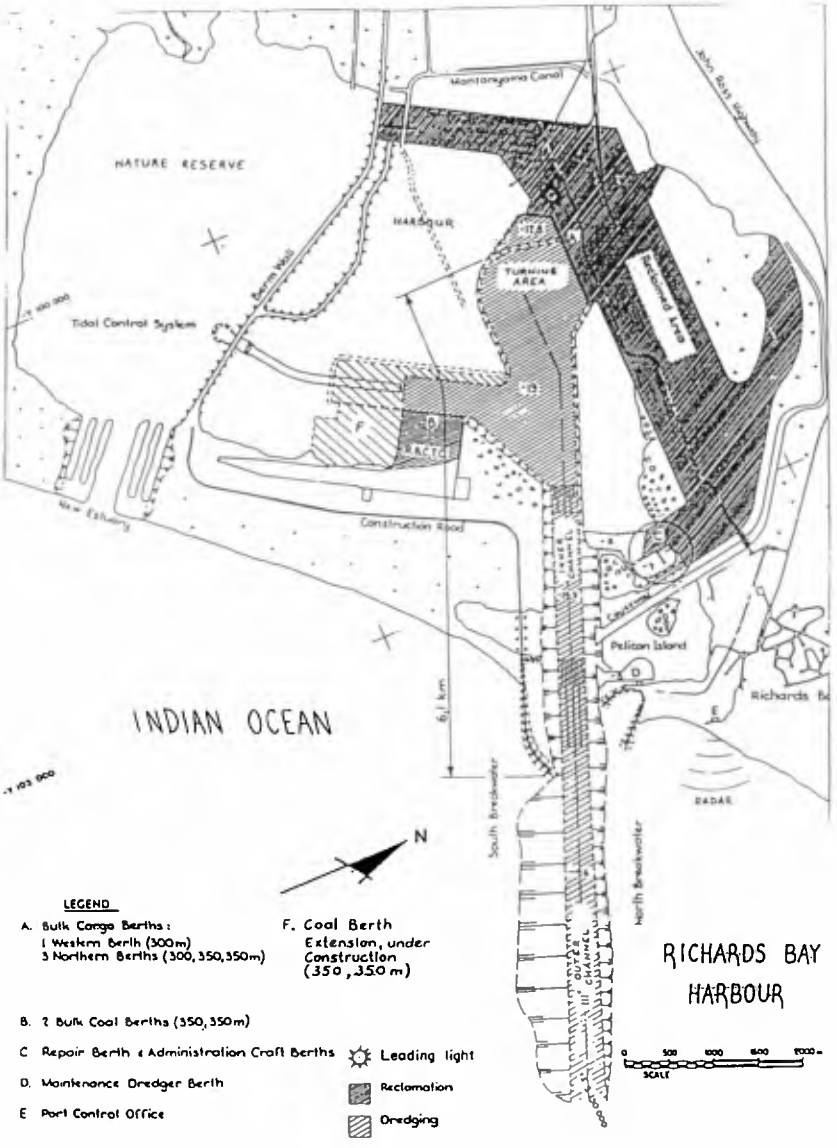

Fig. 2 Harbour layout

depth, outer channel - 24 m CD (Chart Datum ≈ LWOST)
transition area - 22 m CD
inner channel - 19,5 m CD
turning and
mooring area - 19 m CD.

The foundation level of the coal quays was set at -23 m CD. A turning area with a diameter of 1000 m was provided.

Design Criteria

The channel dimensions were originally determined to allow the entry and departure of 17 m draught ships (about 150 000 dwt) for 99 per cent of the time, with a tide level assumed to be at 0,0 CD (Campbell and Zwamborn, 1977). However, the possibility of handling larger ships, up to 20 m draught (about 250 000 dwt), was taken into account throughout the design stage. For this reason, the coal quays were founded at -23 m, to allow for possible future dredging to -22 m CD and the breakwaters were placed in such a way that the entrance channel could be widened and/or deepened if necessary.

Design Studies

The harbour design was assisted by a detailed programme of field measurements, sediment model studies, breakwater stability tests, wave penetration studies and physical ship model tests (Campbell and Zwamborn, 1977; Zwamborn and Grieve, 1974).

The latter were undertaken to assist in the determination of the entrance **channel dimensions.** They were carried out in the 1 in 100 scale wave penetration model using a self-propelled radio-controlled model of a 150 000 dwt, 17 m draught bulk carrier (Hoppe, 1972). Most tests were carried out with near-beam regular waves of near-resonance frequencies, conditions, which occur frequently at Richards Bay. The test results indicated that:

- a maximum overdraught ('sinkage') of 6 m is to be expected for the 1 per cent occurrence SSW'ly swell, indicating a minimum channel depth of 24 m, allowing 1 m underkeel **clearance** (thus underkeel **allowance** is 7 m or 40 per cent of the design draught);

- a channel width of 300 to 400 m would be sufficient for single-lane traffic during all but the SSW design waves for **entry** speeds of 3,5 to 4 m/s (7 to 8 kn) and for ships **leaving** under design conditions at a speed of 3,5 to 4,5 m/s (7 to 9 kn);

- an approximately 150 m wider entrance channel would be necessary for **entry** under the SSW'ly design wave con-

dition, alternatively the entry speed would have to be increased to 4,8 m/s (9,5 kn) to avoid transgression of the 300 to 400 m wide channel bounderies.

Based on information on **stopping distances** available at the time, it was accepted that 150 000 to 250 000 dwt loaded ships entering the harbour at $\leq$ 4 m/s (8 kn) could be stopped within the available 6,1 km stopping length, provided powerful tugs could attach and assist when the ship was moving at a speed of $\leq$ 2 m/s (4 kn).

A group of 20 pilots who were also asked to operate the model concluded that the handling of the model ship was generally realistic but they thought that its movements were somewhat excessive and initially they were reluctant to enter at speeds much in excess of 1,5 to 2 m/s (3 to 4 kn).

Future Expansion

The first-phase development at Richards Bay was mainly based on a 2,5 million tons per year export contract of bituminous coal and anthracite, as from April 1976. As a result of the oil crisis in the early seventies, the demand for coal increased dramatically and the export rate increased rapidly to the present (1981) figure of 26,5 million tons per year.

Extensions to the coal berths and loading facilities (Figure 2) are under way at present to increase the export capacity to 44 million tons per year. These extensions are scheduled to be completed by 1987. Moreover, the South African Government has approved export permits up to a total of 80 million tons per year and further extensions to the harbour must therefore be expected in the future.

The harbour was originally designed for 17 m draught ships. From the start the official draught restriction was 17,1 m (10 per cent underkeel clearance in the inner harbour) although draughts up to 17,3 m were allowed at certain times to assist with the ship motion monitoring programme. Shipping agents approached the harbour authority during 1980 for use of 17,6 m draught ships for early 1983 (about 185 000 dwt). This increase of draught to 17,6 m could be achieved by using the tide, but any further increase would require a certain amount of dredging in the turning/mooring areas and in the inner channel.

Finally, as mentioned above, allowance was made in the foundation level of the coal quay for 20 m draught ships (250 000 dwt) and studies are underway at present to determine the dredging depths in the outer and inner entrance channels required to accommodate these ships for 99 per cent accessibility.

EXPERIENCE IN THE OPERATION OF THE PORT

A maximum degree of flexibility was aimed at in the design of the entrance channel because it was realised that, as experience was gained in the operation of the port, particularly with regard to negotiating the entrance channel, adjustments in the channel dimension or in the limiting operational conditions might have to be made at a later stage. It was, therefore, important to gather any information on possible problems experienced during operation related to the channel depth, width and length.

Ship Statistics

Because Richards Bay is mainly an export port for coal, large bulk carriers normally enter the port light (about 10 to 12 m draught) and leave loaded (up to 17,1 m draught). This reduced the entry problem for this traffic because light ships are much easier to stop than a fully loaded ship although the ship's larger freeboard could cause additional manoeuvring problems during strong SW or NE wind (a 150 000 dwt bulk carrier has a displacement of about 180 000 t when fully laden but only 110 000 t when in full ballast).

However, there are occasions on which fully or near-fully laden bulk carriers come in to 'top up' their coal load or for bunkers and these occurrences were of particular interest in checking the design.

The use of the port by VLC's in excess of 100 000 dwt can be summarised as follows (1981 data):

Ship size (dwt)	< 50 000	50-100 000	100 - 150 000	> 150
Number of ships	367	106	160	29

This gives a total of 662 ship movements (compared with 522 in 1979 or a growth rate of 13,5 per cent per year).

The deepest draught for a **sailing** VLC in 1981 was 17,37 m.

During the year eight ships **entered** in almost fully loaded condition (to 'top up') with a deepest draught of 16,8 m.

Port Control

Apart from the usual lights on the ends of the breakwaters the centre line of the channel is marked by leading lights situated at 6,7 and 9,2 km from the end of the main breakwater at 27 and 50 m above CD, respectively (Figure 2). The lights consist of sealed beam units with the following light power:

- front light, red: 4 800 000 candelas during the day (fixed) and 57 200 candelas at night (flashing);
- rear light, white: 3 600 000 candelas during the day (fixed) and 57 200 candelas at night (flashing).

Radar Responder Beacons (Racons) have been provided on the leading light towers to mark the channel centre line on the ship's radar should the leading lights become obscured by rain or mist (radar particulars: 9 300 to 9 500 MHz, 72 s sweep, 360° coverage, 20 km range, continuous transmission).

The port control office is situated 1,5 km north of the harbour entrance at 55 m above sea level. Apart from the usual radio equipment, 30 and 100 mm wavelength **radar** sets are installed in the operating room. The pilots and the Assistant Port Captain are also stationed at the port control office (Figure 2, E).

Tugs and Pilotage

The following **tugs** are available at Richards Bay to assist with entry/departure manoeuvres:

Type	Number	Power HP/kW	Bollard Pull (t)	
			Ahead	Astern
Kort-Nozzle	2	4400/3200	52	28/32
Voith-Schneider	1	4000/2940	40	34

Compulsory pilot service is provided by the South African Transport Services, at present only during daylight hours, extended to 21h00 on special request for unberthing loaded coal vessels.

For entry, the pilot boards 5 to 9 km offshore, depending on whether the ship is light or fully laden. A 21,5 m long pilot boat is used for this purpose; it goes alongside the ship which makes a lee from the wind and sea. It is virtually always possible for the ship to provide a lee to the pilot boat but during heavy swell and sea conditions (winds

exceeding about 40 kn or 20 m/s) the pilot boat itself becomes difficult to handle.

For departing ships, the pilot boards at the coal quay and normally disembarks just before the ship leaves the protection of the main breakwater. Thereafter, further advice is provided by port control on the basis of the ship's radar image which is carefully monitored as the ship passes through the outer channel.

Entry Manoeuvres

Typically, an entry manoeuvre of a VLC at Richards Bay goes as follows (Figure 3, a):

- pilot boards 7 to 9 km offshore
- ship lines up with leading lights, speed 6 to 8 kn
- approaches entrance with engines slow to dead slow, speed 5 to 7 kn
- enters between breakwaters with engines dead slow to stopped, speed 4 to 6 kn
- tugs attach in inner channel, one or two for'd and one aft
- ship turns to port towards coal quay, reverse power
- starboard turn, reverse towards coal quay
- pilot leaves the ship at the coal quay.

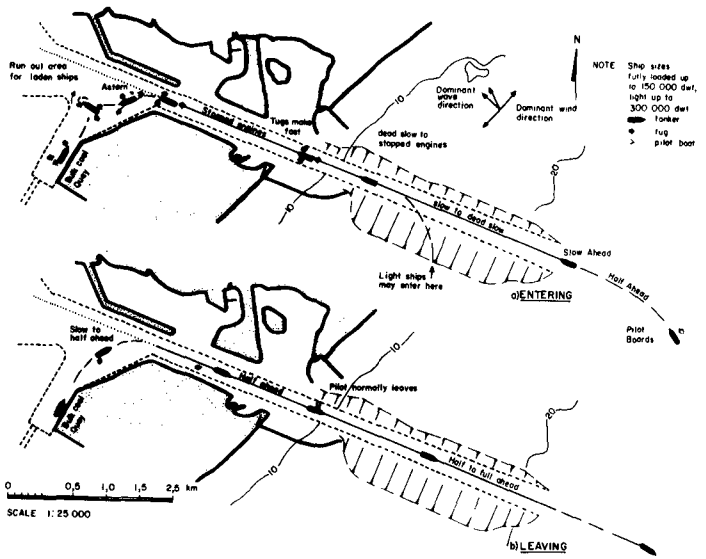

Fig. 3 Typical manoeuvres

Departure Manoeuvres

Normally, the departure manoeuvre goes as follows Figure 3, b):

- pilot boards at the coal quay
- ship lifts off and turns into inner channel, slow to half ahead, one tug in attendance
- ship moves through inner channel, half ahead, speed 5 to 8 kn
- pilot leaves ship between breakwaters
- ship moves through outer channel half to full ahead, speed $\geq$ 9 kn
- progress and position is monitored on radar at port control from where advice is given on course adjustments, if necessary.

Discussion and Comparison with Model Predictions

Ships enter Richards Bay at minimum speeds of between 4 to 6 kn (2 to 3 m/s), depending on the conditions. Entering at these speeds allows, mostly, light ships of the 150 000 dwt class to be stopped and turned in the coal berth area which means a stopping length of 4 to 4,5 km. Further data on the entry of laden vessels under near-design conditions will be collected but, based on present experience, there is little doubt that the 6,1 km available stopping length will be sufficient for up to 250 000 dwt loaded vessels entering at speeds of up to 8 kn (4 m/s), perhaps even 9 kn (4,5 m/s).

Also, tugs can make fast at virtually any manoeuvring speed but only tractor-type tugs can start to assist with **steerage** at speeds of 4 to 5 kn (2 to 2,5 m/s); conventional tugs cannot 'open-up' at speeds above 2 to 3 kn (1 to 1,5 m/s) and can thus only assist a little by reducing the ship's speed. Thus, when tractor tugs are available (at present there is only one tractor tug, the Voith-Schneider tug), relatively higher entry speeds will be possible, if required, for the control of the ship during adverse conditions; alternatively, larger ships could probably be stopped within the available stopping length.

Finally, the available channel width was found to be adequate in most circumstances. However, it is imperative that under southerly wind and wave conditions (near-beam conditions) sufficient speed be maintained to ensure control of the ship, as indicated by the model tests (that is, 7 to 8 kn for entry and 7 to 9 kn for departure). This is borne out by an occurrence where a departing loaded VLC was forced over the north channel bank under these conditions while travelling at only 5 kn (2,5 m/s) and two recent occurrences where similar ships leaving at a speed of about 9 kn were able to remain in the channel although leaving

under near-design conditions (measured wave height, $H_S \simeq$ 2,7 m, wave period, T_Z = 10 s, wave directions, $\emptyset$ = 160°, 25 kn, SSW wind). Both ships first took a sharp turn to port (north) just outside the breakwaters, probably due to a local northbound current. After nearly 'locking' into the waves (heading parallel to the waves) the ships took a very strong 'sheer' to starboard. Although these manoeuvres included course changes of + and -15°, the ships remained in the channel.

SHIP MOTION STUDIES FOR RICHARDS BAY HARBOUR

A programme of free moving ship motion studies has been undertaken for Richards Bay, including prototype measurements, mathematical modelling and physical modelling. The diagram given in Figure 4 shows all the elements of the studies, and also the various interactions between the 'three-legged' approach (the moored ship studies are done for Saldanha Bay harbour and are not discussed here).

Purpose of Studies

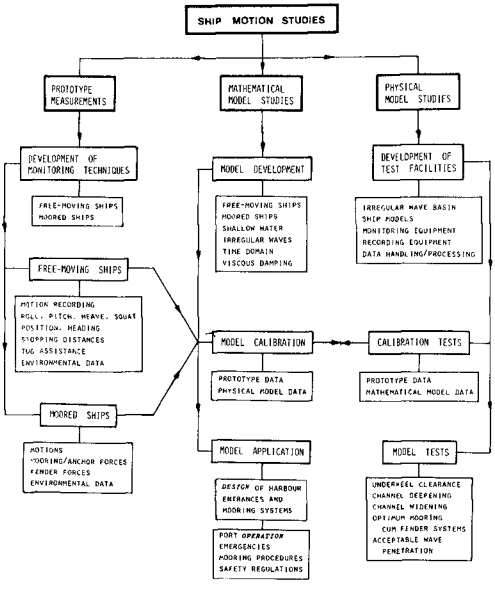

Fig. 4 Ship motion studies flow diagram

The above studies were undertaken for Richards Bay:

(a) to confirm the predictions based on the original hydraulic model tests,

(b) to determine the conditions under which 18 m draught ships could use the present entrance channel safely,

(c) to determine minimum required dredging depths to allow 20 m draught ships to use the port with a maximum downtime of 1 per cent (regarding underkeel clearance), and

(d) to develop guidelines to assist with the safe operation of the port, particularly with regard to required underkeel allowance under various conditions.

Prototype Measurements

A photographic technique has been developed which enables the accurate monitoring of the course, speeds and vertical motions of all ships using Richards Bay harbour (Zwamborn and Van Wyk, 1981). Since August 1978, 175 ships with a dead weight tonnage exceeding 100 000 dwt have been monitored and some of the results are presented in another paper to this conference (Van Wyk, 1982). The results of these measurements provided valuable data with regard to entry and departure speeds vis-à-vis stopping distances and ship handling (discussed above) and they indicated that the adopted underkeel allowances are of the right order.

More data on near-design conditions (small underkeel clearances) are, however, required and arrangements have been made to charter loaded bulk carriers when these conditions occur, to carry out special monitoring runs.

Mathematical Modelling

To determine the required channel depths for ships larger than those using the port at present, a mathematical model will be used. This model will first be calibrated against available prototype data obtained from the measurements. A deep-water strip-theory model was tried first but the results were not satisfactory. A shallow-water version and a shallow-water three-dimensional source technique model are therefore being used at present.

Once properly calibrated, the mathematical model will be invaluable in the operation of the port.

Physical Modelling

As soon as a fully-irregular wave basin becomes available, model runs will be made reproducing typical prototype

measuring runs, to check possible scale efffects. Thereafter, the physical model will be used to provide additional **calibration data** for the mathematical model, particularly regarding different wave directions, as well as for a final check on the required dredging depths to accommodate ships up to 250 000 dwt.

APPLICATION OF SHIP MOTION STUDIES TO PORT OPERATION

The large underkeel allowances at Richards Bay, reducing from 7 m in the outer channel to 2 m inside (at low water), were dictated by the regular occurrence of long waves with near-beam directions. These long waves cause considerably greater sinkages than those due to the squat and trim, which are determinative in many other ports. It was therefore considered necessary to use available information on ship motions due to waves, to determine the expected overdraught during the passage of the ship through the outer and inner entrance channels in order to decide under what heavy weather conditions vessels would be permitted to negotiate the channel. This procedure also requires knowledge of the environmental conditions at or near the time of passage.

Wave Directions

Vertical ship motions are greatly influenced by wave direction and it was therefore necessary to determine the wave directions,preferably those in the entrance channel. This is done by using radar, wave clinometer or by pilot boat observations.

Wave direction in the channel can be read off the **radar** screen, provided there is sufficient backscatter from the water surface,that is, a wind chop superimposed on the swell. For better definition, the short wave length (3 cm) or X band is used. Wave direction is observed in the channel about 1 to 2 km out to sea.

If no radar direction can be observed, a **wave clinometer** direction reading is used. The wave clinometer is an inclined (3°) graduated telescope directed onto a buoy anchored in 13 m water depth at about 800 m offshore and 1600 m north of the entrance channel.

If both methods were to fail or when conditions are such that confirmation is advisable, the **pilot boat** can be used to record/check the swell directions in the channel by heading into the swell and reading the compass direction.

Wave Height

Vertical ship motions are generally assumed to be proportional to wave height. Preferably, the wave heights should

again be measured in the entrance channel but this is impracticable. The measurements are normally made with a **waverider buoy,** anchored in 20 m water 1 km south of the channel and about 1,5 km out to sea, and with a receiver at the port control station.

Available data on ship motions, that is, the maximum expected sinkage during passage through the channel is related to the significant wave height, H_S. A quick estimate of H_S can be made by reading off the waverider chart the maximum wave heights for three consecutive 3 min records and calculating the mean, that is, $H_S \approx H_{rep} = \frac{H_1+H_2+H_3}{3}$. This wave height, H_{rep}, is a conservative value. Assuming Rayleigh wave height distribution and considering that a ship will on average be 20 min in the channel, $H_{rep} \approx H_{S\text{-}20\ min}$ (Longuet-Higgins, 1952).

In the event of waverider failure, an estimated wave height is obtained from the **wave clinometer.** The average vertical movements of the anchored buoy, relative to fixed graduations in the telescope, is determined over a period of three to five minutes.

Wave Period

Vertical ship motions are also very dependent on the **wave periods.** Because of the regular occurrence of long-period swells, near-resonance conditions normally occur, particularly under moderate to heavy swell conditions. Although wave period records are available from the waverider and the wave clinometer, these are not used in the present operational procedures, which assume that most of the wave energy is concentrated near the natural roll/pitch periods of the ships.

Tide Levels and Water Depths

The lowest tide level, Z_O, during the passage of a ship through the channel (on average 20 min) must be used to determine available water depth relative to the proclaimed channel bottom level (taking into account possible siltation, ΔZ).

Tide levels are read from an automatic **tide recorder** or, in the absence thereof, from the tide tables.

Ship Motions in the Outer Channel

Because of the lack of sufficient directional spread in the conditions during prototype monitoring, the first version of an 'operational model' was based on the results of model

tests with a 200 000 dwt tanker (Koelé and Hooft, 1969) and a 150 000 dwt bulk carrier (CSIR, 1976).

Figure 5 gives the expected maximum sinkages as functions of wavedirection for a 18,9 m draught ship, proceeding at 4 m/s (8 kn) in a 10 km long channel of various depths, under irregular swell with H_S = 1,5 m and T_Z = 10 s (zero-crossing wave period). The sinkages also include squat, linearly extrapolated for greater underkeel clearances (CSIR, 1979).

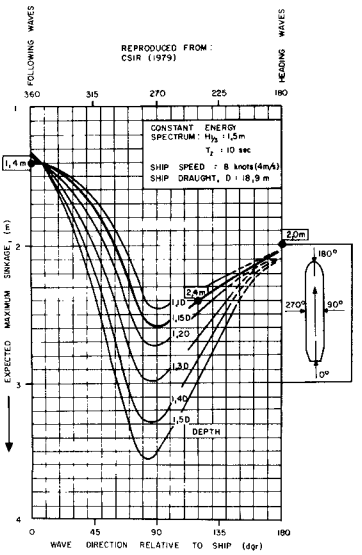

Fig. 5 Sinkage of 200 000 dwt model tanker as function of wave direction and water depth

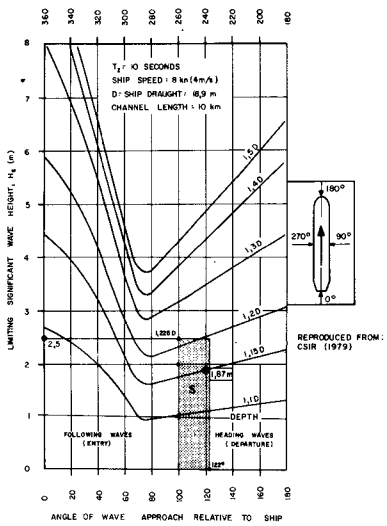

Fig. 6 Limiting significant wave height for which a ship may touch the bottom

Figure 5 was converted into Figure 6 giving the limiting significant wave heights as functions of wave direction and underkeel allowance. In this conversion, linearity was assumed between (a) sinkage due to waves and wave height and (b) sinkage due to squat and trim and underkeel allowance; the latter reduces from 0,7 m for 10 per cent to 0,0 m for 50 per cent underkeel allowance. For example, for a wave direction of 240° and 15 per cent underkeel

allowance, Figure 5 gives a total sinkage of 2,4 m of which 0,65 m is due to squat and trim. The limiting H_S then follows from $0,15\ D = \frac{H_{S-lim}}{1,5}\ (2,4 - 0,65) + 0,65$ or, since D = 18,9 m, H_{S-lim} = 1,87 (see Figure 6).

Using Figure 5 and assuming linearity between sinkage and wave height the expected maximum sinkages for the 200 000 dwt model ship in the Richards Bay channel are compared with the maximum sinkages measured in the original Richards Bay tests using a 150 000 dwt model in Figure 7 (CSIR, 1979). The results are seen to be compatible with a maximum sinkage for beam waves of about 6 m and Figures 5 and 6 were therefore considered to be a safe basis for determining maximum sinkages for bulk carriers up to about 250 000 dwt passing through the Richards Bay outer entrance channel.

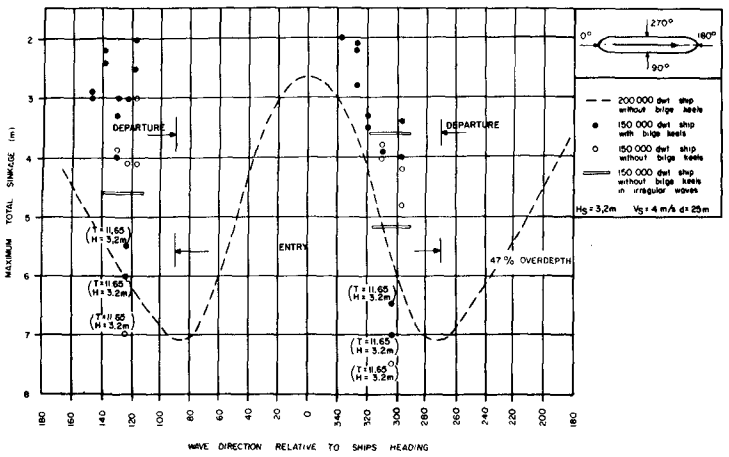

Fig. 7 Comparison of maximum sinkages of 150 000 dwt and 200 000 dwt ships

Ship Motions in the Inner Channel

The waves entering the harbour will run parallel to the channel axis and will therefore be either following (0°) or heading (180°) waves for entering and leaving, respectively (see Figure 6). To determine the ship motions in the inner channel the local wave heights must be known. These were obtained from the results of the Richards Bay physical model tests which showed maximum wave penetration for the

deep-sea wave direction of 146° and very low penetration for ESE, the direction parallel to the channel axis (Zwamborn and Grieve, 1974).

Two specific areas were chosen for ship motions determination, namely, the 'top of slope', where the channel depth changes from -22 m to -19,5 m CD and 'Sandy Point', just before the channel widens into the coal berth area (-19,5 m CD). Figure 8 shows the relationships between wave penetration and wave direction for these two areas using wave refraction data to convert deep-sea to entrance channel wave directions (Moes and Van Niekerk, 1981). Accepted penetration values for the entrance channel directions are also shown in this figure. For example, for the direction sector SE, the penetration factor is 0,6 at 'top of slope' and 0,2 at 'Sandy Point'.

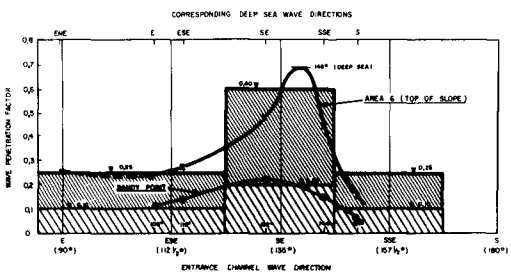

Fig. 8 Wave penetration at 'top of slope' and 'Sandy Point' versus wave direction

On the basis of the above and using Figure 5 (following and heading waves), the limiting wave heights at the positions in the inner channel could be found. For example, taking the available depth at the 'top of slope'at -20 m CD and allowing a minimum underkeel clearance of 1 m, the available depth at low water in this area is 19,0 m. For a ship **entering** under SE'ly waves, the wave penetration factor is 0,6 while the total sinkage for 1,5 m high waves is 1,4 m. Assuming 0,5 m squat and trim the sinkage due to waves is thus 0,9 m. Now the maximum permissible sinkage Z_{max} = $19,0 - D = 0,5 + \frac{0,9}{1,5} \times 0,6\ H_{s-lim} = 0,5 + 0,36\ H_{s-lim}$ or $H_{s-lim} = \frac{18,5-D}{0,36}$, which is a linear relationship between draught D and H_{s-lim}. For a ship **leaving** under SE'ly waves, the total sinkage for heading waves must be used, namely, 2,0 m for 1,5 m high waves. Thus the sinkage due to waves is 1,5 m (0,5 m squat). This leads to the following relationships:

$$Z_{max} = 19,0 - D = 0,5 + \frac{1,5}{1,5} \times 0,6\ H_{s-lim} = 0,5 + 0,6\ H_{s-lim}$$

$$\text{or } H_{s-lim} = \frac{18,5-D}{0,60}.$$

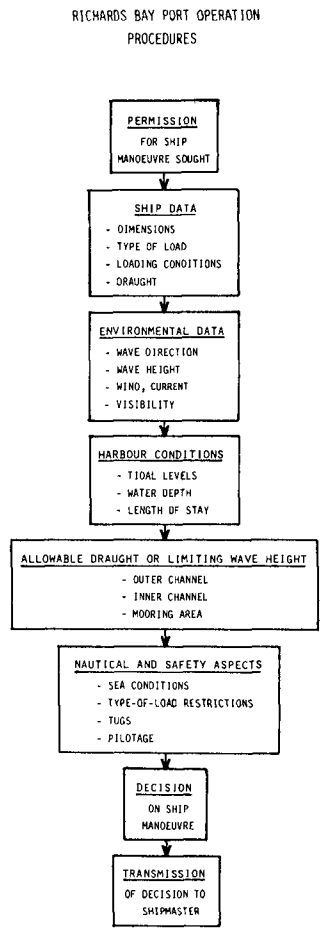

Fig. 10 Port operation procedures

PORT OPERATION MANUAL, MARK I

The first version of a port operation manual (CSIR, 1981) was drawn up on the basis of the data and assumptions discussed above. It is realised that the data are limited and that the problems have been over-simplified; this is the reason for a conservative approach throughout. The main purpose of Operation Manual, Mark I was to provide the nautical operating staff at Richards Bay with a first tool to assist in their decision making, with regard to under-keel clearance, on acceptable conditions for entry/departure of VLC's under severe conditions.

Logistics and Procedures

Port operation logistics are shown diagrammatically in Figure 9. Although for routine operations Port Control can apply the operation manual directly, it is the Harbour Engineer's responsibility to ensure that the manual is correctly interpreted, kept up to date and amended when necessary. The Harbour Engineer should also be consulted on special cases (e.g. emergency entry of larger then design vessels) and he is responsible for providing up-to-date information on possible channel siltation.

Operation procedures are shown diagrammatically in Figure 10. Operation Manual, Mark I, forms an important part of these general procedures. It contains the following steps/instructions:

(i) Obtain details on the ship's draught, D (maximum stationary value), from the ship's master;

(ii) record environmental conditions, including wave direction, $\emptyset$, wave height, H_{rep}, and tide level, Z_o;

(iii) check available water depths in the area concerned and calculate the equivalent draught ($D_{eq} = D - Z_o$); and

(iv) determine the limiting wave height, $H_{rep,lim}$, for a ship with equivalent draught D_{eq} and angle of wave approach, $\emptyset$, and check whether the recorded wave height is equal to or smaller than the limiting wave height, that is, $H_{rep} < H_{rep,lim}$;
alternatively
determine the minimum tide level, $Z_{o,min}$, required for a ship with a draught, D, angle of wave approach, $\emptyset$, and wave height, H_{rep}, and check whether the actual tide is equal to or higher than the limiting tide level, that is, $Z_o > Z_{o,min}$.

Specific instructions on how to determine the environmental and other data are included in the Manual (CSIR, 1981).

Draught Allowance Criteria

To facilitate step (iv) above, easy-to-read coloured draught allowance diagrams were prepared and are also included in the manual, one for entry and one for departure (the latter is shown in Figure 11). These diagrams allow for a minimum underkeel clearance of 1 m anywhere in the harbour or entrance channel. The straight lines in Figure 11 represent the conditions in the inner channel (example equations derived in the above), the dotted vertical line is the limit for the turning and mooring area (see Figure 11, maximum D_{eq} = 19 - 1 = 18 m) and the curved lines represent the limiting conditions in the outer channel.

The latter are obtained from Figure 6. For example, taking the S direction sector (169° to 191°), the wave angles relative to a leaving ship travelling on the channel centre line (111° to north, corresponding to 180° relative to the ship) will be 122° to 100°. Considering the limiting wave height of 2,5 m, the largest required depth for this wave height in the S direction sector is 1,225 D (Figure 6). With a channel depth of 24 m and 1 m underkeel clearance, the allowable draught follows from 1,225 D = 24 - 1 or D = 18,7 m. This gives one point of the curve for S'ly waves (see Figure 11).

It is clear from Figure 11 that a ship with D = 18,7 m would be able to be in the port only when its equivalent draught, D_{eq} = 18 m or with a minimum tide of 0,7 m. This brings out the interesting point that, with the present channel depths, the inner channel forms a greater limitation to large draught ships than the outer channel, particularly for SE'ly waves (see Figure 11).

Example Applications

Example 1: Loaded carrier to leave port

Ship draught	D	=	17,0 m
Recorded wave direction	Ø	=	169°
Recorded representative wave height	H_{rep}	=	3,8 m
Tide level at time of manoeuvre	Z_o	=	0 m

Can this ship leave the port?
Determine $D_{eq} = D - Z_o = 17,0 - 0 = 17,0$ m.
For S direction sector, Figure 11 yields $H_{rep,lim}$ = 3,45 m.

Since this is 0,35 m less than the recorded value, the ship cannot leave the port.

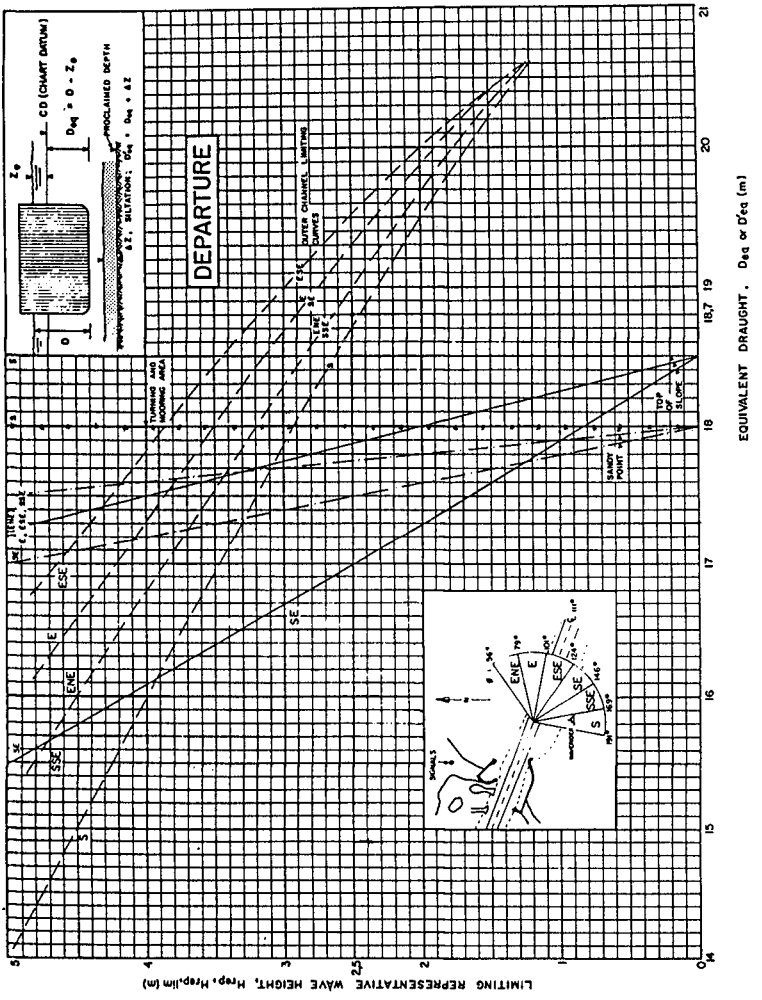

Fig. 11 Allowable draughts during departure

Example 2: Loaded carrier to leave port
Taking the same ship as in Example 1 and assuming that the sea conditions remain the same, what is the minimum tide required for the ship to leave?

For H_{rep} = 3,8 m, D_{eq} = 16,4 m (Figure 11, S direction sector).
Thus, $Z_{o,min}$ = 17,0 - 16,4 = 0,6 m.

Under these severe conditions this ship will thus have to wait until a minimum tidal level of + 0,6 m CD is reached.

Practical Experience in Using the Manual

The "Richards Bay Harbour Port Operation Manual, Mark I" has been in use since October 1981. Records of ships in excess of 100 000 dwt which enter or leave the port under fairly rough conditions are kept on special record sheets provided to 'port control'. These records include information on the ship, its loaded condition, recorded wave direction and height during passage through the channel and tide records. The calculated equivalent draught (D_{eq}) and the limiting wave height ($H_{rep,lim}$) read from the draught allowance diagrams and the decision taken are also recorded on these sheets.

So far (August 1982), 97 departures and one entry of loaded coal carriers between 101 600 dwt and 169 080 dwt have been recorded on the special record sheets (maximum draught up to 17,3 m). Of these there were six occasions on which ships had to be held back, either for the high swell to subside or until the tide level had increased. In one case, the swell height was more than 1 m too high.

Future Improvement to the Manual

It is expected that the manual will be improved in two ways, firstly, by improving the recording system of the environmental data and, secondly, by improving the techniques for determining maximum expected vertical motions.

Wave heights are already recorded on magnetic tape and it is intended to replace the present graphic technique to determine H_{rep} by a spectral analysis technique. Provided the response functions of the ships are known (these will be determined from the prototype measurements), the effect of wave period can then also be included. Since ship motions are very dependent on wave direction, it is also expected that an automatic wave direction recording system will be used in the future.

The results of the present prototype measurements of vertical ship motions and additional physical model tests will be used to calibrate available mathematical ship motion

models. The final aim would be to replace the present draught allowance diagrams by a simplified version of such a model, which would predict the maximum expected vertical motions for a given ship under various wave and tide conditions.

CONCLUSIONS

The main cargo through Richards Bay harbour consists of coal exports using bulk carriers up to about 170 000 dwt, loaded to 17,1 m draught (in certain cases, 17,3 m was allowed).

Experience with the operation of the port indicates that the available stopping distance (6,1 km) is more than adequate for ships, presently calling at Richards Bay, entering at 6 to 8 kn (3 to 4 m/s) although further data on loaded design ships is still needed. Provided outer channel speeds of at least 7 to 8 kn (3,5 to 4 m/s), indicated by the hydraulic model test, are maintained, there is no serious problem in holding the ships in the 300 to 400 m wide channel.

Ship motion research is aimed at determining the minimum required dredging depths for ships up to 20 m draught (about 250 000 dwt) and at developing guidelines to assist in the safe operation of the port. The results of the prototype measurements showed that the underkeel allowance of 7 m accepted in the original design is of the right order of magnitude.

Because of the lack of sufficient direction coverage in prototype data, the Port Operation Manual, Mark I, was based on physical model tests with a 200 000 dwt and a 150 000 dwt model ship. Data on these test results were used to draw up easy to apply draught allowance diagrams which relate equivalent draught and limiting wave height for various wave directions. These diagrams allow for a minimum underkeel clearance of 1 m in the outer channel, the inner channel and the turning/mooring areas. To apply these diagrams to port operation, reliable data on wave heights and directions, tide levels and channel depths must be available.

The manual has been in use at Richards Bay port control since October 1981 and has been found to be of great value in assisting in the safe operation of the port.

The success of this project depended largely on the **understanding and co-operation of the various disciplines** involved, namely, those of the harbour engineers (civil engineering), the nautical staff and the research engineers (civil and mechanical/naval engineering).

THE RESPONSE OF SMALL CRAFT TO WAVE ACTION

by

M. ISAACSON[1], M.ASCE and A.G. MERCER[2], M.ASCE

ABSTRACT

A comprehensive study has been conducted for the Small Craft Harbours Branch, Department of Fisheries and Oceans Canada, to provide improved criteria for acceptable wave climate in small craft harbours (Ref. 3). An important part of the study was directed to model tests of vessel response to waves, and comparisons of these to field measurements and to simplified analytical predictions.

The objective of the present paper is to describe these specific comparisons and present the corresponding results in the context of improving harbour entrance designs. The model tests results and theoretical predictions are adequate to show quantitatively the dependence of a sailboat's response to different wave lengths with sufficient accuracy for wave periods, heights and directions to be selected as variables in formulating the required wave criteria.

INTRODUCTION

A commonly accepted criterion used in the design of small craft harbours is that wave heights within the harbour should not exceed 0.3 m (1 ft). However, it is clear that such a criterion is inadequate to take account of the many variables which give rise to vessel damage within a harbour. Consequently, a comprehensive study has been conducted for the Small Craft Harbours Branch, Department of Fisheries and Oceans Canada, to provide improved criteria for acceptable wave climate in small craft harbours (Ref. 3).

An important part of the study was directed to model tests of vessel response to waves, and comparisons of these to field measurements and to simplified analytical predictions. The model tests were carried out with a 0.8 m long model of a moored, fin-keel sailboat subjected to head and beam seas. The field measurements were carried out with a 7 m long boat similar to the model. The

[1] Dept. of Civil Engineering, Univ. of British Columbia, Vancouver, B.C., Canada.

[2] Northwest Hydraulic Consultants Ltd., North Vancouver, B.C., Canada.

analytical predictions were made for four categories of hull shape using different simplified analytical methods.

The objective of the present paper is to describe these specific aspects of the project and to present the corresponding results. A description of the overall project including the recommended criterion of acceptable wave conditions, is given in a companion paper (Ref. 1).

MODEL TEST PROCEDURE

Tests were carried out in a wave basin with a 0.76 m long model of a high performance fin-keel sailboat. Some of the basic specifications of the model are given in Table 1, and the fundamental configuration of the model is sketched in Fig. 1(a).

The boat was moored to a walkway (dock) which could be either fixed or floating. To arrive at appropriate model characteristics a typical wooden dock, 1.5 m wide and 12.2 m long, was replicated. When the walkway was allowed to float, it was constrained against lateral action by four vertical model piles. For fixed dock tests, the ends of the dock were constrained from vertical motion.

For all tests the model was moored with four lines, bow and stern breast lines set slack and bow and stern spring lines set at a small initial steady state tension. The lines were modelled to represent the elasticity of 1.3 cm braided nylon line commonly used for moorage.

The wave basin at the University of British Columbia used for the tests is approximately 13.7 m long, 4.9 m wide and could take water depths up to 0.6 m. The basin was provided with a wave absorbing beach along the end opposite to the wave generator. The wave generator was a hinged paddle with controls to vary the frequency up to 2 Hz and amplitude of motion up to 0.24 m. Only regular waves could be produced.

The wave height was measured with a capacitance-type wave gauge. A motion transducer was designed to record the three appropriate components of boat motion: heave, surge, pitch for head seas, or heave, sway, roll for beam seas. This comprised of a hinged arm which operates as three parallel systems capable of measuring the three required component motions of the vessel. The weight of the transducer was counterbalanced by a low tension spring or a counterweight in order to eliminate the effective weight of the transducer. In addition, movie film was shot of the vessel's motion with and without the transducer connected in order to establish the importance of the transducer in affecting the vessel motion. The transducer was calibrated over its range of application at the beginning of the tests and checked each day against a single reference point for each motion.

In the series of the tests, measurements were also made of the rise and fall of the dock and of peak hawser forces. Numerous photographs were taken and approximately 300 feet of 16 mm movie film

were shot to provide some documentation of the motions involved.

Preliminary tests were first conducted to measure the vessel's natural periods in roll and pitch, and its static stability characteristics. The curves of pitch and roll angles against applied moment were used to obtain the corresponding hydrostatic stiffnesses and are given in Fig. 2. Subsequently, a series of 148 tests, in which wave period, wave height and wave direction varied, were run and documented. The ranges of conditions for which the tests were carried out were as follows (prototype values for 1:10 scale model are given in parentheses):

water depth:	0.30 and 0.46 m (3.0 and 4.6 m)
water period:	0.5 - 2.0 sec (1.6 - 6.3 sec)
wave height:	0.01 - 0.07 m (0.08 - 0.71 m)
wave direction:	head and beam seas
dock motion:	fixed and floating

FIELD TEST PROCEDURE

The field measurement program, carried out at Fisherman's Cove near Vancouver, developed into several short term activities including:

(i) Calm water tests mostly on a Swiftsure 24 sailboat to obtain data for comparison with the model.

(ii) Wave tests on a Swiftsure 24 and a Bayfield 25 for comparison with model response data.

Measurements were first made of the static moment vs. roll or pitch angle relationships for the Swiftsure 24, and the corresponding curves are compared to those obtained with the model in Fig. 2. Natural periods in roll were measured for a number of vessels using the marina, and these ranged from 2.1 sec to 3.7 sec.

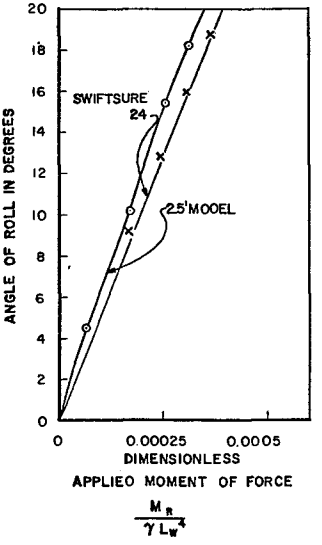
For the wave response tests, the Swiftsure 24 sailboat was moored alongside a gasoline service barge with taut springs and loose breastlines as in the model tests. Wave measurements for the period during testing indicated a significant wave height of 0.37 m and a peak period of 2.4 sec. Measurements of the vessel motions were taken for both head and beam sea conditions, and were carried out with the use of surveying equipment and by photography.

HYDRODYNAMIC ANALYSIS

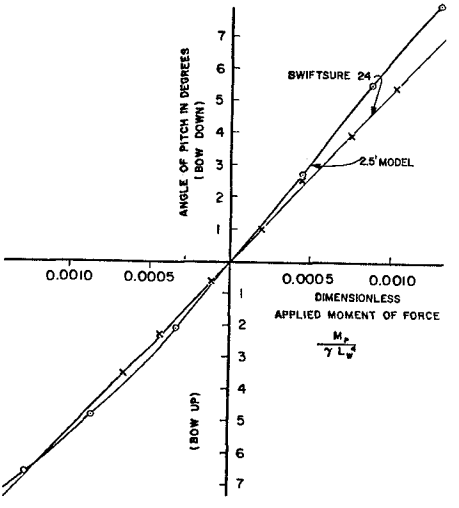
The hydrodynamic analysis of a freely floating vessel responding to wave action is well known and has been reviewed, for example, by Newman (2). In a linear analysis the vessel is taken to oscillate harmonically in six degrees of freedom with displacements given as $\mathrm{Re}\{\xi_j e^{i\omega t}\}$, with $j = 1$ coresponding to surge, $j = 2$ to heave, $j = 3$ to sway, $j = 4$ to roll, $j = 5$ to yaw and $j = 6$ to pitch, and ω is the wave angular frequency.

Fig. 2. Model prototype static test results.

(a) Roll



(b) Pitch



The equations of motion of an unrestrained floating body can be expressed in terms of the complex amplitudes ξ_j by a matrix equation:

$$\{-\omega^2 ([M] + [A]) + i\omega [B] + [C]\} (\xi) = (F) \quad (1)$$

where [M] is the mass matrix, [A] the added-mass coefficient matrix, [B] the damping coefficient matrix, [C] the stiffness matrix, and (F) the exciting force vector. In this notation the components F are the exciting force complex amplitudes, with corresponding time varying forces given as $Re\{F_j e^{i\omega t}\}$. The mass matrix components and stiffness matrix components are simply derived for a given vessel configuration and weight distribution.

In the case of a moored body, the various terms in the equation of motion, Eq. (1), may be extended to reflect the influence of the moorings on the body's motion. In the usual case, the moorings may be treated as linear springs with constant coefficients and the stiffness matrix can be modified to incorporate these.

In a complete hydrodynamic anlaysis, the matricies [A] and [B], and the vector (F) are obtained from a solution to the governing radiation/diffraction boundary value problem. This usually derives from the assumptions of a linear motion (small amplitude waves) and an irrotational flow (flow separation effects neglected). An assumption often made in a motion response analysis of a moored vessel is that the mooring system affects the low frequency (drift) oscillations only, but is too light and flexible to affect the vessel oscillations at higher wave frequencies. However, this assumption is unrealistic in the case of light boats with slack moorings.

In the present study, a complete hydrodynamic analysis of a moored vessel with six degrees of freedom has been considered unwarranted because many of the common assumptions generally made are considered unrealistic in relation to the additional effort and cost entailed in a full three-dimensional analysis. For example, for small craft complicating effects may include flow separation, particularly around a keel in beam seas, asymmetric motions for a nominally symmetric condition (e.g. yaw in head seas), nonlinear mooring conditions (e.g. slack/elastic moorings), wave nonlinearities, etc. The intention has been instead to investigate simplified analytical procedures which would adequately predict measured responses over specific ranges of conditions. These analyses are restricted to head seas (with only surge, heave and pitch motions occurring) and to beam seas (with only heave, sway and roll motions occurring).

Long Wave Approximation (LWA)

When the wave length to vessel length ratio is large, a long wave approximation may be made, whereby the exciting force components can be expressed directly in terms of the added-mass the damping

coefficients and the vessel's hydrostatic characteristics. The underlying theory is given by Newman (2) and appropriate expressions for the exciting force complex amplitudes may thereby be derived. These may be written in terms of $F' = 2F/H$, where H is the wave height, as follows:

Head Seas:

$$F'_1 = \frac{ik}{\omega^2}\left[-\omega^2(m + a_{11}) + i\omega b_{11}\right] \tag{2a}$$

$$F'_2 = S - \omega^2(m + a_{22}) + i\omega b_{22} + kS_1 \tag{2b}$$

$$F'_6 = S_1 + ikmy_B + ikS_{11} \tag{2c}$$

Beam Seas:

$$F'_2 = S - \omega^2(m + a_{22}) + i\omega b_{33} \tag{2d}$$

$$F'_3 = -\frac{ik}{\omega^2}\left[-\omega^2(m + a_{33}) + i\omega b_{33}\right] \tag{2e}$$

$$F'_4 = ik(my_B + a_{34}) + ikS_{33} + \frac{k}{\omega} b_{34} \tag{2f}$$

These equations for the exciting force can be substituted into the RHS of the corresponding equation represented by Eqs. (1) to obtain expressions for peak displacements which can then be solved. Since some terms appear on both sides of the equations considerable simplification arises in many cases.

In the above $k(= 2\pi/\lambda)$ is the wave number, y_B is the vertical ordinate of the centre of buoyancy, S is the waterplane area, and S_1, S_{11} and S_{33} are the waterplane area moments defined as follows:

$$S_1 = \int x\, b(x)\, dx \tag{3a}$$

$$S_{11} = \int x^2\, b(x)\, dx \tag{3b}$$

$$S_{33} = \int \frac{1}{12} b^3(x)\, dx \tag{3c}$$

where $b(x)$ is the sectional beam of the waterplane profile, the integrals are taken over the waterplane length L_ω of the vessel, and x is the horizontal coordinate measured towards the bow.

As part of the approximations carried out in the present analysis, estimates of a_{ij} and b_{ij} (frequency dependent) have been obtained by using published data of the coefficients for related reference configurations. All cross coefficients have been taken equal to zero except a_{34}, b_{34} which couple roll and sway in beam seas. Viscous effects are known to alter the damping coefficients from the predicted potential theory values, particularly for roll motions, and available experimental and theoretical results of drag

coefficients in an oscillatory flow past a flat plate have been used to estimate corresponding values of viscous damping coefficients for vessels (including the model) containing deep keels.

Slender Body Approximation (SBA)

The slender body approximation provides an alternative approximation procedure which is valid for shorter wave lengths of the order of the boat length. This depends on the beam/length ratio being small so that certain terms in the equations of motion which are proportional to higher orders of this ratio may be neglected. In this approximation, the actual Froude-Krylov forces are used in the RHS of Eqs. (1), rather than using Eqs. (2). Simplifications are made by neglecting certain terms in the LHS of Eqs. (1). The method is outlined by Newman (2).

Since mass or stiffness terms are neglected for various modes of motion, resonance behaviour is not predicted for most cases: that is, the resonant frequencies are assumed to occur outside the wave length (frequency) range considered. In order to predict the resonance features found for most modes of motion, an attempt has been made to include additional mass and stiffness terms beyond those used in the formal approximation.

Slack/Elastic Mooring Line Approximation

The non-linear analysis required for a slack/elastic mooring line can be idealized as that pertaining to a spring-mass-dashpot system with non-linear spring characteristics and subjected to a known (exciting) force. The spring constant due to the moorings is approximated to be a constant value (depending on the elasticity of the mooring) for positive vessel displacements and zero otherwise. The corresponding non-linear ordinary differential equation can be approximated as:

$$m\ddot{\xi} + r\dot{\xi} + s\xi = Fe^{i\omega t} \tag{4}$$

where m is the body mass (including added-mass), r is the damping constant, $s = 0$ for $\xi < 0$ and $s = c$ for $\xi > 0$, and c is the elastic constant of the mooring. This non-linear ordinary differential equation can be solved by a Ritz approximation procedure which is particularly simple when extracting the fundamental harmonic of the vessel displacement. The results may be expressed as

$$\xi = Xe^{i\omega t} \tag{5a}$$

with the amplitude of the motion given by:

$$|X| = F\left\{\left(\frac{c}{2} - m\omega^2\right)^2 + r^2\omega^2\right\}^{-1/2} \tag{5b}$$

and the phase relative to that of F given by:

$$\text{Arg}(X) = \tan^{-1}\left[\left(\frac{c}{2} - m\omega^2/r\omega\right)\right] \qquad (5c)$$

These equations have been used to compute the vessel's surge and sway response to a slack/elastic moorage.

Moorage Conditions Analysed

Application of the different approximations described to different moorage arrangements has been accomplished by considering a series of specific cases, including head and beam seas, a freely floating boat, a linear mooring restraining surge only, a slack/elastic mooring for surge or sway only, and stern hinge links which restrain fore-and-after motions but allow the stern to move vertically. These cases are listed in Table 2. The computations have been carried out for four hull configurations corresponding to a deep fin sailboat, a full keel sailboat, a planing power boat and a displacement type power boat, as indicated in Fig. 1, and their principal characteristics are given in Table 1.

RESULTS

Model Test Results

The model test results are presented in Figs. 3 and 4 showing the response amplitude operators (RAO's) as functions of the wave length to vessel length ratio. The response amplitude operators are defined here as:

$$\text{RAO} = \begin{cases} \dfrac{\text{motion amplitude}}{\text{wave amplitude}} & \text{for surge, heave, sway} \\ \dfrac{\text{roll amplitude (rads)}}{2\ H/B} & \text{for roil} \\ \dfrac{\text{pitch amplitude (rads)}}{2\ H/L_w} & \text{for pitch} \end{cases}$$

where H is the wave height, B the beam and L_w the water plane length.

Results for both fixed and floating dock cases are given in Fig. 3 for head seas, and in Fig. 4 for beam seas.

There is some spread of the experimental data points which indicates either non-linear effects, a lack of consistency in the phenomena, or the degree of data taking and instrumentation accuracy. Evidently all three effects were present to some degree.

As mentioned previously, movie footage was taken of several tests with the transducer in place and with it removed. This data has also been plotted in Fig. 3(b) and it fell within the scatter of the transducer data indicating that the transducer did not grossly misrepresent the model motions. A complete discussion of the various trends indicated in the figures is given in Ref. 3.

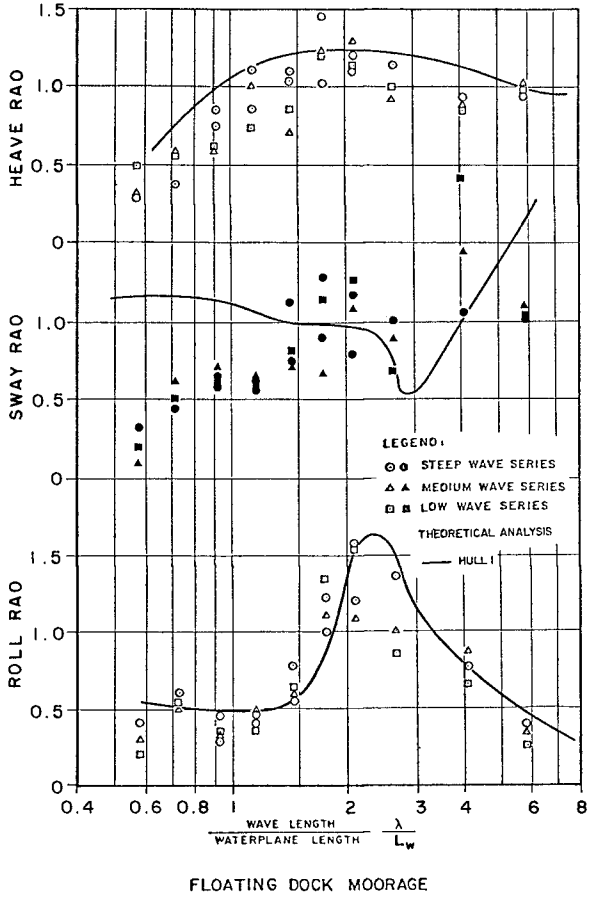

Fig. 4(b). Dimensionless model test results for beam seas - Floating dock moorage.

Field Test Results

The corresponding results for the Swiftsure and Bayfield vessels are superposed with the model test results in Figs. 3(a) and 4(a). The results for pitch are relatively low while those for heave and roll show good agreement with the model data.

Analytical Results

The analytical results for Hull 1 (the model vessel) based on the alternative approximations adopted are given in Fig. 5 for head and beam seas. For head seas, both heave and pitch equations are coupled so that the results are interdependent. For both heave and pitch the LWA produces results close to the SBA for longer waves but they diverge rapidly for shorter waves. In beam seas, sway and roll are also closely coupled and must be treated together. Although moorage constraint is important to sway and roll, the coupling make the constraint difficult to handle so that only free response curves are shown here.

For both head and beam seas, the SBA (modified) is found to provide a better representation of response than the LWA when compared with model results. Thus the SBA analytical results for Hull 1 are compared to the experimental data points in Fig. 3(b) for head seas and in Fig. 4(b) for beam seas. For head seas, the SBA plots will be seen to agree very closely with the measured data over the full range of wave lengths tested. Heave response is shown to be equal to the wave height for longer waves (greater than 5 times boat length) but diminishes for shorter waves until it reaches zero for wave lengths approxiamtely one-half the boat length. Pitch response for longer waves (greater than 4 times the boat length) follows the pitch (slope) of the wave surface. It diminishes for shorter waves approaching zero for wave lengths about one half the boat length. Neither heave or pitch have a resonant condition in head seas under the SBA and this is supported by model data. The response in surge is more complex because surge is heavily constrained by the moorage lines, and free floating response results are expected to be grossly excessive.

For beam seas, the SBA also provides a better representation of response than does the LWA. The roll reaches at least 3 times the equivalent slope of the water surface. The frequency of roll at resonance is very close to the natural period of roll noted in still water. As with surge in head seas, the (free floating) analytical sway results are quite invalid because of the influence of the moorings. Heave response in a beam sea shows a broad resonance condition with boat response as much as 25 percent greater than the wave height. However, as with head seas the heave response ratio approaches unity for long waves and approaches zero for short waves.

Finally, Fig. 6 shows the analytical results based on the SBA for the four hull types indicated previously (Table 1 and Fig. 1). The curves show that responses are very similar except for those

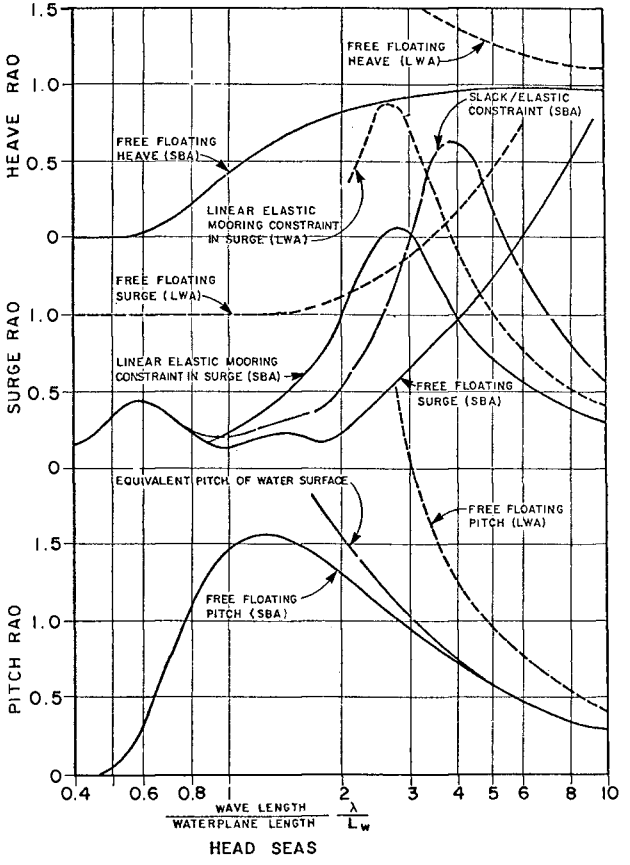

Fig. 5(a). Analytical evaluations of vessel response for Hull 1 - Head Seas.

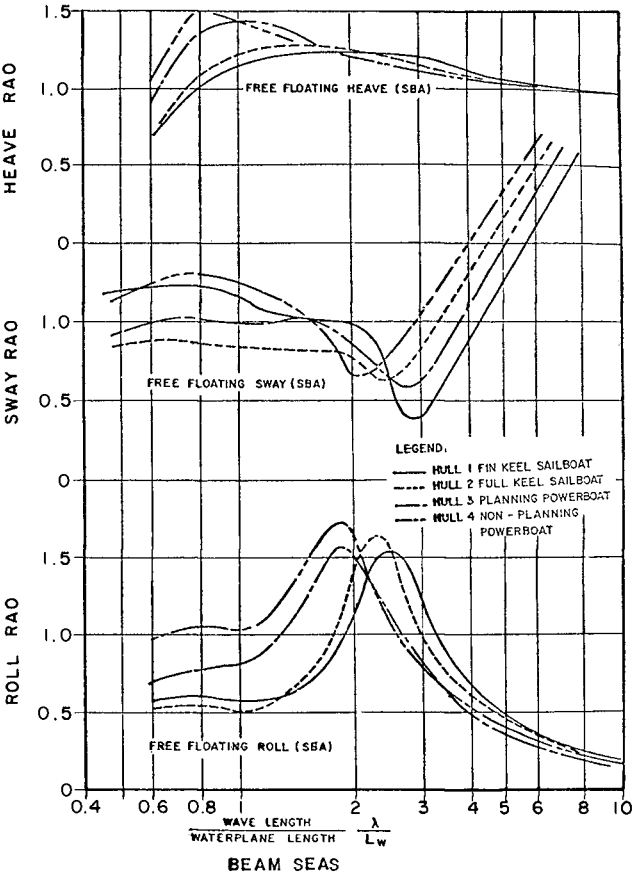

Fig. 6(b). Analytical evaluations of vessel response for four hulls - Beam Seas.

responses involving resonances which include heave in a beam sea and surge with linear elastic constraint. (Sway with moorage constraint also is subject to strong resonances but is not included here.) The resonance in heave is not strong so that the differences between hull types is not large. Nonetheless they are large in surge. Also the response values at the resonant peaks are not too reliable because they vary greatly with amount of damping that is present. As a result, the responses in heave, pitch and roll appear to be reasonably predictable but the responses in surge and sway can only be predicted with a sizeable degree of uncertainty.

CONCLUSIONS

The model test and analytical results have been compared and are generally quite adequate to show quantitatively the dependence of vessel response on wave height, period and direction with sufficient accuracy to enable improved criteria of acceptable wave climate for small craft to be established.

THE MOTIONS OF A MOORED SHIP IN A HARBOR BASIN

T. Sawaragi, Dr. of Eng., Professor,Dept. of Civil Eng., Osaka Univ., Osaka, Japan.
M. Kubo, Dr. of Eng., Associate Professor, Kobe Univ. of Mercantile Marine, Kobe, Japan.

ABSTRACT

In harbors affected by ocean swells,cargo handlings are often interrupted and mooring lines are broken as a result of severe ship motions[1]. In order to decrease such accidents, the moored ship motions in a harbor basin must be studied. In this paper the ship motions in the harbor basin are investigated by using three dimensional Green's function and close agreement between theoretical and experimental results can be found. New methods to reduce moored ship motion are also proposed. The efficiency of these methods is verified theoretically and experimentally.

1. INTRODUCTION

At the initial stage of harbor planning, the hydraulic experiment with respect to stillness in a harbor is usually carried out and the degree of stillness in the harbor has been traditionally evaluated by the wave height. In the field, however, the limits of cargo handling in rough sea condition are judged by the ship movements. Therefore, lately, an analysis of moored ship motions in a harbor basin has become major interest for harbor planning.

As for the ship motions, there are short-period ones induced by wind waves and swells such as surge, sway, heave, roll, pitch and yaw, and long-period ones such as surge, sway and yaw whose natural periods are decided by the moored system. Many studies concerning long-period motions of a moored ship along the quay wall in beam sea have been done. The authors have also presented a paper about the long-period ship motions induced by the harbor oscillations in an arbitrary geometry basin[2]. Therefore, in this paper, the short-period ship motions are investigated by three dimensional method.

The three dimensional analyses are divided into two methods, one is the singularity distribution method[3] and the other is the joining method of divided region[4]. The latter method is used in this paper in order to analyze the ship motions along a straight quay wall and in a slip and these results are verified by the experiments.

On the other hand, Joglekar and Kulkani[5] have proposed the mooring system with the dash-pots in order to reduce the long-period ship motion in bore tide. However, the effects of these dash-pots on the short-period ship motions was not clarified yet. In this paper, the new mooring system with dash-pots is also analyzed theoretically and experimentally.

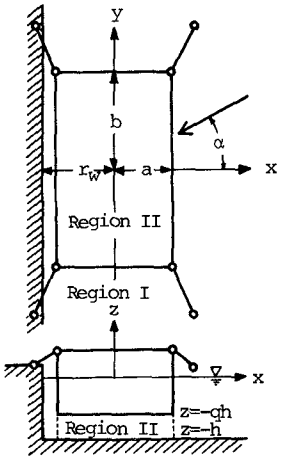

Fig.1 Definition of the coordinate system

2. THEORY OF SHIP MOTIONS

2.1 Motions of Moored Ship Along the Straight Quay Wall.

The authors will try to develop the joining method of divided region into that which can be applied to the ship motions along a straight quay wall. Since very large memory size and a great deal of cost are required in three dimensional analysis, the method of images are applied to decrease memory and cost.

Fig. 1 shows the moored ship and the coordinate system. The amplitudes of ship motions and waves are supposed to be small, and fluid around the ship is assumed to be ideal and irrotational. The coordinates of the center of gravity of the moored ship are given by $(0,0,\bar{Z}_0)$ in still water and by (X_0, Y_0, Z_0) in waves. δ_1, δ_2 and δ_3 show the rotation of the center of gravity of the moored ship around X, Y and Z axis, respectively. Then, the ship motions are expressed by:

$$X_0=\xi^* e^{-i\sigma t} \text{ (sway)}, \quad Y_0=\eta^* e^{-i\sigma t} \text{ (surge)}, \quad Z_0-\bar{Z}_0=\zeta^* e^{-i\sigma t} \text{ (heave)}$$
$$\delta_1=\omega_1^* e^{-i\sigma t} \text{ (pitch)}, \quad \delta_2=\omega_2^* e^{-i\sigma t} \text{ (roll)}, \quad \delta_3=\omega_3^* e^{-i\sigma t} \text{ (yaw)} \tag{1}$$

where ξ^*, η^*, ζ^*, ω_1^*, ω_2^* and ω_3^* are the amplitudes of ship motions, $i=\sqrt{-1}$, $\sigma=2\pi/T$, T is the wave period and t is the elapsed time. The water region is divided into two parts as shown in Fig. 1. The velocity potential in region I is given by:

$$\phi_I^w = \frac{g\zeta_0}{\sigma}[\{f_0(x,y)+f_1(x,y)\}\frac{\cosh k(h+z)}{\cosh kh} + \sum_{n=1}^{\infty} f_2^{(n)}(x,y)\frac{\cos k_n(h+z)}{\cos k_n h}] \tag{2}$$

where g is the gravitational acceleration, ζ_0 is the amplitude of incident waves, h is the water depth and the superscript w means the velocity potential along the quay wall. k and kn satisfy the following equation:

$$\sigma^2 h/g = kh \tanh kh = -k_n h \tan k_n h, \quad (n=1,2,\ldots) \tag{3}$$

The wave function f_0 corresponding to the incident and the reflected waves is given by:

$$f_0(x,y) = -i \exp\{-ik(x\cos\alpha + y\sin\alpha)\} - i\exp[-ik\{(-2\gamma_w - x)\cdot \cos\alpha + y\sin\alpha\}] \tag{4}$$

where γ_w is the distance between the quay wall and the center line of the ship, α is the angle of wave incidence. The functions $f_1(x, y)$ and $f_2^{(n)}(x, y)$ are the terms corresponding to the evanescent modes and they are expressed as Eq.(5) by using the Green's formula:

$$f_1(x,y) = -\frac{1}{2}\sum_{j=1}^{q}\{\bar{A}_{xj} f_1(j) - A_{xj}\bar{f}_1(j)\}$$

$$f_2^{(m)}(x,y) = -\frac{1}{2}\sum_{j=1}^{N}\{\bar{B}_{xj}f_2^{(m)}(j)-B_{xj}\bar{f}_2^{(m)}(j)\} \tag{5}$$

where over bars indicates the normal derivative to the boundary, namely, $\bar{f}_1(j)=\partial f_1(j)/k\partial\nu$, $\bar{f}_2^{(m)}(j)=\partial f_2^{(m)}(j)/k\partial\nu$, N is the number of segments of the boundary of ship and A_{xj}, $\bar{A}_{xj}$, B_{xj} and $\bar{B}_{xj}$ are given by:

$$A_{xj}=-\frac{i}{2}\int_{\Delta s_j}\{H_0^{(1)}(k\gamma_S)+H_0^{(1)}(k\gamma_I)\}k\,ds,\quad \bar{A}_{xj}=-\frac{i}{2}\int_{\Delta s_j}\frac{\partial}{\partial\nu}\{H_0^{(1)}(k\gamma_S)+H_0^{(1)}(k\gamma_I)\}ds,$$

$$B_{xj}=-\frac{1}{\pi}\int_{\Delta s_j}\{K_0(k_n\gamma_S)+K_0(k_n\gamma_I)\}k\,ds,\quad \bar{B}_{xj}=-\frac{1}{\pi}\int_{\Delta s_j}\frac{\partial}{\partial\nu}\{K_0(k_n\gamma_S)+K_0(k_n\gamma_I)\}ds,$$

$$\gamma_S=\sqrt{(x-\xi_j)^2+(y-\eta_j)^2},\quad \gamma_I=\sqrt{(2\gamma+x+\xi_j)^2+(y-\eta_j)^2} \tag{6}$$

where the coordinates (ξ, η) correspond to the boundary of ship, j is the number of segments of boundary of ship and the coordinates (x, y) express the internal point.

On the other hand, the velocity potential in region II is given by:

$$\left.\begin{aligned}\phi_{II}^{W}=&\frac{g\zeta_0}{\sigma}\,[\psi_0(x,y)+\sum_{s=1}^{\infty}\psi_s(x.y)\cos\bar{s}\,(z+\bar{q}h)\\&+i\,\frac{1}{2\bar{q}}\,\frac{\sigma^2h}{g}\{(-\frac{\zeta^*}{\zeta_0}-\frac{\omega_1^*y}{\zeta_0}+\frac{\omega_2^*x}{\zeta_0})((1+\frac{z}{h})^2-\frac{\bar{q}^2}{3})\\&+\frac{1}{4}(\frac{2\zeta^*}{\zeta_0}+\frac{\omega_1^*y}{\zeta_0}-\frac{\omega_2^*x}{\zeta_0})(\frac{x^2+y^2}{h^2})\}],\end{aligned}\right\} \tag{7}$$

where $\bar{s}=s\pi/\bar{q}h$, $\bar{q}=1-q$ and qh is the draft of the ship. When Ps are the wave forces, Ts are the moments of wave forces, Fs are the mooring forces and Ms are the moments of the mooring forces, the equations of motions of moored ship are given by:

$$\left.\begin{aligned}M\frac{d^2X_0}{dt^2}&=Px+Fx,\quad M\frac{d^2Y_0}{dt^2}=Py+Fy,\quad M\frac{d^2Z_0}{dt^2}=Pz+Fz,\\I_x\frac{d^2\delta_1}{dt^2}&=Tx+Mx,\quad I_y\frac{d^2\delta_2}{dt^2}=Ty+My,\quad I_z\frac{d^2\delta_3}{dt^2}=Tz+Mz,\end{aligned}\right\} \tag{8}$$

where M and Is are the mass and moments of inertia of the ship.

The continuity conditions of fluid particle velocity and pressure at the imaginary boundary shown in Fig. 1 are given by:

$$\left.\begin{aligned}\frac{\partial\phi_I^W}{\partial x}&=-i\sigma\{\xi^*-\omega_3^*y+\omega_2^*(z-\bar{z}_0)\},\ (\xi=\pm a,\ 0>z>-qh),\\\frac{\partial\phi_I^W}{\partial y}&=-i\sigma\{\eta^*+\omega_3^*x-\omega_1^*(z-\bar{z}_0)\},\ (\eta=\pm b,\ 0>z>-qh),\\\frac{\partial\phi_I^W}{\partial\nu}&=\frac{\partial\phi_{II}^W}{\partial\nu},\ (-qh>z>-h),\quad \phi_I^W=\phi_{II}^W,\ (-qh>z>-h)\end{aligned}\right\} \tag{9}$$

where a=B/2, B the breadth of the ship, b=Ls/2, Ls the length of the ship. From Eq.(1) to Eq.(9), the amplitudes of ship motions ξ^*, η^*, ζ^*, ω_1^*, ω_2^* and ω_3^* and the unknown functions f_1, $f_2^{(m)}$, $\partial f_1/\partial\nu$, $\partial f_2^{(m)}/\partial\nu$ are obtained.

2.2 Motions of Moored Ship in a Slip

2.2.1 Wave Height Distribution in a Slip

Since the ship motions in a slip are naturally induced by waves in a slip, it becomes important to investigate the accuracy of wave height distributions in advance of the analysis of moored ship motions in the slip. Moreover, the three dimensional analysis of the ship motions especially in a slip requires very large memory size and a great deal of cost, so the method of images are also applied to decrease memory and cost.

The region around the slip is divided into two parts, as shown in Fig. 2. The velocity potential in each region is given by:

$$\left.\begin{aligned}\phi_I &= \frac{g\zeta_0}{\sigma}\{f_0(x,y) + f_1(x,y)\}\frac{\cosh k(h+z)}{\cosh kh}\\ \phi_{II} &= \frac{g\zeta_0}{\sigma} f_2(x,y)\frac{\cosh k(h+z)}{\cosh kh}\end{aligned}\right\} \quad (10)$$

when the incident waves into the slip are given by:

$$\zeta = \zeta_0 \exp\{-i(kx\cos\alpha + ky\sin\alpha + \sigma t)\} \quad (11)$$

the wave function f_0 is expressed by:

$$f_0(x,y) = -2i\cos(ky\sin\alpha)\exp(-ikx\cos\alpha) \quad (12)$$

Using the Green's formula, the wave function f_1 and f_2 are given by:

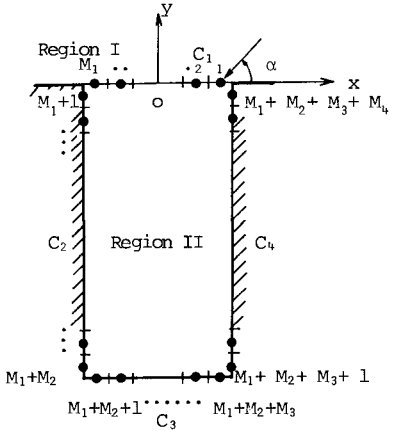

Fig.2 Division of the region around a slip and segmentation of the boundary. The angle of wave incidence is measured anti-clockwise from x-axis.

$$\left.\begin{aligned}f_1(x,y) &= -\varepsilon\sum_{j=1}^{M_1}\{\bar{A}_{xj}f_1(j) - A_{xj}\bar{f}_1(j)\}\\ f_2(x,y) &= -\varepsilon\sum_{j=1}^{N_s}\{\bar{A}_{xj}f_2(j) - A_{xj}\bar{f}_2(j)\}\end{aligned}\right\} \quad (13)$$

where M_1 is the number of segments at the entrance and Ns is the total number of segments of the slip. When (x, y) are on the boundary, ε=1/2, and when (x, y) are in the slip, ε=1.0 . It is not convenient to apply the method of images to the parallel boundaries, because the number of images amounts infinity and the times of computation becames long[6]. So the Green's functions are chosen so as to satisfy the following relations:

$$\bar{A}_{xj} = 0 \quad \text{on } C_2 \text{ , } C_3 \quad (14)$$

As the following equation is satisfied on the boundary,

$$\bar{f}_2(j) = 0 \qquad \text{on } C_2,\ C_3,\ C_4\ , \tag{15}$$

the number of segments in Eq.(13) is reduced from Ns of Lee's method to M_1+M_4. Then the Green's function A_{ij} which satisfies Eq.(14) can be obtained by the method of images as shown in Fig. 3:

$$\left.\begin{aligned}
&A_{xj}=\int_{\Delta s_j}-\frac{ik}{2}\sum_{p=1}^{4}H_0^{(1)}(k\gamma_p)\,ds,\quad \bar{A}_{xj}=\int_{\Delta s_j}\frac{ik}{2}\sum_{p=1}^{4}H_1^{(1)}(k\gamma_p)\frac{\partial\gamma_p}{\partial\nu}\,ds,\\
&\gamma_1=\sqrt{(x_j-x)^2+(y_j-y)^2}, && \frac{\partial\gamma_1}{\partial\nu}=-(y_j-y)/\gamma_1\\
&\gamma_2=\sqrt{(-x_j-2\ell_s-x)^2+(y_j-y)^2}, && \frac{\partial\gamma_2}{\partial\nu}=-(y_j-y)/\gamma_2\\
&\gamma_3=\sqrt{(-x_j-2\ell_s-x)^2+(-2ds-y_j-y)^2}, && \frac{\partial\gamma_3}{\partial\nu}=-(2ds+y_j+y)/\gamma_3\\
&\gamma_4=\sqrt{(x_j-x)^2+(-2ds-y_j-y)^2}, && \frac{\partial\gamma_4}{\partial\nu}=-(2ds+y_j+y)/\gamma_4
\end{aligned}\right\} \tag{16}$$

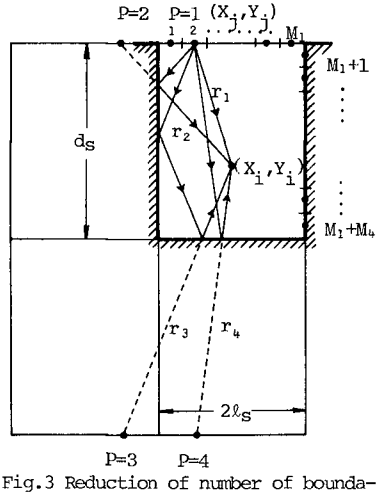

Fig.3 Reduction of number of boundary points by applying the method of images

Besides the above alternations, the computation is carried out in much the same way as the Lee's method[7]. The memory size and cost in this case is one quarter of those in the Lee's method.

Figure 4 shows the response of wave height to the wave period T. The coincidence of numerical and experimental results is fairly well. So the wave height distributions in the slip can be obtained exactly by the above method.

2.2.2 Ship Motions in a Slip

The region around the slip is divided into three parts, that is, the outer part of the slip region I, the under part of the ship region III and the rest part in the slip region II. The velocity potential in the region I is equal to Eq.(2) and is given by:

$$\phi_I^s=\phi_I^w \tag{17}$$

where the superscript s means the velocity potential in the slip. The velocity potential in the region II corresponds to the one which is lacking in $f_0(x, y)$ in Eq.(2) and is given by:

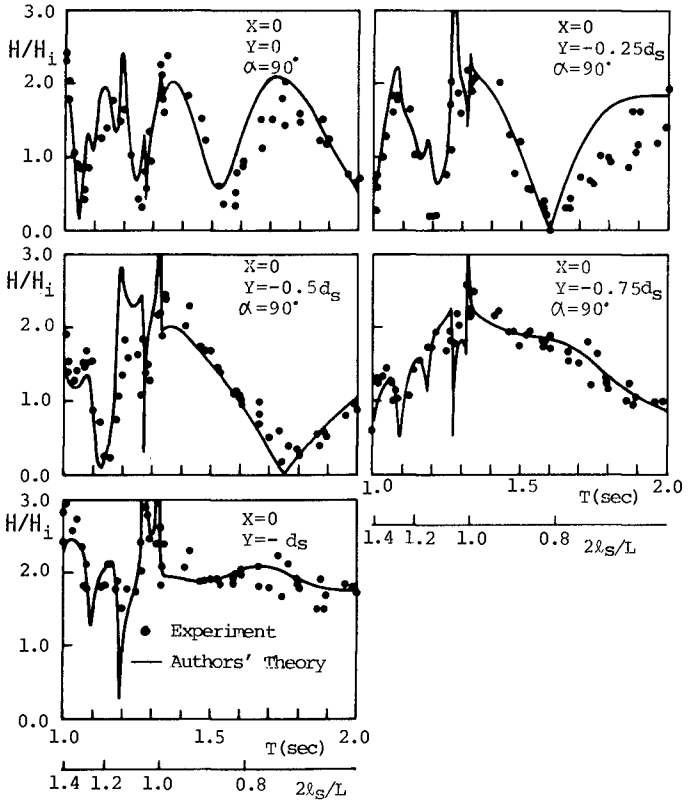

Fig.4 Amplification factor of wave height H at the typical point in the slip, where H_i is the incident wave height.

$$\phi^{s}_{II} = \frac{g\zeta_0}{\sigma}\left[\{f_2^{(0)}(x,y)\frac{\cosh k(h+z)}{\cosh kh} + \sum_{n=1}^{\infty} f_2^{(n)}(x,y)\frac{\cos k_n(h+z)}{\cos k_n h}\right] \quad (18)$$

The velocity potential in region III is the same as Eq.(7)

$$\phi^{s}_{III} = \phi^{w}_{II} \quad (19)$$

As shown in Figure 5, boundaries are chosen as follows: the entrance C_1, the quay walls surrounding the slip C_2, C_3, C_4 and the ship sides C_5. They are divided into M_1~M_5 segments.

At the entrance the following conditions must be satisfied:

$$\phi_I^S = \phi_{II}^S \ , \quad \frac{\partial \phi^S}{\partial \nu} = \frac{\partial \phi^S}{\partial \nu}, \text{on } C_1 \qquad (20)$$

Substituting Eqs.(17) and (18) into (20) and multiplying each term of above equations by cosh k(h+z) and cos kn(h+z), and integrating from z = -h to z = 0, following relations are obtained.

$$\left.\begin{aligned} f_0(i) + f_1^{(0)}(i) &= f_2^{(0)}(i), \\ f_1^{(n)}(i) &= f_2^{(n)}(i), \\ \frac{\partial (f_0(i)+f_1^{(0)}(i))}{\partial \nu} &= \frac{\partial f_2^{(0)}(i)}{\partial \nu}, \\ \frac{\partial f_1^{(n)}(i)}{\partial \nu} &= \frac{\partial f_2^{(n)}(i)}{\partial \nu}, \end{aligned}\right\} \qquad (21)$$

on C_1

where the symbol i shows the i-th position of segment instead of x,y axes. If the coastal line is straight, one of the boundary conditions is simplified as follow:

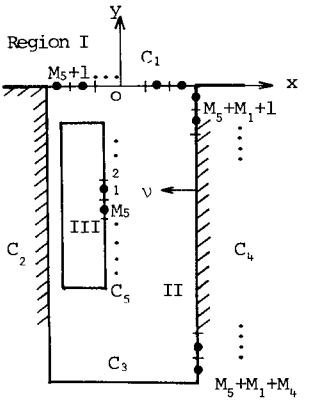

Fig.5 Definition of the coordinate system of the moored ship in the slip

$$\frac{\partial f_1^{(0)}(i)}{\partial \nu} = \frac{\partial f_2^{(0)}(i)}{\partial \nu} \ , \text{ on } C_1 \qquad (22)$$

Since the normal to the boundary is directed outward in region I, the wave function $f_1^{(0)}(i)$ is given from the Green's formula as

$$f_1^{(0)}(i) = -\frac{i}{2} \sum_{j=M_5+1}^{M_5+M_1} \{f_1^{(0)}(j) \frac{\partial H_0^{(1)}(k\gamma)}{\partial \nu} - H_0^{(1)}(k\gamma) \frac{\partial f_1^{(0)}(j)}{\partial \nu}\} \, ds \qquad (23)$$

Substituting Eqs.(21), (22) into Eq.(23), the boundary conditions for $f_2^{(0)}(i)$ is obtained:

$$f_2^{(0)}(i) = f_0(i) + \frac{i}{2} \sum_{j=M_5+1}^{M_5+M_1} H_0^{(1)}(k\gamma) \; k\bar{f}_2^{(0)}(j) \, ds \ , \quad \text{on } C_1 \qquad (24)$$

where $\bar{f}_2^{(0)}(j) = \partial f_2^{(0)}(j)/k\partial\nu$. In the same way, the next condition can be obtained.

$$f_2^{(n)}(i) = \frac{1}{\pi} \sum_{j=M_5+1}^{M_5+M_1} K_0(k_n\gamma) \; k\bar{f}_2^{(n)}(j) \, ds \ , \text{ on } C_1 \qquad (25)$$

where $\bar{f}_2^{(n)}(j) = \partial f_2^{(n)}(j)/k\partial\nu$.

Applying the Green's formula to the boundaries C_1, C_4,C_5, the next equations can be obtained:

$$\left.\begin{aligned} f_2^{(0)}(i) &= -\sum_{j=1}^{M_5+M_1+M_4} \{\bar{A}_{ij} f_2^{(0)}(j) - A_{ij} \bar{f}_2^{(0)}(j)\} \\ f_2^{(n)}(i) &= -\sum_{j=1}^{M_5+M_1+M_4} \{\bar{B}_{ij}^{(n)} f_2^{(n)}(j) - B_{ij}^{(n)} \bar{f}_2^{(n)}(j)\} \\ & \qquad \text{on } C_1, C_4, C_5 \end{aligned}\right\} \qquad (26)$$

where A_{ij}, $\bar{A}_{ij}$, $B_{ij}^{(n)}$, $\bar{B}_{ij}^{(n)}$ are given as follows:

$$A_{ij} = -\frac{i}{2} \int_{\Delta s_j} \sum_{p=1}^{4} \{H_0^{(1)}(k\gamma_p)\} k \, ds, \quad \bar{A}_{ij} = -\frac{i}{2} \int_{\Delta s_j} \sum_{p=1}^{4} \{\frac{\partial}{\partial \nu} H_0^{(1)}(k\gamma_p)\} ds,$$

$$B_{ij}^{(n)} = -\frac{1}{\pi}\int_{\Delta s_j} \sum_{p=1}^{4} \{K_0(k_n\gamma_p)\}k\, ds, \quad \bar{B}_{ij}^{(n)} = -\frac{1}{\pi}\int_{\Delta s_j} \sum_{p=1}^{4} \{\frac{\partial}{\partial n}K_0(k_n\gamma_p)\}ds \qquad (27)$$

where γ_p and $\partial\gamma_p/\partial\nu$ are equal to those given by Eq.(16).

Since the particle velocity normal to the boundary C_4 is zero, the following boundary condition is added:

$$\frac{\partial f_2^{(0)}(j)}{\partial\nu} = \frac{\partial f_2^{(n)}(j)}{\partial\nu} = 0 \text{ , on } C_4 \qquad (28)$$

The above equations from (23) to (28) can be written in the matrix form:

$$\left.\begin{aligned} \mathbf{e}^{(n)} &= \mathbf{G}^{(n)} + \mathbf{H}^{(n)}\bar{\mathbf{e}}^{(n)} \\ \mathbf{f}^{(n)} &= -\bar{\mathbf{A}}^{(n)}\mathbf{f}^{(n)} + \mathbf{A}^{(n)}\bar{\mathbf{f}}^{(n)} - \bar{\mathbf{B}}^{(n)}\mathbf{e}^{(n)} + \mathbf{B}^{(n)}\bar{\mathbf{e}}^{(n)} - \bar{\mathbf{P}}^{(n)}\mathbf{X}^{(n)} \\ \mathbf{e}^{(n)} &= -\bar{\mathbf{C}}^{(n)}\mathbf{f}^{(n)} + \mathbf{C}^{(n)}\bar{\mathbf{f}}^{(n)} - \bar{\mathbf{D}}^{(n)}\mathbf{e}^{(n)} + \mathbf{D}^{(n)}\bar{\mathbf{e}}^{(n)} - \bar{\mathbf{Q}}^{(n)}\mathbf{X}^{(n)} \\ \mathbf{X}^{(n)} &= -\bar{\mathbf{R}}^{(n)}\mathbf{f}^{(n)} + \mathbf{R}^{(n)}\bar{\mathbf{f}}^{(n)} - \bar{\mathbf{S}}^{(n)}\mathbf{e}^{(n)} + \mathbf{S}^{(n)}\bar{\mathbf{e}}^{(n)} - \bar{\mathbf{T}}^{(n)}\mathbf{X}^{(n)} \end{aligned}\right\} \quad , \ n=1,2\ldots \qquad (29)$$

where

$$\mathbf{G}^{(0)} = \begin{pmatrix} f_0(M_5+1) \\ f_0(M_5+2) \\ \\ f_0(M_5+M_1) \end{pmatrix}, \quad \mathbf{G}^{(n)} = \mathbf{0} \qquad (30)$$

and $\mathbf{f}^{(n)}$, $\mathbf{e}^{(n)}$ and $\mathbf{X}^{(n)}$ are the vectors of the wave functions $f_2^{(n)}$ on the boundaries C_5, C_1 and C_4, respectively. $\mathbf{A}^{(n)}$, $\bar{\mathbf{A}}^{(n)}$, $\mathbf{B}^{(n)}$, $\bar{\mathbf{B}}^{(n)}$, $\mathbf{C}^{(n)}$, $\bar{\mathbf{C}}^{(n)}$, $\mathbf{D}^{(n)}$, $\bar{\mathbf{D}}^{(n)}$, $\bar{\mathbf{P}}^{(n)}$, $\bar{\mathbf{Q}}^{(n)}$, $\mathbf{R}^{(n)}$, $\bar{\mathbf{R}}^{(n)}$, $\mathbf{S}^{(n)}$, $\bar{\mathbf{S}}^{(n)}$, $\bar{\mathbf{T}}^{(n)}$ are the known matrices.

Rearranging the expression (29), the wave functions $\mathbf{f}^{(n)}$ and $\bar{\mathbf{f}}^{(n)}$ (n=1,2,...) on the ship boundary can be transformed into:

$$\bar{\mathbf{f}}^{(n)} = \bar{\mathbf{U}}^{(n)}\mathbf{f}^{(n)} + \mathbf{u}^{(n)} \ , \qquad (31)$$

where $\bar{\mathbf{U}}^{(n)}$ is the known matrix and $\mathbf{u}^{(n)}$ is the known vector.

Once the relation between $f_2^{(n)}$ and $\bar{f}_2^{(n)}$ on the ship boundary is obtained, the procedure of the calculation hereafter is the same as that of ship motions along the straight quay wall.

3 EXPERIMENTAL VERIFICATION

3.1 Experimental Apparatus and Procedure

The experimental setup in cases of the quay wall and the slip are shown in Figure 6 (a) and (b), respectively. The wave basin of 30 m long, 20 m wide and 0.6 m deep was used in the experiment. A rectangular floating body of 2.4 m long, 0.455 m wide and 0.098 m deep was used as a ship model. The other dimensions of this ship model are shown in Tables 1 and 2. The ship model was moored by coiled springs whose spring constant was 67 gf/cm. The ship motions were measured by the 6-component measuring instrument.

3.2 Results and Discussion

3.2.1 Ship Motions Along the Quay Wall

The kinds of experiments of the ship motions are carried out under the following conditions. In one group, the wave period is varied and

the angle of wave incidence was kept constant and vice versa in the other group.

(a) Ship motions in beam seas

In Figure 7, the ship motions measured in experiments are compared with the theoretical results. As can be seen in the rolling motion, the calculated period of resonance is little bit smaller than that of the experiment. The reason of this difference is the effect of eddy-making which is not taken into account in this analysis. While experimental results of heaving and swaying motions seem to be predicted fairly well by this theoretical analysis.

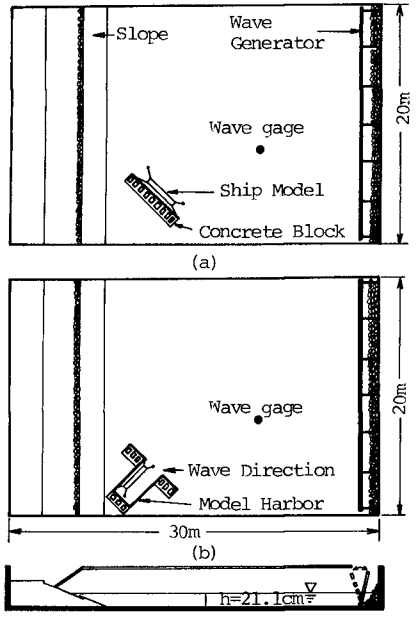

Fig.6 Arrangement of moored ship in the wave basin

If the floating body is symmetric with respect to the x-axis in beams seas, pitching, surging and yawing motions should not occur in the potential theory. Although the solid lines in Fig. 7 in these ship motions show the results considering the difference of the center of gravity from the center of figure in y-direction, there is wide division between theoretical and experimental results especially in yawing motion. The asymmetry of waves and the effect of eddy shedding may account for this discrepancy.

Table 1 Dimensions of moored ship along the quay wall

Natural period (sec)

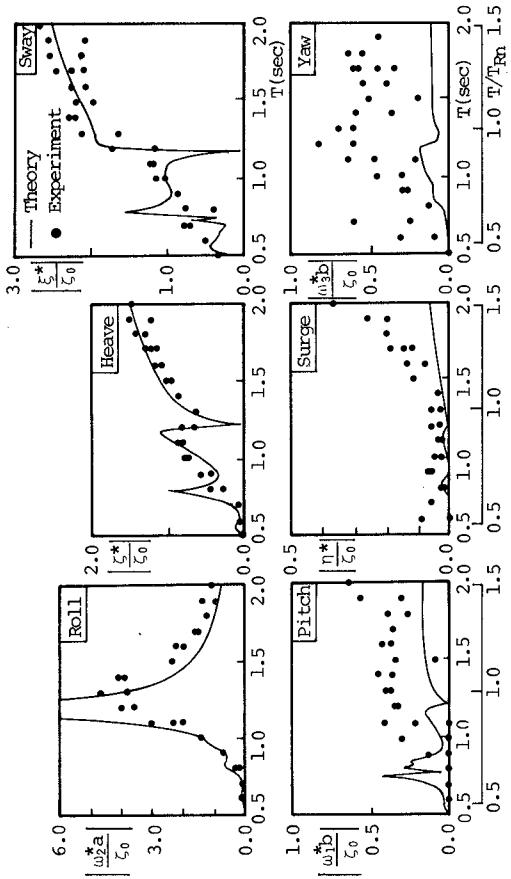

Fig.7 Motions of moored ship along the straight quay wall in beam seas

(b) Ship motions in waves of arbitrary angle of wave incidence

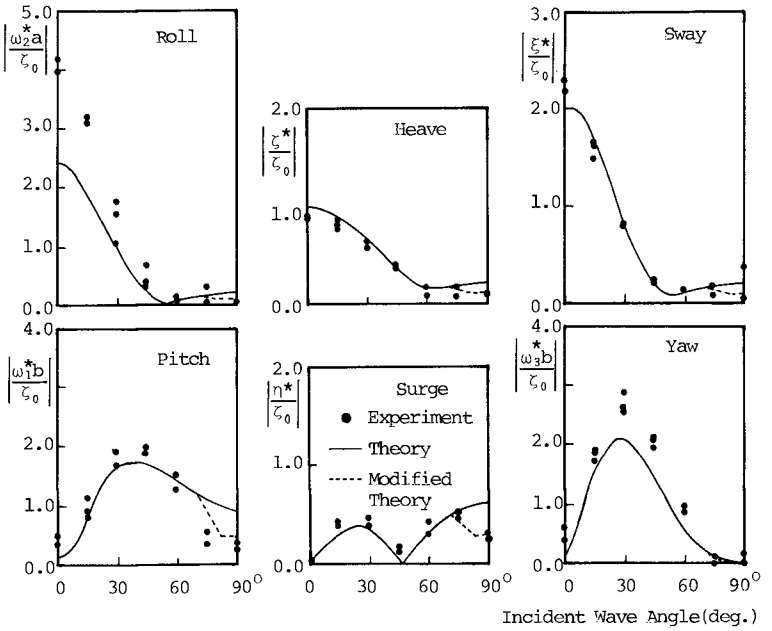

Fig.8 Relationship between ship motions and angle of wave incidence

Figure 8 shows the comparison of the experimental results with the theoretical results when the angle of wave incidence is changed from 0 to $\pi/2$. Both results show fairly good agreement. However, the theoretical results of rolling motions become smaller than the experimental ones at the small angle of wave incidence. The cause of this disagreement seems to be the difference between the numerical resonance period and the experimental resonance period as shown in Figure 7. The yawing motion in the experiment becomes larger than the theoretical one. This enlargement is thought to be caused by the eddies induced at the both ends of the ship. Finally, experimental values of almost all ship motions decrease by one-half of theoretical ones near $\alpha = 90^0$. Figure 9 schematically shows the straight quay wall of finite length and the floating body. The all reflected waves from the quay wall affect the floating body when $\alpha < \alpha_1$ but the effects of the reflected waves on the floating body become small when $\alpha_2 \geq \alpha \geq \alpha_1$, and the effects vanish entirely when $\alpha > \alpha_2$. But the reflected waves always affect the floating body in the theoretical analysis, because the quay wall is assumed to be infinity. This is the reason that experimental

results become smaller than theoretical ones near $\alpha = 90^0$. By the way, as the angle θ_{ir} shown in Fig. 9 becomes small when α approaches 90^0, the effects of the incident waves and reflected waves on the ship motions can be considered nearly equal. From the above facts, the incident wave hieght is considered one half when $\alpha > \alpha_2$ and it is considered to decrease from one to one half when $\alpha_2 \geq \alpha \geq \alpha_1$. The dotted lines show the results conducted by the above modified theory. The experimental results indicate the validity of the above way of thinking.

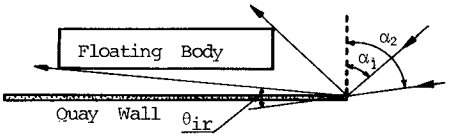

Fig.9 Reflected wave by the quay wall of finite length

3.2.2 Ship Motions in a Slip

Figure 10 shows the ship motions for three angles of wave incidence, $\alpha = 30^0$, 60^0, 90^0. It is clear from these figures that the resonance periods in a slip are different from the natural periods at the open sea. For example, the natural period in heave at the open sea is 0.8 seconds which is represented by T^O_{Hn}, but the natural period in the slip is 2.08 seconds which is expressed by T^S_{Hn} as shown in Figure 10 (b). And the natural period of the rolling motion in the slip is 1.38 seconds which is expressed by T^S_{Rn}, but the resonance periods are 1.15 seconds which are represented by T^T_{Rn} and 1.35 seconds as shown in Figure 10 (c). The resonance at T^T_{Rn} seems to be induced by the lateral oscillation which is the second mode harbor oscillations having loops at the boundaries C_2 and C_4 in Figure 5. Though T^T_{Rn} and T^S_{Rn} do not coincide each other in this experiment, the rolling motion should become large when the both resonance periods coincide.

Another important characteristics of the ship motions are the coupled resonances among mutual ship motions. Namely, as the ship is surrounded by three quay walls, the waves induced by predominant ship motions in one mode affects the other mode of ship motion. And many peaks of ship motions can be seen in Figure 10 in comparison with the ship motions along the straight quay wall or in an open sea. For example, the resonance of heaving motions at $T = T^O_{Hn}$ and T^S_{Hn} induces the new resonance in swaying and rolling motions at the same wave periods. And the resonance of rolling motions at $T = T^T_{Rn}$ and T^S_{Rn} produce the ones of swaying motions at $T = T^S_{Rn}$ and of heaving motions at $T = T^T_{Rn}$ and T^S_{Rn}. The same phenomena can be seen in the other ship motions, though they are not shown in Figure 10. By the way, since the damping forces due to eddy-shedding which will be obtained from free oscillation test are not considered in this analysis, the theoretical peaks of ship motions are fairly larger than the experimental ones. These disagreements should be improved by considering the

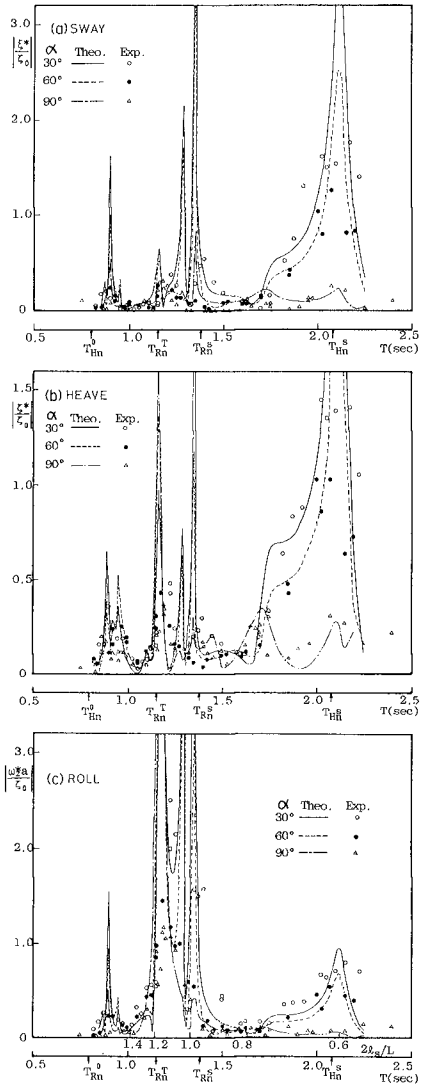

Fig.10 Ship motions in the slip

damping forces in Eq.(8). But it is clarified that the theoretical and experimental results show fairly good agreement except near the resonance periods. So it can be concluded that the short-period ship motions in the slip can be predicted by using the above potential theory.

4 MOORING SYSTEM WITH DASH-POT

The authors have already discussed the effect of the perforated quay wall[8] on the ship motions, but it was found that all ship motions along the perforated quay wall were not always smaller than those along the ordinary quay wall. So the dash-pot system is considered as the another damping system of moored ship motion[9]. In this section, the damping effect of dash-pot system on the short-period ship motion is analyzed.

4.1 Theory of Ship Motions with the Damping System

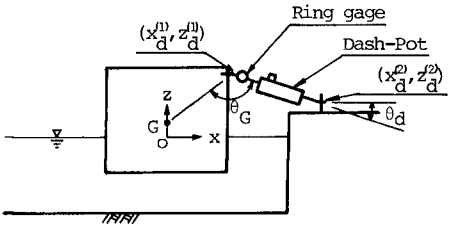

Fig.11 Arrangement of dash-pot(θ_d is measured anti-clockwise from positive x-axis)

In order to simplify the problem, it is analyzed by the two dimensional theory in the simulation. The coordinate system is shown in Figure 11. One end of the dash-pot on the ship has the coordinate $(x_d^{(1)}, z_d^{(1)})$ and the other end on the quay wall has the coordinate $(x_d^{(2)}, z_d^{(2)})$. These ends can rotate freely by universal joints. The length between both ends ℓ_d is expressed by:

$$\ell_d = \sqrt{(x_d^{(2)} - x_d^{(1)})^2 + (z_d^{(2)} - z_d^{(1)})^2} \tag{32}$$

When the ship starts to move, the end of the dash-pot on the ship moves with the ship movements, but the other end on the quay wall does not move. The change of the length of mooring line $\Delta\ell_d$ is approximated by:

$$\Delta\ell_d = \left[\frac{x_d^{(2)} - x_d^{(1)}}{\ell_d}\{\xi^* - (z_d^{(1)} - \bar{z}_0)\omega_2^*\} + \frac{z_d^{(2)} - z_d^{(1)}}{\ell_d}(\zeta^* + x_d^{(1)}\omega_2^*)\right] e^{-i\sigma t} \tag{33}$$

Since the damping force caused by dash-pot can be considered to be proportional to the velocity, the damping force F_{dp} can be given by:

$$F_{dp} = -k_d \frac{d(\Delta\ell_d)}{dt} = \hat{F}_{dp}\, e^{-i\sigma t} ,$$

$$\left.\begin{aligned}\hat{F}_{dp} = &\frac{-i\sigma k_d(x_d^{(2)} - x_d^{(1)})}{\ell_d}\{\xi^* - (z_d^{(1)} - \bar{z}_0)\omega_2^*\} \\ &\frac{-i\sigma k_d(z_d^{(2)} - z_d^{(1)})}{\ell_d}\{\zeta^* + x_d^{(1)}\omega_2^*\}\end{aligned}\right\} \quad (34)$$

where k_d is the damping coefficient. In the case of orifice with constant area, k_d is given as follow[10]:

$$k_d = \frac{8\pi\mu\ell_p A_d}{\{(a_0 + a_p)C_d\}^2}, \quad (35)$$

where μ is the coefficient of molecular viscosity, ℓ_p is the length of the orifice, A_d, a_0 and a_p are the cross-sectional areas of cylinder, orifice and piston clearance, and C_d is the coefficient of discharge. Using $\hat{F}_{dp}$, the forces $\hat{F}x$ in x-direction and $\hat{F}z$ in z-direction and the moment $\hat{M}$ are given by:

$$\left.\begin{aligned}\hat{F}_x &= -\hat{F}_{dp}\cdot\frac{x_d^{(2)} - x_d^{(1)}}{\ell_d}, \quad (36)\\ \hat{F}_z &= -\hat{F}_{dp}\cdot\frac{z_d^{(2)} - z_d^{(1)}}{\ell_d}, \quad (36)\\ \hat{M} &= -\hat{F}_x\cdot(z_d^{(1)} - \bar{z}_0) + \hat{F}_z\cdot x_d^{(1)},\end{aligned}\right\}$$

If above forces and moments caused by dash-pot are substituted into the equations of ship motions (8), the amplitudes of ship motions can be easily obtained by the same method as that of section 2.

4.2 Hydraulic Experiment

In order to verify the short-period motions of ship equipped with dash-pot, the hydraulic experiments are carried out. The arrangement of the experiment is shown in Figure 12. The sketch of the dash-pot is shown in Figure 13, and the characteristics are described in Table 3.

Both results of the ship motions with and without dash-pot are shown in Figure 14. It is found from these figures that the ship motions in every mode with the dash-pot is smaller than those without the dash-pot. Therefore, the new mooring system with dash-pot seems effective to reduce the ship motions.

Furthermore, the theoretical and the experimental results have good agreement each other. So it is clarified that the ship motions with dash-pot can be explained by the above mentioned theory. The force acting on the axis of the dash-pot is measured and is compared with the theoretical results. Both results show the same tendency, however, the theoretical one is larger than the experimental one. One reason of this difference comes from the inaccuracy of the measurement of compressive force by ring gauge. So the method of measurement should be improved hereafter.

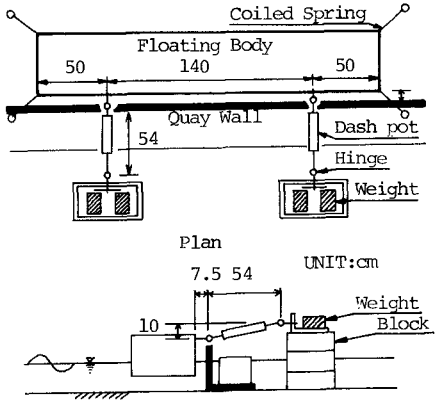

Fig.12 Experimental arrangement

Table 3 Dimensions of dash-pot

$x_d^{(1)}$	0.303m
$z_d^{(1)}$	0.197m
$x_d^{(2)}$	0.843m
$z_d^{(2)}$	0.297m
A_c	9.62cm^2
ℓ_p	10mm
a_0	14.1mm^2
a_{LR}	4.0mm^2

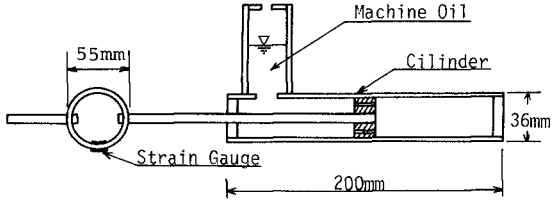

Fig.13 Dash-pot used in the experiment

4.3 Optimum Design of Dash-Pot by Numerical Simulation

Using the above mentioned theory, the optimum design of dash-pot system is investigated. Figure 15 shows the calculated ship motions and axial forces acting on the dash-pot in case of various installed angle of dash-pot θ_d. From these figures, it is found that rolling motions are significantly affected by θ_d and become smallest when $\theta_d = -57^0$, however, θ_d does not affect another nodes. On the other hand, the axial force F is the least when $\theta_d = -57^0$. As it is not favorable that the axial force which is the force acting on the bits on the ship and the quay wall is large, the angle $\theta_d = -57^0$ is the most suitable one to reduce the ship motions by dash-pot. Let θ_G be the angle as shown in Figure 11, $\theta_d = -57^0$ corresponds to $\theta_G = 90^0$. This fact shows that the dash-pot should be equipped so as to make the damping moment maximum and to suppress the rolling motion.

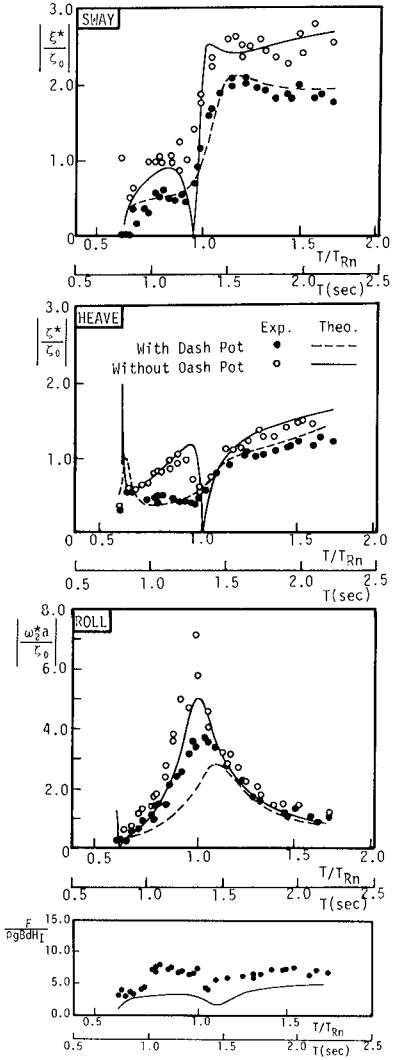

Fig.14 Comparison of ship motion with and without dash-pot, and the axial force of the dash-pot

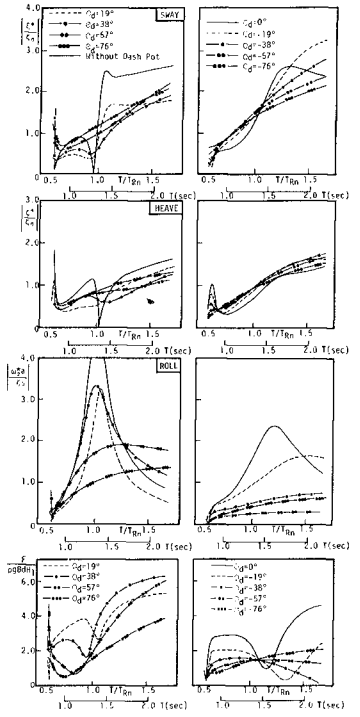

Fig.15 Ship motions and axial force of dash-pot obtained by numerical simulation

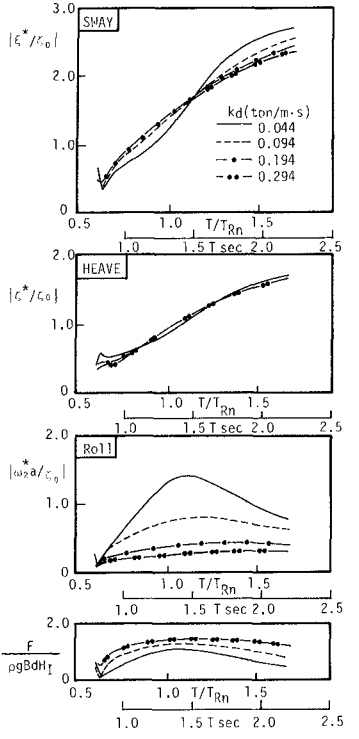

Fig.16 Relationship among ship motions, axial force and damping coefficient when $\theta_G = 90^0$

Figure 16 shows the effects of damping coefficient k_d on the ship motions and the force acting on the dash-pot when $\theta_G = 90^0$. It is noticed that the swaying and heaving motions are not heavily influenced by k_d, but the rolling motion is reduced satisfactorily with the increase of k_d.

The resonance of roll can be seen in the region when $k_d < 0.094$ ton f/(m.sec), but the resonance disappears when $k_d > 0.094$ ton f/(m.sec). The larger k_d becomes, the smaller the roll becomes. While the axial force acting on dash-pot increases. So the smallest value of k_d where the resonance of roll disappears is regarded as the optimum damping coefficient which is expressed as k_{d_0}. Though it is obtained

from the above numerical model, it can be also estimated by the following simple method.

Now, the equation of rolling motion of free oscillation is expressed by:

$$I\ddot{\delta}_2 + k_d \ell_1^2 \dot{\delta}_2 + M \cdot g \cdot GM \cdot \delta_2 = 0 \quad , \tag{38}$$

where I is the virtual moment of inertia in roll, ℓ_1 is the length between the center of gravity of the ship and the one end of the dash-pot on the ship, GM is the metercentric height. Let the natural period of roll be T_{Rn}, and define ε_R and define η_R by:

$$2\varepsilon_R = \frac{k_d \ell_1^2}{I}, \quad \eta_R^2 = \frac{M \cdot g \cdot GM}{I} \fallingdotseq \left(\frac{2\pi}{T_{Rn}} \right)^2 . \tag{39}$$

Then it can be said from the theory of mechanical vibration that the resonance of roll disappears when the following equation is satisfied [10].

$$\frac{\varepsilon_R}{\eta_R} = \frac{1}{\sqrt{2}} \tag{40}$$

The damping coefficient k_d which satisfies the above condition is also the optimum damping coefficient k_{d_0} , so by arranging the expression, k_{d_0} is obtained as follow:

$$k_{d_0} = \frac{1}{\sqrt{2}} \cdot \frac{M \cdot g \cdot GM \cdot T_{Rn}}{\pi \ell_1^2} \quad , \tag{41}$$

Since $T_{Rn} = 0.8B/\sqrt{GM}$ [11] , Eq.(41) is rewritten by:

$$k_{d_0} = \frac{0.8}{\sqrt{2}} \cdot \frac{M \cdot g \cdot B\sqrt{GM}}{\pi \ell_1^2} \tag{42}$$

Now, for example, substituting experimental conditions M = 0.455*0.093 ton/m, GM = 0.13 m, T_{Rn} =1.3 seconds and ℓ_1 = 0.36 m into Eq.(42), k_{d_0} = 0.124 ton f/(m.sec) which is between 0.094 ton f/(m.sec) and 0.194 ton f/(m.sec) is obtained. From this, it is clear that the optimum damping coefficient can be estimated by Eqs.(41) or (42).

5 CONCLUSIONS

The motions of a moored ship in a harbor basin and the mooring system with dash-pots are investigated. The conclusions are summarized as follows:

1) The ship motions along the quay wall and in the slip can be analayzed by the three dimensional analysis.
2) Wave height distribution in the slip can be estimated by the method of images which is suitable to save cost of computation.
3) In order to reduce the short-period ship motions, a new mooring system with dash-pot is proposed. It is clarified that the system is very useful for reducing the rolling motion. Furthermore, it is clear from the numerical simulation that the angle θ_G should be

adjusted to $\pi/2$ and the optimum damping coefficient of the dash-pot is given by Eq. (42).

ACKNOWLEDGEMENT

This study is supported in part by the Research Fund of the Ministry of Education of Japan. The authors also wish to express their gratitude to Mr. S. Aoki, postgraduate student of Osaka University, who assisted us in the experiment.

Study of Ship's Track and Motions at Port Taranaki

G. Greenstreet

ABSTRACT *This paper describes a study carried out at Port Taranaki, New Plymouth, New Zealand to determine ship's track and motions at the port entrance. The results of the study being used to establish the extent (plan area) and optimum depth of proposed capital dredging works. The time lapse photographic technique, incorporating reference levels and bearings in each frame, used to record vessels entering and leaving the port is described. Maximum increases in ship's draft due to sea conditions are given.*

1. INTRODUCTION

Port Taranaki, located in New Plymouth on the West Coast, North Island, New Zealand (Fig.1) is undergoing major development to handle, by 1987 a threefold increase in trade brought about by the utilization of the Maui (off shore) and Kapuni gas and oil fields.

As part of the port development, capital dredging including the port entrance is required to allow for deeper draft vessels (up to 11.0m) and a greater tidal 'window' for arriving and departing ships. The present dredged depth is 9.0 - 10m below chart datum.

This paper describes the work carried out to determine:-
(i) the extent (plan area) or port entrance to be dredged by plotting the tracks taken by vessels at the entrance.

(ii) the optimum increase in dredge depth for vessels using the port by measuring the magnitude of ship's motions (as they effect draft) caused by wave action.

Due to budgetary restraints the study had to be carried out at minimal cost.

*Bruce Wallace & Partners, Auckland, New Zealand.

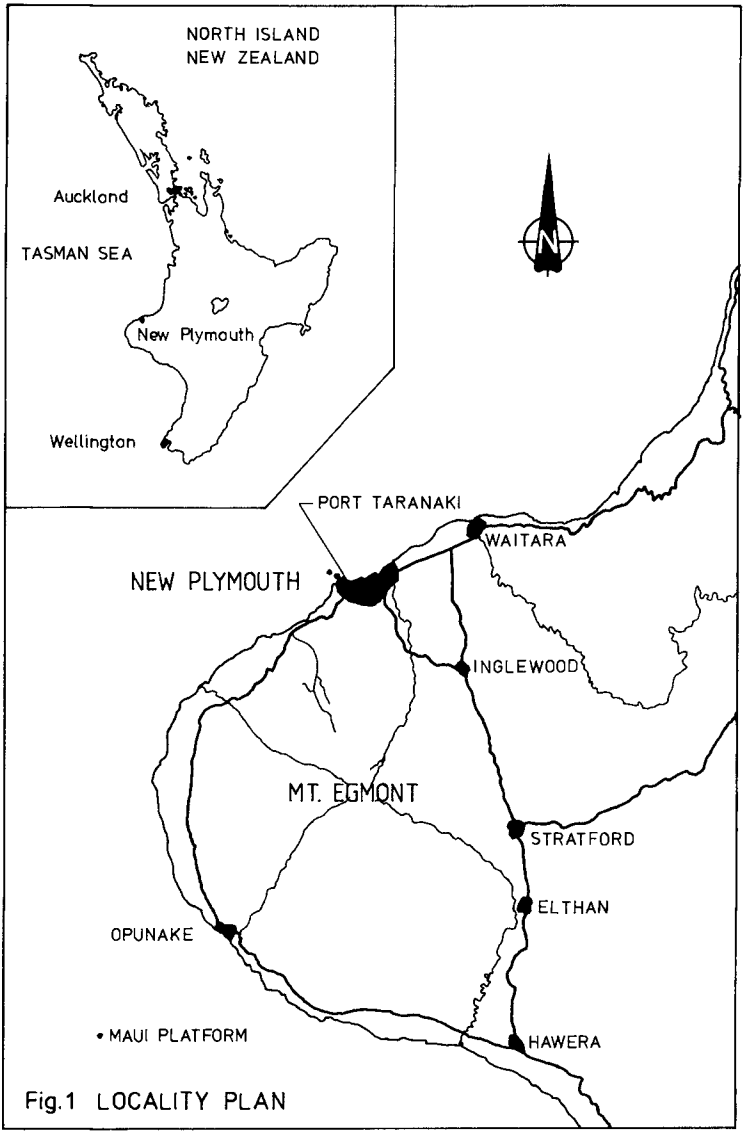

Fig.1 LOCALITY PLAN

2. SEA CONDITIONS

Vessels entering or leaving the port are subject to quarter or beam seas from the prevailing westerly/southwesterly swells and storm waves generated by low pressure systems in the south Tasman Sea.

Significant wave height projections *(1)* for the sea off the port are:

Significant Wave Ht (m)	Average Frequency
0-1.2	49.3%
1.2-2.4	29.5%
2.4-4.6	16.5%
over 4.6	4.7%

3. METHOD

A single camera photographic method was chosen for the recording of the track and motions of ship's at the port entrance after a number alternatives had been investigated. These included:

*Mounting portable measuring equipment on each ship and recording motions. Apart for difficulty in obtaining suitable equipment, its transfer to and from a pilot vessel in storm conditions would have proved difficult and required staff, additional to the pilot, on board.

Based on the experience of Columbia River Entrance Study *(2)* delays of 2-3 hours to set up and calibrate equipment on board a vessel could be expected. This length of delay could not be justified particularly as the average transit time through the entrance was between 5 and 10 minutes. Position fixing equipment was not available at the port.

*Photographic methods using two remotely located cameras syncronised to film simultaneously would have given an accurate fix of ships' position. However, this method would have required more manpower and equipment than the system chosen.

The method employed used a super 8mm cine camera, with time lapse and zoom capabilities, mounted at the end of an existing wharf on a permanent stand. A gradulated horizontal sight board was constructed in front of the camera at a constant 20.0m radius from the camera position.

This radius was approximately the minimum focusing distance when the camera was at full zoom.

Levels (above datum) of the sight board and camera lens were determined (approx 300mm difference) together with co-ordinates of the camera position and a true bearing from the camera to a point on the sight board.

The main area of interest, at the port entrance, was between 500mm and 1500mm from the camera position. The nature of the ship's tracks meant that vessels were photographed from either the bow or stern quarter.

The cameras zoom capability was used to ensure the largest possible image of a vessel was obtained in each frame. Filming was at a rate of a frame every two seconds.

The still water draft (bow and stern) of the berthed vessels was recorded and a copy of the ship's plans obtained for the vessel. Wind speed and direction were recorded together with a visual estimate of wave heights and direction at the port entrance.

4. FILM ANALYSIS

With the incorporation of the sight board, each photographic frame contained a reference scale and bearing together with a reference level datum. Film frames were viewed for analysis by back projection on to a screen faced with plate glass (approx.650mm x 450mm). Distances between various points on the ship and between these points and the sight board were measured in terms of the graduated scale on the sight board (Fig.2). Horizontal distances from the reference bearing to points were also recorded (Fig.3).

Using the measured distances and the fixed references incorporated in each frame, together with the vessels dimensions, the ship's positions (2 co-ordinated points) and the reduced level of three points on the vessel were calculated by trigometric functions using a purpose written computer program. As the orientation of the vessel in relation to the camera was not known, plan dimensions could not be used to determine the distance of ship from the camera. Therefore a vertical dimension which gave a true rather than apparent height in the frame was used. (h1 in Fig.2). The image height focal/length relationship of the camera could not be used to determine distance as the focal length varied with the adjustment of the zoom lense.

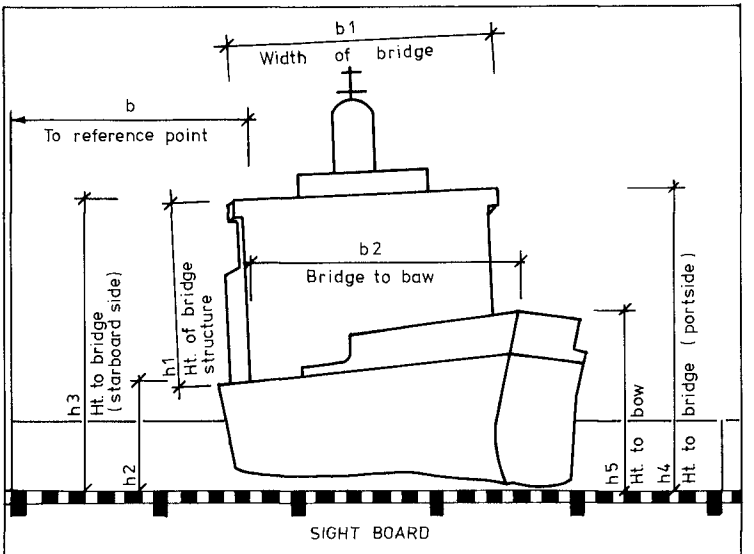

Fig.2 ELEVATION - SHIP MEASUREMENT POINTS

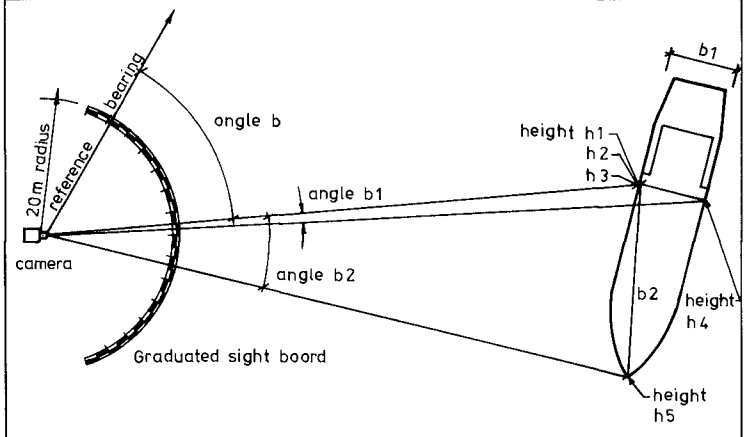

Fig. 3 PLAN - SHIP MEASUREMENT POINTS

Where track only was required, every 10th frame was analysed (i.e. ship's position every 20 seconds) with vessels with significant motion (i.e. rolls over 5^{o}) having additional frames analysed.

From the three calculated levels and the previously recorded still water draft, ship's motions (pitch, roll and heave) were calculated together with the change in draft caused by these motions.

A major factor in the accuracy of the results was the definition of the image obtained, particulary the sight board to which all measurements are related. Based on the limits to which measurement could be taken, errors in position (at approx 1000m from the camera) were estimated to be in the order of $\pm$ 7m with levels of points on the vessel varying $\pm$ 300mm.

5. RESULTS

To date, some 100 vessel movements have been photographed over an 18 month period of which some 20 have been analysed. Of the remainder, light conditions (i.e. dawn, dusk) did not give sufficient definition for accurate measurements or there was no significant ship's motion.

5.1 Ships' Track

A plot of ships' tracks was made (Fig.4) to determine the extent of the port entrance traversed by vessels. Once in port and prior to berthing, ships are turned to starboard (towards the main breakwater) and reversed with the aid of a tug into their berth. Consequently the tracks of arriving ships are closer to the lee breakwater to allow a greater turning radius within the port.

5.2 Ship's Motions

Rolling motions caused by beam or quarter seas were the most significant cause of increase in ship's draft. Rolls over 5^{o} were recorded by eight vessels with two of these being over 10^{o}. The maximum roll observed was in the order of 17^{o} but this was in deep water outside the area of interest.

The most significant results were obtained from two vessels on the same day when an estimated 1.5-2m swell was running at the port entrance with 15-20 knot winds gusting to 30 knots from the southwesterly direction.

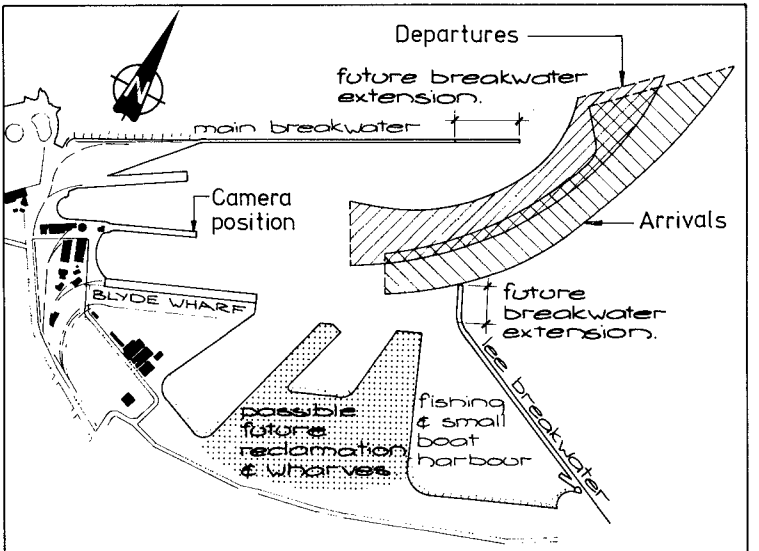

Fig. 4 PLAN - ENVELOPE OF SHIPS TRACKS

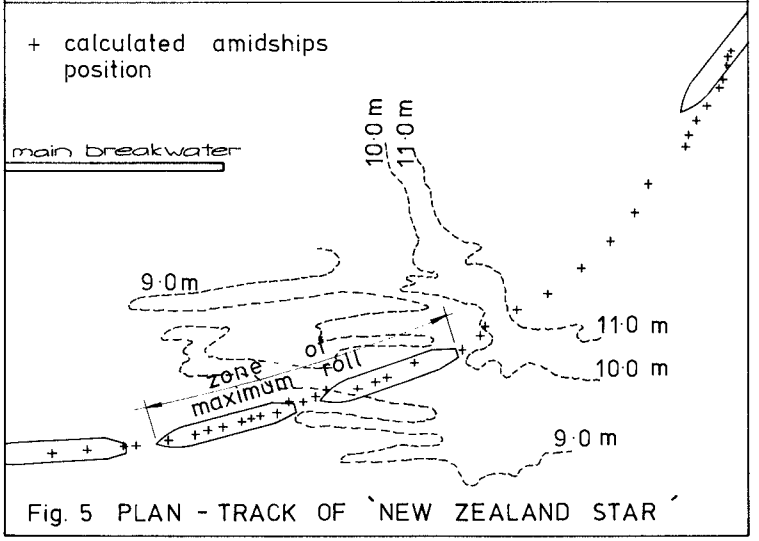

Fig. 5 PLAN - TRACK OF 'NEW ZEALAND STAR'

"New Zealand Star" - 7.0m draft; 170m o/a length (Fig.5) - consistently rolled 10-12° with a 12.8° roll combined pitch and heave (downwards) to give an increase in draft of 3.5m over still water draft. The rolling motion with a period of approx 16 sec increased from 2-3° to over 10° and this amplitude was maintained over 6 or 7 cycles before reducing to the previous figure. This increase was observed twice during the film run.

"Columbus Louisiana" - 9.0m draft; 168m o/a length - a pitching motion (with 2-3° rolls) to give a maximum increase in draft of 2.5m. It was observed, when running the film of the departure at a fast speed (9 frames/sec), that longitudinal flexing of the vessel may also have occured.

The remainder of the vessels analysised gave draft increases of between 0.5m and 1m.

6. EXTENT OF DREDGING

Based on the results of the study the extent and depth of dredging at the entrance to the port was determined.

A dredge depth of 13m below chart datum has been decided for the entrance. Except in servere sea conditions this depth will allow all but the deepest draft vessels to enter the port over the whole tidal range (3.0m at Mean Spring Tides). Depending on sea conditions,movement of large vessels will be governed by the state of the tide.

7. DISCUSSION

Merits of the system employed include:-
-ease of operation. Once the camera and sight board have been set up only one person is required to photograph the vessels and collect tidal and vessel draft data.

-each photographic frame contains all data (except ship dimension and draft) necessary for analysis.

- no on-board equipment is required

- the capital cost of the equipment employed was low

Limitations of the method are:-

-it is dependant on lighting conditions. That is, poor images were obtained at dawn and dusk and sometimes during the day when sunlight reflecting off the sea gave only a silhouette of the vessels. Ideally the camera should have its back to the sun.

- film analysis is time consuming

- data processing and calculation requires computer assistance Initally this was carried out using a programmable desk top calculator and latera micro computer.

Improvements to the system could include increasing the distance of the sight board from the camera (30 to 50m radius) and the use of a larger film size (i.e. 16mm or 35mm) to improve the quality of the enlarged image used for analysis.

Having established the requirements for dredging the port entrance it is intended to continue the study to provide the port's pilots with guidelines as to the likely increase in ship's draft for various sea conditions. To this end, a wave recorder will be installed at the port entrance later in 1983 and a further series of runs recorded. It should then be possible to establish a relationship between ship motions and sea conditions.

8. SUMMARY

The photographic technique employed in the study gave a low budget means of determining ship's track and motions and allowed the dredged area and depth of dredging at the port entrance to be determined.

Significant increases in draft due to ship's motions were recorded (3.5m maxm). These were greater than the normal empirical allowances made for keel clearance. All three types of motion (roll, pitch and heave) contributed to the draft increase.

The accuracy of the method was considered to be within acceptable limits but could be improved by more sophisticated photographic equipment and by increasing the distance between the camera and the reference sight board.

9. ACKNOWLEDGEMENTS

This study was carried out for the Taranaki Harbours Board and the author wishes to thank the Board's Chief Engineer, Mr P.D.L. Holmes, for permission to publish this paper.

Thanks also to the Bruce Wallace & Partners staff members who, due to vagaries of shipping time-tables, spent countless hours, often in adverse conditions, waiting to film the vessels.
