Coastal Engineering

1982 PROCEEDINGS

Proceedings of the

EIGHTEENTH COASTAL ENGINEERING CONFERENCE

Volume I

November 14-19, 1982
Cape Town, Republic of South Africa

Conference held under the auspices of the
Coastal Engineering Research Council
of the
American Society of Civil Engineers,
International Association of Hydraulics Research
and the
Engineering Committee on Oceanic Resources

and organized by the
South African Institution of Civil Engineers
assisted by the
Council for Scientific and Industrial Research

Edited by Billy L. Edge

FOREWORD

Only one International Conference on Coastal Engineering has been held in the same city thus far. Moreover no country has been the venue for more than one Conference except the United States. Although repeat venues are not discouraged, the extremely time consuming activities of planning and conducting a major international conference do not encourage a second effort by the same group. Having the venue in different countries allows the participants to learn first hand about coastal problems and solutions around the world. This approach also allows those engineers and coastal scientists who could not travel to foreign countries to meet the international coastal community.

The papers in this *Proceedings* have been prepared by the authors who made presentations at the 18th International Conference on Coastal Engineering. The authors were asked to make their presentations and submit final papers based on review of the abstracts that were submitted well in advance of the conference. These abstracts were reviewed by a committee of four professionals including representation from the local organizing committee. All papers are eligible for discussion in the Journal of the Waterway, Port, Coastal and Ocean Division. All papers are eligible for ASCE Awards.

Venues for the 19th and 20th conferences are Houston, Texas, and Taiwan, Republic of China, respectively. Countries desiring to host a future conference should contact the Secretary of the Coastal Engineering Research Council to receive information on submitting a proposal.

Billy L. Edge, Secretary
Coastal Engineering Research Council
American Society of Civil Engineers

ACKNOWLEDGEMENTS

NATIONAL ORGANIZING COMMITTEE

Mr. K. G. Witthaus	National Chairman
Mr. J. Rossouw	Deputy Chairman
Mrs. Z. Retief	Ladies Programme Subcommittee
Mr. J. M. Evans	Financial Subcommittee
Dr. D. H. Swart	Papers Subcommittee
Mr. J. F. Kapp	Publicity Subcommittee
Mr. K. S. Russell	Programme Subcommittee
Prof. G. de F. Retief	Social Subcommittee
Mr. J. A. Zwamborn	Technical Tours Subcommittee
Mr. J. P. Möller	Transport Subcommittee
Mr. F. P. Anderson	Other members:
Mr. N. P. Campbell	
Mr. P. Grobbelaar	
Prof. F. A. Kilner	
Mr. D. C. MacLeod	
Dr. A. L. Moss-Morris	
Mr. A. P. M. Vonk	
Mr. R. K. Newman	
Mrs. A. Wissing	Secretariat

SPONSORSHIP

SOUTH AFRICAN INSTITUTION OF CIVIL ENGINEERS (SAICE)

assisted by the

COUNCIL FOR SCIENTIFIC AND INDUSTRIAL RESEARCH (CSIR)

under the auspices of the

Coastal Engineering Research Council (CERC),

International Association for Hydraulics Research (IAHR)

and the

Engineering Committee on Oceanic Resources (ECOR)

SUPPORT

CDM (Pty) Ltd, Oranjemund—Provided free accommodation.
Marine Civil (Pty) Ltd, Cape Town—Sponsored Gans Bay tour.
Borough of Richards Bay, Richards Bay—Entertainment, Richards Bay tours.
Underwater Construction (Pty) Ltd, Cape Town—Sponsored Saldanha Bay tour.
Fisheries Development Corporation of South African Limited, Cape Town.
Land & Marine and Salvage, Cape Town.
Murray & Roberts Civils (Cape) (Pty) Ltd, Cape Town.
The Anglo American and De Beers Chairman's Fund, Johannesburg.
South African Airways, Johannesburg.
SARTRAVEL, Cape Town.
Cape Town City Council, Cape Town—Visit to False Bay coastal development.
Electricity Supply Commission, Cape Town—Visit to Koeberg inlet basin.
National Institute for Oceanology, Stellenbosch—Laboratory visit.
South African Transport Services, Saldanha/Cape Town/Port Elizabeth/Richards Bay—Harbour visits.

Skiboat during beach survey in surf waves at Richards Bay

PART I
THEORETICAL AND OBSERVED WAVE CHARACTERISTICS

Victoria Bay, George

TURBULENCE GENERATED BY WAVE BREAKING ON BEACH

by

T. Sakai[1] , Y. Inada[2] and I. Sandanbata[3]

ABSTRACT

Horizontal and vertical velocities are measured with a hot-film anemometer(HFA) and a two-component laser-doppler velocimeter(LDV) in surf zones on uniform slopes of about 1/30 in two wave tanks. The turbulence generated by wave breaking is detected from the records. Following three aspects of the turbulence are discussed : (1) the distribution of the turbulence intensity in the surf zone, (2) the variation of the vertical distribution of the turbulence during one wave period and (3) the variation of the Reynolds stress during one wave period. It is found that the pattern of the distribution of the turbulence in the surf zone depends on the breaker type. A model is proposed, by extending the turbulent wake theory, to explain the variation of the vertical distribution of the turbulence during one wave period.

1. INTRODUCTION

It is recognized that the turbulence generated by wave breaking in surf zone plays an important role in various phenomena such as generation of longshore current, suspension of sediment and dispersion of material in surf zone.

Peregrine and Svendsen(1978) proposed a qualitative model for the flow field in spilling breaker. They concluded that the turbulent flow, immediately following the breaking, resembles a turbulent mixing layer.

Battjes and Sakai(1981) measured a velocity field in a steady breaker generated behind a wing inserted in a uniform open channel flow. The mean flow, the turbulent intensity, the Reynolds stress and their decays with distance downward and downstream were discussed in comparison with the turbulent shear layer and turbulnet wake theories. They concluded that the whole velocity field resembles the turbulent wake rather than the turbulent shear layer.

The steady breaker, in which Battjes and Sakai measured the velocities,

2) Engineer, Tobishima Cooperation, Tokyo, Japan
3) Graduate student, School of Civil Engg., Kyoto Univ., Kyoto, Japan

is not progressive but standing. Stive(1980) measured the velocity due to progressive breaking waves in a surf zone on a uniform slope of 1/40 in a wave tank by using a laser-doppler velocimeter. He also found a wake type flow in the region behind the crest. Flick, Guza and Inman(1981) measured the velocity in a surf zone on a uniform slope of 1/35 in a wave tank by using a hot-film anemometer. They discussed a difference of the turbulence due to the breaker type.

The conclusions and discussions in above mentioned two works are limited to few experimental conditions. In this study, the velocity fields are measured, under conditions different from those of their works, in surf zones on uniform slopes in two wave tanks by using a hot-film anemometer and a two-components laser-doppler velocimeter. At first, the effects of the breaker type on the overall turbulence distribution in the surf zone are discussed.

Secondly the variation of the vertical distribution of the turbulence during one wave period is discussed. A model is proposed, by extending the turbulent wake theory, in order to explain the variation. Finally a cross product of the simultaneous horizontal and vertical velocity fluctuations is calculated. The variation of this cross product during one wave period and its physical meaning are discussed.

2. EXPERIMENTS

2.1. Arrangements

The experiments were done in two wave tanks. Two wave tanks have nearly the same dimensions. The length is about 30m, the width is about 50cm and the height is about 70cm. A uniform slope of about 1/30 was installed in the tanks. The still water depth in the uniform depth part in front of the slope was always 35cm(see Fig.1). X-axis is taken shoreward from the breaking point. Z-axis is taken upward above the still water level. The experimental conditions are listed in Table 1.

The letters "H" and "L" in the case number indicate that the hot-film anemometer and laser-doppler velocimeter was used in the case respectively. h_1 is the still water depth in the uniform depth part in the tank, i is the slope and T is the wave period. H_0/L_0 is the deep-water wave steepness calculated from the wave height in the uniform depth part or at the breaking point. h_b is the still water depth at the breaking point, H_b is the wave height at the breaking point, and W is the width of the surf zone between the breaking point and the still water line (see Fig.1). The word "transient" in the column of breaker type means that the breaker type was a transient type between the spilling and plunging breakers. "HFA" and "LDV" mean hot-film anemometer and laser-doppler velocimeter respectively.

2.2. Measurements

The water surface elevation was measured at the breaking point and

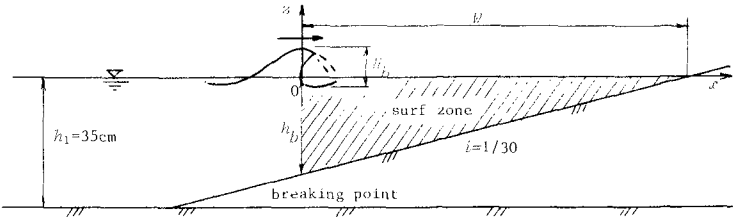

Fig. 1 Experimental Arrangements

Table 1 Experimental Conditions

case	h_1 (cm)	i	T (sec)	H_0/L_0	h_b (cm)	H_b (cm)	W (cm)	breaker type	instrument
H1	35.0	1/31	1.00	0.088	19.4	13.3	600	spilling	HFA
H2	35.0	1/28	1.16	0.066	17.7	12.8	490	spilling	HFA
L	35.0	1/31	1.17	0.063	18.0	12.8	530	spilling	LDV
H3	35.0	1/31	1.32	0.032	14.5	10.4	450	transient	HFA

the velocity measuring point with two capacitance-type wave gauges. In the cases H1 and H3, the water surface elevation was measured in the uniform depth part too.

The hot-film anemometer is DISA type 55M01, and the probe is DISA type 55R13. The hot-film probe was calibrated by using a vertically oscillating plate in still water to which the probe was attached. This probe has a vertical sensor of cylinder type and measures the velocity of the on-offshore direction. In the cases H1 and H3, in which the hot-film anemometer was used, the on-offshore velocity was measured at about 30 points under the level of the wave trough in the surf zone. The recording time at one point was 90sec. In the case H2, it was measured at about 40 points under the still water level in the surf zone. The recording time at one point was 60sec.

The two-components laser-doppler velocimeter is KANOMAX optical system 8143S, and the signal processor is KANOMAX model 8015 of tracker type. It can measure two components of oscillatory flow velocity simultaneouly. The mode of operation was the forward scatter fringe mode. The on-offshore and vertical velocities were measured at about 40 points in the case L under the still water level in the surf zone. The recording time at one point was 60sec.

All outputs from the wave gauges and the velocity meter were recorded in a analog magnetic redorder simultaneously. In the case L , the dropout signals from the laser-doppler velocimeter were also recorded.

3. DATA ANALYSIS

3.1. Distribution of Turbulence in Surf Zone(Cases H1 and H3)

In the cases H1 and H3, the data in the analog recorder were A-D converted every 0.01sec during 60sec for each measuring point. The first part of 24sec in the digital data was plotted graphically. Fig.2 shows two examples of the time profiles of the water level and the on-offshore velocity. In general, hot-film anemometer can not feel the change of the velocity direction. So the output of the measured velocity is rectified.

The figure (1) shows the time profiles at the breaking point. It is clear that the significant turbulence does not yet exist at the breaking point especially in the crest phase. On the other hand, within the surf zone, it is not so easy to find the instance when the direction of the water particle velocity changes in the time record due to the high turbulence(the figure (2)). Waves, in which the instance of the direction change was possible to find, were selected in the record. At most 90% of the waves during 24sec were selected.

The time profile of the velocity varies wave to wave. Turbulence defined as the deviation from the ensemble average of many waves(Stive, 1980) includes above mentioned velocity profile variation. Considering this fact, the measured velocity was smoothed with a moving average method for each selected wave. The time interval of average was 0.1sec.

A root-mean-square of the deviation u' from the smoothed velocity u_w was calculated for each selected wave. This was done separately for the phase of onshore velocity and the phase of offshore velocity(see Fig.3). They are called the horizontal turbulent intensities at the onshore velocity phase and the offshore velocity phase, and are expressed with symbols "$u'_{rms,c}$" and "$u'_{rms,t}$" respectively.

3.2. Variation of Vertical Distribution of Turbulence during One Wave Period(Case H2)

As well as in the cases H1 and H3, the data in the analog recorder were A-D converted every 0.01sec for each measuring point. The first part of 24sec in the digital data was plotted graphically. In order to discuss the variation of the turbulence during one wave period, the velocity record during the full length of 24sec, which contains about 20 waves, was smoothed with the same moving average method as in the cases H1 and H3(see Fig.4).

One wave period was divided into 12 sections of 0.1sec. The first section starts at the phase when the water surface crosses the still water level upward. The length of the last section is shorter than 0.1sec, because the wave period of the case H2 is 1.16sec. Each section of each wave contains 10 data of the deviation u' from the smoothed velocity u_w except for the last section. For each section, a root-mean-square of the deviation u' of all waves was calculated. This is expressed with a symbol "$u'_{rms}(t)$".

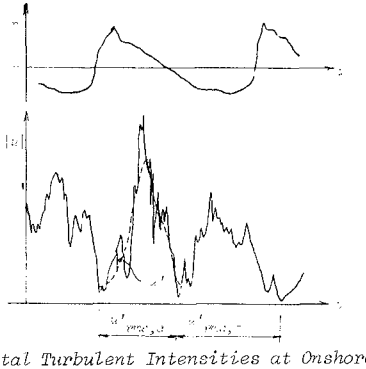

Fig. 3 Horizontal Turbulent Intensities at Onshore and Offshore Vlocity Phases $u'_{rms,c}$ *and* $u'_{rms,t}$

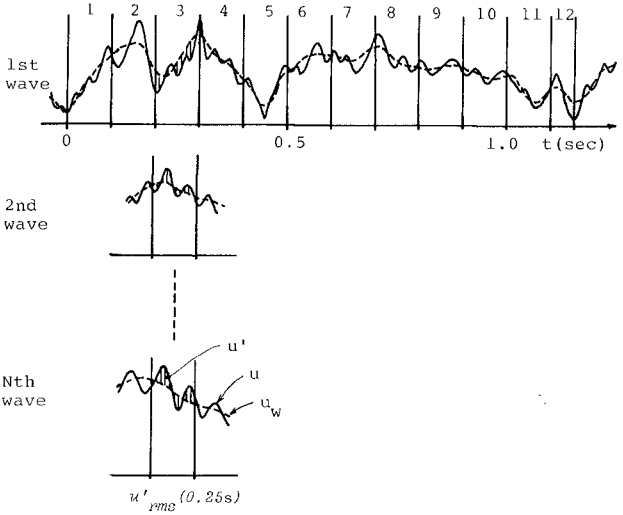

Fig. 4 Variation of Turbulent Intensity "$u'_{rms}(t)$"

3.3. Cross Product of On-offshore and Vertical Deviations u' and w' (Case L)

In the case L, the data in the analog recorder were A-D converted every 0.01sec during 48sec for each measuring point. The water level variations at the breaking point and the velocity measuring point, the on-offshore and vertical velocities and their dropout signals of 48sec were plotted graphically.

In general, laser-doppler velocimeter can not get any information about the flow velocity when no particle is detected by the LDV system. The situation of such no velocity information is called "signal dropout". The signal processor was operated in the so-called track-and-hold mode. The output from the signal processor keeps the value just before the signal dropout(see Fig. 5).

The signal dropout occurs due to several causes. At the measuring point above the trough level, in the trough phase, the laser beam goes out from the water between two glass walls of the tank. Then the dropout occurs. It occurs also when the air bubbles interupt the beams. The time intervals when no signal dropout occurs were selected from the plotted time profiles for the on-offshore and vertical velocities.

The on-offshore and vertical velocities in the no-dropout intervals were smoothed with the same moving average method as in the cases H1, H2 and H3. The product of the simultaneous on-offshore and vertical deviations u' and w' from the smoothed velocities were calculated only

in the time intervals when no dropout occurs both in the on-offshore and vertical velocities(see Fig.5).

The value of the cross product of u' and w' at every 0.01sec in each no dropout interval was smoothed again with the moving average method of 0.1sec. This smoothed value is expressed with a symbol "$\overline{u'w'(t)}$". $-\overline{u'w'(t)}$ is called Reynolds stress here. As the signal dropout occurs sometimes, there are waves in which the data of $-\overline{u'w'(t)}$ are lacked in some part of one wave period.

The Reynolds stress $-\overline{u'w'(t)}$ was ensemble averaged at every 0.01sec for all waves during 48sec. This ensemble averaged Reynolds stress is expressed with a symbol "$<-\overline{u'w'(t)}>$". As mentioned above, there are waves in which the data are lacked in some part of one wave period. Therefore, the number of the ensemble averaging is, in general, equal to or less than the number of total waves during 48sec(about 40).

The time interval of one wave was defined as from the phase 0.5sec after the crest of the preceeding wave to the phase 0.5sec after the crest of the wave. The wave period of the individual wave varies wave to wave. So, near the end of one wave period, the number of the ensemble averaged data decreases rapidly.

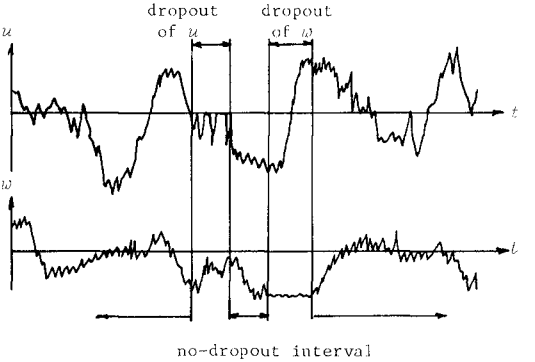

Fig.5 Signal Dropout of Laser-Doppler Velocimeter

4. DISTRIBUTION OF TURBULENCE IN SURF ZONE

4.1. Results

Fig.6,(1) shows the distribution of the horizontal turbulent intensities at the onshore velocity phase and the offshore velocity phase $u'_{rms,c}$ and $u'_{rms,t}$ in the surf zone in the case H1. In the figure, the range of scatter of the value is indicated by connecting the maximum and minimum values of each measuring point. The upper figure shows the on-offshore variation of the measured value at the highest measuring point. Fig.6,(2) shows the similar result in the case H3.

4.2. Error Estimate

In these two cases, the hot-film anemometer was used. The measured values contain some errors. The first error comes from the uncertainty of the calibration curve of the hot-film anemometer. The calibration curve itself has the error of 3cm/sec. This error influences the smoothed velocity u_w directly. But it is thought that it does not influence the deviation u' defined as $u - u_w$ so much.

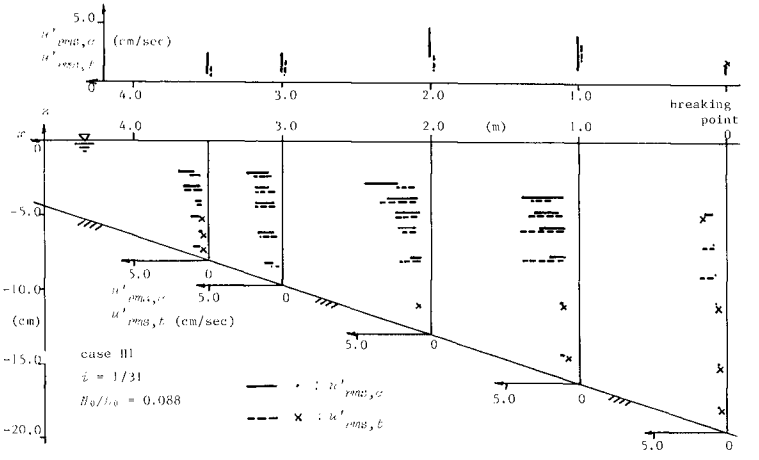
Another possible cause is the vibration of the probe mouting arm. The natural frequency of the arm was increased to more than 50Hz by shortening the length of the arm. So the fluctuation in the velocity due to the vibration was separated from the turbulence, the frequency of which is thought to be lower than 50Hz.

The probe may feel the vertical component of the velocity too especially near the phase when the on-offshore component becomes 0. This was already discussed(Isobe et al., 1979). It is found, using their result, that the error is about 1cm/sec. The ambiguity in the decision of the phase when the water particle velocity changes its direction is thought not to influence the mean value u'_{rms} so much.

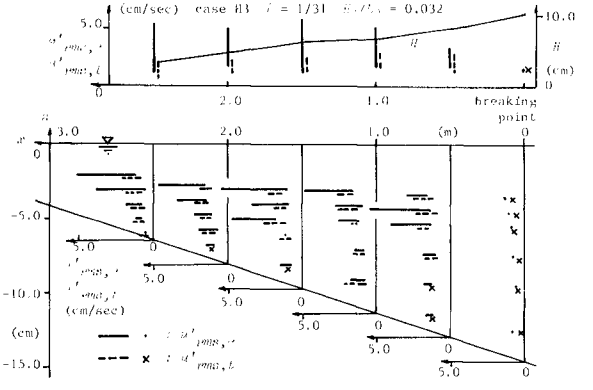
The value of the turbulence defined as the deviation from the smoothed velocity calculated by using the moving average method has one inherent error. The smoothed curve can not follow the abrupt change of the water particle velocity itself at the crest(see Fig.1,(1)). In fact, Fig.6 shows the turbulence of about 1cm/sec at the breaking point. This means that the value of $u'_{rms,c}$ contains the error of 1cm/sec.

The severest error comes from the air bubble interuption of the probe. At present, nothing is done to separate the effect of the air bubble interuption from the velocity measured by using the hot-film anemometer. Only one thing being done to reduce this error was to limit the measuring points under the trough level where the concentration of the air bubble is not so high. Therefore it is impossible to estimate this error quantitatively. The measured value is thought to contain this error to some extent.

4.3. Discussions



(1) case H1



(2) case H3

Fig. 6, (1),(2) Distribution of Horizontal Turbulent Intensities at Onshore and Offshore Velocity Phases $u'_{rms,c}$ *and* $u'_{rms,t}$

From Fig.6, it is found that the turbulent intensity varies largely wave to wave especially in the case H3, in which the breaker type was a transient type from spilling to plunging. The intensity is larger in the case H3 than in the case H1 in which the breaker type was spilling. It should be noticed that the breaking wave height H_b is smaller than that of the case H1(see Table 1).

As already seen in Fig.2,(1), the significant turbulence does not exist at the breaking point. The turbulence begins to grow after the waves propagate some distance from the breaking point. In the case H1, the turbulence damps after it reaches a maximum. But in the case H3, it does not damp so much at least in the measurement region. The wave height H itself decreases monotonically even in the case H3.

The turbulent intensity is larger in the upper part than near the bottom especially in the case H3. It means that the turbulence gererated by wave breaking does not penetrate into the lower part of the water body near the bottom. In the case H3, the turbulent intensity at the offshore velocity phase $u'_{rms,t}$ is smaller than that at the onshore velocity phase $u'_{rms,c}$.

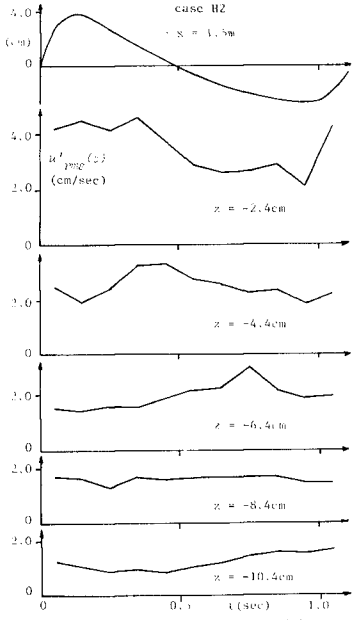
5. VARIATION OF VERTICAL DISTRIBUTION OF TURBULENCE DURING ONE WAVE PERIOD

Fig.7,(1) shows one example of the variation of the horizontal turbulent intensity $u'_{rms}(t)$ during one wave period in the case H2. The $<\eta>$ curve shows an ensemble mean of the time profile of about 20 waves. In this figure t-axis does not coincide with the still water level. Fig. ,(2) shows one example of another representation of the variation of the turbulent intensity during one wave period. In this figure, contour lines are used.

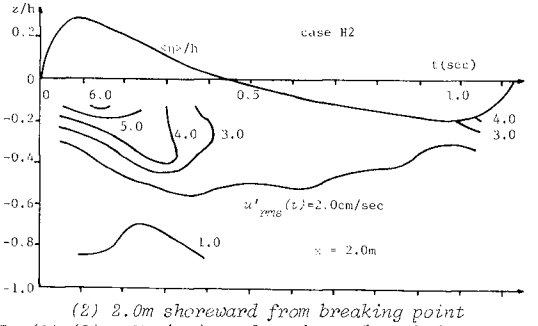
In the case H2, the hot-film anemometer was used. So the measured value contains the same errors as those in the cases H1 and H3. The velocity measurement was done also at the still water level. But, to reduce the error due to the air bubble interuption, the data at the still water level were not used in Fig. .

In this case, the velocity record during the full length of 24sec was smoothed. Therefore, the error due to the fact that the smoothed curve can not follow the abrupt change may occur also near the phase when the water particle velocity changes its direction. At such phase, the velocity becomes zero, and the rectified output drops abruptly to zero. But, as seen in Fig. ,(1), no effect of this error can be seen at the zero crossing phases.

As seen in Fig. ,(1), the phase of the peak in the curve of the variation of the turbulent intensity delays in the downward direction. This is also shown in the contour lines in the figure (2). The similar treand can be seen in Fig.8 of Stive(1980) too.



(1) 1.5m shoreward from breaking point



(2) 2.0m shoreward from breaking point

Fig. 7, (1),(2) Variation of Horizontal Turbulent Intensity $u'_{rms}(t)$ during One Wave Period

6. MODELING OF TURBULENCE VARIATION DURING ONE WAVE PERIOD

Fig.8 shows the turbulence variation during one wave period in form of time series of the vertical profile of turbulent intensity, at two positions 1.5m and 2.0m shoreward from the breaking point in the case H2. The crosses indicate the measured values.

The vertical profile of the turbulent intensity resemble that measured by Battjes and Sakai(1981) under an air entraining turbulent water surface generated behind a wing inserted in an open channel flow(see Fig.3 of their paper). The trend of the variation during one wave period in Fig.8 also resembles the streamwise variation of the vertical profile measured by Battjes and Sakai.

They showed that the streamwise variations of the mean velocity defect near the water surface, the length scale of the vertical profile and the turbulent intensity are explained by the turbulent wake theory(Tennekes and Lumley, 1972). In the following, it is tried to explain the turbulence variation during one wave period shown in Fig.8 by extending the turbulent wake theory.

6.1. Turbulent Wake Theory(Tennekes and Lumley, 1972)

Turbulent wake belongs to free turbulence as well as turbulent jet and turbulent shear layer(see Fig.9). Following assumptions are made in the turbulent wake theory : 1) The length scale in the streamwise direction is larger than the length scale l in the lateral direction, 2) Reynolds number is large, and 3) The order of the velocity defect U_s is same as the order of the turbulence. The equations of motion are simplified according to these assumptions.

One characteristic feature of free turbulence is that there is no characteristic length such as the water depth or the channel width. Then the velocity profile in the lateral direction are similar in the streamwise direction("self preservation"). Therefore the velocity U and the Reynolds stress are functions of only the lateral distance y and the scale l.

From above mentioned fact and the steamwise constancy of the velocity defect, it is found that the velocity scale U_s and the length scale l are proportional to the $-1/2$ power and $1/2$ power of the streamwise distance x. Introducing a constant eddy viscosity, it is found that U and the Reynolds stress are proportional to a function $f = \exp(-1/2 \cdot \alpha \xi^2)$ and $-f'$ respectively. Where $\xi = y/l$ and "'" indicates the differentiation with respect to ξ. α is a constant.

The turbulent intensity is thought to be proportional to the Reynolds stress. The shape of f' is shown in Fig.10. f' decreases near $\xi = 0$. This is not the case of the turbulent intensity, which has a nearly constant maximum value near $\xi = 0$.

6.2. Model of Turbulence Variation during One Wave Period

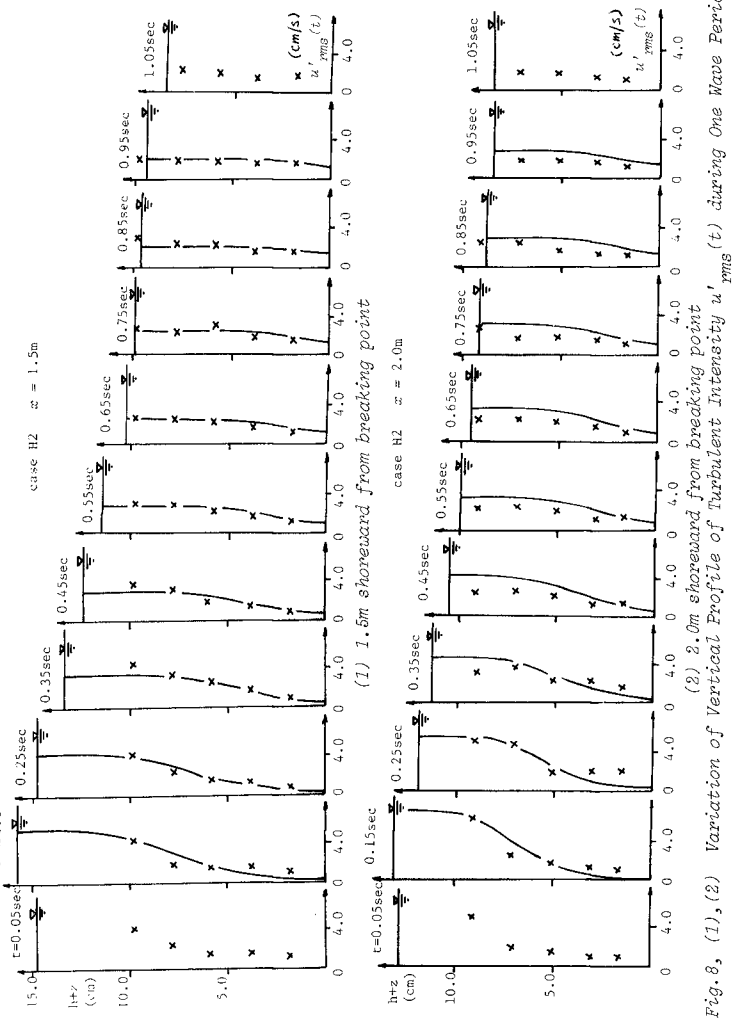


Fig. 8, (1), (2) Variation of Vertical Profile of Turbulent Intensity $u'_{rms}(t)$ during One Wave Period

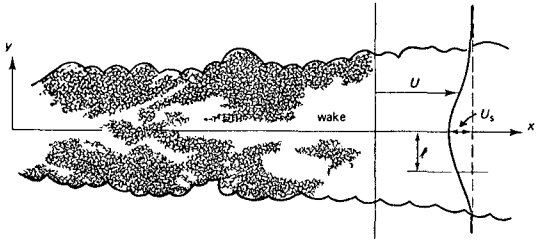

Fig.9 Turbulent Wake(Tennekes and Lumley, 1972)

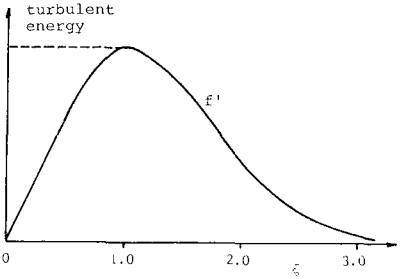

Fig.10 Lateral Profiles of Turbulence and Reynolds Stress(Tennekes and Lumley, 1972)

Before going to modeling, it should be noticed that the phenomenon to be modeled is the variation in time and not the variation in space. The turbulent wake theory itself explains the variation in the streamwise direction. But this model does not treat the variation in the on-offshore direction.

The crest phase is taken as the time origin. The phase to be modeled is limited to the range from the crest to the following trough($t = t_t$).

The instantaneous water level at each phase is taken as corresponding to the center line $y = 0$ of the turbulent wake(see Fig.9). The vertical distribution of the turbulence at each phase is assumed to be expressed by

$$\{u'_{rms}(z,t)\}^2 = \{u'_{rms}(t)_m\}^2 \gamma\{(\eta-z)/l\}, \quad (1)$$

in which η is the water level above the still water level, and l is the vertical length scale explained later. The function γ is assumed to be proportional to a function which takes the value expressed by the solid curve for $\xi > 1.0$ and the peak value of the solid curve in Fig.10 for $0 \leq \xi \leq 1.0$. $u'_{rms}(t)_m$ is a representative turbulent intensity at each phase(explained later).

The functional form of γ is determined by making its maximum value equal to 1.0 as follows :

$$\gamma(z) = \begin{cases} \frac{\eta-z}{l} \exp\left\{-\frac{1}{2}\left(\frac{\eta-z}{l}\right)^2 + \frac{1}{2}\right\} & ; \frac{\eta-z}{l} > 1.0 \\ 1.0 & ; 0 \le \frac{\eta-z}{l} \le 1.0 \end{cases} . \qquad (2)$$

The crest height η_0 above the still water level is taken as the vertical length scale l_0 at $t = 0$(crest phase). According to the turbulent wake theory, l is assumed to increase in proportion to the 1/2 power of the phase :

$$l = l_0\{(t + T)/T\}^{1/2} , \qquad (3)$$

where T is the wave period.

As seen from Eq.(3), $l = l_0 = \eta_0$ at $t = 0$. So $(\eta-z)/l = 1.0$ at $t = 0$ and $z = 0$. Therefore at the crest phase, $\gamma = 1.0$ from the water surface to the still water level. The measured value above the still water level at the crest phase should be taken as $u'_{rms}(0)_m$. Unfortunately there is no data above the still water level. The value of $u'_{rms}(0)_m$ was estimated from the data at the highest point and the profile given by Eq.(2). According to the turbulent wake theory, $u'_{rms}(t)_m$ is assumed to decrease in proportion to the -1/2 power of the phase :

$$\{u'_{rms}(t)_m\}^2 = \{u'_{rms}(0)_m\}^2 \left\{ \frac{\frac{1-K^2}{K^2} t + t_t}{t_t} \right\}^{-1} , \qquad (4)$$

where $K = u'_{rms}(t_t)_m / u'_{rms}(0)_m$.

The maximum measured value at $t = t_t$ was taken as $u'_{rms}(t_t)_m$.

6.3. Comparison with Experimental Results

The phase 0.95sec after the zerp-up crossing phase of the water surface was taken as t_t. The calculated vertical profile of the turbulent intensity is shown with solid lines in Fig. . The model developed here is rather simple. But the vertical profile and the time variation of the turbulence are explained well, at least in the lower part under the still water level.

But it should be recalled that the breaker type of the case H2 is a typical spilling type. Futhermore, the comparisons with the experimental results are limited to the data at the positions 1.5m and 2.0m shoreward from the breaking point. The width of the surf zone is about 500m. In these positions, the waves after breaking propagate just like stable bores. Therefore, it can be said that the model developed here is applicable to the turbulent field in the bore region located at 30 to 40% of the surf zone width shoreward from the breaking point.

7. CROSS PRODUCT OF ON-OFFSHORE AND VERTICAL DEVIATIONS

7.1. Result

Fig.11 shows the variation during one wave period of the ensemble averaged Reynolds stress $\langle -\overline{u'w'(t)} \rangle$ at the location 1.5m shoreward from the breaking point in the case L, in which the two-components laser-doppler velocimeter was used. As explained in 3.3., the ensemble averaged Reynolds stress $\langle -\overline{u'w'(t)} \rangle$ is defined as the ensemble average of the Reynolds stress $-\overline{u'w'(t)}$ at every 0.01sec of all waves during 48sec. But exactly speaking, the value shown in Fig.11 is not the value of this ensemble averaged Reynolds stress.

As explained in 3.3., the time interval of one wave period was defined as the interval from the phase 0.5sec after the preceeding wave crest to the phase of 0.5sec after the present wave crest. This time interval of one wave period was divided into 12 sections of 0.1sec. The value in Fig.11 is an averaged value of the ensemble averaged Reynolds stress in each section.

7.2. Discussions

One simple definition of Reynolds stress is the ensemble average of the product of the deviations u' and w' from the smoothed velocities over many waves. On the other hand, as well known, Reynolds stress is defined originally as a time mean of the product. So the Reynolds stress defined as the ensemble average over many waves is completely different from the original Reynolds stress.

In this study, the Reynolds stress was defined as the time mean. The interval of the time mean is 0.1sec(see 3.3.). The choise of the time length is arbitrary. There is no definite reason to choose 0.1sec. The time interval of no dropout is not always longer than 0.1sec. In a time interval shorter than 0.1sec, the interval of the time mean was reduced. Also in the beginning and end of one interval of no dropout, the interval of the time mean was reduced.

The number attached to each plotted point indicates the number of the averaged data. Near the water surface, it decreases rapidly. If no dropout occurs, it amounts to about 400.

The value itself is small compared with the value of the turbulent intensities $u'_{rms,c}$, $u'_{rms,t}$ and $u'_{rms}(t)$ shown in Fig.s 6 to 8. In many points, it is smaller than $1.0cm^2/sec^2$. $1.0cm^2/sec^2$ is the order of the possible error of the turbulent intensity(see 4.2.). At the position 0.5m shoreward from the breaking point, the calculated value of the ensemble averaged Reynolds stress in each section is less than $0.5cm^2/sec^2$. So, it may be said that the value of the Reynolds stress larger than $0.5cm^2/sec^2$ is meaningful.

As explained in 6.1., the Reynolds stress in the turbulent wake is proportional to $-f'$. Therefore, the cross product itself is proportional

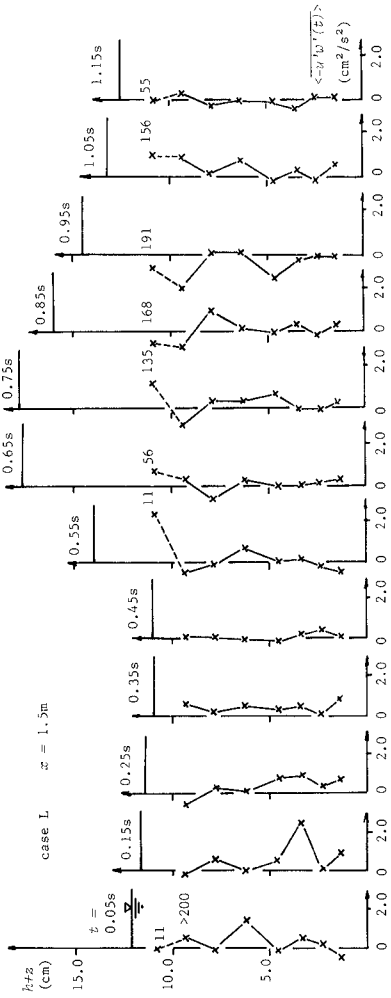

Fig. 11 Variation during One Wave Period of Ensemble Averaged Reynolds Stress $\langle -\overline{u'w'(t)} \rangle$ (1.5m Shoreward from Breaking Point)

to f'. As shown in Fig.4 of Battjes and Sakai(1981), the cross product under a steady breaker generated behind a wing inserted in an open channel flow has a similar vertical profile as f' in Fig.10.

The direction of the positive on-offshore velocity in this study is opposite to that of the turbulent wake in Fig.9. So, if the Reynolds stress obeys the turbulent wake theory, it must be proportional to f'. In Fig.11, there is no such trend. It becomes negative in some parts of the vertical profile. It is also found that at the phase after the crest it has a positive hump in the lower part of the vertical profile.

As mentioned above, the calculated value of the Reynolds stress has many ambiguities. Therefore no definite conclusion is derived from Fig.11. Only thing to be said is that the Reynolds stress field in surf zone may not be explained by the turbulent wake theory which could explain roughly the turbulent intensity generated by wave breaking.

8. CONCLUSIONS

Horizontal and vertical velocities were measured with a hot-film anemometer and a two-components laser-doppler velocimeter in surf zones on uniform slopes of about 1/30 in two wave tanks.

The rectified on-offshore velocity measured with the hot-film anemometer was smoothed with a moving average method of 0.1sec. A root-mean-square of the deviation from the smoothed velocity was calculated for the onshore and offshore velocity phases of individual waves. The following conclusions were obtained : 1) The calculated turbulent intensity varies more and is larger in the case of the transient breaker type between spilling and plunging than in the case of spilling breaker, 2) the turbulent intensity does not damp so much as the waves propagete in the surf zone in the case of transient breaker, while it damps in the case of spilling breaker, and 3) the turbulent intensity is larger in the upper part of the water column than near the bottom.

A root-mean-square of the deviation from the smoothed on-offshore velocity was calculated for every 0.1sec section composing one wave period over about 20 waves in the case of spilling breaker. It was found that the vertical distribution of the calculated turbulent intensity and its variation during one wave period resemble those of the turbulence under a steady breaker generated behind a wing inserted in an open channel flow which was explained by the turbulent wake theory(Battjes and Sakai, 1981). A model was proposed, based on the turbulent wake theory, to explain the variation of the vertical distribution of turbulence during one wave period. It was found that this simple model can explain it roughly.

A time-mean over 0.1sec of the cross product of the on-offshore and vertical deviations from the smoothed values of the velocities measured with the laser-doppler velocimeter was calculated. It was defined as the Reynolds stress. An ensemble average of the Reynolds stress was

taken over about 40 waves. The variation during one wave period of the vertical distribution of the ensemble averaged Reynolds stress was discussed. It was suggested that the turbulent wake theory may not explain the variation of the Reynolds stress in surf zone.

9. ACKNOWLEDGEMENT

This study was partly supported by the Grant-in-Aid for Scientific Research of the Ministry of Education, Science and Culture, Japan, for which the authors express their appreciation.

ON THE RELATION BETWEEN CHANGES IN INTEGRAL QUANTITIES OF SHOALING WAVES AND BREAKING INCEPTION

Takashi Yasuda,[1] Shintaro Goto[2] and Yoshito Tsuchiya,[3] M. ASCE

ABSTRACT

This paper describes a mechanism of breaking waves over sloping bottoms in terms of changes in integral quantities of the waves. Systematic computations are made of wave profiles of shoaling waves up to the numerical unstable points by using the K-dV equation with variable coefficients and internal properties such as horizontal and vertical water particle velocities by a stream function method satisfying the conservation laws of mass and energy. Applicability of the numerical results is examined and a relation between numerical unstable points and actual breaker points is found. Characteristics of the integral quantities of shoaling waves are investigated in relation to the existence of the extremum of the energy of the shoaling waves and their breaking inception.

INTRODUCTION

A sound knowledge on breaking waves is very important for coastal engineering, as stated by Longuet-Higgins(1980) at the Sydney Conference. However, theoretical elucidation on the mechanism of breaking waves on sloping bottoms is not enough, although many prominent theoretical investigations have been carried out on this problem. A series of studies by Longuet-Higgins et al.(1974 & 1975) obtained the very interesting conclusion that the integral quantities, such as the phase speed, momentum and energy increase with wave-height initially, become maxima and then decrease; that is, these quantities reach their extrema at a wave-height preceding the highest wave. So, a great interest is now being taken in the relation between the existence of the extrema of the integral quantities and breaking inception and in the derivation of the breaking inception from the behaviour of the integral quantities which reflect the properties of the whole wave field, by regarding the wave breaking as an instability of the field.

Because symmetrical wave formes were assumed in their calculation, the conclusion obtained by Longuet-Higgins et al. indicates only that the integral quantity of the highest wave is not usually maximum and does not directly show that extrema arise in the integrals of shoaling waves on sloping bottoms. Therefore, it is necessary to calculate the changes in the integral quantities of shoaling waves in order to investigate the mechanism of wave breaking on a sloping bottom which is important in coastal engineering.

Here, based on the results of the authors' studies(1979 & 1982) on the transformation of shoaling waves over sloping bottoms, are made computations on the wave profiles of shoaling waves up to the numerically unstable points by using the K-dV equation with variable coefficients. At the same time, the internal properties such as water particle velocities are computed for the given wave profiles at each water depth by the stream function method, satisfying the conservation laws of mass and energy. The relation between numerically unstable points and the actual breaker points defined by Goda(1980) are also examined, and investigations are made of the characteristics of the integral quantities of shoaling waves over sloping bottoms. It is then shown that whether the energy of shoaling waves has extrema or not is a function of the surf-similarity parameter(1974). Finally, examinations are made of the relation between the existence of the extrema of the energy of shoaling waves and breaking inception or breaker type.

CALCULATION OF INTERNAL PROPERTIES OF SHOALING WAVES ON SLOPING BOTTOMS

1. Reduction of Basic Equation

By considering irrotational wave motion over a uniformly sloping bottom and taking a Cartesian co-ordinate system as Shown in Fig.1, the governing equations are given as

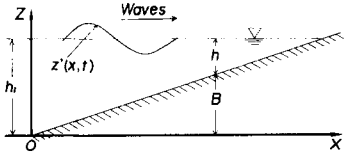

Fig. 1 Co-ordinate system and symbols used

$$\left.\begin{aligned} &\nabla^2\phi=0,\quad \phi_t+(\phi_x^2+\phi_z^2)/2+g(z-h)\big|_{z=h_1+z'}=0,\\ &z'_t+z'_x\phi_x-\phi_z\big|_{z=h_1+z'}=0,\quad \phi_z-B_x\phi_x\big|_{z=B}=0, \end{aligned}\right\}\quad (1)$$

where, the subscripts denote partial differentiation, ϕ is the velocity potential, z' the water surface displacement from the mean water level, B the height of the sea bottom above the horizontal co-ordinate, h_1 the depth of mean water at the origin and g the acceleration of gravity. The above equations can be directly solved by a numerical method, such as the MAC method. However, there arise the problems of the great effort necessary for the computation and the insufficient accuracy of numerical solutions in view of the labour expended, so that the following approach is adopted here.

For our calculations the following four assumptions are made.

i) Bottom slopes are gentle and the water depth changes dependently on $X = \varepsilon x$ in which ε is a small parameter, and therefore,

ii) the wave reflection from the sloping bottom is negligible and mass transport by waves is not bound by a sloping bottom. In addition, according to the conclusion by Stiassnie et al.(1975) that the effect of wave set-down is less than about one percent of the water depth, the third assumption is

iii) the effect of wave set-down is negligible. And lastly,

iv) the effects of nonlinearity and frequency dispersion of waves and bottom slope are of the same order.

By developing Kakutani's approach(1971) to a higher order approximation on the basis of these assumptions, Eq.(1) yields the following tractable wave equation using a new expression of wave profile, η.

$$\eta_\tau + 3\eta\eta_\xi/2c_0^3 + c_0\eta_{\xi\xi\xi} - B^*{}_\tau\eta/4c_0^2 = \epsilon(-c_0^3\eta_{\xi\xi\xi\xi\xi}/15$$
$$-3\eta_\xi\eta_{\xi\xi}/2c_0 - 2\eta\eta_{\xi\xi\xi}/3c_0 - 2c_0\eta_{\xi\xi\tau}/3 + B^*_\tau\eta_{\xi\xi}/2 - 3\eta^2\eta_\xi$$
$$/2c_0^5 - \eta_\xi\Omega_\tau/c_0^2 - 3\eta\eta_\xi/c_0^2 - \Omega_{\tau\tau}/2c_0 - 5B^*_\tau\eta^2/8c_0^4$$
$$+ B^*_\tau\Omega_\tau/2c_0) + o(\epsilon^2) \qquad (2)$$

where

$$\left.\begin{aligned} &c_0 = \sqrt{1-B^*} = \sqrt{h^*},\ \xi = \epsilon^{1/2}(\int dx^*/c_0 - t^*),\ \tau = \epsilon^{3/2}x^*, \\ &B^* = B/h_1,\ x^* = x/h_1,\ z^* = z/h_1,\ t^* = t\sqrt{g/h_1},\ h^* = h/h_1, \\ &\epsilon = (h_1/L_1)^2 \ll 1,\ \zeta = z^* - B^*,\ \epsilon\eta = z'/h_1 \end{aligned}\right\} (3)$$

L_1 is the wave-length at the origin and a new expression of the velocity potential, Ω, has the following relations

$$\Omega_\xi - \eta = \epsilon(c_0\eta_{\xi\xi}/2 + \eta^2/2c_0^2) + o(\epsilon^2) \qquad (4)$$

$$\frac{\Phi}{h_1\sqrt{gh_1}} = \epsilon^{1/2}\left(\Omega - \frac{\epsilon}{2}z^{*2}\Omega_{\xi\xi} + \frac{1}{4!}\epsilon^2 z^{*4}\Omega_{\xi\xi\xi\xi} - \cdots\right) \qquad (5)$$

The applicability of the numerical results of Eq.(2) has already been examined in detail by comparing them with the results of the experiment without the restriction on mass transport by waves due to a sloping end wall of the wave flume and the influence of wave reflection from the end wall. As a result, it was concluded by authors(1979) that the first order solution, which is the numerical solution of the lowest order equation of Eq.(2) given by

$$\eta_\tau + \frac{3}{2}c_0^3\eta\eta_\xi + \frac{1}{3}c_0\eta_{\xi\xi\xi} - \frac{1}{4}c_0^2 B^*_\tau\eta = 0 \qquad (6)$$

is stable and applicable to shoaling waves over sloping bottoms. The second order solution, which is the numerical solution of the second order equation of Eq.(2), however, because of its round-off errors and secular terms, is not as applicable. In Fig.2 is shown an example of the comparisons between the numerical and experimental results of wave profiles of shoaling waves. Here, the thin, broken and solid lines indicate the results of the first and second order solutions, respectively, and the heavy lines indicate the experimental results. Therefore, based on the assumptions i), ii), iii) and iv), and as far as the wave profiles of shoaling waves as concerned, it could be said that the numerical solution of Eq.(6) can be used instead of the direct solution of Eq.(1). Hence, the present problem is reduced to finding the velocity potential ϕ satisfying Eq.

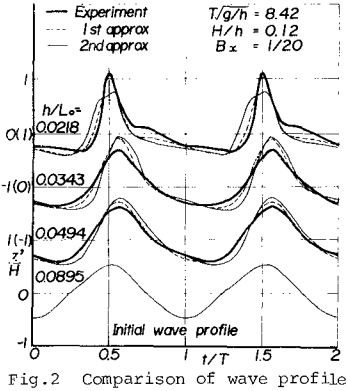

Fig.2 Comparison of wave profiles deter determined from numerical solutions and from experimental data

(1) against the water surface displacement z' derived from Eq.(6). The mathematical formulation of ϕ has already by the authors(1980) as:

$$\frac{\Phi_x}{\sqrt{gh}} = \varepsilon\eta + \varepsilon^2\{\frac{1}{2}\eta^2 + (z^{*2}-1)\eta_{\xi\xi} + B^*_\tau\eta\} + o(\varepsilon^3) \tag{7}$$

The characteristics of the horizontal water particle velocities were numerically examined through Eq.(7), and it was found that the accuracy of the high-order differential quotients computed numerically became lower with shoaling water. So, by paying attention to the physical significance of Eq.(7), i.e., that the velocity potential of shoaling waves is mainly subject to the water surface displacement and suffers the direct effect of bottom slope only in the second order, the following approach is here adopted, where the effect of water surface displacement given by Eq.(6) is evaluated as accurately as possible instead of ignoring the direct effect of bottom slope as assessed in Eq.(7). Therefore, in order to use the WKB method, a fifth assumption must be made:

v) Both water surface displacement and velocity potential depend on two variables, υ and X, expressing the phase change and the gentle change in water depth, respectively:

$$z'(x,t)=z'(\upsilon,X), \quad \phi(x,z,t)=\phi(\upsilon,X,z) \tag{8}$$

where

$$\upsilon=\frac{1}{\epsilon}\int_0^K K(X)dx-\omega t \tag{9}$$

K(X) is the wave-number dependent on the change in water depth and ω, the angular frequency, independent from the change according to the conservation law of wave-number.

This assumption can be sufficiently justified because the expression,

$$z'(\xi,\tau)=z'(\xi-\int c\,d\tau), \qquad c=\frac{3z'}{2\epsilon c_0^3}+\frac{c_0 z'_{\xi\xi\xi}}{3z'_\xi}-\frac{B^*_\tau}{4c_0^2} \tag{10}$$

can be derived by considering that the water surface displacement, z'=$(h_1/\epsilon)\eta$, is a solution of Eq.(6), and then

$$\xi-\int c\,d\tau=\frac{\epsilon^{1/2}}{\omega}\{\int K(X)dx-\omega t\} \tag{11}$$

can be obtained.

Application of the assumptions of i) and v) to Eq.(1) yields the following equation, where the effect of the water depth change rate is explicitly expressed by the small parameter, ε.

$$\left.\begin{aligned}
&K^2\phi_{\upsilon\upsilon}+\phi_{zz}+\varepsilon(K_X\phi_\upsilon+2K\phi_{\upsilon X})+\varepsilon^2\phi_{XX}=0\\
&-\omega\phi_\upsilon+\frac{1}{2}(K^2\phi_\upsilon^2+\phi_z^2)+gz'+\varepsilon K\phi_\upsilon\phi_X+\frac{\varepsilon^2}{2}\phi_X^2=0 \qquad \text{at} \quad z=h_1+z'\\
&-\omega z'_\upsilon+K^2\phi_\upsilon z'_\upsilon-\phi_z+\varepsilon(K\phi_X z'_\upsilon+K\phi_\upsilon z'_X)+\varepsilon^2\phi_X z'_X=0 \ \text{at} \quad z=h_1+z'\\
&-\phi_z+\varepsilon KB_X\phi_\upsilon+\varepsilon^2 B_X\phi_X=0 \qquad \text{at} \quad z=B
\end{aligned}\right\} \tag{12}$$

Here, a final assumption is made concerning the velocity potential ϕ:

vi) The velocity potential ϕ can be expanded as a power series with respect to the small parameter ε as:

$$\phi(\upsilon, X, z)=\phi_0(\upsilon, X, z)+\varepsilon\phi_1(\upsilon, X, z)+\cdots . \tag{13}$$

Moreover, by exchanging υ for a new variable θ and defining the stream function ψ, respectively, as:

$$\frac{\partial}{\partial\theta}=K\frac{\partial}{\partial\upsilon} \quad , \quad \frac{\partial^2}{\partial\theta^2}=K^2\frac{\partial^2}{\partial\upsilon^2} \quad , \quad \theta=x-c(X)t \quad , \tag{14}$$

$$\psi_z=\phi_\theta-c \quad , \quad \psi_\theta=-\phi_z \quad , \tag{15}$$

the following equation, expressed with the stream function, is derived in the lowest order O(1) from Eq.(12).

$$\left.\begin{aligned} &\nabla^2\psi=0 \ , \\ &\frac{1}{2}(\psi_\theta^2+\psi_z^2)+gz'=\frac{1}{2}c^2 \qquad \text{at} \quad z=h_1+z' \ , \\ &\psi=\psi_0 \qquad \text{at} \quad z=h_1+z' \ , \\ &\psi=0 \qquad \text{at} \quad z=B \ , \end{aligned}\right\} \tag{16}$$

where ψ_0 is a constant denoting the total volume rate of flow underneath the steady wave per unit length in a direction normal to the x plane.

As mentioned above, the water depth change rate is of the order ε and from the assumption i) the value of ε could be considered small enough that the velocity potential ϕ can be sufficiently evaluated by the lowest order term ϕ_0, that is, the stream function defined in Eq.(14). Thus, under assumptions i)-v), although ψ is an explicit function of θ and z alone because all terms dependent on the change of water depth, such as bottom slope, are neglected, and although ψ is indirectly affected by water depth change through the conservation laws, the mathematical formulation satisfying both Eq.(15) and the conservation laws against the water surface displacement z' given numerically from Eq.(6) is synonymous with Eq.(1).

2. Examination on Conservation Laws

The effect of wave set-down is ignored by the assumption iii), so that the conservation laws to be satisfied become those of mass and energy alone. They can be expressed in a two-dimensional wave field of steady state, shown in Fig.1, as:

$$\frac{d}{dx}\overline{\left\{\int_B^{h_1+z'}\rho u\,dz\right\}}=0 \tag{17}$$

$$\frac{d}{dx}\overline{\left[\int_B^{h_1+z'}\rho u\left\{\frac{1}{2}(u^2+w^2)+\frac{p}{\rho}+q(z-h_1)\right\}dz\right]}+\rho g\eta_s\frac{d}{dx}\overline{\left\{\int_B^{h_1+z'}u\,dz\right\}}=0 \tag{18}$$

where the bar — indicates averaging over one period, and η_s is wave set-

down. It is found from Eq.(18) that the uniformity of energy flux by waves is satisfied independently from the evaluation of wave set-down when the conservation law of mass is satisfied. Substitution of Eq.(15) into Eq.(17) yields

$$\varepsilon \frac{d}{dX} \{ \int_B^{h_1+z'} K\Phi_{0U}\, dz \} + o(\varepsilon^2) = 0 \tag{19}$$

The conservation law of mass is satisfied unconditionally in the same order O(1) as in Eq.(16), so that it can be considered in the order of ε. Hence, the law is expressed as

$$I = \varepsilon \overline{\int_B^{h_1+z'} (\psi_z + c)\, dz} = \varepsilon \{ \psi_\theta + c(h_1 - B) \} = \text{const.} \tag{20}$$

where I is the mass flux by waves.

By similar examination on the conservation law of energy, the law can be written in the order of ε independently from wave set-down as:

$$W = \varepsilon \overline{\int_B^{h_1+z'} \rho(\psi_z + c) \{ \frac{1}{2}(\psi_z + c)^2 + \frac{1}{2}\psi_\theta^2 + \frac{p}{\rho} + g(z - h_1) \} dz}$$

$$= \frac{\varepsilon}{2} \rho c \{ (3c + \bar{u}) 1 - c\bar{u}(h_1 - B) - 2g\overline{z'^2} \} = \text{const.} \tag{21}$$

where W is the energy flux by waves.

3. Calculation of the Stream Function of Shoaling Waves

By considering the theoretical result(1980) that mass transport velocity $\bar{u}$ is given in Eulerian co-ordinate due to a nonlinear effect when the phase of z' is assumed to agree with that of ϕ, a generalized mathematical formulation of the stream function is assumed as

$$\frac{\psi}{h\sqrt{gh}} = -\{ \frac{1}{X_{(1)} X_{(2)}} - \frac{\bar{u}}{\sqrt{gh}} \} \zeta + \sum_{n=4,6}^{N-1} \frac{\sinh(n-2)\pi X_{(2)} \zeta}{\cosh(n-2)\pi X_{(2)}}$$

$$[X_{(n)} \cos\{(n-2)\pi\chi\} + X_{(n+1)} \sin\{(n-2)\pi\chi\}] \tag{22}$$

where $\zeta = (z-B)/h$, $\chi = (x-ct)/L$, $X_{(n)}$ is the n-th coefficient, especially $X_{(1)} = T\sqrt{g/h}$, $X_{(2)} = h/L$, $X_{(3)} = \psi_0/h\sqrt{gh}$ and T wave-period. The dynamic boundary condition at free surface shown in Eq.(16) can be rewritten with respect $\bar{u}$ as:

$$\frac{1}{2}\bar{u}^2 + (u_w - c)\bar{u} + \frac{1}{2}(u_w^2 + w^2) - cu_w + gz' = 0 \qquad \text{at} \quad z = h_1 + z' \tag{23}$$

where u_w and w are the periodic component of the horizontal and vertical water particle velocities respectively. They are in the following relation with the stream function.

$$\psi_x = -w \qquad \psi_z = \bar{u} + u_w - c \tag{24}$$

Hence, u_w and w are expressed by Eq.(22) and (24), respectively, as:

$$\left.\begin{aligned} u_w &= \sum_{n=4,6}^{N-1} \frac{(n-2)\,X_{(2)}\cosh\{(n-2)\pi X_{(2)}\zeta\}}{\cosh\{(n-2)\pi X_{(2)}\}}\{X_{(n)}\cos(n-2)\pi\chi \\ &\qquad + X_{(n+1)}\sin(n-2)\pi\chi\} \\ w &= -\sum_{n=4,6}^{N-1} \frac{(n-2)\pi\sinh(n-2)\pi X_{(2)}\zeta}{\cosh(n-2)\pi X_{(2)}}\{X_{(n+1)}\cos(n-2)\pi\chi \\ &\qquad - X_{(n)}\sin(n-2)\pi\chi\} \end{aligned}\right\} \quad (25)$$

Moreover, the mathematical formulation of water surface displacement using the stream function is derived through the kinematic boundary condition at free surface:

$$Y_i = \frac{-X_{(1)}X_{(2)}}{1-(\bar{u}/\sqrt{gh})X_{(1)}X_{(2)}}\left[X_{(3)} - \sum_{n=4,6}^{N-1}\frac{\sinh\{(n-2)\pi X_{(2)}(1+Y_i)\}}{\cosh\{(n-2)\pi X_{(2)}\}}\right.$$
$$\left.\{X_{(n)}\cos(n-2)\pi\chi_i + X_{(n+1)}\sin(n-2)\pi\chi_i\}\right] - 1 \quad (26)$$

Hence, as long as the above expression is used, the conditions to be satisfied by Eq.(22) become a binding condition, i.e., the wave profile expressed by Eq.(26) must agree with both the numerical solution given by Eq.(6) and the conservation laws mentioned above. Although these conditions determine the coefficients $X_{(n)}$ uniquely, some of them are subject to nonlinear equations with respect to $X_{(n)}$. So, the determination of the stream function satisfying the above conditions is carried out by a method similar to that used by Rienecker et al.(1981). The unknown coefficients to be determined are $X_{(2)}$, $X_{(3)}\cdots X_{(n)}$, their total number being N-1 quantities.

The conditions to be satisfied by them can be expressed as follows: Firstly, as to the wave profile conditions, the numerical solutions of Eq.(6) and z_c' must agree with the expression shown in Eq.(26), so the conditions written as

$$f_i = z_{ci}/h - Y_i = 0, \quad i = 1, 2, \cdots, N-3 \quad (27)$$

must be satisfied. Here, i indicates the i-th phase during one period divided impartially by N-3. Secondly, the conservation laws of mass and energy expressed in the order of ε are, respectively,

$$f_{N-2} = \varepsilon(I-I_0), \quad f_{N-1} = \varepsilon(W-W_0) \quad (28)$$

where the subscript o denotes the quantity in deep water and I is written by the expression shown in Eq.(22) as:

$$I = \bar{u}h + h\sqrt{gh}\sum_{n=4,6}^{N-1}\tanh\{(n-2)\pi X_{(2)}\}\{X_{(n)}\cos(n-2)\pi\chi_i$$
$$+ X_{(n+1)}\sin(n-2)\pi\chi_i\} \quad (29)$$

Here, the subscript i denotes the pahse giving $Y_i = 0$. The N-1 numbers of equations shown above are solved by Newton-Raphson's method so that the internal properties of shoaling waves can be calculated under the six assumptions mentioned above.

4. Examination of the applicability of Numerical Solutions

An examination by Iwagaki et al.(1974) has already been made of the applicability of Dean's stream function method(1965) to the waves on sloping bottoms. Water surface displacement was given by experimental results at each water depth with normal wave flumes, and its applicability was determined for shoaling waves with deformed wave profiles. Their conclusion was that the stream function method can be applied to waves with asymmetrical wave profiles on sloping bottoms as long as the wave profiles can be accurately calculated, although the method should be primarily developed for uniform waves with symmetrical profiles. Hence, it is thought to be possible to apply the present approach, as well as the calculation by Iwagaki et al.(1974). However, the present approach is different in that the satisfying of the conservation laws, is not required in the usual methods. So, an examination is here made of the applicability of the horizontal water particle velocity computed by the present approach.

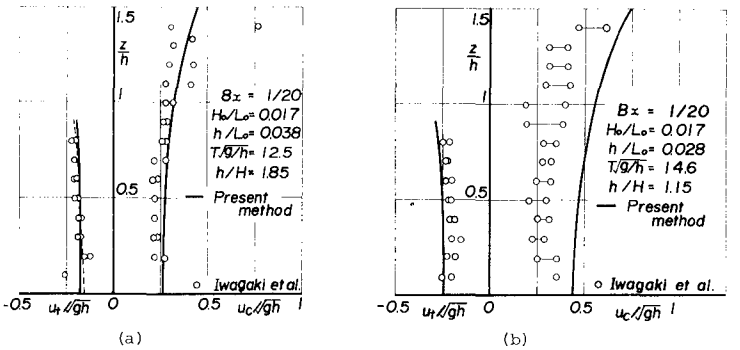

Fig. 3 Comparison between numerical solution and experiment by Iwagaki et al. of vertical distributions of horizontal water particl particle velocities

Fig.3 shows the comparisons between the numerical results obtained by the present approach where the measured wave profile at $h/L_o = 0.069$ was given as initial value and experimental results by Iwagaki et al. of vertical distribution of horizontal water particle velocities of shoaling waves. And Fig.4 shows comparisons of their corresponding wave profiles up to the breaker point noted by $h/L_o = 0.028$ in the figure. Here, the solid line shows the numerical results determined by

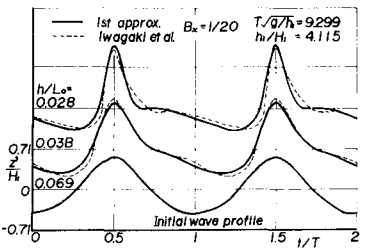

Fig. 2 Comparison of wave profiles determined from numerical solutions and from experimental data

the present approach and both of circles and broken lines show the experimental results. It might be said from the figures that the present approach is applicable for the calculation of the internal properties of shoaling waves up to a breaker point, although the examination was made only of the water particle velocities and wave profiles and although their numerical results seem to give larger values at the breaker point than the experimental ones which probably suffered from the effect of back currents from the end wall of wave flume.

CALCULATION OF INTEGRAL QUANTITIES OF SHOALING WAVES

1. Definition of Integral Quantities

The method used by Longuet-Higgins(1975) can be applied to the present approach, and the expression of the various integrals can be derived as in the following, if the integrals are evaluated in the same order, O(1), as the terms in the equations mentioned above. The potential energy E_p at arbitrary water depth is defined as:

$$E_p = \frac{1}{2}\rho g\bar{z}'^2 \tag{30}$$

and the kinetic energy E_k is defined as:

$$E_k = \int_B^{h_1+z'} \frac{1}{2}\rho\{(\psi_z - c)^2 + \psi_\theta^2\}dx \tag{31}$$

By applying the expression defined by Longuet-Higgins, Eq.(32) can be rewritten as:

$$E_k = \frac{1}{2}\rho\{c^2h - (\bar{u} + c)I\} \tag{32}$$

In the same way, the radiation stress S can be expressed as:

$$S = \int_B^{h_1+z'} (p + \rho u^2)dz - \frac{1}{2}\rho gh^2$$

$$= 2cI - 3E_p \tag{33}$$

Then, the energy flux W shown in Eq.(29) can be expressed as:

$$W = \frac{1}{2}\rho c\{(3c + \bar{u})I - \bar{u}ch - 4E_p\} \tag{34}$$

Therefore, the integral quantities of shoaling waves can easily be calculated within the limits of O(1), as long as the values of the wave celerity, the potential energy and the mass transport velocity can be given at an arbitrary water depth.

2. Definition of Breaker Point

In order to carry out the computation of the integral quantities of shoaling waves up to the breaker point, the breaker points must be reasonably and accurately defined and the computation of the stream function with sufficient accuracy must be possible. The former must be investigated here because the definition of breaker points has not yet been established theoretically, although the latter is satisfied by comparison with experiments including the actual breaker points. So, some

examinations must be made of the breaker points to be used here.

Although the theoretical breaker point is thought to be defined by the singular point of Eq.(6) in the lowest order, the equation has not been yet analytically solved, so the condition for the singularity cannot be obtained theoretically. Therefore, the breaker point is conjectured from the behaviour of the results computed numerically under the conditions of the wave steepness H_o/L_o and bottom slope B_x described in Table 1, where the values of the well-known surf-similarity parameter $\mu = B_x/\sqrt{H_o/L_o}$ are also shown. The computations start from the point of $h/L_o = 0.08$ and the values of L/L_o and H/H_o at the point are computed by the energy flux method(1977).

Table 1 Conditions of wave parameters computed

H_o/L_o	B_x	μ
0.004	1/10	1.58
0.008	1/10	1.12
0.01	1/10	1.00
0.004	1/20	0.79
0.008	1/20	0.55
0.01	1/20	0.50
0.01	1/50	0.20
0.02	1/50	0.14
0.04	1/100	0.05

Fig.5 depicts the changes in wave-heights of shoaling waves computed from Eq. (6) as a function of the surf-similarity parameter. Here, the solid circles indicate the breaker points defined by Goda and expressed as

$$\frac{H_b}{L_0}=0.17\left[1-\exp\left\{-1.5\pi\left(\frac{h}{L_0}\right)\left(1+15\,B_x^{4/3}\right)\right\}\right] \qquad (35)$$

It can be found from the figure that the extrema always exist in the changes in wave-height. The occurence of the extrema is conjectured to be caused by a kind of instability in the numerical solutions, which can be attributed to the excessive value of the curvature of the wave profile at crest. So, the relation between the existence of the extremum noted in the figure and the upper limit of a curvature of water surface displacement at crest of the numerical solution of Eq.(6) were examined to discover the reason for such an extremum. In Fig.6 white circles shows the values of the curvatures at the point of maximum wave-height of the numerical solution, and the points defined by Goda's breaking inception are indicated by solid circles for every value of the surf-similarity parameter. It can be noticed that the upper limit of the curvature exists in the vicinity of the values of 10^4 for every value of the parameter, and the maximum value

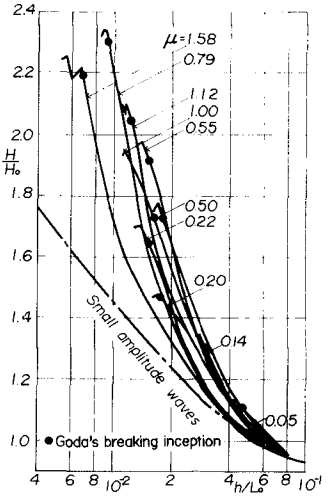

Fig. 5 Changes in wave-height of shoaling waves as a function of the surf-similarity parameter

for wave-height computed by Eq.(6) depends on the upper limit of the curvature of the numerical solution. Therefore, it is assumed that the theoretical breaker point in the numerical simulation generated by Eq.(6) is given by the upper limit.

Fig.7 shows the relation between the theoretical breaker indices, i.e., the ratio of wave-height to water depth at the breaker points, H_b/h_b, and the actual indices defined by Eq.(35). Here, the solid lines

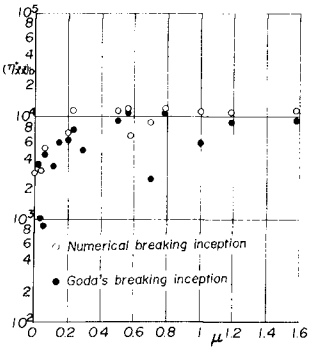

Fig. 6 Curvatures of the heighest waves and the surf-similarity parameter

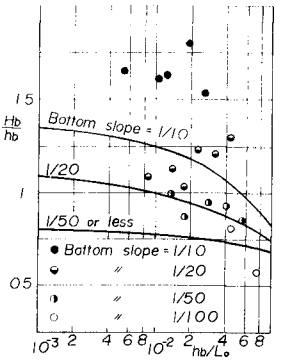

Fig. 7 Comparison between the theoretical breaker indices and the actual ones defined by Goda's breaking inception

describe the breaker indices given by Eq.(35), and circles indicate the theoretical indices for all bottom slope conditions. It could be considered from the results shown in the figure that most of the theoretical breaker indices exceed the actual ones and that the numerical solutions are stable and continue to maintain sufficient accuracy in the shallower water beyond the actual breaker points. And, it is found that the dependency of the theoretical breaker indices on bottom slopes reasonably corresponds to that of the actual breaker indices, although there are a few difference with regard to the

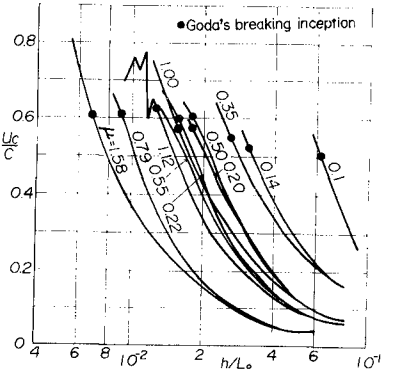

Fig. 8 Changes in the ratio u_c/c of shoaling waves with the surf- similarity parameter

absolute values between them. Thus, the definition of the breaker points as being dependent on the upper limit of the courvature is regarded as reasonable. So, an investigation is made on the relation between the theoretical breaker point and Rankine-Stokes' condition of greatest wave-height.

Fig.8 shows the change in the ratio of the horizontal water particle velocity at crest, u_c, to the wave-celerity, c, of the shoaling waves computed by the present approach up to the theoretical breaker points. It is noticed that all the values of the maximum ratio u_c/c do not exceed 1, although the ratios at the breaker points approach one as the value of the surf-similarity parameter increases. This result means that shoaling waves on sloping bottoms become unstable and begin to break down before Rankine-Stokes' condition is satisfied and that the breaking inception of shoaling waves is controlled by another condition besides Rankine-Stokes' condition.

Fig.9 shows the change in the small parameter σ with the ratio u_c/c definded by Longuet-Higgins(1975) as:

$$\sigma = \frac{1 - (u_c - c)^2 (u_t - c)^2}{c^2 c_o^2} \quad (36)$$

It is found that the parameter σ has a tendency similar to the ratio u_c/c and that any given value of σ does not exceed 1 because of the similarity of the parameter σ to the ratio u_c/c, although the value σ of the highest wave becomes 1 in the calculations by Longuet-Higgins et al..
Therefore, it is to be expected that results considerably different from his will be obtained from the changes in the integral quantities of shoaling waves computed by the present approach.

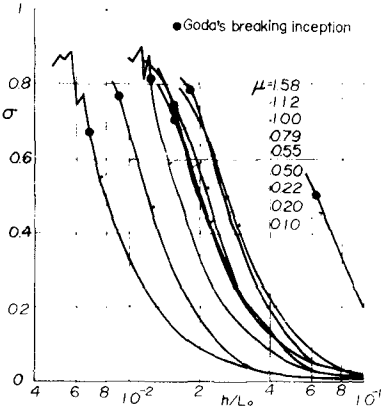

Fig. 9 Changes in the ratio u_c/c of shoaling waves with the surf-similarity parameter

CHANGES IN INTEGRAL QUNATITIES WITH SHOALING WATER

Fig.10 shows the changes in the potential energy of shoaling waves with the surf-similarity parameter up to the theoretical breaker point computed by the present approach. It is found that the extrema of potential energy always exist before both the breaker points are attained and that the integral quantities of the highest wave are not always maxima. This agrees with the result shown by Longuet-Higgins et al.(1974), although the effect of the surf-similarity parameter is not taken into account in their calculation. It is thought that the existence of

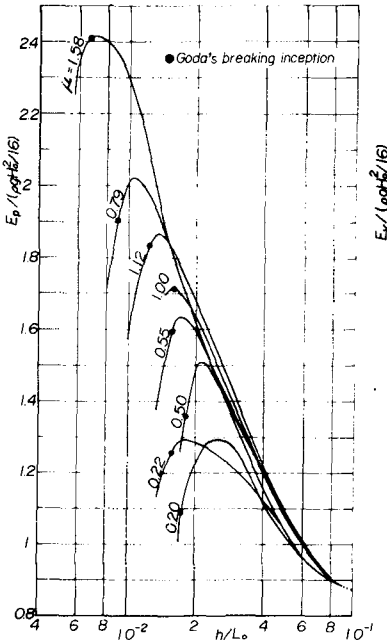

Fig. 10 Changes in the potential energy of shoaling waves with the surf-similarity parameter

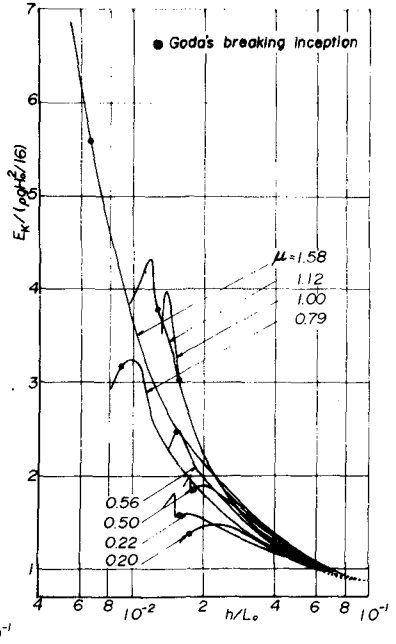

Fig. 11 Changes in the kinetic energy of shoaling waves with the surf-similarity parameter

such extrema is due to the sharpening of the wave crest caused by the tendency of the competition between the nonlinear effect and the dispersive effect to deform the wave profile which is strengthened with shoaling water.

Fig.11 shows the change in the kinetic energy of shoaling waves obtained by the same computation continued to the breaker points. It is found that the extrema of kinetic energy do not always exist before the breaker points are attained, in contrast to the case of potential energy and that the existence of the extrema depends on the value of the surf-similarity parameter. This is very different from the results of Longuet-Higgins(1975) which state that these extrema are always found in both the potential and the kinetic energies. This result indicates that there is a difference in the existence of the extrema of kinetic energy between shoaling waves with asymmetrical wave profiles on a sloping bottom and uniform waves with symmetrical wave profiles on a flat bottom. Therefore, it could be said that there is a difference in the internal properties, such as water particle velocities, between these wave types

and that the conclusion obtained for one cannot be directly applied to the explanation of the wave breaking for the other.

Fig.12 shows the change in the total energy E_t of the same shoaling waves. Several matters are clear from this figure. The existence of the extremum of total energy depends on the value of the surf-similarity parameter just as that of the kinetic energy does. The extrema arise with the value of the parameter μ under 1.12 before the theoretical breaker points are attained and under 0.79 before the actual breaker points are attained. The critical value of the parameter controlling the existence of the extremum seems to be between 1.12 and 1.58 where the theoretical breaker points are applied and between 0.79 and 1 where the actual breaker points are applied. It is well-known from the experiments by Galvin(1969) that the breaker type depends on the value of the surf-similarity parameter and that a spilling breaker occurs when the value of the parameter is less than 0.5. Hence, it could be judged that the existence of the extremum closely relates to the breaker type and that a spilling breaker occurs due to the instability of the transfer of wave energy when the value of the parameter μ is less than the critical value mentioned above. The extremum exists because the conservation law of energy is satisfied in the present approach, the decreasing of the total energy with shoaling water requiring the increasing of the energy transport velocity of shoaling waves.

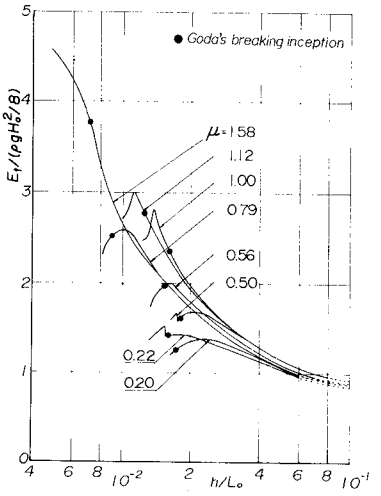

Fig. 12 Changes in the total energy of shoaling waves with the surf-similarity parameter

Fig.13 describes the change in the ratio of the energy transport velocity to the wave-celerity, c_g/c, of shoaling waves continued to the theoretical breaker point. It can be noticed that there is a tendency for the ratios c_g/c at both breaker

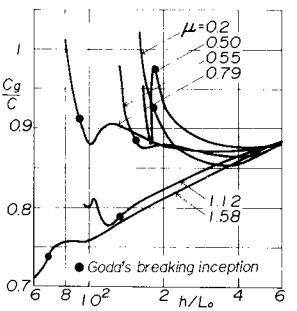

Fig. 13 Changes in the ratio c_g/c of shoaling waves with the surf-similarity parameter

points to decrease away from 1 as the value of the surf-similarity parameter increases, although the computed results scatter considerably of numerical errors in the computed value of wave-celerity. As it is judged that the energy transport velocity cannot physically exceed wave-celerity, instability with regard to energy transfer is considered to occur when the ratio c_g/c exceeds 1. Accordingly, this instability of energy transfer occurs dependently on the parameter and becomes liable to occur as the value of the ratio approaches 1. This instability could be conjectured to be closely related to the mechanism of wave breaking, and, in particular, to the mechanism of the occurence of a spilling breaker, where excess energy not transported by stable waves is exhausted by partial wave breaking. The approach of the ratio to 1 depends on the parameter, as mentioned above, and the instability of energy transfer occurs dependently on the value of the parameter, becoming liable to arise with the approach of the ratio to 1. Thus, it might be said that the instability of energy transfer is closely related to the spilling breaker and that the beginning of the instability is the breaking inception of a spilling breaker.

CONCLUSION

Integral quantities of shoaling waves have been calculated by using the K-dV equation with variable coefficients and the stream function method satisfying the conservation laws of mass and energy, and some investigations have been made on their characteristics. The most significant conclusions of this paper are summarized as follows.

The maximum wave-height of shoaling waves computed by the K-dV equation is controlled by the upper limit of the curvature of wave profiles, where numerical instability arises. Thus, the theoretical breaker point is defined by the limit, and it corresponds reasonably to the actual breaker point defined by Goda's breaking inception. However, Rankine-Stokes' condition of greatest wave-height is not satisfied at the theoretical breaker point of the computed shoaling waves and the wave breaking of shoaling waves seems to occur independently from the condition.

Although the extrema are always found in the potential energy of shoaling waves before the theoretical and actual breaker points are attained and the potential energy of the highest waves is not maximum just as in the results shown by Longuet-Higgins et al., the extrema of the kinetic and total energies are not always found in the shoaling waves with asymmetrical wave profiles before both the breaker points are attained, in contrast to the case of potential energy. In addition, the existence of the extrema depends on the value of the surf-similarity parameter and the extrema occur in the value of the parameter under the critical value controlling the existence. It is found by comparison with the experimental results of Galvin and his examination of the change in the ratio of energy transport velocity to wave-celerity that the existence of the extrema of total energy closely relates to the breaking inception and breaker type, especially to those of the spilling breaker, because it causes the instability of energy transfer of shoaling waves which is conjectured to be the cause of the wave breaking of the spilling type.

A FIELD STUDY OF WAVES IN THE NEARSHORE ZONE

by

S. Hotta[1], M. Mizuguchi[2] and M. Isobe[3]

ABSTRACT

Initial results are described of precise observations of waves shoaling in the nearshore zone. The key technique of the experiments is a 16 mm memo-motion camera system by which long term measurements of waves can be made simultaneously at many locations. Six or seven pairs of synchronized cameras were mounted on a research pier crossing the surf zone. The cameras were focused on target poles mounted on sleds which were towed about 200 m outside the breaker line, and on a line of poles jetted into the sea bottom across the surf zone. Waves transforming in the nearshore zone were observed from about 400 m offshore to the shoreline. At present only the characteristics of the statistical waves, wave height distributions, wave period distributions, and the joint distributions of wave height and period are described as part of the initial analysis.

INTRODUCTION

The authors have been carrying out extensive field studies to better understand the characteristics of waves in the nearshore zone. As a method of measuring waves, we have developed and applied a remote sensing photographic technique utilizing synchronized 16 mm memo-motion cameras to record the water surface elevation at fixed time intervals at poles installed in the nearshore zone. The basic function of this system is to take continuous synchronized pictures over a broad area of the nearshore zone. Some results with this method have been already presented (Hotta and Mizuguchi, 1980; Hotta, Mizuguchi and Isobe, 1981; Mizuguchi, 1982).

The observation time of a single camera is limited by the length of the film. Such a short length of time is insufficient for a quantitative discussion of some subjects, especially the statistical characteristics of waves. This problem was overcome by employing cameras in sets of two and running them alternately. Film changing can

2. Associate Professor, Department of Civil Engineering, Chuo University, Tokyo, 112, Japan.
3. Associate Professor, Department of Civil Engineering, Yokohama National University, Yokohama, 240, Japan.

be done for the camera not in current use, enabling a continuous record without time limitation. Using this method, and poles mounted as targets on sleds, three observation of waves in the nearshore zone were conducted. Data sets long enough to discuss the statistical wave characteristics were obtained at several points from about 400 m offshore and through the breaker zone to a point near the shoreline. In the present article, only the characteristics of the wave height and period distributions and their joint distributions are described as part of the initial analysis.

2. FIELD OBSERVATION

2.1 Study site and observations

The field observation site was at Ajigaura beach facing the Pacific Ocean, and located about 200 km north of Tokyo (Fig. 1). At this beach there is a pier operated by the Public Works Research Institute, Ministry of Construction, for facilitating field studies in the nearshore zone. Observations have been carried out utilizing the pier as a platform for the 16 mm memo-motion camera system. The average tidal range at this beach is about 1.2 m and the beach slope is about 1/60 to 1/70. The beach sand size is in the range of 0.2 to 0.5 mm.

Three observations were carried out. The first was done on Sep. 2, 1980 using six pairs of 16 mm cameras and six sleds. The second and third observaions were done on Sep. 8 and 9, 1981. In the second observation, seven pairs of cameras, six sleds, and a single pole (installed by water jet and positioned near the shoreline) were used. The waves at seven locations from near the shoreline to a position about 400 m offshore were observed. In the third observation, five pairs of cameras were employed to record the shoaling deformation, and the remaining two sets of cameras were used for the observation of wave run-up in the swash zone.

The six sleds were linked together at about 50 m intervals and pulled offshore by a tug boat. The wave conditions were relatively rough and the breaking height of the larger waves was 1.8 to 2.2 m. The width of the surf zone by visual observation was about 200 m, and two or three broken waves existed in the surf zone.

Photo 1 shows the 16 mm camera system in operation on the pier for Ex810908 [The notation is: Ex (beach experiment), 81 (year), 09 (month) and 08 (day)]. Photo 2 shows the sleds before being pulled to sea. Photo 3 shows the sea condition and target poles on the sleds in Ex800902.

Figures 2 and 3 show the positions of the sleds and the beach profiles for the first and second observations, respectively. In Fig. 3, A' to E' are the positions of the sleds for the third observation. The average breaker line by visual observation was between Station C and D for Ex800902 and Ex810908. All stations were positioned seaward of the breaker line for Ex810909.

2.2 Instrumentation

The sleds on which the target poles (8 m high) were mounted are constructed of steel pipe 50 mm in diameter. The sleds are 5.5 m long, 2.4 m wide, and 0.5 m high, and weigh about 200 kgf. The cameras were mounted on the pier. Three kinds of zoom lenses were employed, 150 to 250 mm, 80 to 150 mm, and 17 to 85 mm. Each pair of cameras was equipped with the same type of lens.

The cameras were synchronized by a main control unit and connected by the same number of relay units in pairs. One camera of a set stops operation at a certain frame as directed by the main control unit, and the other camera of the set automatically begins to operate. This procedure is repeated and an observation can continue without time limitation. The sampling interval is variable between 0.1 to 10. In the present observations, a sampling interval of 0.2 s was used. The water surface variation photographed by the cameras is transferred to paper tape using a 16 mm film analyzer and an ultrasonic digitizer graph pen system. Records on the paper tapes are then transferred to magnetic tapes or disk for analysis by computer.

3. RESULTS

3.1 Effective data

Ten rolls of films per set of cameras were taken for Ex800902. Therefore 37,500 frames (7500 s) of data were completely obtained for Stations A to F. During observation Ex810908, it rained after four rolls of film were taken, and the observation had to be terminated early. We had difficulty in handling the film in the rain, and a portion of the data was lost. Effective data were 3800 s for Stations A, B, C, D and E, 3599.4 s for Station F, and 3350 s for Station G. Twelve rolls of film were taken for Ex810909. Data of 9120 s were obtained for Stations A, B, C and D. However, the sled at Station E was moved a few meters shoreward by large waves and went out of frame in the sixth roll. The camera angle was adjusted, but the sled again went out of frame in the twelfth roll. Thus a portion of the data at Station E was also lost. The effective data at Station E was 3508.4 s for the first part of the observation, and 4782 s for the latter part.

3.2 Number of waves defined by the zero-crossing method

Direct application of the zero-crossing methods creates a problem for defining waves in the nearshore zone. That is, many small amplitude short period waves are defined, especially in the surf zone. Figures 4 and 5 show the number of waves defined by the zero-up cross method for the three observations. The number of waves given from limited data were multiplied by the ratios of the total observaton time to the effective time. In Figs. 4 and 5, the number of waves defined with a minimum wave height of 4, 6, 8, 12, 16 and 20 cm are also shown. D indicates this minimum wave height (See also the number of waves defined in Table 1 and Fig. 7). A great number of small amplitude short period waves are defined both inside and outside the surf zone. It does not seem reasonabale to take into consideration such small waves. However, no firm physical criteria has yet been given for excluding small waves.

The problem of how to treat the small waves will not be discussed further here. This and some related matters were treated by Hotta and Mizuguchi (1980). In that reference, waves having a height smaller than 6 cm were ignored, based on accuracy limitations of the measurement process. We further investigated the accuracy of this type of measurement of the sea water surface elevation, and have found that a maximum error of $\pm$ 2.6 cm should be expected. Therefore, we will continue our discussion by ignoring waves lower than 6 cm. The treatment of the time interval associated with the omitted wave is also discussed by Hotta and Mizuguchi. In the present paper, the time intervals of the omitted waves were added to the trailing part of the preceding main wave, referred to as the B-method in the previously-mentioned paper.

Viewing Figs. 4 and 5, it is seen that the number of waves in the surf zone defined by the zero-crossing method is larger than the number in the offshore zone. The number of waves defined is constant in the offshore, although some difference appears at Station E in Ex810909 (attributed to missing data for that station). Therefore, the number of waves is conserved in the offshore zone. The increase in the number of waves defined in the surf zone is produced by the disturbance accompanying wave breaking.

The symbol * in Figs. 4 and 5 is the number of waves defined after applying a numerical filter which cuts waves lower than 0.04 Hz and passes waves higher than 0.05 Hz. Due to filtering, 380 data points (76 s) were cut from the beginning and end of the time series. Because the time periods of the defined waves with and without the filter are not the same, we can not compare the absolute number of waves defined. However, at Station A located near the shoreline in Ex800902 and Ex810908, the number of waves defined after applying the filter is larger than the number defined without the filter. At other stations, (more distant from the shoreline), the difference is small. This result is interpreted as follows. The wave height in the neighborhood of the shoreline is small, and anti-nodes of long period waves, such as edge waves or two-dimensional on-offshore standing waves, can exist there. The amplitudes of these long period waves rapidly decrease in the offshore direction, and the effect of the long period waves on the (ordinary) waves of period less than 20 s is small. We conclude that the long period waves will have a proportionately larger effect on the ordinary waves near the shoreline as compared to offshore.

3.3 Statistically representative waves

Values of the statistically representative waves, the wave grouping parameters, statistics of the sea water surface elevation and spectral parameters for each observation are listed in Tables 1 to 4. Table 2 gives the statistically representative waves defined without cutting the small waves for Ex800902. Table 3(a) (not filtered) shows values obtained by omitting waves lower than 6 cm and adding their time durations to the front part of the following main wave. It can be seen that the average wave heights and periods of the waves in Table 2 are much smaller than those in Table 3, due to the effect of the many small waves defined. However, the respective differences in the one-tenth and significant waves are relatively small. This indicates that the large waves in the wave distribution can be defined with little consideration

of the small waves. Table 3(b) gives the statistically representative waves of Ex800902 after filtering. Concerning the mean wave, only the values for Station A were altered by use of the filter.

Table 4 gives results from Ex810900 and Ex810909. From Tables 3 and 4 it can be seen that in the surf zone, the maximum, one-tenth, and one-third waves defined by the zero-down crossing method are slightly larger than those given by the zero-up crossing method. The zero-down crossing method defines one large wave and one small wave, while the zero-up crossing method defines two waves of almost equal equal height when a wave trails a relatively smaller wave (Hotta and Mizuguchi, 1980). This kind of wave behavior is seen primarily at the breaking point and in the surf zone. This is also the reason why a bi-modal distribution of the wave height, and a double-peaked distribution in joint distribution of wave height and period, are found for waves in the surf zone.

3.4 Shoaling of the statistically representative waves

Figure 6 shows the shoaling deformation of the observed statistically representative waves. The shoaling deformation curve given by linear wave theory is also drawn. The corresponding wave height in deep water was calculated by linear wave theory using the wave period and depth at the furthermost station (Station F for Ex800902, Station G for Ex810908, and Station F for Ex810909). The shoaling coefficient was defined as the ratio of the measured (or calculated) wave height at each station to the wave height in deep water, assuming normal wave incidence. The reason why Station E for Ex810909 was not used is that the periods of the significant, the mean, and the root mean square waves differed somewhat from the respective quantities at the other stations, in spite of the fact that a constant wave period was found for the offshore zone. At present, we can not say why this happened. The one-tenth wave period at Station E for Ex810909 was almost the same as at other stations in the offshore zone.

As can be seen in Fig. 6, the prediction of linear theory agrees well with the shoaling deformation of the statistical waves in this limited distance of approximately 200 m. It is well known that the shoaling deformation given by linear wave theory does not give good agreement with the measured results regular waves in the laboratory and for individual irregular waves on field beaches offshore and in the neighborhood of the breaker line. However, the prediction by linear wave theory agrees very well with the shoaling deformation of statistical waves in the present field observation.

3.5 Wave height and period distributions

The distribution of wave height and period and the marginal distribution of wave height and period at each measuring station are shown in Figs. 7 to 11. Figure 7 shows distributions for Ex800902 including the small waves. Equi-number lines of 10, 30 and 50 waves are drawn respectively with dotted, broken, and solid lines. Figure 7 shows the process of change of the distribution. Figure 8 shows the distributions for Ex800902 omitting waves lower than 6 cm, and applying the filter. Figures 9, 10, and 11 show the distributions for Ex800902, Ex810908 and Ex810909 omitting waves smaller than 6 cm. The distribu-

tions in Figs. 8, 9, 10 and 11 are normalized by the mean wave height and the mean wave period for 1000 waves. Equi-probability density lines of 0.1, 0.5 and 1.0 are drawn with dotted, broken, and solid lines, respectively. The interval of (H/$\bar{H}$) and (T/$\bar{T}$) is 0.2. A probability density of unity requires 40 waves.

From these figures, the following may be pointed out:

1. There is a strong correlation between wave height and period for the waves lower than the mean wave.

2. The marginal distributions of the wave height and period becomes bi-modal, and the joint distribution exhibits two maxima in the neighborhood of the breaking point. This tendency is particularly strong if waves are defined by the zero-down crossing method. The marginal distributions of wave height and period in the offshore approach a distribution similar to the Rayleigh distribution, but one which has a peak on the smaller side of the mean.

3. The range of wave height distribution is broad at the offshore side of the breaking point, whereas the range of wave period distribution is broad in the surf zone. These phenomena can be interpreted from the shoaling and breaking deformation of waves. That is, with approach to the breaking point, the waves increase in height and broaden the range of the distribution. After breaking, the disturbance accompanying the wave breaking generates many secondary waves having small periods, and the range of the period distribution thus broadens.

4. The linear correlation coefficients between individual wave heights and periods for the surf zone are smaller than those at the seaward of the breaking point.

5. From Figs. 8 and 9, it is seen that the long period waves have little influence on the joint distributions.

4. COMMENTS ON THE MEASUREMENT SYSTEM

The photographic technique as described here has the distinguishing merit that the sea water surface elevation can be sampled directly and at closely spaced points over a long observation of time. Also, because the method is direct, the data can be easily reviewed and checked. However, the method has the disadvantage that it takes a great deal of time and much labor to transfer the sea surface elevation from the film to a form suitable for calculation. From the viewpoint of data handling, the 16 mm camera should be replaced by video television in the future. But at the present time, film gives higher resolution than video TV. We would like to suggest to researchers who intend to apply similar methods that a heavier sled than our sled be used to avoid movement as happened in Ex810909.

ACKNOWLEDGEMENTS

The field observations discussed in this paper were carried out under the supervision of Professor K. Horikawa, Department of Civil Engineering, University of Tokyo. The authors would like to thank him for his considerable assistance and advice. We appreciate the permission of the Public Works Institute, Ministry of Construction for use of the pier. We would also like to express our appreciation to our university students who supported the field work. Without their help we could not have carried out these field observations. We would also like to thank Dr. N. C. Kraus and Miss T. Kohno of the Nearshore Environment Research Center for proofreading and typing of the manuscript.

Table 1 Statistical parameters of sea water surface elevation, and spectral parameters.

LIST OF SYMBOLS

d : water depth (m)
N : number of waves defined by zero-crossing method
H max : maximum wave height (cm)
T max : maximum wave period (s)
H 1/10 : one-theth wave height (cm)
T 1/10 : one-tenth wave period (s)
H 1/3 : significant wave height (cm)
T 1/3 : significant wave period (s)
$\bar{H}$: mean wave height (cm)
$\bar{T}$: mean wave period (s)
H rms : root mean square wave height (cm)
T rms : root mean square wave period (s)
r(H,T) : correlation coefficient between individual wave height and period
r(H) : correlation coefficient between successive two wave height
r(T) : correlation coefficient between successive two wave period
WG 1/3 : number of run exceeding significant wave height
$\bar{J}$ 1/3 : mean length of run for WG 1/3
$\bar{1}$ 1/3 : mean length of total run for WG 1/3
WG a : number of run exceeding mean wave height
$\bar{J}$ a : mean length of run for WG a
$\bar{1}$ a : mean length of total run for WG a
σ : standard deviation of sea water surface variation
$\sqrt{\beta_1}$: skewness of sea water surface variation
β_2 : kurtosis of sea water surface variation
$\overline{\eta^2}$: mean root square of sea water surface variation (variance) (cm^2)
η : mean water level from reference elevation (cm)
ε : spectral width parameter defined by $\varepsilon = [1-m_2^2/(m_0 m_4)]^{1/2}$
υ : spectral width parameter defined by $\upsilon = [m_0 m_2/m_1^2-1]^{1/3}$

$$m_n = \int_{-\infty}^{\infty} f^n S(f)\,df$$

Table 4 Statistical representative waves for Ex810908 and Ex810909.

Wave Height Distributions and Wave Grouping in Surf Zone

Hajime Mase[1] and Yuichi Iwagaki, M. ASCE[2]

Abstract

The main purpose of this paper is to propose a model for prediction of the spatial distributions of representative wave heights and the frequency distributions of wave heights of irregular waves in shallow-water including the surf zone. In order to examine the validity of the model, some experiments of irregular wave transformation have been made. In addition, an attempt has been made to clarify the spatial distribution of wave grouping experimentally. Especially the present paper focusses finding the effects of the bottom slope and the deep-water wave steepness on the wave height distribution and wave grouping.

1. Introduction

Battjes (1972) calculated the wave setup of irregular waves by a model of breaking waves that the Rayleigh distribution as the wave height distribution in deep-water is cut off partly by the breaker height determined by the local water depth. Afterwards Battjes (1978a) calculated the changes of the root-mean-square wave height and the wave setup of irregular waves on an arbitrary bottom slope by solving the energy balance equation, and it was reported that the calculated results agreed reasonably with the experimental ones. In that model of wave breaking the energy dissipation due to wave breaking was formulated by the bore model and the wave height distribution was cut off partly similarly to the previous model.

Since it is not realistic that the cumulative distribution function of the wave height is discontinuous at the breaking limit as Battjes's model, Goda (1975) proposed a model of irregular wave breaking that the portion of high waves in the Rayleigh distribution cut off partly is transfered to the portion of low waves with a certain probability due to breaking.

In the models of irregular wave breaking proposed by Battjes (1972) and Goda (1975), the Rayleigh distribution is modified with the breaker height determined by the local water depth, and the spatial propagation of waves with energy dissipation is not considered. On the other hand, it is considered in the model proposed later by Battjes (1978a), but still his model holds a problem that the cumulative distribution function of the wave height is discontinuous at the point of the wave height of breaking limit.

1) Research Associate, Department of Civil Engineering, Kyoto University, Kyoto, Japan
2) Professor, Department of Civil Engineering, Kyoto University, Kyoto, Japan

In this paper, the representative wave heights such as the significant and mean wave heights and the wave height distributions are predicted under the assumption that the wave height change of an individual irregular wave is equal to that of monochromatic waves having the same wave height and wave period and it can be superimposed independently. This method of analysis will be called the individual wave analysis method hereafter.

In addition to the height and period of irregular waves, a phenomenon of wave grouping that large waves continue successively is important, because it seems to be one of main factors for collapses of coastal structures such as rubble mound breakwaters. It was recently reported by Johnson et al. (1978) that even if energy spectra of irregular waves are same, a degree of damage is not same but depends on wave grouping of irregular waves. Accordingly, characteristics of wave grouping in shallow-water must be investigated as an important factor of design waves. The characteristics of wave grouping in shallow-water have not been studied little so far.

2. Calculation method for wave height change of irregular waves in shallow-water

2.1 Formulation for wave height change of individual wave

The wave height change of an individual wave defined by the zero-up-cross method is formulated under the following assumptions: (1) an individual wave among irregular waves is transformed independently, (2) the small amplitude wave theory is applied to wave shoaling before wave breaking, (3) the breaker height is calculated by modifying the breaker index for monochromatic waves proposed by Goda (1970), (4) the bore model adopted by Battjes (1978b) is used in a modified form after breaking, and (5) the temporal change of the mean water level is considered by introducing the effect of surf beats in addition to the spatial change of the mean water level due to wave setup.

The representative wave heights and the wave height distributions are predicted by superimposing the calculated wave height of an individual wave.

Based on the assumption (2), the following equation of the shoaling coefficient K_s is used:

$$K_s = \left[\left\{1 + \frac{4\pi d/L}{\sinh 4\pi d/L}\right\} \tanh \frac{2\pi d}{L}\right]^{-1/2}, \qquad (1)$$

and based on the assumption (3), Goda's breaker index

$$H_b/L_o = A\left[1 - \exp\left\{-1.5\frac{\pi d}{L_o}(1 + 15\tan^{4/3}\theta)\right\}\right], \qquad (2)$$

is applied, in which A=0.17 in the case of monochromatic waves, $\tan\theta$ is the bottom slope, and L_o the deep-water wave length, L the wave length in shallow-water, d the mean water depth, and H_b the breaking wave height.

Concerning the change of the wave height after breaking, the bore model adopted by Battjes (1978b) is used. Both factors of the bottom slope and the deep-water wave steepness can be introduced to this model by using the surf similarity parameter. The non-dimensional wave height in the surf zone is expressed as follows:

$$\left.\begin{aligned} \tilde{H}^{-4} &= (1 - \frac{4}{9}K)\tilde{d} + \frac{4}{9}K\tilde{d}^{-7/2}, \\ K &= (\frac{2}{\pi})^{1/2} B\gamma^{1/2}\xi_o^{-1}, \\ \gamma &= 0.7 + 5\tan\theta \qquad (0.01 \leq \tan\theta \leq 0.1), \end{aligned}\right\} \tag{3}$$

in which $\tilde{H} = H/H_b$, $\tilde{d} = d/d_b$, d_b is the breaking water depth, and $\xi_o = \tan\theta/\sqrt{H_o/L_o}$, the surf similarity parameter in deep-water.

The water depth d in the above equations should be taken as the mean water depth. Battjes (1978b) assumed that the mean water level in the surf zone has a gradient equal to 1/5 of the bottom slope with zero setup at the breaking point; therefore, $\tan\theta$ in Eq. (3) becomes as gentle as 0.8 times of the actual bottom slope.

In this paper, the wave height change is firstly calculated by Eqs. (1), (2) and (3) for the still water depth h, and secondly the wave setup $\bar{\eta}$ is calculated numerically from deep-water to the shoreline by using the obtained wave hiehgts and the following equation:

$$\frac{d\bar{\eta}}{dx} = -\frac{1}{(h+\bar{\eta})}\frac{d}{dx}\left\{\frac{1}{8}H^2\left(\frac{1}{2} + \frac{2k(h+\bar{\eta})}{\sinh 2k(h+\bar{\eta})}\right)\right\} \tag{4}$$

The calculated value $\bar{\eta}$ is added to the still water depth h, and the calculation for the wave height change is repeated for the mean water depth $d = h + \bar{\eta}$. The repeated calculation is closed when the difference of successive wave setup becomes as small as 1% after repeats of several times.

Since the calculated value of $\bar{\eta}$ obtained from Eq. (4) using the measured wave height seem to give an overestimate compared with the experimental results, Eq. (4) is modified with the multiplication factor of 0.6.

Energy dissipation due to wave breaking is composed of various factors such as the horizontal roller, the bottom friction and the tubulence with air entrainment (Sawaragi and Iwata (1974)). Eq. (3) is derived from the energy balance equation in which the energy dissipation due to wave breaking is simplified by simulating that due to a bore. Since Eq. (3) can not always fit the experimental results well in all cases, the value of B in Eq. (3) is determined so that the spatial distributions of the wave height agree with the experimental results by Nakamura et al. (1966), Saeki et al. (1974) and Singamsetti et al. (1978) as follows:

(i) In cases that $\tan\theta > 1/20$,

$$\left.\begin{aligned} &B = 1 && \text{for} \quad 0.9 \leq \tilde{d} \leq 1.0, \\ &B = 13 - 40\tilde{d}/3 && \text{for} \quad 0.6 \leq \tilde{d} \leq 0.9, \text{ and} \\ &B = 5 && \text{for} \quad \tilde{d} \leq 0.6. \end{aligned}\right\} \qquad (5)$$

(ii) In cases that $\tan\theta < 1/20$,

$$\left.\begin{aligned} &B = 11 - 10\tilde{d} && \text{for} \quad 0.6 \leq \tilde{d} \leq 1.0, \text{ and} \\ &B = 5 && \text{for} \quad \tilde{d} \leq 0.6. \end{aligned}\right\} \qquad (6)$$

Fig. 1(a) shows the wave height decay of monochromatic waves with decrease in the still water depth after wave breaking in dimensionless form for the deep-water wave steepness of 0.02 with a parameter of the bottom slope from 1/10 to 1/50, in which the experimental results by Saeki et al. (1974) are plotted herewith. Fig. 1(b) also shows the wave height decay after breaking for the bottom slope of 1/30 with a parameter of the deep-water wave steepness from 0.005 to 0.08. It is seen from these figures that the wave height decay becomes remarkable with decrease in the bottom slope and increase in the deep-water wave steepness.

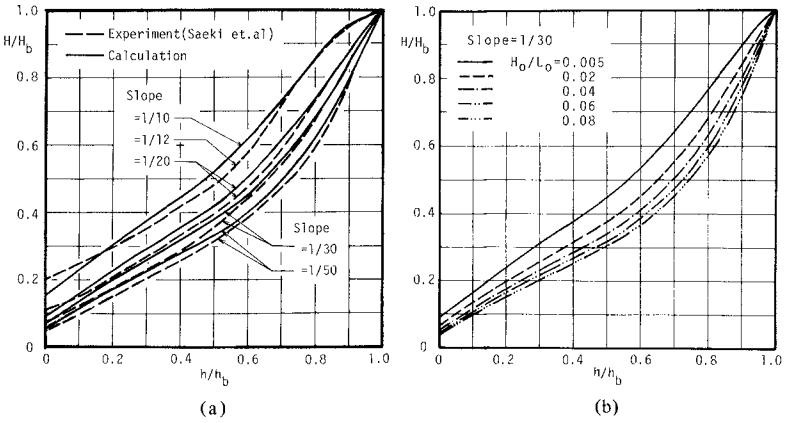

Fig. 1 Wave height decay after wave breaking

2.2 Different points between transformations of breaking irregular waves and monochromatic waves

One of different points between irregular and monochromatic wave transformations in the surf zone is the breaking limit of an individual wave; that is, the breaking wave height of an individual wave of irregular waves is smaller than that of monochromatic waves having the same wave height and period (Kimura and Iwagaki (1978), Sawaragi and Iwata (1981)). The other point is the generation of temporal variations of the water surface having some long-periods, so called surf beats; therefore, they may affect transformations of breaking irregular waves.

With respect to the first point, the reasonable value of A in Eq. (2) is investigated by experiments, and for the second point the following empirical formula of the root-mean-square value of surf beats ζ_{rms} based on the field observation by Goda (1975) is used:

$$\frac{\zeta_{rms}}{H_o} = \frac{0.01\, H_o}{\sqrt{\frac{H_o}{L_o}\left(1+\frac{d}{H_o}\right)}} \quad , \tag{7}$$

in which H_o denotes the significant wave height in deep-water and L_o the wave length in deep-water corresponding to the significant wave period.

In this paper, the surf beat elevation ζ is added to the mean water depth by generating random numbers of the normal distribution with the mean value of 0 and the root-mean-square value of ζ_{rms} by Eq. (7).

2.3 Calculation method for wave height change of irregular waves

As input data, wave heights and periods obtained from the wave record at a constant water depth by the zero-up-cross-method, the bottom slope and the still water depths at all points to predict wave heights are given in this paper.

After calculation of the wave height change of an individual wave for the still water depth and surf beats, the root-mean-square wave heights $\overline{H^2}$ are calculated to obtain the wave setup $\overline{\eta}$ from Eq. (4) with $\overline{H^2}$ instead of H and the wave length corresponding to the significant wave period. Then, the wave height of an individual wave is calculated for the still water depth h, the obtained wave setup $\overline{\eta}$ and the surf beat ζ. Repeating this procedure, the calculation is closed when the difference of successive wave setup becomes less than 1% of the wave setup, and the representative wave heights and the frequency distributions of wave height are obtained. Fig. 2 shows the flow chart for this calculation.

In this calculation program, several supplemental water depths in addition to the water depths of input data are adopted in order to solve Eq. (4) numerically, and many additional water depths are used for determination of the breaking point.

3. Experimental aparatus and procedures

A wave tank, 27m long, 50cm wide and 70cm high, at the Department of Civil Engineering, Kyoto University was used in the present experiments. A wave generator

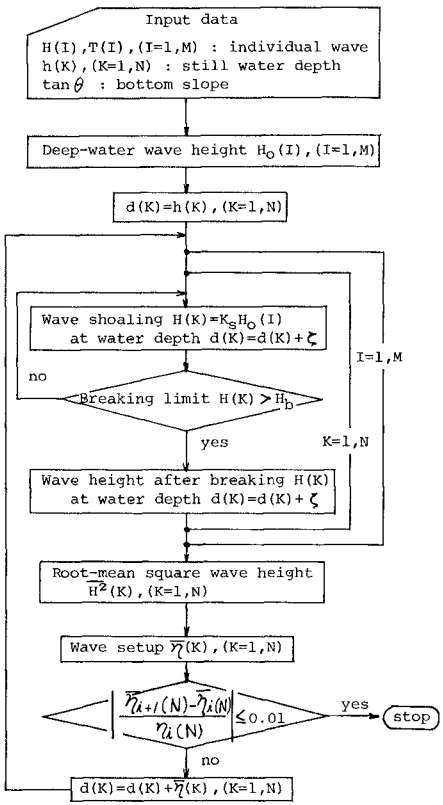

Fig. 2 Flow chart for calculation of wave height change of irregular waves

of irregular waves is installed at an end of the tank.

In order to examine at first the breaker height of an individual irregular wave, some experiments were carried out on the uniform slopes of 1/20 and 1/30 by taking photographs with a 16mm-cinecamera. An experiment for the 1/10 slope was not carried out because the data of breaker height of an individual wave tend to scatter (Kimura and Iwagaki (1978)). In these experiments, the elevation of the top of the slope was ajusted to be equal to the still water level in order to decrease the unsteady back wash which was considered as one of reasons for the difference from the breaking characteristics of regular waves. The range of the breaker depth to be measured by taking pictures was from 10 to 15cm. Irregular waves having the spectra of Pierson-Moskowitz type and two kinds of deep-water wave steepnesses were used. The water depth was kept to be 50cm at the uniform section. The films were analyzed by a film motion analyzer.

In order to examine furthermore the spatial distributions of wave heights and wave grouping of irregular waves with decrease in the water depth, experiments were carried out on the uniform solpes of 1/10 and 1/30 with the water depth of 45cm at the uniform section. Irregular waves having the spectra of Pierson-Moskowitz type and five kinds of deep-water wave steepnesses of 0.005 to 0.07 were used. Water surface elevations were measured by six wave gauges of capacitance type, which were installed at the water depths of 45,20,15,10,5 and 2cm in the case of 1/10 slope and 45,20,12,8,5 and 2cm in the case of 1/30 slope. Additional experiments for the slopes of 1/20 and 1/30 with the water depth of 50cm were carried out by using eleven wave gauges of capacitance type to investigate the change of wave grouping in detail.

Water surface elevations were recorded in a 14-channel analog data recorder. The records were digtized by an A-D converter with 0.04sec time interval and used in analysis.

4. Experimental results and discussions

4.1 Breaking characteristics of individual wave

Figs. 3(a) and (b) show the relationships between H_b/h_b and h_b/L_o on the uniform slopes of 1/20 and 1/30. An individual wave is defined by the spatial zero-up-cross method. The solid lines in the figures represent the results by Eq. (2), and the dashed lines show the results by putting the value of A in Eq. (2) as 0.13,0.14,0.15 and 0.16. The tendency that H_b/h_b decreases with increase in h_b/L_o is similar to that by Eq. (2). However, the experimental data are generally plotted somewhat smaller than the values by Eq. (2). Since the unsteady back wash seems to be weak in the present experiments, the data are plotted a little larger than those by Kimura et al. (1978) and Sawaragi et al. (1981). In determining the breaker height of an individual wave for numerical calculation, the value A in Eq. (2) is taken as 0.16.

4.2 Representative wave heights

Figs. 4(a) and (b) show the changes of the non-dimensional significant wave height $H_{1/3}/H_o$ and mean wave height $\overline{H}/H_o$ with decrease in the water depth on the uniform slopes of 1/10 and 1/30, respectively. An individual wave is defined by the temporal

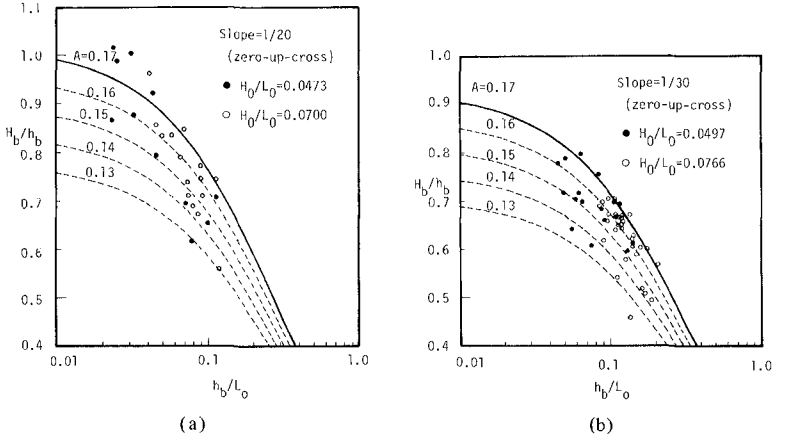

Fig. 3 Relationships between H_b/h_b and h_b/L_o for individual waves

zero-up-cross method, in which the mean water level is determined by simply averaging the water surface elevation. In very shallow water, however, there exist sometimes no intersecting waves with the mean water level. As a result, the significant wave height becomes large and the number of an individual wave decreases compared with the waves obtained from the water surface elevation after the effect of surf beats is eliminated. Therefore, the wave height distributions become different depending on whether the effect of surf beats is eliminated or not, as described later. The curves in Fig. 4(a) and (b) show the calculated results predicted by the individual wave analysis method.

It is found from these figures that the non-dimensional wave heights become large as the deep-water wave steepness, which is estimated from the significant waves at the constant depth by the small smplitude wave theory, becomes small and the bottom slope becomes steep. Concerning the significant wave height, the experimental results are a little larger than calculated ones when the relative water depth h/H_o is less than 1.0, and the calculated results in the region of wave shoaling using the shoaling coefficient by the small amplitude wave theory are a little smaller than the experimental ones. Concerning the mean wave height, the calculated results are somewhat larger than the experimental ones in the case of small deep-water wave steepness. Generally speaking, the predicted curves agree fairly well with the experimental results.

4.3 Wave height distributions

Figs. 5 and 6 show the frequency distributions of wave heights for the cases of

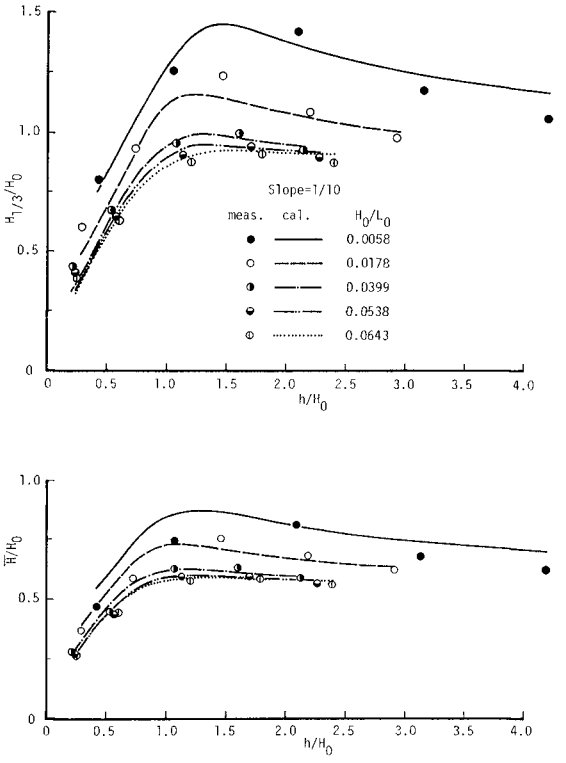

Fig. 4 (a) Change of significant and mean wave heights of irregular waves in shallow-water for 1/10 beach slope

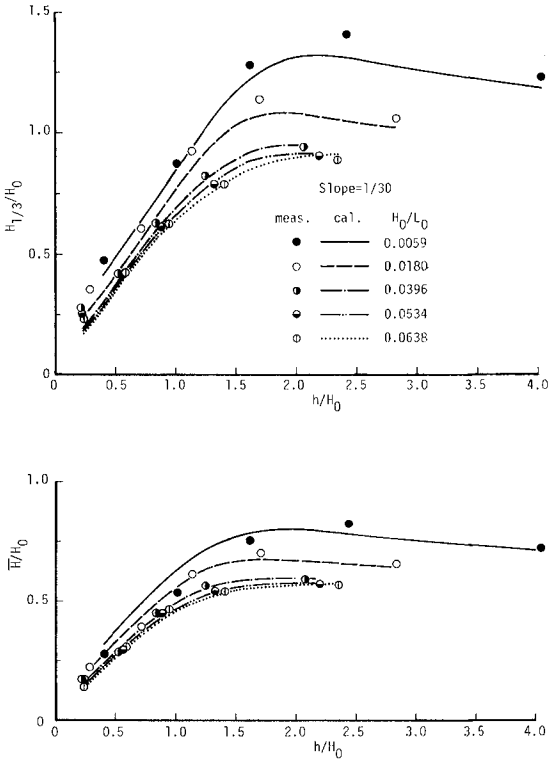

Fig. 4 (b) Change of significant and mean wave heights of irregular waves in shallow-water for 1/30 beach slope

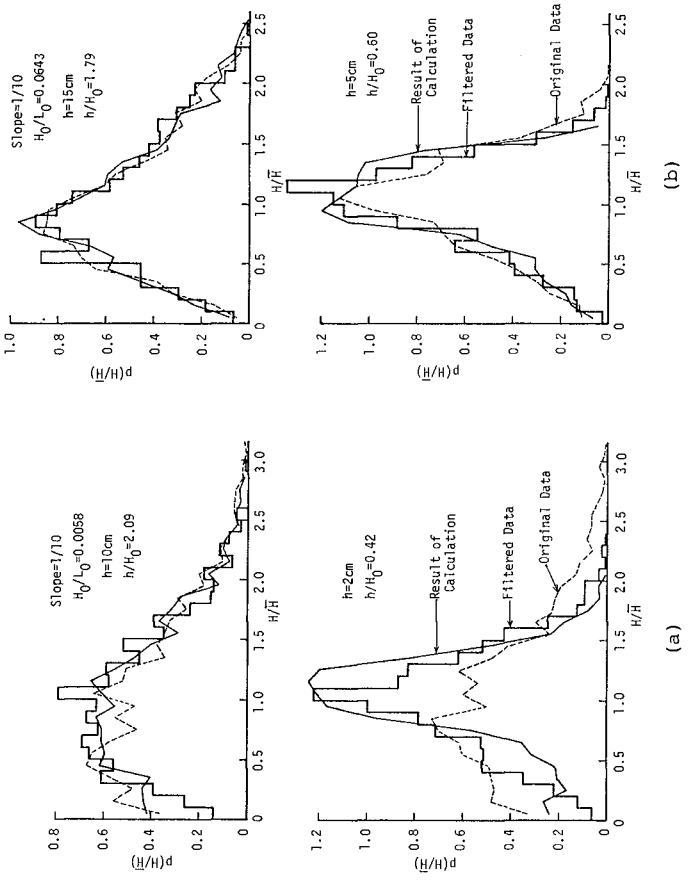

Fig. 5 Wave height distribution in shallow-water for 1/10 beach slope

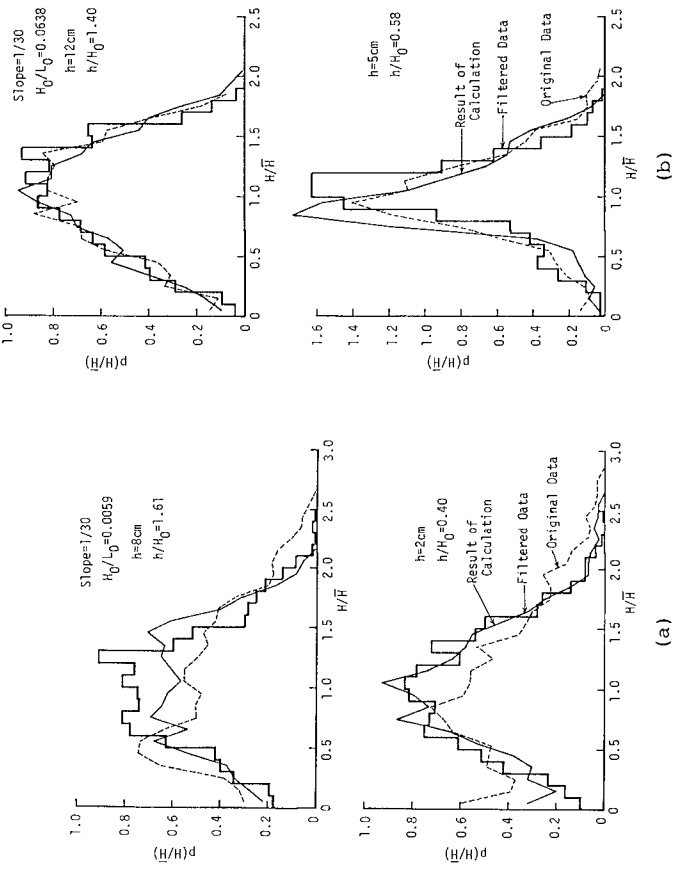

Fig. 6 Wave height distribution in shallow-water for 1/30 beach slope

the smallest and largest wave steepnesses in the experiments on the uniform slopes of 1/10 and 1/30, respectively, in which the wave height is normalized by the local mean wave height. In these figures the bent solid lines show the calculated results by the individual wave analysis method, the bent dashed lines show the experimental results obtained from the simply averaged mean water level denoted by "original data", and the histogram show the experimental results obtained from the "filtered data" of water surface elevations by cutting off the component waves of surf beats having the lower frequency than f_L *Hz* and the component waves having the higher frequency than f_U *Hz*. Cutting off of the high frequency components is for elimination of abrupt rising of the water surface due to splash with breaking and small disturbed waves after breaking. The frequency f_L was determined as $0.5f_p$ (f_p: the peak frequency) from the shapes of energy specta, and f_U was taken as $6f_p$ for convienience. An example of original and filtered water surface variations are shown in Fig. 7.

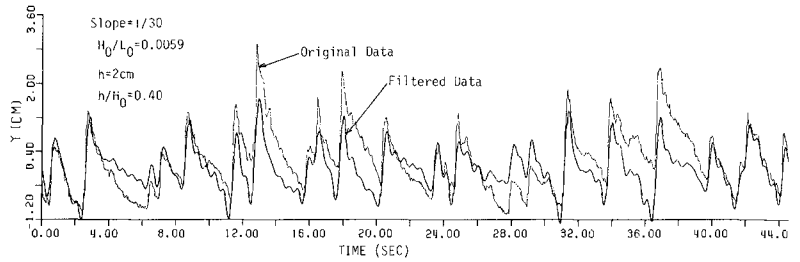

Fig. 7 Original and filtered water surface variations

In the case of large deep-water wave steepness as shown in Fig. 5(b) and Fig. 6(b), the shapes of the dashed line obtained from the original data and the histogram from the filtered date are almost same. It means that the effect of the filter is not so remarkable. However, in the case of small deep-water wave steepness as in Fig. 5(a) and Fig. 6(a), the shapes of the dashed line become flatter than those of the histogram, which means the effect of the filter is remarkable. Comparisons of the calculated wave height distributions with those of original data show fairly good agreement except for the case of small deep-water wave steepness in very shallow water. However, it is found that even in the case of small deep-water wave steepness, if the long-period variation due to surf beats and the high frequency components are removed from the original water surface variation, the calculated results agree well with the experimental ones. In other words, how to define an individual wave in very shallow water becomes important (Hotta (1980)).

4.4 Wave grouping

At present, several indicies are used to represent the degree of wave grouping, Goda (1970) used a run of wave heights $j(H_c)$ defined as the number of sequent waves, the heights of which exceed a definite value H_c and a total run $l(H_c)$ defined as the number

of waves between the first excess over the definite level H_c and the next excess over the same level. Funk et al. (1979) used a Groupiness Factor defined as the coefficient of variation of the time history of wave energy.

In the following, the spatial changes of wave grouping with decrease in the water depth are examined by using the parameter of the mean length of run $\overline{j(H_c)}$ and the mean length of total run $\overline{l(H_c)}$. Figs. 8(a) and (b) show the changes of $\overline{j(\overline{H})}$ and $\overline{l(\overline{H})}$ on the uniform slopes of 1/10 and 1/30, respectively. Figs. 9(a) and (b) show the detailed experimental results of wave grouping for the bottom slopes of 1/20 and 1/30, respectively. The followings can be seen from Figs. 8 and 9: In the case of 1/10 slope the mean length of run $\overline{j(\overline{H})}$ and total run $\overline{l(\overline{H})}$ over the mean wave height are almost constant independently of the deep-water wave steepness when the relative water depth h/H_o is larger than 1.5 and decrease with decrease in the water depth. On the other hand, in the cases of gentle slopes as 1/20 and 1/30, the mean lengths of run $\overline{j(\overline{H})}$ and total run $\overline{l(\overline{H})}$ become large as the deep-water wave steepness becomes large. The mean lengths of total run $\overline{l(\overline{H})}$ in the case of 1/20 and 1/30 slopes decrease with decrease in the water depth in similar way to the case of 1/10 slope. However, the mean lengths of run $\overline{j(\overline{H})}$ take maximum values in the region $1.0 \leq h/H_o \leq 1.5$ and decrease rapidly with decrease in the water depth. This tendency is remarkable in the case of gentle slope and large deep-water wave steepness. The mean lengths of run $\overline{j(H_{1/3})}$ and total run $\overline{l(H_{1/3})}$ over the significant wave height also tend to take maximum slightly as well as $\overline{j(\overline{H})}$ and $\overline{l(\overline{H})}$.

According to the results of numerical simulation by Goda (1970), $\overline{j(H_c)}$ and $\overline{l(H_c)}$ become small with decrease in the spectral peakedness parameter Q_p. From the present experimental results, however, it is noted that $\overline{j(H_c)}$ and $\overline{l(H_c)}$ increase near the relative water depth of 1.5 in spite of decrease in the spectral peakedness parameter due to the rapid decay of a main peak and the grow of the low frequency components of the spectrum by wave breaking.

5. Conclusions

Among the transformation characteristics of irregular waves in shallow-water including the surf zone, the changes of the significant and mean wave heights, the wave height distributions and wave grouping have especially been investigated. In addition to the experiments of irregular waves, a model for prediction of wave heights named the individual wave analysis method has been proposed. The summaries of the results are described bellow.

(1) An individual wave of irregular waves tends to break compared with monochromatic waves having the same wave height and period in the experiments.

(2) Non-dimensional significant wave height $H_{1/3}/H_o$ and mean wave height $\overline{H}/H_o$ become large as the bottom slope becomes steep and the deep-water wave steepness becomes small.

(3) The predicted significant and mean wave heights are in fairly good agreement with the experimental ones.

(4) Comparisons of the predicted wave height distributions with those of the original experimental data show good agreement except for the case of small deep-water wave steepness in very shallow water. Even in such cases, if the long-period variation

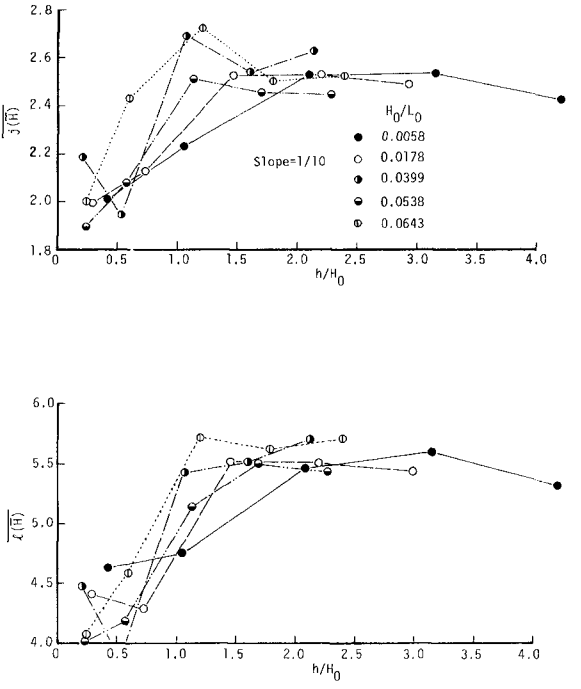

Fig. 8 (a) Change of wave grouping in shallow-water for 1/10 beach slope

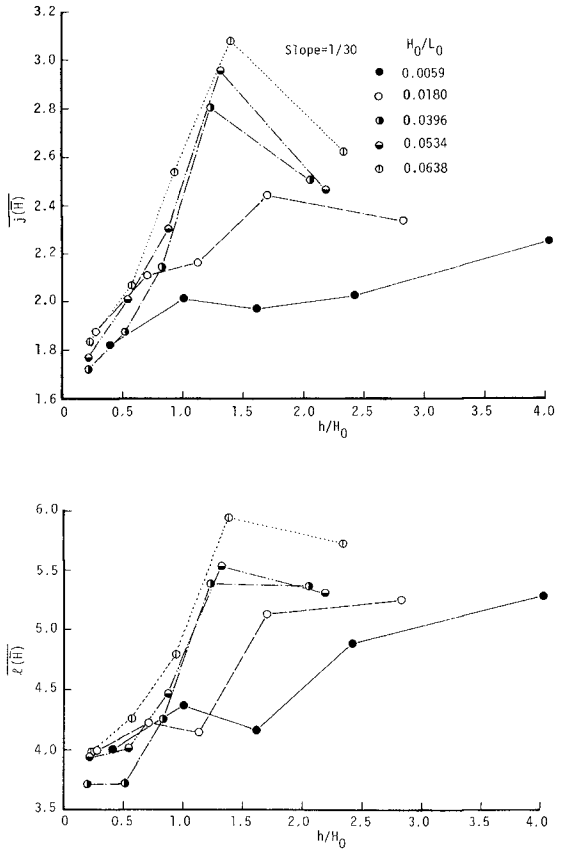

Fig. 8 (b) Change of wave grouping in shallow-water for 1/30 beach slope

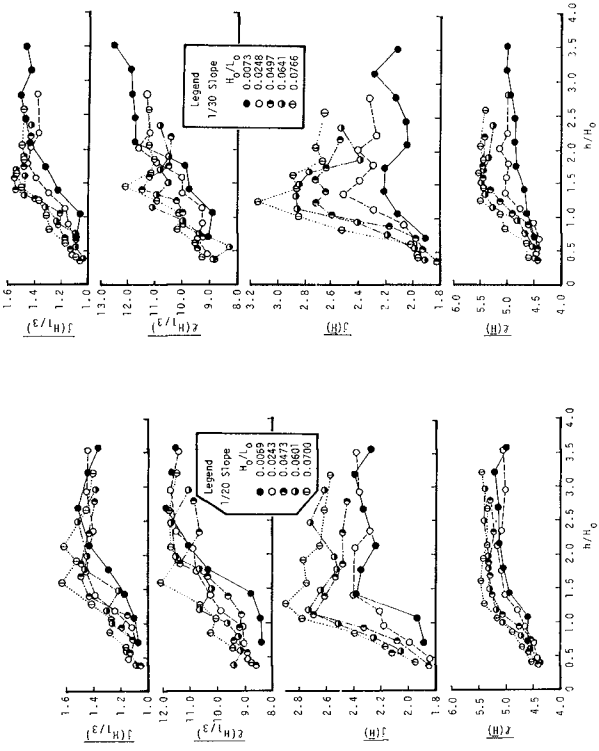

Fig. 9 Change of wave grouping in shallow-water for slopes of 1/10 and 1/30

due to surf beats and high frequency components of the water surface variation are removed, the calculated and experimental results agree well.

(5) Wave grouping becomes remarkable at the range of the relative water depth $1.0 \leq h/H_o \leq 1.5$ with decrease in the bottom slope and increase in the deep-water wave steepness.

NEARSHORE WAVE SPECTRA MEASURED DURING HURRICANE DAVID

Michel K. Ochi* and Ming-Hsing Chiu*

ABSTRACT

This paper presents the results of an analysis carried out on wave spectra measured at three nearshore sites along the United States Florida coast when Hurricane DAVID passed these sites in 1979. Included are (a) the variability of the shapes of wave spectra during the stages of growth and decay of the hurricane-generated seas, (b) the presentation of spectra according to various spectral formulations, and (c) a comparison between spectra measured at the coastal sites and those measured in deep water for the same severity (significant wave height) of hurricane-generated seas.

INTRODUCTION

For the design of onshore, nearshore, and coastal structures, it is highly desirable and, from a safety viewpoint, extremely important to have a precise description of nearshore sea severity. In particular, for structures along coasts, wave data measured during hurricanes provide a vital source of information for establishing design criteria.

Although many observations and measurements have been made on wind-generated waves associated with hurricanes over deep water, we have as yet little information as to hurricane-generated sea severity in coastal waters.

This paper presents the results of analysis carried out on wave spectra measured at three locations in shallow water when a hurricane passed through these sites. That is, on September 3rd, 1979, Hurricane DAVID approached the Florida east coast from the eastern Carribbean with a moving speed of about 10 knots. During this period, wave recorders installed by the University of Florida at Miami Beach, West Palm Beach, and Vero Beach successfully recorded the waves throughout the duration of the storm at each site.

In order to obtain an accurate representation of wave spectra associated with sea conditions arising from hurricanes, the variability of the shapes of wave spectra during the stages of growth and decay of

* Coastal and Oceanographic Engineering Department,
University of Florida, Gainesville, Florida, USA

Hurricane DAVID is examined. The wave spectra are represented by various mathematical formulations to provide information for further analysis of coastal waves. Furthermore, comparisons are made between the shapes of wave spectra obtained at the coastal sites and those obtained in deep water for the same severity (significant wave height) of hurricane-generated seas.

WAVE DATA DURING HURRICANE DAVID

Hurricane DAVID (August 26 - September 6, 1979) approached the east coast of Florida from the Carribbean, and its eye passed over several Florida coastal cities as shown in Figure 1. During this period of moving almost due north at about 10 knots (5.1 m/sec), the hurricane moved inland just north of Palm Beach, then later it again

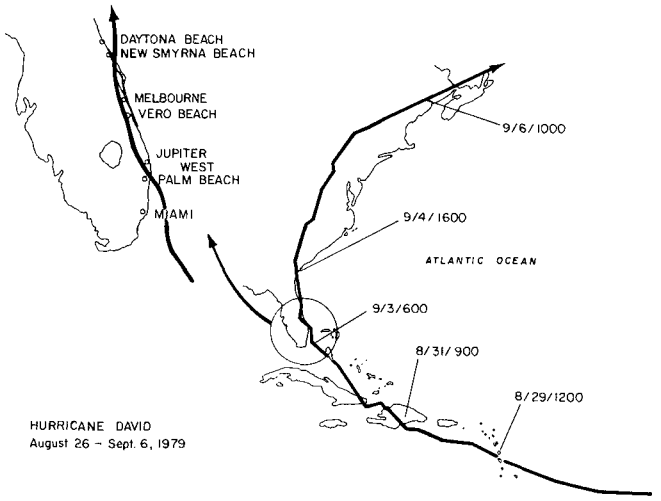

Figure 1 Hurricane DAVID track

moved offshore. The eye diameter was 20 to 30 nautical miles (37 to 56 km) while it was passing over the Florida area, and the highest winds experienced were gusts up to 75 knots (39 m/sec).

The data used in this study were recorded from three measurement sites which are chosen at nearly equally spaced intervals along the Florida east coast. These sites are located at Miami Beach, West Palm Beach and Vero Beach respectively, and are about one kilometer offshore. They are part of the Florida Coastal Data Network system (Howell 1980) which collects long-term diary wave data as well as storm wave data.

The geographic features of these sites and the measured maximum significant wave heights are tabulated in Table 1.

Table 1 Geographic features and measured maximum significant wave heights at three sites

SITE	MIAMI BEACH	WEST PALM BEACH	VERO BEACH
GEOGRAPHIC LOCATION	25°46'06"N 80°07'23"W	26°42'07" 80°01'42"	27°40'20" 80°21'07"
DISTANCE FROM SHORE (km)	0.91	0.61	0.90
WATER DEPTH (m)	6.1	8.5	7.6
SHORTEST DISTANCE TO HURRICANE EYE (km)	70.5	25.0	14.1
MAX. SIG. WAVE HEIGHT (m)	2.65	5.10	3.51

Pressure transducers located about one-half meter above the seabed were used to take data. They were bottom mounted on a completely self-contained electronic cylinder which contains a microcomputer controlled data acquisition system. From surface pressure signals, the pressure energy spectra were computed, and then converted to surface wave spectra by assuming the pressure-wave profile-relation to be linear.

RESULTS OF ANALYSIS

Significant wave height, denoted by H_s, was evaluated from the measured spectra by using the formulation given by $H_s = 4\sqrt{m_o}$, where m_o is the area under the spectrum. The temporal variation of significant wave height and radial distance from the hurricane center measured at sites are shown in Figures 2(a) through 2(c). It can be seen in these figures that the significant wave height decreases rapidly in the decaying stage in comparison with the increase of its intensity in the growing stage.

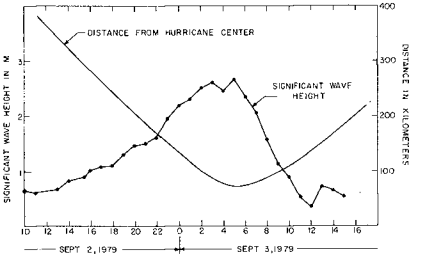

Figure 2 Temporal variations of significant wave height and radial distance (a) Miami Beach

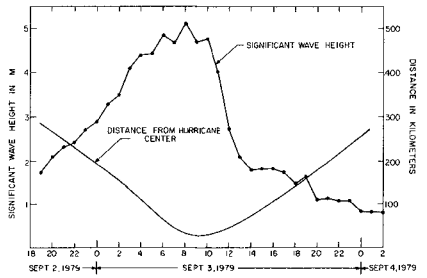

Figure 2 Temporal variations of significant wave height and radial distance
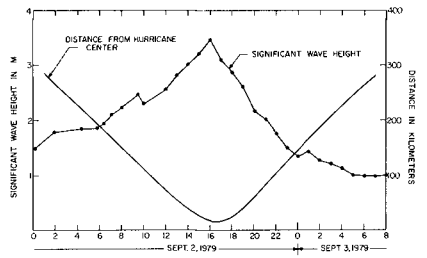
(b) West Palm Beach



(c) Vero Beach

In order to present the overall picture of the growth and decay status of hurricane-generated seas, contour lines of spectral energy densities are constructed from the entire series of spectra, and are shown in Figures 3(a) through 3(c). Each contour in the figure represents spectral density of a certain level (2.0 m^2-sec, 4.0 m^2-sec, etc.) and the inner portions of the enclosed contours correspond to higher spectral densities. The highest spectral density at the innermost portion of the contour lines corresponds to the severest sea state in which the highest significant wave height was obtained.

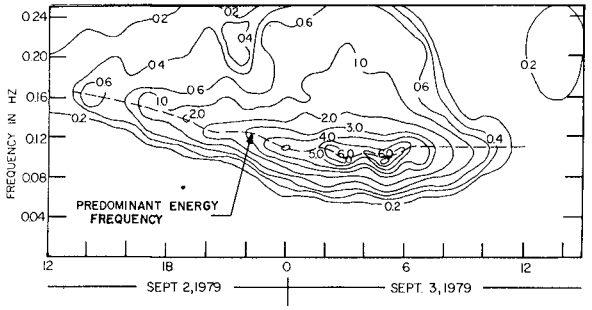


Figure 3 Contours of spectral densities constructed from wave spectra (a) Miami Beach

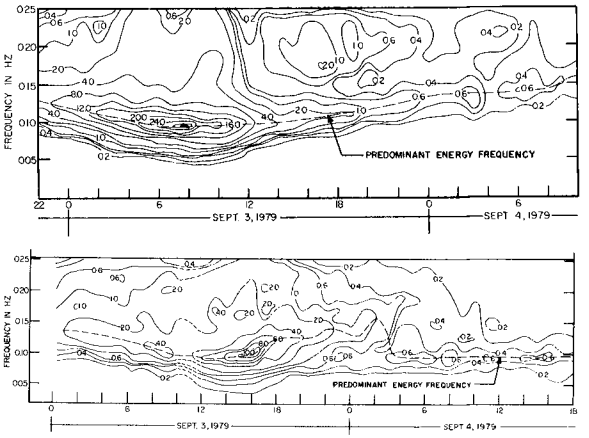

(b) West Palm Beach

(c) Vero Beach

Figure 3 Contours of spectral densities constructed from wave spectra

The severest sea states at the three sites occurred at 5 am, 8 am, and 4 pm, September 3rd, respectively, and the corresponding spectra had approximately the same peak frequency, 0.094 Hz.

It is of interest to compare the shapes of wave spectra obtained in seas of approximately the same significant wave height but under different conditions; one in the growing stage, the other in the decaying stage of the hurricane. As an example, Figure 4(a) shows a comparison of spectra measured at West Palm Beach in a mild sea state of significant wave height of 2.07 m. As can be seen in the figure, the frequency where the spectrum peaks (modal frequency) in the decaying stage is lower than that in the growing stage. This trend holds throughout the storm as can be seen in Figures 4(b) and 4(c). The same trend was also observed for spectra measured in Miami Beach. However, this general trend is reversed when the hurricane passes inland or shoreward of the point of measurements. As Hurricane DAVID

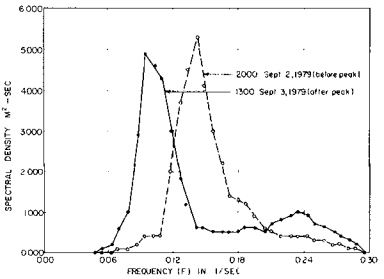

Figure 4 Comparison of wave spectra obtained in the growing and decaying stages of the hurricane, West Palm Beach
(a) Significant height 2.07 m

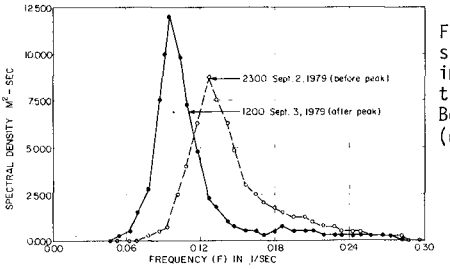

Figure 4 Comparison of wave spectra obtained in the growing and decaying stages of the hurricane, West Palm Beach
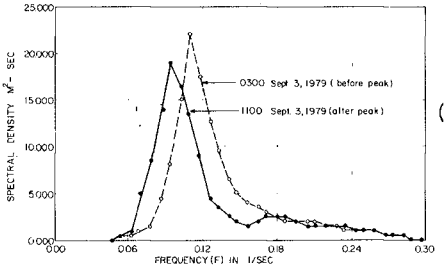
(b) Significant height 2.72 m



(c) Significant height 3.99 m

passed Miami Beach and West Palm Beach, its path was offshore. After it passed West Palm Beach, it moved inland, then later moved offshore again. The hurricane's path was inland throughout the period when severe seas were observed at Vero Beach. This may account for the modal frequency in the growing stage being lower than that in the decaying stage for the Vero Beach data as shown in the example in Figure 5.

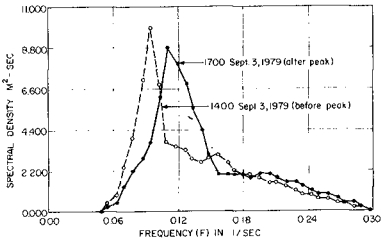


Figure 5 Comparison of wave spectra obtained in the growing and decaying stages of the hurricane, Vero Beach, Significant height 3.08 m

The measured spectra are fitted by various spectral formulations to see how well hurricane-generated nearshore wave spectra can be represented by currently available formulations which have been developed for seas in deep water. These include the one-parameter (Pierson-Moskowitz 1964), and the two-parameter (Bretschneider 1959), three and six-parameter (Ochi and Hubble 1976), and JONSWAP (Hasselmann et al. 1959) spectral formulations. The JONSWAP spectrum used in the comparison is not the mean JONSWAP spectrum; instead it is obtained

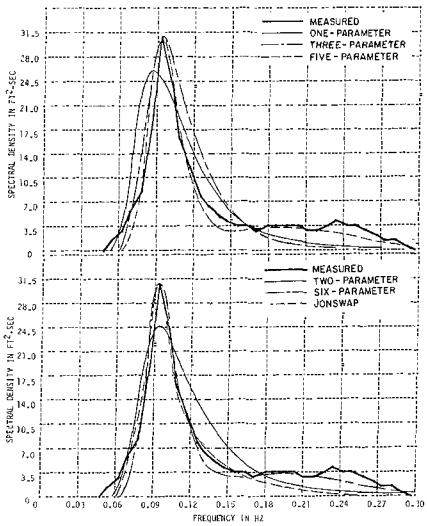

Figure 6 Comparison between measured and mathematical spectra. West Palm Beach, significant height 5.1 m.

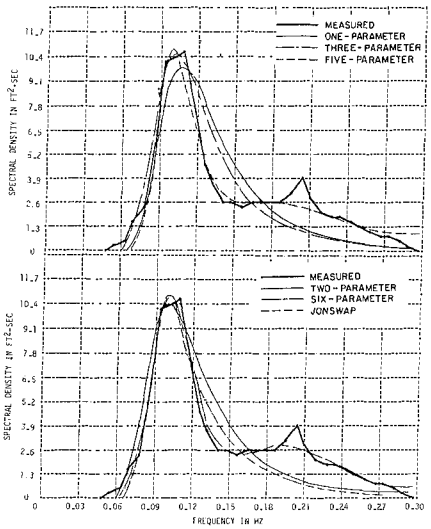

Figure 7 Comparison between measured and mathematical spectra. Vero Beach, significant height 3.5 m

by fitting the measured spectrum through least-square fitting techniques. Included also in the comparison is the five-parameter spectrum which is a combination of a three-parameter formulation representing the lower-frequency range of the spectrum and a two parameter formulation representing the higher frequencies.

The results of the comparison between measured and mathematical spectra show that the five and six-parameter spectra appear to best represent the measured spectra in shallow water areas throughout the various stages of the hurricane. Also, the JONSWAP spectral formulation yields a good fit to the shape of the measured spectra, in general, with the exception of those with a secondary peak or an extended plateau in the high-frequency region. As an example, Figures 6 and 7 show a comparison made for the severest sea state observed at West Palm Beach and Vero Beach, respectively, during the hurricane.

The shapes of hurricane-generated wave spectra obtained at the coastal sites and those obtained during hurricanes in deep water are compared. If the shapes of deep and shallow water hurricane-generated wave spectra are alike under certain conditions, then the results of analysis made on the shapes of deep-water hurricane spectra may be used for those of shallow water. In the comparison of Hurricane DAVID (shallow water) wave spectra with spectra measured in deep water, the results obtained during Hurricane ELOISE in the Gulf of Mexico (Withee and Johnson, 1977) are used, and comparisons are made between spectra having the same significant wave height and the same modal frequency.

As an example, Figure 8(a) shows a comparison between deep and shallow water (8.5 m water depth) wave spectra of significant wave height of 4.8 m with the same modal frequency of 0.098 Hz. Other examples of comparison made in less severe sea states are shown in Figures 8(b) and (c). Although the shapes of hurricane-generated wave spectra measured in deep and shallow water of 7-10 m water depth are significantly different in mild sea conditions (significant wave heights less than 2 meters), the shapes of spectra with the same significant wave height and the same modal frequency appear to be very similar in relatively severe seas as shown in Figure 8.

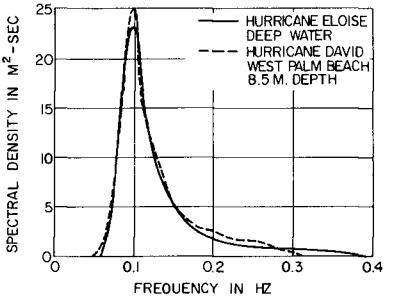

Figure 8 Comparison of hurricane wave spectra measured in coastal and deep waters. (a) Significant height 4.8 m

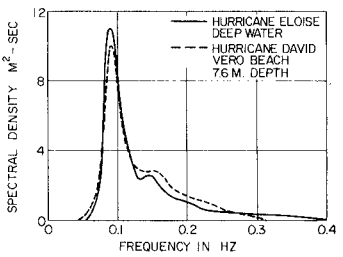
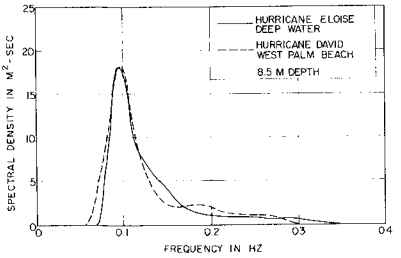


(b) Significant height 3.0 m



(c) Significant height 3.9 m

CONCLUSIONS

This paper presents the results of analysis carried out on wave spectra measured at three nearshore sites along the United States Florida coast when Hurricane DAVID passed through these sites. It is found from the results of the analysis that the peak frequencies of the spectra in the decaying stage of the hurricane-generated coastal waves are, in general, lower than those in the growing stage. This implies that the wave energy in longer wave lengths is dominant in the decaying stage.

The shapes of the measured wave spectra can best be represented by the five and six-parameter spectral formulations throughout various stages of the hurricane. The JONSWAP spectral formulation also yields a good fit to the shapes of the measured spectra, in general, with the exception of those with a secondary peak or an extended plateau in the high-frequency region.

The shapes of the hurricane-generated wave spectra with the same significant wave height and the same modal frequency obtained in coastal and deep water are very similar in relatively severe seas.

A SOUTH AFRICAN WAVE CLIMATE STUDY

by

J Rossouw[1], L W Coetzee[2] and C J Visser[3]

ABSTRACT

A study was made, using all the available sources of deep-sea wave data around the South African coast, to establish a statistical representation of the wave climate in this region. Data obtained from clinometer observations, the Datawell Waverider and voluntary observing ships were found to be the most useful.

The most accurate source of height, period and spectral information came from the Waverider which has been in extensive use in the region since 1969. To optimise the information value of these data a sophisticated data qualification technique was developed for digitised Waverider data in order to exclude poor data. This technique was also found to be useful in optimising the operational efficiency of a Waverider station.

A clear pattern was obtained for the general wave climate around the South African coast; this is in accordance with the pattern that may be expected from the weather climate affecting this region. Of interest are the SE'ly winds generating increased wave heights in proportion to the distance offshore from the west coast as well as the effect of the Agulhas current, opposing the SW'ly waves along the east coast, also creating high-wave conditions.

1. INTRODUCTION

Instrumental recording of waves has been done in South African coastal waters since 1961. Initially a wide variety of instruments were used including clinometers, NIO ship-borne wave recorders, inverted echosounders and pressure recorders. The first Datawell accelerometer buoy

(Waverider) was installed off Mossel Bay in 1969 and the Waverider has since become the main recording instrument to be used in South African coastal waters. The number of Waverider stations varied over the years, but data representative of the open coast were obtained from 11 stations covering the entire South African and South West African coastline.

The main purpose of this study was to investigate all the possible sources of wave data that might be of use to the design engineer, to analyse the data and to publish the data in a form useful to all possible users. The data were also to be stored in a computer data bank to enable fast retrieval for further analysis by interested researchers and engineers.

This paper presents a summary of the main aspects of the study. It describes the development and application of a standard wave analysis and data qualification computer program for digital Waverider data, the system of data handling and storage, the comparison of the Waverider data with information from other sources and the present knowledge of the wave climate around South Africa.

2. WAVE ANALYSIS AND DATA QUALIFICATION

2.1 Data Collection

Waverider data are usually obtained for periods of 20 minutes every six hours from the various wave recording stations around the South African coastline. A sampling interval of 0,5 s is normally used for digital data and the resolution of the water elevation measured is 10 mm.

2.2 Computer Program

The detailed description of the program WAVES can be found elsewhere (Visser et al., 1980; Visser et al., not yet published). WAVES reads digitized wave records, applies qualification criteria to the data, performs spectral analysis, labels records as good, suspect or bad, and stores the processed records in a data bank. An example of a printout with a brief description is shown in Appendix A.

The procedures for spectral analysis are well documented and numerous computer routines for the fast Fourier transform (FFT) can be found in the literature. Writing a program to perform the basic computations is therefore relatively easy. However, the real problem lies in identifying invalid wave records which can result when, for example, noise due to equipment malfunction is superimposed on the data. Some bad records are easily identified, while in others, deficiencies are elusively masked. The influence

of unidentified invalid results in a data bank needs no elaboration.

2.3 Conventional Data Qualification

Examples of methods being used for the identification of invalid wave records are visual inspection and identification of outliers according to the number of standard deviations they are removed from the mean water level. The first method is deemed unpractical because of the dependence on a trained observer and the large amounts of data involved. The second method is based on the assumption of normality of the instantaneous water elevation $x(t_i)$ as a function of time t_i. Outliers change the shape and position of the distribution. The intensity of this depends on the number of outliers, their magnitude and their bias towards the peak or trough side of the record. In many cases this renders the method useless.

2.4 WAVES-program Data Qualification

A rather random approach was adopted in arriving at the present qualification procedure. As many tests as could be thought of were applied to a large number of wave records. The types of tests ranged from crude empirical models to standard statistical tests. The procedure was refined by comparing, for a large number of records of various localities, the outcome of the tests with the judgement of experienced observers. A wave record (usually consisting of 2 048 digitized $x(t_i)$-values) is split into two halves of 1 024 data points each. This facilitates investigating stationarity and provides results when one half of the record is bad or non-existent. Six tests on time-domain and frequency-domain parameters are performed on each half of the record to identify good ("GOOD"), suspect ("BAD?") or bad ("BAD") data. On the basis of the outcome of each test a severity code is assigned to the test. The severity codes are then used to determine a category ("GOOD", "BAD?" or "BAD") for each half. A further scheme is then used to determine a category for a whole record. For example, "GOOD2B" means that the second half is "GOOD" and the first half is "BAD").

The following tests are used to categorize records.

2.4.1 Flatheads ("P2", "P3", "P4" and ">P4" in Appendix A)

A flathead is identified when consecutive $x(t_i)$ have the same numerical value (to the nearest 10 mm, that is, the resolution of the digitizer). Thus the value of "P2" denotes the number of times two (and no more) consecutive $x(t_i)$ with the same value are detected. Similarly for the "P3", "P4" and ">P4" parameters. (For example, if

">P4" = 2, then two occurrences of flatheads with more than four $x(t_i)$ values occurred.)

2.4.2 Rate of change of wave profile ("ERR" in Appendix A)

If the slope of two consecutive data points is greater than the theoretical maximum slope that the water surface can attain, an erratic point is identified. The value of "ERR" denotes the number of erratic points in the record.

2.4.3 Consecutive erratic points ("CON" in Appendix A)

The value of "CON" denotes the number of times two erratic points (see 2.4.2) next to each other are detected.

2.4.4 The sample correlation coefficient ("CORR" in Appendix A)

A linear trend in the data, which can be caused, for example, by zero-drift in recording instrumentation, is detected when the correlation between $x(t_i)$ and t is statistically significant.

2.4.5 Normality of the $x(t_i)$ ("SKEWNESS" and "KURTOSIS" in Appendix A

Experience shows that the instantaneous water elevation $x(t_i)$ of sea waves follows approximately the normal distribution. Tests for normality are done using slightly adjusted distributions for skewness and kurtosis. (Relaxing slightly on the theoretical distributions.)

2.4.6 Low-frequency detector ("LF.DET" in Appendix A)

Most Waverider buoys used in South Africa will respond only to waves with periods in the range 1 to 33 seconds (band width of 0,03 to 1,0 Hz). This covers the domain for most applications. The buoy is "blind" to waves with periods outside the mentioned range (for example, the tide). Therefore, if the power spectrum contains significant spectral information outside the mentioned band width, invalid data that could not be measured with the buoy are indicated. The sum of the first four power spectral density values 0,006 to 0,035 Hz is denoted by "LF.DET".

The test criteria used to assign severity counts to the six parameters are shown in Appendix B.

3. DATA HANDLING AND STORAGE

The main agency dealing with waves in the RSA is the National Research Institute for Oceanology (NRIO) of the

Council for Scientific and Industrial Research (CSIR) at Stellenbosch.

A Wave Study Group was established within NRIO during mid-1980 with one of its primary purposes to develop a system for the more efficient gathering and analysing of digitized wave data, thus providing more effective quality control and faster feedback of the analysed information. At present this group copes with the management of wave data gathered at seven Waverider stations.

System improvements include the following:

3.1 Waverider Data Logger

An improved micro-computer-based Waverider data logger was developed by the Electronic Systems Division within NRIO (Holroyd, 1982). This system features a real-time full calendar clock with built-in leap-year compensation. Recording times are fixed at 00h00, 06h00, 12h00 and 18h00 GMT with additional facilities to initiate recordings at other chosen intervals as well as single recordings. A stand-by battery will drive the clock for about six hours during a power failure. A Memodyne Model 200 cassette data logger is used together with Philips data cassettes. Storage capacity amounts to about 11 days of 4 × 20 minute recordings per day.

Each wave record contains unique station identification, time, calibration and self-test data. File lengths are recorded at exactly 2 100 words of data, sampled at 2 Hz rate and recorded as 12-bit words. A real-time Draper analysis option can be utilized by connecting an 80-column printer to the data logger. H_S, H_1, T_Z and T_C are printed. The data logger is also supplied with an external Esterline Angus servo recorder providing an analogue trace of each wave record.

3.2 Process Control

The present system of gathering, analysing and storing wave data consists basically of the following steps:

- Waverider data are transmitted to nearby shore stations using the 27 MHz band.
- Cassette and analogue recordings are transported to NRIO using the most suitable means.
- Cassette data are transferred to 9-track magnetic tape using the NRIO in-house computer.

- The 9-track tape data are transmitted to the central CSIR computer in Pretoria using the available remote batch facilities.

- Final analysis and storage of the data are performed.

In order to obtain the maximum possible yield of good data from each recording station every effort is made to speed up and maintain a steady flow of data from the station to its final destination in Pretoria.

3.3 Quality Control

At NRIO several checks are done on the data prior to transferring it to the CSIR central computer. This includes a visual examination of the analogue records and also of suspect digital records on a graphics terminal. Time domain analysis is also done on the digital data and includes tests for normality. Useful fault reports are generated at this stage, although it was found that these tests are not critical enough to detect bad or suspect data in a large number of cases. Figure 1 shows digital records which were rejected by WAVES, although the records had passed the test for normality and were also not rejected during the visual test of the analogue record. At this preliminary check stage it is also difficult to decide whether the performance of a station is actually deteriorating, because a certain level of bad data appears to be inevitable, for example, where the station is exposed to heavy, sporadic R/T traffic.

Once the data have been transferred to the central computer, they are analysed by means of the program WAVES described earlier. At this stage information is obtained which forms the basis of a more critical quality control system.

Regarding each cassette as a "unit of wave data", the data are analysed and statistics plotted of the various tests obtained through WAVES. In order to determine whether a particular fault detected occurs consistently over a period of time, time series plots are made of the results of the data qualification tests.

Figure 2 shows the results of a study which was made of the bad performance at the Slangkop recording station during 1982. A backlog of data had inadvertently been allowed to build up at this station and action was therefore taken only when the problem was revealed during the pre-checks at NRIO. Analysis of 4 342 records collected at Slangkop showed that 12,8 per cent of the records had been rejected (Figure 3). This was due mainly to L.F. Detection and the occurrence of erratics. Further analysis showed that all but 1 per cent of the rejections through the detection of

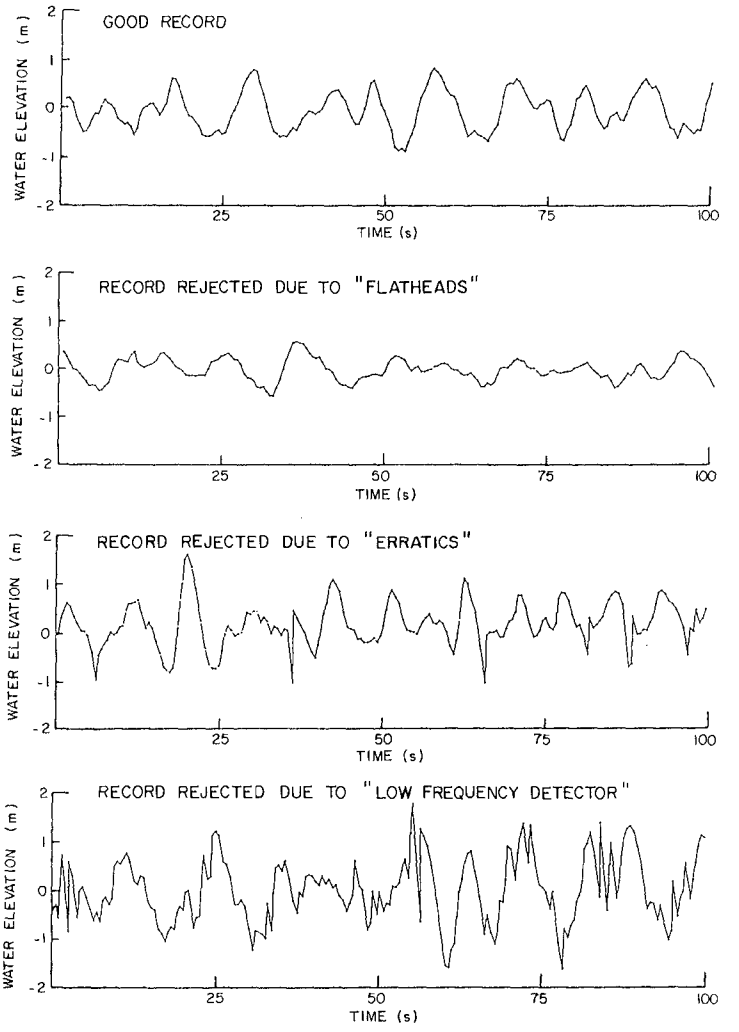

FIG. 1. EXAMPLES OF 100 SECOND PORTIONS OF GOOD AND BAD DIGITAL WAVE RECORDINGS

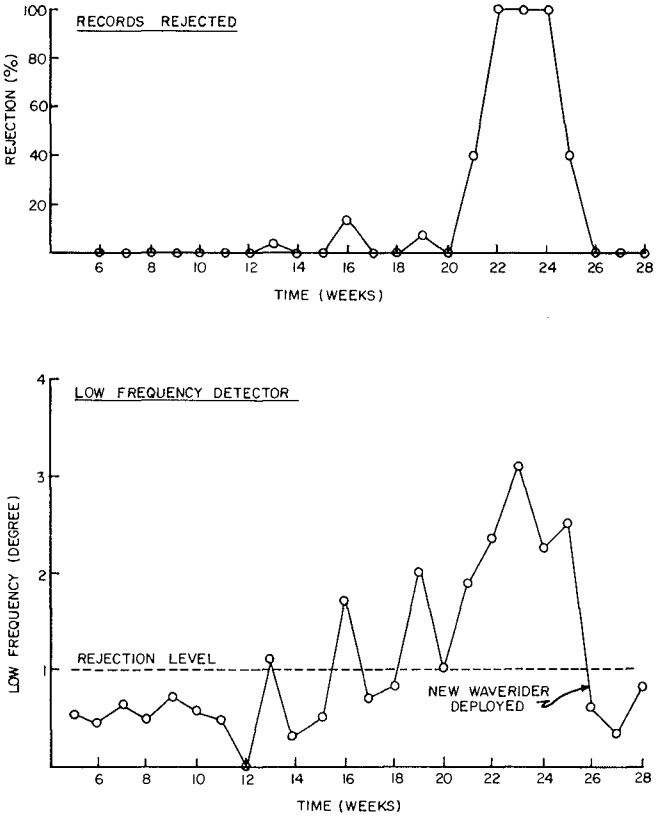

FIG. 2. TREND PLOTS OF LOW FREQUENCY DETECTED AND RECORDS REJECTED (STATION: SLANGKOP, PERIOD: 1982.2.5 TO 1982.7.16)

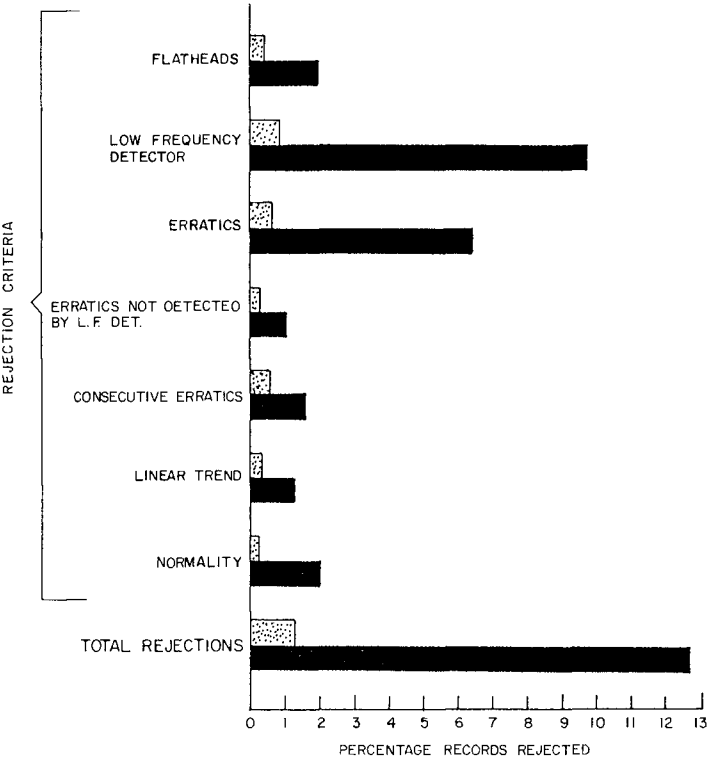

KEY	STATION	PERIOD	NO. OF RECORDS

▒	KOEBERG	NOV. 1977 - FEB. 1982	4386

FIG. 3. WAVE DATA QUALITY ANALYSIS FOR SLANGKOP AND KOEBERG

erratics had also been picked up by the L.F. Detector, thus leaving the main cause for rejection the detection of a low-frequency component. Figure 2 shows that the station performed well up to week 12 after which the L.F. Detector became very unstable. In addition, there is a clear trend indicating that the situation was worsening gradually. Subsequently the Waverider buoy could not be located and it is surmised that it had probably started to drift slowly, dragging its anchor, with a slowly weakening signal and thus became more prone to radio interference. A new buoy was deployed and good records obtained. A similar analysis was done for another station (Koeberg) and the results are included in Figure 3. This waverider is deployed closer inshore and completely away from any normal shipping routes as well as fishing areas, both hazards to which the Slangkop Waverider is exposed. A great improvement in data quality is evident under these improved conditions.

3.4 Data Storage

A prototype scheme for a computerized WAVES data base has been designed and installed on the CSIR central computer. Provision was made to store the entire output of the WAVES program and about three years' data have been stored. The data base is presently being "user-tested" prior to finalising its format.

4. WAVE CLIMATE

4.1 Introduction

In this section the wave climate as evident from all available data sources will be summarised. Wave height and wave period data are based mainly on the analysis of Waverider records since these are considered the most reliable source of such data. Wave direction data are based on clinometer observations that were refracted to deepsea as well as data from voluntary observing ships (VOS).

4.2 Weather Patterns

The major wave-generating system resulting in high waves along the RSA coastline is the regular cold fronts with their associated low pressure systems that pass west to east just to the south of the continent. These fronts together with two permanent high-pressure systems, that is, the South Atlantic high off the west coast and the Indian Ocean high off the east coast, totally dominate the wave-generating forces in the oceans surrounding the southern tip of the continent. A typical example of the passage of such a low-pressure system is shown in Figure 4 (Weather Bureau, 1979). These low-pressure systems normally shift towards the south in summer and towards the north in winter so that high waves occur more frequently in winter. They

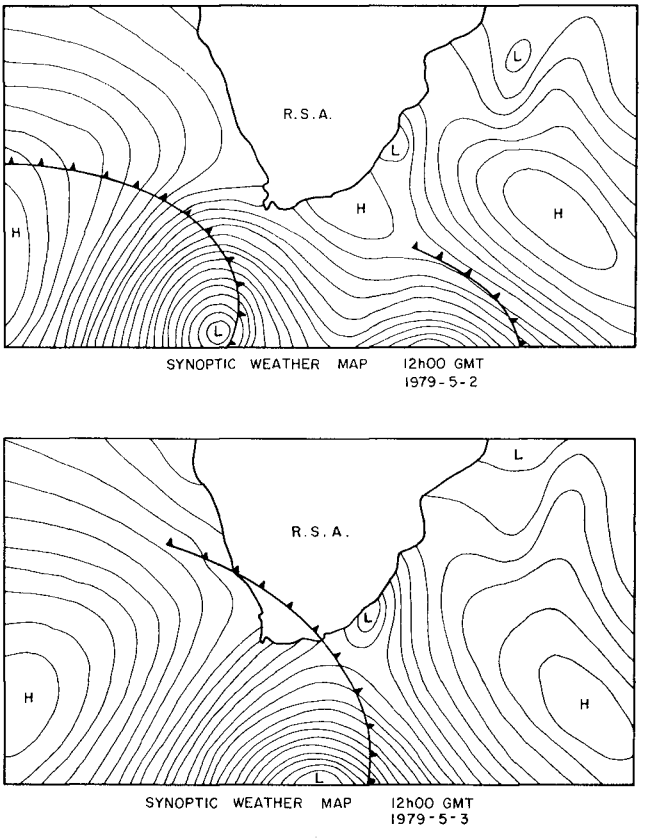

FIG. 4 PASSAGE OF A COLD FRONT CAUSING HIGH WAVES ALONG THE R.S.A. SOUTHERN COAST

do, however, on occasion move far enough north in summer to cause large waves but the occurrence of these high waves is less frequent in summer than in winter.

4.3 Wave Height Distribution

The 0,01 per cent wave height (H_S) obtained from the extrapolation of Waverider data for all the open-coast wave stations is shown in Figure 5. The 0,01 per cent wave height obtained from a shipborne wave recorder on a weathership stationed at 40°S, 10°E is also shown in this figure.

Comparing the wave heights along the west coast from Slangkop in the south to Walvis Bay in the north, it can be seen that a steady decrease in wave height occurs towards the north. This is very much in accordance with the weather patterns described earlier, that is, the wave height decrease with increase in distance from the storm centre.

From Figure 5 it can also be seen that the wave heights at Mossel Bay, Durban and Richards Bay along the east coast are very similar. The 0,01 per cent wave height at these stations vary from 5,5 to 6,0 m. At Gans Bay this wave height is 8,1 m which lies between the values at Mossel Bay and Slangkop.

An interesting wave station is the Waverider off SEDCO-K, a drill rig operating in the area offshore off Mossel Bay. As can be seen from Figure 5 the 0,01 per cent wave height at SEDCO-K is 9,7 m as compared with the 6,0 m at Mossel Bay closer inshore. The reason for this difference is thought to be the protection afforded by the land mass to the Mossel Bay station against the fronts approaching from the west. Another very interesting aspect of the SEDCO-K station is the similarity in wave conditions there with the station at Slangkop, 300 km to the west. Figure 6 illustrates this similarity.

In Figure 5 the 0,01 per cent wave heights obtained from VOS data are summarized for a few areas around the coast. Although these data are considered to be of lower quality with respect to wave height and period than the Waverider data, a few interesting points emerge. Firstly, the decrease in wave height towards the north up the west coast is also apparent from these data. The decrease in wave height is, however, much less pronounced than in the Waverider data and the wave heights are also considerably higher than those obtained from Waverider data. It is also interesting to note that the VOS data show the highest wave heights off East London. The reason for the higher wave heights by VOS in comparison to Waverider along the west coast is explained by wave directions and will be discussed

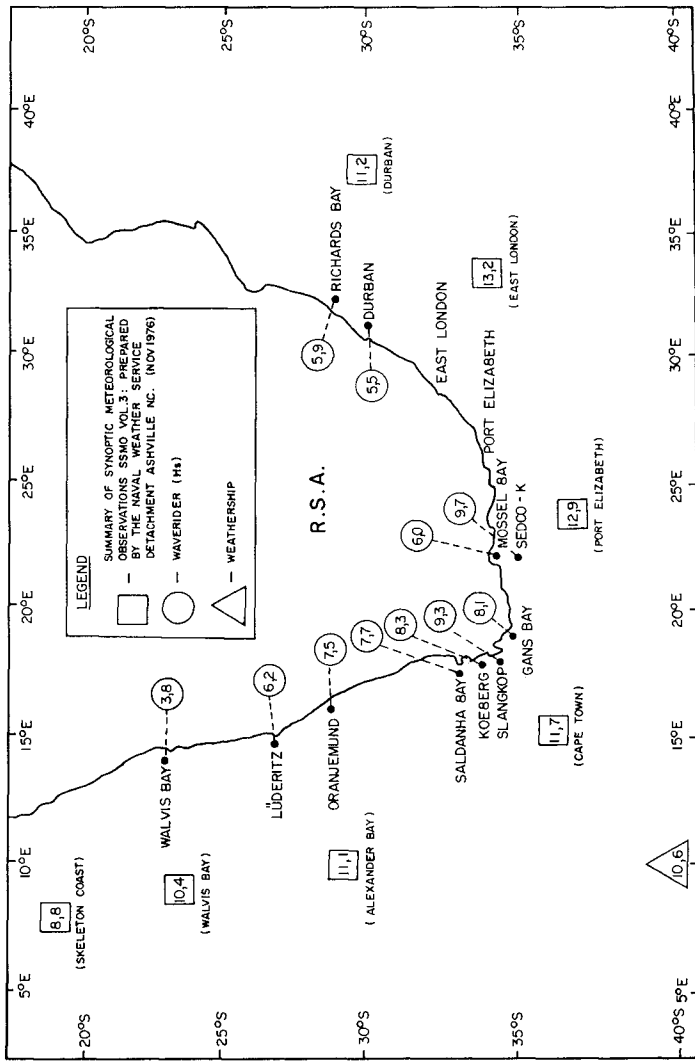

FIG. 5. DISTRIBUTION OF 0,01 PERCENT WAVE HEIGHT FROM WAVERIDERS, VOS AND WEATHERSHIP

in the next section. The reason for the higher waves off the east coast is explained by the presence of the very strong Agulhas current which flows from a NE'ly direction along this coast, directly opposing the dominant SW'ly waves. Energy transfer occurs from current to wave, resulting in so-called "freak" waves along this coast (Schumann, 1976).

4.4 Wave Direction Distribution

The wave direction distribution for four clinometer stations refracted to deepsea are shown in Figure 8 (Ashby, Harper and Van Schaik, 1973). Data from these four clinometer stations fully reflect the general wave direction pattern obtained for all the clinometer stations around the coast. The wave direction distribution for the weathership (Weather Ship Action Committee, 1973) as well as from VOS data (Hogben and Lumb, 1967) are also indicated on this figure.

The direction data obtained from clinometers show good agreement with the known weather patterns. It is clear that the main source of wave data are from the fronts to the south of the continent causing the waves along both the west and the east coast to have a resultant energy component towards the north. This is also in agreement with the known sediment transport pattern along the RSA coastline whereby sediment is transported towards the north on the west and east coasts and towards the east on the south coast.

A few interesting aspects also appear from the VOS data. Along the west coast the wave direction is very dominantly from the south-east, that is, either parallel to shore or in an offshore direction. These SE'ly waves, therefore, never reach the shore, which explains the large difference in wave height between the nearshore Waverider data and the VOS data recorded further offshore.

The wave direction at the weathership is very dominantly from the W'ly directions as can be expected in these latitudes.

Along the south and east coasts the agreement between the clinometer and VOS directional data is good.

4.5 Wave Period Distribution

Researchers normally find poor correlations between wave periods recorded by various means or analysed by different methods. The reason for this is that it is impossible to describe the periodicity of the waves by a single variable such as T_z, T_p, T_c, etc. For the purpose of this paper only the distribution of T_p as recorded at a number

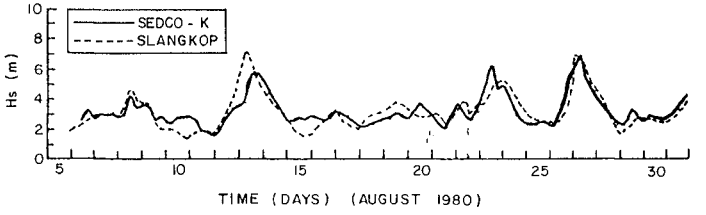

FIG. 6. COMPARISON OF WAVE HEIGHTS (Hs) RECORDED AT SEDCO-K AND SLANGKOP

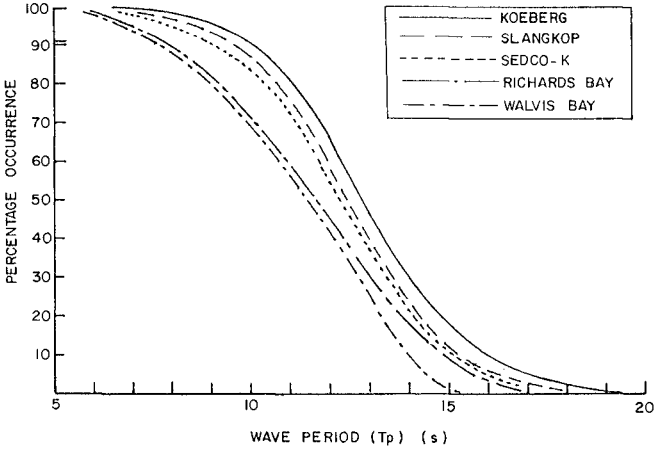

FIG. 7. DISTRIBUTION OF PEAK ENERGY PERIOD (Tp)

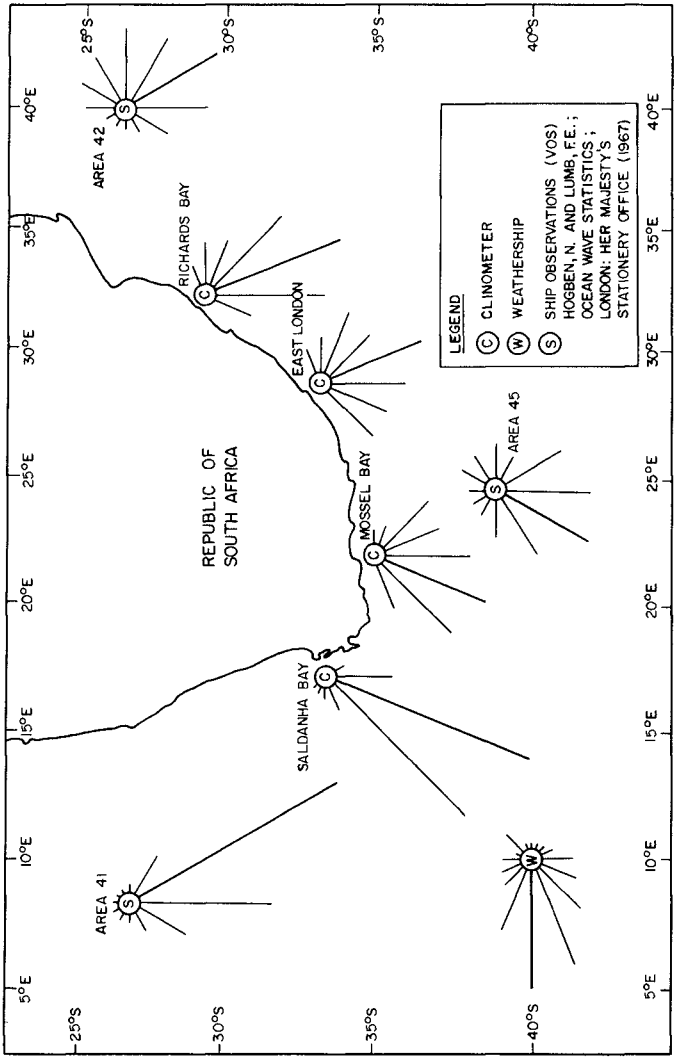

FIG. 8. WAVE DIRECTION DISTRIBUTIONS

of Waverider stations will be discussed, although it is fully realised that discussion and comparison of wave energy density spectra will be more satisfactory. A large quantity of spectral data is available but a lack of space prohibits it being discussed in this paper.

The peak energy period (T_p) distribution for a few Waverider stations is shown in Figure 7. From this figure it is obvious that the wave period distribution is very similar along the entire coastline with the wave periods along the southernmost parts of the country slightly longer than on the more northerly coasts. The period (T_p) exceeded for 50 per cent of the time varies from approximately 12,5 s in the south to 11,5 s in the north along both the east and west coasts.

Comparison between wave period data obtained from VOS and T_p obtained by Waverider shows very poor correlation with the VOS recording wave periods very much lower than the Waverider.

5. CONCLUSIONS

(i) A standard wave analysis program with special emphasis on data qualification routines has been developed for digital wave data.

(ii) The data qualification routines proved invaluable in the analysis of large quantities of data and help to detect hidden faults in the wave recording system.

(iii) A very clear wave pattern emerges from the available Waverider data and this is in accordance with the pattern to be expected from the known weather patterns around the coast.

(iv) Waverider data indicate considerable lower wave heights than those from VOS. The reason for this is thought to be that SE'ly winds generate waves parallel or offshore along the west coast which will lead to increasing wave height with increasing distance offshore. The difference in wave height along the east coast can be explained by energy transfer from the Agulhas current to the opposing SW'ly waves.

APPENDIX A

The "WAVES" Program Printout

The program is designed to print all the information of one record on a single printer page. From the top down, the page is divided into five areas. The areas are described, in order, in points 1 to 5:

1. The header area

   The first three lines of the printout contain the information necessary to identify the record (for example, degrees latitude and longitude) and information about how the sampling took place. The header area also gives the category assigned to the record.

2. Time domain parameter area

   The values of all the time domain parameters calculated are given in this area. As on the whole printout, the values are given separately for the two halves that the record is divided into.

3. Frequency domain parameter area

   The values of the frequency domain parametes calculated are given in this area.

4. Data qualification area

   The severity codes for the tests performed on the record are given in this area. A severity code of 0 means that all the requirements of the test were met. A code of 3 means that the record badly fails the test.

5. The spectral information area

   In this area, the last on the page, the power spectral density is given per frequency for each half of the record. The mean values for the two halves are also given. To facilitate interpreting the values, a small printer plot is provided.

SYNTHESIS OF HURRICANE RESPONSE HYDROGRAPHS

by

Rodney J. Sobey,[1] M.ASCE

ABSTRACT: A hindcasting methodology is described for the total water level and wave hydrographs at a coastal site during a hurricane. It accommodates phasing of the separate components of the sustained water level (astronomical tide, storm tide, breaking wave setup), as well as storm variability and coastal bathymetry. Complete hindcast models are utilised, but an intermediate cost and precision is achieved by compromising the number of complete hindcast storms, rather than the precision of the hindcast model. A synthesis technique is developed to predict the response hydrographs of the remaining storms in the historical data set.

INTRODUCTION

Rational design in the coastal environment should be based on long term frequency estimates of extreme water level and wave conditions but the duration and quality of historical records of both water level and wave conditions during hurricanes are rarely adequate to provide the necessary information. However, suitable historical records of meteorological conditions are often available, which can be used in conjunction with suitable meteorological tide and wave prediction models to hindcast meteorological tide and wave conditions respectively.

---

1 Senior Lecturer, Department of Civil and Systems Engineering, James Cook University, Townsville, 4811, Australia.

In recent years, sophisticated numerical hindcast models have been developed to a respectable level of precision and acceptance. It is an inevitable consequence that they are computationally costly and this has inhibited their use in long term frequency studies where typically fifty storms would require hindcasting. Complete models, based on the long wave equations for storm tides or the radiative transfer equation for wind waves, hindcast the complete time history or hydrograph of the sea response to a storm, allowing consideration of the phasing of the peak storm tide, wave and breaking wave setup responses with the periodic astronomical tide as well as consideration of a number of topographical and shallow water influences. Less complete models rarely allow appropriate consideration of any of these points but they may nonetheless be used because of the frequently prohibitive cost of hindcasting a complete storm data set.

This paper describes a hindcasting methodology in a hurricane environment that provides an intermediate step between the above extremes. It is intermediate in both cost and precision. Site-specific experience is developed from a small number of complete storm hindcasts and this information is used to synthesise the response hydrographs for the remaining storms of the meteorological data set. The approach is broadly similar to the unit hydrograph procedure in surface water hydrology and it has been used successfully in a major hindcast study on Australia's North-West Shelf.

HISTORICAL RECORDS OF SEA RESPONSE

Under ideal circumstances, long term frequency estimates are based on long term records of the particular event. For storm tides, the relevant extreme value series would be drawn from long term records of total sustained water level at the particular site. For wind waves, it would be drawn from long term records of wind waves at the same site. Such ideal circumstances are rarely achieved in practice, for a variety of reasons.

If suitable records are available at all, they are rarely at the particular site in question. The data site may be sufficiently close that it is reasonable to ignore any difference in sea response at the two sites. In many cases however this may not be a reasonable assumption, especially in shallower nearshore areas where interest is frequently centred. Bathymetric and shoreline detail has a major impact on sea response and the storm tide in particular is very site sensitive. For a landfalling storm across a generally open coast, the peak surge level varies moderately rapidly along the coast and is particularly sensitive to the depth and width of the continential shelf, a wide shallow shelf inducing a much more intense surge. Coastal features such as bays and headlands control the

local flow patterns and can have a significant local influence, whose spatial extent is roughly the same order as the spatial scale of the coastal feature. Shallower water influences on wind waves are often more complicated. In addition to spatial and temporal variations in the forcing, the propagation characteristics of wind waves are modified by the continental shelf bathymetry. The waves are refracted, shoal and eventually dissipate on the shore. Refraction may concentrate wave energy around headlands or disperse wave energy within bays. Wave energy may be dissipated by bottom friction, bottom percolation interaction with a cohesionless bed material, bottom motion in a cohesive bed material and perhaps bottom scattering from irregularities in the bathymetry. Wave diffraction will also have a significant influence around major headlands and man-made breakwaters, dispersing wave energy into the geometric shadow of the feature.

Even where records are available at a suitable site, a number of significant problems remain. Storm tide records are rarely collected as such but can often be established from automatically-recording tide gauges which have been standard equipment at most established ports for many decades. The height of the astronomical tide has a major influence on shipping movements in and out of port and records are maintained for this purpose, even though little more than a year of records is necessary for traditional harmonic analysis on which published tide predictions are based. These gauges are sited at the convenience of the port authority and designed to record only the astronomical tide. Storm surge is also a long wave motion and will be recorded by conventional tide gauges, unless the storm surge is sufficiently extreme to damage the instrument or send it off scale. Harbour resonance may also be recorded on the gauge but this component should not be difficult to separately identify. Access to these records is perhaps the major problem. Historical records are mostly in analogue form on strip charts and this recording technique has generally continued to the present day. Consistent quality of such records is not assured. Port authorities naturally see little value in maintaining historical records but it has fortunately become a reasonably established practice, although record achival is often a rather haphazard process. Apart from the record sequences used for harmonic analysis (often a single twelve month period), there will have been little consistent interest in these records. Problems with local datum changes and possible reconstruction, relocation or replacement of the gauge are anticipated, together with the laborious task of separating the storm tide component from the analogue strip charts.

The systemic measurement of wave conditions has become a standard practice only in the last decade or so. Initially records were obtained on strip charts but present practice

records only a discrete record with a typical time spacing of 0.5 s. Good quality records are regularly obtained and an enormous amount of data is amassed in a relatively short time. However, the limitations of this data is estimating extreme events must be clearly recognised (Sobey, 1982), as each year of data contributes only one point to the extreme value series. The total duration of the data series must be considered in the light of potential meteorological trends and multiyear weather cycles, even natural or man-made changes in the local environment. Based on a study by Petrauskas and Aagaard (8), Borgman (2) has suggested that it is unwise to extrapolate beyond twice the duration of the record from the largest observation. Typical record lengths in many situations rarely exceed a few years, whereas design often relates to average recurrence intervals of 50 or 100 years. There is a large measure of uncertainty attached to record extrapolation to such extreme events, even following the adoption of an appropriate probability distribution.

HINDCASTING THE SEA RESPONSE

It is clear from the above discussion that historical data alone is often insufficient to develop satisfactory estimates of long term frequencies of sea response. The alternative is system modelling, in which advantage is taken of long term meteorological records of storm conditions to hindcast the sea response corresponding to the historical storm data.

The long wave response of a homogeneous sea to the meteorological forcing of a hurricane is adequately described by a two-dimensional vertically integrated form of the Reynolds' Equations - the Long Wave Equations. These equations represent the conservation of mass and the conservation of momentum in horizontal directions x and y and time t:

$$\frac{\partial \eta}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0 \qquad (1)$$

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x}\left(\frac{U^2}{\eta-d}\right) + \frac{\partial}{\partial y}\left(\frac{UV}{\eta-d}\right) - fV = -g(\eta-d)\frac{\partial \eta}{\partial x} - \left(\frac{\eta-d}{\rho_w}\right)\frac{\partial p_s}{\partial x} + \frac{1}{\rho_w}(\tau_{sx}-\tau_{bx}) \qquad (2)$$

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x}\left(\frac{UV}{\eta-d}\right) + \frac{\partial}{\partial y}\left(\frac{V}{\eta-d}\right) + fU = -g(\eta-d)\frac{\partial \eta}{\partial y} - \left(\frac{\eta-d}{\rho_w}\right)\frac{\partial p_s}{\partial y} + \frac{1}{\rho_w}(\tau_{sy}-\tau_{by}) \qquad (3)$$

The x-y datum plane is located at the mean water level with the z axis directed vertically upwards. The water surface elevation with respect to datum is $\eta(x,y,t)$, the sea bed is $d(x,y)$ with respect to datum, U and V are depth-integrated flows per unit width, f is the Coriolis parameter and ρ_w is the mass density of sea water. The forcing influence of the hurricane is represented through the

surface wind shear stress vector $\underline{\tau}_s(x,y,t)$, resolved into components τ_{sx} and τ_{sy}, and the x and y gradients of the M.S.L. atmospheric pressure $p_s(x,y,t)$. The effect of bottom stress is represented through the seabed shear stress vector $\underline{\tau}_b(x,y,t)$, resolved into components τ_{bx} and τ_{by}. Numerical solutions of these equations are readily accomplished under quite general conditions of bathymetry, coastal detail and meteorological forcing. One such example is the numerical hydrodynamic model SURGE described by Sobey, Harper and Mitchell (14) and Sobey, Harper and Stark (13). This model has been used extensively in northern Australia at some fifteen different sites for some one hundred and fifty different storms. It can be applied to most coastal regions and includes the effects of undersea bathymetry, offshore islands, reefs and other coastal features, as well as the flooding of low lying land. Tropical cyclone size, intensity and track can be varied continuously throughout a simulation to produce water flow patterns, contours of water level, coastal surge profiles at any time and water level and flow velocity time histories anywhere within the model area. SURGE is a comprehensive software system, in which particular attention has been given to the quite considerable problems of input data format and especially output data selection and presentation.

A complex wind sea is described in terms of the variance spectral densty $E(f,\theta;x,y,t)$ in directional fequency (f,θ) space. In the absence of current, wave energy conservation may be written as

$$\frac{\partial}{\partial t}(C\,C_g E) + C_g \cos\theta \frac{\partial}{\partial x}(C\,C_g E) + C_g \sin\theta \frac{\partial}{\partial y}(C\,C_g E) + \frac{C_g}{C}\left(\sin\theta \frac{\partial C}{\partial x} - \cos\theta \frac{\partial C}{\partial y}\right)\frac{\partial}{\partial \theta}(C\,C_g E) = C\,C_g\,S \qquad (4)$$

where C is the phase speed and C_g the group velocity. The source function $S(f,\theta)$ on the right hand side represents the net transfer of energy to or from or within the spectrum. This equation, known as the Radiative Transfer Equation, formally summarises all the various physical processes that contribute to the evolution of the directional spectrum. In recent years considerable success has been reported in the representation of the source terms and in the numerical solution of the complete Radiative Transfer Equation. One such example is the numerical hydrodynamic model SPECT described by Sobey and Young (16) and Young and Sobey (21). This is a quite general model, applicable in both shallow and deep water. It has been used successfully in Australia for a twenty-eight storm hindcast study on the North-West Shelf, where good agreement with field data was obtained.

The aerodynamics of the hurricane and the hydrodynamics of the underlying water body are coupled by the atmospheric pressure p_s and wind shear stress τ_s at the air-sea

interface. Their estimation throughout the flow field during the passage of a tropical cyclone follows from the adoption of a suitable model of the near-surface meteorological structure of the storm. The model developed initially by Graham and Nunn (4) under the National Hurricane Research Project (NHRP) of the former U.S. Weather Bureau forms the basis of the storm sub-model in both cases. No claim is made that this model is entirely satisfactory; in fact our knowledge of tropical cyclone wind fields is far from complete. It was adopted in the absence of a more suitable alternative. More sophisticated models describing the dynamics of the atmospheric boundary layer in a moving hurricane could be used, but there is a significant computational penalty and the predictive capability of such models is not yet measurably superior for the NHRP model.

Many of the highly empirical aspects of the original NHRP model, such as rate of filling over land and the reduction of over-land wind speeds, have been omitted in favour of representing the major features of the tropical cyclone. In particular the radial wind and pressure profiles, the variation of the radial inflow angle and the asymmetry of the wind field are included and expressed in terms of the four parameters commonly assumed to characterise a hurricane: the central pressure p_o at M.S.L., the maximum sustained wind V_{10} at a height of 10 m above M.S.L., the radius of maximum winds R, the speed V_{FM} and direction θ_{FM} of storm forward movement. All four parameters are varied continuously to represent changes in storm intensity and track. Details may be found in Ref. 13. The over-water wind speed W_{10} at height 10 m above M.S.L. and the resulting shear stress τ_s on the water surface are assumed to be related as $\tau_s = C_{10} \rho_a W_{10}^2$, where C_{10} is a non-dimensional surface friction or drag coefficient and ρ_a is the mass density of air.

Now that sophisticated hindcast models have been developed to a respectiable level of precision and acceptance, hindcasting has many advantages in estimating the sea response to hurricanes. It permits an extreme value series to be esablished where no field records of sea response exist, the duration of which is the duration of the meteorological data and generally long enough to expect a satisfactory estimate of 50 and perhaps 100 year events. It also removes the temptation to use historical sea response data an another site whole characteristics are arguably different from the site in question. Where there is short term measured sea response data at the particular site, the hindcast data has a complementary role in confirming or defining the longer-term trends.

The major disadvantage of the complete hindcasting models (LWE and RTE) is their detail and hence computational and associated personnel costs. Hindcasting a complete data

set (typically of order 50 storms) is mostly well beyond the budget and also the time that is typically allocated to long term frequency estimates. Some compromise is often sought, usually the adoption of a less sophisticated hindcast model which compromises the detail as well as the cost of hindcasting the sea response. The consequences need to be fully recognised. In particular the use of historical data to its fullest potential gives direct consideration to the influence of storm track variability and storm intensification and decay, aspects that are difficult to consider in any less sophisticated approach. A related and perhaps more significant aspect is the phasing of astronomical tide, storm surge and wave conditions (17). Astronomical tides are often significantly variable. On Australia's North West Shelf, for example, the mean spring tide range is large (of order 3 to 4 m) but the mean neap tide range is small (of order 1 m). A peak storm surge of order 2 m would be a major event and its impact clearly depends on the timing and duration of its peak with respect to the astronomical tide. Its arrival at low tide would be little cause for concern and even at a typical high water neaps the total water level would not differ significantly from the highest astronomical tide (HAT). At a typical high water springs however its impact would be substantal. Similar arguments are valid regarding breaking wave setup, with the additional complication that peak wave and surge conditions will not necessarily correspond. Surge and wave response to hurricanes are related but physically distinct phenomena, in their generation and propagation and especially in their reaction to shoaling waters and coastal bathymetry. There is a considerable margin of safety available in the tidal characteristics and a realistic analysis of extreme water levels must give reasonable consideration also to this situation.

The often critical significance of coastal detail and shelf bathymetry has already been mentioned above, yet it is this detail that is first abandoned in less sophisticated hindcast models. For storm tides, the Bathystrophic Storm Tide model proposed by Freeman, Baer and Jung (3) considers only the steady-state momentum balance normal to the coast at the site in question. Mass and longshore momentum conservation is not considered, nor are the dynamics of the sea response. Coastal detail and shelf bathymetry is represented by the seabed profile at the site, other detail being ignored. For this approach to have any validity, it must be restricted to open-coast situations and slowly-moving, large-scale storm systems. An alternative approach to a less sophisticated hindcast model for storm tides is the nomograph method of Jelesnianski (5). This method is also restricted to open-coast situations but is based on computations utilising the complete Long Wave Equations. A standard continental shelf region was defined with a straight coastline and a uniform linear slope as the seabed

profile. A standard storm was defined and directed on a landfalling track normal to the coastline. These results are presented in terms of peak surge amplitude only, to which correction factors have been defined for different linear seabed profiles (the shoaling correction) and different forward speed and direction of the storm (the motion correction).

Less sophisticated hindcast models for wind waves differ in detail but not in spirit. The empirical models of Bretschneider (1), Ross (9), Lee (7) and Shemdin (10) have much in common. All neglect the dynamics of the sea response, assume exclusively deep water conditions and base their parameterisation of the sea response on the Sverdrup and Munk (18) or Kitaigorodskii (6) scaling relationships, which are identical. In quantifying the relationships, Bretschneider uses an integral interpretation of the Sverdrup-Munk fetch graphs, while Ross, Lee and Shemdin use field data from Gulf of Mexico hurricanes. Shemdin's model predicts the significant wave height and peak frequency of the dominant wave conditions ahead of a moving hurricane, giving specific consideration to the forward motion. The other three models predict the space and time variable wave field; the Bretschneider model is restricted to slowly-moving storms and the Ross and Lee models give no specific consideration to storm motion. None of these models predict dominant wave directions and quantitative agreement among the models is quite poor. In addition their is little consideration of storm variability in position and time and no consideration of important coastal detail and shelf bathymetry and associated shallow water effects.

AN ALTERNATIVE APPROACH

It is apparent from the above discussion that there are a range of influences on sea response to hurricanes that can be reasonably accommodated only by a complete hindcast model. The adopted methodology is a direct recognition of this situation. The separate steps are those of the complete approach: (i) hindcast the sea response (storm surge and/or wind waves) and the astronomical tide conditions during each hurricane of the historical storm data set, (ii) superimpose the storm surge, breaking wave setup and astronomical tide hydrographs to give the hindcast total water level hydrographs, and (iii) form extreme value series from total water level and wave hydrograph peaks during each of the historical storms for frequency analysis. The necessary compromise is in the number of storms that are hindcast by complete hindcast models. A limited number of project hurricanes (of order 5) are chosen as representative of the range of storm intensities and particularly storm tracks in the historical data set. Complete hindcasts of sea response for the project hurricanes together with the complete historical hurricane data set comprises the data

base for hindcasting the sea response to all storms in the historical data set. A hindcast model developed from this data base gives explicit consideration to the whole range of site specific and predominantly shallow water influences described above as collectively having a potentially major impact on the sea response at a nearshore site on the continental shelf.

The suggested methodology has been used in the estimation of long term frequencies of extreme wave height and total sustained water level at Mermaid Sound on Australia's North-West Shelf. The historical storm data set contained forty-three tropical cyclones, from which six were chosen as project storms. The specific examples described below have been taken from this study.

SYNTHESIS OF STORM RESPONSE

To synthesise the sea response hydrographs for all storms in the historical data set from the complete hindcasts for the small number of project hurricances, certain assumptions about generalised storm response must be made. The first major assumption of this analysis is that at each site, distinct hydrograph segments (e.g. rising limb, falling limb) can be represented in terms of a single amplitude scale H and a single time scale T, such that in general

$$h(t)/H = f(t/T) \tag{5}$$

h(t) being the response hydrograph at time t. For the rising limb of a hydrograph, H might be the peak height and T the half-life. Each separate hydrograph segment is representated as a two parameter curve, uniquely defined once H and T and the function f are specified.

The second major assumption involves the application of dimensional arguments to determine H and T for each storm. It is assumed that H and T are dependent only on the following variables: $\Delta p_o = p_\infty - p_o$, the central pressure deficit of the storm eye at closest approach; R, the radius of maximum winds at closest approach; V_{FM}, the forward speed of the storm at closest approach; S, the distance of the storm from the site at closest approach; ρ_w, the mass density of sea water and g, the gravitational acceleration. Consequently

$$H,T = f(\Delta p_o, R, V_{FM}, S, \rho_w, g) \tag{6}$$

The variation of Δp_o, R, V_{FM} and S during the passage of a hurricane can be quite considerable and it is an assumption of this analysis that the parameter values at closest approach are applicable. It could be argued that some time-averaged value for each parameter might be more appropriate, but resolution of this point would almost

require complete wave and surge hindcasts for each of the storms in the historical data set, just what the parametric approach is designed to avoid. A similar definition of the revelant storm parameters has been adopted by Ward, Borgman and Cardone (20) in extending hindcast wave data from twenty-six storms to a forty-eight storm historical data set.

Applying dimensional analysis to Equation 6 with R and V_{FM} as the recurring variables gives

$$\frac{H}{R} , \frac{T}{R/V_{FM}} = f(\frac{B_o}{R} , \frac{S}{R} , \frac{V^2_{FM}}{gR}) \quad (7)$$

where $B_o = \Delta p_o / \rho_w g$, the barometric head deficit of the storm eye at closest approach. It is generally recognised that R largely defines the horizontal or spatial scale of the sea response while B_o determines the intensity of the response, recognition of which leads to a reorgnaisation of Equation 7 as

$$\frac{H}{B_o} , \frac{T}{R/V_{FM}} = f(\frac{S}{R} , \frac{B_o}{R} , \frac{V^2_{FM}}{gR}) \quad (8)$$

The functions f are determined from the appropriate project storm hindcasts, as shown below. Intuitively one would anticipate a major dependence of the dimensionless amplitude at each site on S/R but perhaps only a minor dependence of the dimensionless time on B_o/R and S/R. No systematic dependence on the dimensionless Froude Number is anticipated.

SIGNIFICANT WAVE HYDROGRAPHS

Hindcast significant wave hydrographs typically have the same general shape, a rising limb to a single peak and a falling limb at a different and generally faster rate. An appropriate universal profile is sketched in Figure 1, both the rising and falling limbs being represented as Gaussian curves with different half-lives, T_1 and T_2 respectively:

$$h(t) = \begin{cases} H \exp [- c(\frac{t-T_p}{T_1})^2] & \text{for } t \leq T_p \\ H \exp [- c(\frac{t-T_p}{T_1})^2] & \text{for } t > T_p \end{cases} \quad (9)$$

where H is the peak amplitude, T_p is the time of the hydrograph peak and c = ln 2.

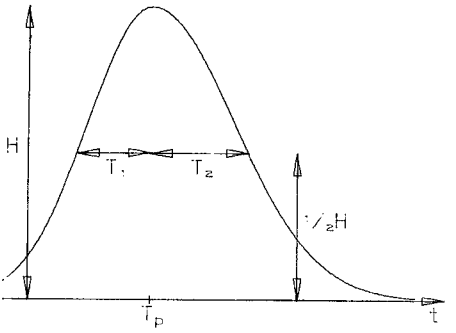

Figure 1. Parameterised Significant Wave Hydrograph

The complete hydrograph can be represented in terms of a single amplitude parameter H and three time parameters T_p - T_o, T_1 and T_2, T_o being the time of closest approach of each project storm. Each of these parameters have been extracted from the project storm hindcast hydrographs and non-dimensionalised and plotted in accordance with Equation 8. The final result for one site within Mermaid sound is shown in Figure 2. Several trial presentations were attempted before these plots were finalised. A major dependence on the direction of rotation of the track about Mermaid Sound was apparent and this was accommodated within the existing dimensional variables by afixing a sign to S, the distance at closest approach. A plus sign implied clockwise rotation and a negative sign anti-clockwise rotation.

The functional dependence indicated by Equation 8 was investigated in as much detail as the data allowed and no systematic dependence on either parameter was established. It seemed most appropriate to represent each dimensionless time as a constant value. The amplitude curve at the top of Figure 2 shows an anticipated intensification of significant wave height for storms passing anti-clockwise about Mermaid Sound. This H/B_o curve was used directly in estimating the peak amplitude for each of the forty-three storms. Each curve has been extrapolated outwards to its intersection with the S/R axis. Outside these intersection points, H/B_o is assumed zero, the storm passing sufficiently far from Mermaid Sound for this to be a reasonable assumption. It is of course possible that significant waves generated closer to the storm centre may propagate to and penetrate into Mermaid Sound. To the extent that such behaviour is not included among the six project storms it can not be accommodated within the present analysis.

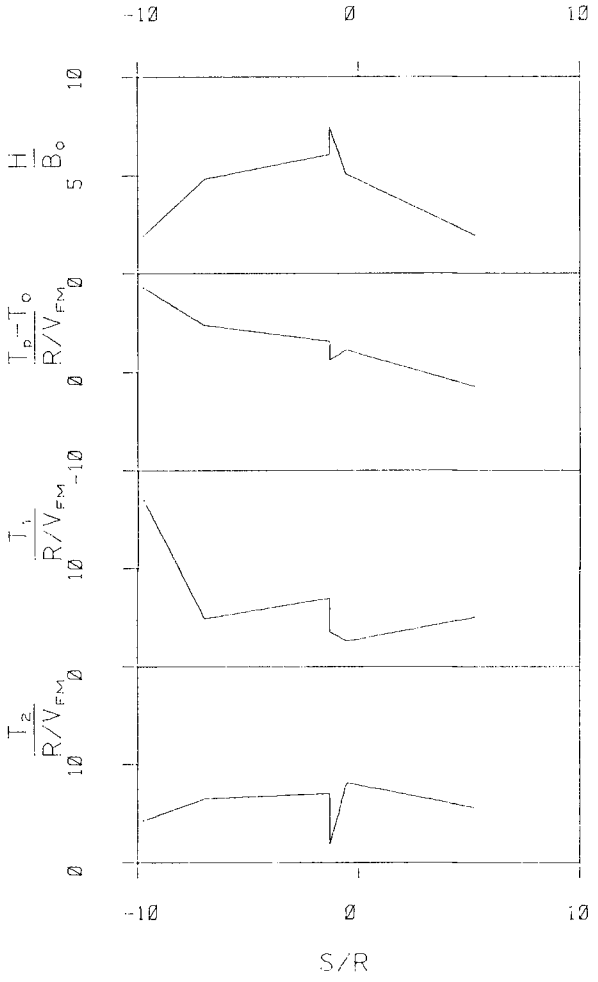

Figure 2. Dimensionless Parameters of Significant Wave Hydrographs

Breaking wave setup is a nearshore phenomenon related to the conversion of the kinetic energy of wave motion to quasi-steady potential energy for waves breaking on a beach slope. Where required, it was estimated from significant wave height in the manner recommended in the Shore Protection Manual (19).

STORM SURGE HYDROGRAPHS

A characteristic of the storm surge hindcasts for Mermaid Sound was the early and sustained response. In addition to the normal peak setup or setdown around the time of closest approach there is typically an initial peak setup or setdown several hours earlier, in response to the regional bathymetry and particularly the coastal topography. For landfalling storms passing to the east of (i.e. clockwise about) Mermaid Sound, an initial setdown is followed by a period of sustained setdown until a fairly rapid fall away after the second peak. For landfalling storms passing to the west of (i.e. anti-clockwise about) Mermaid Sound, an initial setup is followed by a period of sustained setup until the second peak around the time of storm landfall, after which there is again a fairly rapid fall away. For parallel moving storms tracking down the coast (i.e. anti-clockwise about Mermaid Sound), an initial setdown is followed by a somewhat more substantial setup. The reverse pattern of behaviour appears certain for parallel moving storms tracking up the coast although there is no such storm among the six project storms.

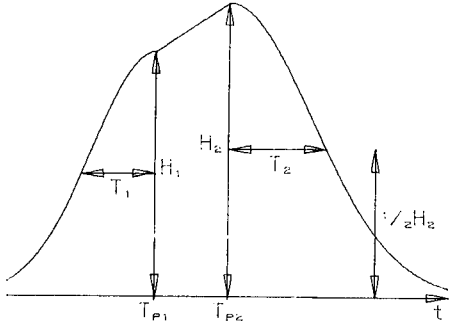

Figure 3. Parameterised Storm Surge Hydrograph

An appropriate universal profile to describe this complex hydrograph is sketched in Figure 3. The initial peak is at T_{p1} and the rising (falling) limb has a Gaussian profile with a half-life of T_1. The intermediate segment between T_{p1} and the major peak T_{p2} is assumed to follow a straight line, both peak water levels H_1 and H_2 being

potentially positive (setup) or negative (setdown). The falling limb from T_{p2} is again a Gaussian profile with half-life T_2.

$$h(t) = \begin{cases} H_1 \exp\left[-c\left(\frac{t-T_{p1}}{T_1}\right)^2\right] & \text{for } t \leq T_{p1} \\ H_1 + \frac{H_2 - H_1}{T_{p2} - T_{p1}}(t - T_{p1}) & \text{for } T_{p1} < t \leq T_{p2} \\ H_2 \exp\left[-c\left(\frac{t-T_{p2}}{T_2}\right)^2\right] & \text{for } t > T_{p2} \end{cases} \qquad (10)$$

The complete hydrograph can be represented in terms of two amplitude parameters H_1, H_2 and four time parameters $T_o - T_{p1}$, T_1, $T_{p2} - T_o$ and T_2. Each of these parameters has been extracted from the hindcast hydrographs, non-dimensionalised and plotted in accordance with Equation 8, in a similar manner to the previous section. The final result for one site within Mermaid Sound is shown in Figure 4.

Following the introductory discussion to this section it was necessary to distinguish between landfalling and parallel moving storms, in addition to the distinction based on direction of rotation about Mermaid Sound. This reduced the data set from six storms to two sets of three storms and required additional assumptions about the surge response to distant storms. This specific assumption has been that storms that do not approach closer than 10R to Mermaid Sound have no influence on water levels within the Sound and that response amplitude falls away towards the 10R position. The project hindcasts and experience elsewhere indicate that this is a reasonable assumption and it has been incorporated into Figure 4 as straight line segments.

Once again it seemed most appropriate to represent each dimensionless time as a constant value over all sites, with different values for landfalling and parallel moving storms. As also in the previous section, the H/B_o curves were used directly in estimating surge peaks for each of the forty-three storms. The shape of these curves follow the anticipated pattern, especially for landfalling storms which show the classic along-coast profile with setdown to the east and more substantial setup to the west.

ASTRONOMICAL TIDE HYDROGRAPHS

Hindcasts of astronomical tide hydrographs are generated from the classical harmonic series represetation of the vertical tide:

$$h(t) = H_o + \sum_{n=1}^{R} f_n H_n \cos(\omega_n t + V_n + u_n - g_n) \qquad (11)$$

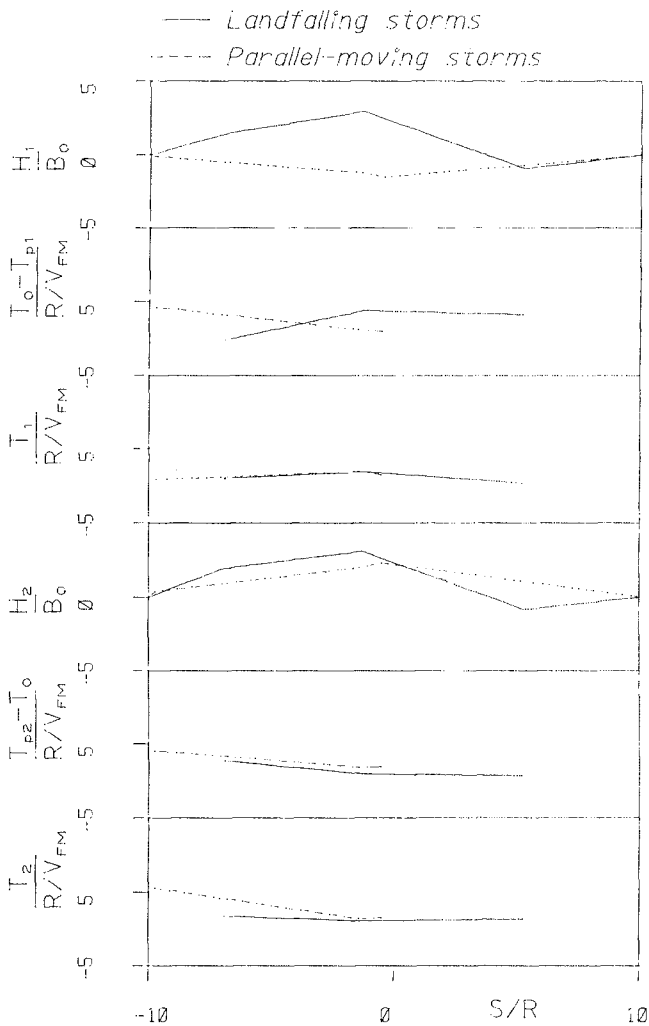

Figure 4. Dimensionless Parameters of Storm Surge Hydrographs

where H_o is the height of the M.W.L. above datum, n identifies a tidal constituent, R is the number of tidal constituents, f_n the node factor for the nth constituent, H_n the amplitude of the nth constituent, ω_n the angular speed of the nth constituent, t the local time, V_n the uniformly changing part of the phase of the nth constituent according to equilibrium theory, u_n the correction of V_n for regression of the lunar nodes, and g_n the phase of the nth constituent. The tidal constituent amplitudes and phases (H_n and g_n), determined originally by harmonic analysis from an historical data set normally of a year's duration, are appropriate for tidal prediction at both past and future time. The astronomical tide can be predicted with greater certainty than perhaps any other geophysical event in the coastal environment.

The hindcasts were completed using computer program HTIDE2 developed by the author, in which the definitions of the separate tidal constituents and the associated astronomical arguments f_n, V_u and u_n are those of Schureman (11). In a typical application the sixty-four major tidal constituents are used.

COMBINED WATER LEVEL HYDROGRAPHS

Hindcast sustained water level hydrographs have been determined from linear superposition of the hindcast astronomical tide hydrograph, the hindcast storm surge hydrograph and, where appropriate, the hindcast breaking wave setup hydrograph for a particular site. Breaking wave setup is only included for coastal sites. No attempt was made to consider any interaction among the separate components.

Figures 5 to 8 are typical results within Mermaid Sound, chosen to illustrate the scope of the technique and not the magnitude of especially extreme events. Figure 5, during Tropical Cyclone 194 (February 1948), is a good illustration of the influence of the diurnal inequality in the astronomical tide. A sustained peak surge of about 1.7 m (M.S.L. datum) coincides with an unusually low high water of +0.3 m and the total water level does not reach HAT. The immediately preceding high water reached +1.2 m and gives a good indication of the safety margin provided by the astronomical tide behaviour. Another characteristic of Figure 5 is the longer duration of the wave setup and its peaking at 0.5 m five hours or so after the peak storm surge.

Figure 6, during Tropical Cyclone 300 (March 1961), almost shows the combination of circumstances that is most dangerous, the coincidence of the peak surge, the peak wave setup and a higher high water (HHW) tide. Neither the storm

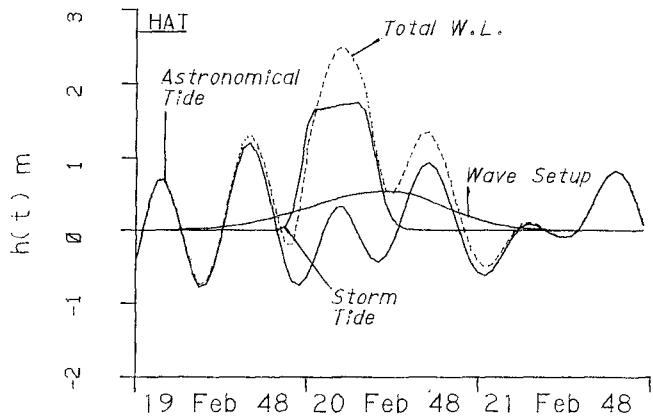

Figure 5. Hindcast Hydrographs during Tropical Cyclone 194

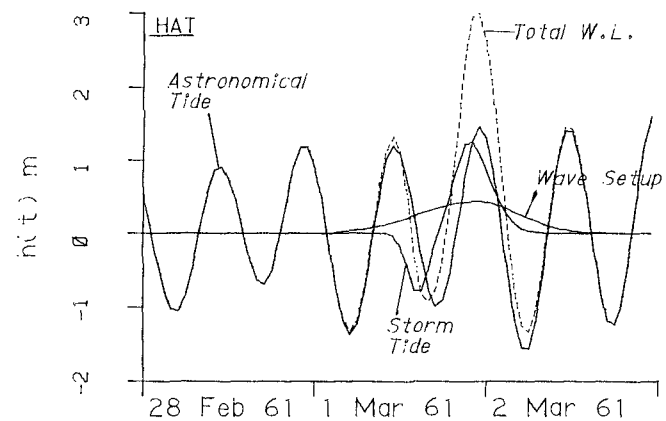

Figure 6. Hindcast Hydrographs during Tropical Cyclone 300

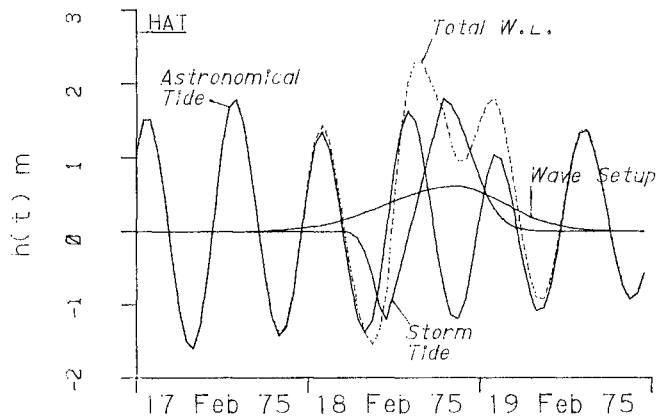

Figure 7. Hindcast Hydrographs during Tropical Cyclone TRIXIE

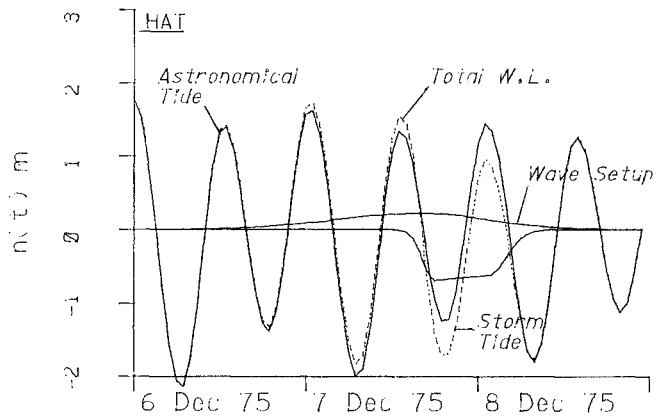

Figure 8. Hindcast Hydrographs during Tropical Cyclone JOAN

surge (+1.2 m) nor the high tide (+1.5 m) are extreme but the total water level nonetheless exceeded HAT by some 0.4 m. Another illustration of the potential safety margin inherent in the astronomical tide behaviour is provided in Figure 7, during Tropical Cyclone 448 TRIXIE (February 1975). The storm tide peaked at 1.8 m and wave setup at 0.6 m, but only an hour or two before the low tde. The maximum water level of +2.3 m is predicted some four to five hours earlier, just after a high tide of +1.6 m, and does not even reach HAT (+2.6 m, M.S.L. datum). Had the storm tide, breaking wave setup and the astronomical tide peaks all coincided a sustained water level of order +4.0 m might have been recorded, emphasising the importance of the phasing of the separate components.

The final example, Figure 8, illustrates the importance of storm track and coastal bathymetry on the storm tide and wave conditions. Tropical Cyclone 600 JOAN (December 1975) was a very significant storm whose central pressure fell to 920 mb but the storm track passed north of Mermaid Sound where predominantly offshore winds were experienced. A sustained storm setdown of order 0.7 m was hindcast in Mermaid Sound, coinciding with a low tide of -1.2 m and little wave setup. This however is perhaps a design constraint in its own right, as the drawdown level is potentially significant in the location of cooling water intakes for industrial plants, especially if the level falls below LAT (-2.6 m). The low water immediately before is -2.2 m and a major setdown at that time might have caused the total water level to fall below LAT.

CONCLUSIONS

A methodology has been demonstrated for hindcasting the total water level and wave hydrographs at a coastal site during a hurricane. It accommodates phasing of the separate components of the sustained water level hydrograph, as well as storm variability and coastal bathymetry. An intermediate cost and precision is achieved by compromising the number of complete hindcast storms, rather than the precision of the hindcast model. Dimensional analysis and the hindcast sea response from a few project storms is used to synthesise the response hydrographs for the remaining storms in the meteorological data set.

SECOND ORDER THEORY OF MANOMETER WAVE MEASUREMENT

F. BIESEL

ABSTRACT

The paper refers to pressure gage wave measurements . First order transformation of the pressure spectrum into a surface level spectrum leads to hitherto unexplained discrepancies with prototype simultaneous pressure and level measurements . Use of second order gravity wave theory allows to draw the following conclusions . Second order effects appear to give a reasonable explanation of the observed discrepancies . A complete check would require specially made wave measurements and analyses . Second order corrections do not significantly affect mean values, such as significant height, if the manometer depth is not unduly large .

1 INTRODUCTION

When measurements of irregular sea waves are carried out with an immersed pressure gage, standard procedures, based on random oscillations theory, allow to compute an estimate of the "pressure" power spectrum . With the further help of linear gravity wave theory, this spectrum can be transformed into a first approximation of the corresponding free surface spectrum .

Simultaneous measurements of pressure and surface levels have shown that this first approximation is not always satisfactory. For instance, CAVALERI (1980) found discrepancies as large as 20 % between wave spectra computed in this way and spectra computed from direct surface measurements . As a rule, wave attenuation with depth appeared to be larger than the theoretical value for the low frequency parts of the spectra and lower for the high frequency parts .

This poor agreement was rather surprising because laboratory tests, made with regular waves, have consistently shown that first order wave theory gives a very reliable estimate of the ratio between wave pressure and wave height . Non linear corrections are only necessary for large wave length to depth ratios or close to breaking wave heights .

The present paper results from an attempt to reconcile fact and theory, using second order wave formulae . This line of research may seem rather doomed beforehand as second order terms have no influence on the pressure to height ratio of "regular" waves . However, this proved not

1 General Manager of AMTEC 8,rue Jean Goujon 75008 PARIS FRANCE

to be the case for irregular waves and, actually, the second order theoretical value of these ratios may widely differ from their first order approximations .

2 NOTATIONS

The space coordinates are x,y and z . The origin is at the mean water level . The x and y axes are horizontal and the z axis is vertical upwards . The other notations are :

t time	g acceleration of gravity	Z surface elevation
H water depth	p_o atmospheric pressure	p water pressure
ρ water unit mass	$Q=(p-p_o)/(\rho \cdot g) + z$	

Random spectra are discretized into I "lines" (regular unidirectional component waves) . The ith line has the following parameters :

a_i amplitude ω_i angular frequency k_i wave number θ_i random phase

α_i angle of wave direction of propagation with positive x axis

For the theoretical outline and numerical examples, only unidirectional waves are considered (i.e. $\alpha_i=0$), moreover, spectral lines are equidistant (i.e. $\omega_i=i \cdot d\omega$, k_i being given by $\omega_i^2=g \cdot k_i \cdot \tanh[k_i \cdot H]$) .

Other parameters are defined to simplify the formulae in the text . Those relating to only one line are defined with the index "i" . Those relating to two lines are defined with indices "i,j" . These latter parameters are either what we shall call "add" type quantities, marked with a prime, or "subtract" type quantities, marked with a double prime . For both these quantities, the indices are not written except when they are different from i,j . "Add" terms exist for i=j but "subtract" terms are not used in this case .

$u_i=k_i \cdot (x \cdot \cos\alpha_i + y \cdot \sin\alpha_i) - \omega_i \cdot t + \theta_i$ $\quad u'=u_i + u_j$ $\quad u"=u_i - u_j$

$c_i= \cos u_i$	$c'= \cos u'$	$c"= \cos u"$
$s_i= \sin u_i$	$s'= \sin u'$	$s"= \sin u"$
	$k' = k_i + k_j$	$k"= k_i - k_j$
	$\omega' = \omega_i + \omega_j$	$\omega"= \omega_i - \omega_j$
		$\gamma"= \cos(\alpha_i-\alpha_j)$
$C_i= \cosh(k_i \cdot H)$	$C'= \cosh(k' \cdot H)$	$C"= \cosh(k" \cdot H)$
$S_i= \sinh(k_i \cdot H)$	$S'= \sinh(k' \cdot H)$	$S"= \sinh(k" \cdot H)$
$CZ_i= \cosh[k_i \cdot (H+z)]$	$CZ'= \cosh[k' \cdot (H+z)]$	$CZ"= \cosh[k" \cdot (H+z)]$
$SZ_i= \sinh[k_i \cdot (H+z)]$		

3 OUTLINE OF SECOND ORDER RANDOM WAVE THEORY

In this section, as mentioned above, we shall use a discretized form of random wave theory which allows numerical computations to be carried out for any spectral shape . We shall also only consider unidirectional waves, travelling in the direction of the positive x axis .

Surface elevation Z1 of such a discretized first order random wave is given by

$$Z1 = \sum_i a_i \cdot c_i$$

This means that we have replaced the continuous power spectrum by a line spectrum . We shall also assume that the spectrum lines are equidistant along the frequency axis . If the frequency step $d\omega$ tends to zero, with a proportional increase in the number of lines and decrease of the line intensities (a_i^2), the resulting motion tends to a truly random one with a spectrum density $S(\omega)$ such that

$$S(\omega_i) = a_i^2/(2 \cdot d\omega)$$

For each set of values given to the random phases θ_i we have different "realizations" of the random function Z1 but our real interest will be in the mean values, over the entire population of these realizations .

Wave elevation to the second order of approximation is given by

$$Z = \sum_i a_i \cdot c_i + \sum_i \sum_j a_i \cdot a_j \cdot B' \cdot c' + \sum_i \sum_j a_i \cdot a_j \cdot B'' \cdot c''$$

B' and B" are rather complex, therefore, their value is given in the appendix together with similar coefficients in the pressure formulae .

At any point (x,z),Z will be a sum of sine functions having frequencies of the form $n \cdot d\omega$. Each of these sine functions will itself be a sum of the nth first order term ($a_n \cdot c_n$) and of a number of second order components which will have one of the two following forms

$$a_i \cdot a_{n-i} \cdot B'_{i,n-i} \cdot c'_{i,n-i} \qquad \text{("add" terms)}$$

$$a_i \cdot a_{i-n} \cdot B''_{i,i-n} \cdot c''_{i,i-n} \qquad \text{("subtract" terms)}$$

Because of the random phase lags in these components, the average intensity A_n^2 of the nth line, in the second order power spectrum of Z, will be the sum of the squares of the components amplitudes

$$A_n^2 = a_n^2 + \sum_i (a_i \cdot a_{n-i} \cdot B'_{i,n-i})^2 + \sum_i (a_i \cdot a_{i-n} \cdot B''_{i,i-n})^2$$

Thus,starting from a "first order" power spectrum with line intensities a_n^2 , we can compute a second order spectrum with line intensities A_n^2 for the wave elevation Z .

We can do the same for the pressure variation at a depth -z . However, rather than the pressure p, we shall use the difference between p and the static pressure, divided by $\rho \cdot g$, i.e. expressed in height of water.

We shall call this quantity Q . We have a similar formula

$$Q = \sum_i q_i \cdot c_i + \sum_i \sum_j a_i \cdot a_j \cdot E' \cdot c' + \sum_i \sum_j a_i \cdot a_j \cdot E'' \cdot c''$$

where $q_i = a_i \cdot (CZ_i / C_i)$

(CZ_i/C_i) is the classical first order ratio between pressure and surface elevation for regular waves . As shown above for Z, these second order formulae allow us to compute the average intensity Q_n^2 of the nth line in the second order power spectrum of Q .

Finally, the apparent pressure reduction,for the frequency $i \cdot d\omega$,will be

$$Q_i / A_i \quad \text{instead of} \quad q_i / a_i = CZ_i / C_i$$

Following CAVALERI's example, we shall use the ratio α of these two ratios

$$\alpha = (Q_i / A_i) / (CZ_i / C_i)$$

to show the numerical results in a simple way .

4 NUMERICAL EXAMPLES

The numerical examples concern an unidirectional storm wave having a JONSWAP type first order spectrum . The peak period is 4 seconds, the peak enhancement coefficient is 5 and the significant height is 2.3 m . This spectrum is approximated by nineteen lines defined as follows

f(Hertz)	a^2 (m^2)	f(Hertz)	a^2 (m^2)
0.025	0	0.275	0.217
0.05	0	0.3	0.05
0.075	0	0.325	0.0286
0.1	0	0.35	0.0221
0.125	1.08 E-08	0.375	0.0169
0.15	0.00014	0.4	0.0129
0.175	0.0054	0.425	0.0099
0.2	0.0237	0.45	0.0077
0.225	0.083	0.475	0.006
0.25	0.235		

The water depth H is 12 meters for all examples .

Figure 1 shows the computed values of α for a manometer resting on the bottom . These values are very close to unity throughout the frequency range of the strong spectrum lines but they drop very steeply at the low frequency end . In such a case, there seems to be practically no significant error due to the neglect of second order terms .

The above spectrum was then slightly modified to incorporate some low frequency agitation such as may be due to surf beats or distant storms. For this purpose, the three first lines of the spectrum were given the

value 0.02 instead of zero . The effect on the values of α were quite significant as shown in figure 2 (thick lines) . This result was much more similar to CAVALERI's observations which are shown in thin lines on the same figure, as published in his paper, for manometer depth of the same order of magnitude . Values of α computed for manometer depth of 6 and 4 meters are shown on figures 3 and 4 together with CAVALERI's results for these depth ranges .

5 PHYSICAL EXPLANATION

A physical explanation can be briefly outlined here . We saw, in section 3, that there were two types of second order terms which we called "add" and "subtract" types . The first are chiefly higher frequency terms, because their frequency is the sum of two component frequencies. The corresponding pressure terms decrease less rapidly with depth than first order terms of the same frequency . This explains why decrease with depth is less for the higher frequencies . The reverse is true for the lower frequencies where subtract type terms decrease faster than their first order counterparts .

6 CONCLUSIONS

Second order theory of random waves appears to offer an explanation of observed discrepancies between attenuation of pressure fluctuations with depth and first order theory . More accurate checks would require to extend spectral analysis of wave records down to very low frequencies . Unfortunately, this raises difficult instrumentation problems .

Some computations were made with multi-directional waves, however, the results were not significantly different from those reported here . It would therefore seem that further investigations may be carried out with relatively "simple" unidirectional waves .

The second order formulae may be used to deduce the first order spectrum from the measured spectrum, neglecting terms of an order higher than two . Incidentally, this raises an interesting philosophical question : in which of the two surface spectra are we more interested, the first or the second order one ?

With moderate manometer depths, it would seem that, for most engineering purposes, second order corrections are not necessary because significant heights are practically unaffected . However, mean frequency of the first order spectrum may be over-estimated, chiefly when there is a sizable amount of low frequency agitation .

APPENDIX GENERAL SECOND ORDER THREE DIMENSIONAL FORMULAE

In sections 2 and 3,we restricted ourselves to unidirectional waves and to discretization with equidistant lines, but the formulae remain valid for multidirectional waves and for any other spectrum discretization . Thus, each line may represent a component wave having an amplitude, a random phase, a frequency and a direction of propagation independently defined, the sole restriction being that no two lines may have both the same frequency and the same direction . To write out the formulae, we still assume that the lines are identified by a single index varying from 1 to I .

The only information that is needed to use the formulae is the value of the second order coefficients, B' and B" for the water level Z , E' and E" for the pressure Q . We shall also define F' and F" for the velocity potential

$$\varphi = \sum_i F_i \cdot CZ_i \cdot s_i + \sum_i \sum_j a_i \cdot a_j \cdot F' \cdot CZ' \cdot s' + \sum_i \sum_j a_i \cdot a_j \cdot F'' \cdot CZ'' \cdot s''$$

where $F_i = a_i \cdot \omega_i / (k_i \cdot S_i)$

The formulae given for F' and F" are taken from BIESEL (1966), with a few changes in notation . Formulae for B',B",E' and E" may be deduced from the latter in a classical way .

$$F' = [\omega_i^3 \cdot S_j / S_i + \omega_j^3 \cdot S_i / S_j + 2 \cdot \omega_i \cdot \omega_j \cdot \omega' \cdot (C_i \cdot C_j \cdot \gamma - S_i \cdot S_j)] / D'$$

where $D' = 2 \cdot S_i \cdot S_j \cdot (\omega'^2 \cdot C' - g \cdot k' \cdot S')$

$$F'' = [\omega_i^3 \cdot S_j / S_i - \omega_j^3 \cdot S_i / S_j + 2 \cdot \omega_i \cdot \omega_j \cdot \omega'' \cdot (C_i \cdot C_j \cdot \gamma + S_i \cdot S_j)] / D''$$

where $D'' = 2 \cdot S_i \cdot S_j \cdot (\omega''^2 \cdot C'' - g \cdot k'' \cdot S'')$

$$B' = F' \cdot k' \cdot S' / \omega' + [k_i \cdot \omega_i \cdot C_i / S_i + k_j \cdot \omega_j \cdot C_j / S_j + (k_i \cdot \omega_j \cdot C_j / S_j + k_j \cdot \omega_i \cdot C_i / S_i) \cdot \gamma] / 2\omega'$$

$$B'' = F'' \cdot k'' \cdot S'' / \omega'' + [k_i \cdot \omega_i \cdot C_i / S_i - k_j \cdot \omega_j \cdot C_j / S_j + (k_i \cdot \omega_j \cdot C_j / S_j - k_j \cdot \omega_i \cdot C_i / S_i) \cdot \gamma] / 2\omega''$$

$$E' = F' \cdot \omega' \cdot CZ' / g - \omega_i \cdot \omega_j \cdot (CZ_i \cdot CZ_j \cdot \gamma - SZ_i \cdot SZ_j) / (2 \cdot g \cdot S_i \cdot S_j)$$

$$E'' = F'' \cdot \omega'' \cdot CZ'' / g - \omega_i \cdot \omega_j \cdot (CZ_i \cdot CZ_j \cdot \gamma + SZ_i \cdot SZ_j) / (2 \cdot g \cdot S_i \cdot S_j)$$

Note : In the double sums, the terms having indices i and j are equal to those having indices j and i . The above coefficients are doubled so that each pair of values i and j must be taken into account only once and, for "add" terms, when i=j, these coefficients must be divided by two .

HEIGHT DISTRIBUTION OF ESTUARINE WAVES

V. Barthel, Dr.-Ing.[1]

ABSTRACT

A field investigation program on waves was carried out in the Weser estuary, German Bight of the North Sea. Wave height and period distributions in this complicated wave climate can be approximated by a Rayleigh distribution. Empirical distributions of the wave heights characterise the different regions of the estuary. The presence of wave grouping as well as the group bounded long waves are shown in a few examples. The necessity of further investigations and analysis is highlighted.

1. INTRODUCTION

The necessity to gain more knowledge about the sea state has become increasingly important with growing demands, especially of the offshore industry, within the last few decades. Not only the needs for basic research work on wave dynamics but the necessity of field data and a fast evaluation of significant values derived even from fragmentary records or visual estimates is evident. This task seems to be simple when dealing ideally with straight shore lines and gradually decreasing water depths.

However, waves travelling from the open sea into shallow water areas of an estuary with a irregular topography and a pattern of deep channels, submerged bars, tidal flats and gullies are modified by shoaling, refraction, diffraction and even reflection processes. Combined with locally generated wind waves a very complex wave climate occurs, to which at a first glimpse hardly any of the existing theories or analysis procedures can be applied.

In 1975 a field investigation program was started in the Weser estuary which is part of the German Bight of the North Sea (Fig. 1). It was designed in order to gain information about the existing wave climate and therefore create a basis for the design of all coastal structures and the development of wave prediction methods.

The mouth of the river Weser opens into a V-shaped estuary with a width of approximately 2 km at its origin and more than 20 km at its transition to the open sea. The main channel divides into two branches in the inner wadden area where wave action is of minor importance for morphological stability. The first impact of waves is to be recognized

[1]Dr.-Ing., Federal Waterways Administration, F.R. Germany; present address: Hydraulics Lab., National Research Council Canada, Ottawa, Ontario K1A 0R6, Canada

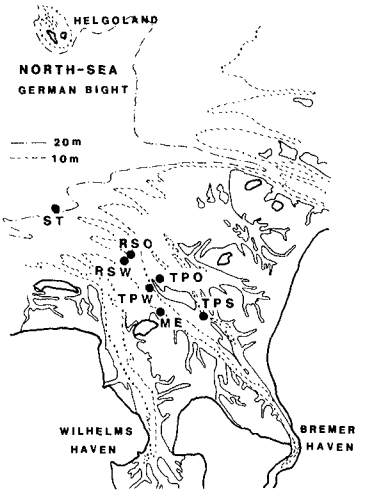

FIG. 1 WESER ESTUARY, GERMAN BIGHT, NORTH SEA
-LOCATIONS OF MEASUREMENTS-

at the edge of the wadden area. Then the major channel is again divided into two branches cutting through the reef region. In this area a strong littoral drift crosses the estuary and causes continuous shifting of bars and channels (1).

To be able to record conditions for typical regions of the estuary the wave recording stations were arranged in deep water (ST), in the reef region, at the edge of a deep channel (RSW), behind a submerged bar (RSO), in the wadden area in the main channel (TPW), in front of (TPO, ME) and behind (TPS) tidal flats.

The locations ST, RSW, RSO and TPW, the results of which are mostly being discussed in the following, were equipped with waverider buoys. Records of 20 min length of each station were stored on digital tape every 80 minutes. Wind measurements were taken on a centrally located lighthouse near RSW.

2. STATISTICAL ANALYSIS

The results of this investigation were to be used for different purposes, i.e. design of offshore and coastal structures and for wave prediction as a basis for the assignment of special ships (dredges, barges, etc.). Therefore, an extended analysis was performed on part of the data, which, among others, included spectral analysis, parameterization of multi-peak spectra and thereby separation of superimposed wave systems. Most of the results are presented in (2), (3) and (4). Since this procedure turned out to be very time-consuming and therefore costly, a simplified method was applied. By evaluating height and

period distributions significant values could be defined. Knowledge about ratios or distributions of different wave parameters allows estimating significant values from a fragmentary record or visual observations. Measured values from a reference station can be transferred to different regions of the estuary.

2.1 Wave Height Histograms

Subsequently the zero-up-crossing wave heights of every record were checked for their possible correspondence with one of the customary theoretical distributions:

a. the normal (Gaussian) distribution (N)
b. the log-normal distribution (NL), which is mostly applied for very long time series (16)
c. the Rayleigh distribution (R)

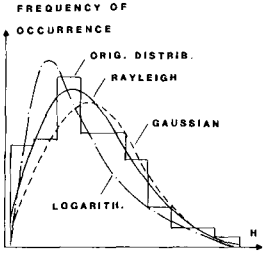

FIG. 2 WAVE HEIGHT DISTRIBUTION

The various possibilities in terms of histograms are shown in Fig. 2.

Fig. 3 shows the comparison for 20-min records of four stations. To find the best correspondence with a theoretical distribution the CHI^2 test, a stringent statistical method, was applied. To summarize the results of most of the 20-min time series obtained with wind coming from two prevailing sectors SW-NW and N-SE, Table 1 shows the percentage of records with a correspondence to the theoretical distributions (col. 2-4). The average probability of correspondence for the best fit (maximum percentage of records) is given in col. 5 whereas col. 6 shows the percentage of records without any theoretical fit. Finally, cols. 7 and 8 show the assignment of the records to periods of flood or ebb current. Percentages not adding up to 100% show that some of the records could not be assigned to either of the tidal phases. From this table it can be concluded that although there is some correspondence with the normal distribution the most likely theoretical one is the Rayleigh distribution. Others are negligible. Obviously the winds

coming from the north-easterly sector show better results, but there is no evidence that deep water location-distributions (ST) have a better fit than those in shallower regions. It has to be mentioned that a percentage likelihood of 25% visually (Fig. 2) means a satisfactory correspondence of staircase function and theoretical function.

Tidal currents influence the height distributions especially at locations where tidal currents are concentrated in the main channel. The better correspondence can be found with currents and waves travelling in the same direction. The influence of currents on wave heights and periods has been discussed in (3).

3.2 Probability Distributions

Already in 1952 Longuet-Higgins (11) pointed out that for a narrow spectrum measured in deep water wave height distributions could be approximated by a Rayleigh distribution. In the meantime it has been mentioned by several authors that Rayleigh fits even broader spectra and is often valid for shallow water waves too. Since the Rayleigh distribution was derived on the basis of a narrow spectrum, it seems to be very likely that for a case of superposed wave systems this theoretical distribution must lie somewhere in between over- and underprediction due to the specific location of measurement. To evaluate this range, typical series of measurements taken either during flood or ebb tide were compared with the theoretical cumulative proportional probability

$$p(\eta) = 1 - e^{\frac{-\pi}{4}\eta\alpha} \qquad \text{with} \quad \eta = \frac{H}{\overline{H}}$$

where the wave height H is normalized with respect to the average wave height $\overline{H}$. In case of a Rayleigh distribution $\alpha=2$.

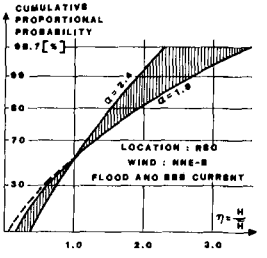

FIG. 4 WAVE HEIGHT DISTRIBUTION

$$p\left(\frac{H}{\overline{H}}\right) = 1 - e^{-\frac{\pi}{4}\left(\frac{H}{\overline{H}}\right)^{\alpha}}$$

It appeared that the cuves ranging in between the boundaries of Fig. 4 were not very smooth and intersected especially in times of changing tide (flood to ebb current and vice versa). However, typical values for the exponent α could be assigned to the various locations of the estuary. Table 2 summarizes the results.

CUMULATIVE PROPORTIONAL PROBABILITY:

$$p(\eta) = 1 - e^{-\frac{\pi}{4}\eta^{\alpha}} \qquad \eta = \frac{H}{\bar{H}} = \frac{H}{H_{AVE}}$$

OPEN SEA (LOC. ST):	$\alpha_F = 2.0$ $\alpha_E = 1.9$
REEF REGION (LOC. RSW):	$\alpha_F = 2.2$ $\alpha_E = 1.95$
REEF REGION (LOC. RSO): (SIT. LEE OF REEF)	$\alpha_F = 1.95$ $\alpha_E = 1.85$
TIDAL FLATS (LOC. TPW/TPO): (SIT. IN A TIDAL GULLY)	$\alpha_F = 1.8$ $\alpha_E = 1.7$

TABLE 2
PROBABILITY EXPONENTS α FOR DIFFERENT REGIONS OF THE WESER ESTUARY
F = FLOOD CURRENT E = EBB CURRENT

It appears that the exponents for flood currents (waves propagating with current) are bigger than the values for ebb conditions (waves propagating against currents). This was only different in a few cases with very strong southerly winds.

Based on these relationships and on the statistics which Longuet-Higgins (11) derived from the Rayleigh distribution or on an approximation of that given by Schüttrumpf (20), relationships between various wave height parameters like H_{MAX}, $H_{1/10}$, $H_{1/3}$ and H_{AVE} can be calculated using the number of waves in a record. According to this the following values were obtained as an average for the whole estuary:

$$H_{1/3}/H_{AVE} = 1.62$$
$$H_{MAX}/H_{1/3} = 1.88$$

2.3 Wave Periods

A comparable analysis was performed on the wave periods too.

TABLE 3 CORRESPONDENCE WITH THEORETICAL DISTRIBUTIONS - WAVE PERIODS

Table 3 shows the comparison of the results of the same four locations in the estuary as given in Table 1. It appears again that the probability of the correspondence with a Rayleigh distribution is higher than others. Although the results seem to be comparable with those from height distributions, the scattering of cumulative probability curves did not allow an assignment of typical distributions to the different regions of the estuary which could lead to the calculation of maximum values of wave periods. During a storm tide in the inner estuary the significant wave period was measured to exceed

$$T_{1/3} > 15 \text{ s}$$

and the maximum value reached

$$T_{MAX} = 18.2 \text{ s}$$

These values were obtained by wave gauges and could not be verified by waverider recordings. The limitation of the waverider buoy for long period waves is a distinct disadvantage for respective investigations.

3. LONG WAVE ANALYSIS

3.1 Grouping of Waves

In recent years it has become more and more accepted that,especially in shallow water, waves tend to form groups which heights exceed a specified wave height, i.e. $H_{1/3}$ or H_{AVE}. The concentration of energy in wave groups could be critical for structures especially if the frequencies involved lie within the range of the characteristic or eigenfrequency of the structure. Ships or other floating structures can respond in a resonant rise. Investigations of grouping phenomena for the Weser estuary using the number of consecutive waves with a height $H_i > H_s$ have been performed by Barthel (2) and for other regions in the North Sea by Siefert (21) and Rye (17). All those seemed to match suggestions by Goda (10) based on theoretical considerations. Descriptions of wave grouping using the envelope of a time series of water surface elevations were given by Nolte and Hsu (14). This method, which simply connects peaks and troughs to indicate the presence of groups, seems to be a rather rough interpretation. Regarding the concentration of energy in a wave group, Funke and Mansard (8) presented the SIWEH-function (SIWEH = Smoothed Instantaneous Wave Energy History). This function

$$E(t) = \frac{1}{T_P} \int_{\tau=-T_P}^{T_P} \eta^2(t+\tau) \cdot Q_1(\tau) d\tau \quad \text{for } T_p \leq t \leq T_n - T_p$$

where T_n = length of the finite wave record
T_P = peak period of the spectrum
$Q_1(\tau)$ = smoothing window which acts as a low pass filter

describes the distribution of energy along the time axis with energy defined as the square of water surface elevations.

The description of the groupiness of a time series of the sea state is given by the dimensionless groupiness factor

$$GF = \frac{\sqrt{m_{0\varepsilon}}}{m_0}$$

where $m_{0\varepsilon}$ = zeroth moment of the SIWEH spectral density
m_0 = zeroth moment of the short wave spectrum.

This factor describes the standard deviation of the instantaneous wave energy about its mean. GF=.9 indicates a highly grouped sea state. GF-values up to 1.1 have been recorded. Typical values range between .5 and .8. Other important factors are the group repetition period, the length of the group and the variation of the group repetition period. A description of groupiness in terms of the SIWEH spectral density is given in Funke and Mansard (8).

In order to define grouping properties of estuarine waves a preliminary analysis using the SIWEH-function and calculating the groupiness factor was applied on a limited number of records. Fig. 5

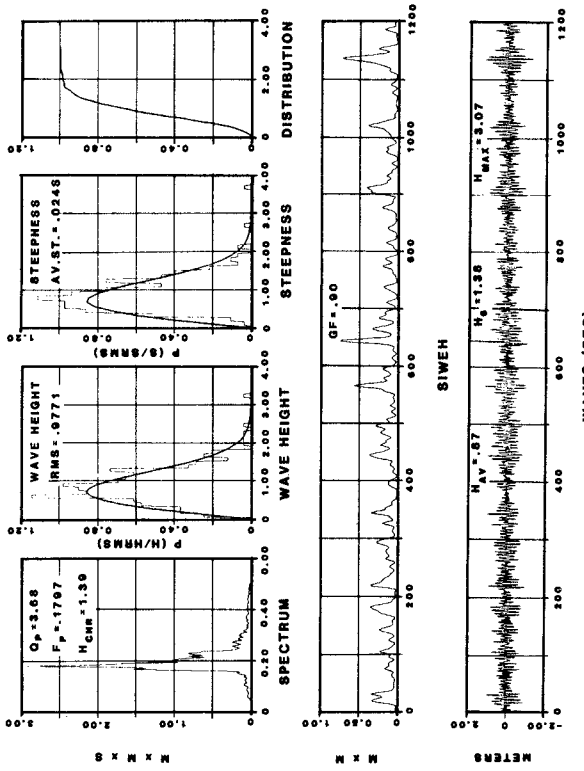

FIG.5 WESER DATA ANALYSIS - LOC. ST 23.4.80 - 17.40

shows an example of the results of the general analysis procedure. This time series recorded at location ST in relatively deep water at wind velocities of 12 m/s already shows distinct wave groups with a high groupiness factor of GF = .9. Wave heights as well as steepness fit visually quite well to the theoretical (Rayleigh) distribution. The variance spectral density shows a single peak spectrum with some energy contents in the low frequency region.

In Fig. 6 different wave parameters are plotted versus time for three locations in the estuary for one recorded long time series

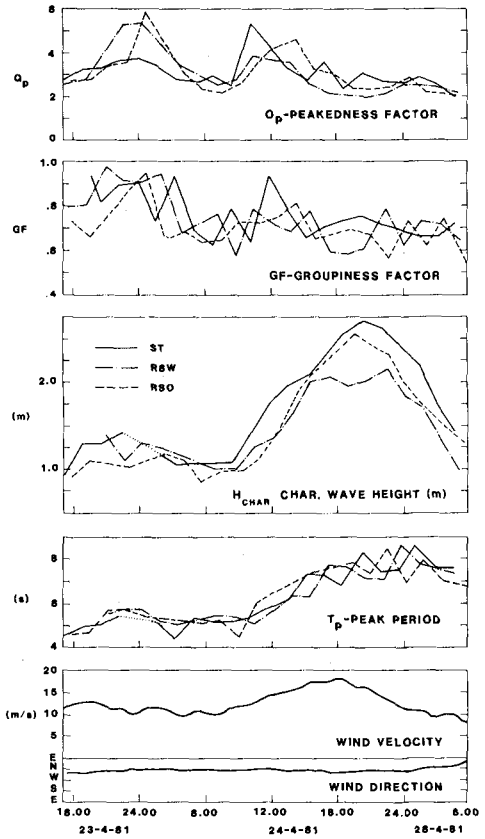

Fig. 6 WAVE PARAMETERS Q_p, GF, H_{CHAR} T_p WESER ESTUARY-ST-23.-25.4.81

available for this analysis. While characteristic wave heights and peak periods follow increasing and decreasing wind velocities nicely, it seems that the groupiness factor GF varies without any correlation to wind and other wave parameters. However, the time variations of the peakedness factor

$$Q_p = \frac{2}{m_0} \int_0^\infty f[S(f)]^2 \, df$$

which was introduced by Goda (9) seem to coincide somewhat with those of the groupiness factor GF. Both parameters grow with increasing wind up to a certain extent and then decrease again which agrees with observations of Rye (7) as far as the formation of groups is concerned. Though wave group formations were found to be more pronounced for a narrow, sharply peaked spectrum (Rye (18), Goda (10)), an interdependency of Q_p and GF could neither be detected in model studies (a synthesised spectrum can keep its shape for different groupiness factors) nor in the analysis of prototype data (13) so far. Spectral peakedness factors Q_p are plotted versus groupiness factors GF in Fig. 7 for the three locations under discussion. In spite of the scatter a distinct trend seems to indicate a relationship. The correlation coefficients are Rxy = 0.75-.78. However, this phenomenon has to be investigated for more records under different conditions.

4.2 Bounded Long Waves

Due to radiation stress, wave groups generate a group bounded long wave. This long wave typically appears as a setdown under the group and a setup in between the groups (Fig. 8) as shown by Longuet-Higgins and Steward (12) for groups of regular waves. As these long waves can

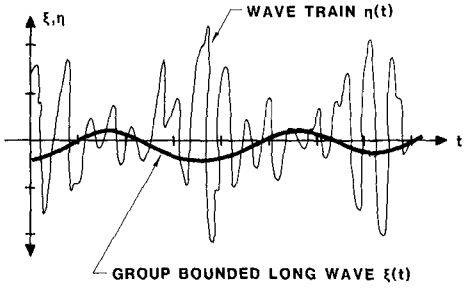

Fig. 8 GROUP BOUNDED LONG WAVES
- DIAGRAMMATIC SKETCH -

excite slow drift oscillations of moored structures and travelling ships or cause harbour resonance, their detection in a record, or rather in the spectrum, is of major importance. Unfortunately, many of the customary wave measuring devices are not capable of picking up these low frequency elevations among the short waves. The commonly used waverider buoy attenuates the output for frequencies below .1 Hz so that a compensation function has to be used. Somewhere between .06 and .05 Hz the instrument fails to record low frequencies. In order to estimate the amount of long wave energy present in prototype data recorded by similar instruments the long wave energy or long wave surface elevations have to be calculated. Bowers (6) and Dean and Sharma (7) used the Laplace-equation to define these second order waves. Another definition, based on the momentum equations, has been given by Ottesen-Hansen (15).

The various long wave components are computed using the Fourier coefficients of the primary wave train. Basically, each pair of frequencies resp. Fourier coefficients generates a long wave contribution. Hence the second order surface elevation becomes

$$\zeta_{nm}(t) = G_{nm}(f,\Delta f)[(a_n a_m+b_n b_m)\cos(\Delta\omega_{nm}t) + (a_m b_n-a_n b_m)\sin(\Delta\omega_{nm}t)]$$

with G_{nm} being the transfer function given by Ottesen-Hansen (15) and discussed by Sand (19).

4.3 Long Waves in Natural Wave Trains

As mentioned before, low frequency oscillations can be dangerous for floating structures. Especially vessels travelling in confined channels of an estuary with a limited water depth could be affected by groups of higher waves as well as by the group bounded long wave dependent on its height and repetition period. In order to get an idea about possible amplitudes and periods of these long waves, two 20-minute records were analysed with respect to long wave energy contents.

The following analysis procedure was used:

a. Fourier analysis is performed on the prototype wave train after application of a band pass filter.

b. All Fourier components for frequencies smaller than a given lower cut-off frequency and all components with an amplitude smaller than a given threshold are set equal to zero.

c. Fourier components of the bounded long wave are computed using the equations of Ottesen-Hansen (15) and Sand (19).

d. Inverse Fourier-transform is applied.

e. Superposition of short and bounded long wave train.

f. Spectral analysis.

g. Zero-crossing analysis on short and long wave train.

The program used for this purpose was developed in the Hydraulics Laboratory of the National Research Council Canada.

Fig. 9 shows the results of a record, obtained at location RSO (water depth = 8.0 m), with a groupiness factor GF = .90. The bounded long wave which is superimposed to the short wave train shows a distinct setdown under the wave groups. Spectral analysis was performed on the original wave train as well as on the superposed wave train (original + calculated bounded long wave). The encircled part in the spectrum on the right hand side was enlarged to show the difference in the low frequency part of the spectrum. From this it can be concluded that the energy contents in the low frequency part is considerably increased by taking the bounded long wave into account. This becomes more obvious by comparing the RMS-values, which were calculated separately for a certain low frequency range, where RMS_M refers to the measured and RMS_C to the superposed wave train. Zero-crossing analysis on both the measured wave train and the calculated bounded long wave yield the wave parameters $\overline{H} \triangleq H_{AVE}$, H_S and H_{MAX} as well as the mean period of the bounded long wave. Under the given conditions already a long wave with maximum height of .17 m and a mean period of 36 s can appear.

Since prototype records with more severe conditions were not at hand for this analysis, a wave train measured off the coast of Newfoundland, Canada, was applied to a water depth found at loc. ST in the Weser estuary. Wave heights and periods of comparable order of magnitude have been recorded at this location before.

Fig. 10 shows the results of the above mentioned analysis on this wave train with a groupiness factor of GF = .94. It appears again, that the superposition with the calculated bounded long wave adds a considerable amount of energy in the low frequency part of the spectrum indicated by the RMS-values which have been calculated only up to .05 Hz. A long wave with a mean wave height of .37 m and a maximum of .65 m

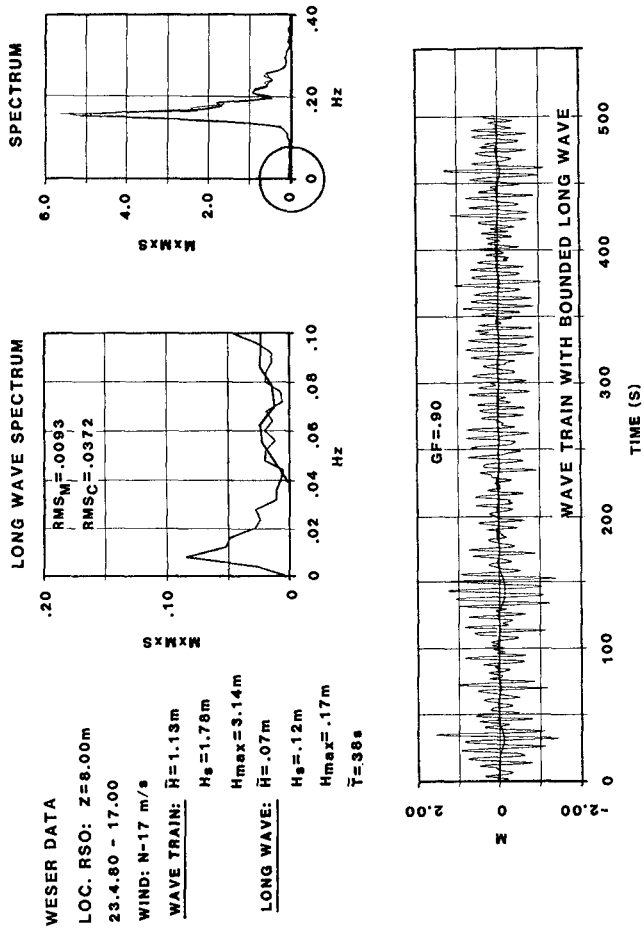

FIG.9 BOUNDED LONG WAVES IN NATURAL WAVE TRAINS

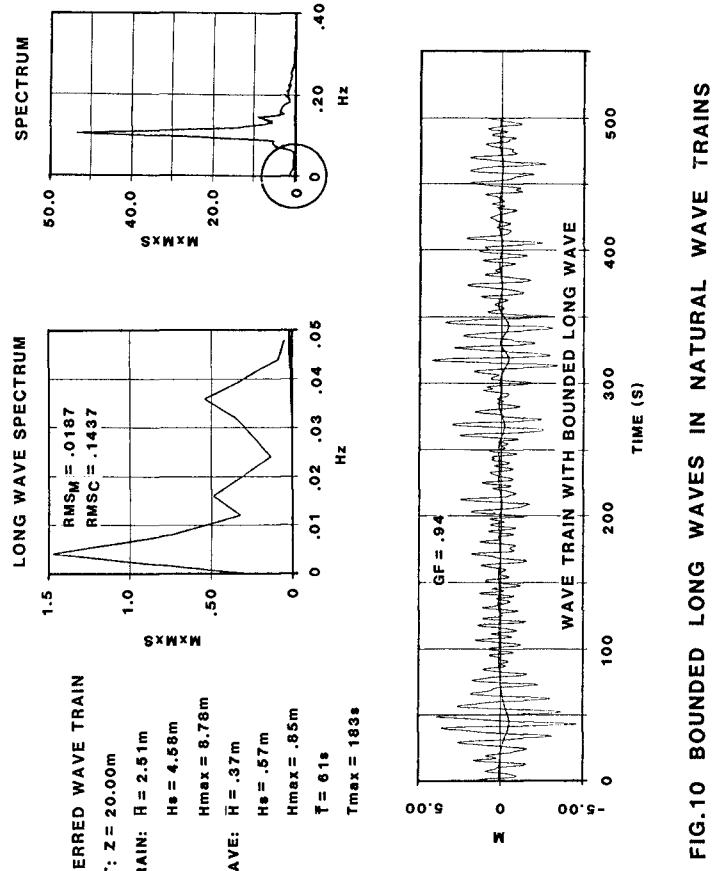

FIG.10 BOUNDED LONG WAVES IN NATURAL WAVE TRAINS

is present under these wave conditions. The mean period is 61 s whereas the maximum period goes up to 183 s. Typically these long waves tend to be stable and travel with the group velocity as long as the group is not attenuated, i.e. by breaking. According to model studies which have recently been done in the Hydraulics Laboratory of the National Research Council of Canada (5), it is very likely that these long waves are partly reflected on shoals. However, in deep channels they will propagate and penetrate into the inner estuary.

It is not yet known to what extent these long waves can affect the motion of travelling vessels. However, it has to be expected that, especially in confined shipping channels with a restricted water depth, a sudden increase of the draught or rather decrease of available water depth connected with grouped wave impact and in addition to squat, can lead to dangerous situations.

Analysis of all available records obtained in critical areas with respect to long wave activity is recommended.

5. CONCLUSIONS

Extended statistical analysis was performed on prototype data obtained in the Weser Estuary mostly with waverider buoys. Height and period distributions of 20-minute records were checked for their correspondence with theoretical distributions. The results permitted the following observations:

- Height and period distributions more likely follow a Rayleigh distribution than others.

- Modified empirical height distributions related to the Rayleigh distribution could be assigned to different regions of the estuary permitting the evaluation of different wave height parameters.

Further analysis using the SIWEH-function (8) and calculation of second order waves highlighted the presence of wave grouping in estuarine waves and the group bounded long waves. The findings suggest that

- in spite of a complex wave climate, grouping can be detected in this area,

- the spectral peakedness seems to be correlated to the groupiness factor,

- the group bounded long wave component, which has not been recorded, can be found and re-established by special analysis techniques.

Further research has to be performed on the long wave problem, including long wave statistics after analysis of all available data. In an additional project the influence of these long waves on travelling vessels ought to be investigated.

6. ACKNOWLEDGEMENTS

The field investigations were carried out during the author's employment with the German Federal Waterways Administration, Wasser-u. Schiffahrtsamt Bremerhaven, and supported by the German Ministry of Research and Technology (BMFT) via the German Coastal Engineering Board (KFKI). Further analysis was done in the Hydraulics Laboratory of the National Research Council Canada. The author would like to thank the management of all those institutions and the "Hafenbautechnische Gesellschaft, Hamburg" for support in presenting this paper at the 18th Conference on Coastal Engineering in Cape Town, South Africa.

ANALOGOUS DISPERSION PROPERTIES OF SURF ZONE AND ELECTROMAGNETIC WAVES

by
FRITZ BÜSCHING [1)]

ABSTRACT

Resonant interaction processes in the surf zone are marked by an anomalous dispersion property ($dc/df > 0$) as it is well known from resonance absorption processes of electromagnetic waves in dielectrics.

INTRODUCTION

At least since 1974 there has been an increasing number of publications dealing with so-called anomalous dispersion properties observed from deepwater wind waves (RAMAMONJIARISOA and COANTIC, 1976; LAKE and YUEN, 1978) as well as from waves in areas of transitional and shallow water depth (MASSEL and CHYBICKI, 1980; BÜSCHING, 1978). Most of the respective experiments are carried out by estimating the cross correlation or the cross spectral density functions from the signals of some wave gauges placed in the wave field appropriately.

From investigations in a large wind-water facility for deepwater wind waves for instance the most striking departure from theoretical values consists in the phenomenon of nondispersiveness $dc/df = 0$ especially at "phase-locked" higher frequency components with phase velocities close to the dominant wave celerity, see Fig. 1. There is, however, another deviation to be seen describing an anomalous dispersion $dc/df > 0$ in the low frequency range coincident with rather small energy

---

Lecturer and Chief Engineer, Dr.-Ing., Leichtweiss-Institute, Dept. Hydrodyn. and Offshore Eng., Techn. Univ. Braunschweig, Federal Republik Germany

densities. By contrast, the author's privious field investigations in the surf zone at heavy storm surge conditions have shown an anomalous dispersion property dc/df > 0 in the whole energy containing frequency range (BÜSCHING, 1978 a).

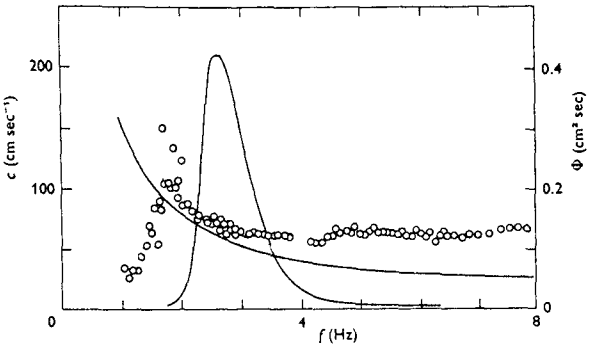

Fig. 1: The variation in phase speed of spectral components measured by RAMAMONJIARISOA (1974). The theoretical phase speed $c = g/2\pi f$ and the spectral shape are also shown.

The anomalous dispersion of low frequency components in "deepwater" wind wave spectra is often attributed to the presence of wave groups travelling with the appropriate group velocity (PHILLIPS, 1978). It is, however, doubted by the author whether the longer period frequency components can really be regarded as deepwater components even in a "large" wind-water facility, and moreover it is questionable whether it can be distinguished between phase velocities on the one hand and group velocities on the other hand both in the same plot based on spectral analysis. In the following it will be demonstrated that resonant interaction effects are responsible for an anomalous dispersion property to occur in the very shallow portion of the surf zone. The present contribution refers to measurements priviously evaluated in detail by the author, see BÜSCHING (1978 b).

ANOMALOUS DISPERSION OF SURF ZONE WAVES

Frequency Domain Data

In the upper parts of figures 2 and 3 two sets of synchronously measured energy spectra of water level deflexions are to be seen both characterizing different wind and water depth conditions at stations 100 m and 85 m distant from the shoreline respectively in a coast perpendicular measuring profile on the isle of SYLT/North Sea.

Although that measurements had been carried out at heavy storm surge conditions coherence $\overline{\gamma^2}$ is quite good at the energy containing frequency components (about $\overline{\gamma^2} = 0.8$ and $\overline{\gamma^2} = 0.7$ respectively). In this cases the phase velocity was calculated from the phase information of the transfer functions plotted below.

As to be seen from the graph at high coherence values the phase information can very well be approximated by a linear regression

$$\Phi(f) = \Phi_n + \alpha \cdot f \tag{1}$$

in which $\alpha \cdot f$ is due to the distance of the two measuring stations $\Delta x = 15$ m, and it can be shown from the conversion into phase velocity applying

$$c(f) = \frac{\Delta x \cdot 360^0}{\Phi(f)} \cdot f \tag{2}$$

that the magnitude of the positive portion of Φ_n decides on the degree of the anomalous dispersion property $dc/df > 0$.

As was found by the author in 1978 the anomalous dispersion gets more distinct with the water depth decreasing; hence, the magnitude of Φ_n in Fig. 3 is greater than in Fig. 2:

$$\Phi_2 > \Phi_1 \tag{3}$$

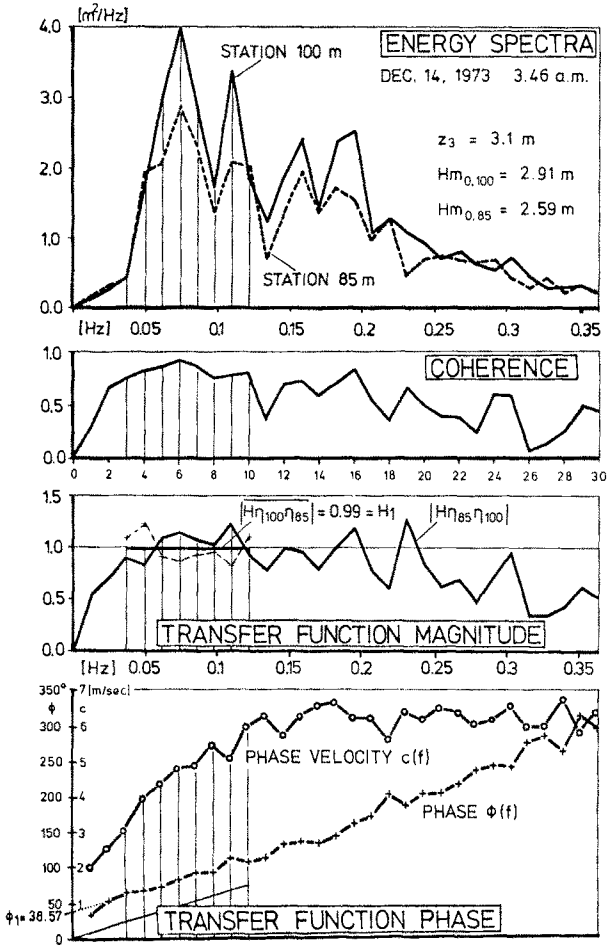

Fig. 2: Spectral functions of two wave gauge signals at a high tide water level.
Gauge distances from shore 100 m and 85 m respectively.

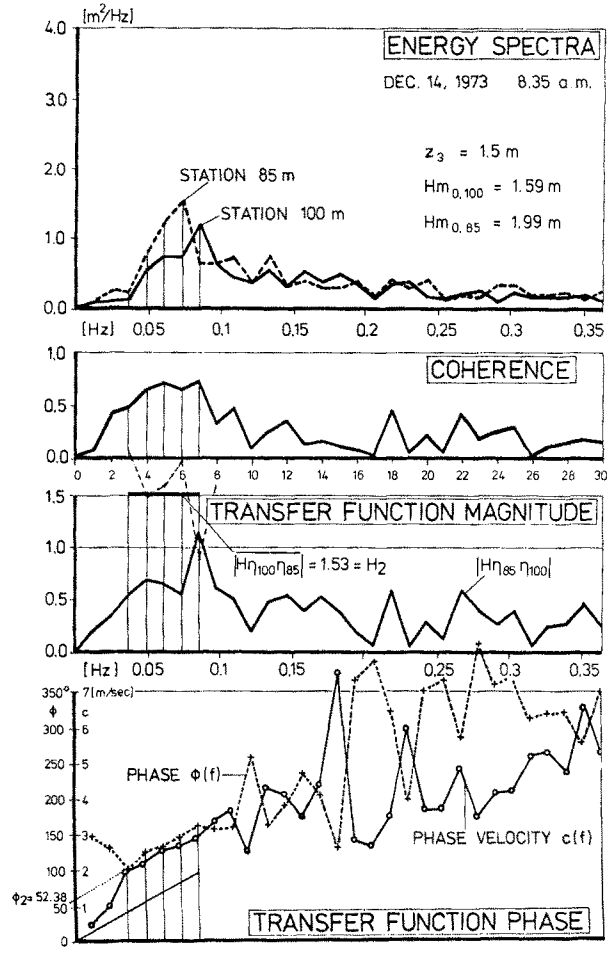

Fig. 3: Spectral functions of two wave gauge signals at a low tide water level.
Gauge distance from shore 100 m and 85 m respectively.

There is, however, another phenomenon to be seen from Fig. 3 representing a very shallow water depth condition. Obviously a peak shift to lower frequencies has happend on the rather short distance of $\Delta x = 15$ m in the upbeach direction, and additionally an increase in the maximum energy density can be watched. This fact also comes out clearly from the magnitude of the transfer function, if its inverse values are considered at high coherence only, resulting in an average value of

$$H_2 = |\overline{H\eta_{100}\eta_{85}}| = 1.53 \qquad (4)$$

Similar energy shifts to lower frequencies due to decreasing water depth are also to be seen from spectra published by SONU, PETTIGREW and FREDERICKS (1974) and GODA (1975). By contrast, at the condition of Fig. 2, marked by a greater water depth, energy density decreases from station 100 m to station 85 m accordingly resulting in an average value

$$H_1 = |\overline{H\eta_{100}\eta_{85}}| = 0.99 < 1 \qquad (5)$$

Time Domain Data

Increasing wave periods in the upbeach direction (in accordance with a peak shift to lower frequencies) could also be detected in the time domain from synchronously taken strip charts.

Figures 4 and 5 show the results of a zero crossing evaluation technique applied to the data of 6 and 5 measuring stations respectively still in operation in the same coast perpendicular measuring profile at normal weather conditions.

Besides the wave heights here the wave propagation velocity is plotted with reference to the water depth, the wave periods and the wave length respectively. Because of the lack of space here only two things shall be pointed out with respect to broken waves.

After breaking the wave deceleration is less than before breaking, and, as a consequence of an increasing "wave period", there is an anomalous

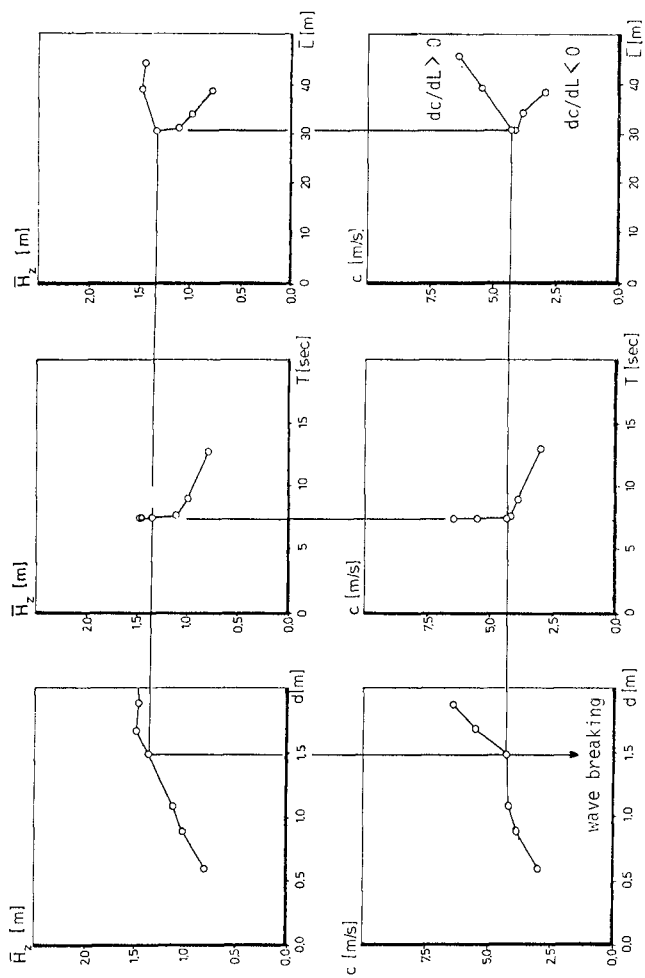

Fig. 4: Variation of mean wave heights $\bar{H}_z$ and propagation velocity c with water depth, wave period and wave length respectively in a coast perpendicular measuring profile on April 3rd, 1973

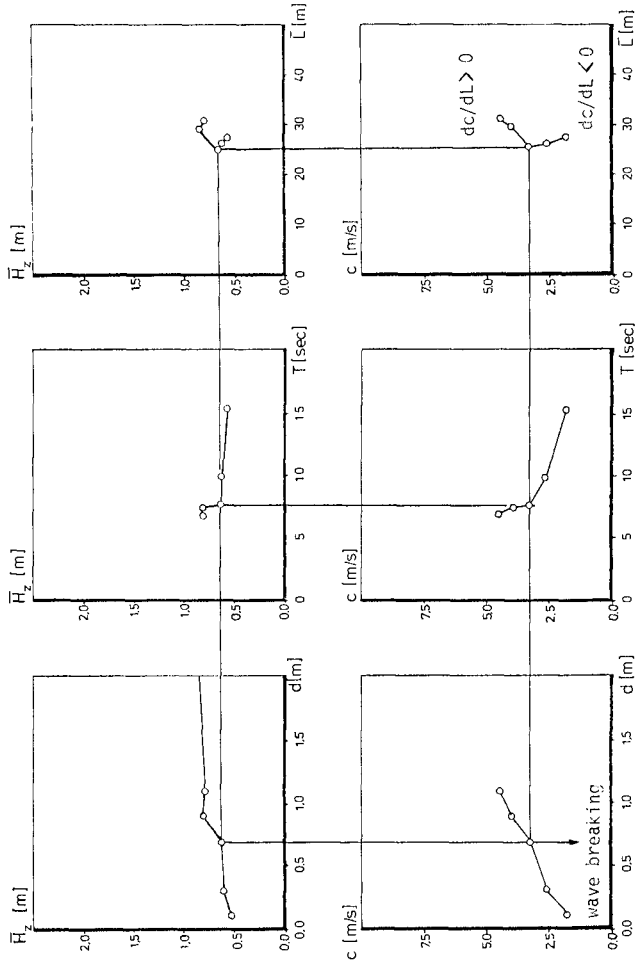

Fig. 5: Variation of mean wave heights $\bar{H}_z$ and propagation velocities c with water depth, wave period and wave length respectively in a coast perpendicular measuring profile on March 18th, 1973

dispersion characterized by $dc/dL < 0$. The details of that measurements are also given in BÖSCHING (1978 b).

ANOMALOUS DISPERSION OF ELECTROMAGNETIC WAVES

From electromagnetic waves it is well known that an anomalous dispersion of frequency components is due to a resonance phenomenon (resonance absorption in dielectrics). If one has an electromagnetic wave propagating through a medium made up of a number of oscillators (electrons or ions) per unit volume one gets a complex refractive index

$$n^* = n - ik \tag{6}$$

in which n is the real refractive index (also representing phase velocity) and $k = n \cdot \kappa$ is an absorption quantity (also representing the amplitude response near resonance).

As to be seen from Fig. 6 both components vary with wave length. By the equation (6) it is stated that resonance, absorption and anomalous dispersion are combined effects. If an incident component wave has nearly the same length or frequency as an oscillator of the medium resonance occurs. The oscillator absorbs the energy from the forcing incident wave. At resonance absorption represented here by k is a maximum, and in the vicinity of the spot of resonance always an anomalous dispersion $dn/dL > 0$ corresponding to $dc/df > 0$ (or $dc/dL < 0$ or $dn/df < 0$) appears. In a light spectrum this means that the sequence of spectral colours here is the inverse to the normal case: refraction of the red colour is a maximum instead of the violet colour. It is because of the coincident maximum of absorption that we are not as familiar with this kind of dispersion as we are with the normal dispersion property. In liquids and solids, due to molecular collisions and strong intermolecular forces, the absorption and dispersion curves become very much broadened, the broadening being very irregular owing to the varying molecular force field. Additionally damping is an essential quantity as it is true to all forced vibration processes.

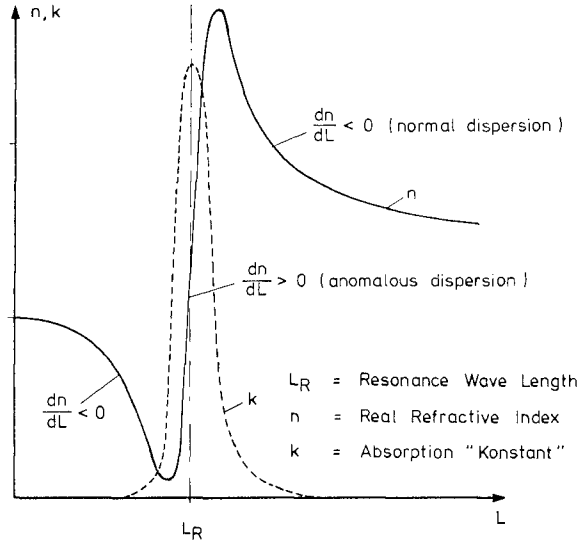

Fig. 6: Absorption above and below a region of anomalous dispersion centered about the resonance wave length

Moreover it is well known from thin film optics that dispersion properties depend on the actual film thickness, see for instance MAYER (1950).

With respect to the transmission of light through a gold film it can be seen from Fig. 7 that an anomalous dispersion property gets more distinct in the visible spectrum with the film thickness decreasing. At a rather thick film (solid line) the visible spectrum is dominated by a normal dispersion whereas at a very thin film there is an anomalous dispersion in the total visible spectrum.

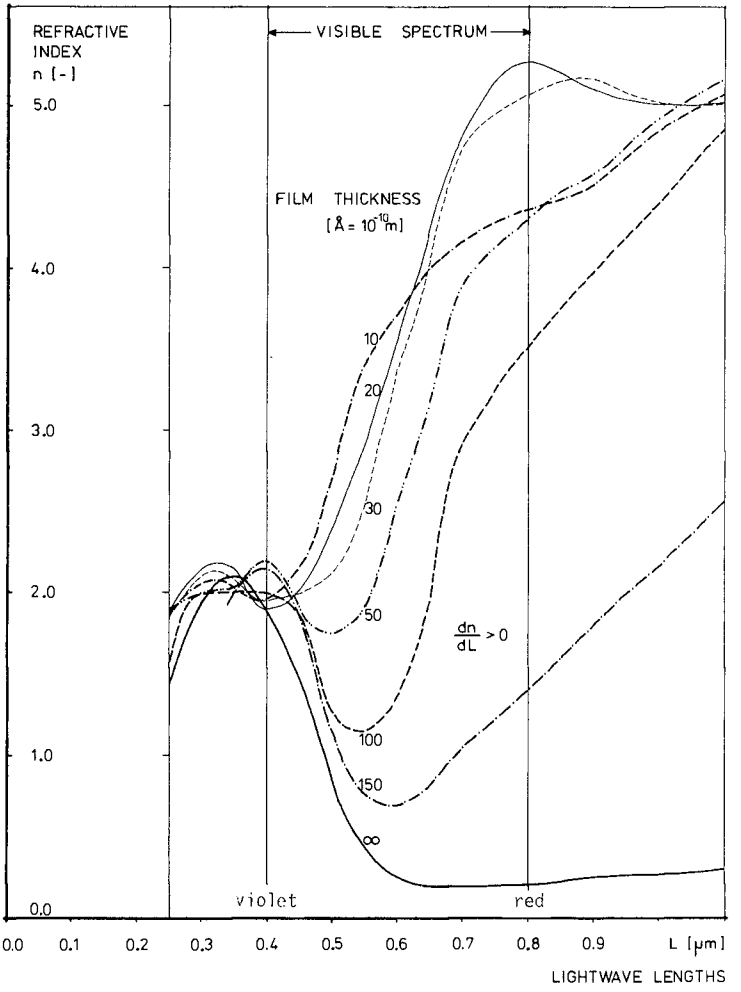

Fig. 7: Variation of dispersion properties at transmission of light through gold films with respect to decreasing film thicknesses

DISCUSSION AND CONCLUSIONS

Formerly the author was able to deduce an anomalous dispersion property combined with a peak shift Δf to lower frequencies from an equation

$$\Delta f = f_0 \cdot \frac{2 \cdot [c(x) - c_0]}{2 \cdot c_0 - c(x)} = f(x) - f_0 \qquad (7)$$

see BÖSCHING (1980) in which f_0 and c_0 are the component frequency and celerity respectively at a known position in the surf zone, and $c(x) < c_0$ and $f(x) < f_0$ are caused by a superimposed (accelerated) current at a certain position on the same wave beam nearer to the shore. Vice versa a positive frequency shift can be produced in applying $c(x) > c_0$. The author is still convinced that superimpored currents do have an important effect on wave deformation processes particularly taking place in the post breaking zone. For example in the lower part of Fig. 8 there are shown some additional spectra measured synchronously at stations 100 m and 85 m from the shore. If the respective sets of spectra are connected with the coast normal component of the mean residual velocities measured at station 85 m (see middle part of Fig. 8) actually different frequency shifts can be seen. In the present case there is

a) a negative frequency shift (red shift) combined with a seaward directed residual current (see first set of spectra),

b) almost no shift in correspondance with minimal residual currents (see second set of spectra) and

c) there is a positive shift (blue shift) coincident with a coastward directed residual current (see third set of spectra).

As, however, the additional phenomenon of an increasing energy density in the upbeach direction, especially at very low water depth conditions (first and third set of spectra), can not be explained in applying equation (7), in the following the question is considered whether the above demonstrated combined effects of resonance, absorption and anoma-

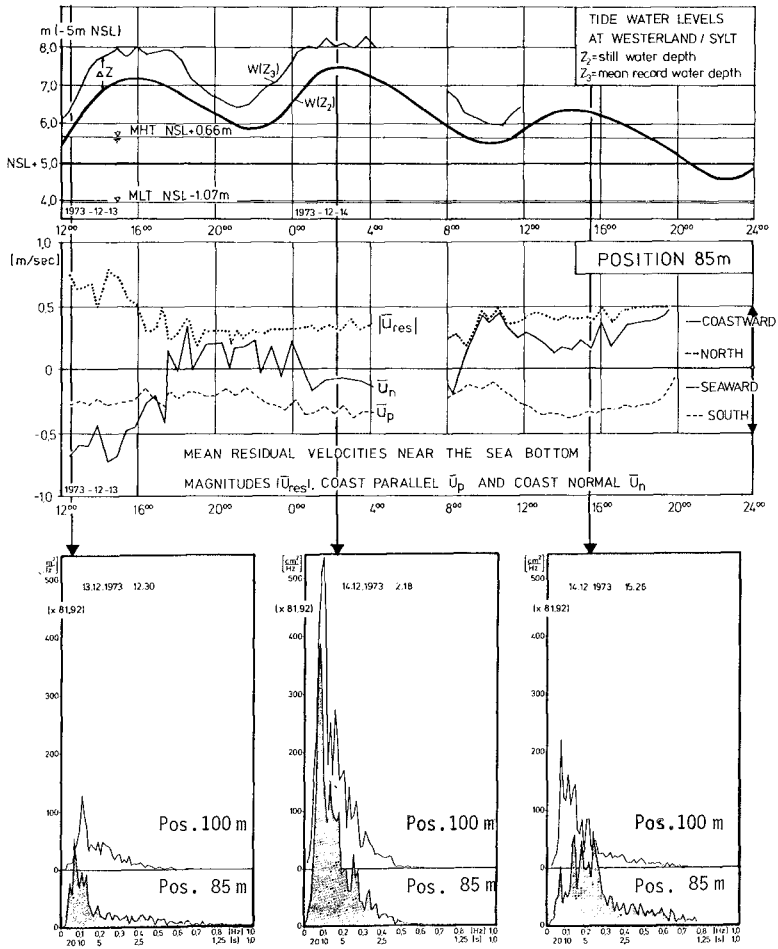

Fig. 8: Different frequency shifts by superimposed accelerated residual currents with respect to the onshore-offshore direction

lous dispersion, known from electromagnetic waves, also apply to surf zone characteristics.

In order to get a better understanding of that mechanism an inspection of the response characteristics of a single degree of freedom oscillator can be helpful, see Fig. 9.
As an analogue to the above shown transfer function this is also subdivided into magnitude and phase. The amplitude response characteristic as well as the phase characteristic both are plotted with reference to the frequency ratio

$$\eta = \frac{\text{forcing frequency}}{\text{natural frequency}} = \frac{f_f}{f_n} \tag{8}$$

instead of the frequency as it is used at the transfer functions.

Both components are significantly marked by the actual damping rate D which is well-defined by the respective families of curves.

Applying this model to the surf zone the forcing frequencies are those coming from offshore, and the volume of water present in the surf zone is characterized by some eigenfrequencies.

A similar concept is well known from edge wave investigations (GUZA and BOWEN, 1976; CHAPELL and WRIGHT, 1978).

In order to check its validity in the following it is tried to compare the response characteristics of Fig. 9 with the transfer function data of Fig. 2 and 3 respectively, both representing different wave conditions and different anomalous dispersion properties.

If the values H_1, Φ_1 and H_2, Φ_2 are transferred to Fig. 9 conditions (1) and (2) can be differentiated by suitable damping rates D and corresponding frequency ratios η.

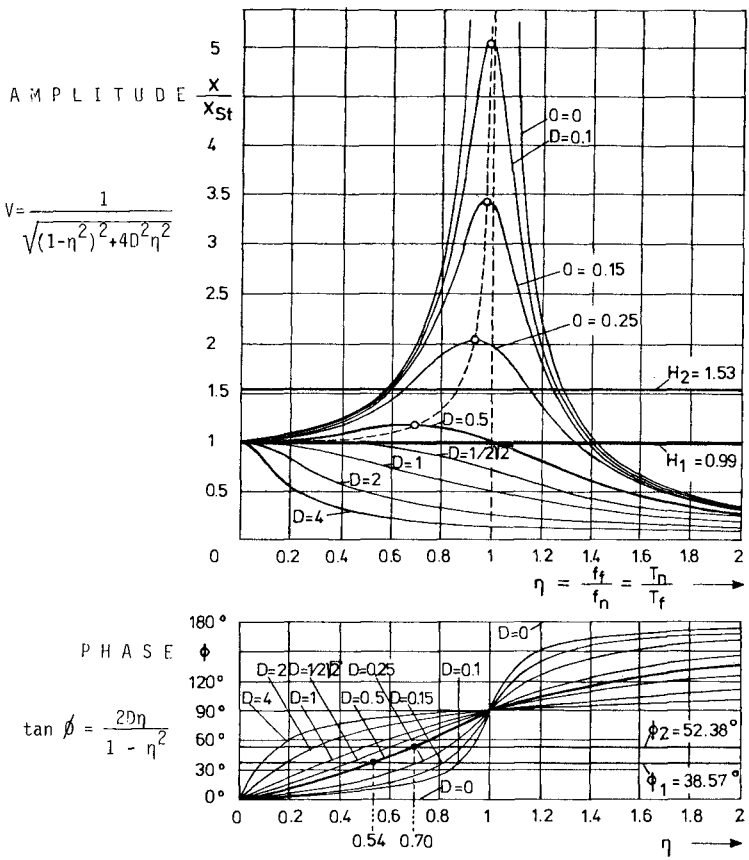

Fig. 9: Response characteristics of a single degree of freedom oscillator

At condition(1)a distinct amplitude and phase response can not be deduced because transfer function magnitude does not differ much from unity, and the phase angle is far from being $\Phi = 90^{o}$. Amplitude and phase characteristics ($H_1 = 0.99$ and $\Phi_1 = 38.5^{o}$) in this case get together at a frequency ratio

$$\eta_1 \simeq 0.46 < 0.54 \tag{9}$$

corresponding to a damping rate

$$0.5 < D_1 < \sqrt{2}/2 \tag{10}$$

Herewith it can be concluded that damping dominates in this case. By contrast, at condition(2)marked by a transfer function magnitude appreciably greater than unity ($H_2 = 1.53$) and a larger phase angle ($\Phi_2 = 52.38$) it is found a frequency ratio

$$\eta_2 \simeq 0.74 > 0.70 \tag{11}$$

and a corresponding damping rate

$$0.25 < D_2 < 0.5 \tag{12}$$

Hence, from this analysis there is an indication that resonant interactions including anomalous dispersion are more likely to occur in the surf zone at lower water depth.

This result, however, is infact in accordance with the above shown example from thin film optics, see Fig. 7. Moreover the analogous behaviour of electromagnetic waves at resonance absorption and surf zone waves is underlined by the fact that the ratio film thickness devided by light wave length is similar to the ratio water depth devided by wave length in the post breaking zone.

NUMERICAL CALCULATION OF SEICHE MOTIONS IN HARBOURS OF ARBITRARY SHAPE

P. Gaillard
Sogreah, Crenoble, France

ABSTRACT

A new method of calculation of wave diffraction around islands, offshore structures, and of long wave oscillations within offshore or shore-connected harbours is presented. The method is a combination of the finite element technique with an analytical representation of the wave pattern in the far field. Examples of application are given, and results are compared with other theoretical and experimental investigations.

lNTRODUCTION

The prediction of possible resonant response of harbours to long wave excitation may be an important factor at the design stage. Hydraulic scale models have the disadvantage of introducing some bias in the results due to wave reflection on the wave paddle and on the tank boundaries. Numerical methods on the other hand can avoid such spurious effects by an appropriate representation of the unbounded water medium outside the harbour.

Various numerical methods exist for calculating the seiche motions in harbours of arbitrary shape and water depth configuration. Among these, the hybrid-element methods, as described by Berkhoff [1] , Bettess and Zienkiewicz [2], Chen and Mei [3], Sakai and Tsukioka [8] use a combination of the finite element technique with other methods for representing the velocity potential within the harbour and in the offshore zone. This paper presents a new method based on the same general approach, with an analytical representation of the wave pattern in the far field. lt differs from the former methods in several aspects stressed hereafter.

We consider here two kinds of applications:

a) the first is the study of wave diffraction by islands or bottom seated obstacles in the open sea and the study of wave oscillations within and around an offshore harbour.

b) the second is the study of wave oscillations within a shore-connected harbour with a totally reflective coastline, which is assumed rectilinear beyond a certain distance.

BASIC EQUATIONS

The numerical calculation of long period water oscillations in harboursof arbitrary shape and bottom configuration is based on the linear shallow water wave equation for an inviscid fluid:

$$\nabla\cdot\left[h\nabla\zeta\right] - \frac{1}{g}\zeta_{tt} = 0 \qquad (1)$$

where $\zeta(x,y,t)$ is the water surface elevation above mean see level,
$h(x,y)$ is the water depth distribution,
g the acceleration due to gravity.

The numerical models based on the present method include two domains:

- in a bounded region D_1 including the harbour and the vicinity of the harbour entrance, the water depth is defined according to the bottom topography on the site studied, and a finite element technique is used for solving the above equation.

- In the outer region D_2 extending to infinity, and bounded by an unlimited rectilinear reflecting coastline in the case of a shore-connected harbour, the water depth is assumed constant, equal to h_0, and an analytical solution of (1) is used in the form of a finite series expansion.

The boundary C_{12} interconnecting both domains is either a full circle in the case of an island-type harbour or structure, or a half circle in the case of a shore-connected harbour, as shown in figure 1.

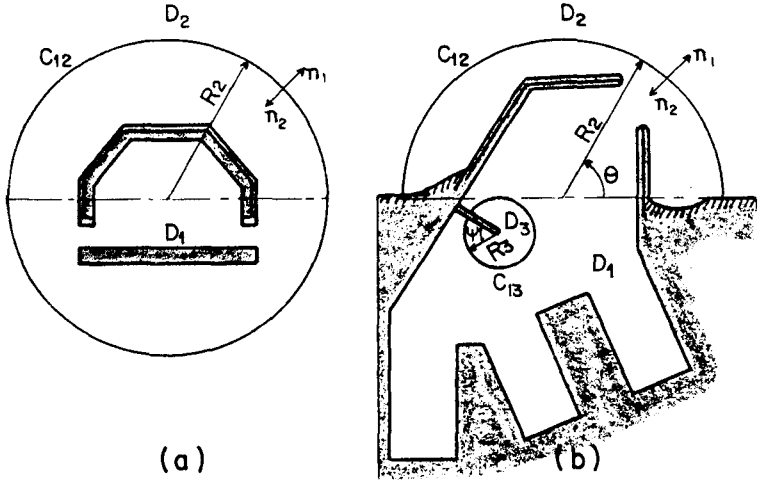

Fig.1 Definition sketch: (a) offshore case ; (b) nearshore case

A periodic excitation by a plane incident wave of arbitrary direction α, frequency f (or angular frequency ω) and height $2a_0$ is taken as input to the model at infinity and the steady-state dynamic response of the model is calculated. A variable frequency scanning technique is used to detect the resonant modes.

We thus reduce the problem to seeking, for a finite number of wave angular frequencies ω, a complex function of space $\bar{\zeta}(x,y)$ such that:

$$\zeta(x,y,t) = \mathrm{Re}\left\{\bar{\zeta}(x,y)\ \exp\ (-i\omega t)\right\} \tag{2}$$

This function is a solution of the Helmholtz equation:

$$\nabla.\left[h\,\nabla\bar{\zeta}\right] + \frac{\omega^2}{g}\,\bar{\zeta} = 0 \tag{3}$$

We shall refer to the solutions of (3) in D_1 and D_2 as $\bar{\zeta}_1$ and $\bar{\zeta}_2$ respectively. The boundary conditions imposed on these solutions are as follows:

$$\frac{\partial\bar{\zeta}}{\partial n} = 0 \qquad \text{on } C_{SB} \tag{4}$$

$$\bar{\zeta}_1 = \bar{\zeta}_2$$

$$\text{on } C_{12} \tag{5}$$

$$\frac{\partial\bar{\zeta}_1}{\partial n_1} = -\frac{\partial\bar{\zeta}_2}{\partial n_2} = G_{12}(\Theta)$$

$$\bar{\zeta}_2 \longrightarrow \bar{\zeta}_A \qquad \text{for } r\longrightarrow\infty \tag{6}$$

The first condition expresses that waves are totally reflected from all solid boundaries i.e. harbour structures and coastline. This assumption is generally valid as wave steepness is low for the periods considered.

The set of conditions (5) express the continuity of the water surface elevation and of the horizontal velocities at the common boundary C_{12}.

The last condition imposes the behaviour of the solution in the far field, behaviour which depends on the type of application considered.

In the case of an offshore harbour or structure $\bar{\zeta}_A$ is representative of the plane incident wave, which can be expressed, in polar coordinates (r,Θ) with the origin at the centre of C_{12}, as:

$$\bar{\zeta}_A = \bar{\zeta}_i = a_0 \sum_{n=0}^{\infty} \epsilon_n (i)^n J_n\,(kr)\,\cos\, n(\Theta-\alpha) \tag{7}$$

with: $i = \sqrt{-1}$

J_n = the Bessel function of order n

k = the wave number associated with frequency ω by:

$$k = \omega(gh_0)^{-1/2} \tag{8}$$

$$\epsilon_n = \begin{cases} 1 & n=0 \\ 2 & n \geqslant 1 \end{cases} \tag{9}$$

In the case of a shore-connected harbour, $\bar{\zeta}_A$ is representative of the superposition of the incident waves and of their reflection on the coastline, which is considered as totally reflective. Taking the origin of along the shoreline, $\bar{\zeta}_A$ is expressed as:

$$\bar{\zeta}_A = 2a_0 \sum_{n=0}^{\infty} \epsilon_n (i)^n J_n (kr) \cos n\alpha \cos n\theta \tag{10}$$

The solution in D_2 is consequently split into two components $\bar{\zeta}_A$ and $\bar{\zeta}_D$, where $\bar{\zeta}_D$ is representative of the diffracted waves due to the presence of the harbour or of the isolated structure under consideration. These waves radiate outward from the latter to infinity, and thus should satisfy Sommerfeld's radiation condition:

$$\lim_{r \to \infty} \left\{ \sqrt{r} \left[\frac{\partial \bar{\zeta}_D}{\partial r} - ik\bar{\zeta}_D \right] \right\} = 0 \tag{11}$$

VARIATIONAL FORMULATION

The solution of the problem is obtained through a variational approach, which is briefly described here. Considering first the two domains independently and the function $G_{12}(\Theta)$ in (5) as a given boundary condition, the solution in D_1 is ascribed to make stationary the functional:

$$F_1(\zeta) = \frac{1}{2} \iint_D \left[h(\nabla\zeta)^2 - \frac{\omega^2}{g} \zeta^2 \right] ds - \int_{C_{12}} h \zeta_1 C_{12} \, d\sigma \tag{12}$$

and the solution in D_2 is associated with the functional:

$$F(\zeta) = -\frac{1}{2} \iint_D \left[\nabla.(h\nabla\zeta) + \frac{\omega^2}{g} \zeta \right] \zeta \, ds + \int_{C_{12}} h \left[\frac{1}{2} \frac{\partial \zeta}{\partial n} + G_{12} \right] \zeta \, d\sigma \tag{13}$$

Since ζ_2 is represented in an analytical form which satisfies a priori equation (3), the first integral in (13) actually vanishes.

If we now consider G_{12} as an unknown function, our objective is to make stationary, for any first variation of ζ_1, ζ_2 and G_{12}, the functional resulting from the addition of (12) and (13), i.e.:

$$F(\zeta) = \frac{1}{2} \iint_{D_1} \left[h(\nabla\zeta)^2 - \frac{\omega^2}{g} \zeta^2 \right] ds + \frac{1}{2} \int_{C_{12}} h \frac{\partial \zeta_2}{\partial n_2} \zeta_2 \, d\sigma + \int_{C_{12}} h G_{12} (\zeta_2 - \zeta_1) d\sigma \tag{14}$$

G_{12} is a periodic function of Θ, which can be represented, in the case of an offshore structure, by a Fourier series expansion with unknown coefficients C_{1m}, C_{2m}. The requirement of stationarity of (14) for arbitrary first variations of these coefficients, leads to the following conditions:

$$\int_{C_{12}} (\zeta_2 - \zeta_1) \begin{Bmatrix} \cos m\Theta \\ \sin m\Theta \end{Bmatrix} d\Theta = 0 \qquad m = 0,1,2... \qquad (15)$$

When these conditions are satisfied, the last boundary integral of (14) vanishes.

In the case of a shore-connected harbour, $G_{12}(\Theta)$ is an even function of Θ. In this type of application, only those conditions in (15) involving cos $m\Theta$ are necessary.

The above functional can be represented in terms of the complex function $\bar{\zeta}$ by insertion of (2). It then appears as a function of time of the form:

$$F(\zeta) = \frac{1}{4} \mathrm{Re} \left\{ F_c(\bar{\zeta}) + F_v(\bar{\zeta}) \exp(2i\omega t) \right\} \qquad (16)$$

$$F_c(\bar{\zeta}) = \iint_{D_1} \left[h \nabla \bar{\zeta}_1 \cdot \nabla \bar{\zeta}_1^* - \frac{\omega^2}{g} \bar{\zeta}_1 \bar{\zeta}_1^* \right] ds + \int_{C_{12}} h \frac{\partial \bar{\zeta}_2}{\partial n_2} \bar{\zeta}_2^* \, d\sigma \qquad (17)$$

$$F_v(\bar{\zeta}) = \iint_{D_1} \left[h(\nabla \bar{\zeta}_1^*)^2 - \frac{\omega^2}{g} (\bar{\zeta}_1^*)^2 \right] ds + \int_{C_{12}} h \frac{\partial \bar{\zeta}_2^*}{\partial n_2} \bar{\zeta}_2^* \, d\sigma \qquad (18)$$

where $\bar{\zeta}^*$ is the complex conjugate of $\bar{\zeta}$.

The values of $\bar{\zeta}_2$ and of its normal derivative along C_{12} depend on the values of $\bar{\zeta}_1$ on this boundary, through the conditions (15). Consequently, the values of $\bar{\zeta}_1$ at N arbitrarily chosen nodes within D_1 and on its boundary constitute a complete set of independent degrees of freedom of the functionals F_c and F_v. By expressing F_c and F_v in terms of these variables, it can be shown that:

$$\frac{\partial F_v}{\partial \bar{\zeta}_1^*} = \left(\frac{\partial F_c}{\partial \bar{\zeta}_1^*} \right)^* \qquad (19)$$

In view of this property, the stationarity of $F(\zeta)$ is ensured at any time t when:

$$\frac{\partial F_c}{\partial \bar{\zeta}_{1n}^*} = 0 \qquad n = 1,2... N \qquad (20)$$

SOLUTION FOR AN OFFSHORE HARBOUR OR STRUCTURE

In the offshore case, in which C_{12} is a full circle, the solution in domain D_2 involves the following series expansion of $\bar{\zeta}_D$:

$$\bar{\zeta}_D\ (r,\theta) = \sum_{m=0}^{\infty} H_m^{(1)}\ (kr)\ \left[\varpi_{1m} \cos m\theta + \varpi_{2m} \sin m\theta\right] \qquad (21)$$

where $H_m^{(1)}$ is the Hankel function of the first kind and of order m.

The insertion of (21) into (15) leads to:

$$\begin{Bmatrix} \varpi_{1m} \\ \varpi_{2m} \end{Bmatrix} = \frac{\epsilon_m}{2\pi H_m} \int_0^{2\pi} (\bar{\zeta}_1 - \bar{\zeta}_A) \begin{Bmatrix} \cos m\theta \\ \sin m\theta \end{Bmatrix} d\theta \qquad m = 0,1,2 \ldots \qquad (22)$$

Where H_m stands for $H_m^{(1)}(kR_2)$, R_2 being the radius of C_{12}.

The integral in (22) which involves $\bar{\zeta}_A$ can be determined exactly for any value of the integer m, since the integrand is expressed in terms of trigonometric functions. On the other hand, the integral which involves $\bar{\zeta}_1$ can only be determined approximately, as the latter function of θ is calculated only at a discrete set of points along C_{12}. Assuming that $\bar{\zeta}_1$ is given at N_2 equally spaced nodes on this boundary, we obtain:

$$\begin{Bmatrix} \varpi_{1m} \\ \varpi_{2m} \end{Bmatrix} = \frac{\epsilon_m}{N_2 H_m} \sum_{p=1}^{N_2} \bar{\zeta}_{1p} \begin{Bmatrix} \cos \theta_{mp} \\ \sin \theta_{mp} \end{Bmatrix} - a_0 (i)^m \frac{\epsilon_m}{H_m} J_m\ (kR_2) \begin{Bmatrix} \cos m\alpha \\ \sin m\alpha \end{Bmatrix} \qquad (23)$$

$$\theta_n = 2\pi n/N_2$$

These expressions can also be derived by a direct identification of $\bar{\zeta}_2$ with $\bar{\zeta}_1$ at the N_2 points of the boundary C_{12}, and by applying a classical Fourier analysis.

It is known from the theory of spectral analysis that the sampling of the periodic function $\bar{\zeta}_1(\theta)$ at discrete points leads to a parasitic effect on the associated Fourier spectrum, so that it would be unrealistic to extend the application of (21) and (23) beyond a limiting value $m = N_2/2$. The order N_s of the finite series expansion used in practice is moreover dependent on the accuracy assigned in the numerical calculations. The latter criterion leads to a dependance of N_s on the value of the parameter kR_2.

It is seen from (23) that $\bar{\zeta}_2$ and its normal derivative along C_{12} are linearly dependent on the value of $\bar{\zeta}_1$ at the N_2 nodes located on this boundary:

$$\bar{\zeta}_2 = \sum_{p=1}^{N_2} \lambda_{2p}(\theta)\, \bar{\zeta}_{1p} \qquad M \in C_{12} \tag{24}$$

$$\frac{\partial \bar{\zeta}_2}{\partial n_2} = \sum_{p=1}^{N_2} \mu_{2p}(\theta)\, \bar{\zeta}_{1p} + \nu_2(\theta)$$

Calculations that will not be given in detail here, lead to the following expressions:

$$\lambda_{2p}(\theta) = \frac{1}{N_2} \sum_{m=0}^{N_s} \varepsilon_m \cos m\,(\theta - \theta_p)$$

$$\mu_{2p}(\theta) = -\frac{k}{N_2} \sum_{m=0}^{N_s} \varepsilon_m P_m(kR_2) \cos m\,(\theta - \theta_p) \tag{25}$$

$$\nu_2(\theta) = \frac{2a_0}{\pi R_2} \sum_{m=0}^{N_s} \frac{\varepsilon_m}{H_m} (i)^{m+1} \cos m(\theta - \alpha)$$

$$P_m(u) = \frac{H_m^{(1)\prime}(u)}{H_m^{(1)}(u)}$$

where the prime stands for the first derivative of the function considered.

Within the domain D_1, the problem is solved by a standard finite element technique. The solution and its spatial derivatives are represented by expressions of the form:

$$\bar{\zeta}_1(x,y) = \sum_n \gamma_n(x,y) \bar{\zeta}_{1n} \tag{26}$$

$$\frac{\partial \bar{\zeta}_1}{\partial x} = \sum_n \gamma_{xn}\, \bar{\zeta}_{1n} \qquad ; \frac{\partial \bar{\zeta}_1}{\partial y} = \sum_n \gamma_{yn}\, \bar{\zeta}_{1n}$$

where the summation extends over the whole set of finite elements, γ_n is an arbitrarily chosen interpolation function, depending on the type of discretisation and on the number of degrees of freedom within each element, and γ_{xn}, γ_{yn} are its spatial derivatives. Zero order continuity is generally sufficient for this class of partial differential equations.

By insertion of (24) and (26) into (17), we obtain:

$$F_c(\bar{\zeta}_1) = \sum_n \left[\sum_m A_{mn}\, \bar{\zeta}_{1m}\, \bar{\zeta}^*_{1n} + \sum_p B_{pn}\, \bar{\zeta}_{1p}\, \bar{\zeta}^*_{1n} + E_n\, \bar{\zeta}^*_{1n} \right] \tag{27}$$

$$A_{mn} = \iint_{D1} \left[h(\gamma_{xm}\,\gamma_{xn} + \gamma_{ym}\,\gamma_{yn}) - \frac{\omega^2}{g}\,\gamma_m\,\gamma_n \right] ds$$

$$B_{pn} = \int_{C_{12}} h\,\mu_{2p}\,\lambda_{2n}\, d\sigma \qquad ; \quad E_n = \int_{C_{12}} h\,\nu_2\,\lambda_{2n}\, d\sigma \tag{28}$$

The summation with index m includes all finite elements which involve node n, and the summation with index p includes all nodes located on the boundary C_{12}, whenever node n is itself located on this boundary. The term E_n, as well, is involved only in the latter situation.

From the previous results, we obtain for the coefficients B_{pn} and E_n:

$$B_{pn} = -\frac{2\pi k R_2 h_0}{N_2^2} \sum_{m=0}^{N_s} \varepsilon_m\, P_m(kR_2)\, \cos m\,(\Theta_p - \Theta_n)$$

$$E_n = \frac{4a_0 h_0}{N_2} \sum_{m=0}^{N_s} \frac{\varepsilon_m}{H_m}\, (i)^{m+1}\, \cos m\,(\alpha - \Theta n) \tag{29}$$

The conditions (20) then lead to the system of linear equations with N complex unknowns $\bar{\zeta}_{1n}$:

$$\sum_m A_{mn}\, \bar{\zeta}_{1m} + \sum_p B_{pn}\, \bar{\zeta}_{1p} = -E_n \qquad n = 1,2 \ldots N \tag{30}$$

The matrix of this system has a banded structure and symmetric coefficients, as can be seen from (28) for A_{mn} and (29) for B_{pn}. Moreover, all nodes which do not belong to the boundary C_{12} are associated with real coefficients. Substantial savings in core memory requirements and in computer time are obtained by taking account of these properties in the implementation of the method.

SOLUTION FOR A SHORE-CONNECTED HARBOUR

In the case of a shore-connected harbour, with a rectilinear coastline bounding D_2, $\bar{\zeta}_D$ is an even function of Θ, which can be represented by (21) with only cosine terms present. The same method then gives:

$$\varpi_{1m} = \frac{\varepsilon_m}{N_2 H_m} \sum_{p=0}^{N_2} \bar{\zeta}_{1p}\, \chi_p \cos \Theta_{mp} - 2a_0 (i)^m \frac{\varepsilon_m}{H_m} J_m(kR_2) \cos m\alpha \tag{31}$$

$$\Theta_n = \pi n / N_2 \qquad ; \quad \chi_p = \begin{cases} 0{,}5 & p = 0 \text{ or } N_2 \\ 1 & p = 1,2,\ldots N_2 - 1 \end{cases}$$

For the reason indicated above, the order N_s of the finite Fourier series should not exceed the value $m = N_2$, assuming that $\bar{\zeta}_1$ is defined at N_2+1 nodes C_{12}. The formula (31) leads to expressions of $\bar{\zeta}_2$ and of its normal derivative along C_{12} which are similar to (24), with the index p starting from zero.

We thus obtain a system of linear equations similar to (30), with the coefficients specified in (28). The expressions of B_{pn} and E_n derived from (31) are:

$$B_{pn} = -\chi_p \chi_n \frac{\pi k R_2 h_0}{N_2^2} \sum_{m=0}^{N_s} \varepsilon_m P_m(kR_2) \cos m\Theta_p \cos m\Theta_n$$

$$E_n = \frac{4a_0 h_0}{N_2} \chi_n \sum_{m=0}^{N_s} \frac{\varepsilon_m}{H_m} (i)^{m+1} \cos m\alpha \cos m\Theta_n \qquad (32)$$

The matrix of this system has the same general properties described for the preceding case.

FLOW AROUND THIN STRUCTURES

It is possible to account for the singularity of flow around the end of thin structures with the same method by introducing subdomains of circular shape D_3 at the tip, as shown in figure 1b. The functional F_c then involves additional integral expressions, in terms of N_3+1 unknown values of $\bar{\zeta}_1$ along the boundary C_{13} of these subdomains D_3:

$$F_c(\bar{\zeta}) = \iint_{D_1} \left[h \nabla \bar{\zeta}_1 \cdot \nabla \bar{\zeta}_1^* - \frac{\omega^2}{g} \bar{\zeta}_1 \bar{\zeta}_1^* \right] ds + \int_{C_{12}} h \frac{\partial \bar{\zeta}_2}{\partial n_2} \bar{\zeta}_2^* \, d\sigma$$

$$+ \int_{C_{13}} h \frac{\partial \bar{\zeta}_3}{\partial n_3} \bar{\zeta}_3^* \, d\sigma \qquad (33)$$

Since the solution of (3) within D_3 should have a finite value at the tip of the structure, its series expansion is of the form:

$$\bar{\zeta}_3(r,\psi) = \sum_{m=0}^{\infty} \rho_m J_{m/2}(kr) \cos \frac{m}{2} \psi \qquad (34)$$

where (r,ψ) is here a local polar coordinate system, with its origin at the tip, and its reference axis aligned with the structure centerline, and $J_{m/2}$ is the Bessel function of fractional order m/2.

Along C_{13}, $\bar{\zeta}_3$ and its normal derivative take a form similar to (24).

Insertion of this into the last integral of (33) provides additional terms in (27) and finally leads to the following system:

$$\sum_m A_{mn}\,\bar{\zeta}_{1m} + \sum_p B_{pn}\,\bar{\zeta}_{1p} + \sum_q D_{qn}\bar{\zeta}_{1q} = -E_n \qquad n = 1,2\ldots N \qquad (35)$$

with:

$$D_{qn} = \int_{C_{13}} h\mu_{3q}\,\lambda_{3n}\,d\sigma$$

$$D_{qn} = \chi_q \chi_n \frac{2\pi k R_3 h_3}{N_3^2} \sum_{m=0}^{N_s} \varepsilon_m\, Q_m\,(kR_3)\cos\frac{m}{2}\psi_q \cos\frac{m}{2}\psi_n \qquad (36)$$

$$Q_m(u) = J'_{m/2}(u)/J_{m/2}(u) \qquad ;\ \psi_n = 2\pi n/N_3$$

In (35), the summation with index q includes all nodes belonging to the boundary C_{13}, whenever node n is itself located on this boundary. The additional coefficients D_{qn} appearing in the matrix of the system are real and symmetric, as can be seen from (36). Thus, the inclusion of subdomains, such as D_3, within D_1 does not require any modification as concerns the numerical resolution of the system.

EXAMPLES OF APPLICATION

Several examples of application of the method will be given here. The first four cases are related to structures and harbours of simple geometry in constant water depth, for which results of other numerical methods and experimental investigations are available in the literature. The last example refers to an actual harbour project study, carried out by Sogreah, in which a complex harbour lay-out and a variable water depth are considered.

Wave diffraction by a circular cylinder

Figure 2a shows the finite element numerical model adopted for the analysis of the wave diffraction pattern around a cylindrical structure of circular shape, of radius R_0, subject to a plane incident wave.

The variation of the calculated relative wave height along the cylinder, for different values of the adimensional parameter kR_0, is shown in figure 3, where it is compared to the analytical solution of Mac Camy and Fuchs [7]. The agreement between both methods is satisfactory.

Figure 4a gives for $kR_0=1$, the spatial distribution of the relative wave height in the whole domain D_1, in the form of level curves.

Figure 4b gives the corresponding water surface level, at the instant of maximum elevation at the most exposed part of the cylinder. In the same

figure are given the direction and length of the major and minor axes of the water particle horizontal displacements and hodographs, which are generally of elliptical form, as shown by the author in [4].

Seiche motions in a rectangular harbour

The second example is the study of resonant wave oscillations in a shore-connected rectangular harbour, with a width to length ratio W/L=0.2, and fully open on its narrow side, as shown in figure 2b. This situation was studied both experimentally and theoretically by Ippen and Goda [5], and by Lee [6], with a ratio W/L=0.193.

Figure 5 gives the frequency response obtained by these various approaches at the back wall of the harbour. The results obtained by the present method agree well with Ippen and Goda's and Lee's analytical solutions, which take explicitly account of the rectangular shape of the harbour. The results obtained by Bettess and Zienkiewicz [2] and by Chen and Mei [3], which are not shown here, also agree with the above results.

The experimental results and Lee's arbitrary shaped harbour theory, based on a boundary integral approach, agree with the other methods for the second mode of resonance, but give a noticeably lower amplification factor for the first mode. Ippen and Goda suggest that this could be due to energy dissipation, since experiments where actually performed with short waves of high steepness. It has not been investigated whether a refinement of the finite element network would improve the agreement with those experimental results.

Case of a partially closed square harbour

The case of a square harbour, partially closed by two thin aligned breakwaters, is given for illustrating the use of circular subdomains D_3 around the tip of harbour structures, as shown in figure 2c.

Figure 6 compares the numerical results obtained by the present method with Ippen and Goda's analytical solution and with their experimental results for an entrance width to harbour lehgth ratio W/L=0.5. The agreement between the different methods is very close.

Case of a circular harbour

The case of a shore-connected circular harbour with a 60° opening is an application involving more complex resonant nodes, which has been investigated both experimentally and theoretically by Lee [6].

Figure 7 gives the frequency response calculated at two different locations with the numerical model shown in figure 2d, together with the results of Lee's investigation.

Figure 8 shows the features of the first four resonant modes, which are obtained for kR_0=0.51, 2.21, 3.43 and 4.09 approximately, with the present method. The water surface elevation is indicated by means of level curves,

corresponding to given percentages of the maximum elevation. The instant taken as reference is that of maximum elevation at the point of highest amplification.

The direction and length of the major and minor axes of the horizontal water particle displacements and velocities are given on the same figure at the centroid of each finite element. The wave motion has essentially the character of purely standing waves in a great part of the harbour, and the water particles horizontal motion is practically rectilinear and oriented in the direction of the local amplitude gradient. This is not the case for particles located near the entrance, either within or outside the harbour, which have elliptical horizontal trajectories.

The resonant modes calculated by Lee are similar to the above. From the frequency response curve of the mean velocity at the harbour entrance, the values of kR_0 corresponding to resonance where found by Lee, to be 0.50, 2.18, 3.38 and 3.97. These figures agree to within 3% with these of the present model.

Case of a harbour of complex shape and variable water depth

Because of accuracy requirements, the maximum size of the finite elements should stay below a certain fraction of the local wave length, which depends on the type of spatial discretisation and interpolation functions used for $\bar{\zeta}$. With triangular elements and linear interpolation, for instance, this limit is of the order of 0.1. In the case of a harbour of variable water depth, the size of the finite elements will thus be dependent on the distribution of water depths to be considered.

Figure 9 is an example of application of the method to a harbour of complex shape and bottom topography (from 2 m to 15 m below MSL), with two main breakwaters extending offshore to protect the entrance channel. This model was set up for the study of the new Damietta Port Project in Egypt.

Figure 10 shows the frequency response curve obtained for one of the reference calculation points, which displays a great number of resonance frequencies. An in-depth investigation of each resonant mode was carried out on the basis of such results.

Figure 11 shows the features of one of the resonant modes of this harbour, in the form described for the circular harbour, i.e., level curves of water surface elevation and major and minor axis length and direction of horizontal water motion.

CONCLUSION

The present method leads to a system of linear equations, with symmetric coefficients, in which the only unknowns are the values of the complex function $\bar{\zeta}$ at nodes distributed within the bounded domain D_1, and along its boundary. In the other hybrid-element methods a larger system is obtained with additional unknowns, which are the Fourier coefficients ϖ_{1m}, ϖ_{2m} in Chen and Mei's method, the normal derivatives in Sakai and Tsukioka's method, the source strengths in Berkhoff's method, and the ζ_1, or velocity potential values, at nodes distributed along infinite elements in Bettess and Zienkiewicz's method.

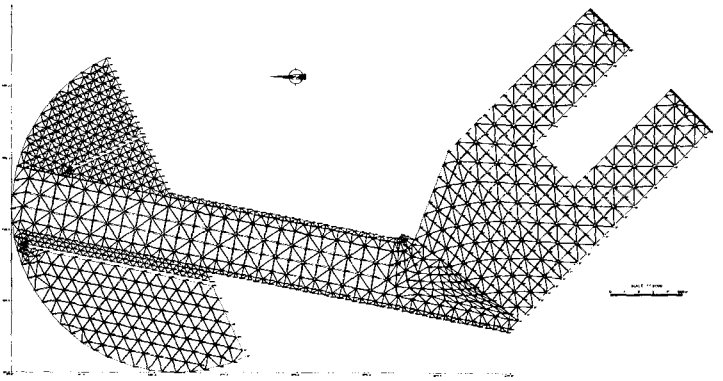

Fig. 9 - Numerical model set up for the study of seiche motions in the new Damietta industrial harbour (Egypt).

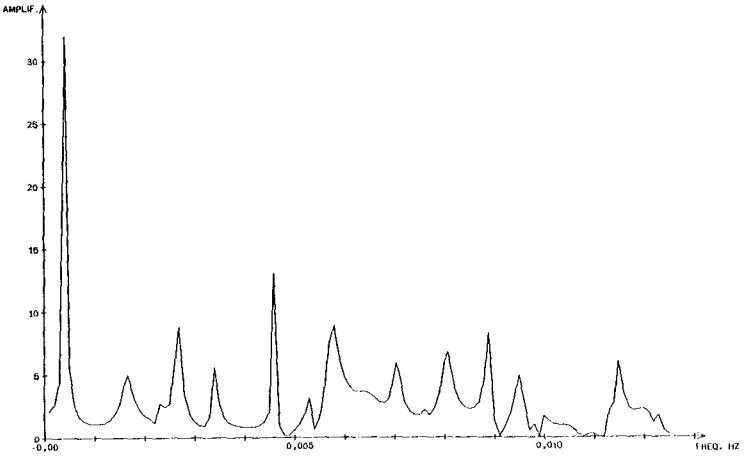

Fig. 10 - Frequency response curve at one of the reference nodes of the Damietta harbour model

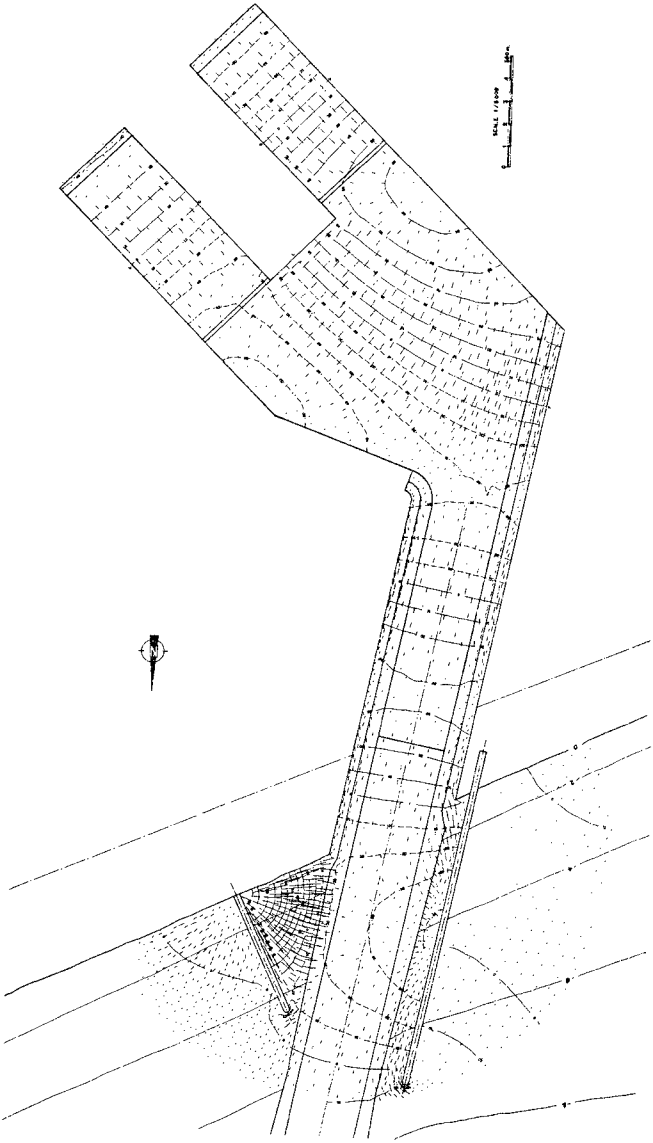

Fig. 11 - Water surface elevation and horizontal displacements for one of the resonant modes of the Damietta harbour model.

The present method is based on the same analytical representation of ζ in the outer domain D_2, as in Chen and Mei's approach. However, here an explicit formulation of ϖ_{1m}, ϖ_{2m} in terms of the incident wave characteristics and of the unknown values of $\bar{\zeta}_1$ along C_{12}, is given. This method is preferable to the matrix inversion technique used by the above authors. Another advantage of the method is the simplicity of form of the functional $F_c(\bar{\zeta})$ involved in (17) and (33), as compared to Chen and Mei's formulation.

The method, presented here in connection with studies of long wave oscillations in harbours, can be applied, with only minor changes as concerns the treatment of domain D_1, to the study of wave oscillations in the short and intermediate period range. It can also be extended to include energy dissipation and partial reflection along the shore and harbour structures.

The application of the present method to various situations for which other theoretical and experimental investigations have been carried out, has led to numerical results in good agreement with the above methods.

STATE OF THE ART IN TIDE PREDICTIONS

B. D. Zetler*

ABSTRACT

1. INTRODUCTION

By the end of the nineteenth century, scientists had succeeded in achieving the ability to make reasonably accurate tide predictions by the harmonic method (Schureman, 1941). Except for the building of larger and more sophisticated mechanical tide prediction machines using the harmonic technique, tidal mathematicians more or less rested on their laurels during the first half of the twentieth century; indeed, many scientists assumed there was no need for further tidal research. It is ironic that one of the very few geophysical sciences that already had acceptable methods of prediction should become the subject of significant improvement during the last half of this century. These improvements include: 1) least square analysis for all tidal constituents simultaneously, 2) response analysis and prediction, 3) extended harmonic analysis, 4) tidal measurements in deep water on the ocean floor, and 5) global numerical models of tides.

2. AIMS AND OBJECTIVES

The harmonic method of tide prediction is purely empirical, using predetermined tidal frequencies related to known astronomical and meteorological periods. It separates an observed time series of water level heights into a set of cosine curves, and then predicts by synthesizing the same curves for a future period. There is little geophysical enlightenment implicit in the procedure. Extended harmonic analysis increases the number of frequencies being considered; the previous limit was related to the use of a mechanical prediction machine, no longer a consideration since the advent of modern electronic computers. Although response analysis improves the accuracy of tidal predictions only slightly, it greatly enhances geophysical interpretation of the results, for the first time separating astronomical and radiational (meteorological) contributions. Pelagic (sea floor) tide data are necessary for global interpretations of tides, particularly for numerical modelers who combine sea-floor bathymetry with Laplace's tidal equations to produce cotidal and co-range charts for particular frequencies.

3. TECHNIQUES

To a large extent, most of the progress noted here has been made possible by the availability of fast electronic computers with large memory capacities.

3.1 Least square analysis.

Analysis of tidal data for n tidal frequencies requires a matrix solution of $(2n+1)$ normal equations, an impossible task 25 years ago, almost trivial today. This has become the usual harmonic method for a long series at many tidal institutions, (Zetler *et al.*, 1965).

3.2 Response analysis.

This uses as input functions the time-variable spherical harmonics of the gravitational potential and of radiant flux on the earth's surface; it computes complex weights for an observed series that are used for future predictions and for computing admittances, (Munk and Cartwright, 1966). At this time, it is primarily a research tool used to optimize geophysical interpretations.

* Scripps Institution of Oceanography, U.S.A.

3.3 Extended harmonic analysis.

This is an extension of (3.1) using many more tidal frequencies for extremely nonlinear tides, (Zetler and Cummings, 1967). If the matrices become too large, it is satisfactory to group constituents by species rather than solving for all simultaneously.

3.4 Pelagic tides.

The ability to accurately measure tides in deep water on the sea floor is a development of the last two decades. A recently published global compendium of tidal harmonic constants for pelagic stations contains information for more than a hundred places, (Cartwright *et al.*, 1979).

3.5 Numerical modeling of tides.

Solutions of Laplace's tidal equations now include energy dissipation, ocean shelf-attraction and the solid earth yielding to the weight of the oceanic tidal column. Some solutions for the principal tidal frequencies are reasonably accurate, (Hendershott, 1973).

4. RESULTS

The methods described in the previous section are to a large extent completed research and the application of these improvements depends largely on economic considerations.

5. RECOMMENDATIONS

The significant improvements described follow a half-century of depending on a methodology achieved by the end of the nineteenth century. Inasmuch as the various traditional tide manuals have not been updated to encompass these developments, this paper may be a useful interim guide to the changes.

INTRODUCTION

In populated areas where tides are important, local predictions have been published in newspapers for as long as living people remember; their availability is taken as much for granted as times of sunrise and sunset. For the most part, their accuracy is also unquestioned, although the public is aware that during storms and hurricanes "tides" much higher, and occasionally lower, than normal (i.e., predicted) may occur.

Although we know that tides result primarily from the tide-producing forces of the moon and sun acting upon the rotating earth, our knowledge of the dynamics of ocean and estuarine tides needs significant improvement; empirical procedures developed in the nineteenth century make it possible to prepare reasonably good tide predictions for any location provided that tide observations have obtained at that place in the past and the local sea-floor topography remains unchanged. It is a tribute to many scientists, in particular Sir William Thomson (later Lord Kelvin) and George Howard Darwin in England and William Ferrel and Rollin A. Harris in the United States, that the state of the art in tide predictions reached so high a plateau in the early twentieth century that significant improvements were not achieved for a half-century.

Although the Coast and Geodetic Survey (now called the National Ocean Survey) celebrated its centenary of published tide predictions in 1968, the Coast Survey had been supplying navigators with information from which they could prepare their own predictions as far back as 1844. This was done by including mean high-water lunitidal intervals (the interval between the moon's upper or lower transit over the local meridian and the following high water) and tidal ranges on the Survey's nautical charts. A published method for improving the crude predictions (presumably derived from John Lubbock's research in England in the 1830's) provided corrections for the effects of the phase of the moon and the declination and parallax of the moon and sun. However, the correlation between some tidal and lunar parameters were known and used long before the time of Newton.

Later in the nineteenth century, Thomson and Darwin developed the harmonic method of analyzing and predicting tides. The method uses sinusoids (tidal constituents) whose frequencies, derived from astronomic observations, are sums and differences of six basic frequencies in

the motions of the earth, moon, and sun: the day, month, year, 8.9 years (lunar perigee), 18.6 years (lunar nodes), and 21,000 years (solar perigee). The amplitude and phase lag behind a theoretical (equilibrium) tide for each constituent are obtained by analysis; a prediction synthesizes the same curves for same future period. The distortion of tides as they move into shallow water is simulated by analyzing for frequencies that are harmonics of the fundamental frequencies or combinations of these.

Sir William Thomson made the first tide-predicting machine in 1873 under the auspices of the British Association for the Advancement of Science; it summed 10 constituents and automatically traced a curve showing the predicted heights. This country's first mechanical tide prediction machine (19 constituents) was designed by William Ferrel of the Coast and Geodetic Survey. The machine, introduced in 1885, provided for times and heights of high and low tides to be read directly from the dial indicators but did not produce a plotted prediction. An improved mechanical predictor for 37 constituents was completed by R.A. Harris and E.G. Fischer of the Coast and Geodetic Survey in 1910. This machine was the first to compute simultaneously the height of the tide and the times of high and low waters, the machine automatically stopping to allow the information to be read from dials. It also produced a continuous plot with time marks for each hour, maximum and minimum. Although the 37 incommensurable curves summed by the machine range from one cycle per year to eight cycles per lunar day (24.8 h), no constituent accumulated a phase error greater than 2 degrees in a year's predictions, a remarkable achievement in designing and fabricating the gear system.

FIGURE 1. First U.S. tide-predicting machine, used 1885-1911.

FIGURE 2. Second U.S. tide-predicting machine, used 1912-1965.

For many North Sea locations, combinations of the customary shallow- water constituents cannot adequately reproduce the shape of the observed tides. Horn in Germany and Doodson in England developed nonharmonic procedures for empirically correcting predictions to improve the accuracy of published tables.

RECENT CHANGES

Rapid proliferation and improvements in electronic computers in the middle of this century finally ended the long status quo in the state of the art for tide predictions. Although the Coast and Geodetic Survey tide predictor withstood the first assault when predictions on an IBM 650 were found to take longer than on the half-century-old machine, its victory was short

lived, and by 1965 it had become a museum piece. A similar change took place at about the same time in England, but Kelvin mechanical tide-predictors may still be in use in some countries.

There were advantages other than speed and efficiency in shifting to electronic computers for tide prediction. As long as the fixed gearing of the mechanical predictor was limited to a finite set of particular constituents, research demonstrating the importance of other constituents had a low priority. Although there were sentimental regrets at replacing such a fine instrument, it was a distinct relief no longer to be dependent on the one machine; it was known to be wearing out, but, even worse, there was a fear of sabotage, particularly during war years.

In addition to the direct application of electronic computers to tide predictions, computer availability made possible more detailed analyses (for example, studies of 50 years of hourly heights, roughly a half million values) and digital recording (thus enhancing the state of the art for tide gauges as well as making possible more tide observations by reducing the manpower needs in data processing). Soon thereafter, dramatic advances were achieved in numerical modeling of tides, permitting for the first time research into the physics of tide generation in the world's oceans. Some of these advances have already contributed to improved predictions, and others will do so in the future.

It seems logical to group these recent improvements as follows:

A. *Data Analysis*

1. Change in harmonic analysis procedure. The traditional analysis in the Coast and Geodetic Survey (now the National Ocean Survey) solves for each constituent separately by a procedure that tries to emulate what would be achieved by cutting the marigram (tide record) into constituent periods (for example, every 25.82 h for O_1, a principal lunar diurnal constituent), piling the cut sections vertically and averaging a mean curve for the constituent period through the pile (Schureman, 1941). By means of stencil overlays, hourly heights (solar time) are identified as constituent hours (with errors not exceeding 0.5 h and algebraically averaging near zero), and then a Fourier analysis for the constituent frequency and possibly some harmonics is made of the constituent hourly means. An augmenting factor is applied to the amplitude to correct for a small reduction caused by using solar rather than constituent hours. Because it is impossible to have a finite length of observations that is commensurable for all tidal frequencies, the length of record chosen for Fourier analysis minimizes but does not completely remove the effect of interfering constituents. This effect is removed to a large extent by a further process called "elimination." In theory, repetitive elimination would refine the results even more, but this was not found necessary.

It is far more direct to solve for all constituents simultaneously, obtaining the complex amplitudes of cosine curves for each constituent that minimize the residuals in a least-square sense. For n constituents, we solve for $2n + 1$ coefficients (including the mean term) and then obtain the harmonic constants (amplitude and phase lag for each constituent) by simple trigonometry. For 37 constituents, a 75×75 matrix could not be solved without very large computers, and hence this approach was unthinkable until recent times. The procedure has been found to be more accurate for one-year analysis than the traditional methods, and it is now used in the National Ocean Survey (NOS) in this country and by the tidal authority in the United Kingdom, the Bidston Observatory of the Institute of Oceanographic Sciences. The process does not require equally spaced data (in the time sense) and will work with data in random time, although the software is more complicated as each data point must be identified in time (Zetler *et al.*, 1965). Comparative tests of the traditional and least-squares analysis procedures for 29-day series (approximate synodic period for phase, parallax, and declination of the moon) disclosed no advantage in the newer method; therefore the classical procedure has been retained in NOS, but the procedure has been modernized (in particular, stencil summing has been done away with). In 29-day analysis only K_1 and O_1 and M_2,S_2, and N_2 can ordinarily be resolved for species 1 and 2 (1 and 2 cycles per day, respectively).* Because the classical

*Principal tidal constituents: K_1 is lunisolar diurnal, O_1 is lunar diurnal, M_2 and N_2 are lunar semidiurnal, and S_2 is solar semidiurnal.

method infers the effect of other disturbing constituents in the elimination process, this probably gives it an advantage over the straightforward least-square analysis for the five constituents that offsets the improvements implicit in the latter process.

2. Extended harmonic analysis. Once tidal predictions were no longer constrained to a finite set of constituents, the door was opened to improving shallow-water predictions by adding additional compound tides (integral sums and differences of principal constituents). Two independent studies used 114 constituents with frequencies up to 12 cycles per day to improve predictions for Anchorage (Alaska) and for the Thames estuary (Zetler and Cummings, 1967; Rossiter and Lennon, 1968). Solving for 114 constituents simultaneously would involve a 229 × 229 matrix; fortunately this is not necessary as it has been demonstrated that sidebands are important only within each species (thus K_1 sidebands do not affect M_2), and therefore the solution may be simplified by requiring only that any particular matrix include all constituents within a species. A.S. Franco (Instituto de Pesquisas Tecnologicas, Sao Paulo, Brazil) has recently developed another approach using a matrix of the Fourier coefficients within a species to solve for constituent harmonic constants including numerous compound tides.

3. Determination of the continuum. On occasion, Walter Munk has used the expression, "Noise exists everywhere but in textbooks on tides." He was referring to the tendency to look only at the tidal lines in the spectrum, disregarding the level of the continuum between the lines. In a plot of energy (or amplitude) versus frequency, the extent to which the value at a tidal line protrudes above the continuum is a measure of reliability of the tidal constants for the constituent. Over a period of a few years, Munk and various associates made a determined effort to evaluate the level of the continuum for a wide band of frequencies. Very sharp filters discriminating against tidal lines were used to establish the continuum between tidal species (Munk and Bullard 1963). Then it was demonstrated that if the noise level is sufficiently low, two tidal constituents can be resolved in a record of length shorter than their synodic period (Munk and Hasselmann, 1964). An extremely fine-resolution analysis in the low frequencies (0 to 0.75 cycle per day) showed the continuum decreasing monotonically in energy for higher frequencies and no significant peaks other than previously determined tidal constituents (Groves and Zetler, 1964). Finally cusps of energy were found between tidal groups (separations of 1 cycle per month) and even between tidal lines within a group (Munk *et al.*, 1965). The knowledge derived in these studies was particularly important in the development of response analysis and prediction (see below) and serves to establish a limit on the accuracy to which one may aspire for barotropic tide predictions in the open ocean.

4. Response analysis and prediction. For any linear system, a input function $\chi_m(t)$ and an output function $\chi_n(t)$ are related according to

$$\chi_n(t) = \int_{-\infty}^{\infty} \chi_m(t-\tau)\omega_{mn}(\tau)d\tau + \text{noise } (t) ,$$

where $\omega_{mn}(\tau)$ is the "impulse response" of the system, and its Fourier transform

$$Z_{mn}(f) = \int_{-\infty}^{\infty} \omega_{mn}(\tau)e^{-2\pi if\tau}d\tau = R_{mn}(f)e^{i\Phi mn(f)}$$

is the system admittance (coherent output/input) at frequency f.

Response tidal analysis and prediction (Munk and Cartwright, 1966) uses as input functions the time-variable spherical harmonics of the gravitational potential and of radiant flux† on the earth's surface. In practice, the integrals are replaced by summations; χ_m, ω, and Z are complex. The discrete set of ω values are termed response weights.

This method is the first successful major departure from the traditional solutions in which the tide oscillations are described by the amplitudes and phase lags for a finite set of predeter-

†A function designed to vary with the radiant energy falling on a unit surface in a unit time; it is related to daily atmospheric pressure and wind variations and to seasonal changes in ocean temperature.

mined frequencies. Subsequently it was recommended that response analysis of short records (about one month) of pelagic tidal measurements use a response prediction at a nearby coastal station as the reference series (Cartwright *et al.*, 1969). The calculation of traditional harmonic constants from response admittances made results of the two methods compatible (Zetler *et al.*, 1969). The optimum number of weights in response analysis depends directly on the length of record and inversely on noise level in a tidal band; more weights degrade the prediction and generate an artificial wiggliness in the admittance (Zetler and Munk, 1975). This study showed for the first time that better results are obtained by centering the lags to a potential retarded by the age of the tide‡ rather than to a potential centered on the prediction time.

SCOR* Working Group 27, "Tides of the Open Sea," conducted an analysis workshop in conjunction with an intercomparison of open sea tidal pressure sensors. The report (Unesco, 1975) shows a clear superiority for response procedures as compared with classical methods used by various national tidal groups. In addition to this statistical advantage, response analysis is more intellectually pleasing in that one uses the entire tide-producing potential rather than having arbitrarily to choose a finite set of tidal frequencies.

The ability to separate gravitational and radiational contributions to the tide resolves an unsatisfactory aspect of results from classical analysis. If one plots the phase angles or the amplitude admittances (ratio of analyzed to equilibrium amplitudes) from traditional analysis against frequency, one usually finds a sharp bend or even a discontinuity at S_2 (30°/solar hour). It is not reasonable that the ocean oceans should exhibit such abrupt changes, particularly always at the same frequency. The smoothness of the plots obtained for the gravitational admittances in Figure 3 (Zetler and Munk, 1975) using response procedures is undoubtedly due to the separation of radiational from gravitational inputs, whereas classical analysis produces combinations of the two.

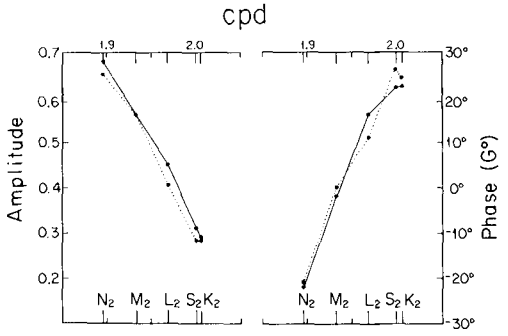

FIGURE 3. Amplitude and phase admittances for Bermuda referred to the gravitational potential. The solid lines are grav admittances from (grav and rad) response analysis; the dotted lines are admittances from traditional analysis. The response analysis was for three 355-day series over a 9-year period. The traditional analysis (1 year, 1934, IHB Spec. Pub. 26, #600) furnishes a lumped (vector) sum of grav and rad admittances.

‡The time interval between a maximum range in the equilibrium tide and a comparable range at a particular place. For example, equilibrium spring tides occur at new and full moon; in the ocean they occur 0.984 (S_2°−M_2°) hours later. There are comparable ages for maximum ranges related to perigee and to maximum declination of the moon.

*Scientific Committee on Ocean Research

B. *Numerical Modeling*

A cotidal chart is one showing an areal distribution of times of high tide for particular constituent relative to the equilibrium (theoretical) time of high tide for the same constituent. The cotidal lines, labeled in either solar or constituent hours, identify the locus of points at which high tide for the constituent occurs simultaneously. A feature of such maps is a system of nodal points, known as amphidromes, at which there is no vertical rise or fall. Some charts also include corange lines, contours of equal constituent amplitude. Near an amphidrome, corange lines tend to be concentric about the amphidrome with amplitudes increasing with distance from the zero amplitude point.

Historically, cotidal charts have been based on seaward extrapolation from coastal and island observations supplemented by general knowledge of how tides behave in mathematically described basins. Inasmuch as ocean tides are modified significantly in the continental coastal zones, use of coastal and, even worse, harbor and estuary observations make these ocean projections quite speculative. Nevertheless, until huge electronic computers became available, these empirical efforts were as good as could be done. In retrospect, some of the early cotidal charts have been found to be remarkably good and have served many useful purposes; those of Rollin Harris are outstanding examples of an advanced state of the art at the beginning of this century (Figure 4).

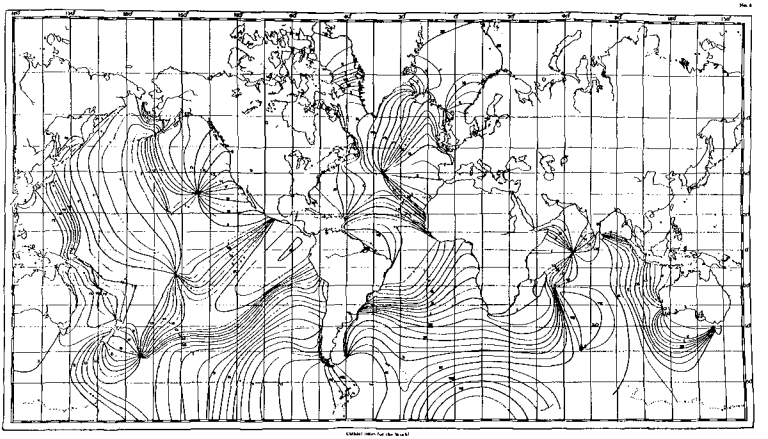

FIGURE 4. Harris cotidal chart for M_2.

In a parallel but quite different effort, hydrodynamicists have traditionally been concerned with solving the tidal equations developed by Laplace in 1775. Because of their complexities, various simplifying assumptions for hypothetical basins (such as flat bottom, boundaries, and stability) have been necessary (Hendershott and Munk, 1970). Although much has been learned in these earlier scientific efforts, the solutions have had little or nothing to do with tides in the real oceans. Realistic calculations require detailed bathymetry and boundaries, inconceivable before the advent of large electronic computers and marginal even today. When Pekeris presented a global solution for M_2 at an international meeting about 15 years ago, Joseph Proudman, a prominent tidal authority, commented that he had not anticipated seeing this degree of success in his lifetime.

A recent summary of the activities of SCOR Working Group 27, "Tides of the Open Sea" (Cartwright, 1975) noted various problems in numerical modeling of tides: "There are

numerous esoteric sub-problems concerning stability, mesh size, boundary and depth topography, friction, but the most important and difficult appear to be representation of energy losses at the boundaries of shallow seas and at places of steep topography where internal tides are generated, and the solution of the equations modified for a yielding Earth."

Hendershott's more recent numerical studies include energy dissipation, ocean self-attraction, and the solid earth yielding to the weight of the oceanic tidal column. Figure 5 is a recent M_2 cotidal chart by Hendershott and Parke. A description of other contemporary numerical tidal solutions (Hendershott, 1973) furnishes information on the tidal frequencies considered, boundary conditions, dissipation mechanisms (if any), and whether earth tides are considered

Thus, theoretical studies are now using real data in realistic ocean models. Solutions are improving; in particular, it appears that an amphidrome first identified in a numerical study is real. However, results indicate that many ocean areas are nearly resonant at semidiurnal

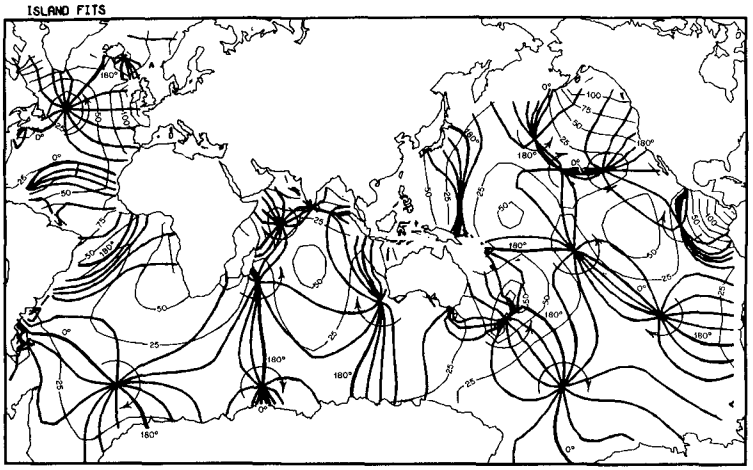

FIGURE 5. Hendershott and Parke cotidal and corange chart for M_2.

periods. As a result, a variation in mean depth of only several hundred meters may change the M_2 amplitude by a factor of 2 or 3. Furthermore, it has been found that changing the coastline slightly or refining the grid from a 2° to a 1° mesh changed the M_2 amplitude by as much as 3 m (Pekeris and Accad, 1969). This extreme sensitivity make it difficult to evaluate empirically the contribution of various parameters.

In the past, physical models of various estuaries have been built in order to determine the effect of proposed man-made structures on the tidal regime in the estuary. For example, the model of San Francisco Bay (built in Sausalito by the U. S. Army Corps of Engineers) has been used in studying the effect of proposed salinity barriers on the tide in the Bay. Garrett (1977) recently used a numerical model to study the effect of a proposed power-generating system in the Bay of Fundy, with the large ranges of tide as the energy source. Ordinarily one would expect such a utilization to diminish the tidal range and would need to consider the economic consequences of the anticipated change. However, Garrett found the resonant peak of the basin to be only slightly higher than the M_2 frequency (thus accounting for large tides) and that the proposed structure would reduce the resonant frequency, bringing it even closer to the M_2 frequency, and so would lead to very little, if any, reduction in amplitude.

C. *Recording*

Pelagic pressure sensors, capable of measuring the tide on the sea floor in the deep parts of the oceans are an important technological development in recent years (Unesco, 1975). Pioneered by Frank Snodgrass at Scripps Institution of Oceanography and Marc Eyries in France, the state of the art has rapidly advanced to the point that only financial considerations deter us from obtaining the global grid of tide observations needed for an optimum set of cotidal and corange charts. A recently published global compendium of tidal harmonic constant for pelagic stations contains information for more than a hundred places, (Cartwright *et al.*, 1979).

In the Unesco report on an international intercomparison of open-sea tidal-pressure sensors, five types of sensor were found to intercalibrate closely (Unesco, 1975). Among the several mooring techniques used in the experiment, the self-contained acoustic "pop-up" unit showed a clear superiority. In the MODE (Mid-Ocean Dynamics Experiment) exercise, tidal data were obtained for the first time from an array of pressure sensors on the sea floor. Figure 6 shows that the phase angles obtained for MODE stations match Dietrich's M_2 and K_1 cotidal charts well (Zetler *et al.*, 1975). The M_2 tidal currents inferred from the gradients of observed

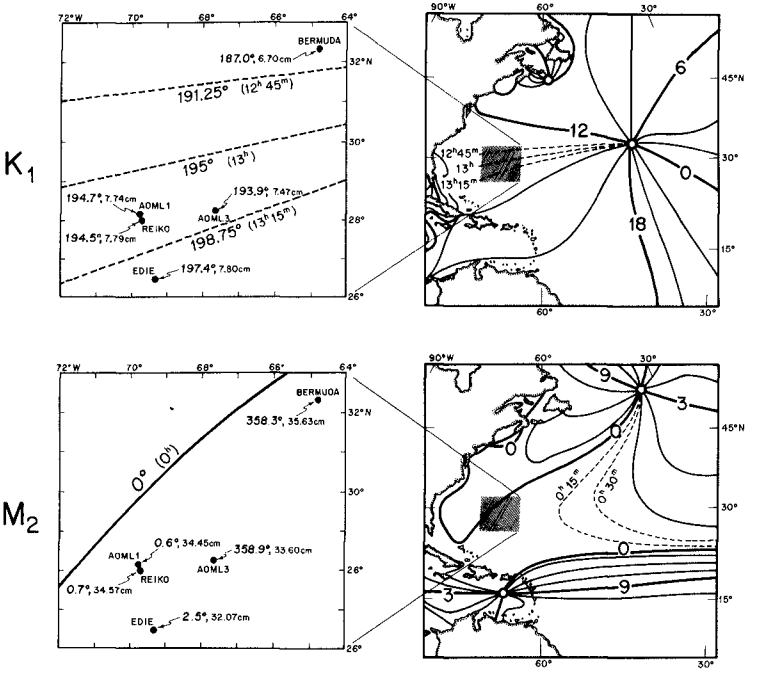

FIGURE 6. Right panels show Dietrich's (1944) cotidal lines in the North Atlantic for K_1 and M_2 tides, respectively. Values are in solar hours, with dashed curves designating interpolation by Zetler *et al.*, (1975). The MODE area falls within the shaded square, which is shown on an enlarged scale in the left panels, for comparison with the results at MODE stations (·).

pressures fit the barotropic component of the observed tidal currents reasonably well; the latter also contain large baroclinic components, whereas the small baroclinic contributions to the pressure gradients have been further reduced because the station spacings are roughly comparable to the baroclinic wavelength.

Numerical modelers have recommended observations at "antiamphidromes" (locations of maximum tidal amplitude) in order to calibrate their results. Furthermore, to work with intermediate scale models (portions of the world's oceans), because of the need for more dense topographic grids, they will need tidal observations at the boundaries of sections in the open ocean. The technology for this is now available, and some programs along these lines are already under way at the Institute of Oceanographic Sciences in England.

Time has passed by the 2000 or so conventional tide gauges used throughout the world; there have been few changes since Lord Kelvin argued the case for using a pencil before the Institution of Civil Engineers in 1882. The gauges continue to measure the height of a float in a stilling well (cylinder with a small orifice near the bottom to filter out wind waves). The only significant change has been the utilization of digital recording on magnetic and punched paper tape; these have significantly reduced tabulation and analysis costs, making it possible to obtain and process more observations with available resources.

CONCLUSION

Subsequent to the preparation of the abstract, a new publication (Zetler, 1982) describes modifications to the computing processes for tide analysis and prediction at the U.S. National Ocean Survey. This publication serves as a supplement to various National Ocean Survey manuals, in particular to Schureman (1941).

AUTOMATED DIGITAL SIMULATION OF TIDES & LONG WAVES

R.F. Henry*

Abstract

A system for indirect programming of shallow-water models is discussed, particular attention being given to facilitating successful operation by novice users. Pre-developed programs are used to check numerical coding of model layout, to execute the finite-difference computations required at each time step and to analyse the computed surface elevations and velocities. Many error-prone steps are thus eliminated and model development is speeded for modest increase in computation costs.

1. Introduction

This paper describes a method which simplifies development of numerical models of long-wave phenomena such as tides, tsunamis and storm surges. The irregular geometry of most coastal seas complicates the programming of numerical models severely, even for the simplest finite-difference representations of the governing shallow-water equations. The principal aim of the system of programs described here is to automate the detailed programming steps necessary to fit a finite-difference scheme to a particular coast. The availability of such programs permits even an inexperienced programmer to develop a working model quickly and, at the subsequent calibration and verification stages, allows experimental changes, such as relocation of boundaries, to be made rapidly without extensive debugging checks. The modeller is thus freed from programming difficulties and delays and is able to concentrate on scientific aspects of the work.

The basic concept used is that, after a suitable grid has been laid out to cover the coast in question, instead of programming the specific computational steps necessary for each variable on the grid, a numerical code is assigned to each variable to indicate the nature of that point and the type of calculation to be carried out there at each time step. In this way the task of programming the finite-difference calculations is split into two distinct stages,

a) numerical coding of coastline layout
b) development of a general time-stepping subroutine, which, given the corresponding code, performs the computation required at each grid-point under the particular finite-difference scheme adopted.

The advantage of this approach is that step b) has to be tackled

* Institute of Ocean Sciences, Sidney, B.C., Canada.

only once for a particular finite-difference scheme, and when the time-stepping subroutine has been fully checked out, a major source of programming errors is eliminated from all models employing it subsequently. Provided that the same governing equations hold, only stage a) has to be carried out when a new model is developed and as shown later, a graphical checking procedure can be used to ensure that no errors are made at that stage.

Leendertse (1967) used numerical coding to specify location of model boundaries but Heaps (1969) seems to have been first to perform all computations on the grid indirectly via numerical codes. Abbott, Damsgaard and Rodenhuis (1973) announced an extensive proprietary software package for indirect programming of shallow-water models, but limited information about this system and its later developments has appeared in the open literature. The work described in the present paper essentially extends Heaps' method, increasing the practicability by using a simpler grid, by breaking the coding process down into stages of which only the simplest has to be carried out by the user and by providing graphical means for checking the coding. The result is a set of programs, which can be used easily in 'black-box' fashion by inexperienced programmers but which are straightforward enough to be altered fairly readily by more experienced users to suit special requirements.

Unfortunately, the combination of grid and difference-scheme used by Heaps proves rather cumbersome for indirect programming. Because both components are defined at all velocity-points, 19 distinct types of velocity point are possible, even though only two types of boundary are permitted. This complexity makes it difficult to code the model geometry correctly. The Richardson grid (Figure 1) used here is better suited to indirect programming, as far fewer distinct configurations can occur at boundaries. This has facilitated development of a plotting program to permit visual checking of coded model layout. A plot of the model boundaries is produced from the allotted numerical codes. Comparison with the original grid diagram then quickly reveals any errors in coding. If the model boundaries are altered during development, the revised layout can be checked similarly. This graphical feedback makes indirect programming considerably more practicable.

To summarize the procedure, the modeller is required to choose a Cartesian grid of suitable orientation, size and spacing for the water body in question and to provide a corresponding array of mean water depths. The position and nature of the various boundaries are then coded numerically as described later and the coding is checked visually using a pre-developed graphical program. The numerical model is then programmed, all the necessary finite-difference calculations being handled by a pre-developed time-stepping subroutine. The modeller must supply a subroutine which provides values of any time-dependent forces or boundary conditions influencing the water body.

A model programmed using this technique takes roughly 20% more computing time than an equivalent model in which the finite-difference equations are programmed specifically for the particular grid in

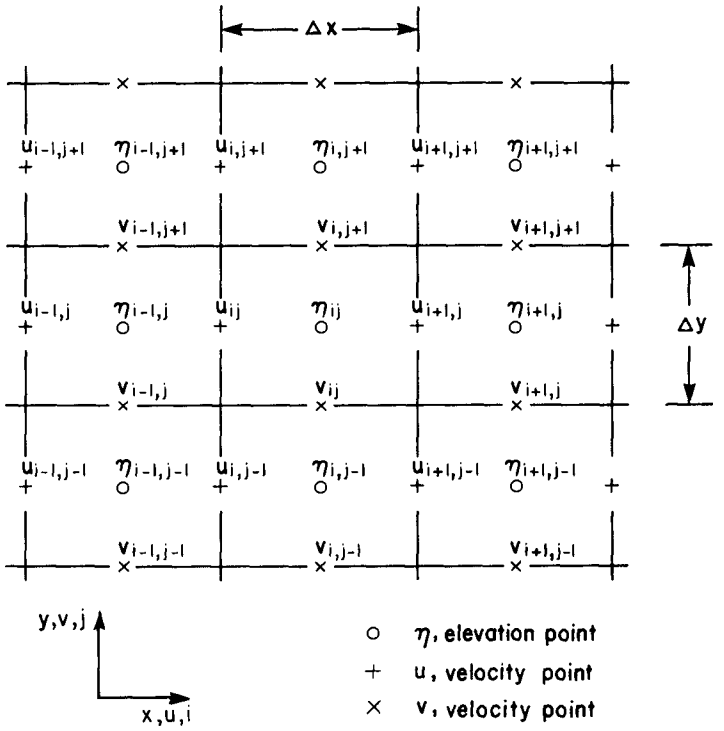

Fig. 1. The Richardson Grid

question, but the saving in initial programming effort and subsequent debugging time is substantial even for an inexperienced programmer. Memory requirements are increased by the need to store the code arrays required. Full details of the various programs which have been developed to implement the graphical and finite-difference operations discussed above are given in Henry (1982).

2. Governing Equations

The methods described in this paper apply to problems governed by the partly linearized shallow water equations

$$\eta_t = -(du)_x - (dv)_y \tag{1}$$

$$u_t = -g\eta_x + fv - F^{(u)} + G^{(u)} \tag{2}$$

$$v_t = -g\eta_y - fu - F^{(v)} + G^{(v)} \tag{3}$$

where

$\eta(x,y,t)$ = elevation of water surface above mean level
$u(x,y,t)$ = depth-averaged velocity in x-direction
$v(x,y,t)$ = depth-averaged velocity in y-direction
$d(x,y)$ = mean water depth
x,y = Cartesian coordinates in horizontal plane
f = Coriolis coefficient (assumed constant)
g = acceleration due to gravity
t = time

$F^{(u)}$ and $F^{(v)}$ represent bottom friction terms. One stepping subroutine makes provision for friction linearly proportional to velocity, i.e. $F^{(u)} = ru$, $F^{(v)} = rv$, while another uses the more commonly assumed quadratic friction forms:

$$F^{(u)} = \frac{ku(u^2+v^2)^{1/2}}{d} \quad ; \quad F^{(v)} = \frac{kv(u^2+v^2)^{1/2}}{d} \tag{4}$$

The respective friction coefficients r and k are currently taken to be uniform throughout the model, but later versions of the stepping subroutines will permit the friction coefficient to vary with position. Also it is intended to supply a version using $(d+\eta)$ in place of d in the denominators of (4), in order to simulate fluid behavior in very shallow water more accurately. By design, these stepping subroutines are readily interchangeable, so that variations on the underlying finite-difference scheme can be tried in the same model with negligible reprogramming. It would be possible to write a master stepping subroutine containing all options likely to be required, but this would be less economical in computing time.

The terms $G^{(u)}$ and $G^{(v)}$ in equations (1) - (3) represent relevant forcing effects due to external influences. In general these will be both time- and space-dependent. Appropriate values for these must be specified for the particular problem considered through a user-provided subroutine.

3. The Richardson-Sielecki Finite-Difference Scheme

The simple Richardson grid shown in Figure 1 was chosen as the basis for the finite-difference scheme because it minimizes storage requirements and permits particularly simple simulation of coastlines. At interior points of the grid, equations (1) to (3) are represented by Sielecki's (1968) scheme.

$$\frac{\eta'_{ij} - \eta_{ij}}{\Delta t} = -\frac{(d_{ij} + d_{i+1,j})u_{i+1,j} - (d_{i-1,j} + d_{ij})u_{ij}}{2.\Delta x} - \frac{(d_{ij} + d_{i,j+1})v_{i,j+1} - (d_{i,j-1} + d_{ij})v_{ij}}{2.\Delta y} \tag{5}$$

$$\frac{u'_{ij} - u_{ij}}{\Delta t} = -g\frac{\eta'_{ij} - \eta'_{i-1,j}}{\Delta x} + f\tilde{v}_{ij} - F^{(u)}_{ij} + G^{(u)}_{ij} \tag{6}$$

$$\frac{v'_{ij} - v_{ij}}{\Delta t} = -g\frac{\eta'_{ij} - \eta'_{i,j-1}}{\Delta y} - f\tilde{u}'_{ij} - F^{(v)}_{ij} + G^{(v)}_{ij} \tag{7}$$

where

Δt = time step
$\Delta x, \Delta y$ = grid interval sizes in in x,y directions respectively
d_{ij} = mean water depth at elevation point η_{ij}

$$\tilde{u}_{ij} = \frac{1}{4}\left[u_{i,j-1} + u_{1+1,j-1} + u_{ij} + u_{i+1,j}\right]$$

$$\tilde{v}_{ij} = \frac{1}{4}\left[v_{i-1,j} + v_{ij} + v_{i-1,j+1} + v_{i,j+1}\right]$$

Primes indicate variables updated during the current time step; unprimed variables are those evaluated at the previous step. The use of old (unprimed) values of v in the Coriolis term in (6) and new (primed) values of u in the corresponding term in (7) eliminates the need to store any but the most recently updated values of each variable, provided that the equations are applied in the order given, that is, at each time step, all η_{ij} are updated, then all of the u_{ij}, and finally all the v_{ij}. The same conclusion applies if

evaluated in the order η,v,u, using old values of u in the v-equation and new values of v in the u-equation. To reduce possible bias, the stepping subroutines provided evaluate the variables in the order η', u', v', on odd-numbered steps and η', v',u', on even-numbered steps.

Sielecki showed that the condition for stability of the above scheme, in the absence of boundaries, is

$$\Delta t \leq \frac{\Delta x \cdot \Delta y}{[g d_{max}(\Delta x^2 + \Delta y^2)]^{1/2}} \qquad (8)$$

4. Numerical Coding of Model Geometry

The choice of grid for a model is necessarily a compromise among many requirements. The location and orientation of the grid is influenced mainly by the accuracy with which the coastlines can be approximated by line segments of the grid. This fit can usually be improved by increasing the grid resolution, which implies using more variable points and taking shorter time steps to maintain numerical stability, thus raising computing costs. Once the grid has been chosen, as objectively as possible, all variable points on the grid are allotted appropriate (primary) integer codes. An elevation point η_{ij} is given the code number $(KE)_{ij} = 1$ if the point lies on a sea-boundary along which surface elevation is to be specified as a function of time; any other elevation point has the code $(KE)_{ij} = 0$.

Points on the grid where velocity components u_{ij} or v_{ij} are defined are each allotted a corresponding subscripted code $(KU)_{ij}$ or $(KV)_{ij}$ which can have the following values:

Primary codes KU,KV at Velocity Points	Location of Velocity Point
1	on line segment representing land boundary (coastline or island)
2	on line segment representing spit or causeway with water on both sides
3	at sea boundary where velocity is to be specified
4	on radiating sea boundary (discussed below)
0	elsewhere

The allocation of these codes will now be illustrated with the aid of the very simple example in Figure 2(a). Here, the velocities u_{11}, u_{12}, u_{13} on the sea-boundary at the left side and v_{41}, v_{51} at the bottom edge of the grid are specified functions of time derived from current meter observations. Elevations η_{72}, η_{73}, η_{74} at the right-hand sea boundary are also known functions of time, obtained from water level gauges.

The upper boundary on which points v_{46},v_{56} are located is a

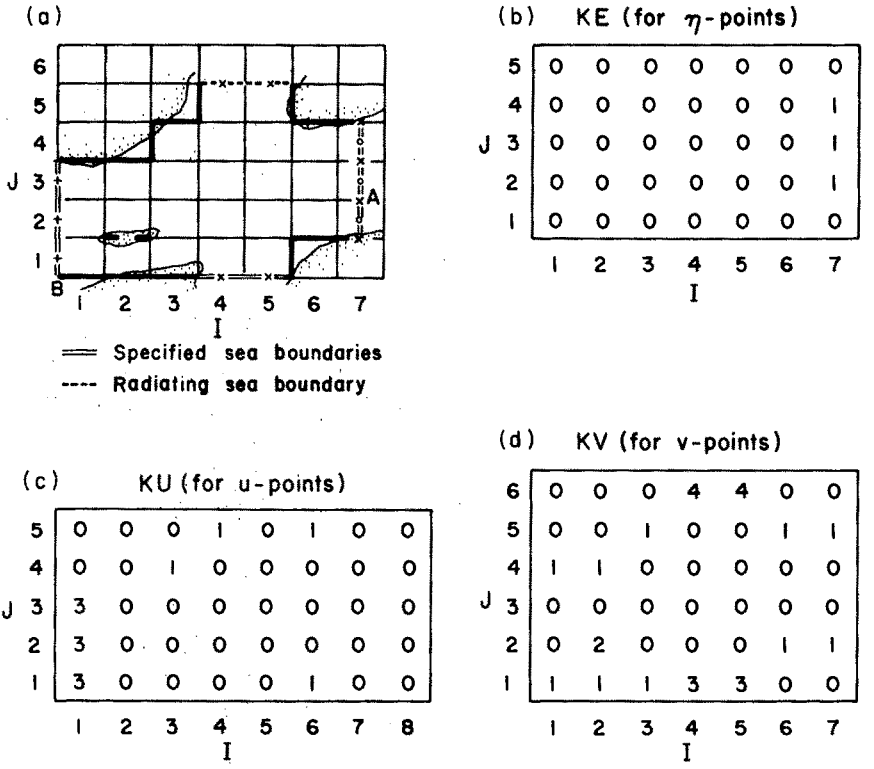

Fig. 2. Sample Water Body and Primary Codes

radiating sea boundary. Where there are good grounds for assuming that no waves enter the model area from an adjacent water body, it is appropriate to use a radiation condition on the sea boundary between the two. This permits waves reaching the sea boundary from the interior of the model to pass out of the model domain.

When choosing the model grid initially, radiating sea boundaries parallel to the x-axis of the model should be placed to run through v-points on the grid (as illustrated in Figure 2). Similarly, those parallel to the y-axis should run through u-points. It is assumed that the radiation problem can be treated one-dimensionally at each velocity point on the sea boundary and thus that the surface elevation and normal velocity at the boundary are related by

$$\text{outward normal velocity} = (g/d)^{1/2} \times \text{elevation}$$

Since there are no elevation points actually on the boundary, the nearest interior elevation value is taken instead, so that the formulas used in the stepping subroutines for u-points on radiating boundaries facing in the positive or negative x-direction are respectively:

$$u_{ij} = (g/d_{i-1,j})^{1/2} \cdot \eta_{i-1,j}$$

or

$$u_{ij} = -(g/d_{ij})^{1/2} \cdot \eta_{ij}$$

Similarly, at radiating sea boundaries facing in the positive or negative y-directions, the formulas used are respectively:

$$v_{ij} = (g/d_{i,j-1})^{1/2} \cdot \eta_{i,j-1}$$

or

$$v_{ij} = -(g/d_{ij})^{1/2} \cdot \eta_{ij}$$

For example, in the model shown in Figure 2, at each time step, the new velocity values v'_{46}, v'_{56}, on the radiating boundary are found from the newly-updated elevations η'_{45}, η'_{55} by putting

$$v'_{46} = (g/d_{45})^{1/2} \cdot \eta'_{45} \; ; \quad v'_{56} = (g/d_{55})^{1/2} \cdot \eta'_{55}$$

This simple but effective radiation condition was introduced by Heaps (1974). In practice, transmission across the boundary is nearly complete for waves impinging normally on the boundary, but there is considerable unwanted reflection when the angle of incidence exceeds 45°. Tests show that use of the radiation condition can reduce the permissible time step by as much as 50%. Equation (8) should therefore be amended to:

$$\Delta t \leq \frac{\Delta x . \Delta y}{2[\,gd_{\max}\,(\Delta x^2 + \Delta y^2)\,]^{1/2}}$$

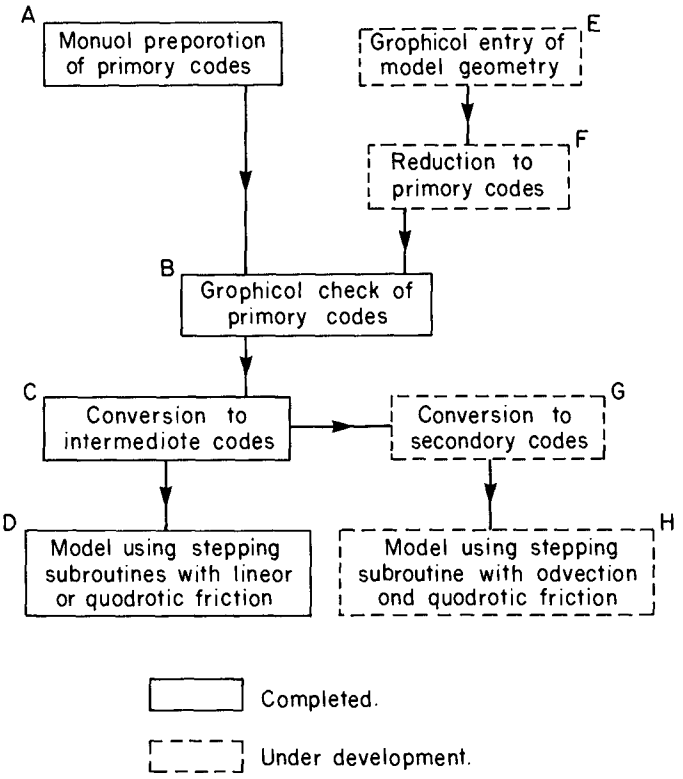

Fig. 3. Preparatory Steps

to ensure stability in models using the above type of radiating boundary.

There is to be no flow across any 'land' boundary in the model and consequently, all the corresponding velocity components, e.g. u_{34}, u_{61}, v_{11}, v_{24}, are to be set at zero. Also, v_{22} is zero, as there can be no transverse flow at the line segment representing the small island where v_{22} is situated.

The arrays of numerical codes which describe the geometry of this model, according to the list given above, are shown in Figures 2(b),(c) and (d). This coding stage of the procedure is represented by box A in Figure 3, which shows the sequence of preparatory steps required for a model. Currently, a file containing the numerical code arrays has to be prepared by the modeller, but work is in progress using interactive graphics (E in Figure 3) to replace manual entry. The coastlines and superposed grid are displayed and the grid segments which are to represent boundaries are then selected and designated using a cursor or light pen. The nature of each boundary is entered at the same time through the keyboard. However, manual entry of the primary codes, which will remain necessary in the absence of suitable graphics hardware, is very straightforward, due to the limited number of codes involved and the provision of a program for graphical checking. The latter requires only an off-line graphics facility.

5. Graphical Check of Primary Codes

Correct description of the location and types of the model boundaries is of such obvious importance that a program has been developed for plotting the model layout defined by the allocated primary codes. The plotting scale used can be set equal to that of the chart on which the model grid was set out, so that by overlaying the plot on the chart the correctness of the numerical coding can be checked very readily. It is also worthwhile repeating this graphical check (C in Figure 3) whenever changes are made to the primary codes, for whatever reason.

Figure 4 shows the plot thus produced from the primary codes given in Figures 2 (b), (c) and (d). The boundaries are distinguished by use of the following line codes:

———	closed boundaries
— —	spit or causeway
═══	sea boundary with specified variable
— — —	radiating sea boundary

The plotting program uses standard CALCOMP plotting subroutines.

6. Conversion from Primary to Intermediate Codes

Although the primary codes describe fully the location and type of every boundary, they do not contain certain information about relative locations required by the time-stepping finite-difference

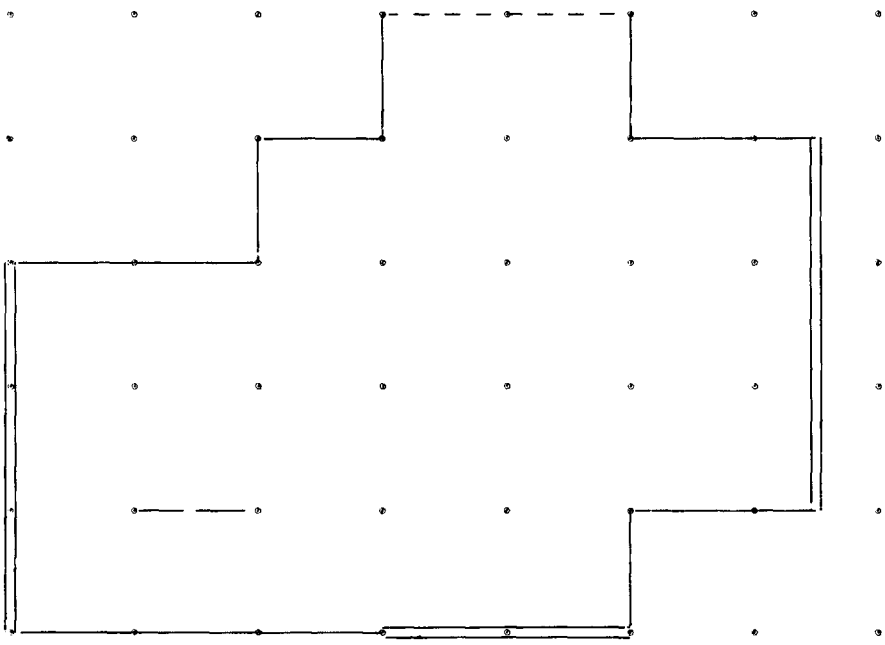

Fig. 4. Layout of Sample Model as Plotted from Primary Codes

subroutines. For this reason, another program is used (B in Figure 3) to convert the primary codes into a more numerous set of 'intermediate' codes. The latter distinguish, for example, between inactive variable points on land (or outside the model domain) and active points in the model interior. The primary to intermediate conversion program also works out the bounds of the area of grid containing active variable points, thus reducing the amount of computation required in the time-stepping subroutines at each time-step. Users generally need not concern themselves with details of the intermediate codes and scanning bounds.

Boxes G and H and Fig. 3 refer to programs being developed to permit substitution of a stepping subroutine based on the full non-linear shallow-water equations in place of the partly linearized versions presently available. An even fuller set of codes, here termed 'secondary', are required in that case to cope with the variety of special cases which occur in the vicinity of boundaries.

7. Programming a Model

After the above preparatory stages of coding, checking and code conversion have been carried out, one proceeds very much as in programming a model by the usual direct method, except that the intricate programming of the finite-difference calculations is replaced by a simple call to the appropriate time-stepping subroutine. The other major difference is that time-dependent forces and boundary values are supplied at each time-step by calling a subroutine which loads specific storage locations with this data, rather then by summoning values directly where required in the finite-difference coding.

It is useful to visualize the linear arrays used to store boundary values as lying parallel to the boundaries on which the values are used, as shown in Figure 5, which refers to the simple example of Figure 2. By having each array the same size as its respective side of the model grid, the same numbering can be used for both. Thus in the example, the values to be supplied at each step for u_{1j} are stored in $(BL)_j$, j=1,2,3; those for v_{i1}, in $(BB)_i$, i=4,5 and those for η_{7j} in $(BR)_j$, j=2,3,4. The storage arrays, which are a fixed feature of the time-stepping subroutines, can be used for holding elevation or velocity values as required for the model in question. Cases where this storage arrangement could lead to values for two different boundary points being allotted to the same storage location hardly ever seem to occur in practice and have not been catered for. Values supplied by the user at each time-step for the forcing terms $G^{(u)}$ and $G^{(v)}$ (equations 2 and 3) at every relevant variable point are stored in two-dimensional arrays where they are subsequently accessed by the stepping subroutine.

Some of the storage locations just discussed go unused in most models - for example, none of the boundary storage array BT pertaining to the upper boundary in Figure 5 is used - but this is a reasonable price to pay for other conveniences of the method.

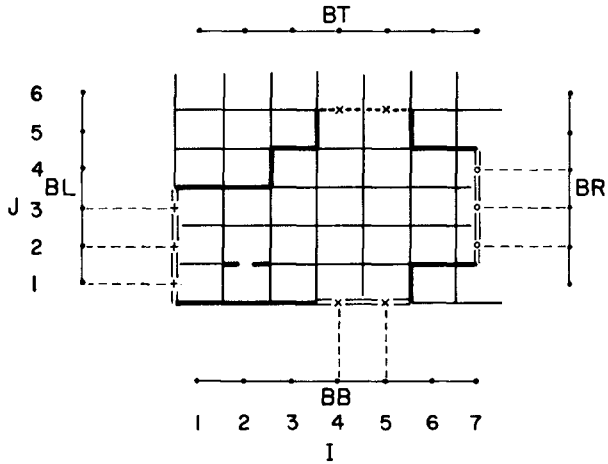

Fig. 5. Storage of Boundary Input Values for Sample Model

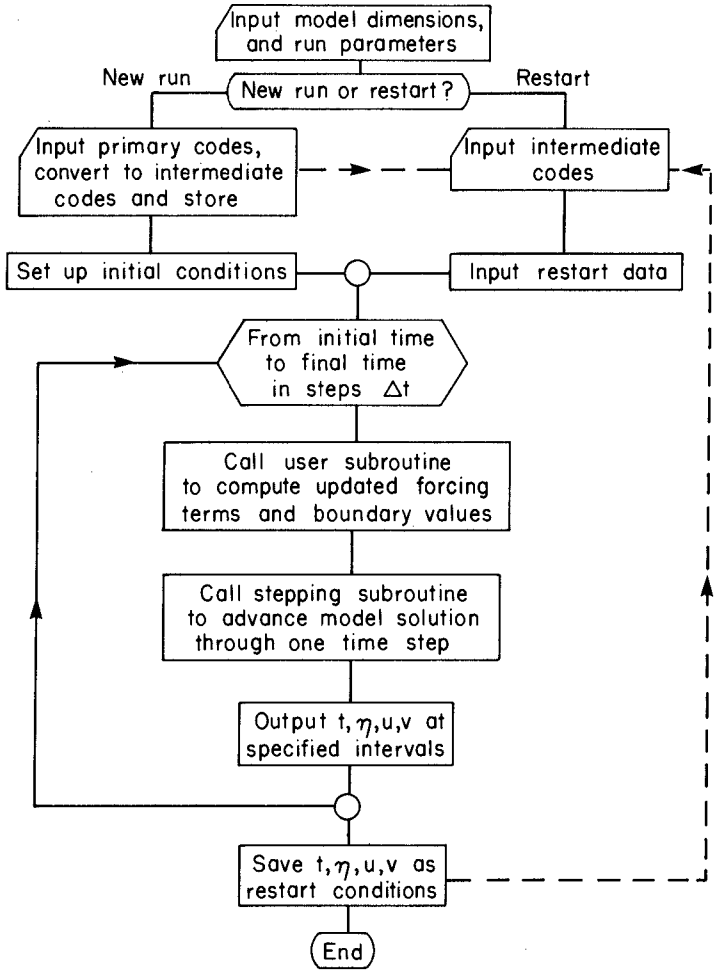

Fig. 6. Typical Model Flowchart

Figure 6 shows a simplified flowchart suitable for many models. The conversion from primary to intermediate code is shown included in the model program, since in many cases, modellers make numerous boundary changes during model development. Some further details are given in Henry (1982) and the results of an actual run with the model shown in Figure 2 are listed there for check-out purposes.

8. Further Developments

Besides extensions already mentioned, a number of auxiliary programs are being developed, mainly for performing standard analyses of results from production runs with the completed model. For tidal studies there is a program which carries out harmonic analysis of computed currents and surface elevations, while for storm surge models another program is being developed to log the maximum height reached at each elevation point during any specified period. Since the model shape is already expressed in the primary codes, the latter are used to confine the analysis computations to active variable points, to organize the layout of printed results of the analyses, and also to produce plots of the boundaries in subsequent graphical programs, such as one which can contour any designated scalar field computed during the analysis.

9. Conclusions

The method of programming shallow water models discussed in this paper is designed to answer a need for rapid, error-free application of well-known finite-difference methods to different coastal areas. The basic concept involved, indirect programming or selection of algorithms via numerical codes, has attracted interest for a number of years but has not come into widespread use. This paper proposes some improvements which should help to make indirect programming into a really practicable tool. These include:

a) the number of different numerical codes needed to describe the model layout is kept very small, the more numerous set of codes required to control the finite-difference computation being produced automatically by a pre-developed program;
b) the user's choice of codes to define the layout is checked graphically for errors;
c) the finite-difference scheme employed can be changed by replacing one subroutine by another.

LONG WAVES OVER THE GREAT BARRIER REEF

by

Eric Wolanski *

ABSTRACT

Low-frequency forcing of water currents over the continental shelf of Australia is quite strong and should be taken into account when the flow for durations greater than 1 day is important. In the case of the Queensland coast, the longshore wind generates barotropic continental shelf waves, raising or lowering the mean sea level by as much as 30 cm and generating longshore currents over the continental shelf, even very close to the coast, that are often larger than the tidal currents. These wind-driven currents can reverse sign, flowing alternately northward and southward, although the longshore wind stress, though fluctuating, does not change direction. To reproduce such phenomena in an analytical or computer model of wind-driven currents, it is necessary to extend the offshore boundaries of the model offshore from the continental shelf break.

1. INTRODUCTION

In 1966, Hamon digitized sea level observations at various ports around Australia, removed the tidal component from the time series and discovered that the "mean sea level" is not a constant. Shelf waves were thus discovered and have since been intensively studied by physical oceanographers (see a review by Allen (1980) and Winant (1980)). In their simplest mode, the continental shelf waves are disturbances of the sea level, highest near the coast and negligible in the deep ocean, with a longshore wave length often exceeding 1500 km, of duration typically one to two weeks, raising or lowering the mean sea level by as much as 50 cm.

Until recently, coastal engineers in Australia have often ignored these waves in many applications where currents were a design parameter, presumably because the sea level disturbance (say, 30 cm) is small compared to the tidal range (say, 2 m). Yet, as will be shown, the currents introduced by shelf waves can be stronger than the tidal currents. Further, the shelf-wave-driven currents can reverse sign, though the wind direction does not change, typically in one to two weeks, so that water current investigations of duration less than two weeks will likely lead to aliased data if the mean flow has to be determined, such as for estimating the dispersion of contaminants from outfalls.

2. FIELD STUDIES IN AUSTRALIA

As part of the research program in physical oceanography by the Australian Institute of Marine Science, I have run a long-term study of water currents over the continental shelf of the Great Barrier Reef.

* Principal Research Scientist, Australian Institute of Marine Science, P.M.B. No.3, Townsville, Q.4810, Australia.

The initial study site was the central region (16 to 20°S lat.) from 1980 to 1981, and more recently the northern region (9 to 15°S) from 1981 to 1982. The study in the central region, which is reviewed here, involved the deployment and maintenance for more than one year of self-recording current meters, water level recorders and weather stations. The location of some of the instruments is shown in Fig. 1.

Wind

It was found (Wolanski, 1982) that, in the trade wind season, the dominant wind direction changed from westward over the Coral Sea to northwestward over the continental shelf. The dominant wind component was found to be highly coherent over distances of at least 1500 km, with negligible time lags from site to site, so that the wind-field over the continental shelf can be treated as time-dependent but stationary. The wind is energetic at all periods greater than a few

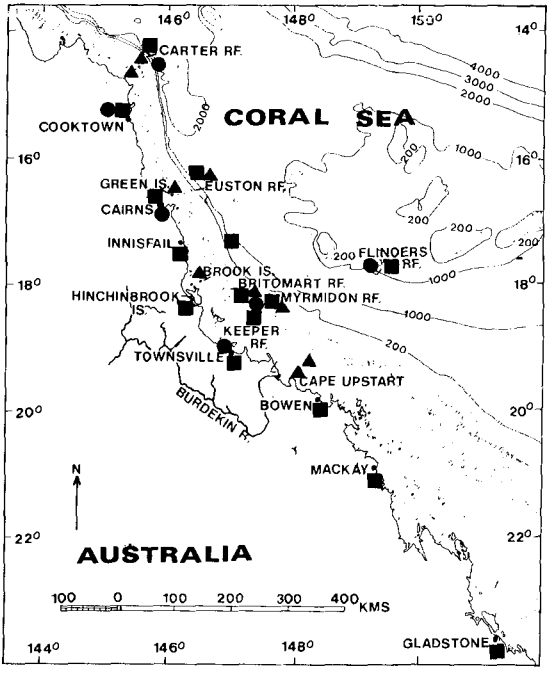

Figure 1 Location map, with depth in m, showing the mooring sites of some of the current meters (▲), water level recorders(■), and weather stations (●).

days, with a suggestion of a peak in the wind autospectrum at about 10 and 30 days duration.

Currents

Because the shelf is fairly flat (Fig. 2), the current meters were all in comparable depth. Baroclinic effects on the shelf are not very important, except near the shelf break (Wolanski and Pickard, 1983), because the shelf waters are well-mixed, the thermocline being located at 100 m depth or so, i.e. offshore from the continental shelf break. In Fig. 3 are shown the low-frequency (after removing the tidal signal) current time series at several locations, over roughly 4 months. At the Green Island mooring site, the tidal component of the currents is so weak that the longshore currents do not reverse sign with the tides, though a spring tidal range of about 3 m is experienced. Instead, as can be seen from Fig. 3, the currents are alternately northward and southward, reversing sign in typically one to two weeks. Such low-frequency forcing is apparent at all sites (Wolanski and Bennett, 1983). At Green Island and Euston Reef, the longshore currents are nearly equal and no residual 'mean flow' is found after several months, although, for practical purposes, the longshore wind component did not reverse sign (Fig. 3).

Sea levels

The variance of the sea level signal is primarily (90%) due to diurnal and semi-diurnal tides. The spring tidal range exceeds 3 m, the neap tide range is about 40 cm. The low-frequency signal is typically 30 cm from peak to trough (Fig. 3) and is found to be highly coherent at all stations

Propagation of the disturbances

Using lagged correlation techniques or coherence and phase calculations, it was shown (Wolanski and Bennett, 1983) that the low-frequency longshore current and sea level disturbances are travelling

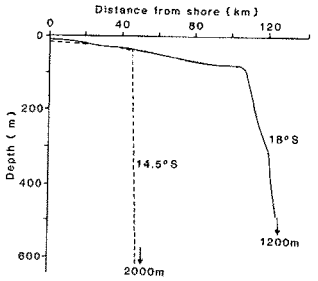

Figure 2 Offshore bathymetry at two locations.

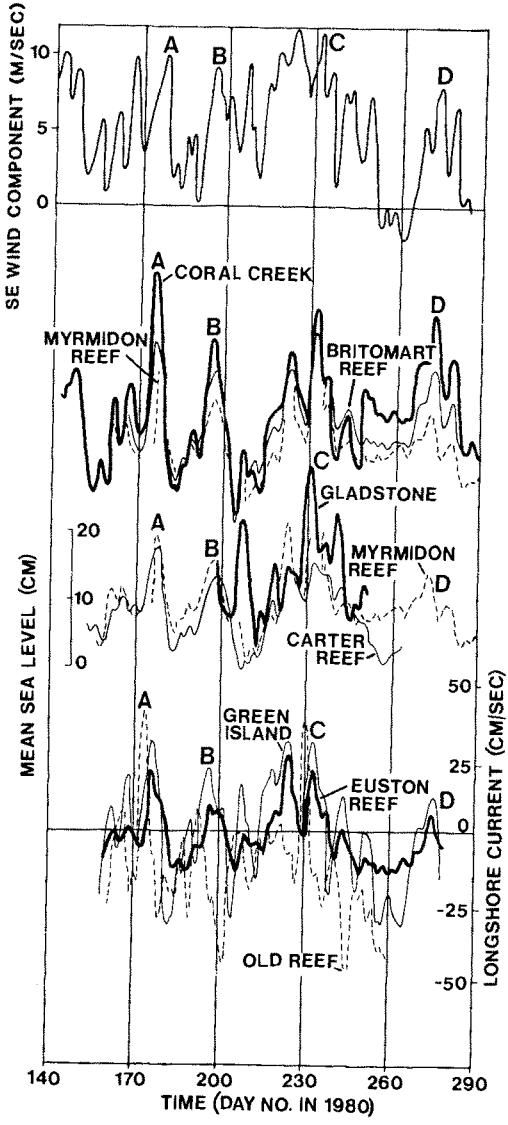

Figure 3

Time series of the low-frequency longshore wind component (positive if northward), of the low-frequency sea level and longshore currents (positive if northward) at various locations. The letters A to D identify some wind-driven events. Note that the longshore wind component is nearly always positive, but that the currents reverse sign.

longshore northward at a speed of roughly 450 km day^{-1}, although the wind field is stationary and the longshore wind component is highly correlated with both the low-frequency longshore currents and the low-frequency sea levels.

3. MATHEMATICAL FORMULATION

The f-plane shallow water wave equations are

$$u_t + uu_x + vu_y - fv = -gh_x + T^x/(H+h) - F^x/(H+h) \quad (1)$$

$$v_t + uv_x + vv_y + fu = -gh_y + T^y/(H+h) - F^y/(H+h) \quad (2)$$

$$h_t + ((H+h)u)_x + ((H+h)v)_y = 0 \quad (3)$$

where t is the time, x and y the horizontal Cartesian coordinates (x is oriented cross-shelf pointing offshore, y longshore poiting northward, the origin being at the coast), u and v the corresponding velocity components, T^x and T^y the wind stress components, and F^x and F^y the bottom friction components. A subscript indicates a partial derivative, g is the acceleration due to gravity, H is the undisturbed water depth, h the sea level disturbance, and f the Coriolis parameter.

Equations (1)-(3) are non-linear but can be greatly simplified without losing the important physical processes controlling the dynamics of water currents over the Great Barrier Reef continental shelf. Using the array of current meter and tide gauge data centered around Brook Island, it was possible (Wolanski and Bennett, 1983) to estimate a number of terms in equations (1)-(3). For example, as is shown in Fig. 4, the sea level vertical velocity, h_t, can be neglected in equation (3). This approximation is called the "rigid-lid assumption" (e.g., see Allen , 1980), and averages out the seiching which occurs during wind set-up. This seiching has a time scale appropriate to the time taken for a long surface gravity wave to traverse the shelf and that is about typically 1-2 hours. The cross-shelf momentum equation (1) is simplified in practice (Fig. 5) to a simple geostrophic balance between the longshore current, v, and the cross-shelf slope of the water surface, h_x. The non-linear terms can be neglected and the total depth (H+h) in equations (1) to (3) can be approximated by the undisturbed depth, H.

With these approximations, originating from the field data, the equations of motion become

$$-fv = -gh_x \quad (4)$$

$$v_t + fu = -gh_y + T^y/H - F^y/H \quad (5)$$

$$(Hu)_x + (Hv)_y = 0 \quad (6)$$

To model the wind-driven currents, we assume a simple topography, shown in Fig. 6 , namely a shelf of uniform depth H_s and extending

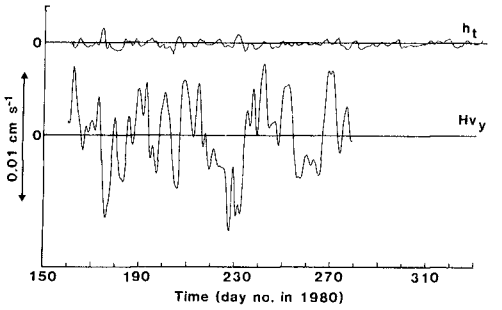

Figure 4 Term balance in the continuity equation (3)

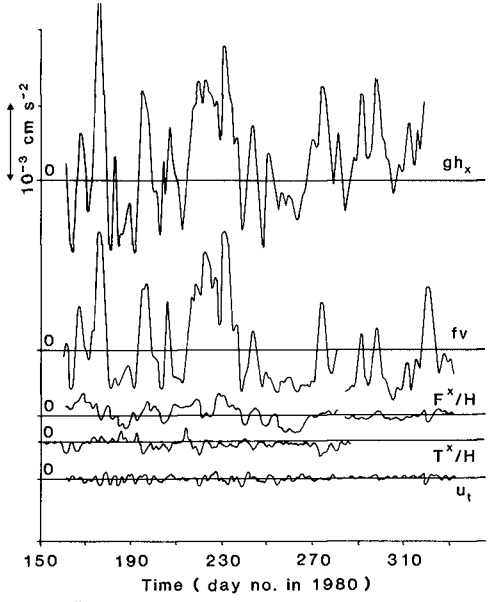

Figure 5 Time series of various terms in the cross-shelf momentum equation (1)

from the shore (x=0) to the shelf break (x=L), the ocean of depth H_o extending from x=L to infinity.

The boundary conditions are continuity of sea level h and of cross-shelf fluxes uH at x=L, the disturbance h vanishing as x goes to infinity (the data showing that the mean sea level perturbations are much smaller over the Coral Sea than over the shelf), and u=0 at x=0.

The forcing is provided by the longshore wind stress (from which the time-averaged mean wind has been substracted as the mean flow is very small)

$$T^y \begin{cases} =0, \text{ for } y < 0 \\ =T_o \exp(iwt), \text{ for } 0 < y < A \\ =0, \text{ for } y > A \end{cases} \qquad (7)$$

where T_o is a constant, w the frequency, A the size of the wind-field, and $i=(-1)^{\frac{1}{2}}$.

The solution, to order H_s/H_o, is

$$u = - xv_y \qquad (8)$$

$$h = (x-L)\, fv/g \qquad (9)$$

$$v = B \exp(iwt) \; (1 - \exp(-iwy/c) \exp(-by/c)) \qquad (10)$$

where

$$B = (T_o/H_s)/(i(w-ib)) \qquad (11)$$

$$b = r/H_s \qquad (12)$$

$$c = - fL \qquad (13)$$

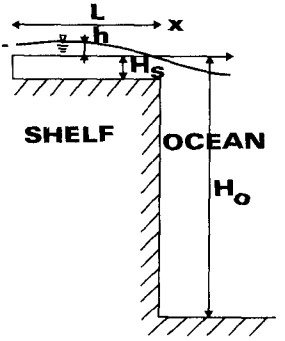

Figure 6 Sketch of the model geometry

where r is the friction coefficient, assuming a linear law

$$F^y = rv \qquad (14)$$

which turns out, from the field data, to be of the order of $2. \times 10^{-4}$ m s^{-1}. c is the phase speed of free shelf waves, about 200-230 km day^{-1} in this region.

A number of features of equations (8) to (10) are in good agreement with observations, namely that v is independent of x, that h is largest at the coast, and that v and h are in phase. Further, the correlation field of sea level and current disturbances propagate northward longshore at a phase speed of 2c, i.e. about 450 km day^{-1}, in good agreement with the observations. From equation (10), it is apparent also that the longshore current, v, can be alternately northward and southward, resulting in a net zero total displacement after one period (wind event).

Near the shelf break, the ocean stratification introduces important baroclinic effects. These are compounded by the effects of the Great Barrier Reef which, as it turns out, result in only a small enhancement of the friction over the shelf by damping the exchange of water between the continental shelf and the Coral Sea. The link between the shelf and the ocean effectively traps the disturbance over the shelf and implies that a mathematical or computer model of wind-driven currents over the shelf must cover an area extending offshore from the continental shelf break.

The low-frequency modulation of sea levels controls the frequency of inundation, hence the flushing of coastal wetlands in Queensland. This modulation of sea level can also be important in harbours where depth is limiting, and in shallow shipping lanes such as Torres Strait (Wolanski and Gardiner, 1981, Wolanski and Thomson, 1983).

CYLINDRICAL LONG WAVE INTO A CYLINDRICAL SHELF

HENRY POWER*
UNIVERSIDAD CENTRAL DE VENEZUELA, VENEZUELA

ABSTRACT

Based on the linear non-dispersive theory, the reflection of a Converging Cylindrical long wave, of wave length L, onto a Cylindrical shelf, of radius r = a and positive or negative height Δ h relative to an otherwise flat bottom, is study analitically. It is found that these linear approximation agrees well with the existing non-linear numerical solution when the ratio a/L is large enough. It is also found that these two-dimensional reflection process is the contrary of the corresponding one-dimensional case, since the solution of these problem gives a negative reflected wave for a positive step and a positive reflected wave for a negative step.

1. INTRODUCTION

In this paper we will discuss the reflection of Cylindrical long waves by a submerged Cylindrical shelf of radius r = a. Solving, analitically the linear nondispersive Cylindrical wave equation.

It is known that for infinitesimal wave on constant depth, water motion in long waves is essentially horizontal, implying that the vertical variation is weak and the pressure is hydrostatic. If we consider a vertical fluid columm of base section $dr\, rd\theta$ and height $h + \eta$, where h is the water depth and η is the wave amplitude measured from the undisturbed water surface, the rate of change of fluid volume in the columm is $\partial\eta/\partial\tau\, rdrd\theta$. If, the vertical variation in the horizontal velocity is ignored as is suggested above, the net rate of volume flux into the columm is

$$-\nabla\cdot\bar{u}\,(h+\eta)\, rdrd\theta,$$

where ∇ denotes the horizontal gradient in polar coordinates

$\left(\frac{\partial}{\partial r}, \frac{1}{r}\frac{\partial}{\partial\theta}\right)$.

Mass conservation is satisfied, if the two rates are equal,(incompressible fluid) hence

$$\frac{\partial\eta}{\partial\tau} + \nabla\cdot\bar{u}(h+\eta) = 0 . \qquad (1)$$

*Profesor Agregado, Instituto de Mecánica de Fluidos, U.C.V.

For waves having a vertical axis of symmetry at all times, the above equation can be written as

$$n_t + \frac{1}{r}\,((h + n)\, r\, u)_r = 0\,, \tag{2}$$

where u is the radial velocity considered constant in the entire depth. In terms of the velocity potential, inviscid and irrotational flow, we have, that the linear version of equation (2) is

$$n_t + \frac{h}{r}\,(r\,\Phi_r)_r = 0\,. \tag{3}$$

In the momentum balance, we only consider horizontal components and neglect convective inertia (non-linear term), therefore

$$\vec{u}_t = -\frac{1}{\rho}\,\nabla p\,. \tag{4}$$

Assuming now, that the pressure is hydrostatic,

$$p = \rho\,(n-z)g\,,$$

The momentum equation becomes

$$\vec{u}_t = -\,g\,\nabla n\,. \tag{5}$$

Introducing the velocity potential into equation (5), we obtain

$$n = -\frac{1}{g}\,\frac{\partial \Phi}{\partial t}\,. \tag{6}$$

Substituting equation (6) into equation (3), we have

$$\frac{1}{C^2}\,\frac{\partial^2 \Phi}{\partial t^2} = \frac{\partial^2 \Phi}{\partial r^2} + \frac{1}{r}\,\frac{\partial \Phi}{\partial r}\,, \tag{7}$$

The above equation is the linear nondispersive Cylindrical wave equation, where $C = \sqrt{gh}$ is the shallow water phase velocity.

Chwang and Wu (1976) investigated the reflection and transmission of a converging cylindrical solitary wave due to a circular step of positive height Δh and radius $r = a$, based on a numerical solution of the three dimensional Boussinesq equation (non-linear theory). Their main conclusion was that after incident wave reaches the circular step, the leading reflected wave takes the form of a negative wave propagating in the positive "r" direction (see figure (1)). Wu (1979) presented a comparative numerical study of the above problem, using different theories of wave propagation. From Wu's work, it is possible to conclude that when a/L is large enough, where L is the wave length, the reflected waves predicted by the Boussinesq theory and the linear nondispersive long wave model are in good agreement (compare figure 2 with figure 1), just as the transmited waves predicted by the mentioned theories are differents, result that can be more appreciated when the waves approach the origin (focusing process). A non-linear analytic solution of this focusing process has been presented by Chwang and Power (1981), based on the inner-outer expansions technique to the Cylindrical Boussinesq equation.

FIG. # 2

The solution of such a problem in one dimension (reflexion of a planar wave due to abrupt change in the water depth) is extremely easy, owing to the simple general integral of the one-dimensional wave equation. As it is known in one dimension we have the deviations from the mean water level as

$$n_I = f(t + \frac{x - x_0}{c_1}) . \tag{8}$$

for the incident wave,

$$n_r = \frac{c_1 - c_2}{c_1 + c_2} f(t - \frac{x+x_0}{c_1}) \tag{9}$$

for the reflected wave, and

$$n_t = \frac{2 c_1}{c_1+c_2} f(t + \frac{x - \frac{c_2}{c_1} x_0}{c_2}) \tag{10}$$

for the transmitted wave, where the incident, transmitted and reflected waves have the same shapes, and for ($C_1 = \sqrt{gh_1}$) > ($C_2 = \sqrt{gh_2}$) the reflected wave takes the form of a positive wave propagating through infinity. The above conclusion for one dimensional wave is totally different from the one found by Chwang and Wu numerical solution for a two dimensional wave.

2. CYLINDRICAL LONG WAVES IN WATER OF CONSTANT DEPTH

In these section we are interested in studing the propagation of cylindrical incoming long waves in water of constant depth, whose maximum wave amplitude is located at $r = r_0$, sufficiently far from the origin when $t = 0$. To do it, we will follow Lamb(1902) original paper, "on wave propagation in two dimensions", and Whithan (1974).

To find a general solution for incoming waves of equation 7, we can use two different approaches, one consist on a Fourier superposition of the periodic incoming solution of equation 7 and the other technic consists on a uniform line distribution on the z axis, of three-dimensional point wave sources, the total disturbance from this line distribution is clearly a function only of the distance r from the z axis and the time t.

The wave equation in spherical coordinates reduces to

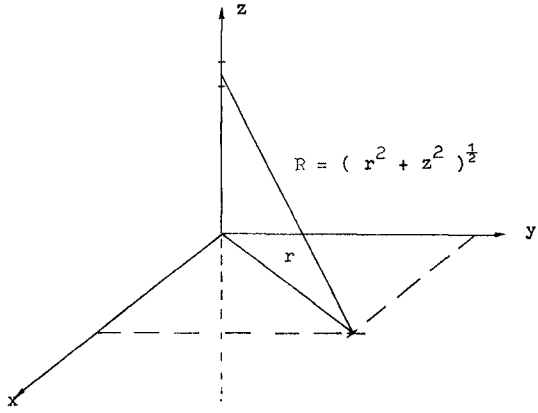
$$\frac{1}{c^2} \frac{\partial^2 \Phi}{\partial t^2} = \frac{\partial^2 \Phi}{\partial R^2} + \frac{2}{R} \frac{\partial \Phi}{\partial R} , \tag{11}$$

when $R = \sqrt{r^2+z^2}$. The source solution of the above equation producing incoming wave whose maximum wave amplitude is located at $R = r_0$, is

$$\Phi = - \frac{1}{4\pi R} f(t + \frac{R - r_0}{c}) . \tag{12}$$

The total potential produced by a line distribution of the above source is

$$\Phi\left(\frac{r-r_0}{c}, t\right) = -\frac{1}{4\pi}\int_{-\infty}^{\infty}\frac{1}{R} f\left(t+\frac{R-r_0}{c}\right) dz \ . \tag{13}$$



Let $z = r \ \text{senh}\ u$, therefore $R = r \cosh u$, and substituting this change of variable in equation (13), we obtain

$$\Phi = -\frac{1}{2\pi}\int_{o}^{\infty} f\left(t-\frac{r_0}{c}+\frac{r}{c}\cosh u\right) du. \tag{14}$$

To verify that the above equation is a solution of equation (7), subject to certain condition, let us substitute equation (14) into equation (7). Then

$$\begin{aligned} 2\pi\left(c^2\left(\Phi_{rr}+\frac{1}{r}\Phi_r\right)-\Phi_{tt}\right) &= \int_{o}^{\infty}\left(\cosh^2 u\, f''(\xi)+\frac{c}{r}\cosh u\, f'(\xi)\right. \\ &\quad \left. - f''(\xi)\right)du \\ &= \int_{o}^{\infty}\frac{c^2}{r^2}\frac{\partial^2}{\partial u^2} f(\xi)du \\ &= \frac{c}{r}\left(\text{senh}\, u\, f'(\xi)\right)_{u=o}^{u=\infty} \ , \end{aligned} \tag{15}$$

where $\xi = (t - r_0/c + (r/c)\cosh u)$. Equation (15) is identically equal to zero, therefore (14) is a solution of (7), if and only if f' tends to zero faster than senh u tends to infinit when u tends to infinite. Then under the above condition, equation (14) is a two-dimensional source of strength f (t - r_0/c), producing cylindrical incoming waves, whose maximum wave amplitude is located at r = r_0 when t = 0. Since

$$
\begin{aligned}
2\pi r\Phi_r &= -\frac{r}{c}\int_0^{\infty} f'(\xi)\cosh u\, du = -\frac{r}{c}\int_0^{\infty}(\operatorname{senh} u + e^{-u})f'(\xi)du \\
&= -\left(\int_0^{\infty}\frac{\partial}{\partial u} f(\xi)du + \frac{r}{c}\int_0^{\infty} e^{-u} f'(\xi)du\right) \\
&= f(t - r_0/c + r/c) - \frac{r}{c}\int_0^{\infty} e^{-u} f'(\xi)du ,
\end{aligned}
\qquad (16)
$$

Therefore, the following limit gives the source strength

$$
\lim_{r\to\infty} 2\pi r\Phi_r = f(t - r_0/c), \qquad (17)
$$

or in other words we have a two dimensional source of strength f(t'), where t' = t - r_0/c, whose initiation time is t' = - r_0/c.

The corresponding wave profile to the above two-dimensional potential is found by substituting equation (14) into equation (6). Then

$$
n\left(\frac{r-r_0}{c}, t\right) = \frac{1}{2\pi g}\int_0^{\infty} f'(t - r_0/c + \frac{r}{c}\cosh u)du, \qquad (18)
$$

Now at t = o we have

$$
n\left(\frac{r-r_0}{c}, o\right) = \frac{1}{2\pi g}\int_0^{\infty} f'\left(\frac{r}{c}\cosh u - \frac{r_0}{c}\right) du. \qquad (19)
$$

Therefore, the problem is reduced to solving the above integral equation of the first kind when the initial wave profile, $n((r - r_0)/c, o) = n_i((r-r_0)/c)$, is known.

The solution of equation (19) is

$$
f'\left(\frac{r}{c}\cosh u - \frac{r_0}{c}\right) = -4g\frac{r}{c}\cosh u\int_0^{\infty} n_i'\left(\frac{r}{c}\cosh u\cosh v - \frac{r_0}{c}\right)dv, \qquad (20)
$$

provided that $n_i(\infty) = 0$

To prove equation (20), let's substitute equation (20) into equation (19)

$$n_i\left(\frac{r-r_0}{c}\right) = -\frac{2}{\pi}\int_0^{\infty}\frac{r}{c}\cosh u \int_0^{\infty} n_i'\left(\frac{r}{c}\cosh u \cosh v - \frac{r_0}{c}\right)dv\,du \qquad (21)$$

Let $z = r/c \cosh u \cosh v$ and $y = r/c \cosh u \operatorname{senh} v$ so that $J(u, v) = (r/c)^2 \operatorname{senh} u \cosh u$ transforming the u and v independent variables in the double integral of equation (21) to z and y variables, then we have

$$n_i((r-r_0)/c) = -\frac{2}{\pi}\int_{r/c}^{\infty}\int_0^{(z^2-(r/c)^2)^{1/2}} \frac{n_i'(z-r_0/c)}{(z^2-y^2-r^2/c^2)^{1/2}}\,dy\,dz$$

$$= -\frac{2}{\pi}\int_{r/c}^{\infty} n_i'(z-r_0/c)\left(\operatorname{sen}^{-1}\left(\frac{y}{(z^2-r^2/c^2)^{1/2}}\right)\right)_0^{(z^2-r^2/c^2)^{1/2}} dz$$

$$= -\int_{r/c}^{\infty} n_i'(z-r_0/c)\,dz$$

$$= n_i\left(\frac{r-r_0}{c}\right), \qquad (22)$$

Since $n_i(\infty) = 0$, and equation (20) has being proved .

3. THE REFLECTION OF A SOLITARY WAVE

Consider a single cylindrical wave moving through the origin in water of constant depth h_1. Due to a discontinuous change in the depth by a Cylindrical shelf of depth h_2 and radius $r = a$, some of the inco - ming energy is transmitted beyond the step and the remaining part is re flected backwards. Let the incident wave be

$$n_I = \int_0^{\infty} g\left(t - \frac{r_0}{c_1} + \frac{r}{c_1}\cosh u\right) du \qquad (23)$$

with $C_1 = \sqrt{g h_1}$ the wave celerity in the region $r > a$, In this region, $r > a$, besides the incident wave there must be a reflected wave propa - gating through infinity that we may choose it to be

$$n_r = \int_0^{\infty} R\left(t + r_r/c_1 - \frac{r}{c_1}\cosh u\right) du . \qquad (24)$$

In a similar way, in the region $r \leq a$ we have a transmitted wave propa pating through the origin with wave celerity $C_2 = \sqrt{gh_2}$ that we may write it as

$$n_t = \int_0^\infty T(t - r_t/c_2 + \frac{r}{c_2} \cosh u\ )\, du. \tag{25}$$

The function g is known and R and T at $r = a$ are to be found from the matching of the pressure and volume flux at the edge of the cylinder $r = a$, as is usually done. Then, we have

$$\begin{aligned} & n_I + n_r = n_t \\ & h_1 \frac{\partial}{\partial r}(\Phi_I + \Phi_r) = h_2 \frac{\partial}{\partial r}\Phi_t \quad , \text{ a t } r = a \end{aligned} \tag{26}$$

In this way, we get

$$R(t + r_r/c_1 - \frac{a}{c_1} \cosh u\ ) = \frac{c_1 - c_2}{c_1 + c_2}\, g\,(t - r_0/c_1 + a/c_1 \cosh u\ ), \tag{27}$$

and

$$T(t - r_t/c_2 + a/c_2 \cosh u) = \frac{2c_1}{c_1 + c_2}\, g(t - \frac{r_0}{c_1} + \frac{a}{c_1} \cosh u\ ). \tag{28}$$

The prolongation of the relation (27) in the region $r > a$, can be given by

$$R\,(t + r_r/c_1 - \frac{r}{c_1} \cosh u\ ) = \frac{c_1 - c_2}{c_1 + c_2}\, g(t - \frac{r_0}{c_1} - \frac{(r - 2a)}{c_1} \cosh u\ ). \tag{29}$$

Substituting equation (19) into equation (24) for the reflected wave. We get

$$n_r = \frac{c_1 - c_2}{c_1 + c_2} \int_0^\infty g(t - \frac{r_0}{c_1} - \frac{(r - 2a)}{c_1} \cosh u\ )\, du\ , \tag{30}$$

The above relation is not a solution of the cylindrical wave equation, as can be seen by substituting the following potential

$$\Phi = \int_0^\infty f(t - \frac{(r - r')}{c} \cosh u)\, du \tag{31}$$

into the cylindrical wave operator. Since

$$(c^2 (\frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r}) - \frac{\partial^2}{\partial t^2}) \int_0^\infty f\,(t - (\frac{r - r'}{c}) \cosh u)\, du =$$

$$\int_0^\infty (\frac{c}{r} f'\,(t - (\frac{r - r'}{c}) \cosh u) \cosh u - f''\,(t - (\frac{r - r'}{c}) \cosh u) \operatorname{senh}^2 u)$$

$$du = \frac{c^2}{(r - r')^2} \int_0^\infty (-\frac{\partial^2}{\partial u^2}\,(f\,(t - (\frac{r - r'}{c}) \cosh u)))\, du - \frac{c}{(r - r')}$$

$$\frac{r'}{r} \int_0^\infty f'\,(t - (\frac{r - r'}{c}) \cosh u) \cosh u\, du$$

$$= - \frac{c^2}{(r - r')} \frac{r'}{r} \int_0^\infty f' \left(t - \frac{r - r'}{c} \cosh u \right) \cosh u / c \, du$$

$$= - \frac{c^2}{(r - r')} \frac{r'}{r} \frac{\partial \Phi}{\partial r} \neq 0 \quad \text{for } 0 < r > \infty, \tag{32}$$

where we used the condition that f' tends to zero as u tends to infinite. Therefore, these standard technique does not bring a solution of the reflection of a general cylindrical long wave. The way around this difficulty is a Fourier superposition of the reflection of a cylindrical periodic wave , where the above technique gives the following solution for the reflection and transmition of the incident periodic waves

$$n_I = A_I H_0^{'} (k_1 r) e^{iwt} \tag{33}$$

propagating through the origin, as:

$$n_r = A_I R(w) H_0^2 (k_1 r) e^{iwt} \tag{34}$$

for the reflected wave and

$$n_t = A_I T(w) H_0^1 (k_2 r) e^{iwt} \tag{35}$$

for the transmitted wave. The function R(w) and T(w), reflection and transmission coefficient respectively, are determined by the matching condition at r = a, and are found to be

$$R(w) = \left(H_1^1(k_1 a) H_0^1(k_2 a) - \sqrt{\frac{h_2}{h_1}} H_0^1 (k_1 a) H_1^1(k_2 a)\right) / \left(H_0^2(K_1 a) H_1^1(K_2 a) \sqrt{\frac{h_2}{h_1}} - H_1^2(k_1 a) H_0^1(k_2 a)\right) \tag{36}$$

and

$$T(w) = \left(H_0^1(K_1 a) + R(w) H_0^2 (k_1 a)\right) / H_0^1(K_2 a), \tag{37}$$

where $K_1 = w/\sqrt{gh_1}$ and $k_2 = w/\sqrt{gh_2}$ and w is the wave frecuency. Therefore, the above equations give the dependency of the reflection and transmission coefficients with the wave frecuency.

By a Fourier superposition of the above problem, we have that an incident wave

$$n_I = \int_{-\infty}^{\infty} A_1(w) H_0^1(k_1 r) e^{iwt} \, dw. \tag{38}$$

will be reflected and transmitted as

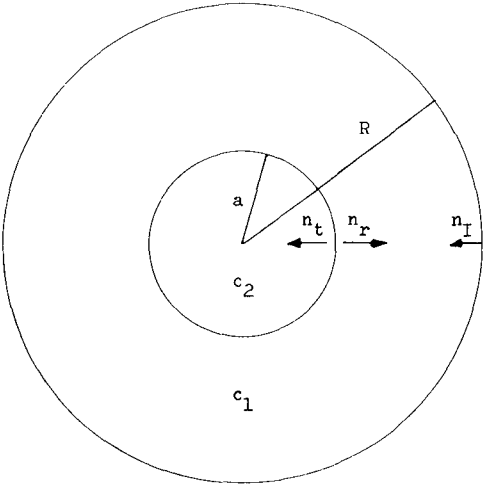
$$n_r = \int_{-\infty}^{\infty} A_I(w)\, R(w)\, H_0^2\,(k_1 r) e^{iwt}\, dw \tag{39}$$

and

$$n_t = \int_{-\infty}^{\infty} A_I(w)\, T(w)\, H_0^1\,(k_2 r)\, e^{iwt}\, dw. \tag{40}$$

Then, the incident, reflect and transmitted waves have differents shapes. Because the Fourier coefficients of the above integrals are different functions of w, this is a new property characteristic of the three dimensional effect of the fluid motion (planar waves are reflected and transmitted with the same shape as the incident waves).

The above technique leads to integrals that must be solved numerically. For this reason in the remaing of the section we will present the following approximate asymptotic analysis of this problem. To do it we will look first for the reflection of a spherical wave due to the presence of a sphere of radius R = a of different density to that of the medium in which the incident wave is propagating.



For an incident wave potential

$$\Phi_I = -\frac{1}{4\pi R}\, f\left(t + \frac{R - r_o}{c_1}\right), \tag{41}$$

Whose maximum is at $R = r_o$ when $t = o$, we will have a reflected wave potential

$$\Phi_r = -\frac{1}{4\pi R}\,Y\left(t-\frac{R-r_r}{c_1}\right), \tag{42}$$

whose maximum is at $R = r_r$ when $t = 0$, and a transmitted potential

$$\Phi_t = -\frac{1}{4\pi R}\,h\left(t+\frac{R-r_t}{c_2}\right), \tag{43}$$

whose maximum is at $R = r_t$ when $t = 0$. where r_r and r_t are to be found later.

The functions Y and h at $R = a$ are determined by the matching - condition at the surface of the sphere of radius $R = a$. From the flux condition, we have

$$\frac{\partial}{\partial R}\left(\Phi_I + \Phi_r\right) = \frac{\partial}{\partial R}\,\Phi_t \qquad \text{at} \quad R=a$$

or

$$\frac{1}{a}\left(f\left(t+\frac{a-r_0}{c_1}\right) - Y\left(t-\frac{a-r_r}{c_1}\right)\right) - \frac{1}{c_1}\left(f'\left(t+\frac{a-r_0}{c_1}\right) - Y'\left(t-\frac{a-r_r}{c_1}\right)\right)$$

$$= \frac{1}{a}\,h\left(t+\frac{a-r_t}{c_2}\right) - \frac{1}{c_2}\,h'\left(t+\frac{a-r_t}{c_2}\right), \tag{44}$$

If a is large enough, the above equation simplies to

$$\frac{1}{c_1}\left(f'\left(t+\frac{a-r_0}{c_1}\right) - Y'\left(t-\frac{a-r_r}{c_1}\right)\right) = \frac{1}{c_2}\,h'\left(t+\frac{a-r_t}{c_2}\right), \tag{45}$$

and from the pressure condition, we get

$$\frac{\partial}{\partial t}\left(\Phi_I + \Phi_r\right) = \frac{\partial}{\partial t}\,\Phi_t \qquad \text{at} \quad R=a$$

or

$$f'\left(t+\frac{a-r_0}{c_1}\right) + Y'\left(t-\frac{a-r_r}{c_1}\right) = h'\left(t+\frac{a-r_t}{c_2}\right), \tag{46}$$

by combination of equation (45) and (46), we obtain

$$h'\left(t+\frac{a-r_t}{c_2}\right) = \frac{2\,c_2}{c_1+c_2}\,f'\left(t+\frac{a-r_0}{c_1}\right) \tag{47}$$

and

$$Y'\left(t-\frac{a-r_r}{c_1}\right)= -\frac{(c_1 - c_2)}{c_1 + c_2} f'\left(t+\frac{a-r_o}{c_1}\right). \tag{48}$$

The prolongation of equation (47) and (48) in the region $R < a$ and $R > a$ respectively can be given by

$$h'\left(t+\frac{R-r_t}{c_2}\right) = \frac{2\,C_2}{c_1+c_2} f'\left(t+\frac{R}{c_2}+\frac{a}{c_1}-\frac{a}{c_2}-\frac{r_o}{c_1}\right). \tag{49}$$

Therefore $r_t = a + C_2 (r_o - a)/C_1$, and

$$Y'\left(t-\frac{R-r_r}{c_1}\right) = -\left(\frac{c_1 - c_2}{c_1 + c_2}\right) f'\left(t-\frac{R}{c_1}+\frac{2a}{c_1}-\frac{r_o}{c_1}\right), \tag{50}$$

Where $r_r = -(r_o - 2a)$, and a is sufficiently large compared to the wave lenght.

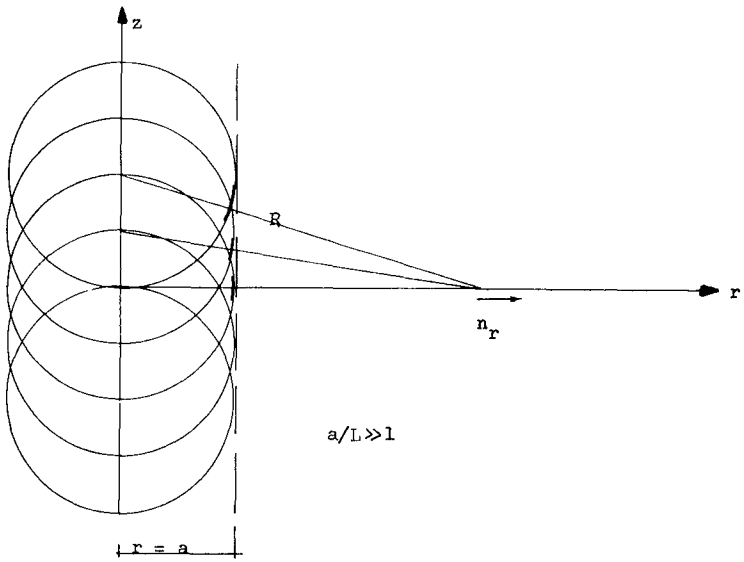
By a superposition of infinite sources on the z axis, line sources, as the ones given by equations (41) and (42), with the relation between y and f given by (50), we will have an outgoing wave

$$n_r = -\frac{1}{2\pi g}\left(\frac{c_1 - c_2}{c_1 + c_2}\right)\int_o^\infty f'\left(t-\frac{r_o-2a}{c_1}-\frac{r}{c_1}\cosh u\right)du \tag{51}$$

That will be the approximate reflected wave, from a cylinder of radius $r = a$, of the incident wave

$$n_i = \frac{1}{2\pi g}\int_o^\infty f'\left(t-\frac{r_o}{c_1}+\frac{r}{c_1}\cosh u\right)du. \tag{52}$$

Since in the integration that we have to do in order to get the reflected wave given by (51), the integrand is proportional to 1/R and therefore the mayor contribution comes from the sources near the origin, where the waves generated by that sources are the reflected waves by a surface almost cylindrical of radius $r = a$ of the corresponding spherical incoming waves, the above approximation tends to the exact solution when the radius r goes to infinite (see the definition sketch given below).



Using the equation(20) of section 2, we get that f' in the above equation is a function of the initial incoming wave profile, given by

$$f'\left(\frac{r}{c_1}\cosh u - \frac{r_0}{c_1}\right) = -4g\,\frac{r}{c_1}\cosh u \int_0^\infty n_i'\left(\frac{r}{c_1}\cosh u \cosh v - \frac{r_0}{c_1}\right)dv \tag{53}$$

or

$$f'\left(-\frac{r}{c_1}\cosh u - \left(\frac{r_0-2a}{c_1}\right)\right) = 4g\,\frac{r}{c_1}\cosh u \int_0^\infty n_i'\left(-\frac{r}{c_1}\cosh u \cosh v - \frac{(r_0-2a)}{c_1}\right)dv \quad . \tag{54}$$

Therefore, when we have an initial incoming wave profile $n_i(r - r_0)/C_1, t = 0)$, the reflected wave can be approximated, for a large r, by

$$n_r = \frac{2}{\pi}\,\frac{(c_1 - c_2)}{c_1 + c_2}\int_0^\infty \left(t - \frac{r}{c_1}\cosh u\right)\int_0^\infty n_i'\left(\left(t - \frac{r}{c_1}\cosh u\right)\cosh v - \left(\frac{r_0-2a}{c_1}\right)\right)dv\,du. \tag{55}$$

In particular a solitary wave, free of discontinuities, can be obtained if Lamb's (1902) source strength is assumed as

$$f(t')= \tau/(t'^2+ \tau'^2) \text{ with } t'= t- \frac{(r_o-2a)}{c_1}, \tag{56}$$

where τ is a parameter, the function f (t') has no definite beginning or ending, but the range of time within which it is sensible can be made as small as we please by diminishing τ . With the above source strength, the asymptotic form of the reflected wave is

$$n_r= - \frac{1}{4\sqrt{2}} \left(\frac{c_1}{c_1} - \frac{c_2}{c_2} \right) \sqrt{\frac{\tau}{r}} \frac{1}{g\tau} \text{ sen } \left(\frac{\pi}{4} - \frac{S}{2} \right) \cos^{3/2} S,$$

where

$$S= \tan^{-1}\left(\frac{1}{\tau} \left(t- \frac{r_o-2a}{c_1} - \frac{r}{c_1} \right) \right). \tag{57}$$

Equation (57) is plotted in figure 3 for the case $C_1 > C_2$, consisting of a negative main wave followed by a longer positive small tail, and it is in agreement with the numerical solutions for both cases $C_1 \gtrless C_2$, where for a positive shelf, $C_1 > C_2$, the reflected wave is negative and for a negative shelf, $C_2 > C_1$, the reflected wave is positive (see figures 1, 2 and 4).

A PROPOSAL FOR WAVE ENERGY CONVERSION NEAR CAPE TOWN

G de F Retief[1], GK Prestedge[2], FPJ Müller[3]

ABSTRACT

The South African wave energy program has been underway for several years and has included an analysis of the temporal and spatial distribution of wave energy along the full coast-line, determination of energy attenuation perpendicular to the coast-line at a site on the south western coast, and the development of a wave energy converter which is most suited to local conditions and requirements.

The resource analysis has shown that the inshore power levels occurring along the south western coast are as promising as any elsewhere in the world. A bottom mounted, V-shaped wave energy conversion device driving an air turbine has been found to be most suited to prevailing conditions.

The conversion characteristics of the device are presented, based on 1:100 scale three dimensional and 1:50 scale two dimensional model studies. Preliminary design studies of the proposed conversion system have underlined its potential viability as a cost effective supplementary source of power.

1. INTROOUCTION

Over 93% of the electricity consumed in the Republic of South Africa is provided through the centralised distribution network of the Electricity Supply Commission (ESCOM) which derives almost all its power from coal-fired stations. ESCOM's presently installed generating capacity of over 19 000 MW will have to be expanded to nearly 70 000 MW by the turn of the century. About 10% of this requirement will probably be met by nuclear power, most of the remainder will be centered around the large coal fields situated to the north east of the country. Although this coal is relatively cheap (providing South Africa with the fifth cheapest electricity in the world) the long transmission distances involved and an awareness of the long term value of non-renewable resources have led to an investigation into the potential utilisation of ocean energy, and more specifically wave energy as a supplementary source of power.

South Africa

Wave energy has attracted interest throughout the world for many years. In a feasibility study of wave energy utilisation Leishman and Scobie (1975) listed some 340 United Kingdom patents, dating back to 1856, of devices which could apparently utilise ocean wave energy. The 1975 study showed that up until 1973 wave energy research had been a very low key activity, but that by 1974 a tremendous surge of interest was taking place, due mainly to the action of the OPEC countries, which had greatly affected the world's oil supplies. A great deal of work has since followed, mainly in the U.K. and Japan but with an increasing number of other countries also examining ways and means of utilising wave energy off their own shores.

Early assessments of the various ocean energy options in the coastal waters of South Africa identified the relative importance of wave energy for this region. Preliminary assessments of the resource were made by Van Wyk (1978) and Dutkiewicz and Nurick (1978), who identified relatively high energy levels to the south west of the country.

The present project which was initiated in 1979 included both a reassessment of the resource as well as the design of an energy conversion system. The resource analysis covered both a temporal and spatial distribution of wave energy using eight years of recorded wave data from a site near Cape Town (to determine long term variability), one year of synoptic wave data from representative sites for the coast-wise analyses and a three-gauge array off the Cape Peninsula to determine energy levels on a line perpendicular to the shore. Development of the wave power conversion system was based on the considerations listed in figure 1 and governed by the design philosophy which is presented in section 3.1.

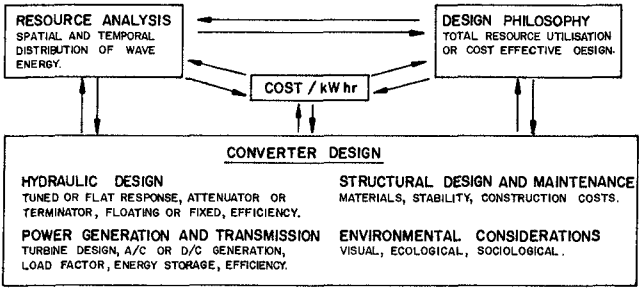

FIG I PROJECT COMPONENT DIAGRAM

2. WAVE POWER RESOURCE

2.1 Analysis procedures.

All the wave data used in this project were obtained by Datawell Waverider buoys recording digitally every six hours at a sample rate of 2 Hz for a record length of approximately 2048 data points. Records were then tested for quality control using the standard program of the National Research Institute for Oceanology (NRIO) which includes checks on successive equal values, wave steepness, low frequency energy, normality, stationarity and a number of other statistical improbabilities. After an FFT analysis the reduced data were stored in spectral density histogram form in a databank before further analysis.

Power computations were based on:

$$P = EnC \qquad (1)$$

using

$$H = H_{rms} = 2\,(2M_o)^{\frac{1}{2}} \qquad (2)$$

and

$$T = T_F = \Sigma\,(\frac{E_i}{F_i}) \;/\; \Sigma\, E_i \qquad (3)$$

All power figures were converted to representative "deep" water values except for the two shallow water stations in the wave gauge array off the Cape Peninsula.

2.2 Coast-wise distribution.

Waves formed in the major generating zone to the south west of Southern Africa undergo very little refraction before arriving at the tip of the sub-continent. A mean annual power level of approximately 45 kW per metre wave crest is typical off-shore of the Cape Peninsula. The remaining south western coastal belt (Danger Point to Saldanha Bay) has an annual average energy flux level of approximately 25 to 30 kW/m which diminishes northwards to levels of about 21 kW/m at Oranjemund and eastwards to constant levels of about 12 kW/m. Figure 2 shows the mean annual power levels at six coastal sites based on an analysis of one year's synoptic data for the period November 1978 to November 1979. The figures in brackets represent the wave power level in kW/m which is exceeded 90% of the year. A mean annual power level at a weather ship site 10^{o}S 400^{o}E is included merely for comparison purposes as the recording period did not coincide with that of the coastal analysis.

At an early stage of the project it was realised that in terms of power utilisation a wave power figure representing an average over a full year has very little value and can in fact be rather misleading. (Mean annual power levels are included in this paper for the sake of comparison with the many other wave energy studies which have limited their analyses to mean figures.)

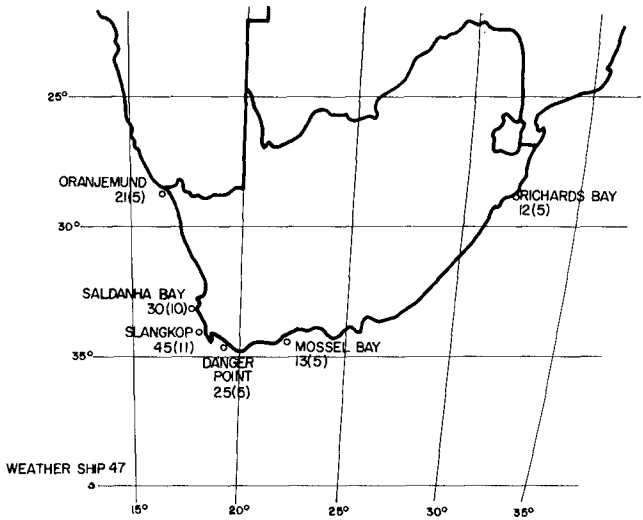

FIG 2 WAVE POWER DISTRIBUTION ALONG THE SOUTH AFRICAN COAST, POWER IN kW/m MEAN ANNUAL, (90% EXCEEDENCE)

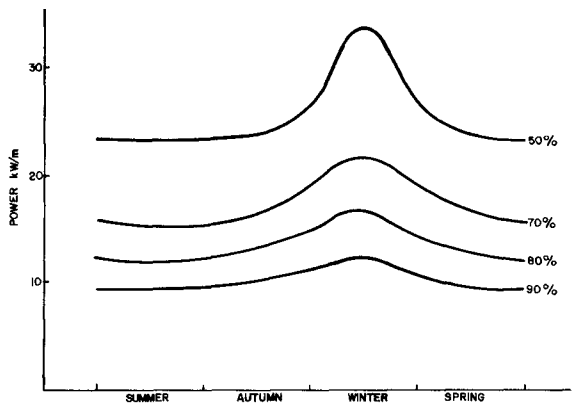

FIG 3 SEASONAL VARIATION OF POWER AT DIFFERENT EXCEEDENCE LEVELS : SALDANHA BAY

It will be noticed that 90% exceedence power levels of about 10 kW/m occur between Slangkop and Saldanha Bay, while the remainder of the coast-line displays a constant level of about 5 kW/m. These results can be very significant in terms of the level of optimum power conversion for which a wave power station is designed. For example, if a device were designed to produce an optimum cost benefit at a power level of 5 kW/m (which would provide power for 90% of the year) the potential application of this device along the coast would be totally different from some other device which was designed to convert all the wave energy it encountered at the highest hydraulic efficiency. Figure 3 shows the seasonal variation of power levels at 50%, 70%, 80% and 90% exceedence for Saldanha Bay.

The final analysis of the wave energy resource is thus of necessity dependent on the conversion characteristics of the proposed wave energy converter and the demand characteristics of the converted power. The interactions involved are shown in figure 1.

2.3 Wave power distribution at Slangkop.

In a joint project between the Universities of Stellenbosch and Cape Town, the Fisheries Development Corporation of SA Ltd and NRIO, three Waverider stations were maintained west of the Slangkop Light House on the Cape Peninsula for a period of over two years specifically to study shoaling effects on wave energy propagation. The dissipative mechanisms involved have been analysed by Shillington (1982).

The three stations were situated in 200 m, 24 m and 15 m water depths, and were backed up by a DOSO direction gauge (Retief and Vonk, 1974) at the 24 m station. A typical annual H-T scatter diagram with 10 kW isodynes for the 200 m station is shown in figure 4. Figure 5 shows the position of the three Slangkop stations with the mean annual and 90% exceedence wave power curves plotted against distance from shore. It can be seen that although there is a 30% reduction in mean annual power between off-shore and 0,8 km from shore (15 m deep station) the 90% exceedence curve displays a reduction of only 20%. The relatively high power levels occurring close inshore favour the use of fixed, shallow water energy converters which will avoid mooring problems and require minimum power transmission distances. Development of the energy converter was thus directed towards the inshore zone from the outset, as opposed to the initial deep-water approach of the United Kingdom researchers where the shallow-water power levels are relatively unfavourable (Crisp and Scott, 1981).

Although the Slangkop records displayed the highest mean levels of wave power measured around the coast this did not necessarily imply that Slangkop was most suited for wave power utilisation. In comparing the seasonal distribution of the 90% exceedence curves for Slangkop, Saldanha and Oranjemund (see figure 6) it was found that the more evenly distributed power at Saldanha suggested more favourable power generating characteristics than that at the higher energy Slangkop station.

Another form of analysis which assists in determining the design characteristics of the power converter is shown in figure 7 for Saldanha,

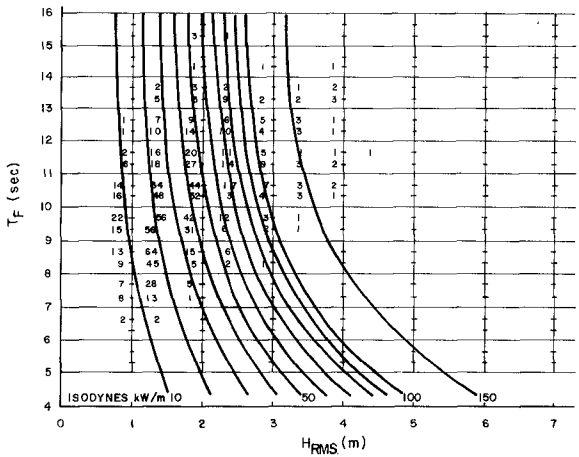

FIG 4 H-T SCATTER DIAGRAM FOR SLANGKOP (200m) VALUES IN PARTS PER THOUSAND

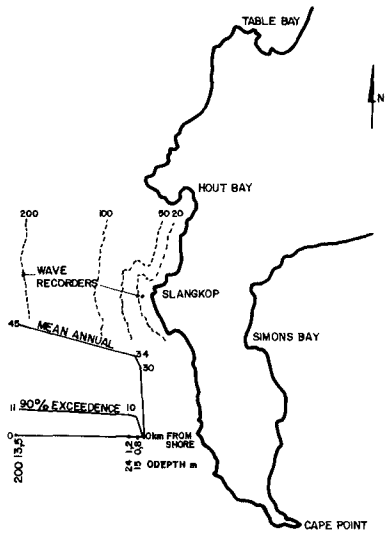

FIG 5 SLANGKOP WAVE POWER CHARACTERISTICS

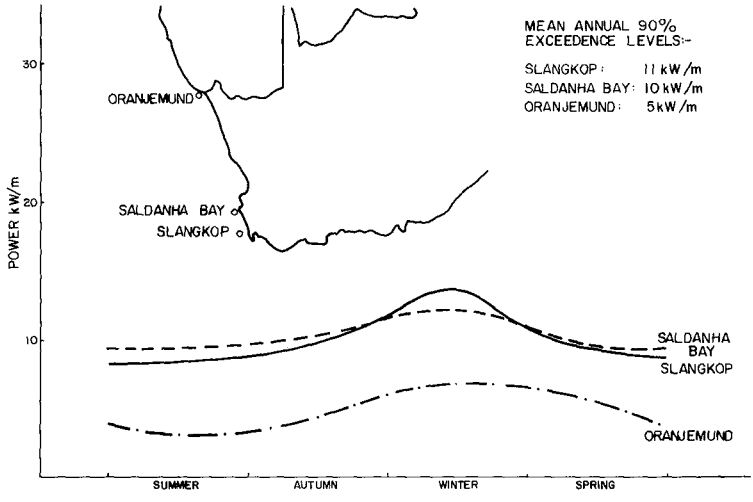

FIG 6 SEASONAL VARIATION OF POWER AT 90% EXCEEDENCE LEVEL FOR THREE STATIONS

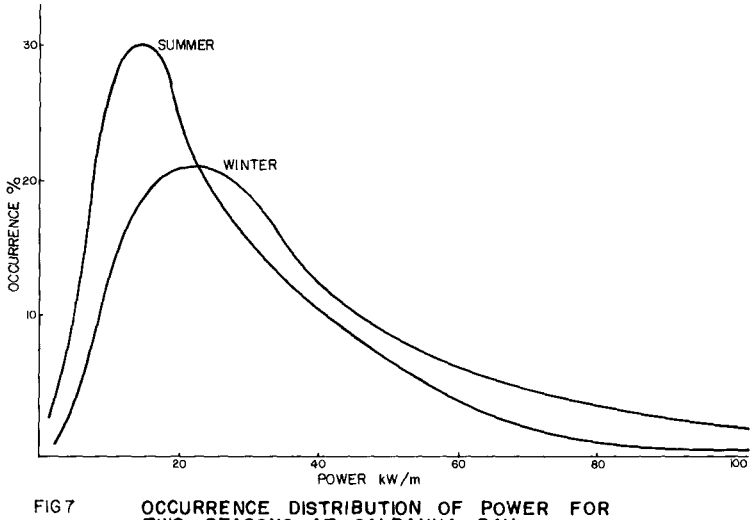

FIG 7 OCCURRENCE DISTRIBUTION OF POWER FOR TWO SEASONS AT SALDANHA BAY

where the occurrence distribution of power for various seasons or demand periods can prescribe optimum generating capability for the period under study.

In figure 7 the highest percentage of power in the summer occurs at about 14 kW/m while in the winter 22 kW/m appears to be most prevalent at this particular site.

Vimukta *et al* (1978) suggested that for a fairly large wave power program which is not combined with storage "there is little point in having a mechanical power cut-off greater than about 25 kW/m". For this project the larger converter described in section 3 was based on a 22 kW/m cut-off, the smaller on 13 kW/m.

3. ENERGY CONVERTER

3.1 Design philosophy.

In figure 1 the component interactions of the program are described and reference has subsequently been made to the concept of a design philosophy. In developing a new system in which a great number of variables interact it becomes essential to establish a well defined philosophy which will reduce the number of variables and qualify the project's stated objectives.

The following statements constituted this project's design philosophy:

- cost efficiency to be of prime importance (hydraulic conversion efficiency of secondary importance *per se*; total resource utilisation was not a specific objective if this should be in conflict with the cost objective).

- the system should not be dependent on energy storage (i.e. device to be optimised at a low power cut-off level).

- over design required for extreme storm events to be avoided.

- environmental impact and possible hazard to navigation to be minimised.

- design and construction of the device should fall within existing local technological capability.

- the apparent high levels of power occurring inshore along the south western coast of Southern Africa should be utilised if this could improve cost efficiency.

The decision to work independently of power storage was made mainly to reduce the number of variables and to produce a system which was more universal and versatile. (Where mountains occur close to the sea, wave power generators can naturally be employed to pump water to storage reservoirs. If sea-water is used and the reservoir is sited at least 600 m above sea-level the system can be used both as a pumped storage power scheme for the winter and a reversed osmosis fresh water

supply scheme for the summer.) The greater majority of previously proposed wave energy converters have been aimed at high hydraulic efficiency, requiring storage of the extreme levels of power generated during storms, contrary to the proposal by Vimukta *et al* (1978) that "the emphasis of research should be switched away from efficient extraction of the large amounts of power available in strong seas and towards cheapness and reliability of supply under ordinary and calm conditions".

3.2 Proposed converter.

The considerations listed under 3.1 led to the following preliminary conclusions:

- the converter should be a fixed structure thus producing an efficient reference frame, simple technology (no mooring or flexible transmission problems) and limited maintenance.

- the device should be submerged to minimise environmental impact and reduce storm loading.

- installation should be close inshore to reduce transmission distance and provide a limited wave direction spectrum and depth limited design wave height.

- the device should be non-tuned and relatively insensitive with robust and simple control requirements.

The simple, yet elegant oscillating water column concept, first developed in Japan and later researched by a number of wave energy groups, was judged as most suitable to meet the above requirements. However, instead of directly extracting power from the oscillating air flow, a manifold system similar to that proposed by French (1979) for the Lancaster Flexible Bag Device was used to provide a rectified air flow. To enhance capture efficiency and improve structural stability the converter is angled to the wave orthogonal. To improve generating cost efficiency a pair of collectors is coupled in a V-formation to a single air turbine and power generator mounted above water level in a tower at the apex of the V. Figure 8 illustrates the principles involved. Figure 9 shows an artist's proposal of a V-converter constructed on ring foot pillars along a sandy shore line in 15 m to 20 m water depth.

3.3 Model studies.

Model studies used in the development of the Stellenbosch Wave Energy Converter (SWEC) covered a variety of cross-sectional shapes and internal proportions for variable collector length, orientation angle and submergence depth. Two dimensional flume tests were carried out at a scale of 1:50 (figure 10), while three dimensional wide tank tests were performed at 1:100 (figure 11) in the hydraulics laboratory of the University of Stellenbosch.

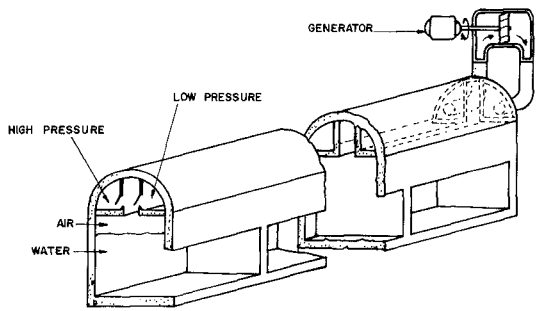

FIG 8 PRINCIPLES OF OPERATION OF THE SWEC

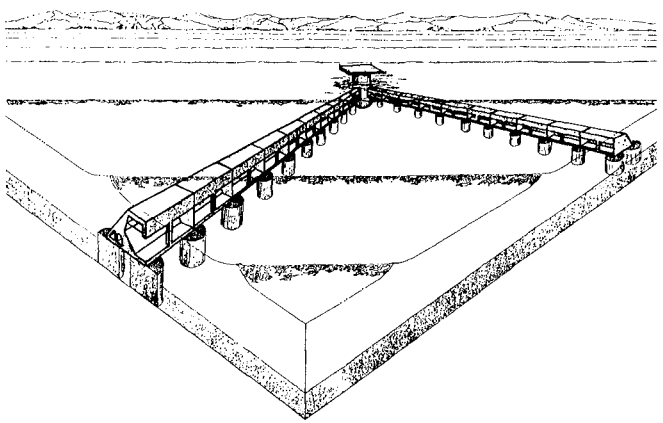

FIG 9 ARTISTS RENDERING OF THE SWEC

FIG 10 TWO DIMENSIONAL MODEL TESTS.

FIG 11 THREE DIMENSIONAL MODEL TESTS OF ONE COLLECTOR ARM.

The three dimensional models were built with the high and low pressure manifold ducts supported outside the model, above water level (see figure 11) so that Reynolds scale effects in the ducts could be minimised and observation and control facilitated. The compressibility of the air contained within the device cannot be scaled. To establish what effect this might have on the model studies a series of tests were carried out with compression chambers attached to the manifold ducts proportioned so that they would simulate the compressibility of air in the prototype. It was found that the compressibility of the contained air did not influence the device's power conversion capability but merely provided a damping effect on the higher frequency pressure fluctuations in the ducts.

Generated power in the model was measured by a sensitive volumetric gas flow gauge (fitted with a throttle control to simulate power loading) and pressure sensors monitoring the pressure gradient across the flow gauge. High frequency pressure fluctuations in the ducts (caused by valve slapping) were electronically filtered out to approximately simulate the prototype turbine response. Water level fluctuations inside the collector compartments were monitored by means of resistence probes. The two dimensional model was fitted with a constant head, variable volume air chamber to simulate the manifold system. Structural stability tests were carried out on a 20 m length of collector arm at a scale of 1:100 in a special test rig which measured horizontal shear and overturning forces simultaneously.

3.4 Converter characteristics.

Although the collector arms will normally be installed at an angle of about 30^{o} to the coast-line it can be seen from figure 12 that precise orientation is not critical in terms of conversion efficiency and can vary by up to $\pm 15^{o}$ of optimum.

Frequency response of the device (figure 13) displays a satisfactory band-width and allows a certain amount of freedom in fixing the length of the collector arm according to site conditions.

An important attribute of this device is that as long as the collector arm is maintained at some constant minimum length (sufficient to provide a smooth air flow through the turbine and dependent on the component of arm length normal to the wave crest) the cross-section of the collector arm can be scaled up or down and the cost efficiency of the system is maintained approximately constant. This implies that depending on the power cut-off level that is considered suitable for a specific site the device can be designed accordingly with no loss in cost efficiency.

The power cut-off is attained by throttling the air flow upstream of the turbine and the resulting conversion characteristics are shown in figure 14 for devices with cross-sectional height dimensions of 5,5 m and 9,0 m. Throttling of the air flow also limits vertical motion of the water surfaces within the collector arm and prevents slamming against the collector roof-slab.

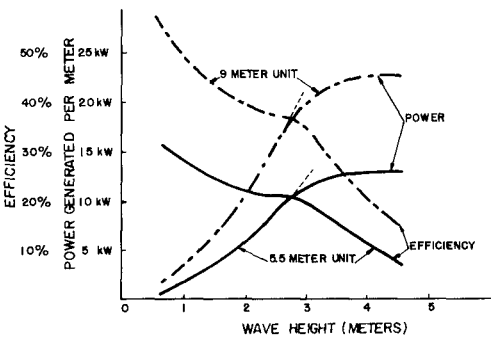

FIG 14 POWER GENERATED AND EFFICIENCY VS, WAVE HEIGHT FOR TWO CONVERTER SIZES

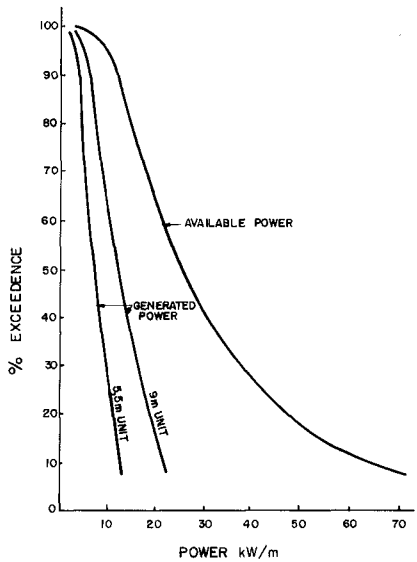

FIG 15 POWER EXCEEDENCE CURVES FOR SALDANHA: AVAILABLE AND GENERATED

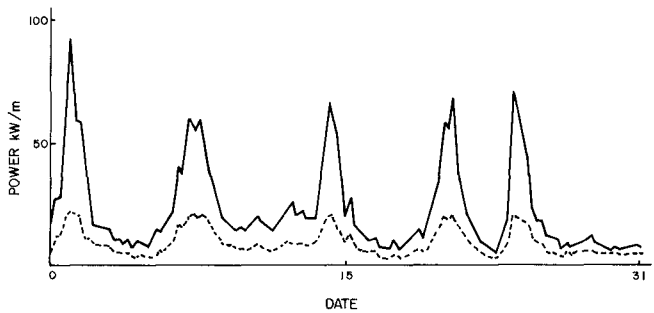

FIG 16 WAVE POWER AT SLANGKOP FOR JANUARY 1982
——— AVAILABLE
- - - - - GENERATED (9m UNIT)

Applying the curves shown in figure 14 to an actual site, the available and generated annual power exceedence curves for Saldanha Bay for the 9 m and 5,5 m units are shown in figure 15. The suppressed conversion characteristics of such a device can also be clearly seen in a time domain plot of available and generated power, as in figure 16 where the generation history of a 9 m unit installed at Slangkop is depicted for a period of one month in midsummer.

3.5 Prototype design.

For costing purposes engineering designs of a 9 m and a 5,5 m unit based on the format shown in figure 9 were drawn up. The design was based on a precast, 15 m long reinforced concrete module which is floated to site and cast into preplaced and ballasted ring foundations. Where installation is to take place on a rocky sea-bed the units will be laid on a prepared bed and fixed by means of rock anchors. The modules are intrinsicly very stable. In the flooded mode, used for placement, and before the units are anchored, they remain stable in waves of up to 3,5 m. This provides a useful weather window for fixing the units in place and coupling the air ducts (by means of flexible "subway" joints). The valves are durable, light-weight material offering low inertia and protected by buoyant "splash flaps". An airpump, housed in the access tower, will maintain the desired air volume in the system. The low pressure air turbine (Francis or axial flow) and coupled power generator will be housed above water level in the access tower so that flooding of the collector arms will not disturb the control and generating gear. Both A/C and D/C generating options have been considered and the rated output varies from 2,5 MW (mean annual) for a 5,5 m "V" collector to 4,4 MW for a 9 m unit. The final cost of A/C power delivered at the coast and based on a 100 MW grouping of "V" collectors along 9 km of coast, has been found to range from 4,5c to 5c per kWhr (RSA currency) which is considered competitive with existing power costs along large sections of the coast-line.

4. CONCLUSION

The Stellenbosch Wave Energy Converter has generally met all the original requirements described in section 3.1. The power produced appears to be cost competitive with existing power and the system relies solely on existing construction technology. Although further quantitative work is required on the potential disruption of littoral processes through the extraction of wave energy a preliminary assessment indicates that this should not be excessive. The device is robust and simple and will be virtually unaffected by marine growth with maintenance operations being largely limited to the access tower. At the end of its economic life the device can be flooded to become an artificial reef.

The primary aim of the above converter is to produce electricity at a viable present day cost. Consequently high hydraulic conversion efficiency was not a fundamental requirement. For an inshore device such as this, environmental considerations will in any case impose a limit on the extraction efficiency. The system is therefore not aimed at total resource utilisation but should offer a useful source of supplementary power for the future. Because of the ease with which the

device can be scaled, the step required to move from laboratory to pilot installation will not require the same level of risk capital as is the case in many previously proposed devices.

SOME PROPERTIES OF SWELL IN THE SOUTHERN OCEAN

by

Jon B. Hinwood[1],
Deane R. Blackman[2], and
Geoffrey T. Lleonart[3]

SUMMARY

Records of pressure from a bottom-resident instrument deployed near the western margin of Bass Strait have been analysed. Discrete wind-sea and swell spectra have been identified and have been related to meteorological events. The spectra fit a finite-depth form of the Wallops spectrum.

1. INTRODUCTION

Research in coastal and ocean engineering at Monash University has been planned to address topics of specific relevance to Australia. The Southern Ocean, effectively with an infinite fetch, is a source of strong swell to which the whole southern half of the continent is exposed. The present project involves the collection of wave data, particularly swell, and the numerical modelling of the generation, propagation and decay of waves in arbitrary bathymetry. An instrument and moorings suitable for a single point or a directional array were designed and made for this project.

The aim of the preliminary field experiment described here was both to test the instruments and to attempt some definition of the swell field impinging on the Strait to guide future experiments.

To the south of Tasmania the strong westerly winds of the Roaring Forties prevail. At the latitude of Bass Strait the weather patterns

are dominated by the eastward-moving succession of high and low pressure regions with its approximately four-day period. The lows are usually more strongly developed and give rise to stronger winds. The lows are often preceded by or merged with one or more cold fronts which are accompanied by strong winds but of short duration. The pattern of highs and lows moves north in winter making the northerly winds dominant from April to September, while southerlies are dominant from November to March. There is no "weather window" in Bass Strait and strong winds may be experienced in any month.

Owing to the dominant strong winds around latitude 40°S, the wave climate is particularly severe on the south-western coast of Tasmania, moderating with distance north —— towards the site of the present measurements. Strong wave and swell events reported here were generated by each of the wind systems: very large atmospheric systems south latitude 40°S, strong lows passing just south of or over Bass Strait and cold fronts passing over Bass Strait.

2. SOURCES OF DATA

Hourly wind speed and direction were obtained from the nearby Baseline Air Pollution Monitoring Station at Cape Grim with the cooperation of CSIRO. This observatory is 45 km south-east of the site of the experiment and stands on a cliff 90 m above the sea. Presently no corrections have been applied to the wind data.

The instrument used to measure the waves is a bottom-resident pressure-sensing recorder. The recorder is a micro-computer controlled digital cassette drive designed for minimum power consumption and capable of conditional sampling of the input. The instrument wakes every four hours and senses the sea state for a period determined by the firmware. If it decides there is sufficient surface activity it logs conditions as described and then enters an extended recording mode. In the present experiment this involved samples at 4 second intervals for a period of 30 minutes each.

The tape has a capacity of approximately 100 30-minute wave records. In the trial, the results of which are reported here, the instrument ran for 39 days. In this time six events reached the threshold value and resulted in wave records.

For this deployment the instrument was placed on the sea bed, though later deployments may use a taut-wire mooring system. Since the maximum depth for the instrument is 60 m, a station at the edge of the shelf was not attainable. The site selected, shown in Fig. 1, was 144° 20'E, 40° 28'S, 2.5 km north-west of Black Pyramid, a site which satisfied the above criteria although the sea bed was not as smooth as desired being a low rocky ridge rising 15 m above the general surroundings to a depth of 57 m below MWL.

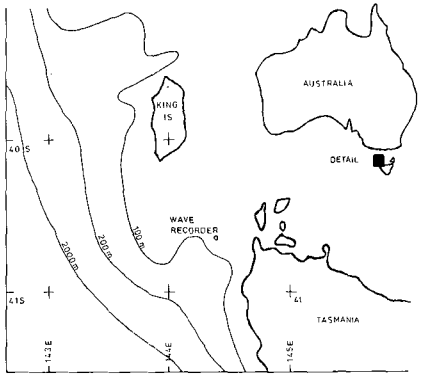

Fig. 1 Location map

3. SPECTRA

To reduce the records of bottom pressure to power spectra of the surface elevation the average of seven hanned periodograms was taken, and the correction for attenuation due to depth corresponding to each frequency component was applied to its spectral value to give the corrected spectrum at the surface. The magnitude of the depth correction factor reaches large values (~ 300) at the highest frequencies considered. For the spectra shown a filter has been applied attenuating components with periods less than 9 s.

The time history of the surface elevation was reconstructed by transforming the whole pressure record, making the depth correction in frequency space, and transforming inversely. The power spectrum of the surface elevation can also be obtained from this history; as expected the results are similar to those obtained from the pressure signal directly, as described above.

4. RESULTS AND DISCUSSION

Records of the hourly wind data from Cape Grim and the four-hourly wave data from Black Pyramid were combined as shown in Fig. 2 to represent a time history of wind and wave parameters during the 39-day period of the experiment. The wave height parameter used in the time history was based on the maximum crest-to-trough pressure difference observed during a 5-minute period. The units are metres of water. Because the wave recorder senses bottom pressure at a depth of 57 m, the description of the sea state obtained from it corresponds principally to swell conditions.

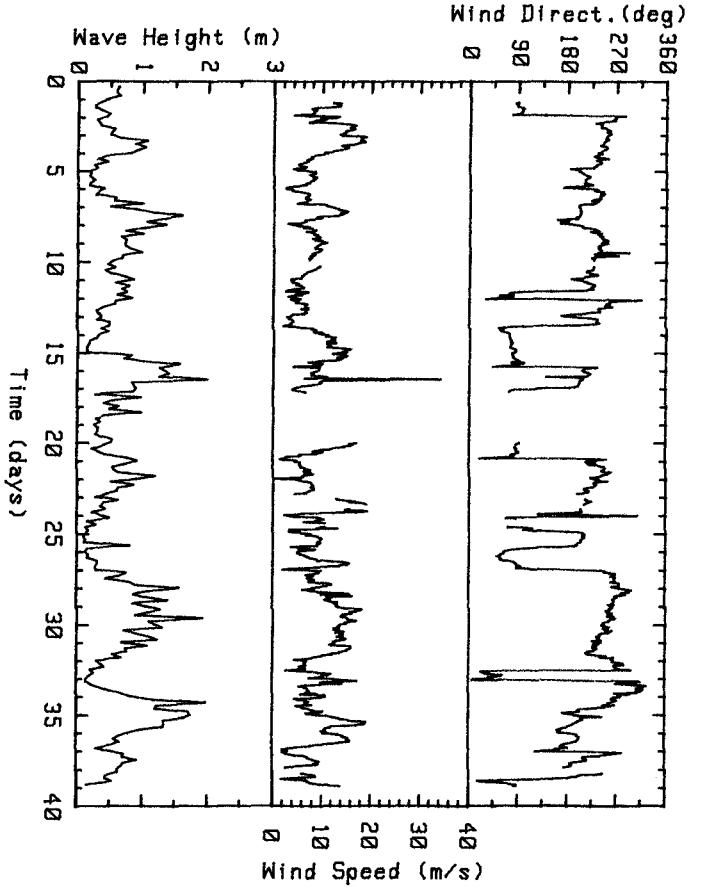

Fig. 2 Time series of measured sea state with wind speed and direction at Cape Grim

Some features of the time history are worthy of note. During the period of the experiment the wind blew mainly from the south-west and only on one occasion exceeded 20 m/s. The significant wave height varied between about 10 cm and 2 m and the periods of high and

low swell activity are clearly shown in Fig. 2. The first significant swell started to build up after day 6 (14 November 1982) and reached a peak between days 7 and 8, then gradually decayed until day 15 at which time it grew considerably. On day 16 (24 November 1982) of the experiment, between 0600Z and 1200Z wind from the SSW reached speeds of 34 m/s. This storm produced a wind sea, which in conjunction with the significant existing swell, was sufficient to trigger the instrument into the extended recording mode.

The first 30-minute wave record was taken during this intense but short-lived frontal storm. Analysis of the wave record obtained indicated a 14.2 s period swell peak in the surface elevation spectrum with an estimated significant wave height H_s of 2.1 m. The spectrum is shown in Fig. 3; clearly evident is a separate peak due to the wind sea.

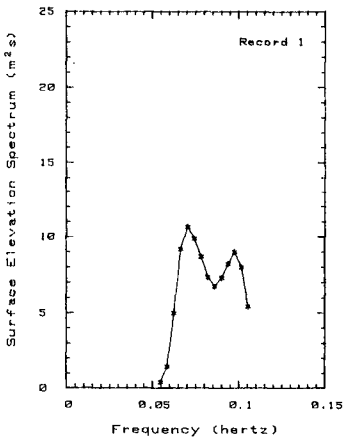

Fig. 3 Surface elevation spectrum showing separate swell and wind-sea peaks

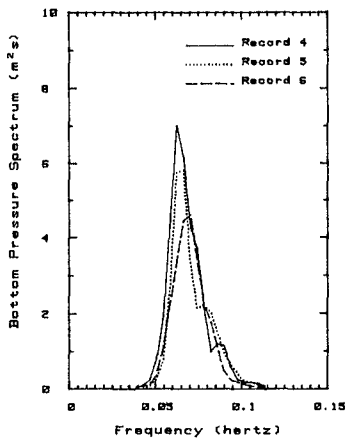

Fig. 4 Bottom pressure spectra showing evolution with time

A further 13 days passed before the second 30 minute record was taken. The swell level decreased from day 16 (24 November) until about day 20 (28 November); it increased slightly before falling to its lowest level on day 25 (2 December). Under the influence of strong west winds the wave activity then built up steadily; record 2, taken on day 30 (7 December), coincided with the passage of a storm of extended duration with winds up to 18 m/s from the west. The surface elevation spectrum corresponding to this record contained a single peak at a frequency of 0.1 Hz. Although the frequency range of the

data obtained from the pressure transducer is limited, an estimate of the H_s was found by fitting the experimental data to a Wallops spectrum modified to account for finite depth. This procedure yielded a H_s of 6.3 m. A Jonswap spectrum with a peak enhancement factor of 4.2 yielded essentially the same result.

Wave activity subsided after day 30 (7 December) to a new low level on day 33 (10 December), it then rose sharply and the swell reached a high level. Records 3, 4, 5 and 6 were taken during this period after which the swell again fell to a low level. The last three wave records obtained were taken successively at 4-hour intervals, commencing on day 35 (12 December) at 1600Z. An increase with time of the frequency associated with the peak in the swell spectrum is clearly evident in Fig. 4, where the bottom pressure spectra of records 4, 5 and 6 are presented. A distance of about 950 km to the source of the swell in these records was inferred from the frequency shift. Although limited in detail, the synoptic weather charts issued by the Australian Bureau of Meteorology indicate a likely storm source located some 1000 km SSW of the site of the experiment.

No swell peak was observed in the spectrum of the storm sea of record 2, but all the other spectra from the records obtained displayed prominent swell peaks, which, with the exception of record 6, were accompanied by locally generated wind-sea peaks.

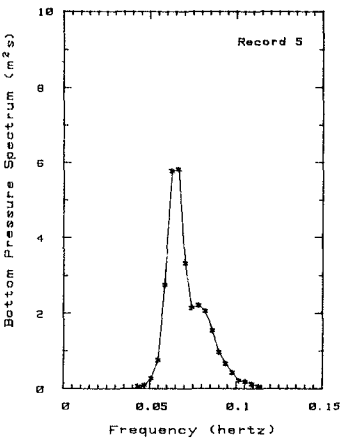

Fig. 5 Typical bottom pressure spectrum - Record 5

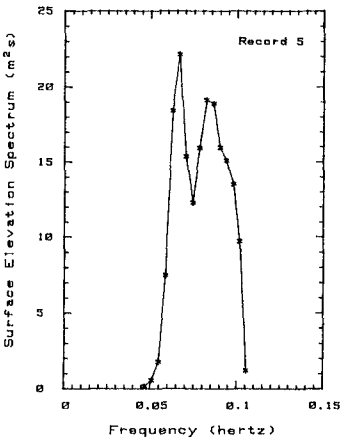

Fig. 6 Typical surface elevation spectrum - Record 5

The period of the swell peaks ranged from 14.2 to 15.3 s, and estimated values of H_s ranged from 2.1 to 3.1 m. Wave record 5 is typical and Figs. 5 and 6 represent respectively bottom pressure and surface elevation spectra for this record; in both representations swell and wind-sea peaks may be identified.

Record 6 was taken soon after the local wind sea had subsided and represents swell resulting from the events of 12 December. In an effort to describe theoretically swell we have modified the recently proposed Wallops spectrum to account for finite depth effects. The Wallops equation for the spectrum of surface elevation given by Huang et al (1981) is:

$$\Phi(f) = \frac{\beta g^2}{(2\pi)^4} \cdot \frac{f_p^{m-5}}{f^m} \cdot \exp\left\{-\frac{m}{4}\left(\frac{f_p}{f}\right)^4\right\} \qquad (1)$$

where f and the frequency of the spectral peak are now measured in Hertz.

As originally given the equation was suitable for deep water conditions. We have modified the functions β and m for intermediate depth water; the derivation of these forms is given in Lleonart, Blackman and Hinwood (1983).

$$\beta = \frac{\left\{2\pi S\left[\tanh\left(k_p d\right)\right]\right\}^2 \cdot m^{\frac{m-1}{4}}}{4^{\frac{m-5}{4}}\,\Gamma\left(\frac{m-1}{4}\right)} \qquad (2)$$

$$m = \left| \frac{\ell n\left(\sqrt{2}\pi S\right)^2 \left[\frac{\cosh\left(k_p d\right)}{\sinh^3\left(k_p d\right)}\left\{1 + \frac{1}{2}\cosh\left(2k_p d\right)\right\}\right]^2}{\ell n^2} \right| \qquad (3)$$

where

$$S \equiv \frac{\left(\bar{\eta}^2\right)^{1/2}}{\lambda_p}$$

$\bar{\eta}^2$ is the mean square surface elevation,
λ_p is the wave length corresponding to the spectral peak,
k_p is the corresponding wave number, and
d is the still-water depth.

These forms differ from those in Huang et al by the inclusion of the factors in square brackets.

Fig. 7 shows good agreement between the field data and the spectrum for surface elevation based on eqns (1) to (3). We have also developed a theoretical description of the spectrum of the swell in terms of bottom pressure, and a comparison of observations with the predictions is presented in Fig. 8. Further comparisons have been made with data from other sources as well as more recent data of our own. We have found agreement to be consistently good. Huang et al suggested it may be possible to apply the Wallops spectrum to cases where the spectrum contains multiple peaks and we have indeed found, for reasonably separated peaks, that two independent Wallops spectra may be combined to describe the full spectrum.

The derived time series of surface elevation were analysed to establish probability distributions and the extent of wave group formation among larger waves. Unlike the Pierson-Moskowitz spectrum, the Wallops spectrum has a variable bandwidth parameter and it should therefore be a valuable tool in characterising the statistics of wave groups.

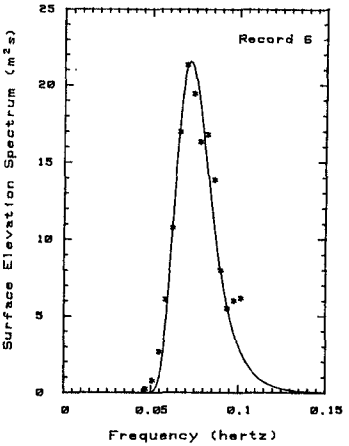

Fig. 7 Comparison of measured surface elevation spectrum with modified Wallops spectrum

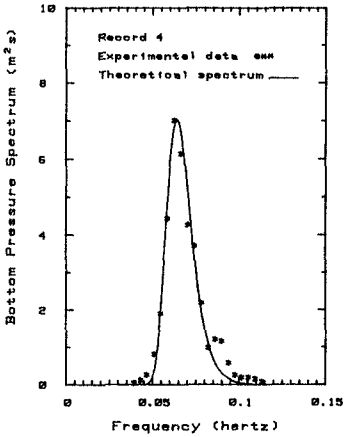

Fig. 8 Comparison of measured bottom pressure spectrum with modified Wallops type spectrum

5. CONCLUSIONS

The data obtained confirm that there is significant swell generated by identifiable meteorological events within the Southern

Ocean. The surface elevation spectra obtained fit a Wallops spectrum modified for the effects of shallow depth. Using the variable bandwidth property of the Wallops spectrum an analytical expression for the length of runs of high waves has been obtained and compared with field data.

UNUSUAL WAVES ON EUROPEAN COASTS, FEBRUARY 1979

by

Laurence Draper[1]

and

Lt. Cdr. T.M. Bownass RN[2] Ret'd

ABSTRACT

A depression in mid North Atlantic moved at a speed such that it generated high waves of unusually long period and large wavelength. These waves travelled in precisely the right direction to carry them into the English Channel, where they arrived during a time of spring tides and when low barometric pressure contributed to long waves impinging high on the foreshore, causing appreciable damage to sea defences and property.

OBSERVED EFFECTS

Unusually high wave activity, which caused considerable damage, occurred along the central and western coasts of The English Channel at about the time of high tide during the morning of Tuesday, 13 February 1979. Locations mentioned are shown on the map. Damage was particularly severe at Chiswell on the Isle of Portland, where waves over-topped Chesil Beach, the crest of which is about 12 metres above high tide level, causing extensive flooding and necessitating virtual rebuilding of parts of the Beach and settlement (Fig. 1). Eye witnesses described a considerable amount of water flooding through the beach, adding to the flooding due to overtopping. Chesil Beach is a narrow spit and is unusual in that the pebbles are graded in size over its ten-mile length, being smallest at the west and largest at the east.

The damage, on a south-westerly facing beach, took place at a time when the local wind was easterly of about 10 knots. This is in contrast to several times Chiswell has been flooded in the past, when

PHOTOGRAPHIC SECTION HMS OSPREY CROWN COPYRIGHT PHOTOGRAPH

the damage was directly attributable to strong winds in the local area which resulted in overtopping of and percolation through the beach. (The most recent previous occasion of this was a strong southerly gale on 13 December 1978.)

In February 1979 there was damage all along the southern English coasts. In harbour in The Isles of Scilly the ship Scillonian tore her mooring bollard off the deck and ripped up her shore moorings. In Plymouth harbour the long waves arrived around 0500hr, high water was at 0700 and the peak activity occurred around 0800. When the dock gates were opened, craft broke moorings until the gates jammed shut. Spray from the waves broke over the breakwater light at the seaward side of Plymouth Sound at 19m. An RAF craft reported that sailing parallel to the crests was like having enormously long walls of sea either side, but that with such a great wavelength no difficulty was experienced.

At Seaton, further up-Channel, coastal structures were badly damaged, and even at Hayling Island, to the east and in the lee of the Isle of Wight, very long length swell waves caused flooding.

Elsewhere, in South Wales these waves caused damage, for example by breaking over the fore-shore at Tenby, and at Sines in Portugal the massive breakwater under construction, and already damaged by previous wave attack, again suffered considerably. Nearby, Leixoes also suffered damage.

An interesting observation of the contrast between effects of the storms of 13 December 1978 and 13 February 1979 was made by Lt. Cdr. J. Roberts, Meteorological Officer of HMS Osprey, Portland. In the former storm the seaward side of the remaining shingle was much too steep to climb up, the pebbles looking as though they had been shovelled out by the sea, leaving a cliff, whilst in the latter case the bank looked like a huge rounded whale-back. In the first case the damage was consistent with attack from short, steep waves, characteristic of locally-generated storm waves, or "sea", which destroy beaches and rip out sand and pebbles from a beach. In the second case, damage was consistent with attack from waves which are very long compared with their height, and are termed "swell", which carry sea-bed material towards the shore and build beaches.

OCEANOGRAPHIC ASPECTS

As the local wind could not have been responsible for generating any waves approaching from a westerly direction, the source of the wave energy must have lain in the Atlantic. Portland subtends only a small angle to the Atlantic, with an arc from perhaps 230 degrees to 260 degrees, so that any wind source must therefore lie within this "window". However, the "window" is not a simple "optical" one, because refraction, which itself will depend on wavelength and therefore ultimately on wind strength, and also on the direction of the original wind, will allow a displacement of the generating

zone into areas adjacent to those in the "optical window". There is, therefore, a range of conditions which could result in a wave orthogonal leading to Portland.

Probably the most important single parameter is the wave period; the periods of the waves at the time of the disaster lay outside the range of periods associated with substantial wave energy ever recorded in many years of wave recording in waters around the British Isles or of the North Atlantic.

WAVE DATA SOURCES

The Taunton laboratory of the Institute of Oceanographic Sciences maintains several wave recorders off the west coasts of the UK for climatological purposes. It has been possible to obtain and analyse data for the relevant times from a recorder on the Sevenstones Light Vessel off Land's End, one near Eddystone Lighthouse and another on the St. Gowan Light Vessel in the Bristol Channel south of Pembroke. The UK Data Buoy DB1 located 120 miles south west of The Isles of Scilly at 48°42'N, 8°58'W, was operated by the Departments of Energy and Industry and the United Kingdom Offshore Operators' Association, and measured meteorological and oceanographic parameters, including wave conditions, and transmitted the data by radio to EMI (Woking). A Waverider was maintained by the Hydraulics Research Station, Wallingford, off Perranporth, on the western Cornish coast south of Newquay; it was exposed to waves approaching from the west. Another was operating well up the Bristol Channel. Elsewhere, a Waverider was operating off the port of Sines in Portugal.

A SEARCH FOR THE GENERATING AREA

In order to find a possible generating area which could be the source of this wave energy and which lies within the "window", it is necessary to study the previous few days' North Atlantic synoptic weather charts. The chart for 1200 on 10 February 1979 shows a new depression (Low 992) south of Newfoundland. This depression deepened rapidly as it moved eastwards and by 0000hr GMT on 11 February it can be seen (Fig. 2) as low H, having deepened to 952 mb. The westerly winds on its southern flank were estimated to be of 50-60 knots. Such wind speeds are by no means uncommon in an Atlantic storm.

By 12 February the depression was incorporated as the southern part of a low pressure system having filled to 968 mb. Finally, by 0600 on 13 February the depression was centred approximately 120 nm south west of Land's End at 970 mb. In general, the longer-period waves generated by an Atlantic depression usually travel faster than the storm and so move out of the storm area, and the storms tend to move on a curved path. In this case the depression moved with roughly the same speed (30 knots) and in the same direction as that of the wave components of about 18-20 seconds which it had generated, and so

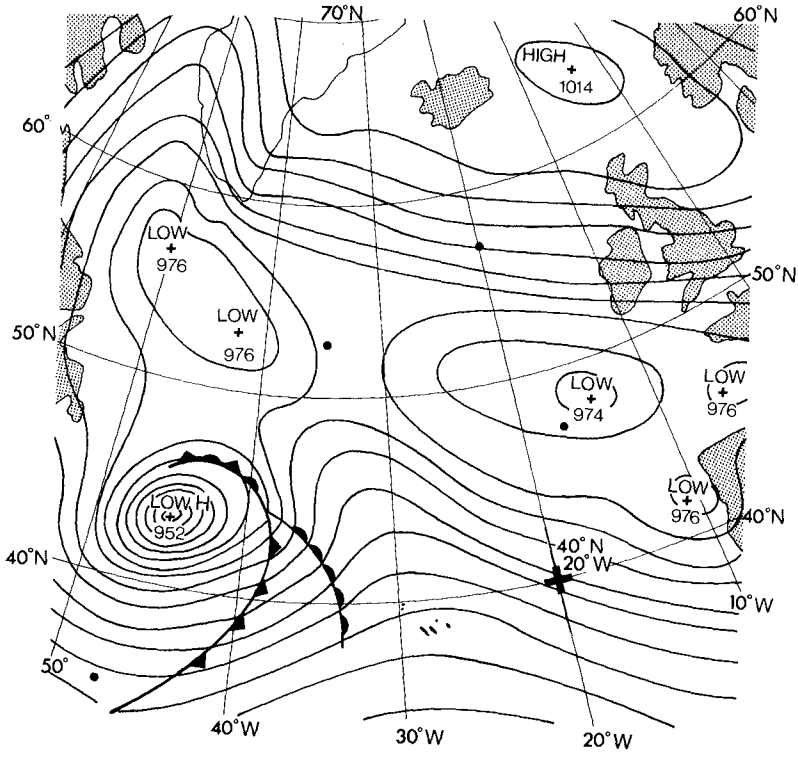

Figure 2 Meteorological Chart for 0000hr GMT 11 February 1979, showing the storm which generated the unusual wave conditions.

continued to input energy preferentially into this longer-period part of the wave spectrum for a considerable time, creating high and unusually long period sea waves. This is the primary cause of the problems at Portland.

A similar event occurred in the South Atlantic in July 1980, but the energy approaching the South African coast on that occasion, when the significant wave height was 3 metres, was only about a fifth of the energy present in the waves described in this paper. That event was described in a careful spectral study and interpretation by Shillington (1981).

THE WAVES ON EURDPEAN COASTS

The depression in mid-Atlantic filled rapidly, but the packet of wave energy it had produced continued eastwards as a swell at about 30 knots, and was detected at about 2400hr on 12 February by DB1 in the western Approaches to The Channel. During 12 February DB1 had consistently recorded waves with a zero-crossing period (T_Z) of around 12 seconds and a significant height (H_S) of about 4 metres, but by midnight the wave period had increased rapidly to nearly 17 seconds and by D100 13 February to over 18 seconds with a significant height of 7 metres. It continued to record these high values until about noon on 13 February. In Figure 3, parameters from DB1 for this storm are superimposed on a scatter diagram for Ocean Weather Station INDIA (59°N, 19°W), the most exposed IDS wave climatology station in one of the roughest oceans. This wave climatology is representative of conditions in the eastern Atlantic from about 45°N to 60°N. The 13 February 1979 conditions are outside the envelope of all data from over 40 previous instrument-years of measurements in all parts of UK waters; about 10 of these have been in locations well exposed to Atlantic conditions. According to the UK Meteorological Office ship routeing wave prediction model, these unusual wave conditions did not extend as far north as station LIMA (57°N 20°W), and this is confirmed by its measurements. (LIMA replaced INDIA in 1976.) (The wave period referred to in this report is the zero-up-crossing wave period, symbolized by T_Z. It is the average interval between successive crossings in the upward direction through the still-water level. The significant wave height, H_S, is the average value of the height of the highest one third of all the waves.) Captain Warren, Master of the oil rig Atlantic I working close to DB1, reported visual estimates of swells of up to 9 metres with periods of over 15 seconds, at times reported to be as high as 20-25 seconds.

Although there was no wave recorder operating at that time off The Isles of Scilly, the tide recorder at St. Mary's showed considerable disturbances starting at about 2200hr on 12 February and continuing until the early afternoon of 13 February. The period is difficult to determine due to heavy filtering by the tide recorder, but a period of about 10 minutes is detectable on the recorder. It seems probable that a local oscillation was induced by the storm waves.

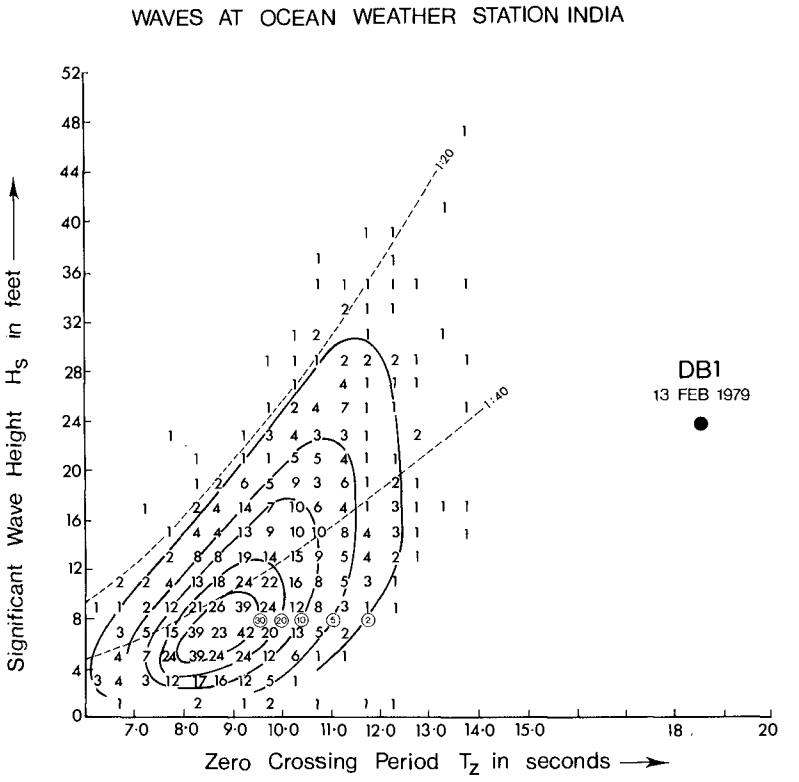

Figure 3 Wave Climatology for the eastern Atlantic as measured at Ocean Weather Station INDIA (59°N 19°W). These data are representative of the eastern Atlantic between about 45°N to 6D°N. The most severe of the parameters measured at DB1 on 13 February 1979 are plotted to show their unusual characteristics. (The wave climate at DB1 is still under confidentiality imposed by the UK Offshore Operators' Association and therefore not available for publication.) The 13 February 1979 conditions are outside the envelope of data from over 40 previous instrument-years of measurements in all parts of UK waters. According to the UK Meteorological Office ship-routeing wave prediction model, these unusual wave conditions did not extend as far north as station LIMA (57°N 20°W), and this is confirmed by its measurements (LIMA replaced INDIA in 1976).

A Shipborne Wave Recorder on the Sevenstones Light Vessel, between Land's End and The Isles of Scilly, measured waves with a significant height of around 3 metres and a zero-crossing period around 10 seconds during the evening of 12 February, but by 0600hr on 13 February the waves increased to over 5 metres in height and over 13 seconds in period. This Light Vessel is partially sheltered from such waves by The Isles of Scilly.

Off Perranporth, the significant height had been about 1 metre on 12 February, gradually increasing to about 1.5m by 2100hr, and then more than doubled by 0300hr on 13 February, staying around 3 metres until 0900 and then decreasing to somewhat over 2 metres by midnight. The direction of approach of these waves was such that they travelled almost parallel to the Perranporth coast, so that their height at the recorder would have been less than that further out at sea. The zero-crossing periods were around 8 or 9 seconds on the 12th until the arrival of the swell late in the day, and in the morning of the 13th reached 13.5 seconds, falling back by noon to 8 or 9 seconds again. Chart records show swell groups of 20 seconds period at Perranporth, and at the Severn Estuary site near Weston-super-Mare, also recorded by HRS.

At Eddystone, which is somewhat sheltered by The Lizard, the wave period had increased considerably by 0300hr on 13 February, and more so by 0600hr with an increase in wave height. The wave heights are lower than at OB1 because of the sheltering. The timing is consistent with the passage of the wave energy past the DB1 location. At St. Gowan in the Bristol Channel, a site well exposed to the source of this wave energy, records show that the wave period (T_z) there increased to 15-16 seconds by 0300hr on 13 February (a value in excess of anything recorded previously in over a year's measurements) and stayed high for at least six hours afterwards. Visual inspection of records from both these sites reveals considerable energy content at around 15 to 20 seconds period. At the NMI research tower in a relatively sheltered position in Christchurch Bay just northwest of the Isle of Wight, off the map to the east, these waves achieved a significant height of over 2 metres. At Hayling Island, to the north east of the Isle of Wight, the attenuated and refracted waves were still 1.5 metres in height at the coast.

The Waverider off Sines, south of Lisbon, experienced unusual conditions and recorded one wave with a height of 17.2 metres and a zero-crossing period of 20 seconds at 0340hr on 13 February. The significant height was 9.4 metres; these waves must have been generated by this same storm.

The ship-routeing wave prediction model run in real time by the UK Meteorological Office had forecast the heavy swell correctly for the morning of the 13th and again forecast heavy swell for mid-Channel for the evening, but apparently at the evening high tide the waves did not have a damaging effect at Chesil Beach. The correctness of the forecast is borne out by the measurements at DB1. However, the most likely explanation of the failure of the swell to arrive at Chesil on the evening tide of the 13th is that

the angle of approach had changed sufficiently (perhaps by only 10 degrees) to place Chesil in the shadow of the south western headlands.

THE APPROACH UP THE ENGLISH CHANNEL

A series of refraction diagrams has been constructed based on the approach of a broad front of waves travelling in directions appropriate to those generated in this storm, approximately towards the east north east. These show that waves of 20 seconds period can come to a focus in the middle of Lyme Bay, those of 18 seconds period focus almost directly onto the Isle of Portland and somewhat shorter period waves come to a real focus further east in The Channel or to a virtual focus inland. Clearly, Portland is particularly vulnerable to the approach of such long period swell coming up-Channel, and in the early hours of 13 February conditions were just right for the waves to make their land-fall in force.

SEA LEVELS

Although the incident occurred at the top of a spring tide predicted for 0740hr at Portland, it was not an unusually high astronomical tide; in fact in the first three months of that year at Portland over forty tides of the value expected for the morning of 13 February, or higher, were predicted, the highest being 0.6 metre higher. However, there was a surge in The Channel that morning, possibly connected with the low pressure centre over the western Channel at that time. At Newlyn, sea level was 0.85 metre above prediction, at Devonport (Plymouth) 0.6 metre and inside Portland harbour 0.52 metre.

The Bidston Laboratory of the Institute of Oceanographic Sciences has analysed surge levels at various ports in the UK and the highest value of surge recorded at Newlyn over an 18-year period was 0.88 metre. Such a surge as occurred on 13 February is unlikely to recur there, on average, more often than once in three years.

In addition to mean water level changes caused by tides and surges, on coasts exposed to wave action the ocean level can be lifted by wave set-up, a mechanism by which the momentum of subsequent waves holds the water carried up the beach by breaking waves and results in an even higher water level at the beach. This effect is not likely to have contributed to the surge levels measured in Newlyn or Portland harbours, but it has been estimated that with these extremely long waves it could perhaps have added about 1 metre to the near-beach water depth at places such as Chesil Beach.

RARITY OF THE EVENT

It seems possible that the situation on 13 February was near to the optimum for severity of effect at Portland. If the speed of the depression had been lower, waves of shorter period would have been enhanced, and focussing, if it occurred at all, would have given enhanced waves but probably further east and in mid-Channel. If the speed of the depression had been higher the enhancement would have taken place for waves of longer period with focussing further west, but the actual total energy at such periods, being even further down the tail of the energy distribution, would have been smaller than actually occurred on 13 February so that the effect at Chesil, and anywhere else in The Channel, would probably have been less.

Without a prolonged historical study of meteorological conditions over the whole Atlantic, it is virtually impossible to ascribe a number to the average return period of such an event. The occasional floodings of Chesil seem to be due to two causes: one, the most likely, occurs when there is a severe local southerly storm coincident with a high tide, and this seems to be the most common. The second, and the cause behind the 13 February 1979 flooding, appears to be a most unusual combination of events; its impact is very much greater because its real-time prediction is orders of magnitude more difficult and expensive, and so far its occurrence has come completely by surprise to the local population, almost literally "out of the blue".

CONCLUSIONS

It is obvious that the coastal damage came about as a result of the compounding of a number of improbable events. Although waves of these heights are likely to occur in the Western Approaches several times each year, it is the coupling with the long wave period which is the most destructive element in this phenomenon. This coupling, which would be directly responsible for wave set-up at an exposed coast, occurring together with a surge and a moderately high tide, is the basic cause of the destruction. At this time it is not possible, or possibly not even sensible, to attempt to quantify the probability of occurrence of such an event, but bearing in mind that the most likely cause of flooding is a local southerly storm, which is predictable, an unheralded flood caused by the factors which caused this one seems purely, on a hunch, to be of the order of a century or longer. This does not, however, mean that it cannot occur again next week; similar but not so severe events may well occur in most years.

The observations made by Lt. Cdr. J. Roberts, Meteorological Officer of HMS Osprey, Portland, of the shapes of the beach in the two floodings of December 1978 and February 1979 are consistent with the known wave conditions and their effects on beaches, and illustrate the completely different nature of the waves on the two occasions.

Needless to say, the effects on the local community were disastrously similar.

The most important engineering implication seems to be that, when an installation is being planned on or near an exposed eastern Atlantic coast, and probably other oceanic coasts as well, the susceptibility to heavy swells with wave periods of around 20 seconds and possibly longer must be considered, because the mechanism for their generation does seem to exist and, by rare chance, occur outside the envelope of all wave measurements covering over 40 instrument years in this part of the North East Atlantic. If inundation from such waves would be disastrous, then the possibility of their occurrence within the typical lifetime of many engineering structures must be considered.

ACKNOWLEOGEMENTS

The authors wish to express their appreciation of the considerable effort expended by many individuals and organizations in providing data and advice. In particular they would like to thank:- Mr. J.G. Berry, Bertlin & Partners; Mr. J.B. Boyle, Mr. J.R. Bishop, and Mr. G. Pearce, NMI; Or. B. Golding and Mr. J. Atkins, Meteorological Office, Bracknell; Mr. Norman Hornbrey, Meteorological Officer RAF Mountbatten; Mr. Howlett, AUWE; Mr. J. Read, G. Maunsell & Partners; Lt. Cdr. J. Roberts, Meteorological Officer HMS Osprey, Portland; Or. F.A. Shillington, University of Cape Town; Mr. R. Shuttler, Hydraulics Research Station, Wallingford; Mr. S. Waites, EMI Woking; Mr. B.O. Watkiss, Southampton Weather Centre; and several colleagues for providing data and advice, and for commenting on the draft.

MEASUREMENTS OF TURBULENCE OVER VORTEX-RIPPLE

by

INTRODUCTION

When a wave propagates over a rippled bed, organized vortices are generated over the leeside slope of crest. They are shedded, collapse and finally supply energy to turbulence in the vicinity of bed. This process plays an important role in the sediment transportation and suspension due to waves. However, quantative measurements of this phenomena have been limited because of some difficulties.

Horikawa and Watanabe(1970) developed the electrolytic transducer and measured the turbulence over a rippled bed. Nakato, Locher, Glover and Kennedy(1977) used a hot-film anemometer controlled by a minicomputer and conducted a phase averaging sampling. One of the authors(1980) tried a phase averaging sampling of velocity field over an artificial ripple by a hot-film anemometer. Du Toit and Sleath(1981) used a He-Ne laser-Doppler anemometer to measure the velocity over artificial and selfformed ripples. Those are the principal contributions in this problem.

One of the difficulties depends on a velocity meter. A hot-film anemometer which is widely used to measure turbulence in an unidirectional flow has some weakness under the circumstances of sediment suspension. Another difficulty lies on a data processing. Because the oscillatory flow turbulence is unsteady process, we can not utilize an analogue data processing technique which is very useful for a steady flow and are forced to handle a large number of digital data.

In the experiments reported here, a laser-Doppler anemometer was introduced in order to overcome a first difficulty. The second one was solved by the combination of a wave-form-recorder-analyser and the desktop computer. The results show the good correlation of the turbulence variation and the movement of shedded vortices. Theoretical considerations on the time averaged turbulence are also presented.

EXPERIMENTAL EQUIPMENT AND CONDITIONS

The wave tank utilized is shown schematically in Fig.1; the test section was 0.4m wide, 0.6m high and 20m long. A 1.8 meter long sand pit was set at the central part of the tank. The same quartz sand, which has a diameter d=0.2mm and density *s=2640 Kg/m3, was used in all cases. An

Table Experimental Conditions

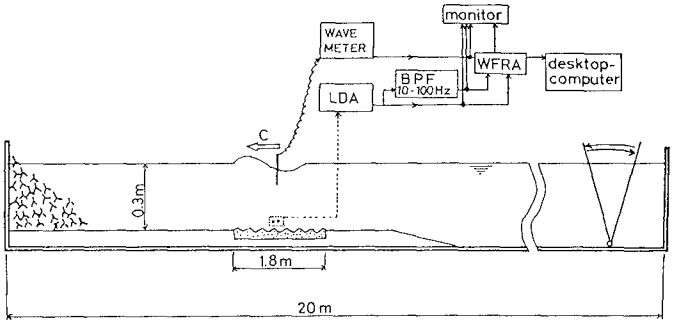

Fig. 1 Sketch of the wave tank.

artificial scratch on the flattened bed made easy to develop a two-dimensional ripple.

The experimental wave conditions and the developed ripples are summerized in Table. No asymmetrical ripple was observed in the experimental range listed here. Fig.2 shows the relation of ripple length Ls and the horizontal excursion length d_o of water particle. Cases 12 and 13 locate in the breakoff range and the others in the equilibrium one where the strong linear relationship are found.

It was confirmed that the length of the equilibrium ripples has a good agreement with the empirical equation reported by Homma and Horikawa (1977). The ripple height, however, was about 20% larger than Homma's results. Yalin and Karahan(1980) also reported the empirical relation of ripple geometry. Their relation gave a good agreement only when the propotional constant C, which they reported 1-1.37, was modified into 1.6.

The He-Ne laser-Doppler anemometer(LDA; Nihon Kagaku Kogyo Ltd.) was used to measure the horizontal velocity under the circumstances of sediment suspension. No seeding was need to pick up the frequency-shifted laser beam. Under the condition of the sediment concentration less than one thousand p.p.m., suspended sediment scarcely disturbed the velocity measurement. The disturbed signals could be easily detected and discarded.

Sampling of the output signal from LDA were synchronized with a wave-meter. Some phase averaged values were statistically online analysed and recorded by the wave-form-record-analyser(WFRA;Kikusui Electronics Co.). Recorded data were also stored on a magnetic casset tape and used for further analysis by the desktop computer(HP9835). The output signal of LDA were filtered by a electrical band-pass-filter in some cases as mensioned later.

DATA PROCESSING METHODS

Four methods were examined in advance.

i) Direct Phase Averaging Method

In an oscillatory turbulent flow, the mean velocity and turbulence should be defined by an ensemble average at a certain phase of wave as follows

$$\left.\begin{aligned} U &= \frac{1}{n}\sum_{i=1}^{n} u(\omega t+2\pi i) \\ \overline{u'^2} &= \frac{1}{n}\sum_{i=1}^{n} [\, u(\omega t+2\pi i) - U(\omega t)\,]^2 \end{aligned}\right\} \quad (1)$$

where u: instantaneous velocity, U: phase averaged velocity and u': turbulence. We refer this averaging PHASE AVERAGING. The phase averaging can be done by WFRA. This technique may give a good results in case of a purely oscillatory flow. In a wave field, however, turbulence evaluated by this method involves two kinds of error. One is due to wave randomness. In a random wave field this is not applicable at all. Furthermore, whatever good wave maker may be used in the experiment, a small amount of fluctuation of a wave period and height exist. The

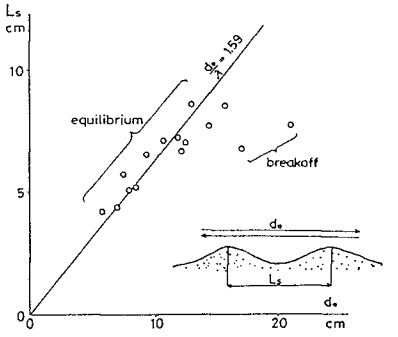

Fig. 2 Relation between the ripple length and the excursion length of water particle.

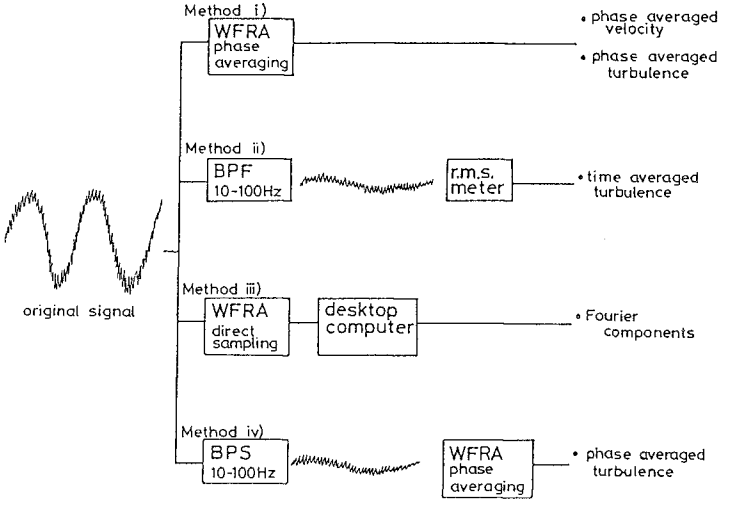

Fig. 3 Data processing methods.

other is due to the imperfect synchronization of sampling. Although the synchronizing signal must be free from any noise or fluctuation, such a situation can not be realized in the experiment. Since turbulence intensity is order of persents of main flow velocity, any fluctuation must be less than one hundredth percent if we want to get an accurate turbulence intensity. Finally, we used this method not to obtain a phase averaged turbulence but only phase averaged main flow velocity.

ii) Electrical Filtering Method

Since phase averaging method is useless in a random wave field, alternative definition of turbulence should be proposed. Turbulence has higher frequency fluctuation than a wave induced periodical velocty variation. So if output signal from LDA was processed by a high pass filter, turbulence velocity fluctuation may be separated. Reading it by a root mean square meter, we obtain long time averaged turbulence intensity as shown in Fig.3. The LDA has inherent noise at higher frequency range than hundreds Hertz, a low pass filter of one hundred Hertz was also used. Cutoff frequency of HPF was determined ten Hertz by trial and error method.

This method seems to be so simple and useful to obtain a set of data at many points. However, it contains a certain amount of error when a turbulence intensity level is low. Because no electrical filter has a sharp cutoff frequency, the high pass filtered signal still has a small fraction of low frequency main flow component which is almost same as or larger than the turbulence. This method was examined at a first stage but finally discarded.

iii) Fourier Expansion Method

The main flow velocity U, which variates in period T, can be expressed by some low frequency terms of the Fourier expansion. Subtracting it from the original variation u, we can obtain an instantaneous turbulent component u' as follows.

$$u' = u - \sum_{i=1}^{N} \left(a_i \cdot \cos(2i\omega t) + b_i \cdot \sin(2i\omega t) \right) \qquad (2)$$

where

$$a_i = \frac{2}{T} \int_0^T u \cdot \cos(2i\omega t)\, dt \qquad \text{and} \qquad b_i = \frac{2}{T} \int_0^T u \cdot \sin(2i\omega t)\, dt$$

If expansion was carried out in each cycle, this method is applicable to the random wave field. The number of expansion was selected by trial and error. Fig.4 shows the time averaged turbulence intensity calculated by this method. The abscissa is the number of expansion. It shows that the number of expansion should be larger than ten or more which coresponds the cutoff frequency higher than five Hertz.

Although this method make available further complicated analysis, it also forces us to process a large number of digitalized data. So it was used only when a detailed consideration was necessary.

iv) Combined Method of Band Pass Filtering and Phase Averaging

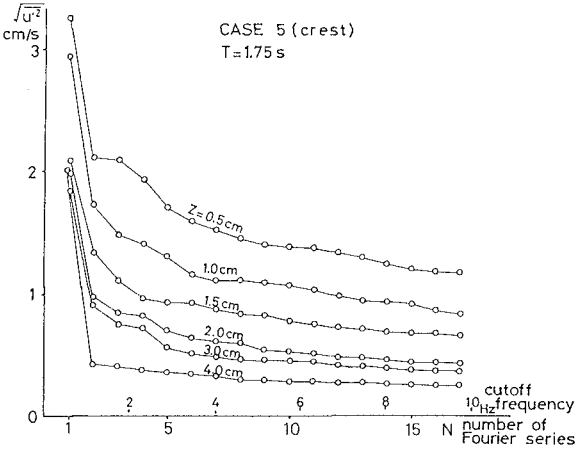

Fig. 4 Variation with N of the turbulence intensity evaluated by eq.(2)

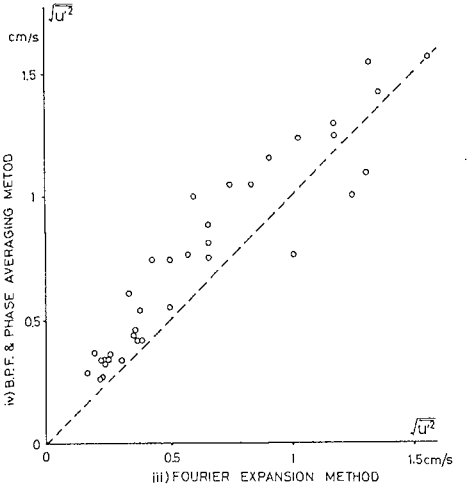

Fig. 5 Comparison of method iii) and iv).

In order to avoid the defects of methods i) and ii), the combined method of them was developed. The signal processed by the band-pass-filter was sampled by phase averaging technique. The low frequency component in the band-pass-filtered signal can be taken away in a sufficient degree by this method. Almost all turbulence data reported here were obtained by this method. The comparison of Method iii) and iv) is shown in Fig.5. The coordinate is the turbulence intensity evaluated by Method iii) and the abscissa is by Method iv) in which the expansion number is selected as 17 (cutoff frequency: 10 Hertz).

RESULTS AND CONSIDERATIONS

1) Turbulence Variation and Distribution

Fig.6-1 shows an example of the phase averaged velocity over a crest. In the figure, Z is a vertical distance from the crest. The variation at Z=6 cm , where the bed configuration has no effect on the velocity variation, is overrapped as a reference variation by broken lines. Fig.6-2 shows the variations of turbulence intensity and Fig.6-3 does velocity and turbulence distributions.

As shown in the figure, turbulence intensity becomes minimum at the phase $\omega t = (4/15)\pi$. At this phase, an organized vortex is growing over the leeside slope, any influence of which is detected at the measuring section. After a flow reversion($\omega t = (10/15)\pi$), the vortex moves over the crest, so the offshoreward velocity is intensified in the vicinity of bed. This phenomenon is noticed by a systematic deviation from the reference velocity variation in Fig.6-1. It is also remarked that the turbulence concentrates in the vicinity of bed. At $\omega t = (18/15)\pi$ another small systematic deviation from the reference velocity is observed. It associates the fact that another vortex developed at the neighbouring ripple passes the measuring section as shown in Fig.6-4 schematically. Because the vortex passes at higher position, the turbulence distributes more widely. Although the vortex passes across the measuring section again at $\omega t = (25/15)\pi$ as shown in Fig.6-4, any sign is not noticed on velocity or turbulence variation and distribution because its organized motion has collapsed by this phase. In another half cycle, almost same phenomenon repeats in the reverse direction.

2) Theoretical Considerations

A turbulence energy budget relation was examined. The turbulence budget equation is written as

$$\frac{D\,\overline{q^2}}{D\,t} = [\text{production}] + [\text{diffusion}] - [\text{dissipation}] \qquad (3)$$

Since the time variation is so complicated, only the time averaged turbulence intensity is considered. The experimental results including the visual observation show that the turbulence energy is supplied by the collapse of vortices in the vicinity of bed and diffused upward by its diffusivity and that the flow field is almost horizontally uniform except in the vicinity of bed. Those facts imply the possibility of two simplified models.

Because the production term does not play any important role except in the vicinity of bed, the diffusion term may balance with the

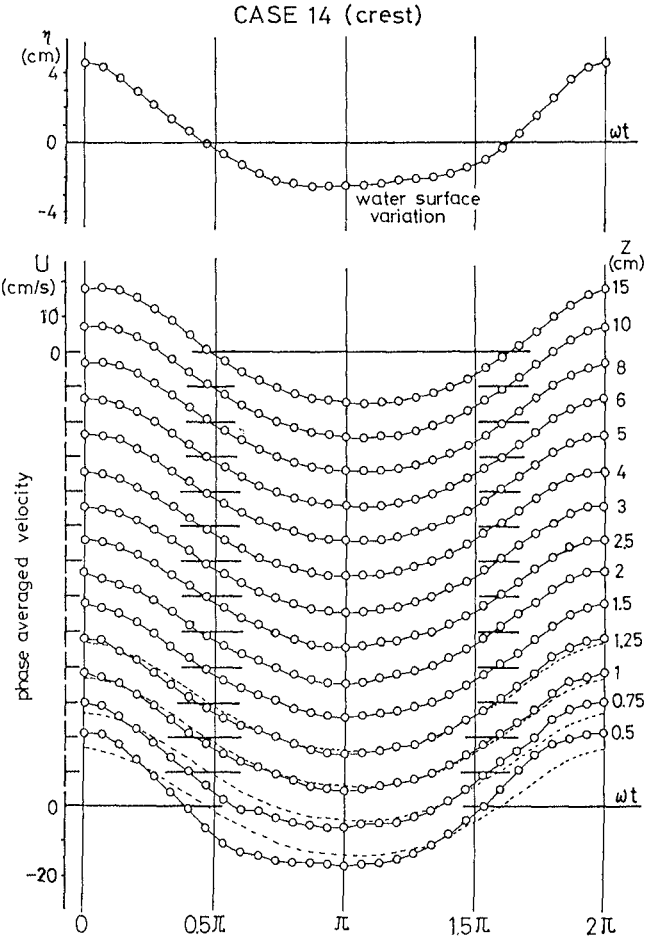

Fig. 6-1 Examples of the phase averaged velocity cycle.

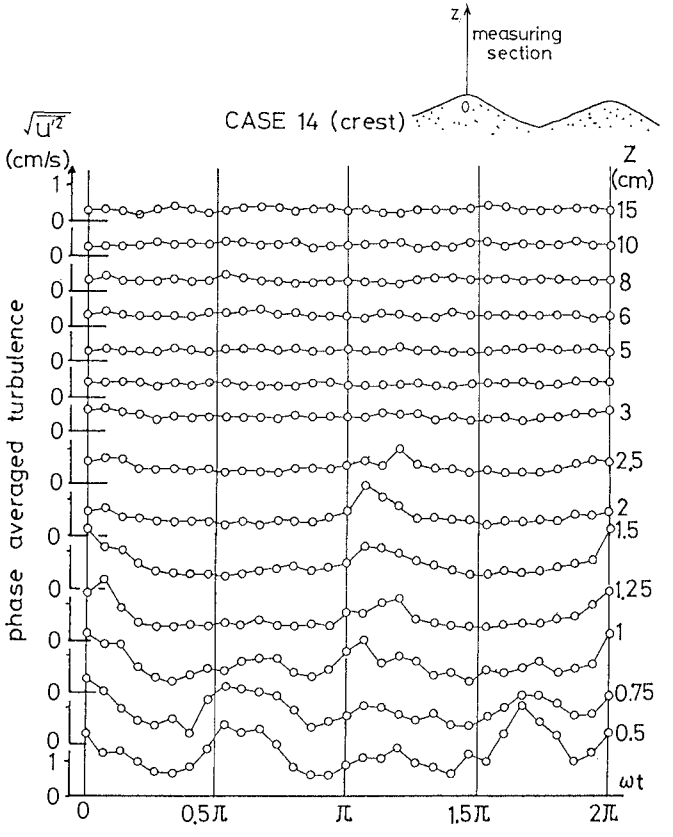

Fig. 6-2 Examples of the phase averaged turbulence variation.

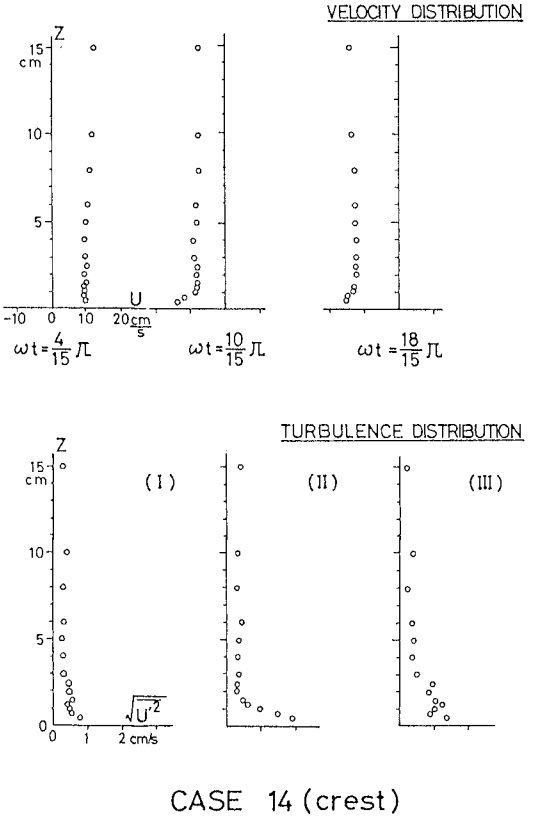

Fig. 6-3 Examples of the phase averaged velocity and turbulence distribution.

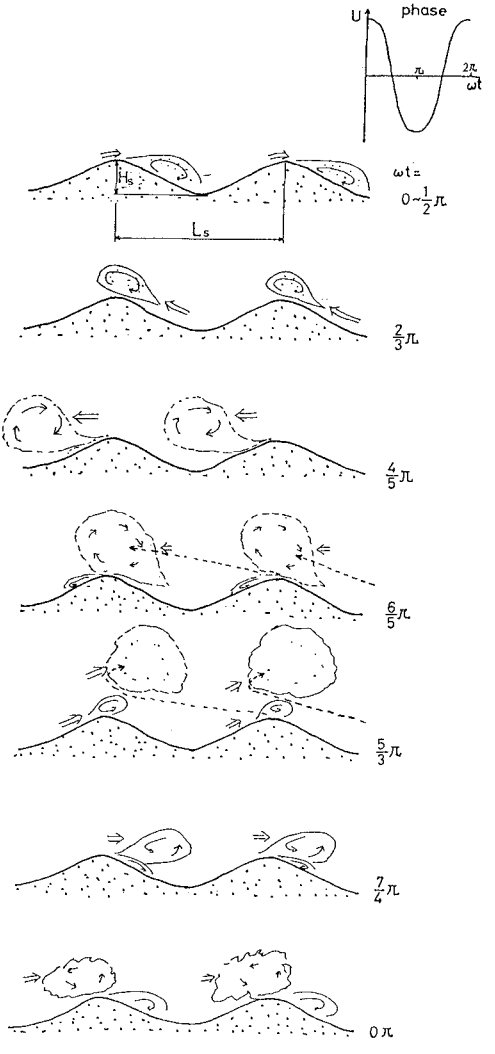

Fig. 6-4 Schematic view of the vortex movement.

dissipation term in the upper region shown in Fig.7. If we assume that Prandtl's mixing length hypothesis is also available in this case, we have

$$\underbrace{\frac{\partial}{\partial Z}\varepsilon_z \frac{\partial \overline{q^2}}{\partial Z}}_{\text{diffusion}} = \underbrace{\frac{A}{L}(\overline{q^2})^{\frac{3}{2}}}_{\text{dissipation}} \tag{4}$$

$$\varepsilon_z = B(\overline{q^2})^{0.5} L \tag{5}$$

where L is the mixing length, $\overline{q^2} = \overline{u'^2}+\overline{v'^2}+\overline{w'^2}$, ε_z is turbulence diffusion coefficient. The value of universal constants A and B are selected as 0.124 and 0.369 by the direct analogy of the unidirectional shear flow. Assuming the mixing length is constant, we obtain

$$\overline{q^2} = \overline{q_0^2}\cdot\exp\left(\frac{1}{L}\sqrt{\frac{2A}{3B}}(Zo - Z)\right)$$
$$\text{or} \tag{6}$$
$$\overline{u'^2} = \overline{u_0^2}\cdot\exp\left(\frac{1}{L}\sqrt{\frac{2A}{3B}}(Zo - Z)\right)$$

where qo is the reference turbulence intensity at the reference level Zo. Fig.8 shows the distribution of time averaged turbulence u'^2 which must be proposional to $\overline{q_0^2}$. The data fall on the curve predicted by eq.(6). In the theory, the mixing length was selected so that it give the best agreement with experiments, because we have no information about it. The values of mixing length L calculated by this criterion are plotted on Fig.9. It shows a good correlation between the mixing length and the geometrical length scale of ripple in the equilibrium range.

In order to determine the reference turbulence, let's consider the control volume shown in Fig.7. The energy production in a cycle must balance with the energy dissipation in it and the upward diffusion from it. The production may relate with the vortex strength Γ. Dimensional consideration concludes that the production during a cycle is proportional to the square of vortex strength; i.e.

$$[\text{production}] = \text{constant}\cdot\Gamma^2$$

The dissipation term is

$$[\text{dissipation}] = \frac{A}{L}(\overline{q_0^2})^{1.5}\cdot Ls\cdot T\cdot Z_0$$

The upward diffusion across Zo is

$$[\text{diffusion}] = -B(\overline{q_0^2})^{1.5}\sqrt{\frac{2A}{3B}}Ls\cdot T$$

Assuming Zo propotional to the ripple length Lo,

$$\frac{\Gamma^2}{LsT} = \text{constant}\cdot(\overline{q_0^2})^{1.5} \tag{7}$$

is concluded. Fig.10 shows the relation of reference turbulence intensity and the vortex strength, which was calculated from an

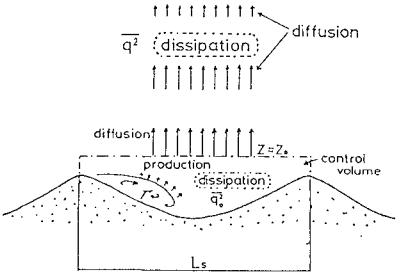

Fig. 7 Schematic relation of turbulence energy budget.

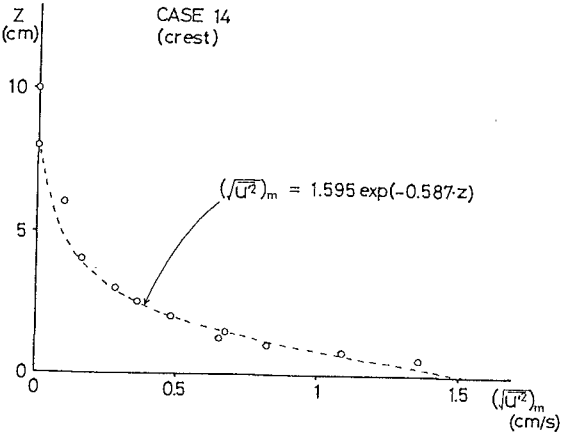

Fig. 8 Example of the time averaged turbulence distribution.

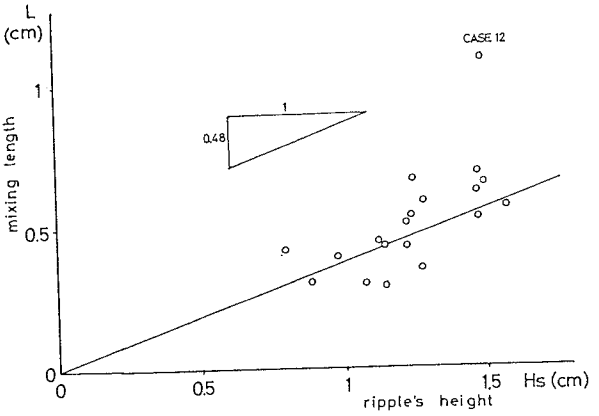

Fig. 9 Variation with the ripple height of the mixing length.

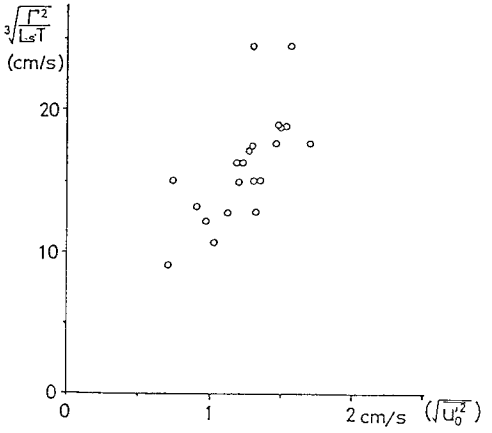

Fig. 10 Relation between the vortex strength and the turbulence intencity.

accumulation of vorticity flux across the section over the crest by the method proposed by the authors(1980). It shows a good correlation between them.

CONCLUSIONS

Turbulence over rippled beds was measured and the followings were concluded.

1. The variation and distribution of turbulence during a cycle closely relate to the movement of organized vortex shedded from the ripple.
2. The turbulence intensity averaged over a period can be explained through a simplified Prandtl's mixing length model
3. The linear relationship of mixing length and ripple's geometrical length is confirmed.
4. The maximum turbulence intencity which occurs near the bottom relates to the vortex strength.

ACKNOLEDGMENTS

The authors wish to express their gratitude to Professor M. Hino, Tokyo Institute of Technology, for his valuable suggestions. The support of the Grant in Aid for Scientific Research is also appreciated.

INVESTIGATIONS ON ORBITAL VELOCITIES AND PRESSURES IN IRREGULAR WAVES

by

K.-F. Daemrich[1], W.-D. Eggert[2], H. Cordes[3]

ABSTRACT

This paper deals with the results of hydraulic model investigations of orbital velocities and pressures in irregular waves. Different simulation methods in the time and frequency domain were checked or developed, and the theoretical results compared with measurements. Using simulation methods based on linear wave theory, results with good correlation are obtained. At locations near the water surface, however, a tendency towards over- or unterestimation exists.

1. INTRODUCTION

Orbital velocities and pressures are important input values for many dimensioning methods in coastal engineering. For regular waves, these values can be calculated using the various wave theories for given wave parameters. Although earlier test results confirm the theories only in a few cases, more recent results provide better agreement, due most probably to better equipment and an advanced control signal generation for the wave machines.

The aim of the investigations described in the following was to develop or check simulation methods which enable orbital velocities and pressures in irregular waves to be calculated theoretically from the wave time-series. The simulation methods were developed in accordance with analysis methods, and are so far based upon linear wave theory.

2. INSTRUMENTATION AND HYDRAULIC BOUNDARY CONDITIONS

The investigations were performed in the FRANZIUS-INSTITUT wave channel. The channel, which is equipped with a servo-controlled, hydraulically driven wave generator, is about

120 m long and 2.2 m wide. The water depth was 1.0 m in all tests. The control signals for the paddle movement of the wave machine are generated by a Wave Synthesizer (Wallingford type).

The wave spectra were JONSWAP spectra with significant wave heights in the range of 8 to 25 cm and with mean periods of 1.5 to 1.9 sec. The sequenth lengths of the wave time-series were typically about 4 to 5 minutes, depending upon the mean periods.

The velocity components and pressures were measured at 0.25m, 0.50 m and 0.85 m below the mean water level (submerged depth). For the orbital velocity measurements, a COLNBROOK inductive-type probe for two components (horizontal and vertical) was used; for the measurement of the wave trains, resistance wave probes (Delft GHM) were installed. The waves and the corresponding velocities and pressures were measured simultaneously in the same cross-section.

3. SIMULATION METHODS

Initial results of the velocity measurements have already been presented at the recent ICCE in Sydney (DAEMRICH, EGGERT, KOHLHASE (1980)), together with a discussion of three simulation methods. To avoide repetition only a brief description is given here. It should be pointed out that the major objective was to calculate and compare the maximum positive and negative velocity components or pressures in every individual wave of the wave train.

The first method, relating to the superposition method with theoretical TRANSFER FUNCTIONS, is based on frequency domain analysis. The FOURIER components of the wave train are calculated and each frequency component is multiplied by the pertinent value of the theoretical transfer function according to linear wave theory. Finally, using an inverse FOURIER-transformation, the theoretical time-series is recalculated or superposed. From this theoretical time-series, positive and negative amplitudes of the individual waves are determined and compared to the measured values.

The next simulation method is based upon time-series calculations. In this method, regular wave parameters must be defined for each individual irregular wave. Following the most common method, the ZERO-DOWNCROSSING parameters for wave height and period (according to IAHR definition) were used to calculate positive and negative maximum velocities and pressures by means of linear wave theory.

Owing to the fact that a comparison between the measured results and those obtained theoretically from the zero-downcrossing method showed very low correlations compared to the transfer function method, the COMPLEMENTARY method was developed. This method is very similar to the zero-downcross-

ing method, but makes use of other definitions for the wave parameters - typically half-waves and pertinent periods. Generally speaking the complementary method involves taking a more effective geometrical part of the wave in the physical sense and completing it, for the theoretical calculation, to a sine wave (or a higher order regular wave).

A definition sketch of the complementary parameters for velocity and pressure simulation is given in Fig. 1.

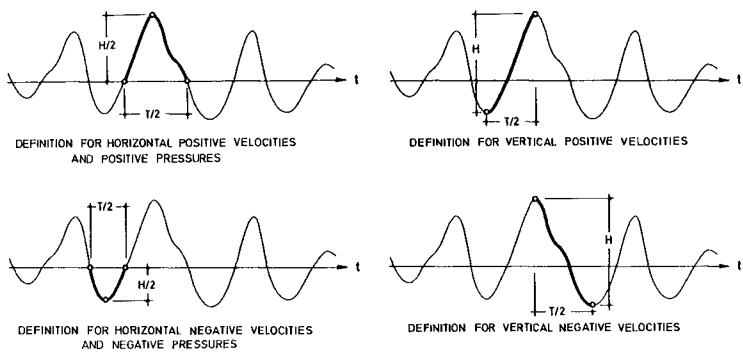

Fig. 1: Definiton sketch for determining wave parameters according to the complementary method

4. RESULTS OF THE ORBITAL VELOCITY INVESTIGATIONS

In Fig. 2, measured and theoretical horizontal velocity amplitudes (submerged depth of the velocity probe: 0.25 m) are compared using the three simulation methods. The results are devided into positive (upper part) and negative amplitudes (lower part of the figure).

The transfer function method and the complementary method both show a reasonable correlation, whilst the scatter in the results obtained from the zero-downcrossing method is markedly higher, and in most cases excludes the application for the calculation of single velocity events.

In the results from the transfer function method and the complementary method there is a general tendency that the measured horizontal velocities are lower than the theoretical ones under a wave crest, and higher than the theoretical ones under a wave trough. From Figs. 3 and 4, which show similar results from measurements for submerged depths of 0.50 and 0.85 m, it may be seen that this tendency decreases with increasing submergence and is no longer present near the bottom for this spectrum.

By comparing the results of calculations based upon higher

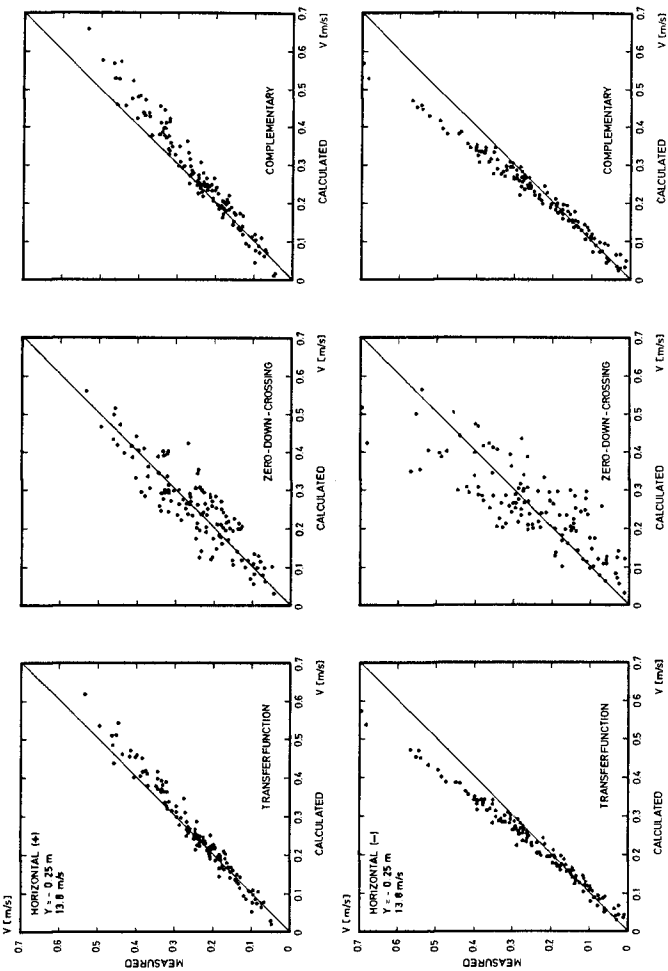

Fig. 2: Comparison between measured horizontal velocities and those calculated by different simulation methods (submerged depth 0.25 m)

(JONSWAP spectrum γ = 3.3, U = 13,8 m/sec., scale 1:20)

order wave theories and from the assumption of small amplitudes for the validity of the linear wave theory, it becomes evident that the latter tendency can be attributed to nonlinear effects.

For further details relating to the results of vertical velocity measurements, the reader is referred to the Proceedings of the ICCE, Sydney (DAEMRICH, EGGERT, KOHLHASE (1980)).

5. RESULTS OF THE PRESSURE INVESTIGATIONS

Corresponding results obtained from the simulation of pressure amplitudes in irregular waves are shown in Fig. 5, 6 and 7.

As before, the scatter in the results calculated by the transfer function method and the complementary method is distinctly smaller than that arising from the zero-downcrossing method. Compared to the velocity measurements, the scatter in pressure amplitudes obtained from the transfer function method is notably smaller.

The tendency to overpredict pressures under the wave crest and to underpredict pressures under the wave trough is similar to that obtained in the horizontal velocity measurements.

Considering the results obtained from the complementary method in more detail, it can be seen that the majority of the data points exhibit a very low scatter and a well-defined trend. A small number of points, however, are clearly overestimated. A visual inspection of the time-series at the relevant positions provides a seasonable explanation. This may be seen for example in Fig. 8, which shows a wave together with its pertinent pressure time-series (submerged depth 0.50 m).

The amplitude marked by an arrow is typical of an overestimated event. Clearly, the influence of the higher frequency component of about twice the basic frequency in this case cannot be neglected when estimating the maximum pressure amplitude. In other words, the actual half-wave form in this case is not properly represented by the complementary parameters, and a modification of the original parameters should be considered.

6. SIMULATION OF WAVE AMPLITUDES FROM PRESSURE MEASUREMENTS

For the recalculation of wave data from pressure measurements, the same simulation methods can be applied. Since, however, the value of the theoretical transfer function at the high frequency end of the spectrum can be exceedingly large, caution is necessary to avoid an upscaling of system noise.

In Fig. 9, a measured wave spectrum is compared with the wave spectrum calculated from the pressure spectrum using

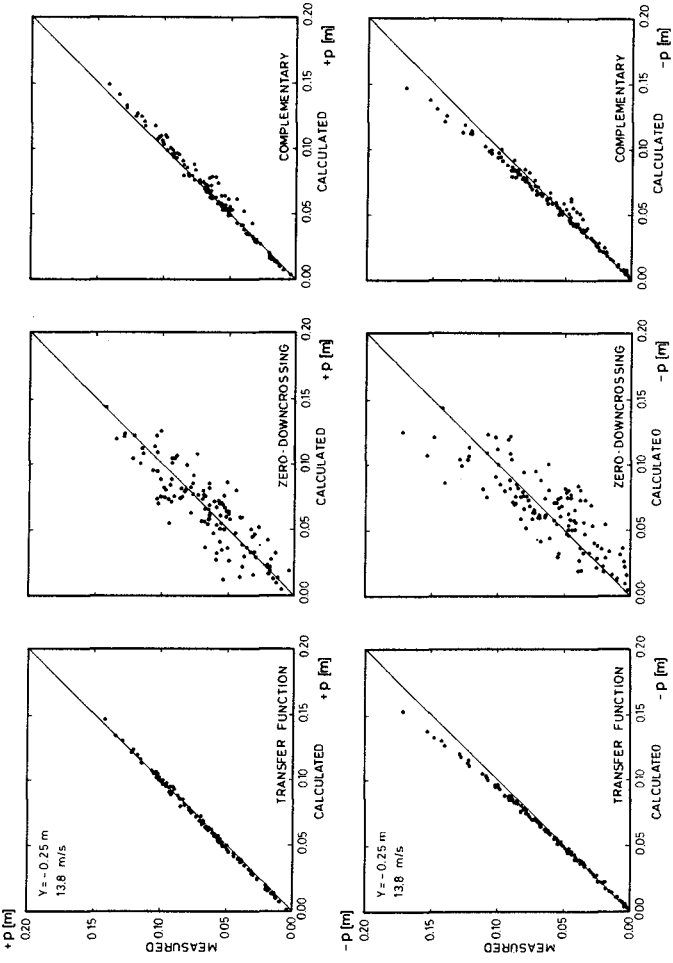

Fig. 5: Comparison between measured pressures and those calculated by different simulation methods (submerged depth 0.25 m)

the theoretical transfer function. The increasing energy at the high frequency end of the calculated wave spectrum clearly indicates the point at which system noise starts to be dominant and from which point the frequency components should be suppressed (the location is marked by an arrow).

Figs. 10 and 11 show results based upon measurements with submerged depths of the pressure cell of 0.25 m and 0.50 m. Although best results are obtained when the pressure meter is situated near the mean water level, the results are also acceptable in a medium water depth for the spectrum considered. With the pressure meter located near the bottom, however, the scatter in the data was found to be relatively high (Fig. 12).

In deciding whether or not pressure meters may be used as wave gauges and at what depth they should be located, it is necessary to consider both the quality of the measuring and data aquisition systems and the desired accuracy of wave measurements.

7. ACKNOWLEDGEMENT

The investigation described in this paper was carried out as part of the research programme of the Sonderforschungsbereich 79 at the FRANZIUS-INSTITUT for Hydraulic Research and Coastal Engineering, University of Hannover. The authors gratefully acknowledge the Deutsche Forschungsgemeinschaft for their finanical support throughout the investigations.

WAVE INDUCED VELOCITIES CLOSE TO A RIPPLED BED

by

C.G. du Toit*

The results are reported of velocity measurements in oscillatory flow over rippled beds. Velocities were measured with a laser-doppler anemometer in both an oscillating tray rig and an oscillatory flow U-tube. Both self-formed and artificial ripples were examined.

The results obtained in the two test rigs were compared and it was concluded that the flow fields obtained in the two cases were dynamically similar.

Measurements of the flow field clearly showed the formation, growth and ejection of vortices, as well as a strong surge of fluid over the ripples during and after flow reversal.

1 INTRODUCTION

A proper knowledge of the flow field in the boundary layer above the ripples on the sea bed is of considerable importance to the coastal engineer. It is essential to be able to fully understand the phenomena of sediment transport and energy dissipation.

A great deal of theoretical work has already been done on the subject and three different approaches can be distinguished. Firstly, it is assumed that the concepts used for turbulent boundary layers in steady flow over rough beds may be extended to oscillatory flow and that the vertical velocities may be neglected. Secondly, it is assumed that the mean velocity distribution may be well represented by a laminar solution if the exchange of momentum from one fluid layer to another is dominated by the mixing produced by the vortices rather than by the much smaller-scale turbulent eddies. Thirdly, a solution has been put forward, based on the "discrete vortex" method.

A number of experimental studies have also been made of the velocity distribution close to beds in oscillatory flow. However, in most cases the beds were essentially flat or the bed profiles did not closely resemble those of naturally occuring ripples. Horikawa & Watanabe (1970) and Nakato et al (1977) did measure velocities above natural sand ripples in oscillatory flow. They were, however, primarily interested in the turbulence

*Senior Lecturer, Department of Civil Engineering, University of Stellenbosch, Stellenbosch 7600, South Africa.

and suspended sediment distribution. A more detailed study of the flow field was made by Sawamoto et al (1980). They measured the velocities above a fixed ripple in an oscillatory flow wind tunnel.

The objective of this paper is to give a short account of measurements that were made of the flow fields above both artificial and natural sand ripples. A comparison of the various available theories with the data has already been made elsewhere by Du Toit & Sleath (1981).

2. EXPERIMENTAL EQUIPMENT

Experiments were carried out both in an oscillating tray rig and an oscillatory flow U-tube.

The oscillating tray rig is shown in Figure 1.
It consisted essentially of a flat tray 0.305 m wide which was oscillated in its own plane in a tank of still water. Simple harmonic motion was created by means of a variable speed motor with feed-back control driving a Scotch Yoke. Baffles, extending down to close to the bed, divided the tank into three sections. These baffles were to prevent vortices shed by the end of the tray from propagating into the central test section. Flow under these baffles were inhibited by compensating cylinders which had the same cross-sectional area as the tray.

Figure 2 shows a sketch of the oscillatory flow U-tube.
It consisted of a U-tube in which the water was caused to oscillate by a paddle driven, via a crank arm, by a variable speed motor with feed-back control. The central test section was 0.305 m wide and 0.45 m high. The arm containing the paddle was circular in section with an area 3.3 times that of the rest of the tube.

The oscillating tray rig could be operated over a wide range of strokes and periods of oscillation, whereas the oscillatory flow U-tube was restricted to periods close to its resonant period of 4.6 s.

The velocities were measured with a laser-doppler anemometer system. With the equipment available it was only possible to measure one component of velocity. The results given below are all for the horizontal component of velocity.

Phases were measured with the aid of a beam of light falling on a photo-electric cell for the oscillating tray rig. A flat plate, rigidly attached to the Scotch Yoke, interrupted the beam of light as the tray passed through the top dead-centre position. For the oscillatory flow U-tube the output from a resistance gauge in the open arm of the tube was used as a phase marker.

The outputs from the laser-doppler system and the phase marker were recorded on magnetic tape and subsequently fed through an analog-to-digital converter into a computor for analysis.

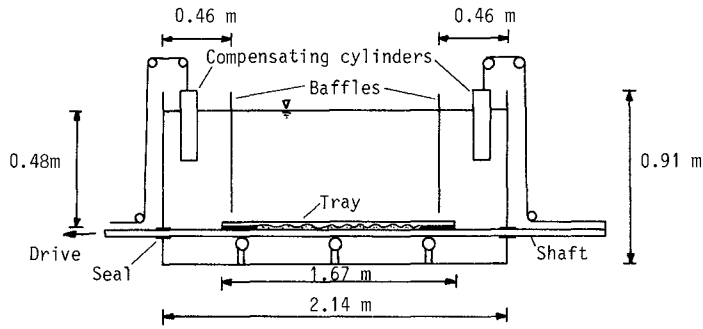

FIG. 1 Sketch of oscillating tray tank

Analog-to-digital conversion was carried out at a rate of between 600 and 720 samples per cycle.

All the tests with natural sand ripples were carried out with a sand of median diameter 0.41 mm, standard deviation 0.10 mm and specific gravity 2.65.

The artificial ripple bed was made out of wood and was machined on a numerically-controlled milling machine to the following profile.

TABLE 1. Test conditions

$$y = \tfrac{1}{2}h(\cos k\xi - 1), \quad x = \xi - \tfrac{1}{2}h \sin k\xi \qquad (1)$$

where the crest-to-trough height h of the ripple was 0.017 m and the wavelength $2\pi/k$ was 0.10 m. This profile was very similar to that of the ripples which form with the 0.41 mm sand.

Further details of the experimental equipment are given by Du Toit (1980).

3. TEST PROCEDURE AND RESULTS

At least one day prior to a test the tank was filled with tap water and left to de-aerate. Natural sand ripples were obtained by selecting the appropriate frequency and amplitude of oscillation and letting the rig run until the ripples reached their equilibrium profile. The rig was then stopped and the ripple geometry measured. On the day of the test the equipment was left on for at least an hour to warm up.

At least two vertical traverses were made during each test. For each traverse records of at least thirty cycles were made at various fixed heights above the bed. In all the tests traverses were made above a ripple crest and a ripple trough when the tray was in its central position. In some tests in the oscillatory flow U-tube two additional traverses were made a sixth and a third of a ripple length from the crest.

The water temperature and output from the various instruments were checked regularly during and the ripple geometry at the end of a test to ensure that no significant changes had taken place.

The conditions under which the various tests were carried out are summarized in Table 1. All the tests were in the fully-developed rough turbulent regime according to the criteria of Kajiura (1968), Sleath (1974a), Kamphuis (1975) and Jonsson (1980), except for a few tests with artificial ripples at the shorter amplitudes of oscillation.

3.1 Ripple and velocity similarity

It has been claimed, e.g. Brebner & Collins (1961), that flow fields simulated in the oscillating tray rig and the oscillatory flow U-tube are not dynamically similar. However, if the ripples are similar, Sleath (1974b) showed theoretically that the flow fields are dynamically similar.

A plot of ripple lengths against the corresponding amplitudes of oscillation for which the ripples had been obtained, is shown in Figure 3.

Added to the present data, are the experimental results of a large number of undergraduates, cf. Sleath & Ellis (1979), at the University of Cambridge in the same oscillating tray rig with the same 0.41 mm sand as the present study.

These are compared with the empirical predictions of Mogridge & Kamphuis (1972) and Sleath (1975), obtained from experiments conducted in wave flumes and oscillatory flow U-tubes.

The minimum and maximum Reynolds numbers $U_0/\sqrt{\omega\nu}$ obtained in the present experiments were respectively 42 and 207. The predictions of Sleath for these two values are shown in the figure.

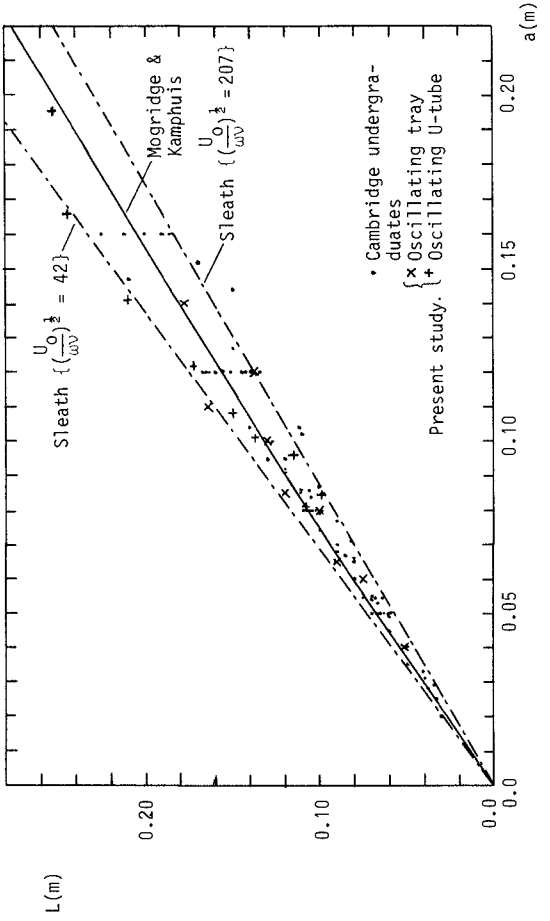

FIG. 3 Variation of ripple length with amplitude of motion

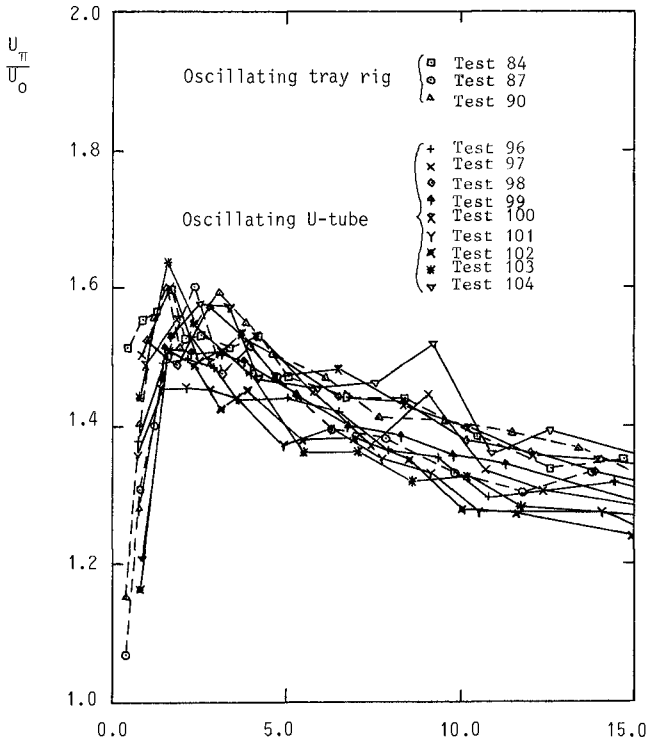

FIG. 4 Variation of $\frac{U_\pi}{U_o}$ with βy above ripple crest

The agreement between the various experiments and the predictions is quite close and there doesn't seem to be any consistent difference between the results obtained in the two different rigs. The ripple lengths obtained in the two cases are, therefore, similar.

In the case of the oscillating tray rig, the ripple is oscillating forwards and backwards past the measuring volume. The only instants, therefore, during the cycle when the velocities can be compared with those measured in the oscillatory flow U-tube for $\frac{a}{L} < 1.0$ and a vertical traverse above the crest, are when the measuring volume is directly above a crest. This occurs at $\omega t = 0$ and $\omega t = \pi$ and corresponds to maximum tray velocity for the

oscillating tray rig and maximum free stream velocity for the oscillatory flow U-tube.

Figure 4 shows how the non-dimensional velocities U_π/U_o change with distance βy above the ripple crest, where

$$\frac{U_\pi}{U_o} = \frac{1}{2U_o} \{U(\omega t = o) - U(\omega t = \pi)\} \quad (2)$$

and $\beta = \sqrt{\frac{\omega}{2\nu}}$. The oscillating flow U-tube velocities were converted to oscillating tray velocities by

$$\frac{U_\pi \text{ (tray)}}{U_o} = 1 - \frac{U_\pi \text{(U-tube)}}{U_o} \quad (3)$$

considering the variation in $\frac{\beta}{k}$, $\frac{h}{L}$ and $\frac{a}{L}$ for the various tests, the agreement is good and there seems to be not apparent difference between the velocity profiles obtained in the oscillating tray rig and the oscillatory flow U-tube. The velocities can, therefore, be taken as similar.

Due to the similarity in ripple lengths and velocity profiles it can, therefore, be concluded that the flow fields simulated in the two rigs are dynamically similar.

3.2 Velocities above an oscillating fixed ripple

The way in which $\frac{U}{U_o}$ changes with ωt for various positions above an oscillating fixed ripple is shown in Figure 5. Figures 5 (a) and (b) are for a crest traverse and Figures 5 (c) and (d) for a trough traverse. The instants when the measuring volume was directly above a crest are indicated in the figure with crosses. It should also be noted that the tray was travelling with the velocity $-U_o \cos \omega t$.

When a rippled bed is oscillated, the fluid in the viscous part of the boundary layer has to travel along with the ripple surface. However, in the outer layer the fluid moves over the crest in a direction opposite to that of the ripple surface, continuity then requires that the fluid over the trough should move in the same direction as the ripple surface. These features are clearly illustrated in Figure 5.

In Figure 5 (a) it can be seen that there is a sharp increase in the velocity in the direction opposite to that in which the ripple is travelling as the crest approaches the measuring volume. This corresponds to the fluid in the outer layer spilling over the ripple crest. As the viscous layer moves past the measuring volume there is a sudden switch in

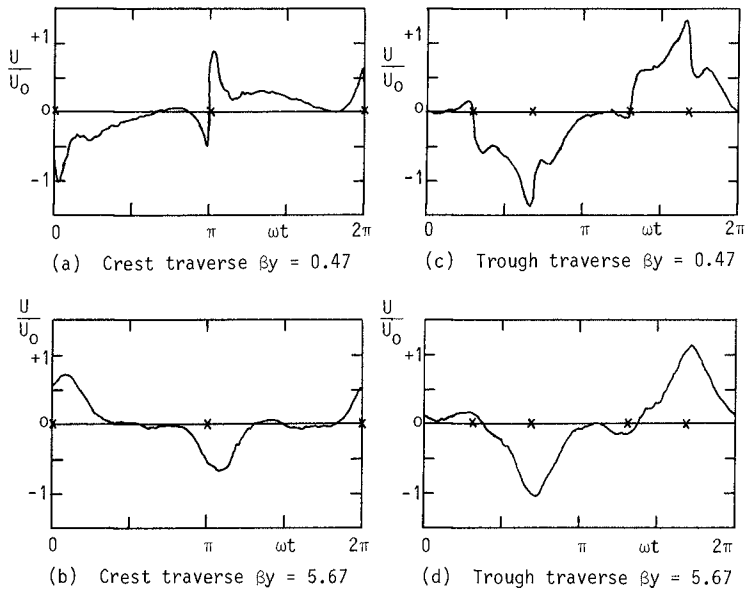

FIG. 5 TEST 32: Average velocity cycles for βy = 0.47 and 5.67 for crest and trough traverses

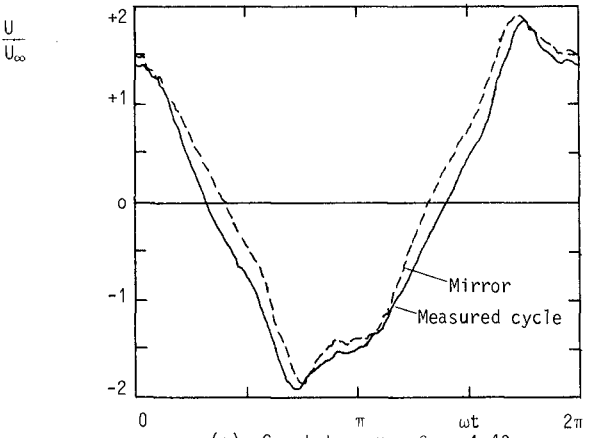
the velocity direction due to the viscous layer travelling with the ripple. This can be observed in Figure 5 (c) as well, though very much weaker. This viscous effect diminishes quickly and in Figure 5 (b) & 5 (d) it can not be observed any more. There the measuring volume is in the outer layer all the time.

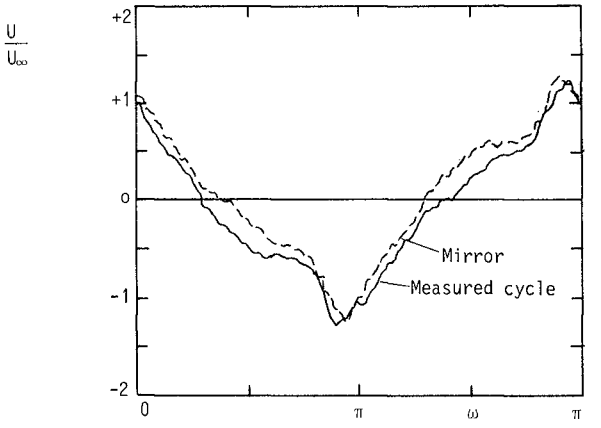
An additional phenomenon can be observed in Figures 5 (c) & 5 (d). Very prominent peaks occur in the velocity cycles at $\omega t = 0.65\pi$ and 1.65π. These peaks occur just after flow reversal and correspond to the fluid surging over the ripple in the direction opposite to that in which the ripple is travelling. It is also associated with the ejection of the vortex which has been on the downstream side of ripple prior to flow reversal. This effect can be seen in the photographs published by Bagnold (1946).

3.3 Velocities above a stationary sand ripple

In contrast with the previous Figure, Figure 6 (a) shows the average velocity for βy = 1.44 above a ripple crest and Figure 6 (b) shows the average velocity cycle for βy = 1.18 above a ripple trough for stationary sand ripple in the



(a) Crest traverse $\beta y = 1.40$



(b) Trough traverse $\beta y = 1.47$

FIG. 6 TEST 101: Average velocity cycles for $\beta y \approx 1.4$ for crest and trough traverses.

oscillatory flow U-tube. Also shown on the Figures are the "mirror" plots of the measured average velocity cycles. These were obtained by shifting the average velocity cycles by π radians and inverting them. Thus the difference between the two curves provides an indication of the magnitude of

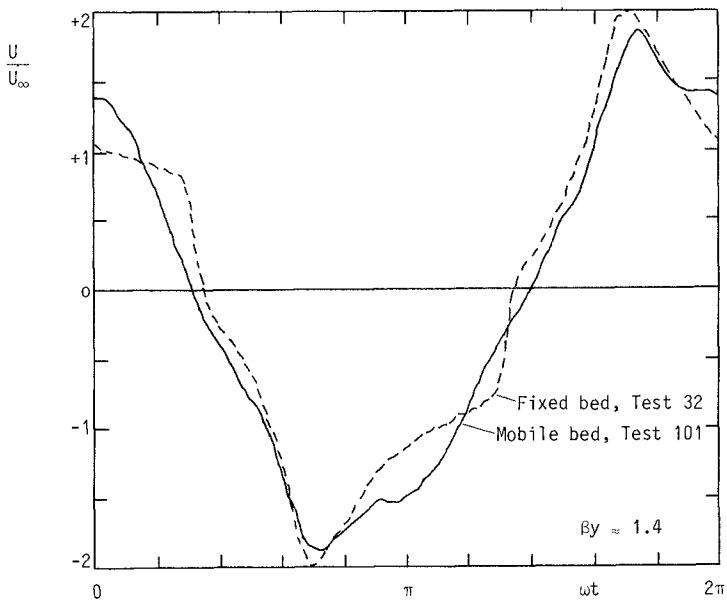


FIG. 7 Comparison between fixed bed and mobile bed velocity cycles.

experimental errors such as mean drift in the tank.

A prominent feature in both figures is the occurence of a peak in the velocity cycle at $\omega t = 0.9\pi$ and 1.9π for the trough plot. During the course of the experiments it was observed that the crest swayed from side to side, forming a small cusp of sand first on one side and then, as the flow reversed, on the other side. It was originally thought that the presence of the peak in the velocity cycles was due the swaying of the crest. However, comparison with results obtained for the fixed wooden bed in the oscillatory tray rig showed the same peak. This is illustrated in Figure 7, where the oscillatory tray velocities were converted to oscillating free stream results.

This peak corresponds to the strong surge of fluid going over the ripple crest and sweeping through the ripple trough, as illustrated in the photographs by Bagnold (1946). The surge occurs just after flow reversal and is associated with the ejection of the vortex which had been on the downstream side of the ripple prior to flow reversal.

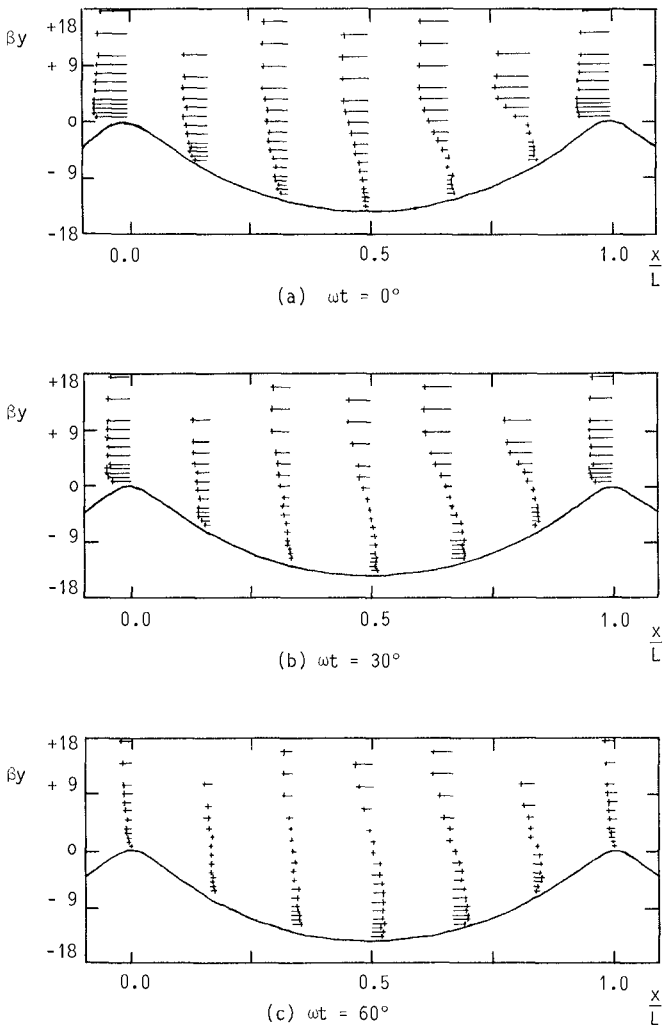

FIG. 8 Variation of the horizontal velocity component of the flow field above a rippled bed with time.

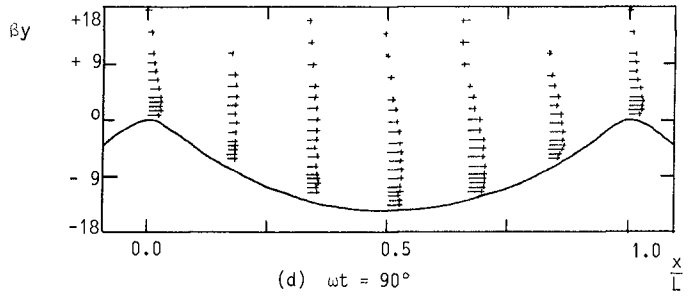

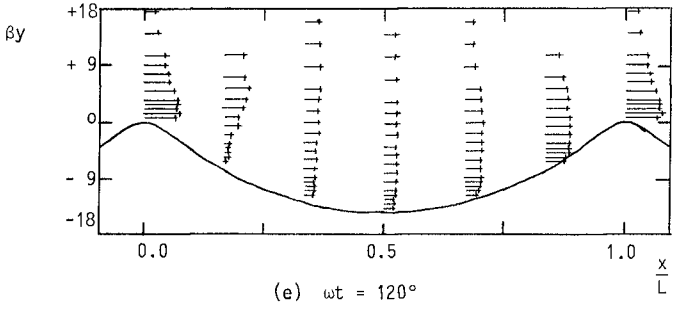

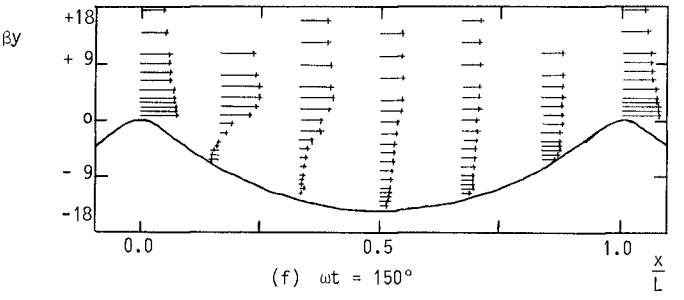

FIG. 8 Variation of the horizontal velocity component of the flow field above a rippled bed with time.

Thus although the change in position of the crest cusp is not the cause of the velocity peak, the velocity peak may be the cause of change in position.

The variation in the horizontal velocities in the flow field above a rippled bed during a half cycle is illustrated in Figure 8.

Only the instants $\omega t = 0$, $\pi/6$, $\pi/3$, $\pi/2$, $2\pi/3$ and $5\pi/6$ are shown.

In Figure 8 (a) the freestream is moving with maximum velocity from right to left and a well defined vortex fills almost half the ripple trough on the downstream side of the ripple. As the freestream decelerates, the vortex increases in size, Figure 8 (b), until it fills almost the whole trough, Figure 8 (c). Although the freestream has not reversed yet at this instant, $\omega t = 2\pi/3$, the flow near the ripple crest is on the brink of reversing. In Figure 8 (d) the freestream reverses. The vortex is being ejected over the crest and a strong surge of fluid sweeping through the ripple trough and spilling over the crest is building up. At $\omega t = 2\pi/3$, Figure 8 (e), the flow has already started separating at the crest and a new vortex starts to form. A jet, associated with the separation, shoots out over the trough and at $\omega t = 5\pi/6$ it has almost reached the trough.

The general flow features show good agreement with those photographed by Bagnold (1946), despite the differences in flow conditions and ripple geometry. Sawamoto et al (1980) used a ripple profile with a smaller steepness and a much more rounded crest and, therefore, the vortex was not as pronounced as in the present study.

4. CONCLUSIONS

The range of flow conditions covered during the present series of tests covers a wide spectrum of conditions encountered in practice. It is believed that the present results could help to improve our understanding of the boundary layer in oscillatory flow over rippled beds and lead to a better understanding of the associated phenomena.

The author would like to thank Dr. J F A Sleath of the University of Cambridge for his encouragement, as well as the South African CSIR, the British NERC and the Sir Henry Strakosch Memorial Trust for their financial support.

MASS TRANSPORT IN VOCOIDAL THEORY

by

J W Gonsalves and D H Swart*

ABSTRACT

The concept of mass transport is theoretically discussed within the framework provided by Vocoidal theory. The Lagrangian mass transport is divided into two parts; firstly treating the fluid as being inviscid and secondly, incorporating viscosity by means of the free surface and bottom boundaries. Eulerian mass transport is defined and is shown to correspond, in deep water, to the net flow predicted by Stokes and others.

INTRODUCTION

The Lagrangian mass transport is defined as the mean velocity of a marked particle and results from the fact that the trajectories of the fluid particles under finite amplitude waves are not closed. Since the original discussion by Stokes (1847), this concept remained theoretically untouched until 1953 when Longuet-Higgins treated it from the point of view of a viscous fluid. Since then many authors, of which Huang (1970) is the most notable, have written on this subject. Eulerian mass transport has only relatively recently been defined in papers by Dalrymple (1976) and Tsuchiya and Yasuda (1981).

Experimentally the effect was observed as early as 1878 by Caligny, the US Beach Erosion Board (1941) and Bagnold (1947). The most comprehensive observations were carried out by Russell and Osorio (1957), whose results confirmed the Longuet-Higgins model. In 1980 Tsuchiya, Yasuda and Yamashita observed drift profiles in a flume incorporating a natural water recirculation process. Results from these tests agreed with both their and the Stokes drift profiles, the net drift being forward throughout the fluid.

VOCOIDAL THEORY

Vocoidal theory was developed to predict the behaviour of non-breaking waves on a horizontal bed (Swart, 1978) and

* National Research Institute for Oceanology, CSIR, Stellenbosch, Republic of South Africa

applies to water of all depths. The theory is two-dimensional and is based on the equations of motion and continuity and adheres to the bed and free surface boundary conditions. The assumptions on which this theory is based can be summarised by the following three definitions.

Wave profile: $\eta/H = \{(\cos^2(\pi X))^P - \eta^*_t\}$ (1)

Wave celerity: $c^2/gd = \tanh(Nkd)/kd$ (2)

Horizontal orbital velocity:

$$u/c = \eta M(X) k \cosh[M(X)kz]/\sinh[M(X)k(d+\eta)] \quad (3)$$

where $X = (x-ct)/\lambda$; z = vertical coordinate (defined from the bed upwards); H = wave height; λ = wave length; k = wave number $(2\pi/\lambda)$; η^*_t is the dimensionless trough elevation and where P, N and $M(X)$ are parameters depending on the wave conditions (H/d, λ/d).

In deep water, when H/d and λ/d are small, Vocoidal theory reverts to Airy wave theory while in shallow water it becomes solitary wave-like. Curve-fitting techniques were used to allow the use of these numerically determined parameters in a predictive manner for an extensive range of H/d and λ/d values.

Because of an approximation to $M(X)$ during the curve-fitting process, a vorticity was introduced, that is, the theory is rotational whereas in principle it should have been irrotational. The vocoidal vorticity is defined by the equation $\omega = \nabla^2\phi$, where $\phi = -c\eta \sinh[M(X)kz]/\sinh[M(X)k(d+\eta)]$ is the vocoidal stream function.

In order to determine to what extent the theory is rotational the induced vorticity was compared with the vorticity generated by the straining in the irrotational motion (Phillips, 1966) and by the laminar bed boundary layer. The argument on which this comparison is based is that the dissipation of energy in a wave is accompanied by a decrease in wave momentum which, as Longuet-Higgins (1969) showed, is distributed throughout the fluid. This decrease in mean momentum must be accompanied by a mean stress across horizontal planes below the surface. A mean second order viscous stress is set up to balance this loss of momentum. Thus a mean second-order vorticity ω is generated below the free surface.

Comparisons of the average vorticity for various wave conditions are given in Table I, which shows that the average vorticity generated by Vocoidal theory is generally much less than that generated by the viscous and bed shear forces. Since the latter effects are regarded as

negligible in most wave theories Vocoidal theory can be regarded as essentially irrotational to second order.

MASS TRANSPORT

The treatment of mass transport by Vocoidal theory will be divided into three parts: the first dealing with the Lagrangian mass transport in an inviscid fluid, the second with the Lagrangian mass transport incorporating viscous and boundary layer effects, while the third part will deal with Eulerian mass transport.

(i) Lagrangian Mass Transport in an Inviscid Fluid

The mass transport in an inviscid fluid will be treated in a general manner.

The horizontal orbital excursion or displacement ξ_x is defined by $\frac{d\xi_x(t)}{dt} = U_\varepsilon(x,y,z,t)$, where $U_\varepsilon(x,y,z,t)$ is the horizontal velocity following the particle's path. Based on this definition the mass transport can be defined as:

$$U_m = \frac{1}{T}\int_0^T U_\varepsilon(x,y,z,t)dt \qquad (4)$$

For progressive waves of a permanent type the streamlines and particle paths coincide. Thus once the elevation of a specific streamline ψ^o is known, the particle Lagrangian velocity along this streamline can be obtained from $U_\varepsilon(x,t) = U(x,z_{ST})$, the Eulerian velocity at position (x,z_{ST}), where z_{ST}, the streamline elevation, is obtained by iteration of the expression:

$$z_{ST} = \frac{\psi^o}{c} + S(z_{ST}) \quad \text{and where the}$$

function S depends on the particular wave theory involved.

The mass transport is thus numerically obtained from the expression:

$$U_m(z_{ST}) = \sum_{i=1}^{n} U(x_i,z_{ST})\Delta t_i \Big/ \sum_{i=1}^{n} \Delta t_i, \qquad (5)$$

where the time interval Δt_i is defined as $\Delta t_i = \Delta x_i(u_i-c)$ and where n is such than $n.\Delta x_i = \lambda$. Results obtained by this method are similar to those of

Stokes, namely, forward at the free surface and backward near the bed.

* Comment: $T_c = T\sqrt{g/d}$

(ii) Lagrangian Mass Transport in a Viscous Fluid

To incorporate the effects of viscosity within the framework of Vocoidal theory an approach similar to that given by Johns (1970) and Isaacson (1976) was used. The bottom boundary layer will be dealt with in some detail.

The horizontal flow velocity outside the bottom boundary is expanded in a Fourier series:

$$U = \sum_{n=-\infty}^{\infty} A_n e^{ik_n X} \tag{6}$$

where $A_o = 0$; $A^*_{-n} = A_n$; $k_n = 2\pi n/\lambda$ and $X = x - ct$. Applying the usual boundary layer approximations we have that the motion within the bottom boundary layer is described by:

$$u_t + uu_x + wu_z = U_t + UU_x + \nu[K(z)\, u_z]_z \tag{7}$$

where u is the boundary layer velocity, U is the velocity above the boundary layer and K(z), the eddy coefficient.

Expanding the boundary layer velocity u by the method of successive approximations (Schlichting, 1968) the equation above reduces to the following two equations:

$$\text{First-order:} \quad u_{1t} = U_t + \nu[K(z)u_{1z}]_z \tag{8}$$

$$\text{Second-order:} \quad u_{2t} + u_1 u_{1x} + w_1 u_{1z} = UU_x + \nu[K(z)u_{2z}]_z \tag{9}$$

Introduce a non-dimensional vertical coordinate η, where $\eta = \sqrt{(\sigma/2\nu)}z$ with $\sigma = 2\pi/T$; T = wave period; ν = kinematic viscosity coefficient and assume laminar flow, K(z) = 1. Further, assuming the first-order boundary layer velocity to be given by:

$$u_1 = \sum_{n=-\infty}^{\infty} A_n[1-F(\eta_n)]e^{ik_n X}, \tag{10}$$

it is found after substitution that the function $F(\eta)$ must satisfy the equation:

$$\frac{d^2F(\eta)}{d\eta^2} + 2iF(\eta) = 0 \tag{11}$$

with boundary conditions $F(0) = 1$ and $F(\infty) = 0$.

Substitution into the second approximation, where the vertical velocity component w_1 is obtained from the continuity equation, and extracting only the real time - independent second-order term, results in an expression for u_2, given by:

$$\bar{u}_2 = \sum_{n=1}^{\infty} \frac{A_n^2}{c} \mathrm{Im}(G(\eta_n)) \tag{12}$$

$\mathrm{Im}(G(\eta))$ is the imaginary part of $G(\eta)$, with $G(\eta)$ satisfying the equation:

$$\frac{d^2G(\eta)}{d\eta^2} = |F(\eta)|^2 - 2\mathrm{Re}(F(\eta)) + \frac{dF^*(\eta)}{d\eta} \int_0^{\eta} (1-F(\eta))d\eta$$

subject to the boundary condition $G(0) = 0$ and $G(\eta)$ finite as $\eta \to \infty$ (* implies the complex conjugate).

Substituting u_1 and $\bar{u}_2$ into second-order mass transport velocity, defined by Longuet-Higgins (1953), namely,

$$U_m = \bar{u}_2 + \overline{u_{1x} \int_0^t u_1 dt'} + \overline{u_{1y} \int_0^t w_1 dt'} \tag{13}$$

gives an equation for the transport above the bottom boundary layer as:

$$U_m = \sum_{n=1}^{\infty} \frac{A_n^2}{c} \mathrm{Im}(H(\infty)) \tag{14}$$

with

$$H(\eta) = G(\eta) + \frac{i}{2}\left[\frac{dF^*}{d\eta} \int_0^{\eta} (1-F(\eta))d\eta - 1 + 2\mathrm{Re}(F(\eta)) - |F(\eta)|^2\right]$$

Generalising the results of Huang (1970) to include both the free surface and interior regions, the mass transport throughout the fluid can be calculated. These results, however, depend on an important approximation, namely that the series solution be arbitrary but finite. If a zero net mass transport is assumed then the mass transport in the interior can be calculated from the expression:

$$U_m = \frac{1}{4} \sum_{n=1}^{m} \frac{A_n^2 \sigma_n k_n}{\sinh^2 k_n d} \left\{2 \cosh 2 k_n d\mu - \frac{3}{2}\left[1-(1-\mu)^2\right] \frac{\sinh 2k_n d}{k_n d} + \frac{9}{2}(1-\mu)^2 - \frac{3}{2}\right\} \tag{15}$$

with $\mu = z/d$ and the bed defined at $\mu = 0$ (that is, $z = 0$).

Calculations have shown that m need not exceed 50, even for the most highly non-linear case. Figures 1 to 4 show typical mass transport profiles for various values of T_c $(= T\sqrt{(g/d)})$ and H/d. For low values of T_c and H/d (Figure 1) we see that, with the exception of Longuet-Higgins, all profiles correspond to that given by Stokes. It should be noted that in order to distinguish between the

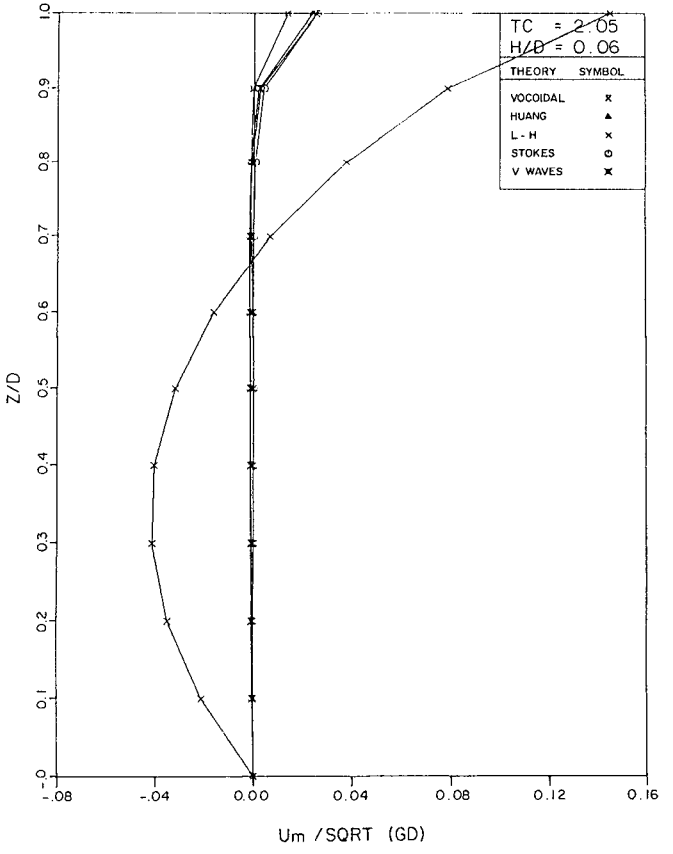

Figure 1 Comparison of the theoretical non-dimensional drift profiles for various wave theories

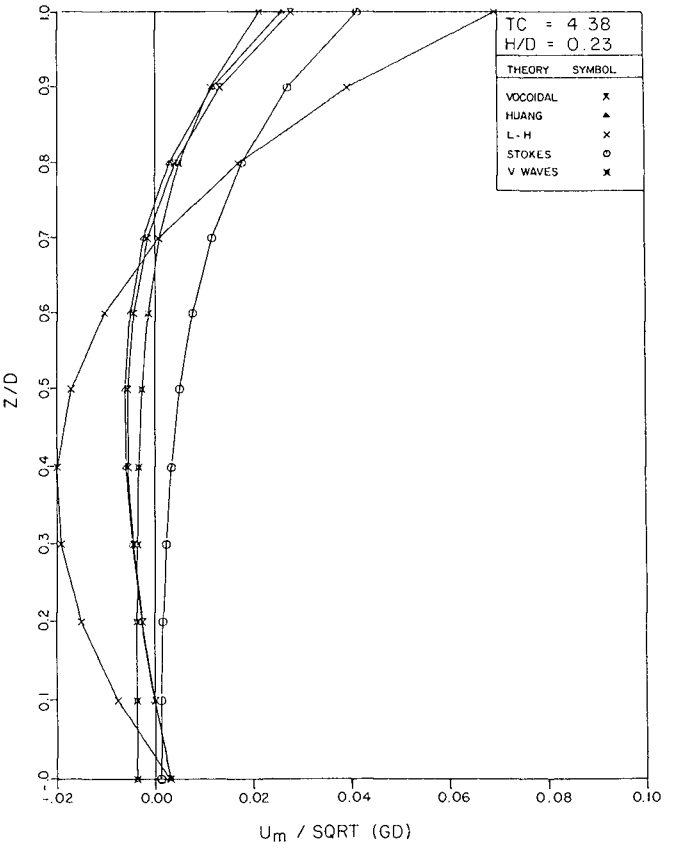

Figure 2 Comparison of the theoretical non-dimensional drift profiles for various wave theories

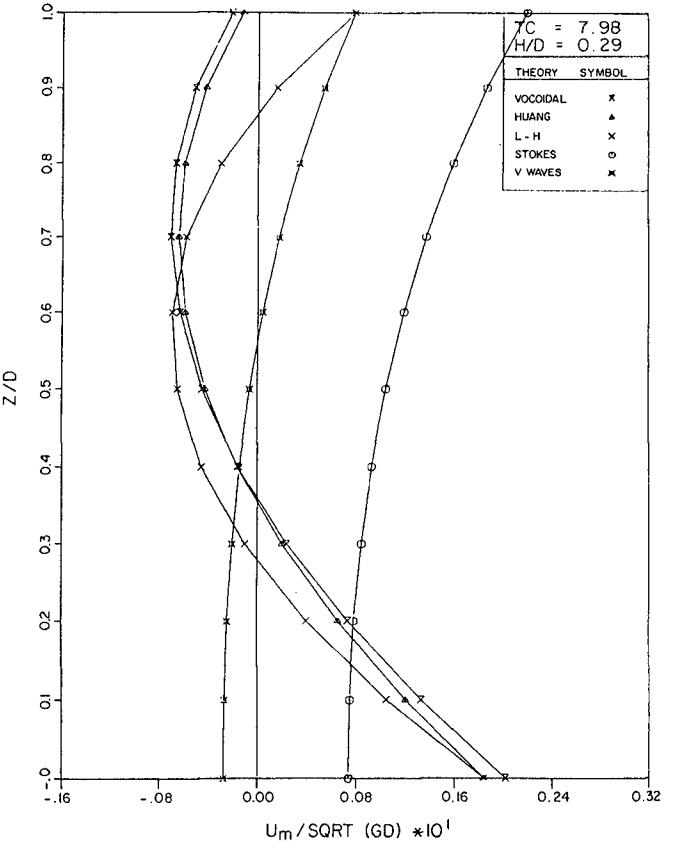

Figure 3 Comparison of the theoretical non-dimensional drift profiles for various wave theories

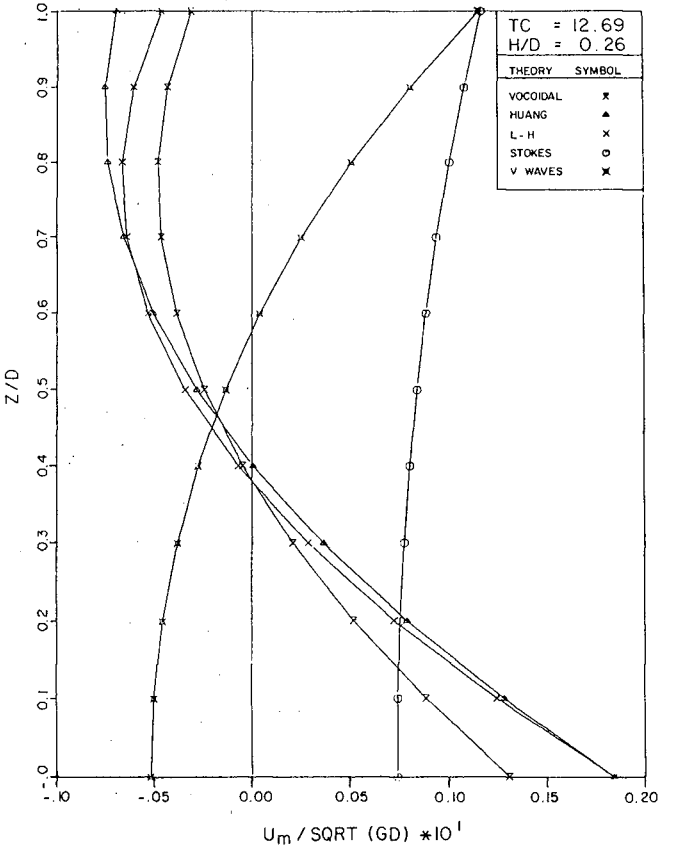

Figure 4 Comparison of the theoretical non-dimensional drift profiles for various wave theories

Stokes mass transport and the Vocoidal inviscid Lagrangian transport (V wave) the Stokes solution was not corrected for zero net mass transport. In order to do this a quantity $-H^2\sigma \coth kd/8d$ must be added to the Stokes results, thus shifting the profile to the left.

In the deep water region (Figures 1, 2 and 3) the mass transport velocity above the bottom boundary layer, as predicted by Vocoidal theory, is greater or equal to the values predicted by Longuet-Higgins and Huang. As the water becomes shallower the opposite is true (Figures 4 and 5). This latter result corresponds to the observations made by Brebner and Collins (1961). Figure 5 gives a comparison of the theoretical profiles with a data set observed by Russell and Osorio (1957).

(iii) Eulerian Mass Transport

The Eulerian mass transport will be determined using Dalrymple's (1976) approach and be defined as the net or average flow past any fixed point in the fluid:

$$M = \frac{\rho}{T} \int_0^T \int_0^{d+\eta} u(z,t)\,dz\,dt \tag{16}$$

Dalrymple obtained, for Airy theory, the well-known solution $M = \rho g H^2/8c$, while for Dean's stream theory he found that $M = -\rho\psi(x,\eta)$, the value of the stream function on the free surface.

Integrating the continuity equation over depth and applying the bed and free surface boundary conditions the net flux in Vocoidal theory is determined to within an integration constant:

$$\int_0^{d+\eta} u\,dz - c\eta = q_m \tag{17}$$

The choice $q_m = 0$ corresponds to a reference frame in which the net mass flux is zero (Tsuchiya and Yasuda, 1981). Assume $q_m \neq 0$, then in the light of Vocoidal theory's second order irrotationality the expression relating kinetic energy density to the momentum flux, namely,

$$\frac{\rho}{\lambda} \int_0^{\lambda} \int_0^{\eta+d} (u^2+w^2)\,dz\,dx = c\rho \int_0^{\lambda} \int_0^{\eta+d} u\,dz\,dx \tag{18}$$

(Starr, 1947; Longuet-Higgins, 1976) can be used to determine q_m. Since $q_m \neq 0$ the expressions for the orbital velocities change so as to include q_m. The resulting quadratic expression in q_m can be numerically

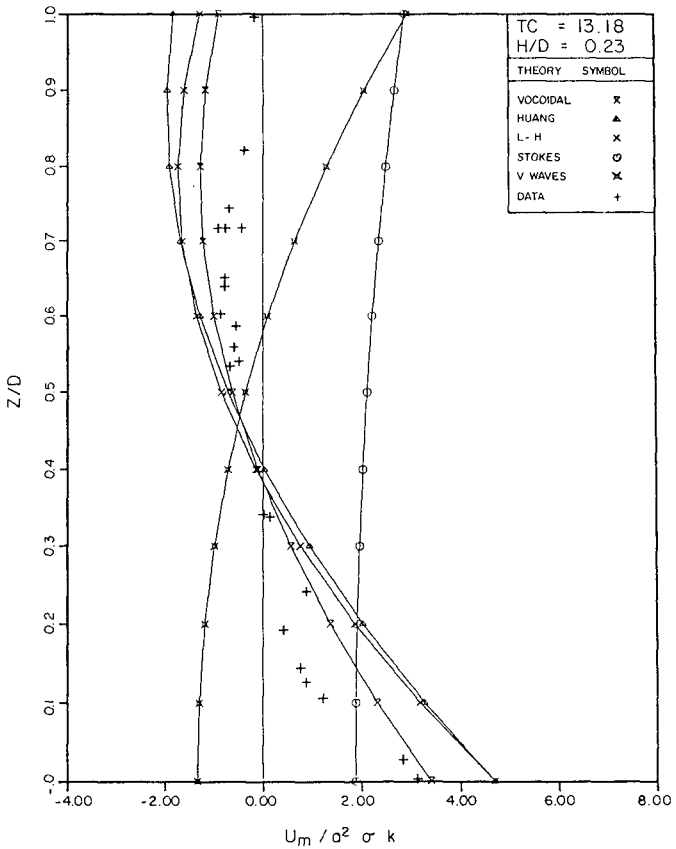

Figure 5 Comparison of the theoretical non-dimensional drift profiles and data observed by Russell and Osorio (1957, Figure 7)

solved, and values for various wave conditions can be seen in Table II. In the deep-water limit the expressions involving q_m reduces to:

$$q_m - q_m^2/cd = H^2g/8c.$$

CONCLUSIONS

(i) If viscosity is neglected the Lagrangian mass transport corresponds in profile to that given by Stokes.

(ii) Vocoidal mass transport including viscous effects is such that in deep water the velocities above the bed are generally greater than those predicted by Longuet-Higgins (1953) and Huang (1970) while for shallow water the reverse is true.

(iii) In deep water both the viscous and inviscid solutions coincide and reduce to the Stokes profile.

(iv) An Eulerian mass transport can be defined which approaches the Stokesian results in deep water but diverge as H/d and λ/d increase.

PROBABILITY DENSITY FUNCTION OF WAVE HEIGHTS OFF THE WESTERN COAST OF TAIWAN

by

Frederick L.W. Tang*

and

Jea-Tzyy Juang**

ABSTRACT

A new probability density function of wave heights off the western coast of Taiwan is submitted in this paper. According to the bathymetry of this area, waves from the central part of Taiwan Strait refract to the point of measurement and minor waves generated by local wind add the energy on the major ones; So an analytical solution is to be worked out by assuming that the wave energies are the linear sum of these two sources and convolution integral is adopted. The new model approaches reality better than Rayleigh's.

1. INTRODUCTION

Since 1952, The probability density function of wave heights is supposed to be Rayleigh's distribution. It will be physically sound if the water depth is infinitive, namely in the case of deep water wave. Another requirement is that the frequency band of wave spectrum should be as narrow as possible. In deep water waves, if the wave heights are defined to be the vertical distance

* Dr. Eng. Professor, Graduate School of Ocean Engineering, Researcher, Tainan Hydraulics Laboratory.

** M. Eng. Senior Graduate Student, Graduate School of Ocean Engineering, National Cheng Kung University, Tainan City 700 Taiwan, R.O.C.

between the tip of wave crest above mean sea water level and the bottom of wave trough below it. Such a restriction is fulfilled if we use zero-crossing method to read out the wave records. However, the probability density functions of wave heights in deep water are scarcely to be Rayleigh distribution exactly.

The authors measured and analyzed wave data off the western coast of Taiwan, and studied the wave height distributions. The curves can not said to be Rayleigh distributions. These curves have following characteristics:

(1) *The peak is higher than Rayleigh's curve and lower in two sides, namely the distribution is more concentrated.*

(2) *Two points of inflection can be found but there is only one in Rayleigh's curve.*

To explain such phenomena, we performed following two approaches.

(1) *Analyze the wave record directly to work out an empirical formula which can be adopted generally.*

(2) *According to the bathymetry off the western coast of Taiwan. The waves advanced to the point of measurement are refracted from the central part of Taiwan Strait and combined with local wind waves. A new statistical model can be worked out based on this situation. The analytical consideration of the wave height distribution caused by two wave spectra combination is described as follows.*

2. *STATISTICAL DISTRIBUTION OF WAVE HEIGHTS AFTER SPECTRA COMBINATION*

As mentioned above, the statistical features of waves in Taiwan Strait are not coincident with the theory. The reasons of such phenomenon are supposed to be as follows:

(1) *All wave records being analyzed are measured at shallow water area of western coast of Taiwan, where the waves are composed*

of two patterns. The larger one is transmitted from the central part of the strait by refraction, and the smaller one is directly generated by the prevailing NE-NNE wind along the coast as shown in Fig. 1.

(2)*Theoretical distribution of wave features are assuming that the water depth is infinite, i.e., the situation of deep water wave. Waves in Taiwan strait are shallow water waves in essence. According to the wave statistics in Taiwan strait as shown in Fig. 2, the Rayleigh distribution shows a lower estimated distribution. A new statistical model sounds necessary.*

Theoretical and practical approaches for explicating this problem are described as below.

Assuming that:

(1)*Wave energy E on a complicated random sea surface is the linear sum of the energies E_i transmitted from different sources with spectral functions $S_i(f)$, i.e.*

$$E = \frac{1}{8}\rho g H^2 = \sum_i E_i = \frac{1}{8}\rho g \sum_i H_i^2 \tag{1}$$

(2)*Wave height probability density function in each spectrum is Rayleigh distribution.*

$$\phi_{H_i}(H_i) = \frac{H_i}{4\sigma_i^2} \exp\left(-\frac{H_i^2}{8\sigma_i^2}\right), \quad 0 \le H_i < \infty \tag{2}$$

where $\sigma_i^2 = \int_0^\infty S_i(f)\,df$

(3)*Wave energies from different spectra are mutually independent random numbers.*

Probability density function of the wave height H of a random sea surface which is composed of two different wave spectra is to be derived as below:

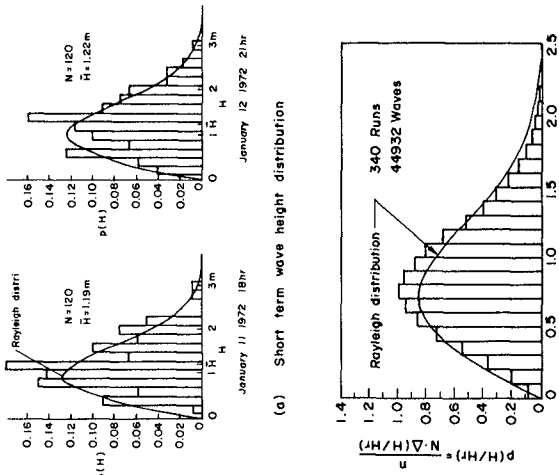

Fig. 2 Wave statistics in Taiwan Strait

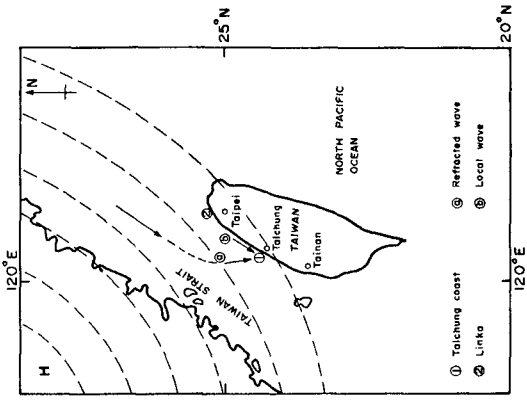

Fig. 1 Wind and wave situation in the winter and location of wave measurement

$$Let \qquad y_i = \frac{8E_i}{\rho g} = H_i^2 \qquad (i = 1, 2) \tag{3}$$

Density function of y can be found as follows

$$\phi_y(y) = \left|\frac{dH}{dy}\right| \phi_H\left(H = \sqrt{y}\right) = \frac{1}{2\sqrt{y}} \phi_H\left(\sqrt{y}\right)$$

$$\left.\begin{aligned} \phi_y(y_1) &= \frac{1}{2\alpha_1} exp\left(-\frac{y_1}{2\alpha_1}\right) \\ \phi_y(y_2) &= \frac{1}{2\alpha_2} exp\left(-\frac{y_2}{2\alpha_2}\right) \end{aligned}\right\} \tag{4}$$

where $\alpha_i = 4\sigma_i^2$

While two series of waves are mixing, their energies add together.

$$Let \qquad Z = y_1 + y_2 = H_1^2 + H_2^2 = H^2$$

$$\phi_z(Z) = \int_0^Z \phi_y(y_1)\, \phi_y(Z - y_1)\, dy_1$$

$$\phi_z(Z) = \frac{1}{2(\alpha_1 - \alpha_2)}\left[exp\left(-\frac{Z}{2\alpha_1}\right) - exp\left(-\frac{Z}{2\alpha_2}\right)\right], \qquad 0 \le Z < \infty \tag{5}$$

$$\phi_H(H) = \frac{H}{\alpha_1 - \alpha_2}\left[exp\left(-\frac{H^2}{2\alpha_1}\right) - exp\left(-\frac{H^2}{2\alpha_2}\right)\right], \qquad 0 \le H < \infty \tag{6}$$

Such a function has two points of inflexion at both sides of the peak whereas there is only one point locating to the right of maximum probability density in Rayleigh distribution.

Wave height distribution functions for the waves transmitted from 3 spectra are able to be calculated by similar way and the

result is as follows.

$$\phi(H) = \frac{\alpha_1 H}{(\alpha_1-\alpha_2)(\alpha_1-\alpha_3)}\left[exp\left(-\frac{H^2}{2\alpha_1}\right)-exp\left(-\frac{H^2}{2\alpha_3}\right)\right]$$

$$-\frac{\alpha_2 H}{(\alpha_1-\alpha_2)(\alpha_2-\alpha_3)}\left[exp\left(-\frac{H^2}{2\alpha_2}\right)-exp\left(-\frac{H^2}{2\alpha_3}\right)\right] \quad (7)$$

While the waves have multiple sources the wave height distribution function can be worked out by repeated convolution integration. A special case $H_1^2 = H_2^2 = \cdots = H_n^2$

let $$W = \sum_{i=1}^{n} H_i^2$$

$$\phi(W) = \frac{W^{n-1}}{(2\alpha)^n \Gamma(n)} exp\left(-\frac{W}{2\alpha}\right) \quad (8)$$

and $$\phi(H) = \frac{2H^{2n-1}}{(2\alpha)^n \Gamma(n)} exp\left(-\frac{H^2}{2\alpha}\right) \quad (9)$$

3. *CHARACTERISTICS OF THE NEW DISTRIBUTION*

From eq. (6), *for convenience, put* $\alpha_1 = a$, $\alpha_2 = b$, *the equation becomes*

$$\phi(H) = \frac{H}{a-b}\left[exp\left(-\frac{H^2}{2a}\right) - exp\left(-\frac{H^2}{2b}\right)\right] \quad (10)$$

$$\left.\begin{aligned} a &= 4m_{o,1} = 4\sigma_1^2 \\ b &= 4m_{o,2} = 4\sigma_2^2 \end{aligned}\right\} \quad (11)$$

The moments could be found as follows

$$m_o = \int_o^\infty \phi(H)\, dH = \int_o^\infty \frac{H}{a-b}\left[exp\left(-\frac{H^2}{2a}\right)-exp\left(-\frac{H^2}{2b}\right)\right]dH$$

$$= 1 \quad (12)$$

$$m_1 = \int_o^\infty H\phi(H)\, dH = \frac{1}{a-b}\left(\sqrt{\frac{\pi a^3}{2}} - \sqrt{\frac{\pi b^3}{2}}\right) \tag{13}$$

$$m_2 = \int_o^\infty H^2\phi(H)\, dH = 2\,(a+b) \tag{14}$$

$$m_3 = \int_o^\infty H^3\phi(H)\, dH = \frac{3}{a-b}\left(\sqrt{\frac{\pi a^5}{2}} - \sqrt{\frac{\pi b^5}{2}}\right) \tag{15}$$

$$m_4 = \int_o^\infty H^4\phi(H)\, dH = 8\,(a^2 + ab + b^2) \tag{16}$$

mean:

$$\mu = m_1 = \frac{\sqrt{\pi/2}}{a-b}\left(a^{3/2} - b^{3/2}\right) \tag{17}$$

variance:

$$\sigma_H^2 = M_2 = m_2 - m_1^2$$

$$= 2\,(a+b) - \frac{\pi}{(a-b)^2}\left(\frac{a^3+b^3}{2} - ab\sqrt{ab}\right) \tag{18}$$

skewness:

$$\sqrt{\beta_1} = \frac{M_3}{(M_2)^{3/2}} = \frac{M_3}{(\sigma_H^2)^{3/2}} \tag{19}$$

$$M_3 = m_3 - 3m_1m_2 + 2m_1^2$$

$$= \frac{3}{a-b}\left\{a^2\sqrt{\frac{\pi a}{2}} - b^2\sqrt{\frac{\pi b}{2}}\right\} - \frac{6\,(a+b)}{a-b}\left\{\sqrt{\frac{\pi a^3}{2}} - \sqrt{\frac{\pi b^3}{2}}\right\}$$

$$+ \frac{2}{(a-b)^3}\left\{\sqrt{\frac{\pi a^3}{2}} - \sqrt{\frac{\pi b^3}{2}}\right\}^3$$

kurtosis:

$$\gamma = \beta_2 - 3 = \frac{M_4}{M_2^2} - 3 \tag{20}$$

$$M_4 = m_4 - 4m_1m_3 + 6m_1^2m_2 - 3m_1^4$$

$$= 8(a^2+ab+b^2) - \frac{12}{(a-b)^2}\left\{\sqrt{\frac{\pi a^3}{2}} - \sqrt{\frac{\pi b^3}{2}}\right\}\left\{\sqrt{\frac{\pi a^5}{2}} - \sqrt{\frac{\pi b^5}{2}}\right\}$$

$$+ \frac{12(a+b)}{(a-b)^2}\left\{\sqrt{\frac{\pi a^3}{2}} - \sqrt{\frac{\pi b^3}{2}}\right\}^2 - \frac{3}{(a-b)^4}\left\{\sqrt{\frac{\pi a^3}{2}} - \sqrt{\frac{\pi b^3}{2}}\right\}^4$$

extreme value occurs at

$$H = \left\{\frac{2ab}{a-b}\, ln\left(\frac{ab - aH^2}{ab - bH^2}\right)\right\}^{1/2} \tag{21}$$

point of inflexion occurs at

$$H = \left\{\frac{2ab}{a-b}\, ln\left[\frac{a^2(H^3 - 3b)}{b^2(H^2 - 3a)}\right]\right\}^{1/2} \tag{22}$$

According to the above mentioned equations, we can found that all the characteristic values are influenced by a and b, i.e., influenced by wave energies of refracted and local wave.

4. *PROCEDURE OF DELINEATE PROBABILITY DENSITY CURVES FOR EXISTING RECORDS*

From eq. (17), *we have*

$$\overline{H} = \sqrt{\frac{\pi}{2}}\left(\frac{a^{3/2} - b^{3/2}}{a-b}\right) \tag{23}$$

let	$\sqrt{a} = x$	$\sqrt{b} = y$
then	$a = x^2$	$b = y^2$
	$a^{3/2} = x^3$	$b^{3/2} = y^3$

Eq. (23) *becomes*

$$\frac{\overline{H}}{\sqrt{\frac{\pi}{2}}} = P = \frac{x^3 - y^3}{x^2 - y^2} \tag{24}$$

The local wave energy b can not be equal to that of waves from the central part of Taiwan Strait.

$$a \neq b \quad , \quad i.e. \qquad x \neq y$$

then $$x^2 + xy + y^2 - Px - Py = 0 \tag{25}$$

This is the equation of an ellipse as shown in Fig. 3.

The total energy is the sum of local and refracted wave energies

$$a + b = 4\ (\ \sigma_1^2 + \sigma_2^2\ ) = 4\,\sigma^2 \tag{26}$$

Following relationship exists

$$\overline{H} = k\sigma \tag{27}$$

Eq. (26) *becomes*

$$x^2 + y^2 = (\ \frac{2\overline{H}}{k}\ )^2 = R^2 \tag{28}$$

This is the equation of a circle with radius R.

From equs. (25) *and* (28), *the energies* x, y, *i.e.*, a, b *can be worked out.*

For standardization

let $$X = \frac{\sqrt{2}}{2}x + \frac{\sqrt{2}}{2}y \qquad Y = -\frac{\sqrt{2}}{2}x + \frac{\sqrt{2}}{2}y$$

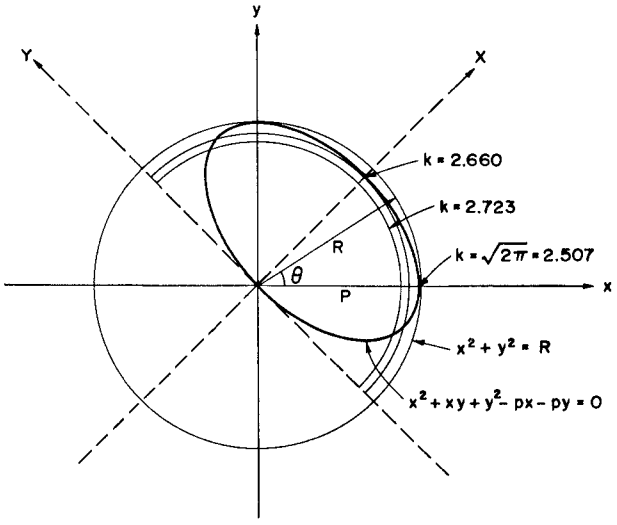

Fig. 3 Graphical solution of simultaneous equations

then $x = \frac{\sqrt{2}}{2}X - \frac{\sqrt{2}}{2}Y \qquad y = \frac{\sqrt{2}}{2}X + \frac{\sqrt{2}}{2}Y$

Eg.(25) *becomes*

$$3X^2 + Y^2 - 2\sqrt{2}PX = 0 \tag{29}$$

that is

$$\frac{(X - \frac{\sqrt{2}}{3}P)^2}{\frac{2}{9}P^2} + \frac{Y^2}{\frac{2}{3}P^2} = 1 \tag{30}$$

The shape of this ellipse was shown as Fig. 3. *Its Center at* $(\frac{\sqrt{2}}{3}P, 0)$, *long axis* $= \frac{2\sqrt{2}}{\sqrt{3}}P$, *short axis* $= \frac{2\sqrt{2}}{3}P$. *When* $Y = 0$, $X = 0$ *and* $\frac{2\sqrt{2}}{3}P$, *the ellipse curve passed at the original point. Besides, when* $y = 0$, $x = P$.

From Fig. 3, *we found that if we want to have solution of equs.*(25) *and*(28), *the condition is* $R \leq P$. *But from equs.*(24) *and*(28), *we have*

$$\frac{2\overline{H}}{k} = R \leq P = \frac{\overline{H}}{\sqrt{\frac{\pi}{2}}}$$

for $\overline{H} \neq 0$, *so* $k \geq \sqrt{2\pi}$ (31)

According to the field data measured at Taichung Harbor (① *in Fig.* 1) *in Taiwan Strait* (*Ou*, 1977), *the value of* $k = 2.723 > \sqrt{2\pi}$. *The new model can be used. But at Linko* (*north coast of Taiwan, as shown in Fig.* 1), $k = 2.461 < \sqrt{2\pi}$, *the new model is not adequate.*

For convenient computation, submit eq.(28) *into eq.*(25) *and*

change it into the polar coordinate

$$R^2 + R^2 (\sin\theta \cdot \cos\theta) - P \cdot R (\cos\theta + \sin\theta) = 0 \qquad (32)$$

$$\frac{1}{4} (\frac{R}{P})^2 \cdot \sin^2 2\theta + [(\frac{R}{P})^2 - 1] \sin 2\theta + [(\frac{R}{P})^2 - 1] = 0 \qquad (33)$$

let $\frac{R}{P} = A$, $\sin 2\theta = Z$

$$Z^2 + \frac{4 [A^2 - 1]}{A^2} Z + \frac{4 [A^2 - 1]}{A^2} = 0 \qquad (34)$$

again, let $\frac{4 [A^2 - 1]}{A^2} = B$

$$Z^2 + BZ + B = 0$$

The solution is

$$Z = \frac{-B \pm \sqrt{B (B - 4)}}{2} \qquad (35)$$

Use computer for computation, if we have k value (from the field data), then R, P, A, B can solved. Consequently, the values of Z, θ, x, y, a, b can fiud out. Therefore, the new distribution for combined wave spectrum is to be worked out.

5. *COMPARISON WITH TRADITIONAL DISTRIBUTION AND DISCUSSION*

Based on the wave statistical result of 21 *sets of field data in Taiwan Strait, the values of k are to be enumerated. They range from* 2.50 *to* 2.95. *After choicing k* = 2.600, 2.660 *and* 2.723. *The new distribution curves can be dipicted in figure* 4. *Also Rayleigh's curves of the same case are delineated.*

From these figures, it can be realized that the new distribution approaches reality much better than traditional Rayleigh's

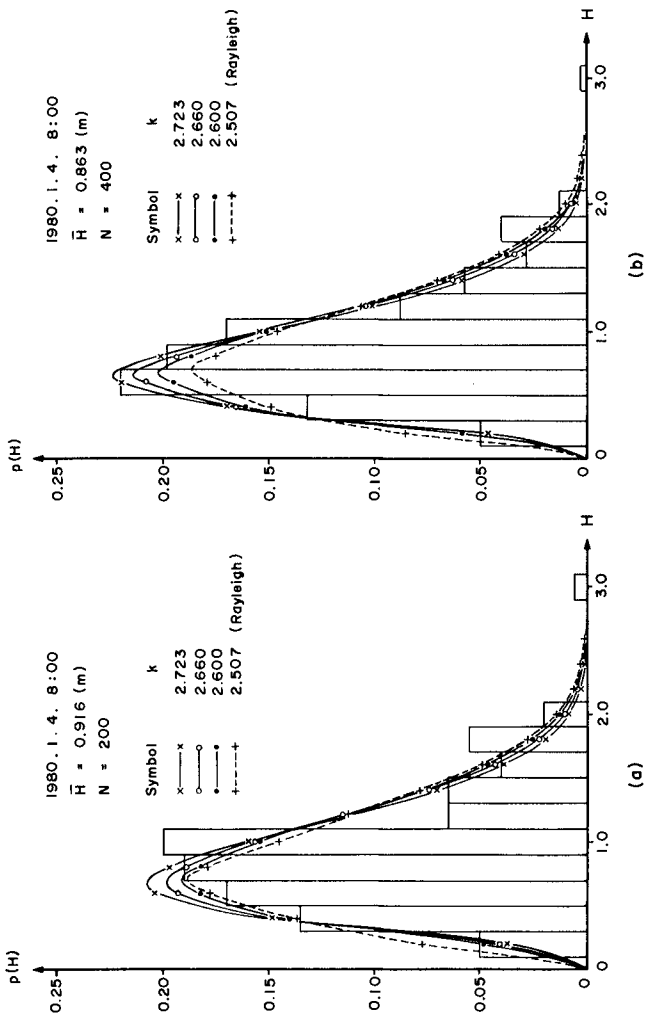

Fig.4 New probability density curve and measured data (1)

density function.

However, in the case of Linko, the winter monsoon attacks the seashore near vertically, the local wind waves are not able to be generated. The assumption of spectral combination is not suitable and the curve of new distribution can not be work out because the values of k is less than $\sqrt{2\pi}$.

In the summer of 1982, *the senior author was invited by Franzius Institute of The University of Hannover to be guest professor. He had the opportunity to analyze the wave records of Sylt. The k value is found to be* 2.46 *for the wind wave is moving depressions are almost approaching frontally to the coast. However, the waves in German Bight are similar to western coast of Taiwan. The wave height distributions over there are to be supposed to fit our new distribution.*

6. *CONCLUSIONS AND SUGGESTION*

1. *The new probability density function of the wave heights fits the reality better than Rayleigh's distribution.*
2. *The new model derived from the idea of the energies of local and refracted waves being combined together, especially conform to situation that the wind direction is parallel to the shoreline.*
3. *At the areas like Linko, local wave can't occur easily, the new model can not be used.*
4. *The forecasting of wave height distribution will be available, provided that the winds can be accurately predicted off the western coast of Taiwan and areas of similar condition.*
5. *Although the new density function approaches reality better than Rayleigh distribution. But the assumption of only two spectra combination will not too sound. Waves in the point of interest are come from every available direction and not able to be divided. However, from the clue used in this paper, it*

can be assumed to be that the wave energy is the linear sum of $S(f)\triangle f_i$, *and* $\triangle f_i$ *is so selected that every* $\triangle E_i = S(f)\triangle f_i$ *are equal, and eq.*(9) *will be a reasonable function to represent the distribution of wave heights if n is suitablely selected.*

ACKNOWLEDGEMENTS

The anthors are deeply indebted to the Gentlemens of Taichung Harbor Bureau and Chinese Petroleum Co. for offering wave data to be analyzed. Also, the authors would greatly appreciate Dr. Shan-Hwei Ou for quote his previous studies and receiving his useful suggestions.

STUDY OF HURRICANE WAVES AROUND THE TAIWAN COAST

By

Hou, Ho-Shong*

S.C. Kuo**

R.S. Tseng***

ABSTRACT

The objective of this research is to study the prediction method of hurricane waves around this island, especially in the Taiwan Strait. The paper describes the prediction of hurricane waves used by Bretchneider's (1976) Method and finds out the predicted waves are different from measured waves, therefore the Bretchneider predicted model is modified by the authors and then the modified model is applied to predict waves again. It is found out that predicted waves match well with the measured waves. The results of the modified Bretchneider model are compared with those of the Ijima tracing method and find out the former is better than the latter.

The second part is to apply the modified model to predict the extreme value of wave heights and compute the worse hurricane wave condition of the surrounding sea area around island, within recent score year (1959-1978). The calculated sites are Chu-Wei, Nan-Liaw, Ta-Shih, Cheng-Kung, Pu-Tai, Tung-Kang, Nan-Wan as shown in Fig.1 and Shiau Liu-Chieu totally 8 stations. Then use the Gumbel Distribution TYPE 1 to predict the extreme wave height of each returned period.

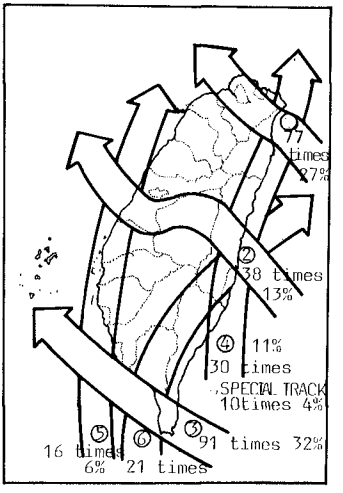

Fig.2b Statistics of Typhoon Track attacked this area

1. INTRODUCTION

"Typhoon" is the most severest atmosphere condition to natural damage when it is threatening the island of Taiwna, Republic of China. Because of the violent wind of typhoon, the induced wave height is stronger than that of the monsoon. Therefore, typhoon waves have to be considered as the design criteria of ocean and coastal engineering.

Usually there are several methods of typhoon wave prediction: (1) Tracing Method of Ijima (2) Graphic Method of Wilson (3) Numerical Calculation Method of Tang (4) Empirical Method of Bretschneider. The first three methods have good accuracy, but the calculation procedures are complicated. As for the Bretschneider empirical method, its calculation procedure and accuracy showed satisfactory results. In this paper, the authors calculated six typhoon waves in Kaohsiung, Taichung and other harbors of Taiwan by use of the empirical method. From the comparison of measured and calculated result, the empirical method have been added some modifications to fit for suitable use of the Taiwan areas.

The modified Bretschneider method is also applied to estimate the highest typhoon waves of Taiwan during the past 20 years. The statistical theory is used to get the possibly extreme waves of the recurrence interval of 100 years, 50 years,..., etc. This conclusion may provide a reference for the design of ocean structures.

2. BASIC THEORY

Typhoon Waves Calculation

The Bretschneider empirical method is modified from the practical application around Taiwan coastal areas. The procedures are as follow:

$$(1)\quad \frac{U_r}{U_R} = -\frac{1}{2}\frac{fR}{U_R}\frac{r}{R} + \sqrt{\left(1+\frac{fR}{U_R}\right)\frac{R}{r}e^{\left(1-\frac{R}{r}\right)} + \left(\frac{1}{2}\frac{fR}{U_R}\frac{r}{R}\right)^2}$$

$$(2)\quad U_R = K\sqrt{\Delta P} - 0.5fR \qquad \text{(Knots)}$$

$$(3)\quad U_{RS} = 0.865U_R$$

$$(4)\quad \Delta U = \frac{1}{2}V_F\cos(\theta+\beta)$$

$$(5)\quad U^*_{RS} = U_{RS} + \Delta U$$

$$(6)\quad H_R = K'\sqrt{R\Delta P}$$

$$(7)\quad H^*_R = H_R(1+\Delta U/U_{RS})^2$$

$$(8)\quad f_0^{-1}/U = 0.4\tanh[\ln(1+\frac{40H_s}{U^2} / 1-\frac{40H_s}{U^2})^{0.5}]^{0.6}$$

$$(9)\quad T_s = \sqrt[4]{\frac{4}{5}}\, f_0^{-1}$$

where U_r, U_R: wind speeds at distance r and R from the typhoon center

f : the Coriolis parameter

ΔP : $P_N - P_0$

P_N, P_0: normal pressure and central pressure, inches of H_g

R : radius of maximum wind, for U_R

K : 67, when latitudes = 20°N - 25°N

U_{RS}: average wind speeds at radius R for the 10m reference plane above mean sea level (Knots)

V_F: actual forward speed of typhoon (Knots)

θ : angle between wind direction and forward direction of typhoon

β= 25°, incurvature angle of wind to tangent of isobars

H_R: wave height at radius R (ft)

K': a coefficient which can be obtained from the following polynomial (Liang 1978)

$$K' = 7.59-41.21(\frac{fR}{U_R})+160.51(\frac{fR}{U_R})^2-219.32(\frac{fR}{U_R})^3$$

H_R^*: wave height at radius R for a hurricane moving at a constant forward speed

T_s: wave period (sec)

3. EXTREME WAVES ESTIMATION

There are a number of methods used in various engineering practices which can be applied to the problem for obtaining design wave height. This paper used a method called "Gumbel Distribution Method". The theory is briefly described as follows:

$$P = (\frac{S'}{S+1})\ 100 \qquad (\%)$$

where S : total number of occurrences on record

S': summation of occurrences, beginning with the highest value to any successive lower values until S'=S

the following equations are used

$$P = \exp(-\exp(-y))$$

$$y = -\ln(-\ln p)$$

Gumbel's theory of extreme values shows that the plot (on extreme-value paper) of a series of observed extreme values of wave heights X should approximate to a straight line.

$$X = X_0 + my$$

where X_0: the modal value of the distribution
m: slope of dx/dy

Gumbel has provided a method of calculating X_0 and m.

$$m = \pi/\sqrt{6}/\sigma_x$$

$$X_0 = \overline{X} - 0.5772/m$$

where σ_x: standard deviation of X_i
$\overline{X}$: average value of X_i

the recurrence interval can be found from

$$I = 100\ \frac{Y}{5P}$$

Y: number of years of record

4. PRACTICAL CALCULATION AND MODIFICATION

Six typhoons are chosen for the case study of wave calculation. Comparisons of the theoretical calculated and the measured waves are made, because of the information of winds and waves are very complete. These typhoons are (1) Judy (May 1966) (2) Agnes (Sep. 1971) (3) Bess (Sep. 1971) (4) Nina (Aug. 1975) (5) Betty (Sep. 1975) (6) Vera (July 1977). The pathes of these typhoons are shown in Fig.2.

There are a few parameters should be determined more carefully because of their significant influence on calculated result. They are discussed individually as follows:

(1) R

R can be determined from the empirical formula of Graham and Nunn (1959)

$$R=28.52\tanh[0.0873(|LAT|-28^{\circ})]+12.22\exp(-\Delta P/33.86)+0.2V_F+37.22$$

where R: radius of maximum wind (Km)
LAT: latitude of typhoon center
ΔP: $1013.2-P_0$ (mb)

(2) ΔP

ΔP can be determined from the formula of Wang (1978)

$$\Delta P = P_N - P_0 \approx 1000 + \frac{(1000-P_0)}{10} - P_0$$

(3) U_R

Bretschneider applies the equation $U_R=K\sqrt{\Delta P}-0.5fR$ in his method to calculate the maximum wind speed U_R. The result of calculation is not always coincident with typhoon record of the Central Weather Bureau. So we use the typhoon record instead of the equation of Bretschneider.

From the above procedures, the waves can be calculated and compared with measured data as shown in Table 1.

	06	5.3	3.7	9.0	7.8

The predicted wave height has good accuracy as shown in Table 1, but the predicted wave period is always greater than the measured data. So we use the wave period modification coefficient G

$$G = \text{average value of } \frac{\text{measured wave period}}{\text{predicted wave period}} = 1.2$$

Comparisons between two Wave Model with measured values are shown in Fig. 3.

5. ESTIMATION OF EXTREME WAVES

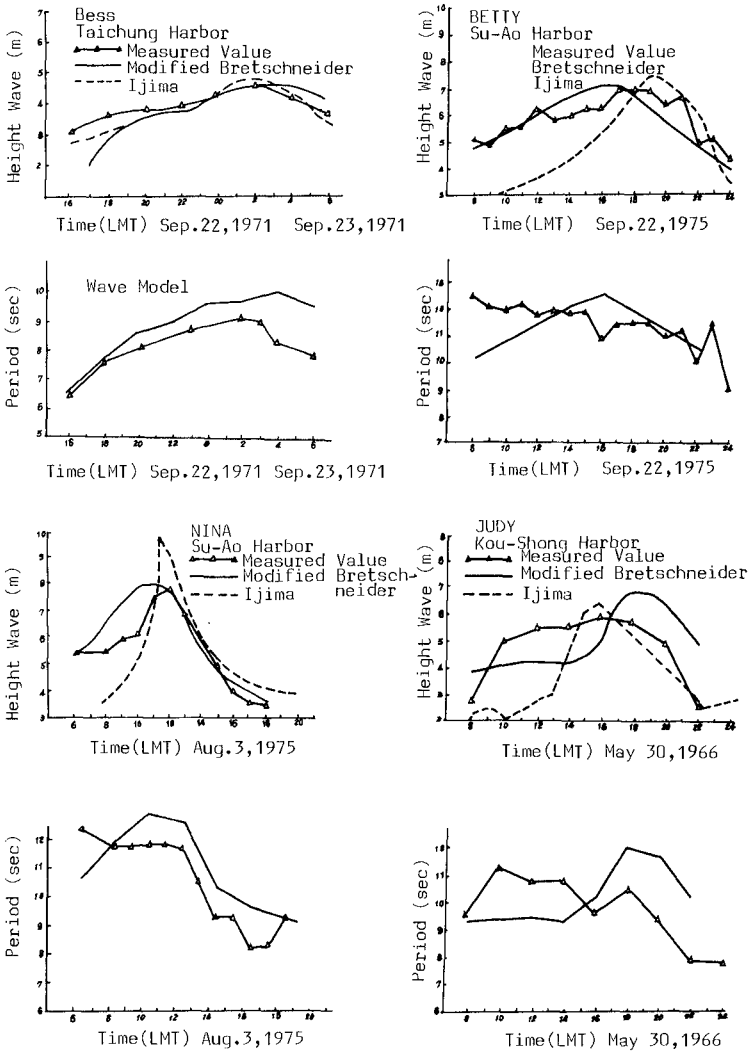

Fig.3 Comparison between Two Hurricane Wave Model

We select eight sites for the estimation of extreme waves. The sites are shown in Fig.1.

The calculation procedures are shown in the following:

(1) Select all typhoons from 1959 to 1978 (20 years) that influenced the coastal areas of Taiwan. Decide their best tracks and other information.

(2) Apply the modified Bretschneider method to calculate $H_{1/3}$ and H_{max} caused by these typhoons at the eight sites.

(3) If $H_{1/3} > 4m$, $H_{max} > 8m$, and typhoon passing within 3 degress of the estimation site, then it can be used to estimate the extreme waves.

(4) Apply the Gumbel distribution method to calculate the extreme waves.

From the above procedures, the extreme waves of eight sites can be obtained and enlisted in Table 2.

Table 2 Extreme Waves of Eight Sites

Site 1: Chu-Wei 25.1°N 121.2°E 30m depth					
$H_{1/3} = 1.600y + 5.928$ $H_{max} = 2.768y + 10.86$					
I(year)	100	50	30	20	10
$H_{1/3}$ (m)	14.3	13.2	12.3	11.7	10.5

Site 4: Cheng-Kung 23.1°N 121.4°E 30m depth					
$H_{1/3}$ = 1.412y + 5.423 H_{max}= 2.381y + 10.369					
I(year)	100	50	30	20	10
$H_{1/3}$ (m)	12.9	11.9	11.2	10.6	9.6
H_{max}(m)	22.5	20.9	19.6	18.7	17.0

Site 5: Pu-Tai 23.4°N 120.1°E 30m depth					
$H_{1/3}$ = 1.329y + 5.126 H_{max}= 2.209y + 10.013					
I(year)	100	50	30	20	10
$H_{1/3}$ (m)	11.7	10.8	10.1	9.5	8.6
H_{max}(m)	20.4	18.8	17.7	16.8	15.2

Site 6: Tung-Kang 22.5°N 120.4°E 30m depth					
$H_{1/3}$ = 1.252y + 5.345 H_{max}= 2.174y + 9.878					
I(year)	100	50	30	20	10
$H_{1/3}$ (m)	11.5	10.7	10.0	9.5	8.6
H_{max}(m)	20.6	18.9	17.7	16.8	15.3

Site 7: Shiau Liu-Chieu 22.4°N 120.4°E 30m depth					
$H_{1/3}$ = 1.269y + 5.30 H_{max}= 2.2y + 9.696					
I(year)	100	50	30	20	10
$H_{1/3}$ (m)	11.7	10.8	10.1	9.6	8.7
H_{max}(m)	20.6	19.0	17.9	17.0	15.4

Site 8: Nan-Wan 21.9°N 120.8°E 30m depth					
$H_{1/3}$ = 1.172y + 5.386 H_{max}= 2.001Y + 9.939					
I(year)	100	50	30	20	10
$H_{1/3}$ (m)	11.3	10.5	9.9	9.4	8.6
H_{max}(m)	19.9	18.5	17.5	16.6	15.2

6. CONCLUSION

(1) The modified empirical method has pretty good accuracy in maximum hurricane wave height prediction. Therefore, it is very suitable for coastal areas of Taiwan.

(2) The extreme wave heights $H_{1/3}$ of 100 years recurrence interval at the eight sites are ranked by order: 15.8m, 14.3m, 13.5m, 12.9m, 11.7m, 11.7m, 11.5m, 11.3m. This result may be considered as design criterias of the ocean and coastal engineering at these sites.

(3) Bretschneider (1973) had used the ship observed data and typhoon information of past 10 years (1961-1970) to estimate the waves of Taiwan offshore areas. The result of his estimation was 16m ($H_{1/3}$ of 100 years recurrence interval), a little greater than the result of this paper. The reason of this small deviation may be the site depth - Bretschneider's estimation was in the deep sea, this paper's estimation was in the coastal sea.

WIND TURBULENCE OVER SEAS IN TROPICAL CYCLONES

W.H. Melbourne[1] and D.R. Blackman[2]

ABSTRACT

A study of wind data collected from the Waglan Island anemometer (Hong Kong) during 39 tropical cyclones indicates that turbulence intensity values in excess of 20% at a reference height of 50 m are likely during extreme wind conditions in a tropical cyclone. The implied surface drag coefficient of approximately 0.01 in these extreme wind conditions is consistent with wind flow over a land surface roughness of trees and suburban housing, but is much higher (by a factor of five) than that predicted by the currently accepted formulae from the reviews of Garratt and Wu for wind flow over a fully developed sea in neutral atmospheric conditions. For wind loading design calculations in extreme wind in tropical cyclone conditions it is recommended that mean wind and turbulence intensity profiles should be calculated with a roughness length z_0 = 0.20 m in the Deaves and Harris wind model.

1 INTRODUCTION

Major structures planned and being built in ocean environments are becoming increasingly wind sensitive as the frequency of their first mode becomes lower. The response of such structures to wind action is not only a function of wind speed but is significantly dependent on the turbulence structure of the wind flow, more explicitly on the turbulence intensity and spectral distribution. Similarly, wind loading on harbour and onshore structures are dependent on these same characteristics. It is important therefore to have estimates of the turbulence characteristics of wind flow over the sea surface in extreme wind conditions, such as might occur for return periods of 20 to 2000 years to cover limit state serviceability and collapse conditions.

Wind data collected in Hong Kong at several anemometer sites for 123 tropical cyclones causing persistent gales since 1884 have been corrected recently for anemometer position error and used to estimate design wind speeds for this area. In particular, model tests to correct wind data collected at a height of 75 m above sea level on Waglan Island, in a full ocean exposure, have given some access to wind turbulence data over the sea in tropical cyclone, extreme wind conditions. These results will be presented to provide some full scale information about wind structure over the sea in extreme wind conditions.

2 WIND MODELS OVER SEA AND LAND

2.1 Over Land

The most recent review of data compiled to derive a wind model over land is that by Deaves and Harris (1978). The Deaves and Harris model of the structure of strong winds is a most thoroughly researched model and is in wide use in the wind engineering field. It is based on classic logarithmic law mean wind speed profiles and defines surface roughness in terms of the roughness length, z_o.

$$\text{i.e.} \quad \frac{\bar{V}_z}{u_*} = \frac{1}{\kappa} \ln\left(\frac{z}{z_o}\right) \qquad (1)$$

where u_* is the friction velocity $\left(= \sqrt{\frac{\tau}{\rho}} \right)$

$\bar{V}_z$ is the mean wind speed at height z

z is height above ground level

z_o is a roughness length

κ is the von Karman constant (=0.4)

ρ is air density

τ is surface wind shear stress

For the purposes of this study the central parameter is turbulence intensity, I_z, defined as,

$$I_z = \sigma_{v_z} / \bar{V}_z \qquad (2)$$

where σ_{v_z} is the standard deviation of wind speed at height z

A summary of the equations used in the Deaves and Haris wind model are given in Appendix 1. A study has been carried out (Melbourne 1980) using the Deaves and Harris wind model with a 50 ms^{-1} mean gradient wind speed (appropriate to strong wind, design conditions) and varying z_o, until a best fit with profiles for four defined surface roughness categories was obtained. A summary of the relevant turbulence intensity characteristics and roughness length values, with a little rounding, for four surface terrain roughness conditions is given in Table 1.

TABLE 1

TURBULENCE INTENSITY CHARACTERISTICS FOR THE DEAVES AND HARRIS MODEL OVER FOUR SURFACE TERRAIN ROUGHNESS CONDITIONS

Terrain Roughness	Height (m)	Turbulence Intensity I_z
1. Flat desert, snow, (z_o = 0.002 m) ($C_{D_{10}}$ = 0.0022)	5	0.165
	10	0.157
	50	0.128
	100	0.108
	200	0.085
2. Level grass plains, isolated trees, airfields (z_o = 0.02 m) ($C_{D_{10}}$ = 0.0041)	5	0.196
	10	0.183
	50	0.151
	100	0.131
	200	0.107
3. Trees, suburban housing (z_o = 0.2 m) ($C_{D_{10}}$ = 0.0104)	5	-
	10	0.239
	50	0.188
	100	0.166
	200	0.139
4. Forests, hilly terrain, city centres (z_o = 2.0 m) ($C_{D_{10}}$ = 0.061)	5	-
	10	0.448
	50	0.270
	100	0.233
	200	0.196

2.2 Over Sea

In spite of a bounteous literature, until very recently it has been a matter of contention whether the drag coefficient of the wind over the sea assumes a constant value for strong winds. The experimental difficulties probably account in large measure for this imprecision, but it will come as no surprise to find that measurements of strong wind parameters over the sea are very sparse, still less that adequate mathematical representations are wanting.

Garratt (1977) in his review of drag coefficients over oceans and continents concluded, that "observations are consistent with Charnock's (1955) relation,

$$z_o = \frac{\alpha u_*^2}{g} \qquad (3)$$

where α is a constant" (later to be given a value of 0.0185)

and that "for $4 < \bar{V}_{10} < 21$ ms^{-1} a neutral drag coeffficient (referred to 10 m) could be given by

$$\text{or} \quad \begin{aligned} C_{DN_{10}} \times 10^3 &= 0.51\ V_{10}^{0.46} \\ C_{DN_{10}} \times 10^3 &= 0.75 + 0.067\ V_{10} \end{aligned} \qquad (4)$$

which is similar to that proposed by Deacon and Webb (1962) and Wu (1969) for wind speeds less than 15 ms^{-1}, and that observations did not support a constant C_{DN} above 15 ms^{-1} as deduced by Wu (1969)" (p926).

Wu (1980) revisited the field and with more data further confirmed the relevance of Charnock's relation and suggested that the most appropriate value for the constant, α, was 0.0185 with $\kappa = 0.40$, and that

$$C_{10} = (0.8 + 0.065\ V_{10}) \times 10^{-3} \qquad (5)$$

which he also showed (Wu, 1983) is in close agreement for a reference height of 10 m to the generalised expression obtained from (1) and (3), i.e.

$$C_{D_z} = \frac{\tau}{\rho \bar{V}_z^2} = \left[\frac{u_*}{\bar{V}_z}\right]^2 = \left[\frac{\kappa}{\ln(1/a\ C_{D_z} F^2)}\right]^2 \qquad (6)$$

where F is a form of Froude number

$$\left(F = \bar{V}_z/\sqrt{g\ z}\right)$$

Wu (1983) also suggested on the basis of some new data that Charnock's relation and equation (5) appear to be applicable to much higher wind speeds than previously thought, even in hurricanes.

The conclusions of this recent work, in respect of values of drag coefficient and roughness length for wind flow over the sea surface as function of wind speed are summarised in Table 2. Values of the roughness length of the order 0.010 m, commensurate with a mean wind speed of 40 ms^{-1} at 10 m over the sea from Table 2, bear no relation to the physical scales apparent in a fully aroused sea. Of course, a reference height of 10 m is an obvious nonsense at such wind speeds when wave heights in excess of 20 m are likely to be present. It is not surprising that the applicability of current formulae for wind flow over land and sea is being challenged in respect of extreme (design) wind storm events over the sea.

3 FULL SCALE MEASUREMENTS FROM WAGLAN ISLAND

The initial analysis of the Waglan Island data was based on the highest mean and three-second maximum gust wind speeds recorded by Dines anemometers for each tropical cyclone causing persistent gales in the Hong Kong region. These data were corrected for anemometer position error from wind tunnel topographical model studies of the anemometer sites. During the analysis of this data it was realised that the anemometer on Waglan Island, which is a small rock outcrop SE of Hong Kong Island, was ideally sited for the purpose of obtaining wind data over the sea in extreme wind conditions, because it is completely exposed to the open ocean for wind directions NE to SW and for the remainder the ocean fetch is mostly 5 km or more. The anemometer at Waglan Island is on a mast, approximately 20 m above ground level and 75 m above mean sea level. The anemometer position errors were initially measured to give freestream conditions at a reference height of 10 m. For extreme wind conditions and attendant wave heights this is obviously quite an artificial reference. Subsequent wind tunnel measurements have been made to correct these anemometer readings to the height of the freestream streamline passing through the anemometer.

3.1 Anemometer Position Error Corrections

A 1/600 scale model of Waglan Island, shown in Figure 1, was tested in two turbulent boundary layer wind models. The wind models were generated in a 2 x 2 x 15 m working section using triangular vorticity generators at the front followed by surface roughness blocks. The two wind models had the scaled characteristics of wind flow over open terrain and suburban/treed terrain, i.e. $z_o \approx 0.02$ and 0.2 respectively or in terms of power law profiles, for exponents $\alpha = 0.15$ and 0.24, where $\left(\bar{V}_z = \bar{V}_g (z/\bar{V}_g)^{\alpha} \right)$. The ratios of the parameters, mean and gust wind speed at the anemometer position and at a scaled height of 50 m in the freestream flow, was measured using hot wire anemometry. In fact, there have been four anemometer positions on Waglan Island since 1952. Between 1952 and 1963 the anemometer was placed on the Observatory Building with good exposure. From 1964 to July 1966 the anemometer was located 3 m above the Signal Tower roof, and being in

FIG. 1 1/600 scale wind tunnel model of Waglan Island used to determine anemometer position error corrections.

the wake of the building, these wind records are useless. In July 1966 the anemometer was raised to 19.5 m above ground level and was then shifted slightly again in December 1971 to its current position. An example of the position error corrections for mean wind speed, $\bar{V}$, and maximum gust wind speed, $\hat{V}$, are given in Figure 2 for the current anemometer position. Since these measurements were made, a set of mean velocity anemometer corrections was measured at the University of Western Ontario, Surry *et al.* 1981, for all anemometer positions and which compare well with the corrections shown in Figure 2.

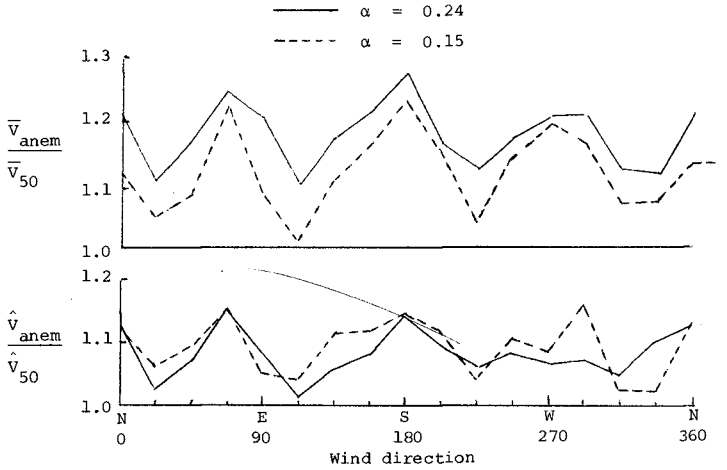

FIG. 2 Mean and gust wind speeds at the Waglan Island anemometer position (1971-) relative to freestream at 50 m above MSL as a function of wind direction for two surface roughness conditions (i.e. two boundary layer profiles)

Apart from the fact that a 10 m freestream reference height is physically meaningless there was another very important reason for correcting anemometer records to a greater height in the freestream flow: the sensitivity of the position error corrections to variations in the approach profile increases with reduction of the freestream reference height. It was therefore decided to use a reference height approximately the same as the freestream height of the streamline which passes through the anemometer on top of the buildings on the island (75 m). Accordingly a freestream reference height of 50 m above MSL was chosen. As can be seen in Figure 2 the correction ratios for the two approach profiles are almost the same for mean and gust wind speeds. The maximum mean and gust wind speeds from the Waglan Island anemometer for each tropical cyclone causing persistent gales in Hong Kong since 1982 (excluding records from January 1964 to June 1966), corrected to refer to a height of 50m above MSL in freestream flow, are given in Table 3.

3.2 Turbulence Intensity Measurements

In Table 3 values of the peak gust over mean wind speed ratio have been calculated. There have been a number of formulae offered in the literature which relate turbulence intensity to the ratio of the maximum gust over mean wind speed, most of which effectively state the number of standard deviations above the mean one might expect the maximum value to occur on average for a given short averaging period. This relationship depends on the response time of the anemometer as well as the averaging period. Deaves and Harris in reviewing

available data recommended the use of the following expression for a Dines anemometer, from which the maximum gust wind speed is estimated to be the maximum for a 3 second averaging period in an hour.

$$\frac{\hat{V}}{\overline{V}} = \left(1 + 3.7 \frac{\sigma_v}{\overline{V}}\right)$$

given turbulence intensity as

$$\frac{\sigma_z}{\overline{V}} = \left(\frac{\hat{V}}{\overline{V}} - 1\right)/3.7 \qquad (7)$$

Turbulence intensity for each storm has been evaluated in Table 3 and is given in Figure 3 as a function of wind speed.

4 TROPICAL CYCLONE DATA COMPARED WITH WIND DATA OVER THE SEA

The turbulence intensity of the wind in tropical cyclones as measured at Waglan Island imply a range of wind structure characteristics when fitted to, or compared with, the Deaves and Harris strong wind model. It is not suggested that the Deaves and Harris strong wind model is necessarily appropriate for wind flow over the sea surface in a tropical cyclone, but it is a wind model based on classical log profiles and in which there are well defined relationships between roughness length, friction velocity, drag coefficient, mean and gust wind speed and turbulence intensity profiles, all of which can be related to a surface roughness condition as characterised in Table 1. On Figure 3 three terrain roughness conditions from Table 1 are shown as a function of the turbulence intensity at a height of 50 m.

Inspection of the parameters implied by the Deaves and Harris strong wind model in Figure 3 indicates that as the wind speed increases the characteristics in the wind flow over the sea in a tropical cyclone take on progressively the characteristics of flow over (a) a flat desert at the lower wind speeds, (b) the flow over grass plains, and (c) the flow over trees and suburban housing at the higher wind speeds. In terms of the physical heights of the surface roughness (waves) this progression is not altogether unexpected.

These characteristics can now be compared with currently accepted characteristics of wind flow over the sea as described in §2.2. Possibly the most convenient parameter for comparison is the surface drag coefficient and this comparison is given in Figure 4. At the lower wind speeds the wind flow over the sea in a tropical cyclone is as predicted by Equation 4 from the reviews of Garratt and Wu. However that is where the similarity ends, because at progressively higher wind speeds the wind flow over the sea in a tropical cyclone shows a progressively higher surface drag coefficient, and hence implied higher surface roughness, than is predicted for wind flow over the sea by Equation 4.

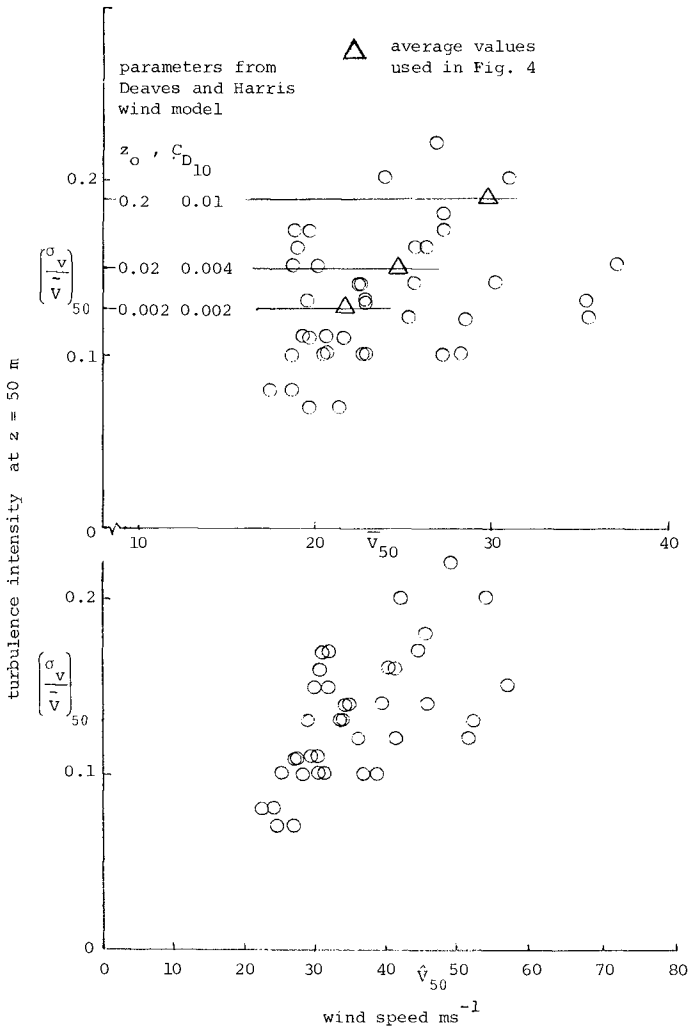

FIG. 3 Turbulence intensity at a height of 50 m above MSL from Waglan Island tropical cyclone data.

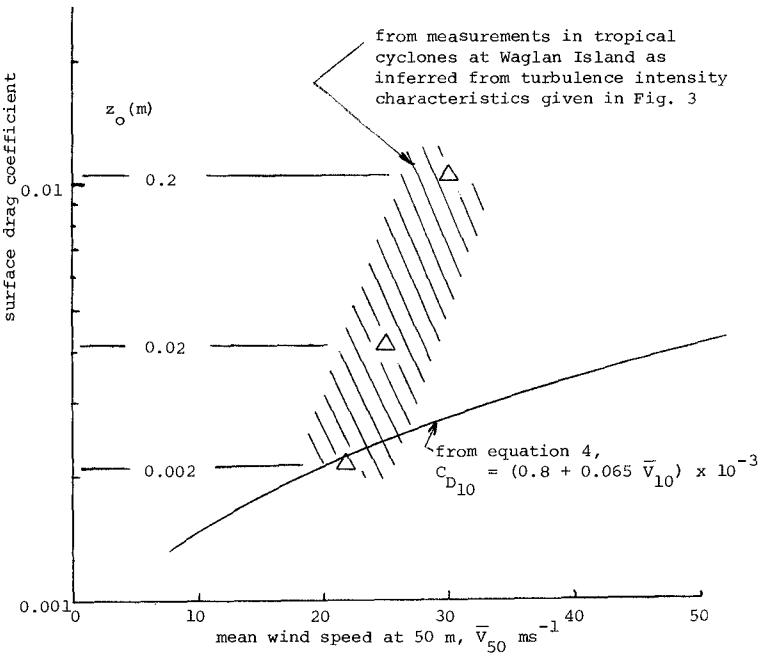

FIG. 4 Surface drag coefficients from Waglan Island tropical cyclone data and the reviews of Garratt (1977) and Wu (1980, 1983).

Further support for this observation is given by Choi (1978) who reported on the mean wind and turbulence characteristics of tropical cyclones in the lower 70 metres of the atmosphere. His work was based on anemometer measurements taken on a tower at Cape D'Aguilar, on a low lying headland stretching out from the southern tip of Hong Kong Island, close to Waglan Island, and with a similar exposure to the Pacific Ocean from where the typhoons approach. Choi fitted log law profiles to data from several tropical cyclones and the values of u_* and z_o are given in Table 4, along with typical values from a monsoon.

TABLE 4

PARAMETERS OF LOG-LINEAR PROFILE OF MEAN WIND SPEEDS IN TROPICAL CYCLONES, AFTER CHOI (1978)

Typhoon	$\bar{V}_{10}$ (ms^{-1})	u_* (ms^{-1})	z_o (m)
Freda	15.0	2.69	0.91
Freda	11.9	3.68	2.30
Rose	13.3	3.71	2.00
Rose	17.7	3.85	1.43
Rose	20.6	4.90	1.64
Dot	15.6	1.90	0.34
Dot	18.6	1.79	0.15
Dina	11.5	2.44	1.25
Monsoon	7.0	0.3	0.05

It can be seen, in comparison with monsoon winds, that u_* is an order of magnitude higher during tropical cyclones, even though wind speeds are only doubled. In the full scale situations the values of z_o reported cannot be taken too seriously because of the difficulty of establishing a zero plane for the site, however the values of u_* can be accurately estimated.

Obviously there are some aspects of the representation of the boundary layer over land and the boundary layer over the sea which do not apply in tropical cyclone or possibly other extreme wind conditions. Whether this is due to the convective conditions found in tropical cyclones, to the shorter wave length in the short fetch wave development, to a model which is simply not applicable to fully aroused sea states, or some other cause must await future investigation.

5 CONCLUSIONS

A study of wind data collected from the Waglan Island anemometer (Hong Kong) during 39 tropical cyclones indicates that turbulence intensity values in excess of 20% at a reference height of 50 m are likely during extreme wind conditions in a tropical cyclone. The implied surface drag coefficient of approximately 0.01 in these extreme wind conditions is consistent with flow over a land surface roughness of trees and suburban housing, but is much higher (by a factor of five) than that predicted by the currently accepted formulae from the reviews of Garratt and Wu for wind flow over a fully developed sea in neutral atmospheric conditions.

Whether these conditions of apparently greater effective surface roughness in tropical cyclones are due to convective conditions, the shorter wave length in the short fetch wave development or some deficiency in the wind model (when applied to wind flows in a tropical cyclone) is yet to be discovered. In the meantime it is concluded, for wind loading design calculations in extreme wind in tropical cyclone conditions, that the mean wind speed and turbulence intensity profiles should be taken as for a surface drag coefficient of 0.01, i.e. for a value of roughness length z_o = 0.20 m in the Deaves and Harris wind model.

APPENDIX 1

Main equations from the Deaves and Harris (1978) Mathematical Model of the Structure of Strong Winds.

(1) Mean wind speed profile.

$$\bar{V}_z = \frac{u_*}{0.4}\left\{\ell n\left(\frac{z}{z_o}\right)+5.75\left(\frac{z}{z_g}\right)- 1.88\left(\frac{z}{z_g}\right)^2-1.33\left(\frac{z}{z_g}\right)^3+0.25\left(\frac{z}{z_g}\right)^4\right\} \quad \text{A1-1}$$

where z is height above ground level

z_o is the roughness length

u_* is the friction velocity, obtained from

$$\frac{V_g}{u_*} = \frac{1}{0.4}\left\{\ell n\frac{u_*}{z_o x 10^{-4}} + 1\right\} \quad \text{A1-2}$$

z_g is the gradient height, obtained from

$$z_g = \frac{u_*}{6x10^{-4}} \quad \text{A1-3}$$

V_z is the mean wind speed at height z (nominally hourly mean)

$\bar{V}_g$ is the mean gradient wind speed

(2) Turbulence intensity profile,

$$\frac{\sigma_{V_z}}{\bar{V}_z} = \frac{u_*}{\bar{V}_z}\, 2.63\eta\left\{0.538 + 0.09\ell n\left(\frac{z}{z_o}\right)\right\}^{\eta^{16}} \quad \text{A1-4}$$

where $\eta = 1-\left(\frac{z}{z_g}\right)$ A1-5

σ_{V_z} is the standard deviation of wind speed at height z

(3) Gust wind speed,

The 3 second maximum gust wind speed (which is defined as the maximum wind speed average over 3 seconds occurring in one hour) can, for a Dines anemometer, be expressed as

$$\hat{V} = \bar{V}\left\{1 + 3.7\left(\frac{\sigma_V}{\bar{V}}\right)\right\} \quad \text{A1-6}$$

A COMPUTER MODEL FOR THE REFRACTION OF NON-LINEAR WAVES

by

J B Crowley[1], C A Fleming[2] and C K Cooper[2]

ABSTRACT

A non-linear wave refraction model was developed which allows for the combined refraction and shoaling of Vocoidal waves over an arbitrary sea bed. The effects of bed friction and percolation are also catered for. The method is based on the cirular arc technique which is widely used for linear wave refraction. The method was extensively tested against Vocoidal wave refraction results obtained previously for a plane beach. A comparison of Vocoidal and linear wave refraction over an arbitrary sea bed indicated that Vocoidal waves refract less than linear theory, thereby yielding higher wave heights and angles of incidence at the breaker line. This result is in line with results of non-linear refraction over parallel bed contours quoted for other non-linear wave theories in literature. Further work is required before caustics can be adequately treated. Future research should include wave spectrum transfer and the re-evaluation of empirical relationships in use in the shallow water region and which will use this new higher-order refraction technique.

1. INTRODUCTION

The transformation of waves in shoaling water involves a change in wave height, length and velocity with depth. Wave refraction theory has been developed from solutions for light wave optics and its application is usually confined to the use of linear wave theory.

Wave ray methods are well suited to modelling of short waves. They solve the initial value problem so that there are few difficulties that can be encountered with boundary conditions as occurs with other methods. However, a number

---

1) National Research Institute for Oceanology, CSIR, Stellenbosch, RSA

2) Sir William Halcrow and Partners, Swindon, UK

of deficiencies have been identified. These are associated with the representation of topography, methods of computation and interprestation of wave refraction coefficients and the validity of using linear wave theory right up to the breaker line.

A number of theoretical investigations into wave refraction results with non-linear wave theories have been carried out. These have mostly been confined to the simplest cases of parallel contoured slopes, the only exception being a model developed in France for the refraction of third order Stokes waves over arbitrary contours (Gaillard, personal communication, 1982). Nevertheless, they have shown that the results obtained from non-linear theories can be significantly different to the linear counterparts.

One of the reasons in the past that non-linear wave refraction has not been rigorously persued for the case of arbitrary topography would seem to be the lack of non-linear wave theory that would allow wave speeds to be calculated with reasonable ease and economy. The Vocoidal wave theory combined with a circular arc solution provides an excellent basis for a fast and accurate numerical model.

2. MOTIVATION FOR USING VOCOIDAL THEORY

Depth refraction using first order cnoidal wave theory has been investigated for the simple case of straight parallel bottom contours (Skovgaard and Petersen, 1977). It was shown that the cnoidal wave would theoretically break at a greater water depth than linear waves due to greater amplification. Also the cnoidal wave orthogonal was found theoretically to refract less than the linear wave.

In fact it was concluded in all previous shoaling and refraction studies that linear wave theory progressively underpredicts both wave height and angle of incidence to a greater extent as the wave shoals towards the breaker line (see for example Sakai and Battjes (1980); Chaplin (1980); Skovgaard and Petersen (1977); Skovgaard et al. (1976); Dean (1973)). This is of fundamental importance to coastal engineers involved in nearshore modelling particularly in the surf zone where theory dictates a strong sensitivity to breaking wave conditions, particularly the angle of attack.

Figure 1 gives an example comparison between refraction for Vocoidal and linear wave theories over a plane beach with parallel contours. The same tendency as for the other well-known higher-order theories, such as Dean's stream function, cnoidal and Cokelet's theories is observed, with this exception that the wave height does not increase as sharply close to the breaker line as predicted by, for example, Cokelet.

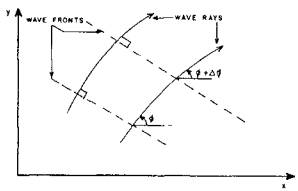
Although the non-linear refraction results referred to above differ from those for linear wave refraction, it still remains to ascertain whether this difference is significant or not. Swart and Loubser (1979) made a comprehensive comparison of measured wave properties with predictions from 13 different theories. The results indicate that although linear theory provides an adequate description of wave profile, wave celerity and orbital motions in deep water, the comparison deteriorates as the relative water depth becomes less (see for example Figure 2). This is also apparent in the mean error in the prediction of wave length:

F_C range	Mean error in λ/d	
	Airy theory	Vocoidal theory
0 - 50	0,012	0,021
50 - 100	0,030	0,041
100 - 200	0,006	0,028
200 - 500	-0,041	0,010
500 - 1 000	-0,069	-0,018
1 000 - 60 000	-0,093	-0,017

Since refraction depends heavily on the wave celerity (or wave length) this result is significant for the application of linear theory in wave refraction where results are required near or at the breaker line.

Swart and Loubser (1979) finally concluded that Vocoidal theory is the only readily-applicable analytical wave theory with a good correspondence to measured data and a good adherence to the original wave boundary value problem in the whole range of non-breaking waves. This theory therefore not only provides a good correspondence to data but also a sound framework for the derivation of expressions for the prediction of secondary wave-induced phenomena, and as such also of refraction.

3. LINEAR WAVE REFRACTION



WAVE REFRACTION DIAGRAM

Wave refraction as a water-wave phenomenon has been realised for a long time. Early solutions used graphical techniques assisted with a template (Wiegel, 1963) and this still provides a useful means of obtaining a rapid overview for cases with simple topography. With the advent of the computer finite difference solutions were developed which used predictor-corrector techniques. A number of different schemes for representation of the bottom topography were proposed and included linear and quadratic surface fitting schemes. Topographic smoothing may also be recommended largely to reduce the number of caustics that may arise from small, but severe bottom irregularities. An interesting study was carried out by Poole (1975) who investigated a number of different interpolation functions for representation of sea bed topography. He found that for the cases tested there were broad similarities in the refraction patterns, but significant local variations occurred.

Abernethy and Gilbert (1975) investigated the anomalies than can arise when constructing conventional refraction diagrams, that is, a selected number of rays refracted from the offshore boundary towards the shoreline. They presented examples for which the method can result in large variations in refraction coefficients, depending on the density of rays used in the calculation. They concluded that there can be an inherent bias towards high wave heights, an excessive sensitivity to frequency, offshore direction and position which is greatest in region where refraction coefficients are large.

The curvature of a wave ray in still water expressed in cartesian coordinates is

$$\frac{d\theta}{ds} = -\frac{1}{c}\left(\frac{\partial c}{\partial x}\sin\theta - \frac{\partial c}{\partial y}\cos\theta\right) \qquad \ldots \quad (1)$$

where x and y are the coordinates, s the distance along the orthogonal and θ the angle between the orthogonal and the x-axis. This type of relationship or its equivalent can be solved most conveniently and accurately by using the 'circular arc' technique developed at the Hydraulics Research Station, Wallingford. Briefly the mehtod is based on the fact that, given linear variation of wave speed across a small triangular element, the ray path is described by a circular arc whose centre lies on the line of zero celerity and is tangential to corresponding arcs in adjacent elements. This provides a fast numerical solution which is not restricted to the use of linear wave theory.

The wave refraction coefficient reflects the change in wave height of a wave train purely due to convergence or divergence of the wave orthogonals. Over complex topography the ray separation factor may be evaluated from the

well-known expressions derived by Munk and Arthur (1952) whence:

$$\frac{d^2\beta}{ds^2} + p(s)\frac{d\beta}{ds} + q(s)\beta = 0 \quad \ldots (2)$$

where $$p(s) = -\frac{1}{c}\left(\frac{\partial c}{\partial x}\cos\theta + \frac{\partial c}{\partial y}\sin\theta\right) \quad \ldots (3)$$

$$q(s) = \frac{1}{c}\left(\frac{\partial^2 c}{\partial x^2}\sin^2\theta - \frac{\partial^2 c}{\partial x\,\partial y}\sin 2\theta + \frac{\partial^2 c}{\partial y^2}\cos^2\theta\right) \quad (4)$$

In the above β is the ray separation factor which is related to the wave refraction coefficient K_r by the square root of its inverse, that is,

$$K_r = \beta^{-0,5}.$$

Some of the deficiencies in forward tracking methods discussed above may be overcome by back tracking very closely spaced rays from a point of interest for a wide range of frequencies. This allows the computation of energy transfer from two-dimensional energy direction spectra and provides results that are usually consistent and stable. The two main disadvantages are that results can only be obtained for individual points of interest after quite a large computational effort and it is not possible to introduce wave decay due to bottom friction as the method relies on the independence of wave height in order to provide a complete family of results. The first problem may be overcome by applying statistical treatment to forward tracking results over discrete areas (Bouws and Battjes, 1982). The second requires the introduction of wave height into the calculation and is only really sensible for forward tracking methods (Skovgaard et al., 1976) until such time that bivariate distributions of wave height and frequency can be reasonably well-defined.

The following sections will show how the circular arc technique has been extensively extended to deal with wave refraction of non-linear waves using Vocoidal wave theory. It is shown that there can indeed be significant differences in comparative results, particularly when the sea bed topography is complex.

4. VOCOIDAL WAVE REFRACTION

The principle adopted was to use an existing refraction model using the circular arc technique and to adapt it in such a way as to cater for non-linear vocoidal waves. The specific model used is based on the Wallingford refraction program (Abernethy and Gilbert, 1975) and has the

capability of containing more than one grid up to a maximum of ten with a grid spacing that need not be the same for all grids. Each grid can contain up to 5 000 grid points. A more comprehensive review of the techniques used will be included in Swart and Crowley (1983b).

As stated previously, the application of the circular arc technique is not restricted to the linear wave theory, provided that wave celerities are available at the corner points of the grid element under consideration. This poses the first problem in the application of the circular arc method to predict refraction for higher-order waves, namely, **the celerity of higher-order waves is a function of the wave height, which is not known until after the wave refraction has been done.**

Furthermore, since the celerity is a function of wave height, which is determined in turn by refraction, shoaling, friction and percolation, it is not possible to separate the effects of these four processes as is customary for linear waves. In fact, the wave height change due to each of these processes in turn depends on the resultant of the others. A technique will therefore have to be found to solve for the wave height along the ray in an analogous way as was done for linear theory by using the ray separation equation (2) and which also includes the effect of percolation and bed friction.

This dependence of wave propagation on the wave height will make it difficult to deal with wave rays near caustics. Ways and means of overcoming this problem for the case of very irregular topographies should be investigated.

These three aspects will be discussed below. For the present only forward tracking is considered.

Wave celerity at grid points

Swart (1981) tabulated values of various wave properties in terms of H/d and $T\sqrt{g/d}$. From this tabulation one can observe the following typical variation in $c^2/(gd)$:

$T\sqrt{g/d}$	Values of $c^2/(gd)$					
	H/d=0,01	0,1	0,45	0,5	0,55	1,0
5	0,553	0,554	0,590	0,593	0,596	-
10	0,872	0,878	1,015	1,040	1,065	-
15	0,942	0,950	1,103	1,133	1,168	1,677
20	0,968	0,976	1,131	1,162	1,211	1,789
30	0,986	0,995	1,148	1,179	1,245	1,884
40	0,992	1,002	1,151	1,190	1,261	1,923

It is apparent that the value of c^2/gd is indeed strongly dependent on wave height.

An indication of the error introduced in $c/\sqrt{gd}$ as a result of using a wrong value of H/d, can be obtained by looking at the tabulated values for H/d = 0,45; 0,5 and 0,55.

$T\sqrt{g/d}$	5	10	15	20	30	40
[1] $E_{10\%}$ in %	0,25	1,20	1,43	1,71	2,04	2,30

$E_{10\%}$ is the error in $c/\sqrt{gd}$ for a 10 per cent deviation from the assumed mean value for H/d of 0,5.

It can thus be seen that the error in $c/\sqrt{gd}$ increases to about 20 per cent of the error in H/d for very high values of $T\sqrt{g/d}$. Since there is some correlation between the wave period and the wave height in the incident wave spectrum, one normally finds that the value of the parameter $T\sqrt{g/d}$ at wave breaking rarely exceeds 30. It can therefore be safely assumed that the error in $c/\sqrt{gd}$ will be restricted to 20 per cent of that in H/d.

On the other hand, if the celerities at H/d = 0,5 and 1,0 are compared with those at H/d = 0,01, it is found that the errors are appreciably more substantial.

$T\sqrt{g/d}$	5	10	15	20	30	40
[1] $E_{0,5}$ in %	3,43	8,43	8,88	8,73	8,55	8,70
[2] $H_{1,0}$ in %	-	-	25,05	26,44	27,66	28,18

1) $E_{0,5}$ is the relative difference in $c/\sqrt{gd}$ for H/d = 0,01 and 0,5, if the $c/\sqrt{gd}$ at H/d = 0,5 is assumed to be the correct value.

2) $E_{1,0}$ is the same as $E_{0,5}$ but with H/d = 1,0.

It is therefore quite clear that linear wave celerities, which are very close to those in Vocoidal theory for H/d = 0,01, should not be used for refraction of finite waves in shallow water.

The behaviour of Vocoidal wave celerity outlined above will form the basis of the discussion of a method for obtaining wave celerities at the corner points of grid elements.

Swart (1981) tabulated values of wave height H and angles of incidence θ for combined shoaling and refraction of Vocoidal waves on a plane beach with parallel depth contours, for deep water angles of incidence of 0°, 5°, 10°, 20°, 30°, 40°, 50° and 60°. The values of H/d and θ were tabulated for values of the ratio deepwater wave height H_o to water depth d between 0,01 and 1,30 and for values of the period parameter T_c ($= T\sqrt{g/d}$) between 1 and 60.

Results were obtained by simultaneously solving the energy flux equation, Snell's law and the Vocoidal wave length relationship.

The technique adopted for the computation of celerities at the corner points of the grid elements was based on these tabulated values of combined refraction and shoaling and consists of the following steps:

(i) It is assumed that the grid element is plane, that is, the contours across the element are parallel.

(ii) The entry conditions, that is, wave height, angle of incidence relative to grid element contours and water depth, at the point where the wave ray first enters the grid element, are used to refract the ray back to deepwater assuming contours parallel to those in the grid element. For this purpose the above-mentioned shoaling/refraction tables (Swart, 1981) were used to obtain curve-fitted equations for fictitious deepwater wave conditions, H_o and θ_o, which would have existed if the offshore bed topography had indeed consisted of a plane bed with contours parallel to those in the grid element under consideration.

(iii) These deepwater conditions are then used in the same curve-fitted equations to in turn obtain wave heights at the corner points of the grid element under consideration, again by assuming a plane bed seawards of the element. It should be emphasized that the wave heights computed in this manner do not form part of the output of the refraction computation, but are only used to obtain celerities at the corner points of the grid element which are in turn used as basis for the application of the circular arc method. A systematic comparison was made between values of wave height computed in this way and those obtained from the tables (Swart, 1981). It was concluded that the wave height is predicted to within acceptable limits. The extent of the difference between the tabulated (true) values of wave height and those computed in the manner described above depends on the variation in water depth over the grid element. Tests were done for

water depth variations of up to 100 per cent between the minimum and maximum depths in the element. Nevertheless, the difference in wave height was less than 10 per cent with a corresponding difference in predicted wave celerity which was always less than 2 per cent and mostly much less than 1 per cent. It will be shown later that this accuracy is sufficient to ensure an accuracy in the predicted wave heights and angles of incidence along the wave ray which are of the order of 0,1 per cent. The results also showed that the accuracy of predicted wave height can be significantly improved by reducing the grid size in the shallow water region, which can be easily done in the refraction program used.

(iv) The wave heights and celerities at the corner points of the grid element, computed in this manner, are then used to apply the circular arc method in exactly the same way as for linear wave theory.

(v) the accuracy of this procedure can be tested by comparing the angle of wave incidence along the wave ray for refraction over a plane beach against the tabulated results (Swart, 1981). An extensive comparison was made for a wide range of initial conditions and it was found that the true vocoidal angle of incidence at any relative water depth from deep water to the breaker line never differed from the computed angle by more than 0,01 degree. The method described is therefore considered to yield the correct result, even though the wave heights and celerities at the corner points of the grid elements did contain some inaccuracies.

Wave height along wave ray

The output of the circular arc method consists of the ray trajectory and thus also the ray orientation at the intersection points of the wave ray with the grid elements. The computations are continued until wave breaking occurs. The specific choice of the wave breaking criterion is left to the user of the program. Apart from the ray trajectory, however, wave heights are also required along the ray. In the linear wave theory the wave height along the ray is found by calculating the wave shoaling and refraction as well as the wave height reductions due to bed friction and percolation separately at each intersection point. The wave height H at that point is then simply the product of these four effects.

$$H = K_S K_r K_f K_p H_o \quad \text{(for linear theory)} \qquad \ldots \quad (5)$$

where K_s, K_r, K_f and K_p are coefficients of shoaling, refraction, friction and percolation relative to the starting point and H_o is the wave height at the starting point of the calculation.

This method does not hold for any higher-order theory, for the reasons given in the introduction to this section. Equation (2) which defines the ray separation factor β in linear wave theory, can however be used as the basis for the calculation of wave height by using the principle of energy flux conservation along the wave ray, namely,

$$\beta \, Enc = (Enc)_o \qquad \ldots (6)$$

where β is again the ray separation factor, E is the total wave energy per unit surface areas, c is the wave celerity and n is the ratio group velocity/wave celerity. Subscript "o" refers to the starting point of the wave ray. By putting $(Enc)_o = K_o$, where K_o is a parameter defined by the starting conditions, equation (6) can be rewritten as

$$\beta = K_o \zeta \qquad \ldots (7)$$

where $\zeta = (Enc)^{-1}$ $\qquad \ldots (8)$

Combination of equations (2) and (7) yields

$$K_o \frac{d^2\zeta}{ds^2} + p(s) \, K_o \frac{d\zeta}{ds} + q(s) \, K_o \, \zeta = 0$$

or

$$\frac{d^2\zeta}{ds^2} + p(s) \frac{d\zeta}{ds} + q(s) \, \zeta = 0 \qquad \ldots (9)$$

This equation can be solved numerically along the wave ray using Vocoidal wave properties in the same way as equation (2) was solved for linear wave theory. Values of wave height H along the ray are then found from equation (8) by using the Newton-Raphson iteration technique. This approach is necessary since E, n and c are all functions of wave height H (see Swart, 1978).

An extensive comparison was made between wave heights obtained in this way for refraction of a plane underwater topography and those tabulated by Swart (1981). In this comparison it was assumed that the effect of bed friction and percolation can be neglected. It was found that the difference between these two quantities was never more than 0,1 per cent of the "true" wave height, as interpolated from the tables. However, at least part of this already negligible difference can be attributed to rounding off

errors in interpolating from the tables. It is therefore considered that the method described herein for the computation of a total wave height along the wave ray yields reliable results of comparable accuracy to those obtained for linear wave refraction by using the ray separation technique.

Effect of dissipative forces

The effect of bed friction and percolation can be included in the technique described above by realising that the effect on wave height of these two phenomena can be assumed to be

$$H_{fp}/H_o = e^{-(\alpha_f+\alpha_p)t} \quad \ldots (10)$$

(Swart and Crowley, 1983a)

where H_{fp}/H_o is the additional wave height reduction due to bed friction and percolation, t is the time travelled by the wave and the parameters α_f and α_p are coefficients of friction and percolation respectively. These latter two parameters can be expressed in terms of vocoidal wave parameters. The effect of these two dissipative processes on the refraction is included by reducing the wave heights at the corner points of each grid element and the wave height along the ray trajectory in accordance with equation (10) before equation (8) is used with Newton-Raphson to solve for the wave height H. Since no test runs have as yet been done to test this part of the program, it will not be discussed further at the present.

5. DISCUSSION

The Vocoidal refraction program VOCREF developed along the lines outlined in Section 4 is at present being tested extensively for a number of prototype applications in parallel with a version of the program which used linear wave theory (LINREF). After completion of this sensitivity analysis and production testing it is intended to use this method (VOCREF) for routine analysis instead of LINREF. A number of interesting results have been obtained to date.

Since wave propagation is so strongly dependent on wave height in the case of non-linear waves and because of the fact that non-linear waves are not really defined for wave heights in excess of the cirtical breaker height, problems are encountered at or near caustics. Two ways of dealing with this problem have been investigated. By smoothing the bed in a linear manner in both directions along grid lines a sea bed topography is obtained which although smoother still exhibits the same overall tendencies as before smoothing. This process of two-way linear smoothing can be

repeatedly applied. With each application the contours are smoothed even more. Obviously there should be some optimal number of smooths beyond which the effect of the irregular topography becomes mushed. Kluger (CSIR, 1979) concluded that about eight smooths would be optimal in the case of very irregular topography for linear wave refraction although this would seem to be very high. See for example Figure 3 for the effect of three degrees of smoothing as compared to the unsmoothed case. Smoothing tends to reduce the number of caustics and allows for wave propagation across areas of possible caustic action. Figure 4 shows the results of refraction with various degrees of smoothing. The refraction diagrams are very similar except for the fact that a caustic at the right of the plot for the unsmoothed case is eliminated for three and eight smooths of the bed. The reason for the wave ray terminating at a caustic is that for higher-order theory it is not possible to calculate wave heights at the corner points of the grid elements in areas where the wave height would be higher than the critical breaker height.

At present the effect is being investigated of artificially putting the wave height equal to the critical breaker height in the vicinity of a caustic for as long as the wave height as obtained from the method given in Section 4 is higher than the critical height. In this manner the non-linear wave rays can be allowed to propagate through the region of the caustic.

It has proven useful to include in the standard output of the program a series of four plots containing the breaker line values of breaker depth, breaking wave height, angle of incidence at the breaker line relative to the local bed contours and the longshore energy flux factor $(0{,}5e_t H^2 nc \sin 2\theta$, where e_t is the total energy coefficient) (see Figure 5). Such plots clearly outline shore areas where caustic activity play a role. Overall tendencies in breaker line characteristics are also visible at a glance. At present the possibility is investigated of using the Monte Carlo technique as described by Bouws and Battjes to render the breaker line data even more useful. The effect of more smooths on the breaker line characteristics is to smooth out the variability and to enhance the clarity of the tendencies in these characteristics.

It appears that about three smooths of the contours would be optimal in defining all parameters sufficiently.

At a first glance the refraction diagrams produced by LINREF and VOCREF are very similar (see Figure 6). However, a comparison of breaker line characteristics shows up the differences remarkably (compare Figures 5 and 7; note that the scales in these figures are not all the same). In general the breaking wave height and the angle of incidence

relative to the local contours at the breaker line are higher for VOCREF than for LINREF. Correspondingly the longshore energy flux factor is also appreciably higher for the non-linear case. This has important consequences for sediment transport prediction and in fact for all design work in and near the breaker zone. The area affected by caustics is shifted laterally (alongshore) by going from linear to non-linear refraction, which is again of importance in interpreting refraction diagrams for design purposes.

Although comparisons between results of linear and vocoidal refraction over arbitrary contours is still in the early stages, it is already abundantly clear that it will be essential to preferentially use the non-linear refraction program VOCREF. However, it is quite clear that before the use of non-linear refraction programs such as the one described here can become standard practice a substantial re-evaluation of presently used empirical techniques will have to be carried out. While this is being done the present model should be extended to also include wave spectrum transfer. To allow this the problem of defining three-dimensional spectra or some relationship between the wave height distribution and frequency should be tackled.

6. SUMMARY AND CONCLUSIONS

The main conclusions of this study can be summarised as follows:

(i) A computer program was developed which allows for the computation of the combined shoaling and refraction of non-linear Vocoidal waves over an arbitrary sea-bed topography and which includes the dissipative effect of bed friction and percolation. The basis of the derivation is the circular arc method which is extensively used in linear wave refraction.

(ii) The computer program was verified by comparing its output for the case of combined refraction and shoaling over a plane bed with parallel bed contours with known results for this case.

(iii) Comparison of results obtained from the Vocoidal refraction model and its linear theory counterpart for the case of irregular topography indicates, in line with previous findings quoted in literature for non-linear wave refraction on a plane slope, that Vocoidal waves refract less than linear waves. Consequently the breaker-zone wave characteristics, that is, wave height and angle of incidence, are higher for Vocoidal than for linear refraction.

(iv) The influence area of caustics is shifted alongshore when Vocoidal refraction is done instead of linear refraction.

(v) Future reseach should be aimed first, at finding a workable solution for the problem of caustics (such as, for example, the Mote Carlo approach of Bouws and Battjes, 1982) and second, at the extension of the technique to include wave spectrum transfer.

(vi) In parallel to the research indicated under (v) all presently used empirical techniques for processes within the shallow-water area, such as longshore current prediction, should be re-evaluated to assess the effect of non-linearity of the waves on the values of the emprirical parameters.

WAVE AND CURRENT INTERACTION IN THE NEAR BED REGION.

Patrick H. Kemp and Richard R. Simons.

ABSTRACT.

The question of how waves and currents interact, especially in the near-bed region is of considerable importance in relation to sediment suspension and sediment transport. Whereas empirical relationships provide useful estimates and indications in relation to the data on which they are based, a more thorough understanding of the physical processes at work is necessary for interpreting sediment transport behaviour in a more generalized way. Clearly the conditions under which flow reversal occurs near the bed, and also the extent to which wave motion may modify the current induced turbulence in the boundary layer, are both of great interest, and these and other aspects have been included in the present study.

The research program was designed to look initially at the interaction between waves and currents in the absence of sediment, in order to define the mean velocity components, the structure of the turbulence, and the shear stresses. The study proceeded from experiments on waves alone, to waves propagating with the current and against the current. In all three cases the tests were carried out in the first instance with a smooth bed and subsequently with a rough bed consisting of two dimensional triangular slats. One of the main areas of interest was the height to which the water was disturbed above the bed when acted on by waves alone, and the comparable situation when a current was superimposed on the waves. Since the characteristics of the turbulent current were measured independently, it was possible to deduce whether there had been any interaction between the waves and the current, and also to infer what might happen to the distribution of the sediment which it was assumed would be put into suspension in the two cases. In the second stage of the research separate experiments were carried out in a standing wave channel and an oscillating water tunnel, using lightweight bed materials, in order to observe whether the inferences made from the clear water study were borne out by comparable changes in the distribution of the sediment in suspension.

Authors: Patrick H. Kemp, Reader in Fluid Mechanics, University College London, and Richard R. Simons, Research Engineer, University College London.

The results show that the sediment reflected the fluid motion characteristics, the sediment remaining in a band close to the bed under the action of waves alone, but rapidly dispersing when a turbulent current was introduced.

INTRODUCTION.

Comparatively little previous work has been carried out on the interaction between waves and currents, particularly near the bed. Grant & Madsen (1979) produced a theoretical analysis of combined wave and current flow over a rough boundary, predicting an increase in apparent bed roughness and shear stress when waves are superimposed on the current. A similar theory has been presented by Christoffersen (1980). Bakker & van Doorn (1978) also found an increased apparent bed roughness. George & Sleath (1979) described the cycle of vortex formation and ejection around spherical roughness elements in the presence of a weak current. The stronger downstream vortex was found to induce a weak reverse mean current just above the roughness elements.This is consistent with the observations of Inman & Bowen (1963) and Bijker, Hijum & Vellinger (1976), who both reported enhanced upstream sediment transport when a weak current was superimposed on waves. The present authors have carried out an extensive investigation on the subject of wave and current interaction, and a report of the main results may be found in Kemp & Simons (1982) and Kemp & Simons (1983). Since little information was available prior to these latter publications on the detailed flow structure under these condition, any inference between the flow characteristics and sediment in suspension has been tentative. Tunstall & Inman (1975) observed that in the case of waves alone, there was a limited thickness of the wave-induced vortex layer over a rippled bed, suggesting that sediment would be concentrated in this near bed layer. Bijker (1980), using first order wave theory and the assumption of a logarithmic profile, has formulated an expression for sediment concentration under waves and currents. The expression however contains a coefficient which is dependent on the wave motion and the bed roughness.

APPARATUS, INSTRUMENTATION AND ANALYSIS.

The investigation, and the apparatus used for the study of waves and currents in the absence of sediment, are described in the paper by Kemp & Simons (1982). This part of the work was carried out in a channel 14.5m long, 457mm wide and 690mm deep, with provision for flow in either direction and wave generation by a bottom-hinged paddle at one end. Two bed conditions were used in these tests. The first consisted of a smooth metal surface coated with gloss paint, and the second consisted of 5mm high triangular wooden strips stuck across the channel width and spaced at 18mm centres along the line of flow. The latter was chosen so as to generate a rough turbulent boundary layer both with the unidirectional current, and also with the larger waves in the absence of a current. It was also of similar geometrical form

to that used by Jonsson & Carlsen (1976) in their tests in an oscillating water tunnel. The height and spacing of the roughness elements also came within the range of possible ratios of height to length found in natural sand ripples. Fluid velocities were measured using a laser-Doppler anemometer, and the analysis of turbulent and wave-induced velocities was carried out by an on-line PDP8E minicomputer. The computer was programmed to produce ensemble average velocities, Reynolds stresses and wave elevation data. The cycle was sampled at 200 separate phase positions with up to 250 observations at each position. Measurements were made at up to 30 points in the vertical.

Measurements of wave attenuation and reflection were included in the program. In the case of waves opposing the current the current had to be introduced at the beach end of the channel. In order to avoid jetting and turbulence due to the presence of the beach, a wave absorbing device consisting of a slightly sloping metal plate submerged a short distance below the still water level, proved very effective. The device is referred to in Kemp & Simons (1983).

Observations of the behaviour of various lightweight sediments under the action of standing waves, and planar oscillatory motion, were carried out in a rocking channel which produced standing waves of comparable period to that in the water tunnel, which had a natural period of 2.3 seconds. The water tunnel could produce oscillations of different amplitudes, and in addition a current could be imposed in one direction, of variable strength. The materials investigated included various grades of pumice, anthracite, plumstone and polystyrene, with median diameters in the range 500 to 1000 micron, and fall velocities from 22mm/s to 52 mm/s. The polystyrene, however, was the one material which fell outside these ranges, with a median diameter distribution lying between 400 and 600 micron, and with a fall velocity in the region of 5 mm/s. These values were considered in relation to the r.m.s values of turbulence measured in the clear water tests, where for the case of the current alone the r.m.s. values in the lower half of the boundary layer lay between 13 mm/s and 15 mm/s, and for waves and currents combined the comparable figures were 18mm/s to 25 mm/s. As a result of these tests the polystyrene particles were used in the study of sediment concentrations under waves and currents in the water tunnel.

Measurements of sediment concentration were achieved by aiming a low-power laser through the water tunnel onto a photodetector whose voltage output, related to the blockage caused by the sediment, was recorded by the on-line computer. The photosensor was mounted in a blackened tube and protected by band-pass optical filters to minimise the effects of extraneous light. It was necessary to use neutral density filters to control the initial power of the laser beam to avoid the saturation of the photodetector when no particles were present.

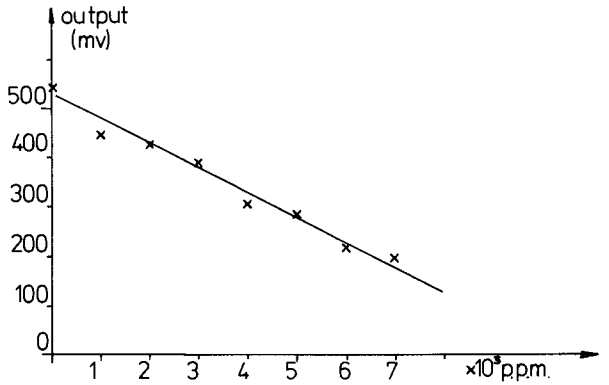

Fig. 1 Calibration curve for the laser sediment concentration meter using plumstone.

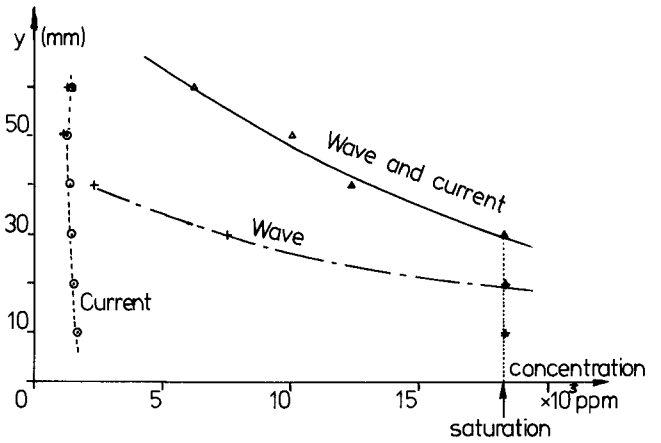

Fig. 2 Measurements of polystyrene concentration over a bed roughness apex, for combined wave and current, current alone and wave alone.

The system required calibration for the particular sediment in use, and this was done with the aid of a small perspex box of the same width as the water tunnel, placed between the laser and the photodetector. The box was filled with a mixture of glycerol and water, and a known volume of sediment added and shaken into suspension. The sediment was thus almost neutrally buoyant. For each concentration the box was oscillated across the beam, simulating the fluid motion anticipated in the tunnel, and the photodetector reading noted at regular intervals. The relationship between voltage and concentration was found to be closely linear for the plumstone (Figure 1), whereas for the polystyrene the curve was logarithmic. The glycerol mixture used maintained the sediment in suspension for long enough to give a reasonable sample length, while still allowing movement of the particles to produce an even distribution throughout the volume of the box.

RESULTS.

Waves and currents in the absence of sediment.

It was found that the unidirectional turbulent boundary layer is reduced in thickness by the superposition of waves propagating with the current over both rough and smooth beds. For all combined wave and current tests, flow reversal was experienced near the bed.

Waves propagating with the current over a rough boundary progressively reduce the mean velocities near the bed as the wave height is increased. For the smooth bed, however, waves with the current increase the velocity. Similar behaviour is experienced for waves on an opposing current.

In the outer flow the bed roughness effect becomes negligible. Here, for waves propagating with the current, mean velocities are reduced, whereas for the opposing current velocities are increased.

Figure 3 shows velocity profiles over a rough bed. The symbol WCR indicates waves and currents over a rough boundary. The mean centre-line velocity was 185mm/s. The wave heights in order were 22.7, 31.6, 40.4 and 46.6mm.

For the rough boundary tests the mean bed shear stress and roughness length scale were increased by the superposition of waves. Within two roughness heights of the rough bed the turbulence characteristics are dominated by the periodic formation of vortices. The overall increase in turbulence is limited to a region within six or seven roughness heights of the bed.

From these extensive initial tests and observations it was inferred that the combined stresses are likely to result in a considerable increase in sediment pick-up from a rippled bed.

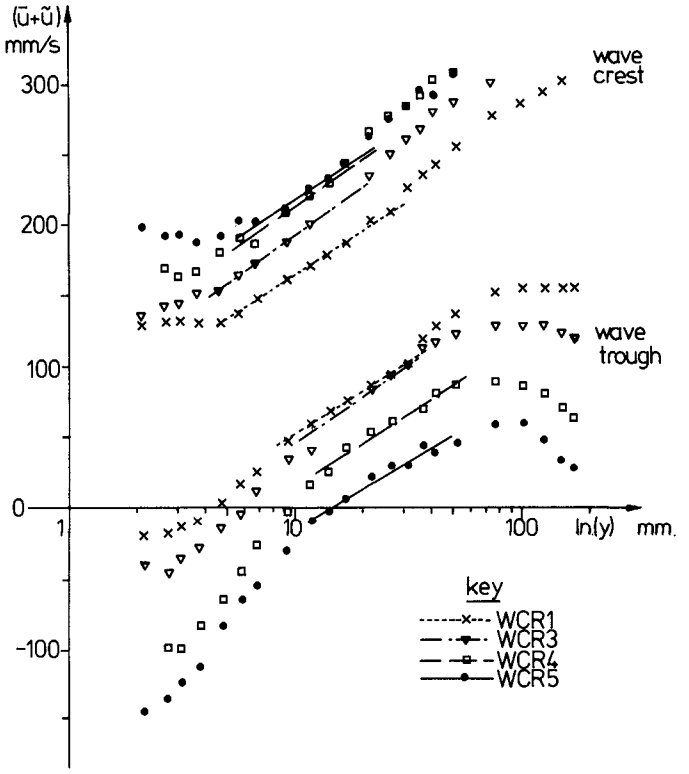

Fig. 3 Semi-logarithmic velocity profiles over a rough bed at phases corresponding to wave crest and wave trough; measured over the roughness apex.

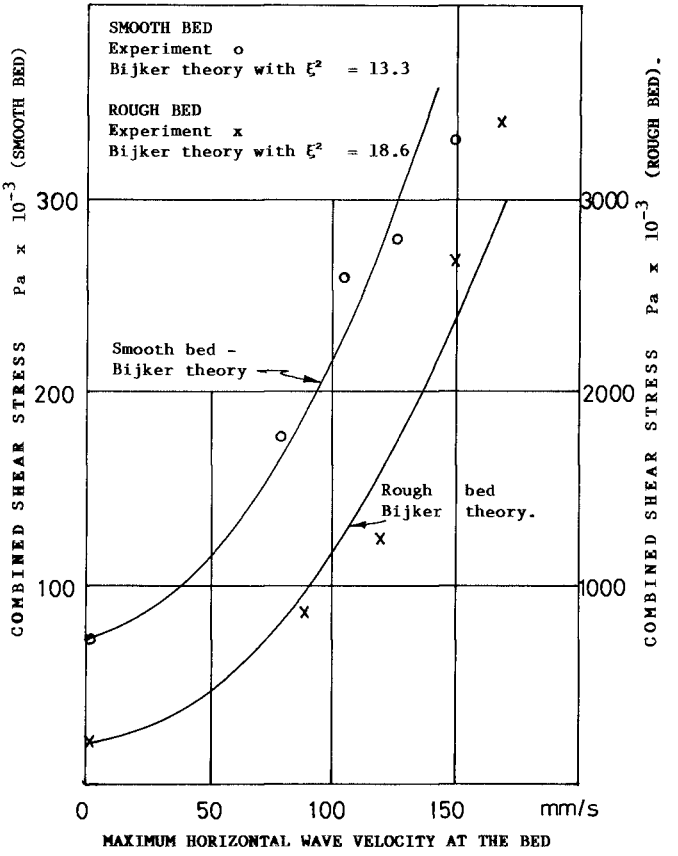

Fig. 4 Experimental values of combined wave & current shear stress, compared with the theory of Bijker (1980). See Appendix to this Paper.

Sediment response to the action of waves and currents.

Observations in both the standing wave rocking channel and in the small oscillating water tunnel showed that under the action of waves alone the sediment over the rough boundary, which consisted of triangular slats across the direction of motion, the sediment was put into suspension under the action of the vortices induced by the roughness elements. As predicted by the previous study in clear water reported above, the sediment layer was confined to a band only a few roughness heights in thickness. In the oscillating water tunnel the polystyrene particles under the action of the current alone produced only a very low concentration in the flow, and much of this consisted of the lighter particles which were maintained in suspension in the form of wash load. However, when this current was superimposed on the situation produced by the waves alone, the narrow band of vortex induced sediment in suspension rapidly expanded under the action of the turbulence. This is illustrated in Figure 2.

DISCUSSION AND CONCLUSIONS.

The main points arising from the clear water tests have already been set out under that heading above. However, from an experimental point of view and also in relation to the interpretation of the results and observations from other work in this area, the fact that the wave/current interaction reduces the boundary layer thickness both at the walls and the bed, means that the current is redistributed across the channel. All experiments of this nature should therefore take this into account.

So far as the sediment concentration is concerned when a current is superimposed on waves, it has been demonstrated that whereas the current alone might only produce slight movement of the bed particles, and the waves alone a dense concentration confined to a few roughness heights, the combination of the waves and currents produces a dramatic diffusion of the sediment layer.

Since the clear water tests provide data on shear stress under the action of waves and currents for both smooth and rough boundaries, it is of interest to substitute these in the expression proposed by Bijker (1980). This has been done in Figure 4 and the parameter ξ derived from these curves is shown on the diagram for the two cases.

APPENDIX. Comparison of experimental values of combined wave and current shear stress with the theory of Bijker (1980)

According to Bijker : $V_{*cw} = V_{*c}\{ 1 + \tfrac{1}{2}(\xi\tilde{u}_o/\overline{V})^2 \}^{\frac{1}{2}}$

which can be written : $\tau_{cw} = \tau_c \{ 1 + \tfrac{1}{2}\xi^2\tilde{u}_o^2 /\overline{V}^2 \}$

The experimental results of Kemp & Simons in the present Paper have been used to evaluate the shear stresses as follows:-

SMOOTH BED: $\tau_{cw} = \{\nu.\frac{d}{dy}(\overline{u} + \tilde{u}_{max})\}_{bed}$

ROUGH BED : $\tau_{cw} = \{\rho(\widetilde{u'v'})_{max} + \tilde{u}_{max}\tilde{v}_{max}\}$

where τ_{cw} = wave + current shear stress; τ_c = current alone shear stress; ξ = wave and bed roughness factor; $\tilde{u}_o$ = max. orbital velocity at the bed; $\overline{V}$ = mean current velocity; ν = kinematic viscosity; $\overline{u}$ = local mean current velocity; $\tilde{u}_{max}$ = local orbital velocity; $\tilde{u}'$ and $\tilde{v}'$ = horizontal & vertical turbulent velocities.

EFFECT OF WAVE-CURRENT INTERACTION ON THE WAVE PARAMETER

Yu-Cheng Li[1] and John B. Herbich[2]

1. ABSTRACT

The interaction of a gravity wave with a steady uniform current is described in this paper. Numerical calculations of the wave length change by different non-linear wave theories show that errors in the results computed by the linear wave theory are less than 10 percent within the range of $0.15 \leq d/L_S \leq 0.40$, $0.01 \leq H_S/L_S \leq 0.07$ and $-0.15 \leq U/C_S \leq 0.30$. Numerical calculations of wave height change employing different wave theories show that errors in the results obtained by the linear wave theory in comparison with the non-linear theories are greater when the opposing relative current and wave steepness become larger. However, within range of the following currents such errors will not be significant. These results were verified by model tests. Nomograms for the modification of wave length and wave height by the linear wave theory and Stokes' third order theory are presented for a wide range of d/L_S, H_S/L_S and U/C. These nomograms provide the design engineer with a practical guide for estimating wave lengths and heights affected by currents.

2. INTROOUCTION

With increasing human activities in both the coastal and immediate offshore region, the problem of wave-current interaction has been evaluated by a number of researchers. From an engineering practice point of view, the effect of wave current interaction on the wave parameters must be known. Previous research involved different assumptions and considerations. Several researchers employed the linear wave theory combined with the idea of conservation of energy flux (5,12,13), or combined with the idea of conservation of wave action flux (8,9); others employed the non-linear wave theory (6,15). The problem concerning the interaction of waves and currents in an inlet has also been studied (3,7). Additional research (11,18) describes the change of velocity distribution due to the interaction of waves with currents.

One purpose of this study was to evaluate the difference between the change in wave parameters when employing either the equation of conservation of wave energy flux or the equation of conservation of wave

[2]Professor and Head, Ocean Engineering Program, Texas A&M University, College Station, Texas 77843, U.S.A.

action flux. The results were evaluated with reference to practical engineering applications. Another purpose of this study was to determine the error in the calculated wave parameter by employing both the linear wave theory and non-linear wave theories (Stokes' third order wave theory was mainly considered). A two-dimensional case was considered and both the following and the opposing currents were analyzed.

3. THEORETICAL CONSIDERATIONS

Evaluation of change in the wave parameters may be obtained in two steps: a) evaluation of the change in wave length, and b) evaluation of the change in wave height. In both cases, the energy dissipation in wave propagation was neglected.

3.1 Change in Wave Length

The linear wave theory was considered first. The influence of non-linearity of waves is evaluated in the latter part of this section. The wave celerity in the current may be calculated as follows:

$$C_a = U + C_r \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

where

$$C_r = \sqrt{g/k_r \, \mathrm{Th}\, k_r d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (2)$$

Equation 1 can be rewritten as

$$\frac{L}{T_a} = U + \frac{L}{T_r} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (3)$$

From Equations 1, 2 and 3, the following equation can be obtained

$$\frac{L}{L_s} = \frac{C}{C_s} = \frac{1}{(1 - \frac{U}{C})^2} \frac{\mathrm{Th}\, k\, d}{\mathrm{Th}\, k_s d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (4)$$

and $L = L_a$, $C = C_a$.

In engineering applications, the value of $C = C_a$ is unknown, therefore, the ratio U/C is also unknown. Thus the following formula may be used

$$C_r/C_s = \sqrt{L/L_s \; \mathrm{Thkd}/\mathrm{Thk}_s d} = \frac{1}{1 - \frac{U}{C}} \frac{\mathrm{Thkd}}{\mathrm{Thk}_s d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (5)$$

Combining equations 6 and 7, the relationship between L/L_s with U/C_s and $k_s d$ can be obtained from

$$L/L_s = C/C_s = f(\frac{U}{C_s}, \frac{d}{L_s}) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (6)$$

and

$$\frac{U}{C_s} = \frac{U}{C}\frac{C}{C_s}$$

3.2 Change of Wave Height

The process of the interaction of progressive waves with a steady uniform current (the following or the opposing current only) may be evaluated as follows: (a) in the first step only currents and waves propagate separately, (b) in the second step the combined current and waves interact and finally a steady motion of wave-current combination propagates as shown in Figure 1. If we neglect the change in the current profile because of the wave-current interaction, the current energy flux will remain the same before and after the interaction process.

To-date, two concepts, i.e. the conservation of wave energy flux (12,13) and the conservation of wave action flux (1,8) were employed. However, since there is no major difference between the two methods, the principle of conservation of wave action flux was selected for the analysis.

The idea of conservation of wave action flux was first suggested by Garrett and evaluated by Bretherton and Garrett (1). Jonsson (8) described a practical application for the case of interaction of waves with a steady uniform current. In the present case (as shown in Fig. 1) the following equation may be used

$$\frac{d}{dx}\left\{\frac{E}{\omega_r} C_{ga}\right\} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (7)$$

Equation 7 indicates that the wave action flux before and after interaction must be the same, i.e.

$$\frac{E}{\omega_r} C_{ga} = \frac{E_s}{\omega_s} C_{gs} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (8)$$

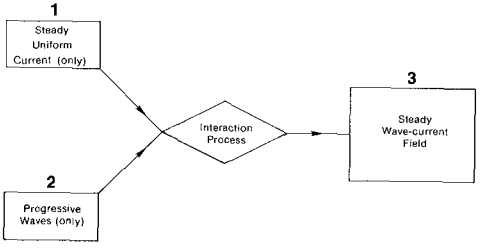

Fig. 1. Wave-current interaction

where

$$\omega_r = \omega_a - kU = \omega_s - kU \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

$$C_{gs} = \tfrac{1}{2} C_s A_s \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

$$C_{ga} = U + C_{gr} = U + \tfrac{1}{2} C_r A \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

$$C_{gr} = \tfrac{1}{2} C_r A \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

$$A = 1 + \frac{2kd}{\mathrm{Sh}2kd} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

$$A = 1 + \frac{2k_s d}{\mathrm{Sh}2k_s d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Thus Equation 8 can be rewritten as follows

$$\frac{E}{E_s} = \left(1 - \frac{U}{C}\right) \frac{L_s}{L} \frac{A_s}{A} \left(1 + \frac{U}{C} \frac{2-A}{A}\right)^{-1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

Accordingly, the wave height change can be determined by the following equations:

3.2.1 Linear wave theory

$$\frac{H}{H_s} = \left(1 - \frac{U}{C}\right)^{\frac{1}{2}} \left(\frac{L_s}{L}\right)^{\frac{1}{2}} \left(\frac{A_s}{A}\right)^{\frac{1}{2}} \left(1 + \frac{U}{C} \frac{2-A}{A}\right)^{-\frac{1}{2}} = R \quad \ldots\ldots\ldots\ldots (16)$$

When non-linear wave theory is employed, Equation 12 is no longer correct. Generally, the error in using this eouation instead of the correct one for non-linear waves will not be greater than 6 percent. Thus as a simplification for the non-linear wave analysis, Equations 12 and 15 may be used and will not produce a significant error. The results by Skjelbreia (14), Tsuchiya and Yasuda (17) were employed in calculating the wave energy.

3.2.2 Skjelbreia's Stokes' Third-Order Wave Theory (Old)

Wave energy E may be calculated by the following equation

$$E = \frac{\gamma H^2}{8} \left\{1 + \pi^2 \left(\frac{H}{L}\right)^2 \left[B + \frac{3}{(32)(256)} \pi^2 \left(\frac{H}{L}\right)^2 F\right]\right\} \quad \ldots\ldots\ldots\ldots (17)$$

where

$$B = \tfrac{1}{2} \left(\frac{1}{\mathrm{Th}\frac{2\pi d}{L}}\right)^2 \left(1 + \frac{3}{1+2\left(\mathrm{sh}\frac{2\pi d}{L}\right)^2}\right)^2 + \frac{9}{32} \frac{\mathrm{Ch}\frac{4\pi d}{L}}{\left(\mathrm{Sh}\frac{2\pi d}{L}\right)^6} \quad \ldots\ldots\ldots\ldots (18)$$

and

$$F = 3\left(\frac{1+8\left(Ch\frac{2\pi d}{L}\right)^6}{\left(Sh\frac{2\pi d}{L}\right)^6}\right) + \tfrac{1}{2}\frac{Th\frac{2\pi d}{L}\,Sh\frac{12\pi d}{L}\left(11-2Ch\frac{4\pi d}{L}\right)^2}{\left(Sh\frac{2\pi d}{L}\right)^{14}} \quad \ldots\ldots\ldots(19)$$

Accordingly, wave energy in still water, E_S, can be calculated similarly as

$$E_S = \frac{\gamma H_S^2}{8}\left\{1 + \pi^2\left(\frac{H_S}{L_S}\right)^2\left[B_S + \frac{3}{(32)(256)}\pi^2\left(\frac{H_S}{L_S}\right)^2 F_S\right]\right\} \quad \ldots\ldots\ldots(20)$$

where B_S and F_S may be obtained from a similar formula as B and F in Equations 18 and 19 (changing L to L_S only). The wave height change can then be calculated as follows

$$\frac{H}{H_S} = R\,\frac{\left\{1+\pi^2\left(\frac{H_S}{L_S}\right)^2\left[B_S + \frac{3}{(32)(256)}\pi^2\left(\frac{H_S}{L_S}\right)^2 F_S\right]\right\}^{\frac{1}{2}}}{\left\{1+\pi^2\left(\frac{H}{L}\right)^2\left[B + \frac{3}{(32)(256)}\pi^2\left(\frac{H}{L}\right)^2 F\right]\right\}^{\frac{1}{2}}} \quad \ldots\ldots\ldots(21)$$

where R is determined by Equation 16. This equation must be solved by iteration.

3.2.3 Tsuchiya's Stokes' Third-Order Wave Theory (New)

Energy flux, W, can be determined by the following equation

$$W = \frac{1}{8}\gamma H^2 C\left\{\tfrac{1}{2}A + \left(\frac{\pi H}{L}\right)^2 G\right\} \quad \ldots\ldots\ldots(22)$$

where A is defined by Equation 15, and G is

$$G = \frac{Ch^2 2kd + 3Ch2kd + 2}{16Sh^4 kd} + \frac{3}{4}Sh^2 kd + \frac{9(2kd + Sh2kd)}{64Sh^7 kdChkd}$$

$$+ \frac{3(Chkd + Ch3kd)}{8Sh^4 kdChkd} + \frac{kdThkd + Sh^2 kd}{2Sh^4 kd} \quad \ldots\ldots\ldots(23)$$

Since

$$W = \tfrac{1}{2}EC_r\left(1 + \frac{2kd}{1 + Sh^2 kd}\right) \quad \ldots\ldots\ldots(24)$$

Thus wave energy may be determined as follows

$$E = \frac{1}{8}\gamma H^2\left\{1 + 2\left(\frac{\pi H}{L}\right)^2\frac{G}{A}\right\} \quad \ldots\ldots\ldots(25)$$

and wave energy in still water E_S is

$$E_S = \frac{1}{8}\gamma H_S^2 \{1 + 2(\frac{\pi H_S}{L_S})^2 \frac{G_S}{A_S}\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

where G_S can be determined similarly as G from Equation 23, and the wave number k is changed to k_S in the case of still water. As a result, the wave height change can be calculated as follows

$$\frac{H}{H_S} = R \frac{\{1+2(\frac{\pi H_S}{L_S})^2 \frac{G_S}{A_S}\}^{\frac{1}{2}}}{\{1+2(\frac{\pi H}{L})^2 \frac{G}{A}\}^{\frac{1}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

where R is determined by Equation 16. Equation 28 must also be solved iteratively. When the non-linear wave theory is used, the wave celerity is determined not only by the parameter of kd, but also by the wave steepness H/L. Due to the interaction of wave and current, the wave steepness H/L can be changed, as the wave length determined by the non-linear wave theory L_N is not the same as that determined by the linear theory L, i.e., $L_N \neq L$. The value of L_N/L can be determined as follows

3.2.4 Employing Skjelbreia's Method

$$\text{Wave celerity } C_N = (\frac{g}{k}\text{Thkd})^{\frac{1}{2}} \{1 + (\frac{\pi H}{L})^2 \frac{14+4Ch^2 2kd}{16Sh^4 kd}\} \quad \ldots\ldots\ldots (28)$$

$$\text{and } L_N/L = 1 + \frac{1}{16}(\frac{\pi H}{L})^2 \frac{14+4Ch^2 2kd}{Sh^4 kd} = N_1 \quad \ldots\ldots\ldots\ldots (29)$$

where wave steepness H/L is the value under wave-current interaction.

$$\text{Thus, } L_N/L_S = \frac{L_N}{L} \cdot \frac{L}{L_S} = N_1 \frac{L}{L_S} \quad \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

3.2.5 Employing Tsuchiya's Method

$$\text{Wave celerity } C_N = (\frac{g}{k}\text{Thkd})^{\frac{1}{2}} \{1 + \frac{1}{16}(\frac{\pi H}{L})^2 \frac{1}{Sh^4 kd}(8Ch^4 kd - 4Ch^2 kd + 5)\}$$

$$= (\frac{g}{k}\text{Thkd})^{\frac{1}{2}} N_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

and

$$L_N/L = N_2 = \{1 + \frac{1}{16}(\frac{\pi H}{L})^2 \frac{1}{Sh^4 kd}(8Ch^4 kd - 4Ch^2 kd + 5)\} \quad \ldots\ldots\ldots (32)$$

Thus

$$L_N/L_S = \frac{L_N}{L} \cdot \frac{L}{L_S} = N_2 \frac{L}{L_S} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

Coefficients N_1 and N_2 show the influence of non-linearity of waves.

4. DATA ANALYSIS AND RESULTS

4.1 The Results of Modification of Wave Length by the Linear Wave Theory Due to Wave-Current Interaction

Using Equations 4, 5 and 6 different combinations of dimensionless parameters U/C (or U/C_S), and d/L_S may be calculated. The results are shown in Figures 2 and 3. As shown in Figure 2, it is clear that the wave length change L/L_S with the relative current U/C is greater in deep water than in shallow water.

4.2 Modification of Wave Length by Non-Linear Wave Theory and Error Estimates Due to Linear Theory

Numerical calculations of the wave length were made employing Stokes' third order wave theory (14,17). The ratio of wave length computed by the non-linear wave theory with that computed by the linear wave theory is given in Table I. It can be seen that the wave length calculated by the non-linear wave theory is usually greater than that calculated by the linear theory. Within the range of $0.15 \leq 0.40$, $0.01 \leq H_S/L_S \leq 0.07$ and $-0.15 \leq U/C_S \leq 0.30$, the wave lengths computed by the linear wave theory are approximately 10 percent less than those computed by Stokes' third-order wave theory. Table II shows a comparison of the results obtained by the linear wave theory with data obtained by the non-linear wave theories and with model test data. It appears that the results obtained employing different methods are quite similar. Also a comparison of the wave length (obtained by the linear wave theory) with Hales' and Herbich's model tests data (2) are given in Table III; the agreement is considered quite good.

4.3 Modification of Wave Height

The results obtained with the linear wave theory (Equation 17) are shown in Figure 4.

The results given by Skjelbreia's Stokes' third-order wave theory for different wave steepnesses (i.e. $H_S/L_S = 0.01 \sim 0.07$) (Equation 26) are shown in Figures 5-8.

The results shown by Tsuchiya's modification of Stokes' third-order wave theory are presented in Figures 9-12 for wave steepness $H_S/L_S = 0.01 \sim 0.07$.

A comparison of the results employing the linear theory (Figure 4) with that of Skjelbreia's method (Figures 5 through 8) is shown in Table IV. The following observations were made:

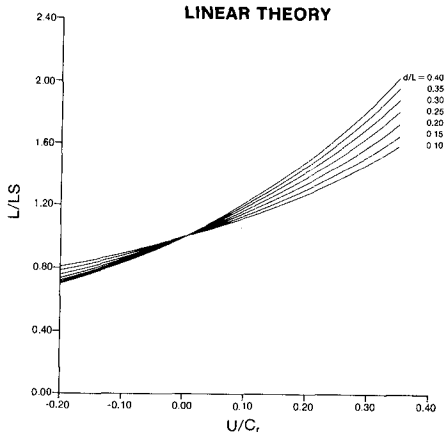

Fig. 2. Wave length change computed by linear wave theory (L/L_S versus U/C)

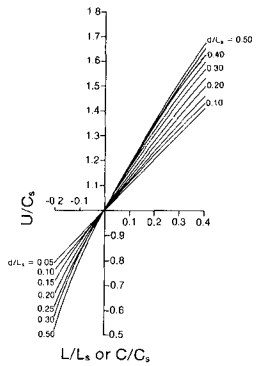

Fig. 3. The wave length change computed by linear wave theory (L/L_S versus U/C_S)

(1) In the following current, errors in wave height change by the linear wave theory are minimal in comparison with the results obtained by the non-linear wave theories.

(2) When there is an opposing relative current and the wave steepness is sufficiently large, errors in wave height employing the linear theory will be greater than errors obtained employing the non-linear theories.

(3) When the relative current velocity U/C increases, the change of wave height by Tsuchiya's theory differs from the above results. Using his method, under deep water conditions the wave height change H/H_s increases with the increase of U/C and reaches a peak value, after which the value of H/H_s decreases with the increase of U/C.

4.4 Comparison of Numerical Solution Experimentally Obtained Results

Table V shows a comparison of the results of the wave height change by computation (Equation 21) with the experimental data. It can be seen that the computed values agree reasonably well with experimental data. The mean error is less than 8 percent.

Table V. Comparison of Calculated Values With Authors' Test Data

d/L_s	H_s/L_s	U/C	Experimental Data	H/H_s Calculated Value
0.093	0.048	0.083	0.97	0.89

0.159	0.063	0.145	0.70	0.81

Table VI shows a comparison of the results of the wave height change by numerical calculation (Equation 21) with the results of Hales' and Herbich's empirical formula (2). Their formulas are as follows:

Wave height change due to the following current:

$$\frac{H}{H_s} = 0.90760 - 0.98801 \frac{U}{C_s} + 0.21123 \left(\frac{U}{C_s}\right)^2 + 0.00164 \frac{L_s}{d} + 0.00006 \left(\frac{L_s}{d}\right)^2$$

$$+ 0.88017 \frac{H_s}{L_s} + 1.05971 \left(\frac{H_s}{L_s}\right)^2 - 0.00312 \frac{U}{C_s} \left(\frac{L_s}{d}\right) + 0.88371 \frac{U}{C_s} \left(\frac{H_s}{L_s}\right)$$

$$+ 0.24931 \frac{H_s}{L_s} \left(\frac{L_s}{d}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

Table VI. Comparison of Calculated Values With Hales' and Herbich's (H&H)

$\frac{d}{L_s}$	$\frac{H_s}{L_s}$	U/C_s = 0.10		0.20		0.30	
		H&H	Cal.	H&H	Cal.	H&H	Cal.
0.20	0.01	0.841	0.865	0.748	0.781	0.659	0.745
	0.03	0.886	0.862	0.795	0.780	0.689	0.743
	0.05	0.932	0.859	0.843	0.780	0.726	0.741
	0.07	0.979	0.853	0.891	0.779	0.764	0.737
0.30	0.01	0.834	0.848	0.742	0.765	0.653	0.736
	0.03	0.871	0.847	0.780	0.764	0.687	0.735
	0.05	0.929	0.844	0.820	0.763	0.724	0.732
	0.07	0.976	0.840	0.860	0.760	0.762	0.727
0.40	0.01	0.832	0.845	0.738	0.765	0.650	0.763
	0.03	0.865	0.843	0.773	0.764	0.686	0.734
	0.05	0.898	0.842	0.808	0.762	0.723	0.731
	0.07	0.933	0.838	0.844	0.759	0.761	0.727

Since Hales' and Herbich's model test data were discrete during the opposing current, a comparison of numerical calculations with their empirical equations was not made. From Table V it can be seen that the wave height change H/H_S decreases with the increase of relative depth d/L_S both by the theoretical method and by Hales' and Herbich's formula. It appears that the wave steepness variable has a greater influence in Hales' and Herbich's empirical formula than in the theoretical equation. On the average, the difference in the results given by these two methods is within a range of 5 to 7 percent.

5. CONCLUSIONS

1. There is no dominant difference in the results obtained for the change of wave length due to the wave-current interaction by using either the linear or the non-linear wave theories. Within the range of $0.15 \leq d/L_S \leq 0.40$, $0.01 \leq H_S/L_S \leq 0.07$ and $-0.15 \leq U/C_S \leq 0.30$, errors by the linear wave theory are less than 10 percent as compared with the results obtained employing the non-linear wave theories.

2. Numerical calculations of wave height change by different wave theories indicate that the errors resulting from the use of the linear wave theory in comparison with errors resulting from the non-linear theories are greater when the opposing relative current

and wave steepness both become larger. However, within the range of the following currents such errors will be minimal.

3. The important factors influencing the change of wave parameter are relative current velocity U/C (or U/C_s), relative water depth d/L_s and wave steepness H_s/L_s. The relative current velocity U/C is the most important parameter. In case of the wave-current interaction, not only the wave parameter is changed but also the velocity distribution of steady flow with depth is changed. In this paper the change of steady surface velocity due to wave-current interaction is neglected. This should be considered in further research.

4. For engineering purposes, the nomogram provided in this paper may be used to estimate the change of wave parameter due to wave-current interaction. Figure 3 and Figures 5 through 8 are recommended for the calculation of wave length and wave height changes, respectively.

APPENDIX II - NOTATION

The following symbols are used in this paper:

C = wave celerity;
Ch = hyperbolic cosine;
d = water depth;
E = wave energy;

H = wave height;
K = wave number;
L = wave length;
Sh = hyperbolic sine;
Th = hyperbolic tangent;
T = wave period;
U = surface current velocity;
ω = angular frequency.

Subscripts:

a = apparent value by the observer;
g = group velocity;
r = relative value of wave to current;
s = value in still water.

RESONANCE IN SOUTH AFRICAN HARBOURS

by

W A M Botes,* K S Russell* and P Huizinga*

1. INTRODUCTION

The geographic situation of Southern Africa, and the associated climate of the South Atlantic Ocean, cause the harbours on the west and south coasts of South Africa to be subjected to resonance or range action caused by long-period 50 s to 300 s waves.

Since the construction of Duncan Dock in Table Bay in 1940, Table Bay harbour has become a classical example of resonance. Range action in the harbour has been studied extensively in the past and extensive physical model studies were undertaken to optimise the layout of the Schoeman Dock, construction of which was completed in 1976.

In 1976 South African Railways and Harbours (now South African Transport Services) commissioned the Coastal Engineering and Hydraulics Division of the National Research Institute for Oceanology to optimise plans for future extensions to Table Bay harbour. As a preliminary study, the advantages and disadvantages of all existing methods of simulating resonance were reviewed. For this investigation it was decided to adapt an existing "finite-difference" numerical model developed by Leendertse (1967).

Prototype long-wave data were gathered in Table Bay and at a later stage at the cooling water intake basin of the Koeberg Nuclear Power Station. These data were used to calibrate the numerical model and an attempt was made to find a correlation between long waves and short wind waves in order to determine the frequency of occurrence of long waves.

A method was also developed to incorporate a range of frequencies in one model-run instead of single wave input conditions. This resulted in a considerable reduction of expense and time.

---

* Hydrodynamics Division of the National Research Institute for Oceanology, CSIR, Stellenbosch, Republic of South Africa

This resonance study method was used extensively in the Table Bay study and it has also been applied to investigations of alterations and proposed extensions on resonance in other South African harbours (ref. Section 5).

2. PROTOTYPE LONG-WAVE DATA ACQUISITION

2.1 Instruments

Pressure transducers housed in Teflon cannisters were used. The cannisters were attached to galvanized stands on the sea bottom or fixed to permanent harbour structures such as quay walls. Waterproof cables connected the transducers to the recorders which were installed in lockable containers accessible under all weather conditions. These instruments satisfied the following requirements:

(a) Record fluctuations of periods 30 s to 300 s at a sampling rate of 1,0 s.

(b) Automatic switch-on every 12 hours for a 50 min record.

(c) The recorders could be switched to a continuous mode during resonane conditions.

(d) The recorders were synchronised for the determination of the response beween different locations.

2.2 Sampling

It was necessary to obtain an entrance recording so as to be able to determine the response of the locations inside the harbour to that at the entrance. It was necessary that this recorder should be as far outside the harbour as practicable in order that a "clean" input record could be obtained without the influence of the harbour response and the reflections.

At both Table Bay and Koeberg harbour recorders were installed at the heads of the main breakwaters. In Table Bay six recorders were used inside the harbour and in Koeberg three recorders were used.

Records were obtained in Table Bay for a period of six months during 1978. Recording in Koeberg started in April 1981 and will continue until April 1983.

2.3 Analysis

Data analyses were done with the aid of Butterworth digital filters, computation of spectral densities by the auto-covariance method and the determination of responses with direct spectra-to-spectra relations and the cross-spectral

analysis method. Details of the analytical methods are described by Botes (1980).

A flow diagram of the data analysis exercise is schematized in Figure 2.

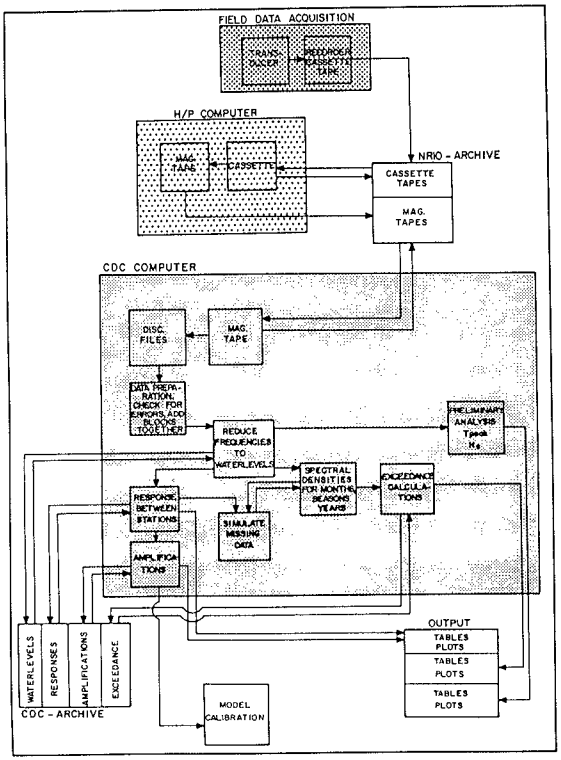

Figure 1 Flow diagram of the data analysis

2.2.1 Preliminary analysis

Raw data are expressed in frequencies and in blocks of 10 minutes each. These data are reduced to water-levels and five blocks joined together form 50 min data blocks. All data are filtered to obtain desired frequency bands and a preliminary spectral analysis is carried out for the qualification of the data and to obtain significant heights and peak periods.

2.2.2 Correlation with short waves

Until now long-wave data have been sampled for specific purposes such as for the calibration of a model. Occurrence figures for long waves in South Africa are virtually non-existent. This and a better knowledge of the origin and generation of long waves are becoming an urgent need.

A waverider is in operation ≈ 3 km from the entrance of Koeberg. An attempt was made to determine whether there is any correlation between increased short waves and long waves. The wave heights during a month were normalised by dividing the measured heights with the mean of the month for the short (1 to 30 s) and long waves (50 to 110 s). These waves were measured independently by means of a waverider and pressure transducer. The relationship between the short and long waves for April and September 1982 is illustrated in Figures 2 and 3.

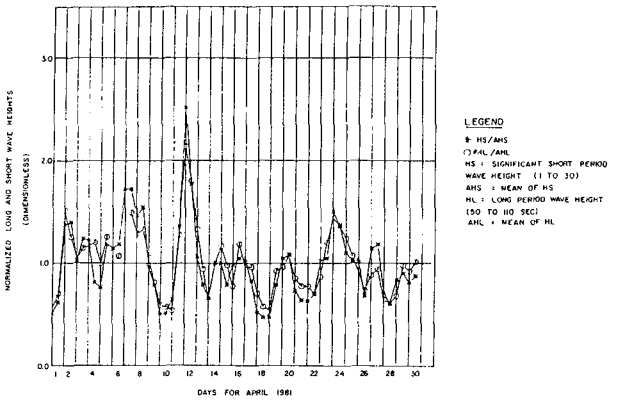

Figure 2 Normalised long and short period wave heights (April 1981)

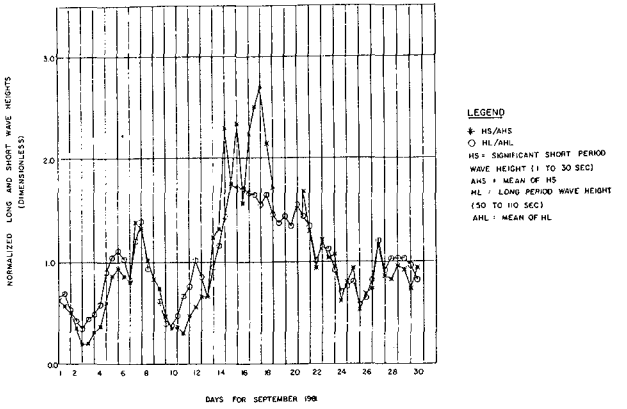

Figure 3 Normalised long and short period wave heights (September 1981)

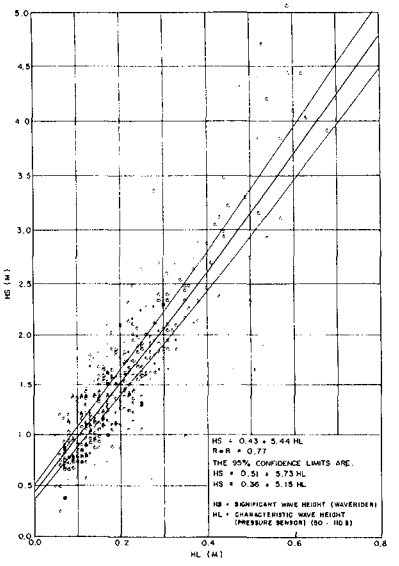

Figure 4 Correlation between long- and short-period wave heights

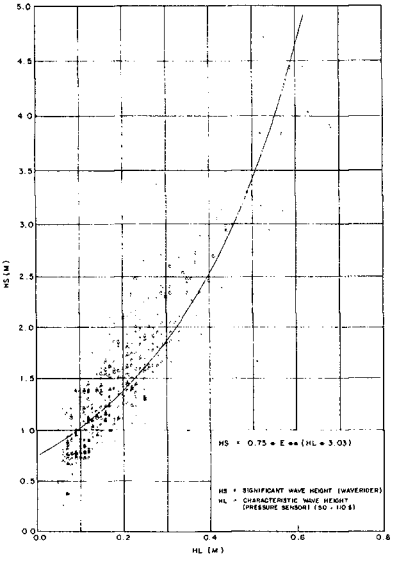

Figure 5 Correlation between long- and short-period wave heights

The height of short-period and long-period waves for 1981 were plotted and the following correlation was determined:

$$HS = 0,43 + 5,44\ HL \quad \text{(Figure 4)}$$
$$(R^2 = 0,77)$$

The 95% confidence limits are:

$$HS = 0,51 + 5,73\ HL$$
$$HS = 0,36 + 5,15\ HL$$

where HS = short period wave height (m) (1 to 30 s)
HL = long period wave height (m) (50 to 110 s).

An exponential fit is even more realistic as the long wave heights will not increase indefinitely (Figure 5).

$$HS = 0,75\ e^{3,03\ HL}$$

An attempt will now be made to find a correlation between the steepness of the short- and long-period waves.

The waverider data can then be used to determine a height and period occurrence of the long-period waves for several years.

2.2.3 Spectral density exceedance curves

In order to be able to obtain an idea of the magnitude of the wave spectra at Koeberg over a period, spectral density exceedance graphs were determined for all recording positions. From these figures it is also clear that each position in the harbour has its own characteristic spectrum as shown in Figures 6 and 7. Figure 8 indicates that the form of the spectra stay the same during calmer conditions.

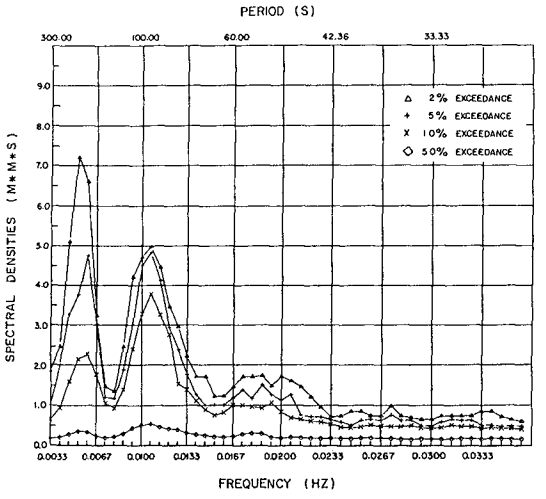

Figure 6 Spectral density exceedances for September 1981 at the entrance of the harbour

2.2.4 Response

The response between two stations is determined by means of a direct spectrum-to-spectrum relation or by means of a cross-spectral analysis technique. Examples of responses between different locations for Koeberg are illustrated in Figures 9 and 10.

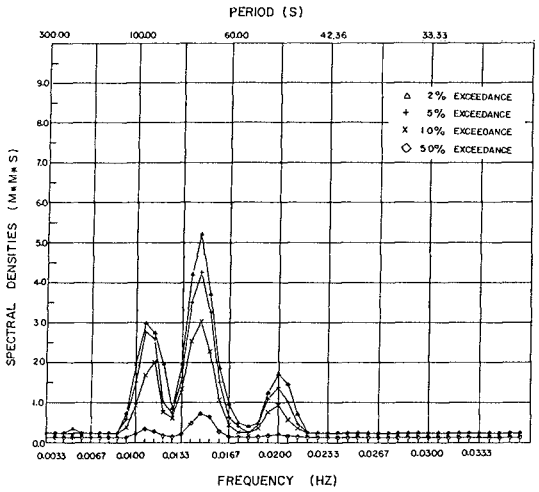

Figure 7 Spectral density exceedances for September 1981 inside the harbour

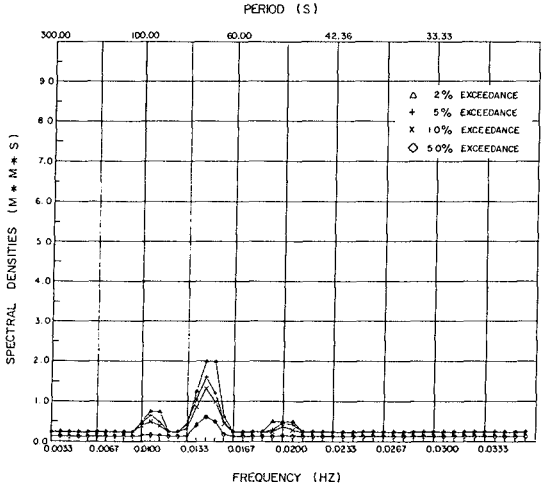

Figure 8 Spectral density exceedances for October 1981 inside the harbour

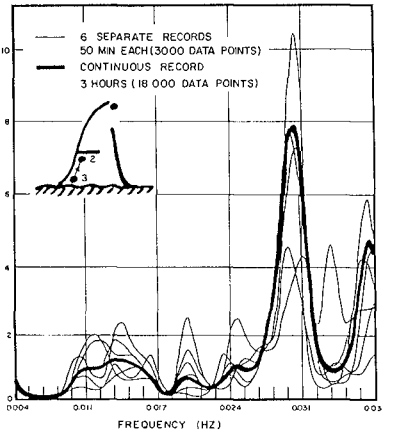

Figure 9 Response between positions 2 and 3

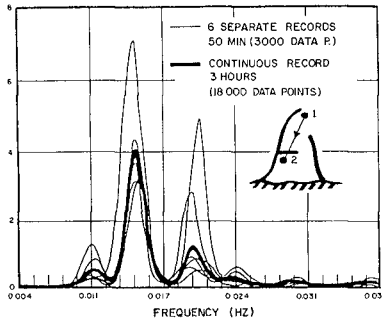

Figure 10 Response between positions 1 and 2

3. NUMERICAL MODEL

3.1 Description

The computations are based on the approximation of the hydrodynamic equations (conservation of mass and momentum

equations in terms of the water elevation and the depth average velocity) by using finite-difference techniques. The finite-difference model, originally developed by Leendertse (1967) was adapted to accommodate any harbour layout (Russell and Huizinga, 1978). The modifications include radiative open boundaries which can be applied to any of the model boundaries and permit the passage of reflected waves.

The model area is represented by a two-dimensional grid system; at each grid point the depth and bottom roughness are described and the water velocities and water levels are calculated.

3.2 Input Conditions and Calibration

An input open boundary is installed as the boundary of the model orientated to the dominant wave direction. Originally only single-period sine waves were used as input conditions. During the analysis of data sampled at Table Bay harbour it was found that the average spectrum at the entrance of the harbour was almost flat which could be simulated by the bandpass-filterng of a white noise spectrum as illustrated in Figure 11.

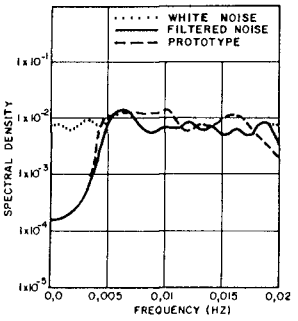

Figure 11 Simulated input spectrum for Table Bay Harbour

With the random noise as input condition, model spectra and model responses between the entrance position and other locations were obtained which were similar to those for the prototype (Figures 12 and 13).

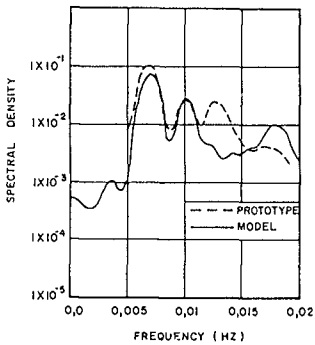

Figure 12 Model and prototype spectral density estimates

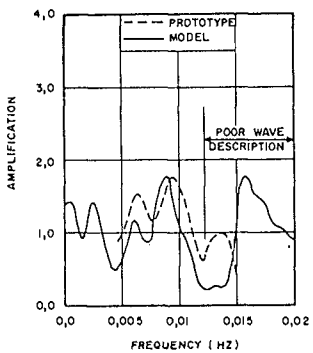

Figure 13 Model and prototype amplifications

This method of using a spectrum as input condition was a considerable improvement on previous studies as one model run accommodates a range of frequencies, instead of numerous expensive and time-consuming tests with single-period sine waves.

After a model run with a spectrum as input condition the frequencies which caused peak amplifications were selected and these were then used as input conditions in order to obtain amplification over the entire model area.

4. APPLICATIONS

4.1 Table Bay Harbour

The study was undertaken in 1976 on behalf of South African Railway and Harbours (South African Transport Services) to optimise plans for future extensions to the harbour. The results of a preliminary investigation have been given elsewhere (CSIR, 1978). Prototype data were recorded during 1978 (CSIR, 1979), after which the model calibration followed (CSIR, 1980a) and the investigations were made of the influence of future extensions (CSIR, 1980b). An example of the amplifications of one of the peak frequencies (93 s) is illustrated in Figure 14.

4.2 Mossel Bay Harbour

A preliminary study was carried out on behalf of the Fisheries Development Corporation of South Africa to determine whether proposed alterations in the harbour would

affect the long-wave response of the layout (CSIR, 1980c). The harbour layout and contours with the model grid superimposed on it is illustrated in Figure 15.

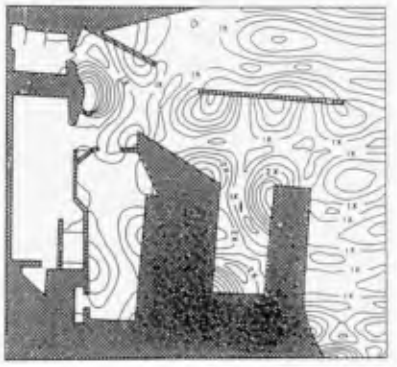

Figure 14 Maximum amplification for a wave period of 93 s (Table Bay Harbour)

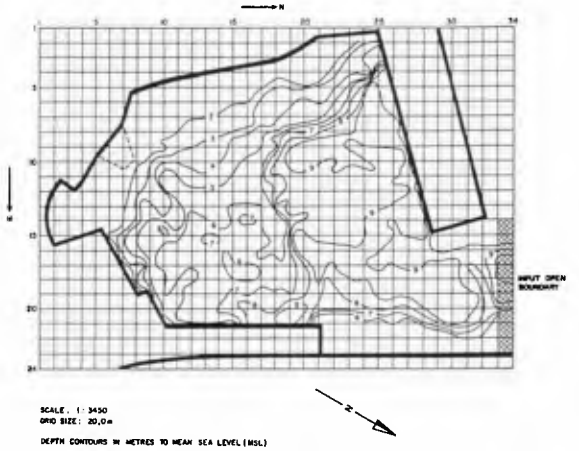

Figure 15 Mossel Bay Harbour layout with model grid superimposed on it

The amplifications of the original layout and a proposed layout for two positions are shown in Figure 16.

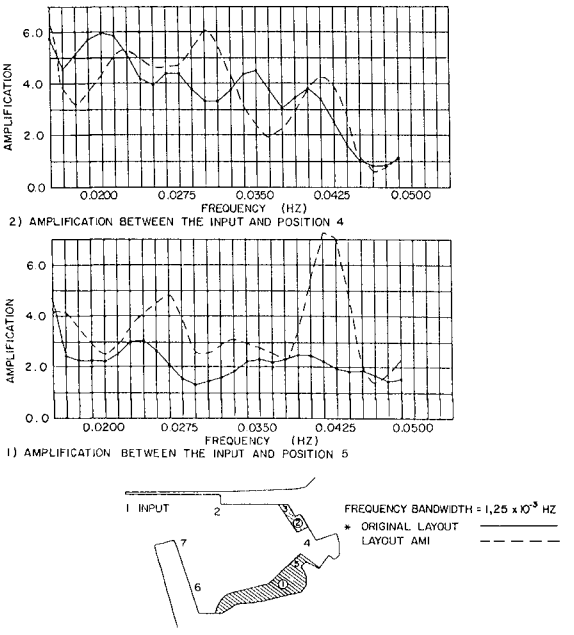

Figure 16 Amplifications for different layouts

4.3 Granger Bay Harbour

A proposed small-craft harbour at Granger Bay (situated next to Table Bay harbour) was tested to determine whether range action will be within the required design criteria for this type of harbour (CSIR, 1981).

Prototype conditions will be similar to Table Bay harbour. The harbour layout with the computational grid superimposed on it is illustrated in Figure 17.

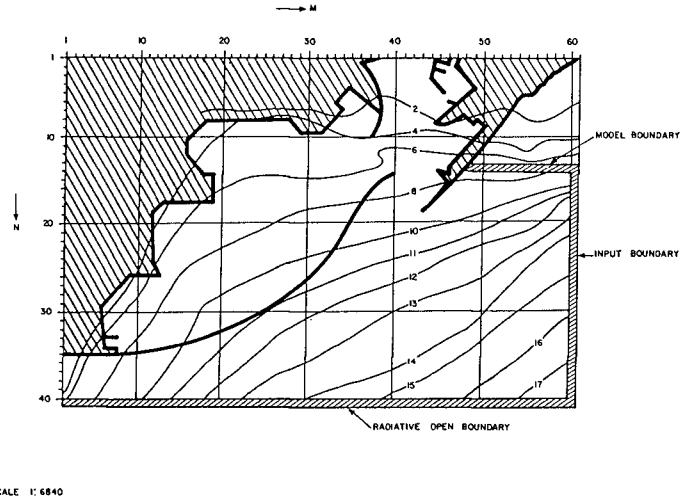

Figure 17 Granger Bay Harbour layout with the model grid superimposed on it

The maximum amplifications of a 60,0 s sine wave are shown in Figure 18.

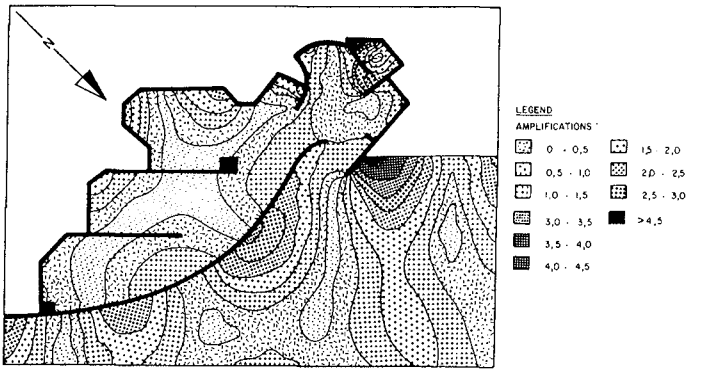

Figure 18 Maximum amplification for a period of 60,0 s

4.4 Koeberg

Prototype long-wave data were sampled at the cooling water intake basin of the Koeberg Nuclear Power Station as part of a post-construction monitoring program in order to determine the occurrence of long waves and the magnitude of the amplifications in the basin. The initial analyses of these data are described in Section 2. The data will also be used for the further verification and refinement of the model techniques and the investigation of the origin and generation of the long waves on the South African west and south coasts.

NUMERICAL MODEL STUDY OF TEMPERATURE DISTRIBUTIONS IN A HARBOUR

by

ROGER A. FALCONER[1]

ABSTRACT

The paper gives details of a study to predict numerically the background temperature rise in Poole Harbour and Holes Bay, in Dorset, England, caused by the siting of either a 700MW or a 350MW power station. The numerical model is based on the numerical integration of the flow equations which simulate the water movements of tides and upon numerical integration of the advective-diffusion equation representing the movement of heat.

The results of the study predominantly suggest that the temperature field is proportional to the station capacity, with the maximum and mean temperatures across the basin for the 700MW station capacity being almost exactly double the corresponding values predicted for the 350MW station capacity. Observations from the velocity fields and tidal prism ratios both tend to suggest that Poole Harbour and Holes Bay have poor flushing characteristics, which confirm the relatively high temperature predictions in that only a relatively small volumetric percentage of the heated water is flushed out of the basin during each flood tide.

INTRODUCTION

A two-dimensional numerical model has been developed to predict the depth average velocity fields and temperature distributions in narrow entranced harbours, within which a warm water outfall may be located. In a study for the Central Electricity Generating Board the model has been applied to Poole Harbour and Holes Bay, in Southern England, where the main objectives have been to determine the tide induced velocity fields and to make an assessment of the background temperature rise in the harbour as a result of a heated discharge from a power station having two possible capacities, i.e. either 700MW or 350MW. Water extracted from the entrance to Holes Bay, which is connected to the northern part of Poole Harbour and diametrically opposite the harbour entrance, flows through the condensers of the power station to be heated through 10K before being discharged back into

---

1 Lecturer in Civil Engineering, University of Birmingham, Birmingham, England

the middle of Poole Harbour through a diffuser located approximately 500m south of the northern shoreline of the Harbour, see Fig.1.

The numerical model is based on the depth integration of the governing hydrodynamic equations which define the tidal water movements within the basin, and upon integration of the advective-diffusion equation representing the movement of heat. The geometry of Poole Harbour is of particular interest to the numerical modeller since the narrow entrance illustrated in Fig.1, gives rise to relatively large advective accelerations. Also, the plan wetted surface area of the harbour changes considerably throughout the tidal cycle, with the surface area at low tide being appreciably smaller than the corresponding surface area at high tide.

Other difficulties encountered in the numerical model study were the treatment of the open boundary conditions, particularly for temperatures at the seaward boundary on the flood tide, and also the simulation of the temperature discontinuity at the point source outfall.

GOVERNING EQUATIONS

The governing equations used in the numerical model to determine the water elevations, the depth averaged velocity components and the horizontal temperature variations in Poole Harbour were the two momentum equations, describing the fluid motion in the horizontal plane, and the equations of mass and heat balance. For a constant density turbulent fluid flow on a rotating earth, the depth integrated momentum equation for flow in the x-direction can be expressed as, (see Falconer (1976) and Goldstein (1938):-

$$\frac{\partial q_x}{\partial t} + \beta\left[\frac{\partial Uq_x}{\partial x} + \frac{\partial Vq_x}{\partial y}\right] - fq_y + gH\frac{\partial \eta}{\partial x} + \frac{gq_x\sqrt{q_x^2+q_y^2}}{H^2C^2}$$

$$- \varepsilon\left[2\frac{\partial^2 q_x}{\partial x^2} + \frac{\partial^2 q_x}{\partial y^2} + \frac{\partial^2 q_y}{\partial x \partial y}\right] = 0 \qquad \ldots\ldots (1)$$

and similarly for momentum conservation in the y-direction:-

$$\frac{\partial q_y}{\partial t} + \beta\left[\frac{\partial Uq_y}{\partial x} + \frac{\partial Vq_y}{\partial y}\right] + fq_x + gH\frac{\partial \eta}{\partial y} + \frac{gq_y\sqrt{q_x^2+q_y^2}}{H^2C^2}$$

$$- \varepsilon\left[\frac{\partial^2 q_y}{\partial x^2} + 2\frac{\partial^2 q_y}{\partial y^2} + \frac{\partial^2 q_x}{\partial x \partial y}\right] = 0 \qquad \ldots\ldots (2)$$

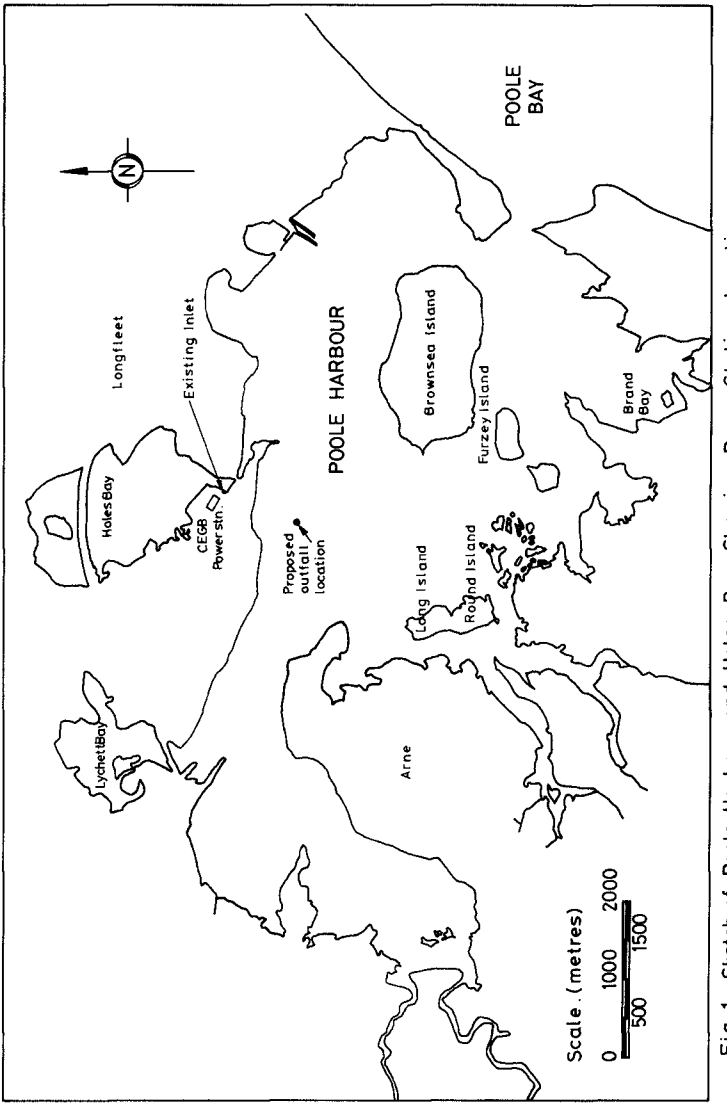

Fig. 1. Sketch of Poole Harbour and Holes Bay Showing Power Station Location.

where q_x and q_y = discharges per unit width in the x and y directions, with U and V being the corresponding depth averaged velocity components, β = a correction factor for the non-uniformity of the velocity distribution, H = total depth of flow, η = water surface elevation above chart datum, f = Coriolis parameter = $2\omega\sin\phi$ where ω is the angular velocity of the earth's rotation and ϕ the geographical latitude (assumed to be 50.012°), g = gravitational acceleration, C = Chezy's roughness coefficient = $H^{1/6}/n$ where n is Manning's roughness coefficient (assumed to be 0.035) and ε = depth mean eddy viscosity which, for an assumed logarithmic velocity profile in the vertical plane, becomes $0.07\sqrt{g(q_x^2+q_y^2)}/C$.

The depth integrated conservation equations for mass and heat transport can be expressed in a similar manner, giving for mass:-

$$\frac{\partial \eta}{\partial t} + \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} = 0 \qquad \ldots\ldots (3)$$

and for heat, see Fischer (1978):-

$$\underbrace{\frac{\partial TH}{\partial t}}_{(1)} + \underbrace{\left[\frac{\partial Tq_x}{\partial x} + \frac{\partial Tq_y}{\partial x}\right]}_{(2)} = \underbrace{-\frac{E(T-T_E)}{\rho Cp}}_{(3)}$$

$$+ \frac{(T_{IN}+\Delta T)Q_{OUT}}{A_{OUT}} + \underbrace{\frac{\partial}{\partial x}\left[HD_{xx}\frac{\partial T}{\partial x} + HD_{xy}\frac{\partial T}{\partial y}\right] + \frac{\partial}{\partial y}\left[HD_{xx}\frac{\partial T}{\partial x} + HD_{yy}\frac{\partial T}{\partial y}\right]}_{(5)} \qquad \ldots\ldots (4)$$

where T = depth averaged temperature, E = surface heat exchange coefficient (assumed to be $30W/m^2/K$), T_E = equilibrium temperature (assumed to be zero), ρCp = specific thermal capacity of fluid (assumed to be $4.2MJ/m^3/k$ for water), T_{IN} = temperature at power station inlet, ΔT = temperature rise across the condensers (assumed to be 10K), Q_{OUT} = discharge from the power station outlet (corresponding to $23.4m^3/s$ for a 700MW power station and $11.7m^3/s$ for a 350MW power station), A_{OUT} = plan cross-sectional area of outfall from power station and D_{xx}, D_{xy}, D_{yx} and D_{yy} = depth averaged dispersion coefficients in the x, y directions respectively, which have been shown by Preston (1981a) to be of the form:-

$$D_{xx} = \frac{(D_\ell q_x^2 + D_t q_y^2)\sqrt{g}}{\sqrt{q_x^2+q_y^2}\,C} \qquad D_{yy} = \frac{(D_\ell q_y^2 + D_t q_x^2)\sqrt{g}}{\sqrt{q_x^2+q_y^2}\,C}$$

$$D_{xy} = D_{yx} = \frac{(D_\ell + D_t)\, q_x q_y \sqrt{g}}{\sqrt{q_x^2 + q_y^2}\, C}$$

where D_ℓ and D_t are constants referring to the longitudinal dispersion and lateral diffusion components of the depth averaged dispersion coefficients and have assumed values of 5.93, after Elder (1959), and 0.15, after Fischer (1973), respectively for a logarithmic velocity profile. The numbered terms of the heat balance equation (4) refer to temperature variations within the domain as a result of : local effects (1), advective effects (2), net surface heat transfer (3), heat source such as an outfall (4) and turbulent diffusion and dispersion (5).

FINITE DIFFERENCE REPRESENTATION

The finite difference equations corresponding to the governing differential equations were expressed in an alternating direction implicit form with all terms being fully centred in both space and time, except for the pressure gradients in the momentum equations and the cross-product diffusion terms in the heat balance equation, see Falconer (1980 and 1981). The first order scheme, with accuracy $O(\Delta t, \Delta x^2)$, involved the discrete values of the variables being represented on a space staggered grid scheme in which water elevations and temperatures were described at different grid point locations to the discharges per unit width in the x and y directions.

The only terms requiring special mention are the advective accelerations expressing the lateral transport of momentum in the x and y directions of the momentum equation, e.g. the Vq_x product term in Eq.(1). These terms were represented in the finite difference scheme as for the Marker and Cell Technique so that their spatial locations were dependent upon the direction of the velocity components perpendicular to the axis direction being considered, see Williams and Holmes (1974).

The boundary conditions used for the hydrodynamic model of Poole Harbour included zero discharges per unit width perpendicular to the closed boundaries, with known uni-directional inflows being specified for the rivers and the power station throughflow. At the seaward boundary, just outside the harbour entrance, water elevation variations were assumed to vary in the same manner as for the mean spring and neap tidal curves given on the Admiralty Chart No.2611. The local discharge of heated water from the power station outlet was accounted for in the model by increasing the local water elevation in the mass conservation equation by an appropriate amount at the discrete point coinciding with the outfall.

For the heat balance equation the temperatures at the open boundaries also needed to be described as a function of time, together with the river inflow temperatures which were assumed to be zero at all times. At the outer seaward boundary, temperatures for the ebb tide were extrapolated linearly from values computed within the

computational field, as given by Leendertse and Gritton (1971). In this approximation only transport of heat by advection to the boundary was simulated, with dispersive heat transport assumed to be negligible. This method of determining the boundary temperature was also used to evaluate the temperature at the power station inlet, where flow was always in the outward direction across the boundary as for the ebb tide.

For the flood tide temperature variations at the open boundary PRESTON (1981b), in a study of the temperature variations at the mouth of Poole Harbour, suggested three possible methods for determining the governing temperatures. Of the possible representations given, the tidally averaged model was adopted due to its mathematical simplicity and relatively straightforward computational requirements. Based on a number of physical assumptions and assumed values for certain relevant data, Preston suggested that the boundary temperature could be expressed as:-

$$T(t) = \bar{\theta}\,\bar{\bar{T}} \qquad \ldots\ldots (5)$$

where $T(t)$ = tidal and spatially averaged input boundary temperature at time t, $\bar{\theta}$ = a tidally averaged integral function which, based on Preston's assumed data, had a value of 0.863, and $\bar{\bar{T}}$ = mean outflow temperature across the boundary, defined as:-

$$\bar{\bar{T}} = \frac{\int_{t_1}^{t_2} \left[\int_0^x q_x(t)T(t)dx + \int_0^y q_y(t)T(t)dy \right] dt}{\int_{t_1}^{t_2} \left[\int_0^x q_x(t)dx + \int_0^y q_y(t)dy \right] dt}$$

where, for any tidal cycle, t_1 and t_2 = the initial and final times of ebb flow across the boundary and x and y = the open boundary lengths in the x and y directions respectively. Once the mean outflow temperature $\bar{\bar{T}}$ had been determined for the ebb tide, the corresponding value was used in Eq.(5) to give the mean boundary temperature during the subsequent flood tide.

The local discharge of heat from the power station outfall gave rise to a local temperature discontinuity, in that the fluid flowing through the warm water outfall grid squares underwent an abrupt temperature rise. This discontinuity gave rise to a series of spurious wave-type temperature oscillations across the harbour, occurring as a consequence of the inability of the finite difference technique to represent rapidly varying variables in space, see Leendertse and Gritton (1971).

In order to overcome the problem of spurious temperature predictions, a number of different numerical schemes were studied for the heat balance equation. The first method considered was Lax's method, see Lax (1954), in which the temperature at the lower time-step for the time derivative in the heat balance equation was expressed as the average of the temperatures at the four surrounding

grid points. However, although this scheme eliminated the spurious solutions, the method introduced an effective artificial diffusion coefficient into the heat equation which, for this study, was found to be intolerably large, see Falconer (1981).

The second scheme considered involved using upstream differencing for the advective terms, with the addition of an anti-diffusion term to improve on the initial poor accuracy of the scheme, as used by Miles (1980). However, this method was found to be unsatisfactory for this particular study since the anti-diffusion term either had to be removed fully or reduced near to the outfall, thereby appearing to introduce small amplitude temperature waves.

The final scheme studied, and subsequently adopted, involved treating the temperature discontinuity as a shock front, and thereby introducing just sufficient artificial diffusion to counteract the disturbances caused by the temperature discontinuity at the outfall. The artificial diffusion term was chosen so that the required additional diffusive effect was obtained when adjacent temperature valves were widely different in the numerical model, but negligible when they were nearly equal, see Leendertse and Gritton (1971). Thus, added to the true diffusion terms in the heat balance Eq.(4) were two further diffusive terms of the form:-

$$D = \frac{\partial}{\partial x}\left[HD_x \frac{\partial T}{\partial x}\right] + \frac{\partial}{\partial y}\left[HD_y \frac{\partial T}{\partial y}\right] \qquad \ldots\ldots (6)$$

where the required diffusion coefficients are of the form:-

$$\left.\begin{aligned} D_{x_{j+\frac{1}{2},k}} &= \left[\frac{T_{j+1,k} - T_{j,k}}{T_{j+1,k} + T_{j,k} - 2T_b}\right]^2 \left[\frac{q_x \Delta x}{2}\right] \\ D_{y_{j,k+\frac{1}{2}}} &= \left[\frac{T_{j,k+1} - T_{j,k}}{T_{j,k+1} + T_{j,k} - 2T_b}\right]^2 \left[\frac{q_y \Delta x}{2}\right] \end{aligned}\right\} \qquad \ldots\ldots (7)$$

where j and k = grid point locations in the x and y directions respectively, and T_b = initial mean temperature, or base temperature, within the domain. Although the use of such an artificial diffusive term is by no means ideal in treating the temperature discontinuity arising at an outfall, the apparent advantage of this method is that the artificial diffusion falls off rapidly away from the outfall - where advection is often the dominant mode of heat transport.

In Poole Harbour large areas of shallow water exist such that marshes alternately dry and flood with each tidal cycle, and with much of the land-water boundary therefore being time dependent. In

simulating this moving boundary in the numerical model the procedure adopted was similar to that used by Leendertse and Gritton (1971), whereby the location of the land-water boundary was assumed to be a function of the current value of the depth. There were, however, two basic differences between Leendertse and Gritton's procedure and that used in this study. Firstly, the first and second checks in Leendertse and Gritton's method on whether or not a grid point should be dry were combined and carried out between the calculation for the new water elevation field and the temperature field. Also, only the two cross-sections in the implicit direction were considered rather than all four cross-sections for each grid square. Secondly, in the third check on a grid cell drying, the average water elevation was used in calculating each cross-section rather than just the water elevation at the grid point being considered. These changes allowed a reduction in the computational cost and appeared to reduce the influence of the instabilities generated in that the same cross-sections were used in these checks as in the finite difference equations themselves.

NUMERICAL MODEL APPLICATION AND RESULTS

The region of Poole Harbour and Holes Bay illustrated in Fig.1 was simulated in the numerical model using a finite difference mesh of 65 x 58 grid points, with an equal grid spacing of 150m. At the centre of each grid square a representative depth between chart Datum and the bed was determined by equating the corresponding cross-sections in the numerical model to those defined by the actual bed topography. The tidal data required at the open seaward boundary was obtained from the Admiralty Chart No.2611 and data provided by the Poole Harbour Commissioners.

The cold water inlet to the power station was approximated by a horizontal sink, which was represented by an open boundary grid square of length 150m. For the proposed outfall, which was coincident with the centre of four grid squares, it was assumed that the heated fluid was discharged vertically upwards and that complete mixing occurred equally among the four adjacent grid squares. The advantage of using four rather than one grid square for the outfall, was that in discharging the heated water over a larger plan cross-sectional area a more realistic localised temperature field was predicted in the vicinity of the source itself. However, since heat rather than temperature was being conserved in the model, it was not surprising to find that when comparisons were made between using one and four grid cells to represent the outfall, little difference occurred in the predicted temperatures across the domain - except in the region very close to the outfall.

The model was always started at high tide, with the assumption that the initial velocities and temperatures were zero everywhere and that the outfall temperature rise above the intake temperature was 10K. Each simulation was run for a maximum of fourteen repetitive tidal cycles, a restriction placed on the model by the relatively small grid spacing and the stability requirement given by Falconer (1976 and 1980), i.e. that the time step $\Delta t < \Delta x U$ - where U is the maximum depth averaged

velocity in the field and Δx the grid spacing (=150m). The resulting predicted water elevations, velocity components and temperatures were evaluated at each grid point, with the results being printed out in both numerical and graphical form at various phases of the tidal cycle.

In general, it is always preferable to be able to check the predicted results obtained from a numerical model with field measurements or otherwise before proceeding with any analysis of the numerical results; the same being true for a laboratory model investigation. For this particular study it was not possible to make any worthwhile comparisons between any measured and predicted velocities or temperatures, since no appropriate field data was available at the time. However, since the model has been applied to a number of rectangular harbours with different aspect (or length to breadth) ratios and has been shown to give good agreement with scaled physical model results, see Falconer (1980), then it was assumed that the results obtained for this study ought not to differ markedly from any similar laboratory model investigations.

The velocity and temperature fields were reproduced graphically for four main simulations. These simulations included predictions for both a 700MW and a 350MW power station and for fourteen consecutive spring and neap tidal cycles respectively. The results are documented and compared in some detail in Falconer (1981), with some typical velocity and temperature field predictions being given in Figs. 2-5 for the spring tide simulations with a 350MW power station. Comparison of Figs. 2 and 3 gives an indication of the variation in the plan cross-sectional wetted area during the tidal cycle, and with the advective effect of the tide on the thermal plume being clearly illustrated in Figs. 4 and 5. Similarly, low neap tide results are given in Figs. 6 and 7.

In comparing the temperature predictions obtained for the various simulations, see Falconer (1981), it appears that the mean temperature and the standard deviation across the harbour were almost exactly double for the 700MW station capacity as for the 350MW capacity. For the 700MW power station the mean temperature rise across the harbour for the spring tides was 0.8K and with a standard deviation of 1.2K, whereas the corresponding values for the 350MW capacity were 0.4K and 0.6K respectively. Similarly, the corresponding neap tide predictions for the mean and standard deviations were 1.1K and 2.1K respectively for the 700MW station, and 0.6K and 1.1K for the 350MW station. The build-up of the mean temperature in the harbour during the fourteen tides for both the spring and neap tidal cycles is shown in Fig.8 for the 350MW power station. More recent numerical model studies on Poole Harbour by the Author, however, indicate that the temperatures predicted in this study might well be on the pessimistic side for two reasons. Firstly, the simulation of conditions in the harbour for fourteen identical neap tides means that a pessimistically low sequence of tidal ranges has been assumed over the period modelled, giving rise to a lower degree of flushing than would occur in reality. Secondly, the assumption that 86% of the heat discharged out through the open seaward boundary returns on the next flood tide appears to be conservative in comparison with recent field data measurements recorded

for other substances such as nitrates and phosphates.

Other indications from the numerical model study were that Poole Harbour and Holes Bay both appear to have poor flushing characteristics, particularly for neap tides where results showed that the net tidally averaged heat outflow across the entrance was extremely small.

CONCLUSIONS

A numerical model has been developed which is capable of predicting both the velocity and temperature distributions within a narrow entranced harbour, with a heated discharge being located within the basin. The results obtained have proved to be encouraging, with numerically stable predictions having been obtained for relatively large advective accelerations and appreciable changes in the plan-form wetted area during the tidal cycle.

The numerical difficulties associated with the finite difference representation of the temperature discontinuity arising at the outfall have been overcome by a weighted artificial diffusive term, where the weighting factor is proportional to the square of the temperature difference between adjacent grid cells.

The results of the study show that for the 350MW power station the mean temperature rise across the harbour is 0.4K for spring tides and 0.6K for neap tides, with the standard deviations for the tempertaure fields being 0.6K and 1.1K respectively. The corresponding predictions made for the 700MW power station were, in almost all cases, exactly double the temperatures predicted for the 350MW station. However, for the reasons given in the previous section these predictions are thought to be on the conservative side.

ACKNOWLEDGEMENTS

The study was funded by the Central Electricity Generating Board under the supervision of Mr. I. T. Hughes, Station Planning Engineer. The author is also grateful for the assistance provided by Mr. N. Ames and Mr. N. P. Baldwin of the Central Electricity Generating Board, Mr. R. W. Preston of the Central Electricity Research Laboraties and Miss G. Vaisey of the Department of Civil Engineering, University of Birmingham.

NOTATION

A_{OUT} = plan cross-sectional area of outfall from power station

C = Chezy coefficient

c_p = specific heat of fluid

$D_{xx}, D_{xy}, D_{yx}, D_{yy}$ = Combined depth averaged dispersion and diffusion coefficients in the two-dimensional plane

D_ℓ = longitudinal dispersion coefficient

D_t = lateral turbulent diffusion coefficient

E = surface heat exchange coefficient

f = Coriolis parameter

g = acceleration due to gravity

H = total depth of fluid

j,k = finite difference co-ordinates in x, y directions respectively

q_x, q_y = discharges per unit width in x,y directions respectively

Q_{OUT} = discharge from power station outlet

t = time

t_1, t_2 = initial and final times of ebb flow across boundary

T = depth averaged temperature at a grid point

T_b = base temperature, or temperature at start of simulation

T_E = equilibrium temperature for heat surface exchange

$\bar{T}$ = mean outflow temperature across the boundary

T_{IN} = temperature at power station inlet

U,V = depth averaged velocities in x,y directions respectively

x,y = longitudinal and lateral co-ordinates in the horizontal plane

X,Y = open seaward boundary length in the x,y directions

β = correction factor for non-uniformity of vertical velocity profile

Δt = time step

ΔT = temperature rise across condensers

Δx = grid spacing

ε = depth mean eddy viscosity

η = water surface elevation

$\bar{\theta}$ = tidally averaged integral function after Preston (1981b)

ρ = density of fluid

WAVE ENERGY VARIATION NEAR CAPE TOWN, SOUTH AFRICA

F.A. Shillington, Physical Oceanography,
University of Cape Town,
Rondebosch 7700, RSA.

ABSTRACT

A three month time series of wave height measurements taken every six hours for twenty minutes duration at two sites (one in 24 m deep water and the other in 15 m deep water) off the South African coast have been used to examine wave energy dissipation. The rocky nature of the bottom has ruled out the possibility of dissipation due to sediment motion and percolation and only dissipation due to bottom friction has been considered. The theoretical work of Hasselmann and Collins 1968 has provided the basic technique. Average friction factors obtained have been in the range 0.17 to 0.50 but have very large scatter. Such large friction factors were not considered possible until recently (Grant and Madsen 1982) when it has been shown that if the hydraulic roughness is of the same order as the bottom orbital excursion, the friction factor tends to a value of 0.23. An attempt will be made in future work to reduce the scatter of the results by careful selection from a longer subsection of the original time series.

INTRODUCTION

In 1980 a collaborative field measuring and analysis programme was set up with participants from the departments of Oceanography at the University of Cape Town, and Ocean Engineering at the University of Stellenbosch, and help from the National Research Institute for Oceanology (NRIO) Stellenbosch and Fisheries Development Corporation (FISCOR) Cape Town, to measure wave parameters on a line perpendicular to the shore. The main objectives were:

(a) to examine processes involving wave energy dissipation in shoaling water
(b) to obtain a long term series of wave heights and wave energy spectra to establish suitable statistics for wave energy extraction design studies. (Retief et al 1982).

SITE

The site chosen for the study resulted partly from historical programmes of NRIO. A 200 m deep wave recording station near Cape Town was initiated and maintained by NRIO for a number of years as a prime

research station for S.A. waters (van Ieperen 1976). It was decided that this station should serve as the outer or deep station for this study. New stations in 24 m deep water and 15 m deep water were deployed by this project. Only records from the 24 m and 15 m deep stations are discussed in this preliminary report.

The bottom topography of the site region is displayed in figure 1. The location of the three Datawell waverider buoys is indicated. The topography is reasonably regular and both SCUBA diver inspection and a later side scan sonar survey indicated that the bottom is composed of large, smooth sandstone slabs. These rocky slabs are covered with biological growth and the kelp *Laminaria pallidae* which ranges from 1 - 2 m tall. There are relatively small patches of sand in some of the gullies.

In order to estimate the incoming wave direction, a bottom mounted OOSO direction guage (see Retief and Vonk 1974) was deployed at the 24 m deep site. This instrument was later removed when it became obvious that the tripod on which it was mounted shifted its orientation under storm conditions. An idea of the boundary roughness can be obtained from an echo sounding profile shown in figure 2.

INSTRUMENTATION ANO OATA ANALYSIS

Wave heights were measured with standard DATAWELL waverider buoys; the analogue signal being transmitted ashore to a nearby lighthouse at Kommetjie. Here the signal was received and stored simultaneously on an analogue strip chart and on cassette magnetic tape as a 17.1 minute (2048 datapoints) time series of digitised wave heights sampled once every 0.5 s. The height resolution of the digitally recorded wave heights is 4 cm. Records were taken every 6 hours at all stations. The digital data on the cassettes were then transferred to 9 track CCT at FISCOR and then put onto disc storage on the UNIVAC 1100/80 computer at UCT. Spectra were then calculated by using standard FFT algorithms together with a wave data qualification suite of programmes (Visser et al 1980) described elsewhere in these proceedings (Rossouw et at 1982). The spectra have a frequency resolution of 0.01 Hz, a Nyquist or folding frequency of 1 Herz, and 20 degrees of freedom leading to 80% confidence bands of 0.7 times the spectral estimate x and 1.6 times x where x is the expected spectral energy density value. The wave directions measured with the OOSO in the early stages of the field have not been used in this study.

WAVE OISSIPATION MECHANISMS

Shemdin et al 1980 have conveniently summarized the possible wave dissipation mechanisms into two groups:

(a) linear processes
Percolation; wave induced bottom sediment motion; bottom scattering.

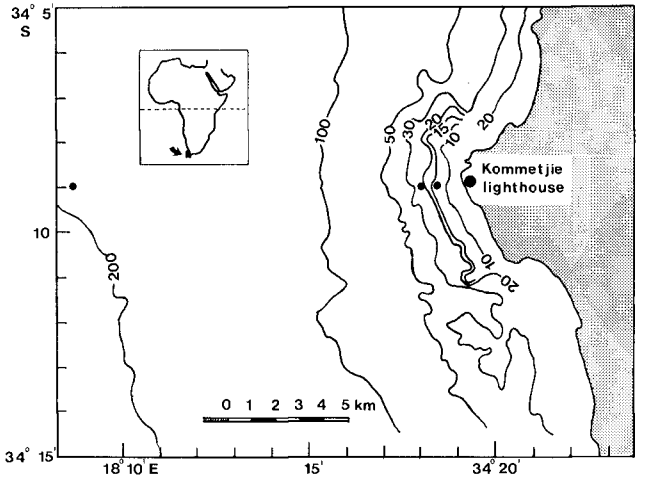

Figure 1. Site location of Datawell waverider buoys and bottom topography.

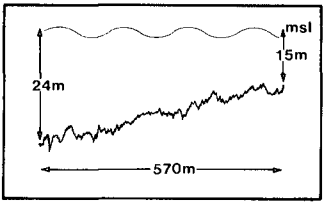

Figure 2. Typical bottom slope between shallow wave recorders from echo sounding profile.

(b) non linear processes
Bottom friction; weak non linear wave interactions in finite depth water.

In this experiment, due to the rocky bottom, it is assumed that the dominant dissipation mechanism would be bottom friction. Techniques for estimating the bottom friction coefficient have been derived by Hasselmann and Collins 1968 and Collins 1972, and have been subsequently used by various workers including van Ieperen 1975 in South African waters.

Hasselmann and Collins 1968 assume that the bottom shear stress is given by a quadratic law:

$$\tau_b = - \rho f_w \tilde{u}_b |\tilde{u}_b| \tag{1}$$

where f_w is the friction coefficient; $\tilde{u}_b$ is the bottom orbital velocity vector due to the waves passing overhead. Since it is difficult to measure $\tilde{u}_b$ directly in the field, we use linear theory to estimate $\tilde{u}_b$ from the surface wave height measurements. (This is justified for most wavelengths and moderate wave heights in this depth of water - see for example, Swart 1978).

$$\tilde{u}_b(k) = \frac{g\ k\ \eta(k)}{\sigma \cosh (kH)} \tag{2}$$

where $\eta(k) = A \cos (\tilde{k}.\tilde{x} - \sigma t)$, $2A$ is the surface wave height, σ the radian frequency, $\tilde{k}$ the wavenumber ($= \frac{2\pi}{L}$), H is the water depth.

We assume that there is no wind wave generation between the stations and that the wave field is steady, in which case we can write the radiative transfer equation as

$$Cg \frac{\partial E}{\partial x}(f,x) = - \Phi(f) \tag{3}$$

where Cg is the group velocity of component frequency f, and the sink function $\Phi(f)$, is given approximately by Collins 1972 as

$$\Phi(f) = \frac{f_w\ g\ k^2 E(f) < \tilde{u}_b >}{\sigma^2 \cosh^2 (kH)} \tag{4}$$

with

$$< \tilde{u}_b > = \left\{ \Sigma_f \frac{E(f)\ g^2 k^2\ \Delta f}{\sigma^2 \cosh^2 (kH)} \right\}^{\frac{1}{2}}$$

$E(f,x)$ is the wave energy density spectral function and $<\tilde{u}_b>$ gives the average steady bottom velocity as a linear superposition of exponentially depth decayed orbital velocities of the different wavenumbers present in the spectrum.

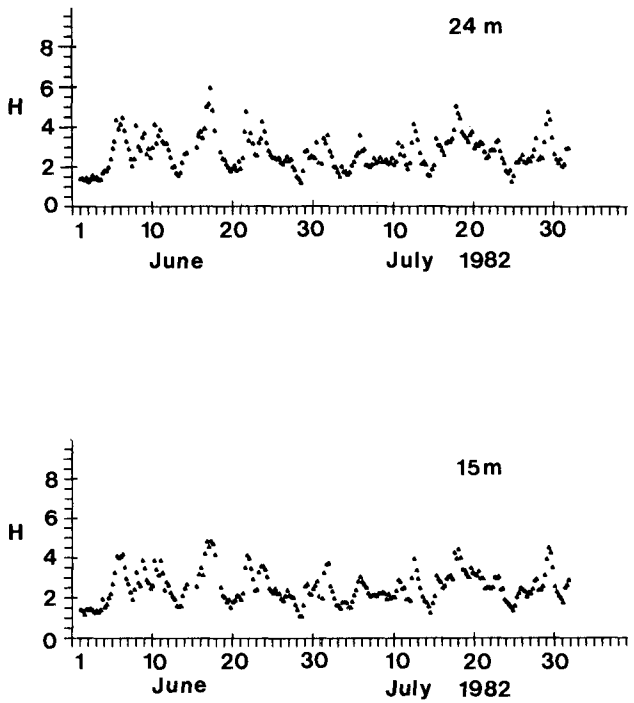

Figure 3. Time series of average significant wave height in 24 m and 15 m depth for June and July 1982.

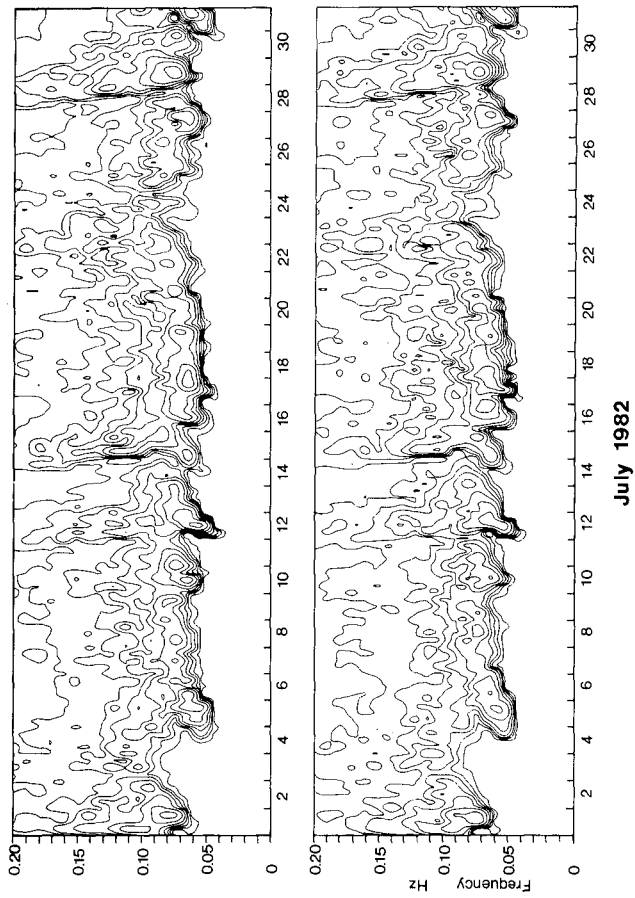

Figure 4. Energy, frequency, time diagram for 24 m (above) and 15 m (below) stations off Kommetjie, South Africa. Energy contours in decibels above 1 m^2sec with contour levels at -2.5, 0, 2.5, 5, 7.5 etc decibels.

RESULTS

As a preliminary analysis, a three month subset of the data for June, July, August 1982 has been used. Figures 3 and 4 show respectively the average significant wave height during June, July 1982 at the 24 m and 15 m depths and the energy-frequency time contour diagram for July 1982, also at both depths. The spectra were computed four times per day for both the 24 m and 15 m stations. Equation (4) was used to compute the friction factor f_w at each of the twenty frequencies

$$f(i) = (0.006 + \frac{5i}{1024}) \text{ Hz} \qquad \text{for } i = 0, 1, \ldots 19.$$

The friction factors for the entire data set (322 values at each frequency) were averaged in time and are shown in brackets in Table 1. The main data shown in Table 1 were selected using a criterion that H_s at the 24 metre deep station should be greater than H_s at 15 metres depth. As can be seen from the scatter diagram in figure 5, sometimes the shallower station experiences larger waves than the deeper one. This is considered to be due to convergent refraction of energy under southerly wave directions.

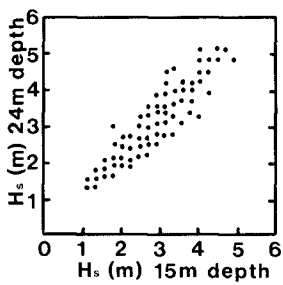

Figure 5. Plot of significant wave height in 24 m versus wave height in 15 m deep water.

Figure 6 shows a percentage occurrence diagram of friction factors f_w at selected frequencies. There is some tendency for the friction factor to increase in magnitude with increasing frequency, but the large scatter in the results makes it difficult to place confidence in such a conclusion.

DISCUSSION

Traditionally it is assumed that friction factors of order 10^{-2} are typical on sandy bottoms under waves. However, more recent work has

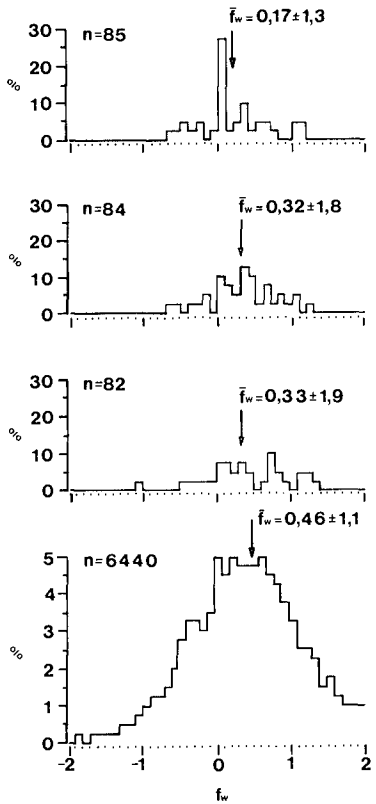

Figure 6. Percentage occurrence of friction factor f_w for frequencies from top: (a) 0.045 Hz, (b) 0.094 Hz, (c) 0.143 Hz and combined for all frequencies, bottom.

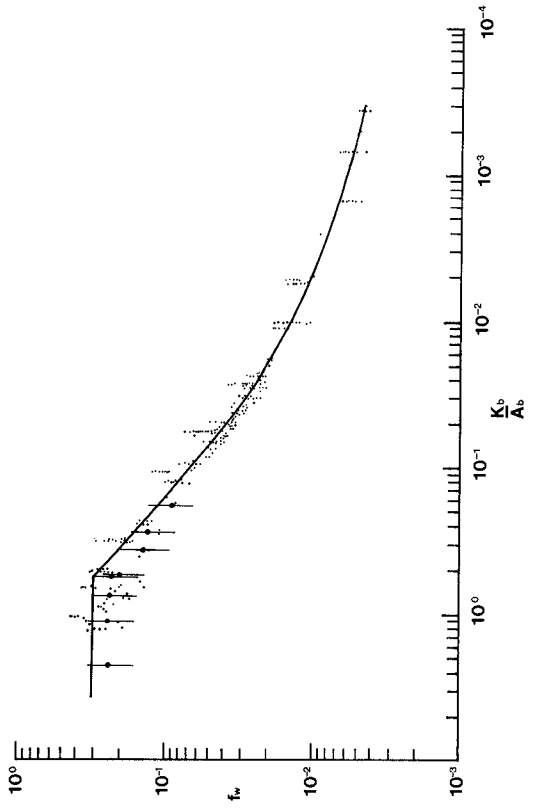

Figure 7. Friction factor f_w for wave tank observations at different hydraulic roughness lengths k_b as a function of $\frac{k_b}{A_b}$ where A_b is the bottom orbital excursion amplitude. (After Swart, unpublished, see also Grant and Madsen 1982).

shown that larger values of the friction factor are being obtained under various conditions. It appears from figure 7 (after Swart, pers comm.) that a limiting value for the friction factor is 0.3. This is also confirmed in recent work of Grant and Madsen 1982. In these instances the high friction factors result when the hydraulic roughness is of the same order as the bottom orbital excursion amplitude. Thus, in this experiment, it is assumed that the large values of the friction factor are due to a large hydraulic roughness. Grant and Madsen show that for values of $\frac{k_b}{A_b} > 1$ (where k_b is the hydraulic roughness length, A_b the bottom orbital excursion amplitude) that friction factor $f_w = 0.23$.

The main problem with the results is the large scatter. This scatter has been attributed to changes in wave direction as the storm pass to the south of the Cape, which then result in changes of energy due to refraction. It is anticipated that the scatter can be reduced by carefully selecting portions of the data set that might be expected to arrive from a particular direction.

No attempt has yet been made to model the effect of the large kelp on dissipating energy. Considering a boundary layer with a scale the same order of magnitude as the size of the kelp, one could consider the kelp in the sense of a percolation model. One would imagine that the kelp would be transparent to low frequency energy, but not so to high frequency energy.

ACKNOWLEDGEMENTS

The author would like to thank the SANCOR division of CSIR for the funding required by this project. The work would also not have been possible without the help of Mr R.C. Wyness in the maintenance and smooth operation of the wave recording equipment. Computer and diving assistance was obtained from the Fisheries Development Corporation.

INDIVIDUAL WAVE ANALYSIS OF IRREGULAR WAVE DEFORMATION IN THE NEARSHORE ZONE

by

Masaru Mizuguchi*

ABSTRACT

In a field observation, water surface fluctuations were measured at many points on line from the shoreline to just outside the surf zone. The data were analyzed by an individual wave method, where the concept of primary individual wave is introduced in order to investigate irregular wave deformation. Primary individual waves are defined by applying the zero-down crossing method with a suitable band width at the zero level to the high-pass filtered water surface fluctuation. It is shown that a wave thus defined behaves like a regular wave with a fixed period in the nearshore zone. A deterministic model based on wave height change of monochromatic waves on non-uniform beaches is then introduced. The model is found to describe the observed deformation process expressed by the primary individual waves.

1. INTRODUCTION

Shallow water wave deformation including wave breaking in the field is usually treated on the basis of representative waves such as the significant wave. A representative wave is a regular wave with a given period and deep-water wave height. However, use of one of the standard regular waves can give considerably different results in applications as compared with irregular waves. For example, a regular wave has a fixed breaking point with locally extreme phenomena at that point. In contrast, irregular waves have a broader wave breaking area and local extrema are largely non-existant.

The purpose of this study is to show how shallow water deformation, including wave breaking, can be described once a wave train is known outside the surf zone where the water depth is still not large.

There are two well-known methods to describe irregular waves; spectral analysis and individual wave analysis. Spectral analysis assumes that irregular wave trains consist of numerous small amplitude waves with random phases. In the nearshore region, however, nonlinearities in the existing finite amplitude waves are an essential feature, especially in the wave breaking process. The component waves in the frequency domain do not break, but real waves or individual waves in the time domain do break. Therefore, in treating shallow water wave deformation, including breaking, individual wave analysis appears more appropriate than spectral analysis.

* Department of Civil Engineering, Chuo University, Kasuga, Bunkyo-ku, Tokyo, 112 JAPAN

A few attempts have been made to model two (or one)-dimensional irregular wave deformation near the surf zone by using individual wave analysis. One approach is that of Goda (1975). He introduced the concept of selected wave breaking, which allows individual waves to break independently when they satisfy a breaking condition. Goda assumed that the wave height distribution changes due to the wave breaking in such a way that the broken wave heights are redistributed in proportion to the remaining distribution. This redistribution process is a probablistic one which can be doubted. Battjes and Janssen (1978) reported that the change of r.m.s. values of wave height in the surf zone could be well explained by their probabilistic model. They assumed a Rayleigh distribution with a cutoff at the maximum wave height for the wave height distribution in the surf zone. In the studies, mentioned above, the deformation process was treated from a probabilistic point of view, and the wave period distribution was ignored.

There have been reported in Japan several experimental studies on shallow water deformation of irregular waves (Iwagaki, Kimura and Kishida, 1977; Sawaragi, Iwata and Ishii, 1980; Isobe, Nishimura and Tsuka, 1980; Iwagaki, Mase and Tanaka, 1981). Most of these studies defined the individual waves automatically by applying a zero-cross method, and compared the behavior of the individual waves with that of a regular wave. Among them it is of worth pointing out that Isobe et al. (1980) demonstrated that an individual wave defined by the zero-down crossing method are not independent from the succeeding trough in the process of deformation.

Recently it has become possible to obtain field data of waves at many points in the nearshore zone by taking photos of the water surface elevation at poles with several sets of synchronized 16 mm memo-motion cameras. In the present paper, field data thus obtained are analyzed by an individual wave analysis, with emphasis on the question, "what is the best way to define the individual wave in the nearshore zone?". It will be shown that the individual waves as defined here behave like independent regular waves. A deterministic model is then developed and compared with the observed results. The model is found to predict the wave deformation process fairly well.

2. FIELD OBSERVATION

The field observation was conducted on December 14, 1978 at Ajigaura beach, Japan, facing east to the Pacific Ocean. In the field observation, the water surface elevation at many closely-spaced points was obtained by filming a large number of poles installed in the nearshore zone with twelve synchronized 16 mm memo-motion cameras. Forty-eight poles were set on a line directed on-offshore, extending from the shoreline to just outside of the surf zone. The distance between poles was about two meters. The techniques employed in the observation are described by Hotta and Mizuguchi (1980)

The observation period was 12 minutes 45.4 seconds and the sampling time was 0.2 s. In Fig. 1 are shown the bottom profile along the pole array and the mean water level. The bottom profile has a rather steep slope (about 1/12) near the shoreline, and an almost constant depth area

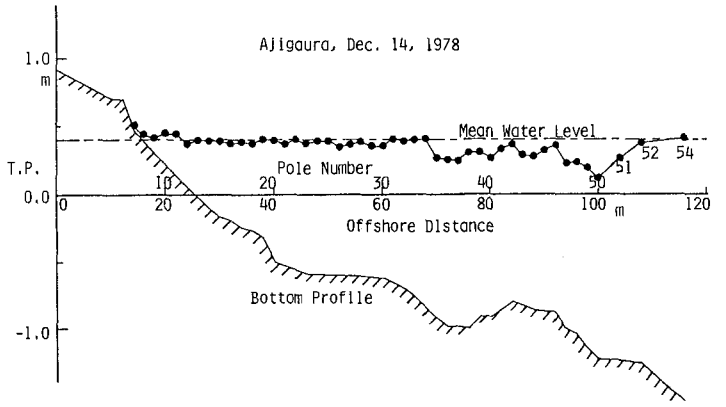

Fig. 1 Bottom profile, pole positions, and mean water level.

in the surf zone. As will be seen later, the average breaker zone was around Pole 43 at the offshoreward convex area. Outside the surf zone a uniformly sloping beach of about 1/40 is expected. The mean water level was obtained by averaging the water surface fluctuations over the observation period. One may consider the depression in the mean water level around the breaking point as wave set-down. However, the possible error in level surveying is too large to draw definite conclusions about the depression.

In this observation the horizontal current velocity near the bottom was measured at several points with electro-magnetic current meters including at Pole 23, the data of which will be used here. The current data gives some information about the wave directional properties (Nagata, 1964). The principal direction θ_p and modified long-crestedness γ^2 at Pole 23 were 2.3° and 0.112 respectively. Considering the error in directional alignment of the current meter placement, one can conclude that the waves were normally incident. The long-crestedness γ^2 is related to the n-th power of a $\cos^n\theta$ type directional spectra,

$$\gamma^2 = \frac{1}{n+1} \tag{1}$$

if the power is independent of the wave frequency. The calculated value of $\gamma^2 = 0.112$ corresponds to n = 8. The large value of n indicates that the incident waves were almost unidirectional.

3. INDIVIDUAL WAVE ANALYSIS AND PRIMARY INDIVIDUAL WAVE

We now apply an individual wave analysis to the obtained data. In the analysis, there are three points to be addressed.

3.1 Methods to Define Individual Waves

The first point in the wave analysis is to determine a method suitable to describe wave transformation in the nearshore zone. The choices are the zero-up crossing method, the zero-down crossing method, the trough to trough method, and the peak to peak method. Among these, the trough to trough method may give the most reasonable definition of an individual wave, since the dominant features of waves are largely determined by their peak configuration. However, technically it is difficult to determine trough points for shallow water waves with a long flat trough. Furthermore, theoretical treatments of irregular wave trains are based on the zero-cross methods (For example, Longuet-Higgins, 1975). Therefore, here we compare the two zero-cross methods.

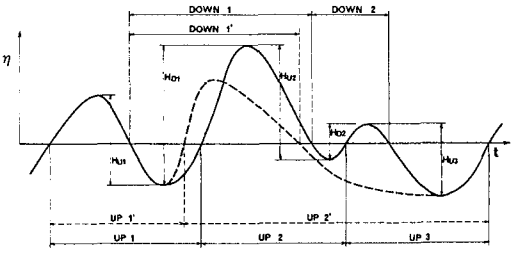

Fig. 2 Schematic illustrating the difference between zero-down crossing method and zero-up crossing method (after Hotta and Mizuguchi, 1980).

In Fig. 2 a clear difference is seen between the two zero-crossing methods when applied to waves with secondary waves, denoted by the solid line. The up method fails to define the small secondary waves by giving two almost equivalent waves denoted by UP 2 and UP 3, in contrast to the success of the down-method, which gives two waves denoted by DOWN 1 and DOWN 2. In this respect, the down method is superior to the up method in clearly reproducing one of the characteristic features of shallow water wave deformation, that is, development of secondary water surface fluctuations. In addition, the front rise of the wave peak is more important than its tail-down in the process of wave deformation in the surf zone. Therefore, the zero-down crossing method should be employed when treating shallow water deformation of individual waves.

Figure 3 shows the wave height and wave period distributions given by the zero-down crossing method and zero-up crossing methods at three representative locations. The two methods were applied to high-pass filtered data. A reading error of E_R = 1 cm (minimum value expected) was used, which gives a band width at zero level, and will be discussed later. At pole 54 in Fig. 3 (outside the surf zone), no appreciable

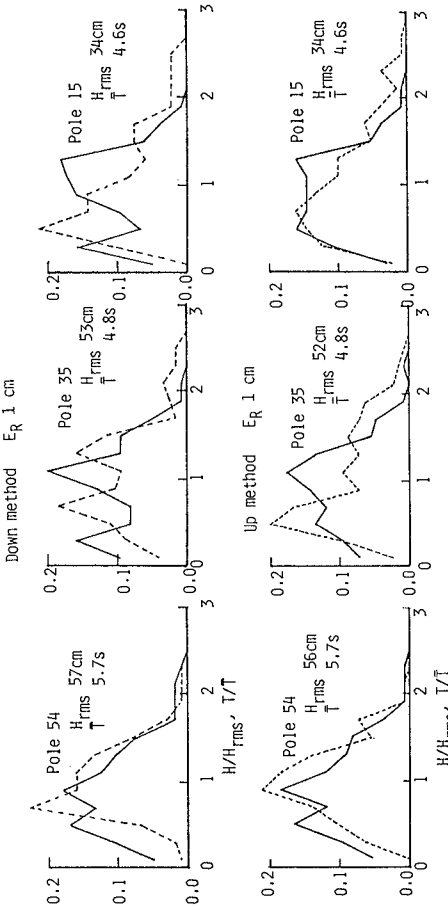

Fig. 3 Wave height (solid lines) and period (dotted lines) distributions both outside and in the surf zone.

difference is observed between the results at the two methods. The two methods thus give the same result when the irregular wave train consists of a summation of infinitesimal waves with random phases. This means that the two methods are equivalent as long as secondary fluctuations do not exist. However, at poles 35 and 15 in Fig. 3, the wave height distribution by the down method exhibits a double peak, contrary to the mono-peaked distribution given by the up method. This is expected from the previous discussion concerning Fig. 2, and confirms the superiority of the down method for use in the shallow water region.

It should be mentioned that statistical quantities, such as the significant wave height, $H_{1/3}$, and significant wave period, $T_{1/3}$, also differ according to the method used when secondary fluctuations exist. Generally, the down method gives larger values than the up method for quantities which are calculated by taking an average only over waves of height greater than a certain value. The smaller the quantity E_R employed, the larger is the difference. Figure 4 gives an example of the difference between the two methods with $E_R = 0$.

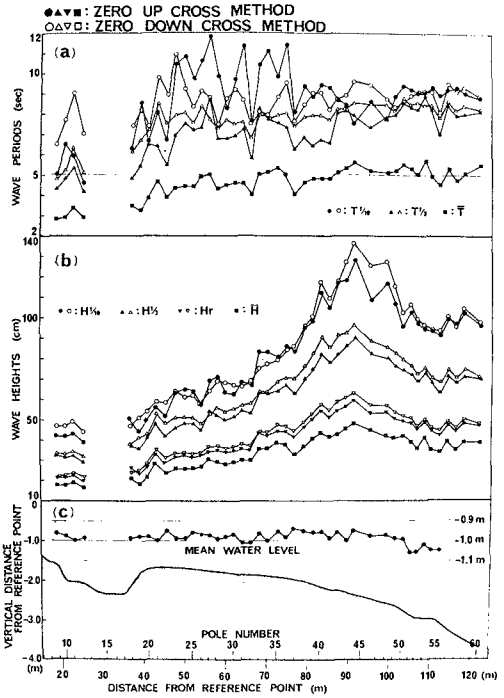

Fig. 4 Change of statistical quantities in shallow water transformation (after Hotta and Mizuguchi, 1979).

3.2 Long Period Fluctuations

The second point to be discuseed concerning the problem of defining waves is the well-known one that low frequency fluctuations have non-negligible power in the nearshore zone. These fluctuations affect the zero level for progressive individual waves, which is of concern here.

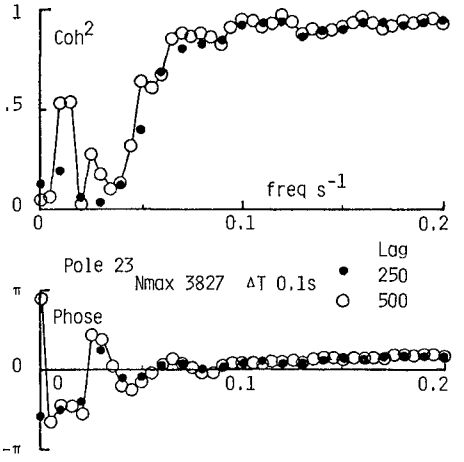

Fig. 5 Cross spectra between water surface fluctuation and onshore velocity at Pole 23.

Figure 5 gives an example of the cross spectra, coherence squared, and phase function between the water surface fluctuation and onshore velocity at Pole 23, about 20 m offshore at a depth of about 1.0 m. The cross spectra were calculated by the Blackman - Tukey method with the two lag numbers of 250 and 500 on 3827 data points. Generally speaking, a smaller lag number gives a more statistically reliable result for the spectra. Application of a spectral window, used to decrease statistical deviation due to the finiteness of the data length, requires neighboring frequency components be in phase when they are correlated. However, as shown in Fig. 5, the smaller lag number gives a lower value of the coherence than the larger lag number, especially in the low frequency region. This means that the lag number of 250 or the equivalent bandwidth of 0.01 s^{-1} failed to detect the rapid sharp change of the phase function in the lower frequency region, possibly due to the existence of standing waves. Therefore, in calculating the cross spectra by applying a small lag number for reliability, the result may be more contaminated because of taking the average over a wider frequency range.

Here, we will focus on the result with the lag number of 500. One notices that in the frequency region lower than 0.05 Hz, the coherence shows sharp fluctuations between zero to rather high frequencies, and

that the phase function shows regular shifts between plus $\pi/2$ to $-\pi/2$. These two observations indicate that the lower frequency components arise from standing waves. A standing wave in the on-offshore direction has a phase difference of $\pm\pi/2$ between surface fluctuation and onshore velocity, in contrast to the in-phase relationship for progressive waves. Further discussion on long period fluctuations in the nearshore zone can be found in Hotta, Mizuguchi, and Isobe (1981), and in Mizuguchi (1982). It is a future problem to investigate the interaction between the longer period standing waves and the shorter period progressive waves. At present, neglecting this interaction, the long period fluctuations should be removed in order to obtain well-defined individual waves.

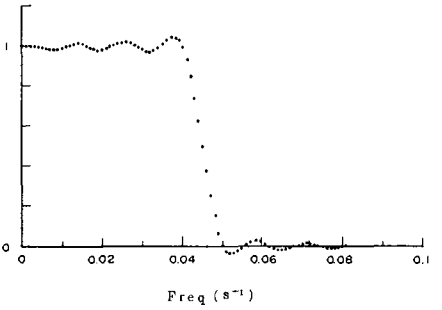

Fig. 6 Frequency response of applied numerical low-pass filter.

In the present analysis, we simply applied the low-pass filter shown in Fig. 6 to enhance the low frequency components. The cutoff frequency of 0.045 Hz was determined by the results shown in Fig. 5.

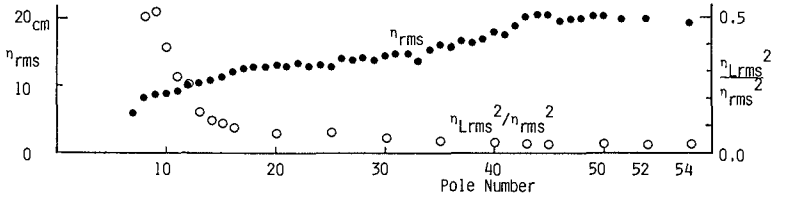

Fig. 7 Ratios of long period fluctuation and r.m.s. values of water surface fluctuation.

In Fig. 7 are shown the ratios of r.m.s. values between the long period fluctuation η_{Lrms} of the water surface fluctuation and the raw fluctuation η_{rms}. In this observation the long period fluctuation becomes significant near the shoreline. Standing waves are somewhat amplified near the shoreline and have a finite amplitude there, although progressive waves decay to disappear due to breaking. In Fig. 7 is also

shown the r.m.s. raw water surface fluctuation η_{rms}. The average breaking point was at Pole 43, at which point the r.m.s. values of η start to decrease. A wave reformation area, where the significant wave breakings ended and η_{rms} became constant, was visually observed to be between Poles 30 and 20. Secondary wave breaking was observed at Pole 18 where η_{rms} again started to decrease.

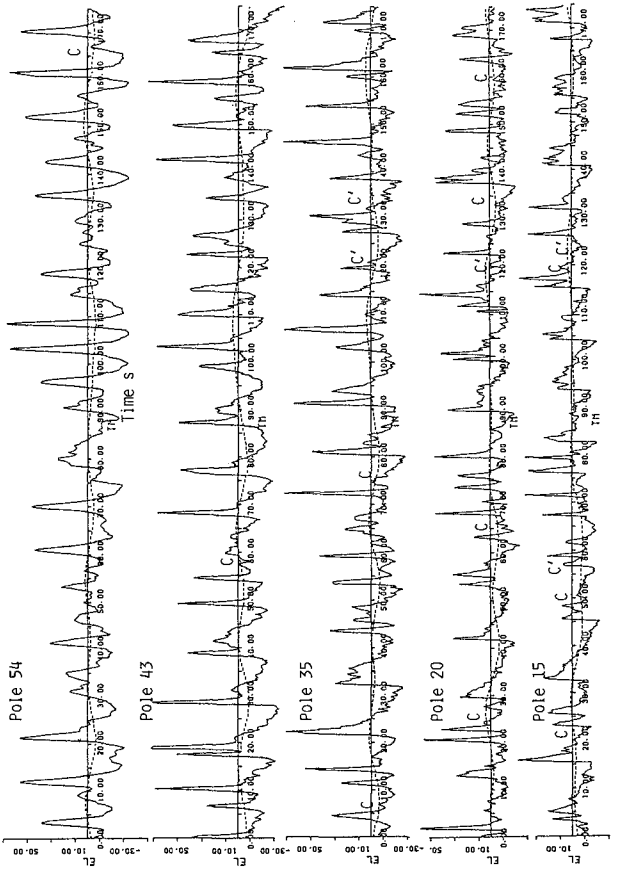

Fig. 8 Examples of observed water surface fluctuations (solid lines) and long period fluctuations (dotted lines).

The influence of the long period fluctuation on the individual wave analysis is shown in Fig. 8. Raw water surface fluctuations are plotted in solid lines, and long period fluctuations are plotted in broken lines at representative locations. When the long period fluctuations are significant, some zero-cross points will be missed. Those points are denoted by C, where the raw data is seen to miss crossing the mean water level but does intersect the level of the long period fluctuation. The points indicated by C' are opposite cases. Generally, the number of points C are greater than points C' in the surf zone, in particular near the shoreline. In the following, we will discuss the high-pass filtered data obtained by subtracting the long period fluctuation from the measured water surface fluctuation.

3.3 Reading Error and Secondary Fluctuations

Finally is discussed the reading error E_R as introduced previously. Reading errors are inevitable when the photographed surface elevation is digitized. The film was projected on a scale of 1/20 and the minimum scale reading was 1 mm. Therefore errors on the order of 2 cm are expected. This error may produce false zero-cross points, especially for waves with a mild slope tail-down. Therefore, a band width of magnitude E_R is introduced at the zero level. Then only the zero-down crossing points with successive peak and trough larger than E_R remain to define the individual wave.

Figure 9 shows examples of individual wave decompositions by the zero-down crossing method with E_R = 2 cm for high-pass filtered water surface fluctuations at representative locations. At Pole 54, the most offshoreward pole, no wave breaking was seen; Pole 43 was at the average breaking point; significant wave breaking terminated at Pole 35; Pole 20 was in the so-called reformed wave region; the secondary wave breaking zone was at Pole 15. The defined waves were numbered starting at Pole 54. The numbered waves were then traced as they propagated, as shown in the figure. Numbers joined by plus signs indicate that the waves united at that location; bracketed numbers denote wave separation. However, it should be noted that combination and separation is a matter of the defining process of the individual wave.

A characteristic feature observed in Fig. 9, and which should be emphasized, is that most of the primary wave peaks are easily identified throughout the observation area. This fact suggests introduction of the concept of "Primary Individual Wave", hereafter called PIW, characterized by an eminent peak, in order to describe irregular wave deformation in a deterministic way. In the nearshore zone, secondary waves are often observed, as already mentioned. Wave breaking also generates turbulent surface fluctuations. These problems are not easy to treat quantitatively at present. Here, as an expedient, the band width E_R, originally introduced to remove the effect of the error in reading, is adjusted to suppress these secondary fluctuations. Then the individual waves thus defined may have a one to one correspondence to the above-mentioned eminent peaks.

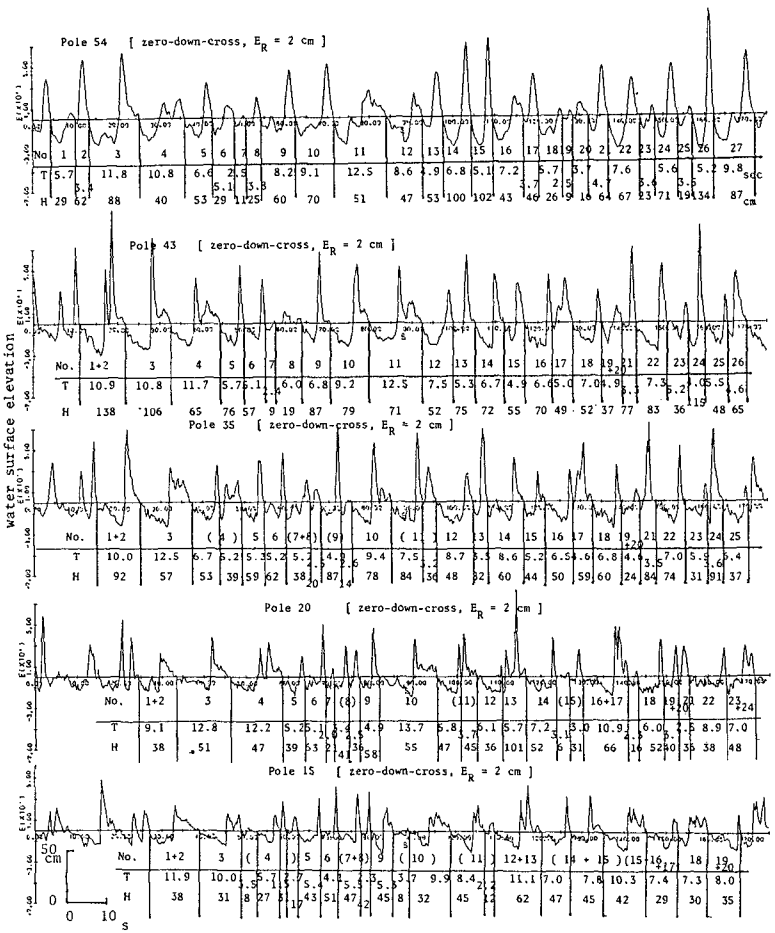

Fig. 9 Examples of individual wave decomposition by the zero-down crossing method with E_R = 2 cm.

What is an appropriate value of E_R for our purpose? As shown in Fig. 9, E_R = 2 cm is so small that some of the decomposed individual waves may correspond to secondary peaks. Figure 10 shows how wave height and period distributions change with increase of E_R at Pole 35, a location where secondary waves and turbulent surface fluctuations appear. The wave height destribution tends to be mono-peaked, neglecting small disturbances or secondary waves. The respective wave height and period distributions for E_R = 4 cm are almost the same, as for E_R = 5 cm. The representative wave height and wave period such as $H_{1/3}$, H_{rms}, and $T_{1/3}$, increase considerably with increase of E_R. A properly chosen value of E_R should give proper values for those quantities. Figure 11 shows the decrease in numbers of defined waves, N_w, at various locations with increase of E_R. The decrease in the surf zone is considerable, and the numbers of waves defined with E_R in the range from 3 to 5 cm are almost the same at all locations. Therefore there may be a suitable value of E_R which gives almost the same number of waves through the nearshore zone, and which also gives a stable joint probability distribution of wave height and period at each location.

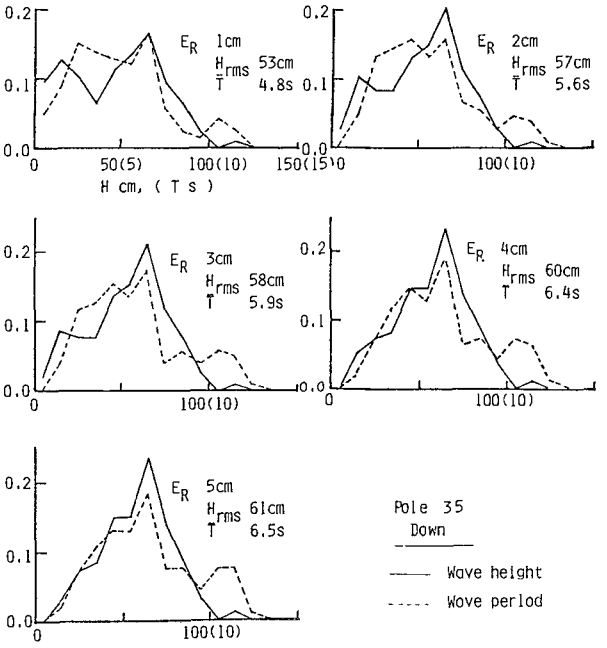

Fig. 10 Change of wave height and period distribution at Pole 35 by the down method with increase of E_R.

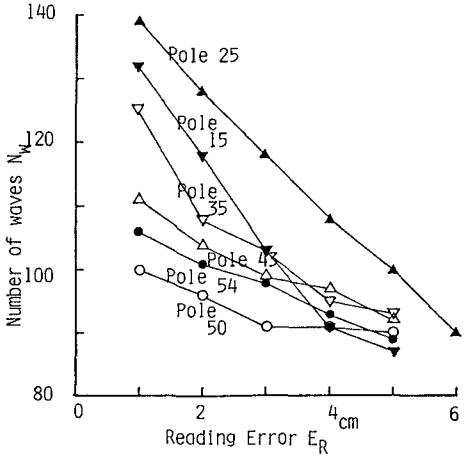

Fig. 11 Decrease in number of waves with increase in E_R.

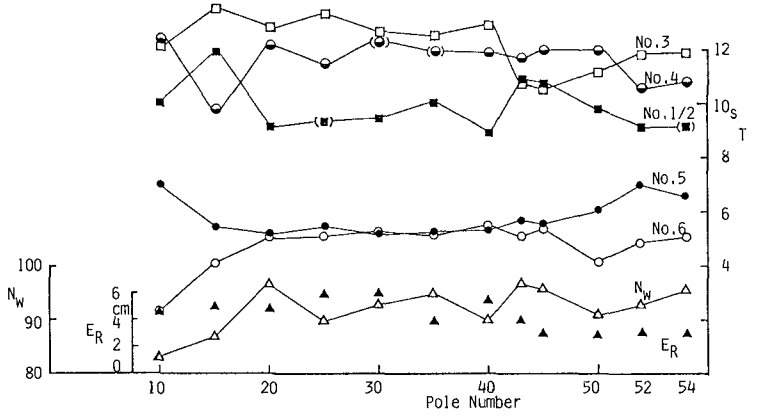

Fig. 12 Applied value E_R, numbers of waves defined with E_R, and changes in period of the first six observed waves.

3.4 Primary Individual Wave and its Deformation

The concept of PIW is now clear. A PIW can be defined by applying the zero-down cross method with a suitable value of E_R, a band width at the zero level, to the high-pass filtered water surface fluctuations. The suitable value of E_R may differ according to location. The proper value of E_R can be determined, as here, to give the same number of waves throughout the observation area as for the most offshore-ward region. It is conjectured that the ratio of E_R to wave height may depend on both the Ursell number and on the relative distance from the breaking point.

The deformation of the observed PIW in the nearshore zone will now be discussed. In Fig. 12 are shown the applied value of E_R, the resultant number of waves, and wave periods changes of the first six (or five) waves. The values of E_R were determined as mentioned above, with the magnitude of the observed secondary fluctuations taken into consideration. The number of waves is almost constant except very near the shoreline, where the PIW itself become small and can not be distinguished from the secondary fluctuations. Thus Fig. 12 demonstrates the fact that the wave period of the PIW does not change through the observation area.

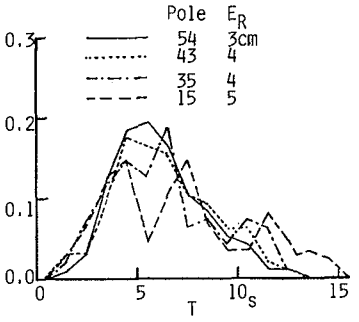

Fig. 13 Wave period distributions.

The corresponding wave period distributions shown in Fig. 13 are also seen to be essentially constant. Therefore, we can say that wave periods of the PIW are constant through the area of concern. This can be expected from the fact that wave celerity in the shallow water region can be well expressed by non-dispersive long wave theory. Therefore, each PIW can be treated as a regular wave. However, viewing the details of the distributions in Fig. 13, one can notice that they become flat near the shoreline. This suggests that near the shoreline, where the water depth is very shallow, secondary fluctuations are not negligible and should be included in modeling of the wave transformation. For the PIW, the wave height changes as it propagates, but the period does not.

4. MODELLING OF PIW DEFORMATION

We now attempt to model wave height change, and compare the calculation with the observed results. Outside the surf zone, the wave height is assumed to obey the relation

$$H^{5/2}[(gHT^2/d^2)^{1/2} - 2\sqrt{3}] = \text{const.} \tag{2}$$

where, H: wave height, d: water depth and, g: gravitational acceleration. Equation (2) was obtained by Shuto (1974), based on finite amplitude long wave (first order cnoidal wave) theory, and is valid only for large Ursell number.

The breaking criterion employed is that given by Sunamura and Horikawa (1974) for depth-controlled wave breaking.

$$H_b/H_o = s^{0.2} (H_o/L_o)^{-0.25} \tag{3}$$

Here, H_b: breaking wave height, H_o: deep-water wave height, s: slope of uniform beach, and L_o: deep-water wave length. This is an empirical formula for uniformly sloping beaches. Wave height change in two-dimensional laboratory experiments up to breaking has been found to be well described by Eq. (2) with Eq. (3) (e.g., Mizuguchi and Mori, 1981).

For the wave height change after breaking, a constant ratio of wave height to water depth has been used in many applications. However, it is clear that this ratio can not be constant on a real beach. Here an heuristic model developed by the author (Mizuguchi, 1980) is employed.

$$\frac{d}{dx}(Ec_g) = -\epsilon \tag{4}$$

$$\epsilon = \rho g \nu_e (kH)^2/2 \tag{5}$$

$$\nu_e = \nu_{eb}(H/\gamma d - c/\gamma)^{1/2} \tag{6}$$

where, c_g: group velocity, ϵ: energy dissipation ratio, ρ: fluid density, ν_e: eddy viscosity, k: wave number, ν_{eb}: eddy viscosity at the breaking point, γ: wave height to water depth ratio at the breaking point, and c: wave height to water depth ratio in the wave reforming zone. The critical point of this model is the form of the eddy viscosity in Eq. (6), which enables waves to recover under certain situations. The eddy viscosity ν_{eb} at the breaking point is determined by the wave conditions and the beach profile before breaking. This model was shown to well reproduce the experimental results of regular waves on various non-uniform beach profiles, except very near the shoreline (Mizuguchi, 1980)

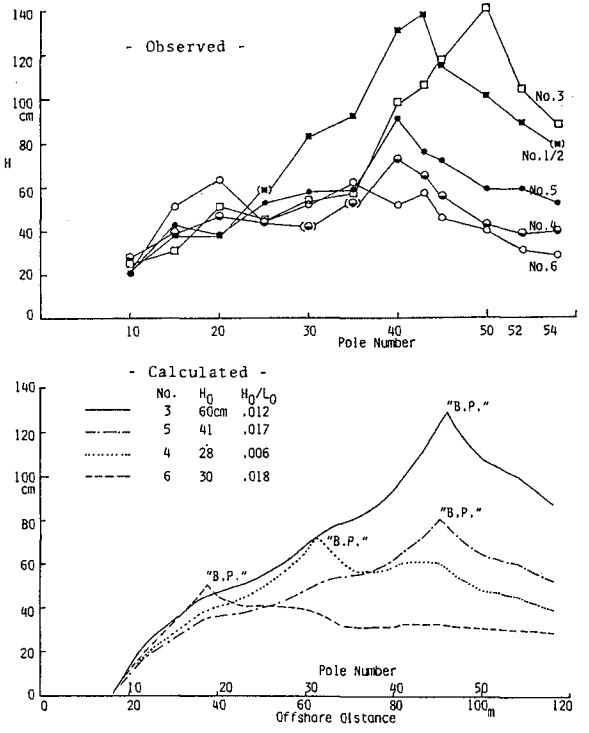

Fig. 14 Wave height changes of PIW, observed and calculated.

Figure 14 shows both the observed wave heights across the surf zone of the first five (or six) waves and the wave heights calculated by the model. Except for wave No. 4, the agreement is good, although decay after breaking is more rapid in the observation than in the calculation. An energy dissipation model of breaking waves based on the similarity to a hydraulic jump (Le Mehaute, 1962) gives a dissipation rate proportional to the third power of wave height. This model may better predict the observed rapid decay. For wave No. 4, the breaking position differs considerably. This is attributed to the fact that breaking condition in the calculation was not satisfied at the offshoreward slope; the continuing deeper area or trough in the bottom profile can not cause the wave to break in the present formulation. As previously stated, the zero-down crossing method has the defect that the succeeding tail-down of a peak is not fully included in the wave description. Isobe et al. (1980) found in laboratory experiments that the succeeding deeper trough

of a wave tends to delay the wave breaking. It has also been reported (Iwagaki et al., 1977) that individual waves defined by the zero-up crossing method tend to break, before satisfying the breaking criterion for regular waves on a uniformly sloping laboratory beach. The breaking criterion for PIW in a regular wave train on non-uniform beaches should be investigated further.

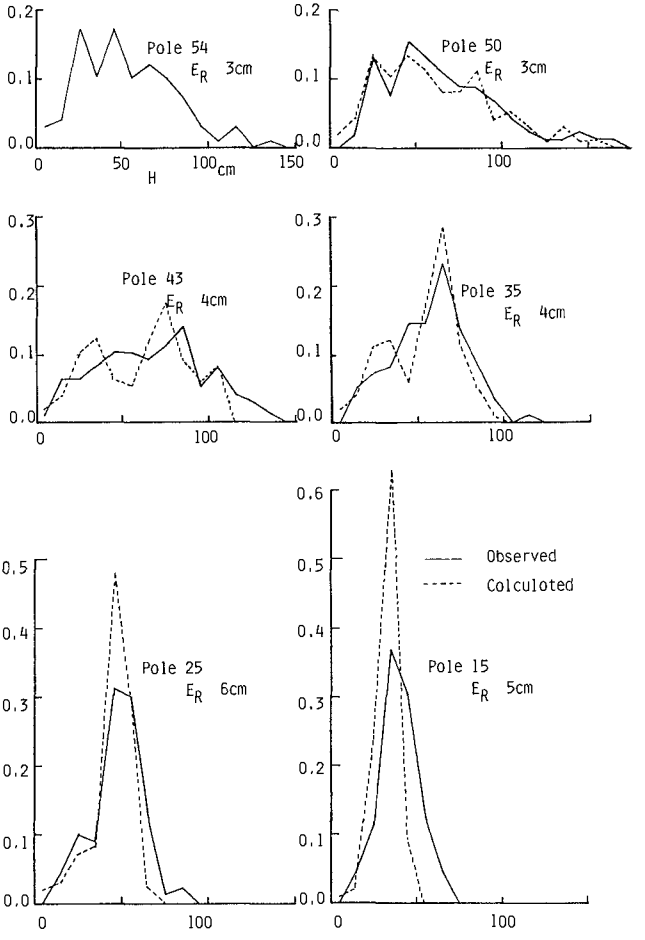

Fig. 15 Comparison of wave height distributions of PIW.

Near the shoreline, this model always predicts a smaller wave height than observed, since the wave height at the shoreline in the model is assumed to be zero, although in actuality there is always some run-up with finite wave amplitude at the shoreline. Wave set-up also has a little to do with the underestimation, as shown in Fig. 1.

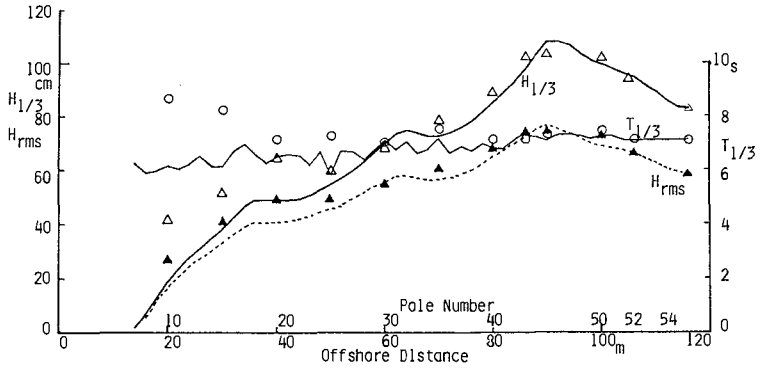

Fig. 16 Comparison of statistical quantities resulting from a PIW analysis. Symbols denote observed values and lines denote calculated ones.

Figure 15 gives comparisons between the observed wave height distributions of PIW and the calculated ones. The agreement is fair. The lack of agreement near the shoreline in the modelling is attributed to the two reasons given in the previous paragraph. Lack of agreement is also caused by the inapplicability of the concept of PIW near the shoreline as stated in the former section. The calculated statistical quantities are compared with the observed ones in Fig. 16. Again, agreement is good except near the shoreline. A local extreme, such as an unusually large wave height increase at the breaking point, expected in a representative wave approach, is not found either in the observation or in the calculation.

5. CONCLUSIONS

The following conclusions can be made:

First, a Primary Individual Wave can be defined by applying the zero-down crossing method to the high-pass filtered water surface fluctuation using a suitable band width E_R at the zero level. Second, the thus-defined PIW shows a regular wave-like behavior in the nearshore zone. Third, the shallow water wave deformation of an irregular wave train in and near the surf zone can be described with the PIW, except very near the shoreline, by applying a wave height change model as given here.

Finally, however, there are still some important topics remaining to be investigated in order to obtain full understanding of the shallow water deformation of field waves. These are mainly long period fluctuations, secondary fluctuations, and the effect of non-uniformity of the bottom profile.

ACKNOWLEDGEMENTS

This study was originally carried out in 1980 with assistance of Mr. C. Matsuda, who was an undergraduate student at Chuo University. The data used were obtained during a cooperative research project with Mr. S. Hotta, Tokyo Metropolitan University, in a joint field experiment under the supervision of Prof. K. Horikawa, University of Tokyo. The manuscript was proofread by Dr. N.C. Kraus, Nearshore Environment Research Center.

NEW EQUATION OF SURACE ELEVATION IN WAVE MOTION

by

Y. C. Ouyang* Y.Y. Chen** Frederick L.W. Tang***

ABSTRACT

A nonlinear solution of wave profile equation directly derived from stream function is submitted. In stead of expressing by trigonometric series to approach the real solution, implicit function is adopted. In the era of electronic computer, Such an expression will be convenient for practical utilization.

Equations in either deep water or in finite water depth are worked out. They are proved more reasonable in graphical shape of wave profile and consistant in the continuity of wave celerity in various depth in comparison with Stokes theory.

INTRODUCTION

For more than 100 *years, Stokes' wave theory has been applied to various engineering problems. However, the theory is an approximate solution strictly. Furthermore, we all have the experience that the* $(n+1)$ *th solution is not guaranteed to be better*

than nth. The only merit is that the equation is expressed explicitly. In the eva of electronic computer, implicit equation can be solved promptly. It is not necessary to be stuck on explicit equation. Reasonable solutions of wave profiles in deep and intermediate water area are worked out directly from stream function in following sections. Their validity and consistancy are examined closely.

FUNDAMENTAL EQUATIONS

(A) *Governing equations*

Water is supposed to be incompressible and irrotational, then the governing equations of wave motion are as follows :

$$\nabla^2\phi = 0 \quad , \quad \nabla^2\phi = 0 \tag{1}$$

$$\nabla^2 = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right)$$

x : *abscissa along the water surface, being positive toward the wave direction.*

y : *ordinate vertical to the water surface, being positive upward*

$\psi = \psi (x , y , t)$: *stream function*

$\phi = \phi (x , y , t)$: *velocity potential*

t : *time*

(B) *Boundary condition equations on free surface*

(a) *Dynamical equation*

$$\left(\frac{\partial \phi}{\partial t} \right)_{y=\eta} + g\eta + \frac{1}{2} \left[\left(\frac{\partial \psi}{\partial x} \right)^2 + \left(\frac{\partial \phi}{\partial y} \right)^2 \right]_{y=\eta} = Q(t) \tag{2}$$

g : *gravitational acceleration*

$\eta = \eta(x, t)$: *fluctuation of water surface elevation with respect to* $x-$*axis*

$$\frac{\partial \psi}{\partial x} = -\frac{\partial \phi}{\partial y} = v \ , \ \frac{\partial \psi}{\partial y} = \frac{\partial \phi}{\partial x} = -u$$

u , v : *horizontal and vertical velocity of water particle*

$Q(t)$: *Bernoulli's number varys with time only*

(b) *Kinematic equation*

$$\left(\frac{\partial \phi}{\partial y}\right)_{y=\eta} = \frac{\partial \eta}{\partial t} + \frac{\partial \eta}{\partial x}\left(\frac{\partial \phi}{\partial x}\right)_{y=\eta} \tag{3}$$

(C) *Boundary condition in bottom*

$$\left(\frac{\partial \phi}{\partial y}\right)_{y=-d} = \left(\frac{\partial \psi}{\partial x}\right)_{y=-d} = 0 \tag{4}$$

d : *vertical distance from* $x-$*axis to the bottom*

(D) *Assumptions of solution*

The solutions of above mentioned Laplace equation i.e. equation (1) *are to be assumed as follows* :

$$\psi(x, y, t) = \sum_{n=1}^{\infty} C_n e^{-nkd}\left\{e^{nk(d+y)} - e^{-nk(d+y)}\right\} cosnk(x - ct)$$

$$\phi(x, y, t) = \sum_{n=1}^{\infty} C_n e^{-nkd}\left\{e^{nk(d+y)} + e^{-nk(d+y)}\right\} sinnk(x - ct) \tag{5}$$

The stream function of free surface is :

$$\psi(x, \eta, t) = 0$$

So that

$$\eta(x,t)=\sum_{n=1}^{I}\frac{C_n}{c}e^{-nkd}\left[e^{nk(d+\eta)}-e^{-nk(d+\eta)}\right]\cos nk(x-ct)$$

C_n : *constants to be worked out*

n : 1 , 2 , 3 ……

e : *exponential*

k : *wave number*, $k=2\pi/L$

L : *wave length*

c : *wave celerity*

The motion is altered to be steady flow by adding an opposite velocity c, $(x-ct)$ *in above equations will be replaced by* x, *then*

$$\phi(x,y)=cy-\sum_{n=1}^{\infty}C_n e^{-nkd}\left[e^{nk(d+y)}-e^{-nk(d+y)}\right]\cos nkx$$

$$\phi(x,y)=cx+\sum_{n=1}^{\infty}C_n e^{-nkd}\left[e^{nk(d+y)}+e^{-nk(d+y)}\right]\sin nkx$$

$$\eta(x)=\sum_{n=1}^{\infty}\frac{C_n}{c}e^{-nkd}\left[e^{nk(d+\eta)}-e^{-nk(d+\eta)}\right]\cos nkx \tag{6}$$

NEW EQUATION IN DEEP WATER

In above equations , $d\to\infty$, $n=1$, *we get*

$$\phi(x,y)=cy-C_1e^{ky}\cos kx \tag{7}$$

$$\eta(x)=\frac{C_1}{c}e^{k\eta}\cos kx \tag{8}$$

η_{max} *and* η_{min} *are the elevation of crest and trough of wave profile.*

$$\eta_{max}=\eta_1=\frac{C_1}{c}e^{k\eta_1} \tag{9}$$

$$\eta_{min} = \eta_2 = \frac{C_1}{c} e^{k\eta_1} \tag{10}$$

Invoke a parameter ω *which is defined as the ratio of maximan particle velocity at the wave crest,* q_c*, to wave celerity,* c*, namely*

$$\omega = q_c / c = -\left(\frac{\partial \psi}{\partial y}\right)_{y=\eta_1} / c \tag{11}$$

ω *is to be* 0 *when wave is breaking, and will be* -1 *on calm water surface i.e.*

$$-1 \leq \omega \leq 0 \quad or \quad 0 \leq 1+\omega \leq 1$$

Substitute (7) *to* (11)

$$(1+\omega)/k = \frac{C_1}{c} e^{k\eta_1} \tag{12}$$

From equation (9)

$$(1+\omega)/k = \eta_1 = \frac{C_1}{c} e^{k\eta_1} \tag{13}$$

$$C_1 = \frac{c(1+\omega)}{k e^{(1+\omega)}} \tag{14}$$

is obtained.

Consequently:

$$\psi(x, y) = cy - \frac{c(1+\omega)}{k e^{(1+\omega)}} e^{ky} \cos kx \tag{15}$$

$$\eta(x) = \frac{1+\omega}{k e^{(1+\omega)}} e^{k\eta} \cos kx \tag{16}$$

From equations (9), (10) *and* (13)

$$-\frac{e^{k\eta_2}}{\eta_2}=\frac{e^{k\eta_1}}{\eta_1}=\frac{k e^{(1+\omega)}}{1+\omega} \tag{17}$$

H denotes the wave height $H=\eta_1-\eta_2$ 。

Accordingly

$$\frac{k e^{(1+\omega)}}{1+\omega}=\frac{e^{k(\eta_1-H)}}{H-\eta_1}=e^{(1+\omega)}e^{-kH}/\left(H-\frac{1+\omega}{k}\right)$$

i.e. $$kH=(1+\omega)(1+e^{-kH}) \tag{18}$$

Let $\delta=H/L$ *namely the wave steepness, equation* (18) *is altered to be*

$$1+\omega=\frac{2\pi\delta}{1+e^{-2\pi\delta}}=\theta \tag{19}$$

and

$$\psi(x,y)=cy-\frac{c\theta}{ke^{\theta}}e^{ky}\cos kx \tag{20}$$

$$\eta(x)=\frac{\theta}{ke^{\theta}}e^{k\eta}\cos kx \tag{21}$$

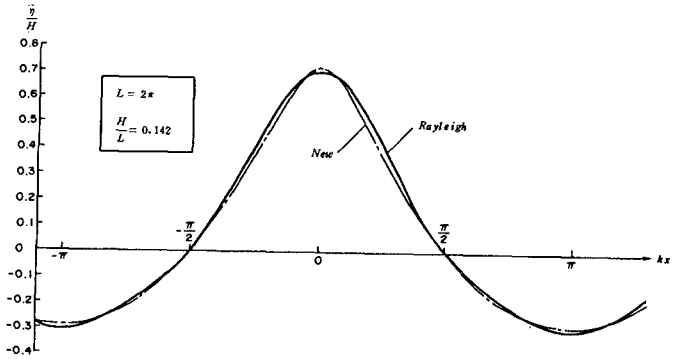
are oblained. Equation (21) *is an implicit equation, however, it is to be solved by Newton—Raphson's method promptly through computer.*

The curve is to be depicted for a critical case i.e. $\delta=0.142$ *and compared with Rayleigh's solution.*

Wave celerity c is worked out by following procedure.

In steady flow, $(\partial\phi/\partial t)$ *vanishes and* $Q(t)$ *becomes constant Q in dynamic boundary condition of free surface. Subslitute the new wave profile equation* (21) *to equation* (2)

$$\frac{\theta}{ke^{\theta}}e^{k\eta}\cos kx+\frac{1}{2g}\left\{c^2-2c^2\frac{\theta}{e^{\theta}}e^{k\eta}\cos kx+\frac{c^2\theta^2}{e^{2\theta}}e^{2k\eta}\right\}=\frac{Q}{g}=h$$



Wave profile in deep water

Put $e^{2k\eta} \doteqdot 1 + 2k\eta = 1 + \frac{2\theta}{e^{\theta}} e^{k\eta} \cos kx$, *this equation becomes*

$$\left(c^2 + \frac{c^2\theta^2}{e^{2\theta}} \right) + \frac{2\theta}{e^{\theta}} \left(\frac{g}{k} - c^2 + \frac{c^2\theta^2}{e^{2\theta}} \right) e^{k\eta} \cos kx = Q \qquad (22)$$

Q is a constant, the coefficient of variable term $e^{k\eta} \cos kx$ *must be zero. So we can get*

$$C^2 = \frac{g}{k} \left(1 - \frac{\theta^2}{e^{2\theta}} \right)^{-1} = \frac{g}{k} \left[1 - \left(\frac{2\pi\delta}{1 + e^{-2\pi\delta}} \right)^2 / exp \left(\frac{4\pi\delta}{1 + e^{-2\pi\delta}} \right) \right]^{-1} \qquad (23)$$

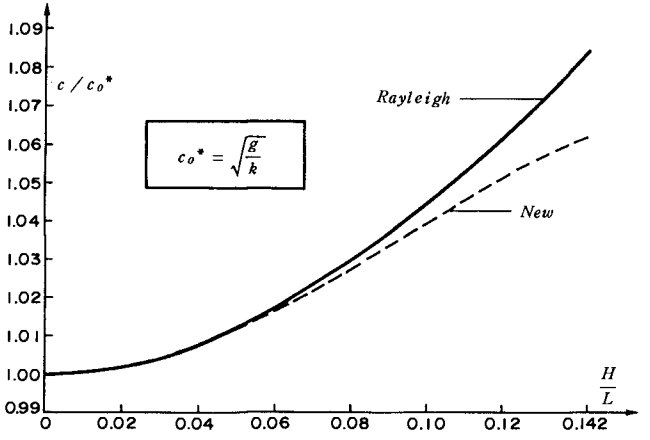
According to this equation, wave celerity increases with wave steepness exponentially in stead of linearly with the square of wave steepness in Rayleigh's theory, however, while δ *is small*

$$(c^2)_{\delta\to 0} = \frac{g}{k}\{\,1+(\frac{2\pi\delta}{1+e^{-2\pi\delta}})^2 / exp\,(\frac{4\pi\delta}{1+e^{-2\pi\delta}})\,\}$$

$$= \frac{g}{k}\{\,1+k^2\,(\frac{H}{2})^2\,\} \qquad (24)$$

Wave celerity calculated by the two theories are almost identical.

Following diagram shows the comparison of the wave celerities calculated by these two theories.



Comparison of wave celerity in deep water

The mean level of wave profile is worked out by the following equation

$$\xi = \frac{1}{L}\int_0^L \eta\,dx$$

Let $\eta \doteqdot \frac{\theta}{ke^{\theta}}(\,1+k\eta\,)\cos kx$

$$\eta = \frac{A\cos kx}{1-Ak\cos kx} \qquad A = \frac{\theta}{ke^{\theta}}$$

Substitute this expression to the integration

$$\xi = \frac{1}{k}\left[\frac{1}{\sqrt{1-A^2k^2}} - 1\right]$$

$$\xi = \frac{1}{k}\left[\frac{1}{\sqrt{1-\theta^2/e^{2\theta}}} - 1\right] \doteqdot \frac{1}{2k}\left[\frac{\left(\frac{2\pi\delta}{1+e^{-2\pi\delta}}\right)^2}{exp\left(\frac{4\pi\delta}{1+e^{-2\pi\delta}}\right)}\right] \qquad (25)$$

While the steepness is small i.e. $\delta \to 0$

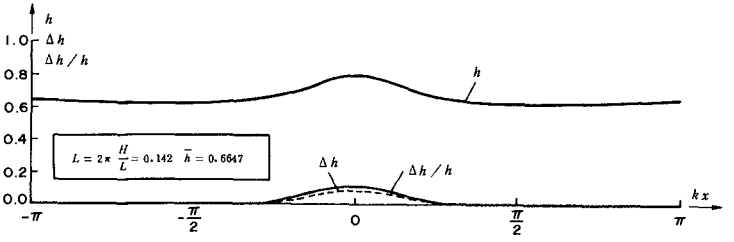
$$\xi = \frac{4\pi^2\delta^2}{2k} = \frac{\pi H^2}{L}$$

coinciding to Rayleigh's theory.

To check the relative error, substitute the value of c i.e. equation (23) *to the following equation to calculate the difference of total water head due to adopting* $1+2k\eta$ *in stead of* $e^{2k\eta}$

$$\Delta h = \frac{1}{2g}\frac{e^2\theta^2}{e^{2\theta}}\left(e^{2k\eta} - 1 - 2k\eta\right) \qquad (26)$$

The result is shown in following figure, the relative error of total water head in the case of extreme heigh wave is about 10 %.



Relative accuracy in deep water wave

ENW EQUATION IN FINITE WATER DEPTH

Set $n = 1$ *in equations of number* (6)

$$\phi(x, y) = cy - C_1 e^{-kd}\left[e^{k(d+y)} - e^{-k(d+y)} \right] \cos kx \tag{27}$$

$$\eta(x) = \frac{C_1}{c} e^{-kd}\left[e^{k(d+\eta)} - e^{-k(d+\eta)} \right] \cos kx \tag{28}$$

$$\eta_1 = \eta_{max} = \frac{C_1}{c} e^{-kd}\left[e^{k(d+\eta_1)} - e^{-k(d+\eta_1)} \right] \tag{29}$$

$$\eta_2 = \eta_{min} = \frac{-C_1}{c} e^{-kd}\left[e^{k(d+\eta_2)} - e^{-k(d+\eta_2)} \right] \tag{30}$$

Parameter ω *is also invoked*

$$1 + \omega = \frac{C_1}{c} e^{-kd} \cdot k\left[e^{k(d+\eta_1)} + e^{-k(d+\eta_1)} \right] \tag{31}$$

$$0 \leq 1 + \omega \leq 1$$

From equation (29)

$$(1+\omega) / k\left[e^{k(d+\eta_1)} + e^{-k(d+\eta_1)} \right] = \frac{C_1}{c} e^{-kd}$$

$$= \eta_1 / \left[e^{k(d+\eta_1)} - e^{-k(d+\eta_1)} \right]$$

$$1 + \omega = k\eta_1 \coth(d + \eta_1) \tag{32}$$

is abtained.

From the following relationship and equation (31)

$$k(\eta_1 + d) = \tanh^{-1}\left(\frac{\eta_1}{1+\omega}\right) = \frac{1}{2} \ell n \frac{(1+\omega) + k\eta_1}{(1+\omega) - k\eta_1} \tag{33}$$

$$(1+\omega) c / k = C_1 e^{-kd}\left[\sqrt{\frac{1+\omega+k\eta_1}{1+\omega-k\eta_1}} + \sqrt{\frac{1+\omega-k\eta_1}{1+\omega+k\eta_1}} \right]$$

C_1 *is found to be*

$$C_1 = \frac{c}{k} e^{kd} \frac{\sqrt{(1+\omega)^2 - k^2\eta^2}}{2} \tag{34}$$

From equation (32)

$$1-(k^2\eta_1^2)/(1+\omega)^2=1-tanh^2k(d+\eta_1)=seeh^2k(d+\eta_1)$$

$$\sqrt{(1+\omega)^2-k^2\eta_1{}^2}=(1+\omega)\,sech\,k(d+\eta_1) \tag{35}$$

Conseqently

$$\phi(x,y)=cy-c\eta_1\frac{sinh\,k(d+y)}{sinh\,k(d+\eta_1)}\,cos\,kx \tag{36}$$

$$\eta(x)=\eta_1\frac{sinh\,k(d+\eta)}{sinh\,k(d+\eta_1)}\,cos\,kx \tag{37}$$

η_1 *should be expressed by wave height, length and water depth. From equations* (30) (34) *and* (35)

$$-\eta_2=H-\eta_1=\frac{\sqrt{(1+\omega)^2-k^2\eta_1{}^2}}{2k}\left[e^{k(d+\eta_1-H)}-e^{-k(d+\eta_1-H)}\right]$$

$$=\frac{(1+\omega)}{2k}\,sech\,k(d+\eta_1)\left[\frac{e^{k(d+\eta_1)}}{2e^{kH}}-\frac{e^{kH}\cdot e^{-k(d+\eta_1)}}{2}\right] \tag{38}$$

Substitute (33) *to* (38)

$$H-\eta_1=\frac{\sqrt{(1+\omega)^2-k^2\eta_1{}^2}}{2k}\left[\frac{\sqrt{(1+\omega)+k\eta_1}}{e^{kH}\sqrt{(1+\omega)-k\eta_1}}-\frac{e^{kH}\sqrt{(1+\omega)-k\eta_1}}{\sqrt{(1+\omega)+k\eta_1}}\right]$$

$$=\frac{1}{2k}\left[\frac{(1+\omega)(1-e^{2kH})+k\eta_1(1+e^{2kH})}{e^{kH}}\right]$$

$$=\frac{1}{k}\left[k\eta_1\cosh kH-(1+\omega)\sinh kH\right]$$

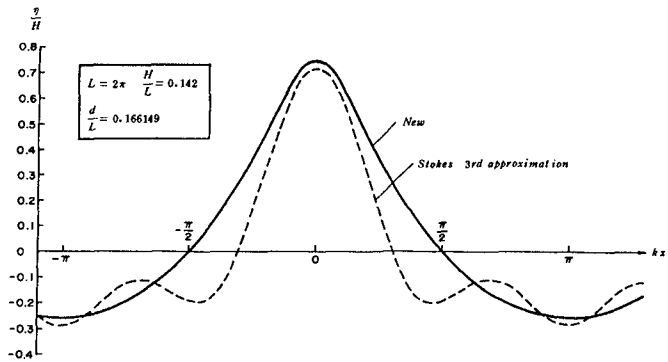
From equation (32)

$$kH=k\eta_1\left[(1+\cosh kH)-coth\,k(d+\eta_1)\sinh kH\right] \tag{39}$$

or

$$\delta = \frac{H}{L} = \frac{\eta_1}{L} \left[\left(1 + \cosh 2\pi\delta \right) - \coth k(d+\eta_1) \sinh 2\pi\delta \right] \qquad (40)$$

η_1 can also be computed by Newton – Raphson's method, then the stream function and wave profile are to be worked out, The curve of the new theory is shown in following figure, it is much reasonable in comparison with Stokes 3rd approximate curve.



***Wave profile** in finite water depth*

The wave celerity can be calculated by adopting the same method in deep water. Substitute equation (37) to the dynamic boundary condition of free surface,

$$\frac{\eta_1 \sinh k(d+\eta)}{\sinh k(d+\eta_1)} \cos kx + \frac{1}{2g} \left\{ c^2 - 2c^2 k\eta_1 \frac{\cosh k(d+\eta)}{\sinh k(d+\eta_1)} \cos kx \right.$$
$$\left. + c^2 k^2 \eta_1{}^2 \frac{\sinh^2 k(d+\eta) + \cos^2 kx}{\sinh^2 k(d+\eta_1)} \right\} = \frac{Q}{g} = h \qquad (41)$$

Put the coefficient of variable term to be zero, the wave celerity is worked out to be

$$c^2 = \frac{g}{k} \tanh kd / \{ 1 - k^2\eta_1^2 \frac{\sinh^2 kd}{\sinh^2 k(d+\eta_1)} \} \tag{42}$$

For theoretical consistancy, wave celerity formulas in deep and shallow water must be continuous. Set $d \to \infty$ *in equation* (42)

$$(c^2)_{d\to\infty} = \frac{g}{k} [1 - (k^2\eta_1^2 / e^{2k\eta_1})]^{-1}$$

Substitute equations (13) *and* (19) *to this equation*

$$(c^2)_{d\to\infty} = \frac{g}{k} [1 - \frac{(\frac{2\pi\delta}{1+e^{-2\pi\delta}})^2}{exp(\frac{4\pi\delta}{1+e^{-2\pi\delta}})}]^{-1} \tag{43}$$

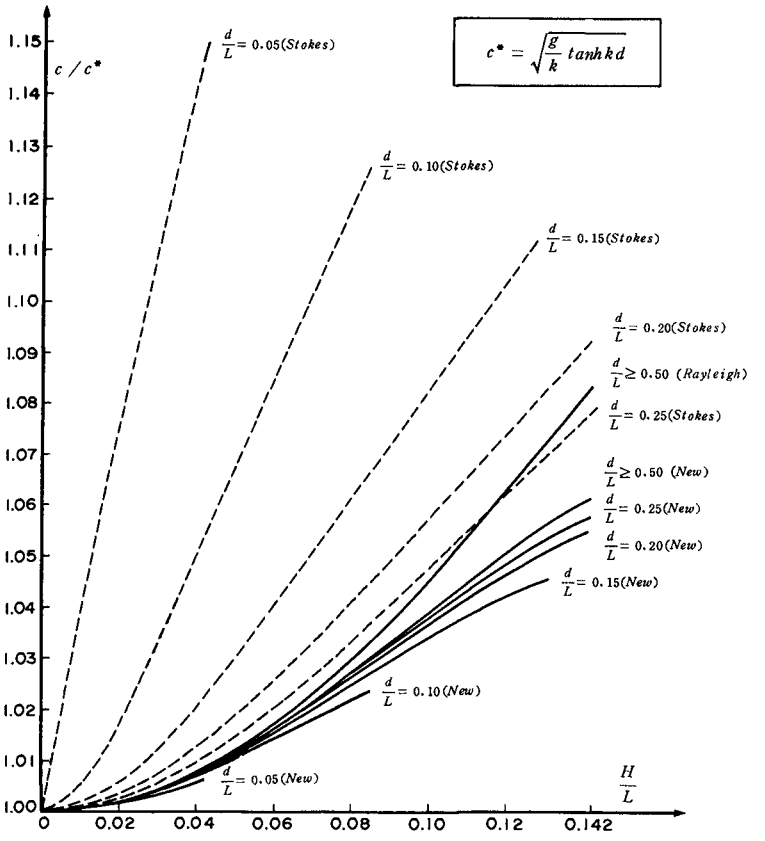
The reality shows that the new theory is superior to the Rayleigh's and Stokes.

The wave celerities in various relative depth are shown in following figure.

In this figure we also see lhat the new theory is better than Stokes which is unrcasonable that the wave celerities increase more rapidly in shallow water area.

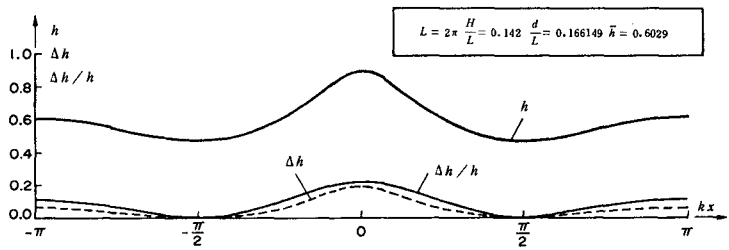
The relative accuracy of water head is estimated as follows.

$$\Delta h = \frac{1}{2g} \{ -2c^2k\eta_1 \frac{\cosh k(d+\eta) - \cosh kd}{\sinh k(d+\eta_1)} \cos kx + c^2k^2\eta_1^2 \cdot \frac{\sinh^2 k(d+\eta) - \sinh^2 kd - k\eta \sinh 2kd + \cos^2 kx}{\sinh^2 k(d+\eta_1)} \}$$
$$+ \eta_1 \frac{\sinh k(d+\eta) - \sinh kd}{\sinh k(d+\eta_1)} \cos kx \tag{44}$$



Comparison of wave celerity in finite water depth

The result of calculation is depicted in the following diagram, for very high waves, the relative errors are up to 20 %.



Relative accuracy in finite water depth

The mean level in the waves in this case is to be calculated as follows.

$$\xi = \frac{1}{L}\int_0^L \eta\, dx = \frac{2}{L}\int_0^{L/2} \eta\, dx$$

Equation (37) *can be expressed approximately by* :

$$\eta = \frac{\eta_1 \sinh k(d+\eta)}{\sinh k(d+\eta_1)} \cos kx$$

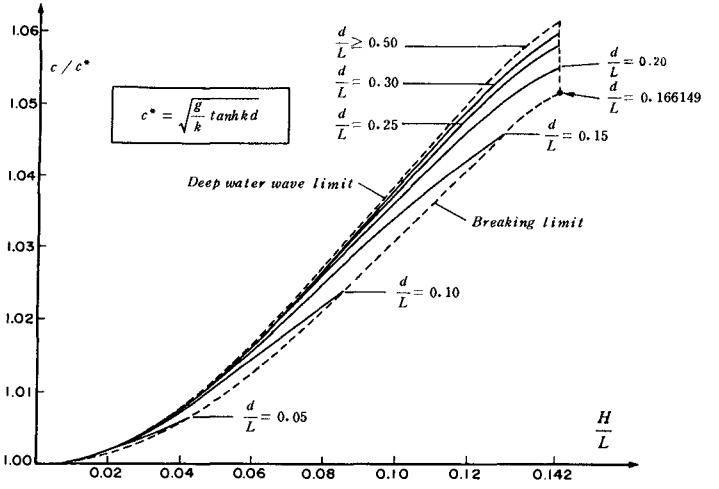
$$\doteqdot \frac{\eta_1 \sinh kd\, e^{k\eta}}{\sinh k(d+\eta_1)} \cos kx \doteqdot B(1 + k\eta)\cos kx$$

$$\eta \doteqdot \frac{B\cos kx}{1 - Bk\cos kx} \qquad B = \frac{\eta_1 \sinh kd}{\sinh k(d+\eta_1)}$$

$$\xi = \frac{2}{L}\int_0^{L/2} \frac{B\cos kx}{1 - Bk\cos kx}\, dx = \frac{1}{k}\left[\frac{1}{\sqrt{1 - B^2k^2}} - 1\right] \qquad (45)$$

It can be proved thad while $d \to \infty$, $B = A = \theta / ke^{\theta}$

Finally the significant range of this theory is shown in the next figure.



Significant range of the new wave theory

CONCLUSION

1. *The new wave profile equation describes the wave motion by an implicit function, can be seid to be an exact solution because no approximation approach is adopted.*
2. *In the procedure of calculating wave celerity, some approximate expressions are used, so that some errors will be acknowledged in total water head calculation. However, the wave celerity equation has been proved to be continuous, such a fact shows the new theory is superior to the Rayleigh's and Stoke's.*
3. *The relationship between wave celerity and relative depth d/L in Stokes theory is unreasonable. It is more consistant and*

will coincide with the reality in the new theory.

4. *In the era of electronic computer, the new wave profile equation is suggested to be adopted in practical use after some complement such as the exact position of x — axis is made.*

Engineering Approach to Nonlinear Wave Shoaling

James Walker[1], Ph.D., P.E., M. ASCE
John Headland[2], AM. ASCE

ABSTRACT

Determination of a design wave height at a coastal structure requires calculation of a shoaling coefficient or determination of the maximum probable breaking wave height at the point of interest. In shallow water over a sloping bottom, low steepness waves are not accurately predicted by linear shoaling coefficients. Empirical breaking indices are inconsistent with both linear and nonlinear wave theories. Nevertheless, the coastal engineer must select a design wave in order to responsibly design the structure. A graphical procedure is presented herein to relate the equivalent deepwater wave to a breaking wave as it transitions into shoaling water. The procedure provides the coastal engineer with a more consistent understanding of the shoaling process. The results furthermore identify regions of relative depth and steepness where discrepancies arise when using linear shoaling coefficients that may significantly alter engineering design and laboratory studies.

INTRODUCTION

The purpose of this paper is to present a shoaling coefficient that can be used by coastal engineers to better describe the shoaling of finite height waves over sloping bottoms. The linear shoaling coefficient developed from Airy theory in conjunction with a $H_b = 0.78d$ breaking criterion predicts a wave height at the breaking point that is considerably lower than the breaker height predicted by empirical breaking indices commonly used in coastal engineering practice. Several investigators, cited later, have presented nonlinear shoaling curves to describe the phenomena, but they are not consistent with empirical breaker indices over sloping bottoms. These theories tend to predict greater wave heights at a given relative depth than suggested by empirical breaking coefficients. The coastal engineer requires a shoaling curve that is consistent with these commonly accepted breaking indices. This paper utilizes breaker indices as upper limits and the characteristics of theoretical and experimental nonlinear shoaling curves are used to develop a transition of wave height from deep to shallow water.

The problem is illustrated by the following example. Figure 1 shows a typical beach profile over which a long jetty is to be constructed. The design wave at various stations along the jetty is required to determine the armor unit size. For illustrative

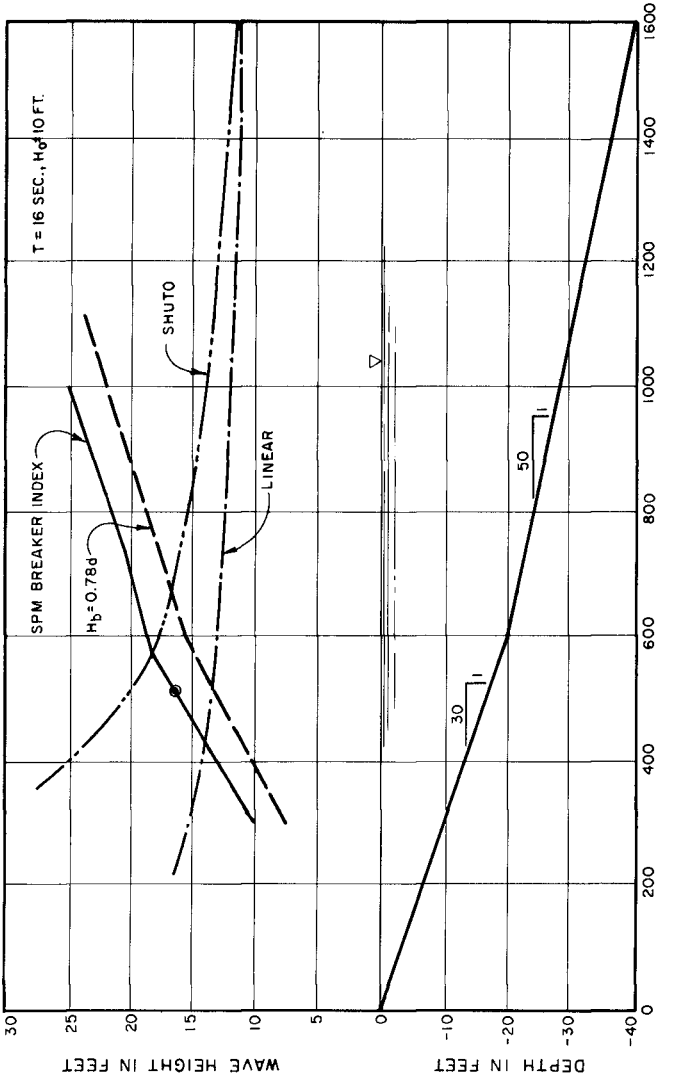

Figure 1. Example Problem for Nonlinear Shoaling.

purposes, a 16-second period is used with a 10-foot deepwater wave height. The dot-dash line represents the linear shoaling curve as determined by Airy theory. The circle represents the breaking height and depth as determined by empirical curves presented in Shore Protection Manual (1977). These data were developed by Goda (1970) and Weggel (1972).

The linear shoaling curve falls significantly below the empirically determined breaker point. Design wave heights shoreward of the breaker point can be determined by the limiting height criteria, but no consistent method exists to determine wave heights seaward of the breaker point. The linear shoaling curve is inconsistant with the breaker data. The theoretical nonlinear shoaling curve of Shuto (1974) is also plotted in figure 1. This curve predicts shoaling at a rate that exceeds the breaker point. While such a curve may be conservative, a shoaling curve more consistent with the breaker index is required for design applications.

EMPIRICAL BREAKER CURVES

Methods to determine breaker height and breaker depth over a given bottom slope for a given deepwater wave steepness are presented in Shore Protection Manual (1977). These procedures are widely used by coastal engineers. The work in this paper assumes these procedures to be representative of the best available data for use in engineering design.

Figure 2 is a graph for predicting breaking wave indices H_b/H'_o based on the work of Goda (1970). Goda reworked data of Iverson (1953) by correcting for side-wall friction and normalized this data using the nonlinear shoaling calculation of LeMehaute and Webb (1964) in deeper water and Iwagaki's (1968) procedure for more shallow regions. Figure 3 presents a graph which gives the ratio of breaker depth to height, d_b/H_b, based on the work of Weggel (1972). In his study Weggel consolidated breaking wave characteristics reported by a relatively large number of investigators.

The above two procedures account for the effects of bottom slope and implicitly include nonlinear shoaling effects. The procedures are widely accepted for use with monochromatic waves and are believed to provide reliable, conservative, estimates of breaking wave characteristics.

The empirical breaker data of figures 2 and 3 can be plotted as limit points in the form of a shoaling graph. The shoaling coefficient is defined as;

$$K_s = H/H'_o \qquad (1)$$

where H is the local wave height, and
H'_o is the equivalent deep water wave height.

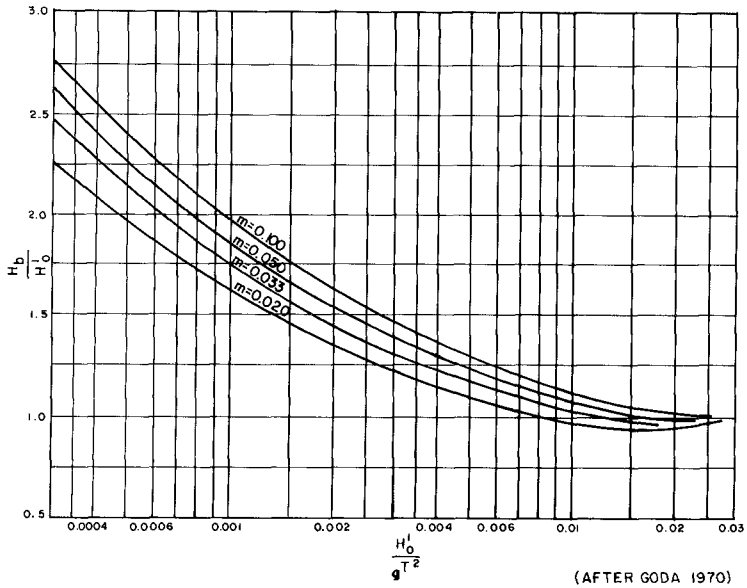

Figure 2. Breaker Height Index.

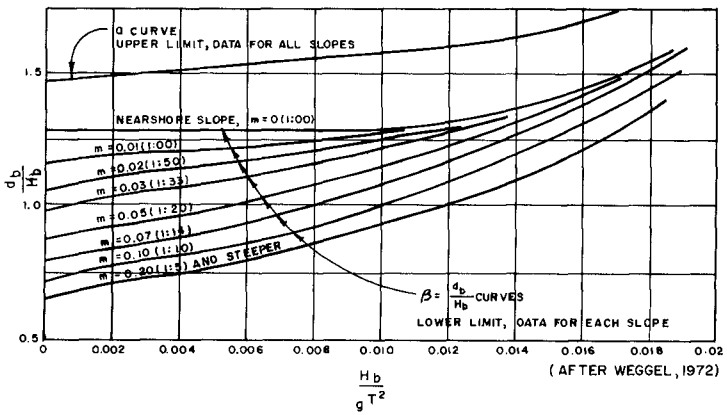

Figure 3. Relative Breaker Depth.

For linear theory, K_s, plotted in figure 4, is a function of relative depth, d/L_o, where d is the water depth, and L_o is the deep water wave length. For non-linear waves, K_s is also a function of bottom slope, m, and H'_o/L_o. The limiting breaker height, H_b/H'_o, determined from figure 2, can be used to find H_b/L_o for a given m and H'_o/L_o

$$H_b/L_o = (H_b/H'_o)(H'_o/L_o) \tag{2}$$

where H_b is the breaker height.

Finally, the relative depth can be determined using H_b/L_o found by equation (1) and d_b/H_b from figure 3.

$$d_b/L_o = (d_b/H_b)(H_b/L_o) \tag{3}$$

Results of these calculations are presented in Table 1.

H_b/H'_o is plotted in figure 4 as a function of d_b/L_o for $.001 \leq H'_o/L_o \leq .14$ and $.02 \leq m \leq .1$. Isolines of equal H'_o/L_o connect through the limit waves for the various slopes, m. Isolines of m were drawn through the data and these are shown in figure 5. It is noted that for the lowest value of wave steepness the m = .1 and m = .05 slopes tend to converge. The reason for this is not clear, but could be attributed to wave reflection, data reduction methods, or laboratory scale effects. The data points plotted in figure 4 represent the maximum value of a shoaled wave height over a sloping bottom, m, for a given H'_o/L_o.

THEORETICAL AND EMPIRICAL SHOALING CURVES

The purpose of this paper is to develop a shoaling curve that is consistent with the limit breaking points shown in figure 4. Several investigators have used various wave theories to develop nonlinear shoaling curves. LeMehaute and Wang (1980) present a discussion of nonlinear shoaling and determined that no single theory can accurately account for wave shoaling from deep to shallow water. Sakai and Battjes (1980) present an excellent comparative review of several theoretical studies and present a shoaling curve based on the work of of Cokelet (1977). The Cokelet shoaling curve is compared with the empirical breaking data in figure 6. The third order Stokes curve of LeMehaute and Webb (1964); the hyperbolic curve of Iwagaki (1968); cnoidal curve of Svendsen and Brink-Kjaer (1972), Shuto (1974), and Yamaguchi and Tsuchiya (1976) all have a slightly lower shoaling rate compared with Cokelet theory, but from a practical standpoint are in very close agreement. Figures 7 and 8 compare the nonlinear shoaling curves of Svendsen and Brink-Kjaer, and Shuto, respectively, to the empirical breaking data. The cnoidal shoaling theory of Svendsen and Brink-Kjaer (1972) is based on

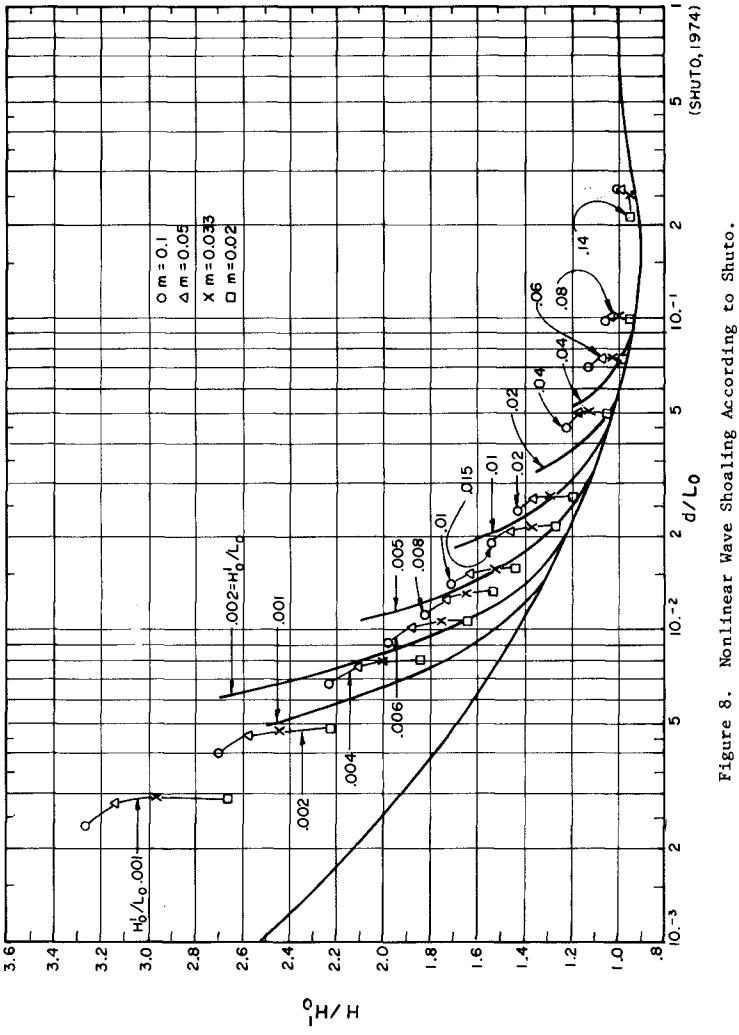

Figure 8. Nonlinear Wave Shoaling According to Shuto.

matching the wave energy flux according to cnoidal and sinusoidal wave theories at a relative depth $d/L_o = .1$. Experimental work done by Svendsen and Buhr-Hansen (1977) indicated that cnoidal wave theory more closely predicted their experimental results if wave height instead of wave energy is matched at $d/L_o = .1$. The effect of this change is to shift the cnoidal steepness curves, shown in figure 7, slightly to the right and upwards. Shifting the isolines of steepness towards the right moves them farther from the empirical breaker indices. Cnoidal wave theory predicts the data of Svendsen and Buhr-Hansen (1977) well but does not predict the breaker index data used to develop figures 2 and 3. This may be attributed to the free second harmonic waves generated by the sinusoidal motion of a piston-wave-generator, which were eliminated in Svendsen and Buhr-Hansen experiments. Sakai and Battjes found that the effect of finite height wave theory on deep water wave length has a relatively minor effect and that all of the above theories present shoaling curves that are in reasonably good agreement except near the breaking point.

Figures 6 through 8 clearly indicate that the above nonlinear approaches predict a significantly higher rate of shoaling than indicated by the experimental breaking limits. This indicate's that either a lower shoaling rate may exist or the emperical breaker indices are in error.

A theoretical nonlinear shoaling theory which accounts for beach slope was developed by Iwagaki and Sakai (1972). Iwagaki and Sakai presented theoretical nonlinear shoaling curves for several values of bottom slope, but limited these curves to values of $.006 \leq d/Lo \leq 0.0157$ and values of $H_o/L_o \leq 0.004$. Figures 9 and 10 compare the theoretical curves of Iwagaki and Sakai to the empirical breaker limits for values of $H_o/L_o = 0.001$ and 0.002 respectively. The qualitative agreement of these curves with the breaker limits is encouraging, however the limited range of conditions preclude their universal use.

Hydraulic model studies of wave shoaling have been conducted by Wiegel (1950), Iverson (1951), Ippen and Eagleson (1950), Eagleson (1956), Iwagaki (1968), Iwagaki and Sakai (1972), Walker (1974), Svendsen and Buhr-Hansen (1977), and Flick (1978). The more recent studies have been used primarily to verify various nonlinear shoaling curves cited in the previous section. The general result has been that the theories are comparable to the experimental data, except they tend to over predict shoaling near the breaker zone. The shoaling curve of Walker (1974) are compared with the limit breaking data in figure 11 for low values of wave steepness. This investigation shows a closer fit to the breaker limits than theory for low d/L_o.

SHOALING DIAGRAM

The form of the H_o/L_o curves suggests that a unique nonlinear shoaling curve exists for each beach slope. This is supported by the theoretical work of Iwagaki and Sakai (1972),

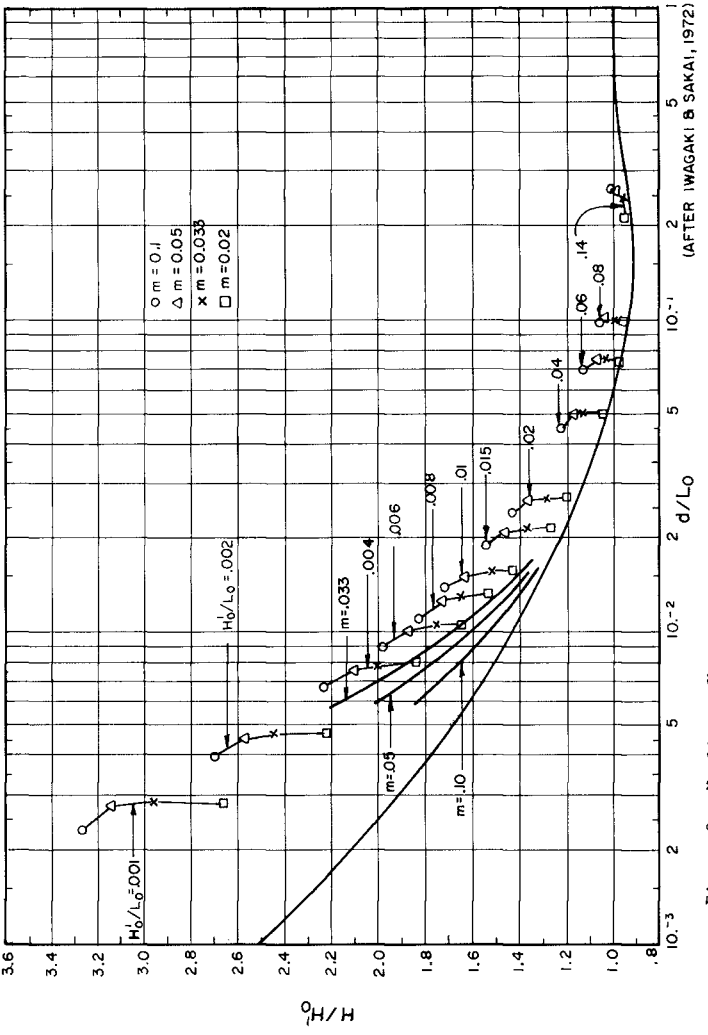

Figure 9. Nonlinear Shoaling According to Iwagaki and Sakai for H'_o/L_o = .001 and Several Values of Bottom Slope.

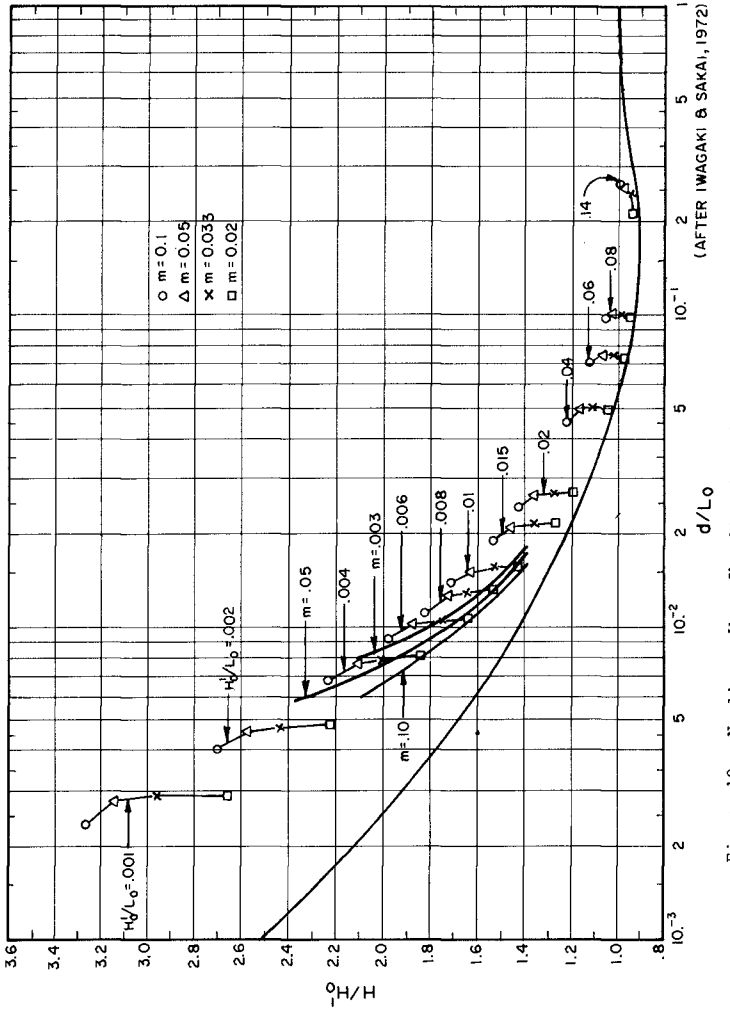

Figure 10. Nonlinear Wave Shoaling According to Iwagaki and Sakai for H_o'/L_o = .002 and Several Values of Bottom Slope.

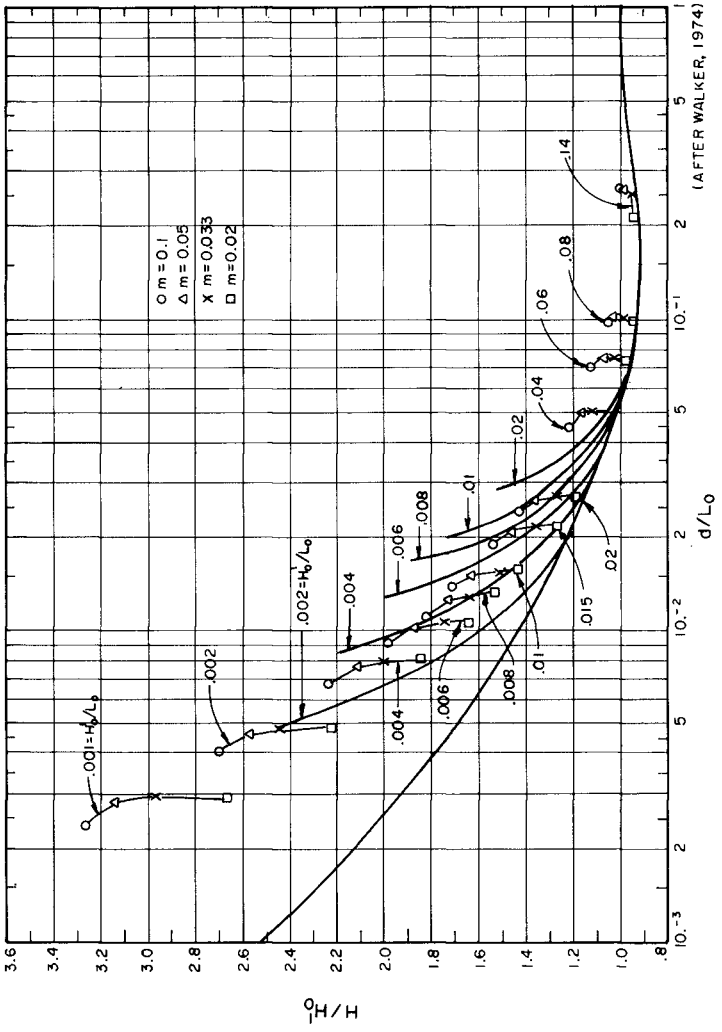

Figure 11. Nonlinear Wave Shoaling from Experimental Data.

but they only give curves for a limited range of values. The approach taken in this report was to draw isolines of steepness weighted towards m = .033 slope. This was done for several reasons. First m = .033 is found often in nature. Secondly, while the steepness curves were drawn to conform to the m = .033 slope, in most cases the curves also intersected, or nearly intersected, the m =.05 and m = .1 endpoints.

The isolines of wave steepness were drawn weighted towards the m = .033 endpoints starting from the linear curve at the point defined by Shuto (1974) were he found that linear shoaling no longer applies;

$$\frac{L_o H}{d^2} \sim \frac{30}{2\pi} \qquad (4)$$

The resulting curves are shown in figure 12. While constructing these isolines of wave steepness, each line was compared to the theoretical curves of Cokelet, Shuto and Svendsen and BrinkKjaer (cnoidal) and the experimental curve of Walker. The theoretical curves predict a faster rate of shoaling than the empirical curve. Furthermore, the H_o/L_o curves are shifted towards the right hand side of the diagram (higher d/L_o values). In general the nonlinear shoaling curve based on Cokelet's theory predicts the highest rate of shoaling and is farthest from the empirical data. The experimental isolines of H_o/L_o = .002, and .004 given by Walker are closest to the breaker data. The H_o/L_o = .006 line given by cnoidal theory is closest to the empirical curve although the cnoidal curve still lies to the right of the empirical curve. The empirical curve for H_o/L_o = .001 is shifted considerably towards the left from any of the curves. The empirical H_o/L_o = .02 curve is very well predicted by the cnoidal theory except in the region where they intersect the linear shoaling curve. The empirical H_o/L_o = .04 appears to be an average of the curves given by cnoidal theory and by Shuto. For higher values of H_o/L_o the only curves for comparison to the empirical curves are those given by Cokelet. All of these curves lie considerably to the right of the empirical curves and exhibit a different type of assymptotic behavior to the linear curve.

Theoretically, Iwagaki and Sakai (1972) found that the effect of beach slope on shoaling is that the rate of shoaling is lower on steeper slopes than flatter slopes. However the experimental data indicate that waves reach higher breaking values for steeper slopes. Therefore the effect of weighting the steepness lines towards the m = .033 endpoint is to overpredict wave shoaling for the m = .05, and m = .1 slopes and underpredict the wave shoaling for the m = .02 slope. There are insufficient theoretical and experimental results to estimate the error involved in quantitative terms. However, the error appears to decrease for higher wave steepness values. In terms of predicting peak shoaling values (i.e. shoaling coefficients at breaking)

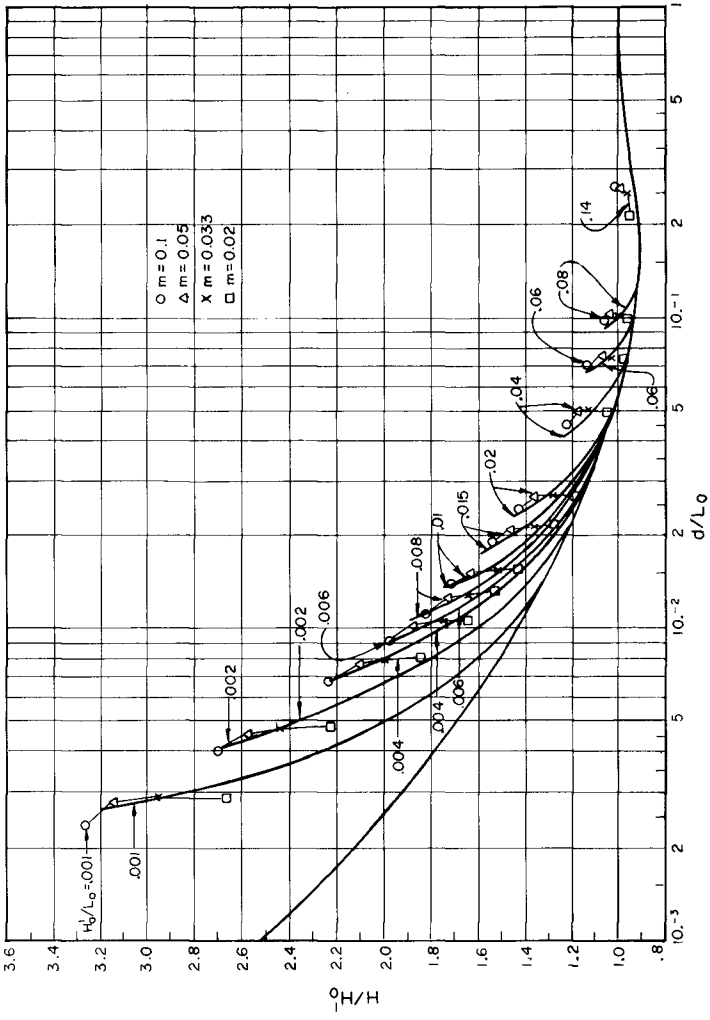

Figure 12. Isolines of H'_o/L_o.

weighting the curve towards m = .033 has the effect of underpredicting the breaker heights for the m =.02 slope, but predicts the breaker heights well for the other slopes. Again the largest error occurs for the lowest steepness values. Despite the fact that there is some error involved for the m = .02 it represents a better fit than linear theory. For more accurate estimates of breaker height and depth, one should use figures 2 and 3.

Superposing figures 5 and 12 results in a diagram for estimating nonlinear wave shoaling over a sloped beach. This curve is shown in figure 13. The linear curve is used for a flat beach (m = 0). This diagram is reasonably consistent with empirical breaking data now widely used for design purposes.

CONCLUSIONS

A nonlinear shoaling curve which provides the coastal engineer a reasonable means of determining wave heights over a sloped bottom seaward of breaking has been developed. The curve indicates that deviations from linear theory are relatively small for values of relative depth, $d/L_o > .05$. Deviations from linear theory reach a factor of 2 or more for $d/L_o > .003$. The curve indicates that wave shoaling is mildly dependent on beach slopes but insufficient data are available to quantify this effect.

The paper outlines the inconsistencies of various nonlinear wave theories compared with commonly used breaker indices. It is recommended that further experimental studies be conducted carefully to avoid adverse tank effects and that these studies be carried out over a range of beach slopes and wave steepnesses to verify nonlinear wave shoaling.

It is further recommended that design curves for wave runup, overtopping and similar phenonenom which use a linear shoaling coefficient to normalize wave height data be critically reviewed. As indicated in this paper use of the linear shoaling coefficient may lead to serious inconsistencies and unconservative designs.

Finally it is noted that the shoaling procedures in this paper apply to monochromatic waves.

WAVE REFLECTION FROM UNDULATING SEABED TOPOGRAPHY

by

A D HEATHERSHAW

Institute of Oceanographic Sciences, Crossway
Taunton, TA1 2DW, UK.

ABSTRACT

The results of experiments are described which show that surface waves may experience a resonant interaction with undulations on the seabed. This interaction manifests itself in a strong reflection of incident wave energy when the wavelength of the bottom undulation is about half that of the surface wave. It is shown that such a mechanism might enable a region of undulating seabed topography (eg sand bars or sand-waves) to extend in an up-wave direction, into a region of otherwise plane bed.

INTRODUCTION

The interaction of surface water waves with undulating seabed topography is a problem of fundamental importance to coastal engineers. While it has been shown, that, in the nearshore zone, quite complex patterns of wave motion (eg edge waves) may lead to beach cusps, shore parallel bars and even crescentic shore welded sand bars (Holman and Bowen, 1982), the problem that is considered in this study is how waves are likely to interact with a pre-existing pattern of regular undulations on the seabed. Such a pattern may consist of shore parallel bars formed by plane reflections of low amplitude swell waves from a beach, leading to standing waves of the type observed by Suhayda (1974). Alternatively, standing waves may occur seaward of the surf zone as a result of the time varying breakpoint forcing mechanism described by Symonds et al (1982). In this case a forced wave having incident wave group periodicity is radiated seaward from the breaker zone. Such a wave, interacting with incoming infragravity waves having periods in the range 30-300s, might lead to standing waves and consequently to bar formation. This latter mechanism seems to provide the most likely means of generating the multiple shore parallel bars which have been observed by Short (1975) and which would require wave periods of the order 100s.

A pre-existing pattern of bottom undulations might also be formed by tidally generated features such as sand waves (eg Langhorne, 1982) or sand ridges lying transverse to the general direction of wave propa-

gation and, as such, may occur well offshore away from the coastline.

In general, surface wave/seabed interactions may occur in any depth of water where the waves are able to "feel the bottom". It follows that such interactions may occur for a wide range of surface water wavelengths and bedform length scales.

Recent theoretical work Davies, 1980, 1982, has shown that large amounts of wave energy may be reflected as a result of resonant interactions between surface water waves and bottom undulations, the wavelengths of which lie in the ratio 2:1 approximately.

Davies (1980, 1982) has used linear perturbation theory to show that, to a first approximation, wave reflection from a finite number of submerged sinusoidal bars, having small amplitude and on an otherwise plane bed, is given by the wave reflection coefficient

$$K_r = \frac{a_r}{a_i} = \frac{2bk}{\{2kh + \sinh(2kh)\}} \cdot \left[\left(\frac{2k}{\ell}\right) \left| \frac{\sin\left(\frac{2k}{\ell}.m\pi\right)}{\left(\frac{2k}{\ell}\right)^2 - 1} \right| \right] \qquad (1)$$

where a_r and a_i are the reflected and incident wave amplitudes respectively, well away from the region of bedforms, b is the bar amplitude, h is the water depth, m is the number of bars and k and ℓ are the free surface and bar wavenumbers. Here $k = 2\pi/L$ and $\ell = \frac{2\pi}{L_b}$, where L and L_b are surface and bar wavelengths respectively. It should be noted that, strictly speaking, this is a two-dimensional formulation of the problem requiring long crested surface waves collinear with the bottom undulations.

Equation (1) illustrates that for a given number of bars (m), the wave reflection coefficient is oscillatory in $2k/\ell$, that is the quotient of twice the surface wavenumber and the bed wavenumber. The reflection coefficient is also resonant in the region $2k/\ell \cong 1$ and, at $2k/\ell = 1$ itself, is proportional to m which suggests that peak reflection coefficients are linearly dependent on the number of bars.

These results were without any detailed experimental proof and this paper describes experiments carried out in a wave tank to examine the nature of resonant interactions between surface waves and simple sinusoidally varying topography. Preliminary aspects of this study have already been described by Heathershaw (1982).

EXPERIMENTAL PROCEDURE

To test Davies' (1980, 1982) theoretical predictions, and in particular Equation (1), detailed measurements of wave reflection from submerged bars were carried out using the 45.72 x .91 x .91 m wave tank facility at the US Army Coastal Engineering Research Center, Fort Belvoir, Virginia, USA. Test sections of 10, 4, 2 and 1 x 1 m wavelength, .05 m amplitude sinusoidal bars were constructed in the tank and set in a false bottom. The barred test sections were

situated approximately mid-way between a hydraulically driven piston type wave generator, at one end of the tank, and a 1:10 slope wave absorbing beach at the other. Water surface elevations were measured using standard parallel-wire resistance type wave gauges and wave reflection coefficients determined using the method of Goda and Suzuki (1976).

Two pairs of gauges and a single gauge were used to make two types of measurement; first, incident and transmitted wave conditions were measured with one gauge pair 5 m on the up-wave side of the bars and the second gauge pair 5 m on the down-wave side. The remaining gauge was positioned midway along the test section. The up-wave gauge pair thus gave information on wave reflection from the bars while the second gauge pair provided data on the transmitted wave heights and the amount of wave energy reflected from the beach. In the second type of measurement two pairs of gauges were moved along the tank in such a way as to give surface elevation data every 0.25 m and to determine how wave reflection varied throughout the tank, first from the barred test section and finally from the beach. The remaining gauge was positioned at the end of the tank at the foot of the beach. These experimental arrangements are illustrated in Fig 1, with further details given in Davies and Heathershaw (1983).

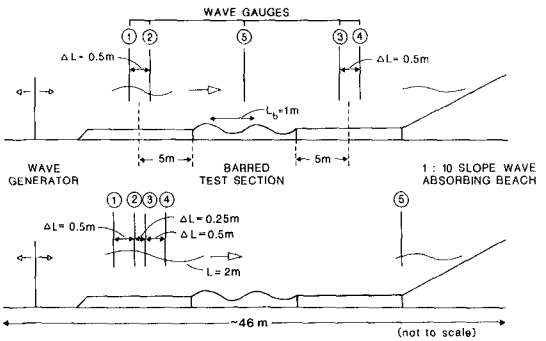

Figure 1 Position of gauges, in relation to barred test section (2 bars only), and wave absorbing beach, for two main types of measurements. Typical values of the wave gauge spacing ΔL are also shown.

With the bar wavelength, L_b, fixed at 1 m, incident surface wavelengths were varied over a range giving $.5<2k/\ell<2.5$, by varying the wave period in steps of .01 s. Thus, good resolution in non-dimensional wavenumber space $2k/\ell$, of the order of .01, enabled detailed investigations to be made of the oscillatory nature of the wave reflection coefficient and of the main resonant interaction peak. These tests were carried out using small amplitude monochromatic waves only. For the results shown here, water depths were varied to give bar amplitude - water depth ratios, b/h, in the range $.08<b/h<.40$.

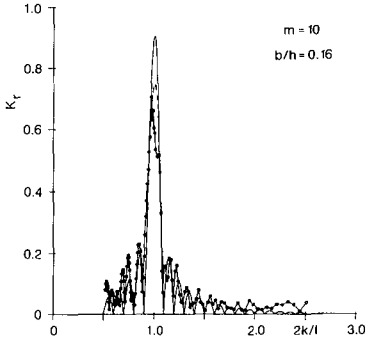

Figure 2a The variation of wave reflection coefficient K_r with the ratio $2k/\ell$ for m = 10 bars and for b/h = .16 (h = 31.3 cm). The broken and solid curves represent corrected and uncorrected theoretical predictions respectively; corrected theoretical predictions assume a linear attenuation of incident wave amplitude across the bar patch and uncorrected predictions assume no attenuation.

RESULTS

For surface water wavelengths approximately twice the bar wavelength, strong resonant interactions were observed leading to large reflection coefficients (in some cases as large as $K_r = .8$) and to dramatic partially standing wave patterns on the up-wave side of the bars. On the down-wave side of the bars the standing wave pattern gives way to progressive waves leaving the test section and travelling towards the wave absorbing beach.

Figure 2 shows the variation of wave reflection coefficient, K_r, with the wavenumber ratio $2k/\ell$ for 10, 4 and 2 bars and bar amplitude/water depth quotients of b/h = .16 and .32, corresponding to depths of h = 31.3 cm and h = 15.6 cm respectively. Also shown are the first order predictions from Davies (1980, 1982) both corrected and uncorrected for the effects of wave attenuation as the incident waves propagate over and are reflected by the bars. A striking feature of

these results is the large resonant interaction peak at $2k/\ell = 1$, and the oscillatory nature of K_r in respect of $2k/\ell$. Figure 2a, for m = 10 bars, shows that the measured reflection coefficients follow the

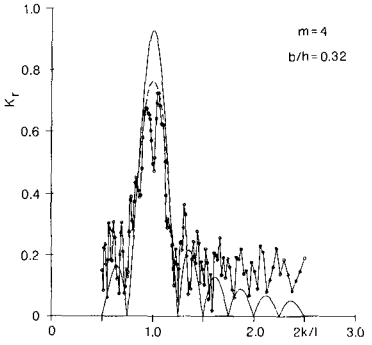

Figure 2b The variation of wave reflection coefficient K_r with the ratio $2k/\ell$ for m = 4 bars and for b/h = .32 (h = 15.6 cm). The broken and solid curves represent corrected and uncorrected theoretical predictions respectively (see Fig 2a).

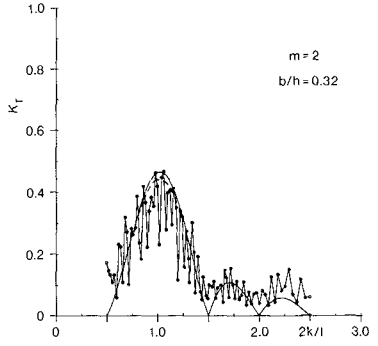

Figure 2c Variation of the wave reflection coefficient K_r with the ratio $2k/\ell$ for m = 2 bars and b/h = .32 (h = 15.6 cm). The broken and solid curves represent corrected and uncorrected theoretical predictions respectively (see Fig 2a).

trend of the theoretical curves closely throughout the resonant peak and on either side of it. Similarly in Figures 2b and 2c for m = 4 and 2 bars the central resonant peaks are well reproduced. However, in these cases the level of the measured reflection coefficient is in general above that predicted by the theory. Davies and Heathershaw (1983) have shown that this is probably due to a small, though non-negligible, amount of wave energy (less than ∿4%) being reflected from the wave absorbing beach at the far end of the tank.

The solid curves in Figure 2 represent theoretical values calculated assuming no attenuation of the incident waves across the bar patch and, consequently, no proper energy balance. The broken curves represent theoretical values calculated assuming a linear attenuation of the incident wave across the bars and giving the required energy balance. Details of the energy balance procedure may be found in Davies (1980).

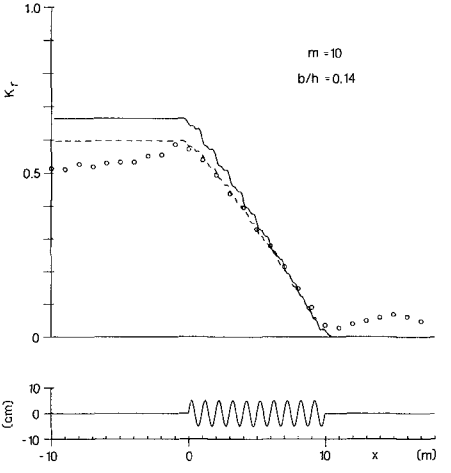

Figure 3a The variation of measured reflection coefficient K_r over the barred test section and on either side of it for m = 10 bars and for b/h = .14 (h = 35.7 cm). Broken and solid curves represent corrected and uncorrected theoretical predictions respectively. The corrected theory assumes a linear decrease in incident wave amplitude across the bar patch.

Figure 3 shows the results from 10 and 4 bars, of measurements of the reflection coefficient, K_r, at resonance, at different positions, x, along the tank and throughout the barred test section. In particular it should be noted that K_r is a value calculated by the method of Goda and Suzuki (1976) and that this may only be expected to agree with

the K_r given by (1) well away from the bars on the up-wave side of the bar patch. Measurements are shown for bar amplitude-water depth quotients b/h = .14 and .32, corresponding to water depths of 35.7 cm and 15.6 cm respectively. The resonant wave period settings for these measurements were 1.28 s and 1.73 s.

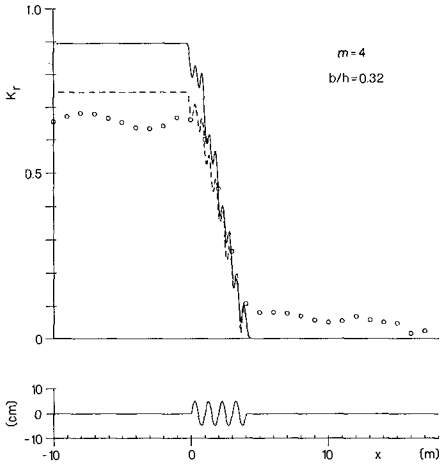

Figure 3b The variation of measured reflection coefficient K_r over the barred test section, and on either side of it for m = 4 bars and for b/h = .32 (h = 15.6 cm). Broken and solid curves represent corrected and uncorrected theoretical predictions respectively. The corrected theory assumes a linear decrease in incident wave amplitude across the bar patch.

The measurements show good agreement with theoretical predictions throughout the barred test section although in general they underestimate the theory on the up-wave side of the bars and overestimate it on the down-wave side. The results in Figure 3 show that on the up-wave side of the bars the measured reflection coefficient is more or less constant and rises to a peak value within a few water depths of the bars before falling, linearly throughout the test section, to a value of the order of .05 or less, which is the reflection from the beach alone. The increase in K_r towards the patch is believed to be due to viscous dissipation in the tank (see Davies and Heathershaw, 1983).

Figures 4a and 4b represent corresponding measurements of the amplitude of surface elevation throughout the barred test section and on either side of it for the conditions described above. These wave envelope observations confirm the presence of a standing or partial standing wave between the bars and the wave generator and show how

this gives way to progressive waves leaving the test section and propagating towards the beach. The results in Figures 4a and 4b show good agreement with the corrected theoretical curve (b), supporting the use of linear attenuation of incident wave amplitude across the bar patch. Details of the theoretical predictions of surface elevation amplitudes, in the vicinity of the bar patch, are given in Davies and Heathershaw (1983).

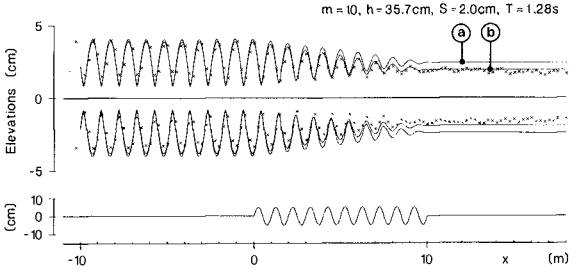

Figure 4a Surface elevation amplitudes measured throughout the barred test section and on either side of it for m = 10 bars and b/h = .14 (h = 35.7 cm). Curves (a) and (b) represent uncorrected and corrected theoretical predictions respectively. The corrected theory assumes a linear decrease in incident wave amplitude across the bar patch.

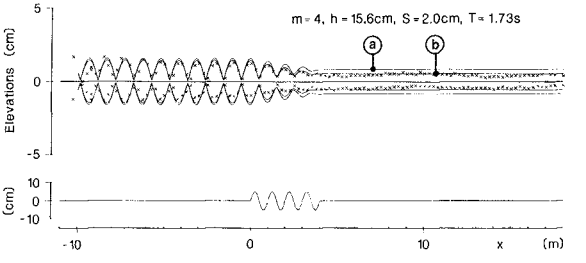

Figure 4b Surface elevation amplitudes measured throughout the barred test section and on either side of it for m = 4 bars and b/h = .32 (h = 15.6 cm). Curves (a) and (b) represent uncorrected and corrected theoretical predictions respectively. The corrected theory assumes a linear decrease in incident wave amplitude across the bar patch.

Results illustrating the variation of the maximum possible value of K_r with the number of bars (m) and the bar amplitude-water depth quotient (b/h) are shown in Figure 5. For each case, measurements of K_r were made over a range of $2k/\ell$ values at or near resonance and the reflection coefficient values averaged. Further details of these measurements and the averaging procedure are given in Davies and Heathershaw (1983). It should be noted that the number of measurements of K_r at or near a resonant peak may not have been representative of the true variation in K_r and for this reason values of K_r in Figure 5 are shown as means with standard deviation error bars.

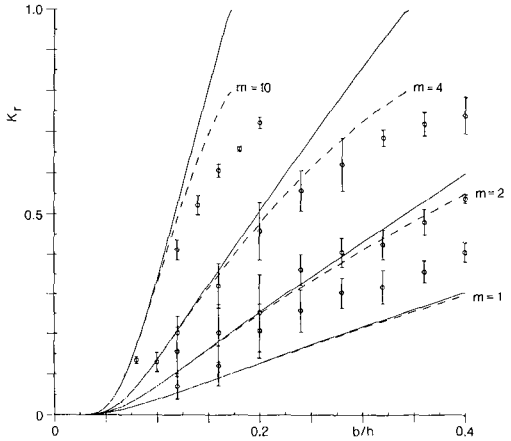

Figure 5 Measured peak reflection coefficients for m = 1, 2, 4 and 10 bars and for different values of b/h.

Results are shown in Figure 5 for m = 10, 4, 2 and 1 bars. For 10 and 4 bars (m = 10 and 4) measured reflection coefficients in general underestimate the theory which is shown uncorrected (solid curve) and corrected (broken curve) for the effects of wave attenuation across the bars. For 2 and 1 bars (m = 2 and 1) the measurements tend to overestimate the theory and, as shown by Davies and Heathershaw (1983), since the measured bar reflection coefficient is equal to the actual bar reflection coefficient plus or minus the value for the beach (dependent upon phase) this result most probably indicates the increasing importance of beach reflections as the predicted value of the bar reflection coefficient decreases with a smaller number of bars. Despite these shortcomings the measurements are generally supportive of the main theoretical conclusion that the peak wave reflection coefficient increases linearly with the number of bars (m) and as the water depth is decreased (b/h increased). However, it should be noted

that strictly speaking, K_r is only expected to increase linearly with m at $2k/\ell = 1$ and that in most cases the peak values shown in Figure 5 correspond to mean $2k/\ell$ values which are not exactly equal to 1 but which are in the range .9647 - 1.0171 with standard deviations of .0077 - .0538. Further details of these results may be found in Davies and Heathershaw (1983).

Following a suggestion of Davies (1980, 1982) some observations of sediment movement were also carried out in the wave tank. Davies suggested that as a result of the partial standing wave which forms up-wave from a reflecting bar systems, the pattern of wave orbital motions near the bed may lead to areas of preferential erosion and deposition of sediment. Potentially, at least, this provides a mechanism for bars to grow in the up-wave direction.

To confirm this result, fine sand of about 235μm mean diameter was sprinkled in a thin uniform layer throughout the barred test section (with 2 bars only) and for about 2-3 m on either side of it. Small amplitude waves were started and the wave amplitude increased until sediment motion was initiated. Sediment movement was then observed for a resonant wave reflection condition ($K_r = .34$) and the evolution of ripple patches recorded. On the up-wave side, ripple patches with a 1 m spacing were observed while down-wave a more or less continuous sheet of ripples developed. Erosion, and ripple formation, was observed to occur beneath the nodes of surface elevation of the partially standing wave. With increasing time, ripple heights were observed to grow on the up-wave side of each patch in such a way as to bring about an accumulation of material approximately mid-way between node and antinode and roughly in the position where bar crest formation would be expected to occur. These results confirm that a potential bar-growth mechanism exists up-wave of the bars but not on the down-wave side.

An example of the observed sediment distribution is shown in Figure 6. It should be noted that sediment accumulation at an antinode would not be expected in this case since the horizontal component of the wave induced current at this location is minimal and usually below the threshold of movement of all but the finest sediment. As was observed in this study, sediment accumulation and the cessation of sediment transport, would be expected to occur at a point intermediate between the high velocities at the nodes and the low velocities at the antinodes. This result may be contrasted with that of Nielsen (1979) who found that for fine sand ($d_{50} = 80\mu m$), sediment accumulation did occur beneath the antinode of a partially standing wave. In this case sediment movement was principally as suspended load whereas in this study material moved mainly as bedload or in a thin suspension layer due to vortex shedding from ripple crests.

CONCLUSION

In conclusion the results of these experiments have shown that significant and large amounts of wave energy may be reflected from submerged bar like structures and that these reflections are brought about by

resonant interactions between surface water waves and the bedforms. In particular, at resonance, incident surface water wavelengths are approximately twice the bedform wavelengths. The results have implications not only in terms of wave reflection from naturally occurring bedforms, say bars on beaches, but also for sediment transport processes in general.

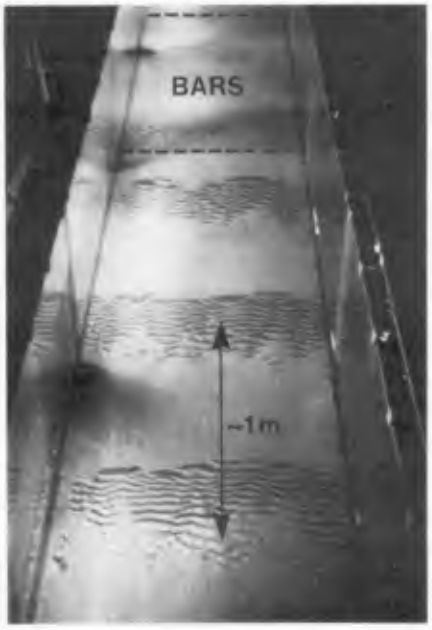

Figure 6 Ripple patches with a 1 m spacing formed beneath a partial standing wave on the up-wave side of 2 x 1 m wavelength bars. The bar amplitude is 5 cm and for these observations the water depth was h = 15.6 cm and the wave reflection coefficient was $K_r \cong .34$. Maximum ripple heights and wavelengths, in the ripple patches, were of the order 1.5 cm and 5.5 cm respectively.

ACKNOWLEDCEMENTS

I am grateful to the Commander and Director of the US Army Corps of Engineers, Coastal Engineering Research Center, Fort Belvoir, Virginia, USA for experimental facilities and to Dr A C Davies for much valuable discussion.

THE EFFECT OF BED SLOPE ON WAVE CHARACTERISTICS

by
R.C. Nelson, Department of Transport and Construction, Australia

1. INTRODUCTION

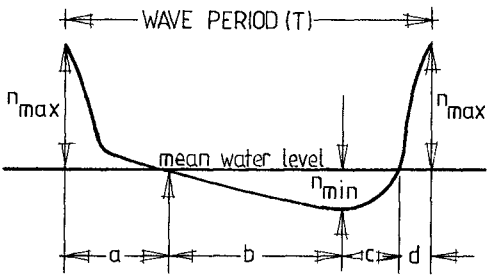
In all wave theories used in engineering applications it is assumed that the profile of the bed is horizontal which results in a symmetrical wave shape and velocity field, so that, strictly speaking, they can be applied only to this condition. Nearshore bottom profiles are, however, seldom horizontal, and a wave moving over a shoaling slope has an asymmetrical profile which is associated with an asymmetrical velocity field within the wave which, in turn, directly influences the movement of bed sediment. As a matter of necessity, but within reason, engineers have ignored the influence of bed slope on the wave theory used. This course of action was justifiable on many counts, not the least of which was that inaccuracies associated with the theories used were far greater than any inaccuracies introduced by ignoring bed slope parameters. However, wave theories developed in recent years have become increasingly accurate and reliable so that it may now be necessary to take account of bed slope parameters in applying these wave theories before further improvements can be made in the techniques used to predict wave-induced sediment transport.

2. AIMS AND OBJECTIVES

This paper describes an experimental programme which assessed and quantified the influence of bed slope on the characteristics of non-breaking waves. The objective was to determine, for individual wave characteristics, the maximum slope up to which insignificant effects are induced and, for steeper slopes, to describe quantitatively the divergence from those results for a horizontal bed. The specific wave characteristics measured and compared for various slopes were:

(i) wave profile (n versus t);
(ii) wave celerity (and hence, by definition, wavelength);
(iii) potential energy;
(iv) ratio of crest time to wave period;
(v) ratio of trough time to wave period:
(vi) ratio of crest height to wave height;
(vii) ratio of trough depth to wave height;
(viii) crest skewness;
(ix) trough skewness; and
(x) ratio of asymmetrical wave slope to bed slope.

The definitions of these characteristics are given in Figure 1.



WAVE PROFILE (n versus t)	
WAVE CELERITY (and hence, by definition, wave length)	
POTENTIAL ENERGY	
RATIO OF CREST TIME TO WAVE PERIOD	$(a+d)/T$
RATIO OF TROUGH TIME TO WAVE PERIOD	$(b+c)/T$
RATIO OF CREST HEIGHT TO WAVE HEIGHT	$\eta_{max}/(\eta_{max}+\eta_{min})$
RATIO OF TROUGH DEPTH TO WAVE HEIGHT	$\eta_{min}/(\eta_{max}+\eta_{min})$
CREST SKEWNESS	$d/(a+d)$
TROUGH SKEWNESS	$b/(b+c)$
RATIO OF WAVE SLOPE TO BED SLOPE	$\lvert\eta_{min}\rvert/b \tan\theta$

3. PREVIOUS WORK

Adeyemo (1968) investigated experimentally, for six bed slopes ranging from 1:4 to 1:18, the effects of bed slope on the ratio of crest height to wave height and various measures of crest skewness. The work covered a wide range of wave non- linearity using values of d/λ between 0.08 to 0.26. Adeyemo demonstrated that crest skewness was greater on steeper bed slopes and that it increased as the wave moved into shallower water, being a maximum at the breaker point. He also found that for small values of d/λ the ratio of crest height to wave height became progressively less on steeper slopes. Unfortunately, Adeyemo did not give any observed values of H/d at the points of measurement which limited severely the comparisons that can be made with other experimental studies and prevented the incorporation of the results into such studies. The work described in this report demonstrates, for example, that the ratio of crest height to wave height is also a function of the ratio of wave height to water depth.

Adeyemo (1970) investigated experimentally the relationship between wave shape asymmentry and wave-induced velocities near the breaker zone. From the results of experiments using a fixed wave period of 0.8 seconds, bed slopes of 1:9 and 1:18 and values of d/λ between 0.0800 and 0.1245, he concluded that there are qualitative and quantitative relationships between the asymmetry of wave shape, caused by bed slope, and the asymmetry of the resulting velocity field. Indeed, his observed velocity profiles shown in his Figures 3 and 4 for the two slopes tested demonstrate all the characteristics and trends shown on the observed wave shape profiles of Figure 4 in this paper.

4. EXPERIMENTAL EQUIPMENT AND TECHNIQUE

The basic apparatus used for the experimental programme was a glass-walled tilting flume with a test section 30m long, 0.99m deep and 0.75m wide. Tilting was effected by means of electrical drives about a central pivot point. The flume had a tilting slope range of between horizontal and 1:67. Other slope ranges could be obtained by building in fixed slopes with respect to the flume, and tilting these. The flume was fitted with a pneumatic, uniform wave generator. A mobile instrument carriage located on rails along the top of the flume was fitted with two parallel-wire, resistance wave transducers located centrally in the flume and 0.22m apart along the flume axis.

The carriage also carried the associated electrical equipment together with a water level follower and two analogue chart recorders. The carriage instrumentation was in turn connected to a Hewlett Packard System 1000, model 31 computer with a 21MXE central processing unit, an RTE II operating system and a 2240A measuring and control processor.

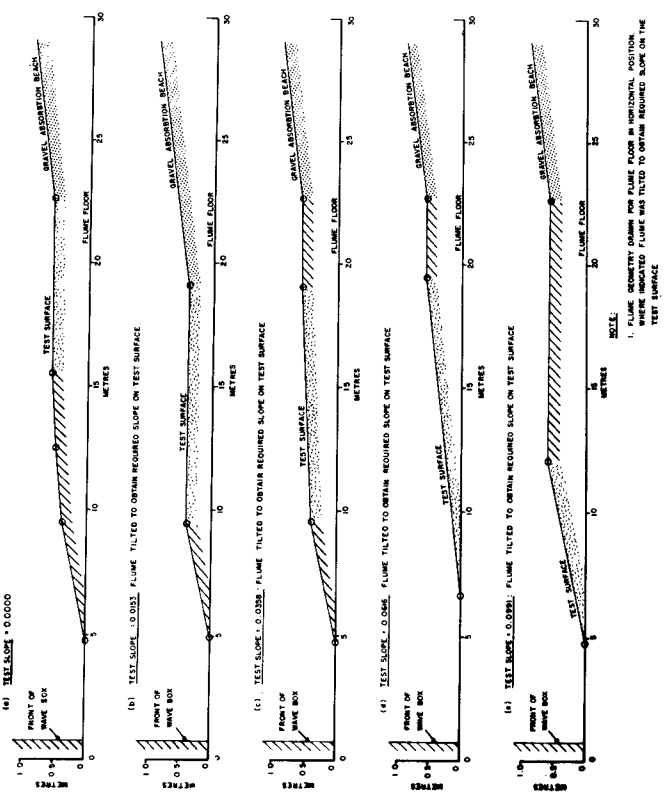

FIGURE 2 : Flume Profiles Used in Test Programme

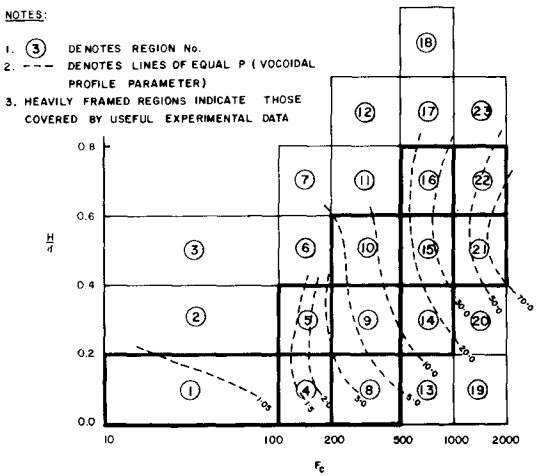

FIGURE 3 : Adopted Regions on H/d, Fc Field

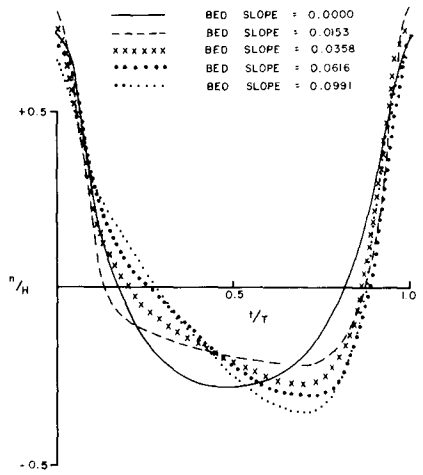

FIGURE 4 : Typical Observed Wave Profiles

All instrument calibration and data acquisition were performed on-line to the computer, the data being analysed immediately and then stored on disc file as well as printed out as a hard copy. Water level readings from each probe were logged every 30 milliseconds. A sample comprised of a number of consecutive, individual readings acquired simultaneously at each probe during a time period of at least two wave periods. A test run comprised of a specified number of samples acquired simultaneously at each probe, the wave height, water depth and wave period being the same for each sample.

It was possible to acquire any number of samples for any given test run but three was determined to be the optimum. This number was based on the results of pilot experiments in which no definite improvement in the standard deviation of the measured characteristics could be discerned for greater numbers of samples.

The occurrence of any water level set-down or set-up at the wave transducers was automatically accounted for in the data acquisition system.

Five slopes were used during the experimental programme, namely, 0.0000, 0.0153, 0.0358, 0.0616 and 0.0991. The flume profiles are shown in Figure 2. The slopes were not tested in this order. The testing order was 0.0153, 0.0358, 0.0000, 0.0991 and 0.0616. The order was determined as the programme proceeded but was governed mainly by two factors:

(i) the ease with which the flume could be adapted to another slope, and

(ii) the desire to test extremes so that the intermediate slopes that should be tested could be determined.

It was found that the experimental technique used precluded experimentation on slopes steeper than 0.100 because:

(i) wave reflection created significant secondary effects,

(ii) random ripples caused by wave-breaking and downrush created significant secondary effects, and

(iii) differences in depth between probes became significant.

5. EXPERIMENTAL DESIGN

Any dimensionless numbers used in the basic classification or grouping of data had to be free of theory-dependent parameters and preferably contain only those which could be measured directly. The only parameters capable of direct measurement at a point over a sloping bed, with a high degree of precision, are wave period (T), water depth (d) and wave height (H). Hence, use was made of the non-linearity parameter, Fc, after Swart (1978) and Swart and Loubser (1979). This is defined as;

$$Fc = (H/d)0.5 \quad (Tc)2.5$$

$$Tc = T\ (g/d)0.5$$

One helpful property of Fc is that waves of equal Fc have approximately the same relative wave shape. It was decided, therefore, to establish a system of comparison based on the measured experimental values of H/d and Fc.

Another problem to be solved was that a combination of test values T, d and H used on one slope would be physically impossible to reproduce exactly on each of the other slopes tested. The solution lay in the division of the H/d versus Fc plane into regions so that groups of resuts from identical regions could be compared. For this to be done two criteria would have to be satisfied. One of these was that the range of relative profile shape covered by each region should not be too large. The second, and more important criterion, was that the standard deviation of results obtained over any one region should not be too large, otherwise no significance could be attributed to differences between mean values obtained from various regions on different slopes. To determine the boundaries and size of these regions a pilot experiment was undertaken and the results investigated statistically. Regions were adopted which required between 4 and 6 test runs per region. The regions adopted are shown in Figure 3 together with the relationship between H/d, Fc and P the vocoidal wave profile parameter, which is a measure of relative wave shape after Swart (1978) and Swart and Loubser (1979).

It will be noted later that in Tables 1, 2 and 3 experimental values of celerity have not been used on their own, but rather the ratio of observed celerity to that predicted by vocoidal theory. This is called the celerity ratio and is simply a device to reduce the standard deviation of celerity measurement over any one region. The experimental values of celerity on their own showed too great a variation. This device in no way makes the final objective (the influence of slope on wave celerity) dependent on any wave theory. Any wave theory could have been used providing its celerity estimates varied with respect to T, d and H in a manner similar to that in real situations on horizontal beds. Obviously the greater this similarity, the less would be the standard deviation. It is emphasized that it is this similarity of variation with T, d and H that is important here and not the accuracy of the absolute value of celerity predicted by the theory. However, if there was similarity in this respect also, the ratio should be close to 1.0 in each region for a horizontal bed. This was in fact so when vocoidal theory was used.

6. EXPERIMENTAL RESULTS

6.1 Coverage of Fc, H/d Field

It was not possible to acquire useful data in all the regions shown in Figure 3. The regions for which useful data were acquired, and their relation to other regions, are shown in Figure 3. In general, the extent of the coverage achieved was limited by the following factors.

(i) Secondary wave effects (solitons) became significant at values of Fc greater than 2 000

(ii) The occurrence of solitons and/or random ripple effects became significant in regions 13, 19 and 20

(iii) Test runs in regions 11, 12, 17, 18 and 23 could not be obtained because of wave breaking

(iv) Test runs in regions 2, 3 6 and 7 were precluded because the necessary wave heights could not be achieved by the wave generator at smaller wave periods.

The coverage obtained on the two extreme test slopes (0.0000 and 0.0991) requires some additional discussion. Testing beyond Fc = 1 000 was not possible on the 0.0991 slope, because of secondary effects caused by wave reflection and random ripples created by wave breaking and down-rush. Testing beyond Fc = 1 000 on the horizontal slope was also precluded because of the presence of solitons in the wave form. This was partly because when tests were done at small depths on the test surface, water depths at generation were less than those for other test slopes for which the flume was tilted to maximise the depth at the generator. Earlier preliminary testing had shown that solitons were less evident for greater depths at generation (see also Hulsbergen (1972) and Van Wyk (1975)).

However, of greater importance was the fact that values of H/d greater than 0.55 could not be obtained over a horizontal bed due to wave instability and wave breaking. This was confirmed by using three different arrangements of the experimental equipment. Initially, testing on the horizontal slope was attempted using the test surface shown in Figure 2b with the flume in the horizontal position, but this failed to produce ratios of H/d greater than 0.50 because of wave instability and wave breaking. This was conceivably due to the sharp change in bed slope at the top of the shoaling slope. Further testing on the horizontal bed was postponed until the arrangement of Figure 2a could be constructed with a smooth transition between the initial shoaling slope and the horizontal test surface. This arrangement had the added advantage of increasing the depth at generation. However, the same limitation on values of H/d remained but experimentation was continued and as large a coverage as possible was achieved.

When testing had been completed on all five test slopes a third attempt was made to achieve values of H/d greater than 0.55 over a horizontal bed using a modification of the flume profile shown in Figure 2d. A horizontal, symmetrical contraction to half the flume width was constructed over the top 5m of the shoaling slope, so that a horizontal bed, half the flume width, was available prior to the absorption beach. This increased the number of available combinations of T, d and H but the same phenomena of wave instability and wave breakup were observed.

The value of H/d of 0.5 at which breaking of waves occurred over a horizontal bed was well below the values of 0.8 and greater obtained on beds with slopes as low as 0.0153. The experience of other researchers (see Nelson, 1980) tend to confirm this limiting value of H/d for horizontal beds, and leads to the conclusion that unbroken, regular waves with values of H/d exceeding 0.55 cannot exist on a horizontal bed.

6.2 Statistical Significance and Magnitude of Slope Influence

One objective of the project was to determine those slopes on which wave characteristics became significantly different from those of waves moving over horizontal beds. Unfortunately, for five of the eleven regions tested no data were obtainable for the horizontal bed. For three of these regions (8, 14 and 21) this was due to secondary wave effects. The limiting value of H/d of 0.55 accounted for the other two (16 and 22). The fact that values of H/d of 0.8 were possible for these two regions on slopes as small as 0.0153, in itself indicates a significant slope effect.

For the six remaining regions (1, 4, 5, 9, 10 and 15) a direct comparison of all four finite slope results with the horizontal bed results, was possible for all measured wave characteristics. A statistical test of significance at the 5 per cent level was made to determine which slopes produced results which varied significantly from those obtained on the horizontal bed. Table 1 shows the percentage variations of regional means from the horizontal-bed result where a statistically significant variation occurred. All tables show that with respect to the combined considerations of magnitude of variation, range of slopes responsible and Fc range affected, the ranking in Table 2, in rising order of slope influence, applies.

The only parameter which was treated differently was the ratio of asymmetrical wave slope to bed slope. The reason for a different treatment is that it was difficult to read off (define) the asymmetrical wave slope when (i) the wave height to water depth ratio H/d was less than 0.2, and (ii) the non-linearity parameter Fc was less than 200. Sometimes the asymmetrical slope could be interpreted in more than one way. Such results were also neglected. Therefore the regional mean data were lumped together in two different ways rather than interpreting them separately, namely,

(i) by grouping the wave profile data for all regions together for any slope; and

(ii) by grouping all wave profile data for the same region (all slopes) together.

These results indicate that the overall mean of ($C \tan\theta/\tan\alpha_\omega$) has a value of about 2.50 with a standard deviation of 0.25. This implies that the 95 per cent confidence band would extend from about 2.0 to 3.0 with a best estimate of 2.50. No subgroup (population comprising the results of a given slope or region) had a mean result which differed significantly at the 95 per cent level from this overall mean result.

6.3 Recommended Values of Wave Characteristics

For the range of slopes tested, all the experimental data were used to derive empirical relationships for wave characteristics. These are shown in Table 3. Oue cognizance must be given to the remarks shown in the table when using these relationships.

The tables apply to bed slopes of less than 0.100. They show that wave characteristics can be functions of Fc, H/d and tan θ. This is so for the ratios of crest time to wave period, trough time to wave period, crest height to wave height and trough depth to wave height. The observation that for shallower water, the ratio of crest height to wave height becomes progressively less on steeper slopes agrees with the findings of Adeyemo (1970).

Crest and trough skewness are shown to depend only on Fc and tan θ. The results indicate that there may be some dependence on H/d but that it is either very small, or the data are inconclusive and conflicting.

For all practical purposes the potential energy coefficient is a function of only Fc and H/d on slopes less than 0.100, and the celerity ratio is independent of all three parameters. Since the celerity ratio used was that of experimentally measured values to those predicted by the vocoidal wave theory, the results tend to enhance the practicability of applying the vocoidal theory to a wide range of slopes for the purpose of celerity and wave length determinations.

The asymmetrical wave slope depends on the bed slope and the wave celerity and can be used in conjunction with the skewness parameters to reconstruct the wave profile schematically.

6.4 Typical Observed Wave Profiles

To assist the reader to appreciate the progressive influence of bed slope on wave profile some typical observed profiles are shown for region 15 in Figure 4.

7. CONCLUSIONS AND RECOMMENDATIONS

Experiments on the influence of bed slope on some parameters associated with unbroken regular waves lead to the following findings:

(i) It is doubtful whether unbroken, regular waves on a horizontal bed with wave height-to-water depth ratios exceeding 0.55, can ever exist. Bed slopes as low as 0.015 influence the wave mechanics sufficiently to increase this ratio to greater than 0.80. Therefore, the characteristics of waves near breaking on a gentle slope cannot be assumed to be the same as those on a horizontal bed.

(ii) The effect of bed slopes of less than, or equal to, 0.100 on potential energy and wave celerity is minimal and, for all practical purposes, can be ignored.

(iii) Bed slopes greater than or equal to 0.062 can significantly influence the ratios of crest height to wave height, trough depth to wave height, crest time to wave period and trough time to wave period. These modifications of profile shape will create a redistribution of potential bed particle transport because of consequent changes in the positive and negative wave-induced bed velocities.

(iv) The greatest influence of bed slope is on crest and trough skewness and the asymmetrical wave slope and becomes significant on bed slopes as low as 0.015. These resulting asymmetries of wave profile will result in an asymmetry of the velocity field within the wave, which will have a direct influence on potential bed-particle transport.

(v) Functional relationships relate bed slope and wave characteristics and these are as shown in Table 3.

SENSITIVITY OF PARAMETERS AND APPROXIMATIONS IN MODELS OF TIDAL PROPAGATION AND CIRCULATION

by
Jan J. Leendertse* and Shiao-Kung Liu*

Introduction

In the last ten years a system has been designed for the two-dimensional simulation of the hydrodynamics and water quality in well-mixed estuaries, coastal seas, harbors, and inland waters. The system called SIMSYS2D or WAQUA, can simulate the hydrodynamics in complicated geographical areas, and the model can determine the land/water boundary during simulation [1]. The system accounts for the sources of discharges, tidal flats, islands or dams, and time-varying or time-invarying flow restrictions such as generated by openings in dams, sluices, or storm-surge barriers. In the SIMSYS2D system numerous finite difference approximations of the vertically integrated hydrodynamic equations and their boundary conditions are available to the investigator.

A large number of models and model experiments with two-dimensional models have been described in the literature. In many instances, authors have emphasized the advantages of the particular approximations they were using in their model and sometimes made comparisons with other approximations by use of hypothetical geographical areas. Generally, no comparisons are given of different computation methods applied to actual estuaries.

Currently, no comprehensive overview of the comparative importance of the approximations of the terms of the hydrodynamic equations based on experiments of typical estuaries, is available. Nor has a practical assessment been made on the comparative importance of timestep size, grid size, depth accuracy, roughness estimates, and approximation of the closure term by viscosity or other expressions.

To obtain an insight into the relative importance of computational and systems parameters, a large number of experiments were made with models of the Eastern Scheldt using the SIMSYS2D system in many of its modes. Some of the more important results of this extensive analysis will be presented in this paper.

Method of Analysis

The Eastern Scheldt model, used for most of the experiments, had a grid size of 800 m. For a few experiments a model with a grid size of 400 m was used (Fig. 1).

A periodic tide was taken at the boundary of the model. The amplitude and phase relation of the boundary points to a fixed observation station near the location of the boundary was determined by means of cross-spectral analysis from a 5½ day simulation of a model with a grid size of 800 m, which included the coastal region outside the estuary and the estuary itself [2].

* The Rand Corporation, Santa Monica, California

After determination of a yearly averaged tide from observations at the fixed station, amplitudes and phases of every boundary point could be calculated from the amplitude and phase relations for the M_2, M_4, and M_8 tidal component.

Simulations, as long as 15 tidal cycles, indicated that a quasi-steady state condition was never obtained. The tidal residual currents computed as low-passed filtered Eulerian transports did slowly fluctuate. Mean water levels computed by the same low-pass filter (tidal eliminator) also showed some fluctuation. In addition, the computation appears to contain noise in a few areas due to the large grid size and the discrete changes in area's size when tidal flats and sandbars become dry or flood.

Consequently, comparisons of tidal wave propagation and amplification by means of a Fourier analysis of the computed records at stations along the periphery of the estuary were difficult to make. A much better approach appeared to be optimal estimation of amplitude and phase relationships between pairs of stations by cross-spectral analysis. In addition to the amplitude and phase relations, data about the confidence of the linear estimate could be computed.

Simulations of 5½ days were made and as at least one day is required for dissipation of the starting transient, 100 hours of the simulation was available for analysis. The 100 hours is a short series for cross-spectral analysis as only eight cycles of the primary tide are available, nevertheless, a very high coherency was always obtained for this frequency. This was not the case for the quarter- and sixth-diurnal tides. These appeared to be influenced by leakage from the very strong semi-diurnal tidal component.

To alleviate that problem, band pass filters, as described by Godin [3], were applied to the computed time series which eliminated the semi-diurnal tide but retained the quarter-diurnal or the sixth-diurnal tide. Subsequently, cross-spectral analyses were made on pairs of the resulting time series. The analyses were made of the records of adjacent stations on a line along the estuary as shown in Fig. 1.

To investigate the effect of the method of approximation of the finite difference equations or the sensitivity of certain parameters on residual circulation, (Eulerian residual transport) the mass transport rates through certain cross-sections were filtered with a low pass filter. Also, the mass transport rate at each section with a dimension of the grid size of Δx was computed and filtered with a boxcar filter with the length of the tidal period. Alternately, the filtering was done with a low pass filter which completely eliminated components in the tidal frequencies. Subsequently, the vector plots of the residual transport fields could be prepared.

Effects of the Main System Parameters

In this study an alternating direction implicit scheme is used to solve the set of partial differential equations which represent the two-dimensional equations representing the two-dimensional flow [4]. For the analyses of the effects of modifications of the main system parameters a higher order finite difference approximation in space was used as the base case. This representation was first used by Arakawa and

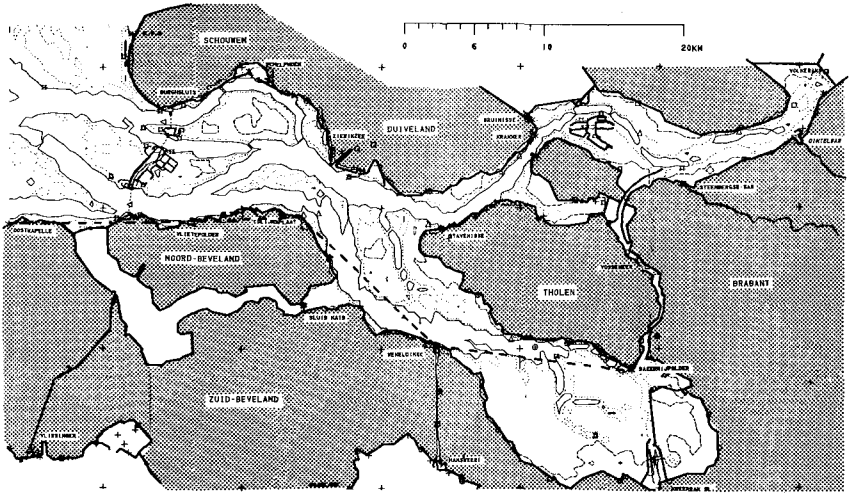

Fig. 1--Model area used for the experiments (dashed line indicates line of stations used for determination of amplification and phase lags)

has a second order accuracy in time [4]. The bottom stress terms in the semi-momentum equations were computed in a conventional manner using a Chezy value. The Chezy values were computed every half-hour from the transport depth from the bottom roughness expressed with a Manning's n coefficient.

In an earlier study it was indicated that the finite difference methods cause dispersion and amplification of a propagating tidal wave compared to solutions of the differential equations. These effects can be expressed with the complex amplification factor [5]. The dispersion and amplification is a function of the timestep, the grid size, and of the period of the wave. The base case was a simulation with the model which was already adjusted.

For the study of the effects of the main system parameters, five simulations were made, each one was a variation of the base case. We investigated a 10% decrease in Manning's n, a 5% increase in depth, a 50% increase in the multiplier (α) of the advection term, a doubling of the momentum diffusion and a reduction of 50% of the timestep (Fig. 2).

In the base case, we used for the momentum diffusion a value of 15 m^2/sec, $\alpha = 1$ and a timestep of 2.5 min. To show the effect of the parameter modifications the time lag between a boundary station (Oostkapelle) and an inland station (Razernijpolder) was computed for several components. The confidence intervals shown in this figure are for the analysis of the last two stations on the line. It will be noted that the confidence interval for the sixth-diurnal tide is much larger than for the semidiurnal tide. In the figure the results of an analysis of

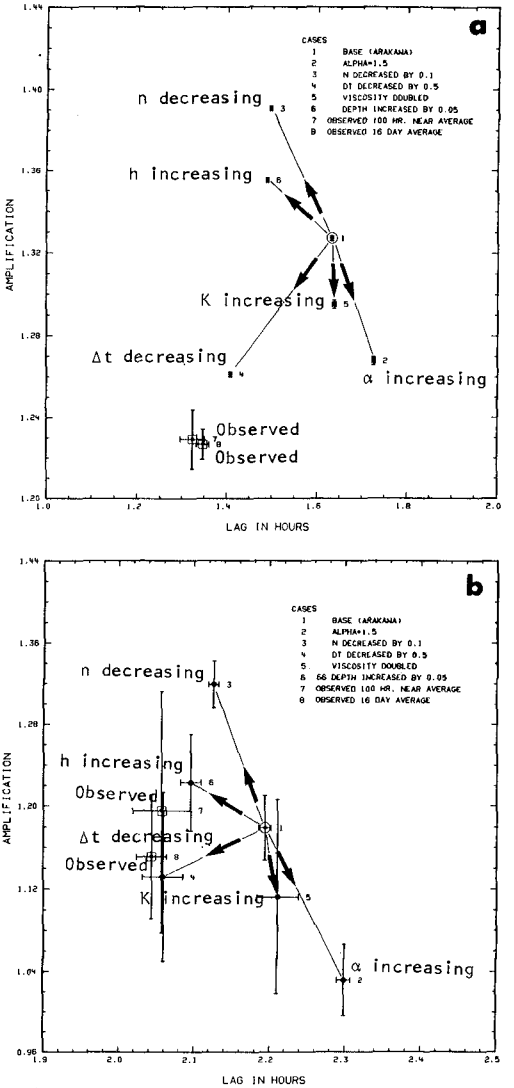

Fig. 2--Amplification versus phase lag for the relation between a station near the boundary (Oostkapelle) and an inland station (Razernijpolder): (a) semidiurnal tide (b) sixth-diurnal tide

field data is also shown. The spectral densities of the observed records in the main tidal frequency bands was nearly the same as for the boundary conditions used in the experiments.

Even though the use of a multiplier for the advection is commonly used in one-dimensional computations to account for the non-linear velocity distributions over the vertical, this multiplier is not used much for two-dimensional models.

From the results shown here it can be inferred that use of this coefficient does not seem effective as increasing n will give similar effects as increasing α.

Adjustment of parameters other than the timestep appears to be ineffective in obtaining better results. This conclusion can also be reached by a careful analysis of the behavior of the complex propagation factor. Only when the timestep is reduced does the amplification and phase lag approach the observed amplification in lag. A good agreement of all tidal components including the overtides could be obtained by reducing the grid size from 800 m to 400 m. Figure 3 shows the comparison between the observed and the computed tide at the inland station for 4 September 1975.

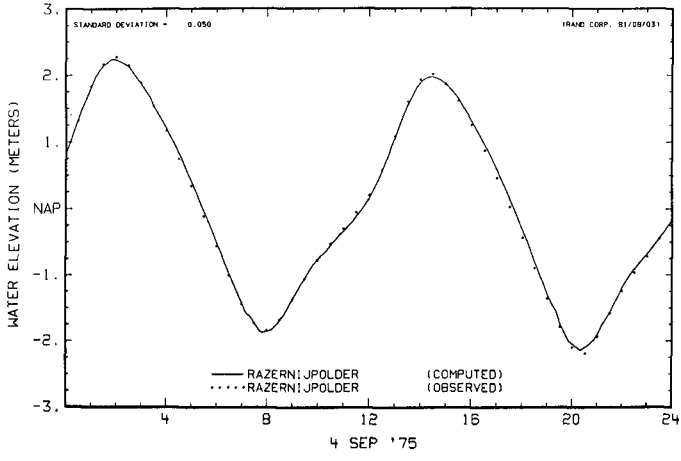

Fig. 3--Comparison of computed and observed water levels at an inland station (400 m grid model)

Choice of Advection Approximation

The approximation used for the advection terms in the momentum equations influences the tidal amplification and the transfer of energy of the primary tides to overtides.

Simulations were made with different advection terms. It appeared that the most simple advection term was the most effective in transferring energy from the semidiurnal tides to other tidal frequencies as can be seen from the amplification and phase lag plot (Fig. 4). The amplification and phase of other tidal components was not influenced much by the choice of the approximation. The choice of the approximation influences the residual circulations to a certain extent, but it did not change the general pattern. Omission of the advection terms reduces the computed residual circulations and one can conclude that advection is the primary mechanism generating residual circulations. A comparison of the computed residual circulation with and without the advection term is presented in Fig. 5.

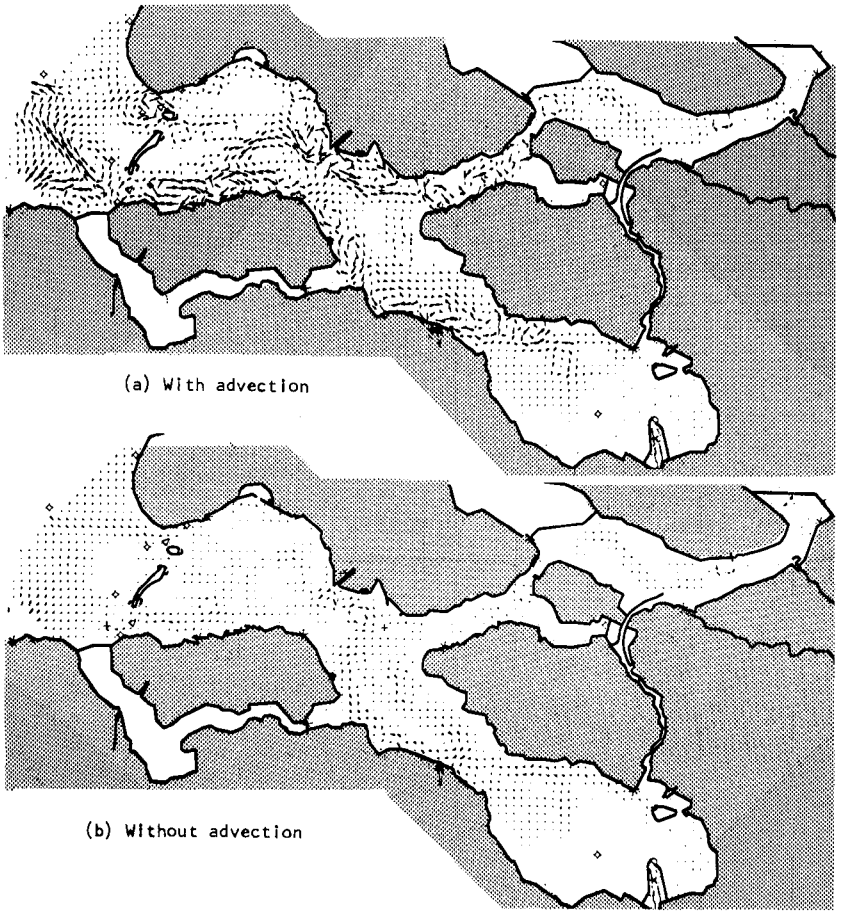

Fig. 5--Computed Eulerian residual transports for a computation with and without the advection terms

Bottom Stress Approximation

In tidal computations the bottom stress is generally taken as a function of the squared velocity and of the inverse of the depth and the squared Chezy coefficient.

In the design of a finite difference model the modeler has the option to compute the bottom stress term on the lower time level or make an expression which is central in time. Comparison of simulations with these options indicated that for practical purposes the same results are obtained. Nevertheless, the expression which is central in time is to be preferred when tidal flats and wind effects are simulated. Otherwise, a strong wind will accelerate water with a very limited depth which has just started to participate in the computational field due to flooding, to unrealistic high velocities because the bottom friction is zero.

The bottom stress can also be expressed as a function of the root of the local subgrid scale energy, the local velocity and a length scale. The local subgrid scale energy is computed as a constituent in the mass transport model. The energy is generated by the bottom stress and this generation is taken exactly the energy loss in the momentum equations. Its decay is taken as a function of the 3/2 power of the local energy intensity. The mixing length was assumed to be a fraction of the depth. By making these computations one has a two-dimensional model with a simple turbulence closure. Comparison of a simulation made with this closure model and a simulation with the bottom stress computed directly from the velocities reveal only minor differences as shown in Fig. 6.

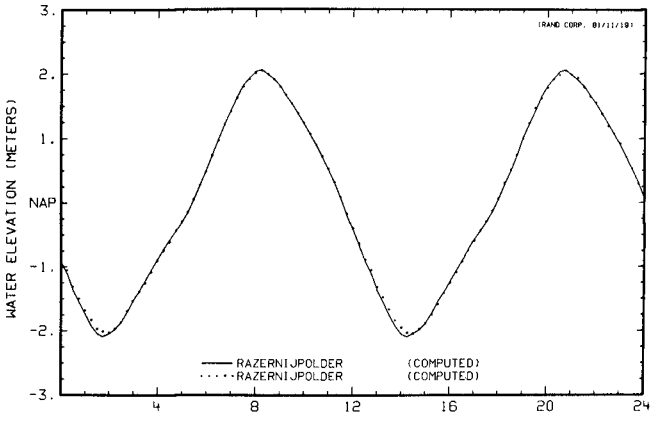

Fig. 6--Comparison of water levels at an inland station computed with a simple turbulence closure model (····) and computed by use of a stress term which is a function of the squared velocity (——)

Conclusions

From the experiments with an estuary model and from analytical considerations it can be concluded that a high resolution in time and space is required to obtain a good agreement between model and prototype. Adjustments of depth, viscosity or bottom roughness cannot compensate for insufficient resolution.

The advection terms cannot be omitted from the model as otherwise the tidal residual circulations are not properly computed. A simple expression for the advection terms appears to be the most effective in transferring tidal energy from the main tidal frequency to the overtides.

The use of a simple turbulence closure model appears to give virtually the same results as a computation with the bottom stress computed in a conventional manner.

A NEW TWO DIMENSIONAL TIDAL MODELLINC SYSTEM

J.P. BENQUE[1], M.I. CHENIN[2], A. HAUCUEL[3],
S. SCHWARTZ[2], A.M. ASCE

ABSTRACT

A new method for numerical simulation of tidal currents is presented. Based on a technique involving the splitting of operators, it allows an accurate calculation of momentum advection, and wave propagation for large Courant numbers. It also provides a satisfactory treatment of tidal flat uncovering and flooding, and permits the use of a curvilinear computational grid. The generation method for such grids is presented here, followed by an engineering application on cartesian grid.

1. INTRODUCTION

Mathematical modelling of coastal shallow water areas where currents are influenced by tide and wind became a common engineering practice during the 1970's. Corresponding techniques are still developing and improving not only because faster and bigger computers are available, but, more importantly, because greater emphasis is being given to the environmental aspects of engineering works. To design the facilities themselves free surface elevation and global discharges are usually sufficient, and a fairly coarse modelling is satisfactory. However, the study of the impact that such works have on the environment asks for more refined models, in particular for a reliable simulation of currents.

(3) Head of the Research Division, LNH-EDF, Chatou, France.

In order to satisfy these requirements the Laboratoire National d'Hydraulique (LNH-Electricité de France), Chatou, and Sogreah, Crenoble, France developed jointly a new method of numerical simulation of tidal currents and a new modelling system called CYTHERE ES 1. A schematic diagram of the system, as used at Sogreah, is shown in Fig. 1.

This system was evolved for simulation of currents and consequently great care was taken to avoid three main drawbacks inherent in many programs developed in the 1970's, namely: numerical spurious damping and dispersion, inaccuracies and "polarisation" of velocity fields in ADI (alternating direction implicit method) for greater computational time steps, and inadequate simulation of uncovering tidal flats during ebb flow. Another difficulty is the choice between finite difference and finite element algorithms, the former being more economical, the latter representing the topography more accurately; an intermediate solution was chosen.

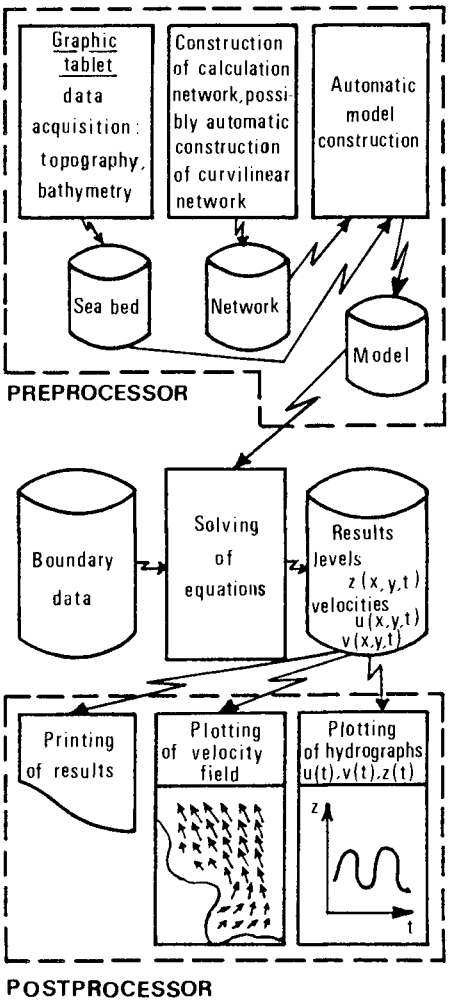
2. EQUATIONS

Nearly all industrially applied modelling systems use finite difference (FDM) discretisation of equations. Although finite elements (FEM) are often mentioned in technical literature, their application to the tidal flow equations is not common because it is expensive.

Indeed, they are no more suitable than FDM where hyperbolic equations are concerned and they lead to much higher computational costs. Their advantage as compared to FDM is that they give a much better fit with topographically complicated boundaries which are represented by stair-like steps in FDM. In order to minimise this disadvantage while using the more economical finite difference method, CYTHERE ES 1 can use an orthogonal curvilinear computational grid which improves boundary and current simulation in narrow estuaries and bays. The choice of an arbitrary (non-orthogonal) curvilinear system of coordinates was discarded because of the inaccuracies which such a transformation of equations would have introduced. Equations of tidal flow are written for an orthogonal curvilinear coordinate system by including projection parameters and metric coefficients. This allows the use of CYTHERE ES 1 in Cartesian coordinates as a special case of orthogonal curvilinear coordinates. In order to render the system efficient a preprocessor which generates a boundary fitted orthogonal curvilinear grid was developed. Its main principles are described later in this paper.

Figure 1

DIAGRAM OF CYTHERE ES1 SYSTEM USED BY SOGREAH



The two-dimensional tidal flow equations written for an orthogonal system of curvilinear coordinates (α,β) are:

$$\underbrace{\frac{\partial \vec{U}}{\partial t}}_{I} + \underbrace{\vec{U}\,\overrightarrow{\text{grad}}\,\frac{\vec{U}}{h} + \frac{\vec{U}}{h}\,\text{div}\vec{U}}_{II} + \underbrace{gh\,\overrightarrow{\text{grad}}Z}_{III} + \underbrace{\frac{\vec{\tau}_B - \vec{\tau}_S}{\rho}}_{IV} \underbrace{-2\vec{\Omega}\wedge\vec{U}}_{V} \underbrace{-\text{div}(K\overrightarrow{\text{grad}}\vec{U})}_{VI} = 0 \quad (1)$$

$$\underbrace{\frac{\partial Z}{\partial t} + \text{div}\vec{U}}_{III} = 0 \quad (2)$$

Where:

$\vec{U}$ = (U,V) = unit width discharge vector through depth h;
Z = free surface elevation;
$\vec{\tau}_B, \vec{\tau}_S$ = bottom friction and wind stresses, respectively;
$2\vec{\Omega}\wedge\vec{U}$ = Coriolis term, $\vec{\Omega}$ being the earth's rotation speed;
K, ρ = horizontal momentum diffusivity, water density.

As mentioned in previous publication [1], it is useful to give a physical interpretation to the six groups of terms of Eqs. (1) and (2) as follows:

I. Local flow acceleration,

II. Momentum transport by advection,

III. Mass conservation and momentum transfer by propagation,

IV,V. Momentum sources or sinks due to Coriolis force, surface wind stress and bed friction,

VI. Horizontal diffusion of momentum.

The three dependent variables of Eqs. (1),(2) are:
$U(\alpha,\beta,t)$, $V(\alpha,\beta,t)$ and $Z(\alpha,\beta,t)$.

3. FRACTIONAL STEP ALGORITHM

A qualitative examination of Eqs. (1) and (2) shows that they represent three physical processes with distinctive features and for which numerical approximations present different kinds of difficulties:

(i) momentum advection, groups I and II,
(ii) momentum diffusion, groups I, V and VI,
(iii) propagation, groups I,III and IV.

The algorithm used in CYTHERE ES 1 is based on the recognition of three physical phenomena and proceeds as follows. Suppose that the state of the model is known at time $n\Delta t$ (Z^n, U^n, V^n known at all points), the new state at time $(n+1)\Delta t$ is computed by the successive resolutions of the advection, diffusion and propagation operators. Each step is solved by a different numerical method so as to increase the accuracy and economy of the solution.

3.1 First step - Advection

The finite difference discretisation of advective terms in flow equations is the most important source of spurious damping and dispersion, both due to discretisation errors. To avoid this, space-centered finite differences are used such as:

$$\frac{\partial u}{\partial x} \simeq \frac{u_{i+1,j} - u_{i-1,j}}{2\Delta x} \quad ; \quad \frac{\partial u}{\partial y} \simeq \frac{u_{i,j+1} - u_{i,j-1}}{2\Delta y} \tag{3}$$

Where:

(x,y) = horizontal coordinate axes,

$u(x,y,t)$ = flow velocity in x-direction,

(i,j) = indices of computational points in x- and y- directions respectively,

$(\Delta x, \Delta y)$ = space computational steps in x- and y- directions respectively.

Approximation equation (3) is of 2^{nd} order if Δx = const, Δy = const. Numerical damping due to this approximation is negligible but dispersion is important and hampers the results so much that higher order approximations (4th order) are sought. The results are apparently more satisfactory, but this approach was not followed by the authors, who think that the high accuracy may often be misleading. Indeed, if the computational grid is not uniform ($\Delta x, \Delta y$ variable) the order of approximation decreases. More importantly a higher order of approximation is theoretically better when assuming that $\Delta x, \Delta y$ are small. Typically these intervals vary between 100 m and 1000 m. For a computational grid with Δx = 200 m Eq. (3) approximates the derivative with a difference of two velocities at points which are 400 meters apart! Fourth order approximation would involve 5 points distributed over a distance of 1000 m. In such a situation, the higher order approximation has the effect of smoothing and spreading out the differences through interpolation polynomials and local variations of advective currents cannot be accurately computed.

For the above reasons advective terms in the modelling system presented here were treated by the method of characteristics based on the principle derived by Holly and Preissmann [4]. During the advection step the following system of equations is solved between the time n Δt and an intermediate time notation n+1/3:

$$\frac{u^{n+1/3} - u^{n}}{\Delta t} + \frac{u_\alpha}{e_\alpha}\frac{\partial u}{\partial \alpha} + \frac{u_\beta}{e_\beta}\frac{\partial u}{\partial \beta} = 0 \; ; \quad \frac{v^{n+1/3} - v^{n}}{\Delta t} + \frac{u_\alpha}{e_\alpha}\frac{\partial v}{\partial \alpha} + \frac{u_\beta}{e_\beta}\frac{\partial v}{\partial \beta} = 0 \qquad (4)$$

Where:

(u,v) = velocity components along x- and y- axes of cartesian coordinate system,

u_α , u_β = projections of the velocity vector on the α- and β- axes of curvilinear coordinate system,

e_α, e_β = metric coefficients such that:

$$e_\alpha = \left[\left(\frac{\partial x}{\partial \alpha}\right)^2 + \left(\frac{\partial y}{\partial \alpha}\right)^2\right]^{1/2} \qquad e_\beta = \left[\left(\frac{\partial x}{\partial \beta}\right)^2 + \left(\frac{\partial y}{\partial \beta}\right)^2\right]^{1/2} \qquad (5)$$

The solution $u^{n+1/3}$, $v^{n+1/3}$ of Eq(4) is obtained by the method of characteristics in two dimensions as described in [1]. Although the computations are made at specified intervals, the method described in [4] enables numerical damping and dispersion to be almost completely avoided. Once intermediate velocities $u^{n+1/3}$, $v^{n+1/3}$ are found for all computational points, unit discharges $U^{n+1/3} = h^n u^{n+1/3}$, $V^{n+1/3} = h^n v^{n+1/3}$ can be computed.

3.2 Second step - Diffusion

Diffusion step equations are solved between two intermediate time notations n+1/3 and n+2/3 in terms of unit discharges.

$$\frac{U^{n+2/3} - U^{n+1/3}}{\Delta t} = \frac{1}{e_\alpha e_\beta}\left[\frac{\partial}{\partial \alpha}\left(K\frac{\partial U}{\partial \alpha}\frac{e_\beta}{e_\alpha}\right) + \frac{\partial}{\partial \beta}\left(K\frac{\partial U}{\partial \beta}\frac{e_\alpha}{e_\beta}\right)\right] + FV \qquad (6)$$

$$\frac{V^{n+2/3} - V^{n+1/3}}{\Delta t} = \frac{1}{e_\alpha e_\beta}\left[\frac{\partial}{\partial \alpha}\left(K\frac{\partial V}{\partial \alpha}\frac{e_\beta}{e_\alpha}\right) + \frac{\partial}{\partial \beta}\left(K\frac{\partial V}{\partial \beta}\frac{e_\alpha}{e_\beta}\right)\right] - FU \qquad (7)$$

Where F is the Coriolis acceleration parameter. Eqs.(6) and (7) are well-known parabolic equations. Their numerical solutions are accurate even with crude methods, so an ADI approach based on a fully implicit finite difference scheme is used for this step in CYTHERE ES 1. It gives new values $(U,V)^{n+2/3}$ at all computational points.

3.3 Third step - Propagation

This step is a crucial one because of the computer time it requires and also because of the numerical inaccuracies generated when economy in computer time is sought by using inadequate methods. "Polarisation" of velocity fields when using Alternating Directions (ADI) methods was described firstly in [3] then in [1]. Let us define Courant number Cr as:

$$Cr = \Delta t \sqrt{gh} \sqrt{\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2}} \tag{8}$$

where:

Δt = computational time step,
h = local flow depth,
g = acceleration due to gravity.

Nearly all industrial programs use implicit finite difference schemes which enable Cr values of greater than 1 to be used, whereas explicit schemes are numerically unstable in these conditions. Since the fully implicit methods lead to excessive computational times, the ADI implicit methods are widely used. These methods, however, may give completely wrong results for Courant numbers greater than 5 to 10. Indeed the velocity fields become "polarized" along either x- and y- axes when the time step Δt corresponds to Cr greater than 5. This phenomenon is described in reference [1] and examples of obviously absurd results obtained with the ADI method for higher Cr values are given. Moreover the ADI method cannot correctly compute velocity fields along and across channels which are not parallel to the x- or y- axis, as has been shown in [6]. For these reasons a more efficient and accurate algorithm was used by the authors.

Working equations for the propagation step are:

$$\frac{Z^{n+1} - Z^n}{\Delta t} = - \frac{1}{e_\alpha e_\beta} \left[\frac{\partial}{\partial \alpha} (U_\alpha e_\beta) + \frac{\partial}{\partial \beta} (U_\beta e_\alpha) \right] \tag{9}$$

$$\frac{U_\alpha^{n+1} - U_\alpha^{n+2/3}}{\Delta t} = - gh \frac{1}{e_\alpha} \frac{\partial Z}{\partial \alpha} + \frac{U_\alpha}{h} \frac{\partial Z}{\partial t} - g \frac{U_\alpha \left\| \vec{U} \right\|}{C^2 h^2} + \frac{1}{\rho} \tau_{S\alpha} \tag{10}$$

$$\frac{U_\beta^{n+1} - U_\beta^{n+2/3}}{\Delta t} = - gh \frac{1}{e_\beta} \frac{\partial Z}{\partial \beta} + \frac{U_\beta}{h} \frac{\partial Z}{\partial t} - g \frac{U_\beta \left\| \vec{U} \right\|}{C^2 h^2} + \frac{1}{\rho} \tau_{S\beta} \tag{11}$$

Where:

C = Chezy coefficient,
$\left\| \vec{U} \right\| = (U_\alpha^2 + U_\beta^2)^{1/2}$.

Lack of space does not allow the authors to give details of the discretisation, the main principles of which can be found in [1]. Essentially, right hand terms of Eqs (9) to (11) are written under implicit formulation such as:

$$\frac{gh}{e_\alpha}\frac{\partial Z}{\partial \alpha} = \frac{g}{e_\alpha}\left[\theta h^{n+1}\left(\frac{\partial Z}{\partial \alpha}\right)^{n+1} + (1-\theta)h^{n}\left(\frac{\partial Z}{\partial \alpha}\right)^{n}\right] \qquad (12)$$

Then, from Eqs. (10) and (11) expressions for increments ΔU, ΔV during one time step Δt, as functions of known values and Z^{n+1} are extracted, (Note: $\Delta U = U^{n+1} - U^{n+2/3}$, etc). These increments are substituted into Eq (9) which, discretised, becomes an algebraic system of equations for the Z_k^{n+1}, ($k = 1, 2, \ldots, m$), where m is the number of computational points in the model.

This final system of equations is solved by an iterative method which is based upon the conjugate gradient method and is, with the method of characteristics used for the advection step, of crucial importance in the algorithm. Indeed, nowadays models of tidal areas can contain anywhere between 2000 and 8000 computational points; this effectively prohibits matrix inversion. Explicit formulation would lead to excessively small time steps. The ADI methods may give, as mentioned above, misleading results even when the time step is physically reasonable, hence the use of a special development of the conjugate gradient method (iteration through alternating direction operator with coordinator) described in [5].

The iteration procedure permits the use of high Courant numbers (20 and more) without loss of accuracy even when simulating channels angled at 45° to the coordinate axes. It should be stressed that with efficient programming one iteration needs less computer time than resolution of the propagation step by the explicit method.

4. ORTHOGONAL CURVILINEAR GRID GENERATION

The generation of curvilinear computational grid is semi-automatic in the CYTHERE ES 1 system at the preprocessor level (see Fig. 1). The details of the method, developed by Sogreah, are given elsewhere [2], only the main features are followed here.

The mathematical tool used to generate the orthogonal curvilinear grid is the conformal transformation. It is assumed that for a given domain D, D being a coastal zone or an estuary for example, which satisfies a number of conditions, there is a conformal transformation f which associates a rectilinear domain D' to D (a rectilinear domain is defined as a domain bounded by straight lines intersecting at right angles).

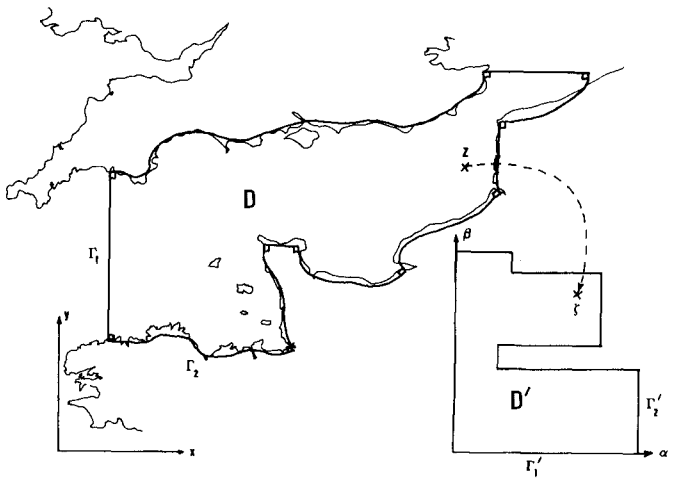


Fig. 2a Simplified domain D for the English Channel

Fig. 2b A priori shape of domain D'

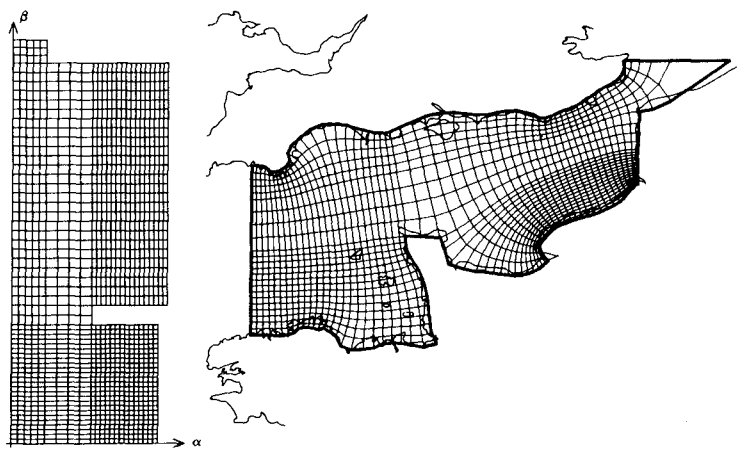

Fig. 3a Final shape of D' with cartesian grid

Fig. 3b Orthogonal Curvilinear grid in D

Using complex notations, to any point $Z = x + iy$ in D, f associates a point $\zeta = f(Z) = \alpha + i\beta$ in D'. The function f is analytic, hence α and β form a conjugate harmonic pair $\Delta\alpha = 0, \Delta\beta = 0$ and they satisfy the Cauchy-Riemann equations:

$$\frac{\partial \alpha}{\partial x} = \frac{\partial \beta}{\partial y} \qquad \frac{\partial \alpha}{\partial y} = - \frac{\partial \beta}{\partial x} \tag{13}$$

which implies that lines of constant α are orthogonal to lines of constant β . These conditions must hold true on the boundaries which are formed of segments on which either α or β is constant.

This method is applied to jagged coastlines or estuaries. In a first approach, the real topography of the domain is approximated by a simplified contour which represents only the most characteristic features. The size of the features to be taken into account for the model depends, of course, on the scale of the phenomenon to be modelled. The physical domain is thereby schematised into a simplified domain D (e.g. Fig. 2a).

The domain D must satisfy a number of conditions. It must be simply connected in the (x,y) plane, i.e. its boundary is a continuous line and D does not contain holes. Next, its boundary Γ has to be composed of an even number of curved segments Γ_i intersecting at right angles, $\Gamma = \cup \Gamma_i$. Hence, the transformed domain D' will be delimited by a contour $\Gamma' = \cup \Gamma'_i$, Γ'_i being the image of Γ_i, so that all straight segments Γ'_i and Γ'_{i+1} intersect at right angles, since the conformal transformation keeps the values of angles. Using this property, the contour Γ' can be drawn a priori, simply by turning at the end of each Γ'_i of an angle equal to the angle between Γ_i and Γ_{i+1}.

Thus, the domain D' is defined in a (α,β) plane where the α- axis is parallel to horizontal segments and the β- axis parallel to vertical ones. The direction of axes is chosen according to the contour orientation (see Fig. 2b).

The conformal mapping f is then computed numerically, with the help of a finite element method by solving a Laplacian equation with a Neumann boundary condition given on the contour Γ, and the final shape of D', i.e. the length of each Γ'_i is determined, as explained in [2].

In the second stage a Cartesian grid is built inside the transformed rectilinear domain D' parallel to the α and β axes, the spacing between vertical and horizontal lines need not to be constant (Fig. 3a). Using the inverse conformal transformation f^{-1}, this Cartesian grid will be mapped into an orthogonal curvilinear grid inside D (see Fig. 3b) since the property of orthogonality is conserved.

Numerical computation of f^{-1} uses the same finite element program as for f, for the simultanous resolution of four Laplacian equations with Dirichlet boundary conditions. Finally projection parameters and metric coefficients e_α, e_β of Eq. (5) are computed automatically.

The spacing between Cartesian grid lines in D' has been chosen to suit the desired spacing in the curvilinear grid, however the packing of the curvilinear grid lines obtained may be slightly different from that expected. It is not possible to add lines after the resolution of the second stage computations unless the process is reiterated from a new Cartesian grid inside D'. On the other hand, some of the lines can be eliminated provided that the new spacing satisfies a regular increase or decrease acceptable by the finite difference program. According to user's choice, one final program "erases" lines of the curvilinear grid, checks the regularity of the spacing and establishes a correspondence between the lines that have been kept and integer numbering of the finite difference grid (I = 1, 2,... ; J = 1, 2,...). The example of the orthogonal grid generated by the preprocessor shown in Fig. 3b illustrates the method. All points are determined by the intersection of two orthogonal lines, but since they are joined on the drawing by straight segments which do not exactly coïncide with the lines, some drafted angles are different from 90°, as in the top-right corner.

5. EXAMPLE OF AN APPLICATION TO AN ENGINEERING STUDY

The CYTHERE ES 1 modelling system has recently been used by Sogreah for a complex engineering study of development in South Korea: Kwang Yang Bay. The project consists of reclaiming a vast area in the bay located on river delta soils, and of dredging from a nearby area. A steel mill will be built on the reclaimed site together with a harbour for raw materials and finished products, for up to 250,000 dwt ships. The study involved:

- in-situ measurements;
- two-dimensional mathematical modelling of tidal currents in the bay with the projected steel mill, two options of river discharge: average or flood, and three tide conditions;
- one-dimensional mathematical modelling of the tide influenced section of the major river flowing into the bay;
- mathematical modelling of large ship navigation in the entrance channel in the bay, based on currents predicted for the new conditions (reclaimed and dredged area);

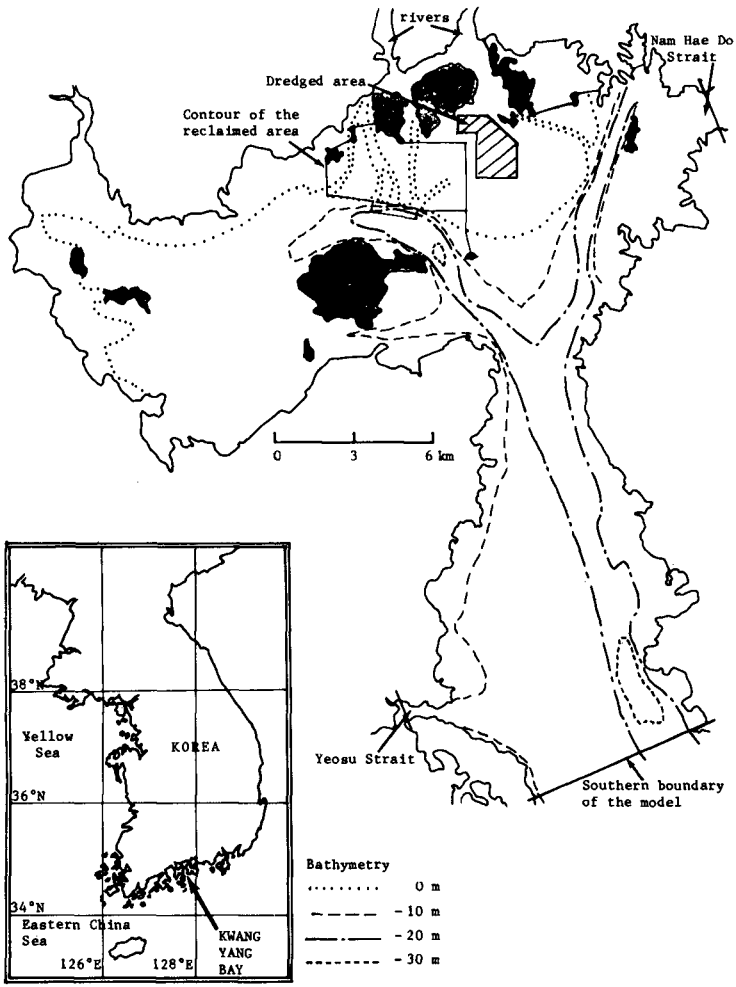

Fig. 4 Map of Kwang Yang Bay (islands in dark)

- scale model tests (1:25), in a specially equipped lake, of ship manoeuvres in the harbour, conducted by ship's pilots. The lake dimensions are 255 m by 190 m and the test crafts were scaled to represent up to 250,000 dwt ships;

- sediment transport evaluation.

Figure 4 shows a map of the bay, which has five open boundaries; two rivers to the north with given constant discharge, and three boundaries with time dependent water conditions obtained from in-situ measurements: the southern boundary directly connected to the Eastern China Sea, the Nam Hae Do Strait to the north east and Yeosu Strait to the south west, both connected to adjacent bays.

The grid was cartesian with irregular intervals in the x and y directions, and varying Strickler friction coefficients were used to account for sea weed culture on the tidal flats.

A most important feature of the model was its rapidly varying bathymetry: within a distance of less than 600 meters (three computational points) the bottom depth goes from a positive value (above lowest low water datum) to -20 meters. The original tidal flat computation procedure used in the propagation step (see [1]) and its link with deep water computation proved to be the critical point of the simulation.

Once the calibration of the model was completed, computed levels and currents compared very well with measured values (fig. 5). The current phase agreement was quite remarkable, and of particular importance as currents computed with the proposed facilities were to be analysed to define the time period of ship entry into the harbour. Current fields were drawn at different times during the tidal cycles. Figure 6 shows the currents in the vicinity of the steel mill, they are parts of the current charts drawn for spring tide at high water and at 4 hours before high water.

6. CONCLUSION

The original mathematical method used in the CYTHERE ES 1 method enables very good accuracy to be obtained at a reasonable computer cost. It has been applied to many engineering studies including modelling of the thermal impact of 30 coastal nuclear power plants in France by the LNH [7], investigation of ocean eroding action (river Canche estuary, France, LNH), a pollution study (bay of Saint-Brieuc, France, Sogreah), ... New developments include modelling of wind-induced currents and this is being applied to the study of a lake.

A THREE-DIMENSIONAL MODEL OF BERING AND CHUKCHI SEA

by
Shiao-Kung Liu* and Jan J. Leendertse*

Introduction

A part of the continental shelf area of the Bering and Chukchi Sea are now being opened up for oil exploration. For engineering and ecological risk analyses, extensive field data collection efforts are being carried out by various United States agencies and petroleum corporations to understand the hydrodynamic behavior of this vast offshore area.

In addition, modeling studies are being made for which a three-dimensional model of the area, outlined in Fig. 1, has been developed. This model is dynamically coupled to a two-dimensional stochastic weather model. This weather model contains a Markov synoptic component and a storm track component. The parameters of this model are derived from a 20-year data base.

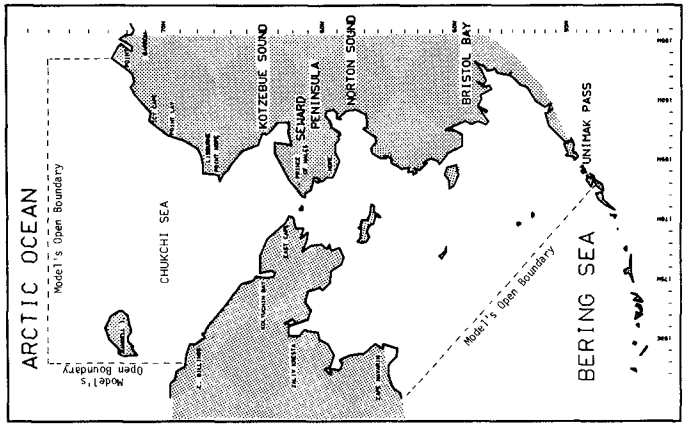
This paper presents a description of the three-dimensional model and the results of a series of simulations using the model to compute tidal propagation and circulations induced by tides and wind. The results of a simulation of a moving storm through the eastern Bering Sea are also presented.

The Three-Dimensional Modeling System

The modeling system used for the study is formulated according to the equations of motion for water and ice, continuity, state, the balance of heat, salt, pollutant and turbulent energy densities, on a three-dimensional finite difference grid. The vertical momentum, mass, heat and turbulent energy exchange coefficients are computed from the turbulent energy, thus the model contains a turbulence closure computation. Turbulent energy dissipation due to mixing of heavier water with lighter water is accounted for in the turbulence closure.

The horizontal grid conforms with the earth's ellipsoidal coordinates while the arbitrary vertical grid spacing approximates the bottom topography of the modeled area. The results are subsequently transformed on the Universal Mercator projection for graphical representation. For simplicity, the system of modeling equations is presented here by use of the standard finite difference notation on a regular spatial grid network in the horizontal direction, and on an irregular grid in the vertical (Fig. 2). The coordinates i, j, k, n, are used to denote discrete points on the x, y, z, t, domain. The finite difference formulation adapted for the computation takes the following form:

*The Rand Corporation, Santa Monica, California



Location map showing eastern Bering Sea and Chukchi Sea modeling area.

Fig. 1

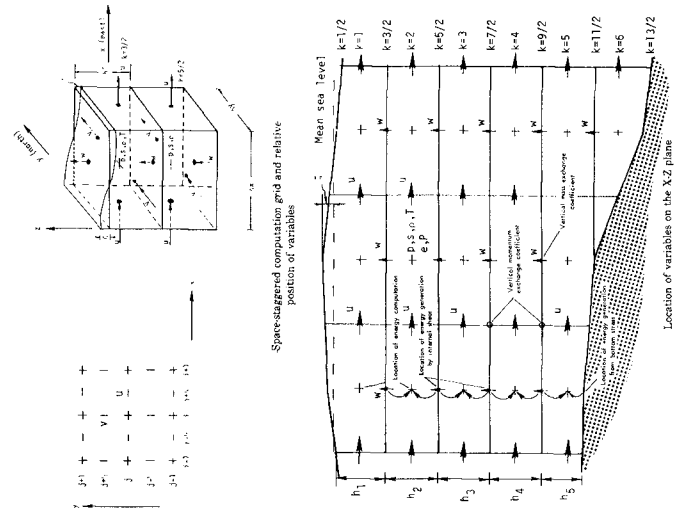


Fig. 2

$$\overline{\delta_t \zeta} = - \sum_k \left[\delta_x (\overline{h}^x u) + \delta_y (\overline{h}^y v) \right] \qquad \text{at } i, j, n \qquad (1)$$

where the variation of the water level ζ is derived from the continuity equation by vertical integration, and h is the layer thickness.

The momentum equation in the x-direction

$$\overline{\delta_t (\overline{h}^x u)}^t = - \delta_x (\overline{\overline{h}^x u}^x \overline{u}^x) - \delta_y (\overline{\overline{h}^y v}^x \overline{u}^y) - \overline{h}^x \delta_z (\overline{u}^z \overline{w}^x) + f \overline{h}^x \overline{v}^{xy} - \frac{1}{\overline{\rho}^x} \overline{h}^x \delta_x p$$

$$+ \frac{1}{\overline{\rho}^x} \left[h \delta_z \left(E_x \delta_z \overline{u}^{2t} \right) + \delta_x \left(h A_x \delta_x u \right)_- + \delta_y \left(\overline{\overline{h}^x A_y}^y \delta_y u \right)_- \right] \qquad (2)$$

$$\text{at } i + \tfrac{1}{2}, j, k, n$$

where E_x is the vertical momentum exchange coefficient, and A_x, A_y are horizontal exchange coefficients in x-direction and y-direction, respectively.

The momentum equation in the y-direction,

$$\overline{\delta_t (\overline{h}^y v)}^t = - \delta_x (\overline{\overline{h}^x u}^y \overline{v}^x) - \delta_y (\overline{\overline{h}^y v}^y \overline{v}^y) - \overline{h}^y \delta_z (\overline{v}^z \overline{w}^y) - f \overline{h}^y \overline{u}^{xy} - \frac{1}{\overline{\rho}^y} \overline{h}^y \delta_y p$$

$$+ \frac{1}{\overline{\rho}^y} \left[h \delta_z \left(E_y \delta_z \overline{v}^{2t} \right) + \delta_x \left(\overline{\overline{h}^y A_x}^x \delta_x v \right)_- + \delta_y \left(h A_y \delta_y v \right)_- \right] \qquad (3)$$

$$\text{at } i, j + \tfrac{1}{2}, k, n$$

The mass-balance equation for salt,

$$\overline{\delta_t (hs)}^t = - \delta_x (\overline{h}^x u \overline{s}^x) - \delta_y (\overline{h}^y v \overline{s}^y) - h \delta_z (w \overline{s}^z)$$

$$+ \delta_x \left(\overline{h}^x D_x \delta_x s \right)_- + \delta_y \left(\overline{h}^y D_y \delta_y s \right)_- - h \delta_z \left(\kappa \delta_z \overline{s}^{2t} \right) \qquad (4)$$

$$\text{at } i, j, k, n$$

where D_x and D_y are the horizontal diffusion coefficients and k is the vertical mass exchange coefficient. For temperature

$$\overline{\delta_t(h\bar{T})}^t = -\delta_x(\bar{h}^x u\bar{T}^x) - \delta_y(\bar{h}^y v\bar{T}^y) - h\delta_z(w\bar{T}^z)$$

$$+ \delta_x\left(\bar{h}^x D_x \delta_x T\right)_- + \delta_y\left(\bar{h}^y D_y \delta_y T\right)_- + h\delta_z\left(\kappa'\delta_z \bar{T}^{2t}\right) \qquad (5)$$

at i, j, k, n

where κ' is the vertical thermodiffusion coefficient.
For the SGS energy density in the system,

$$\overline{\delta_t(he)}^t = -\delta_x(\bar{h}^x u\bar{e}^x) - \delta_y(\bar{h}^y v\bar{e}^y) - h\delta_z(w\bar{e}^z)$$

$$+ \delta_x\left(\bar{h}^x D_x \delta_x e\right)_- + \delta_y\left(\bar{h}^y D_y \delta_y e\right)_- + h\delta_z\left(E_e \delta_z \bar{e}^{2t}\right) \qquad (6)$$

$$+ h\bar{S}_e^z - D_e h \qquad \text{at i, j, k, n}$$

where E_e is the vertical momentum exchange coefficient. For the pollutant constituent concentration,

$$\overline{\delta_t(hP)}^t = -\delta_x(\bar{h}^x u\bar{P}^x) - \delta_y(\bar{h}^y v\bar{P}^y) - h\delta_z(w\bar{P}^z)$$

$$+ \delta_x\left(\bar{h}^x D_x \delta_x P\right)_- + \delta_y\left(\bar{h}^y D_y \delta_y P\right)_- + h\delta_z\left(\kappa\delta_z \bar{P}^{2t}\right) \qquad (7)$$

$$+ hS_p - D_p h \qquad \text{at i, j, k, n}$$

The equation of state is approximated by

$$\rho = \left[5890 + 38T - 0.375T^2 + 3s\right] \Big/ \left[\left(1779.5 + 11.25T - 0.0745T^2\right) - \left(3.8 + 0.01T\right)s + 0.698\left(5890 + 38T - 0.375T^2 + 3s\right)\right] \qquad (8)$$

at i, j, k, n + 1

The continuity equation is used to compute the vertical velocity:

$$\delta_z w = -\delta_x\left(\bar{h}^x u\right) - \delta_y\left(\bar{h}^y v\right) \qquad \text{at i, j, k, n + 1} \qquad (9)$$

Similar equations for velocity components u and v can be written for the top and bottom layers, but now the effects of wind and bottom friction must be considered. We have at the surface:

$$\overline{\delta_t(\overline{h}^x u)}^t = -\delta_x(\overline{\overline{h}^x u}^x \overline{u}^x) - \delta_y(\overline{\overline{h}^y v}^x \overline{u}^y) - \overline{h}^x \delta_z(\overline{u}^z \overline{w}^x) + f\overline{h}^x \overline{v}^{xy} - \frac{1}{\overline{\rho}^x}\overline{h}^x \delta_x p$$

$$+ \frac{1}{\overline{\rho}^x}\left[\theta \rho_a w_a^2 \sin\psi - \left(E_x \delta_z \overline{u}^{2t}\right)_{k=3/2} + \delta_x\left(hA_x \delta_x u\right)_- + \delta_y\left(\overline{\overline{h}^x A_y}^y \delta_y u\right)_-\right]$$

$$\text{at } i + \tfrac{1}{2},\ j,\ 1,\ n \qquad (10)$$

where ψ is the clockwise angle between the model's y-axis and the direction toward which the wind is blowing. In the y-direction, the momentum equation becomes

$$\overline{\delta_t(\overline{h}^y v)}^t = -\delta_x(\overline{\overline{h}^x u}^y \overline{v}^x) - \delta_y(\overline{\overline{h}^y v}^y \overline{v}^y) - \overline{h}^y \delta_z(\overline{v}^z \overline{w}^y) - f\overline{h}^y \overline{u}^{xy} - \frac{1}{\overline{\rho}^y}\overline{h}^y \delta_y p$$

$$+ \frac{1}{\overline{\rho}^y}\left[\theta \rho_a w_a^2 \cos\psi - \left(E_y \delta_z \overline{v}^{2t}\right)_{k=3/2} + \delta_x\left(\overline{\overline{h}^y A_x}^x \delta_x v\right)_- + \delta_y\left(hA_y \delta_y v\right)_-\right]$$

$$\text{at } i,\ j + \tfrac{1}{2},\ 1,\ n \qquad (11)$$

where θ represents the wind-stress coefficient, w_a is wind speed, and ρ_a represents the density of air. At the bottom layer, the momentum equation becomes

$$\overline{\delta_t(\overline{h}^x u)}^t = -\delta_x(\overline{\overline{h}^x u}^x \overline{u}^x) - \delta_y(\overline{\overline{h}^y v}^x \overline{u}^y) - \overline{h}^x \delta_z(\overline{u}^z \overline{w}^x) + f\overline{h}^x \overline{v}^{xy} - \frac{1}{\overline{\rho}^x}\overline{h}^x \delta_x p$$

$$+ \frac{1}{\overline{\rho}^x}\left\{\left(E_x \delta_z \overline{u}^{2t}\right)_{k=K-\frac{1}{2}} - \overline{\rho}^x g u_- \left[u_-^2 + \left(\overline{v}_-^{xy}\right)^2\right]^{\frac{1}{2}} \Big/ \left(\overline{C}^x\right)^2\right.$$

$$\left. + \delta_x\left(hA_x \delta_x u\right)_- + \delta_y\left(\overline{\overline{h}^x A_y}^y \delta_y u\right)_-\right\} \qquad \text{at } i + \tfrac{1}{2},\ j,\ K,\ n \qquad (12)$$

$$\overline{\delta_t(\overline{h^y}v)}^t = -\delta_x(\overline{\overline{h^x u}^y \overline{v}^x}) - \delta_y(\overline{\overline{h^y v}^y \overline{v}^y}) - \overline{h^y}\delta_z(\overline{v^z w^y}) - f\overline{h^y u}^{xy} - \frac{1}{\overline{\rho^y}}\overline{h^y}\delta_y p$$

$$+ \frac{1}{\overline{\rho^x}}\left\{\left(E_y \delta_z \overline{v}^{2t}\right)_{k=K-\frac{1}{2}} - \overline{\rho^y} g v_- \left[\left(\overline{u_-}^{xy}\right)^2 + v_-^2\right]^{\frac{1}{2}} \Big/ \left(\overline{C}^y\right)^2\right.$$

$$\left. + \delta_x\left(\overline{\overline{h^y A_x}^y}\delta_x v\right)_- + \delta_y\left(hA_y\delta_y v\right)_-\right\} \quad \text{at } i,\ j+\tfrac{1}{2},\ K,\ n \qquad (13)$$

where C is Chezy coefficient.

In the modeled area, each vertical motion of water mass has to work against buoyancy forces induced by the density gradient. If the available kinetic energy of the turbulent motion is insufficient to overcome this stabilizing effect, turbulence is inhibited and suppressed. As a consequence, the process of momentum and mass-heat exchange will be lower than the neutral stability condition. The criteria for the onset of this turbulence-suppressing process in the system can be obtained by the local density gradient and turbulent energy level. Therefore, the variability of the vertical exchange coefficients in the model is computed by a turbulence closure technique using local turbulence intensity e.

$$E_y = \overline{\rho}^{yz} L\overline{\sqrt{e_-}}^{xz} \qquad (14) \qquad E_x = \overline{\rho}^{xz} L\overline{\sqrt{e_-}}^{xz} \qquad (15)$$

$$E_e = a_1 L\overline{\sqrt{e_-}}^{z} \qquad (16) \qquad \kappa = a_4 L\overline{\sqrt{e_-}}^{z} \qquad (17)$$

where a_1, a_4 are turbulence closure constants and L denotes the length scale, which can be approximated by an additional transport equation or by a parametric expression such as

$$L = k'z(1 - z/d)^{\frac{1}{2}} \qquad (18)$$

κ' is the von Karman constant, z represents the vertical distance from the bottom to the point considered, and d is the vertical distance from the surface to the bottom.

In the horizontal direction, the exchange coefficient is computed in two parts as a function of the local vorticity gradient and the local grid dimension. The first part is

$$A = \gamma \left| (\delta_x \overline{\omega}^y + \delta_y \overline{\omega}^x) \right| (\Delta \ell)^3 \tag{19}$$

where ω is the vorticity, γ is a coefficient, and $\Delta\ell$ is the local grid size. This part represents the exchange for a wave number lower than the spatial Nyquist frequency. The second part represents the contribution from the homogeneous subgrid scale turbulence above the spatial Nyquist frequency, which can be computed according to Kolmogorov's turbulence spectrum theory. The gross horizontal exchange coefficient is therefore

$$D_x = \bar{A}^x + a_5 \Delta \ell^{4/3} \qquad D_y = \bar{A}^y + a_5 \Delta \ell^{4/3} \tag{20} \quad (21)$$

where a_5 is a function of the energy dissipation rate. In the model, the amount of reduction in the vertical exchange due to stratification is based on the direct computation of the local gain in potential energy induced by vertical mixing. The exact amount is then taken out of the local turbulent (kinetic) energy budget. In the equation of energy (Eq. 6), the generation and dissipation terms become

$$\bar{S}_e^z - D_e = \underbrace{a_3 \overline{L\sqrt{e}}^z \left[(\delta_z \overline{u}^x)^2 + (\delta_z \overline{v}^y)^2 \right]}_{(1)} + \underbrace{a_3 \overline{L\sqrt{e}}^z \frac{g}{\bar{h}^z \rho} (\delta_z \overline{\rho}^z)}_{(2)} \underbrace{- a_2 e^{3/2}/L}_{(3)} \tag{22}$$

where the first term denotes production, the second term represents the portion supplied that is used in potential energy increase, and the third term is dissipation.

Modeling of Tides and Currents

Tide enters the Bering Sea through the central and western Aleutian, and enters the Chukchi Sea from the East Siberian Sea. The largest tidal amplitudes are found over the Bering shelf region and in these regions substantial tidal velocities can be observed. The tidal velocities in the Chukchi Sea are much smaller except in areas north of the Bering Strait where two tidal systems interact.

To study the tidal dynamics of the coastal system, the deep water tides at the model's open boundaries are generated using astronomical tidal prediction coefficients obtained from field measurements. A period in the beginning of August 1976 was selected for simulation as current data was available for this period which could be used for comparison of model results with field data. The simulations indicated that the propagation of tide in the study area is dominated by the bathymetry (Fig. 3), and to a certain extent, also influenced by the vertical density structure. The latter was known to cause the shifting of the location of amphidromic points during summer when strong pycnocline exist. Figure 4 shows an instantaneous distribution of computed tidal currents and water level in the modeled area projected on the Mercator plotting scale. As the figure indicates, at 0600 hours (GMT) on August 2, 1976, ebb tide occurred over the shelf break in the eastern Bering Sea. At the same time, water levels were rising in the Bristol Bay, Norton Sound, and over most of the Chukchi Sea.

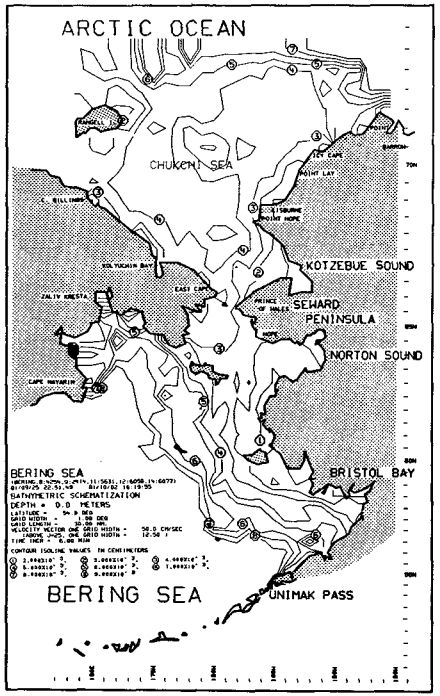
To represent the tidal propagation in an efficient way co-tidal and co-range charts were prepared. The computed co-tidal chart for the semi-diurnal tidal component (Fig. 5) indicates that there are six major amphidromic systems in the modeled area. Over the eastern shelf area, the computed amplitude and phase, as well as the locations of the amphidromic points, agree extremely well with the observed values (Fig. 6) compiled by the National Oceanic and Atmospheric Administration. The computed co-tidal chart for the diurnal tidal components (Fig. 7) also agrees extremely well with the chart derived using observed data (Fig. 8).

Tidal currents in the study area have also been compared to the field data. Using a more detailed sub-model of the Bristol Bay, the computed tidal currents agree extremely well to the observed current data (Figs. 9, 10).

Tide-induced and Baroclinic Circulation

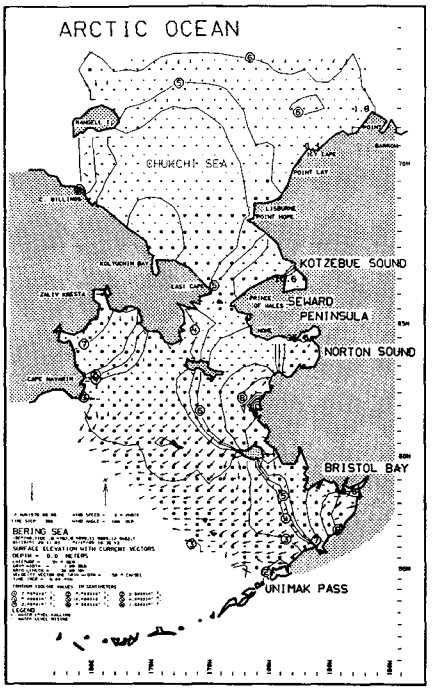
Circulation and transport associated with tidal propagation constitute one of the most important and everlasting driving mechanisms in coastal waters. The non-linear mechanisms generate net circulation over the shallow water in addition to the tidal excursion. This net "residual" transport is usually responsible for carrying constituents to areas much beyond the extent of tidal excursion over the time span of weeks or months. Therefore, one of the major functions of the three-dimensional model has been the determination of the tidal residual circulations.

When a long wave (e.g., the tide) propagates from the deep water through the shallow areas, the non-linear advection terms in the equation of motion, along with non-linear transport terms, generate higher harmonics of the fundamental frequency. In particular, the second harmonic increases in amplitude with the distance of propagation. Bottom friction generates odd harmonics. The varying depth and complicated boundaries



Bathymetric schematization of the three-dimensional model of Bering and Chukchi Sea.

Fig. 3



Computed instantaneous tidal currents and water level distributions in the Bering/Chukchi Sea system. A plus (+) sign denotes water level rise while a square (□) indicates falling of local water surface.

generate dispersion of energy by a combined effect described above and by the generation of local circulation through advection. Due to the non-homogeneity of the density in the vertical, the velocities over any vertical are generally not uniform in magnitude and direction. Since advection is the main mechanism by which the tidal residual is generated, a three-dimensional model is required to compute this non-linear circulation at various levels in the water column. The tidal residual circulation pattern is extremely difficult to establish by measurement as only a limited number of current meters can be employed in these vast area's. In addition, these residual currents are difficult to measure accurately because its magnitude is usually below the sensitivity of most current meters. Even with drogues, the wind effects are difficult to separate from the tidal residual components.

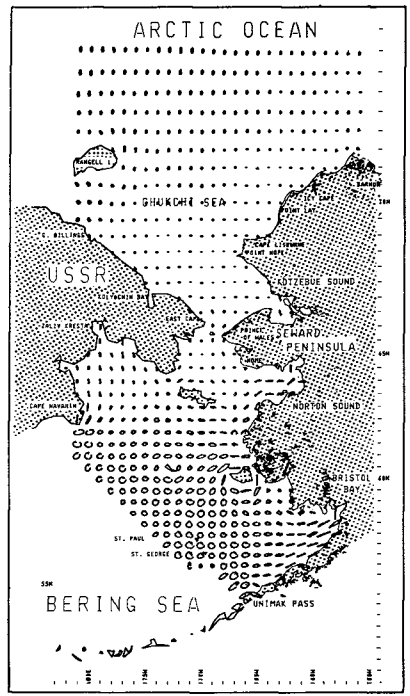
The seasonal changes of the density field in the horizontal direction contributes also to the residual circulation through the mechanisms in the baroclinic modes. Consequently, the residual circulation of a coastal area should be studied by considering both barotropic (tides, etc.) and baroclinic modes. In most cases, residual circulations derived from models using field data for adjustments, is extremely difficult to separate the contributions from these two different modes.

Field data collected over the past decades seems to indicate that the residual transport is from the Pacific Ocean to the Arctic Ocean through the Bering Strait. However, because of the vast area involved, it is rather difficult to obtain a set of records free from the weather's (wind) influence on the residual transport. In order to determine the net circulation pattern, simulations were made using the model with only tides and density field as its inputs. The computed tidal ellipses and residual circulation pattern in the surface layer for the summer season are shown in Figs. 12 and 13. It is derived by a numerical filtering process using a tidal eliminator. Again, the residual transport contains contributions both from tide and from the density field. One of the significant features is the northward transport along the shelf break (depth = 300 m) and along the 50-m isobath. Along this isobath is a transition from a well-mixed system in the shallower area to a two layer system. The general direction of the transport at this transition agrees with the basic theory of coastal residual circulations of non-homogeneous waters. It also agrees with the general drift of satellite-tracked drogues released in various locations in the Bering Sea.

Residual transport through the Bering Strait have been the subject of significant interest in the oceanography of the Pacific Ocean and the Arctic Ocean. The computed residual transport through the Bering Strait is about 0.5 Sv. in the absence of the north-south atmospheric gradient. This agrees with the value observed by Tripp, et al (Ref 1). Another large scale field monitoring program is presently being conducted to further confirm this.

Figure 14 shows the components of the tidal velocities at six different depths of a station in the Bering Strait. The east-west component of the velocities are predominately eastward and only during a short period in the tidal cycle the flow reverses.

The north-south components of the velocities are nearly always directed toward the north. The maximum velocity is in the surface layer and is 22 cm/sec. The magnitude of the current at that time is about 23 cm/sec and the direction is about 17° from the North. Higher modes (overtides)



Computed 12.5-hour tidal ellipses in the second layer using a plotting scale of 86 cm/sec per horizontal grid-spacing

Fig. 11

Fig. 12

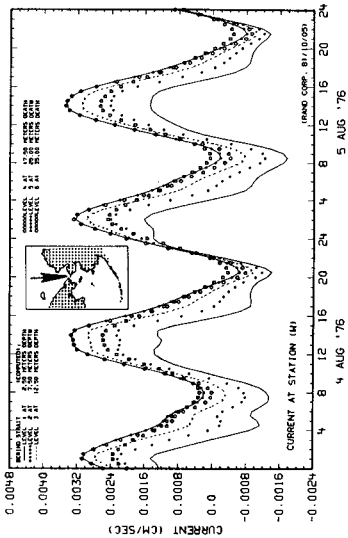

Fig. 13 Computed tidal velocities (U = E-W, V = N-S components) in six representative layers at a station in the Bering Strait.

Fig. 14 Computed vertical velocity (W) and the turbulent energy intensities in six representative layers at a station in the Bering Strait.

can be noticed in the computed currents. They appear mainly in the lower layers where frictional effects are strong and the velocities lag behind those in the upper layers. These characteristics are more obvious in the computed vertical velocity components (top graph, Fig. 14).

The turbulence variation in the bottom layer leads the variation on the upper layers as the transfer is inefficient by the vertical pycnostructure as shown in the bottom graph of Fig. 14. Note that the greatest turbulence intensity exist in the bottom layer. The intensities in this layer are indicated by small squares.

The vertical variation of velocities, energy densities and their phase differences are due mainly to the density variation (Fig. 15). The depth of thermocline in this area are generally deeper than the pycnocline associated with the salinity. This may be due to the more efficient heat diffusion process than the vertical mass exchange.

Residual circulation and stratification-related turbulence field also influence the diffusion process. The amount of diffusion and the net displacement varys throughout a water column. As illustrated in Fig. 16, for a case without surface wind stress particle group releases in the top layer experiences different amounts of advection, turbulent diffusion and net transport than the group release in a lower layer over a 24-hour period.

Storm-Induced Responses

The modeled area is situated within the climatological zone of "Aleutian Lows" which is one of the two major storm areas in the northern hemisphere (the other, Icelandic Lows). The average occurrence of a storm is approximately 3.5 per month with an average duration of 1.5 days.

Many simulations with a moving storm have been made. The weather inputs were derived from a simulation of the weather model. A typical wind and pressure field generated by the stochastic weather model (Ref. 2) is shown in Fig. 17. This particular storm is moving with a speed of 5.1 m/sec.

The computed flow field in the surface layer of the three-dimensional model are shown in Fig. 18, together with the contour lines of the water levels.

At the time of the graph a storm setup occurs in Bristol Bay and in the area northeast of Cape Navarin while low water levels are present in Norton Sound.

Model Use

The three-dimensional model and the stochastic weather are used together with a wind variability model to make simulations of the movements of spilled oil in case accidents would occur during oil exploration or exploitation. The movements are simulated for periods of one to two months originating from selected hypothetical spill sites. The movements can be traced either on the water surface, in or under the ice cover or dispersed in the water column

Results of many simulations are subsequently used to define the risk that certain sensitive areas are exposed to accidentally discharged oil.

A FINITE ELEMENT METHOD FOR THE SHALLOW WATER EQUATIONS

by

A. HAUGUEL (1), G. LABADIE (2) and B. LATTEUX (3)

ABSTRACT

The paper reports the current progress in developing a finite element method for the shallow water equations. The main feature of the method is the special care given to the advective and diffusive parts of the equations, so that it can be of interest to use it when dealing with flows strongly influenced by convective and boundary layer effects. The solution procedure has been chosen so as to allow a calculation with a big number of nodes.

Section 3 of the paper outlines the method. In section 4, is detailed the procedure for the advective terms, involving the determination of the characteristic curves. Section 5 is devoted to the diffusion and propagation terms. Finally numerical results are presented in section 6.

1. INTRODUCTION

Environmental hydraulics often requires the calculation of flows in complex domains. Moreover, one often wishes a finer description for some zones of particular interest, while most of the domain can be approximated by a rather coarse grid. The finite element method provides such a flexibility and a growing interest is taken in its potential.

However the size of the resulting discrete system restricts the possibilities of using it. An interesting approach, presented here, leads to consider separate problems on each of the scalar variables (water level and flow discharge components) and hence allows to reduce the storage requirement.

2. NOTATION

$\underset{\sim}{F}$ = Coriolis and friction forces (components F_i)
$\underset{\sim}{g}$ = acceleration due to gravity
h = depth of water
h_m = average of h in time
K = momentum diffusion coefficient
$\underset{\sim}{Q}$ = uh flow rate per unit length (components Q_i)
$\underset{\sim}{u}$ = velocity field (components u_i)
z = free surface elevation.

3. EQUATIONS

The shallow water equations consist of the mass conservation equation and two momentum equations :

$$\frac{\partial z}{\partial t} + \nabla . \underset{\sim}{Q} = 0$$

(1)

$$\frac{\partial Q_i}{\partial t} + \nabla . (Q_i \underset{\sim}{u}) + gh \frac{\partial z}{\partial x_i} - K \Delta Q_i = F_i$$

A fractional step algorithm is used to decompose the equations into a pure convection system and the remainder.

$\underset{\sim}{Q}^n$, Z^n being given at time t^n, the unknowns at time t^{n+1}, $\underset{\sim}{Q}^{n+1}$, Z^{n+1} are computed by the two following successive steps :

- Determination of auxiliary unknown $\underset{\sim}{Q}^{n+\frac{1}{2}}$ solution of the convection equations :

(2) $$\frac{\partial Q_i}{\partial t} + \nabla . (Q_i \underset{\sim}{u}^n) = 0$$

- Resolution of the diffusion and propagation problem :

$$\frac{\partial z}{\partial t} + \nabla . Q = 0$$

(3)

$$\frac{\partial Q_i}{\partial t} - K \Delta Q_i + gh \frac{\partial z}{\partial x_i} = F_i$$

with initial conditions Z^n, $\underset{\sim}{Q}^{n+\frac{1}{2}}$

4. ADVECTION STEP

It involves the resolution of equations (2), which can be transformed into equations on velocity, by use of the continuity equation :

$$(4)\quad \frac{\partial u_i}{\partial t} + \underset{\sim}{u}^n : \nabla u_i = 0$$

This form has been prefered to the original form (2) as explained in section 6.

A characteristics method has been used to solve those equations (4). It requires two steps :

- computation of the characteristic curves passing through the nodal points ;
- interpolation at the foot of those curves.

The method is unconditionally stable and the time step has just to be small enough to catch the time variation of the velocity field $\underset{\sim}{u}$.

Moreover the amount of computation needed is very reasonable. In particular, there is no non-symmetric system to assemble and solve at each time step, as would appear in a standard implicit method.

As for accuracy, it is quite satisfactory, although somewhat depending on the time-step ; the only significant error being made when performing the interpolation at the foot P_j of the characteristic, the accuracy decreases when P_j is far from a mesh-point, particularly when using a linear interpolation. Finally, conservativity is not ensured by the scheme ; this is probably the main drawback of the method.

This technique has been applied for a long time in the solution of the Navier Stokes equations and is described in more detail in [1]. Some more research is done on the subject [2].

5. DIFFUSION AND PROPAGATION STEP

An implicit discretization has been chosen for system (3) except for the non linear term $gh\nabla Z$ which is partly explicited. There is no need for a second order scheme in time for such long waves as the tide.

If we drop, for sake of simplicity, the superscripts n+1, the system to solve in this step is of the form :

$$(5)\quad \alpha z + \nabla . \underset{\sim}{Q} = R$$

$$(6)\ \alpha \underset{\sim}{Q} - K\Delta \underset{\sim}{Q} + g h_m \nabla z = \underset{\sim}{T}$$

$$\text{with : } \alpha = \frac{1}{DT} \ ; \ R = \frac{1}{DT} z^n \ , \text{ and } \underset{\sim}{T} = \frac{1}{DT} \underset{\sim}{Q} + \underset{\sim}{F}^n - g(h^n - h_m)\nabla z^n$$

(h_m being the average in time of h, that is a function of space coordinates only).

The discretization of equations (5), (6) with their boundary conditions (Q given) yields to a large size linear system. A natural idea to reduce this size, is to eliminate Q between equations (5) and (6). This is achieved by applying the divergence operator to (6) and plugging (5) into the result. The equation obtained is :

$$(7)\ \alpha^2 z - \nabla . (K\alpha + g\, h_m)\nabla z = W$$

$$\text{with : } W = \alpha R - K\Delta R - \nabla . \underset{\sim}{T}.$$

Equation (7) is an elliptic equation, giving by discretization a symmetric matrix. It can easily be solved if a boundary condition is provided for z. If so, Q can be straight forwardly computed from equation (6) where the term $g h_m \nabla z$ is now a known function and can be rejected into the right hand side. With Dirichlet boundary conditions, equation (6) decomposes into two decoupled equations, one for each component Q_i of Q leading to the same symmetric matrix for the discrete system.

The problem then amounts to the determination of the trace of z on the boundary. The procedure used for this purpose is an extension of the technique proposed by Glowinski-Pironneau [3] for the Stokes problem. It is described in detail in [5].

This technique is advantageous on the point of view of computational efficiency. Two "domain" matrices have to be stored, one for the variable z, another for each component of Q (it is the same matrix for the two components). They are symmetric and sparse and small enough to be processed by an in-core solver such as an incomplete Choleski preconditioned conjugate gradient. In addition, the matrix of the boundary operator has to be factorized and stored.

6. NUMERICAL RESULTS

Several applications have been performed, from a very schematic case, in order to have a first view on the possible problems, to a realistic complex one, to give a more comprehensive test of the method.

SCHEMATIZED MASSACHUSSETS BAY

6.1. Schematized Massachussets Bay

In this first experiment, emphasis has been laid on the general behaviour of the method rather than the comparison with actual data. Thus neither the friction and Coriolis force, nor the varying bottom topography were simulated. The domain was coarsely approximated by a rectangle (fig.1) divided into 192 triangular elements with respectively 119 and 429 nodes for piecewise linear and quadratic approximations. Both components of the flow discharge were prescribed on the boundaries ; this discharge was taken to be zero on the land limits, and was schematized on the ocean limit by a sinusoidal uniform flow.

Results as regards current fields and free surface elevation (fig. 2 and 3) were found to be quite satisfactory ; in particular global mass conversation has been insured at less than 1% of the total mass flux over a whole tide.

Teachings of this first application are as follows :

- linear and quadratic approximations for the water height, together with quadratic approximation for the flow discharge, have given closely the same results ;

- there exists some stability condition for the diffusion step ; the nondimensional number $(K.DT/DX^2)$ has to be more than about 10^{-4} to avoid oscillations of the computed solution (probably because of the conflict arising between a nearly hyperbolic system to solve and boundary conditions related to the diffusion, i.e. prescribed velocity on the limits) ;

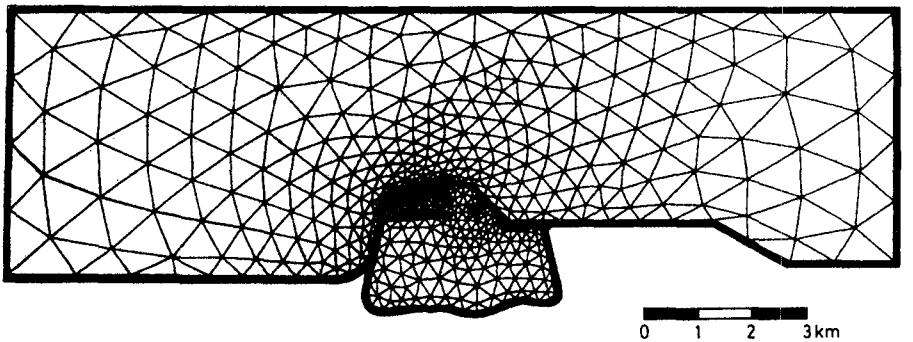
- some kind of "overshoot" can appear in the advection step near the boundary when the flow gets out, due to a bad property of the quadratic interpolation on the flow discharge.

6.2. Dunkirk outer harbour

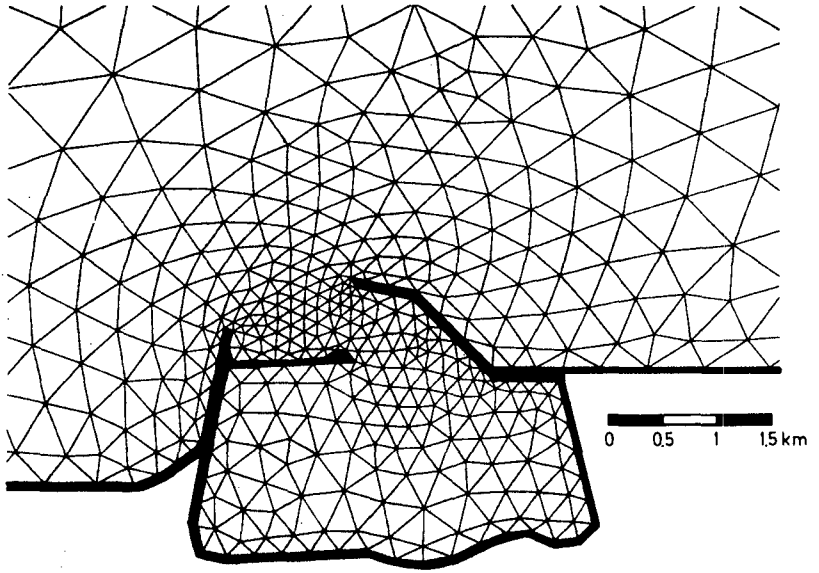
The second application, which is less schematic, concerns the computation of the tidal flow pattern in the vicinity of the new outer harbour of Dunkirk, located on the french coast of the North Sea.

This example has been chosen for two main reasons :

- the shape of the domain and the complexity of the laying out of the limits give the typical case where a finite element method turns out to be specially suitable (good boundary representation and local refinement facilities) and provide a rather severe test of the model ;



a. Mesh of the whole area



b. Detail of the harbour

Fig. 4 - FINITE ELEMENTS MODEL OF DUNKIRK OUTER HARBOUR

this case has been previously studied by means of a scale model and of a finite difference model ; so there exist references to which compare the results of the finite element model.

The finite element grid (fig.4) has been generated automatically by a program developed in our laboratory. As it can be noticed from this illustration, a special mesh refinement has been introduced near the limits, in order to obtain a better consideration of the boundary conditions (which is particularly useful for the land boundaries).

In this experiment a piecewise quadratic approximation has been used for each variable ; there are about nine hundred triangular elements and two thousand calculation nodes.

The characteristics of the computation are as follows :

. tide range is about five meters ;
. maximum velocity is about 1,5 m/s ;
. tide and current are in phase (that is to say that the tide wave is here quite purely progressive) ;
. eddy viscosity coefficient is equal to 5 m^2/s ;
. time step is sixty seconds and Courant number for propagation varies locally from 1 to 5.

Finally both components of the flow discharge are prescribed on the boundaries.

In fact two computations have been carried out successively in this case of Dunkirk : the first one under schematic conditions and the second one in a more realistic way.

6.2.1. Schematic computation

In the first trial the flow discharge is assumed to be sinusoidal and parallel to the upper limit ; the bottom is flat and bed friction is not considered, just as in the example of Massachussets Bay.

Some instabilities appeared in the current field during the computation ; the problem turned out to come from the advection step, solved at first on the flow discbarge Q :

$$\frac{\partial Q_i}{\partial t} + \underset{\sim}{u}^n \cdot \nabla Q_i = - Q_i \nabla \cdot \underset{\sim}{u}^n$$

The discontinuity of the term in the right hand side was found to he responsible for the instabilities. When using the formulation on velocity only, those instabilities actually disappeared.

Fig. 5 shows the evolution of the flow pattern in the vicinity of the harbour at the beginning of the flood current (slack occurs about three hours before high tide) : the flow deflection in front of the harbour and the formation of two eddies can be noticed :

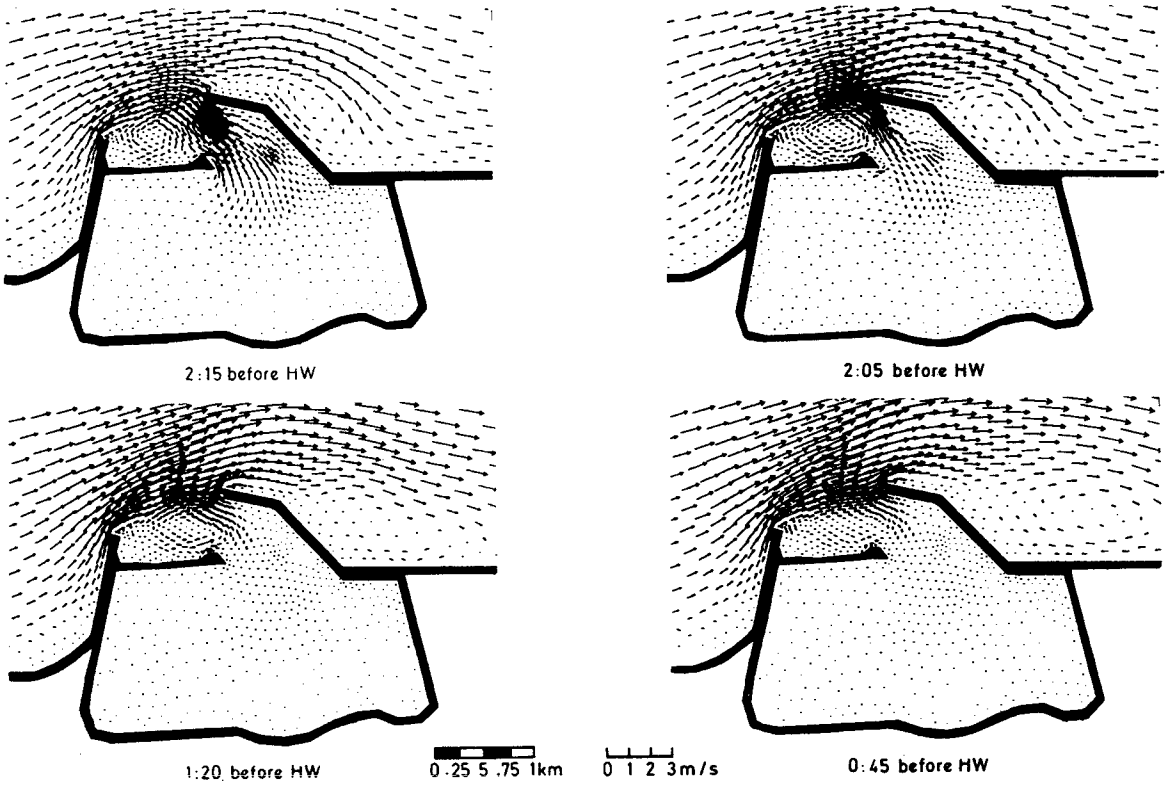


Fig.5_ SCHEMATIC MODELISATION OF DUNKIRK OUTER HARBOUR
Detail of the current fields

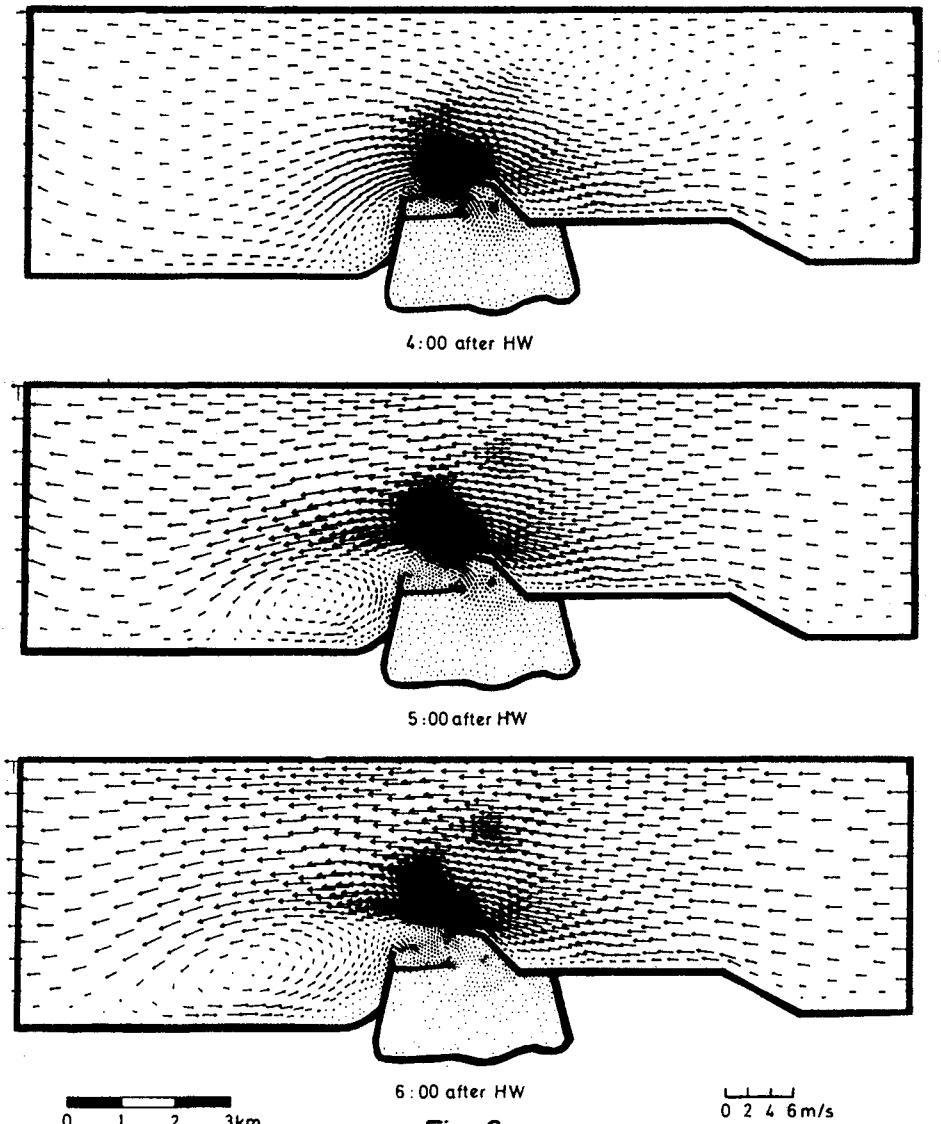

Fig. 6

SCHEMATIC MODELISATION OF DUNKIRK OUTER HARBOUR
COMPUTED CURRENTS IN THE WHOLE DOMAIN

. The first one in the harbour entrance ; it becomes weaker and weaker as the harbour fills in.

. The second eddy downstream the east jetty expands gradually eastwards and in fact it will fill at the end of the flood the whole eastern part of the domain because of the absence of bed friction and because the boundary conditions don't allow it to get out.

Fig. 6 points out in the whole domain the same phenomenon during the ebb ; an eddy appears at the beginning of the ebb on the left of the west jetty and expands progressively till the end of the ebb.

Finally mass conservation was found to be as satisfying as for the first example ; here also the global error regarding the free surface elevation over one tide is less than 1 % of the tide range.

6.2.2. Realistic computation

A second computation has been carried out after the insertion in the model of the bed friction and of the variability of the bed topography.

Fig. 7 exhibits the bathymetry in the vicinity of the harbour ; the depths are quite variable, especially because of the navigation channel for oil tankers ; the steepness of the edges of the channel (about 1:10) is in fact a severe condition for the shallow water equations.

Boundary conditions are now deduced from the results of a previous computation made with a finite difference method on a larger domain.

The computation has been worked out during more than one tide, and the results have been compared to the data obtained by photographs of surface floats on the scale model, built about twelve years ago for the study of the new outer harbour.

Fig. 8 to 10 display this comparison during the most interesting period, from the beginning of the flood till high water.

On fig. 8, at the beginning of the flood, an eddy appears in a similar way on both models, just behind the end of the west jetty, while the harbour fills in ; half an hour later, both eddies have shifted and spread out likewise.

Afterwards (fig. 9) the eddy expands gradually till it covers the whole entrance in both models, with perhaps a slight difference in the shape. The flow deflection due to the harbour can be noticed farther than one kilometer away from the entrance in both cases.

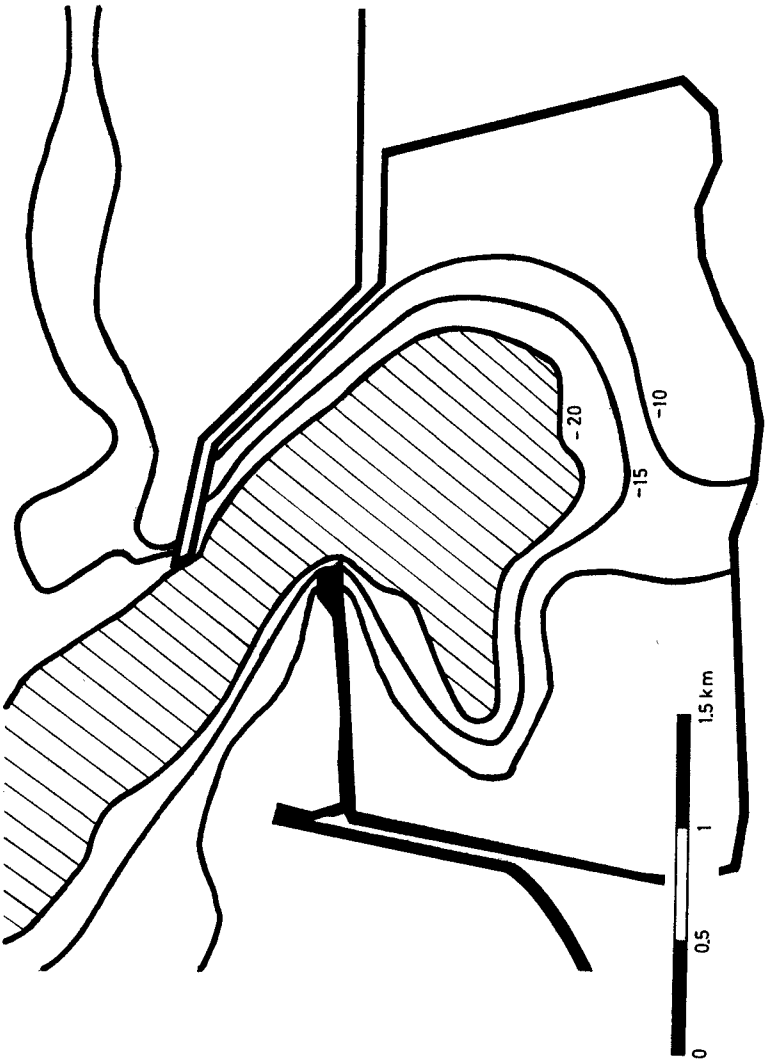

Fig. 7_DUNKIRK OUTER HARBOUR REAL BED TOPOGRAPHY

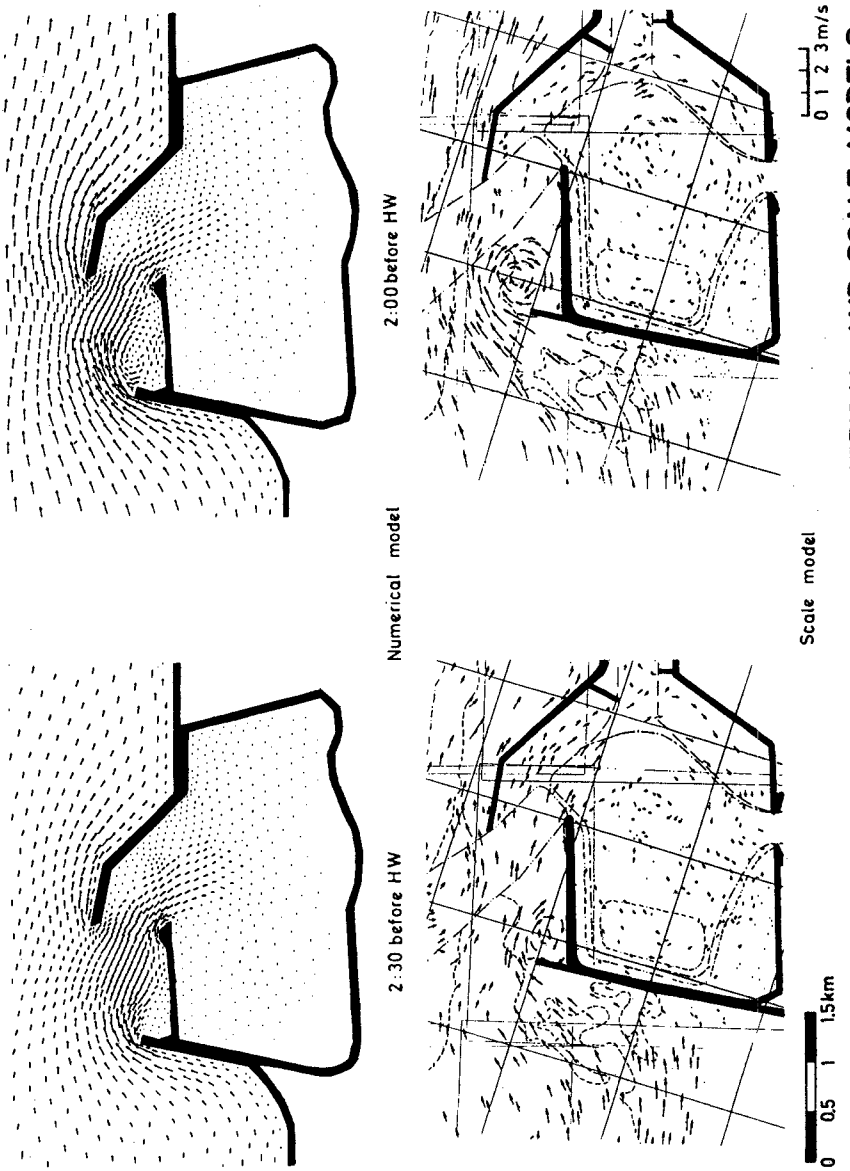

Fig. 8_COMPARISON OF THE RESULTS OF NUMERICAL AND SCALE MODELS

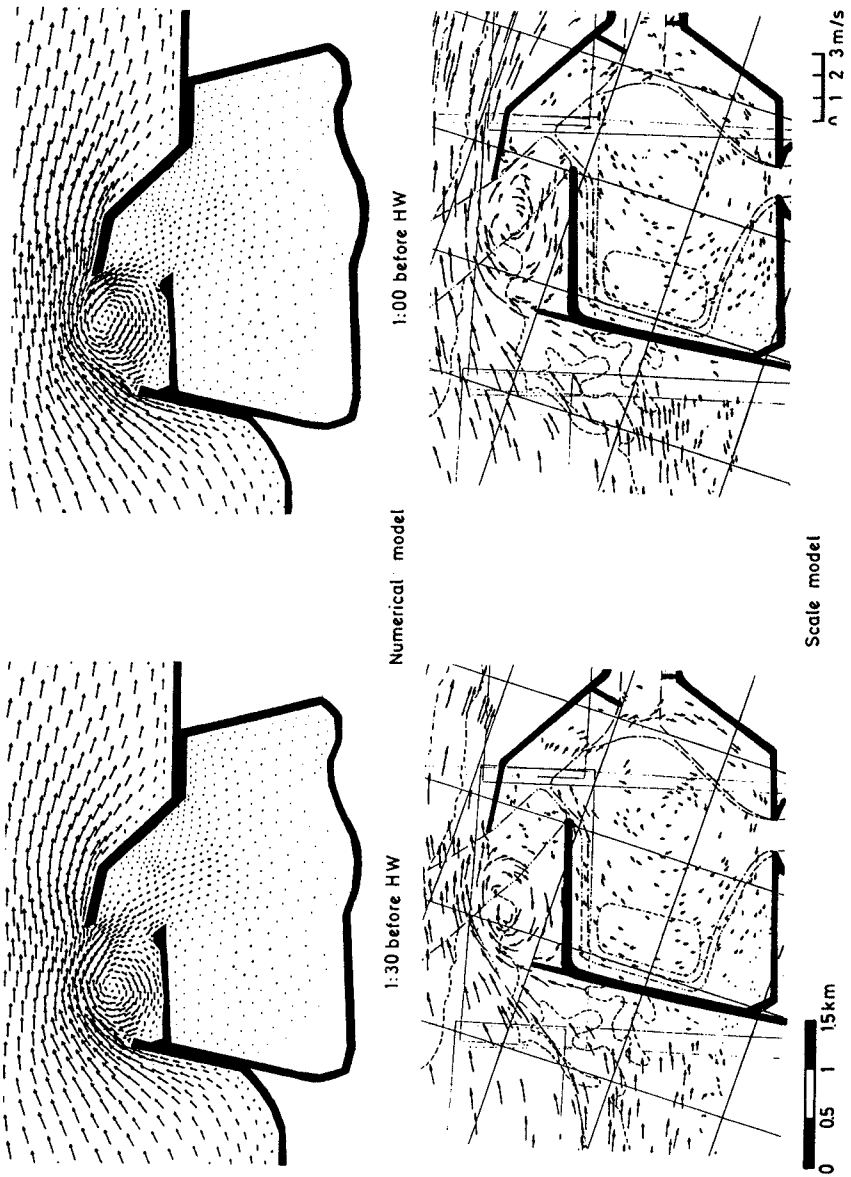

Fig. 9 COMPARISON OF THE RESULTS OF NUMERICAL AND SCALE MODELS

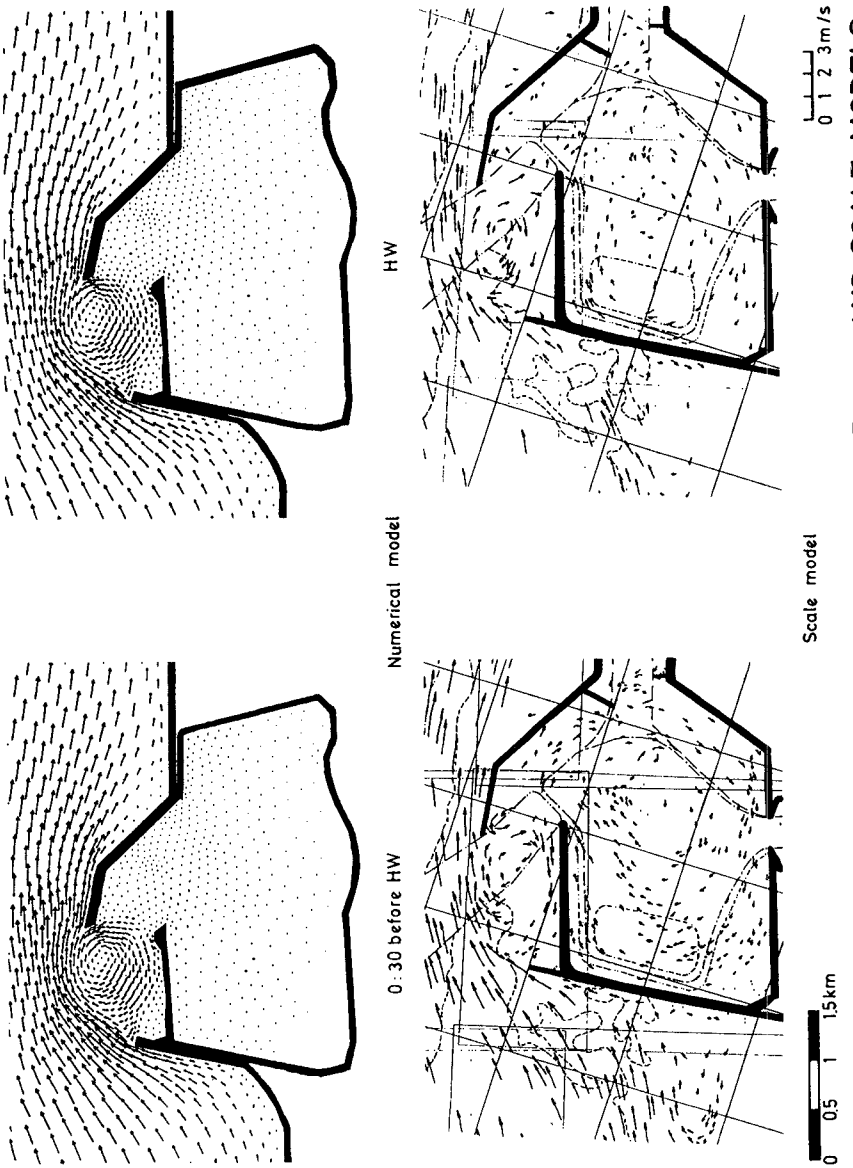

Fig.10_COMPARISON OF THE RESULTS OF NUMERICAL AND SCALE MODELS

From one hour before high water till high water (fig. 10) the eddy remains stable ; downstream the harbour, a slight flow separation can be noticed, but the computation does not develop a big eddy as in the case of the first computation (fig. 5).

The mass conservation is less accurately obtained than in the previous experiments : the global level error over one tide is about 3 % of the tide range ; this seems to be due to the steepness of the sea bed near the breakwaters ; the problem can probably be overcome by taking a more severe threshold of convergence in the numerical resolution of the linear systems.

7. CONCLUSION

Compared to the classical finite difference method, which is now currently used to solve the shallow water equations, this finite element method presents many advantages, such as a better description of the boundaries and a greater flexibility of the grid ; on the other hand, the implementation of the model is rather longer and more complex, and involves a bigger consumption of processing time ; nevertheless, due to the special care given to reduce the size of the systems to be solved, the in-core memory requirements are quite reasonable. As an example computation over one tide (12 h 24 mn) using nearly 2 000 nodes of discretization and a time step of sixty seconds has required about 2 hours of CRAY 1 processing time and 1 000 K bytes of in-core memory.

Numerical experiments have clearly shown that even under rather severe conditions the model has a nice behaviour and exhibits a fair comparison with experimental data .

At present, improvements are in progress, with the implementation of an incident wave condition and the consideration of the influence of wind stress and atmospheric pressure field. The model will soon be used on a domain covering the whole English Channel up to the edge of the continental shelf (fig. 11), with two purposes :

- firstly to examine the impact of a possible tidal power plant on the tidal pattern in this area ;

- secondly to study the generation and propagation of storm surges in the English Channel.

TRIDIMENSIONAL NUMERICAL MODEL FOR TIDAL AND WIND GENERATED FLOW

M.C. BURG* A. WARLUZEL** Y. COEFFE***

Abstract :

This report presents a three-dimensional numerical model, which calculates by a finite-difference method the vertical profile of horizontal velocities. The unsteady three-dimensional Navier-Stokes equations with a free surface are governing this flow. We assume a hydrostatic pressure, and simulate the turbulent effects by the Prandtl's mixing-length hypothesis. The model is validated by experiments carried out in a laboratory flume with a prismatic channel inclined 45° over the flow. Then, the model is applied successfully in Gironde estuary and coastal areas in France for the computation of tidal and wind generated currents.

I. INTRODUCTION

Very little information is presently available about currents induced by tides and wind in their time and space variations. In the particular case where the bathymetry is very irregular, the two-dimensionnal models cannot be used, considering the important three-dimensional aspect of this flow.

The purpose of this paper is to describe a numerical model dealing with this kind of flow and to present different applications.

II. ASSUMPTIONS AND EQUATIONS

The unsteady three-dimensional Navier-Stokes equations with a free surface are governing this flow. In the case of tidal or wind induced flows and if the slope of the bottom does not exceed 10 %, the flow pattern is almost horizontal. It is then possible to simplify these equations. The vertical acceleration can be assumed small compared with gravity. The pressure is thus directly related to the movement of the surface by a hydrostatic relationship.

* Engineer of the Research Division, Laboratoire National d'Hydraulique EDF Chatou. France.

** Engineer of the Research Division, Laboratoire National d'Hydraulique EDF Chatou. France.

*** Head of the Maritime Division, Laboratoire National d'Hydraulique EDF Chatou. France.

The second assumption is related to turbulent effects. The vertical mixing is modelled with the Prandtl's mixing-length hypothesis : the turbulent fluxes of momentum are simulated by vertical and horizontal eddy viscosities ν_z and ν_h. ν_z is expressed by

$$\nu_z = \ell^2 \left| \frac{\partial \vec{V}}{\partial z} \right|$$

where ℓ, mixing-length is assumed to be constant in the fluid except near the bottom and the sea-surface where it linearly varies with the distance from boundary. Horizontally, the velocity gradients are generally small and the convection transfers are predominant compared with the diffusion effects. Then it is possible to choose a constant horizontal diffusion coefficient with a reasonnable value.

In order to represent the bottom topography and the free surface, a curvilinear coordinate z* is used to get a flat and independant of time domain of integration. A rectilinear irregular finite difference will be used on this transformed domain (fig. 1).

z* is expressed as

$$z^* = \bar{S} \frac{(z - zf)}{(S - zf)} \qquad (1)$$

Where $\bar{S}$ is a horizontal reference level, i.e. water surface level at initial time

z_f (x,y) bed level

S (x,y,t) water surface level

z (x,y) vertical coordinate at any point.

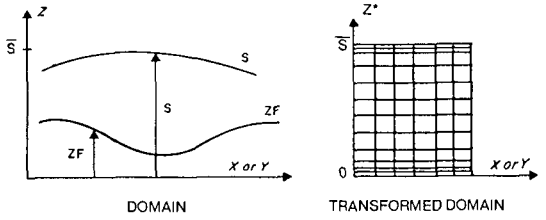

Fig. 1 - Vertical transformation.

The equations written with this new coordinate are of the same form, if a vertical velocity w* is introduced (see [1], [2], [4]).

$$w^* = \frac{\partial z^*}{\partial t} + u \frac{\partial z^*}{\partial x} + v \frac{\partial z^*}{\partial y} + w \frac{\partial z^*}{\partial z} \qquad (2)$$

Then the modified equations must be solved with appropriate boundary conditions.

A) Boundary conditions

Generally on open sea boundary, mass-currents integrated over the depth are known through field measurements or by mean of a two-dimensional computation of tide at a larger scale.
In order to obtain a velocity profile on the boundaries an Ekman type relation is used. In that case, it is necessary that around the boundaries the bathymetry is regular, in order to neglect horizontal gradients.

The Ekman type integration is done by solving the following relations.

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial z}\left(\nu z \frac{\partial u}{\partial z}\right) + fv - \frac{1}{\rho}\frac{\partial P}{\partial x} \qquad (3)$$

$$\frac{\partial v}{\partial t} = \frac{\partial}{\partial z}\left(\nu z \frac{\partial v}{\partial z}\right) - fu - \frac{1}{\rho}\frac{\partial P}{\partial y} \qquad (4)$$

where the pressure gradient is expressed in terms of mean currents (u, v) over the depth through depth averaged long wave equations Tox, Toy being shear stresses at sea bed, and f Coriolis parameter.
Integration over the depth gives :

$$\left.\begin{aligned} -\frac{1}{\rho}\frac{\partial P}{\partial x} &= \frac{1}{H}\frac{\partial \bar{u}H}{\partial t} + \frac{Tox}{H} - f\bar{v} \\ -\frac{1}{\rho}\frac{\partial P}{\partial y} &= \frac{1}{H}\frac{\partial \bar{v}H}{\partial t} + \frac{Toy}{H} + f\bar{u} \end{aligned}\right\} \quad (5)$$

B) Coastal boundary

Velocity components are taken to be zero.

C) Free surface

- Without wind we assume

$$\frac{\partial u}{\partial z} = 0 \qquad \frac{\partial v}{\partial z} = 0 \qquad w = 0$$

- With wind, it is assumed that wind action produces only a surface shear stress which is expressed in term of the wind speed at some standard height above the sea surface : $Tow = 1{,}3 \times CD \times |v_w| \times v_w$, where CD is a frictional coefficient evaluated by experimentations.

The shear stress can be related to the fluid flow field by the equations

$$\frac{\partial u}{\partial z} = \frac{1}{\rho}\frac{Towx}{\nu z} \qquad (6)$$

$$\frac{\partial v}{\partial z} = \frac{1}{\rho}\frac{Towy}{\nu z} \qquad (7)$$

the eddy viscosity being : $\nu_z = \ell^2 \sqrt{(\frac{\partial u}{\partial z})^2 + (\frac{\partial v}{\partial z})^2}$ (8)

In this condition, at the sea surface, the viscosity is related only to shear stress by a relation independant of time

$$\nu_z = \ell\sqrt{\frac{Tow}{\rho}} \qquad (9)$$

where ℓ is the mixing length.

D) Sea bed

Two types of condition have been tested :

- the velocity is zero. This first type of condition imposes to have a very small discretization near the bottom, in order to have a good description of the gradient. Therefore another solution was tested.

- Condition of slip on the sea bed.

A slip velocity condition has been imposed by assuming that shear stress is a quadratic function of the bed velocity. Introducing a constant c, the imposed relation can be written in the following form :

$$\nu z \frac{\partial u}{\partial z} = \frac{u\sqrt{u^2 + v^2}}{c^2} \qquad \nu z \frac{\partial v}{\partial z} = \frac{v\sqrt{u^2 + v^2}}{c^2}$$

with $\nu_z = (0,41)^2 \Delta z^2 \sqrt{(\frac{\partial u}{\partial z})^2 + (\frac{\partial v}{\partial z})^2}$

Where Δz (distance between the point where the condition is applied and the bottom) is chosen in order to stay in the logarithmic boundary layer.

It is possible, in the hypothesis of unidimensional flow, to calculate this new constant c in function of the mean diameter of the roughness, or if prefered in function of the mean water depth and the Chezy coefficient.

III. NUMERICAL SCHEME

The numerical discretization uses finite differences on an irregular rectilinear grid in three directions x, y, z*. In fact, the introduction of the vertical coordinate z* instead of z (real coordinate) leads to a curvilinear grid in the vertical direction, which fits very well the bottom topography and the sea surface.

Due to the large number of unknowns and computation points in the area, a complete implicit solution of all equations leads to an excessive storage requirement, and prohibitive computation time. On the other hand, a completly explicit solution would induced severe restrictions upon the time-step for the different parts of the resolution. These restrictions are mentionned below :

Surface-wave stability along the two horizontal directions.

$$t \leqslant \min \left(\frac{\Delta x}{\sqrt{g(S - zf)}}, \frac{\Delta y}{\sqrt{g(S - zf)}}\right)$$

Stability for horizontal and vertical diffusion.

$$\Delta t \leqslant \min \left(\frac{\Delta x^2}{2 \nu h}, \frac{\Delta y^2}{2 \nu h}\right) \text{ and } \Delta t < \left(\frac{\Delta z^2}{2 \nu z}\right)$$

Stability for horizontal and vertical advection.

$$\Delta t \leqslant \min \left(\frac{\Delta x}{u}, \frac{\Delta y}{v}, \frac{\Delta z}{w}\right)$$

For a channel in a not very deep sea, the order of magnitude of the unknowns are

$\Delta x = \Delta y = 100$ m

νh from 1 to 10^{-3} m^2/s

u from 0,5 to 1 m/s.

νz 5 10^{-2} m^2/s.

(S - zf) depth 20 m

i.e. for a time-step.

$\frac{\Delta x}{\sqrt{g(S - zf)}}$	$\frac{\Delta x}{\sqrt{g(S - zf)}}$	$\frac{\Delta x^2}{2 \nu h}$	$\frac{\Delta z^2}{2 \nu z}$	$\frac{\Delta x}{u}, \frac{\Delta y}{v}, \frac{\Delta z}{w}$
7 s	7 s	10 s	10 s	100 s

Among all these restrictions upon time-step, the most inconvenient are those of the free surface wave and the vertical diffusion. For solving these equations we have then been led to use the so-called fractionary step method, where the stages are treated by the best fitted method (implicit or explicit).

- Horizontal diffusion and advection.

This stage is entirely solved by explicit method and the time-step must respect the restrictions relative to this operator. The advection is treated with the help of characteristic method.

- Vertical diffusion.

The system is solved by a double sweep algorithm, the discretization used is implicit.

- Continuity and pressure or sea surface gradient.

The last left terms plus the continuity operation are solved together. The average over the depth of the remaining equations gives 2D equations relating sea surface elevation and the two components of the fluxes. These are solved first by a 2D implicit method in the same way than in our shallow water wave model. (see ref. [1]).

Then the horizontal velocity profiles are modified with the new sea surface gradient and the vertical velocity is calculated by integration of the local continuity equation.

IV. APPLICATIONS

To validate the model and evaluate the eddy viscosity, some measurements were carried out in a schematic physical model. A prismatic channel was set in a flume and a steady current was run with an incidence of 45° with the channel (fig. 2 and 3).

Different horizontal velocities profiles were obtained in the channel by micro-current meter of 0,01 m diameter. They showed an important deviation of the velocity near the bottom although there is a small deviation near water surface.

The numerical model includes the central part of the flume over 5,5 m length and 2,50 m width. The horizontal grid size is 0,212 m. The model includes 27 x 13 horizontal points and 24 points over the depth. The horizontal grid is regular, but the vertical discretization is very irregular ; the grid size is smaller near the bottom. The flow characteristics are the following :

- depth in the channel 0,125 m
- depth out of the channel 0,080 m
- mean up-stream velocity 0,17 m/s
- Reynolds number $2{,}5\ 10^4$
- Froude number $5\ 10^{-2}$.

Up-stream, the velocities being quite stable, we can adjust the constants of the turbulence model in order to obtain, at point 2, a velocity profile as close as possible of the measured one. This calibration has led to adopt the following values :

$\alpha = 0{,}2 \qquad k = 0{,}12.$

α is the fraction of the depth on which length scale is linear, k is the Karman constant.

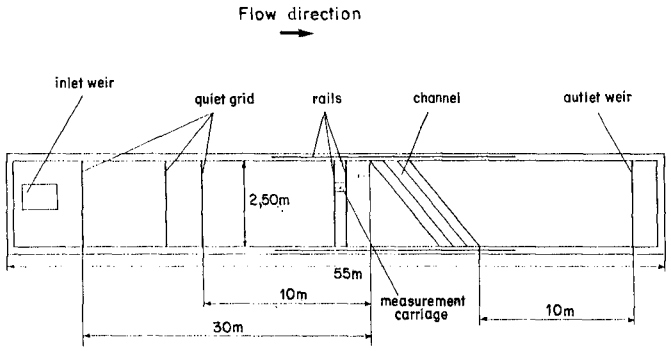

Fig. 2 - Physical model.

Experimental set up.
Velocity measurements : module velocity micro current-meter 0,01 m in diameter.

head whool thread.

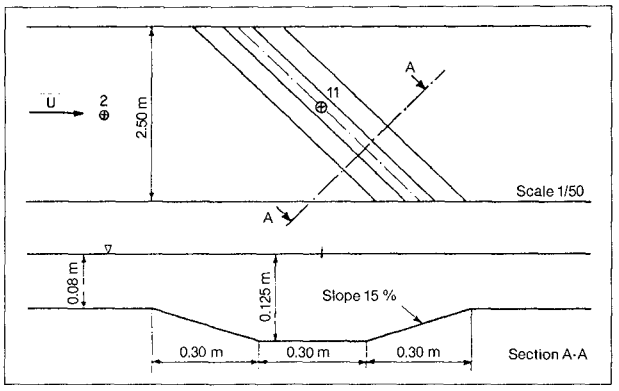

Fig. 3 - Prismatic channel.

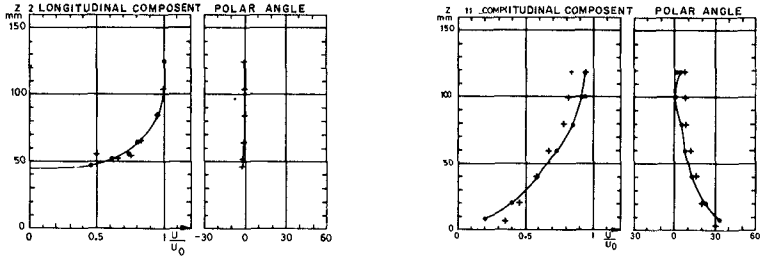

Fig. 4 - Vertical velocity profiles.

The value of constant k is small (k = 0,12) compared with value (k = 0,41) generally adopted. That probably comes from a low level of the turbulence in the flume (see [2], [4]).

With this tested value, the measured and predicted velocity profiles are rather similar as illustrated for point 11 situated in the center of the channel (fig. 4).

An important error appears between measured and predicted velocities at points near vertical wall along the flume. In fact near the walls, the numerical model does not take into account the effects of boundary layer.

With a non slip condition at the bed, the bottom stresses are not accurate enough to calculate the resulting sediment transport. Another computation was done with a condition of slip on bottom but with a Karman constant k = 0,41, a first mesh of 0,75 mm and a roughness of 0,3 mm. In that case the bed shear stress pattern obtained is more satisfying (see fig. 5). The knowledge of bed shear stresses permits to estimate bed transport using Meyer-Peter and Müller relation.

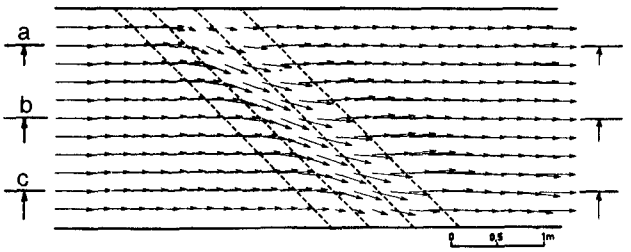

Fig. 5 - Bottom stresses before evolution.

Then, the bottom evolution is computed from the equation of conservation of sediment. The two computations are coupled. A bottom evolution changes the current pattern and the bottom stresses, which induce new bottom evolution. In order to take into account the difference of time scales between bottom and current evolutions, the current pattern is not re-computed at each time step of bottom evolution but after a time inducing significant changements (currently 900 time steps).

The predicted channel evolution is qualitatively quite satisfying. The accretion is greater on left upstream side, which is normal because the right side is more supplied by the cross flow from the channel. On the other hand the erosion is more important on the right side (fig. 6 et 7.).

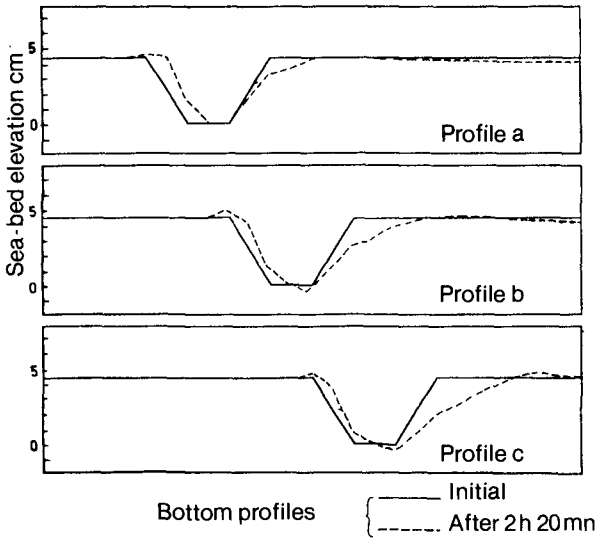

fig. 6 - Bottom profiles.

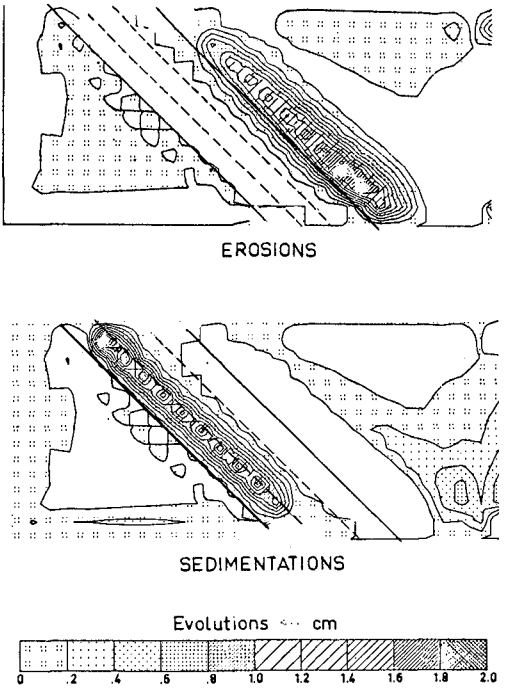

Fig. 7 - Evolutions (cm) after 2h 20 mn.

Tidal current computations

The model was successfully applied in estuaries and coastal areas in France for the computation of tidal and wind generated currents (fig. 8). At first, a study of tidal flow pattern in navigation channel of Verdon Harbour in Gironde was realized (model 1 of fig. 8). On the boundaries, the mass currents were obtained through a two-dimensional computation. In order to correctly represent the bathymetry, the grid size was fixed equal to 300 m. The area is included in a rectangle of 10 x 15 km, and is discretized by 36 x 51 horizontal points, and 15 points over the depth, the depth varies from 5 to 30 m. The time step is 120 s. One tide requires 40 mn of computer time on the CRAY ONE computer. The chosen tide is a mean spring tide (coefficient 95). The flow pattern was established after one tide and the results of the 2nd tide are compared to those obtained by a bidimensional model and measurement.Generally, a good agreement is obtained between predicted and measured velocities (see ref. [3]).

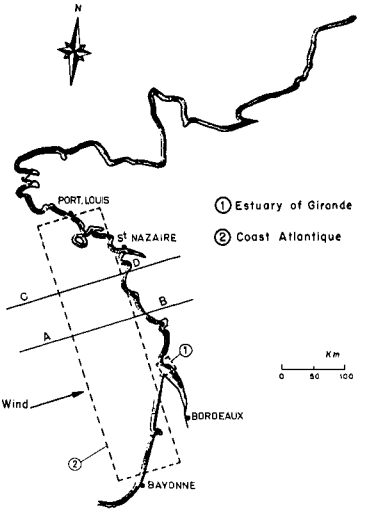

Fig. 8 - Coastal area model.

During flood tide and ebb-tide the flow is in the direction of channel axis and the bathymetry has no influence upon direction of flow near sea bed. At the end of the ebb-tide (low tide fig. 9) we observe a difference of head between sea bed and surface water, specially in the northern part of the channel submitted to a cross flow, at this moment of the tide. Likewise at the end of flood (high tide fig. 10), it is in the Northern and Central part that the differences are most important.

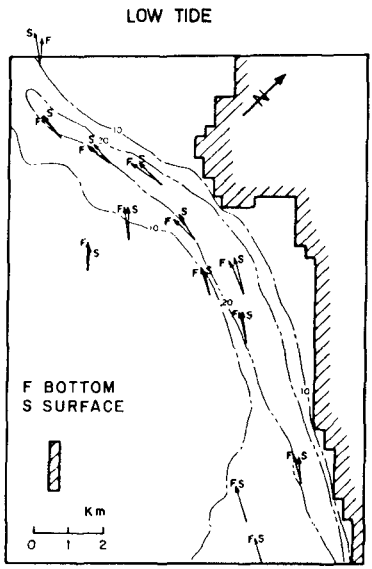

Fig. 9 - Currents at sea bed and free surface.

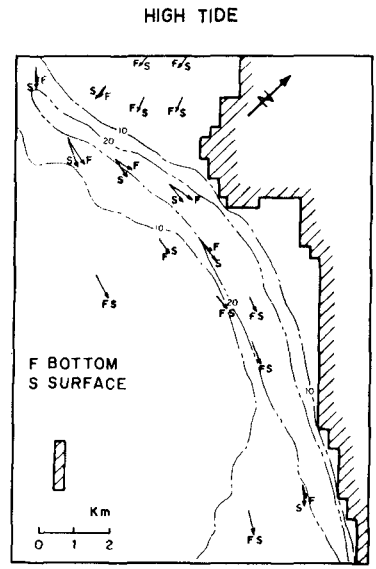

Fig. 10 - Currents at sea bed and free surface.

The present model has also been used to study wind induced circulation patterns on Atlantic French coast (model 2 on fig. 8). On the boundaries, the mass currents has been obtained through a two-dimensional computation of larger scale. At sea bed we have a no-slip condition with zero velocities. In order to simplify the 3D problem, the Atlantic has been schematically represented by a rectangle of 110 x 460 km. (see fig. 11). The bathymetry used is presented in fig. 12. In the in-coast areas, a schematic regular bottom shape has been introduced. The depth varies from 140 m to 10 m near coasts. There is a very deep region (500 m) in open sea in front of Gironde estuary. On the vertical axis the depth was divided into 23 elements of different length. The smallest are near bed and near free surface. The first grid size near the bed is 0,3 % of the depth and the last near free surface is 0,1 %.

The horizontal grid size is 10 km. On the whole area, there are 13500 points.

The time step is 120 s. A tide requires 1200 s of computer time on the Cray 1 computer. The computations of tide were made without or with a wind of 22 m/s parallel to Ox direction.

The shear stress induced at sea surface by wind is calculated with a coefficient CD = 0,9 10^{-3} if wind speed is smaller than 10 m/s, and CD = 2,9 10^{-3} if wind speed is greater than 10 m/s. The sudden change of value of CD is subjected by different behaviour of wind suddenly transformed at this speed of 10 m/s.

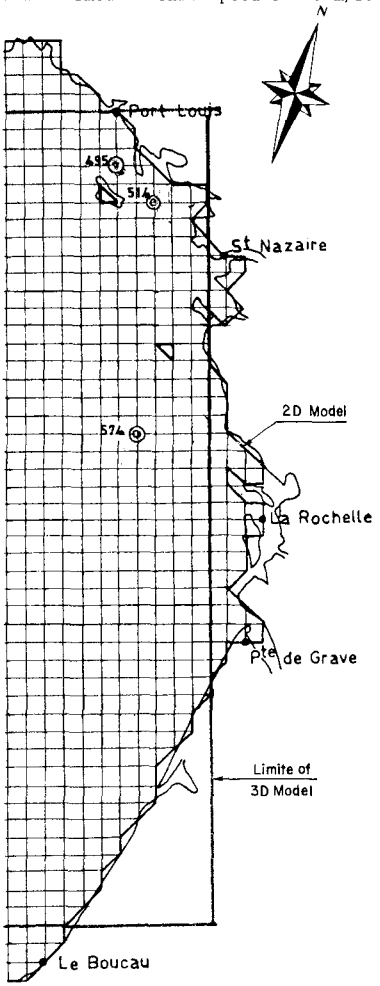

Fig. 11 - Area of coast Atlantic.

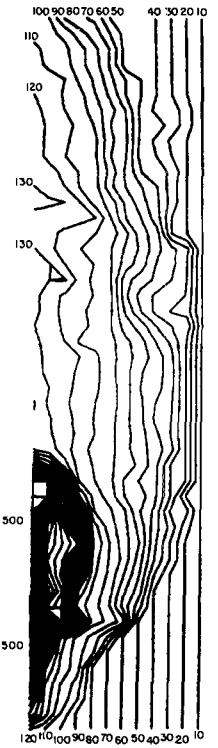

Fig. 12 - Bathymetry of 3D model

Without wind the results are in good agreement with field measurements and with two-dimensional computations particularly on tide level.
The circulation pattern is very modified by a prevailing western wind.
The flow pattern is influenced not only near surface where a large velocity is established but also near the bed. The velocity induced at surface is about 3,5 % of wind speed. The different directions between surface and bottom create a vertical circulation of water.
It is important at the ebb tide when wind is in reverse direction.
The depth of the reverse points is a function of depth flow (fig. 13).
Preliminary studies on only one vertical axis (solution of Ekman's equation in one point) seem to show that it is possible to discouple in that case the calculation of a tidal action from the one of wind, since the predicted velocities induced by coupled tide and wind are nearly equal to the addition of separate action of wind and tide. In the whole area, the results showed that the velocities induced near surface can also be computed separately. The error is 3 % of surface velocity.
However in the average mass currents calculated for a tide of period T by

$$\bar{u}_m = \frac{1}{T} \int_{t = to}^{t = to + T} u\,dt$$

are a few differences between coupled or separated action of wind and tide. In fact the velocities induced into the depth are different even if the surface velocities are the same. (fig. 14)

CONCLUSION

We have presented in this paper a numerical three-dimensional hydrostatic model and different applications. The turbulent effects are simply taken into account by an eddy viscosity. This model was successfully tested against laboratory flume data, then was applied in studies where three-dimensional effects were very important : navigation channel and wind-induced currents. This numerical model which gives velocity profiles over the depth and induced bottom stresses for tidal and wind generated flows is an important tool for a large range of studies : sea-surface, pollution transport, dispersion of a polluant in the water column (where vertical velocity profiles are fundamental), transport of sediment near the bottom, etc...

COMPUTATION OF PARTICLE PATHS USING THE LAGRANGIAN LONG WAVE EQUATIONS

M. A. Savoie[1] and J. van de Kreeke[2]

0. ABSTRACT

The Lagrangian long wave equations and the Lagrangian expressions for stress and strain are derived. Retaining the dominant terms the long wave equations are solved using an explicit finite difference method.

Using the numerical solution, particle paths are computed for the tidal motion in a basin connected to the ocean by a single inlet. At the open boundary particle displacements are described. Computations are carried out with snd without the Coriolis force and for linear and nonlinear bottom friction.

1. INTRODUCTION

With regard to the physical oceanography of estuaries and lagoons, the coastal engineer's interest traditionally has been with current velocities and tide levels. Only recently as a result of the development of water quality models knowledge of water particle trajectories have become important. The current method of computing particle trajectories is to first solve for the Eulerian velocity field and then to calculate the successive particle positions by numerical integration and interpolation.

This paper illustrates the calculation of particle paths by integrating the Lagrangian form of the long wave equations. The Lagrangian long wave equations describe the particle position as a function of its original particle position and time, whereas the Eulerian equations describe the velocity (flow) at a fixed position in space. In addition to the particle trajectories, the Lagrangian long wave equations yield the water level and depth associated with a traveling parcel of water.

The Lagrangian equations are often overlooked because of the severe nonlinearity of some of the terms, the difficulty in calibrating and verifying the results and the lack of appropriate boundary conditions. Nevertheless the technique has been successfully applied to 2-D vertical fluid flow problems.

The general three-dimensional Lagrangian form of the Navier-Stokes equations can be found in various text books, e.g. Lamb [1932]. Neumann and Pierson [1966], Defant [1961] etc. Because a literature search revealed no previous studies aimed at specifically developing the Lagrangian form of the two-dimensional horizontal long wave equations a rather detailed derivation of these equations together with a derivation of the expressions for strain and stress is presented. Wherever possible, equations are derived starting from physical principles rather than applying a straight transformation from Eulerian to Lagrangian variables.

Past work utilizing the Lagrangian form of the fluid flow equations has been mainly in the area of surface gravity waves. Miche [1944] uses a perturbation technique to solve the Lagrangian equations for first and second order surface gravity waves. To a first order of approximation his results yield a wave profile similar to Gerstner's trochoidal wave, whereas in the Eulerian system this isn't possible until the third order of approximation. Goto [1979] and Shuto and Goto [1978] numerically computed tsunami run-up using the nonlinear 1-D long wave equations. In the equations bottom friction and viscosity was neglected. Brennen [1970] and Brennen and Whitney [1970] present a numerical solution to the problem of unsteady free surface gravity waves using the 2-D vertical Lagrangian equations.

Other studies of interest utilizing the Lagrangian equations are mainly in the field of turbulence, Pierson [1962], and the related problems of stirring, mixing and dispersion.

2. THE MOTION OF A FLUID ELEMENT; STRESS AND STRAIN

2.1 Coordinate System

Considered is a fixed Cartesian coordinate system x, y, z. The position of a particle is designated $s(a,b,c,t)$, $p(a,b,c,t)$ and $r(a,b,c,t)$ where s, p and r, and a, b and c are measured in respectively the x, y and z direction. $(a,b,c,0)$ represents the original position of the particle. In some instances it is convenient to use the particle positions $s'(a,b,c,t)$, $p'(a,b,c,t)$ and $r'(a,b,c,t)$ where $s' = s-a$, $p' = p-b$ and $r' = r-c$. The original position of the particle is then $s' = 0$, $p' = 0$ and $r' = 0$.

In the following only planar motion in the x, y plane will be considered.

2.2 Fluid Deformation

A fluid element subject to stresses undergoes deformation. For a rectangular element the deformation after a time Δt is shown in Fig. 1. In general the deformation is a combination of normal strains, shear strains and rotation.

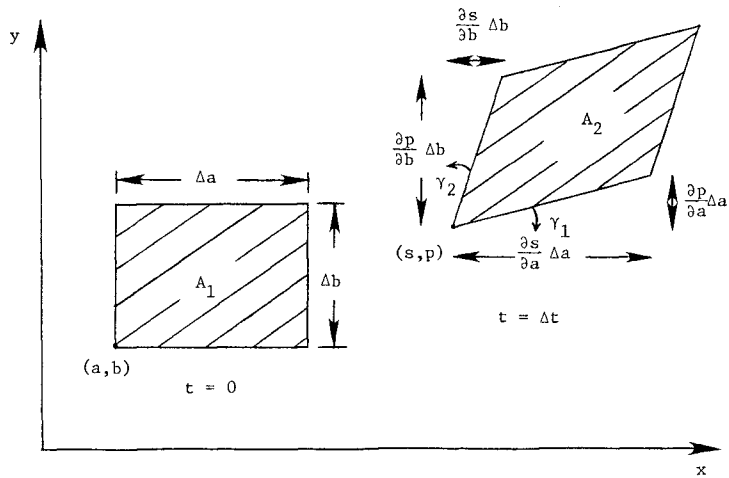

Figure 1. Deformation of a Fluid Element

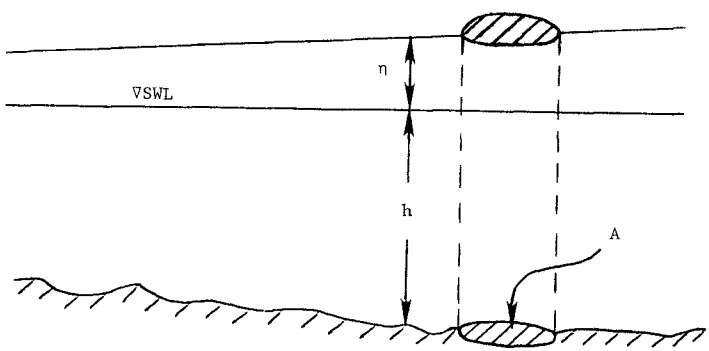

Figure 2. Cylinder of Fluid Extending from Free Surface η to the Bottom -h.

The position of the lower left hand corner of the element is designated s(a,b,t) and p(a,b,t).

2.3 Normal Strain

Normal Strain is defined as the change in length of a fluid element divided by its initial length. Accordingly, normal strain in the x direction is given by

$$\varepsilon_x\,(a,b,t) = \lim_{\substack{\Delta t \to o \\ \Delta a \to o}} \frac{\left.\frac{\partial s}{\partial a}\right|^{t+\Delta t} \Delta a \;-\; \Delta a}{\Delta a}$$

and thus

$$\varepsilon_x = \frac{\partial s}{\partial a} - 1 \tag{2.1}$$

similarly

$$\varepsilon_y = \frac{\partial p}{\partial b} - 1 \tag{2.2}$$

By convention an increase in length corresponds to a positive normal strain.

2.4 Shear Strain

Shear Strain is defined as the change in angle between two originally perpendicular lines as the element deforms. Referring to Fig. 1, for small deformations

$$\gamma_1 = \frac{\dfrac{\partial p}{\partial a}}{\dfrac{\partial s}{\partial a}} \simeq \frac{\partial p}{\partial a} \quad \text{since} \quad \frac{\partial s}{\partial a} = 1 + \varepsilon_x \simeq 1$$

similarly

$$\gamma_2 = \frac{\dfrac{\partial s}{\partial b}}{\dfrac{\partial p}{\partial b}} \simeq \frac{\partial s}{\partial b}$$

and thus the shear strain is

$$\gamma_{xy} = \gamma_1 + \gamma_2 = \frac{\partial p}{\partial a} + \frac{\partial s}{\partial b} \tag{2.3}$$

Shear strain is positive for a decrease in the angle between two originally perpendicular line elements.

2.5 Rotation

Rotation is defined as $\gamma_1 - \gamma_2$. Counter-clockwise rotation is taken as positive. Accordingly for small deformations the rotation in the x-y plane may be written as

$$\Theta_{xy} = \gamma_1 - \gamma_2 = \frac{\partial p}{\partial a} - \frac{\partial s}{\partial b} \tag{2.4}$$

2.6 Normal Stress

Water can be considered a Newtonian fluid where the stresses are linearly related to the time rate of strain, rather than to the strain itself as in elastic solids. Assuming an incompressible fluid, the normal stresses in the x direction are given by

$$\sigma_x = \bar{\sigma} + 2\mu \frac{\partial \epsilon_x}{\partial t} \tag{2.5}$$

where $\bar{\sigma}$ is the mean normal stress and μ is the dynamic viscosity coefficient. Based on experiments with incompressible fluids Daily and Harleman [1966], the mean normal stress $\bar{\sigma}$ is just the pressure as given below.

$$\bar{\sigma} = \frac{1}{3}(\sigma_x + \sigma_y + \sigma_z) = -p \tag{2.6}$$

Substituting for the mean normal stress in Eq. (2.5) and makinhg use of Eq. (2.1)

$$\sigma_x = -p + 2\mu \frac{\partial}{\partial a}\left(\frac{\partial s}{\partial t}\right) \tag{2.7}$$

similarly

$$\sigma_y = -p + 2\mu \frac{\partial}{\partial b}\left(\frac{\partial p}{\partial t}\right) \tag{2.8}$$

2.7 Shear Stress

The shear stress is linearly related to the time rate of change of the shear strain in the fluid.

$$\tau_{xz} = \tau_{yx} = \mu \frac{\partial}{\partial t}(\gamma_{xy}) \tag{2.9}$$

Substituting for the shear strain in Eq. (2.9) yields the shear stress

$$\tau_{xy} = \mu \frac{\partial}{\partial t}\left(\frac{\partial p}{\partial a} + \frac{\partial s}{\partial b}\right) \tag{2.10}$$

2.8 Vorticity

Vorticity is related to the time rate of change of rotation as follows.

$$\zeta = \frac{1}{2} \frac{\partial}{\partial t} (\Theta_{xy}) \tag{2.11}$$

Substituting the expression for rotation, the vorticity is

$$\zeta = \frac{1}{2} \frac{\partial}{\partial t} \left(\frac{\partial p}{\partial a} - \frac{\partial s}{\partial b}\right) \tag{2.12}$$

which is one half times the curl of the Lagrangian velocity vector.

3. CONSERVATION EQUATIONS

3.1 General Mathematical Relations

When mapping a region A_2 in the sp-plane into a region A_1 in the ab-plane (see Fig. 1), the Jacobian operator is

$$J = \frac{\partial(s,p)}{\partial(a,b)} = \begin{vmatrix} \frac{\partial s}{\partial a} & \frac{\partial p}{\partial a} \\ \frac{\partial s}{\partial b} & \frac{\partial p}{\partial b} \end{vmatrix} \tag{3.1}$$

The Jacobian operator is used when transforming double integrals from one coordinate system to another. Referring to Fig. 1,

$$\int_{A_2} F(s,p)dsdp = \int_{A_1} F[s(a,b,t), p(a,b,t)]\, J\, dadb \tag{3.2}$$

where F is an arbitrary function. For a geometric interpretation of the Jacobian set F = 1. The left hand side of Eq. (3.2) represents the area A_2, which can be expressed as the magnitude of the cross product of the vectors representing two adjoining sides.

$$A_2 = \left| \left(\frac{\partial s}{\partial a} \Delta a \hat{i} + \frac{\partial p}{\partial a} \Delta a \hat{j}\right) \times \left(\frac{\partial s}{\partial b} \Delta b \hat{i} + \frac{\partial p}{\partial b} \Delta b \hat{j}\right) \right|$$

which reduces to

$$A_2 = J\, A_1 \tag{3.3}$$

Other mathematical relations that will be used in the derivation of the conservation equations are the Lagrangina Del operator (∇_h) and the Lagrangian Laplacian (∇_h^2). The subscript h designates a 2-D horizontal operation. In the s-p system the Del operator is written as

$$\nabla_h = \frac{\partial}{\partial s}\hat{i} + \frac{\partial}{\partial p}\hat{j} \tag{3.4}$$

A direct transformation from the s-p space to the a-b space will be employed to find the Del operator in Lagrangian coordinates. The partial derivatives $\partial/\partial a$ and $\partial/\partial b$ are

$$\frac{\partial}{\partial a} = \frac{\partial}{\partial s}\frac{\partial}{\partial a} + \frac{\partial p}{\partial a}\frac{\partial}{\partial p} \tag{3.5}$$

$$\frac{\partial}{\partial b} = \frac{\partial s}{\partial b}\frac{\partial}{\partial s} + \frac{\partial p}{\partial b}\frac{\partial}{\partial p} \tag{3.6}$$

Equations (3.5) and (3.6) are solved for the partials $\partial/\partial s$ and $\partial/\partial p$

$$\frac{\partial}{\partial s} = \frac{\begin{vmatrix} \frac{\partial}{\partial a} & \frac{\partial p}{\partial a} \\ \frac{\partial}{\partial b} & \frac{\partial p}{\partial b} \end{vmatrix}}{\begin{vmatrix} \frac{\partial s}{\partial a} & \frac{\partial p}{\partial a} \\ \frac{\partial s}{\partial b} & \frac{\partial p}{\partial b} \end{vmatrix}} = \frac{\partial(\ ,p)}{\partial(a,b)}\ \frac{1}{J} \tag{3.7}$$

similarly

$$\frac{\partial}{\partial p} = \frac{\partial(s,\ )}{\partial(a,b)}\ \frac{1}{J} \tag{3.8}$$

Substituting Eqs. (3.7) and (3.8) into Eq. (3.4), the Lagrangian Del operator is obtained

$$\nabla_h = \left[\frac{\partial(\ ,p)}{\partial(a,b,)}\hat{i} + \frac{\partial(s,\ )}{\partial(a,b)}\hat{j}\right]\frac{1}{J} \tag{3.9}$$

The derivation of the Lagrangian Laplacian operator follows along the same lines as the Del operator and yields

$$\nabla_h^2 = \frac{\partial[\frac{\partial(\ ,p)}{\partial(a,b)}\frac{1}{J},\ p]}{\partial(a,b)} + \frac{\partial[s,\ \frac{\partial(s,\ )}{\partial(a,b)}\frac{1}{J}]}{\partial(a,b)}\ \frac{1}{J} \tag{3.10}$$

The Laplacian becomes highly nonlinear when converted to Lagrangian coordinates. A similar 3-D expression for the Lagrangian Laplacian operator is presented in Pierson [1962].

In deriving the conservation equations use will be made of the Reynolds' or Kinematic transport theorem. This theorem expresses the rate of change of a property moving with a body of fluid.

Let s(a,b,c,t), p(a,b,c,t) and r(a,b,c,t) be the coordinates of a fluid particle, where a, b and c are the coordinates of the original position. V is the volume of the fluid body under consideration. Take F(s,p,r,t) to be any function representing for example momentum or constituent concentration, and introduce the volume integral G(s,p,r,t).

$$G(s,p,r,t) = \iiint_V F(s,p,r,t)\, dsdpdr \tag{3.11}$$

The Reynolds' transport theorem is used in order to find the change in G with time, that is the total derivative dG/dt.

$$\frac{dG}{dt} = \frac{d}{dt} \iiint_V F(s,p,r,t)dsdpdr \tag{3.12}$$

Since the volume is deforming with time, the order of integration and differentiation cannot be interchanged. Making use of the 3-D equivalent of Eq. (3.1), it follows from Eq. (3.12)

$$\frac{dG}{dt} = \frac{d}{dt} \iiint_{V_o} F[s(a,b,c,t),p(a,b,c,t),r(a,b,c,t),t]\, Jdadbdc \tag{3.13}$$

V_o is the volume at t = 0. Because V_o is constant, the order of integration and differentiation can be interchanged.

$$\frac{dG}{dt} = \iiint_{V_o} \frac{d}{dt} (FJ)dadbdc = \iiint_{V_o} (\frac{dF}{dt} J + F \frac{dJ}{dt})dadbdc \tag{3.14}$$

It can be shown, Aris [1962] pp. 84, that

$$\frac{dJ}{dt} = [\nabla.(\frac{\partial s}{\partial t} \hat{i} + \frac{\partial p}{\partial t} \hat{j} + \frac{\partial r}{\partial t} \hat{k})]J \tag{3.15}$$

where the Del operator is the 3-D equivalent of ∇_h in Eq. (3.9). Substituting Eq. (3.15) in Eq. (3.14) yields the Reynolds' transport theorem.

$$\frac{dG}{dt} = \frac{d}{dt} \iiint_V F dsdpdr = \iiint_{V_o} [\frac{dF}{dt} + F\nabla.(\frac{\partial s}{\partial t} \hat{i} + \frac{\partial p}{\partial t} \hat{j} + \frac{\partial r}{\partial t} \hat{k})]Jdadbdc \tag{3.16}$$

where $\partial s/\partial t$, $\partial p/\partial t$ and $\partial r/\partial t$ are the particle velocities in respectively the x, y and z directions. This result will be used repeatedly in the derivation of the conservation equations. For further reference on the Reynolds' transport theorem see Aris [1962].

3.2 Basic Assumptions

In deriving the Lagrangian form of the long wave equations the

following basic assumptions will be employed.

1) Incompressible homogeneous fluid

2) Hydrostatic pressure, i.e. $\partial^2 r/\partial t^2 << g$

3) Vertical variations in horizontal velocity are negligible, i.e. planar motion

3.3 Conservation of Mass; Continuity

Consider a cylinder with volume V moving with the fluid and consisting of the same fluid particles. The surface and bottom of the cylinder are respectively $\eta(s,p,t)$ and $h(s,p)$. η and h are measured from the Still Water Level. From the assumption of planar motion it follows that the cylinder remains a cylinder even though the horizontal cross-section is allowed to deform; see Fig. 2.

Continuity implies that when moving with the fluid the volume of the cylinder remains the same.

$$V = \iint_A (h+\eta)dsdp = \text{constant} \tag{3.17}$$

where A is the cross-sectional area of the cylinder. The change in volume with time is zero. Making use of the 2-dimensional form of the Reynolds' transport theorem, Eq. (3.16), with $F = h+\eta$.

$$\frac{dV}{dt} = \iint_{A_0} \left\{ \frac{d(h+\eta)}{dt} + (h+\eta)\left[\nabla_h \cdot \left(\frac{\partial s}{\partial t}\hat{i} + \frac{\partial p}{\partial p}\hat{j}\right)\right] \right\} Jdadb = 0 \tag{3.18}$$

Because A_0 is an arbitrary area the integrand must be equal to zero. From this and Eq. (3.15) it follows

$$\frac{d}{dt}\left[(h+\eta)J\right] = 0 \tag{3.19}$$

When integraing Eq.(3.19) with respect to time from t = 0 to some later time t, the condition of continuity can be written in the form.

$$[h(a,b,t) + \eta(a,b,t)]\, J = h(a,b,0) + \eta(a,b,0) \tag{3.20}$$

It is noted that for 3-D and 2-D vertical incompressible fluid motion the continuity equation is simply J = 1, Lamb [1932], Neuman and Pierson [1966], Defant [1961], Miche [1944], Goto [1979] and Shuto and Goto [1978], where J is respectively the 3-D and 2-D equivalent of Eq. (3.1).

3.4 Conservation of Momentum; Equations of Motion

The rate of change of momentum within a material volume (cylinder) moving with the fluid equals the sum of the external forces. For the

momentum equation in the x-direction.

$$\frac{d}{dt} \iint_A \rho \frac{\partial s}{\partial t} (h+\eta) ds dp = \Sigma F_x \tag{3.21}$$

Using the 2-dimensional form of the Reynolds' transport theorem, Eq. (3.16), with F replaced by $\rho(h+\eta)\ \partial s/\partial t$.

$$\frac{d}{dt} \iint_A \rho \frac{\partial s}{\partial t} (h+\eta) ds dp = \iint_{A_o} \rho(h+\eta) \frac{\partial^2 s}{\partial t^2} J da db \tag{3.22}$$

The external forces acting on the cylinder consist of the surface forces (F_s) i.e. pressure and internal stresses, bottom shear stress (F_b) and Coriolis Force (F_C). Shear stress and horizontal gradients of the normal stress at the free surface, i.e. wind stress and atmospheric pressure respectively are assumed to be zero. In the following each of the external forcing terms will be discussed separately.

The total force associated with the pressure and internal stresses in the x-direction is given by the line integral

$$F_s = \oint [\sigma_x^* dp - \tau_{xy}^* ds] \tag{3.23}$$

in which

$$\sigma_x^* = \int_{-h}^{\eta} \sigma_x dr \text{ and } \tau_{xy}^* = \int_{-h}^{\eta} \tau_{xy} dr$$

The line integral is along the intersection of the cylinder and a horizontal plane. Green's theorem in the plane may be applied to Eq. (3.23) to transform the line integral into a double integral

$$F_s = \iint_A [\frac{\partial \sigma_x^*}{\partial s} + \frac{\partial \tau_{xy}^*}{\partial p}] ds dp \tag{3.24}$$

where as before A is the cross-sectional area of the cylinder. Substituting the expressions for σ_x^* and τ_{xy}^*

$$F_s = \iint_A [\frac{\partial \int_{-h}^{\eta} \sigma_x dr}{\partial s} + \frac{\partial \int_{-h}^{\eta} \tau_{xy} dr}{\partial p}] ds dp \tag{3.25}$$

The normal stress σ_x is composed of pressure and normal stresses associated with deformations. Considering the contribution of the

pressure only, Eq. (3.25) reduces to

$$F_{s1} = \iint_A \frac{\partial \int_{-h}^{\eta} -p \, dr}{\partial s} \, dsdp \tag{3.26}$$

(note the difference between the notation p for pressure and p for particle displacement in the y direction). The subscript 1 refers to the contribution of pressure to the surface force term in the x-direction. Transforming to the a-b space and making use of Eq. (3.7)

$$F_{s1} = \iint_{A_o} \left[\frac{\partial \int_{-h}^{\eta} p \, dr}{\partial a} \frac{\partial p}{\partial b} - \frac{\partial \int_{-h}^{\eta} p \, dr}{\partial b} \frac{\partial p}{\partial a}\right] dadb \tag{3.27}$$

From the assumption of hydrostatic pressure $p = \rho g r + \rho g \eta$, the pressure may be vertically integrated to yield

$$\int_{-h}^{\eta} p \, dr = \frac{1}{2} \rho g \, (h+\eta)^2 \tag{3.28}$$

Substituting in the expression for F_{s1}, the pressure force is obtained

$$F_{s1} = - \iint_{A_o} \rho g (h+\eta) \left[\frac{\partial(h+\eta)}{\partial a} \frac{\partial p}{\partial b} - \frac{\partial(h+\eta)}{\partial b} \frac{\partial p}{\partial a}\right] dadb$$

$$= \iint_{A_o} \rho g (h+\eta) \frac{\partial(h+\eta, p)}{\partial(a,b)} \, dadb \tag{3.29}$$

An attempt was made to evaluate the contribution of the viscous stresses, F_{s2}, by substituting in Eq. (3.14) the Lagrangian formulation for the normal stress σ_* and shear stress τ_{xy} respectively Eqs. (2.7) and (2.10). This resulted in a long and cumbersome expression. In order to arrive at a simpler and manageable result a direct transformation from Eulerian to Lagrangian variables is applied. Noting that f(s,p,t) is equivalent to f(x,y,t), the Eulerian expressions for the normal and shear stresses (Daily and Harleman [1966] pp. 102-104) can be written as

$$\sigma_* = 2\mu \frac{\partial(\frac{\partial s}{\partial t})}{\partial s} - p$$

$$\tau_{xy} = \mu[\frac{\partial(\frac{\partial s}{\partial t})}{\partial p} + \frac{\partial(\frac{\partial p}{\partial t})}{\partial s}]$$

Neglecting the pressure part of the normal stress term since it has already been accounted for, and substituting the expressions for the stresses in Eq. (3.25) yields

$$F_{s2} = \iint_A \left\{ 2\mu \frac{\partial[(h+\eta)\frac{\partial(\frac{\partial s}{\partial t})}{\partial s}]}{\partial s} + \mu \frac{\partial[(h+\eta)\frac{\partial(\frac{\partial s}{\partial t})}{\partial p}]}{\partial p} \right.$$

$$\left. + \mu \frac{\partial[(h+\eta)\frac{\partial(\frac{\partial p}{\partial t})}{\partial s}]}{\partial p} \right\} dsdp \qquad (3.30)$$

or, when rearranging

$$F_{s2} = \iint_A \left\{ \mu(h+\eta)\left[\frac{\partial^2(\frac{\partial s}{\partial t})}{\partial s^2} + \frac{\partial^2(\frac{\partial s}{\partial t})}{\partial p^2}\right] + 2\mu \frac{\partial(h+\eta)}{\partial s}\frac{\partial(\frac{\partial s}{\partial t})}{\partial s} \right.$$

(small)

$$+ \mu \frac{\partial(h+\eta)}{\partial p}\frac{\partial(\frac{\partial s}{\partial t})}{\partial p} + \mu \frac{\partial(h+\eta)}{\partial p}\frac{\partial(\frac{\partial p}{\partial t})}{\partial s}$$

(small) (small)

$$\left. + \mu(h+\mu)\frac{\partial}{\partial s}\left[\frac{\partial(\frac{\partial s}{\partial t})}{\partial s} + \frac{\partial(\frac{\partial p}{\partial t})}{\partial p}\right] \right\} dsdp \qquad (3.31)$$

$= 0$ (continuity)

If typical values are taken for the particle velocities in long waves $[\partial s/\partial t = \eta\sqrt{g/h}\sin(k_x s + k_y p - \omega t)]$, it can be shown that the first term on the righthand side of Eq. (3.31) is the dominant term.

Thus,

$$F_{s2} = \iint_A \mu(h+\eta)\,\nabla_h^2(\frac{\partial s}{\partial t})\,dsdp \qquad (3.32)$$

Transforming to the a-b space

$$F_{s2} = \iint_{A_o} \mu(h+\eta) \nabla_h^2 \left(\frac{\partial s}{\partial t}\right) \mathrm{J}\,da\,db \tag{3.33}$$

In the case of turbulent motion the coefficient of dynamic viscosity, μ, is replaced by the eddy viscosity or momentum transfer coefficient A_h.

In addition to stresses on the cylinder wall, the bottom of the cylinder is subjected to a shear stress. In general, the horizontal components of this stress are taken proportional to the square of the velocity. E.g. in the x-direction

$$\tau_{xz} = \rho F \frac{\partial s}{\partial t} \sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2}$$

where F is the friction coefficient. Integrating over the cross-section of the control volume, the bottom frictional force is

$$F_b = - \iint_{A_o} \rho F \frac{\partial s}{\partial t} \sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2}\ \mathrm{J}\,da\,db \tag{3.34}$$

Sometimes the bottom stress is taken proportional to the velocity. In that case, the expression corresponding to Eq. (3.34) is

$$F_b = - \iint_{A_o} \rho F_\ell \frac{\partial s}{\partial t}\ \mathrm{J}\,da\,db \tag{3.35}$$

where F_ℓ is the linear bottom friction coefficient.

Assuming the vertical velocities to be small compared to horizontal velocities the Coriolis force per unit volume can be written as

$$\rho f \frac{\partial p}{\partial t} \qquad \text{x-direction}$$

$$-\ \rho f \frac{\partial s}{\partial t} \qquad \text{y-direction}$$

where $f = 2\Omega \sin \phi$

Ω = angular velocity of earth

ϕ = latitude

Integrating the Coriolis force over the volume of the cylinder, the force acting on the control volume in the x-direction is

$$F_{cx} = \iint_{A_o} \rho(h+\eta)\ f \frac{\partial p}{\partial t}\ \mathrm{J}\,da\,db \tag{3.36}$$

Similarly for the Coriolis force in the y-direction

$$F_{cy} = - \iint_{A_o} \rho(h+\eta)\, f\, \frac{\partial s}{\partial t}\, J\,da\,db \tag{3.37}$$

Equating the rate of change of momentum and the external forces for the x-direction, omitting the integral signs (this is justified because the integration is over an arbitrary area) and dividing by $\rho(h+\eta)$ yields

$$\left[\frac{\partial^2 s}{\partial t^2} + \frac{F}{h+\eta}\,\frac{\partial s}{\partial t}\sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2} - f\,\frac{\partial p}{\partial t} - \frac{A_h}{\rho}\,\nabla_h^2\left(\frac{\partial s}{\partial t}\right)\right] J = - g\,\frac{\partial(h+\eta,\ p)}{\partial(a,b)} \tag{3.38}$$

This is the Lagrangian conservation of momentum equation for long waves in the x-direction. Similarly for the y-direction

$$\left[\frac{\partial^2 p}{\partial t^2} + \frac{F}{h+\eta}\,\frac{\partial p}{\partial t}\sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2} + f\,\frac{\partial s}{\partial t} - \frac{A_h}{\rho}\,\nabla_h^2\left(\frac{\partial p}{\partial t}\right)\right] J = - g\,\frac{\partial(s,\ h+\eta)}{\partial(a,b)} \tag{3.39}$$

An alternate form of the Lagrangian equation of motion is obtained by multiplying Eq. (3.38) by $\partial s/\partial a$ and Eq. (3.39) by $\partial p/\partial a$. This yields

$$\left[\frac{\partial^2 s}{\partial t^2} + \frac{F}{h+\eta}\,\frac{\partial s}{\partial t}\sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2} - f\,\frac{\partial p}{\partial t} - \frac{A_h}{\rho}\,\nabla_h^2\left(\frac{\partial s}{\partial t}\right)\right]\frac{\partial s}{\partial a} \tag{3.40}$$

$$+ \left[\frac{\partial^2 p}{\partial t^2} + \frac{F}{h+\eta}\,\frac{\partial p}{\partial t}\sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2} + f\,\frac{\partial s}{\partial t} - \frac{A_h}{\rho}\,\nabla_h^2\left(\frac{\partial p}{\partial t}\right)\right]\frac{\partial p}{\partial a} = - g\,\frac{\partial(h+\eta)}{\partial a}$$

Similarly multiplying Eq. (3.38) and (3.39) by $\partial s/\partial b$ and $\partial p/\partial b$ respectively and adding

$$\left[\frac{\partial^2 s}{\partial t^2} + \frac{F}{h+\eta}\,\frac{\partial s}{\partial t}\sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2} - f\,\frac{\partial p}{\partial t} - \frac{A_h}{\rho}\,\nabla_h^2\left(\frac{\partial s}{\partial t}\right)\right]\frac{\partial s}{\partial b} \tag{3.41}$$

$$+ \left[\frac{\partial^2 p}{\partial t^2} + \frac{F}{h+\eta}\frac{\partial p}{\partial t}\sqrt{\left(\frac{\partial s}{\partial t}\right)^2 + \left(\frac{\partial p}{\partial t}\right)^2} + f\frac{\partial s}{\partial t} - \frac{A_h}{\rho}\nabla_h^2\left(\frac{\partial p}{\partial t}\right)\right]\frac{\partial p}{\partial b} = -g\frac{\partial(h+\eta)}{\partial b}$$

3.5 Boundary and Initial Conditions

In order to solve the Lagrangian long wave equations, boundary conditions have to be specified. The type and number of boundary conditions that are necessary are given below.

for inviscid flow ($A_h = 0$)

at closed boundaries: normal particle displacement is zero

at open boundaries: particle path or water level along path is prescribed.

for viscous flow ($A_h \neq 0$)

at closed boundaries: normal and parallel particle displacement's are zero

at open boundaries: particle path or water level along path is prescribed

Initially the system is assumed to be at rest, i.e. the water level is at the Still Water Level and all particle displacements are taken to be zero.

4. NUMERICAL SOLUTION OF THE 2-D LONG WAVE EQUATIONS

For small deformations the non-linear terms in Eqs. (3.20), (3.40) and (3.41) can be neglected. Introducing the variables s' and p' (see section 2.1). Equations (3.20), (3.40) and (3.41) reduce to respectively

$$h\frac{\partial s'}{\partial a} + h\frac{\partial h'}{\partial b} = \eta + [h-h(a,b,0)] = 0 \qquad (4.1)$$

$$\frac{\partial^2 s'}{\partial t^2} - f\frac{\partial p'}{\partial t} + g\frac{\partial(h+\eta)}{\partial a} = -\frac{F}{h+\eta}\frac{\partial s'}{\partial t}\sqrt{\left(\frac{\partial s'}{\partial t}\right)^2 + \left(\frac{\partial p'}{\partial t}\right)^2} \qquad (4.2)$$

$$\frac{\partial^2 p'}{\partial t^2} + f\frac{\partial s'}{\partial t} + g\frac{\partial(h+\eta)}{\partial b} = -\frac{F}{h+\eta}\frac{\partial p'}{\partial t}\sqrt{\left(\frac{\partial s'}{\partial t}\right)^2 + \left(\frac{\partial p'}{\partial t}\right)^2} \qquad (4.3)$$

When assuming linear bottom friction the righthand sides of Eqs. (4.2) and (4.3) are respectively $-F_\ell\, \partial s'/\partial t/h+\eta$ and $-F_\ell\, \partial p'/\partial t/h+\eta$

The employed difference equations are

$$\eta^n_{i,j}+h^n_{i,j}[(s^n_{i,j}-s^n_{i-1,j})/\Delta a + (p^n_{i,j}-p^n_{i,j-1})/\Delta b]+h^n_{ij} = h^0_{i,j} \qquad (4.4)$$

$$\frac{1}{\Delta t^2}(s^{n+1}_{i,j} - 2s^n_{i,j}+s^{n-1}_{i,j}) - \frac{f}{4\Delta t}(p^n_{i,j}+p^n_{i+1,j}+p^n_{i,j}+p^n_{i+1,j-1}-p^{n-1}_{i,j}$$

$$- p^{n-1}_{i+1,j}-p^{n-1}_{i,j-1}-p^{n-1}_{i+1,j-1}) + \frac{F_\ell}{2^{x_{(\overline{h+\eta})}}\Delta t}(s^{n+1}_{i,j}-s^{n-1}_{i,j})$$

$$= -\frac{g}{\Delta a}[(h+\eta)^n_{i+1,j} -(h+\eta)^n_{i,j}] \qquad (4.5)$$

$$\frac{1}{\Delta t^2}(p^{n+1}_{i,j} -2p^n_{i,j}+p^{n-1}_{i,j}) + \frac{f}{4\Delta t}(s^n_{i,j}+s^n_{i-1,j}+s^n_{i,j+1}+s^n_{i-1,j+1}-s^{n-1}_{i,j}$$

$$-s^{n-1}_{i-1,j}-s^{n-1}_{i,j+1}-s^{n-1}_{i-1,j+1}) + \frac{F_\ell}{2^{y_{(\overline{h+\eta})}}\Delta t}(p^n_{i,j}-p^{n-1}_{i,j})$$

$$= -\frac{g}{\Delta b}[(h+\eta)^n_{i,j+1}-(h+\eta)^n_{i,j}]$$

with

$$x_{(\overline{h+\eta})} = \frac{(h+\eta)^n_{i,j} + (h+\eta)^n_{i+1,j}}{2}$$

$$x_{(\overline{h+\eta})} = \frac{(h+\eta)^n_{i,j} + (h+\eta)^n_{i,j+1}}{2}$$

$$h^n_{i,j} = \text{function}\left[\frac{s^n_{i,j} + s^n_{i-1,j}}{2}, \frac{p^n_{i,j} + p^n_{i,j-1}}{2}\right]$$

These equations operate over a finite number of points on a spatial and temporal grid. For a nonlinear bottom stress, the difference form of the friction term in the x momentum equation is written as

$$\frac{F}{h+\eta}\frac{\partial s'}{\partial t}\sqrt{\left(\frac{\partial s'}{\partial t}\right)^2 + \left(\frac{\partial p'}{\partial t}\right)^2} = \frac{F}{2^{x_{(\overline{h+\eta})}}\Delta t}(s^{n+1}_{i,j}-s^{n-1}_{i,j})\left[\frac{1}{\Delta t^2}(s^n_{i,j}-s^{n-1}_{i,j})^2\right.$$

$$\left. + \frac{1}{16\Delta t^2}(p^n_{i,j}+p^n_{i+1,j}+p^n_{i,j-1}+p^n_{i+1,j-1}-p^{n-1}_{i,j}-p^{n-1}_{i+1,j}-p^{n-1}_{i,j-1}-p^{n-1}_{i+1,j-1})^2\right]^{1/2}$$

Given the bottom topography the depth can be found as a function of the particle position.

Computations are started from rest. First $h^n_{i,j}$ is computed using the known bathymetry and particle positions at $n\Delta t$. Then $\eta^n_{i,j}$ values are computed from the continuity equation, Eq. (4.4). Last the particle positions, $s^{n+1}_{i,j}$ and $p^{n+1}_{i,j}$ at the next time step are computed from the momentum equations, Eqs. (4.5) and (4.6). For an analysis of the stability of the scheme the reader is referred to Savoie and van de Kreeke [1981].

5. NUMERICALLY COMPUTED WATER PARTICLE TRAJECTORIES IN A SEMI-ENCLOSED BASIN

Considered is a semi-enclosed basin of constant depth connected to the ocean by an inlet; see Fig. 3. The values used in the computations for the length of the basin, depth of the basin, and the tidal period are respectively L = 6,400 m, h = 3 m, T = 43,300 sec. The length and width of the inlet are equal to L/2.

Assuming nonlinear bottom friction, the water motion is described by Eqs. (4.1) - (4.3). For linear bottom friction the appropriate expressions for the friction terms are substituted. The friction terms are further simplified by assuming $h+\eta \approx$ = constant.

The boundary conditions at the open boundary are given by the particle trajectory p = 2000 sin $(2\pi t/T)$ m. This results in a tidal range of approximately 0.7 m when assuming the water level in the basin to fluctuate uniformly. The boundary conditions at the closed boundary require that a particle initially at the wall stays at the wall, that is the particle is allowed to slip but no flow is permitted through the wall.

The trajectories of the particles originally located at the position of the water levels (+ in Fig. 3), are computed for different values of the linear friction factor, the nonlinear friction factor, and the Coriolis coefficient.

The equations are solved using the explicit finite difference scheme presented in section 4, where the time step Δt = 90 sec and the space step $\Delta a = \Delta b$ = 800 m, see also Fig. 3.

Examples of computed particle paths are presented in Figs. 4, 5 and 6. In these figures the particle paths starting from t = 0 (designated by the symbol x) to t = 2T are shown. For linear friction and zero Coriolis acceleration the computed particle paths are presented in Fig. 4. The particle paths are virtually straight lines.

The straight line paths can be explained as follows. When neglecting the Coriolis term and assuming linear bottom friction and $h+\eta = h \approx$ constant in Eqs. (4.2) and (4.3), the corresponding vorticity equation is

$$\frac{\partial \zeta}{\partial t} + \frac{F_\ell \zeta}{h} = 0 \qquad (5.1)$$

FRICTION COEFFICIENT F_ℓ = .0005
CORIOLIS COEFFICIENT f = 0.0

Because the basin is initially at rest, it follows from Eq. (5.1) $\zeta(t) = 0$. Thus the fluid motion is irrotational which allows introducing a (Lagrangian) velocity potential $\phi(a,b,t)$. Substituting in Eq. (4.1) yields

$$\nabla^2\phi = -\frac{1}{h}\frac{\partial \eta}{\partial t} \tag{5.2}$$

For a basin with dimensions much smaller than the wavelength

$$\frac{\partial \eta}{\partial t} \approx \frac{\omega A_c}{h A_b}\ \hat{\ell}\ \cos\omega t \tag{5.3}$$

where A_c is the cross-sectional area of the inlet, A_b is the surface area of the basin and $\hat{\ell}\sin\omega t$ represents the motion of the plunger. Combining Eqs. (5.2) and (5.3)

$$\nabla^2\phi = -\frac{\omega A_c}{h A_b}\ \hat{\ell}\ \cos\omega t \tag{5.4}$$

The solution to Eq. (5.4) is of the form

$$\phi(a,b,t) = \phi(a,b)\cos\omega t \tag{5.5}$$

It follows that the particle velocities

$$\frac{\partial s}{\partial t} = \frac{\partial \phi}{\partial a} \text{ and } \frac{\partial p}{\partial t} = \frac{\partial \phi}{\partial b}$$

are in phase and thus the path of a particle is a straight line.

The results when the Coriolis force is added to the linear equations is presented in Fig. 5. The Coriolis acceleration causes moving particles to follow elliptical trajectories in the direction of the indicated arrows.

Nonlinear bottom friction is employed to compute the particle paths presented in Fig. 6. Particle paths are elliptical as opposed to the straight lines in the case of linear friction. When using linear friction particles in the basin are found to oscillate about their initial locations. For nonlinear friction particles encounter an initial displacement when the computation is first started and then oscillate about the new equilibrium position. The initial displacement can be explained by means of the equations for the mean particle displacement and mean water level.

To derive these equations the Lagrangian long wave equations, Eqs. (3.38) and (3.39) are written in the form

$$\frac{\partial^2 s'}{\partial t^2} - f\frac{\partial p'}{\partial t} + g\frac{\partial \eta}{\partial a} + \frac{F_\ell}{h}\frac{\partial s'}{\partial t} = NL_1 \tag{5.6}$$

$$\frac{\partial^2 p'}{\partial t^2} - f\frac{\partial s'}{\partial t} + g\frac{\partial \eta}{\partial a} + \frac{F_\ell}{h}\frac{\partial p'}{\partial t} = NL_2 \tag{5.7}$$

$$h\left[\frac{\partial s'}{\partial a} + \frac{\partial p'}{\partial b}\right] + \eta = NL_3 \tag{5.8}$$

NL_1, NL_2 and NL_3, constitute the (higher order) nonlinear terms. It is assumed that the bay bottom is horizontal, i.e. $h(a,b,y) = h$. The nonlinear friction is approximated by a linear friction; the difference is contained in the terms NL_1 and NL_2.

Assuming a periodic forcing at the open boundaries in terms of s', p' or η, the solution to the Eqs. (5.6) - (5.8) can be written as

$$s'(a,b,t) = \langle s'\rangle(a,b) + s'_p(a,b,t) \tag{5.9}$$

$$p'(a,b,t) = \langle p'\rangle(a,b) + p'_p(a,b,t) \tag{5.10}$$

$$\eta(a,b,t) = \langle\eta\rangle(a,b) + \eta_p(a.b,t) \tag{5.11}$$

s'_p, p'_p and η_p are periodic in t with a period equal to the tidal period. $\langle\ \rangle$ denotes averaging over the tidal period. Substituting in Eqs. (5.6) - (5.8) and averaging the equations over the tidal period yields the equations for the mean particle displacement $\langle s'\rangle$, $\langle p'\rangle$ and the mean water level $\langle\eta\rangle$.

$$g\frac{\partial\langle\eta\rangle}{\partial a} = \langle NL_1\rangle \tag{5.12}$$

$$g\frac{\partial\langle\eta\rangle}{\partial b} = \langle NL_2\rangle \tag{5.13}$$

$$h\left[\frac{\partial\langle s'\rangle}{\partial a} + \frac{\partial\langle p'\rangle}{\partial b}\right] + \langle\eta\rangle = \langle NL_3\rangle \tag{5.14}$$

For the semi-enclosed basin, when using the linear equations, i.e., NL_1, $NL_2 = NL_3 = 0$, it follows from Eqs. (5.12) - (5.14) and the boundary condition that $\langle s\rangle = \langle p\rangle = \langle\eta\rangle = 0$ everywhere. Particles thus oscillate about their original position. When the values of NL_1, NL_2 abd NL_3 are not all zero, e.g., when using nonlinear friction, particles encounter a net displacement $\langle s'\rangle$ (a,b), $\langle p'\rangle$ (a,b) and will oscillate about this position.

6. SUMMARY AND CONCLUSIONS

A rigorous derivation of the Lagrangian long wave equations, and expressions for the deformation of a fluid parcel is presented. In the derivation no use is made of the corresponding Eulerian form of these equations and expressions. The purpose of this is to preserve a true Lagrangian approach to the problem even though in some instances

it would have been easier to transform directly from the Eulerian equations.

The equations of motion and continuity are highly nonlinear in Lagrangian form. The nonlinearities are associated with the deformation of the horizontal cross-section of a traveling water column. The Lagrangian expressions for stress, strain, rotation, and vorticity remain relatively simple.

An explicit finite difference solution is presented for the simplified set of equations i.e. neglecting the nonlinear terms except for the bottom friction. The technique is applied to a square bay of constant depth connected to the ocean by a single inlet. Particle trajectories in the basin are computed for different values of the friction coefficient and Coriolis parameter. The boundary condition i.e. the particle displacement in the inlet is described by a simple harmonic function of time. For nonlinear friction the particles tend to follow clockwise elliptical trajectories, whereas for linear friction the trajectories become straight lines. The Coriolis acceleration also induces an elliptical motion. In the case of linear friction the particles in the basin oscillate about their original locations. For nonlinear friction there is an initial displacement when the computations are started, but after the first tidal cycle the particle trajectories become virtually identical.

In summary it can be stated that

1) The numerical solution to the Lagrangian long wave equations when neglecting the nonlinear terms is not more involved than the numerical solution to the Eulerian equations.

2) Aside from the difficulties in prescribing the open boundary conditions, the method of computing particle trajectories using the Lagrangian equations rather than the Eulerian equations has a clear advantage in that it bypasses the computation of the velocity field.

2- AND 3-DIMENSIONAL DETERMINISTIC FREAK WAVES

by

SØREN PETER KJELDSEN
Senior Research Engineer[1)]

1. ABSTRACT

The present paper deals with a new non-linear technique for generation of violent breaking freak waves (plunging breakers) at specified positions and times in wave basins. First, results concerning generation of non-linear wave trains, Stokes-waves and wave solitons in deep water are given. Then the technique for generation of non-linear wave transients are given with specified non-linear dispersion properties. Finally, the new techniques are used to obtain collisions between non-linear solitons coming both from the same direction (2-dimensional case), and from different directions (3-dimensional case) leading to generation of steep and violent plunging breakers.

2. INTRODUCTION

The amount of high violent breaking waves that is contained in a sea, is a most important factor to consider for design of both offshore structures, coastal structures and ships. Some critical events might happen just in certain kinds of steep extreme waves, but the same events do not happen in a normal sea state described and simulated in the laboratory by the use of the traditional wave spectrum. Stochastic simulations contain normally a low amount of breaking waves, and in most cases they do not contain extreme wave events, such as very high waves breaking as plunging breakers in deep waters. Further, the wave spectra might be identical for two wave simulations, one containing a very violent and dangerous freak wave leading to a critical event, the other not containing such a wave. Thus, use of a wave spectrum is not a complete and adequate description of a sea state and the effect it might have on structures. Finally, in stochastic simulations of irregular seas in the laboratory it is very often observed that the ratio between the maximum observed wave height and the significant wave height is too low. (The required ratio is 2 in most cases.)

An alternative technique for a fast, efficient and accurate determination of extreme responses and critical events that might occur at sea, is a new non-linear technique for generation of solitons that interact and break as very violent freak waves at a predetermined position and time in deep waters. The critical events that are under consideration here, are shown in Fig. 1.

1) NORWEGIAN HYDRODYNAMIC LABORATORIES
Division: Ship and Ocean Laboratory
P.O. Box 4118 - Valentinlyst
N-7001 Trondheim / Norway

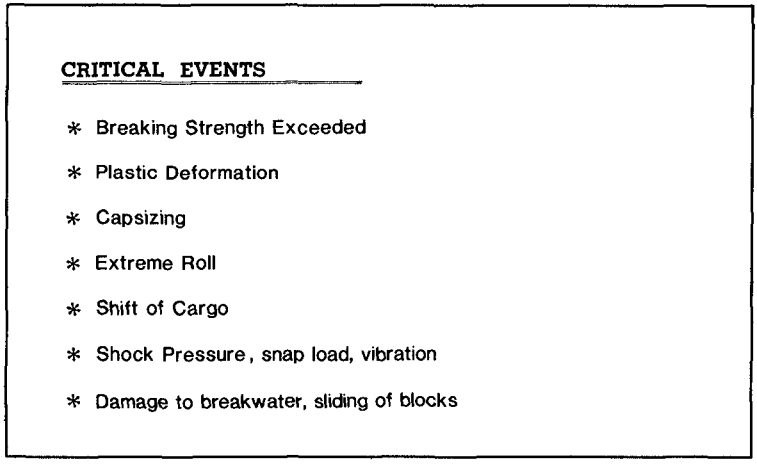

Fig. 1 Critical events.

Very often the designer has to investigate if such a critical event might happen or not. If the answer is yes, the designer then has to decide if such an event is acceptable or not. Very often he will then raise the question: "What is the probability for such an event?" If the probability is very low, he might then find that the conditions are acceptable. However, if the probability is high, he will often find that the conditions are not acceptable and he will develop a new design. Therefore, at the Norwegian Hydrodynamic Laboratories a new design philosophy is derived as follows:

1. Generate an extreme breaking freak wave in the laboratory.
2. Determine from wave statistics the statistical probability for occurrence of such a wave.
3. Measure the extreme response in an experiment.
4. Observe if a critical event occurs and repeat the experiment.
5. Give the probability for failure of the structure.

The procedure is shown graphically in Fig. 2.

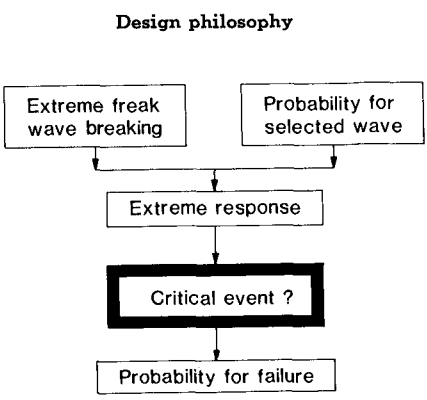

Fig. 2 Design philosophy.

This philosophy was first derived in a research programme "Ships in Rough Seas" (see publication from NSFI/RINA (1982)), but has now obtained much more international attention, and have recently been used in two projects performed for the offshore industry with experimental simulations performed at the Norwegian Hydrodynamic Laboratories. The same kind of philosophy might very well be applied to coastal structures. The present paper will only deal with the generation of extreme breaking freak waves in deep waters. Selection of design waves and probability calculations is given by Kjeldsen (1981).

3. STATE-OF-THE-ART IN WAVE GENERATION TECHNIQUES

In the following a brief summary of available wave generation techniques shall be given. Perfection of generation techniques for steady state longcrested, regular gravity waves (Stokes waves, cnoidal waves and sinusoidal waves) may be regarded as a first step in state-of-the-art of wave generation in hydrodynamic laboratories. The most interesting here is the non-linear generation techniques for Stokes waves in deep waters and cnoidal waves in shallow waters. However, it is also very well known that a sinusoidal command signal applied to a wave generator will not lead to generation of a sinusoidal wave train. Instead irregular waves are observed in the wave flume with the basic frequency superposed with freely travelling higher harmonics. Thus, the simple demand to reproduce a "clean" sinusoidal wave train in a wave flume without parasitic disturbances demands a laborous phase-compensating tehcnique, in which higher harmonics is supplied artificially in anti-phase with the unwanted parasitic noise. This technique is well known and described by Buhr Hansen, Schiolten & Svendsen (1975). The present paper will deal with the more complicated non-linear generation technique for generation of Stokes waves in deep waters.

The second step in state-of-the-art of wave generation techniques in laboratories is then the generation of a steady state stochastic sea containing irregular wave fields in 2- or 3-dimensions. The available techniques for generation of stochastic seas are all linear and are based on the use of Fourier analysis and one-dimensional or directional wave spectra. However, both the directional spectra for the 3-dimensional wave field, and the common frequency spectra for the 2-dimensional longcrested wave field must necessarily be truncated, due to the physical limitations in the frequency range that is present when a prescribed spectrum is simulated artificially with mechanical wave generators. In simulations of a directional spectrum the selection of the truncation parameter affects the magnitude of the spectral moments m_0, m_2 and m_4, and also the obtained crest lengths that

are achieved in the experiment (Kjeldsen & Price (1982)). Further, it is well documented that the frequency spacing in the spectral simulation is essential for correct reproduction of slow-drift phenomena. However, even the two-dimensional directional sea spectrum appears to be insufficient, for a proper description of sea states containing extreme waves, wave trains with sequences of breaking waves and wave groups. Several radically different time series have been found -some containing violent breaking freak waves or wave groups - others not, and all have the same wave spectrum (Johnson, Ploeg, Mansard (1978)). A quite high frequency both of damages to coastal and marine structures and of capsizings of smaller vessels that recently have been experienced in different parts of the world, suggest that state-of-the-art in selection of proper design waves or design spectra for various kinds of maritime structures is just not good enough (Baird et al. (1980), Bruun (1979), Nedrelid (1978), Stephens et al. (1981)).

With this background a third and more advanced step in wave generation techniques is under rapid development (Kjeldsen (1978), Funke & Mansard (1979), Takezawa (1981), Kjeldsen & Myrhaug (1980), Kjeldsen, Vinje, Myrhaug, Brevig (1980), Mansard, Funke, Barthel (1982)). These new techniques contain sequences of deterministic transient waves leading either to violent breaking freak waves or to formation of wave groups with specified characteristics, and these sequences might be included in a stochastic time series in such a way that a certain specified wave spectrum is matched. The present paper will deal with the following 2 subjects:

1) Description of development of a new non-linear experimental technique for deterministic generation of freak waves both in 2 dimensions (longcrested freak waves) and in a directional 3-dimensional shortcrested wave field.
2) Discuss various possible combinations of superposition of deterministic sequences containing wave transients, with stochastic time series as obtained in a 3-dimensional wave field.

Fig. 3 gives a summary of all available combinations.

Development of wave generation techniques for case no. 4, 8, 10 and 12 will be dealt with in the present paper and is therefore circled. Thus, in the following we shall concentrate on

case 4) Generation of non-linear steady-state wave trains.

case 8 & 10) Interaction and collisions between non-linear solitons in 2- and 3-dimensions.

case 12) A combination of the steady state stochastic simulation with the transient state deterministic simulation. This last case is linear because the stochastic directional sea is simulated using linear assumptions.

All the experiments and developments referred to in this study are performed at the Norwegian Hydrodynamic Laboratories in Trondheim, Norway.

4. GENERATION OF SOLITONS

The familiar non-linear Schrödinger equation (4.1) as first derived by Zakharov (1968) describes a wide variety of physical situations. Here, we shall limit the description of the theory to gravity water waves in deep water. The equation is:

$$i\left(\frac{\delta A}{\delta t} + \frac{\omega_o}{2k_o}\frac{\delta A}{\delta x}\right) - \frac{\omega_o}{8k_o^2}\cdot\frac{\delta^2 A}{\delta x^2}$$

$$- \frac{1}{2}\,\omega_o k_o^2 \cdot |A|^2 A = 0 \qquad (4.1)$$

Here, A is the complex envelope:

$$A = a \cdot e^{i\theta} \qquad (4.2)$$

and a is the physical amplitude.

According to the theory there exists a carrier wave number k_o and a corresponding cyclic frequency ω_o which remains constant throughout the evolution. Thus, variations in k can be described as deviations from the carrier wave number:

$$k = k_o + \Delta k \qquad (4.3)$$

The mathematical solution of eq. (4.1) relevant to deep water waves is given by Zakharov & Shabat (1972). Their main results are:

1) An initial wave envelope pulse of arbitrary shape will eventually disintegrate into a number of solitons and an oscillatory tail. The number and structure of these solitons and the structure of the tail are completely determined by the initial conditions.

2) Each soliton is defined as a permanent progressive wave solution to eq. (4.1) and has the form:

$$S_n = a_n \cdot \sec\sqrt{2}\,k_o^2 a_n \cdot \left[(x - \chi_n)\right.$$

$$\left. - \left(\frac{\omega_o}{2k_o} + V_n\right)t\right] + \exp\left\{-\frac{i}{4}k_o^2 a_n^2 \omega_o t\right.$$

$$\left. - \frac{4ik_o^2}{\omega_o}\cdot V_n\left[(x - \chi_n) - \left(\frac{\omega_o}{2k_o} + V_n\right)t + \theta_n\right]\right\} \qquad (4.4)$$

(Here, n is an index that refers to the n^{th} soliton. a_n is its amplitude and V_n is its velocity relative to the group velocity $\omega_o/2k_o$. χ_n and θ_n is its position and phase.)

3) Provided that wave breaking does not occur, the solitons are stable in the sense that they can survive collisions and interactions with each other with no permanent change except a possible shift in position and phase.

4) The remaining tail is relatively small and unimportant for a pulse initial condition. It disperses linearly resulting in a $1/\sqrt{t}$ decay of the amplitude.

Experiments with monochromatic steep non-linear wave trains were carried out in a 78 m long wind-wave flume at the Norwegian Hydrodynamic Laboratories. It was found that it was possible to use a sinusoidal command signal and a wave flap hinged at the bottom to produce highly non-linear solitons that dispersed in well controlled transient experiments with phase velocities and group velocities that exceeded predictions made from linear theory. Also a tail was observed behind the solitons that dispersed linearly. Further, it was found that the dispersion velocities for the obtained solitons agreed very well with numerical results given by Cokelet (1977) for high order Stokes waves.

With this knowledge a series of very well controlled experiments were then carried out in which two monochromatic steep non-linear wave trains with different frequencies were generated at different times. This was performed in such a way that two solitons were brought into interaction with each other at a position 60 m from the wave generator. This resulted in the generation of a violent plunging breaker in deep water obtained as a result of a collision between only two solitons.

An example of such an experiment is given by Kjeldsen, Vinje, Myrhaug & Brevig (1980) (Fig. 5, page 323 and Fig. 9, page 325). A large summary report containing all performed experiments will also be available Kjeldsen (1983).

5. THEORETICAL STORM MODEL

In the following a new theoretical model for travelling of wave transients with non-linear dispersion properties shall be derived. We introduce the operator:

$$\Lambda(\omega) = e^{-j\omega / \omega \sqrt{\frac{x}{g}} \frac{1}{\kappa}} \tag{5.1}$$

Λ is a frequency response function for non-linear waves that relates wave heights measured at two points separated by a distance x in the direction of travel. ω is the cyclic frequency, g is the gravity acceleration, while κ is a non-linear dispersion factor depending on wave steepness. As shown in section 6 the produced waves are solitons with a synoptic shape that shows a high degree of coherence with Stokes waves as calculated by Cokelet (1977) (using Padé approximants with series expansions to the order ε^{110}). Thus, for the non-linear wave transients under consideration here Cokelet's results are very good approximations. Fig. 4 shows κ as a function of wave steepness.

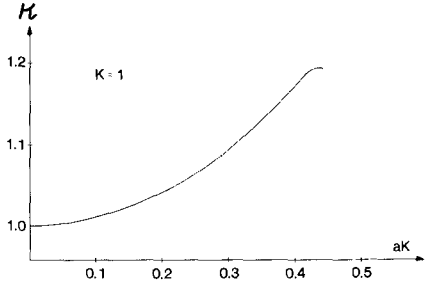

Fig. 4 Wave dispersion factor as a function of wave steepness $\left(a \cdot K = \frac{H}{L} \cdot \pi\right)$ (From Cokelet (1977)).

For non-linear waves we now introduce a "unit impulse response function" λ defined by the transformation:

$$\lambda(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \Lambda(\omega) \cdot e^{j\omega\tau} \cdot \frac{1}{\kappa}\, d\omega \tag{5.2}$$

The unit impulse response function λ represents a convenient method of determining the response $q(t)$ to an input of any form $Q(t)$ through the method of Duhamel's convolution integral:

$$q(t) = \int_{-\infty}^{\infty} \lambda(\tau) \cdot Q(t-\tau)\, d\tau \tag{5.3}$$

Substituting eq. (5.1) into eq. (5.2) gives:

$$\lambda(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-j\omega/\omega/\frac{x}{g}\cdot\frac{1}{\kappa}} \cdot e^{j\omega\tau}\,\frac{1}{\kappa}\, d\omega \tag{5.4}$$

introducing trigonometric terms we obtain:

$$\lambda(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \cos\left(\omega^2 \frac{x}{g}\frac{1}{\kappa} - \omega\tau\right) d\omega$$

$$+ \frac{i}{2\pi}\int_{-\infty}^{\infty} \sin\left(\omega\tau - \frac{\omega^2 x}{g}\frac{1}{\kappa}\right) d\omega \tag{5.5}$$

By use of the symmetry relations we finally obtain:

$$\lambda(\tau) = \frac{1}{\pi}\int_{0}^{\infty} \cos\left(\omega^2 \frac{x}{g}\frac{1}{\kappa} - \omega\tau\right) d\omega \tag{5.6}$$

We now consider non-linear waves of constant steepness κ.

We introduce the substitutions:

$$\xi = \frac{x^{1/2}}{g^{1/2}} \cdot \frac{1}{\kappa^{1/2}} \left(\omega - \frac{g\tau}{2x}\right) \tag{5.7}$$

$$\frac{d\xi}{d\omega} = \frac{x^{1/2}}{g^{1/2}}\,\frac{1}{\kappa^{1/2}} \tag{5.8}$$

and:

$$\sigma = \frac{g^{1/2}\cdot\tau}{2x^{1/2}\cdot\kappa^{1/2}} \tag{5.9}$$

We then obtain:

$$\lambda(\tau) = \frac{1}{\pi}\frac{\kappa^{1/2}\cdot g^{1/2}}{x^{1/2}}\int_{-\sigma}^{\infty} \cos(\xi^2 - \sigma^2)\, d\xi \tag{5.10}$$

and:

$$\lambda(\tau) = \frac{1}{\pi}\,\frac{g^{1/2}\cdot\kappa^{1/2}}{x^{1/2}}\left\{\cos\sigma^2\left[\int_{-\sigma}^{0}\cos\xi^2\,d\xi + \int_{0}^{\infty}\cos\xi^2\,d\xi\right] + \sin\sigma^2\left[\int_{-\sigma}^{0}\sin\xi^2\,d\xi + \int_{0}^{\infty}\sin\xi^2\,d\xi\right]\right\} \tag{5.11}$$

We can now recognise the well known relations for Fresnel's integrals:

$$\int_0^\infty \sin\xi^2\,d\xi = \int_0^\infty \cos\xi^2\,d\xi = \frac{1}{2}\sqrt{\frac{\pi}{2}} \tag{5.12}$$

and:

$$C(\mu) = \int_0^\mu \cos\left(\tfrac{1}{2}\pi\mu^2\right)d\mu \tag{5.13}$$

$$S(\mu) = \int_0^\mu \sin\left(\tfrac{1}{2}\pi\mu^2\right)d\mu \tag{5.14}$$

Substitution then gives:

$$\lambda(\tau) = \left(\frac{g\kappa}{2\pi x}\right)^{1/2}\left\{\left[\cos\sigma^2\right]\cdot\left[\frac{1}{2}+\frac{\sigma}{|\sigma|}\cdot C\left(\sqrt{\frac{2}{\pi}}\sigma\right)\right] + \left[\sin\sigma^2\right]\cdot\left[\frac{1}{2}+\frac{\sigma}{|\sigma|}\,S\left(\sqrt{\frac{2}{\pi}}\sigma\right)\right]\right\} \tag{5.15}$$

We now introduce a new parameter:

$$b = \left(\frac{\kappa\cdot g}{2\pi x}\right)^{1/2} \tag{5.16}$$

Eq. (5.9) then gives:

$$\sigma = \sqrt{\frac{\pi}{2}}\cdot\frac{b\tau}{\kappa} \tag{5.17}$$

and we finally obtain:

$$\lambda\left(\frac{b\tau}{\kappa}\right) = b\left\{\left[\cos\frac{\pi}{2}\frac{b^2\tau^2}{\kappa^2}\right]\cdot\left[\frac{1}{2}+\frac{\tau}{|\tau|}\,C\left(\frac{b\tau}{\kappa}\right)\right] + \left[\sin\frac{\pi}{2}\frac{b^2\tau^2}{\kappa^2}\right]\cdot\left[\frac{1}{2}+\frac{\tau}{|\tau|}\,S\left(\frac{b\tau}{\kappa}\right)\right]\right\} \tag{5.18}$$

This is thus the final expression for the "unit impulse response function" λ, expressed with Fresnel's integrals which are functions of the dimensionless time parameter $b \cdot \tau / \kappa$ that governs the non-linear interactions.

The freak wave is now approximated with the Dirac-function defined by:

$$\delta(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\omega t} \, d\omega \tag{5.19}$$

This function has the properties:

$$\delta(t) = 0 \quad \text{if } t \neq 0 \tag{5.20}$$

$$\int_{-\infty}^{\infty} \delta(t) \, dt = 1 \tag{5.21}$$

$$\int_{t_1}^{t_2} q(t) \quad \delta(t-t_o) \, dt = \begin{cases} q(t_o) & \text{if } t_1 < t_o \leq t_2 \\ o & \text{otherwise} \end{cases} \tag{5.22}$$

(Eq.(5.22) is valid if q(t) is continuous at t_o and t_1, t_2 are constants with $t_2 > t_1$) If index 1 refers to the position of wave generation and index 2 refers to the position of the freak wave, then the time history at position 1 is given by Duhamel's integral eq. (5.3) as:

$$\eta(x_1, t) = \int_{-\infty}^{\infty} \lambda(\tau) \cdot \eta(x_2, t - \tau) \, d\tau \tag{5.23}$$

This can also be expressed as:

$$\eta(x_1, t) = \Lambda(\omega) \cdot \eta(x_2, t) \tag{5.24}$$

Eqs. (5.23) and (5.24) are the time domain equivalents of:

$$N(x_2, \omega) = \Lambda(\omega) \cdot N(x_1, \omega) \tag{5.25}$$

where N is the transform of the time histories obtained as:

$$N(x, \omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \eta(x, t) \cdot e^{-i\omega t \frac{1}{\kappa}} \, dt \tag{5.26}$$

The freak wave at position 2 is now approximated with a Dirac-function and we have:

$$\eta(x_2, t) = \delta(t) \tag{5.27}$$

Then

$$N(x_2, \omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \eta(x_2, t) \, e^{-i\omega t \frac{1}{\kappa}} \, dt = \frac{1}{2\pi} \tag{5.28}$$

and

$$N(x_1, \omega) = \frac{1}{2\pi} \Lambda^{-1}(\omega) \tag{5.29}$$

The inverse transform is then obtained as:

$$\eta(x_1, t) = \int_{-\infty}^{\infty} N(x_1, \omega)\, e^{i\omega t \frac{1}{\kappa}}\, d\omega \tag{5.30}$$

or:

$$\eta(x_1, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\{\omega^2 \frac{x}{g} \frac{1}{\kappa}) - \omega t\}}\, d\omega \tag{5.31}$$

or:

$$\eta(x_1, t) = \frac{1}{\pi} \int_{0}^{\infty} \cos(\frac{\omega^2 x}{g} \frac{1}{\kappa} - \omega t)\, d\omega \tag{5.32}$$

Eq. (5.32) is identical with eq. (5.6) and it is thus shown that the unit impulse response function λ represents the time series $\eta(x_1, t)$ at position 1. Eq. (5.18) can then be used directly to produce a command signal for the wave generator. For large values of σ, we obtain the simplification:

$$C(\mu) = S(\mu) \simeq \frac{1}{2} \tag{5.33}$$

and

$$\lambda(\tau) = \sqrt{2}\, b \cos(\frac{\pi}{2} \frac{b^2 \tau^2}{\kappa^2} - \frac{\pi}{4}) \tag{5.34}$$

Thus, we have obtained an extension and non-linear modification of a technique for linear transient waves described by Davis & Zarnick (1964).

6. DEVELOPMENT OF COMMAND SIGNALS FOR 2-DIMENSIONAL FREAK WAVES

The theoretical storm model given in section 5 can now be directly used to develop command signals for wave generators. Thus, eq. (5.18) or eq. (5.34) can be directly used to prepare analog signals for wave generators. Since 1977 experiments of this kind have been performed at the Norwegian Hydrodynamic Laboratories in 3 different wave flumes, first one 33 m long, 1 m wide and 1.6 m deep, second one 78 m long, 4 m wide and 1.6 m deep, and the third one 280 m long, 10 m wide and 10 m deep, all equipped with flap-type wave generators. Fig. 5 gives an example of such an experiment performed in the third wave flume. A large plunging breaker with a wave height 0.74 m is generated 41 m from the wave generator and 66 seconds after the start of the transient signal.

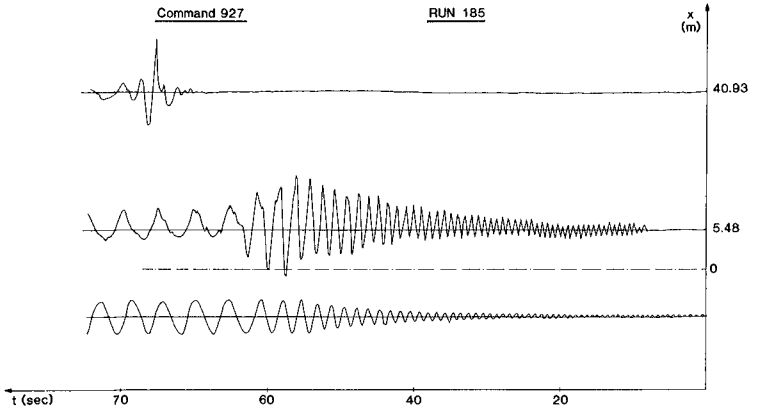

Fig. 5 Deep water plunging breaker generated from an interaction of 43 single wave components. The command signal to the wave generator is shown at the bottom.

It is most important to consider the fact that the analytical model developed in section 5 for dispersion of storm waves makes the assumption that all generated wave components have the same steepness. Thus, κ becomes a constant. To achieve this eq. (5.18) or eq. (5.34) has to be multiplied by a correction factor, that is an increasing function of time. With such a correction analog signals were prepared for the wave maker. At the wave maker waves were generated with a constant initial steepness 0.10, starting at a frequency 2 Hz. In this way the final plunging breaker obtained as a result of the collision of the 43 wave components was very close to the maximum that might be achieved. Fig. 6 shows results from 11 repeated experiments of this kind. Measured parameters are trough-to-crest wave height H_{zd}, zero-downcross wave period T_{zd}, horizontal asymmetry factor μ defined as the ratio between crest height and wave height, and finally crest front steepness ε_t (defined in Kjeldsen & Myrhaug (1980)). For each parameter both the mean value and the standard deviation σ are shown. From this result compared to 16 mm high speed film recordings of the plunging breaker, we conclude that the repetition in the generated freak waves is very high. Fig. 7 shows a non-dimensional plot of synoptic wave shape where experimental obtained values were compared with Cokelet's results for high order Stokes waves with the same steepness. $\varepsilon^2 = 0.70$ is Cokelet's expansion parameter.

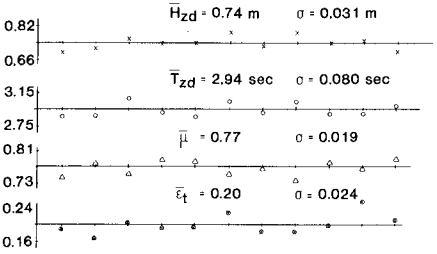

Fig. 6 Control of repetition in experiments.

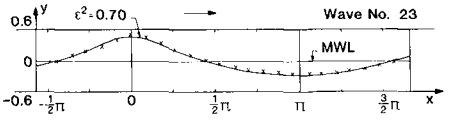

Fig. 7 Non-dimensional synoptic comparison of experimental wave component No. 23 at x = 5.5 m and Cokelet's results for high order Stokes waves.

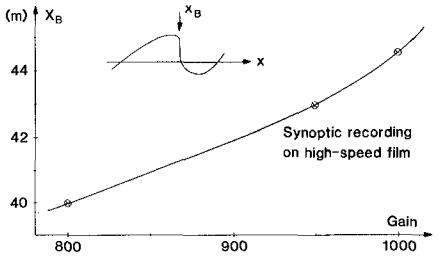

Fig. 8 Non-linear transfer of breaking point as a result of increase in gain on analog signal to wave generator.

The experimental wave component (No. 23) shown in Fig. 5 and measured at 5.5 m is converted from time domain to synoptic domain using equations given by Cokelet (1977, page 210). A coherence between experimental values and Cokelet's results is observed with steep wave crests and flat troughs. This is remarkable because Cokelet's results refer to a steady state condition, while the experiment is a highly transient condition. Thus, we take the observed coherence as a confirmation of the soliton theory used here. Finally, Fig. 8 shows a comparison between 3 identical transient tests with the same analog command signal but with a different gain on the wave maker. The positions x_B where the wave fronts become vertical are recorded and measured on high speed film and shown on the figure. Thus, when the gain is changed from 800 to 1000 the plunging breaker is shifted downwards in the wave flume from x_B = 40 m to x_B = 44.3 m. This is a true non-linear behaviour. Dispersion velocities of all wave components increase with increasing amplitude, and the experimental technique and control are advanced enough to keep the wave focusing properties. Thus, this new non-linear experimental technique can be used to finally adjust a violent plunging breaker to give a very direct strike on a test structure placed for instance 42 m from the point of wave generation.

7. DEVELOPMENT OF COMMAND SIGNALS FOR 3-DIMENSIONAL FREAK WAVES

The same technique was also extended to 3-dimensions. Experiments were carried out in the new ocean basin at the Norwegian Hydrodynamic Laboratories. The basin is 80 m long, 50 m wide and 10 m deep. At the 80 m long side 144 individually controlled single flap type wave generators are installed in an array. Each flap is a "Belofram" sealed membrane hinged 1.02 m below mean water level. At the other sides are efficient energy absorbing parabolic beaches. 144 different command signals of the same type as described in section 5 were prepared for these wave generators in such a way that focusing of wave energy would take place from many directions simultaneously resulting in a large pyramidal breaking wave close to the far end of the basin 40 m from the wave generators. Fig. 9 shows a very steep shortcrested breaking wave (pyramidal breaker) obtained at sea, while Fig. 10 shows a reproduction of the same situation in the ocean basin. The general conclusion from these tests is that non-linear effects in steep waves changed directional propagation and amplified energy focusing. Further, the small flap generators produced linear waves from linear command signals. Thus, it was not possible to generate non-linear solitons as described in section 5. (The wave maker used for the experiments shown in Fig. 5 is a large flap hinged 2.6 m below mean water level.) However, extreme non-linear waves were obtained in the end in the ocean basin as a result of the wave focusing, as can be seen in Fig. 10, but this was first obtained after a non-linear adjustment of wave phases. Finally, some experiments were carried out in which large freak waves were superposed at a certain time on a given directional spectrum using linear theory. However, this leads in all cases to spilling breakers and no plunging breakers were obtained in this way. A 16 mm film showing 3-dimensional experiments were shown at the conference. Further details on these experiments are given by Kjeldsen (1983).

Fig. 9 A dangerous wave captured at sea by Fukumi Kuriyama, Nikkor Club, Nippon, Kogaku, K.K. Japan.

Fig. 10 Reproduction of a pyramidal breaker at the ocean basin.

8. CONCLUSIONS

1) Linear wave theory failed to predict the experiments. Instead an analytical theory is developed that takes into account the observed non-linear dispersion of wave solitons. Command signals for generation of freak waves can thus be obtained as modified versions of equations (5.18) and (5.34).
2) Close to breaking individual wave components can no longer be regarded as travelling independently of each other. Instead, wave-wave interactions take place leading directly to generation of violent plunging breakers in deep waters.
3) The final amplitude of the obtained freak waves cannot be found as a sum of individual wave components measured close to the point of wave generation. A more complicated physical process determines the maximum amplitude where onset of wave breaking is the upper frame.
4) Transient non-breaking wave shapes can be generated with steepnesses that significantly exceed the theoretical value 0.14 for limiting steepness of steady state non-linear waves.
5) Application of this new non-linear transient wave generation technique showed the following advantages:

a) In most conventional tests performed with various structures in deep water plunging breakers are absent. In many conventional tests the total amount of breaking waves (spilling breakers, plunging breakers and bores) is too low. If a plunging breaker occasionally occurs in a simulated stochastic sea "by chance", it is nearly always out of the test section and far away from the structure under investigation. The transient test technique, however, can locate a most violent plunging breaker at a predetermined time and space that strikes exactly at the structure and repeats with great accuracy.

b) Both the total amount of breaking waves and the different types of breaking waves are main factors to consider in simulated seas. The amount of plunging breakers in simulated seas might determine if a critical event takes place or not (i.e. exceeding of breaking strength, capsizing of vessel). The transient deterministic test technique has been developed far enough to excitate resonance and amplify certain dangerous frequencies in a non-linear coupling. After establishment of a resonance a violent plunging breaker strikes the structure as the last wave in a long wave train.

c) The obtained 3-dimensional extreme waves represent a close approximation of the maximum wave height that might be obtained in a given directional wave spectrum with the physical restrictions and all the non-linear effects from wave interaction present. Thus, it represents an alternative choice, to the 100-year design wave obtained from an often uncertain mathematical extrapolation of limited field data from a short period of years.

d) Scale effects can be reduced because higher wave amplitudes and higher Keulegan-Carpenter numbers can be achieved. Conventional use of wave makers leads to lower wave amplitudes and larger scale effects.

e) Transient tests are more accurate than conventional test techniques. The deterministic transient tests can be programmed and planned in such a way that unwanted noise and parasitic disturbances on the responses can be avoided. The parasitic disturbances considered here are unwanted higher harmonics generated by the mechanical wave generators and unwanted reflections from beaches and flume walls. For this reason the transient test technique is a most efficient method to obtain the frequency transfer functions for responses of various structures in waves.

f) Application of transient deterministic test technique for mapping of extreme responses, means much more efficiency in the laboratory and lower costs, due to the fact that the extreme situation can be repeated with great accuracy many times in a single day of testing. On the other hand, conventional test programs for structures in deep waters very often have a long test period and in many cases not a single strike is obtained directly on the structure from a plunging breaker.

6) It was found that traditional stochastic experiments using wave spectra can be directly misleading in some cases. Stochastic experiments and transient experiments were performed on the same structure and the same maximum wave height was expected. However, the trough to crest oscillation in a measured mooring force became twice as high in the transient experiment compared to the stochastic experiment. Thus, conventional test methods give results that are on the non-conservative side in some cases and might lead to a severe underestimation of the wave forces the oceans are able to create.

LABORATORY PHOTOGRAMMETRIC WAVE HEIGHT MEASUREMENT

J.D. POS[1] and F.A. KILNER[2]

ABSTRACT

The paper describes the experimental procedure used to produce a computor contour plot of the wave height distributions and wave directions in a model basin, using photogrammetric techniques. Only monochromatic waves are analysed. A technique is outlined to simulate and measure waves entering a basin of infinite extent, in other words to photograph the penetration of a wave train into a harbour basin before the pattern has been contaminated by reflections. Proof is offered that this infinite basin technique is a valid representation of the steady state situation of a continuous wave train entering an infinite basin.

INTRODUCTION

Model harbours are used by coastal engineers as an aid in the optimization of harbour designs. The models predict wave heights in full scale harbours, the results being used to reduce these wave heights to a minimum in order to prevent damage to moored ships, to the wharf structure and to the mooring systems. Two main limitations in experimental procedures are encountered, however, when attempting to measure accurately the wave height distributions within model harbours; these are:-

(1) Wave heights in model harbours are commonly measured using parallel wire resistance or capacitance wave probes. A number of these probes are usually mounted on a moveable instrument carriage which can traverse the wave basin to measure the wave heights. Such a configuration was used by Harms [3]. The disadvantage of this system is that the wave height at only a limited number of discrete locations can be measured at any one time. The system is also time consuming, since the instrument carriage has to be moved within the wave basin until the entire water surface has been measured. Furthermore, excessive spacing of these wave probes may result in points of maximum wave heights being overlooked.

---

[1] Ph.D. candidate, Civil Engineering Dept., University of Cape Town, South Africa.

[2] Associate Professor, Civil Engineering Dept., University of Cape Town, South Africa

(2) Wave measurements using the above system necessitate (in most cases) that the wave paddle must run continuously. This enables secondary effects, (such as wave reflections, basin oscillations, cross waves, etc.) to develop and distort the generated wave, thus causing marked anomalous wave height variations along the generated incident wave crests. These problems are discussed in depth by Harms [3].

The two abovementioned problems effectively prevent the achievement of accurate wave height and pattern measurement in model harbours. This paper describes research at U.C.T. directed towards solving these problems by using stereophotogrammetry. A photogrammetric technique is described which enables an instantaneous, synoptic and permanent three dimensional record to be obtained of the deformed water surface in a model harbour. A procedure is also described to achieve a computer generated contour plot of the experimental wave height distributions in a wave basin.

DEVELOPMENT OF THE TECHNIQUES USED

In some early attempts at using stereo-photography for the measurement of a deformed water surface, it was appreciated that in clear water it is difficult to distinguish surface features from bed details, thus some method was needed for making the water surface opaque. The substance used must not significantly affect the wave process under investigation, ideally it should also be cheap and non-contaminating with regard to laboratory installations. Surface applications such as aluminium powder and confetti were first tried and were found to be very inconvenient, then various solutions such as P.V.A. in water were tried but were found to settle out quite quickly. Eventually it was found that a low concentration of cutting oil in water, about 0,7 per cent, gave a suitably milky fluid which satisfied the above requirements.

It was found necessary to arrange for special illumination for the water surface and this was achieved by employing 4 conventional lecture room type overhead projectors placed 4m above the water surface in the plan positions shown in Fig. 1. However, when faced with the viewing and interpretation of stereopairs, it was found impossible to identify corresponding points in the photographs without introducing some optical contrast onto the water surface, and this was effected by placing transparencies in the projectors containing black geometrical shapes alternating with translucent areas. Initially, pattern geometry was used, for example concentric black rings, but this was abandoned because it was found that the pattern interfered with the viewer's three dimensional perception. Subsequently random assemblies of black stars and arrows were used, and this is now our standard practice. With regard to photography, two Zeiss Jena metric cameras were used at an elevation of about 5m above water surface and 1.9m apart. At first, the cameras, coupled to their synchronization device, were relied upon to give synchronized exposures of identical duration, but detailed examination of the camera performance showed that this was not reliable, and therefore the projectors were converted into flash units

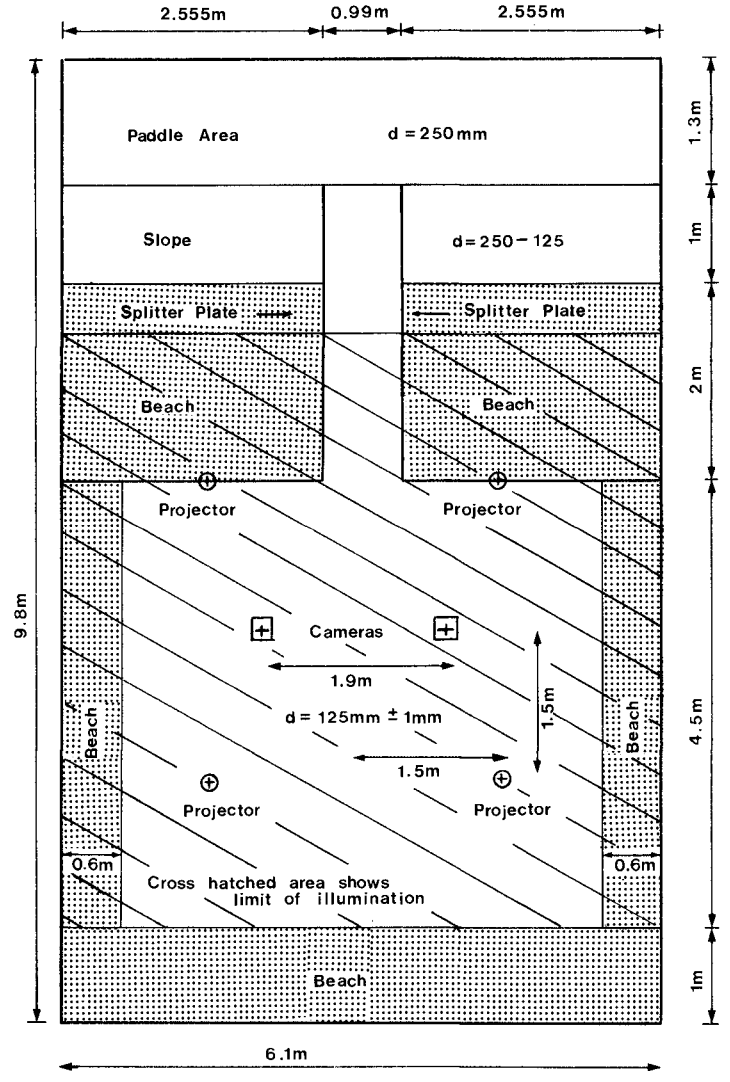

Fig. 1 TYPICAL HARBOUR CONFIGURATION

by replacing the conventional bulbs with flash bulbs, placed at the focal points of the focusing lenses, and fired by a common capacitance. A shutter speed setting of 1/30 second was used, to allow both shutters to be open a sufficient time to encompass the flash duration (allowing for the variation in shutter speeds between the cameras and their lack of synchronisation) and to ensure that the illuminated control points were adequately exposed. All photography took place at night. Due to the very short flash duration, of less than a millisecond, the water surface detail was effectively "frozen" (i.e. very little image movement) in the stereopairs.

The next concern is to consider how the photographs are to be interpreted to yield information about wave heights at points in the field of view. Bearing in mind that a wave height is the vertical distance between a crest at a selected point and a subsequent (or preceding) trough at that point, it is clear that two stereopairs are needed, and these were arranged to be taken such that the waves imaged in the 2nd stereopair are 180° out of phase relative to the waves imaged in the 1st stereopair, making use of two electronic microswitches triggered by the wave paddle mechanism. Algebraic subtraction of the two resulting deformed water surfaces gave the wave heights at all points where a crest or trough appeared in either stereopair. In the earlier stages of the investigation a Zeiss (Jena) Topocart stereoplotter was used to analyse the photographic plates, and was found capable of measuring the wave heights with an average error of 2 mm. This method, however, requires the use of very expensive metric survey cameras in addition to the very expensive stereoplotter (plus a specially trained operator), and therefore a cheaper and slightly more accurate alternative approach was adopted. These earlier stages of the investigation are described in full by Adams and Pos [2].

It was decided that the water surface elevations would be measured using projective transformations. A brief description of the theory of projective transformations is given by Adams [1]. The advantages of this method are that the plates can be viewed by a relatively inexperienced operator using a less expensive Zeiss (Jena) stereocomparator, (i.e. less expensive than a stereoplotter). The water surface elevations are determined by microcomputer using the theory of projective transformations. This method is inherently more accurate than the previous one since the human error involved in the relative and absolute orientation of the stereoplotter is eliminated. Also the projective transformation calculations enable the inner orientation elements (principal distance and principal point) of the cameras to be determined for each stereopair. (Thus far cheaper non metric cameras can be used).

PROJECTIVE TRANSFORMATION THEORY

The theory and mathematical techniques employed are described by Adams [1] and Welham [4]. For ease of reference the appropriate formulae and their solutions are summarised below.

Calculation of Transformation Parameters

$$X_i b_{11} + Y_i b_{12} + Z_i b_{13} + b_{14} - x_i X_i b_{31} - x_i Y_i b_{32} - x_i Z_i b_{33} = x_i, \quad (1)$$

$$X_i b_{21} + Y_i b_{22} + Z_i b_{23} + b_{24} - y_i Y_i b_{31} - y_i Y_i b_{32} - y_i Z_i b_{33} = y_i, \quad (2)$$

where

X_i, Y_i, Z_i are free net space co-ordinates of point P_i ,

x_i, y_i are comparator image co-ordinates of point P_i referred to an aribtrary origin,

b_{ij} are transformation parameters.

In the solution of the transformation parameters, both the image and object co-ordinates are assumed to be error free and the best mean b_{ij} terms are determined using normal equations formed from quasi-observation equations as follows:

b_{11}	b_{12}	b_{13}	b_{14}	b_{21}	b_{22}	b_{23}	b_{24}	b_{31}	b_{32}	b_{33}	= l
X_1	Y_1	Z_1	1	0	0	0	0	$-x_1X_1$	$-x_1Y_1$	$-x_1Z_1$	x_1
X_2	Y_2	Z_2	1	0	0	0	0	$-z_2X_2$	$-x_2Y_2$	$-x_2Z_2$	x_2
.	.	.	.	.	.	.	.	.	.	.	.
.	.	.	.	.	.	.	.	.	.	.	.
X_n	Y_n	Z_n	1	0	0	0	0	$-x_nX_n$	$-x_nY_n$	$-x_nZ_n$	x_n
0	0	0	0	X_1	Y_1	Z_1	1	$-y_1X_1$	$-y_1Y_1$	$-y_1Z_1$	y_1
0	0	0	0	X_2	Y_2	Z_2	1	$-y_2X_2$	$-y_2Y_2$	$-y_2Z_2$	y_2
.	.	.	.	.	.	.	.	.	.	.	.
.	.	.	.	.	.	.	.	.	.	.	.
0	0	0	0	X_n	Y_n	Z_n	1	$-y_nX_n$	$-y_nY_n$	$-y_nZ_n$	y_n

A matrix — L matrix

From these quasi-observation equations, the 'B' matrix can be solved as usual from $B = (A^TA)^{-1} A^TL$.

Most modern desk top or microcomputers can deal with a matrix inversion of this size (11 x 11) and the solution equations adopted take into account any redundant control points imaged and used for calculating the most likely b_{ij} values.

Calculation of Space Co-ordinates using Stereopair

$$\left.\begin{aligned}
(x_i b_{31} - b_{11})X_i + (x_i b_{32} - b_{12})Y_i + (x_i b_{33} - b_{13})Z_i &= b_{14} - x_i \\
(y_i b_{31} - b_{21})X_i + (y_i b_{32} - b_{22})Y_i + (y_i b_{33} - b_{23})Z_i &= b_{24} - y_i \\
(\bar{x}_i \bar{b}_{31} - \bar{b}_{11})X_i + (\bar{x}_i \bar{b}_{32} - \bar{b}_{12})Y_i + (\bar{x}_i \bar{b}_{33} - \bar{b}_{13})Z_i &= \bar{b}_{14} - \bar{x}_i \\
(\bar{y}_i \bar{b}_{31} - \bar{b}_{21})X_i + (\bar{y}_i \bar{b}_{32} - \bar{b}_{22})Y_i + (\bar{y}_i \bar{b}_{33} - \bar{b}_{23})Z_i &= \bar{b}_{24} \quad \bar{y}_i
\end{aligned}\right| \qquad (3)$$

where the unbarred elements refer to the left hand picture and the barred elements to the right hand picture. Let 'C' be the matrix of the left hand coefficients and 'L' the matrix of the right hand terms. The space co-ordinates of an image point (X, Y, Z) can be found from

$$\begin{pmatrix} x \\ y \\ x \end{pmatrix} = (C^T C)^{-1} C^T L.$$

It will be noted that the traditional elements of inner and relative orientation are not apparent, but these can be obtained from a knowledge of the b_{ij} elements if so desired.

Summarised, the appropriate inner orientation equations are:

Non-zero scalar λ:

$$\lambda^{-2} = b_{31}^2 + b_{32}^2 + b_{33}^2 \qquad (4)$$

Principal point co-ordinates (comparator system):

$$x_p = (b_{11}b_{31} + b_{12}b_{32} + b_{13}b_{33})\lambda^2 \quad , \qquad (5)$$

$$y_p = (b_{21}b_{31} + b_{22}b_{32} + b_{23}b_{33})\lambda^2 \quad , \qquad (6)$$

Equivalent principal distance:

$$c_x^2 = (b_{11}^2 + b_{12}^2 + b_{13}^2)\lambda^2 - x^2 p \quad , \qquad (7)$$

$$c_y^2 = (b_{21}^2 + b_{22}^2 + b_{23}^2)\lambda^2 - y^2 p \quad , \qquad (8)$$

Use average of c_x and c_y.

Unless it is intended to plot from the stereopair using a stereoplotter, the inner orientation elements are of academic interest only and therefore only equations (1), (2) and (3) are relevant.

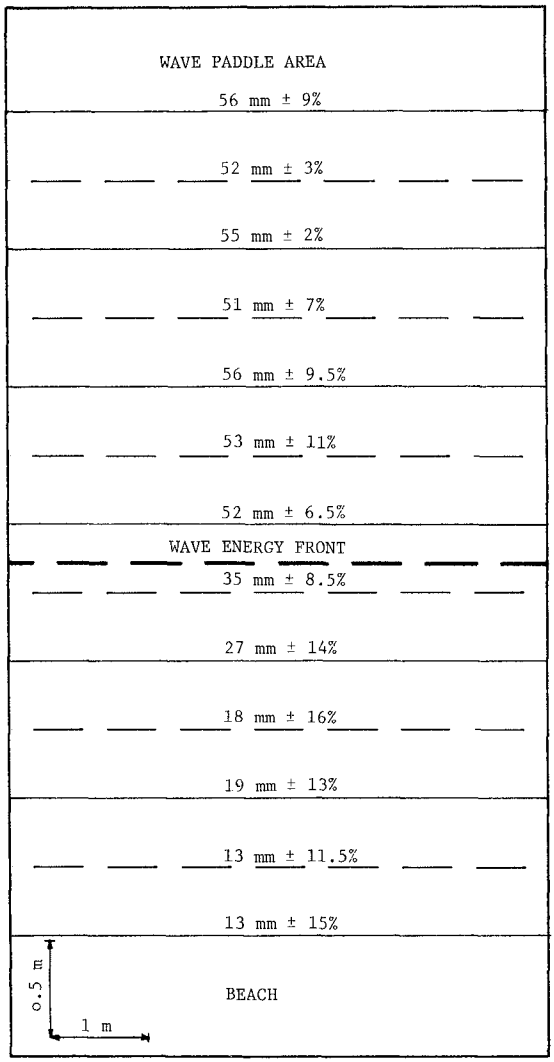

Fig.2 WAVE ENERGY FRONT

CONTROL POINT CONFIGURATION

Initially 12 control points were used (a minimum of 6 control points imaged in the overlap area of the stereopairs are required), 8 at levels above the water surface and 4 at levels below the wave surface (in open canisters). This was done since it was postulated that more accurate results would be obtained if the surface to be measured was straddled by control points, i.e. interpolation, rather than extrapolation as was the case for the first configuration (as described in [2]) which had 4 control points above the water surface. Stereopairs, using the infinite basin technique, were taken of the energy front of a plane long crested wave train entering an area of still water. On analysing the stereopairs it became obvious that the 280 mm maximum vertical distance between the two planes of control points was inadequate to determine the projective transformation parameters with sufficient accuracy. This problem was subsequently overcome by constructing an additional plane of 4 control points approximately 540 mm above the original upper control points.

To determine the XYZ positions of the 16 control points they were first levelled and then 48 inter control points measurements were taken using a steel tape. The corrected data was analysed using a least square adjustment program written for the Tektronix 4051 by Dr. H. Rüther of the Survey Department, U.C.T., and an accuracy in X, Y of better than 1 mm was achieved. Research work done by Welham [4] indicates that the control configuration used was more than adequate for the accurate determination of the projective transformation parameters. Since photography took place at night each control point was individually illuminated.

THE INFINITE BASIN TECHNIQUE

An analysis of the steady state results coupled with visual observations of the deterioration of the wave field in the basin after a very short period of wave paddle action lead to the development and adoption of the infinite basin technique. It was observed that when the wave paddle was subsequently stopped and the main wave train had traversed the basin, a marked reflection and resonsance mode was evident in the basin, which took a few minutes to dissipate. This reflection and resonance mode was obviously superimposed upon the wave field in the basin under steady state conditions.

It was hypothesized that it would be possible to simulate the steady state situation of a continuous wave train entering an infinite basin by sending a wave train into a model basin of still water and taking a stereopair of the water surface just as the wave energy front reached the peripheral beaches. To test this hypothesis, two stereopairs were taken of the wave energy front region of a typical wave train entering an open basin of initially still water. On analysis it was found that the wave heights of the crests immediately behind the wave energy front were closely equal to the mean wave height between the front and the generator. The experimental configuration analysed and the results obtained is shown in fig. 2 . A wave train of period T=0,74 seconds was propagated in a water depth d=138 mm. The crestlines observed in the 1st stereopair are shown as solid lines, while the trough lines

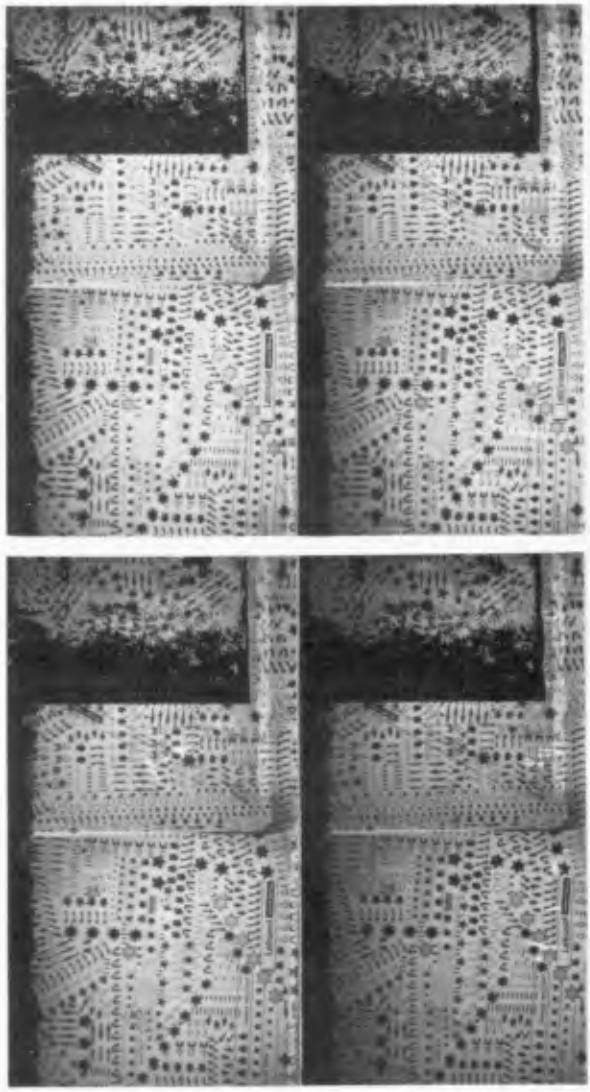

FIG. 3 STEREO PAIRS TAKEN OF MODEL HARBOUR CONFIGURATION

observed in the 1st stereopair are shown as dashed lines. The calculated position of the wave energy front is shown as a thick dashed line. The mean wave heights plus the observed percentage variation from the mean is shown for each crest and trough line. Note the trough lines observed in the 1st stereopair are coincident with the crest lines observed in the 2nd stereopair and vice versa.

MODEL HARBOUR CONFICURATION ANALYSED USING INFINITE BASIN TECHNIQUE

The stereopairs in fig. 3 show waves entering the model harbour basin shown in fig. 1. The basin is 4,5 m long and 4,8 m wide. (These dimensions do not include the crushed stone beaches along the side and back walls of the basin.) The incident wave train has the following characteristics: wave period 0,67 seconds, wave height approx. 55 mm, and wave length (calculated using Airy wave theory) 604 mm. The gap to wavelength ratio (i.e. B/L ratio) is 1,64 The water depth is 125 mm ±1 mm. The stereopairs shown were taken 14,5 seconds after starting the wave paddly at which stage the wave energy front was at the toe of the back wall beach. The second stereopair was taken with the waves in the basin 180° out of phase relative to the waves imaged in the first stereopair. This means that the troughs imaged in the second stereopair occupy the positions of the crests imaged in the first stereopair. If one substracts the crest and trough elevations of the first stereopair from their corresponding elevations in the second stereopair, one will achieve a plot of wave height distribution within the basin. Since the harbour configuration is symmetrical about the centre line, only the left hand side of the basin is shown in fig. 3.

WAVE HEIGHT MEASUREMENT PROCEDURE

The process of achieving a plot of wave height distributions within the model basin is briefly summarised in fig. 4. The stereopairs are analysed using a Zeiss (Jena) stereocomparator which is interfaced via an analog to digital converter and a data communications interface with a Tektronix 4051 microcomputer. The microcomputer, under program control, stores the X, Y and PX, PY data obtained from the stereocomparator for each point observed. The stereopairs can also be analysed on a digitiser tablet using a modified stereoscope and a special double cursor (as described by Welham [4]). Using this alternative technique the wave heights can be measured with an accuracy of 5 to 6 mm. Once a set of points has been observed, the raw data is edited, prepared for transfer to flexible disc, and then stored on tape. The tape is then transferred to a second Tektronix 4051 which has a flexible disc file manager, and the data transferred from tape to disc, under program control. All subsequent analysis is performed on the second Tektronix 4051.

The analysis procedure which is outlined by the procedural flowchart in fig. 5 is as follows: the control points and crests imaged in the first stereopair and the control points imaged in the second stereopair are observed using the stereocomparator. The observed data is then analysed using the program "Waveheight", written by the first author, to yield:- the inner orientation elements and projective transformation parameters for the 1st and 2nd stereopairs, the crest elevation data

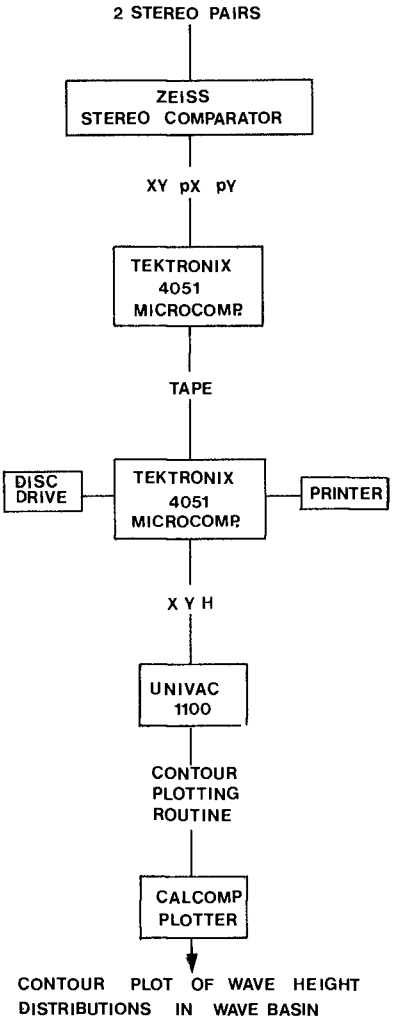

Fig.4 SEQUENCE OF ANALYSIS

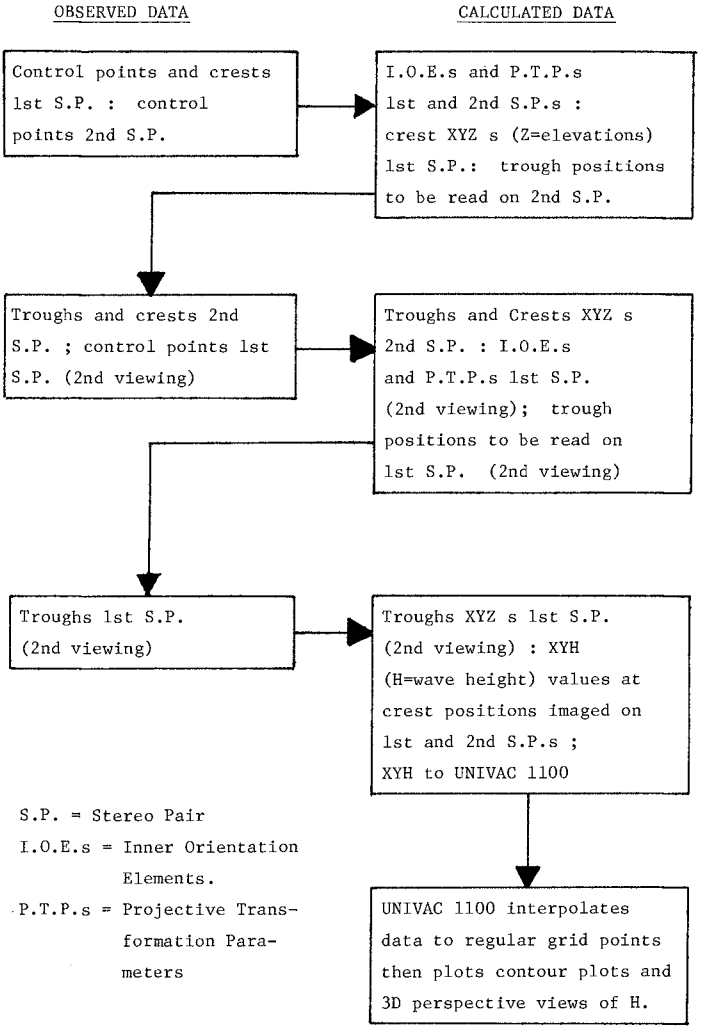

Fig.5 PROCEDURAL FLOWCHART

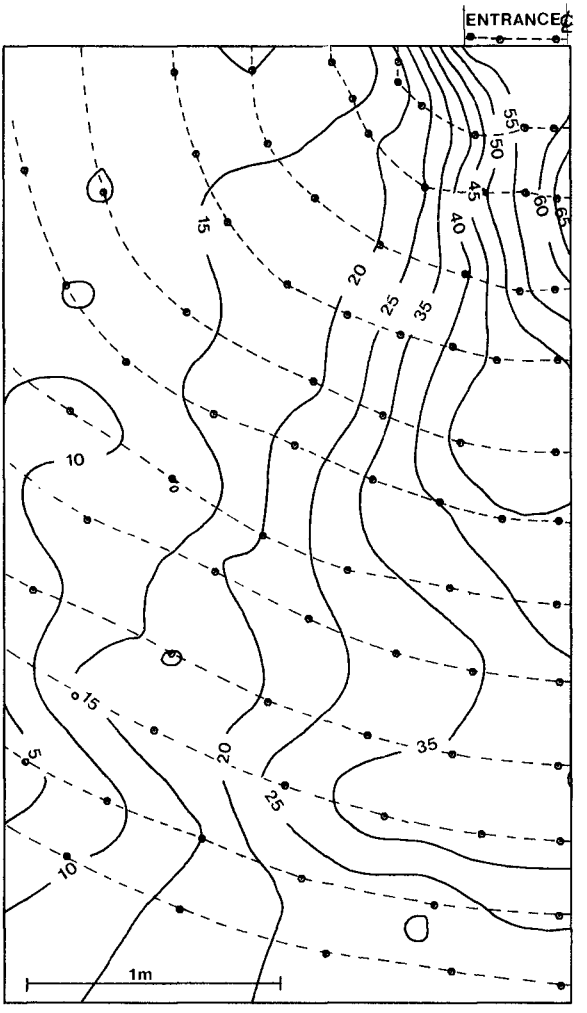

Fig.6 COMPUTER CONTOUR PLOT OF WAVE HEIGHTS IN A MODEL HARBOUR (HEIGHTS IN MM)

(crest XYZ data) for the 1st stereopair, and the positions at which the troughs must be observed on the 2nd stereopair. The troughs imaged in the 2nd stereopair are then observed at the predetermined points, while the crests are observed at arbitrary points selected by the observer. The 1st stereopair is again placed in the stereocomparator and the imaged control points are observed. This observed data is analysed using the programme "Waveheight" to yield: trough and crest XYZ data for the 2nd stereopair, inner orientation elements and projective transformation parameters for the 1st stereopair (2nd viewing), and the trough positions to be observed in the 1st stereopair (2nd viewing). The troughs imaged in the 1st stereopair are then observed. The observed data is then analysed using the program "Wave height" which yields: The trough XYZ data for the 1st stereopair and the XYH values along the crest lines imaged in the 1st and 2nd stereopairs, H is the wave height at a point within the basin. From the results obtained it is estimated that the wave heights can be measured with an accuracy of better than 2 mm.

The XYH data is then transfered to a file on the UNIVAC 1100 at U.C.T. The Saclant Graphics Package installed on the UNIVAC is then used to interpolate the raw data onto a rectangular equidistant grid. The interpolated data can then be used to plot a contour plot or a 3 dimensional perspective picture of the wave height distributions within the model harbour basin. The stereopairs, shown in fig. 3, were analysed using the procedure described above to yield the contour plot of wave heights within the basin, shown in fig. 6. Since the harbour configuration is symmetrical about the centre line, only the left hand side of the basin is shown. The dashed lines indicate the crest lines plotted from both stereopairs. The black dots indicate the crest line sampling points plotted from both stereopairs.

CONCLUSIONS

The two major problems which prevent the accurate measurement of wave heights in model harbours using conventional techniques (as described in the introduction) have been successfully solved using the photogrammetric technique. Problem (1) is solved since the two stereopairs of photographs can be taken in a much shorter period than is required for a scan using wave probes, and the information contained on the plates is permanent, synoptic and detailed. Furthermore, there is no instrumental interference in wave processes being observed. Problem (2) can be overcome by using the infinite basin technique, that is by photographing before the wave energy is reflected from internal walls, thus eliminating the distorting effects of wave reflections within a model basin. The infinite basin technique effectively enables the researcher to accurately model the situation of a continuous wave train entering a basin of infinite extent.

Three areas of utilisation for the photogrammetric wave height and pattern recording technique appear possible, the first is the routine use in applied investigations where refraction or diffraction effects are important, for example, the analysis of model harbour configurations. The second is to make use of the procedures as a check on the validity of various existing wave theories, where the information obtained (instantaneous and high accuracy) should be decisive. The third area of utilisation is to apply the technique in close conjunction with

mathematical modelling (such as finite element modelling) in order possibly to calibrate the models and thus improve their predictions.

ACKNOWLEDGEMENTS

The authors would like to thank Professor L.P. Adams, Dr. H. Rüther and Mr. L.G. Welham of the Department of Surveying, University of Cape Town, South Africa, for their assistance in the development of the photogrammetric technique.

A NEW APPROACH TO TRANSIENT WAVE GENERATION

E.P.D. Mansard[1] and E.R. Funke[2]

ABSTRACT

An analytical model of an "episodic" wave as a function of time is given. The linear dispersion theory is applied to the transient to hindcast the wave train at a wave board which is a specified distance up-wave from a test site. First order wave board theory and linear system theory is used to convert the wave train at the wave board into a control signal. Conversion of the time discrete control signal into a smooth analog voltage signal by means of a real time digital program is described. Examples of numerical simulations and physical measurements are given.

INTRODUCTION

Testing of coastal structures in hydraulic laboratories is generally performed by wave attack with either regular or irregular waves. Occasionally it is desirable to study fixed or floating structures by exposing them either to extremely large waves or to particular successions of large waves as may be encountered in wave groups.

Whereas many researchers believe that the use of long sequences of random waves for testing purposes offers a high probability that all extreme test conditions will be encountered sooner or later, experience at NRC has indicated that this is not generally the case. During a capsize test of a communication buoy, irregular waves for a fully developed sea failed to capsize the buoy whereas a particular transient wave, designed to break at the buoy location, achieved a capsize every time (Photographs 1 and 2). Other examples for the application of transient wave conditions are overtopping tests and the measurement of pressure and forces due to extreme waves. Purely from the point of view of being able to exercise more precise control of wave profiles at the test site as well as the greater testing efficiency and resulting time saving, the deterministic approach to wave generation has an appeal to the experimental scientist.

Episodic waves have been generated successfully by various laboratories using a "sweep frequency" technique. The span and the

SEA KEEPING TEST OF A COMMUNICATION BUOY

sweep rate were determined experimentally to achieve a breaker at a certain distance from the wave board. A variation of this method was described by Funke and Mansard (1979) which determines the sweep rate by calculating the periods of successive wave singlets in a wave train which is being assembled to achieve breaking at a predefined distance from the wave board. This technique is described in Figure 1 which illustrates the principle that the singlet of period $1/F_a$ requires T_a seconds to travel a required distance D at group velocity. Therefore, if a second singlet is to be generated, which can catch up and overtake the first singlet within distance D, then it must do so in $T_a - 1/F_a$ seconds. Because there is now less time available, the second singlet must, of necessity, be of a longer period than the first because longer period waves travel faster.

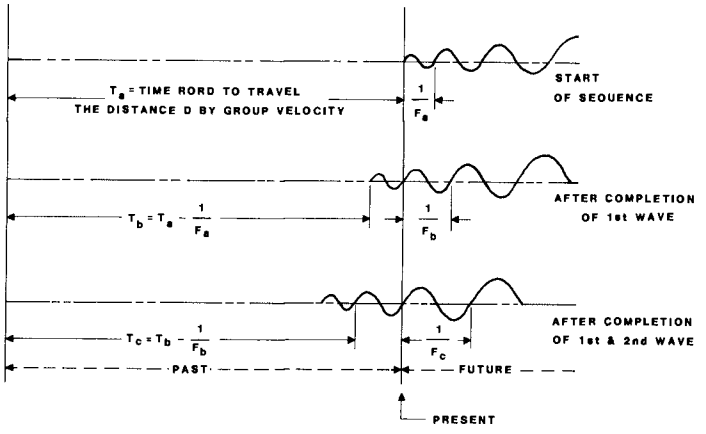

FIG.1 TRANSIENT WAVE GENERATION BY SWEEP FREQUENCY METHOD

Although the "sweep frequency" methods have proven that control over the wave breaker location is possible, they do not permit any control over the profile of the wave transient. The method by Funke and Mansard (1979) assumed that every singlet should have an amplitude of 1/10 of the associated wave length. As a result, the actual breaking occurs when the wave becomes critically steep due to the superposition of waves and not necessarily when all wave singlets have achieved phase coincidence.

The new method described here is based on a description of the desired wave transient at the test site and on the principle that, through the application of linear dispersion theory, the corresponding wave sequence at the location of the wave board can be hindcasted. It should therefore be possible to generate wave groups with an arbitrary number of waves per group and with arbitrary steepness. Limitations are, of course, imposed by physical realizability.

DEFINING THE WAVE TRANSIENT

To illustrate the method, the generation of a wave group with a finite number of waves is being described. In the absence of an analytical description of such a wave or wave train as a function of time, a mathematical function has been composed which gives the water surface elevation $\eta(t)$ as may be observed at a single point at the test site in a wave flume or basin. This function is given as:

$$\eta(i\cdot\Delta t) = \sum_{n=1}^{n_{max}} \frac{H\cdot T\cdot e^{-(\gamma\cdot t)^2}\cdot \sin(n\pi\rho/T}{\pi^2\cdot n^2\cdot\rho\cdot(1-\rho/T)} \cdot \sin(2\pi n\cdot i\Delta t/T) \qquad (1)$$

where n_{max} = is the maximum number of participating harmonics

H = is the wave height of an unmodulated saw tooth wave form

T = is the period of the saw tooth

γ = $\sqrt{3}/(\beta\cdot T)$

β = is the half amplitude width of the Gaussian envelope function

ρ = is a steepness parameter.

Equation (1) may best be understood with reference to Figure 2. See also Moskowitz and Racker (1951). The term

$$\frac{H\cdot T\cdot \sin(n\pi\rho/T)}{\pi^2\cdot n^2\cdot\rho\cdot(1-\rho/T)}$$

gives the nth Fourier coefficient for a saw tooth wave form with steepness parameter ρ. If ρ=0.5, the saw tooth is symmetrical with front and back steepness being equal. If ρ=1.0, then the wave front is infinitely steep. In practice, ρ=0.75 appears to be satisfactory. The

second graph in Figure 2 illustrates five cycles of a saw tooth wave for H=0.5 m, ρ=0.75, T=2 seconds and n_{max}=4. This trace results from evaluating $\sin(2\pi \cdot n \cdot i\Delta t/T)$ for $0<i\Delta t<10$ seconds.

n_{max}, in the summation of equation 1, may be limited in order to avoid very sharp, non-realizable crests and troughs in the saw tooth. Alternatively, n_{max} may be used to limit the maximum frequency in the wave machine control signal.

The term $e^{-(\gamma \cdot t)^2}$ in equation (1) gives an amplitude modulator which is applied to the saw tooth. $\gamma=\sqrt{3}/(\beta \cdot T)$ may be used to control the width of this bell shaped function. In the example, β=2, which implies that the half amplitude width is $\beta \cdot T=4$ seconds, the bell function is centred at $t=1.21 \cdot \beta \cdot T$.

The result of modulating the saw tooth is given as the third trace in Figure 2. This is the theoretical wave transient as a function of time and represents the wave which is to be generated at a test site some distance from the wave board.

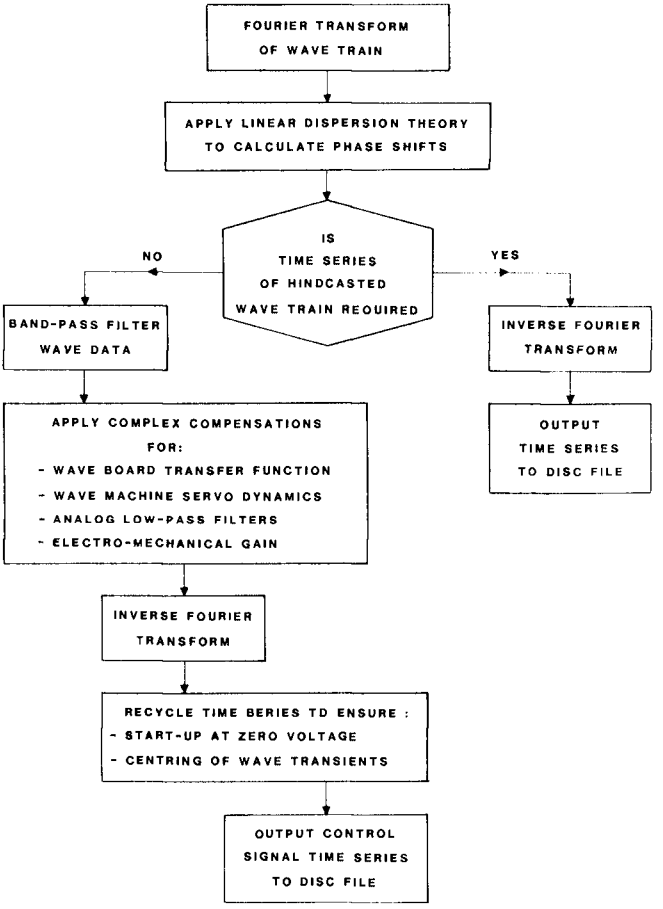

FIG.3 SUMMARY OF OPERATIONS REQUIRED FOR CONVERTING A WAVE TRAIN TO A WAVE MACHINE CONTROL SIGNAL

Discrete Fourier transform considerations require that a recycling period is specified. Also, for purposes of conducting a test, it is preferable to introduce a quiescent period between successive wave transients in order to permit disturbances in the flume to settle down after each transient has traversed the length of the flume. For this reason a recycling period T_n is introduced which was set to 50 seconds for the example of Figure 2.

COMPUTATION OF THE WAVE GENERATOR CONTROL SIGNAL

The conversion of the wave train, defined in Equation (1) and Figure 2, to a wave generator control signal is accomplished by first submitting the time series to a program known as RWREP which is described by Funke and Mansard (1983). This computer program performs a variety of operations which are summarized in Figures 3 and 4.

All these operations are being implemented in the frequency domain and therefore the desired wave train is first Fourier transformed.

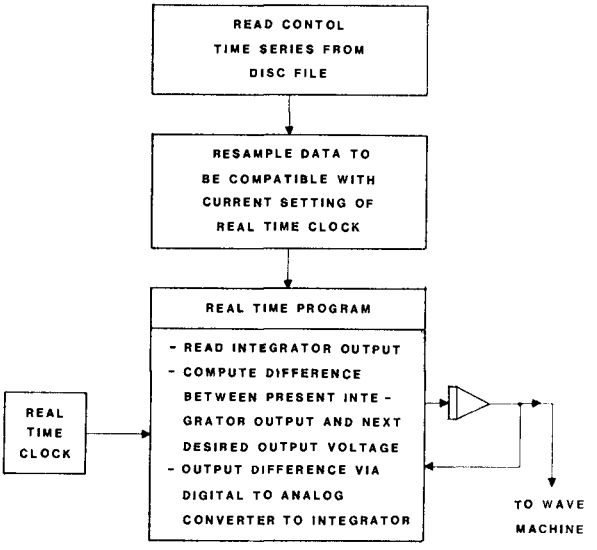

FIG.4 CONVERTING A CONTROL TIME SERIES TO A VOLTAGE SIGNAL

Linear dispersion theory states that all individual frequency components, which are constituent parts of a progressive wave train, propagate at their own phase velocity. This is, however, a function of both period and water depth. Under shallow water depth conditions, the phase velocities are all the same. But, under intermediate and deep water conditions, the low frequency waves propagate faster than the high frequency waves.

Experiments have indicated that the linear dispersion theory is a reasonable assumption under non-breaking wave conditions. Figure 5 illustrates the results of one experiment carried out in a wave flume with 0.92 m depth of water. A "random" wave train with a Pierson-Moskowitz spectrum with f_p=1 Hz was generated. Ten wave probes were placed along the wave flume at various intervals from 2 to 19 meters from the wave board. The signals monitored by each of the probes were Fourier analysed and the phase lags, relative to the first wave probe, were computed for 5 frequencies from 0.9 to 1.3 hz. Figure 5 gives the results and compares these with the phase shift based on linear dispersion theory. From this it was concluded that linear dispersion relations represent a reasonable approximation in calculating phase shifts for frequency components in complex wave trains and this is being applied by the program RWREP to hindcast the wave train in terms of its Fourier transform at the wave board.

The next step in Figure 3 gives the option to inverse Fourier transform the hindcasted data in order to provide a time series describing the wave train which will be generated at the wave board. The fourth trace on Figure 2 provides an interesting example of the wave train which must be generated at the wave board in order to produce the wave transient shown in the third trace. Although the sweep of frequencies from high to low frequencies are reminiscent of previously used techniques, the groupy modulation of amplitudes are a surprising result.

Following the computation of the hindcasted wave train, the data is optionally band pass filtered and then compensated for a variety of dynamic transfer functions which are in the path of a computer generated control voltage. The wave board transfer function described by Gilbert, Thompson and Brewer (1970) was expressed as a complex function to allow for the $\pi/2$ phase advance between the wave board position and the water surface elevations. To convert the time series for water surface elevation at the wave board to a time series of wave board position, the Fourier transform of the former is divided by this wave machine transfer function.

The electro-hydraulic servo transfer function of the wave machine can be obtained from measurements. Depending on the depth of water and the particular settings of the control loop parameters, this transfer function may vary somewhat. For most machines currently in use at the National Research Council this transfer function was found to be:

$$G(j\omega) = \frac{1}{(j\omega+1)^3}$$

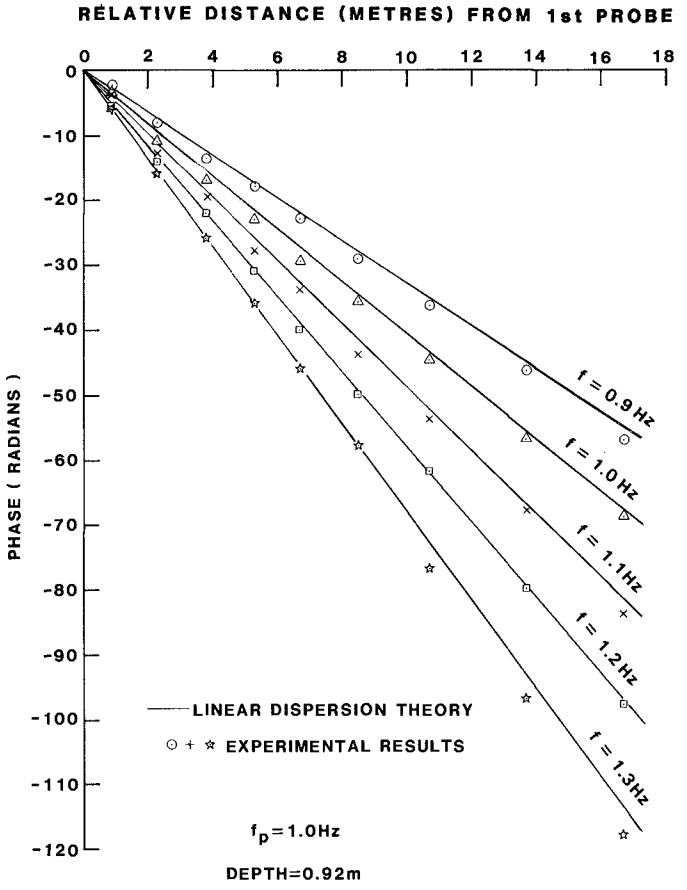

FIG.5 PHASE PROPAGATION OF INDIVIDUAL FREQUENCY COMPONENTS IN A PIERSON MOSKOWITZ SPECTRUM

Consequently, the Fourier transform of the wave board position signal is divided by $G(j\omega)$.

A low pass filter is frequently introduced at the output of a digital to analog converter in order to remove the sharp corners of the converter's output or to protect the machine from dynamic shock. A correction for such a filter should also be included.

At this stage all dynamic effects have been allowed for. However, in order to convert a wave board position signal to a voltage signal, a known wave machine calibration factor in terms of meters of board displacement per voltage input to the servo must be applied as a scale factor. It is also important to ensure that a positive value in a digital control signal leads to forward displacement of the wave board.

Application of the inverse Fourier transform supplies then the time series for the wave generator control signal. Some adjustments are then made to avoid severe start-up discontinuities or, as is the case for the generation of wave transients with long quiescent periods following the transients, the control signal is cycled around the vector length to ensure that the signal starts during the quiescent stage and not in the middle of the transient.

SIGNAL GENERATION

Whereas the above computations are all carried out in a digital computer resulting in a time series of the desired control signal, the ultimate step is the conversion of the time series into a smooth analog voltage signal. This is performed by a real time computer program operating in the "foreground" under control of the computer's real time clock as shown in Figure 4.

The real time clock is usually preset to be compatible with the highest frequencies which may have to be generated. Experience at the National Research Council over a period of ten years has indicated that a real time clock rate of 10 steps per second is more than adequate. However, during the digital wave synthesis process, such as described by equation (1), the intersample spacing, Δt, may not necessarily be 0.1 seconds. Therefore, an operation of re-sampling may be required to preserve the temporal integrity of the control signal. Under the GEDAP operating system described by Funke, Crookshank and Wingham (1980) this operation is transparent.

The actual operation of generating a smooth analog signal is performed by a digital to analog converter in conjunction with an integrator. The real time program monitors the output of the integrator by means of an analog to digital converter and computes the difference between the present integrator output and the desired integrator output one time step later and transmits this value to the digital to analog converter. This results in a straight line interpolation of analog voltages between successive discrete digital values as described in Funke, Crookshank and Wiegert (1981).

EXPERIMENTAL RESULTS

An example similar to Figure 2 has been tested in a flume and the results are shown in Figure 6 for various distances from 1.8 m to 22.8 m. This test was carried out at a depth of water of 0.60 meters. The transient was synthesized for a focal distance of 20 meters. It may be noticed from Figure 6 how the wave transient converges as it propagates towards its cataclysmic destiny. It should be noted that the actual breaking took place at about 23.4 meters. Photograph 3 shows the resultant appearance of the plunger.

Further experimental results are illustrated in Figure 7. The first three traces 'a' to 'c' show the degree of success with which a variety of wave groups can be generated. There are notable differences between the desired and the measured transients which may be explained by the fact that the formulation of a wave group in terms of equation (1) is not physically realizable for the water depth to wave length conditions of the test. The desired vertical asymmetry in Figures 7b and 7c did not reproduce and, instead, a severe horizontal asymmetry resulted.

PHOTO 3

PLUNGING WAVE ON A CONICAL STRUCTURE

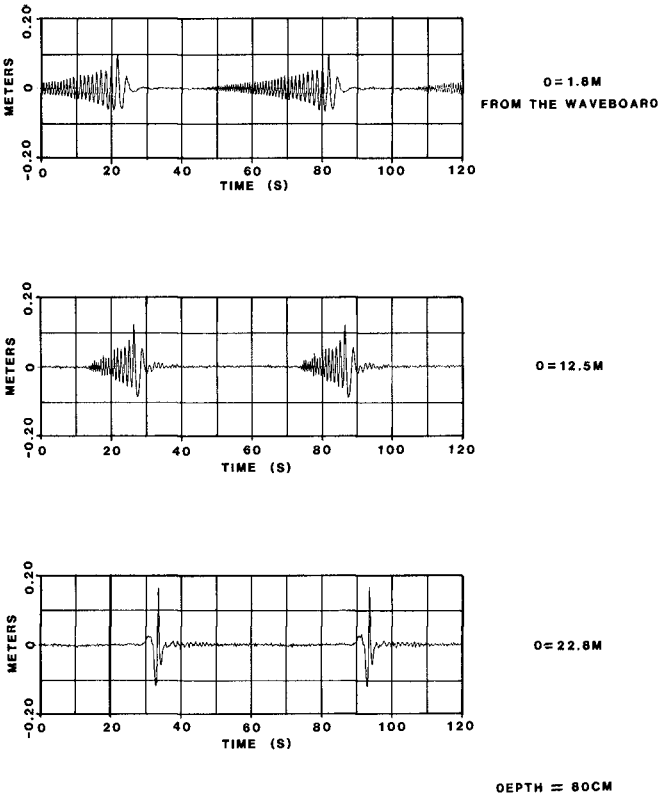

FIG.6 EPISODIC WAVE AS OBSERVED ALONG THE FLUME

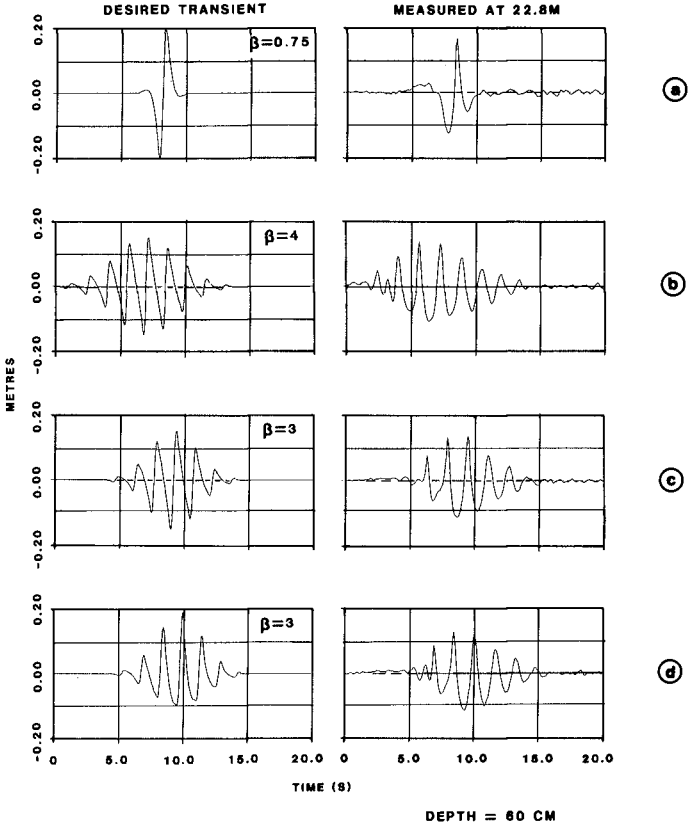

FIG.7 GENERATION OF WAVE TRANSIENTS IN THE FLUME

In order to improve on the formulation of equation (1), a new technique was introduced which was to lead to a more realistic definition of the wave transient. This technique is described by Funke and Mansard (1982). It involves a variety of non-linear distortions designed to increase crest heights while reducing the size of troughs and to shorten crest durations while lengthening trough durations without altering wave periods.

Figure 7d is an example of such a non-linear transformation applied to the group of Figure 7c. The resultant measured wave shows some improved reproduction which suggests that, through trial and error, further improvements may be realizable.

CONCLUSIONS

It has been demonstrated that transient wave forms can be generated in a flume or basin. Episodic waves could be generated with larger amplitudes than has previously been possible. The fidelity of reproduction is reasonable but can probably be improved by the application of non-linear dispersion theory and second order wave generator theory. The definition of the desired transient is, at this time, restricted to an amplitude modulated saw tooth with controlled front steepness. It is hoped that improved theoretical models of extreme wave transients as a function of time may also contribute in realizing more accurate generation of extreme wave conditions in the laboratory environment.

THE CONTROL OF WAVE ASYMMETRIES IN RANDOM WAVES

E.R. Funke[1] and E.P.D. Mansard[2]

ABSTRACT

The concept of wave asymmetry is reviewed and a prototype wave record is analysed. A three stage non-linear transformation, together with a Fourier transform substitution technique, is described. The method is tested by numerical simulation using statistical analysis procedures. Physical realizations are compared graphically.

1.0 INTRODUCTION

Nearly all techniques for the synthetic generation of "random" waves in laboratory flumes or basins assume that wind generated waves can be adequately described by a Gaussian stochastic process. This assumption has simplified both the process of wave generation and wave data analysis. However, many wave parameters are known to depart from the Gaussian hypothesis. Although these deviations are usually small in a statistical sense, they can represent significant factors in the study of structural responses to wave attack. Some of these non-Gaussian wave parameters deal with wave asymmetries which have recently been parameterized by Kjeldsen and Myrhaug (1979).

In this regard it is interesting to reminisce that, during the 1950 and 1960 period, one of the justifications in the defence for the construction of costly wind-wave flumes was based on the argument that the wind was essential to "steepen-up" the waves. This appears to be a correct observation because, as many experimenters in coastal engineering know, a random wave simulation based on a Pierson-Moskowitz spectrum for a fully developed sea, but without the use of wind, does not contain a significant number of breakers; a condition which does not correspond to Nature.

Such simulations are typically produced either from filtered white noise or by inverse Fourier transformations of amplitude spectra in association with randomly selected phases. Either of the two methods lead to functions of time which have Gaussian amplitude distributions. Such Gaussian stochastic processes are, on the average, perfectly symmetrical, that is to say that the average crest height equals the average trough height and that the crest front steepnesses are, on the average, equal to the crest rear steepnesses. However, the presence of

[1]B.Sc., M.Sc., Senior Research Officer, Hydraulics Laboratory, National Research council Canada, Ottawa, Ontario K1A 0R6, Canada.
[2]Dr.-Ing., Associate Research Officer, Hydraulics Laboratory, National Research Council Canada, Ottawa, Ontario K1A 0R6, Canada.

wave breakers implies that there is a strong preference for crest fronts to be steeper. This is a condition which must be considered a departure from the Gaussian hypothesis. In terms of spectral concepts, wave asymmetries imply a correlation of phases of harmonically related frequencies; a concept still requiring proof.

Wave profiles, however, do change when a wave propagates from deep into shallow water and begins to feel the bottom. The crest becomes larger and shorter while the trough becomes flatter and longer. Whereas it may not be unreasonable in deep water and in the absence of wind and currents to approximate "random" waves by Gaussian stochastic processes, this may not necessarily be so under other conditions. It is not uncommon to place a wave generator in "deep" water and then let the natural shoaling process transform the wave profiles. This can, at the expense of floor space, overcome the limitations of the generation technique. On the other hand, if possible, one should attempt to control the wave machinery to realize, at the boundary, all wave properties which are measurable in Nature. This approach to "random" wave generation has been referred to as a deterministic approach and has led to a number of innovations such as the generation of specific wave transients (Mansard and Funke 1982, S.P. Kjeldsen 1982), the control of the distribution of energy in the time domain (H. Lundgren and S.E. Sand 1978, Funke and Mansard 1980), and the generation of the correct group bound long wave components (Barthel et al 1983, and Sand 1982). This paper describes a method which imposes non-linear transformations in the time domain to a Gaussian function of time for the purpose of controlling wave asymmetries. These distorted functions of time are then used to create wave generator control signals which can produce the desired wave characteristics at the test site some distance away from the wave board.

2.0 WAVE ASYMMETRIES

Kjeldsen and Myrhaug (1979) have parameterized wave asymmetries as given in Figure 1. According to this, the horizontal asymmetry factor is $\mu = \eta'/H$ where η' is the crest height and H is the zero down crossing wave height. The horizontal asymmetry factor gives, therefore, the asymmetry about the horizontal axis at the mean water level. For Gaussian processes this should, on the average, be 0.5.

The vertical asymmetry factor, on the other hand, gives the asymmetry about the vertical axis at the point of the wave crest. This is given as $\lambda = L''/L'$ where L" is the crest rear length and L' is the crest front length, both measured along the horizontal axis. Intuition suggests that, for Gaussian processes, this ratio should be near one as the number of crests with steep fronts is expected to be equal to the number of crests with steep backs. However, as shown in Appendix A1, even if the waves are symmetrical, the expected value of this ratio is always greater than one. This ratio is therefore not a very useful measure for the detection of preferential asymmetries in crest steepnesses.

Two other parameters are the crest front steepness which is given by $\varepsilon = \eta'/L'$ and correspondingly the crest rear steepness which is

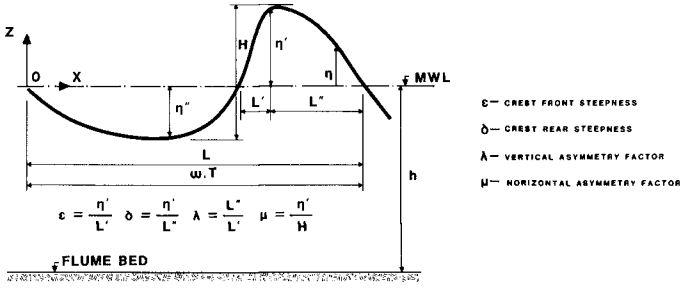

FIG.1 DEFINITION SKETCH OF WAVE ASYMMETRIES

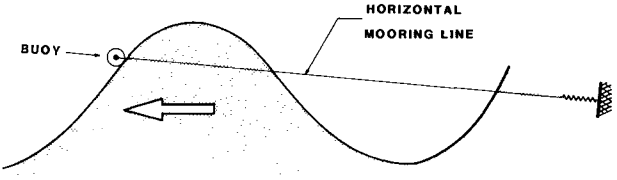
$\delta = \eta'/L"$. These two prove more sensitive for the determination of departure from Gaussian behaviour.

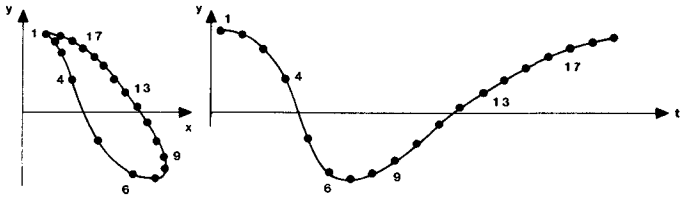
A more traditional concept of steepness is the ratio of H/L where H is the zero down crossing wave height and L the associated wave length. Whereas this parameter provides some useful information about the development stage of the sea, it has nothing to do with asymmetrical distortions of the waves.

The measurement of wave asymmetry parameters at sea is not a simple matter. There are a number of difficulties which limit the accuracy of such measurements. Foremost of these is the fact that the greatest majority of wave records were obtained by means of Waverider buoys which are presumed stationary at a single point in space. Their output is derived from a double integration of a band limited acceleration signal. This results in a water surface elevation as a function of time. Wave length measurements are therefore not directly available and must be computed by relating individual zero crossing wave periods to wave lengths. Because an individual zero crossing wave period is a consequence of the superposition of several free running frequencies, it is not likely that the simple use of this individual period will lead to a correct calculation of the actual wave length. Nevertheless, there is little else one can do at the moment and one may be consoled by the fact that, whatever mistakes are being made, are also made under laboratory conditions. Therefore, comparative results are still valid.

Another, more serious, problem deals with the mooring system of a wave recording buoy. Figure 2 gives a highly simplified version of a buoy mooring system which assumes that the compliant mooring line



BUOY WITH HORIZONTAL MOORING
INTERACTING WITH A SINUSOIDAL PROGRESSIVE WAVE



STROBO GRAPH OF BUOY

TIME HISTORY OF BUOY'S VERTICAL POSITION

FIG.2 NON-LINEAR DISTORTIONS DUE TO BUOY

exerts a nearly horizontal restraining force on the buoy. As a wave progresses from right to left, the buoy climbs up along the wave front. The additional uplift force, due to acceleration and friction, results in a stretch of the compliant line. When the buoy reaches the wave crest, it starts to slide down the rear of the crest, propelled by both the gravitational force as well as the spring force of the mooring line. This results in a rapid descent from the crest.

To illustrate this motion a hypothetical strobo-graph is shown in Figure 2 in which points represent buoy positions at constant time intervals. Points 1 to 7 represent the rapid descent whereas 8 to 19 correspond to the rise of the buoy to the crest. The corresponding time history, which is shown to the right of the strobo-graph, gives the same information except that all points are placed at constant time intervals along a time axis. From this it can clearly be seen how the mooring system causes a distortion of the water surface elevation measurement. This results in a crest rear steepness η'/L'' which is larger than the crest front steepness η'/L'.

Evidently, the examples in Figure 2 have been exaggerated to make a point. Nevertheless it must be expected that prototype wave recordings obtained from Waverider buoys do not supply reliable vertical asymmetry factors or crest steepnesses.

To overcome this problem, one may wish to investigate wave recordings obtained from staff gauges mounted on stable platforms. However, it should be remembered that these records do contain a set-down which depresses the mean water level under wave groups. In order to be strictly correct, such wave data should be high pass filtered prior to zero crossing analysis or else the wave asymmetry parameters may not be calculated correctly.

Figure 3 gives an example of a statistical analysis of wave asymmetry parameters for wave data recorded in the Hibernia field area off the east coast of Newfoundland using a Waverider buoy. It is noteworthy that the average crest rear steepness is 5% larger than the crest front steepness; a condition which is opposite to what one would expect in a severe storm. This indicates that the mooring system probably distorted the wave record. The horizontal asymmetry indicates a minor deviation from 0.5, which suggests that wave crests are slightly higher than wave troughs.

3.0 THE NON-LINEAR TRANSFORMATION

The non-linear transformation assumes the existence of a time series from a Gaussian stochastic process; in other words, a time series which is known to be symmetrical on the average.

The transformation takes place in three distinct steps; - the amplitude distortion, - the time distortion, and - the crest distortion.

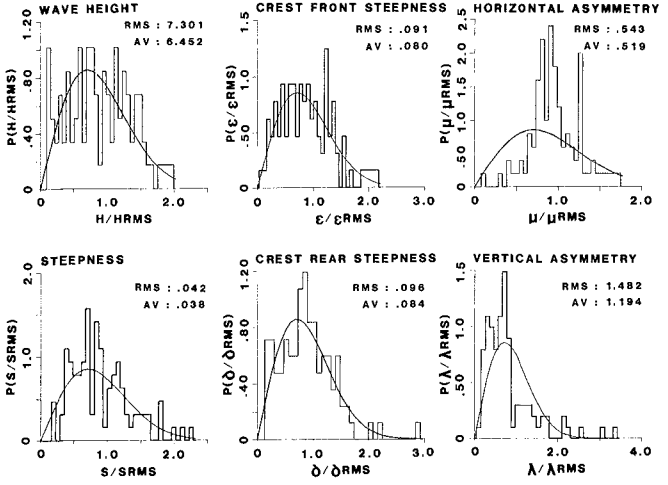


FIG.3 ZERO CROSSING ANALYSIS OF WAVE DATA RECORDED EAST OFF NEWFOUNDLAND IN 95M OF WATER

3.1 The Amplitude Distortion

The non-linear amplitude transformation is given as:

$$\eta 1_i = \eta_i + C_p \cdot \eta_i^2/\sigma_\eta \quad \text{for} \quad \eta_i > 0 \tag{1}$$

$$\eta 1_i = \eta_i + C_n \cdot \eta_i^2/\sigma_\eta \quad \text{for} \quad \eta_i < 0 \tag{2}$$

$$\eta 1_i = \eta_i \quad \text{for} \quad \eta_i = 0 \tag{3}$$

where:

η_i is the ith sample of the symmetrical time series

C_p and C_n are the non-linear transformation coefficients, and

σ_η is the standard deviation of the time series η_i and is introduced to permit the use of a normalized, non-dimensional transformation coefficient. By convention, the standard deviation σ_η is evaluated over the total length of the time series which is to be transformed. As an exception, when this transformation is applied to a wave transient, the evaluation of σ is limited to the duration of the transient only.

Naturally, a non-linear distortion of the type described in equations (1) to (3) must have an effect on the spectrum of the primary input signal. If this distortion were to be imposed on a pure sinusoid, one would notice that the spectrum of the distorted signal contains energy at frequencies which are second and higher harmonics to the fundamental.

The intent of this transformation is, however, not to modify the primary input spectrum and it is therefore a necessary condition for the transformation to succeed, that the primary input spectrum contains enough energy in those bands of frequencies which may serve as second or third harmonics to the lower frequency band of the same spectrum. In other words, narrow band spectra without a high frequency tail are not suitable for the generation of asymmetrical waves.

A corollary to this observation is that asymmetrical waves must have a broad spectrum.

In order to preserve the primary input spectrum, a technique is being used which makes a substitution of the Fourier amplitude spectrum and is therefore referred to as the Fourier transform substitution method. A similar technique has been used by Funke and Mansard (1980) and it works as follows. After the non-linear transformation of the primary input time series has been completed, a Fourier transform of the distorted time series is undertaken. This transform is resolved in terms of its amplitude and its phase spectrum. The amplitude spectrum is then discarded and replaced by the primary input spectrum after which an inverse Fourier transform is performed. Evidently, the resultant time series may not be as severely distorted as was initially intended but, if the spectrum is broad enough, the differences are hardly noticeable.

It is worthwhile to make two comments on this Fourier transform substitution. The fact that the input and the output amplitude spectra are identical, while their two respective time series exhibit different wave form distortions, means that the non-linear transformation described here only causes a realignment of the phase spectrum. Secondly, if the input time series had been a pure sinusoid, a violation of the broad spectrum condition, then the Fourier transform substitution would have restored the distorted sine wave back to its original pure sinusoidal shape.

Figure 4.1 illustrates a symmetrical time function with Gaussian amplitude distribution, referred to as the reference wave. Superimposed on this is a time series after the first non-linear transformation

and Fourier transform substitution. C_n and C_p values used in this example were 0.71 with σ = 0.048 m. To enhance comparison, a section from 45 to 60 is shown enlarged in Figure 5.1. This figure shows also the two variance spectral densities of the reference and the distorted wave train.

As an option, Appendix A2 gives a method for calculating C_n and C_p as a function of the parameter α defined in Section 3.2.

3.2 The Time Distortion

Whereas the time series was, up to this point, a series of regularly spaced samples $\eta 1_i$, it is now necessary to convert the data to a two-dimensional series of $(t_i, \eta 1_i)$ values. Then, for each zero down crossing interval, i.e. for an interval embracing a trough and the following crest, the time coordinates are transformed in two stages; first for the jth trough period according to:

$$t_i'' = (1 + \alpha) \cdot t_i' \tag{4}$$

where:

t_i' is measured from the instance of the relevant zero down crossing, and

α is a scaling parameter which is greater than zero,

and then for the jth crest period according to

$$t_i'' = (1 + \alpha) \cdot t_i' - \alpha' \cdot (t_i' - TNZ_j) \tag{5}$$

where:

α' is a scaling parameter greater than zero and is given by: $TZ_j \cdot \alpha / (TZ_j - TNZ_j)$

TNZ_j is the length of the jth trough period, and

TZ_j is the length of the jth zero down crossing period.

This transformation will expand the trough period and contract the crest period but not change the length of the total zero down crossing period. As a result, the transformation will affect the vertical asymmetry as well as the crest wave steepnesses. However, the symmetry of the crest steepness will not be affected.

A factor of α = 0.2 was applied to the reference wave train. Referring to Figure 4.2, the transformed wave train may be compared to this reference. The enlarged section between 45 and 60 seconds is presented in Figure 5.2 which shows quite clearly how the time scale distortion has been realized. It should also be noticed from this figure that the variance spectrum has not been affected to any significant extent. This suggests again that the only difference is in the realignment of the phase spectrum.

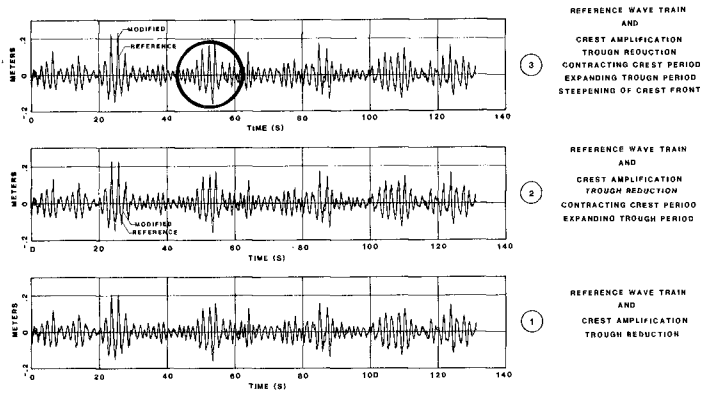

FIG.4

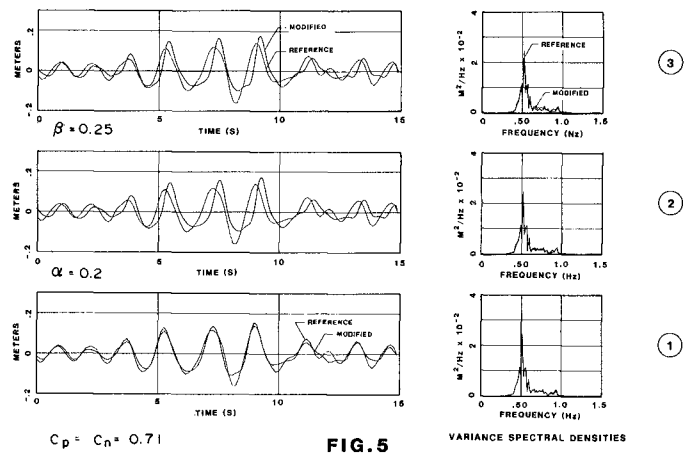

FIG.5 VARIANCE SPECTRAL DENSITIES

NUMERICAL SIMULATION OF WAVE ASYMMETRIES

It must also be pointed out that the compression of the crest duration and the associated expansion of the trough duration leads to an unavoidable shift in the mean value which must be removed subsequently. This adjustment in mean value has an effect on the horizontal asymmetry as is evident from Table I.

3.3 The Crest Distortion

The third transformation has the purpose of moving the location of the wave crest maximum forward, thereby increasing the crest front steepness and decreasing the crest rear steepness. First, the crest periods are identified by zero up crossings and following zero down crossings. Then, for each crest period, the time coordinates are transformed according to:

$$\tau_i'' = (1 - \beta)\cdot\tau_i' + \beta\cdot(\tau_i')^2/TZC_j \qquad (6)$$

where:

τ_i' is measured from the instance of a zero up crossing

TZC_j is the jth crest period, and

β is a scaling parameter greater than zero.

A factor $\beta = 0.25$ was applied to the reference wave train and Figure 5.3 illustrates the result of this last transformation which is only minor and therefore requires very close inspection to be noticed.

4.0 STATISTICAL ANALYSIS OF RESULTS

A statistical analysis was carried out on the four numerical simulations shown in Figure 4, the first of which is the reference wave and the other three represent the three stages in the non-linear transformations. Table I gives the results of this analysis.

Table I provides both the mean and the root-mean-square value (RMS) for each of the wave asymmetry parameters. These are given in diagonally opposite corners of each box. Inspection of the table reveals the following:

a) The average wave height has not changed significantly as a result of the transformations.

b) The average steepness has decreased by 10% after the first transformation but thereafter remained constant. It is not clear why this should be, in view of the fact that the average wave height remained unchanged and wave periods have not been altered in any way. The Fourier transform substitution, which takes place after the first transformation, will have some uncontrolled consequences which may be the reason for this phenomenon.

	WAVE HEIGHT	AVERAGE STEEPNESS	CREST FRONT STEEPNESS	CREST REAR STEEPNESS	HORIZONTAL ASYMMETRY	VERTICAL ASYMMETRY

WAVE ASYMMETRY PARAMETERS
BY NUMERICAL SIMULATION

TABLE 1

c) The crest front and crest rear steepnesses must be considered as pairs because as one increases, the other must, of necessity, decrease. Because the reference wave train has a Gaussian amplitude distribution, it could be expected that the crest is symmetrical and therefore the crest front steepness should be nearly equal to the crest rear steepness. According to Table I, this symmetry is preserved until the last transformation at which point the crest front becomes steeper than the rear. On the other hand, as the crest is being amplified, both crest steepnesses increase. Also, as the crest period is being decreased, crest steepnesses increase as well.

d) The vertical asymmetry of the reference wave is larger than one as can be expected according to Appendix A1. It is not clear why the crest amplification increases the average vertical asymmetry. It is suspected that the Fourier transform substitution is the cause of this. Reducing the crest period means that the scatter of crest front and rear steepnesses is reduced and therefore the average of the ratio of these steepnesses, namely the average vertical asymmetry is also reduced. Finally, the last non-linear transformation causes the vertical asymmetry to increase significantly.

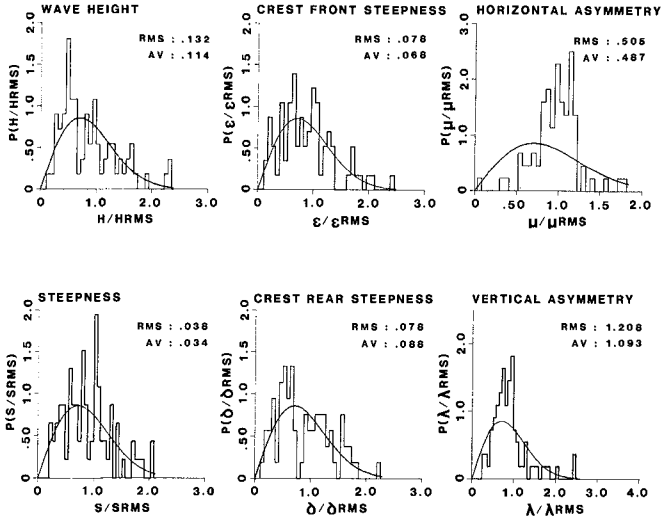

FIG.6 PROBABILITY DISTRIBUTION OF WAVE ASYMMETRIES

(NO DISTORTIONS)

A more detailed description of this statistical analysis is provided in Figures 6 and 7 together with Rayleigh distribution functions which were matched to the first and second moments. From these it may be noticed how the distribution of crest steepnesses changes as a result of the non-linear transformation. The vertical asymmetry distribution also demonstrates a change, leading to a reduced scatter of values.

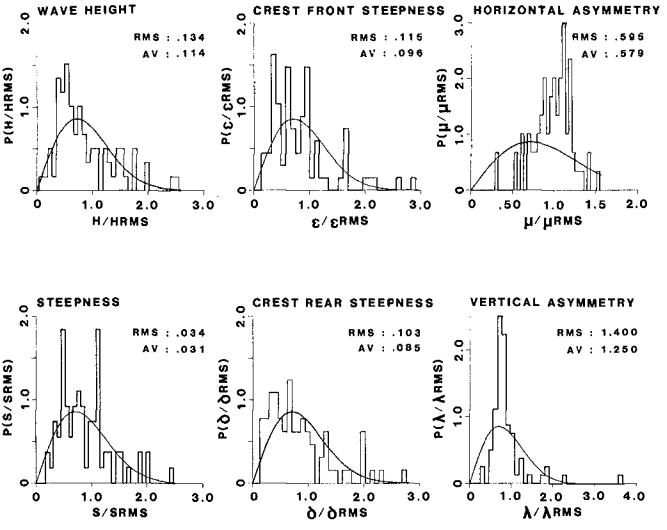

FIG.7 PROBABILITY DISTRIBUTION OF WAVE ASYMMETRIES

(WITH DISTORTIONS)

5.0 PHYSICAL REALIZATION OF ASYMMETRICAL WAVES

A prerequisite for the generation of asymmetrical waves in a wave flume or basin is the ability to reproduce a symmetrical wave train with reasonable fidelity. This is accomplished by a method described by Funke and Mansard (1983) which is based on linear dispersion theory and linear wave board theory. Figure 8 gives an example of such a reproduction from which one may clearly recognize and compare the various wave groups in the two wave records. Whereas wave grouping reproduces quite well, the accuracy of reproduction of individual waves is not perfect. However, this is, more or less, what is possible with present day technology.

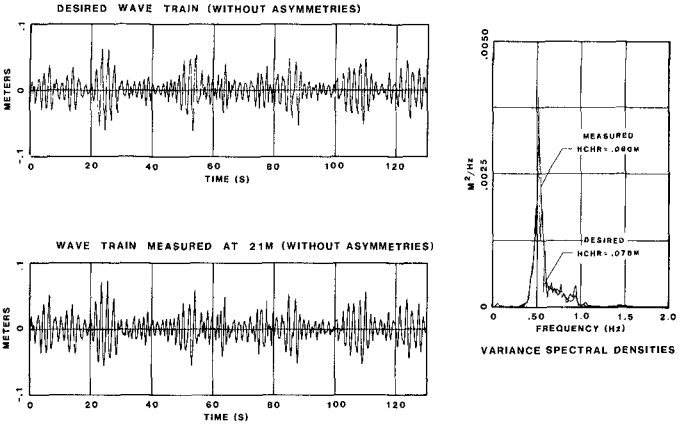

FIG.8 REPRODUCTION OF WAVE TRAIN IN THE FLUME (WITHOUT ASYMMETRIES)

Figure 9, on the other hand, compares the measured wave train without asymmetries to a wave train with asymmetries. Figure 10 shows a section from 40 to 120 seconds of the same waves at an amplified scale. Several of these waves show the effect of wave asymmetry transformations.

All operations for the synthesis, generation, data acquisition, analysis and graphic output were realized through the GEDAP software system operating on a HP 1000 computer (Funke et al 1980).

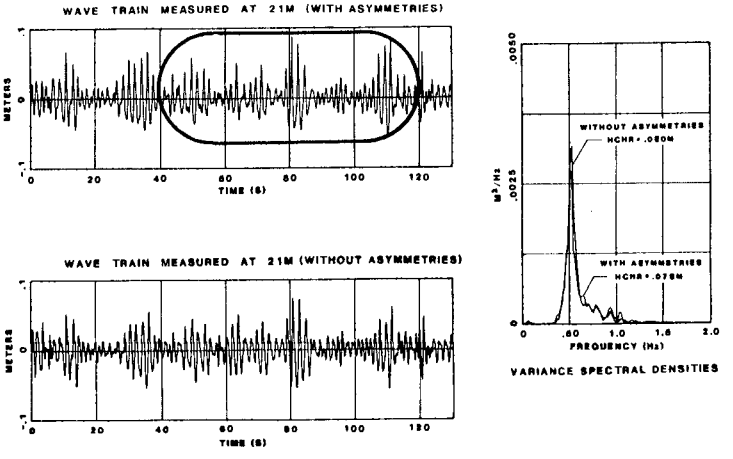

FIG.9

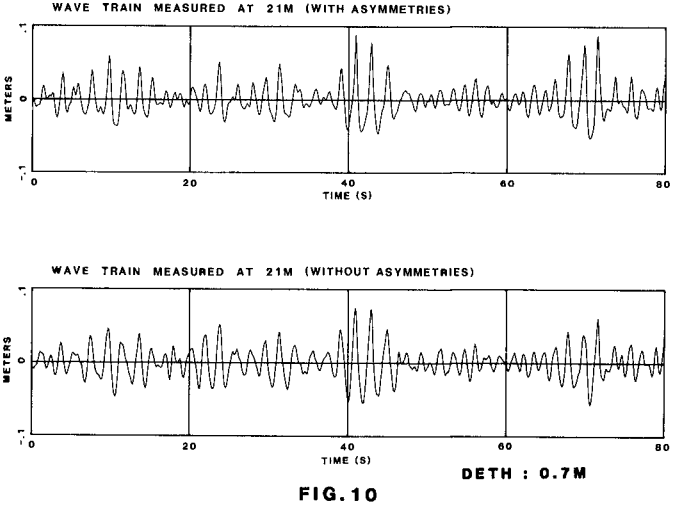

FIG.10

COMPARISON OF WAVE TRAINS MEASURED WITH AND WITHOUT ASYMMETRIES

6.0 CONCLUSIONS

A technique was described for the transformation of Gaussian stochastic functions into wave trains with various degree of wave asymmetry using two, three of four transformation parameters. The technique was tested by numerical simulation which indicated that the technique achieved the expected results. Physical reproduction of asymmetrical waves was shown to be possible although with reduced fidelity.

Insight, which resulted from the application of the non-linear transformation, suggests that waves with significant asymmetries must have broad spectra, that wave trains with and without asymmetries may have identical variance spectral densities and therefore, that the difference between the two must be contained in their respective phase spectra.

The ability to make a meaningful analysis of wave asymmetries on the basis of Waverider recorded wave data is limited because of distortions introduced by their mooring system.

Future research must explore the extent of physical realizability of wave asymmetry in wave flumes and basins, and match the distortion parameters to c, α and β to conditions observed in Nature. The sensitivity of experimental measurements for structural response to wave asymmetry simulations must also be determined. It is hoped that a non-linear transform can be developed for the compensation of Waverider records for their mooring effects.

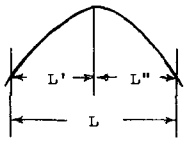
APPENDIX A1

Expected Value of a Ratio of Two Random Variables



Suppose there are two random variables L' and L" such that:

$$L = L' + L'' \qquad \text{(A1)}$$

Assume also that:

$$L' = L/2 + \delta \qquad \text{(A2)}$$

where L is assumed constant, and

δ is a random variable with zero mean, i.e.

$$E\{\delta\} = 0$$

In order to estimate the expected value of L'/L" equations (A1) and (A2) are arranged as follows:

$$L'' = L/2 - \delta$$

and

$$\begin{aligned} L'/L'' &= (L/2 + \delta) \,/\, (L/2 - \delta) \\ &= (1 + 2\delta/L) \cdot (1 - 2\delta/L)^{-1} \\ &= (1 + 2\delta/L) \cdot (1 + 2\delta/L + (2\delta/L)^2 + (2\delta/L)^3 + +) \\ &= 1 + 2 \cdot (2\delta/L) + 2(2\delta/L)^2 + 2(2\delta/L)^3 + + \end{aligned}$$

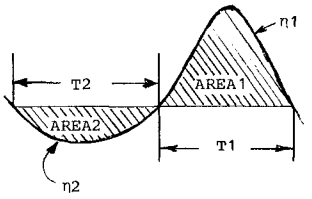
Because the expected value $E\{2\delta/L\} = 0$, we have, as a first approximation for the assumptions given above, that:

$$E\{L'/L''\} = 1 + 2E\{(2\delta/L)^2\} > 1$$

This proves that even for symmetrical crests, i.e. $E\{\delta\} = 0$, the expected value of the vertical asymmetry is always greater than 1.

APPENDIX A2

Derivation of C-Coefficients as a Function of α



Let $\eta 1 = \eta(t) + C_p \cdot \eta^2(t)/\sigma$ for $\eta(t) > 0$
and $\eta 2 = \eta(t) + C_n \cdot \eta^2(t)/\sigma$ for $\eta(t) < 0$
Also let $T1 + T2 = T$
and $T1 = T/2(1 - \alpha)$
and $T2 = T/2(1 + \alpha)$

Object: To find C_n and C_p as a function of α.

Solution:

Assume $\eta(t) = A \cdot \sin(\pi t/T1) + (C_p/\sigma) \cdot A^2 \cdot \sin^2(\pi t/T1)$ for $\eta(t) > 0$
and $\eta(t) = A \cdot \sin(\pi t/T2) + (C_n/\sigma) \cdot A^2 \cdot \sin^2(\pi t/T2)$ for $\eta(t) < 0$

then

$$AREA1 = (C_p/\sigma) \cdot A^2/2 \cdot T1 + 2A \cdot T1/\pi$$
and
$$AREA2 = (C_n/\sigma) \cdot A^2/2 \cdot T2 - 2A \cdot T2/\pi$$

For the mean value to be zero, set

AREA1 = AREA2 or

$$(C_p/\sigma) \cdot A^2/2 \cdot T1 + 2A \cdot T1/\pi = (C_n/\sigma) \cdot A^2/2 \cdot T2 - 2A \cdot T2/\pi$$

Substituting for T1 and T2,

$$\frac{T}{2}(1-\alpha) \cdot \left[(C_p/\sigma) \cdot A/2 + 2/\pi\right] = \frac{T}{2}(1+\alpha) \cdot \left[(C_n/\sigma) \cdot A/2 - 2/\pi\right]$$

Hence

$$\alpha\left[\frac{A}{2\sigma}(C_n+C_p)\right] = \frac{A}{2\sigma}(C_p-C_n) + 4/\pi$$

If $C_n = C_p = C$

$$C = 4\sigma/(\pi \cdot \alpha \cdot A)$$

If the undistorted wave is a sinusoid, then

$$\sigma = A/\sqrt{2}$$

and

$$C = 2 \cdot \sqrt{2}/(\pi \cdot \alpha) \text{ for a sinusoid}$$

If the undistorted wave is a Gaussian stochastic function, then one may wish to set "A" corresponding to the wave crest of a wave with significant wave height, i.e.

$$\sigma = A/2$$

and

$$C = 2/(\pi \cdot \alpha)$$

THREE-DIMENSIONAL MARINE MODELS FOR IMPACT STUDIES

Jacques C.J. NIHOUL* and François C. RONDAY**

Abstract.

A three-dimensional non-linear hydrodynamic model is developed for the determination of the mesoscale (tides, storm surges, ...) and macroscale (residuals, gyre, ...) circulations in the North Sea. The model consists of a hierarchy of submodels of different grid sizes, with interactive coupling at boundaries.

The model is used to study the impact of coastal engineering projects along the Belgian coast and in the Scheldt estuary.

Introduction.

Considerable attention is now being paid to the possible environmental impact of coastal engineering works.

The consequences on surface elevations, currents and sediment transport of such large scale projects as the building of an important new harbor on the Belgian coast, — with the subsequent deployment of industrial activities —, and the modification of passes in the coastal zone and in the Scheldt estuary, have been investigated by means of a mathematical model, working in close cooperation with a reduced-scale hydraulic model of the area.

In the following, the mathematical model is described and tested on a series of in situ observations. Examples of application are given in illustration.

Mesoscale and macroscale models.

The general circulation of the North Sea can be, conveniently, divided into a macroscale or "residual" component, a mesoscale, "long wave", component and microscale turbulence. The reference is here made to the time-scales of the phenomena which range from a few minutes or less for microscale turbulence, a few hours to a few days for mesoscales processes like tides and storm-induced motions and to a few weeks or more for macroscale residual currents.

The mesoscale processes, tides, storm surges, ... are the most intense hydrodynamic phenomena with current speeds exceeding sometime $1\ m\ s^{-1}$. Marine chemists and marine biologists, however, are more interested in the much weaker residual circulation (a few $cm\ s^{-1}$), the characteristic times of which are comparable with typical ecological time scales (e.g. Nihoul, 1981).

* Professor of Geophysical Fluid Dynamics. University of Liège and University of Louvain, Belgium.

** Lecturer in Physics and Meteorology, University of Liège, Belgium.

Depth-integrated hydrodynamic models of the mesoscale circulation in the North Sea have been developed in several countries from the early "long wave" models applied to the computation of tidal currents and elevations (e.g. Hansen, 1956, 1966; Fisher, 1959; Leendertse, 1967).

The models of the present generation are highly accurate and appropriate to routine forecasting (e.g. Davies, 1976; Nihoul, 1976, 1982; Nihoul and Ronday, 1976; Ronday, 1976, 1979; Prandle and Wolf, 1978; Flather, 1979; Pingree and Griffiths, 1981a,b).

Three-dimensional models, on the other hand, are still at an early stage of development (e.g. Heaps, 1976; Nihoul, 1977, 1982; Backaus, 1979).

The macroscale ("residual") circulation is much more difficult to apprehend.

It is convenient to define the residual circulation as the mean circulation over a time T sufficiently large for mesoscale processes to roughly cancel out in the mean but sufficiently small to leave macroscale processes almost untouched in the averaging (e.g. Nihoul, 1975, 1982; Nihoul and Ronday, 1975; Maier-Reimer, 1977; Prandle, 1978).

The equations governing the residual circulation are then obtained, from the general hydrodynamic equations, by averaging over T *. Averaging the non-linear terms gives two contributions; the first of which is related to the product of the means while the second contains the mean products of mesoscale fluctuations.

This second contribution appears as an additional forcing on the residual flow and can be viewed as the action of mesoscale Reynolds stresses — analogous to the turbulent Reynolds stresses of microscale turbulence — on the mean flow.

If one excepts limited areas like the Norwegian Trench, the North Sea is shallow and the water column is always fairly well-mixed. The stratification which may occur in the summer is restricted to the Northern part.

Being essentially concerned by the Belgian coastal zone and the Southern Bight and mainly interested in winter situations when the most dramatic hydrodynamic events occur, one may assume vertical homogeneity (zero buoyancy) and write the basic equations in the form (e.g. Nihoul, 1982)**

$$\nabla . \mathbf{v} = 0 \tag{1}$$

$$\frac{\partial \mathbf{v}}{\partial t} + \nabla . (\mathbf{v}\mathbf{v}) + 2\,\boldsymbol{\Omega} \wedge \mathbf{v} = -\nabla q + \nabla . \mathbf{R} \tag{2}$$

where $\boldsymbol{\Omega}$ is the Earth's rotation vector,

---

* One of the characteristics of the North Sea is the distinct predominance of mesoscale motions. As a result, the solution of the time-dependent hydrodynamic equations (where only microscale turbulence has been parameterized) represents essentially the mesoscale circulation. The macroscale circulation is included but it is of the same order of magnitude as the error (e.g. Nihoul and Ronday, 1976; Nihoul, 1980; Nihoul and Runfola, 1981).

As a result, the direct determination of the residual circulation, by solving these equations and later averaging the solution over T, is often vitiated by an error which can be as high as a hundred percent as non-linear errors do not cancel in the averaging process.

On the other hand, this solution can be used to compute with satisfactory accuracy the mesoscale Reynolds stresses and these can be substituted in the average equations to give the residual circulation with great precision (Nihoul and Ronday, 1976; Nihoul and Runfola, 1981).

** The model has been extended to deeper, stratified seas (Nihoul, 1982) and is now being applied to the Adriatic.

$$q = \frac{p}{\rho} + g x_3 \ ,$$

p is the pressure, ρ the specific mass of sea water, x_3 the vertical coordinate and $\mathbf{R}$ the turbulent Reynolds stress tensor (the stress is here per unit mass of sea water) resulting from the non-linear interactions of three-dimensional microscale turbulent fluctuations.

The turbulent Reynolds stress tensor can be parameterized in terms of eddy viscosity coefficients. In microscale three-dimensional turbulence, these coefficients are of the same order of magnitude in the horizontal and vertical directions. Then, horizontal length scales being much larger than the depth, the last term in the right-side of eq. (2) can be written simply, with a very good approximation

$$(3) \qquad \nabla . \mathbf{R} = \frac{\partial \boldsymbol{\tau}}{\partial x_3} = \frac{\partial}{\partial x_3} (\tilde{\nu} \frac{\partial \mathbf{v}}{\partial x_3})$$

where $\tilde{\nu}$ is the vertical eddy viscosity and $\boldsymbol{\tau}$ the turbulent Reynolds stress (vector).

The residual flow is defined as the mean flow over a time T sufficiently large for mesoscale processes to roughly cancel out in the mean but sufficiently small to leave macroscale processes almost untouched in the averaging. If the subscript $_0$ denotes such an average, one may write, neglecting small terms (e.g. Nihoul, 1982),

$$(4) \qquad \mathbf{v} = \mathbf{v}_0 + \mathbf{v}_1$$

with

$$(5) \qquad (\mathbf{v})_0 = \mathbf{v}_0$$

$$(6) \qquad (\mathbf{v}_1) = \mathbf{0}$$

and

$$(7) \qquad 2\ \boldsymbol{\Omega} \wedge \mathbf{v}_0 = - \nabla q_0 + \frac{\partial \boldsymbol{\tau}_0}{\partial x_3} + \nabla . \mathbf{N}$$

where

$$(8) \qquad \mathbf{N} = (- \mathbf{v}_1 \mathbf{v}_1)_0$$

$$(9) \qquad \frac{\partial \mathbf{v}_1}{\partial t} + \nabla . (\mathbf{v}_1 \mathbf{v}_1) + 2\ \boldsymbol{\Omega} \wedge \mathbf{v}_1 = - \nabla q_1 + \frac{\partial \boldsymbol{\tau}_1}{\partial x_3}$$

with

$$(10,11) \qquad \nabla . \mathbf{v}_0 = \nabla . \mathbf{v}_1 = 0$$

One can see that the equation for $\mathbf{v}_1$ is essentially the same as the equation for $\mathbf{v}$ (they only differ by terms which are orders of magnitude smaller). It is the reason why, one can, with the appropriate boundary conditions, determine the mesoscale velocity $\mathbf{v}_1$, in a first step, and the residual velocity $\mathbf{v}_0$, in a second step, taking the coupling between the two types of motion into account in the calculation of $\mathbf{v}_0$ only. [$\mathbf{N}$ is explicitly computed from the results of the mesoscale model (eq. 9) and substituted in the macroscale model (eq. 7) which is then solved for the residual flow $\mathbf{v}_0$].

The tensor $\mathbf{N}$ plays, for mesoscale motions a role similar to that of the turbulent Reynolds stress tensor $\mathbf{R}$ in eq. (2) and may be called the "mesoscale Reynolds stress tensor". The last term in the right-hand side of eq. (7) represents an additional force acting on the residual flow and resulting from the non-linear interactions of mesoscale motions (tides, storm surges, ...).

The importance of this force was discovered, first, by depth-integrated numerical models of the residual circulation in the North Sea (Nihoul, 1975; Nihoul and Ronday, 1975) and the associated stress was initially referred to as the "tidal stress" to emphasize the omnipresent contribution of tidal motions.

In the absence of stratification, the vertical eddy viscosity* is parameterized in the form

$$\tilde{\nu} = L\, u_* \tag{12}$$

where u_* is the bottom friction velocity and L a length scale, evaluated as a function of the distance to the bottom and the free surface by a quadratic law of which the coefficients are adjusted to the local conditions (Nihoul, 1977, 1982)**. A similar parameterization has been proposed by Leendertse and Liu (1978).

In essence, the three-dimensional model can be described as the superposition of a two-dimensional model and a one-dimensional model (Nihoul, 1977, 1982).

The two-dimensional model is obtained by integration of the equations over depth. In this process, the bottom stress is introduced into the equations and it must be parameterized in terms of the depth-averaged velocity.

The one-dimensional model is obtained by solving eq. (2) locally, regarding the non-linear advection term as a given forcing, computed from the results of the two models at neighbouring grid points and previous time steps. As boundary conditions (at the surface and at the bottom), the wind stress and the bottom stress are imposed. The no-slip condition ($\mathbf{v} = \mathbf{0}$) at the bottom provides the extra equation needed to relate the bottom stress, the wind stress and the depth-averaged velocity.

The two-dimensional model and the one-dimensional model proceed thus "hand-in-hand" with a continuous double iteration on the bottom stress and the non-linear terms. The details of the procedure and its numerical implimentation are given in (Nihoul, 1982).

In the North Sea, the equation relating the bottom stress and the depth-averaged velocity can be shown to reduce, with a very good approximation, to the classical algebraic, quadratic bottom friction law (e.g. Nihoul, 1975) except during limited periods of weak currents (at tide reversal, in the absence of significant wind). Then, the direction of the bottom stress with respect to the mean flow is modified by a non-negligible Ekman veering and its magnitude is no longer directly related to the (evanescent) mean velocity but depends essentially on sustained turbulence in the bottom current (Nihoul, 1977, 1982).

However, when the currents are small, the advection terms are negligible. The one-dimensional model can be linearized and solved analytically by series expansions in the eigenfunctions of the vertical turbulent diffusion operator (Nihoul, 1977). It can be shown, then, that the bottom stress can be written in the simple form

---

* One emphasizes that the horizontal eddy diffusion of momentum is found negligible and that no artificial horizontal diffusion is introduced in the *numerical* model where advection terms are discretized by decentred forward finite differences.

** The model has been extended to include the effect of stratification. In this more elaborate version, u_* is replaced by the rootsquare of the mean turbulent kinetic energy which is a function of depth. An additional equation is included in the model for the mean turbulent kinetic energy.

$$(13) \qquad \boldsymbol{\tau}_b = D^{1/2} \|\boldsymbol{\tau}_b\|^{1/2} \bar{\mathbf{u}} - m \boldsymbol{\tau}_s + \gamma H \left(\frac{\partial \bar{\mathbf{u}}}{\partial t} + f \mathbf{e}_3 \wedge \bar{\mathbf{u}}\right)$$

where $\boldsymbol{\tau}_b$ and $\boldsymbol{\tau}_s$ are respectively the bottom stress and the wind stress (per unit mass), $\bar{\mathbf{u}}$ is the depth-averaged horizontal velocity, D is the drag coefficient, m and γ two numerical factors.

Eq. (13) can be used to determine $\boldsymbol{\tau}_b$ at time t in terms of simultaneous values of $\bar{\mathbf{u}}$ and $\boldsymbol{\tau}_s$ and the immediate past history of $\bar{\mathbf{u}}$ [$\bar{\mathbf{u}}(t - \Delta t)$]. One can thus run the 2D-model alone in regions where one doesn't need the highest accuracy or the details of the vertical structures. Large scale 2D-models provide then boundary conditions for the coastal 2D-models which are coupled with local 1D-models operated on a par with the former.

Depth-integrated models of the North Sea and the Southern Bight.

Fig. 1 shows the characteristics of the numerical grids used in modelling the North Sea (NS Model) and the Southern Bight (SB Model). The flow normal to the coasts is taken as zero. (The coast is a single streamline from one estuary to the next, in the model of the residual circulation, and the streamfunction increases at estuaries by amounts equal to the rivers' inflows.) Along open-sea boundaries, different types of boundary conditions, surface elevations*, velocities, velocity gradients and more or less sophisticated radiation conditions (e.g. Orlanski, 1976) have been tested for the mesoscale models (Ronday, 1976; Ronday and Nihoul, 1978, 1979; Clément et al., 1981).

Taking into account the data available on open-sea boundaries, the following boundary conditions were chosen for routine applications of the model (e.g. Daubert and Graffe, 1967; $\mathbf{n}$ is the unit vector normal to the boundary surface pointing outwards) :

(i) $\mathbf{v}.\mathbf{n} > 0$: surface elevation ζ ;

(ii) $\mathbf{v}.\mathbf{n} < 0$: surface elevation ζ , zero gradient of the normal velocity $\mathbf{v}.\mathbf{n}$ **.

In the macroscale models, the residual inflow is given at the open-sea boundaries (Ronday, 1976; Nihoul, 1982).

The open-sea boundary conditions for the SB-Model are determined by interpolation of the results of the NS-Model.

Fig. 2 shows a more sophisticated version of the models. The NS-Model (divided in two parts covering respectively the Western Channel and the Northern North Sea) and the SB-Model are now interactively coupled each of them providing boundary conditions for the others.

Comparison of the model's predictions with observations shows a fairly good agreement (slightly better with the NB-Model than with the NS- and SB-Models). Fig. 3 shows for instance a comparison between predicted and observed amplitude and phase of the current at the point 51°47'20 N 2°20'20 E of the Jonsdap 76 experimental network (Riepma, 1980).

---

* Surface elevations are determined by interpolation between Morlaix and Plymouth for the Western boundary and between the field observations along the line B.M for the Northern boundary (fig. 1).

** This additional condition is needed because the equations are non-linear (Daubert and Graffe, 1967).

Three-dimensional models of the coastal zone and the Scheldt estuary.

Fig. 4 shows the characteristics of the numerical grids used in modelling the coastal zone (CZ-Model), the region of Zeebrugge (ZZ-Model) and the Scheldt estuary (SE-Model). The SE-Model is interactively coupled with a one-dimensional model of the Scheldt river from Doel to Gentbrugge (SR-Model).

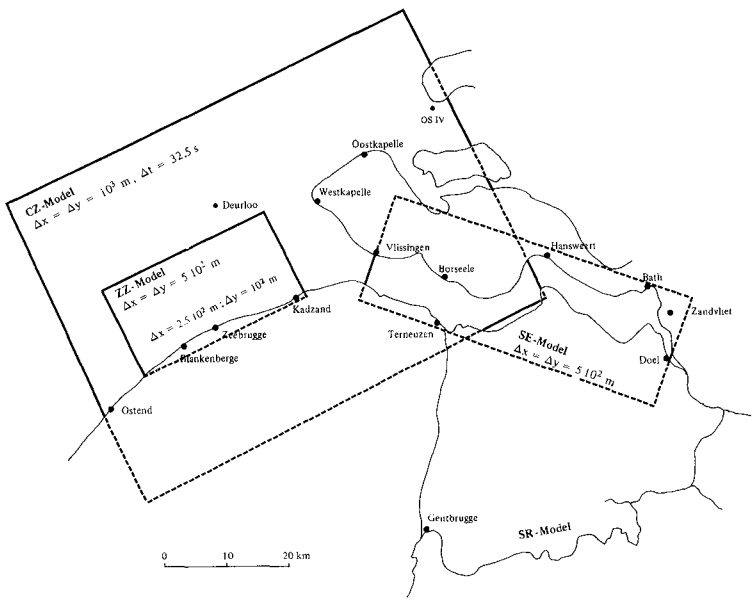

fig. 4.
Models of the coastal zone and the Scheldt

Open-sea boundary conditions are determined for each grid by the results of the larger scale model completed by the available field observations. Open-sea boundary conditions for the CZ-Model are provided by the NB-Model of the North Sea. The conditions at the coastal boundary points of the NB-Model can be computed by the coastal models – which have a more detailed resolution of the coastline and the sand banks' topography – and fed back in the NB-Model to improve the overall computation.

Figs 5, 6 and 7 show a very good agreement between the models' predictions and the observations*.

* Note that both observed and computed values are the actual values for that particular day (with the appropriate atmospheric and boundary conditions). No smoothing, filtering or harmonic analysis has been performed.

Comparison between computed (——) and observed (·····) values of the surface elevation at four points of the Scheldt estuary during the storm of Jan. 3, 1976.

Applications.

The model has been applied to the routine forecasting of currents and water levels along the coast and in the Scheldt, to the prediction of the action of the sea on harbors, passes, dykes, ... and to the evaluation of the environmental impact of coastal engineering projects.

The influence of meteorological conditions on tidal elevations and velocities was determined for mean, spring and neat tides and for different wind conditions (mean wind, most frequent wind lasting at least three days, ...). The vertical profile of the horizontal velocity was calculated at several points of interest (dumping, sedimentation, bottom erosion, ...). Fig. 8 shows for instance the evolution of the velocity profile at a point near the coast under typical wind conditions. The veering of the velocity vector with height which one can see at tide reversal requires a more elaborate parameterization of the bottom stress as explained in section 1.

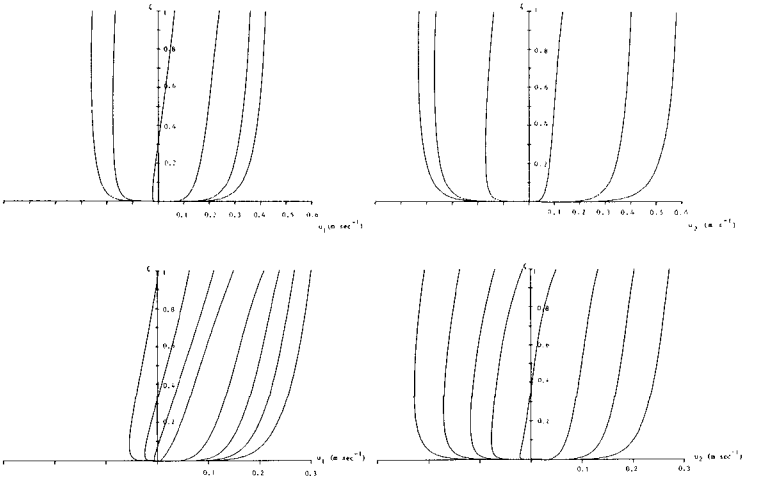

fig. 8.

Evolution with time of the vertical profile of the horizontal velocity vector **u** (left : eastern component; right : northern component) at the point 52°30'N 3°5'E.
Above : evolution over one half tidal period (the curves from right to left are vertical profile computed at 54' interval).
Below : evolution at tide reversal (the curves from right to left are vertical profile computed at 18' interval).
$\xi = (x_3 + h)/H$, $h \sim 22$ m, wind stress oriented to the North-East and equal to $2\ 10^{-4}\ m^2\ s^{-2}$ (per unit mass).

The impact of Zeebrugge's harbour on tidal and residual currents and elevations was studied for the existing and several proposed configurations as well as related dredging activities and industrial development on the coast. Fig. 9 shows, for instance, the predicted evolution, over a tidal period, of a patch of cold water produced by regasification at a planned gaz terminal on the new harbour's precinct.

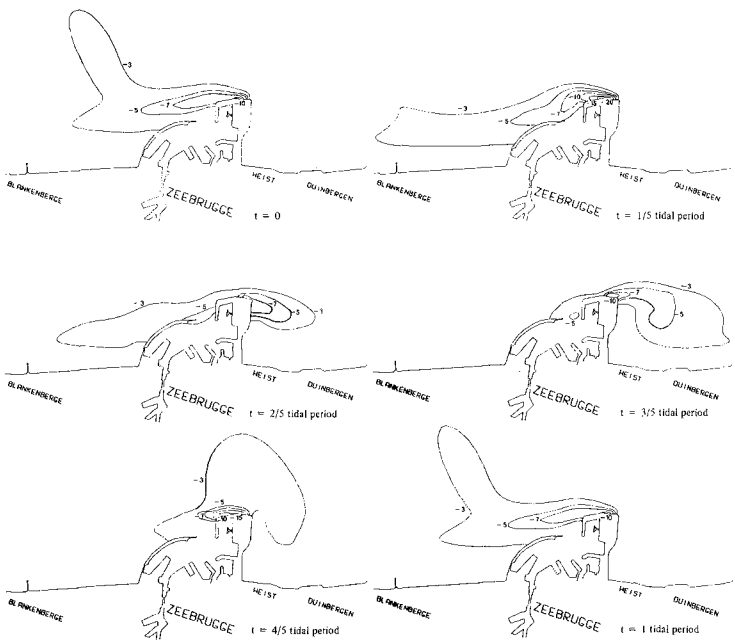

fig. 9.

Evolution over a tidal period of a patch of cold water released by a 110 MW source on the jetty of the new harbour at Zeebrugge (gasification process at a liquid-gaz terminal). The curves are graduated in 10^{-2} K (temperature degrees).

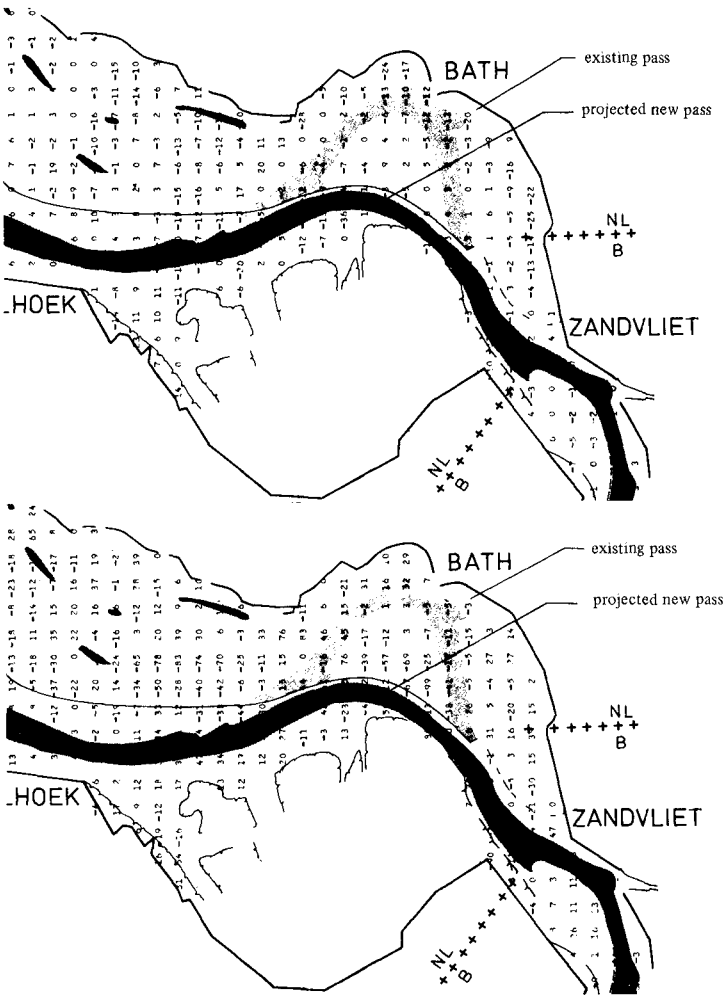

fig. 10.

Effect on the modification of a pass in the Scheldt estuary on maximum water level (above) and maximum velocity at flood-tide (below) during the storm of Jan. 3, 1976. (The numbers represent the differences between the predicted results for the new and the existing bottom topography.)

The effect of modifying passes in the Scheldt estuary was investigated in different tidal and wind conditions by hindcasting known situations with existing and proposed bottom topographies. Fig. 10 shows, for instance, the differences in water level and flood-velocities that would have been produced in the region of Bath, by a rectification of the pass.

The difficulty of "measuring" the residual currents* motivated an extended study of the macroscale circulation. Fig. 11 shows the residual streamlines in the North Sea in a typical situation.

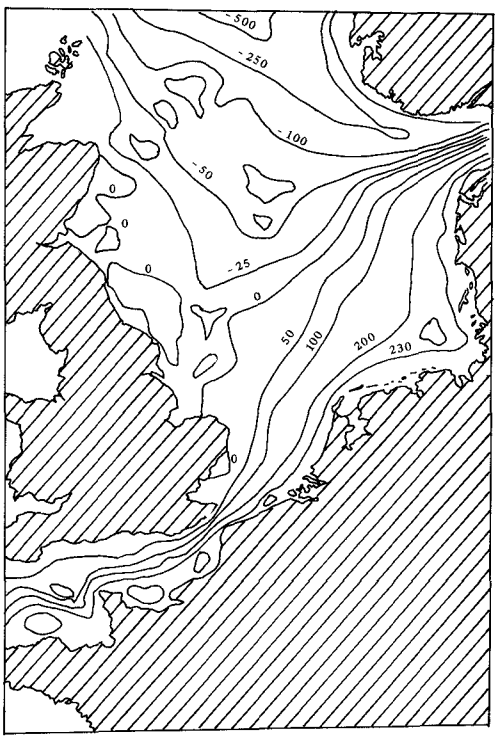

fig. 11.

Residual depth-averaged circulation in the North Sea. Streamlines ψ = const in 10^3 m^3 s^{-1}. [Real 1973 wind situation, boundary inflows according to Ronday (1976), residual bottom friction coefficient function of depth, mesoscale velocity and rugosity length (Ronday, 1976).]

* The residual currents constitute a very small part of the current meters' signal, of the order, in fact, of the instrumental error. Because of the non-linearities of the instruments (averaged speed, instantaneous direction) errors do not cancel with time averaging and experimental values can often be wrong by as much as 100 %.

The presence of a gyre off the Northern Belgian coast, confirmed by the results of the coastal models (fig. 12) and by observations (e.g. Beckers et al., 1976) is responsible for a south-bound coastal current which entrains the highly turbid Scheldt waters to the South.

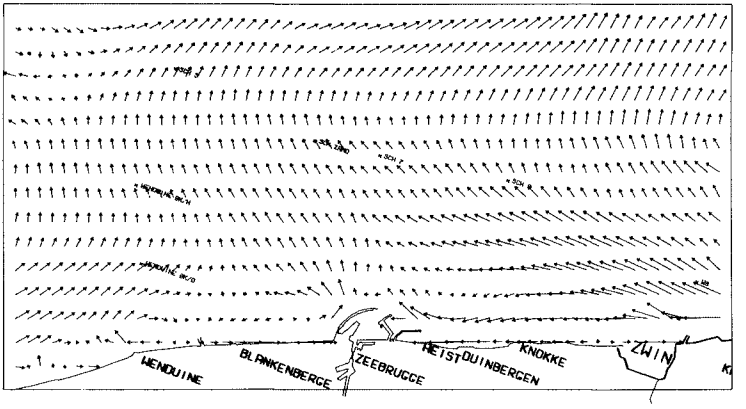

fig. 12.

Residual (depth-averaged) currents in the region of Zeebrugge, showing a south-bound coastal current along the Northern Belgian coast, in relation with the coastal gyre shown in fig. 11.

The predicted accumulation of silt along the Northern coast is confirmed by the observations (fig. 13).

Acknowledgements.

The present work was carried out under several private and official contracts. The authors are indebted to Distrigaz, Electrobel and TVZ 2 and to the Departments of Health, National Education, Public Works and Science Policy for their help, financial support and kind permission to use some of the results.

ANALYSIS OF TIDAL RECORDS OF THE 1964 ALASKAN TSUNAMI

Basil W. Wilson*, F.ASCE

abstract

The 8.5 magnitude Alaskan earthquake of March 27, 1964, generated a great tsunami in the Pacific Ocean. This paper presents results of energy spectrum analyses conducted on a sampling of 24 of the marigrams from some 105 tide-stations which recorded the waves. In the numerical digital procedure used, two important properties of the evolving energy spectra are invoked; the frequency resolution and statistical confidence. High confidence is obtainable only at the expense of poor resolution, and *vice versa*. Excessive resolution may give rise to physically unreal spectral peaks, just as excessive restrictions for confidence may cause blunting of the spectrum and possible loss of physically real spectral components. A trial-and-error compromise between these properties was sought by testing the effects on the energy spectra, for Hilo, Hawaii, of the parameters that control the digital process. An optimum selection of spectrum parameters was finally made so that the primary and secondary wave forms of components, identified by the analysis for the marigram of San Francisco, Calif., most closely agree with the corresponding wave forms obtained by use of Chrystal's (1904) graphical method of *residuation* analysis. Using the parameters so determined, and by application of band-pass filters in the digital analysis, the most prominent peaks of spectral energy in the marigrams of the 24 stations are isolated and their wave-forms computer-plotted. In all cases a recognizable long-period wave component is found having a frequency between 0.50 and 0.65 cy/hr (average period 1.73 hrs). General similarity of these primary wave forms as to period and shape of beats suggests their common origin at the source of the earthquake disturbance. The secondary wave forms of higher frequency (periods generally less than 40 mins) are ascribed to local free oscillations forced by the primary wave trains at the receiving stations. In some, but not all of the marigrams there is evidence of wave systems averaging 3.2 hrs in period. These are thought to be an independent wave-train originating at source.

1. INTRODUCTION

On March 27, 1964, a great earthquake in Prince William Sound, Alaska, (magnitude ≈ 8.5, Richter scale), generated a tsunami which swept the entire Pacific Ocean. Its coastal effects were recorded by some 105 tide-gauges at mainland and island stations throughout the area[1]. This paper reports on energy-spectrum analyses of the marigrams from a sampling of 24 represent-

* Consulting Oceanographic Engineer, Pasadena, California, U.S.A.

ative stations distributed along the periphery of the Pacific Ocean and on islands within its circumference. Fig. 1, which is derived from the arrival times of the tsunami at coastlines and islands, and allows for the refraction of the wave-fronts in accord with the ocean depths, shows the advance of the front at hourly intervals and the locations of the tide-stations selected for marigram-analysis.

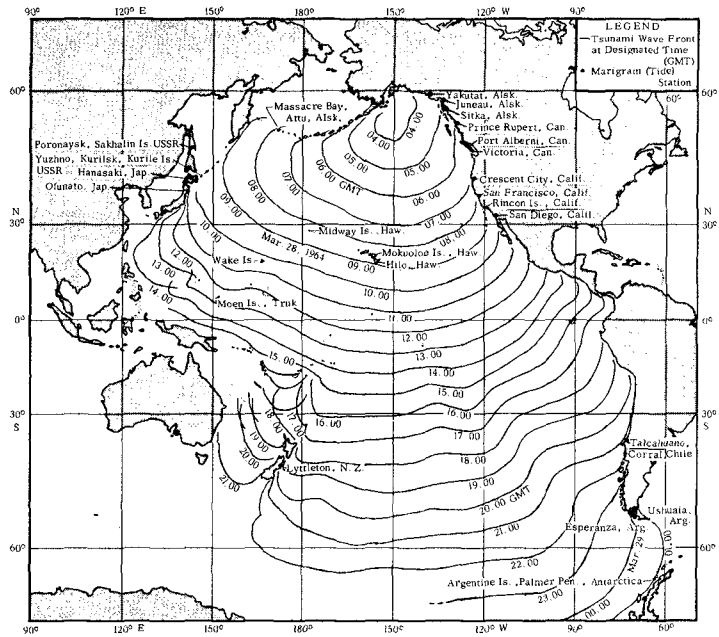

FIG. 1 - APPROXIMATE HOURLY (GMT) WAVE-FRONTS OF THE ALASKAN TSUNAMI OF MARCH 28-29, 1964. (Mercator projection).

A primary purpose of this investigation was to confirm of negate earlier analyses [2], undertaken during report preparation, (of necessity, hurriedly and at minimal cost), by use of Chrystal's graphical method of *residuation* [3]; thereby to verify the existence in the marigrams of exceptionally long-period wave systems, identified by those analyses, but hitherto unsuspected in tsunami occurrences (cf. Cox [4]). This paper summarizes a report of 1971 [5].

2. RESIDUATION VERSUS POWER-SPECTRUM ANALYSIS

Before numerical power-spectrum analysis had become one of the standard tools of oceanographic science in the 1950's [6,7,8], and preceded only by periodogram analysis [e.g. 9], (which in days before high-speed electronic computers was clumsy and time-consuming), Chrystal's method of *residuation*

offered a relatively quick and easy way of interpreting the composition of wave or seiche records. The method follows sound theoretical principles on the precept that a wave record can be approximated by a discrete spectrum of sinusoidal wave components. The writer made extensive and effective use of the method in the period 1940-'67 [e.g., 10], and is not ashamed that this period was overlapped by the ascendancy of the modern method of continuous power-spectrum analysis. In referring to the Residuation method, the writer, at various times, has named it "subjective", in the sense that, initially, it relies on the personal judgements of an analyst as to the periods of the discrete components supposed to exist in a wave record. In point of fact, however, as Chrystal showed, the method can be as objective as the analyst will allow, simply by use of a process of successive approximations. In the writer's experience, it has seldom been necessary to invoke closer approximations than first estimates, because one or more shorter-period components in a wave record can usually be detected unambiguously as to periodicity. The very process of "residuating", or eliminating, a suspected sinusoidal component, tends to reveal lower-order components more distinctly, so that they too, in succession, can be subtracted out from the residual record by the graphical method.

While the Residuation method of wave analysis is hardly to be recommend- for modern usage, it seems pertinent to point out that the now popular power-spectrum analysis, by use of the Fourier Double Integral Theorem and auto-correlation techniques, of itself yields only an estimate of the composition of a wave record, and is thereby subject to varying degrees of reliability. This aspect has been fully discussed elsewhere [5, 11], and will therefore be only briefly alluded to here. The method, it turns out, is quite sensitive to certain parameters which enter into the mathematical systems used, and, of necessity, have to be selected by the wave analyst. These parameters are:

(a) the number of digitized data-points, N, in the length of a wave record, T;
(b) the time increment, Δt, between adjacent data-points
(c) the number of lags, M, used for auto-correlation purposes
(d) the number of points, P, assigned to a numerical filter

Three important derivative parameters depend on the choice of (a), (b) and (c), namely:
(e) the frequency increment, or measure of *resolution*:

$$\left.\begin{array}{lll} \text{(i)} & \Delta\sigma = 2\pi(2\,\Delta t\,M)^{-1} & \text{radians-(time)}^{-1} \\ \text{or} \quad \text{(ii)} & \Delta f = (2\,\Delta t\,M)^{-1} & \text{cycles-(time)}^{-1} \end{array}\right\} \quad (1)$$

(f) the frequency range, or Nyquist cut-off frequency:

$$\left.\begin{array}{lll} \text{(i)} & \sigma_n = 2\pi(2\,\Delta t)^{-1} & \text{radians-(time)}^{-1} \\ \text{or} \quad \text{(ii)} & f_n = (2\,\Delta t)^{-1} & \text{cycles-(time)}^{-1} \end{array}\right\} \quad (2)$$

(g) the number of degrees of freedom, ν, or measure of *confidence*:

$$\nu = [\,N - M/4\,](M/2)^{-1} \approx 2N\,M^{-1} \qquad \text{when } M \ll N \qquad (3)$$

It is anomalistic that in seeking high confidence of results in auto-correlat-

ion, the number of lags M in Eq.(3) should be chosen as small as possible, although, thereby, the frequency increment, $\Delta\sigma$ or Δf, in Eq.(1) is also rendered large, and the resolution of the power spectrum therefore low. Confidence and resolution, unfortunately, are two mutually antagonistic properties. Poor resolution of the spectral density estimates results in excessive blunting of spectral peaks in the spectrum. Too high resolution, on the other hand, inevitably lowers the confidence that spectral peaks of energy are real. The tendency in spectrum analysis seems to have been to lean towards high confidence rather than strong resolution, with the result that wave energy spectra often appear to be devoid of sharp peaks. A question of importance for this study was to know the best common meeting ground for good resolution and reasonable confidence in the estimates of spectral energy density of the tsunami records.

3. SPECTRUM PARAMETERS FOR THE MARIGRAMS OF HILO, HAWAII, AND SAN FRANCISCO, CALIFORNIA

To test the effects of different values of spectrum parameters on resulting spectra, two cases, Hilo, Hawaii, and San Francisco, California, were selected initially for analysis. Hilo was chosen as being one station for which it was contended by Van Dorn and Cox [12], on the basis of spectrum analyses made by Loomis [13], that the marigram showed no evidence of the presence of waves as long in period as 1.8 hrs. The writer on the other hand, using the Residuation process, had found them to be present [2], and desired verification.

The tide records were digitized on a trace follower and read directly on to magnetic tape, from which co-ordinates of points were then transferred to decks of punched cards. Counts were recorded at time intervals of 0.02 hr over record lengths of 36 hrs. Fig. 2(a) is a computer-plot of the original marigram

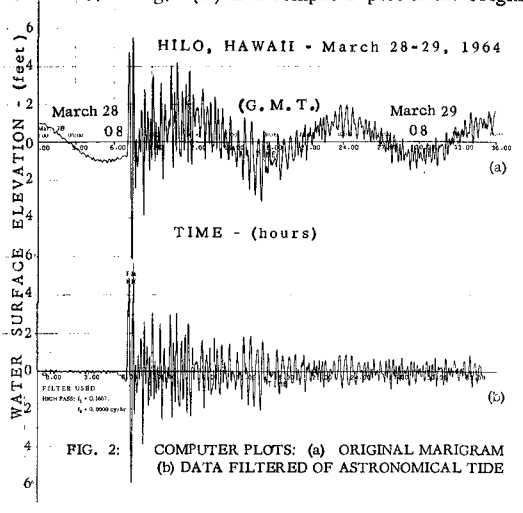

FIG. 2: COMPUTER PLOTS: (a) ORIGINAL MARIGRAM (b) DATA FILTERED OF ASTRONOMICAL TIDE

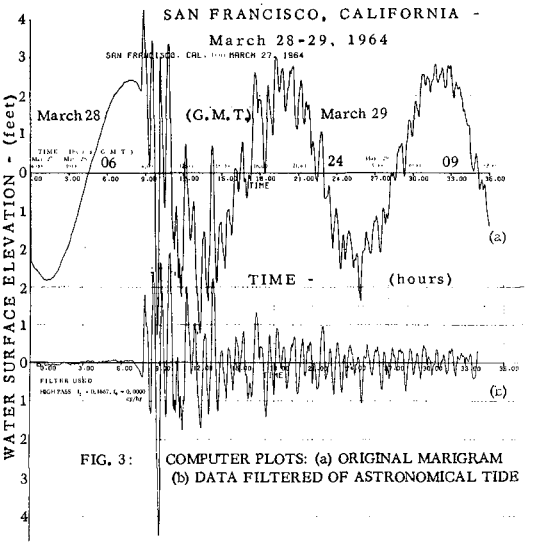

FIG. 3: COMPUTER PLOTS: (a) ORIGINAL MARIGRAM (b) DATA FILTERED OF ASTRONOMICAL TIDE

for Hilo, Hawaii, obtained in this fashion. Fig. 3(a) is the corresponding marigram for San Francisco, California. The digitized data were pre-filtered through a high-pass (2P + 1 =) 51-point filter for elimination of tides and other long wave effects in the frequency range 0 to 0.167 cy/hr (T > 6 hrs) with the results shown in Figs. 2(b) and 3(b). The filtered data were then analyzed to yield the energy spectra, substantially in accord with the principles detailed in references [5,11], and utilizing the spectrum parameter sets B to F given in Table I.

Loomis' spectra of 1966 [14], using the set A_1 in Table I, failed ro show any indication of an energy density peak at or near the frequency f = 0.555 cy/hr, (period 1.8 hrs). The resolution of A_1 is seen to be rather poor and the confidence only moderately good. In his later work of 1972 [13], Loomis' parameters A_2 yield somewhat better resolution at high confidence. Examination of his spectrum in this case does suggest the presence of somewhat low energy long waves at about 0.54 cy/hr (period T ≈ 1.85 hrs). This was apparently overlooked, or otherwise dismissed as noise, by Van Dorn and Cox [12].

The important effects of resolution, found by use of the parameter-sets C, D, E and F of Table I on the marigram for Hilo, Hawaii, are shown in the spectra of Figs. 4(a) to (d). Fig. 4(a), with low resolution and good confidence, fails to show any evidence of an energy peak at 0.55 cy/hr frequency (T≈1.8 hr). Fig. 4(b) reveals the emergence of several minor peaks as resolution improves and confidence recedes. The use of 51-point filters with parameters C and D led to difficulties in the plot-out of wave forms. Parameter set E was made

TABLE 1: SETS OF SPECTRUM PARAMETERS USED OR TESTED

Parameter Set	Investigator & Reference	SPECTRUM PARAMETERS ADOPTED							
		Record Length T_r (hrs)	No. of Points N	Time Interval Δt (hr)	Nyquist Frequency f_n (cy/hr)	No. of Lags M	Degrees of Freedom (Confidence) ν	Frequency Increment (Resolution) Δf (cy/hr)	No. of Filter Points 2P+1
A_1	Loomis (14)	8	249	0.03	15	41	12	0.372	?
A_2	Loomis (13)	34	1024	0.03	15	60	34	0.250	?
B	Wilson (5)	30	300	0.10	5	160	4	0.031	51
C	" (5)	36	1800	0.02	25	200	18	0.125	51
D	" (5)	36	1800	0.02	25	300	12	0.083	51
E	" (5)	36	1800	0.02	25	300	12	0.083	255
F	" (5)	36	1800	0.02	25	400	9	0.063	153

identical to D in all respects save for the adoption of 255-point filters. The more finely tuned filters had the influence of reducing energy losses in the high-pass filtering process, and as Fig. 4(c) shows, allowed emergence of more prominent spectrum peaks, compared to Fig. 4(b), including a small one at 0.56 cy/hr frequency ($T \approx 1.79$ hrs). In the case of Fig. 4(d) the number of lags was increased further (M = 400) and filter points reduced to 153 (P = 75). Resolution was hereby increased still further and confidence somewhat reduced ($\nu = 9$). The smaller value of P was a concession to reduction of computing time and reduction of terminal losses of output record-lengths resulting from application of filters. Fig. 4(d) further enhances the spectral energy peaks, including some residual tidal energy (unshaded) not completely removed by the initial high-pass filter.

In the case of the marigram for San Francisco (Fig. 3), application was made of the spectrum parameters B, E and F, with results shown in the spectra of Figs. 5(a), (b) and (c). It is very evident from Fig. 5 that the tsunami at San Francisco was composed primarily of two almost discrete wave systems with periods approximating 1.8 hrs and 40 mins. The high resolution of parameter-set B elicits some minor peaks in the equivalent spectrum Fig. 5(a). These are virtually smoothed away by the use of the parameter-set F [Fig. 5(c)], and are non-existent in Fig. 5(b), obtained from use of parameter-set E.

4. COMPARISON OF THE WAVE-FORMS FROM SPECTRUM AND RESIDUATION ANALYSIS

In Fig. 6 the primary (P) and secondary (S) wave systems of periods, respectively, $T_1 \approx 1.8$ hrs and $T_2 \approx 40$ mins, have been separated out from the San Francisco marigram by use of appropriate filters, for comparison with the results of the Residuation analysis, P(d) and (S). The computer results from

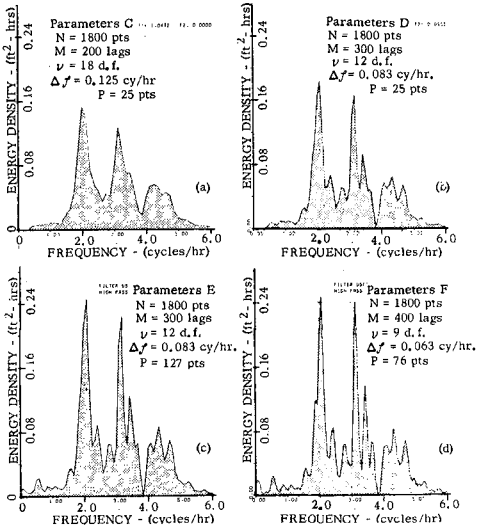

FIG. 4 - COMPARATIVE WAVE-ENERGY SPECTRA FROM HILO, HAWAII, MARIGRAM OF MAR. 28-29, 1964. T_r = 36 hrs; Δt = 0.02 hr.

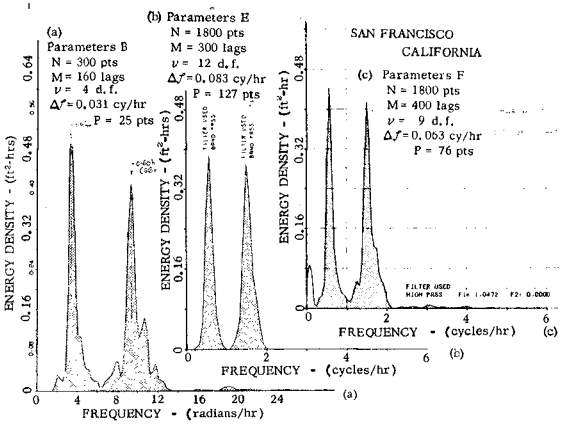

FIG. 5 - COMPARATIVE WAVE-ENERGY SPECTRA FROM SAN FRANCISCO MARIGRAM OF MAR. 28-29, 1964. T_r = 36 hrs; Δt = 0.02 hr.

use of the spectrum parameters E appear to accord most closely with the Residuation wave forms in period, amplitude and beat-shapes.

In the case of the Hilo, Hawaii, record, the wave form of the small peak of low frequency energy, centered at 0.56 cy/hr in Fig. 4(d), was obtained by passing the digitized wave data through a numerical band-pass filter having cut-off frequencies at $f_1 = 0.30$, $f_2 = 0.80$ cy/hr. The plot-out is shown as P(a) in Fig.7, and it is to be compared with P(b), obtained by the Residuation method [2]. The long-wave system P(a) in Fig. 7, obtained by use of a band-pass

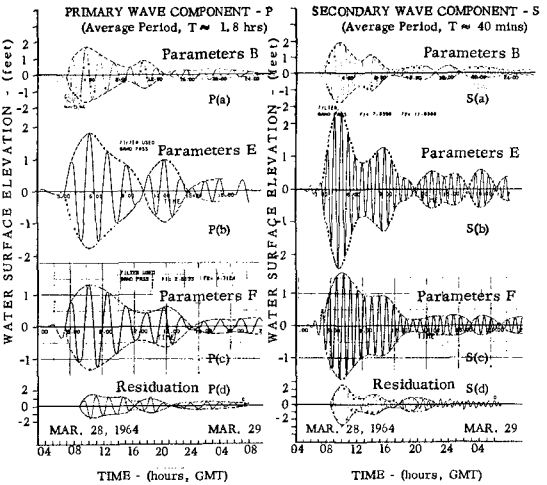

FIG. 6 - WAVE FORMS OF PRIMARY (P) AND SECONDARY (S) COMPONENTS OF MARIGRAM OF MAR. 28, 1964, SAN FRANCISCO, CALIFORNIA. Spectrum analyses a, b and c are derived from parameters B, E, F respectively (Table I); Residuation analyses d are graphical.

filter with cut-off frequencies $f_1 = 0.30$, $f_2 = 0.80$ cy/hr, retains some high-frequency contamination, but its envelope shape and maximum amplitude are generally similar to P(b). The remaining residual wave forms, after elimination of P(a) and P(b) are shown in Fig.7 as S(a) and S(b). There is again general similarity of shape and amplitude.

On the basis of this experimental probing, it was decided to adopt the spectrum parameter-set F as capable of yielding reliable results for spectrum analysis of the sampling of 24 marigrams. The parameter-set F was adopted in preference to E, the more desirable set, in the interests of economy, research funds being limited.

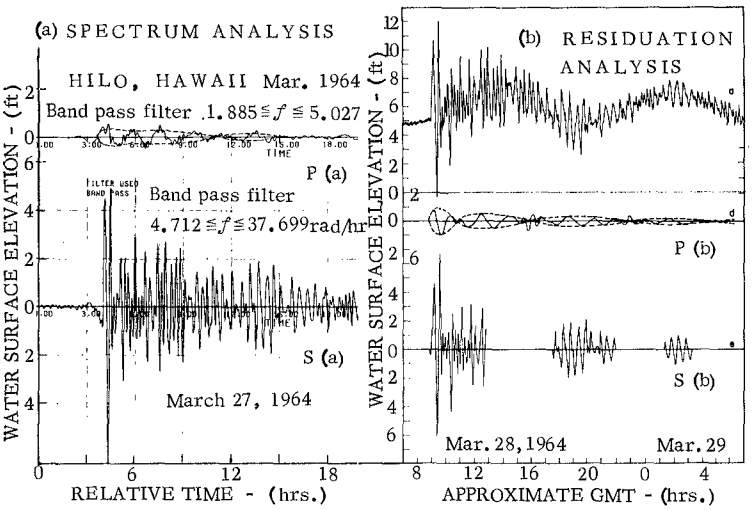

FIG. 7 - WAVE FORMS OF LOW-FREQUENCY COMPONENTS (P) AND SECONDARY COMPONENTS (S) IN MARIGRAM OF MAR. 28, 1964, FOR HILO, HAWAII. Spectrum analyses (a) used parameters F (Table I); Residuation analyses (b) are graphical.

5. SPECTRUM ANALYSIS RESULTS

As an example of the procedure followed in the spectrum analyses of the 24 marigrams, we give here briefly, the main elements of the analysis of the record for Hilo, Hawaii, being a case already cited, and one of the more complicated of all those analysed.

Use of the parameters F of Table I was shown to yield the spectrum given already in Fig. 4(d). The next step, typically followed, was to inspect the power spectrum for any peak in the frequency range 0.30 to 0.80 cy/hr. Within this band Residuation analysis had shown, in all cases, that a definitive wave component was to be expected [2]. In the case of Hilo, Hawaii, as already discussed, use of a band-pass filter with these frequency limits isolated the minor peak of energy shown in Fig. 8(a). The residual spectrum from S(a) in Fig. 7 is shown in Fig. 8(f). By using successive band-pass filters applied to the data, (in all cases, pre-filtered of tides), the important peaks of wave energy were isolated in succession, as in (b), (c), (d) and (e) in Fig. 8. The wave-form associated with each such peak or group of peaks was next computer-plotted to yield the wave components reproduced in Fig. 9. Fig. 9(a) and (b) are the same, respectively, as P and S in Fig. 7. Fig. 9(c) is the wave-form corresponding to the energy group of Fig. 8(b); 9(d), that of 8(c); 9(e),

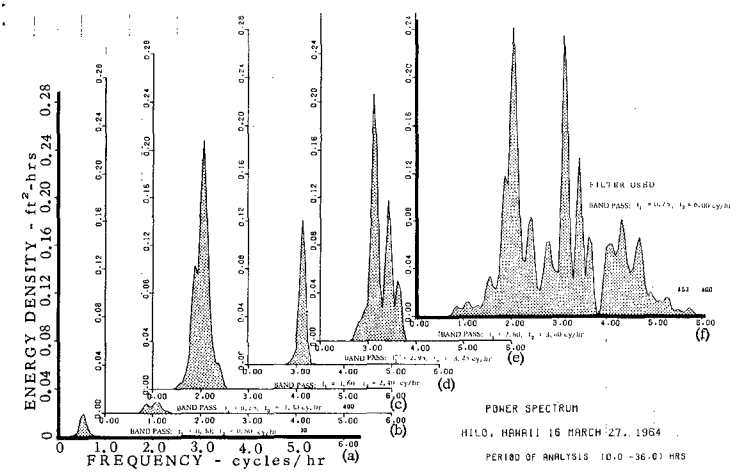

FIG. 8 - WAVE-ENERGY SPECTRA FROM DATA S(a) IN FIG. 7, AS FILTERED THROUGH BAND-PASS FILTERS (a) TO (f), HILO, HAWAII.

that of 8(e), and 9(f), that of 8(d).

Fig. 9 thus shows that the most dominant low-frequency components of the Hilo marigram were oscillations of periods 1.82 hrs, 1.0 hr, 29.1 mins and 19.2 mins. The latter, as revealed by Fig. 9(f), is a remarkably steady oscillation of long duration, (about 9 ins amplitude over 9 hours), before dying away. It is modulated, however, as apparent in Fig. 9(e), by the two wave components of periods 17.5 and 16.5 mins.

6. "PRIMARY" WAVES OF THE SPECTRUM ANALYSES

It is not possible in this short paper to reproduce results of all the spectrum analyses, as conducted in the form of Figs. 8 and 9. They are given, however, in full detail in Reference [5]. We limit ourselves here to presenting results for the lower frequency components of the tsunami at the different stations. Fig. 10 thus gives comparative evidence for the presence in all 24 marigrams studied, of a long wave component at a frequency between 0.50 and 0.65 cy/hr (average period 1.75 hrs). In all cases a definable peak of energy exists at or near this period, being very pronounced at stations close to the tsunami source, and at a few stations far afield. The relative heights of the energy peaks in the spectra are given along the top of the composite diagram as percentages in relation to 100% for Yakutat, Alaska. The spectrum peaks in Fig. 10, of necessity, have different ordinate scales. It will be seen that response at Port Alberni, Canada, was 10 times that of Yakutat. At Talcahuano, Chile, and at Lyttelton, New Zealand, about two thirds the distance across the Pacific Ocean from the source, in a north-south direction, the responses were 43% and 63%, .

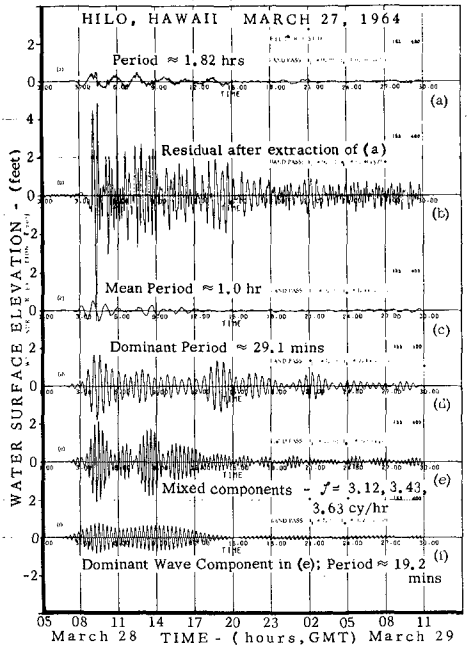

FIG. 9 - NUMERICALLY FILTERED AND PLOTTED WAVE-FORMS OF COMPONENTS OF THE ALASKAN TSUNAMI AT HILO, HAWAII, MARCH, 1964

respectively, virtual proof that this long-wave component was exciting some degree of resonance in the embayments at these locations.

The wave-forms corresponding to the spectrum peaks of Fig. 10 are computer plotted in Figs. 11 and 12; the vertical scales, be it noted, are not uniform. Considerable interest attaches to the beat-shapes of the envelopes of the wave-forms, which are often quite similar, as between stations fairly close together; even over great distances they still retain a general similarity. It appears that the number of waves in the first beat increases with distance in the north-south direction along the eastern boundary of the Pacific, from 5 near the source, to 6 at Prince Rupert, Canada, 7 at San Francisco, 8 at Talcahuano, Chile, and to semi-uniform wave-train formation near Antarctica. In the east-west and central north-south directions across the Pacific, the beat-shapes of the long waves, shown in Fig. 12, are quite markedly different from those of Fig. 11. Except in the cases of Hilo and Mokuoloe Is., Hawaii, the beats are all extremely long and phase changes apparently did not occur.

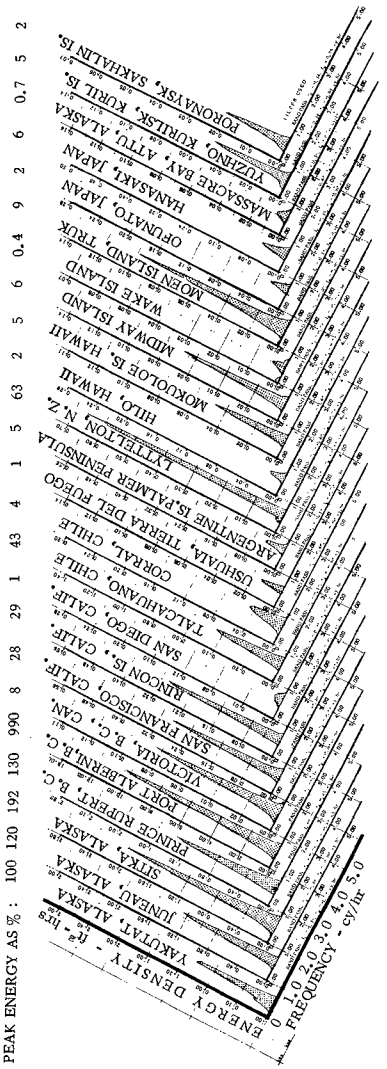

FIG. 10 - COMPARATIVE POWER-SPECTRA FROM BAND-PASS FILTERED DATA, ESTABLISHING THE PRESENCE IN ALL 24 MARIGRAMS OF PACIFIC OCEAN TIDE-STATIONS OF A DISTINCTIVE TSUNAMI COMPONENT-WAVE-FREQUENCY BETWEEN 0.50 AND 0.65 CY/HR (AVERAGE PERIOD 1.75 HRS). Note that ordinate scales are not all uniform.

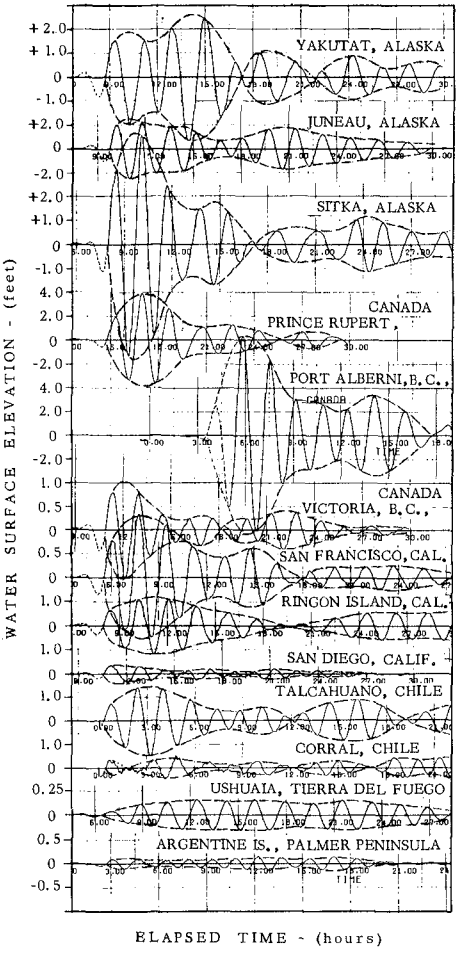

FIG. 11 - COMPUTER-PLOTTED WAVE-FORMS OF LONG-PERIOD COMPONENT (AVERAGE PERIOD 1.73 HRS) OF THE MARCH, 1964, ALASKAN TSUNAMI, NUMERICALLY DETERMINED FROM MARIGRAMS OF PACIFIC OCEAN TIDE-STATIONS.
Note: ordinate scales are not all uniform; dash-line envelopes are hand-drawn.
The plot for Port Alberni is intentionally set back to avoid confusion with adjacent plots.

It is of interest at this point to compare some samples of the Residuation analyses [2, 5], (as discussed earlier in Sections 2 and 4), with those obtain-in Figs. 11 and 12. Thus, Fig. 13 gives a selection of "primary" wave-trains *residuated* graphically from the marigrams of seven tide-stations. It is evident at once that the Residuation method succeeded in isolating the correct forms of the primary waves, both as to beat-shapes and number of waves in

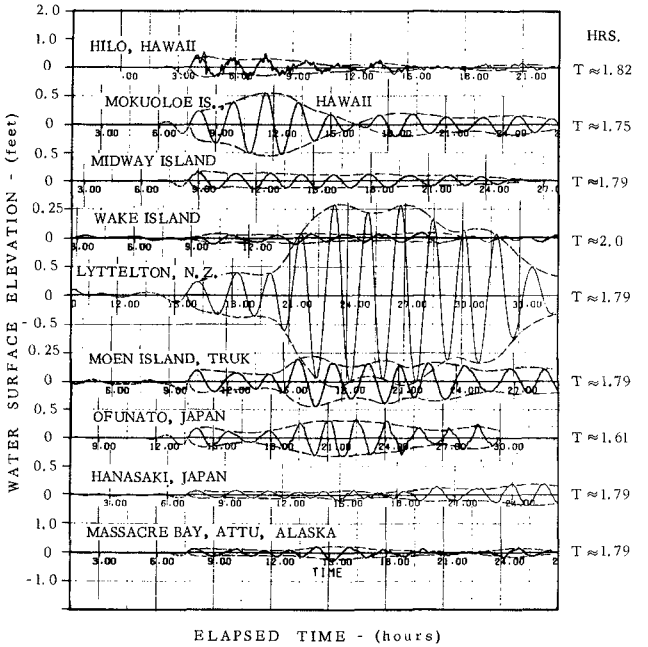

FIG. 12 - COMPUTER-PLOTTED WAVE-FORMS OF LONG-PERIOD COMPONENT (AVERAGE PERIOD 1.77 HRS) OF THE MARCH, 1964, ALASKAN TSUNAMI, NUMERICALLY DETERMINED FROM MARIGRAMS OF PACIFIC OCEAN TIDE-STATIONS: (ordinate scales not uniform; envelopes hand-drawn).

beats. Agreement on amplitudes is somewhat less satisfactory, but values are well within "ball-park" range of each other. The degree of concurrence of results from the two analysis methods is sufficient to validate the general reliability of the Residuation process used in Reference [2].

When the average period of the first three waves occurring in each wave-train of Figs. 11 and 12 are plotted as histograms of their relative frequency of occurrence, as in Fig. 14(a) and (b), the inference seems to be that along the west coast of the Americas, the predominant wave period of what we have called the *primary* waves was about 1.73 hrs, within a range from 1.55 to 1.95 hrs. In the west Pacific Ocean the dominant wave period was about 1.77 hrs within a tighter range of about 1.70 to 1.90 hrs.

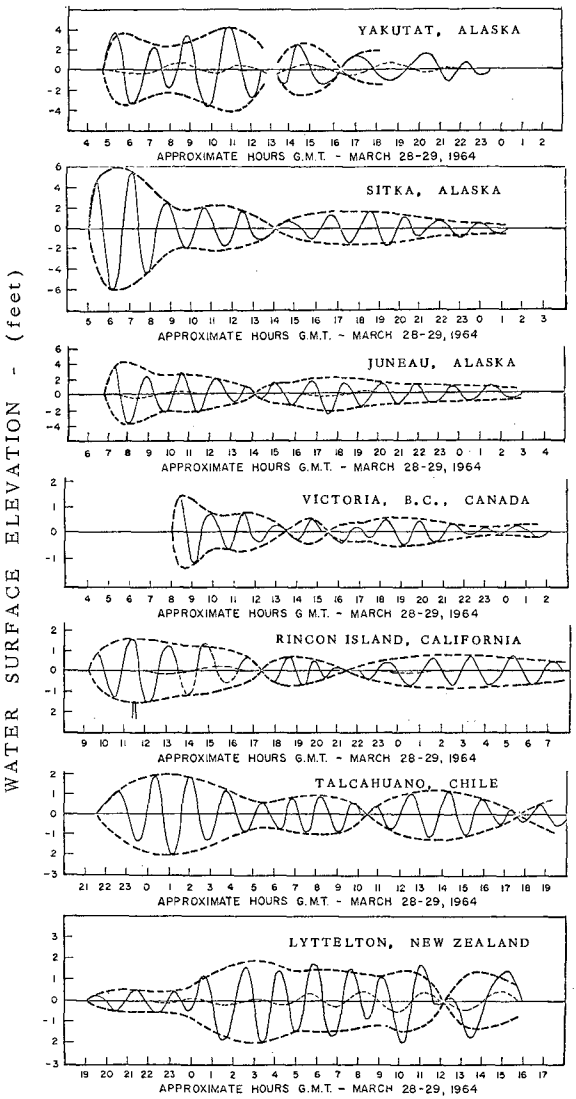

FIG. 13 - SAMPLES OF 'PRIMARY' WAVE TRAINS AS DETERMINED BY GRAPHICAL RESIDUATION OF THE MARIGRAMS FOR THE SEVEN TIDE-STATIONS; AVERAGE PERIOD 1.75 HRS: (Compare with computer-plots of 'Primary' waves obtained from Numerical Energy Spectrum Analyses in Figs. 11 and 12).

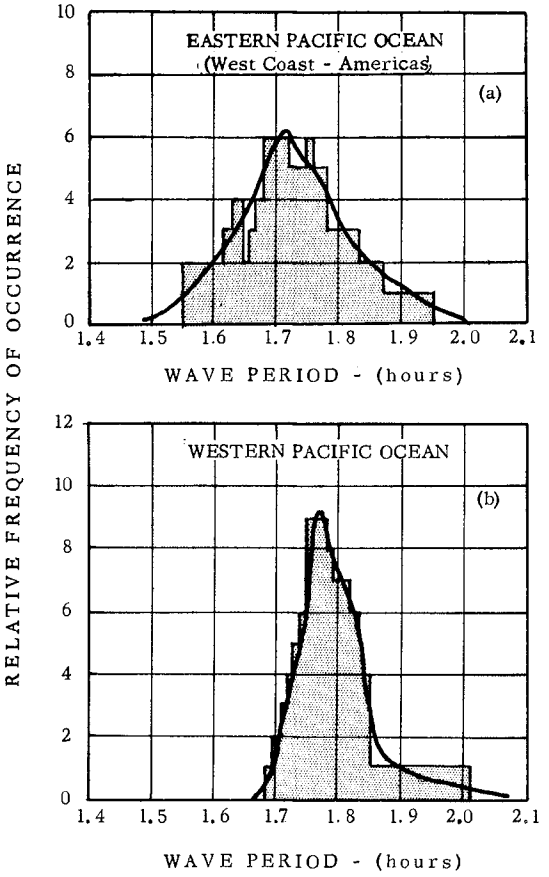

FIG. 14 - HISTOGRAMS OF WAVE PERIODS FOR "PRIMARY" LONG WAVE COMPONENT OF MARCH, 1964, ALASKAN TSUNAMI: (a) EASTERN PACIFIC OCEAN; (b) WESTERN PACIFIC OCEAN; (based on first three waves in Figs. 11 and 12)

On the supposition that the beats of long waves resulted from the interference of just two trains of periods T_1 and T_2 (frequencies f_1 and f_2), thereby yielding beat frequencies f_b and apparent wave frequencies f_a, it is readily shown that:

$$\left.\begin{array}{ll} \text{(i)} & T_1 = 1/f_1 = [\, f_a + f_b \,]^{-1} = [\, 1/T_a + 1/T_b \,]^{-1} \\ \text{(ii)} & T_2 = 1/f_2 = [\, f_a - f_b \,]^{-1} = [\, 1/T_a - 1/T_b \,]^{-1} \\ \text{(iii)} & T_b = 2(n-1)\,T_a \end{array}\right\} \quad (4)$$

where T_a and T_b, respectively, are the periods of the waves apparent in the beat and of the beat itself, n being the number of waves occurring in the beat. Adopting $T_a = 1.72$ hrs for the Eastern Pacific, the values of T_1 and T_2 for particular values of T_b and n are found in Table II. For the Western Pacific Ocean they are given in Table III, for the apparent wave period $T_a = 1.77$ hrs.

Table II shows that the periods T_1 and T_2 in the last columns, are contained quite easily in the period-spread of the histogram, Fig. 14(a). Table III, likewise, shows similar containment in the histogram spead of Fig. 14(b). The idea gains support, therefore, that the envelope shapes of the long wave systems are the result of interfering frequency components with periods of the

TABLE III - RANGE OF INTERFERING FREQUENCIES TO ACCOUNT FOR BEATS OF LONG WAVES (NOMINAL PERIOD 1.77 HRS)

(Western Pacific Ocean)

No. of Waves in beat	Beat Period [Eq. (7)]	Beat Frequency	Wave Frequency	Component Wave Frequencies		Component Wave Periods	
n	T_b (hrs)	f_b (cy/hr.)	f_w (cy/hr.)	f_1 (cy/hr.)	f_2 (cy/hr.)	T_1 (hrs)	T_2 (hrs)
7	21.24	0.0471	0.5650	0.6121	0.5189	1.63	1.93
8	24.78	0.0404	0.5650	0.6054	0.5246	1.65	1.90
10	28.32	0.0353	0.5650	0.6003	0.5297	1.67	1.89
12	31.86	0.0314	0.5650	0.5964	0.5336	1.68	1.87

order given by T_1 and T_2 in Tables II and III. The seemingly consistent trends of change with distance, suggested by the increasing number of waves in a beat, and the varying periods given in Tables II and III are interesting, but as yet unexplained. It may be that this simplified an interpretation of the beat phenomena cannot be justified, because the declining component period T_2 with distance runs counter to an expected increase of period over distance and time for expanding waves. Despite this difficulty, the overall consistencies of change with distance from the origin suggest that the wave formations of Figs. 11 and 12 must have originated at the source and not as mere local excitations.

7. EXISTENCE OF ULTRA-LONG PERIOD WAVE-TRAINS

Both the Residuation and the Numerical Spectrum analyses have revealed that, for about half of the marigrams studied, there is evidence of still longer period wave-trains in the composition of the tsunami than those already discussed. They are found to lie within a frequency range of about 0.30 to 0.35 cy/hr, (average period 3.2 hrs). The strongest such wave-train of period 3.0 hrs occurred at Yakutat, Alaska, close to the tsunami source (Fig. 1). Its height (Fig. 15) was comparable to the height of the 1.85 hr period waves shown in Fig. 11 for Yakutat. For the marigrams in which these extremely long waves were detectable, as in Fig. 15, the largest effects besides those of Yakutat, occurred at Victoria, Canada, at the Palmer Peninsula, Argentine Island, Antarctica, and at Lyttelton, New Zealand. Some of the wave-trains in Fig. 15 overlie residual astronomical tide-waves, not completely eliminated in the numerical filtering for the 3.2 hr period waves.

At Yakutat, near the mouth of triangular-shaped Yakutat Bay (natural period of oscillation about 41 mins), the marine topography is not favorable to any resonance of incident waves with periods as large as 3.0 or 1.8 hrs. The much smaller triangular Monti Bay, at the head of which Yakutat harbor actually lies, is an offshoot of Yakutat Bay at its mouth, and therefore in a nodal position with respect to any oscillations of Yakutat Bay. Because of this and the fact that Monti Bay has a fundamental period of free oscillation of about 17 mins only, there could have been no possibility of resonant amplification of 1.8 and 3.0 hr tsunami wave components. The waves of these periods, shown in Figs. 11 and 15, would therefore have been incident waves enhanced only by the shoaling and funnelling effect of the small Monti Bay, to the extent perhaps of 6 times their deep-water height (in accord with Green's Law). The inference from this is that the nominal 1.8 and 3.2 hr component long waves of the tsunami originated from the source and propagated across the Pacific Ocean.

At Victoria, Canada, the natural periods of oscillation of the Juan de Fuca Strait (fundamental, about 4.3 hrs; second mode, about 1.8 hrs), would have been conducive to some enhancement of the long wave-trains, as Figs. 11 and 15 suggest. A pseudo-resonance effect would also have occurred at Lyttelton, N.Z., where the period of free oscillation for Port Lyttelton Channel and Pegasus Bay is about 2,6 hrs. The marigram for Lyttelton harbor, in fact, recorded 2.6 hr oscillations prior to the arrival of the tsunami waves; they were probably locally generated by barometric fluctuations or other causes. The

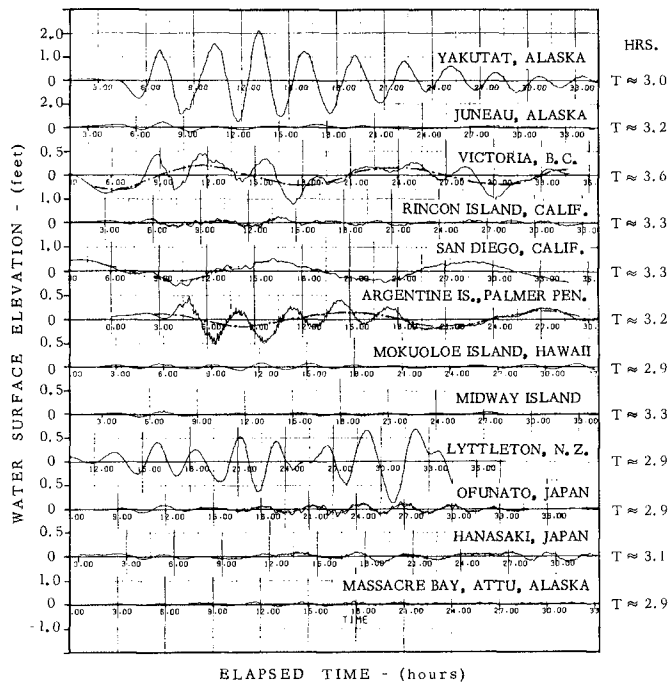

FIG. 15 - COMPUTER-PLOTTED WAVE-FORMS OF ULTRA-LONG PERIOD (AV. 3.2 HRS) OF THE MARCH, 1964, ALASKAN TSUNAMI.

enhancement of the 3.2 hr waves at Palmer Peninsula, Antarctica, probably relates to the shoaling and restrictive effect of the Antarctic Sound. As to why these ultra-long period waves drew no strong responses at other stations where the 1.8 hr period waves recorded well, as in Figs. 11 and 12, cannot be known without a detailed wave-refraction study and examination of the oscillating characteristics of the areas.

8. CONCLUSIONS

Numerical power-spectrum and graphical Residuation analyses have been shown to be mutually supportive of the existence in the records of the Alaskan tsunami of March, 1964, of very long wave-trains with periods approximating 1.75 and 3,2 hrs, originating at the source and propagating across the Pacific Ocean. In the north-south direction encompassing the eastern half of the Pacific Ocean, the 1.75 hr (nominal) period waves occurred in beats, their numbers per beat increasing with time and distance.

Wave run-up caused by natural storm surge waves

by

Joachim Grüne *)

Abstract

This paper describes results of field measurements on wave run-up caused by storm surge waves. The measurements have been done with newly developed run-up probes at two locations at the German Bight with different dyke profiles. It was found from the results that the wave run-up, measured under real sea state conditions, have greater values than predicted by commonly used formulae. Furthermore the wave climate and the breaker type seem to have an influence on the magnitudes of wave run-up.

Introduction

For the design of seadykes the rising of the stillwater level due to wind stress during storm surges may be calculated with an exactness of some decimeters, whereas the appertaining wave run-up often has to be estimated in a range of up to meters. This results not only from the fact, that the wave climate on the nearshore of the dykes mostly is unknown, but also from the multitude of excisting formulae, which create different values (FÜHRBÖTER, Ref. 5).

There has been done a lot of investigations on wave run-up carried out in small-scale models with regular waves, some with wave spectra. But only a few results from field investigations are known (in respect of investigations at the german coast see COLDEWEY (Ref. 2), ERCHINGER (Ref. 3) and NIEMEYER (Ref.10)).

Due to unsolved problems with scale effects, which occur in breaker processes in small scale models and due to random characteristics of the waves in shallow water, there is still a great need to verify formulae, developed by model tests, under real sea state conditions.

*) Dipl.-Ing., research engineer, deputy operation manager of LARGE WAVE CHANNEL (University Hannover and Technical University Braunschweig), LEICHTWEISS-Institut (Div. of hydromechanics and coastal engineering) - Technical University Braunschweig, Germany

Field Measuring Equipment

For measuring the wave run-up in situ a probe was newly developed (GRÜNE, PIECHACZEK, Ref. 6), which should accomplish the following requirements:

1. Linearity over a total length up to 30 meters
2. One analog output signal for the actual run-up
3. Insensitive to the loads caused by waves and floats

This has been achieved by a 60-step-probe (Fig. 1). Each step consists of two electrodes, which are,electrically isolated,fixed in a small frame box and casted with synthetic epoxy resin. These steps are fixed on 2 meter long support frames in an optional distance,depending on the slope and the wanted accuracy (Fig. 2). The electronic circuit scheme is shown in Fig. 3. When the water of the run-up passes the electrodes of a step, an electric impuls will be released by closing an electronic circuit due to the conductivity of the water. This impulse actuate a awitch relay, which gives a defined voltage to an adder. The defined voltage of each individual step can be adjusted to the vertical range of each step (vertical distance to the preceding step). Therewith one gets an output aignal, which is linear to the vertical run-up, independent of the actual distance between the steps or of variations of the slope. The analog output signal, which gives the actual wave run-up, is formed by adding all defined voltages. To be recorded, the signal optional can be filtered by a low pass filter and attenuated.

Fig. 4 ahows the front of the electronic device with the LED-visual displays of each step. An example of a synchronous record of wave run-up and waves is given in Fig. 5.

Fig. 1: Wave run-up probe

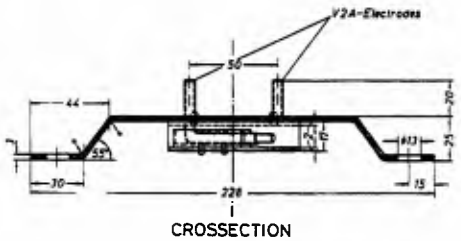

Fig. 2: Construction of steps and support frames

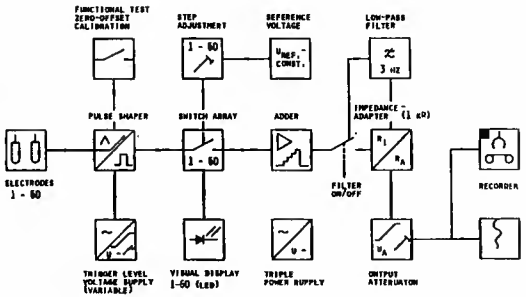

Fig. 3: Electronic circuit scheme

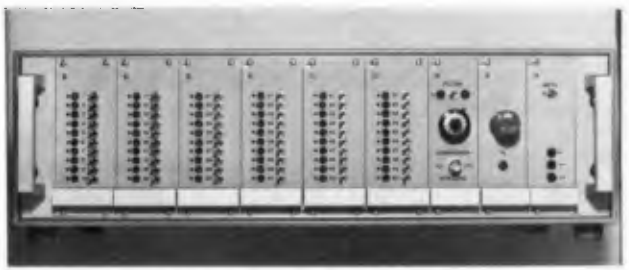

Fig. 4: Front view of electronic device

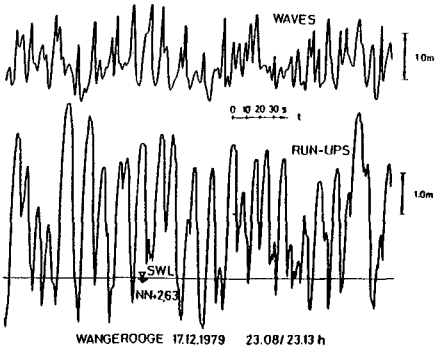

Fig. 5: Synchronous record of waves and run-ups

Such wave run-up probes as described above have been installed at two locations at the coast of the German Bight: WANGEROOGE and EIDERDAMM (Fig. 6).

At the location WANGEROOGE (an east frisian island) a heavy revetment with slope 1 : 4 was used (Fig. 7), which has a sand core and a cover layer made from asphalt concrete. In the upper part artificial roughness elements (prism concrete blocks - type Beverkoppen) are pasted on the asphalt layer. The run-up probe extend over 27 meters on the slope up to 6.2 m above Mean High Tide Level (MThw) with a vertical distance between the steps from 9 cm at the lower part up to 12 cm at the upper part of the probe. Fig. 1 shows the installed wave run-up probe on the revetment. Waves have been measured with a pressure transducer, which is situated 15 m in front of the revetment on the level NN + 0.15 m. The pressure data have been transfered to surface elevation by means of correction factors for wave heigths and wave periods as described later on.

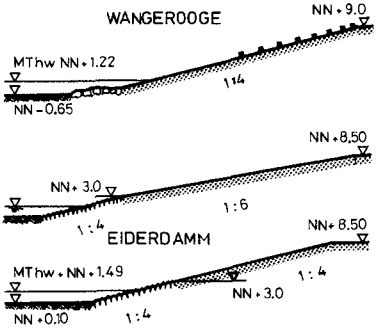

Fig. 7: Dyke profiles with run-up probes

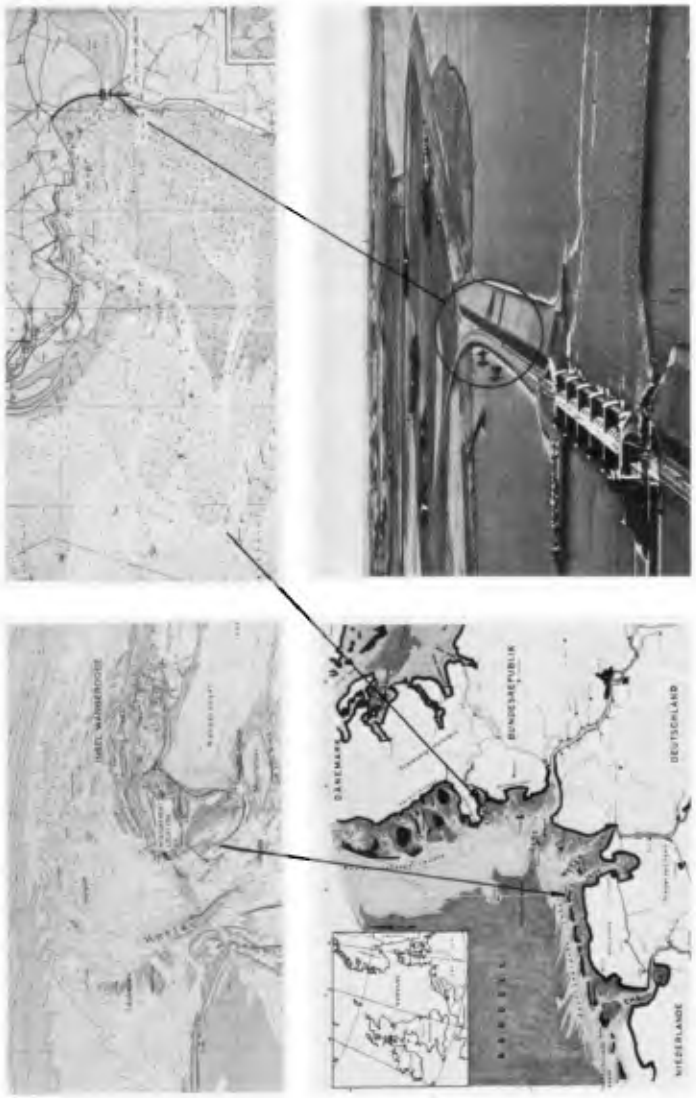

Fig. 6: German bight with measuring locations

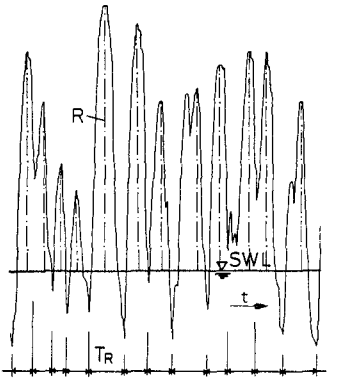
Fig. 8: Air view of EIDERDAMM with measuring sections

The other location is the adjacent dam at the south side of the EIDER-river storm surge barrier. This dam has a sand core with bended slopes of 1 : 4 and 1 : 6. Thelower part with a slope 1 : 4 up to 1.5 meters above Mean High Tide is covered with a concrete-jointed natural stone revetment, whereas the subjequent slope 1 : 6 is covered with asphalt concrete (Fig. 7). Additionally there is a test section with a constant slope of 1 : 4, also with sand core and covered with asphalt concrete above the level NN + 3.0 m (Fig. 7). On both sections run-up probes have been installed on the asphalt layer (above the level NN + 3.0 m). The vertical distances between the steps vary from 8 cm to 12 cm on slope 1 : 4 and from 7 cm to 11 cm on slope 1 : 6 (smaller values at the lower part). In Figure 8 this two sections with run-up probes are markes with a circle. A pressure transducer on the lower part of the slope 1 : 4 was used to measure waves. Transferring pressure data to surface elevations will be described later on.

Measurements and data analysis

Waves and wave run-ups were recorded synchronously during several storm surges with a rise of the still water level up to 1.4 m above Mean High Tide Level (MThw) at WANGEROOGE and upto 2.3 m above MThw at EIDERDAMM location. An example of a record is shown in Fig. 5.

Due to some failures of analog magnetic tape recording system at EIDER-DAM location first all measurements were analysed in the time domain, the data presentation in this paper will be restricted to this analysis. The direct paper records were used to digitize the run-ups and the crests and troughs as shown in Fig. 9 with a semi-automatical device. Further data processing was then done with computer. It was defined that each run-up must have an substantial trough, "double-peaks" and "ondulations" have been ignored. The time interval between the troughs was defined as run-up period. Waveheights were defined as zero-down cros-



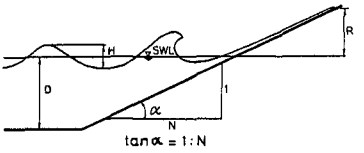


Fig. 10: Definitions of run-ups

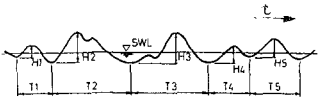

Fig. 9: Definitions of recorded run-ups and waves

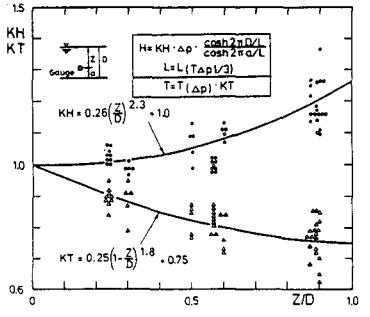
sings heights, whereas for the periods(the same manner as for run-ups) the time intervals between the troughs were used.

Because the waves were measured with pressure cells, these data had to be transfered to surface elevations in means of two-dimensional progressive waves. It was found,existing formulas for wave pressure attenuation of previous investigations were not suitable for the measured wave climate conditions. This leads to do some calibration tests in a small-scale wave flume (scale appr. 1 : 5) with random sea state conditions with respect to the depth-, period- and windvelocity-conditions of the field measurements. An example of the results is shown in Fig. 11 for constant depth. The wellknown formula of pressure attenuation for linear wave theory was found useful by extending it with a Correctionfaktor KH, which is function of the relative depth Z/d of the pressure transducer. For the periods Correctionfactors were found also as a function of relative depth. Similar Correctionfactors were derived from the results of calibration tests for pressure transducers on a slope 1 : 4 (EIDERDAMM location). To compare wave data of both locations, the data from EIDERDAM, which were measured on the slope 1 : 4 closed to the breaker-zone and consequently affected by shoaling, furthermore are transfered to those in front of the dyke by means of a shoaling factor $KAS = H_B/H_I$, calculated by a formula,derived by LE MEHAUTE et al. (Ref. 9). Comparing the results of field measurements,done with pressure transducers 12 meters in front of the dyke and on the slope synchronously, this formula was modified by using the measured wave height and lenght on the slope near the breaker point:

$$KAS = 0.76 \cdot s^{1/7} \cdot (H_B/L_B)^{-1/4}$$

In the manner described above all wave data for both locations were transfered to those 15 m in front of the dyke profiles. The records were devided in consecutive time intervals, which are 15 to 20 minutes for WANGEROOGE location and 10 to 15 minutes long for EIDERDAMM location. For each time interval the mean still water level(SWL) as a constant value was determined from records of tidal gauges, which are at EIDERDAMM approx. 500 meters and at WANGEROOGE approx. 3000 m far from the field measuring devices.



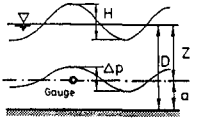


Fig. 11: Results of tests on wave pressure attenuation

Results

As mentioned before, results in this paper will be restricted to time domain analysis. Waves and run-ups first have been analysed statistical for each time interval. As an example the log-normal distributions of waves and run-ups are plotted in Fig. 12 for one time interval. In Fig. 13 the statistical values of the wave run-up R MAX, R 1/10 and R 98 are plotted against the mean values RM (WANGEROOGE). All ratios found with regression lines through zero, are listed in Table 1 for all dyke profiles at both locations:

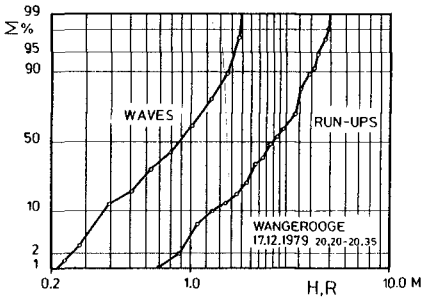

Fig. 12: Log-normal distribution of waves and run-ups for one record

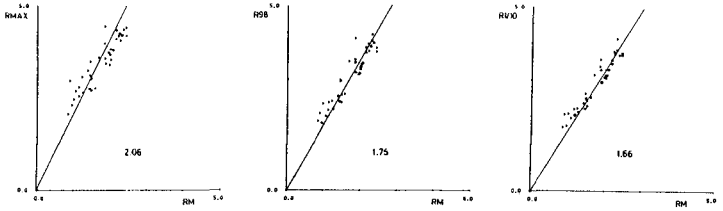

Fig. 13: Statistical values measured at WANGEROOGE

Table 1: Ratios of statistical values of wave run-up

Location	R MAX / RM	R 1/100 / RM	R 1/10 / RM	R 1/3 / RM	R 98 / RM	R 95 / RM	R 90 / RM
WANGEROOGE N = 4	2.06	1.90	1.66	1.39	1.75	1.60	1.46
EIDERDAMM N = 4	1.97	1.97	1.63	1.38	1.69	1.60	1.43
N = 6	1.90	1.86	1.58	1.34	1.69	1.57	1.40

There are no essential differences in this ratios apart from scattering and slightly smaller values for slope 1 : 6. Similar values are found by COLDEWEY (Ref. 2).

The statistical wave run-up value R 98, mainly used for practical engineering purposes, has been applied for comparing the measured wave run-ups with the calculated ones. Two well-known traditional formulae were used for calculation:

1. The formula $R_{98} = K \cdot H_S \cdot 1/N$ with K = 8, known as DELFT-formula and derived by WASSING (Ref. 14), which takes the significant wave-height and the slope into account.
2. The formula $R\ 98 = C \cdot T_m \cdot H_S \cdot g \cdot 1/N$ with C = 0.5, derived by HUNT (Ref. 8) and extended to irregular waves by VINJE (Ref. 13), which takes supplementary the period into account.

Comparisons of measured data with data calculated by these formulae are given in Fig. 14 to Fig. 16. It must be remarked, that the plots in Fig. 14 include only those data, which are not affected by the roughness elements on the upper part of the revetment. It was found that the regression line does not give smaller values for the empirical factors K or C, unless the maximum wave run-up does not pass over the third row of roughness elements (the effect of the roughness elements will be commented in the following). It must be considered that the data of the two slopes in Fig. 15 can't be compared directly, because the slope 1 : 6 is a bended slope (Fig. 7). Fig. 16 contains additionally data with significant waveheights, which had to be hindcasted from results of previous wave measurements at the same location, due to wave gauge defect. In all plots there is a certain amount of scatter, which always occur in wave related data, particularly from field measurements in surf zones. A conclusion of the plots in Fig. 14 to Fig. 16 indicate two main facts:

1. Wave run-up data, measured under real sea state conditions, normally have greater values than predicted by the common used formulae.
2. There are substantial differences between the data of both locations.

The empirical factors K and C for slope 1 : 4 are listed in Table 2. The measured run-up at EIDERDAMM compared to that of WANGEROOGE are 17 % higher, using the DELFT formula and 30 % higher, using the HUNT-VINJE-formula. A certain part of the differences might be caused to the manner of wave data transferring at EIDERDAMM location, described as above, but nevertheless this does not explain the total amount of differences.

Table 2: Comparison of empirical factors C and K for slope 1 : 4

	C			K		
	regression line through zero	max	min	regression line through zero	max	min
WANGEROOGE	0.71	0.92	0.53	11.32	13.80	7.52
EIDERDAMM	0.92	1.14	0.62	13.30	15.76	12.00

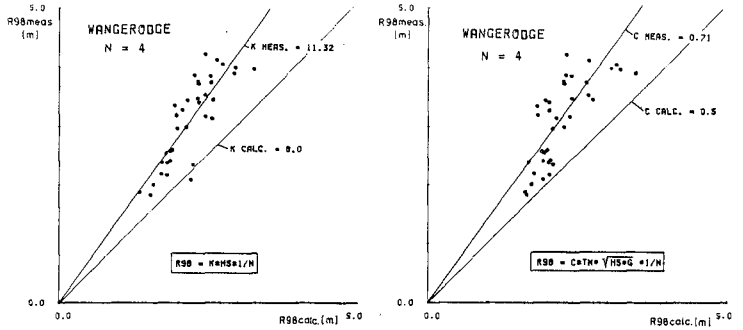

Fig. 14: Comparison of measured to calculated wave run-up

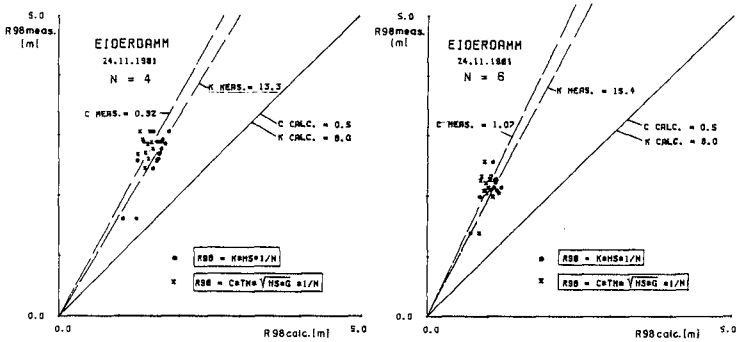

Fig. 15: Comparison of measured to calculated wave run-up

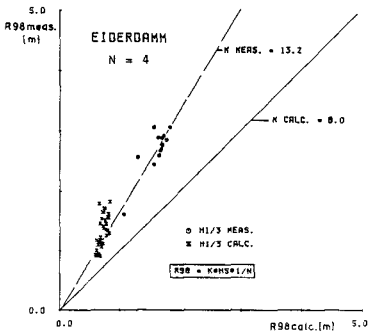

Fig. 16: Comparison of measured to calculated wave run-up

Previous investigations of VAN OORSCHOT and D'ANGREMOND (Ref. 12) showed considerable variation of the empirical factor C (C_n in Ref. 12, using the maximum energy density period $\hat{T}$ instead of statistic mean value T_m) in dependence on the shape of the wave energy spectrum (in means of spectral width parameter ε). Unfortunately this could not be checked due to the fact that there was no possibility to analyse the data in the frequency domain for both locations yet as mentioned above. On the other hand, comparisons of joint distributions of wave heights and periods for some time intevals let assume, that there is no significant variation of the wave energy spectrum shape, which may explain the differences of emperical factors C and K completely. As an example the joint distributions of two time intervals with approx. the same value C are shown in Fig. 17.

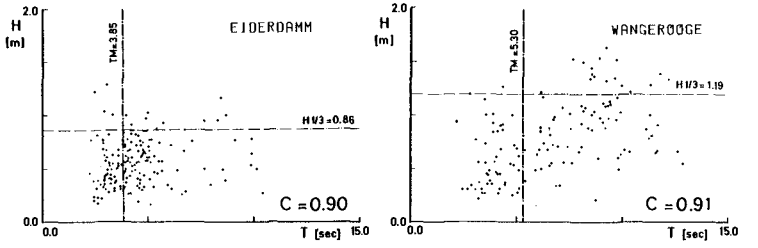

Fig. 17: Joint distributions of two measured time intervals

Furthermore the analysed data were used to find out the influences of environmental and wave parameters:

In Fig. 18 the ratio of measured to calculate run-up is plotted versus the windvelocity U_{oh} during the measurement, which gives a slightly increasing of the empirical factor with increasing windvelocity. The influence of the winddirection (the wave approach direction has not been measured) seems to be negligible as shown in Fig. 19, where β is the angle between winddirection during the measurement and the line of full dip of the slopes (positive β turns to north). This confirms, that the wave approach essentially is determined by the topography in such shallow water areas. Visual observations resulted in values for wave approach angle related to perpendicular direction, of $\pm$ 10° at WANGEROOGE location and of $\pm$ 20° at EIDERDAMM location.

From Fig. 20 follows that the influence of wave steepnees has the same trend for both locations, but there are different orders of magnitude. It can be stated that the empirical factor C increase with increasing Period and / or increasing wave height comparativly. The dependence on relative waterdepth D/H_s is shown in Fig. 21 for the factors C and K and for the ratio number of run-ups to number of waves NR/NW. Whereas the ratio NR/NW decreases with increasing relative waterdepth, the empirical factors C and K are increasing with increasing relative water-

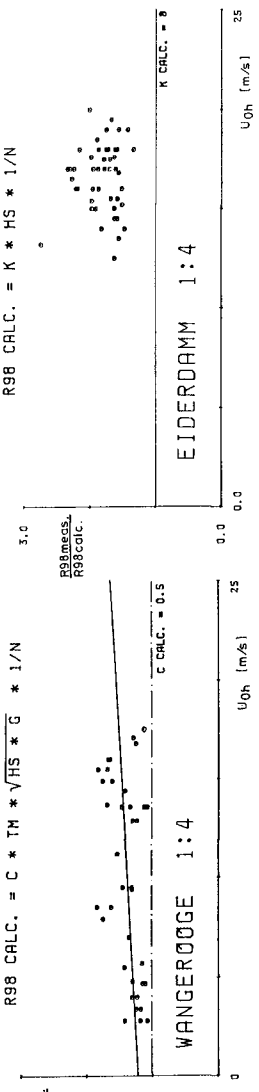

Fig. 18: Measured to calculated run-up versus windvelocity

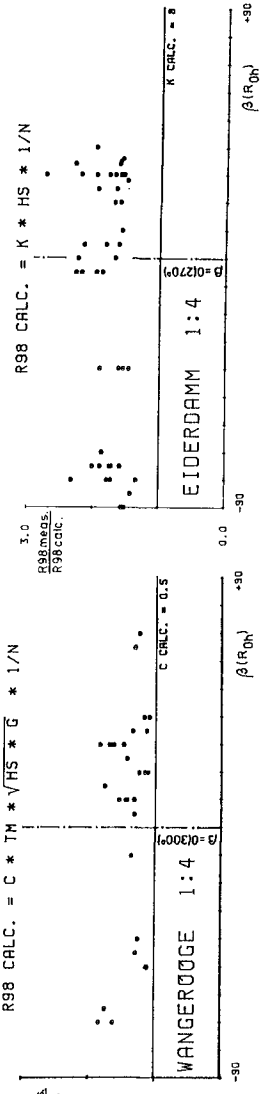

Fig. 19: Measured to calculated run-up versus winddirection

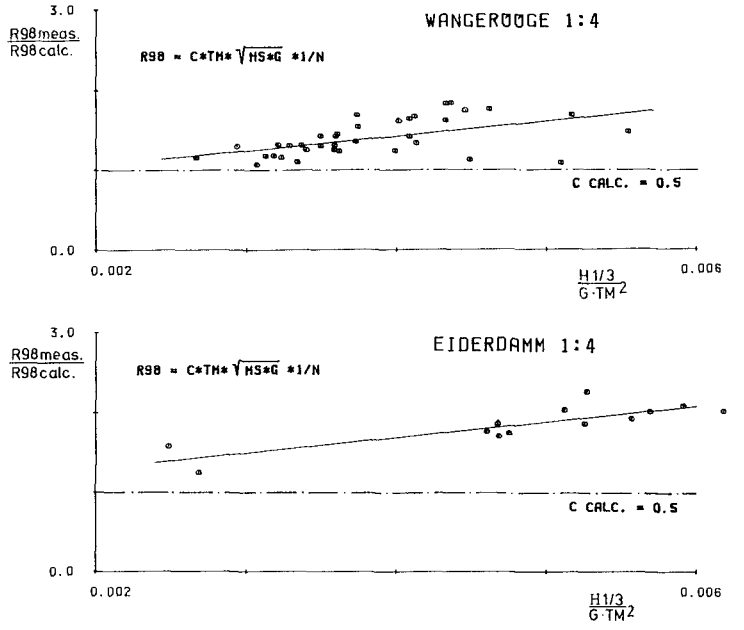

Fig. 20: Measured to calculated run-up versus wave-steepness

depth. From the influence of the relative waterdepth and the wave steepness one can suppose, that there might be a dependence on the breakertype for the empirical factors in the used formulae. An impression of the typical wave climate conditions at both locations is given in Fig. 22. At WANGERROGE the breaking waves are of the spilling and plunging type, whereas at EIDERDAMM only occur plunging type waves. This observations are in agreement with breakertypes, calculated with the BATTJES-Parameter $f_b = 1 : N / \sqrt{H_b/L_o}$. (Ref. 1). To determine, whether the waves break on the nearshore or on the dyke slope, the breakerdepth stated by HENSEN (Ref. 7) was used. He found by investigations on waves on tidal flats with nearly constant depth that waves begin to break with relative waterdepth smaller than 2.3. The values of relative waterdepths D/H and breaker parameter f_b are listed in Table 3:

Table 3: Wave parameters related to the wave run-up data

Location	$H_{1/3}$[m]	T_M [s]	$D/H_{1/3}$	D/H_{MAX}	$f_{b(H1/3)}$	breaker type
WANGEROOGE	0.6 to 1.6	4.5 to 7.3	1.9 to 3.2	2.3 to 2.2	0.10 to 0.15 (nearshore) 1.4 to 2.0 (dyke)	spilling / plunging
EIDERDAMM	0.5 to 0.9 (0.35)	3.7 to 5.2	4.1 to 5.2	2.7 to 4.0	1.3 to 2.0 (dyke)	plunging

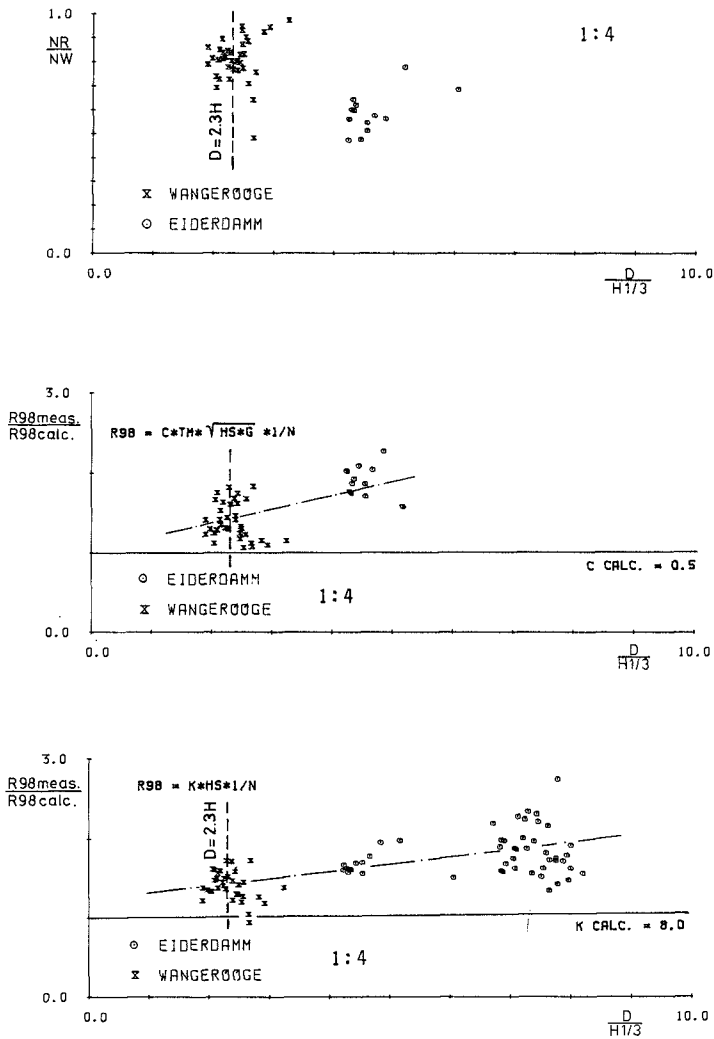

Fig. 21: Measured to calculated run-up versus relative waterdepth

WANGEROOGE 1:4

EIDERDAMM 1:4

Fig. 22: Typical wave climate at WANGEROOGE and EIDERDAMM

From Fig. 21 and Table 3 it is obvious, that at location WANGEROOGE at least the higher waves break on the nearshore and hence there must be a mixture of spilling and plunging breakers, which is in agreement with visual observations. From this results it can be supposed, that in general the wave run-up is relatively higher for plunging breakers than for spilling breakers. These investigations have to be continued to get more and detailed informations on criterions, which lead to a breaking on the nearshore or on the dyke slope or on both sections and to relate this criterions to the wave run-up data.

As mentioned before, the effectiveness of artificial roughness elements was found to be poor, if the elements only extend in the upper part of the run-up (Fig. 23). The solid line refers to experimental data of FRANZIUS (Ref. 4 and 12). For a comparison it must considered, that FRANZIUS used cubes with a constant distance to each other, whereas at WANGEROOGE prismn with triangle crossection were placed in rows. The distances between the rows decrease to the top of the dyke and the rows itself contains 2 single rows of prismn in the lower part and 3 single rows in the upper part.

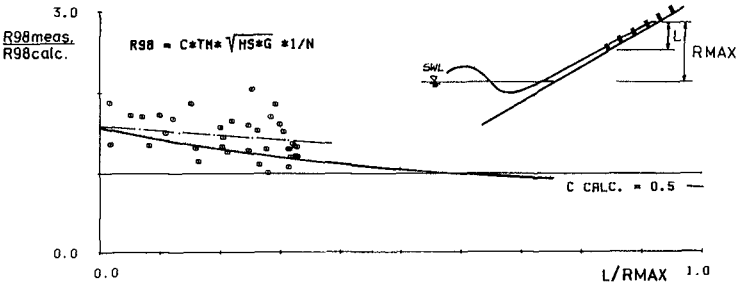

Fig. 23: Effectiveness of roughness elements (WANGEROOGE)

It may be stated , that a higher effectiveness in small scale models is created from the relatively higher amount of turbulence caused by such elements compared to real sea state conditions.

Results for a convex bended profile (Fig. 7) are shown in Fig. 24. The ratios of measured run-up for both dyke profiles are plotted versus the relative distance of the still water level to bending point $\Delta D/H_s$. There is no significant difference between both profiles, if the still water level is below the bending point. Further the influence of the lower slope seems to be neglectible small, if the still water level is more than two times the significant wave height higher above the bending point.

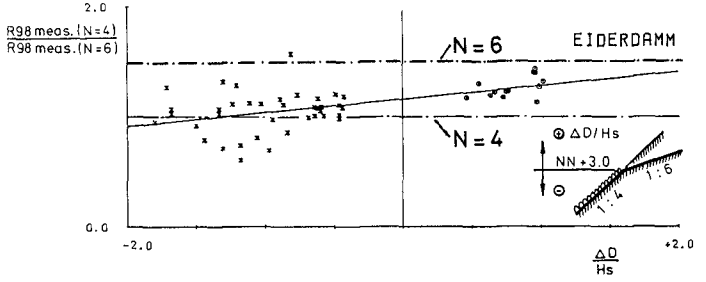

Fig. 24: Comparison of results for constant and bended slope (EIDERDAMM)

Conclusion

Wave run-up data, measured under real sea state conditions at two locations at the coast of the German Bight, in general are found to have greater values then predicted by common used formulae. Based on the formula

$$R\ 98 = C \cdot T_m \cdot \sqrt{H_s \cdot g} \cdot 1/N$$

a comparison for the empirical factor C with results of some previous investigations with irregular waves in model tests is given in Table 4:

Table 4: Comparison of empirical factors C:

		C	
VAN OORSCHOT / D'ANGREMOND	(Ref. 12)	0.60 to 0.77	$\hat{T}/T_m$ =1.05
BATTJES	(Ref. 1)	0.59 to 0.74	analytical model based on RAYLEIGH-distribution
TAUTENHAIN	(Ref. 11)	0.70 to 0.86	not comparable directly, based on wave distribution
AUTHOR		0.53 to 1.14	2 different locations

Data of field measurements, reported by ERCHINGER (ref. 3) and COLDEWEY (Ref. 2) cannot be compared directly with those of the author, due to different dyke profiles (bended profile with 3 different slopes in Ref. 3), but those data show the same trend in respect to higher measured run-up compared to calculated one.

It must be mentioned, that the breaker type has an influence on the order of magnitude of the empirical factor C.

The ratio number of run-ups to number of waves decreases with increasing relative waterdepth in the range of 0.95 to 0.50.

The effectiveness of artificial roughness elements is found to be poor, if the elements only extend in the upper part of the run-up.

WAVE RUN-UP AT SEA DIKES UNDER OBLIQUE WAVE APPROACH

by

E. TAUTENHAIN[1], S. KOHLHASE[2], H.W. PARTENSCKY[3]

1. INTRODUCTION

Besides wave impact forces, erosion of the inner side of a sea dike is a serious cause of destruction. Therefore, wave run-up and overtopping effects have to be considered with respect to the safety of a dike. Strong relations were found between both these influences (TAUTENHAIN et.al., 1980, 1981, 1982), based on experiments in a wave flume and using an energy conservation concept. However, under natural conditions, an oblique wave approach has to be considered. This paper deals with the influence of wave direction on wave run-up on a smooth dike slope in order to provide a basis for calculating the overtopping rates for both regular and irregular waves.

2. PERFORMANCE OF EXPERIMENTS

The experiments were performed in a wave basin of 18 x 45 m, equipped with a servo-hydraulic wave generator. A dike with a uniform smooth slope of 1:6 was installed (Fig. 1).

The direction of the dike relative to the wave direction was varied stepwise in the range of $\beta = 0$ (normal wave approach) and $\beta = 60^{o}$. The wave heights and periods were varied between H = approx. 5 to 15 cm and T = 1 to 3 sec., respectively. The water depth was d = 35 cm for all test runs.

For the measurements of wave run-up and down-rush effects, a video-system was used. Wave absorbing elements were installed besides the dike structure to suppress model-induced reflections.

The notations and measured quantities are shown in Fig. 2.

3. EVALUATION OF TESTS

As already mentioned, the theoretical background is based on an energy conservation concept which combines the wave parameter in front of the dike and the actual energy of the uprushing wave, and includes the influence of the respective pre-wave of a given time series of incident waves as schematically drawn in Fig. 3.

Assuming that the energy of a monochromatic wave $\tilde{E}$ available for the wave run-up can be equated with the energy E of an equivalent wave of the spectrum, the following equation results (TAUTENHAIN and KOHLHASE, 1980)

$$E_{pot_{A_n}} = 2 \cdot \psi \cdot \tilde{E}_{pot_{A_n}} - E_{pot_{A_{n-1}}} \qquad (1)$$

where A_n = wave run-up of the wave n of a time series and
A_{n-1} = run-up of the pertinent pre-wave
ψ = form parameter

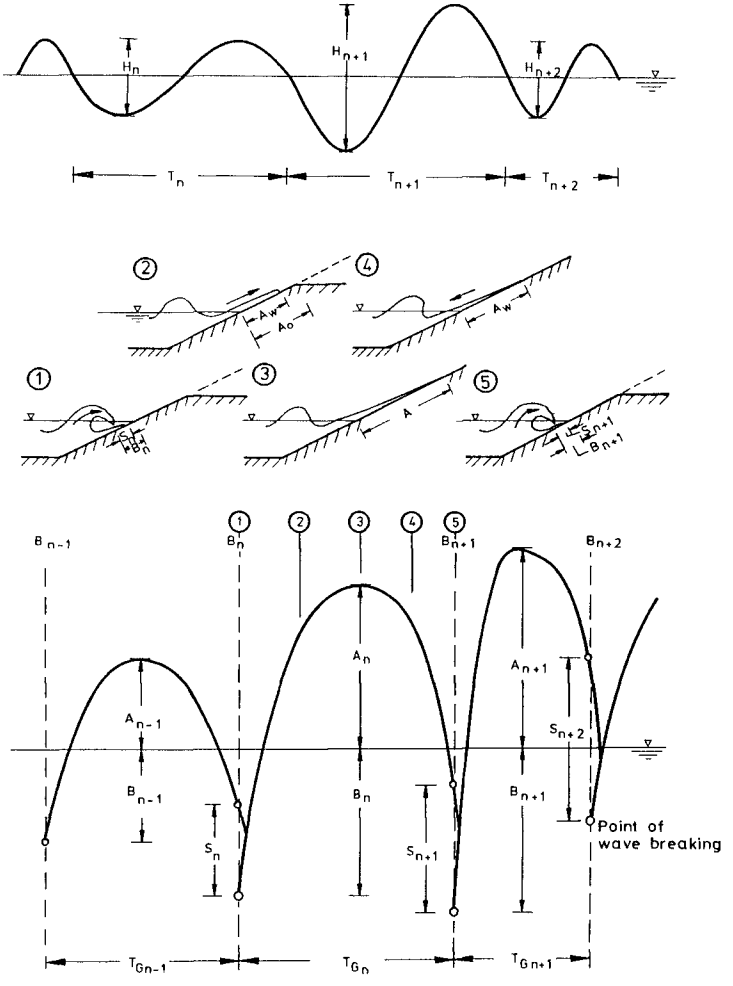

Fig. 3: Phases of wave run-up and down rush and intersections

The wave run-up A_n is given as follows

$$A_n = \tilde{A}_n \cdot \sqrt[3]{2 \cdot \psi - (\tilde{A}_{n-1}/A_n)^3} \qquad (2)$$

From two-dimensional experiments, the form parameter ψ was found (correlation coefficient, r = 0.96) to vary between $\psi = 0.63$ and $\psi = 0.73$ (average $\psi = 0.7$).

The wave run-up $\tilde{A}_n$ is given by

$$\tilde{A}_n = 1.29 \sqrt{H \cdot L_o}\ (1 - \kappa_R')/\cos\alpha \qquad (3)$$

in which κ_R' is the reflection coefficient related to the wave parameter H and L_o in front of the dike.

Equations (1) to (3) have been derived for normal wave approach and must be extended when applied to oblique wave directions.

Considering regular waves, the wave run-up $\tilde{A}_\beta$ was derived as follows

$$\tilde{A}_\beta = \tilde{A}_n \cdot \bar{k}_\beta \qquad (4)$$

where

$$k_\beta = \frac{\tilde{A}_\beta}{\tilde{A}_n} = \cos\beta \cdot \sqrt[3]{2 - \cos^3 2\beta} \qquad (5)$$

is an averaged parameter which includes both refraction and friction effects (wave breaking) as well as the angle of the down-rushing wave in relation to the up-rushing wave.

The parameter $\bar{k}_\beta$ was determined by means of comparative investigations for normal and oblique wave directions, as outlined in the following section.

4. EXPERIMENTAL VERIFICATION

The experiments were performed in two stages. In the first stage, two-dimensional tests were run because of slightly different boundary conditions and the reduced scale of the wave basin compared with previous investigations in a wave flume. The results of these experiments are plotted in Fig.4.

As may be seen in Fig. 4, the experimental results were found to comply well with the wave run-up equation (3). The observed differences of 2.6 % only were not thought to be due to model scale effects but rather to the limited number of tests.

The test results for an oblique wave approach are plotted in Fig. 5 for the measured wave directions $\beta \neq 0^\circ$. It can be readily seen that the basic equation (3) is also generally fulfilled for an oblique wave direction as indicated by the rather high correlation coefficients between the measured

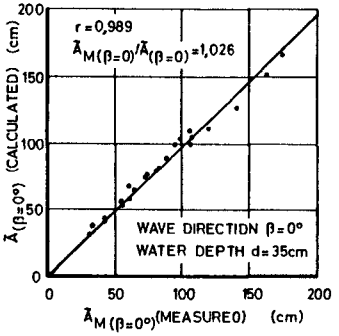

Fig. 4: Verification of equation (3) (ß = 0°)

wave run-up $\tilde{A}_M$ for ß = 0° and ß ≠ 0°, respectively. Therefore, it may be concluded that the influence of the wave direction can be generally summarized by the wave direction parameter k_β, as already illustrated. The effects of wave height and period are of lower order.

The results for all measured wave directions (regular waves) are summarized in Fig. 6.

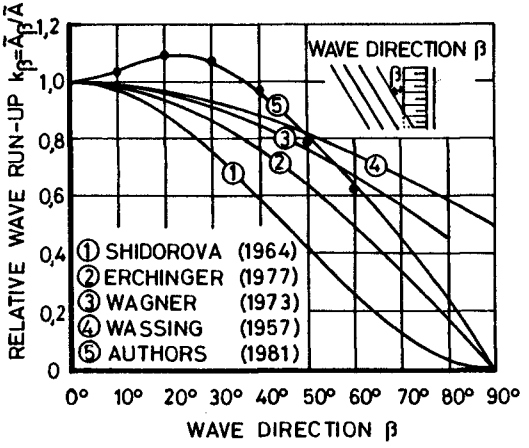

Fig. 6: Relative wave run-up. Summation of results ß ≠ 0.

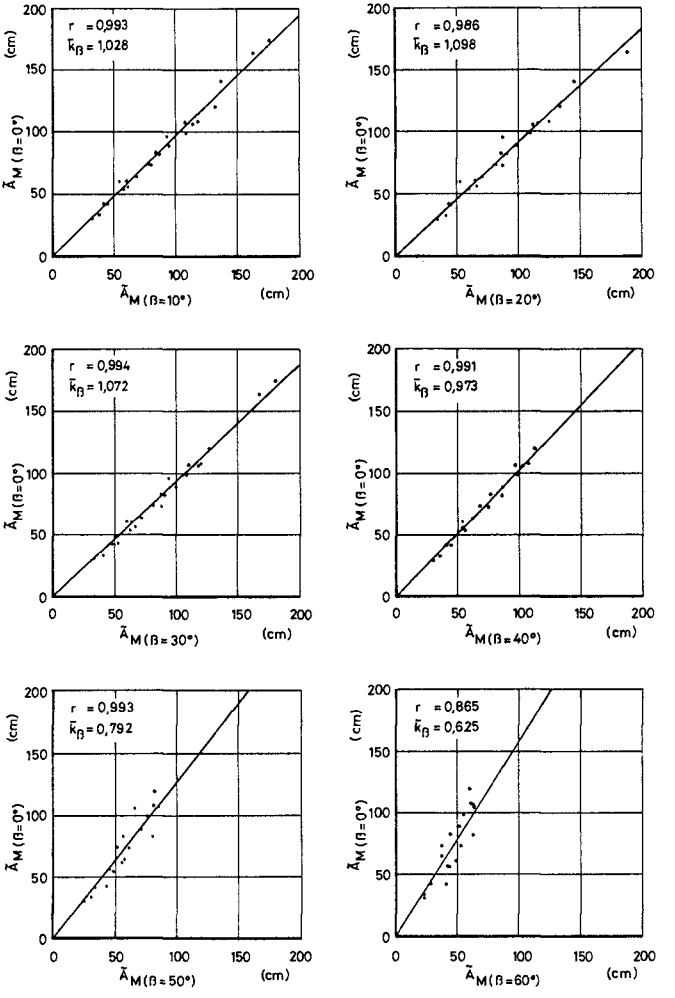

Fig. 5: Influence of wave direction on wave run-up

For the purpose of comparison, the results of a number of authors are also plotted in Fig. 6. The differences between the calculated (equ. 4) and mean measured relative run-up heights are in the order of ± 2 %, which may be neglected.

5. CONCLUSION

With respect to wave run-up at sea dikes, comparative investigations have been carried out for different angles of wave approach. The investigation has clearly shown that, in contrast to previous investigations by other authors, a remarkable increase of run-up heights compared to normal wave approach will occur for wave directions in the range of approx. $0 < \beta \leq 35^{o}$.

Since the maximum increase in comparison to normal wave approach conditions is of the order of 10 %, it is important that this effect should be considered in practice.

Water Waves Propagating on Beaches of Arbitrary Slope

by

*Y·Y. Chen** *Dr. H. H. Hwung***

ABSTRACT

When a small amplitude wave climbing along an arbitrary sloping beach from deep water toward the shore, the variation of characteristics in the process of wave motion has been described in this paper. From the results of theoretical derivation, it is found out that the variation of water surface and amplitude are function of beach slope(α) and dimensionless distance (kx) from the shore. And under the condition of the beach slope is $\alpha = 0$ and $\alpha = \infty$ that the solution will become a progressive wave and a standing wave respectively.

1. *INTRODUCTION*

Concerning the problems of water waves propagating on beaches of arbitrary slope, E.T. Hanson (1926) *assumed the angle of bottom with still water surface to be of the form $\pi/2q$ with integral q, and constructed a progressive wave derived from two standing waves. Lewy, H.* (1946) *gave a contour integral representation for a progressive wave for all angles between bottom and surface. Then, Stoker* (1947) *derived the exact linear theory and obtained approximate solution for surface waves in variable water depth. Biesel* (1952) *expressed the first-order approximation of the free surface equations and the trajectory of surface*

* *Associate Researcher of Tainan Hydraulics Laboratory National Cheng Kung University. Taiwan. R.O.C*

** *Director of Tainan Hydraulics Laboratory & Associate Professor of Hydraulic and Ocean Engineering Graduate School, National Cheng Kung University. Taiwan. R.O.C*

particle by Lagrangian form. Carrier & Greenspan (1957) *presented the explict solutions based on the non-linear shallow water theory.*

All the above investigations concentrated on the behavior of wave motion in the region near the coast, however, they didn't include the entire process of wave motion. Therefore, in this paper, the authors pay attention to the theoretical analysis on the variation of the water surface and amplitude when the water waves propagating on beaches of arbitrary slope under the condition without breaking.

2. *THEORETICAL CONSIDERATION*

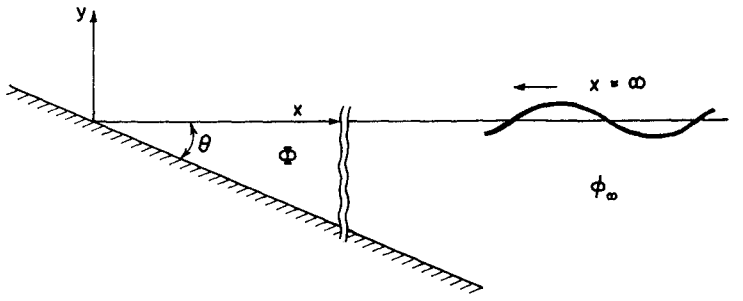

Fig. - 1

From the sketch diagram of water wave propagating from deep water toward shallow water area as shown in Fig. 1, *the governing equations of wave motion in two dimensional incompressible fluid are given by the follows:*

$$\Phi_{xx} + \Phi_{yy} = 0 \qquad \eta(x,t) \geq y \geq -h(x) \quad (1)$$

$$\Phi_t + g\eta + \frac{1}{2}(\Phi_x{}^2 + \Phi_y{}^2) = C \qquad y = \eta(x,t) \quad (2)$$

$$\Phi_y = \eta_t + \Phi_x \eta_x \qquad y = \eta(x, t) \tag{3}$$

$$\Phi_y = -h_x \Phi_x \qquad y = -h(x) \tag{4}$$

The subscripts of the above equations denote partial differentiation, and Φ *is velocity potential,* η *is water surface variation,* $h(x)$ *is water depth which can be expressed as* $h(x) = x \cdot \tan\theta = \alpha x$, *and C is Bernoulli's constant, g is gravity acceleration.*

From Cauchy's integral theorem, there is a constant M existence in the process of wave motion under the conditions without breaking. that

$$|\Phi| + |\Phi^{(n)}| < M \quad \text{for } 0 \le x \le \infty,\ \eta(x,t) \ge y \ge -h(x) \tag{5}$$

where $\Phi^{(n)}$ *denotes the* n^{th} *order's partial derivatives of* Φ *with respect to x, y or t. Furthermore, since the original source of wave motion comes from deep water, so that*

$$\lim_{x \to \infty} \Phi = \phi_\infty \tag{6}$$

According to the above consideration that seems reasonable to coincide with physical grounds and there is not any singularity taken place in the entire process of wave motion from deep water toward the shore. In the following derivation, it is convenient to express the quantities evaluated for $y = \eta(x, y)$ *by a bar, "—", over the quantity, and for* $y = -h(x)$ *by a bar under the quantity. Thus we have*

$$\int_{-h(x)}^{\eta(x,t)} \Phi_{yy}\, dy = \overline{\Phi_y} - \underline{\Phi_y} = \overline{\Phi_y} + h_x \underline{\Phi_x} \tag{7}$$

and

$$\int_{-h(x)}^{\eta(x,t)} \Phi_{yy}\, dy = -\int_{-h(x)}^{\eta(x,t)} \Phi_{xx}\, dy = -\frac{\partial}{\partial x} \int_{-h(x)}^{\eta(x,t)} \Phi_x\, dy + \overline{\Phi_x}\, \eta_x + \underline{\Phi_x}\, h_x \tag{8}$$

From eq. (7) and eq. (8), we get

$$\overline{\Phi}_y = -\frac{\partial}{\partial x}\int_{-h(x)}^{\eta(x,t)} \Phi_x dy + \overline{\Phi}_x \eta_x \tag{9}$$

Then the integral term of eq. (9) will be the following relation through integration by parts

$$\int_{-h(x)}^{\eta(x,t)} \Phi_x dy = \eta \overline{\Phi}_x + h \underline{\Phi}_x - \int_{-h(x)}^{\eta(x,t)} y \Phi_{xy} dy \tag{10}$$

and also the relation will be as

$$\int_{-h(x)}^{\eta(x,t)} h(x)\Phi_{xy}\, dy = h(x)\overline{\Phi}_x - h(x)\underline{\Phi}_x \tag{11}$$

Eliminating $\underline{\Phi}_x$ from eq. (10) and eq. (11), and this in turn lead through use of eq. (9) to

$$\begin{aligned}\overline{\Phi}_y &= -\frac{\partial}{\partial x}\left[h(x)\overline{\Phi}_x - \int_{-h(x)}^{\eta(x,t)} (y+h)\Phi_{xy} dy \right] + \eta_x \Phi_x - \frac{\partial}{\partial x}(\eta \overline{\Phi}_x) \\ &= -(h\overline{\Phi}_x)_x + \frac{\partial}{\partial x}\int_{-h(x)}^{\eta(x,t)} (y+h)\Phi_{xy} dy - \eta \overline{\Phi}_{xx}\end{aligned} \tag{12}$$

From the kinematic condition at free surface of eq. (2), taking the partial derivative with respect to t, so that

$$\eta_t = -\frac{1}{g}\left[\overline{\Phi}_{tt} + \left(\overline{\Phi}_x \overline{\Phi}_{xt} + \overline{\Phi}_y \overline{\Phi}_{yt} \right) \right] \tag{13}$$

Then substituting eq. (13) into eq. (3), we get

$$\overline{\Phi}_y = -\frac{1}{g}\left[\overline{\Phi}_{tt} + \left(\overline{\Phi}_x \overline{\Phi}_{xt} + \overline{\Phi}_y \overline{\Phi}_{yt} \right) \right] + \overline{\Phi}_x \eta_x \tag{14}$$

Thus, from eq. (12) and eq. (14), we have

$$\overline{\Phi}_{tt} = (gh\overline{\Phi}_x)_x - (\overline{\Phi}_x\overline{\Phi}_{xt} + \overline{\Phi}_y\overline{\Phi}_{yt}) - g\left\{\frac{\partial}{\partial x}\int_{-h(x)}^{\eta(x,t)} (y+h)\Phi_{xy}dy\right\} + g(\eta\Phi_x)_x \tag{15}$$

Up to now we have made no assumptions in addition to those made in deriving the non — linear theory. In other words, water waves propagating along an arbitrary sloping beach will be described completely in eq. (15). *Unfortunately, since eq.* (15) *is a high order non — linear partial differential equation, so that analytical solution is not able to be obtained and the approximate solution will be presented in this paper.*

From eq. (6), *we know that wave motion propagating along an arbitrary sloping beach comes from deep water. Accordingly, it is reasonable to imagine that the velocity potential in deep water,* ϕ_∞, *is part of wave motion in the propagating process. In this case, the velocity potential would be proposed by the following form,*

$$\Phi = \phi + \phi_\infty \tag{16}$$

The above equation makes a brief statement that the velocity potential, Φ, *existed in the propagating process is consisted of the velocity potential in deep water,* ϕ_∞, *and the velocity potential due to shoaling and reflection,* ϕ, .

After susbstituting ϕ_∞ *into the last three terms of the right side of eq.* (15), *then the first — order approximation of wave motion will be given as*

$$\overline{\Phi}_{tt} = (gh\overline{\Phi}_x)_x - \left[(\overline{\phi}_\infty)_x(\overline{\phi}_\infty)_{xt} + (\overline{\phi}_\infty)_y(\overline{\phi}_\infty)_{yt}\right] - g\left\{\frac{\partial}{\partial x}\int_{-h(x)}^{\eta(x,t)} (y+h)(\phi_\infty)_{xy}dy\right\} + g\left[\eta(\overline{\phi}_\infty)_x\right]_x \tag{17}$$

Furthermore, expanding the integral term of eq. (17) *and from the*

condition that ϕ_∞ substituted in eq. (14), we have

$$\overline{\Phi}_{tt} = (g h \overline{\Phi}_x)_x - [g h (\overline{\phi}_\infty)_x]_x + (\overline{\phi}_\infty)_{tt} \tag{18}$$

Because ϕ_∞ is part of Φ, we know that ϕ_∞ is a particular integral of wave motion. In other wordes, eq. (18) involves a particular solution and a complementary function which will satisfy the following homogeneous equation.

$$\overline{\Phi}_{tt} = (g h \overline{\Phi}_x)_x \tag{19}$$

Since the complementary function is due to shoaling and reflection of sloping bottom boundary, that the velocity potential at water surface is well to be proposed as the following form.

$$\phi = e^{i(kx-\sigma t+\epsilon)} Z(x) \tag{20}$$

where the exponential in eq. (20) represents the factor due to reflection, k and σ are wave number and angular frequency in deep water respectively, ϵ is the change in phasse as wave climbing along beach. $Z(x)$ is the function of water surface elevation resulted from shoaling and reflection.

After substituting eq. (20) into eq. (19), and taking real part, that it is easy to transform the result into zero order of Bessel function. And the solution will be given as

$$Z(x) = A J_0 \left(2 \sqrt{\frac{k x}{\alpha}} \right) \tag{21}$$

where J_0 is the Bessel function of the first kind of order zero, and A is a function of α, which has to be determined by an appropriate condition. Therefore, the velocity potential due to shoaling and reflection will be

$$\overline{\phi} = A J_0 \left(2 \sqrt{\frac{k x}{\alpha}} \right) \cos (kx - \sigma t + \epsilon) \tag{22}$$

Then the solution of wave motion can be expressed as

$$\overline{\Phi}=\overline{\phi}+\overline{\phi}_{\infty}=-\frac{gA_0}{\sigma}J_0\left(2\sqrt{\frac{kx}{\sigma}}\right)\cos(kx-\sigma t+\epsilon)+\frac{ag}{\sigma}\cos(kx+\sigma t) \tag{23}$$

The last term of the above equation is the solution of progressive small amplitude wave at water surface, and a is the amplitude, A is to be of $A_0=-\frac{\sigma}{g}A$ 。

From the theory of reflection as light—wave, the change of phase, ϵ *, is function of bottom slope,* α *, will be found out, as*

$$\epsilon=\epsilon(\alpha)=2\tan^{-1}\alpha \tag{24}$$

Combining eq. (23) *and eq.* (24) *then substituting in eq.*(2)*, and take the first — order approximation that we have the water surface elevation*

$$\eta(x,t)=A_0J_0\left(2\sqrt{\frac{kx}{\sigma}}\right)\sin(kx-\sigma t+2\tan^{-1}\alpha)+a\sin(kx+\sigma t) \tag{25}$$

Based on the energy conservation at the intersecting point of mean water level and bottom boundary, where the potential energy exists only, that we find

$$A_0(\alpha)=a\left[\cos(2\tan^{-1}\alpha)+\sqrt{\cos^2(2\tan^{-1}\alpha)+3}\right] \tag{26}$$

The relationship between A_0 *and* α *has been shown in Fig.* — 2 *From this figure, it illustrates that* A_0 *decreases with* α *increases, and as* $\alpha=\infty$ *, it becomes standing wave,* $\alpha=0$ *that it will be a progressive wave.*

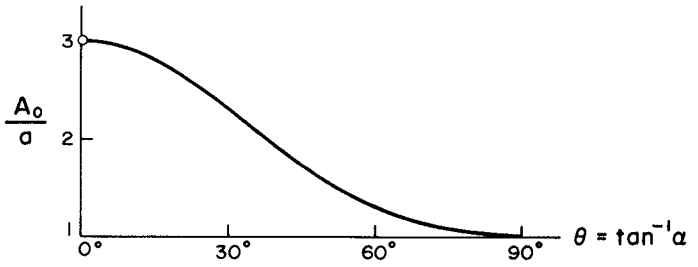

Fig. – 2

After substituting eq. (26) into eq. (25), the water surface elevation, $\eta(x, t)$, will be obtained. There are three examples presented through Fig. – 3 to Fig. – 5

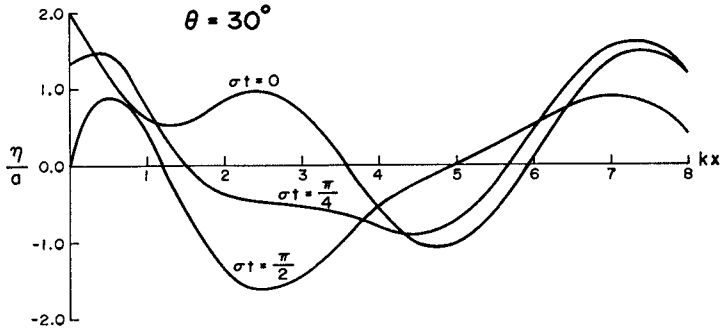

Fig. – 3

Furthermore, arrange the result of the expansion of eq. (25), that the relationship among water surface elevation, wave amplitude, wave number, bottom slope and dimensionless distance can also be expressed as the following forms,

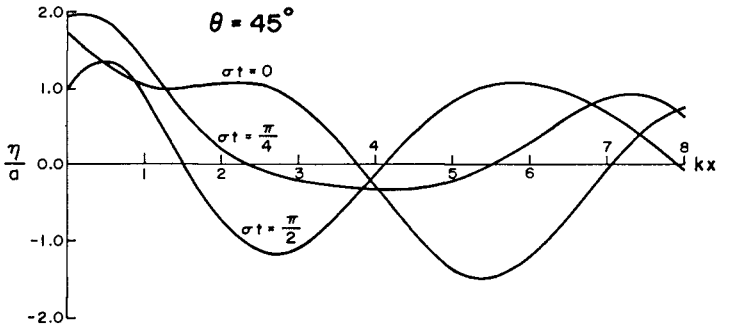

Fig. – 4

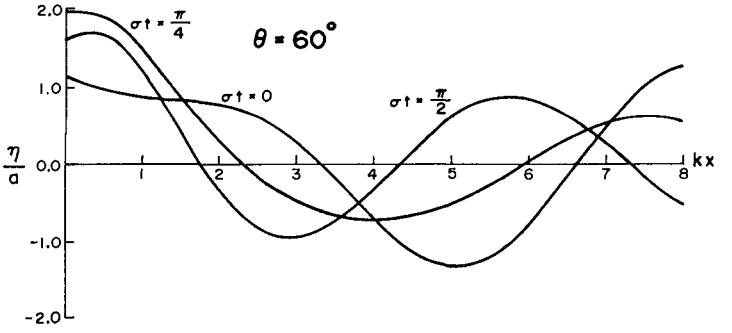

Fig. – 5

$$\eta(x,t)=\left[A_0J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\sin(kx+\epsilon)+a\sin kx\right]\cos\sigma t$$

$$+\left[a\cos kx-A_0J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\cos(kx+\epsilon)\right]\sin\sigma t$$

$$=B(x,\alpha)\sin\left[m(x,\alpha)\cdot x+\sigma t\right] \tag{27}$$

and

$$B(x,\alpha)=\left\{\left[a\sin kx+A_0J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\sin(kx+\epsilon)\right]^2\right.$$

$$+\left\{ a\cos kx - A_0 J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\cos(kx+\epsilon)\right\}^2\Big\}^{1/2} \tag{28}$$

$$m(x,\alpha) = \left[\tan^{-1}\left\{\frac{a\sin kx + A_0 J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\sin(kx+\epsilon)}{a\cos kx - A_0 J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\cos(kx+\epsilon)}\right\} + n\pi\right]/x \tag{29}$$

where n is a positive integer.

From the expression of eq. (27), the amplitude of wave motion climbing along an arbitrary sloping beach has been abtained as eq. (28) and it is function of the dimensionless distance kx and bottom slope α. That is to say, the amplitude varies along the horizontal distance due to shoaling and reflection as water waves propagate from deep water toward the shore. Several illustrations have been presented in Fig. – 6 for $\alpha = 0$, $1/\sqrt{3}$, 1 , $\sqrt{3}$ *and* ∞

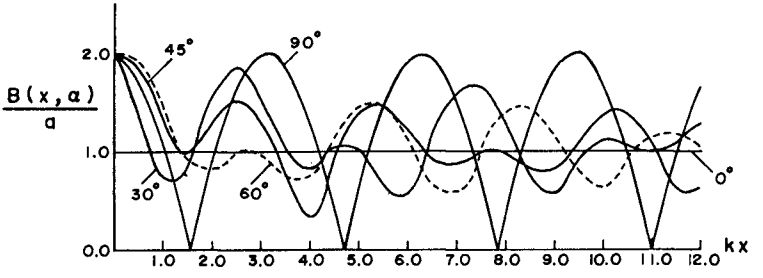

Fig. – 6

Figure – 6 illustrates the solutions for the bottom slope 0° , 30° , 45° , 60° *and* 90° *according to eq. (28). And we can see that all the variation of water surface will gradually decrease and become small amplitude wave in deep water except for the case of,* $\theta = 90°$ *, under that condition , it becomes a standing*

wave.

3. *DINCUSSION AND CONCLUSION*

From the theoretical results as above metioned that the variation of water surface and amplitute are function of beach slope and dimensionless distance from the shore. And the results will be more reasonable than Stokers' (1947) *which is expressed in eq.* (30)

$$\bar{\Phi}(x,t) = A_1\left[\cos(\sigma t-\epsilon_1)Y_0\left(2\sqrt{\frac{kx}{\alpha}}\right) + \sin(\sigma t-\epsilon_1)J_0\left(2\sqrt{\frac{kx}{\alpha}}\right)\right] \tag{30}$$

where A_1 , ϵ_1 *are the same significance as in this paper. But Stoker's solution, because contains only the linear terms so that the solution for the deep water becomes a straight line. Our solution, on the other hand, give a more reasonable solution which is a small amplitude wave when we include the potential function in deep water.*

EXAMPLES OF STORM SURCE PREDICTION MODELS

by
P. Lencioni[1] - J.P. Benqué[2] - Y. Coëffé[3]

ABSTRACT

For a given site, deterministic models may be applied to predict the tide level with a rather good accuracy. However, a difference is observed between the observed and predicted tide level under storm condition. This difference is called storm surge. Two different storm surges prediction models are presented for the site of Le Havre : an autoregressive model ; a model using wind and pressure local data.

The autoregressive model can be used for a prediction 5 hours in advance. The availability of accurate wind and pressure predictions by the Meteorological Service of Le Havre within 36 hours in advance makes the use of the second model of great interest because it provides the possibility of predictions within 39 hours in advance.

1. INTRODUCTION

For a given site, deterministic models based on harmonic analysis may be applied to predict the tide levels with a rather good accuracy. However, differences are observed between the real and predicted tide levels under storm conditions. These differences are called storm surges (fig. 1).

In many cases, prevision of theoretical tide levels is not sufficient and it is very useful to know the possible storm surges. For instance, in coastal projects, the design of structures is often influenced by the largest storm surges possible. In that case, exceptionnal storm surges associated with a prescribed risk level are needed. On another side it is also useful to predict storm surges a few hours in advance, either for navigation aid, or to protect coastal work in progress.

1 REP-EDF, Principal engineer, Nuclear Safety Service, France
2 LNH-EDF Chatou, Head of Department "Laboratoire National d'Hydraulique, France
3 LNH-EDF Chatou, Head of Maritime Hydraulic Division, France.

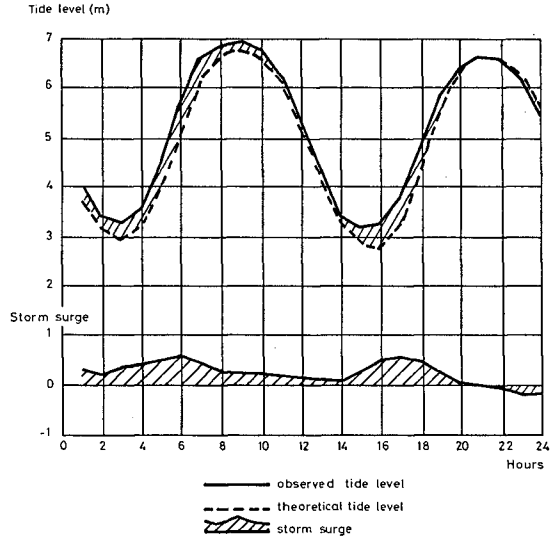

Fig. 1. DEFINITION OF A STORM SURGE

The present study is specially devoted to this second kind of prediction models, applied to the site of Le Havre (harbour of the Seine Estuary), but results obtained may be also used to predict exceptionnal storm surges by the mean of simulation.

The following steps of the study are described :

- analysis of storm surges, from the tide levels observed every hour on the site of Le Havre, from January 1976 to June 1978,
- elaboration of two storm surges prediction models :
  . an autoregressive model, where the storm surge at the time $t + k$ t is estimated knowing storm surges until the time t,
  . a model using wind and pressure local data, these variables being available from Meteorological Services with 36 hours prediction.

2. ANALYSIS OF STORM SURGES RECORDED AT LE HAVRE

Storm surge is the algebraic difference between the real and predicted tide levels. The analyzed data set of storm surges resulted from tide levels recorded, every one hour, at Le Havre harbour from the 1/1/1976 to the 30/6/1978 and tide levels predicted by the S.H.O.M. (Marine Hydrological and Oceanographical Service), giving 21 888 values.

Graphic examination of storm surges and corresponding wind and pressure data, give the main tendancies of the phenomenon (fig. 2).

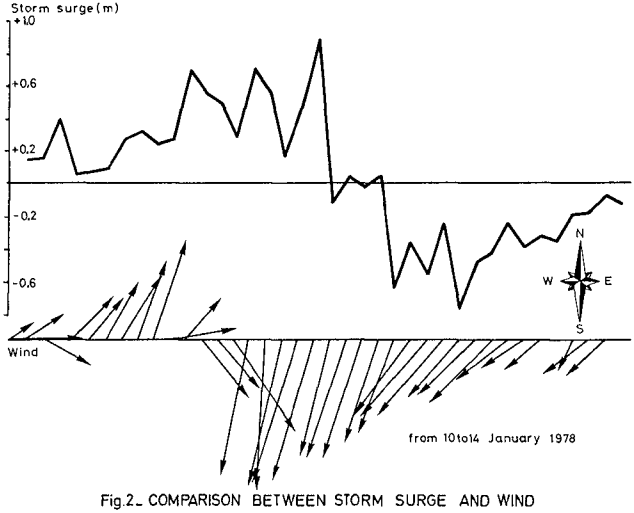

Fig.2_ COMPARISON BETWEEN STORM SURGE AND WIND

A quiet meteorological situation induces low storm surges. A low pressure and a strong intensity of wind raises high positive storm surges, with a 12 hours period (tide cycle). The maximum of the storm surge is generally situated around mean water level showing that the effect on tide may be seen as an increase (or decrease of mean water level) and a phase shift of the theoretical tide. To a high pressure corresponds negative storm surge.

Spectral analysis and autocorrelation functions of these storm surges (fig. 3 & 4) confirm the 12 hours period. Moreover three scales of time appear from the spectral analysis (6 hours, 12 hours and period greater than 24 hours). Autocorrelation functions show the high correlation between two values of storm surges separated by a short interval of time ; this is at origin of autoregressive model.

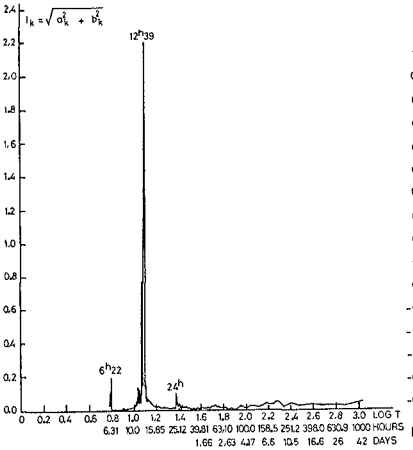

Fig.3_ SPECTRAL ANALYSIS OF STORM SURGES

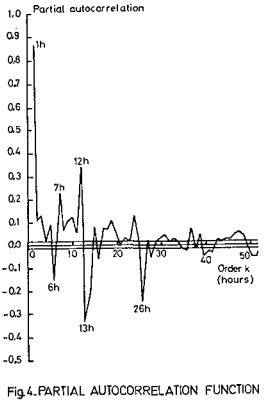

Fig.4_PARTIAL AUTOCORRELATION FUNCTION

3. AUTORECRESSIVE MODELS

In autoregressive models the storm surge at the time t + k Δt is estimated knowing storm surges until the time t. The examination of autocorrelation function and partial autocorrelation allowed to retain the following regressive models :

$$\hat{S}\ (t + k\Delta t) = C_o\ (k\Delta t) + C_1\ (k\Delta t)\ S\ (t + k\Delta t - 12) + C_2\ (k\Delta t)\ S\ (t) \qquad (1)$$

where

$\hat{S}$ predicted storm surge

S observed storm surge

kΔt prediction time (1 to 12 hours)

C_i model coefficient, function of kΔt, estimated from the totality of available observations (January 1976 to June 1978, 21 900 values), by least square method.

The multi correlation coefficient decreases when kΔt increases. Four values of kΔt were tried, respectively 1, 3, 6 and 12 hours. Multi correlation coefficients range between 0,89 with a 1 hour prediction and 0,68 with a 12 hours prediction.

The introduction of a Kalman filter was tried in this autoregressive model but did not give any better short term prediction.

Interest of Kalman filter is to use the last available observation to put model parameters straight. But autoregressive models also take into account this information and this can explain that for a short-range forecast model, Kalman filter does not improve results.

With or without Kalman filter multi correlation coefficient with a 1 hour prediction is 0,89. In 95 cases on 100, prediction error is ± 0,15 m. Figure 5 give a comparison between observed storm surges and predicted storm surges obtained by the autoregressive model with a 1 hour prediction.

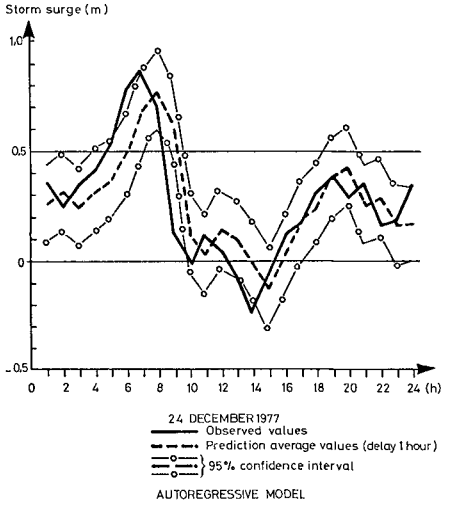

Fig.5- COMPARISON BETWEN OBSERVED AND PREDICTED STORM SURGES

4. MODEL USING WIND AND PRESSURE LOCAL DATA

Previous models cannot be really used with a prediction period greater than 12 hours.

A data analysis has shown that wind and local pressure data are able to explain the storm surges. The main interest to predict storm surges using these meteorological factors is that these variables can be given by Meteorological Services with a 36 hours prediction. Models based on wind and pressure data were then developped.

Spectral analysis of storm surges, pressure and wind at Le Havre was made. We considered the two components of wind, projected on rectangular axis ; E-W - 30° and N-S - 30°, these directions allowing the best correlation between wind and storm surge.

In this prediction model, the storm surge S has been splitted in 3 parts, according to spectral analysis and graphic examination of storm surges and concomitant meteorological data

$$S = S_1 + S_2 + S_3$$

S storm surge
S_1 storm surge corresponding to periods greater than 24 hours highly depending on recent meteorological events (wind, pressure)
S_2 storm surge corresponding to periods between 6 and 24 hours corresponding to tide periodicity. This cycle comes from a phase shift on tide theoretical cycle induced under some meteorological conditions (low pressure)
S_3 storm surge corresponding to periods smaller than 6 hours.

Standard deviations are respectively :
$\sigma(S) = 0,17$ m
$\sigma(S_1) = 0,14$ m $\quad \sigma(S_2) = 0,08$ m and $\sigma(S_3) = 0,05$ m

the most important part comes from S_1.

Each component is separatedly examined.

4.1. Component S_1 (period greater than 24 hours)

For a given class of wind direction, S_1 is computed from wind intensity and pressure by the following regression model :

$$\hat{S}_1(t) = a_o(\alpha) + a_1(\alpha)\, V(t-3) + a_2(\alpha)\, V^2(t-3) + a^3(\alpha)\, P(t-3) \qquad (2)$$

where :

α wind direction (18 classes of 20°)
$V(t-3)$ wind mean intensity at the time $t - 3$ hours
$P(t-3)$ pressure at the time $t - 3$ hours, zero pressure level corresponding to 1 013 mbars
a_i model coefficients, functions of wind direction.

The mean wind is determinated on 12 hours ; the two mean components EW and NS are computed as :

$$\bar{V}_{EW} = \frac{1}{5} \sum_{j=-2}^{2} V_{i-j} \cos \alpha_{i-j}$$

$$\bar{V}_{NS} = \frac{1}{5} \sum_{j=-2}^{2} V_{i-j} \sin \alpha_{i-j}$$

and the wind mean intensity

$$V(t) = \sqrt{\bar{V}^2_{EW} + \bar{V}^2_{NS}}$$

and its direction

$$\alpha(t) = \text{arc tg} \frac{\bar{V}_{NS}}{\bar{V}_{EW}}$$

Correlation coefficients between S_1 and P are highly significant and negative (this means S_1 increases while pressure decreases). Wind introduction allows increasing of multiple correlation coefficients.

Residue values, difference between real and estimated values of S_1 are biassed so that the model overvalues S_1 if S_1 is small and undervalues S_1 if S_1 is great. This is corrected by an empirical factor C

$$S = \hat{S}_1 + C$$

where :

$\hat{S}_1$ is given by regression model (2)

$C = 0,1\ (\sqrt{1 + 5\ \hat{S}_1} - 1)$ if $\hat{S}_1 > - 0,2$ m

$C = 0,1$ if $\hat{S}_1 < - 0,2$ m

In 95 cases on 100, the real value S_1 appears to be in the range of predicted $S_1 \pm 0,18$ m.

4.2. Component S_2 (periods between 6 and 24 hours)

Modelisation of S_2 is based on the time phase shift observed between real and predicted tide levels which can be detected from the presence in storm surges evolution of the tide periodicity. That induced cycle has zero value at high and low tide, extremum occuring during increasing or decreasing tide level.

This shape of the cycle of S_2 is confirmed if we consider the average of S_2 during a tide cycle in function of the pressure level (see fig. 6).

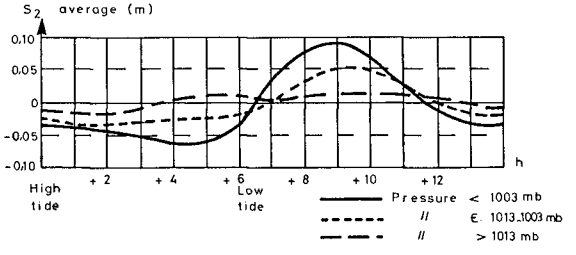

Fig.6. AVERAGE CYCLE OF S_2 FUNCTION OF THE PRESSURE LEVEL

Cycle is especially important for low pressures ; in opposite when pressure is greater than 1 013 mb, average of S_2 has pratically zero values.

The amplitude A of this cycle is computed in function of the pressure level, according to 3 classes, by the following relations :

. Low pressure $P < 1\ 003$ mb
the amplitude A is function of mean wind (V_M, α_M), as previously defined

$$A = 0,153 + 0,014\ V_M \cos \alpha_M$$

however if $A < 0,15$ m $\quad A = 0,15$ m

. Mean pressure $1\ 003 < P < 1\ 013$ mb
the amplitude A is constant $\quad A = 0,14$ m

. High pressure $\quad P > 1\ 013$ mb
in this case $S_2 = 0$

4.3. Component S_3 (periods smaller than 6 hours)

S_3 represents a white noise which is difficult to explain from wind and pressure, though its variability must be function of wind.

S_3 has been neglected in prediction.

4.4. Results

From comparison between real and predicted storm surges at the same time we can say, in 95 cases on 100, prediction error is :

$\pm$ 0,20 m if storm surge value is smaller than 0,20 m
$\pm$ 0,30 m if " " " " greater " "

Storm surges range being included between - 0,50 m and 1 m, this error can appear important, but evolution in the course of time is well reproduced (fig. 7).

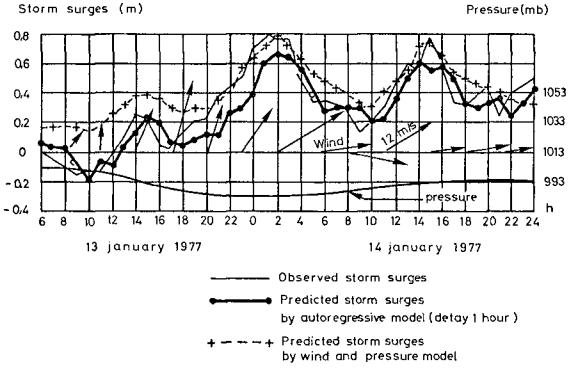

Fig.7. COMPARISON BETWEEN OBSERVED AND PREDICTED STORM SURGES

This model predict storm surges at the instant t, knowing pressure and wind (intensity and direction computed over 12 hours) at the instant t - 3 h. Correlation coefficient between observation and the 3 hours prediction is 0,75, slightly smaller than the value obtained by autoregressive model.

For the case where only storm surge prediction corresponding to high or low tide is needed, component S_1 gives directly the prediction of storm surge. In that case prediction error is limited to $\pm$ 0,18 m for 95 cases over 100.

It must be noticed that knowing a large sample of wind and pressures, it is possible, using this kind of model, to generate storm surges values which allow to predict exceptionnal storm surges of low probability.

5. CONCLUSION

The present study has shown that in the case of Le Havre an autoregressive model can be used for a prediction up to 5 hours in advance with a reasonable accuracy. For a more extended forecast, it is better to use models based on meteorology. The availability of accurate wind and pressure predictions by Meteorological Services of Le Havre within 36 hours in advance makes the use of the second model of great interest as it provides the possibility of prediction within 39 hours in advance.

When the interest is restricted to storm surges predictions high and low tides, the model based on meteorology appears to be especially easy to handle and reasonably accurate.

However, it is clear that local wind and pressure data are not enough to explain the totality of some storm surges. Such occurences cannot be predicted without knowing more on the interaction between large scale meteorological patterns and the tide propagation over the domain of interest.

This problem will be investigated by using a tide propagation deterministic model of the whole English channel, based on Saint-Venant equations. The results of interaction between typical meteorological patterns and the tide propagation should lead to a deeper understanding of the physical phenomena involved and allow the choice of adequate parameters for future prediction models.

WATERWAVES CALCULATION BY NAVIER-STOKES EQUATIONS

by O. DAUBERT*, A. HAUGUEL** and J. CAHOUET***

Abstract : N.S.L. program is a finite-difference code for two-dimensionnal flows with a free surface in a vertical plane. Basic equations are Navier-Stokes équations with a simple simulation of turbulent effects by an eddy viscosity coefficient related to the mixing length and the mean velocity gradient. Theses equations are solved in a variable domain in time. The main features of the numerical method are presented. Some comparisons with theoretical solutions give a good validation of the code both in linear and non linear cases. Other examples of application are given.

1. INTRODUCTION

Large computational programs, solving time-dependant Navier-Stokes equations, in two and even three space dimensions, are now well developped for industrial design. Their adaptation to waves problems should be a new and powerful mean of investigation in theoretical and practical studies, because non linear and viscous effects are taken into account.

The N.S.L. program "Navier-Stokes à Surface Libre" presented here, is a first step to this ambitious objective. It solves numerically N.S. equations in a vertical plane - i.e. only for two-dimensionnal flows - with a free surface. The free surface is a moving boundary for the computational domain, and is also an unknown of the problem. Time-varying pressure and velocity fields are the other results of this program for suitable initial and boundary conditions, and any given bottom shape. In order to give a more pratical background to the study, N.S.L. program can be considered as a "numerical wave flume". It allows simulation of all sorts of waves, in deep or in shallow water, with small or large amplitude, except perhaps breaking ones.

** Head of the Research Division, Laboratoire National d'Hydraulique, France.

*** Assistant Engineer, Research Division, Laboratoire National d'Hydraulique, France.

2. MATHEMATICAL FORMULATION

2.1. General equations :

In the fluid, velocities and pressure are related by dynamical and continuity equations :

$$(1)\quad \frac{DV}{Dt} + \frac{1}{\rho}\nabla p^* = \mathrm{Div}\ (\nu_T \nabla V)$$

$$(2)\quad \mathrm{Div}\ V = 0 \qquad\qquad (p^* = p + gz)$$

The turbulent viscosity coefficient, is given empirically by :

$$(3)\quad \nu_T = \nu + K^2 \ell^2\ (2\ \mathrm{Dij.Dij})^{1/2}$$

with $\mathrm{Dij} = \frac{1}{2}\ (V_{i,\,j} + V_{j,\,i})$

The mixing length l is constant in the fluid except near the bottom, where l is proportionnal to the distance from the bottom.

2.2. Computational domain and boundary conditions

They are summarized on figure 1.

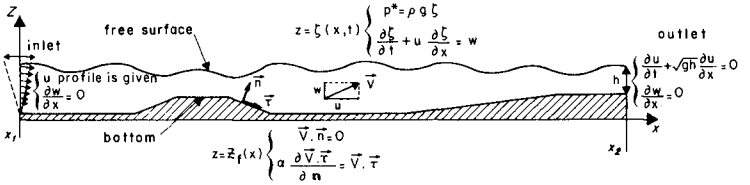

Figure 1 - Boundary conditions - Left b.c. simulates a wave- machine (e.g. $U = U_0(z)\ \sin \omega t$) - Right b.c. is absorbing if h is small enough to eliminate dispersive phenomena. On the bottom, the second b.c. simulates a tangential stress in a boundary layer.

2.2.1. Sea surface boundary conditions :

The second relation, shown in figure 1, is a partial differential equation which can be used for the free surface determination. It must be solved along the whole ζ -line, with its own boundary conditions. These ζ -boundary conditions, in $x = x_1$ and $x = x_2$, can be deduced from the u-ones, by using the horizontal projection of eq. (1), and the surface relation : $p^* = \rho g \zeta$.

$$(4)\quad \frac{\partial \zeta}{\partial x} = \frac{1}{\rho g}\frac{\partial p^*}{\partial x} = -\frac{1}{g}\left(\frac{Du}{Dt} - \mathrm{Div}\ (\nu_T \nabla u)\right) \simeq -\frac{1}{g}\frac{Du}{Dt}$$

Theoretically, another boundary condition is required, along the free surface, in order to well pose the problem - a zero tangential stress, for instance-. But this point is ignored in the present, because viscous terms are almost vanishing near the free surface, as long as wind effects are not studied.

2.2.2. Bottom boundary conditions :

The first one traduces the impermeability of a fixed bottom. The second one comes from the idea that the tangential stress

$$(5)\quad \rho \nu_T \frac{\partial(\vec{V}.\vec{\tau})}{\partial n} = \rho u_*^2$$

is prescribed. Its value is calculated by doing the hypothesis that the velocity profile, near the bottom, follows a logarithmic law, for instance :

$$(6)\quad \vec{V}.\vec{\tau} = u_* \left(\frac{1}{K} \text{Log} \frac{y}{d} + 8.5\right)$$

where y is the distance from the bottom.

As ν_T, near the bottom, reduces to

$$(7)\quad \nu_T \simeq K^2 y^2 \frac{\partial \vec{V}.\vec{\tau}}{\partial n}$$

one has, by elimination of u_*, a relation of the form

$$(8)\quad \alpha \frac{\partial \vec{V}.\vec{\tau}}{\partial n} = \vec{V}.\vec{\tau}$$

2.2.3. Lateral boundary conditions :

These conditions are fitted to wave flume simulation : the left one simulates a wave machine and the right one, allows the waves to get out without reflection. The absorbing boundary condition :

$$(9)\quad \frac{\partial u}{\partial t} + c \frac{\partial u}{\partial x} = 0$$

must be used in a shallow water situation. In dispersive waves, the celerity c depends on the wave length. It is thus necessary, for irregular waves, to reduce the depth with a mild slope, in order to have only shallow water waves at the boundary, and then a unique celerity $c = \sqrt{gh}$.

3. NUMERICAL METHOD

3.1 Coordinate transformation

Before solving numerically the system (1) (2) and its boundary conditions, a coordinate transformation is done :

$$(10) \qquad \begin{cases} \xi = x \\ \eta = H\ (z - Z_f(x))/(\zeta\ (x,t) - Z_f(x)) \end{cases}$$

This transformation maps the physical variable domain in a fixed one, with boundaries parallel to the coordinate-axis (figure 2).

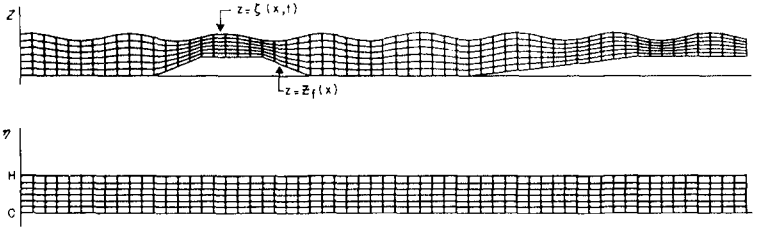

Figure 2 - The semi-curvilinear grid, transformed in a rectilinear one by the transformation : $\eta = H(z-Z_f/(\zeta - Z_f)$.

Equations and boundary conditions are expressed in the new independant variables (ξ, η, t).
Calculations are performed on the transformed domain, by solving a finite difference approximation of the transformed equations. These involve, in each derivative, one of the following factors :

$$(11) \qquad \eta_x = -\ (H\ Zf_x + \ (\zeta_x - Zf_x))/(\zeta - Z_f)$$

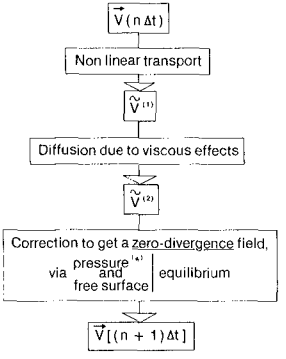
$$(12) \qquad \eta_z = H/(\zeta - Z_f)$$

$$(13) \qquad \eta_t = -\eta\zeta_t/(\zeta - Z_f)$$

which vary in time (due to the free surface motion) and are evaluated at each time step.

3.2. Algorithm of a time step

A fractionary step method is used [1]. This method is illustrated by the following scheme :



Each time step is splitted in three parts which are solved successively ; the velocity field $V^n = V(n\,\Delta t)$, being known at time $n\,\Delta t$, intermediate fields $\tilde{V}(1)$ and $\tilde{V}(2)$ are computed verifying respectively :
- a transport equation solved by the Characteristics method.

$$(14) \qquad \frac{\tilde{V}(1) - V^n}{\Delta t} + V^n \otimes \nabla V^n = 0$$

- and a diffusion equation solved by an explicit method

$$(15) \qquad \frac{\tilde{V}(2) - \tilde{V}(1)}{\Delta t} - \mathrm{Div}\,(\nu_T \nabla \tilde{V}^{(1)}) = 0$$

The definitive, zero-divergence velocity field, at time $(n+1)\,\Delta t$, V^{n+1}, is calculated via a pressure and free surface equilibrium, which is expressed by the following system of equations :

$$(16) \qquad \frac{V^{n+1} - \tilde{V}(2)}{\Delta t} + \frac{1}{\rho} \nabla p^* = 0$$

$$(17) \qquad \mathrm{Div}\, V^{n+1} = 0$$

in the domain

$$(18) \qquad p^* = \rho g \zeta$$

$$(19) \qquad \frac{\partial \zeta}{\partial t} + u^{n+1} \frac{\partial \zeta}{\partial x} = w^{n+1}$$

on the free surface

Elimination of V^{n+1} between (16) and (17), give a Poisson equation for pressure

$$(20) \qquad \Delta p^* = \frac{\rho}{\Delta t} \mathrm{Div}\, \tilde{V}^{(2)}$$

This equation is solved with Neumann boundary conditions, derived from the normal projection of equation (16), in which V(n+1).n is known, on the bottom and on lateral boundaries. On the free surface, p* verify the Dirichlet boundary condition (18). As ζ is related to V(n+1) by eq. (19), the system (16) to (19) is solved iteratively.
Discretisations, in space and time which are not specified in the formulas (14) to (19), are performed in a staggered grid, as shown in figure 3.

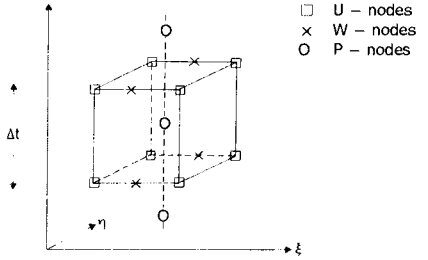


Figure 3 - Numerical staggered grid, in space and time.

Pressure nodes, on this figure, are drawn on three time levels to indicate that, in equation (16), the pressure gradient is splitted on three time steps ; let us write p^* without star :

$$(21) \quad \nabla p \simeq \alpha \nabla p^{n+\frac{3}{2}} + \beta \nabla p^{n+\frac{1}{2}} + \gamma \nabla p^{n-\frac{1}{2}}$$

$$\alpha + \beta + \gamma = 1$$

Wheighting coefficients α, β, γ are choosen as close as possible to 1/4, 1/2, 1/4 respectively ; nevertheless, α must be slightly greater than γ, in order to insure the stability of the numerical scheme(*). Of course, equation (20) is modified in consequence :

$$(22) \quad \Delta p^{n+\frac{3}{2}} = \frac{1}{\alpha} \text{Div} \left[\frac{\rho}{\Delta t} \tilde{V}^{(2)} - \beta \nabla p^{n+\frac{1}{2}} - \gamma \nabla p^{n-\frac{1}{2}} \right]$$

Pressure fields at $(n+\frac{1}{2})\Delta t$ and $(n-\frac{1}{2})\Delta t$ are assumed to be already calculated, and $p^{n+\frac{3}{2}}$ is the unknown of this equation.

It is thus necessary to prescribe, as initial conditions, not only velocities, but also pressures at two consecutive time levels. Equation (19), involving $\zeta^{n+\frac{3}{2}}$, and $\zeta^{n+\frac{1}{2}}$, is approximated with a centered discretisation.

Simpler methods have been studied, but they have shown a very poor accuracy in the tests presented hereafter.

4. COMPARISONS BETWEEN COMPUTED AND THEORETICAL RESULTS

N.S.L. program has been tested through numerous comparisons between computed and theoretical results, specially in two cases :

- the Stokes linear wave solution for small amplitude waves,
- the solitary wave's solution.

For these comparisons, viscous effects have been neglected.

4.1. Tests for small amplitude waves.

Figure 4 shows the waves calculated in the numerical wave flume, when the left boundary condition simulates a piston-wave-machine with period 4.5 s, and maximum velocity 0.2 m/s ; the right boundary condition is a radiative condition.

Water is at rest, at t = 0 ; then waves begin to propagate from left to right with a celerity about 5 m/s. At t = 50 s, five waves have gone out by the right boundary ; the movement is considered established ; celerity, wave lenght and wave amplitudes can be compared to the theoretical values given by the linear first order solution for irrotationnal waves of small amplitude.

(*) This method is a generalization of the one used by HAUGUEL in the numerical model of storm waves in shallow water [2] and [3].

Other tests have been done with a pivot-wave-machine, and with different depths. Comparisons with theoretical values are summarized in table I : the last case presented in this table, corresponds to figure 4 ;

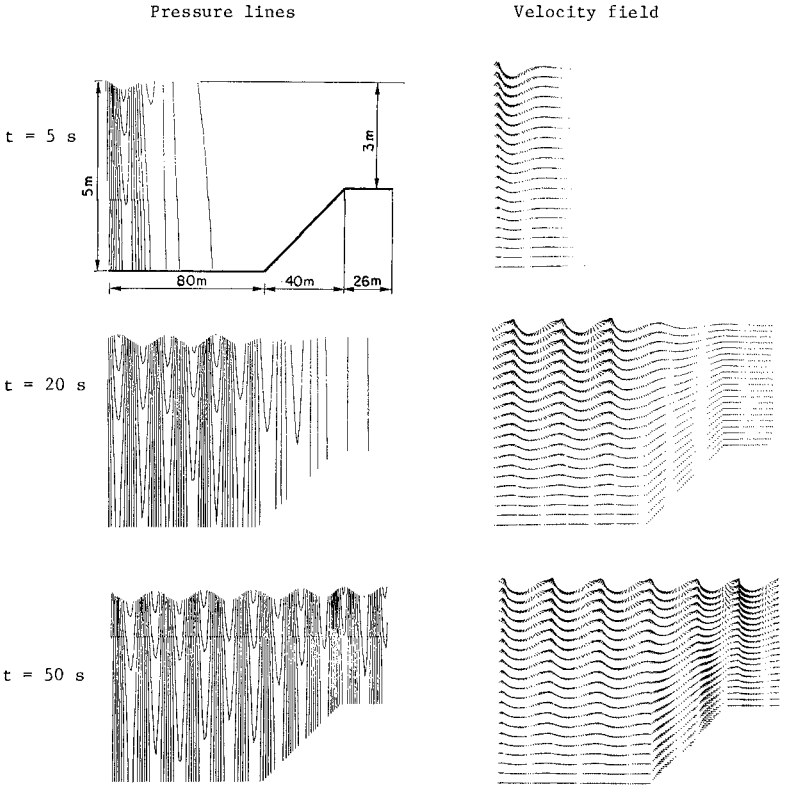

Figure 4 - Waves calculated in the numerical wave flume.
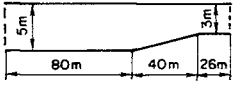
The left b.c. simulates a piston wave-machine (period = 4.5 s, maximum velocity = 0.2 m/s). The right b.c. is a radiative condition. (Δx = 1 m ; Δt = 0.15 s ; Δz = 0.25 m in the deep part of the flume)

Table 1 : Comparisons between computed and theoretical results for linear waves.

Flume characteristics		Wave-machine characteristics			Computed results and theoretical values(*)				
Depth	length		Period	Velocity maximum	wave length	celerity	wave height	top velocity	$\frac{\text{top } V^{ty}}{\text{bottom } V^{ty}}$
15 m	250 m		4.5 s	0.3 m/s	31.7 m (31.6)	7.05 m/s (7.02)	0.78 m (0.82)	0.58 m/s (0.56)	14 (10)
			4.5 s	0.3 m/s (on surface)	31.5 m (31.6)	7.0 m/s (7.02)	0.57 m (0.60)	0.45 m/s (0.42)	10 (10)
5 m	250 m		4.5 s	0.2 m/s	26.1 m (26.3)	5.8 m/s (5.84)	0.30 m (0.31)	0.26 m/s (0.26)	1.8 (1.8)
variable 5 m slope 5 % 3 m	80 m 40 m 26 m		4.5 s	0.2 m/s	26.0 m (26.3) 21.5 m (22.1)	5.78 m/s (5.84) 4.78 m/s (4.91)	0.29 m (0.31) 0.27 m (0.32)		



(*) Theoretical values are in parenthesis.

The others are performed in a longer horizontal wave flume ; in these cases, results are analyzed before the occurence of perturbations comming from reflection on the right boundary. Computed values are very similar to theoretical ones, indicated in parenthesis.

In these tests, the computing time is about 200 s of CPU for 50 s of physical time, on a CRAY 1.

4.2. Solitary wave tests

One is shown on figure 5 : on the left boundary (x = 0 m), the analytical value of the time-varying u-component is imposed ; w-component and free-surface level are computed results. The wave appears progressively in the domain of calculation, and propagates without deformation, like the theoretical solution [3] drawn on the same figure. The good quality of this result, insure that non linearities are well calculated.

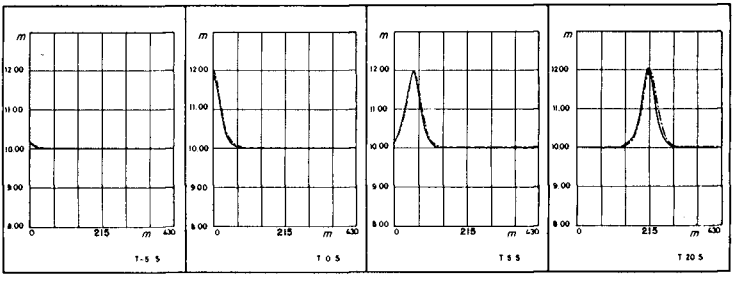


Figure 5 - Free surface of a solitary wave at t = -5 s, 0 s, 5 s, 20 s.
——— Theoretical solution -·-·- Computed solution by NSL program.

5. PRESENTATION OF SOME APPLICATIONS

As an example of the program possibilities, figure 6 shows how the solitary wave is transformed when it propagates on a rise. A similar case will be studied both numerically and experimentally. The numerical model is then able to give informations on the waves deformation by the bathymetry and then to test the validity of different integrated wave theories.

Another application, presented on figure 7, is specially devoted to the simulation of viscous effects ; it is the calculation of a permanent flow over a dredged trench. Drawings show the beginning of the flow : free surface remains nearly horizontal, and transient recirculations can be seen near the bottom. This flow has been studied experimentally in the Delft Hydraulic Laboratory [4], and it will be possible to use velocity measurements, in order to fit the parameters occuring in the turbulence simulation of the mathematical model : mixing length and bottom roughness. In the next future, the model will allow the study of viscous effects on propagating waves.

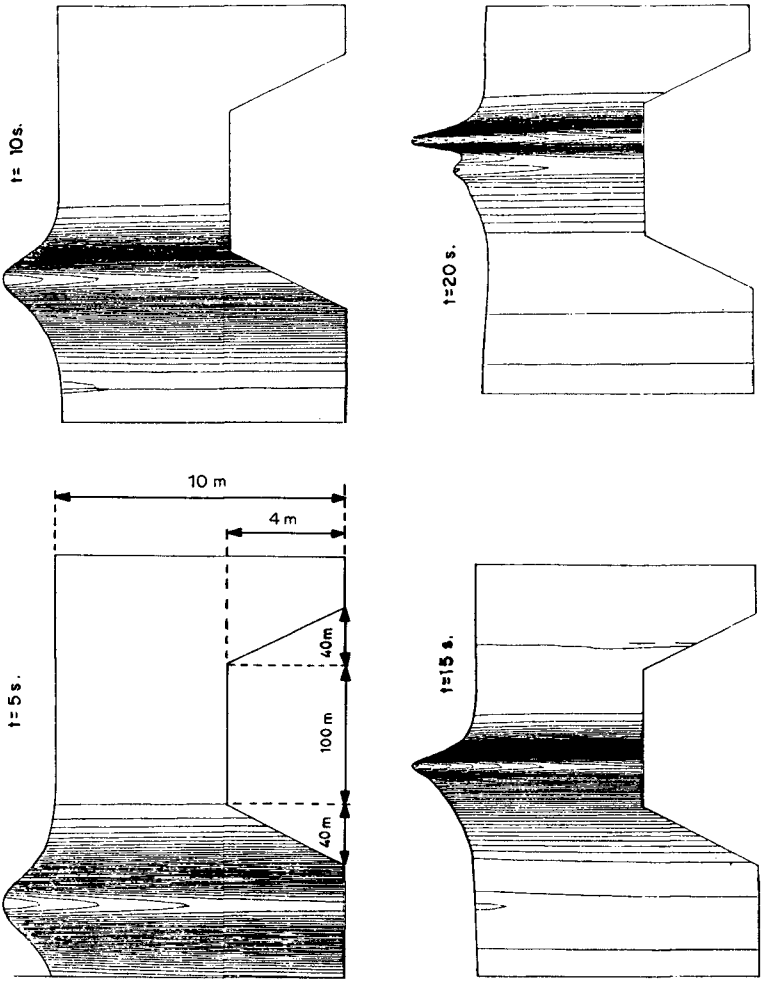

Figure 6 - Solitary wave propagating on a rise
Pressure field p^* (step = 0.05 m of water).

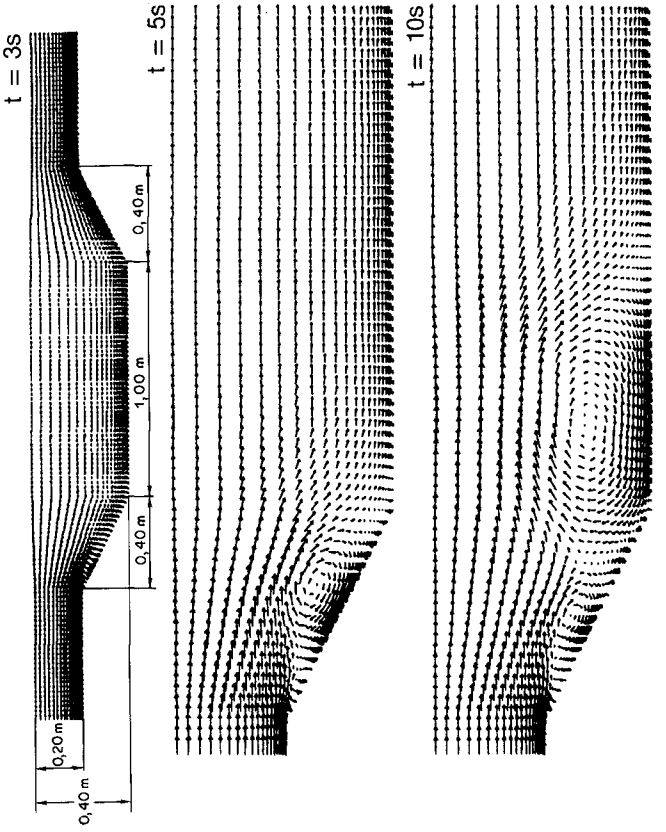

Figure 7 - Flow computation over a dredged trench. Velocity field.

N.S.L. program has also been stated to the study of irregular waves. On figure 8, the calculated heights in three points of a "numerical wave flume" are given. These level variations result from the superposition, at the left boundary of velocity profiles corresponding to three sinusoïdal waves, whose periods are 5 s, 8 s, and 13 s, and height 0.5 m, respectively. The evolution of the sea surface is quite comparable to what is expected in that case, and then, non-linear interactions taken into account in the numerical model, seem to be properly reproduced.

As the space and time steps, in this case, are chosen small enough to get a good precision for shortest wave (Δt = 0.15 s, Δx = 1 m, Δz = 0.75 m in the deep part of the flume), calculations need more computing time than the previous ones : about 800 s of CPU time in the CRAY 1, for 100 s of physical time. But this first test demonstrate the possibility to use the model on irregular conditions with a single simulation.

All these applications have ensured us that the idea of "numerical non linear wave flume" is viable. Further developments and applications will be made to demonstrate this possibility.

6. CONCLUSION

The main difficulty to tide over, for a numerical simulation of waves, was to get a good accuracy in propagation phenomena. Numerical models are often affected by excessive damping or phase-shift errors. The cases which have been choosen to test NSL program : - linear cases, as the first-order Stokes wave, and non-linear ones, as the solitary wave, - have lead to an efficient and accurate numerical method.

The other aspect to be tested now, are the turbulence and bottom boundary layer simulation in wave conditions.

N.S.L. program appears already to be an interesting tool for various fundamental studies, as velocities and pressure distributions in random waves, or in waves over immerged obstacles.

Developments of the code are projected to adapt its possibilities to stresses calculations on sharp obstacles and eventually on floating bodies in waves.

APPLICATIONS OF A NUMERICAL SHALLOW WATER WAVES MODEL

by

A. HAUCUEL (1), and PH. PECHON (2)

ABSTRACT

This paper relates three applications of a numerical model of storm waves in shallow waters developed in LNH. The equations are recalled at first and then the applications performed are presented.

The numerical model has been used in the case of the port of Fecamp, on the English Channel coast, on which the results of a scale model were available. The computed results compare well with the scale model measurements.

The second case is the simulation of a tsumami induced by a submarine landslide which appeared in 1979 near Nice ; the model has permitted the simulation of the rising of the wave.

The last applications consisted in simulating breaking waves by introducing a dispersion term in the equations. This simulation has been tested with a one-dimensional model at first. The results show that the numerical model reproduces the elevation of the mean sea surface due to the loss of energy in breakings. Then the longshore current induced by breaking waves coming obliquely over a rectilinear sloping shore has been reproduced with a two dimensional model.

The results show that the model is able to compute with a good accuracy refraction, diffraction and reflection, and that it appears to be very interesting for longshore currents simulation.

1. INTRODUCTION

This paper follows a previous one presented in the 17th conference, on the numerical model of storm waves in shallow waters developed in LNH. In this previous paper, the different assumption required and the governing equations (more complete than the Boussinesq type equations) were presented. Several indications were also given and the importance of non linear effects in storm waves problems was pointed out.

During the last two years, practical applications have been performed, and new possibilities have been introduced in the model. The applications presented are the computation in the port of Fecamp (English Channel coast) on which the results of a scale model were available, the simulation of a mini-tsunami which appeared near the works of the new airport of Nice in 1979, and the simulation of wave set-up and longshore currents induced by wave breaking over a rectilinear sloped shore.

2. EQUATIONS

By assuming that the vertical velocity linearly increases from the bottom to the surface, instead of assuming a hydrostatic pressure distribution, it is possible to average the Navier - Stokes equations to obtain the Serre type equations :

$$\frac{\partial h}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0$$

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x}\left(\frac{UV}{h}\right) + \frac{\partial}{\partial y}\left(\frac{UV}{h}\right) + \frac{\partial}{\partial x}\left(\frac{g+ß}{2} + \frac{\alpha}{3}\right)h\Big) = -(g+ß+\frac{\alpha}{2})h\,\frac{\partial z}{\partial x} - g\,\frac{U\sqrt{U^2+V^2}}{C^2 h^2}$$

$$\frac{\partial V}{\partial t} + \frac{\partial}{\partial x}\left(\frac{UV}{h}\right) + \frac{\partial}{\partial y}\left(\frac{V^2}{h}\right) + \frac{\partial}{\partial y}\left(\left(\frac{g+ß}{2} + \frac{\alpha}{3}\right)h\right) = -(g+ß+\frac{\alpha}{2})h\,\frac{\partial z}{\partial x} - g\,\frac{V\sqrt{U^2+V^2}}{C^2 h^2}$$

Where h is the water depth, U and V are x - and y - volume fluxes, z is the bed elevation, g the gravitational acceleration.

The new terms α and ß come from the new assumption, and characterize the vertical accelerations raised by the steepness of the waves and the slope of the bed :

$$\alpha = \frac{d^2h}{dt^2}\,,\quad ß = \frac{d^2z}{dt^2}\quad \left(\text{with } \frac{d}{dt} = \frac{\partial}{\partial t} + \frac{U}{h}\frac{\partial}{\partial x} + \frac{V}{h}\frac{\partial}{\partial y}\right)$$

A condition at the seaward boundary which simulates entering waves in the model at the seaward boundary and allows outgoing waves, is introduced in the following form :

$$-\vec{V}.\vec{n} + C\,(h + z) = (1 - \vec{u}.\vec{n})\,C\,Wi$$

where $\vec{V}$ is the volume flux
$\vec{n}$ is the outgoing unit-vector, perpendicular to the boundary side.
$\vec{u}$ is the unit - vector of propagation direction
Wi is the sea surface elevation of the incident wave
C is the wave celerity

The same sort of condition has been imposed on inside boundaries to model partial reflections :

$$-\vec{V}.\vec{n} + C\,(1 - r)\,(h + z) = 0$$

Where r is a coefficient of reflection (if r = 1 : total reflection, if r = 0 : no reflection).

3. AGITATION IN THE PORT OF FECAMP

The calculation is fitted to computations of non-linear agitation (periodic or not) in harbours of any bathymetry, including partial reflections. It has been used in the case of the port of Fecamp on the English Channel coast.

In 1970, a scale model was done in order to study the agitation in this port. The comparison between computed and scale model results has been performed to check the numerical model.

The figure 1 presents the port shape. Break-waters are situated along the sides of the access channel and the other boundaries are vertical quays. The wave characteristics at the entrance were very severe (height = 6m, period = 7s).

The available results of the physical model (fig. 2) display a great agitation in the center of the outer-harbour.

The characteristics of the calculation used are :

mesh dimension : DX = 3,5 m
time step : DT = 0,35 s

The free surface and the agitation contours are shown in figure 3 for a coefficient of reflection equal to 0,90 at the place of the break-waters. Considering the way of measuring agitation which smooths the agitation pattern, the computed results and the scale model results compare well since the computed agitation pattern displays the areas of great agitation in front of the "Grand Quai" and in the centre of the outer-harbour which appears in scale model.

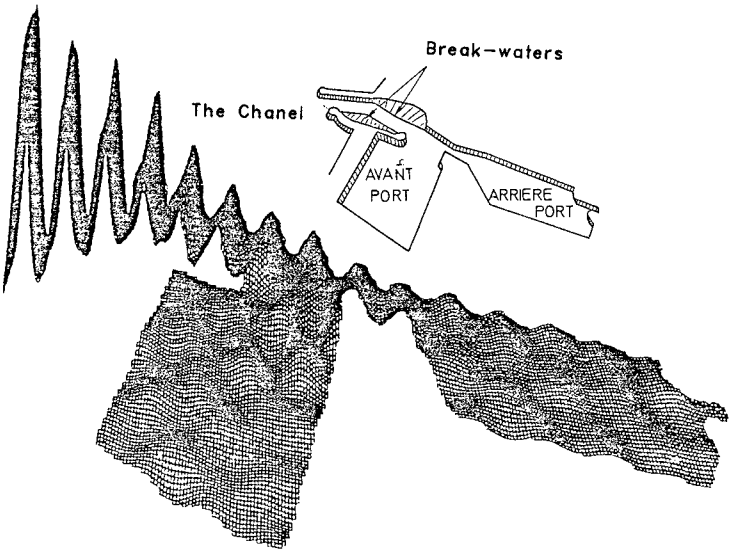

Fig.1 Computed Agitation Pattern

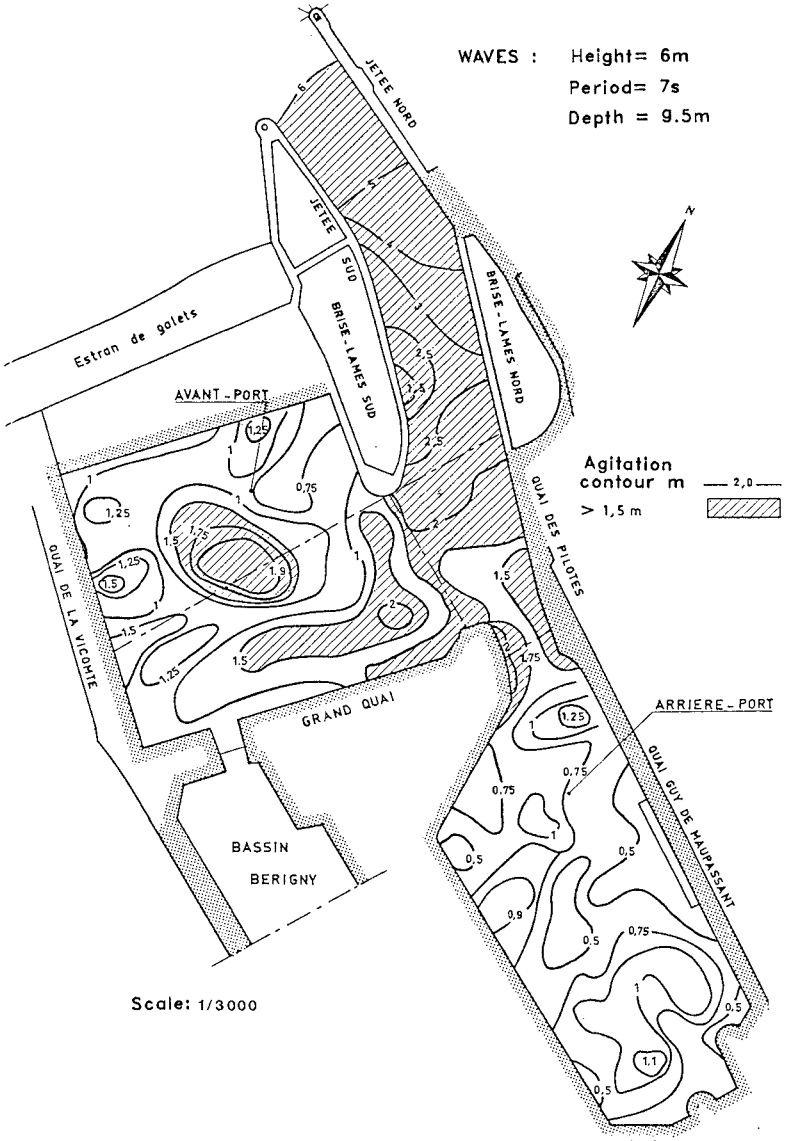

Fig.2 Agitation Contours of the Scale Model

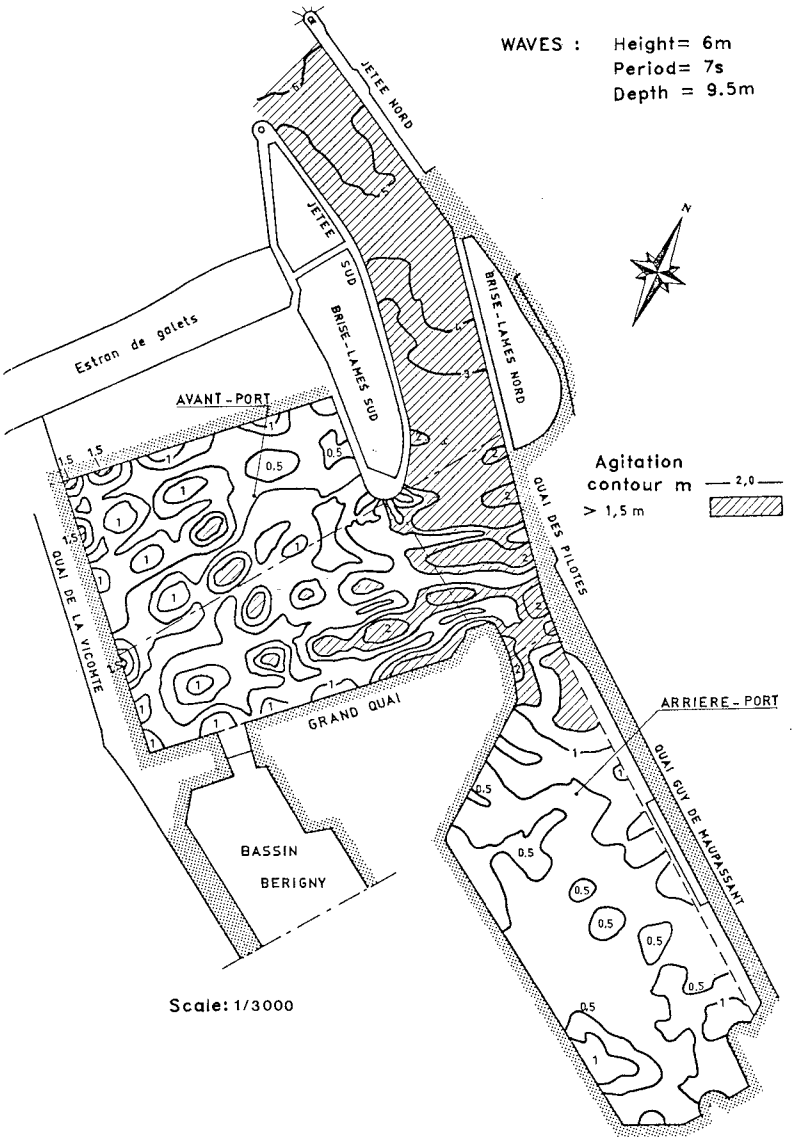

Fig.3 Agitation Contours of the Numerical Model

4. SUBMARINE LANDSLIDE NEAR NICE AIRPORT

As the model takes into account vertical accelerations resulting from the bottom shape, it allows the modelling of tsunamis. In october 1979, a mini-tsunami induced by a submarine landslide near the works of the new airport of Nice, damaged a part of the coast of "La Baie des Anges" in Mediterranean sea.

The introduction of sea-bottom changes, from the bathymetry before the tsunani to the bathymetry after it, has induced the rising of the wave (figure 4).

The model has been able to reproduce the first waves which occurred at the beginning of the landslide but secondary waves of great height which appeared 3 minutes after the first ones were not reproduced in the numerical model. This results shows that the secondary waves did not come from reflection effects but that they could be induced by turbidity currents or a second landslide.

5. SIMULATION OF BREAKING WAVES

Description

A simulation of breaking waves has been added in the numerical model. Taking into account the fluctuation of velocity (u', v') over the depth, the following terms appear in the governing equations :

$$\bar{\bar{T}} = \frac{1}{h} \begin{bmatrix} \int_0^h u'^2 \, dz & \int_0^h u' v' \, dz \\ \int_0^h u' v' \, dz & \int_0^h v'^2 \, dz \end{bmatrix}$$

Assuming an analogy with Fick's law for turbulent momentum fluxes, the tensor T is written :

$$\bar{\bar{T}} = - R \, \mathrm{grad} \, \vec{V}$$

Where $\vec{V}$ is the average of horizontal velocity over the depth.

Before breaking, the dispersion coefficient R is equal to zero, whereas it is high in the breaking zone so that the large variations of velocity over the depth in the breaking zone are simulated.

Wave breaking is assumed to occur at the location where the wave height H exceeds the Weggel's criterion :

$$H = (b(m) - a(m) \frac{H}{T^2}) \quad d$$

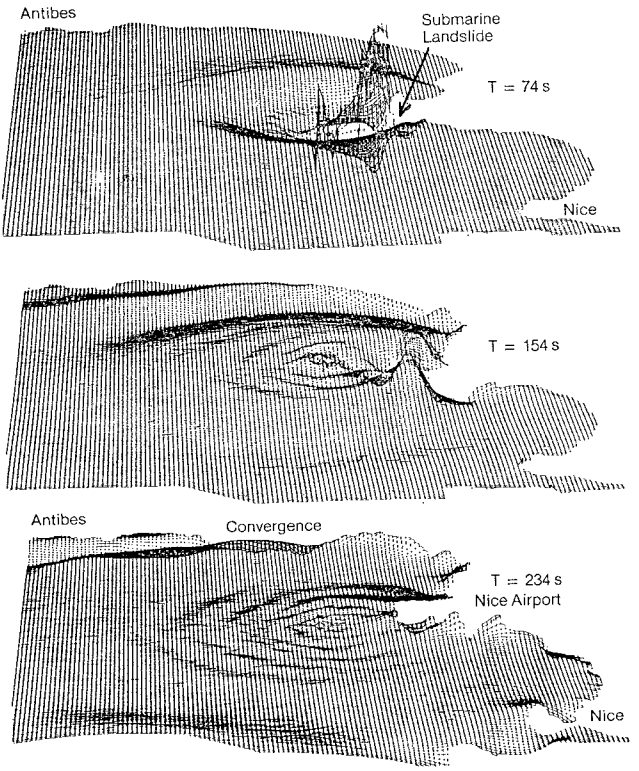

Fig.4 Simulation of a Submarine Landslide Near Nice Airport

Where m = bottom slope
T = period
d = still water depth (wave set-up is neglected).
$a(m) = 4,46\ (1 - e^{-19m})$
$b(m) = 1 / 0,64 \cdot (1 + e^{-19,5m})$.

The simulation of breaking waves has been tested over two cases :

- in a flume with a constant sloped bottom, using a one dimensional model

- in a rectilinear beach, limited by two groynes, under the action of waves with an offshore incidence of 30°.

One - dimensional model

The propagation and the breaking of waves over a constant sloped bottom has been tested in a flume geometry with various wave conditions and slope values.

When the wave height is smaller than Weggel's criterion, the dispersion coefficient is equal to zero.

When this criterion is reached, the dispersion coefficient is high from the breaking line to the coast. This value is chosen so that the ratio of wave height over still water depth is constant in this domain.

The bottom friction is assumed to be proportional to the squared velocity :

$$\vec{\pi} = - \frac{\rho g}{C^2} \vec{V} ||\vec{V}||$$

Considering Naher's studies, the coefficient of Chezy is equal to 25 $m^{1/2}/s$.

The obtained propagation in the flume is presented in fig. 5, with the following characteristics.

Off-shore wave conditions: period 9 s, wave height 2 m

Bottom slope 1,3 °/₀

Dispersion coefficient in the surf zone : 5 m^2/s
out the surf zone : 0 m^2/s

At first the wave is refracted and its height increases. When the height exceeds Weggel's criterion, the wave breaks, the height decreases from the breaking line to the coast. The wave surge coming from the wave energy loss has been obtained in the surf zone. In this case, the set-up is of 0,47 m.

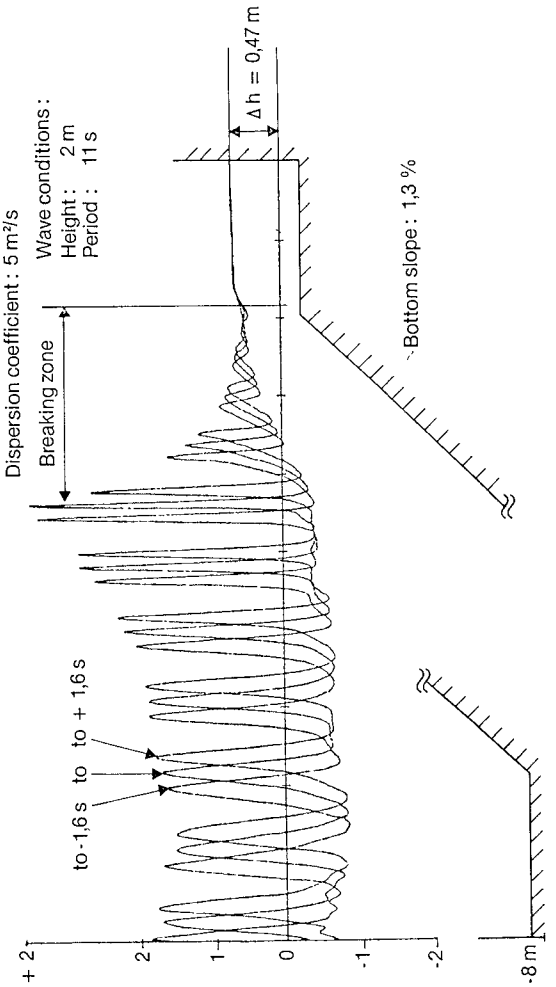

Fig.5 Wave Breaking Test with a One-dimensional Model

The dispersion coefficient has been estimated for various values of the slope and of the ratio of the wave-height over the wave length (fig. 6)

The one-dimensional tests have shown that the numerical model is able to simulate wave breaking and to predict wave surge.

A two-dimensional case has been computed to simulate longshore currents.

Two - dimensional model

The current induced by breaking waves has been studied in a 700 meters length rectilinear shore, limited by two groynes under the action of waves generated at the seaward boundary (fig. 7)

The off-shore wave conditions are : height 3 m
period 12 s
angle of incidence 30°

The mean level set-up at the coast is equal to 0,21 m (fig. 8)

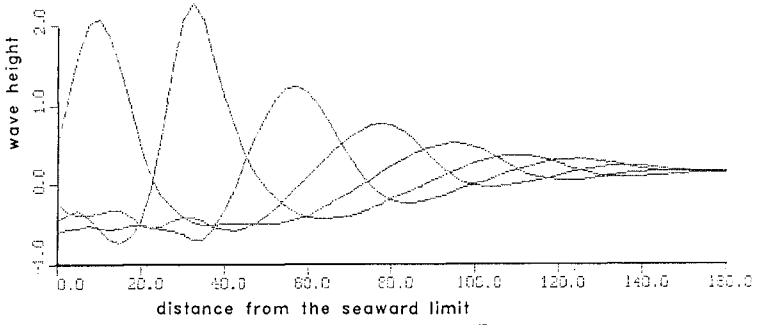

Fig.8 Wave Propagation along Section A-A

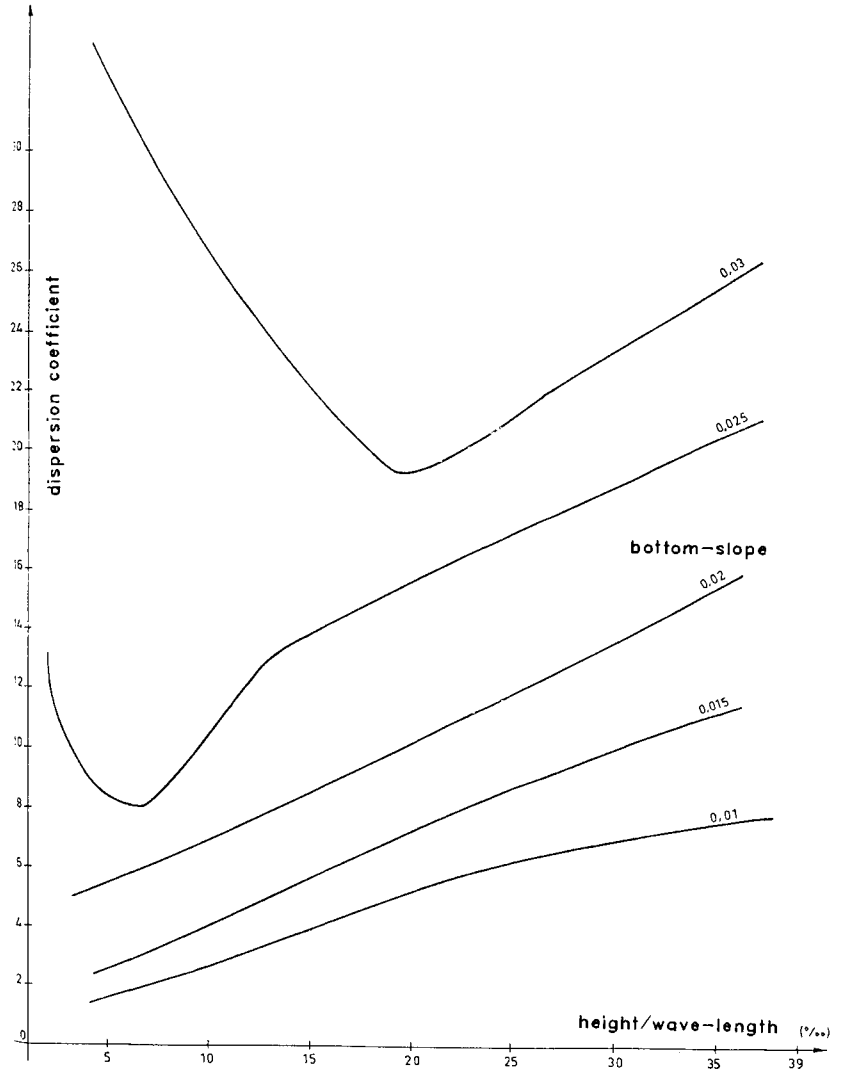

Fig.6 Dispersion coefficient R

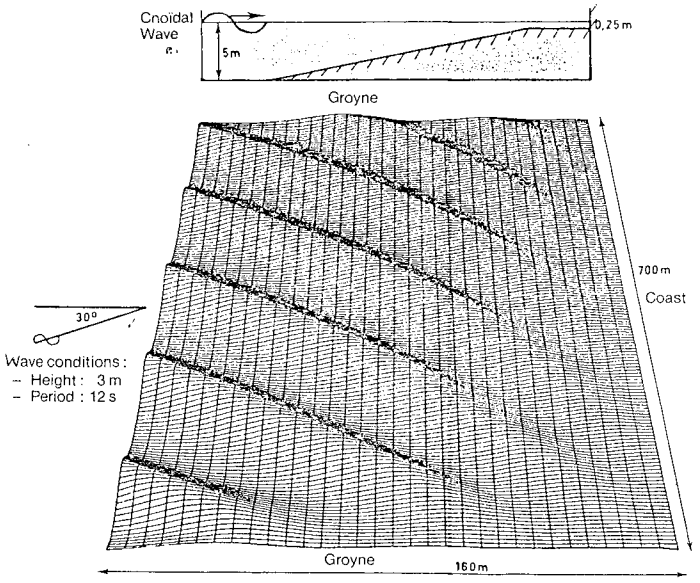

Fig.7 Simulation of Longshore Currents

The fig. 9 shows the instantaneous fluxes and the longshore current obtained by averaging fluxes over a period. A mean current parallel to the coast appears ; this is in good agreement with natural phenomenon. But a current takes place in the domain between the off-shore limit and the breaking line, in the opposite direction. Vortices appear between these two zones. This last current is due to the boundary condition which permits the waves to go out of the domain but prevents mean currents to go out.

The velocity distribution in a section perpendicular to the coast is shown on fig 10. The maximum value does not reach 0,3 m/s. This value seems rather small compared to measurements in scaled models or in nature. The reason of this difference could be imputed to the back current.

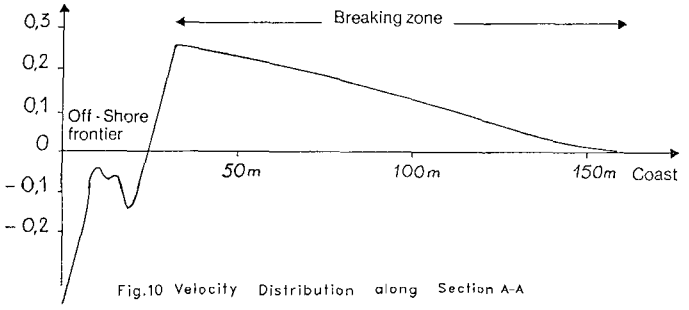

Fig.10 Velocity Distribution along Section A-A

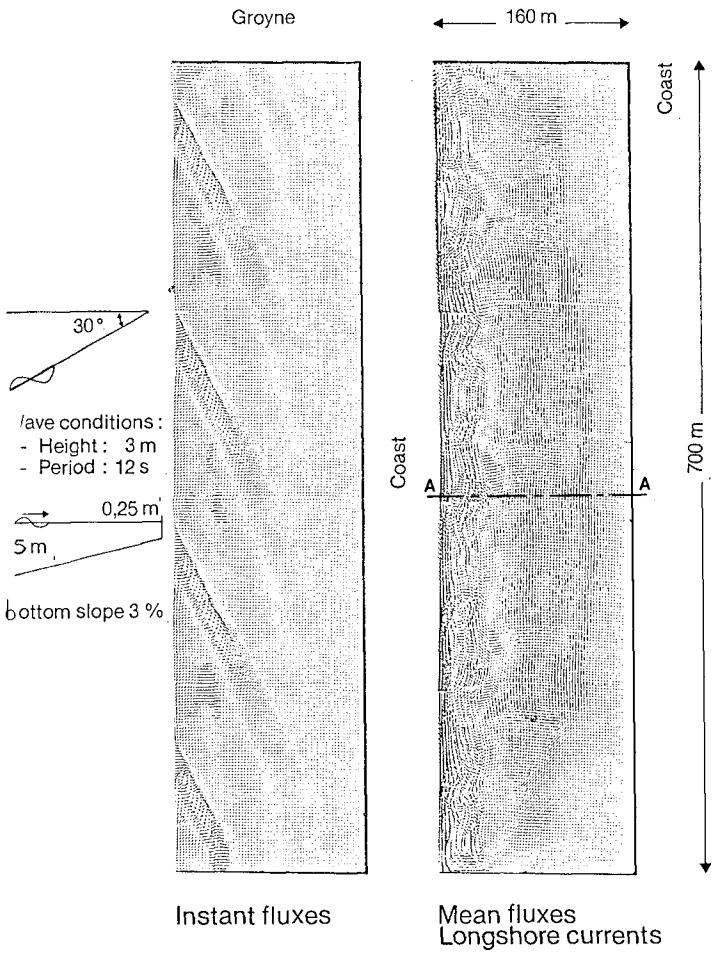

Fig.9 Fluxes Pattern in a Reactilinear Shore

6. CONCLUSION

The results of the numerical model applied to the agitation in the port of Fecamp and the submarine landslide near Nice airport show that the model is able to compute refraction, diffraction and reflection for non linear waves over any given bathymetry with a good accuracy.

The model appears to be very useful for breaking waves studies applied to longshore currents predictions. In the near future such results could give interesting informations for sedimentological studies concerning sea-bottom evolutions under waves action.

As the cost of numerical models is moderate in front of physical models, it is thought that the use of such numerical models in studies will increase substantially.

On the Variation of Characteristics of Two Wave Trains Crossing in Intermediate Depth

by

*Dr. H. H. Hwung** *C. P. Tsai***

ABSTRACT

In this paper , the authors paid attention to the non-linear interaction of two free wave trains crossing in intermediate water depth. From theoretical approaches , the velocity potential and water surface elevation have been expanded to the second-order by perturbation method. And wave height , velocity of fluid particles , pressure distribution , wave thrust and energy density of the common wave are also investigated. In order to verify the theoretical results , elaborated and numerous experiments have been performed. Some of the remarkable coincidence are obtained and the conclusions have been presented in this paper.

1. *INTRODUCTION* :

Concerning the non-linear interaction of the shortcrested waves has been obtained by Fuchs (1952) *for a second-order solution. Chappelear* (1961) *extended this to third-order in the same manner using a formal power expansion. Hsu & Silve-*

* *Associate Professor of Hydraulics and Ocean Eng. Graduate School , National Cheng-Kung University , Tainan , Taiwan , Rep , of China.*
Director of Tainan Hydraulics Laboratory.
** *Graduate Student of Institute of Oceangraph , National Taiwan University , Taipei , Rep. of China.*

ster (1979) have also presented the third-order solution which encompass all angles of incidence and can be extended to the limits for both standing and stokes waves. Further , the second-order Eulerian water particle velocities throughout the bottom boundary layer , mass transport of the first approximation and the limiting cases of progressive and standing waves have been obtained by Hsu , Silvester and Tsuchiya (1980). A comparision is also made with their available experimental data.

The above comprehensive program of research on short-crested waves are only applicable for the same period and height of the two component waves. However , for the non-linear interaction between pairs of intersecting gravity wave trains of arbitrary wavelength and direction on the surface in deep water has been developed by O. M. Phillips (1960). And the conclusion was made that the second-order terms give rise to Fourier components with wave numbers and frequencies formed by the sums and differences of those of primary components , and the amplitudes of these secondary components is always bounded in time and small in magnitude. But the third-order terms can give rise to tertiary components whose amplitude grows linearly with time in a resonant manner as the interactions are satisfied to the resonance loop. Furthermore , Longuet-Higgins (1962) has found that the rate of growth of the tertiary wave with time is a maximum when $\theta \doteqdot 17°$; the rate of growth with horizontal distance is a maximum when $\theta \doteqdot 24°$, where θ denotes the angle between the two primary wave components.

Based on the approaching method of Longuet-Higgins (1962) , *the paper presents the second-order solutions of*

velocity potential and wave profile after two wave trains crossing in intermediate water depth. Then the water particle velocity , pressure distribution , wave thrust and energy desity are also investigated. Moreover , the verification of the experiments has been performed in the laboratory.

2. *THEORETICAL APPROACH*

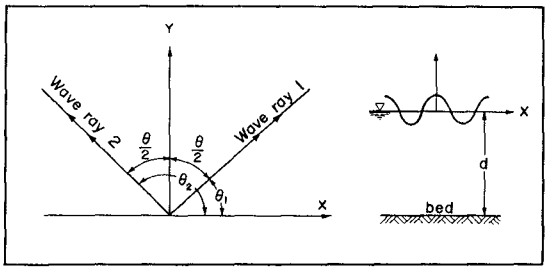

Fig. 1

Let us suppose that two free wave trains are crossing in the uniform , impervious intermediate water depth as shown in Fig. 1. *Since the presence of vorticity is very small , so that it is permissible to assume the existence of a potential function ϕ for the velocity U in an imcompressible non-viscous flow : thus*

$$U = \nabla \phi \quad , \quad \nabla^2 \phi = 0 \qquad \cdots\cdots\cdots(1)$$

And let Z be the vertical coordinate , then we have the dynamic condition at the free surface , as

$$g\eta+\phi_t+\frac{1}{2}U^2=F(t) \qquad at\ Z=\eta \qquad \cdots\cdots\cdots(2)$$

where $F(t)$ is Bernoulli's constant for linear case , but the nonlinear which can be expressed by Longuet-Higgins (1953)

$$F(t)=\left(\frac{1}{2}\overline{\eta^2}\right)_{tt}+\frac{1}{2}\left(\overline{(\nabla_h\phi)^2}-\overline{w^2}\right) \qquad \cdots\cdots\cdots(3)$$

Here " — " denotes the average for wave period and

$$\nabla_h=\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y}\right)$$

The kinematic condition at the free surface is

$$\eta_t-\phi_z+\phi_x\eta_x+\phi_y\eta_y=0 \qquad at\ Z=\eta \qquad \cdots\cdots\cdots(4)$$

For notational simplicity that it is better to denote the partial differentiation by the subscript , $\phi_x=\partial\phi/\partial x$ $\phi_{tz}=\partial^2\phi/\partial t\,\partial z$ etc. Then taking the material derivative , D/Dt , of eq (2) *and subtracting g times eq* . (4) *, we obtain*

$$\phi_{tt}+g\phi_z+(U^2)_t+U\cdot\nabla\left(\frac{1}{2}U^2\right)=0 \qquad at\ Z=\eta \qquad \cdots\cdots\cdots(5)$$

Now let eq . (2) *and eq* . (5) *be expanded in Taylor's series about $Z=0$ to give*

$$g\eta+\left[\phi_t+\eta\phi_{tz}+\frac{1}{2}\eta^2\phi_{tzz}+\cdots\right]+\left[\frac{1}{2}U^2+\eta\left(\frac{1}{2}U^2\right)_z+\cdots\right]=Q$$

$$at\ Z=0 \qquad \cdots\cdots\cdots(6)$$

$$\{(\phi_{tt}+g\phi_z)+\eta(\phi_{tt}+g\phi_z)_z+\cdots\}+\{(U^2)_t+\eta(U^2)_{tz}+\cdots\}$$

$$+\{U\cdot\nabla(\frac{1}{2}U^2)+\cdots\}=0 \qquad at\ Z=0 \qquad \cdots\cdots(7)$$

Suppose that we define ϕ_{ij} , η_{ij} , U_{ij} *and* Q_{ij} *by the formal expressions* :

$$\left.\begin{aligned}
\phi &= (\alpha\phi_{10}+\beta\phi_{01})+(\alpha^2\phi_{20}+\alpha\beta\phi_{11}+\beta^2\phi_{02})+\cdots\cdots\\
\eta &= (\alpha\eta_{10}+\beta\eta_{01})+(\alpha^2\eta_{20}+\alpha\beta\eta_{11}+\beta^2\eta_{02})+\cdots\cdots\\
U &= (\alpha U_{10}+\beta U_{01})+(\alpha^2 U_{20}+\alpha\beta U_{11}+\beta^2 U_{02})+\cdots\cdots\\
Q &= (\alpha Q_{10}+\beta Q_{01})+(\alpha^2 Q_{20}+\alpha\beta Q_{11}+\beta^2 Q_{02})+\cdots\cdots
\end{aligned}\right\}\ \cdots\cdots(8)$$

where α , β *are to be small , independent and proportional to the surface slopes ,* $\alpha\phi_{10}$ *and* $\beta\phi_{01}$ *represent the first approximation of two crossing wave trains. The remaining terms represent wave interaction. Then substitute eq.* (8) *in eq.* (1) , (6) , (7) , *that we obtain* :

$0(\alpha)$:

$$\nabla^2\phi_{10}=0 \qquad \cdots\cdots(9)$$

$$g\eta_{10}+\phi_{10t}=Q_{10} \qquad at\ Z=0 \qquad \cdots\cdots(10)$$

$$\phi_{10tt}+g\phi_{10z}=0 \qquad at\ Z=0 \qquad \cdots\cdots(11)$$

$$\phi_{10z}=0 \qquad at\ Z=-d \qquad \cdots\cdots(12)$$

$0(\alpha^2)$:

$$\nabla^2 \phi_{20} = 0 \qquad \cdots\cdots(13)$$

$$g\eta_{20} + \phi_{20t} + \eta_{10}\phi_{10tz} + \frac{1}{2}U_{10}^2 = Q_{20} \quad at\ Z = 0 \qquad \cdots\cdots(14)$$

$$\phi_{20tt} + g\phi_{20z} + \eta_{10}(\phi_{10tt} + g\phi_{10z})_z + (U_{10}^2)_t = 0 \quad at\ Z = 0 \cdots\cdots(15)$$

$$\phi_{20z} = 0 \qquad at\ Z = -d \qquad \cdots\cdots(16)$$

$0(\alpha\beta)$:

$$\nabla^2 \phi_{11} = 0 \qquad \cdots\cdots(17)$$

$$g\eta_{11} + \phi_{11t} + \eta_{10}\phi_{01tz} + \eta_{01}\phi_{10tz} + U_{10} \cdot U_{01} = Q_{11} \quad at\ Z = 0 \qquad \cdots\cdots(18)$$

$$\phi_{11tt} + g\phi_{11z} + \eta_{10}(\phi_{01tt} + g\phi_{01z})_z + \eta_{01}(\phi_{10tt} + g\phi_{10z})_z + 2(U_{10} \cdot U_{01})_t = 0 \qquad at\ Z = 0 \qquad \cdots\cdots(19)$$

$$\phi_{11z} = 0 \qquad at\ Z = -d \qquad \cdots\cdots(20)$$

And the terms of $0(\beta)$, $0(\beta^2)$ *are the same expressions as* $0(\alpha)$, $0(\alpha^2)$ *but the subscript of* 10, 20 *from eq.* (9) *through eq.* (16) *will be changed by* o1, o2. *If we assume that the water is intermediate for the first-and second-order waves that the solutions will be obtained as* :

$$\phi_{10} = A_1 \cosh k_1(z+d) \sin\varphi_1 \qquad \cdots\cdots(21)$$

$$\eta_{10} = \frac{\sigma_1 A_1}{g} \cosh k_1 d \cos\varphi_1 \qquad \cdots\cdots(22)$$

$$\sigma_1^2 = g k_1 \tanh k_1 d \qquad \cdots\cdots(23)$$

$$\phi_{20} = \frac{3}{8} \frac{k_1^2 A_1^2}{\sigma_1 \sinh^2 k_1 d} \cosh 2 k_1 (z + d) \sin 2\varphi_1 \qquad \cdots\cdots(24)$$

$$\eta_{20} = \frac{k_1^2 A_1^2}{4 g} \frac{\cosh^2 k_1 d (\cosh 2 k_1 d + 2)}{\sinh^2 k_1 d} \cos 2\varphi_1 \qquad \cdots\cdots(25)$$

and

$$\phi_{01} = B_1 \cosh k_2 (z + d) \sin\varphi_2 \qquad \cdots\cdots(26)$$

$$\eta_{01} = \frac{\sigma_2 B_1}{g} \cosh k_2 d \cos \varphi_2 \qquad \cdots\cdots(27)$$

$$\sigma_2^2 = g k_2 \tanh k_2 d \qquad \cdots\cdots(28)$$

$$\phi_{02} = \frac{3}{8} \frac{k_2^2 B_1^2}{\sigma_2 \sinh^2 k_2 d} \cosh 2 k_2 (z + d) \sin 2\varphi_2 \qquad \cdots\cdots(29)$$

$$\eta_{02} = \frac{k_1^2 B_1^2}{4 g} \frac{\cosh^2 k_2 d (\cosh^2 k_2 d + 2)}{\sinh^2 k_2 d} \cos 2\varphi_2 \qquad \cdots\cdots(30)$$

for convenience , where

$$\varphi_1 = k_1 x - \sigma_1 t \quad \textit{and} \quad \varphi_2 = k_2 x - \sigma_2 t$$

Combining the solutions of the first-order from eq. (17) *through eq.* (20) *, then* ϕ_{11} *and* η_{11} *of the nonlinear term will also be found out.*

$$\phi_{11} = A_1 B_1 k_1 k_2 \left[\frac{F_1}{F_3} \cosh k' (z+d) \sin (\varphi_1 + \varphi_2) \right.$$

$$\left. + \frac{F_2}{F_4} \cosh k'' (z+d) \sin (\varphi_1 - \varphi_2) \right] \quad \cdots\cdots(31)$$

$$\eta_{11} = \frac{1}{g} A_1 B_1 k_1 k_2 \left\{ \left[(\sigma_1 + \sigma_2) \frac{F_1}{F_3} \cosh k' d + \frac{1}{4} G \right.\right.$$

$$\left. \cdot \cosh (k_1 + k_2) d - \frac{1}{4} H \cosh (k_1 - k_2) d \right] \cos (\varphi_1 + \varphi_2)$$

$$+ \left[(\sigma_1 - \sigma_2) \frac{F_2}{F_4} \cosh k'' d - \frac{1}{4} H \cosh (k_1 - k_2) d \right.$$

$$\left.\left. + \frac{1}{4} G \cosh (k_1 + k_2) d \right] \cos (\varphi_1 - \varphi_2) \right\} \quad \cdots\cdots(32)$$

where

$$F_1 = \frac{1}{2} \left(\frac{\sigma_1^2}{\sigma_2} \frac{\sinh k_2 d}{\sinh k_1 d} + \frac{\sigma_2^2}{\sigma_1} \frac{\sinh k_1 d}{\sinh k_2 d} \right) + 2 (\sigma_1 + \sigma_2)$$

$$\left(\frac{\cos \theta}{2} \cosh k_1 d \cosh k_2 d - \frac{1}{2} \sinh k_1 d \sinh k_2 d \right)$$

$$F_2 = \frac{1}{2} \left(\frac{\sigma_1^2}{\sigma_2} \frac{\sinh k_2 d}{\sinh k_1 d} - \frac{\sigma_2^2}{\sigma_1} \frac{\sinh k_1 d}{\sinh k_2 d} \right) + 2 (\sigma_1 - \sigma_2)$$

$$\left(\frac{\cos \theta}{2} \cosh k_1 d \cosh k_2 d + \frac{1}{2} \sinh k_1 d \sinh k_2 d \right)$$

$$F_3 = (\sigma_1 + \sigma_2)^2 \cosh k' d - g k' \sinh k' d$$

$$F_4 = (\sigma_1 - \sigma_2)^2 \cosh k'' d - g k'' \sinh k'' d$$

$$G = \frac{(\sigma_1 + \sigma_2)^2}{\sigma_1 \sigma_2} - 2\cos^2 \frac{\theta}{2}$$

$$H = \frac{(\sigma_1 + \sigma_2)^2}{\sigma_1 \sigma_2} - 2\sin^2 \frac{\theta}{2}$$

$$k' = |K_1 + K_2|, \quad k'' = |K_1 - K_2|$$

$$\theta = |\theta_1 - \theta_2|$$

If a_1, a_2 denotes the amplitude of two primary wave components respectively. Then both of the velocity potential and water surface elevation function of the second-order solution of the common wave will be given by

$$\phi = \frac{a_1 g}{\sigma_1} \frac{\cosh k_1 (z+d)}{\cosh k_1 d} \sin\varphi_1 + \frac{a_2 g}{\sigma_2} \frac{\cosh k_2 (z+d)}{\cosh k_2 d} \sin\varphi_2$$

$$+ \frac{3}{8} a_1^2 \sigma_1 \frac{\cosh 2k_1 (z+d)}{\sinh^4 k_1 d} \sin 2\varphi_1 +$$

$$+ \frac{3}{8} a_2^2 \sigma_2 \frac{\cosh 2k_2 (z+d)}{\sinh^4 k_2 d} \sin 2\varphi_2 + \frac{a_1 a_2 \sigma_1 \sigma_2}{\sinh k_1 d \sinh k_2 d}$$

$$\cdot \left[\frac{F_1}{F_3} \cosh k' (z+d) \cdot \sin(\varphi_1 + \varphi_2) \right.$$

$$\left. + \frac{F_2}{F_4} \cosh k'' (z+d) \sin(\varphi_1 - \varphi_2) \right] \qquad \cdots\cdots (33)$$

$$\eta = a_1 \cos\varphi_1 + a_2 \cos\varphi_2 + \frac{a_1^2 k_1}{4} \frac{\cosh k_1 d}{\sinh^3 k_1 d} (\cosh 2k_1 d + 2) \cos 2\varphi_1 + \frac{a_2^2 k_2}{4} \frac{\cosh k_2 d}{\sinh^3 k_2 d} (\cosh 2k_2 d + 2) \cos 2\varphi_2$$

$$+ \frac{a_1 a_2 \sigma_1 \sigma_2}{\sinh k_1 d \sinh k_2 d} \cdot \{ [(\sigma_1 + \sigma_2) \frac{F_1}{F_3} \cosh k' d +$$

$$+ \frac{1}{4} G \cosh (k_1 + k_2) d - \frac{1}{4} H \cosh (k_1 - k_2) d]$$

$$\cdot \cos (\varphi_1 + \varphi_2) + [(\sigma_1 - \sigma_2) \frac{F_2}{F_4} \cosh k'' d$$

$$- \frac{1}{4} H \cosh (k_1 - k_2) d + \frac{1}{4} G \cosh (k_1 + k_2) d] \cos (\varphi_1 - \varphi_2) \} \quad \cdots\cdots (34)$$

From above two equations , examples of water surface elevation after two wave trains crossing are graphed in Fig. 2. and Fig. 3. In Fig. 2, curve A is the first-order solution of common wave , curve B is the solution of Stokes wave which obtained from the front of four terms on the left side of eq. (34) , and curve C is the solutiom of eq. (34) , also representing the condition of short-crested wave , as noted by Hsu et al (1979). In Fig. 3 , the dash-line and solid-line denotes the solution of first-order and second-order respectively , and it is evident that the period of the common wave is equal to the least common multiple of the two primary wave components.

Based on the velocity potential and water surface elevation funtion , the water particle velocity , pressure distribution , wave thrust and energy density can also be investigated as the following form :

(1) *water particle velocity :*

After two wave trains crossing , the components of water particle velocity (u , v , w) for the second-order can be expressed as

$$u = u_1 \cos\varphi_1 + u_2 \cos\varphi_2 + u_3 \cos 2\varphi_1 + u_4 \cos 2\varphi_2 + + u_5 \cos(\varphi_1 + \varphi_2) + u_6 \cos(\varphi_1 - \varphi_2) \quad \cdots\cdots(35)$$

$$v = v_1 \cos\varphi_1 + v_2 \cos\varphi_2 + v_3 \cos 2\varphi_1 + v_4 \cos 2\varphi_2 + + v_5 \cos(\varphi_1 + \varphi_2) + v_6 \cos(\varphi_1 - \varphi_2) \quad \cdots\cdots(36)$$

$$w = w_1 \cos\varphi_1 + w_2 \cos\varphi_2 + w_3 \cos 2\varphi_1 + w_4 \cos 2\varphi_2 + + w_5 \cos(\varphi_1 + \varphi_2) + w_6 \cos(\varphi_1 - \varphi_2) \quad \cdots\cdots(37)$$

from the above three equations , we have

$$(u_1, v_1, w_1) = \frac{a_1\sigma_1}{\sinh k_1 d}(\cos\theta_1 \cosh k_1(z+d), \sin\theta_1 \cosh k_1(z+d), \sinh k_1(z+d))$$

$$(u_2, v_2, w_2) = \frac{a_2\sigma_2}{\sinh k_2 d}(\cos\theta_2 \cosh k_2(z+d), \sin\theta_2 \cosh k_2(z+d), \sinh k_2(z+d))$$

$$(u_3, v_3, w_3) = \frac{3a_1^2\sigma_1 k_1}{4\sinh k_1 d}(\cos\theta_1 \cosh 2k_1(z+d),\ \sin\theta_1 \cosh 2k_1(z+d),\ \sinh 2k_1(z+d))$$

$$(u_4, v_4, w_4) = \frac{3a_2^2\sigma_2 k_2}{4\sinh^4 k_2 d}\{\cos\theta_2 \cosh 2k_2(z+d),\ \sin\theta_2 \cosh 2k_2(z+d),\ \sinh 2k_2(z+d)\}$$

$$(u_5, v_5, w_5) = \frac{a_1 a_2 \sigma_1 \sigma_2}{\sinh k_1 d \sinh k_2 d}\frac{F_1}{F_3} k'\{\cos\alpha_1 \cosh k_1(z+d),\ \sin\alpha_1 \cosh k'(z+d),\ \sinh k'(z+d)\}$$

$$(u_6, v_6, w_6) = \frac{a_1 a_2 \sigma_1 \sigma_2}{\sinh k_1 d \sinh k_2 d}\frac{F_2}{F_4} k''\{\cos\alpha_2 \cosh k''(z+d),\ \sin\alpha_2 \cosh k''(z+d),\ \sinh k''(z+d)\}$$

where , α_1 *is the angle between the vector of* (k_1+k_2) *and x axis* , α_2 *is the angle between* (k_1-k_2) *and x axis.*

$$\alpha_1 = \arctan\left(\frac{k_1\sin\theta_1 + k_2\sin\theta_2}{k_1\cos\theta_1 + k_2\sin\theta_2}\right)$$

$$\alpha_2 = \arctan\left(\frac{k_1\sin\theta_1 - k_2\sin\theta_2}{k_1\cos\theta_1 - k_2\cos\theta_2}\right)$$

(2) *pressure distribution* :

From Bernoulli's equation , the pressure can be expressured by the following form :

$$\frac{P}{\rho}=-gz-\phi_t-\frac{1}{2}u^2+F(t) \qquad \cdots\cdots(38)$$

from the perturbation method , and assume that

$$\frac{P}{\rho}+gz=(\alpha P_{10}+\beta P_{01})+(\alpha^2 P_{20}+\alpha\beta P_{11}+\beta^2 P_{02}+)\cdots \qquad \cdots\cdots(39)$$

$$F(t)=(\alpha F_{10}+\beta F_{01})+(\alpha^2 F_{20}+\alpha\beta F_{11}+\beta^2 F_{02})+\cdots \qquad \cdots\cdots(40)$$

then substitute eq (39) , (40) *and eq* (8) *in eq* (38) , *that we have* :

$$O(\alpha) \quad : P_{10}=-\phi_{10t}+F_{10} \qquad \cdots\cdots(41)$$

$$O(\alpha^2) : P_{20}=-\phi_{20t}-\frac{1}{2}\boldsymbol{u}_{10}^2+F_{20} \qquad \cdots\cdots(42)$$

$$O(\alpha\beta) : P_{11}=-\phi_{11t}-\boldsymbol{u}_{10}\cdot\boldsymbol{u}_{01}+F_{11} \qquad \cdots\cdots(43)$$

As for $O(\beta)$, $O(\beta^2)$ *which corresponds to* $O(\alpha)$, $O(\alpha^2)$ *but the subcripts* 10 , 20 , *will be changed into* 01 , 02 *respectively. Since* $F_{10}=F_{01}=0$, $F_{20}=\frac{1}{4}A_1^2k_1^2$, $F_{02}=\frac{1}{4}B_1^2k_1^2$ *and* $F_{11}=0$, *that the pressure after two wave trains crossing will be given by* :

$$\frac{P}{\rho}=-gz+a_1 g\,\frac{\cosh k_1(z+d)}{\cosh k_1 d}\cos\varphi_1+a_2 g\,\frac{\cosh k_2(z+d)}{\cosh k_2 d}\cos\varphi_2$$

$$+\frac{a_1^2 g k_1}{2\sinh 2k_1 d}\left\{\left[\frac{3\cosh 2k_1(z+d)}{\sinh^2 k_1 d}-1\right]\cos 2\varphi_1+\right.$$

$$+\left[1-\cosh 2k_1(z+d)\right]\}$$

$$+\frac{a_2^2 g k_2}{2\sinh 2k_2 d}\left\{\left[\frac{3\cosh 2k_2(z+d)}{\sinh^2 k_2 d}-1\right]\cos 2\varphi_2\right.$$

$$\left.+\left[1-\cosh 2k_2(z+d)\right]\right\}$$

$$+\frac{a_1 a_2 \sigma_1 \sigma_2}{\sinh k_1 d \sinh k_2 d}\left\{\left[(\sigma_1+\sigma_2)\frac{F_1}{F_3}\cosh k'(z+d)\right.\right.$$

$$-\frac{\cos\theta}{2}\cosh k_1(z+d)\cosh k_2(z+d)$$

$$\left.+\frac{1}{2}\sinh k_1(z+d)\sinh k_2(z+d)\right]\cos(\varphi_1+\varphi_2)$$

$$+\left[(\sigma_1-\sigma_2)\frac{F_2}{F_4}\cosh k''(z+d)-\frac{\cos\theta}{2}\cosh k_1(z+d)\right.$$

$$\left.\cdot\cosh k_2(z+d)-\frac{1}{2}\sinh k_1(z+d)\sinh k_2(z+d)\right]$$

$$\left.\cdot\cos(\varphi_1-\varphi_2)\right\} \qquad \cdots\cdots(44)$$

(3) *wave thrust*

From Longuet-Higgins & Stewart (1964) , *wave thrust will be written as the following form*

$$S_{ij}=\int_{-d}^{\eta}(P\delta_{ij}+\rho\mu_i\mu_j)\,dz+\int_{-d}^{0}\rho g z\,dz \qquad \cdots\cdots(45)$$

where " — " denotes the average of common wave period , and δ_{ij} *is Kronecker's delta. For the second-order approximation , then the above equation can be simplified as*

$$S_{ij} = \frac{1}{2}\rho g\overline{\eta^2}\delta_{ij} + \rho\int_{-d}^{0}\left(\overline{\mu_i\mu_j} - \overline{w^2}\delta_{ij}\right)dz \qquad \cdots\cdots(46)$$

thus :

$$S_{xx} = \frac{1}{2}\rho g\overline{\eta^2} + \rho\int_{-d}^{0}\left(\overline{u^2} - \overline{w^2}\right)dz \qquad \cdots\cdots(47)$$

$$S_{yy} = \frac{1}{2}\rho g\overline{\eta^2} + \rho\int_{-d}^{0}\left(\overline{v^2} - \overline{w^2}\right)dz \qquad \cdots\cdots(48)$$

$$S_{xy} = S_{yx} = \rho\int_{-d}^{0}\overline{uv}\,dz \qquad \cdots\cdots(49)$$

where S_{xx} , S_{yy} *represents the flux of horizontal momentum parallel to the* x , y *axis and* S_{xy} , S_{yx} *represents the flux of* $x-$, $y-$ *momentum across the plane* $y =$ *constant and* $x =$ *constant respectively. Then suppose* $E_1 = \frac{1}{2}\rho g a_1^2$, $E_2 =$ $E_2 = \frac{1}{2}\rho g a_2^2$, *that the components of wave thrust of the common wave will be given by*

$$S_{xx} = E_1\left\{\cos^2\theta_1\left(\frac{1}{2} + \frac{k_1 d}{\sinh 2k_1 d}\right) + \frac{k_1 d}{\sinh 2k_1 d}\right\}$$

$$+E_2\left\{\cos^2\theta_2\left(\frac{1}{2} + \frac{k_2 d}{\sinh 2k_2 d}\right) + \frac{k_2 d}{\sinh 2k_2 d}\right\}$$

$$+\frac{8E_1E_2k_1k_2}{\rho\sinh 2k_1 d\sinh 2k_2 d}\left\{\frac{F_1^2}{F_3^2}k'^2\left[\cos^2\alpha_1\left(\frac{\sinh 2k'd}{4k'} + \frac{d}{2}\right)\right.\right.$$

$$-\left(\frac{sinh2k'd}{4k'}-\frac{d}{2}\right)\Big]+\frac{F_2^2}{F_4^2}k''^2\Big[cos^2\alpha_2\left(\frac{sinh2k''d}{4k''}+\frac{d}{2}\right)$$

$$-\left(\frac{sinh2k''d}{4k''}-\frac{d}{2}\right)\Big]+\frac{1}{2g}\Big[\left(\sigma_1+\sigma_2\right)\frac{F_1}{F_3}\,cosk'd$$

$$+\frac{1}{4}Gcosh\left(k_1+k_2\right)d-\frac{1}{4}Hcosh\left(k_1-k_2\right)d\Big]^2$$

$$+\frac{1}{2g}\Big[\left(\sigma_1-\sigma_2\right)\frac{F_2}{F_4}\,coshk''d-\frac{1}{4}Hcosh\left(k_1-k_2\right)d$$

$$+\frac{1}{4}Gcosh\left(k_1+k_2\right)d\Big]^2\Big\} \qquad \cdots\cdots(50)$$

$$S_{yy}=E_1\left\{sin^2\theta_1\left(\frac{1}{2}+\frac{k_1d}{sinh2k_1d}\right)+\frac{k_1d}{sinh2k_1d}\right\}$$

$$+E_2\left\{sin^2\theta_2\left(\frac{1}{2}+\frac{k_2d}{sinh2k_2d}\right)+\frac{k_2d}{sinh2k_2d}\right\}$$

$$+\frac{8E_1E_2k_1k_2}{\rho sinh2k_1dsinh2k_2d}\Big\{\frac{F_1^2}{F_3^2}k'^2\Big[sin^2\alpha_1\left(\frac{sinh2k'd}{4k'}+\frac{d}{2}\right)$$

$$-\left(\frac{sinh2k'd}{4k'}-\frac{d}{2}\right)\Big]+\frac{F_2^2}{F_4^2}k''^2\Big[sin^2\alpha_2\left(\frac{sinh2k''d}{4k''}+\frac{d}{2}\right)$$

$$-\left(\frac{sinh2k''d}{4k''}-\frac{d}{2}\right)\Big]+\frac{1}{2g}\Big[\left(\sigma_1+\sigma_2\right)\frac{F_1}{F_3}\,coshk'd$$

$$+\frac{1}{4}Gcosh\left(k_1+k_2\right)d-\frac{1}{4}Hcosh\left(k_1-k_2\right)d\Big]^2$$

$$+\frac{1}{2g}\Big[\left(\sigma_1-\sigma_2\right)\frac{F_2}{F_4}\,coshk''d-\frac{1}{4}Hcosh\left(k_1-k_2\right)d$$

$$+\frac{1}{4}Gcosh\left(k_1+k_2\right)d\Big]^2\Big\} \qquad \cdots\cdots(51)$$

$$S_{xy}=S_{yx}=E_1\{\sin 2\theta_1\left(\frac{k_1 d}{2\sinh 2k_1 d}+\frac{1}{4}\right)\}$$

$$+E_2\{\sin 2\theta_2\left(\frac{k_2 d}{2\sinh 2k_2 d}+\frac{1}{4}\right)\}+\frac{8E_1E_2k_1k_2}{\rho\sinh 2k_1 d\sinh 2k_2 d}$$

$$\cdot\{\frac{F_1^2}{F_3^2}k'^2\left[\sin 2\alpha_1\left(\frac{d}{2}+\frac{\sinh 2k' d}{4k'}\right)\right]$$

$$+\frac{F_2^2}{F_4^2}k''^2\left[\sin 2\alpha_2\left(\frac{d}{2}+\frac{\sinh 2k'' d}{4k''}\right)\right]\} \qquad \cdots\cdots(52)$$

(4) *average energy density* :

The total average energy density is the sum of the kinetic and potential energy density , thus

$$\overline{E}=\overline{E}_p+\overline{E}_k \qquad \cdots\cdots(53)$$

according to the definition that

$$\overline{E}_p=\overline{\int_{-d}^{\eta}\rho g z\,dz}-\int_{-d}^{0}\rho g z\,dz=\frac{1}{2}\rho g\overline{\eta^2} \qquad \cdots\cdots(54)$$

$$\overline{E}_k=\frac{1}{2}\rho\overline{\int_{-d}^{\eta}u^2 dz} \qquad \cdots\cdots(55)$$

Then substitute the solutions of η *and* U *in the eq.* (54) , (55) , *the second-order solution of average energy density will be given by*

$$\overline{E}=(E_1+E_2)+\frac{2E_1E_2k_1k_2}{\rho\sinh 2k_1 d\sinh 2k_2 d}\{\frac{F_1^2}{F_3^2}k'^2\sinh 2k' d$$

$$+\frac{F_2^2}{F_4^2}k''sinh2k''d+\frac{2}{g}\left[\left(\sigma_1+\sigma_2\right)\frac{F_1}{F_3}coshk'd\right.$$

$$+\frac{1}{4}Gcosh\left(k_1+k_2\right)d-\frac{1}{4}Hcosh\left(k_1-k_2\right)d\Big]^2$$

$$+\frac{2}{g}\left[\left(\sigma_1-\sigma_2\right)\frac{F_2}{F_4}coshk''d+\frac{1}{4}Gcosh\left(k_1+k_2\right)d\right.$$

$$\left.-\frac{1}{4}Hcosh\left(k_1-k_2\right)d\Big]^2\right\} \qquad \cdots\cdots(56)$$

3. *EXPERIMENTAL RESULTS*

The experiments of two wave trains crossing in intermediate depth have been performed at Tainan Hydraulics Laboratory. A number of different testing runs are listed in Table. 1 , *and the comparison of the theoretical and experimental results are shown through Fig.* 4 *to Fig.* 10.

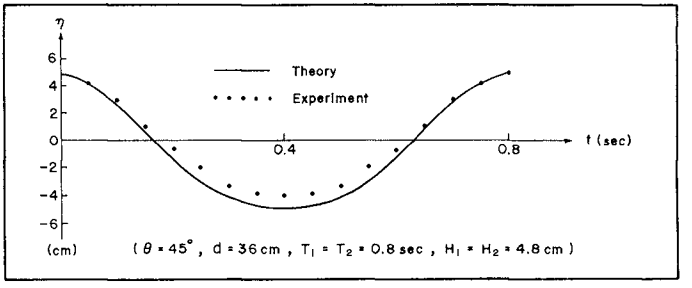

Fig. 5

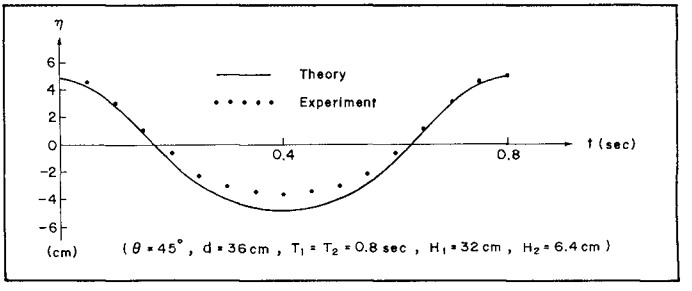

Fig. 6

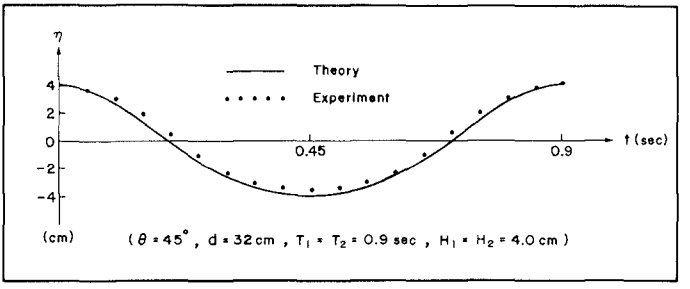

Fig. 7

The variation of water surface elevation for the same wave period and height or the same period but different wave height of two primary wave components crossing are illustrated from Fig. 4 to Fig. 7. It is obvious from these figures that the profiles of common wave are sinusoidal curves and the theoretical values of common wave height are just equal to the sum of two primary waves. Although , those of the experimental values are less than theoretical values but they are coincident very well. The above mentioned results are in agreement with Hsu (1979).

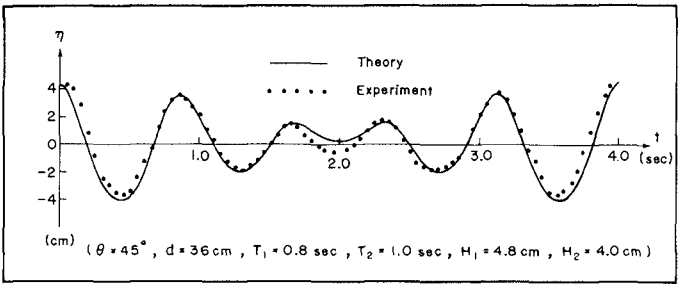

Fig. 8

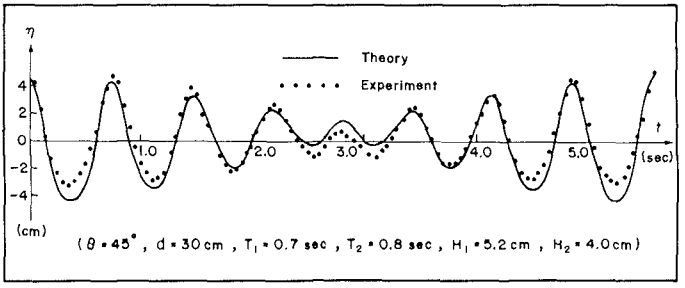

Fig. 9

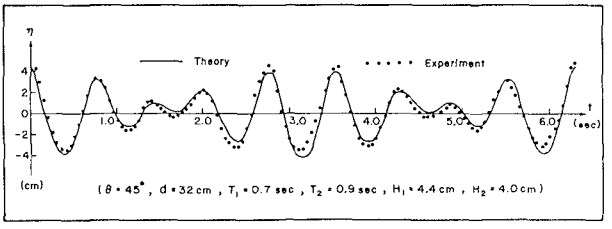

Fig. 10

Moreover, for the cases of different wave period and height, the variation of water surface elevation are shown from Fig. 8 *to Fig.* 10. *It is interested to find that the period of common wave are equal to the least common multiple of two primary wave components exactly and wave profiles of common wave are more complicated but the available experimental data are also coincident with theoretical curves. The comparative values of the theoretical and experimental results are presented in Table.* 2.

4. *CONCLUSIONS*

In this paper , the authors pay attentiom to the non-linear interaction of two free wave trains crossing in intermediate water depth. From theoretical approaches , the velocity potential and water surface elevation have been expanded to the second order by perturbation method. And wave height , velocity of fluid particles , pressure distribution , wave thrust and energy density of the common wave are also investigated. In order to verify the theoretical results , elaborated and numerous experiments have also been performed in our laboratory. Some of the remarkable conclusions can be submitted as follows :

(1) *After the interaction of two free wave trains , the common wave period is just equal to the least common multiple (L.C.M.) of the period of two primary component waves.*

(2) *From the theoretical calculation and experimental verification of the non-linear wave interactions , the maximum common waves height are higher about* 20 % *to* 41.4 % *than those derived from energy superposition.*

(3) *It is well simplified from the theoretical results developed by the authors : as* $k_1 = k_2$, $a_1 = a_2$, *that it becomes short-crest waves ; as* $k_1 = -k_2$, $a_1 = a_2$, *it becomes standing wave and as* $k_1 = k_2$, $a_1 = a_2$ *it becomes stokes progressive wave. Here* $k_1 = |K_1|$, $k_2 = |K_2|$. K_1 , K_2 *and* a_1 , a_2 *are wave numbers vector and wave amplitude of the two primary wave components respectively.*

The tertiary interactions are proceeding continuously in our series researches and will be presented later.

INTEGRAL PROPERTIES FOR VOCOIDAL THEORY AND APPLICATIONS

G.P. Bleach

ABSTRACT

A comparison is made between two reference frames that can each be used to define "still water" for finite amplitude waves on water of finite depth. The reference frame characterized by zero mass flux due to the waves is used to find some exact relations between the wave integral properties. The averaged Lagranian (wave action) approach and the energy/momentum approach to the interaction of finite amplitude waves with slowly-varying currents are also derived in this reference frame. Results in many cases are simpler than those in the more commonly chosen reference frame characterized by zero mean horizontal velocity under the waves.

An application of the integral properties is made to Vocoidal wave theory, which is defined in the zero mass flux frame. It is shown that the rotation present in the orbital velocity field of Vocoidal waves is not always negligible.

INTRODUCTION

In the study of periodic surface gravity waves of finite amplitude on water of finite depth, Stokes (1847) considered two reference frames that can be used to define "still water". These are:

(i) reference frame R1, characterized by zero mean horizontal velocity beneath the wave trough;

(ii) reference frame R2, which has zero mass flux associated with the waves.

Stokes showed that these two reference frames are not equivalent (see section 2, equation (2.7); also Peregrine (1976)) and a choice must be made between them. Most surface gravity wave theories have used R1 to define still water; Stokes (1847) and Cokelet (1977) are examples. An exception in this respect is Vocoidal theory, defined in R2. (Swart and Loubser 1978, 1979a, b). Despite the predominance of R1, there has been recent interest in the use of R2. Reinecker and Fenton (1981) note that wave tank measurements often have zero mass flux, which makes comparison with wave theories defined in R1 more difficult. Whitham (1974) and Jonsson (1978) consider R2 to be valuable in the

Department of Physical Oceanography, University of Cape Town, S.A.

analysis of wavetrains on slowly-varying currents in water of slowly-varying depth. Stiassnie and Peregrine (1979) also speculate on the possible benefits of R2 for such wave/current work.

In view of this interest in R2 and prompted by the availability of the Vocoidal wave theory defined in R2, it was decided to investigate in R2 both the wave integral properties of Longuet Higgins (1975) and the equations governing wave/current interactions as given by Crapper (1979) and Stiassnie and Peregrine (1979). Results are presented for the transformations of wave integral properties between R1 and R2, for exact relations between the integral properties in R2 and for the governing equations for finite amplitude waves interacting with currents varying slowly along the stream. In numerous cases the relative simplicity of the results in R2 compared to those in R1 is evident, particularly in the wave/current interaction equations. This is true for both the momentum/energy interaction equations (Phillips (1966)) and for the averaged Lagranian approach to wave/current interaction (Whitham (1974)).

An application of the integral properties is made in R2 to Vocoidal theory in order to ascertain the amount of rotation present in the only orbital velocity field. It is found that the rotation is negligible only for deep water waves of small amplitude (approximating Airy waves) and for shallow water waves of large amplitude (nearly solitary waves).

REFERENCE FRAMES FOR PERIODIC GRAVITY WAVES ON STILL WATER

In this section the reference frames R1 and R2 are defined and compared. Two dimensional inviscid irrotational motion is assumed and periodic surface gravity waves are considered. The waves propagate in the positive x direction with the z axis vertical, positive upwards, and y is reserved for (later) use as the remaining horizontal coordinate. The bottom is flat and located at $z = -h$.

The most general form of the velocity potential for a periodic surface gravity wave is (Peregrine 1976)

$$\phi = \Phi(\chi,z) + \bar{u}x - \gamma t, \tag{2.1}$$

where the phase χ is related to the wavenumber k and frequency ω (relative to a fixed observer) by

$$\chi \equiv kx - \omega t. \tag{2.2}$$

Φ is the periodic part of ϕ and the constants $\bar{u}$ and γ are determined by the choice of horizontal and vertical reference frames respectively. $\bar{u}$ represents a depth independent current and γ is related to the mean water level. Here, t is taken as zero for convenience and γ is dispensed with (although it can always be found from the Bernoulli equation) until later.

Vertical reference frame

The choice made here is that z = o at the mean water level, i.e.

$$\overline{\overline{\eta}} \equiv o \tag{2.3}$$

where $$\overline{\eta} \equiv \frac{1}{\lambda}\int_o^\lambda \eta dx \tag{2.4}$$

and $\eta(\chi)$ is the wave elevation.

Horizontal reference frame

The reference frame is to be chosen so that there is no background current. There are two obvious choices, firstly to choose the mean horizontal velocity beneath the wave trough to be zero (reference frame R1) and secondly to choose the mass flux associated with the wave (reference frame R2) to be zero.

zero mean horizontal velocity (R1): $\overline{u} \equiv \frac{1}{\lambda}\int_o^\lambda u dx = o$ (2.5)

zero mass flux (R2): $$\overline{u}_m \equiv \frac{1}{\lambda h}\int_o^\lambda \int_{-h}^{\eta} = o \tag{2.6}$$

$\overline{u}$ is the mean horizontal velocity from the velocity potential ϕ and $\overline{u}_m$ is the (Eulerian) mass flux velocity.

Stokes (1847) showed that $\overline{u}$ and $\overline{u}_m$ are not equivalent, since $\overline{u}_m$ can be rewritten as follows, using ϕ from (2.1).

$$\overline{u}_m \equiv \frac{1}{\lambda h}\int_o^\lambda\int_{-h}^{\eta} \frac{\partial\phi}{\partial x}\, dzdx$$

$$= \frac{1}{\lambda h}\int_o^\lambda \int_{-h}^{\eta} \left(\frac{\partial\Phi}{\partial x} + \overline{u}\right) dzdx$$

Since $\overline{\eta} \equiv o$, $$\overline{u}_m = \frac{1}{\lambda h}\int_o^\lambda \int_{-h}^{\eta} \frac{\partial\Phi}{\partial x}\, dzdx + \overline{u} \tag{2.7}$$

The remaining integral for Φ is the average mass flux velocity due to the periodic wave motion and turns out to be positive, so $\overline{u}_m > \overline{u}$.

A choice must therefore be made between R1 and R2. The latter is not often used, despite the advantages mentioned earlier. These advantages are now explored below with the definition in R2 of wave integral properties and the relations they satisfy (following Longuet-Higgins' (1975) work in R1), followed by the analysis of wave/current interaction in the following section.

INTEGRAL PROPERTIES AND THE EXACT RELATIONS BETWEEN THEM

Integral properties for periodic surface gravity waves involve wave properties that have been averaged over the phase χ. If the averaging is done at a particular time t, this is equivalent to an average over the wavelength λ. Longuet-Higgins (1975) defined gravity wave

integral properties and derived relations between them, working in R1 in almost all cases. (See also Crapper 1979).

Here the transformations between R1 and R2 are given, followed by definition of the integral properties in R2 and the derivation of the relations they satisfy.

Notation: (i) printed quantities are those defined in R2

(ii) an overbar $\overline{(\ )}$ denotes $\frac{1}{\lambda}\int_0^\lambda (\ )dx$ throughout

Let U_r be defined as the velocity of translation of R2 with respect to R1. The velocities u and $\overline{u}$ and the velocity potential ϕ transform as follows:

$$u' = u - U_r \tag{3.1}$$

$$\overline{u}' \equiv \frac{1}{\lambda}\int_0^\lambda u'dx = \frac{1}{\lambda}\int_0^\lambda udx - U_r$$

$$\therefore \quad \overline{u}' = -U_r \text{ using (2.5)} \tag{3.2}$$

$$\phi' = \phi - U_r x \tag{3.3}$$

Integral properties for periodic surface gravity waves

The following definitions of the wave integral properties are essentially of Longuet-Higgins with the density ρ inserted. They are not yet specific to any reference frame. All definitions are per unit horizontal surface area.

Mean mass flux $$I \equiv \frac{\rho}{\lambda}\int_0^\lambda\int_{-h}^{\eta} u\, dzdx \tag{3.4}$$

$$= \rho h\, \overline{u}_m \qquad \text{by (2.6)}$$

Mean kinetic energy $$T \equiv \frac{\rho}{2\lambda}\int_0^\lambda\int_{-h}^{\eta} (u^2+w^2)dzdx \tag{3.5}$$

Mean potential energy $$V \equiv \frac{\rho}{\lambda}\int_0^\lambda\int_0^{\eta} gz\, dzdx \tag{3.6}$$

Radiation stress component $$S_{xx} \equiv \frac{\rho}{\lambda}\int_0^\lambda\int_{-h}^{\eta} [\frac{p}{\rho} + u^2]dzdx - \tfrac{1}{2}\rho g h^2 \tag{3.7}$$

Mean energy flux $$F \equiv \frac{\rho}{\lambda}\int_0^\lambda\int_{-h}^{\eta} [\frac{p}{\rho} + \tfrac{1}{2}(u^2+w^2)+gz]u\, dzdx \tag{3.8}$$

Additional quantities used by Longuet Higgins are as follows:

Mass flux in the steady flow relative to an observer moving with the phase velocity c

$$-Q \equiv \rho \int_{-h}^{\eta} (u-c)dz \tag{3.9}$$

Bernoulli constant $$B \equiv p + \frac{\rho}{2}[u^2 - 2uc+w^2] + \rho gz \tag{3.10}$$

Total head $$R \equiv p + \frac{\rho}{2}[(u-c)^2 + w^2] + \rho g(z+h) \tag{3.11}$$

$$= B + \rho gh + \frac{\rho c^2}{2}$$

Transformations of the integral properties between R1 and R2

The quantities defined in (3.4-11) are transformed from R1 to R2 by using (3.1-3). The relations (2.5, 2.6) that define R1, R2 are then used to simplify the results.

eg. mass flux $$I' \equiv \frac{\rho}{\lambda}\int_0^{\lambda}\int_{-h}^{\eta} u'dzdx \quad \text{by (3.4)}$$

$$= \frac{\rho}{\lambda}\int_0^{\lambda}\int_{-h}^{\eta} (u-U_r)dzdx$$

$$= I - \rho hU_r$$

Since $I' \equiv 0$, $$I = \rho hU_r \tag{3.12}$$

$$T' = T - \frac{\rho hU_r^2}{2} \tag{3.13}$$

$$S' = S_{xx} - \rho hU_r^2 \tag{3.14}$$

$$F' = F - U_r[3T-2V + \rho h\overline{(u_b)^2}] \tag{3.15}$$

where u_b is the u velocity component at the bottom (z = -h), the pressure p' = p and the vertical velocity w' = w.

The constants Q', B', R' are found to be:

$$Q' = Q \tag{3.16}$$

$$B' = B + \rho U_r[c-U_r] \tag{3.17}$$

$$R' = R \tag{3.18}$$

Exact relations between the integral properties in R2

A number of exact relations between the integral properties are given by Longuet-Higgins (1975). All except his relation (2.4) are in R1 and here his approach is followed to derive the equivalent relations in R2, making use of the fact that $I' \equiv o$ and using some of the above transformations for confirmation of the results. The results of L.H. are given for comparison, with ρ inserted and referenced by his equation numbers (or letters).

$$Q' = \rho c' h \qquad (3.19)$$

$$Q = \rho c h - I \qquad \text{L.H.(A)}$$

$$2T' = \rho c' h U_r \qquad (3.20)$$

$$= Q' U_r \qquad \text{essentially L.H.(2.4)}$$

$$2T = c\, I \qquad \text{L.H.(B)}$$

$$2T' = \left(\frac{c'}{\lambda}\right) \int_o^\lambda \eta \{c' - [1+(\frac{\partial \eta}{\partial x})]^{\frac{1}{2}}[2R' - 2\rho g(h+\eta)]^{\frac{1}{2}}\}dx \qquad (3.21)$$

The corresponding expression for 2T is identical in form (L.H.(E)). (A typographical error in L.H.(E) is the omission of the first η symbol). Note that the choice $\overline{\eta} \equiv o$ (2.3) removes the $\eta c'$ term after integration.

$$S_{xx}' = 4\,T' - 3V' + \rho h\overline{(u_b')^2} \qquad (3.22)$$

where

$$\overline{(u_b')^2} = \overline{(u_b^2)} + U_r^2 \qquad (3.23)$$

The corresponding Sxx expression (L.H.(c)) is again identical in form to the R2 expression.

$$F' = [3\,T' - 2\,V' + \tfrac{1}{2}\rho h\overline{(u_b')^2}]c' \qquad (3.24)$$

$$F = [3\,T - 2\,V]c + \tfrac{1}{2}[\rho h c + I]\overline{u_b^2} \qquad \text{L.H.(3.10)}$$

Note that the energy flux relation is simpler in R2 since the I' term is zero. This type of simplification occurs frequently in the conservation equations to be derived below and is a primary advantage of working in R2.

CONSERVATION EQUATIONS FOR WAVES ON SLOWLY-VARYING CURRENTS OVER SLOWLY-VARYING TOPOGRAPHY

Phillips (1966) derived a set of conservation equations for waves interacting with depth-independent currents that vary slowly along or

across the stream. These equations are mass, momentum and energy equations that have been vertically integrated and then horizontally averaged. Whitham (1974) derived an alternative set via a variational approach and the two sets were made fully compatible by Stiassnie and Peregrine (1979). A general review of wave/current interactions is given by Peregrine (1976).

All the above work is effectively in R1; the mean horizontal velocity at a fixed point below the wave trough is the current velocity. Stiassnie and Peregrine speculate that it may be better to work in a reference frame in which the total mass flux divided by ρd (where d is the water depth) is the current; i.e. the wave mass flux is zero, which is the defining property of R2.

The present work follows Phillips' approach in R2 and confirmed that the governing equations take a simpler form than in R1. The alternative approach of Whitham is also investigated in R2 and expressions are found for Luke's Lagrangian (Luke 1967), the Bernoulli term γ' (2.1) and Whitham's averaged Lagrangian. Once a suitable wave theory has been chosen, the wave action equation can be derived from the averaged Lagrangian given here.

Notation and definitions

Motion is now in three dimensions and Greek subscripts refer to components in the horizontal ($x_1 = x$, $x_2 = y$) plane. Since slowly varying waves and currents may change the water level from its undisturbed value at $z = o$, the water depth is denoted by $d(x_\alpha t)$. The slowly varying bottom is at $z = -h(x_\alpha)$, and $\partial_{\alpha\beta} \equiv 1$ if $\alpha = \beta$, else $\partial_{\alpha\beta} \equiv o$.

$$d = \frac{1}{\lambda}\int_o^\lambda (\eta+h)dx \tag{4.1}$$

The integral properties (3.4-3.8) are easily generalised for motion in the (x,y) plane with mean water level at $z = d-h$; the overbar represents (as before) the average over the wavelength.

$$I'_\alpha \equiv \overline{\rho\int_{-h}^{\eta} u'_\alpha dz} \equiv o \tag{4.2}$$

$$T' \equiv \overline{\frac{\rho}{2}\int_{-h}^{\eta}(u'_\alpha u'_\alpha + w^2)dz} \tag{4.3}$$

$$V' \equiv \frac{\rho g}{2}[\overline{\eta^2} - (d-h)^2] \tag{4.4}$$

$$S'_{\alpha\beta} \equiv \overline{\rho\int_{-h}^{\eta}(u'_\alpha u'_\beta + \frac{p}{\rho}\partial_{\alpha\beta})dz} - \tfrac{1}{2}\rho g d^2\partial_{\alpha\beta} \tag{4.5}$$

$$F'_\alpha \equiv \rho\int_{-h}^{\eta} u'_\alpha[\tfrac{1}{2}(u'_\beta u'_\beta + w^2) + \frac{p}{\rho} + g(z+h-d)]dz \tag{4.6}$$

Averaged mass, momentum and energy conservation equations.

The kinematic conservation equation is common to both approaches and is (Peregrine (1976)):

$$\omega' = \sigma' + k'_\alpha U'_\alpha \tag{4.7}$$

where ω is (as before) the wave frequency relative to a fixed observer, σ' is the frequency relative to the current and U'_α are the components of the depth independent current.

The mass, momentum and energy conservation equations in R2 are derived following Crapper (1979) - essentially Phillips' approach. In each case, the flow velocity is split into $U'_\alpha + u'_\alpha$ in the local conservation equation and the equation is then integrated over depth and averaged over a wavelength, which introduces the integral properties (4.2-4.6). Boundary conditions and the zero mass flux condition (4.2) are used finally to simplify the results. The method is sketched below for the mass conservation equation and the results for mass, momentum and energy conservation are compared with the corresponding results in R1 obtained by Stiassnie and Peregrine.

Mass conservation.

Local continuity equation: $$\frac{\partial}{\partial x_\alpha}(U'_\alpha + u'_\alpha) + \frac{\partial w}{\partial z} = 0 \tag{4.8}$$

Now $$\frac{\partial}{\partial x_\alpha}\int_{-h}^{\eta}(U'_\alpha + u'_\alpha)dz - (U'_\alpha + u'_\alpha)_{z=\eta}\cdot\frac{\partial \eta}{\partial x_\alpha} - (U'_\alpha + u'_\alpha)_{z=-h}\frac{\partial h}{\partial x_\alpha}$$

$$+ w|_{z=\eta} - w|_{z=-h} = 0 \tag{4.9},$$

where Leibnitz' rule has been used to reverse the order of differentiation and integration.

The kinematic surface boundary condition is

$$\frac{\partial \eta}{\partial t} + (U'_\alpha + u'_\alpha)\frac{\partial \eta}{\partial x_\alpha} = w \qquad \text{at } z = \eta \tag{4.10}$$

and the corresponding bottom condition is

$$-(U'_\alpha + u'_\alpha)\frac{\partial h}{\partial x_\alpha} = w \qquad \text{at } z = -h \tag{4.11}$$

The mass conservation equation is obtained after inserting (4.10) and (4.11) into (4.9), averaging over a wavelength and using $I_\alpha \equiv 0$.

$$\rho\frac{\partial d}{\partial t} + \frac{\partial}{\partial x_\alpha}[\rho d U'_\alpha] = 0 \tag{4.12}$$

Compare the result (in R1) of Stiassnie and Peregrine:

$$\rho\frac{\partial d}{\partial t} + \frac{\partial}{\partial x_\alpha}[\rho d U_\alpha + I_\alpha] = 0 \tag{4.13}$$

(The mass conservation equation also appears in the averaged Lagrangian approach described later.)

Momentum conservation.

The momentum conservation equation is found similarly, and is:

$$\frac{\partial}{\partial t}(\rho d U'_\alpha) + \frac{\partial}{\partial x_\beta}[\rho d U'_\alpha U'_\beta + S'_{\alpha\beta} + \tfrac{1}{2}\rho g d^2 \partial_{\alpha\beta}] - \rho g d \frac{\partial h}{\partial x_\alpha} = 0 \tag{4.14}$$

Compare the R1 expression:

$$\frac{\partial}{\partial t}(\rho d U_\alpha + I_\alpha) + \frac{\partial}{\partial x_\beta}[(\rho d U_\alpha + I_\alpha)(\frac{I_\beta}{\rho d} + U_\beta) + S_{\alpha\beta} + \tfrac{1}{2}\rho g d^2 \partial_{\alpha\beta} - \frac{I_\alpha I_\beta}{\rho d}]$$

$$- \rho g d \frac{\partial h}{\partial x_\alpha} = 0 \tag{4.15}$$

Energy conservation.

Energy conservation in R2:

$$\frac{\partial}{\partial t}[\tfrac{1}{2}\rho d(U')^2 + \tfrac{1}{2}\rho g(d-h)^2 + T' + V']$$

$$+ \frac{\partial}{\partial x_\alpha}[U'_\alpha\{\frac{\rho d}{2}(U')^2 + \rho g d(d-h) + T' + V'\} + F'_\alpha + S'_{\alpha\beta} U_\beta] = 0 \tag{4.16}$$

Corresponding equation in R1:

$$\frac{\partial}{\partial t}[\tfrac{1}{2}\rho d U^2 + \tfrac{1}{2}\rho g(d-h)^2 + T + V + U_\alpha I_\alpha]$$

$$+\frac{\partial}{\partial x_\alpha}[U_\alpha\{\tfrac{1}{2}\rho d U^2 + \rho g d(d-h) + T + V + U_\beta I_\beta\} + F_\alpha + I_\alpha[g(d-h)+\tfrac{1}{2}U^2]$$

$$+ S_{\alpha\beta}U_\beta = 0 \tag{4.17}$$

The relative simplicity of the equations in R2 is clear, since all terms involving I_α' are eliminated.

Averaged Lagrangian approach to wave/current interactions

Whitham's method (Whitham (1974), Peregrine (1976), Crapper (1979)) requires a Lagrangian to be chosen and an averaged Lagrangian to be obtained for the system. Here, Luke's (1967) lagrangian is used in R2.

Luke's Lagrangian: $$L' \equiv -\rho\int_{-h}^{\eta}\left[\frac{\partial\phi'}{\partial t} + \tfrac{1}{2}\left(\frac{\partial\phi'}{\partial x_\alpha}\cdot\frac{\partial\phi'}{\partial x_\alpha} + \left(\frac{\partial\phi}{\partial z}\right)^2 + gz\right]dz \quad (4.18)$$

where $$\phi' \equiv U_\alpha' x_\alpha - \alpha' t + \Phi(\chi', z), \quad (4.19)$$

and $$\chi' \equiv k_\alpha' x_\alpha - \omega t \quad (4.20)$$

The averaged Lagrangian $\mathcal{L}'$ is defined as

$$\mathcal{L}' \equiv \frac{1}{2\pi}\int_0^{2\pi} L'\,d\chi' \quad (4.21)$$

Use of L' from (4.18) and choosing a particular value of t to make the phase integral equivalent to an integral over the wavelength, one obtains:

$$\mathcal{L}' = \rho d(\gamma' - \tfrac{1}{2}U_\alpha' U_\alpha') - T' - V' - \tfrac{1}{2}\rho g[(d-h)^2 - h^2] \quad (4.22)$$

Compare $$\mathcal{L} = \rho d(\gamma - \tfrac{1}{2}U_\alpha U_\alpha) + T - V - \tfrac{1}{2}\rho g[(d-h)^2 - h^2], \quad (4.23)$$

obtained by Crapper (1979) in R1. The discrepancy in sign of the kinetic energy term is removed if expressions for γ, γ' are found. The Bernoulli equation for the whole flow is evaluated at z = - h, averaged and then (3.20) is used in the R2 expression to obtain:

$$\gamma' = g(d-h) + \frac{U_\alpha' U_\alpha'}{2} + \frac{u_\alpha' u_\alpha'}{2}\Big|_{z=-h} + \frac{2T'}{\rho d} \quad (4.24)$$

$$\gamma = g(d-h) + \frac{U_\alpha U_\alpha}{2} + \frac{u_\alpha u_\alpha}{2}\Big|_{z=-h} \quad (4.25)$$

On inserting these expressions into (4.22) and (4.23) respectively, the form of the averaged Lagrangians $\mathcal{L}'$ and $\mathcal{L}$ is identical:

$$\mathcal{L}' = \rho d\left(\frac{u'_\alpha u'_\alpha}{2}\Big|_{z=-h} + \frac{gd}{2} + \frac{T'}{\rho} - \frac{V'}{\rho}\right) \qquad (4.26)$$

The averaged Lagrangian can be used to obtain a set of conservation equations for the wave/current interaction. These are the mass conservation equation (identical to (4.12)), consistency conditions replacing the momentum equations and the wave action equation which replaces the energy equation. (See Peregrine (1976)). This completes the analysis of the conservation equations in R2 and shows their relative simplicity compared to the more commonly used equations derived in R1.

APPLICATIONS OF THE INTEGRAL PROPERTIES TO VOCOIDAL WAVE THEORY

Swart and Loubser (1978, 1979a,b) developed the Vocoidal gravity wave theory in an attempt to provide a theory that was relatively simple to use yet accurate. Swart et al (1979) found that Vocoidal theory matched 600 experimental data sets better than twelve other commonly used wave theories. (Cokelet's theory was not considered due to its complexity). Two rather unusual features of Vocoidal theory are that it is defined in R2 and that the orbital velocity field contains a small amount of rotation. The integral properties (3.4) - (3.8) have been defined for Vocoidal theory, but not the exact relations between them and the wave/current results above. These relations and results are valid only for irrotational wave motion. In this section, the amount of rotation in Vocoidal theory is checked by investigating the vertical dependence of $\overline{u'}$ since $\overline{u'}$ is independent of depth for an irrotational motion. This is shown by considering $\frac{\partial u'}{\partial z}$.

$$\frac{\partial u'}{\partial z} = \frac{\partial}{\partial z}\left[\frac{1}{\lambda}\int_0^\lambda u'\,dx\right]$$

$$= \frac{1}{\lambda}\int_0^\lambda \frac{\partial u'}{\partial z}\,dx$$

Irrotationality $\Rightarrow$ $\frac{\partial u'}{\partial z} = \frac{\partial w'}{\partial x}$

$$\therefore \frac{\partial u'}{\partial z} = w'(\lambda) - w'(0)$$

$$= 0 \quad \text{by periodicity of } w' \qquad (5.1)$$

Numerical integration of u' at various depths below the wave trough for Vocoidal waves of various steepnesses in a variety of water depths indicates that the theory is virtually irrotational both for low waves in deep water, where Vocoidal theory tends to Airy theory, and for high waves in shallow water, where the Vocoidal wave is virtually a

solitary wave. For situations in between these extremes, the rotation causes $\overline{u^r}(z)$ to vary considerably with z. Two typical results are shown below in Table 1 for a wave of period 4,0 seconds in 1.0 m water depth. (The low wave/deep water equivalence of Vocoidal and Airy waves is not shown). The parameter Z_r shows the relative depth under the wave trough at which $\overline{u^r}(z)$ has been calculated; Z_r = o at the bottom and Z_r = 1 at the trough. H is the wave height (crest to trough).

Table 1: Mean horizontal velocity $\overline{u^r}(z)$ at various depths

H(m)	Z_r	$\overline{u'(z)}$ (m/s)
0,20	1,0	- 0,006
	0,9	- 0,009
	0,8	- 0,012
	0,7	- 0,014
	0,6	- 0,016
	0,5	- 0,018
	0,4	- 0,020
	0,3	- 0,021
	0.2	- 0,022
	0,1	- 0,022
	0,0	- 0,022
1,40	1,0	- 0,522
	0,9	- 0,530
	0,8	- 0,536
	0,7	- 0,542
	0,6	- 0,547
	0,5	- 0,551
	0,4	- 0,554
	0,3	- 0,557
	0,2	- 0,559
	0,1	- 0,560
	0,0	- 0,560

Because of the rotation present in the theory, the exact relations (3.21), (3,22), (3.24) are unlikely to be obeyed accurately.

Numerical integration of the appropriate Vocoidal expressions on the right hand side of (3.21,2,4) and comparison with the Vocoidal values for $2T'$, S'_{xx}, F' respectively shows that there is good agreement in deep water but divergences of up to 50% elsewhere.

CONCLUSIONS

Although the existence of the two reference frames R1 and R2 have long been known, (see Stokes 1847) there has been little use made of R2. In this paper, some advantages of R2 are demonstrated, namely that the exact relations between the integral properties are as simple or simpler in form than those in R1 and that the equations for the interaction of finite amplitude waves with slowly varying currents in water of slowly varying depth are considerably simplified. Transformations from R1 to R2 are also given to facilitate the use in R2 of a wave theory originally defined in R1.

Vocoidal theory is defined in R2 from the outset and could easily be used in the wave/current interaction equations presented here if it were not for the presence of a small amount of rotation. This rotation is investigated via the mass horizontal velocity below the trough and it is found that the rotation is small for deep water waves of small height and for steep shallow water waves.

The presence of rotation is also reflected in the inaccuracies found when the exact relations (3.21, 2, 4) are tested for Vocoidal theory.

A further test for rotation that would be of interest would be that proposed by Truesdell (see Serrin, 1959 - section 27) who defines the following parameter Ω as a measure of rotation:

$$\Omega \equiv \frac{\omega_r}{\sqrt{2\, D_{ij}\, D_{ij}}} \tag{6.1}$$

where ω_r is the magnitude of the angular velocity. Dij are the components (xz plane) of the deformation tensor

$$Dij \equiv \tfrac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{6.2}$$

For irrotational motion, $\Omega = 0$ and for rigid rotation $\Omega = \infty$. Serrin uses $\Omega < 10\%$ as an indicator of the presence of significant rotation.

ARTIFICIAL MANIPULATION OF BEACH PROFILES

Timothy W. Kana[1] and Michael Svetlichny[2]

ABSTRACT

A field study was conducted at Myrtle Beach, South Carolina (U.S.A.), to determine the response of natural beaches to artificial manipulation by sand scraping. Between March 1981 and May 1982, a total of 100,000 m^3 of sand was shifted from the lower beach to the backbeach on three occasions over a 14-km length of shoreline. Fifty-four profile stations were surveyed to the -1.0 meter contour as many as ten times during the study to determine the effect of scraping and fill along a stable-to-slightly erosional beach. The purpose of the scraping and fill was to provide temporary erosion relief, protect existing dunes and structures, and provide a wider recreational beach at high tide. It was found that scraping and fill had little adverse effect on the beach cycle in the northern zone of the project area, which is fronted by a natural dune system. Fill placed at a gentle slope along the seaward margin of the dunes remained in place for up to ten months before eroding to the prefill surface. In contrast, similar quantities of fill along shore protection structures in the southern zone eroded in several weeks to four months. The study found significant differences in the response of armored versus unarmored shorelines with higher erosion rates and slower recovery of the beach at armored stations.

INTRODUCTION

A field study was conducted at Myrtle Beach, South Carolina (U.S.A.) to determine the response of a natural beach to artificial manipulation by sand scraping. One purpose of the study was to establish limiting criteria for the degree of berm or dune maintenance feasible on moderate energy sand beaches, without adverse impact to the natural beach cycle.

Several U.S. east coast beach communities including Ocean City, Maryland (Kerhin and Halka, 1981), and Hilton Head Island (South Carolina) have made a practice for a number of years of borrowing sand from the lower beach and backfilling the berm or dune area. In the case of Myrtle Beach, the purpose of the artificial beach manipulation has been to widen the recreational, high tide beach and reduce the erosion rate of dune scarps. This practice has been controversial

[1]Coastal Dynamics Division, Research Planning Institute, Inc., 925 Cervais Street, Columbia, South Carolina, U.S.A. 29201

[2]Marathon Oil Company, Post Office 120, Casper, Wyoming, U.S.A. 82602

since it does not add sediment to the littoral system but merely shifts it around. The simplistic view holds that scraping adversely steepens the beach profile, making subsequent erosion more likely and severe. To our knowledge, this notion has not been tested.

GEOMORPHIC SETTING AND DEVELOPMENT PRACTICES

Myrtle Beach, located along the northern coast of South Carolina on the U.S. east coast (Fig. 1), is a mainland, strand shoreline. It consists of a broad, 16-km arcuate section of coastline backed by Pleistocene beach ridges. No major tidal inlets or marshes occur at that locality. In recent historic times, the shoreline has been slightly erosional experiencing dune recession rates averaging approximately one-third to one-half meter per year over the last century (Hubbard et al., 1977). Although erosion is slow, it has progressed to a point where the quality and character of the beach, on which much of the tourist economy depends, is becoming degraded. Rapid and sometimes haphazard development practices combined with steady recession of the shoreline have forced construction of retaining walls, bulkheads, and rock revetments to protect existing development.

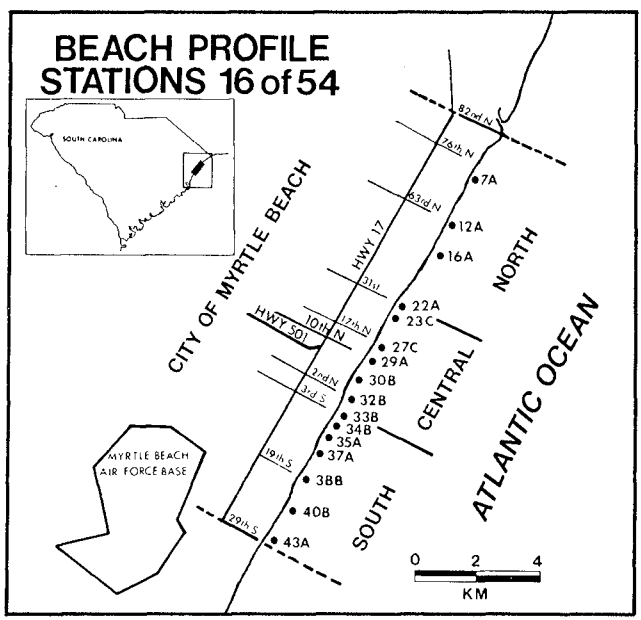

FIGURE 1. Location of Myrtle Beach (South Carolina) along the U.S. east coast. Selected beach profile stations along the northern-central and southern portion of the City are shown.

The shoreline along the City of Myrtle Beach is dominated by private residences in the northern half and hotels in the southern half (Fig. 2). Several piers and minor swashes (tidal channels emptying along the beach) interrupt an otherwise broad, arcuate shoreline. Isolated outcrops of Pleistocene-age mud or marsh clay deposits occur near the low watermark. Nearest navigable inlets are Little River (27 km to the northeast) and Murrells (21 km to the southwest). As Figure 2 shows, a narrow dune remains seaward of most residences in the northern portion of the city. The central area of the city shoreline has an increasing concentration of hotels. Natural dunes are rare; however, the shoreline edge is generally "soft" with landscaping or artificial fill along the seaward property boundaries. The southern third of the shoreline (Fig. 2c) is dominated by hard structures along the backbeach, with little or no setback of developed property.

NEARSHORE PROCESSES

The study area lies in a broad, wave-dominated embayment that forms an arc between Cape Fear (North Carolina) and Winyah Bay (South Carolina). A mean tidal range of 1.6 m (5.1 ft) and a spring tidal range of 1.8 m (6.0 ft) places Myrtle Beach in the high end of the microtidal (<2.0 m) class.

Nearshore bathymetry from the shoreline to 400 m offshore is characteristically concave upward and steep, with an average slope of 14 m/km. From 400 m to 4 km offshore, the rate is only 0.8 m/km and from 4 km to 12 km, the rate is 0.4 m/km (Brown, 1977).

Without the influence of inlet-associated tidal currents, the major mechanism affecting sediment transport is wave action. At Myrtle Beach, both longshore and onshore/offshore transport are significant in the surf zone. The observed cyclic changes of the beach profile are largely a result of the onshore/offshore component. Short-period storm waves erode beach sediment and transport it offshore where it commonly deposits as a bar. During fair-weather conditions, lower-energy waves move sediment back onshore. The longshore component is highly correlated with the prevailing seasonal winds that determine the direction and angle of wave approach and the resulting longshore current direction. On an annual basis, the net longshore sediment transport in South Carolina is to the south (Hubbard et al., 1977).

PREVIOUS WORK

There have been few studies dealing with beach scraping as a soft approach to beach restoration. Among the nonstructural means of restoring shorelines, artificial nourishment from offshore, inlet, and inland sources (Strock and Noble, 1975; Walton and Purpura, 1977; CERC, 1977) has been widely preferred and employed over the cannibalization of sand from portions of the beach. Beach scraping has generally been performed on a small scale, mainly to protect one or a few properties from wave attack.

FIGURE 2A) Northern Zone: Predominantly residential with existing low, natural foredune. Few shore protection structures.

FIGURE 2B) Central Zone: Transition from residential to predominantly hotels. Note encroachment of development up to dune line. Shore protection structures are generally fronted by landscaped, soft edges along the backbeach.

FIGURE 2C) Southern Zone: Dominated by hotels and hard structures along the backbeach. Natural dunes essentially nonexistent.

FIGURE 2. Representative oblique aerial photographs of the northern (2A), central (2B), and southern (2C) portions of the project area at Myrtle Beach, South Carolina. All photos taken at low tide on 3 February 1981.

Documentation on the effects of beach scraping projects have dealt with the comparison of beach volumes and morphologic changes along the manipulated profile; however, statistical applications for significance testing have not been performed. In a study of beach scraping conducted at Ocean City (Maryland), Kerhin and Halka (1981) report accelerated erosion in the backshore due to artificial disruption of the natural beach profile. Their project, however, preceded a winter season that proved to be one of the stormiest in recent history. Conclusions made from sweep-zone profile plots indicated that bulldozing of the lower foreshore oversteepened an already steep beach slope and interfered with the seasonal readjustment to an equilibrium profile, allowing erosion at a greater rate.

Tye (in press) presents a comparison of morphologic changes between scraped and nonscraped profile stations at Folly Beach (South Carolina) shortly after the passage of Hurricane DAVID (1979). Analyses of sequential profile plots had indicated an interrupted natural recovery cycle along scraped portions of the beach due to mechanical steepening of the lower foreshore, allowing a transformation in breaker type from spilling to plunging and inducing a net offshore movement of sediment. His emphasis from this study was placed on the importance of a quantitative assessment of the initial erosion and subsequent recovery as a baseline for implementing a more prudent beach scraping program.

Another concept of placing sand on the beach, practiced during the 1960s at Jupiter Island (Florida), is that of the Sauerman drag scraper (Department of Coastal and Oceanographic Engineering, University of Florida, 1969). In this project, borrow zones were located offshore, seaward of the normal surf zone, ranging frem 50 to 240 m from the shoreline. Approximately one year after scraping, a survey revealed a much steeper backshore and beach face, largely attributed to a coarser grain size transported from the offshore borrow area. The total volume of sand comprising the supratidal beach, however, was greater at the end of the study than before scraping. The beach fill had a positive effect in preventing any large-scale erosion, although it probably did not stop overall erosion along the profile.

Foredune construction through various sand-fencing materials and methods has been practiced at Cape Cod (Massachusetts), Core Banks (North Carolina), and Padre Island (Texas) (CERC, 1977). Recently, the townships of Ortley Beach and Lavalette (New Jersey) have experimented with erecting closely spaced sand fencing along the backshore, angled normal to the predominant northeast winds (S. Halsey, N.J. Environmental Protection Agency, pers. comm.). During fall and winter, sand is trapped by the fence, building up the backshore. Prior to the summer season, the fence is removed and the accumulated sand is mechanically redistributed both landward and seaward, creating an artificial berm and simultaneously decreasing the beach slope. These beach scraping and nourishment programs have all been conducted along highly developed, critically eroding barrier islands on the Atlantic coast, often in sediment-starved beaches. At Myrtle Beach, the erosion rate is considerably lower, and sediment supply is apparently more readily available from the eroding Pleistocene ridges and updrift sources.

DESIGN

Low cost attracted the City of Myrtle Beach to implement a beach-scraping maintenance program to enhance the backshore and provide temporary protection from shoreline recession, at least until longer-term solutions could be financed and implemented. This soft-engineering approach, though temporary, was considered cost-effective and aesthetically preferable to hard structures in 1981.

The plan for backbeach restoration followed the design shown in Figure 3 (Kana and Dinnel, 1981). Borrow areas were generally located along broad, low-relief intertidal ridges with higher volumes removed at localized accretion fillets around piers. Fill zones were graded to a gentle slope (approximately 1:10) as illustrated in Figure 4. Typical unit width volumes of borrow and fill were 6-8 m^3/linear meter of beach. Construction was by means of pan earth movers and bulldozers. The design of borrow zones attempted to distribute any adverse effects of scraping by identifying broad sections of the low-tide beach where relatively more sand was available, and by limiting the depth of scraping to within 0.3 to 0.5 m. This was determined by comparison of the total unit width volumes from 54 reference cross-sections.

DATA BASE

NETWORK OF STATIONS

The data base for design and evaluation of the Myrtle Beach scraping program consists of 54 beach profile stations (Fig. 1) measured up to ten times each between February 1981 and May 1982 (300 data sets total). Stations were spaced approximately 250 m apart and surveyed from the backshore to the -1.0 m mean sea level (MSL) contour.

The stations represent a variety of beach conditions and backbeach configurations ranging from natural dune/beach areas to armored shorelines. Erosional scarps of semilithified Pleistocene mud are also common along the central third of the project area. The most common armoring of the backbeach is by means of vertical concrete bulkheads; timber and sheetpile bulkheads are next common; riprap of 50-500 pound stone (typical) occurs at several stations.

These data offer a detailed comparison of short-term beach response due to artificial manipulation as well as natural changes along armored and unarmored beaches.

STANDARDIZED BEACH SEGMENTS

The basis for spatial and temporal comparison of profiles were standard unit width cross-sections of the intertidal beach from the base of scarps or armoring to the -1.0 m MSL contour (Fig. 5). These sections included backbeach, mid-beach, and low-tide ridge areas for evaluating the effect of scraping and fill on particular parts of the profile. Segments were normalized against mean beach section for statistical comparison and significance testing.

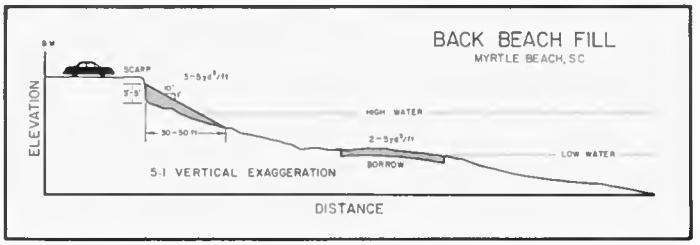

FIGURE 3. (Above) General design for beach scraping and backbeach fill at Mrytle Beach.

FIGURE 4. (A-C) Construction sequence showing pan earthmovers scraping near the low watermark on an intertidal ridge (4A); grading to a gentle 1:10 slope along the backbeach (4B); and the final condition after raking (4C). In general, mean high water was shifted seaward 10-15 m to the base of the fill zone.

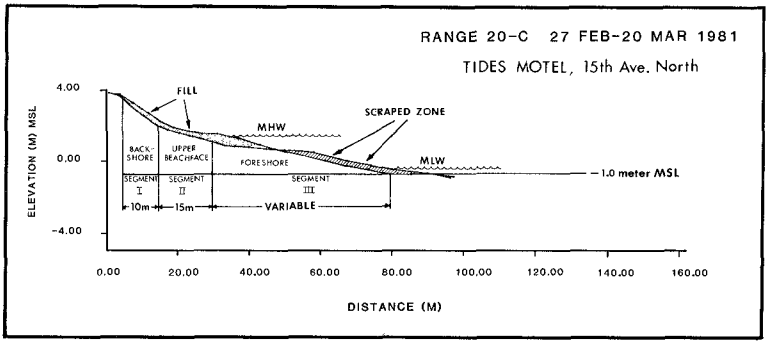

FIGURE 5. Representative reference beach cross-section in the central zone of Myrtle Beach. Principal borrow zones were along Segment III (foreshore) on intertidal ridges. Fill zones were located along Segment I (backshore) at or above the high watermark up to existing dune scarps or shore protection structures.

The backshore (Segment I) consists of a 10-m-wide section of the beach from the base of dunes or shore-protection structures and coincides with the zone of fill near high water. The upper beach face (Segment II) is designated as an arbitrary 15-m-wide zone which generally was undisturbed by scraping or fill. The lowermost segment (III) included the entire low-tide terrace and ridge system extending to the -1.0 m MSL contour. Width of Segment III varied from approximately 60 to 100 m, becoming narrower in the southern portion of the city, and incorporated all borrow zones. Table 1 is a summary of backshore station types over the project area. Note that the northern portion of the shoreline is dominated by dunes or sand fill, whereas the southern district is more commonly armored.

TABLE 1. Distribution of stations (%).

Region	Shoreline Length	No.	Armored	Natural Erosional Scarps	Dunes/ Old Fill
North	6.6 km	17	6%	12%	82%
Central	3.9 km	22	9	37	54
South	4.2 km	15	68	13	19
Overall	14.7 km	54	26%	21%	53%

Mean unit width beach volume from the dune line to the approximate -1.0 m MSL contour is given in Figure 6 for each zone of the project area. Also indicated are the proportion of armored versus natural stations and number of stations for each zone. Note the general decrease in unit beach volume from north to south. There was an average of 20 percent less sand in the reference sections along the more heavily armored southern zone than along the northern zone. All profiles were ohtained over a 3-day period in November 1981.

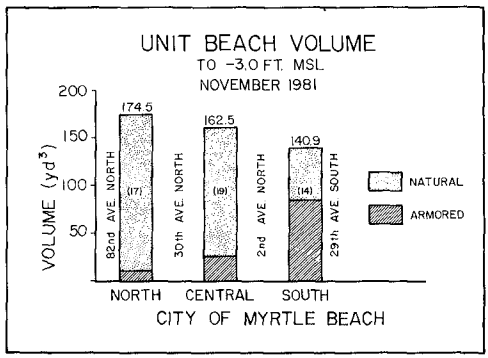

FIGURE 6. Mean unit-width beach volume for reference sections between the base of the dunes or the shoreline structures to the -3.0 ft (approx. -1.0 m) MSL contour. Relative proportion of armored versus unarmored stations and number of stations are indicated on each bar. Note the 20 percent decrease in unit volume from north to south correlating with increase in proportion of armored stations.

ARTIFICIAL BEACH CHANGES

Between March 1981 and May 1982, portions of Myrtle Beach were scraped along the lower beach and backfilled along the upper beach on three occasions. Approximately 25-50 percent of the project shoreline was directly affected by scraping or filling on the first two occasions. In some cases, borrow sections did not correspond to fill sections. This allowed evaluation of stations which were borrowed but not filled and vice versa. Total volume moved was approximately 29,000 m^3 during operations in March and June 1981. During a second-phase plan beginning January 1981, over 80 percent of the shoreline was scraped and filled (estimated volume 75,000 m^3).

PERFORMANCE EVALUATION

PHASE I CHANGES

Soon after the first sections of shoreline were scraped and backfilled, a minor northeast storm on 22 March impacted the Myrtle Beach area. The storm was sufficiently large enough to destroy a section of an ocean pier in the central zone of the project area. Beach measurements before and after the storm allowed evaluation of the effect of scraping and backbeach fill on selected portions of the shoreline. Figure 7 shows pre- and poststorm changes to the reference beach section (Segments I, II, and III, combined) for eight representative stations. All profiles were obtained between 21 and 24 March 1981. Figure 7 shows a trend of increasing erosion from north to south and somewhat higher erosion at armored stations (on average).

During the ensuing months, considerable natural recovery occurred. To illustrate how several representative stations responded, backbeach (Segment I) unit volume changes are given in Figure 8 for the period February-November 1981. The data represent short-term

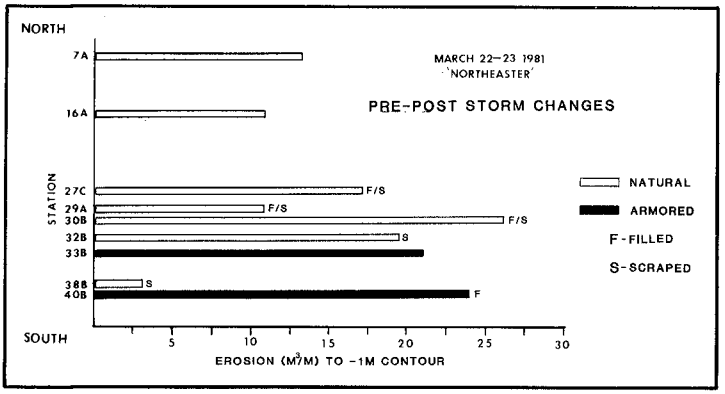

FIGURE 7. Pre- and poststorm beach changes at Myrtle Beach for 8 representative stations. Erosion is measured as the unit-width volume change (m^3/m) for a reference cross-section from the base of dunes or armor walls to the -1.0 m MSL contour.

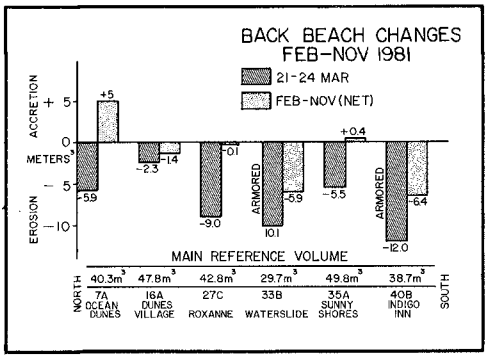

FIGURE 8. Representative poststorm (21-24 March) and six-month (February-November) backbeach volumetric changes for six variously armored, scraped, or filled stations along the project area. See Table 2 for status of each station.

erosion after the minor NE storm on 22 March 1981, and the net backbeach volumetric change along the landwardmost 15 m of beach. Profile data indicated were obtained on 27 February, 21 March, 24 March, and 8 November 1981. Table 2 gives the status of each station.

The zone that is compared in Figure 8 is the recreational backbeach area (Segment 1). The response at each station varied, but several trends were obvious. All stations eroded along the backbeach between 21-24 March; losses being greatest at the two armored stations (33B and 40B). At Station 7A, the fill placed in June accounts for much of the observed recovery after the storm. But at the other

TABLE 2. Status of each station given in Figure 8.

STATION) LOCALITY:	NOTES
7A) Ocean Dunes Hotel:	Scraped and backfilled with 8.5 m^3/m in June 1981; natural beach and dune system.
16A) Dunes Village:	Not scraped or filled; natural beach and dune.
27C) Roxanne Motel:	Filled with 8.5 m^3/m on 13 March before storm, but not scraped; Pleistocene scarp.
33B) Waterslide:	Not scraped or filled; vertical concrete bulkhead.
35A) Sunnyshores Motel:	Scraped and filled on 12 March before storm; natural scarp, no armoring.
40B) Indigo Inn:	Filled with 10 m^3/m on 20 March, but not scraped; vertical concrete bulkhead.

five stations, no fill was placed after the storm of 22 March. The response of these stations varied in large part as a function of the backshore armoring. Armored stations, 33B and 40B, eroded more during the storm (21-24 March volume change) and recovered less between March and November. On the other hand, unarmored stations generally eroded less and recovered to approximately their prestorm volumes. These trends were generally consistent for the entire data set of 54 profiles.

CHANGES THROUGH MAY 1982

Beach surveys were completed on ten occasions between February 1981 and May 1982 before, during, and after the three scraping and beach fill projects. Figure 9 summarizes the results, giving mean unit volume changes by zone (north, south, and entire shoreline); by beach segment (backbeach, upper heach face, and foreshore as defined in Figure 5); and by shoreline type (armored vs unarmored). Mean unit volumes were computed for each category for a particular survey and compared with the preceding survey to give the average change. Major trends of this data set include:

1) Erosion from February to April 1981 (pre- and poststorm of 22 March).

2) Accretion for the period May through October 1981.

3) Erosion between October 1981 and February 1982.

4) Net erosion for the entire period for armored stations.

5) Little net change for the period along unarmored stations.

6) Greater net change in the southern zone compared with the northern zone.

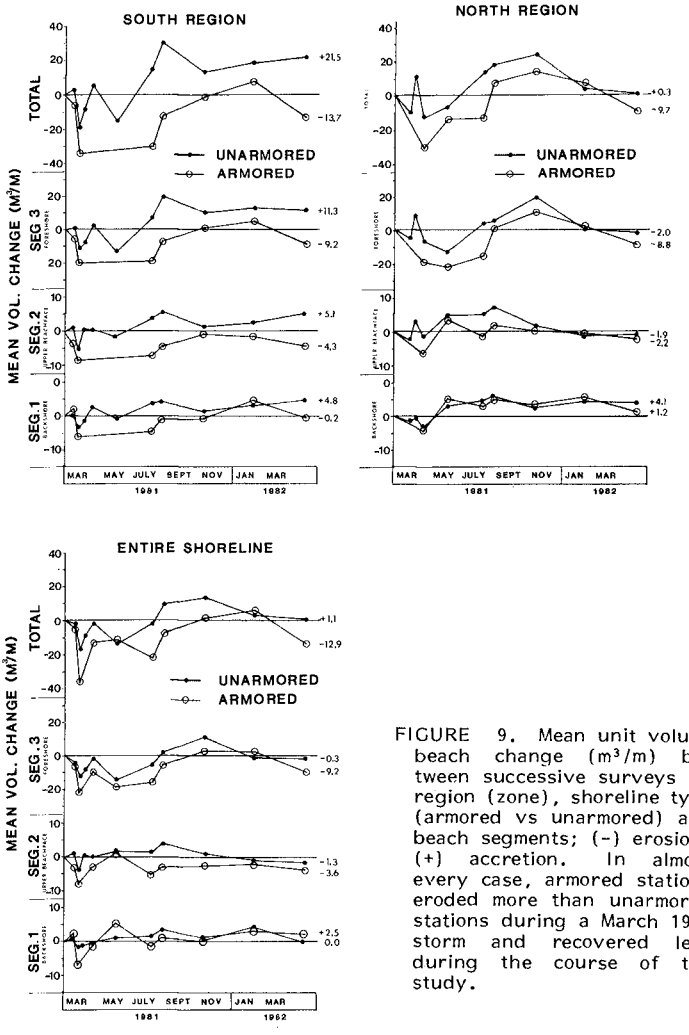

FIGURE 9. Mean unit volume beach change (m^3/m) between successive surveys by region (zone), shoreline type (armored vs unarmored) and beach segments; (-) erosion; (+) accretion. In almost every case, armored stations eroded more than unarmored stations during a March 1981 storm and recovered less during the course of the study.

Note that in almost every division of the data, armored shorelines showed greater losses, although erosion/deposition patterns were similar in form between successive time periods.

Comparative profile plots in Figures 10 and 11 illustrate two extremes between a northern station (16A) backed by a natural dune field and a southern station (40B) backed by a vertical bulkhead. In the case of Station 16A, fill placed along the backbeach was aided by buildup of a low-tide ridge (June-November 1981) which provided additional sand to the profile and reduced the threat of erosion at high tide. This station had a higher-than-average beach cross-section. Station 40B, however, had a lower-than-average beach cross-section to begin with and a poorly developed, low-tide ridge. Despite the addition of fill on two occasions from an updrift source (i.e., the lower beach at that station was not scraped), the station continued to erode at a high rate. Empirical evidence suggests the higher erosion rate was at least partly due to the presence of a vertical wall at the station which was exposed to wave action at high tide.

There was considerable deviation from the mean in net volumetric beach change from one station to another for the period. Figure 12 gives the variation in unit beach volume change proportioned about the mean by zone for the entire data set. Banded areas indicate stations which were armored or responded like armor stations [such as cohesive mud scarps (Station 12A)]. In general, there is a correlation between net erosion and the presence of vertical walls or scarps. The greatest variation occurs between Stations 32A and 35A which are affected by a minor swash inlet and an exposed rock outcrop along the lower beach.

SIGNIFICANCE TESTING AND DISCUSSION

Numerous comparisons were made between portions of the data set by Svetlichny (1982) to determine the significance of the observed changes in profile volume. Various combinations of station types and scrape/fill status were tested using standard statistical procedures to evaluate difference of the means (Ostle and Mensing, 1975). Figures 13 and 14 give two results.

Figure 13 shows overall means by beach segment for armored versus unarmored stations. For the indicated time period, the backshore and foreshore segments were significantly different at the 90 percent confidence level applied to a t-test supporting the notion that erosion was greater along armored stations.

Figure 14 provides a comparison between scraped, filled, and unaltered stations for the generally accretional period, March-November 1981. Combining means for armored and unarmored stations by each division of the data, it was found that there was no significant difference (at the 90 percent confidence level) between scraped and filled stations compared with unaltered stations. However, stations scraped but not filled eroded significantly more than unaltered stations or stations which were scraped and filled. The data of Figure 14 compare changes during an overall accretionary period and indicate the backbeach (Segment I) changes were dwarfed by natural changes along the

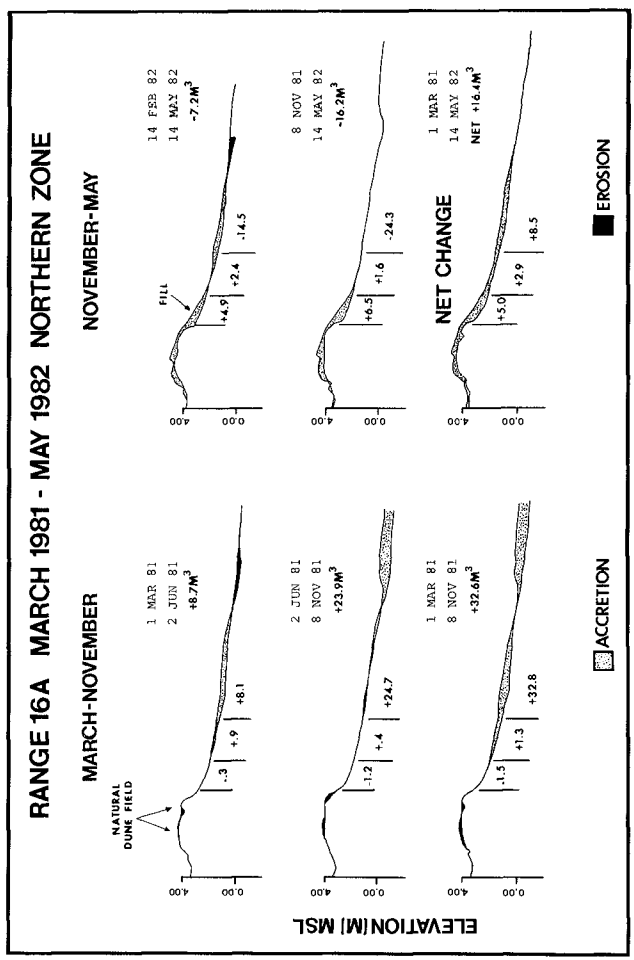

FIGURE 10. Comparative profiles for station 16A in the northern zone between 1 March 1981 and 14 May 1982. This station was backed by a natural dune field and developed a sizable, low-tide ridge during summer and early fall 1981. The lower beach was scraped and the backbeach filled with approximately 8 m^3/m in March 1981. Net accretion for the study period was double this amount.

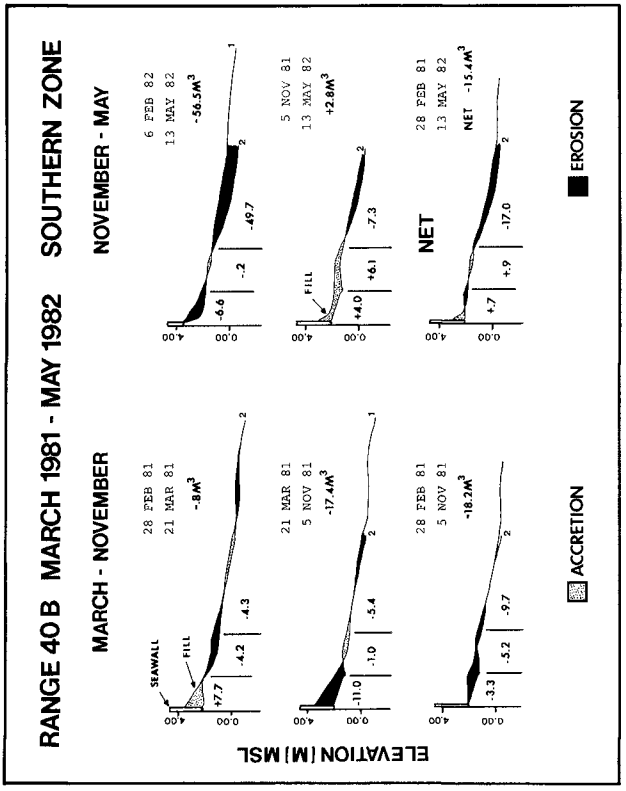

FIGURE 11. Comparative profiles for an armored station (40E) in the southern zone. This station was filled, but not scraped on two occasions, in March 1981 and February 1982. Note erosion of fill as well as the lower beach. Despite the addition of over 10 m^3/m from updrift sources, the station lost 15 m^3/m during the study period.

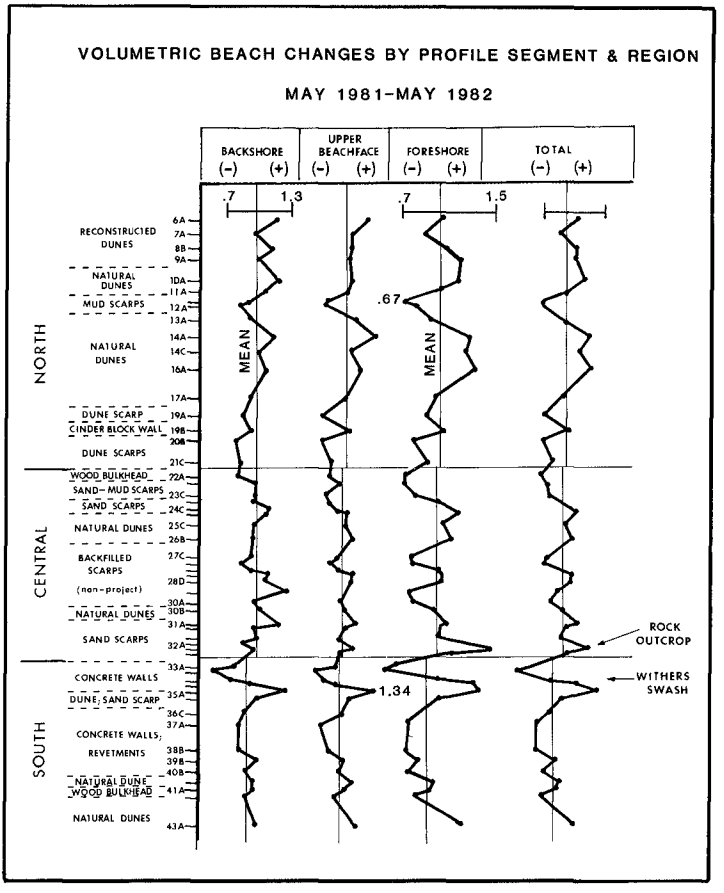

FIGURE 12. Mean unit volumes for 54 stations plotted as a ratio about the mean regional volumes for the northern, central, and southern zone. The left column describes the backshore configuration. Note that positive values generally occur where dune systems exist. Negative values generally correspond to shore protection structures or cohesive mud scarps.

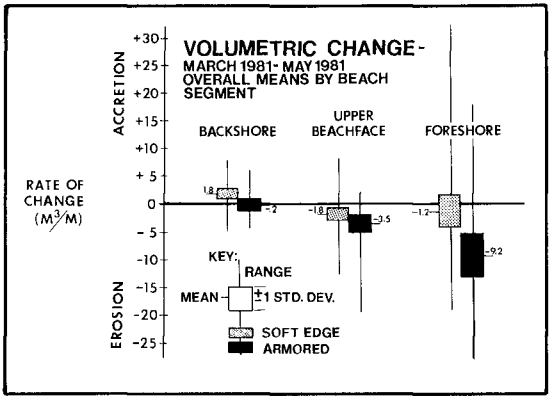

FIGURE 13. Bar graphs depicting the average rate of unit volume beach change between armored and unarmored stations for the study period. The differences are significant at the 90 percent confidence level for backshore (Segment I) and foreshore (Segment III).

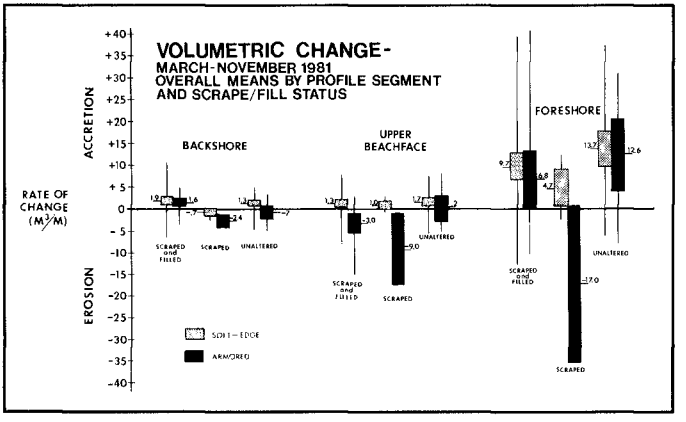

FIGURE 14. The average rate of changed by scrape-and-fill status. See text for explanation.

lower beach. (Note: There was an insufficient number of unaltered control stations for testing after November 1981.)

These results suggest that there were conditions under which beach scraping had no adverse effect on the profile, namely, along unarmored stations which had average or greater unit-width beach volumes; or during time periods when the shoreline tended to be naturally accretional. The data also indicate that scraping without concomitant beach fill adversely affected the profile [although areas where this was practiced generally had more sand at the time of the redistribution as per design (Kana and Svetlichny, 1981)].

In general, unarmored stations readjusted more rapidly to scraping than armored stations. It was found that the lower beach (Segment III) along natural profiles accreted twice as much as the lower heach fronting armored stations (10.7 m^3/m vs 4.9 m^3/m) between March and November 1981.

Tests for the 15-month study period revealed a distinct contrast in the response of armored and unarmored heaches to beach scraping. The foreshore at armored sections did not recover following the February 1981 scraping and yielded a net erosion of 9.2 m^3/m over the 15-month study. During the winter and spring, the foreshore at unarmored beaches eroded by 11.9 m^3/m, but recovered sufficiently so that the net change between March 1981 and May 1982 was only -1.2 m^3/m. The upper beach face (Segment II) eroded at an approximately uniform rate along the entire shoreline. Fill at armored backshores (Segment I) was completely eroded (net change was -0.2 m^3/m). Fill at soft-edge backshores was only partially eroded and had resulted in an average of 1.8 m^3/m more sediment than the initial (March 1981) prefill unit volume.

SEDIMENT BUDGET

A sediment budget was estimated for the study period March 1981 to May 1982 extrapolating from the reference profile cross-sections. As shown in Table 3 in units of m^3/km, the positive effect of beach scraping and backbeach fill was greatest in the northern zone where the backbeach had a net gain of over 2.2 m^3/m. The northern zone gained more recreational, high-tide beach as a result of scraping with virtually no overall loss of volume in the overall beach section. In addition, the fill in this area tended to remain in place for an entire year, protecting previously erosional dune scarps. Fill in the central and southern zones added little volume overall to the recreational backbeach due to the continuous erosion of the lower beach. Fill lasted several weeks to four months at most locations along the southern zone before erosional scarps or seawalls were reexposed. While it certainly provided some temporary recreational benefit (more high-tide beach) and some protection to the existing edge, it may have created a somewhat false sense of security, judging from the sediment losses along the lower beach (3-6 m^3/m). Although the backbeach fill held the shoreline stable near the high watermark in the central and southern zones, the potential remains for accelerated erosion due to losses along the lower beach.

TABLE 3. Sediment budget. Annualized by zones (March 1981-May 1982).

ZONE	VOLUMES (m^3/km)			
	Backshore	Upper Beach	Foreshore	Net Change
North	+2240	-1840	- 430	- 80
Central	+ 160	-2240	-5600	-7680
South	+ 480	- 400	-2960	-2880

CONCLUSIONS

There are a number of perspectives from which to judge the success or benefit of sand scraping and backbeach fill at Myrtle Beach. From the recreational standpoint, it provided a wider high-tide beach for a period of several weeks to almost one year at different localities. The benefit decreased from north to south and was least where most needed, in front of vertical walls. From a dune protection standpoint, the project delayed the time before reactivation of erosional scarps and further retreat of the strandline. Similarly, the buffer of gently sloping fill in front of shore protection structures reduced wave impact forces and potential damage to seawalls for the limited time it remained in place.

From a geological standpoint, the degree of profile manipulation by man was generally dwarfed by the natural cycle of beach changes, although there is some evidence that scraping in the northern zone promoted onshore movement of sand. In this latter case, the borrow zones tended to be narrower than existing low-tide ridges, leaving intact an effective breakpoint bar.

Finally, from a cost standpoint, the project was a relatively inexpensive experiment. Unit costs were approximately US$1.50-2.00 per linear foot of shoreline fill during each project. This compares with US$200 per foot for a typical bulkhead along the South Carolina coast.

Along stable or accretional shorelines, small-scale beach scraping should be highly preferred over armoring. Along slightly erosional shorelines such as the southern portion of Myrtle Beach, the scheme is at best temporary, but may be a suitable interim measure until long-term beach restoration can be implemented. In our opinion, this is preferable from an aesthetic as well as cost standpoint and should be considered as another shore protection option. Along highly erosional shorelines, scraping will obviously produce little benefit and may, in fact, accelerate erosion of the backbeach much like armoring appears to do.

FIELD STUDY ON ONSHORE-OFFSHORE SEDIMENT TRANSPORT

by

Masataro Hattori*

ABSTRACT

The mechanism of onshore-offshore sediment transport and the process of beach profile evolution were studied through field investigations performed at Oarai Beach, Japan. The principal data set consists of twenty-four profile surveys taken at hourly intervals on each of two parallel lines spaced 10 m apart and of length 150 m. The lines extended from the backshore of the beach to a point on the sea bottom at a depth where no sand movement occurred. Simultaneous measurements of the waves and wave-induced currents were also made; the essential requirement of two-dimensionality was found to hold during the experiment. The profiles were used to calculate the net sediment transport rate on-offshore, and for an empirical eigenfunction analysis. A negative correlation was found between the transport direction (and resultant bottom change) and the mean sea level change. The sediment transport rate in the foreshore region was found to be proportional to the wave power, whereas outside the surf zone and near the breaker position it was proportional to the tractive force.

1. INTRODUCTION

Many laboratory studies have been undertaken to investigate the mechanism of onshore-offshore sediment transport on wave-formed beaches. However, there are several problems involved in transferring laboratory results to the prototype, such as the similarity law of movable bed models, scale effects, and so on. On real beaches, onshore-offshore sediment transport produced by waves and wave-induced currents occurs under very complicated conditions. It depends not only on the characteristics of the incident waves and bed material, but also on the specific location and bed form in the nearshore zone.

To understand the phenomena of sediment transport, more knowledge of the spatial and temporal dependence of the net rate and direction of transport is necessary. If adequate prototype data are available, onshore-offshore sediment transport as well as beach profile evolution can be inferred quantitatively with the aid of laboratory results. However, no analogous field studies have been performed because it is difficult to find sites where two-dimensionality in coastal processes is dominant. This paper reports such a field study made on onshore-offshore sediment transport processes.

---

* Professor, Department of Civil Engineering, Chuo University, Kasuga, Bunkyo-ku, Tokyo 112 JAPAN

The principal aims of this study are as follows:

(1) To relate the sediment transport rate to the onshore-offshore current velocity near the bottom.

(2) To clarify processes of sediment transport and beach profile evolution about the mean sea level due to the tide.

(3) To give a physical interpretation of the results by analysis of the beach profile.

Since this study aimed to investigate the onshore-offshore sediment transport in relation to beach profile change, it was necessary to measure accurately the bottom level changes along one or more lines running offshore. Many field studies have been made of the change in beach profile under waves in order to study the mechanism of sediment transport and the process of seasonal beach change. In only a few studies (e.g., Inman and Ruwnak, 1956; Nordstrom and Inman, 1975) were accurate measurements of the beach profile change performed. In most of the other studies, the profile data were usually contaminated by inaccuracies in the measurements. This resulted in difficulties in interpretating the phenomena of interest.

In laboratory experiments using two-dimensional wave flumes, the net rate and direction of the onshore-offshore sediment transport are usually calculated from a time series of bottom profile data by use of the continuity equation for bottom material (e.g., Watanabe, Riho and Horikawa 1982; Hattori and Kawamata 1982),

$$\frac{\partial h}{\partial t} = \frac{1}{(1-\lambda)} \frac{\partial q_x}{\partial x} \tag{1}$$

in which $h(x,t)$ is the water depth, q_x is the sediment transport rate on-offshore (along the x-axis), λ is the porosity of the bottom sediment, and t is the time. The coordinate system and notation are shown in Fig. 1.

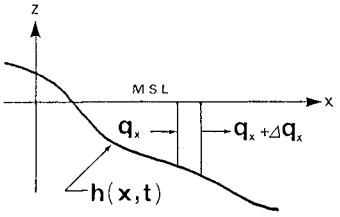

Fig. 1 Coordinate system and notation.

A preliminary experiment (Hattori and Komatsu, 1980) made in 1979 at the same study site (described below) indicated that the method of calculating the sediment transport rate in laboratory experiments could be applied to the field, if accurate measurements of the bottom change could be made. Based on this conclusion, a linear pole array technique was employed to measure the bottom level at fixed points on the beach.

2. EXPERIMENTAL PROCEDURE

2.1 Study Site

The field experiment was performed in August 1980 at Oarai Beach, Ibaragi Prefecture. The study area is a sandy beach with uncomplicated bathymetry, and is located adjacent to Oarai Harbor facing the Pacific Ocean (Fig. 2). The local beach material is quartz sand of median diameter 0.18 mm. Nearshore bottom profiles were measured by means of two linear pole arrays (labelled A and B in Fig. 2). The site selected for placement of the pole arrays was located 200 m north of the jetty. Diffraction at the breakwater 1400 m seaward produces relatively calm wave conditions of exceptional two-dimensionality. The pole arrays were of sufficient length to extend beyond the critical depth of sand movement during the experiment.

The spacing between the poles was 2 m and the total length of the pole arrays was 150 m. A reference point was defined, located on the backshore and landward of the maximum runup of swash. The pole array consisted of steel pipes 6.4 cm in diameter and 2 m to 5 m long. The pipes were driven into the sand bottom to a depth of about 1 m by means of a jet water pump.

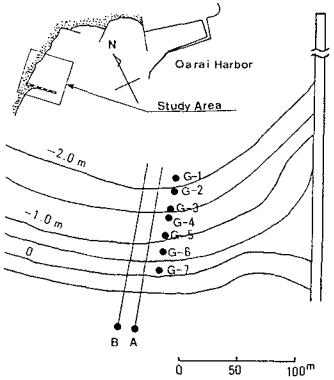

Fig. 2 Map of the study site.

Simultaneous measurements of the waves and wave-induced currents were made with capacitance-type wave gages and two-component electromagnetic current meters at seven locations indicated by G-1 to G-7 in Fig. 2. The seven wave gage stations were alined 10 m east of pole array A.

2.2 Profile survey

Surveys along the pole arrays were made every hour to yield a time series of the profile data over the 24-hr experiment period. Positions of the poles and absolute elevations of the pole tops were measured by using standard survey techniques and a bench mark on the backshore, which was derived from a permanent bench mark. Two supplemental reference points for measuring bottom level elevation were marked on each pole at distances of 1 m and 2 m. The height of the reference point from the bottom was measured by reading the scale of a survey rod, specially designed to avoid scouring around the pole and rod. From the survey result for the elevation of the tops of the poles, the bottom depth could be determined. The estimated accuracy of the absolute elevation of the bottom level was about 0.5 cm. The beach profile surveys were completed within about 15 min.

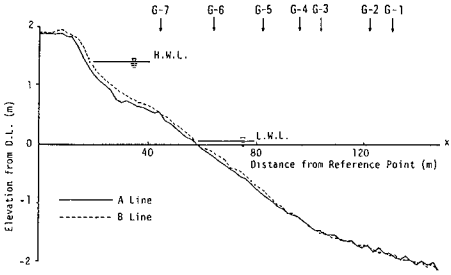

Fig. 3 Mean beach profiles at the study site.

Figure 3 illustrates mean beach profiles along the pole arrays, which were obtained by averaging the 24 sets of profile data taken over the experimental period. Arrows at the top of the figure indicate the positions of wave gage stations, G-1 to G-7. Figure 4 shows the positioning survey results of the pole arrays and wave gage stations. Pole positions are indicated by solid and open circles. The two pole arrays formed almost straight lines.

2.3 Instrumentation

Simultaneous measurements of the waves and wave-induced currents on the study beach are essential to understand the processes of sediment transport, and to confirm two-dimensionality of the various phenomena. Each wave gage station consisted of a capacitance-type wave gage and a two-component electromagnetic current meter. The wave gage, developed by Sato et al. (1980), has a superior frequency response than other conventional field wave gages, but has the shortcoming that the output signal level sometimes is reduced due to adherence of polluted sea water film to the capacitance line.

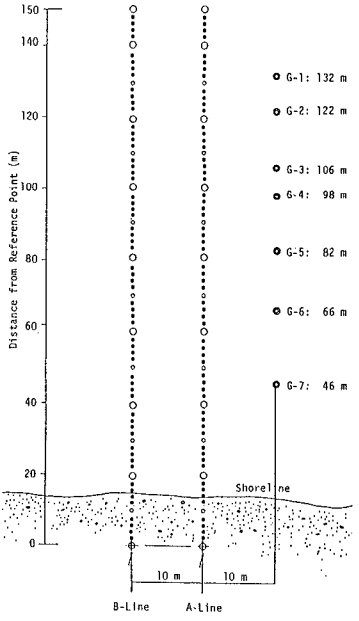

Fig. 4 Positioning survey results of the pole arrays and wave gage stations.

The current meters, used for measurements of the wave-induced current velocity, were fixed to steel frames at a height of 20 cm from the bottom of the frame. They were set on the sea bottom so that one of the two transducer axes was directed on-offshore. To supplement the measurements of the local wave characteristics on the beach, additional wave measurements were made about 200 m seaward of the tip to the jetty by means of a linear array of three pressure sensors (Fig. 5).

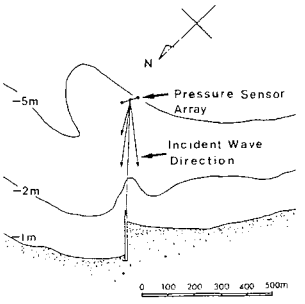

Fig. 5 Location of the pressure sensor array and the directional distribution of incident waves.

2.4 Data analysis

The survey data of the bottom level for each pole array were punched on cards for computer input and then stored on a magnetic disk for plotting profiles and for calculating the transport rate of sediment transport. Output of the wave gages and electromagnetic current meters was recorded on open-reel digital data recorders with a sampling interval of 0.2 s. Statistical characteristics of the waves and current velocities were calculated for each 16 min. of the collected data. In these calculations, wave components longer than 25 s entering in the free surface and in current velocity variations were cut off by using a high pass filter. The mean sea level variation on the study beach was not measured. Instead, the tide gage record at Oarai Harbor was used.

3. WAVE AND CURRENT VELOCITY

3.1 Characteristics of incident waves in the offshore

Figure 6 shows time histories of significant wave height and period measured at the pressure sensor array (Fig. 5), and the tide gage record at Oarai Harbor. This figure indicates that wave height and period in the offshore zone were almost constant over the duration of the experiment, 0.35 m and 7.3 s, respectively. The distribution of the incident wave direction obtained at the pressure sensor array is also given in Fig. 5. It is noticed from this figure that waves were incident normal to the study beach.

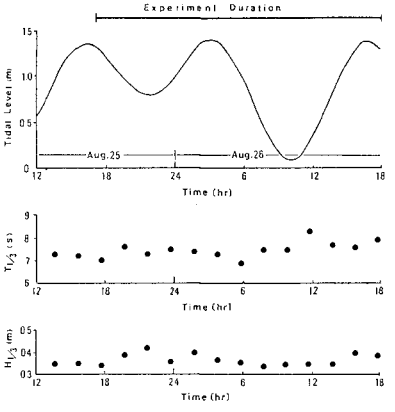

Fig. 6 Time histories of incident wave height and period at the pressure sensor array (Fig. 5) and tide gage record at Oarai Harbor.

Figure 7 gives examples of the record monitors of the free surface variations, η , at wave gage stations G-3 to G-7. It is seen that the waves proceeded to Station G-5 without wave breaking and that the breaking position was located near Station G-6. Solid lines on this figure indicate the propagation process of the marked wave.

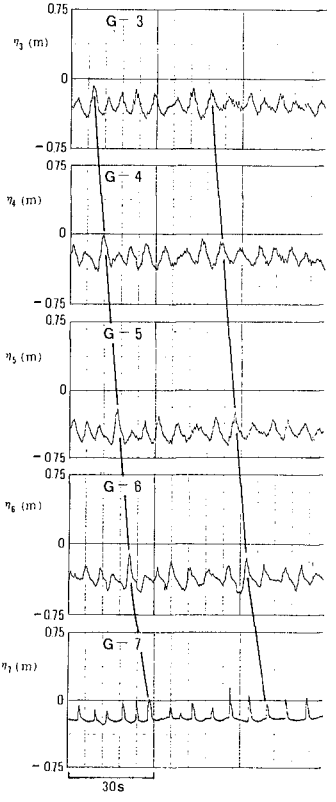

Fig. 7 Comparisons of the records of the free surface variation at Stations G-3 to G-7.
G-3 to 5: outside the surf zone,
G-6: near the breaker position,
G-7: inside the surf zone.

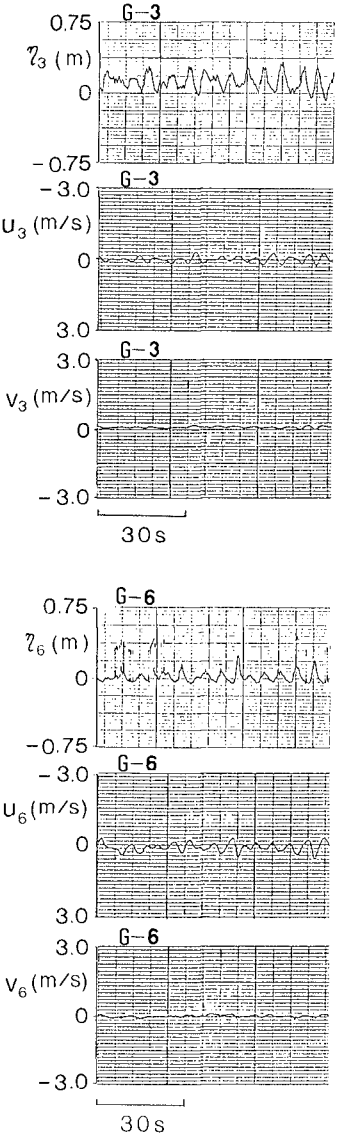

Fig. 8 Comparison of records of the free surface variation and of the on-offshore and longshore current velocities at Stations G-3 and G-6.

Figure 8 gives comparisons of monitor records of the free surface variation and of the on-offshore and longshore components of current velocity, U and V, respectively, at the wave gage stations G-3 and G-6. This figure clearly shows that the on-offshore current velocity fluctuated in phase with the free surface variation, and that the longshore component was very weak. Similar tendencies were observed at various locations on the beach over the entire duration of the experiment.

Based on the measured wave direction and current velocity, it is concluded that the coastal processes of interest on the beach maintained two-dimensionality, an essential requirement for this study.

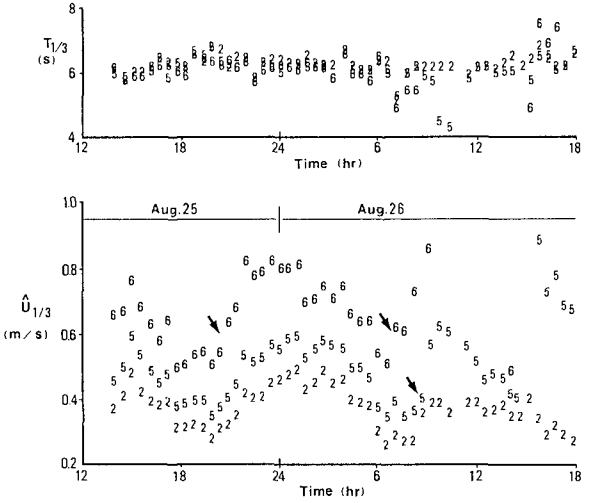

Fig. 9 Time histories of $\hat{U}_{1/3}$ and $T_{1/3}$ of the on-offshore current velocity at Stations G-2, G-5, and G-6.

Figure 9 illustrates time histories of the significant full amplitude and period of the on-offshore current velocity, $U_{1/3}$ and $T_{1/3}$. Plotted numbers represent the wave gage station where the data were taken. The velocity amplitude varies with the variation of the mean sea level due to the tide, but the period is almost constant (about 6.3 s).

According to Fig. 5, the mean period of the incident waves at the pressure sensor array is about 7.3 s, which is longer than the period derived from the on-offshore current velocity. Two factors may be pointed out as reasons why this difference in measured period occurred: (1) The frequency response of the electromagnetic current meter, 10 Hz, is higher than that of the pressure sensor. (2) In analysis of the on-offshore current velocity, the long period components were removed by a high-pass filter. The mean period of the incident waves was therefore taken to be 6.3 s for the experiment period.

Interesting behavior of the time histories of $\hat{U}_{1/3}$ can be noted. Rapid increase of $U_{1/3}$, indicated by thick arrows, indicates that the breaker position, in a statistical sense, was located near or at the wave gage station where the current velocity data were taken.

Since the longshore component of the current velocity was very weak, its mean with respect to time was negligibly small. On the other hand, a steady component of the on-offshore current velocity, $\bar{U}$, was observed at various locations of the beach. Figure 10 illustrates time histories of $\bar{U}$ at the wave gage stations G-2, 5, and 6. From this figure, it was found that, except during the rising period of sea level, from 14 hr to 17 hr Aug. 26, the steady current velocity was much lower than the maximum water particle velocity due to wave motion and was directed offshoreward. It is considered that this current did not have any significant influence on the onshore-offshore sediment transport.

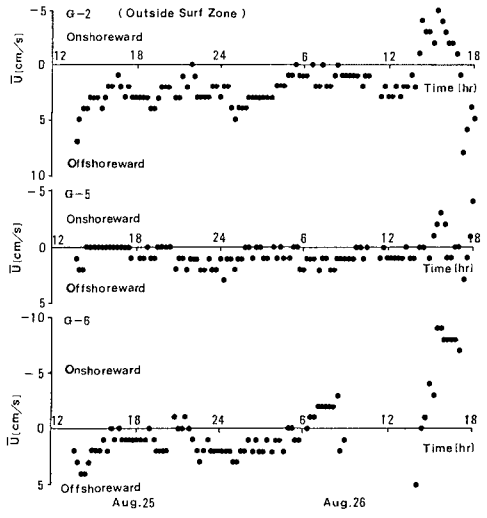

Fig. 10 Time histories of the steady on-offshore current velocity.

The breaking waves were mainly of the plunging type. The position of wave breaking was estimated by 1) visual observation facilitated by the pole arrays, 2) comparisons between time histories of the variations of the free surface and on-offshore current velocity (Huntley and Bowen, 1975), 3) rapid increase of the significant full amplitude of on-offshore current velocity (Fig. 9), and 4) spatial variation of the statistical characteristics of the waves and wave-induced currents.

4. RESULTS AND DISCUSSION ON THE SEDIMENT TRANSPORT

4.1 Net transport rate

The net rate of onshore-offshore sediment transport, q_x, was calculated from the time series of the profile measurements taken every two hours. Figure 11 shows the on-offshore distributions of q_x. In these calculations, the profile used was that given by the mean obtained from the two arrays. The numerals in the figure give the month, day, and time when the profile measurements were made. Locations of wave gage stations are indicated by arrows.

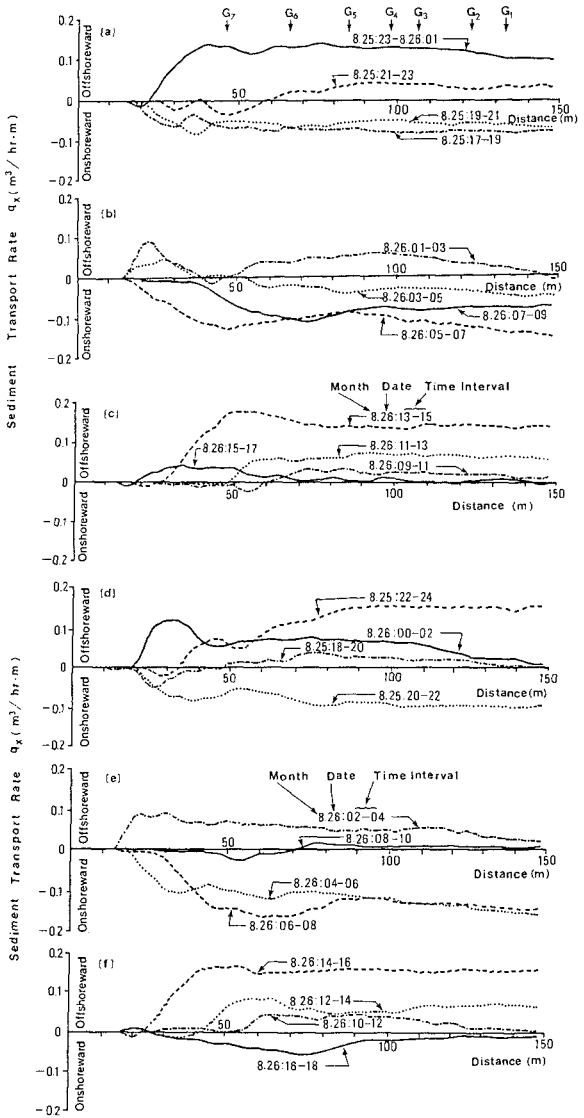

Fig. 11 Calculated results of the net rate of sediment transport.

It was found from the distributions of q_x that about half of the results did not satisfy the condition for the sediment budget. The distributions were calculated with the boundary condition $q_x = 0$ at the reference point on the backshore. Under calm sea conditions, sediment movement due to waves in the offshore zone is not active and bottom level changes are very small. When the change in sand level fell below 0.5 cm, inaccuracy in the profile measurements in the offshore led to a cumulative error in the calculation of q_x.

It was originally intended to express $|q_x|$ in terms of the significant full amplitude of the on-offshore current velocity, $\hat{U}_{1/3}$; however, no meaningful correlation could be found. This suggests the interesting possibility that sediment transport under irregular waves is mainly determined by the statistically averaged curreent velocity. It is therefore believed that the beach profile does not respond quickly to variations in current velocity caused by different incident wave forms. Instead of U_{max}, the maximum velocity of the on-offshore current velocity, for convenience the mean velocity $\hat{U}_{1/2}$ was used.

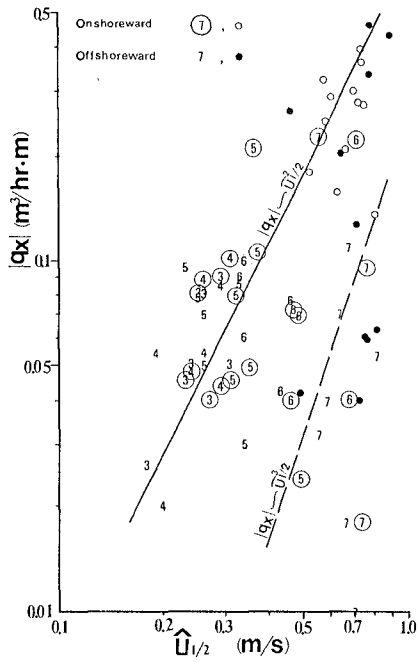

Fig. 12 Relationship between $|q_x|$ and $\hat{U}_{1/2}$.

The calculated absolute values of the net transport rates, $|q_x|$, at various locations were plotted against the mean full amplitude of the onshore-offshore current velocity, $\hat{U}_{1/2}$ as shown in Fig. 12. Numbers in the figure indicate the wave gage station. Filled and open circles denote data obtained in the preliminary experiment of 1979. Open circles and numbers in circles denote onshore transport, and filled circles and numbers without circles denote offshore transport.

Two distinct relationships between $|q_x|$ and $\hat{U}_{1/2}$ are apparent in Fig. 12. The solid line passes through the data obtained outside the surf zone and near the wave breaking position. The dashed line passes through the data obtained inside the surf zone. The slopes of the fitted lines are approximately 2.0 and 3.0 respectively. The standard expression for the shear stress acting on the bottom, τ_b, is given by

$$\tau_b = \frac{1}{2} \rho f_w u_{max}^2 \tag{2}$$

in which f_w is the wave friction coefficient, u_{max} is the maximum velocity near the bottom, and ρ is the density of the fluid. Although waves exhibit nonlinearities both inside and outside the surf zone, u_{max} will be replaced by $\hat{U}_{1/2}$. Thus Eq. (2) can be rewritten as

$$\tau_b = k \rho f_w \hat{U}_{1/2}^2 \tag{3}$$

where k is a coefficient representing the nonlinearity of the wave motion. Using Eq. (3), the two relationships in Fig. 12 can be written

$$|q_x| \sim \hat{U}_{1/2}^2 \sim \tau_b \qquad \text{(outside the surf zone and near breaking position)} \tag{4}$$

and

$$|q_x| \sim \hat{U}_{1/2}^3 \sim \tau_b \hat{U}_{1/2} \qquad \text{(inside the surf zone)} \tag{5}$$

The two empirically-based relationships between q_x and $\hat{U}_{1/2}$ expressed by Eqs. (4) and (5) indicate that two different processes of onshore-offshore transport can exist in the nearshore zone. In the present study, outside the surf zone and near the breaker position, the net transport rate was proportional to the tractive force acting on the bottom surface. Therefore, the dominant process of sediment transport was that of bed load. On the other hand, inside the surf zone, the net transport rate was proportional to the wave power, so that the dominant process was that of suspended load.

As seen in Fig. 11, the net transport rate varies with the distance offshore as measured from the reference point on the backshore. Figure 13 gives the time histories of the breaker position and location where the net transport rate takes a maximum value. From this figure, it can be noted that the maximum transport rate occurs near the breaker position.

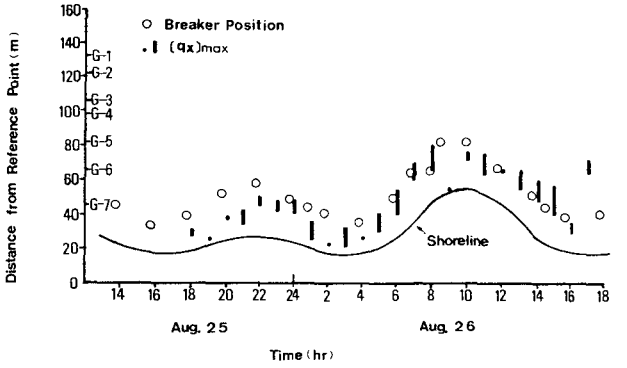

Fig. 13 Time histories of breaker position and location of $q_{x,max}$.

4.2 Direction of the Sediment Transport

To investigate effects of the mean sea level change due to the tide, temporal changes in the distributions of q_x were drawn schematically in Fig. 14, which gives the tidal record at Oarai Harbor. This figure clearly indicates that during ebb tide q_x was directed predominantly onshore, while during flood tide it was directed offshore. This suggests that the predominant direction of the net sediment transport on-offshore was governed significantly by the tide.

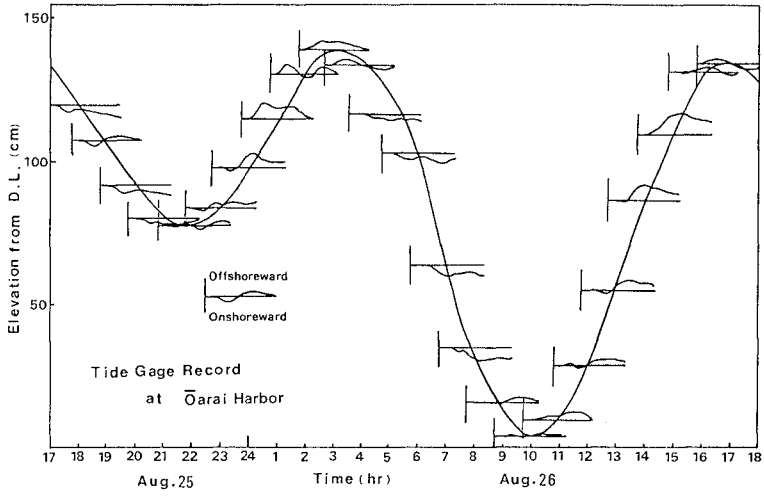

Fig. 14 Tide gage record and q_x distribution (Fig. 11).

As seen in Fig. 13, the range of the wave breaking position over the duration of the experiment covered a distance between 25 m to 80 m from the reference point. As the tide rose, the location of wave breaking advanced shoreward and the width of the surf zone became narrower, whereas when the tide fell, the surf zone became wider. From the mean beach profile in Fig. 3, the mean beach slope inside the surf zone during the high water period is estimated to be 1/20, and that during the low water period 1/32. Due to the beach cut pattern, the morphodynamic state of the surf zone and beach over a tidal cycle appeared to change from a reflective mode during the flood tide to a dissipative one during the ebb tide (Wright, 1982).

Hattori and Kawamata (1982) proposed a criteria for predicting the predominant direction of sediment transport on-offshore,

$$\frac{(H_o/L_o)\tan\beta}{(w_s/gT)} = C \begin{cases} > \\ 0.5 \\ < \end{cases} \begin{matrix} \text{(offshore transport)} \\ \\ \text{(onshore transport)} \end{matrix} \qquad (6)$$

in which H_o/L_o is the deepwater wave steepness, w_s is the fall velocity of the sediment, T is the incident wave period, $\tan\beta$ is the mean beach slope inside the surf zone, and g is the acceleration of gravity. The value of C during the high and low water periods are 0.76 and 0.47 respectively (H_o = 0.35 m, T = 6.3 s, d_{50} = 0.18 mm, and w_s = 2.3 cm/s). It is thus concluded from Eq. (6) that the direction of sediment transport during the flood tide was offshoreward whereas during the ebb tide it was onshoreward.

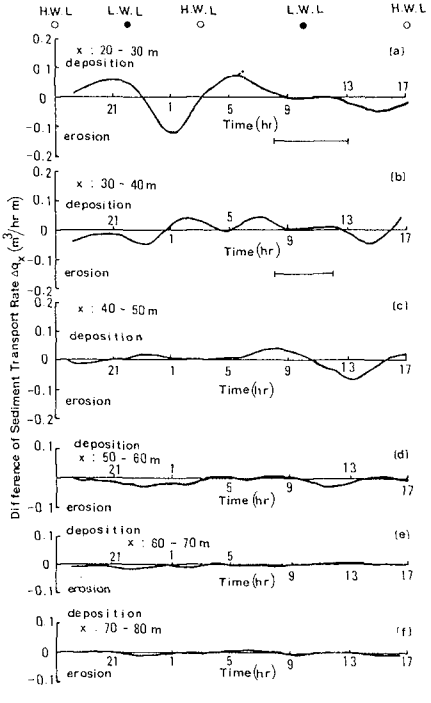

Fig. 15 Time histories of the rate of beach profile change inside the surf zone.

Figure 15 shows time histories of the difference of net transport rate, Δq_x, between adjacent locations inside the surf zone. This figure was obtained by using the q_x distribution curves given in Fig. 11. Horizontal solid lines indicate the duration the bed was dry during the ebb tide. At the top of the figure, the times of occurrence of H. W. L. and L. W. L. are indicated by open and filled circles. Since Δq_x expresses the rate of bottom change, comparison of these time histories indicates the trend of the beach profile evolution. During the flood tide, erosion on the upper beach was accompanied by sand accretion near the breaker position. During the ebb tide sand removed immediately from outside the surf zone was deposited on the low water terrace and foreshore. These trends of beach evolution support the hypothesis that the direction of net sediment transport is closely related to the change in the morphodynamic state of the beach over a tidal cycle.

5. DATA ANALYSIS BY EMPIRICAL EIGENFUNCTIONS

Seasonal patterns of onshore-offshore sediment movement and seasonal beach changes can be well described by means of the empirical eigenfunction technique. The application of this statistical technique promises to give further progress in our understanding of the process of beach profile evolution (Winant, Inman, and Nordstrom, 1975; Aubrey, 1979). The empirical eigenfunction technique was employed to analyze the profile data in order to get a more definite physical interpretation of the experimental results (Hashimoto and Uda, 1979).

The analysis was made taking into account the mean sea level due to the tide for the time series data of deviations from the arithmetic mean profile, as shown in Fig. 3 (Katoh, Tanaka, and Nadaoka, 1981). Since, in general, the data sets involve physical quantities with different units, each quantity was normalized so that its mean value was zero and its variance unity. The normalizing procedure is given in Eqs. (7) to (9).

$$F_{i,t} = (F_{i,t} - \bar{F}_i)/S \tag{7}$$

$F_{1,t} \sim F_{75,t}$: Bottom elevation

$F_{76,t}$: Sea level

$$\bar{F}_i = \frac{1}{n_t} \sum_{t=1}^{n_t} F_{i,t} \quad (n_t = 24) \tag{8}$$

$$S = \frac{1}{n_t - 1} \sum_{t=1}^{n_t} (F_{i,t} - \bar{F}_i)^2 \tag{9}$$

In these equations, $F_{i,t}$ is the physical quantity, (elevations of the bottom, and the sea level), $F'_{i,t}$ is the deviation of $F_{i,t}$ from the mean, $\bar{F}_i$ and S are the mean and variance of $F_{i,t}$. The subscript i is an index ranging between 1 and 76. The range from 1 to 75 covers the total number of points along the profile and the index 76 denotes the sea level. The subscript t is an index ranging between 1 and n_t, the total number of times the measurements were made (24).

The set of deviations from the mean value at time t, Φ_t, is given by Eq. (10),

$$\Phi_t = (F'_{1,t}, F'_{2,t}, \cdots\cdots, F'_{76,t})^T \tag{10}$$

where the superscript T is the matrix transpose operator. Then, Φ_t is expressed in terms of spatial and temporal eigenfunctions, e^*_n and $c^*_{n,t}$,

$$\Phi_t = \sum_{n=1}^{n_t} c^*_{n,t}\, e^*_n \tag{11}$$

where the subscript n denotes the order of the eigenfunction. Equation (11) means that the temporal characteristics of Φ_t is expressed by $c^*_{n,t}$. The correlation coefficient, $R_{n,i}$, between $c^*_{n,t}$ and $F^*_{i,t}$ is given by Eq. (12),

$$R_{n,i} = \sqrt{\lambda_n}\, e^*_{n,i} \tag{12}$$

in which λ_n is the n-th eigenvalue.

Since the index i indicates the location of the i-th pole from the reference point of the pole array, the relation between $R_{n,i}$ and i can be easily converted into a spatial dependence of R_n, which is equivalent to the spatial dependence of the eigenfunction e^*_n as shown by Fig. 16. The solid and broken lines in Fig. 16 represent the first and second eigenfunctions, respectively. The horizontal line at the top of the figure indicates the range of the breaking position.

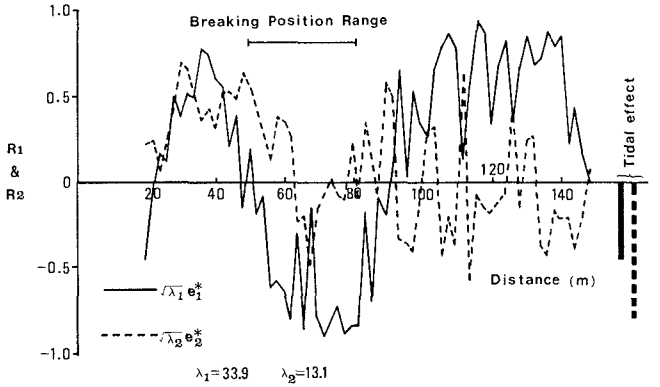

Fig. 16 Spatial dependence of the eigenfunctions, e^*_1 and e^*_2.

The first eigenfunction, e^*_1, exhibits a maximum near the foreshore, a broad maximum in the offshore, and a broad minimum over the range of the breaker position. In addition, e^*_1 indicates that a negative correlation exists between the effect of the tide and profile changes both in the foreshore and offshore, while a positive correlation exists over the range of breaker position. These results mean that as the tide fell, sand removed from the wave breaking zone was transported both shoreward and seaward, and was deposited on the foreshore and offshore.

The second eigenfunction, e_2^*, shows a broad maximum on the foreshore, but it does not exhibit any distinct dependence in the offshore. Since the correlation between the profile change and the tidal effect for e_2^* is stronger than that for e_1^*, e_2^* appears to represent the accretion of the foreshore caused by onshore sediment transport inside the surf zone due to seaward dislocation of the breaker position during the ebb tide. These interpretations of the spatial structures of e_1^* and e_2^* are supported by the time histories of beach profile change which are given in Fig. 15.

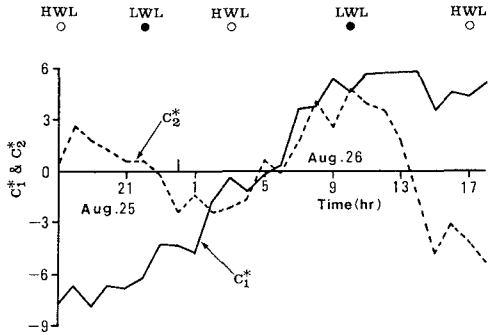

Fig. 17 Temporal dependence of the eigenfunctions c_1^* and c_2^*.

Figure 17 shows temporal variations of the eigenfunctions, c_1^* and c_2^*, denoted by solid and broken lines respectively. At the top of the figure, the times of occurence of H.W.L. and L.W.L. are indicated by open and filled circles. c_1^* shows a trend of gradual increase with time. This means that the study beach was accretive over the duration of the experiment (24 hr). On the other hand, the time dependence of c_2^* exhibits a strong periodicity indentical to that of the tide. During the ebb tide, the beach profile shows a tendency to accrete, while during the flood tide it shows an erosive tendency. Based on these temporal trends, the second temporal eigenfunction appears to adequately represent the profile change in the foreshore. It is thus substantiated by empirical eigenfunction anaysis that beach profile evolution as well as onshore-offshore sediment transport over a tidal cycle are greatly influenced by the mean sea level change caused by the tide.

6. CONCLUSIONS

The main conclusions from the present field study are now summarized.

(1) Two distinct relationships for the onshore-offshore sediment transport rate were found in the present experiment; i) the net transport rate was proportional to the tractive force acting on the bottom outside the surf zone and near the breaker position, and ii)

inside the surf zone the net rate was proportional to the wave power. The maximum transport rate occurred near the breaker position.

(2) The predominant direction of sediment transport during the flood tide was offshoreward, while during the ebb tide it was onshoreward. The effect of the tide on the direction of sediment transport was produced by the change in the morphodynamic state of the beach, as being either reflective or dissipative. The migration of the breaker position plays an important role in the change of beach characteristics.

(4) Analysis by the empirical eigenfunction method also indicated a negative correlation between the beach profile changes in the foreshore and offshore zones and tidal variation, while a positive correlation existed between the profile change and tide in the area of the breaker position.

(5) The first and second temporal eigenfunctions, respectively, were found to describe the evolutionary trend of the study beach and the trend of profile change in the foreshore, and were found to have the same periodicity as that of the tide.

ACKNOWLEDGEMENTS

The field work in this study was carried out through the sincere cooperation of many people, and I would like to thank all of them. In particular, I would like to express my appreciation to Mr. S. Hotta, Tokyo Metropolitan University, who suggested the idea of measuring beach profiles by means of a linear pole array system. I would also like to thank Dr. N. C. Kraus of the Nearshore Environment Research Center for proofreading the manuscript.

MORPHOLOGY AND DYNAMICS OF CRESCENTIC BAR SYSTEMS

by

V. Goldsmith[1], D. Bowman[2], K. Kiley[3], B. Burdick[3], Y. Mart[4] & S. Sofer[4]

ABSTRACT : Aerial photograph and field studies in the southeastern Mediterranean, involving bathymetric mapping, and concurrent and antecedent wave measurements, have been used to delineate the sequential development of crescentic bars and associated dynamics. The bar sequence includes multiple parallel or wavy bars, ridge and runnels, oblique/transverse bars, single crescentic and double crescentic bars, and occurs during a calming down of wave activity from 2.5 to 0.5 m waves. The concomitant wave data, including wave directions, energy spectrum, significant wave height, and length of the calm period, showed strong correlation with the bar stages.

An increase in total bar occurrence during summer is related to a major wave energy decrease in the spring, when significant wave heights (H_s) $\leq$ 1 m sharply increase to 70-85% in April-May. Inner single crescentic and initial double-crescentic bars are largely restricted to the calmest wave months of May/April to October/November, which reflects their sensitivity to wave energy. The aseasonal occurrence is best shown by the mature double crescentic type, which apparently is the final stage in the crescentic bar development sequence.

Two bar developmental sequences were delineated: one shore-normal and the other initially oblique, but gradually rotating to shore-normal in the mature stage. Out of phase relationships between inner and outer bar systems resulted from the lag in response of the outer bars behind changes in wave direction. Among the inner crescentic bars and shore rhythms, phase-correlation was the rule.

Crescentic bars are well developed on this coast because of the dissipative conditions and the distinct wave climate. High waves in the winter remove the existing bars, and extended calms allow the full development of the crescentic bar sequence. Similar bar types occur on different coasts in different sequences and in different proportions of time. Thus, it is suggested that these differences are attributable to global differences in the occurrences of threshold wave height conditions.

INTRODUCTION : During the past 15 years, several studies have attempted to define the specific dynamic conditions promoting the development of crescentic bars (e.g. Bowen & Inman, 1971; Greenwood & Davidson-Arnott, 1975; Owens, 1977). A global bar classification was proposed (Greenwood & Davidson-Arnott, 1979) including ridge and runnel, cusp, multiple parallel, transverse and straight bars, as well as sinuous to crescentic bars.

Recently it was shown that crescentic bars occur within a bar developmental sequence on both high wave energy macrotidal coasts (Short, 1979; Wright et al., 1979) and moderate wave energy microtidal coasts (Goldsmith et al., 1982). On the high wave energy Australian coast, Short (1979) observed that as wave heights decreased from 3 m to 1 m, the accretional bar stage sequence went from a parallel bar and channel to crescentic bars, megacusps, welded bar, and terminated in cusps and berm. Similarly, on the dissipative, moderate wave energy Israeli coast, Goldsmith et al. (1982) observed that as wave heights decreased from 2.5 m to 0.5 m, the accretional bar sequence went from multiple parallel bars to ridge and runnel, transverse/oblique bars, single and then to double crescentic bars. The first concern of this study is to further delineate the wide range of nearshore bars and shoal patterns along the southeastern Mediterranean microtidal coastline, and to widen our knowledge of environmental conditions of the different bar types. The second aim is to delineate the sequential stage developments of meandering-crescentic bar systems at HaHoterim coast, northern Israel (Fig. 1), and to relate this to specific wave parameters.

METHOD : The study includes all available air photos of the southeast Mediterranean taken in the period 1949-1980. Accordingly, 123 flights showing 150 clear coastal segments were available for bar pattern recognition. Also, a series of eight consecutive maps of the nearshore zone and beach at HaHoterim were made for depicting the bathymetry, rhythmic topography, and sequential bar development. Twenty-two repetitive overflights were conducted, twelve of which were taken at regular weekly intervals.

The air photos were compared to concomitant wave data, up to 60 days prior to each air photo date. The energy spectrum was computed for each digitized wave record, twice a day for one year, using a Fast Fourier Transform algorithm described in Clairbout (1976). The equations from Goda (1974) were used for height and period statistics.

THE SOUTHEASTERN MEDITERRANEAN : The 270 km long study area (Fig. 1) is a relatively smooth coast, with beaches generally narrowing to the north (Goldsmith, in press). Submerged and eroded eolianite remnants occasionally compose rocky outcrops in the inshore and along the water line. Haifa Bay is the northern border of the quartz sedimentary province of the Nile delta (Goldsmith & Golik, 1980). Well-sorted medium beach sand decreases in size from Egypt northwards to Tel-Aviv (Emery & Neev, 1960). Calcium carbonate is 6-8% in southern Israel, and is 65% of the sediment at HaHoterim, south of Haifa. At HaHoterim the beach sand is medium size (1.82 ϕ), moderately to well-sorted (S.D. = 0.45 ϕ), slightly negatively skewed and mesokurtic (Gwirz, 1982).

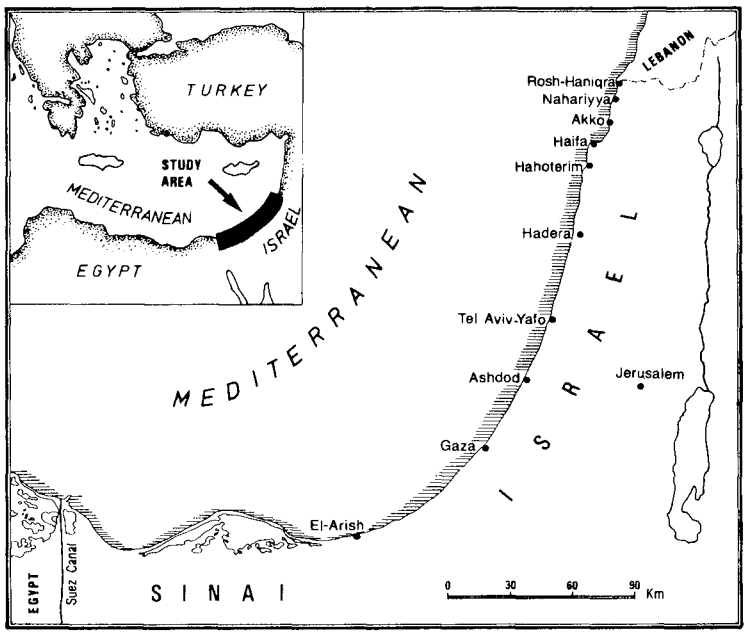

Figure 1. Location of study area in the southeastern Mediterranean.

The wave climate consists of three wave seasons (Goldsmith & Sofer, 1983): the highest wave months are December-March ($\bar{H}_s$ = 1.0 to 1.5 m); the lowest wave months are May, September-October ($\bar{H}_s$ = 0.6 to 0.8 m); and the intermediate wave months are June-August. The winter wave months are dominated by storm fronts passing at an average of 5-7 day intervals. Maximum winter significant waves reach 5 m and 13 sec, although only about 10% of H_s are $\geq$ 2 m high.

The same nearshore slope gradient of 0°20' to 1° dominates the nearshore. However, the slopes of the offshore facing bar flanks are considerably steeper, ranging from 1° to 5°. The Israeli coast, in spite of its low to medium wave height, and because of its high wave steepness and low mean beach gradient, falls mainly within the dissipative regime with $\varepsilon >> 33$ (Bowman & Goldsmith, in press). Field evidence for the extremely dissipative character is provided by the relatively wide (100-300 m) barred inshore, segmented into longshore sub-regions of troughs and shoals, and by the rhythmic beaches, abundant bar-types and dominant spilling breakers.

BAR MORPHOLOGY : The bars observed along this coast may be grouped within three distinct "families" (Bowman & Goldsmith, in press).

1. Non-rhythmic parallel bars. During severe storms (i.e., $H_s \geq 2.5$ m), it appears that the crescentic and other bars are destroyed. As the storm waves decrease, multiple parallel bars are discerned first by the multiple breaker lines, and then they are observed directly. These bars may be straight or meandering. Since during severe wave conditions the whole nearshore zone is filled with breaking waves, it is very difficult to determine the bar patterns. Nevertheless, it is clear that pre-existing bar patterns are completely removed. Observations made by helicopter appear to indicate that the multiple parallel bars form and migrate shoreward only when waves decrease to $H_s \leq 2$ m and when the strong rip current systems ameliorate. The rip current systems were observed to migrate in the longshore direction. During less severe storms ($2 > H_s \geq 1$ m), pre-existing crescentic bars are modified, but not totally removed.

As the waves decrease, the bars migrate shoreward. As the most landward bar approaches shore, it tends to migrate onshore non-uniformly in the form of a ridge and runnel, and portions of the ridge weld onto the beach, resulting in non-uniform widening of the beach.

2. Single crescentic bars. Initially oblique and transverse bars form, resulting from the non-uniform widening of the beach. Within a few days, and with wave heights $H_s < 1$ m, the seaward ends of the bars connect to form crescentic bars, while simultaneously, the landward ends of the oblique/transverse bars become detached from the shore (Fig. 2). The beach is usually in phase with bar cyclicity, forming a dominantly cuspoidal shoreline.

3. Double crescentic bars. Double crescentic bars form when low wave heights persist for several weeks after the single crescentic bars are formed (Fig. 2). The inner system consists of embryonic crescents

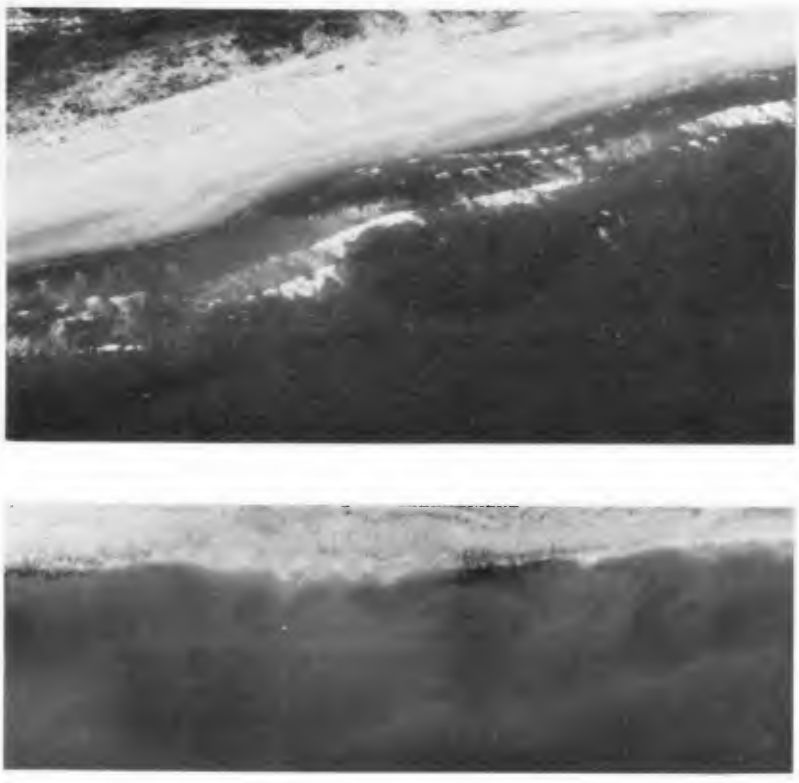

Figure 2. Single crescentic (top) and double crescentic (bottom) bar systems along the Israeli coast.

extending across the seaward end of recurring small rip channels. Wave data indicate that the formation of these inner double crescentic bars is preceded by a short energy pulse of $1.0 > H_s > 0.5$ m of a few hours to a day duration. In the mature stage they extend more than half way across the inshore width (i.e., between the shore and the initial single crescentic bars).

Phase correlation between the inner and outer bar systems is usually not evident. Since the inner crescentic bars form at a different time and under different wave conditions than the outer crescentic bars, one set may be either skewed or symmetric, differently than the other set. Groins and other coastal structures interfere mainly with the inner bar systems, whereas the outer bars often remain continuous and undisturbed.

BAR SEQUENCES : The sequence of bar developments, which was observed by mapping, overflights, and study of the historical aerial photographs, is summarized in Figure 3. The sequence includes, in order: multiple bars, ridge and runnels, transverse/oblique bars, outer crescentic and nested inner crescentic bars. The detailed sequence is discussed in Goldsmith et al. (1982).

In the storm stage, the shoreline is irregular, and the rip heads extend 200-300 m from shore. In the post-storm stage, the outer and inner meandering bars block the former rips and feeders, indicating circulation atrophy (Fig. 3, Seq. B). Three main levels of inshore bathymetry are discerned: 1) the deepest, which are the entrenched, stagnant rip channels; 2) shoals, which are the shallowest; and 3) the main accumulative bodies, which are the meandering and oblique bars.

The early stages of crescentic bar development are documented in a box core obtained in a shore-attached oblique bar at a distance of 80 m from shore, at a water depth of 1 m (Fig. 4). Five distinct units are shown. The lowest unit (A) represents an onshore-migrating bar. Unit B displays offshore-dipping foresets, indicating a rip current. Unit C, the thickest and largest unit, displays approximately one-half of a mega-trough, which may indicate a longshore channel or wave orbital scouring. The upper unit (E) again indicates onshore bar migration. The wave history shows that a severe storm ($H_s = 3$ m) occurred three weeks prior to obtaining the box core. Such storms tend to destroy all bars. This suggests that this entire core was formed during a post-storm sequence, although the depth of activity was not documented. The top unit, landward-dipping planar bedding, reflects the asymmetrical shoaling waves, which may correlate with the low waves prior to sampling.

During the extended calm, the sediment fill "blurs" the stagnant rip channel (Fig. 3, post-storm, Seq. B). Nested "micro" transverse bars and cusps, in phase with embryonic rips, dominate the foreshore and the shallow inshore. Also during extended-calm, a new, shore-normal inner microsystem grows out of the former shoals and embryonic rips. The inner system shows discontinuous crescents that match the shoreline microembayments. The inner system becomes less complex, and both bar systems, separated by a trough, are in phase with the shoreline and the trans-

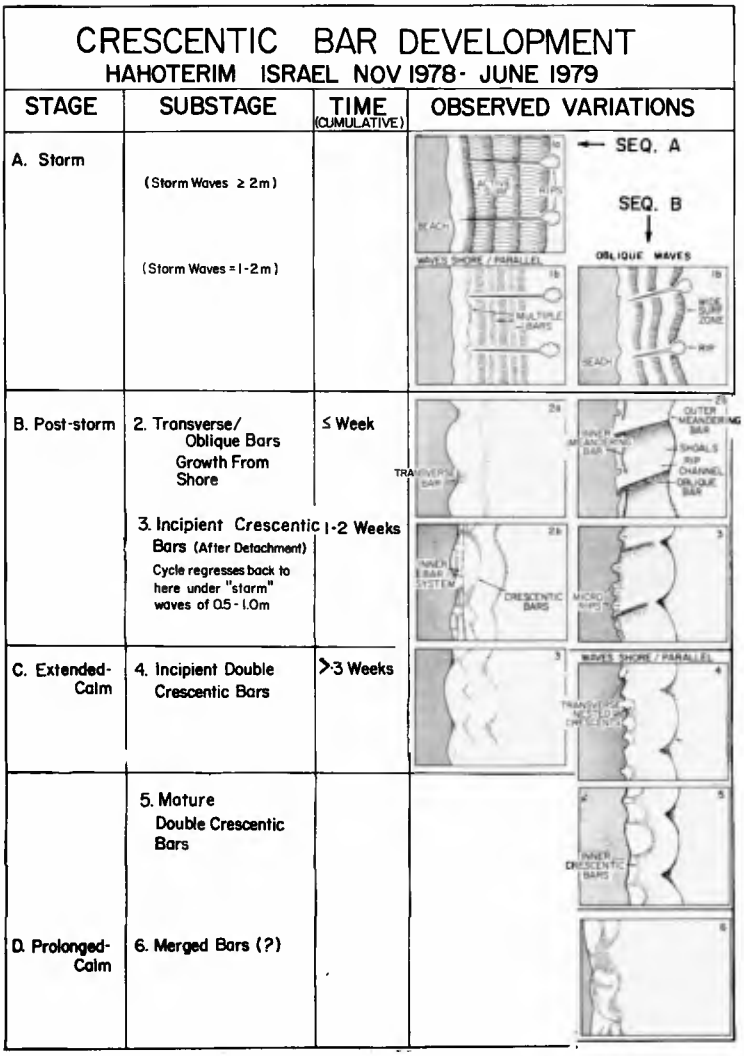

Figure 3. Crescentic bar development and concomitant waves in the south-eastern Mediterranean.

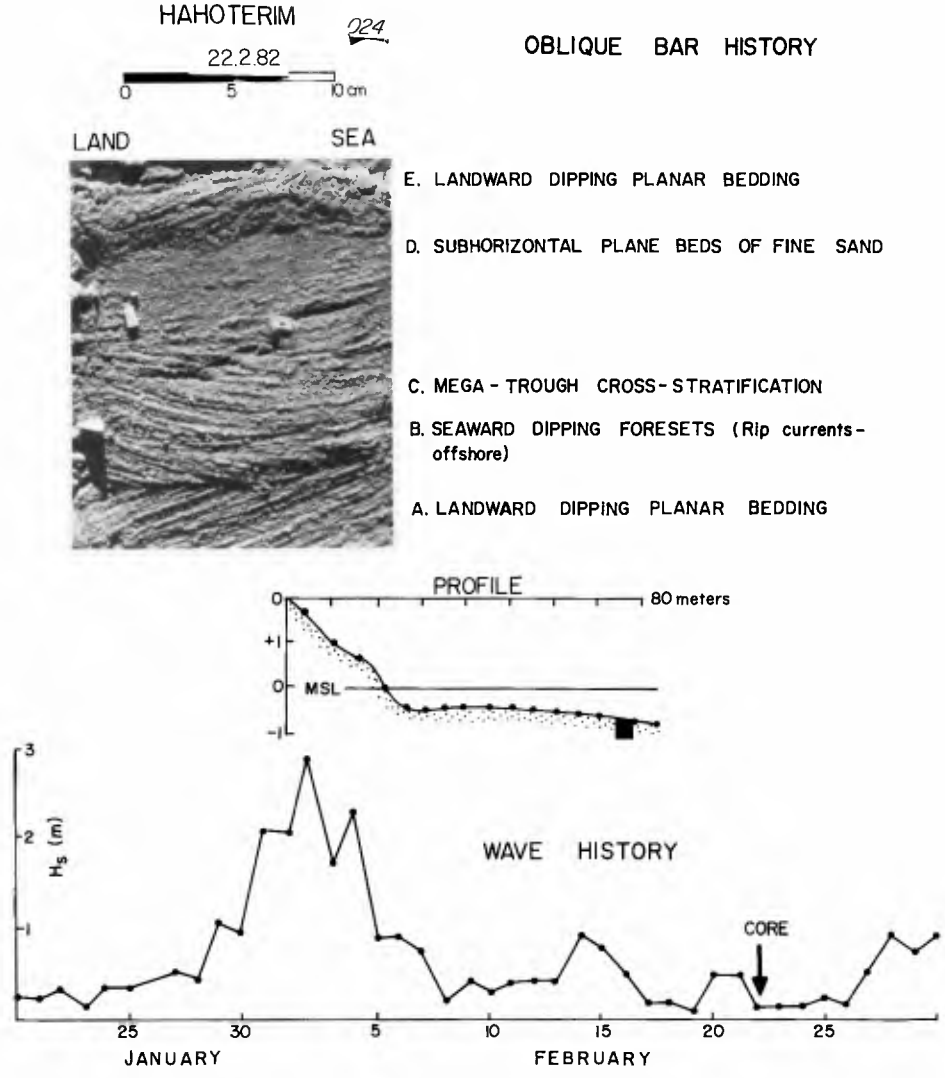

Figure 4. Sedimentation and wave history on an oblique bar, HaHoterim.

verse bars. The outer bars did not evolve during the inner crescentic low energy regime, but persisted from the moderate storms, and should be regarded as inherited. Their "memory" results in out-of-phase relationships between the outer and inner crescentic systems, i.e., the center of the outer crescentic bar corresponded to an inshore shoal, and the outer horns pointed toward an inshore rip channel. Sequence B (extended calm, Fig. 3) indicates the complete removal of the antecedent morphology under the influence of low waves. Phase correlation between the inner bars and the cuspate shore rhythms usually dominates this mature double crescentic stage.

The following wave characteristics were defined coincident with bar stages:

1) Storm, above threshold conditions for bar formation; spilling-plunging breakers, $H_s > 1.0$ m, main range of spectral density $> 10^{-1}$ m^2/Hz. These conditions typify stage A.

2) Wave energy conditions decrease below threshold; collapsing-surging breakers, $H_s < 0.5$ m, main range of spectral density 10^{-2} to 10^{0} m^2/Hz. These conditions indicate the start of crescentic development.

3) Calm, $H_s < 0.3$ m, main range of spectral density $< 10^{-2}$ m^2/Hz indicating the double crescentic bar stage. Minor storms in the range of 10^{-2} to 10^{-1} m^2/Hz did not modify the double crescentic bar pattern.

BAR AND WAVE SEASONALITY : Although the 150 observations of bars during the 1948-1980 period were spread throughout all months of the year, there is a definite tendency for more bars to occur during the six lowest wave months, June through November (62%), than the remaining six months (Fig. 5A). This tendency is explained by the monthly frequency of low waves ($H_s \leq 1$ m) during the 1948-1978 period (Fig. 5B). The parallelism between months of low waves and the annual distributions of bars is quite striking. Most notable is the increase in bars related to a major wave energy threshold in the spring, when the frequency of $H_s \leq 1$ m sharply increases from 58% in the winter months to 70% frequency in April and 85% in May. The calmer and barred summer composes an uninterrupted period of lower waves, explaining the observed seasonal stability of some of the bar types. Summer shows two peaks of low wave activity (Fig. 5B). May to June composes one low wave peak which, when one allows for the lag time needed for bar formation, is clearly related to the high occurrence of bars in June. July is stormier, and therefore both July and August have fewer occurrences of bars. August and September compose a second summer low wave peak, and this is mainly related to the bar-richest month of September. Thus peaks of bar occurrence and wave energy do not match perfectly, but rather indicate a lag in the adjustment of bars to wave power, also observed by Short (1979).

The mature double crescentic bars occur throughout the year, lacking seasonality (Fig. 6). The single crescentic and the initial double crescentic bars are the most energy-sensitive types, being non-existent during winter but abundant from May to November. Non-rhythmic morphologies also seem to occur most of the year (Fig. 6). The major excep-

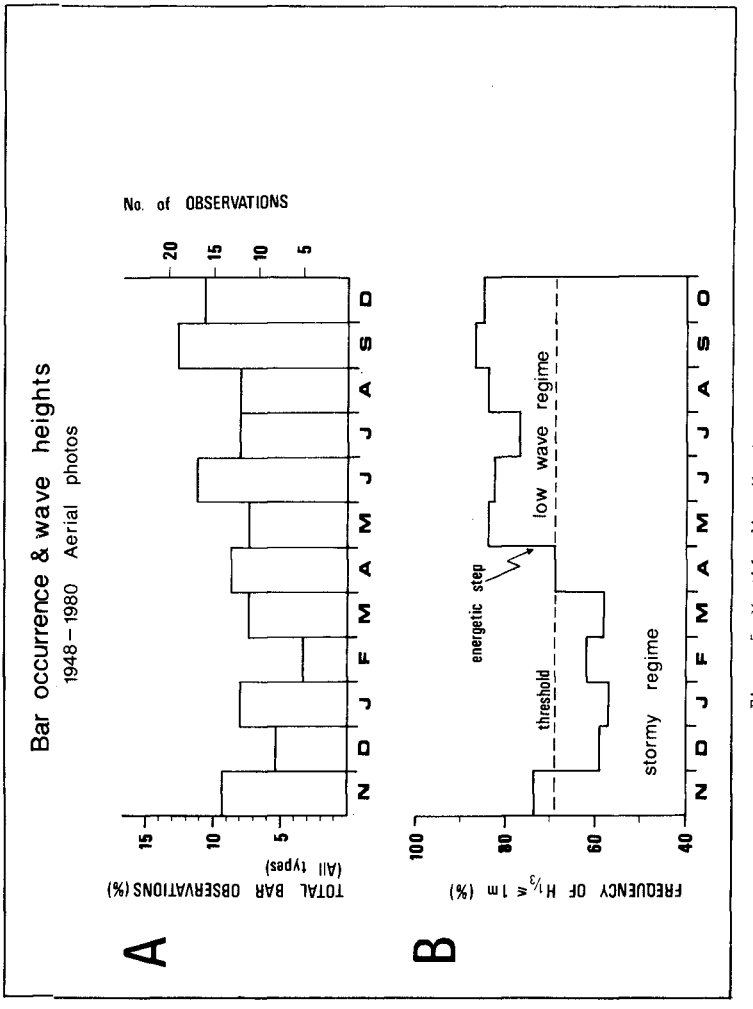

Figure 5. Monthly distribution of (A) bar frequency and (B) wave heights (H_s), 1948-1980.

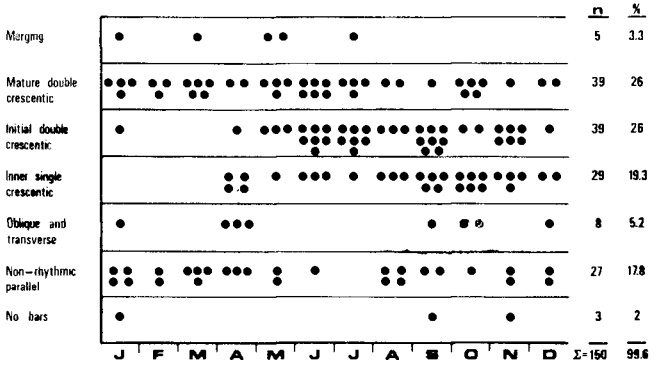

Figure 6. Seasonal distribution of bar types in the southeastern Mediterranean, 1949-1980.

tions are the months of May to July, when the crescentic families dominate. Because July has higher waves, August shows the reappearance of noncyclic systems. This antiphase relationship between non-rhythmic and crescentic bar families continues in September/October.

DISCUSSION : The coast of Israel is highly dissipative, and is dominated by single and double crescentic bar families, which compose 71% of the bars. Because of the cyclicity of storm waves followed by extended times of low waves, the sequence of bar types recurs several times per year. Therefore this may well be one of the best places to study bar sequences.

Thus, this coast is different from the Australian coast (Short, 1979; Wright et al., 1979), where the inner single crescentic bars, defined as megacusps and welded bars, dominated. This may be related to the higher Australian wave energy. This, in turn, differs from the observations of Greenwood and Davidson-Arnott (1979), who reported a lack of seasonal bar changes and continuous dominance of crescentic bars.

Similar bar types occur on most coasts, despite large differences in wave climate, tidal conditions, nearshore slopes and grain size. Most importantly, bars occur successively within definite sequences. However, on different coasts the bar types tend to occur in different sequences and in different proportions of time. It is suggested that these differences are directly attributable to global differences in the occurrences of threshold wave conditions. This, in turn, may be partly due to differences in sediment size and inner continental shelf slopes, as well as to the differences in wave climate.

ACKNOWLEDGEMENTS : This study emanated from a project on nearshore bar systems supported by the Geography Programs, Office of Naval Research, Contract No. N00014-78-C-0645, NP 388-148, V. Goldsmith, Principal Investigator. Additional support was furnished by the Israel Ministry of Energy and Infrastructure.

LONGSHORE TRANSPORT DETERMINED BY AN EFFICIENT TRAP

by

R. G. Dean[1], M. ASCE, E. P. Berek[2], A.M. ASCE, C. G. Gable[3], and R. J. Seymour[4], M. ASCE

ABSTRACT

The Nearshore Sediment Transport Study (NSTS), sponsored by the National Sea Grant Office included a field component to quantify the total longshore sediment transport relationship. This component was conducted at Santa Barbara, California and encompassed a period of eighteen months during which ten surveys were conducted. To date, eight of these surveys have been analyzed, yielding seven intersurvey periods. A total of 288,600 m^3 of net sediment transport was documented by these eight surveys. The wave characteristics are based on one of two S_{xy} gages located in a water depth of 7 m. The most widely used correlation constant, K, in the relationship $I_\ell = KP_{\ell s}$ is 0.77. The values found from the data were 0.93 and 1.23 for linear and log best-fit values, respectively. The corresponding values of K_* relating I_ℓ and S_{xy} are 2.60 and 2.63 m/s, respectively.

INTRODUCTION

Many coastal engineering projects and interpretation of nearshore phenomena depend on an accurate quantitative relationship between total longshore sediment transport and the wave (and other) characteristics which cause the transport. Although a number of field studies have been carried out, the characteristics of most studies are such that considerable uncertainty exists in either the characterization of the forcing function (i.e. waves) or of the sedimentary response. In particular most of the early data sets

relied on visual observations or hindcasts for wave direction. Additionally a number of the programs were based on tracer studies for determination of sediment transport quantities. In studies of this type, substantial uncertanties exist due to the approximations required to determine the effective vertical and lateral limits of transport.

The present paper describes a field measurement program carried out at Santa 8arbara, California. The wave characteristics were determined by an "S_{xy} gage" comprised of four pressure sensors positioned on the bottom at the corners of a 6 m square array in 7 m of water depth. These wave conditions were transformed to the breaker line where both P_{ls} and S_{xy} were established for correlation with the sediment transport. The net longshore sediment transport reported herein was established by means of eight surveys, each consisting of 67 beach profiles and 63 survey lines. The "near total" trap is the spit of sand which is attached to the eastern end of the Santa 8arbara breakwater and portions of the updrift beaches. The surveys encompassed a period of 13 months during which a total of 288,600 m^3 of net sediment transport was documented. Correlations are presented of the net longshore sediment transport with P_{ls}, the longshore component of energy flux at breaking and S_{xy}, the flux in the onshore direction of the longshore component of momentum.

PREVIOUS RELATED INVESTIGATIONS

The number of field investigations of longshore transport is very limited. Greer and Madsen (1979) undertook an evaluation of the field data sets available in 1978. These included a sediment trap at South Lake Worth Inlet, Florida, reported by Watts (1953), a study of erosion downdrift of a jetty at Surfside, California, reported by Caldwell (1956), and sand tracer experiments at El Moreno Beach, Mexico, and Silver Strand 8each, California, by Komar (1969). Greer and Madsen find convincing reasons for rejecting all but the Komar results and find that these, at best, are only order of magnitude estimates.

Subsequent to the Greer and Madsen review, three more data sets were reported at the Seventeenth Coastal Engineering Conference that overcame many of their objections to the first three. Seymour et al (1981) describe a sediment trap experiment at Santa Cruz, California, with an adjacent directional wave measurement array. Bruno, Dean and Gable (1981) report a series of experiments with a trap at Channel Islands Harbor, California, with a pair of wave gages nearby providing low resolution wave directional information. Inman et al (1981) describe tracer experiments at Torrey Pines Beach, California, employing a linear wave measurement array. In addition, Kraus et al (1981) report a series of tracer experiments at Ajigaura and Oarai Beaches in Japan.

The most widely used relationship to predict longshore sediment transport was formulated by Bagnold, Inman and Komar and is often referred to as the SPM method because of broad exposure through the Shore Protection Manual, U.S. Army Engineers (1977). The longshore transport rate is given by

$$I_{\ell} = K P_{\ell s} \quad (1)$$

where I_{ℓ} = immersed weight longshore sediment transport rate
$P_{\ell s}$ = longshore component of wave energy flux at breaking
K = proportionality factor

Values of the coefficient, K, have been established for each of the data sets noted above. The range of these values is shown in Table I. It can be seen that the values of K span over two decades. However, the two trap experiments with direct wave measurements (Seymour et al and Bruno et al) encompass a range of less than a factor of two.

SITE OESCRIPTION

Santa Barbara is located on a sandy lowland on the coast of Southern California approximately 150 km northwest of Los Angeles. It is located on the Santa Barbara Channel which is an elongate marine feature bounded on the north and east by the mainland shoreline of Santa Barbara and Ventura Counties, in the south by the Channel Islands (San Miguel, Santa Rosa, Santa Cruz, and Anacapa) and bordered on the West by the open waters of the Pacific Ocean, Figure 1. The coast in the vicinity of Santa Barbara lies in an east-west direction and is generally rugged. It is characterized by projecting headlands of rock and boulders with intervening coves having cobble covered shores or sandy pocket beaches backed by high bluffs. There are no large rivers, but numerous steep streams, with torrential flow during rainy seasons, that run through arroyos and discharge onto the shore. Santa Barbara is located approximately in the middle of the Santa Barbara littoral cell which extends from Point Conception to Point Mugu. The shoreline between Point Conception and Santa Barbara trends east-west and is composed of sedimentary rocks and shale bluffs

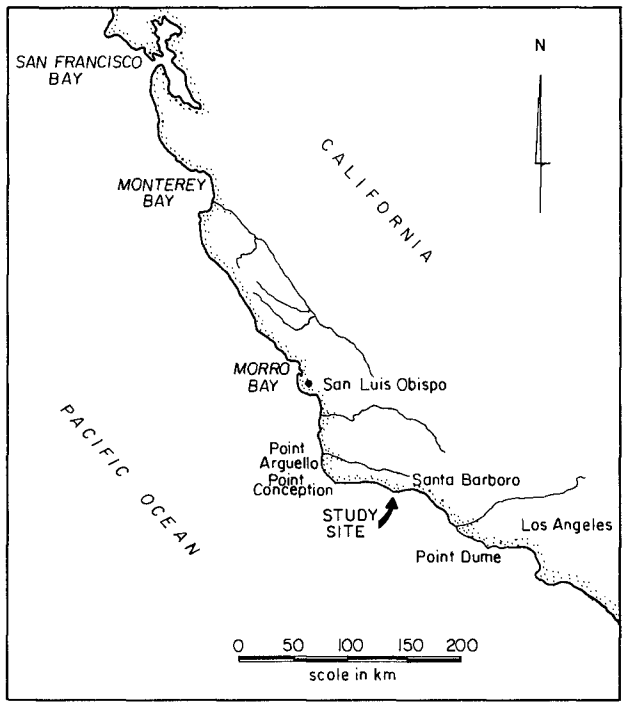

Figure 1 Geographic Location of Santa Barbara (from Trask, 1955).

fronted by sand and cobble beaches. The climate in Santa Barbara is Mediterranean and is controlled primarily by the position and intensity of the semi-permanent Pacific high pressure system over the ocean to the west. During the summer this high pressure feature covers the eastern North Pacific Ocean and deflects eastwardly moving storms to the north. During the winter months this Pacific high migrates southward and weakens, allowing occasional frontal systems that originate in the Aleutians to move through southern California. The most intense extratropical storms are those that develop between Hawaii and the California coast. These storms, because of their southerly position and intensity, often produce large westerly ocean swells which propagate into the Santa Barbara Channel between Point Conception and San Miguel Island.

Before the construction of the Santa Barbara Harbor breakwater the flow of sand was uninterrupted and was transported naturally to the beaches to the east within the Santa Barbara littoral cell. In

early 1930 when the harbor breakwater was completed, sand began accumulating west of the shore arm of the breakwater creating what is now known as Leadbetter Beach. Eventually, sand migrated along the breakwater and deposited in the lee or shadow of the structure forming a sand spit in the channel as shown in Figure 2. As a result, the sand spit created a navigation problem as well as stored the sand that was naturally previously transported to the downcoast beaches. Therefore, a dredging program was initiated in 1935 for placing obstructing material within the harbor on the starved downcoast beaches to prevent further erosion. This annual harbor maintenance and beach nourishment program is still in progress. There were two dredging episodes within the time frame of this experiment.

The wave climate at Santa Barbara is generated either between the Channel Islands and the coast (local wind waves) or generated in the ocean seaward of the Islands. The local wind waves from the south are usually insignificant with only choppy seas and small waves. Wiegel (1959) reports that local storms from the southeast have a fetch of 145 km and generate waves toward the Santa Barbara coast with significant wave heights ranging from 244 to 488 cm. The predominant waves are from the southwest and west that enter the Santa Barbara Channel between San Miguel Island and Point Conception. Leadbetter Beach is protected by the Channel Islands and Point Conception from swells generated by distant storms from all other active sectors. Wiegel (1959) reports that waves from the southwest and west range from 30 to 500 cm but average about 91 cm. The average wave period is 12 seconds, but ranges between 8 and 16 seconds. Leadbetter Beach is a feeder beach for the sandspit formed in the shadow of the breakwater. It is characterized by a steep beach slope, narrow surf zone, unique wave climate with a narrow window of approach and high angle of incidence, unique wave refraction effects, and a unidirectional longshore current of high magnitude. The sand is well sorted with a median size of approximately 0.22 mm. Gable (1980) provides a detailed description of the experiment site.

DESCRIPTION OF SURVEYS AND TECHNIQUES

The accumulation of sediment was measured at approximately 6-8 week intervals with profiles extending from the dry beach to a depth of about 10 meters. A total of ten beach and nearshore surveys of the sediment trap at Santa Barbara Harbor and the adjacent updrift "Leadbetter Beach" were completed between 18 October, 1979 and 26 February, 1981. Surveys were scheduled to coincide with days of large tidal ranges. The schedule was modified occasionally according to weather and dredge operations. Each survey required 4-5 days to complete. The starting dates for each survey were: (1979): 18 October, 30 November, (1980): 20 January, 25 February, 10 April, 3 June, 25 August, 22 October, 17 December, (1981): 26 February. The survey plan is shown schematically in Figure 3. A total of 63 nearshore profile lines was surveyed using an Automated Bathymetry System (ABS) on-board a small survey boat provided under contract by Ocean Surveys, Inc. (OSI). Each of these profile lines was surveyed with ABS three times to enable the averaging out of long period ocean swells. The beach surveys were carried out to wading depths, used conventional rod and level techniques and consisted of 67 profile

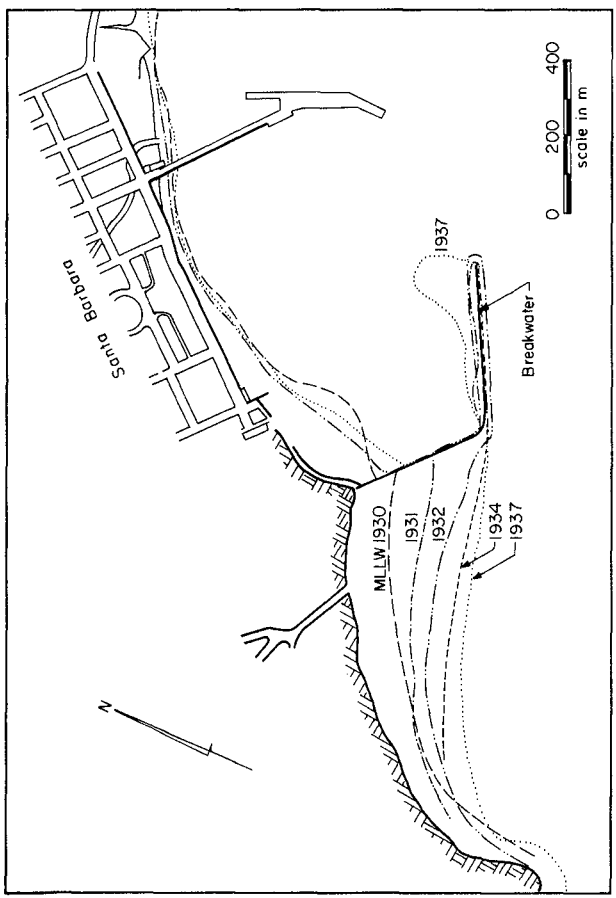

Figure 2 Shoreline Changes Upcoast of the Santa Barbara Breakwater (after Johnson, 1957).

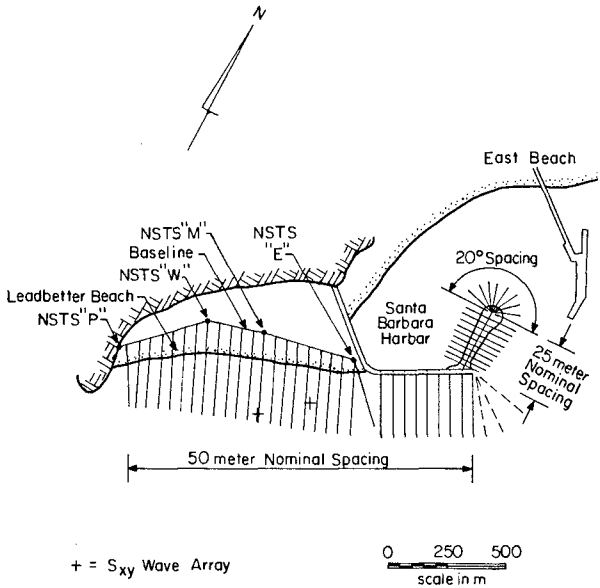

Figure 3 Plan of Sediment Impoundment Study and Location of Directional Wave Gages

lines. The nearshore and beach profiling were conducted over the maxima and minima of large tidal ranges, respectively, to achieve as much overlap as possible. Tide data necessary to reduce depth readings to the MSL datum were collected using a tide staff and a NOAA recording tide station. Range lines were defined by two survey points marked by flags, which a rodman aligned before each survey reading. Rod locations were established rapidly using a specially constructed plastic coated stainless steel survey line marked at 5 meter intervals seaward of the benchmark except where pronounced changes in slope occurred. An engineer's level and rod provided vertical control. Measurements were made out into the water by the tapeman paying out the tape in 5 meter increments from a fixed point on the baseline. The profile was terminated when the water became too deep for the rodman to wade or the breaking waves made it impossible to plumb the rod.

The nearshore bathymetry was measured using an ABS onboard a small survey boat. The "boat" surveys usually took three full days to profile all 63 lines (each three times) and required one boat operator, one field electronics engineer, and a minimum of two experienced surveyors. To assure that the boat remained on the given range azimuth and to assure accurate replication of the survey lines

from survey to survey, a transit and Cubic Autotape positioning responder were set up over each of the profile bench marks. The transit operator would turn the proper azimuth from a known backsight and give course corrections to the boat operator via FM radio. Two orange survey cones on-range were placed on the beach to provide the boat operator a visual line. Distance offshore measured from the responder located over the benchmark was continually monitored by the electronics operator on board the boat. This technique ensured that the proper cut-off distance offshore was met. The second responder of the Autotape positioning system was installed over a bench mark a sufficient distance up or down the beach to provide an accurate measure of the distance off-line at each position fix. The ABS consists of the following equipment: a Raytheon DE-719B Fathometer, Innerspace Model 412 Digitizer, Cubic DM-40A Autotape Range-Range Positioning Navigation System, Hewlett Packard Model 5150A Thermal Printer, and a Sea Data Model 1250 Data Logger and Cassette Recorder, see Figure 4. This equipment was secured into a 6.7 meter survey boat

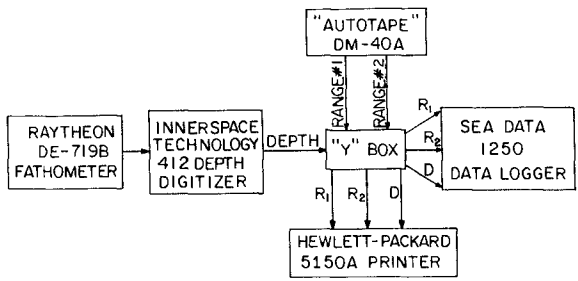

Figure 4 Block Diagram of OSI's Data Acquisition System

(Boston Whaler). The survey boat was conned along each transect by a transit operator on shore. However, boat position was fixed by logging two ranges of the Cubic Autotape positioning system. As the range determinations of the Autotape are updated at approximately one second intervals, the Autotape is designated the master for the automated system. At each update, a print command is sent to a Hewlett Packard Model 5150A thermal printer and a scan command is sent to the Sea Data Model 1250 digital cassette magnetic tape data logger. The range-range data, in parallel binary coded decimal (BCD), is thus recorded on both printed paper tape (hard copy backup and visual presentation of digital data for field data quality control) and magnetic tape. On command from the Autotape, both the printer and the data logger also record the current depth reading. Depth data are available from the Innerspace Model 412 depth digitizer. The digitizer accepts "start-stop" pulses from the Raytheon Fathometer. The interval of time between the start and stop pulses is directly proportional to depth. The fathometer records on strip chart and

provides depth readings to the digitizer nine times per second. Accordingly, the depth data are virtually instantaneously available at each Autotape command. Communication between all components of the system is provided to assure that position and depth data are not being updated at the instant of recording. An automatic "event" is also recorded at every 16th Autotape command on the cassette tape, printer paper tape, and fathometer strip chart. This event mark allows data processors to correlate the three recording media to check accuracy. As a "bookkeeping" function, each sequential event is numbered on the cassette tape. The cassette tape data logger also records times in the "header" for each data record as well as a manually entered run number, set by the operator at the beginning of each run. A "Y" box receives the BCD depth and range data and splits these signals for separate transmission to the printer and data logger allowing continued operation of the system should a failure occur in either of the recording media. A block diagram of the data acquisition system has been presented as Figure 4. The depth sounder and digitizer establish the elapsed time interval between transmission of an acoustic pulse and receipt of a return echo from the seafloor. To precisely relate this time interval to water depth, an adjustment is necessary on both instruments for the speed of sound in the water at the site. This was accomplished by conducting "bar checks", a process of lowering a target "bar" on a calibrated line to known depths below the depth sounder transducer. Both the depth sounder and digitizer are then adjusted to display this depth precisely. Bar checks were performed at nominally three hour intervals and at the beginning and end of each recording period. A more detailed description of the survey system and techniques is provided by Gable (1980).

WAVE ANALYSIS

The incident wave climate was measured using two slope arrays at a depth of approximately 7 m. A description of the hardware and the data retrieval and recording methods for a similar installation is contained in Seymour et al (1981). The location of these arrays is shown in Figure 3. Each array consists of four pressure sensors at the corners of a 6 m square frame. Pressures were sampled at 1 hz and 1024 samples (17+ minutes of data) were obtained at nominal six hour intervals for the duration of the experiment.

Two different approaches were used in analyzing the wave data to allow estimation of the longshore transport. The first method provides input for Equation (1). In this approach, the pressure signal from one of the sensors in each array was Fourier transformed, corrected to surface elevations by application of linear wave theory, and converted to an energy spectrum. A weighted characteristic frequency for this spectrum was then calculated. Using the cospectra of the surface elevation with the sea surface slope components, a characteristic wave approach direction was calculated. Employing the total energy in the spectrum, a singular wave was constructed having the characteristic frequency and direction. This wave was then refracted to the break point using linear shoaling theory. Finally, P_{ls} was calculated for this breaking wave.

In the second approach, the longshore component of shoreward directed radiation stress, S_{xy}, was calculated for each array. The slope array facilitates this calculation since, as shown in Higgins, Seymour and Pawka (1981), S_{xy} is proportional to the cross-spectra of the sea surface slopes.

Since the nearshore bathymetry is marked by non-parallel contours, the two arrays produce somewhat different values for either of the two parameters. In this work the data from the east array were employed.

RESULTS

The principal results are the correlations between the immersed weight longshore sediment transport rates, I_ℓ, and measures of the wave forcing as characterized by $P_{\ell s}$ and S_{xy}. For purposes of establishing, I_ℓ, the volume changes were based on the following areas: the spit in the lee of the breakwater, the area fronting the breakwater and the portion of Leadbetter Beach encompassed by the survey lines to the east of the easterly S_{xy} gage, see Figure 3.

Table II presents the characteristics of and results from the seven intersurvey periods. It is seen that there was much more sediment transported during some of the intersurvey periods than during others. For example, during the third intersurvey period the average immersed weight transport rate was almost 300 N/S whereas during the following intersurvey period, the rate was less by more than an order of magnitude. The seventh column of Table II presents the K value calculated from each individual data set and it is seen that these values range from 0.32 to 1.63, a range of approximately five. However the smallest value which exhibits the greatest deviation from the norm is associated with the fourth intersurvey period which is characterized by a very small value of I_ℓ. If this one point is not included, the ratio of the largest to smallest of the remaining individual K values is less than two, which appears reasonable for this type of measurement. Unless stated otherwise, the results presented herein will exclude this one "outlier" value. The I_ℓ vs $P_{\ell s}$ data are plotted in Figure 5 on a log-log scale. Values of K were determined that provided best least squares fits between I_ℓ and $KP_{\ell s}$ and between log I_ℓ and log $KP_{\ell s}$. The corresponding K values were 0.93 and 1.23, respectively. It is noted that a previous study for Santa Barbara by Galvin (1969) had combined sediment accumulation values developed by J. W. Johnson with wave characteristics deduced by Galvin based on wave hindcasts and a wave direction which yielded the maximum $P_{\ell s}$, (i.e. minimum K); Galvin's mean value of K was 1.60. The K value of 1.23 determined from the present study is smaller than that determined by Galvin and larger than the values (0.77) referenced in the Shore Protection Manual (1977) and most often employed. As shown in Figure 6 the value determined herein is in approximate agreement with an earlier correlation of K with sand size developed by Dean (1978), where the characteristics of the other data points presented in Figure 6 are described.

It seems plausible that I_ℓ should correlate reasonably well with the total longshore force, S_{xy}, acting on the surf zone, in the form

TABLE II

SUMMARY OF FIELD RESULTS BY INTERSURVEY PERIOD

Intersurvey Period	No. of Days	Dredging Event	Total Volume Change(m^3)	Immersed Weight Transport Rate I_ℓ(N/S)	Net Longshore Component of Wave Energy Flux at Breaking, $P_{\ell s}$(N/S)	$K = I_\ell / P_{\ell s}$	Net Onshore Flux of Longshore Component of Momentum S_{xy}(N/m)	$K_* = I_\ell / S_{xy}$ (m/s)
10/13/79-11/30/79	48	No	32,820	85.3	52.2	1.63	27.8	3.06

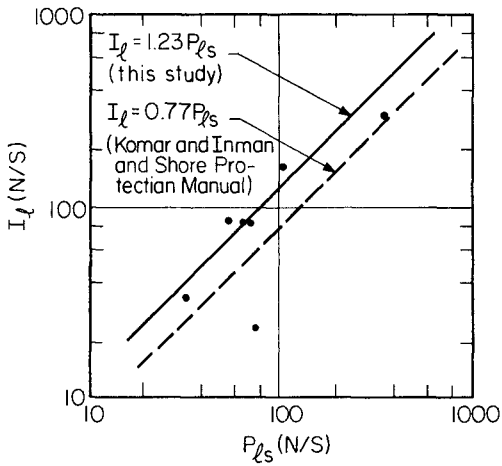

Figure 5 Data From Santa Barbara Field Experiment. I_ℓ vs $P_{\ell s}$, Present and Past Correlations.

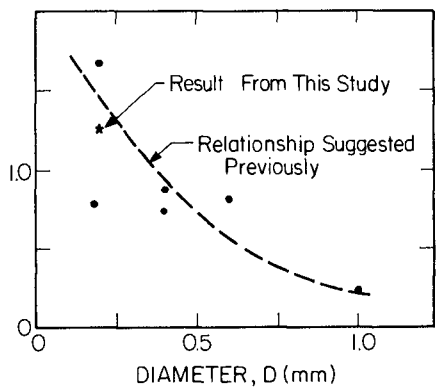

Figure 6 Plot of K vs D. Results of Present and Previous Studies (Modified from Dean, 1978).

$$I_{\ell} = K_{*} S_{xy} \quad .$$

One disadvantage of this form is that K_{*} is dimensional, whereas K (Eq. 1) is dimensionless. The S_{xy} and K_{*} values for each of the intersurvey periods are presented in Table II where it is seen that if the one "outlier" (small value) is not considered, the ratio of the maximum to minimum values of K_{*} is 1.83, only slightly less than the corresponding ratio for K. The I_{ℓ} vs S_{xy} values are plotted in Figure 7. Best fit linear and logarithmic values of K_{*} are 2.60 and 2.63 m/s, respectively.

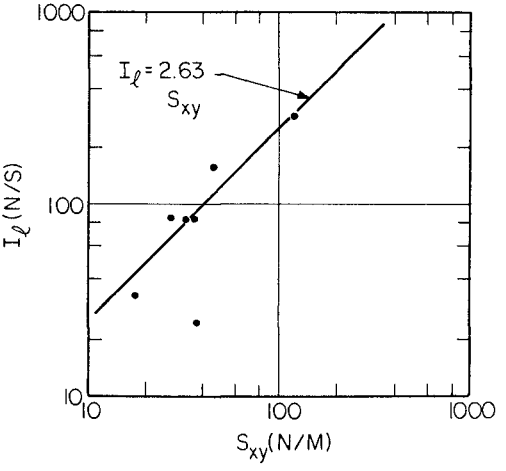

Figure 7 Data From Santa Barbara Field Experiment. I_{ℓ} vs S_{xy} and Best Least Squares Fit.

The values of K and K_{*} based on the cumulative I_{ℓ}, $P_{\ell s}$ and S_{xy} over all seven intersurvey periods are 1.07 and 2.40 m/s. Excluding the one "outlier", the values are 1.17 and 2.67 m/s.

SUMMARY AND CONCLUSIONS

Summary

A field experiment has been carried out with high-quality measurements of directional wave characteristics and the associated sediment transport. The results, documented herein, span approximately 13 months and include surveyed volumes of 288,600 cubic meters of sediment transport. The analysis, based on six intersurvey periods, yield best-fit linear and logarithmic values of K of 0.93 and 1.23, respectively. The corresponding values of K_{*} relating the immersed weight sediment transport rate, I_{ℓ}, and S_{xy}, the flux in the

onshore direction of the longshore component of momentum, are 2.60 and 2.63 m/s, respectively. While the value of K is somewhat larger than the most-often referenced value of 0.77, it is reasonably consistent with the value (1.6D) determined in an earlier study of Santa Barbara by Galvin and also is consistent with an earlier trend established by Dean of K with sediment diameter, D.

Conclusions

1. The results developed here are supportive of a variation of the sediment transport coefficient, K, with diameter, D. It is likely that K varies with other parameters: beach slope and morphology, wave characteristics, etc. Well documented (waves and sediment transport) field programs at locations with widely different conditions would be valuable in further defining the variation of K with other parameters of importance.

2. Although the two variables P_{gs} and S_{xy} are related and appear to provide approximately equally good fits to the longshore sediment transport, investigation should be continued of the relative merits of these two as correlating parameters.

ACKNOWLEDGEMENTS

The financial support provided by the Sea Grant Program to this component of the Nearshore Sediment Transport Program is greatly appreciated. The encouragement and guidance of Dr. David Duane as Technical Monitor of that program was especially valuable. The dedicated and professional efforts of Ocean Surveys, Inc. in the field surveys contributed significantly to the quality of the field data. Finally, the University of California at Santa Barbara was very helpful by providing vessels and highly competent personnel to assist in the field efforts.

FIELD EXPERIMENTS ON LONGSHORE SAND TRANSPORT IN THE SURF ZONE

by

Tamio O. Sasaki[4] and Kiyoshi Horikawa[5]

ABSTRACT

Eight fluorescent sand tracer experiments were performed in energetic surf zones on natural beaches and on beaches near structures to measure the short-term longshore sand transport rate. Tracer of up to four distinct colors was injected on a line crossing the surf zone to investigate the on-offshore distributions of the longshore sand advection velocity and transport rate. The tracer advection velocity, v_a, and the depth of mixing into the bed, b, were determined from large numbers of cores taken in situ throughout the sampling area. The sand advection velocity and mixing depth were not constant across the surf zone, but usually exhibited a maximum either toward the shoreline or toward the breaker line, or in both regions. The local breaking wave height, H_b, and horizontal current velocity in the surf zone (yielding an average longshore current velocity $\bar{V}$) were also measured. The data were interpreted with simple dimensional arguments to give the following results: $b = 0.027\ H_b$, $v_a = 0.014\ \bar{V}$, and the volumetric transport rate $Q = 0.024\ H_b^2 \bar{V}$. Agreement was also found between the measured total longshore sand transport rate and a predictive expression due to Bagnold involving the breaking wave power and average longshore current velocity. Although the results appear reasonable and consistent, a problem remains concerning the apparent decrease in tracer advection speed alongshore recorded in most experiments at the longer sampling times.

1. INTRODUCTION

The longshore sand transport rate is usually the principal factor determining erosion or accretion along a coast. If the longshore sand transport rate can be estimated, a qualitative picture may be formed of the general evolution of the coastline, including changes of the shoreline around structures. This picture can be brought to a

quantitative level with numerical models of shoreline change. Such models require a predictive formula for the total longshore transport rate in terms of the average wave and current conditions. Because structures extend across the nearshore zone, a predictive expression for not only the total transport rate, but also the distribution of the longshore transport rate, is required to accurately describe changes which occur in the sea bottom and shoreline in the vicinity of such structures.

Only a limited number of field measurements of the longshore sand transport rate have been attempted. For example, Bruno et al. (1980) discuss 56 field data points. Most of these measurements may be rejected for violating certain criteria or because of experimental uncertainties (Greer and Madsen, 1978; Bruno et al., ibid).

The goals of our sand tracer field experiment program were 1) to obtain data for evaluating predictive expressions for the short-term (order of hours) total longshore sand transport rate, 2) to obtain some knowledge of the distribution of the transport across the surf zone, and 3) to determine the applicability and limitations of tracer techniques applied to real surf zones. Five of the experiments were part of a comprehensive multi-institutional cooperative field investigation conducted in Japan from 1978 to 1982.

2. BACKGROUND OF EXPERIMENTS

2.1 Study Sites

Fig. 1 Location of experiment sites.

The experiments were performed on four beaches: Ajigaura, Oarai, Hirono and Shimokita, facing the Pacific Ocean on the east coast of Japan (Fig. 1). The experiments are referred to by the beach name, and year, if necessary, except for the two experiments at Hirono performed on consecutive days in 1980, termed Hirono-1 and Hirono-2. The experiments at Oarai were performed to investigate the influence of structures on the waves, current, and sediment transport. Table 1 gives the basic characteristics and brief descriptions of the sites.

The tidal range on these beaches is rather small, about 1 m. As much as possible, the experiments were performed during or near an inflection point in the tide to minimize its effect. The tide is considered to have had negligible influence except possibly for a rising tide occurring near the end of Oarai 81.

TABLE 1 Characteristics of beach experiment sites.

Experiment	Median grain size d_{50} (mm)	Sorting coef. $(d_{75}/d_{25})^{1/2}$	Specific gravity	Composition	Nearshore beach slope	Comments
AJIGAURA 78	0.23	1.1 (estimated)	2.65	quartz	1/50 to 1/70	Coast is 9 km long with no significant structures; Ajigaura 78 performed near south headland, Ajigaura 79 performed near middle of coast

2.2 Experiment Design

A schematic of the general experimental arrangement is shown in Fig. 2. A summary of the arrangements and sampling schedules of all eight experiments is given in Table 2. Four features distinguish these experiments from previously reported ones. These are:

i) Multicolor tracer injections were often applied to measure the distribution of the longshore transport rate, and to separate longshore and on-offshore effects.

ii) Core samples were taken in situ at all times and at all locations. Before 1980, hand-held wedge-shaped PVC tubes were used for sampling. From 1980, a special coring device was used (Kraus et al., 1981).

iii) Two to four samplings by the spatial integration method were made in all experiments. In addition, sampling by the time integration method was made in four of those experiments.

iv) Three experiments were performed near structures.

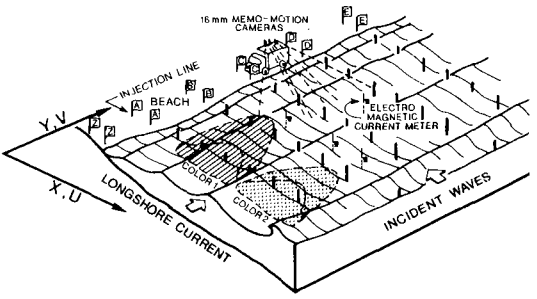

Fig. 2 Schematic of multicolor tracer experiments, and axes convention.

Two sampling methods were used. The spatial integration method (SIM) involves near-simultaneous sampling on a two-dimensional grid to determine the location of the tracer center of mass. The time integration method (TIM) involves frequent sampling on a line crossing the surf zone and down-current from the injection line to record passage of the tracer. Komar (1969) extensively used the SIM. Inman et al. (1980) performed the SIM and TIM in combination as we did in four experiments. In our experiments a one-time injection of tracer was used. Duane and James (1980) used a continuous injection method. These and other sampling methods have been described by Lean and Crickmore (1963) for tracer techniques applied to transport in rivers.

Sand from the area of the beach face and tagged with one of four fluorscent colors was presoaked in a solution of water and detergent and injected as a line source. We have found that injections in amounts of 1 kgf/m on-offshore yield acceptable results. If the amount is too large, the counting time increases due to high concentrations; if too little tracer is injected, statistically significant amounts will not be recovered. Normally, injection was made by carefully cutting open small bags of tracer held on the surf zone bottom. In Oarai 82 the tracer was injected to a depth of 5 cm by operating the core samplers "in reverse": no appreciable difference was noted.

The samples were segmented to a certain nominal depth, typically 6, 10 or 14 cm, depending on the results of a preliminary analysis of the mixing depth. In three experiments (Ajigaura 78, Ajigaura 79, and Oarai 82), all samples were processed as core samples (yielding on the order of a thousand segments of thickness 1 or 2 cm per experiment). In the other experiments, only samples on certain longshore and on-offshore lines were finely segmented in 1- or 2-cm lengths. The remainder were processed in 4- or 6-cm segments and treated as grab samples in the analysis. These data sets of several hundred to a few thousand segments per experiment provide a detailed picture of the horizontal and vertical movement of the tracer over a wide area of the surf zone.

The tracer was counted by hand under ultraviolet light. Concentrations were expressed as a number per unit volume of sample, in effect the number of grains per centimeter in the bed for a fixed sampler surface area. A spectrofluoroscopic counting method was devised for high concentrations (Farinato and Kraus, 1981). However, the method was not implemented because of the necessity for a chemical technician.

It was decided to make local wave measurements to avoid introducing uncertainties such as might arise from refracting waves from deep water, use of a breaking criterion, complications of diffraction from structures, etc. The wave field was measured by capacitance wave gages and by filming the water surface elevation at poles with 16mm cameras from a high elevation on the beach (Fig. 2; Table 2). The camera system is very reliable and has provided otherwise unobtainable data on wave characteristics in the nearshore zone (Hotta and Mizuguchi, 1980).

Except for Ajigaura 78, the current was measured with electromagnetic current meters, usually at three points on a line crossing the surf zone and near the injection line. Ideally, measurements should be made in the swash zone, in the midsurf zone, and just inside the breaker line. However, it is difficult to record in shallow water because the meter sensor is often exposed. Therefore the instruments usually had to be placed in the mid- and outer surf zone. The sensors of these two-component current meters were positioned 10 to 50 cm from the bottom.

3. METHOD OF ANALYSIS

3.1 General

Experiments based on a one-time injection of tracer require measurement of two quantities: 1) the sand advection velocity in the longshore direction, v_a, determined from the movement of the center of mass of the tracer and 2) the depth of mixing, b, determined from cores of material removed from the bed. The total volumetric rate of sand transport in the longshore direction, Q, is calculated by forming the product of these quantities with the width through which the transport takes place, usually the width of the surf zone, x_b:

$$Q = v_a \, b \, x_b \tag{1}$$

A conceptual model with the conditions and time scales for which Eq. 1 is expected to hold is given in Kraus et al. (1981).

Both the advection velocity and depth of mixing may vary across the surf zone. It is therefore appropriate to consider the volumetric transport rate per unit width of the surf zone, q, given by

$$q = v_a\, b \tag{2}$$

This quantity depends only on the sediment response. In multicolor tracer experiments, if the tracer remains localized on-offshore as it moves alongshore, q gives an estimate of the distribution of the transport rate on-offshore.

3.2 Tracer Center of Mass and Advection Velocity (SIM)

An element of the grand concentration array containing the number of recovered tracer grains per unit volume (or per centimeter in the bed) is represented by N(c,i,j,k,n), where the index c denotes the tracer color, i denotes the offshore grid coordinate, j denotes the longshore grid coordinate, k denotes the segment coordinate and n denotes the sampling time. In some experiments there were sufficient numbers of divers to sample the grid rapidly. Then the samples were taken semi-randomly proceeding from the injection line. In other experiments two teams of divers sampled simultaneously on their respective lines on-offshore. In this case a sampling took about 20 to 30 min, depending on the size of the grid and the wave conditions.

Formulae for calculating the tracer advection velocity are derived in the Appendix. In application, the notation is simplified by the following conventions: the offshore limit is assumed to be the station at the breaker line, the symbol $N_{i,j}$ represents a sum over k of all segments at the location (i, j), and the symbol c for color and summations over color are suppressed.

The longshore position of the tracer center of mass is given by

$$Y = t_o \sum_{i,j} \frac{y_j}{t_j} N_{i,j} \left(1 - \frac{y_j}{t_j} \frac{\Delta t_j}{\Delta y_j}\right) \Delta y_j \Big/ \sum_{i,j} N_{i,j} \left(1 - \frac{y_j}{t_j} \frac{\Delta t_j}{\Delta y_j}\right) \Delta y_j \tag{3}$$

The advection velocity is simply $v_a = Y/t_o$, where t_o is taken to be the time of sampling on the injection line. The position of the tracer center of mass on-offshore was calculated by the simple approximation

$$X = \sum_{i,j} x_i\, N_{i,j}\, \Delta y_j \Big/ \sum_{i,j} N_{i,j}\, \Delta y_j \tag{4}$$

3.3 Depth of Mixing

The depth of tracer mixing is a matter of definition. It has been variously defined as the depth of greatest burial (Komar, 1969; Gaughan, 1978) or as one of several kinds of concentration- or depth-weighted averages (Crickmore, 1967; Gaughan, 1978; Inman et al., 1980). In our experiments, most of the tagged sand in the cores was typically contained in the upper 6 cm, but frequently some grains were found as deep as 20 cm. This makes a maximum depth or depth-weighted definition of b either unrealistic or highly subjective.

Under steady waves and currents, a developing core concentration profile should have a maximum in the surface layer and decrease monotonically with depth. At equilibrium, the tracer should be uniformly distributed from the surface to some maximum depth. In reality, conditions are not steady and samples often exhibit one or more positive concentration gradients with depth, indicating the occurrence of two or more high energy turbulence events, or that local erosion or accretion took place.

We developed a definition of the depth of mixing with a variable parameter, the percentage of tracer contained in a core to a certain depth, in order to investigate the effect produced by the various irregular concentration profiles (Kraus et al., 1980, 1981). Within any core segment (typically of thickness 1 or 2 cm), the tagged grain concentration is assumed to be uniformly distributed. Then for each core, a local mixing depth is calculated which includes a specified percentage of the total tagged grains of a particular color. The mixing depth, b, is then defined as a simple average of a particular subset of local mixing depths. In previous work we used a concentration-weighted average but, because recovered numbers of tagged grains in a core can vary over two or three orders of magnitude, a simple average was later adopted. This procedure was strengthened with a criterion requiring that at least one segment contain more than a specified number of grains. After examining thousands of core profiles from several experiments, the minimum cutoff was set at 5 grain/cm. Assuming that this criterion eliminates statistically unreliable cores having a high "noise" content, the cores accepted for analysis can then be considered of equal weight.

An additional criterion was imposed in an attempt to remove cores suspected of being contaminated by erosional or accretionary events. Cores were rejected if a segment with no tagged grains appeared between segments containing 50% of the tracer in the upper part of the core. This criterion reduced values of b by approximately 25% from those calculated previously.

The effect of the cutoff percentage on the average mixing depth was examined. It was found that a linear relation is maintained to a certain cutoff percentage, after which the relation deviates significantly from linearity. An example is shown in Fig. 3 for Oarai 82. This result indicates that uniformity in mixing exists to a certain depth, after which the amount of tracer rapidly tails off. We found that a cutoff percentage of 80% was suitable for all the experiments, similarly to Kraus et al. (1980, 1981). A complete description of the experimental results and analysis of the depth of mixing is in preparation (Kraus and Isobe, in prep.)

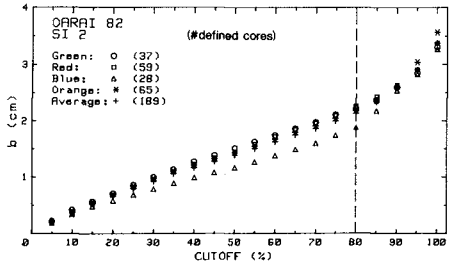

Fig. 3 Depth of mixing vs cutoff percentage.

4. RESULTS

4.1 Budget of Tracer

An estimate of the total number of tracer grains transported over the sampling grid can be made by assuming that the number of grains recovered at a site is representative of the surrounding area. Since the tracer grains in the samples were counted to their point of extinction, the calculation can be made without reference to the depth of mixing. Knowledge of the number of tracer grains per unit weight of the injected tracer allows comparison between the number of grains injected and the number accounted for by the sampling.

Although this procedure is straightforward in principle, in practice one cannot be certain of the absolute value of the calculated recovered amount because of the difficulty in counting the number of tagged grains in, say, 1 gf of tracer. Therefore, the acceptability of the measurements was judged by comparing the relative amounts recovered at the different (SIM) samplings. If a significantly smaller amount of tracer was recovered compared to other samplings, that sampling was considered unreliable. Most of the rejected measurements were from the earlier sampling times. This is attributed to the fact that the grid was relatively coarse with respect to movement of the tracer at the earlier times. Results associated with the earlier samplings were therefore not included in correlations employing waves and current.

4.2 Sediment Response

The principal results of the sediment response for the SIM experiments are summarized in Table 3. Background data on the average wave and current conditions are summarized in Table 4. In what follows, $(H_b)_{1/3}$ will be written as H_b. Values for the current in Table 4 are averages over the elapsed time of the final spatial sampling.

(1) Position of tracer center of mass (X, Y)

In Table 3, the notation "outer, mid, inner" refers to the relative positions of the different colors of tracer. It is seen from the X-entries that the tracer remained localized on-offshore (with the exception of Hirono-1 discussed in Subsection (4) below), even though the shore-normal component of the current was usually directed offshore (Table 4). An explanation for this might be that the transport produced by the steady offshore current in the surf zone, which we and co-workers have found to exist in the great majority of our field experiments, is balanced by the transport resulting from the large onshore component of wave orbital velocity due to wave asymmetry.

The purpose of performing two or more spatial samplings was to eliminate start-up or equilibration effects. We wished to check the reproducibility of the results by reference back to a previous position of the center of mass, not necessarily the injection line. Unfortunately, as can be seen from the Y-values in Table 3, for most experiments a large translation of the tracer alongshore was recorded at the earliest sampling and then very little movement took place in the later samplings. This result may also be attributed to the relative grid coarseness at the early samplings.

(2) Depth of mixing (b)

The depth of mixing was calculated for each color of tracer according to the procedure discussed in the previous section. In Table 3, it is observed that the depth of mixing tended to increase slightly with time. In some experiments a bimodal distribution in b is noted whereas in other experiments a maximum is found either near the shoreline or near the breaker line. An unambiguous maximum was not found in the midsurf zone. Mechanical stirring of the bottom, which would result in large concentrations of suspended sediment and greater mixing depths, is expected under certain breaking waves and in the swash zone. There is normally no similar stirring process in the middle of the surf zone.

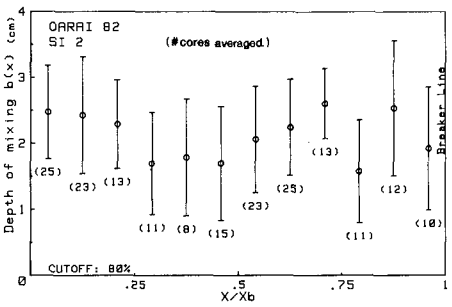

Fig. 4 On-offshore distribution of the depth of mixing (Oarai 82).

Figure 4 plots the on-offshore distribution of the mixing depth for the second spatial sampling at Oarai 82. The bars are two standard deviations. This representative result shows that there is great variability in the mixing depth at any one location. An average mixing depth calculated from a small number of cores would therefore be unreliable. It is seen that the mixing depth had maxima in the swash zone and near the breaker line in this experiment.

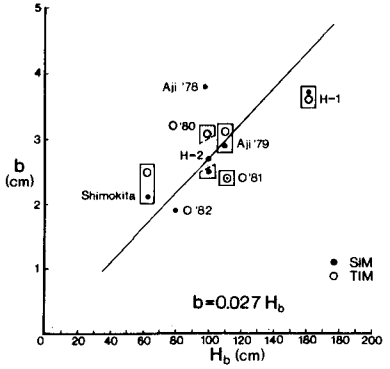

Fig. 5 Depth of mixing.

It is reasonable to assume that the mixing depth is proportional to the breaking wave height. The experiment-average values of b have been plotted against the significant breaking wave height in Fig. 5. It should be emphasized that these values are each the average of many cores. A best-fit straight line through the origin gives

$$b = 0.027\ H_b \qquad (5)$$

Equation 5 pertains to mixing depths resulting from steady waves, with minimal influence of the tide.

(3) Tracer advection velocity (v_a)

If the transport is fully developed, we expect the sand advection velocity to be proportional to the mean longshore current. Advection velocities for elapsed times greater than 60 min (SIM) are plotted against the average current over that time in Fig. 6. Although there is considerable scatter, by fitting a line through the origin, we get

$$v_a = 0.014\ \bar{V} \qquad (6)$$

The advection velocity determined by the TIM was always greater than that from the SIM. For the two experiments in which the TIM was performed on two distinct lines (Ajigaura 79 and Shimokita 79), the calculated advection velocity was essentially proportional to the distance from the injection line to the sampling line.

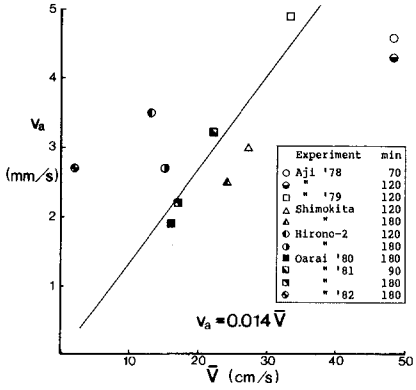

Fig. 6 Sand advection velocity.

To understand these results, the numbers of tagged grains found on the temporal sampling lines were plotted as a function of time. The numbers did not systematically increase and then decrease through the duration of the sampling as one would expect, but rather remained almost constant. Large numbers of grains were thus recovered both at the earlier and later samplings. The appearance of large numbers of grains at the early samplings produces a high transport rate because the TIM gives more weight to early times (Eq. A-5). The fact that large numbers were recovered at later

sampling times indicates that the tracer center of mass did not pass the sampling line, a result in contradiction to values computed with the SIM. Inman et al. (1980) also report higher advection velocities for the TIM. It appears that the TIM sampling line should have been located closer to the injection line (say, 5m), but in view of the SIM results this requirement is puzzling.

(4) On-offshore distribution of the transport rate (q)

The entries for q in Table 3 show that the distribution of the transport rate in the field does not take a universal form. The multicolor tracer experiments gave a constant distribution for Shimokita, a distribution with a maximum toward the breaker line for Oarai 81 and Ajigaura 78, a definite bimodal distribution for Ajigaura 79, and a distribution with a maximum toward the inner surf zone for Oarai 80 and Oarai 82. The diversity in distributions can be explained by considering the combined effects of the current and the mode of transport (bed load or suspended load).

It is the authors' experience that the typical longshore current profile in the field is rather flat across most of the surf zone, unlike the velocity distribution observed and predicted for a uniformly sloping (laboratory) beach, which is well peaked in the midsurf region. A flat profile was found in Ajigaura 79 and Shimokita (Table 4). Another such field example was reported by Kraus and Sasaki (1979). A broad flat longshore current profile may be explained to be a result of the step-type bottom which is usually found on gently sloping beaches (Mizuguchi and Horikawa, 1978). That is, waves can break, reform, and break again on nonplanar beaches. In the vicinity of structures, the longshore variation in wave height due to diffraction may also considerably alter the current distribution. For the beach at Oarai, the variation in breaking wave height produced by the harbor breakwater has been measured, calculated, and related to the sediment transport and shoreline change using a numerical model of shoreline evolution (Kraus and Harikai, 1983). Other three-dimensional processes on a real beach will also alter the idealized longshore current distribution (Sasaki, 1980).

Therefore, there is no reason to expect a well-defined peak in the longshore transport in the field on the basis of theoretical considerations of the longshore current on a plane beach (Komar, 1977), or as measured in laboratory experiments (Sawaragi and Deguchi, 1978; Tsuchiya, 1982). It does seem reasonable that the longshore transport would exhibit a peak, however, in regions where suspended load transport is high (swash zone and breaker zone under certain conditions). This approach must be refined by considering the criteria for the existence of a swash zone, and the breaker type (e.g., as done by Kamphuis and Readshaw, 1978).

The surf zones encountered for Hirono-1 and Oarai 82 illustrate this point. During Hirono-1, high waves arrived on this steep beach as collapsing breakers and continued to run up as a turbulent bore. The entire surf zone consisted of intense swash which moved up the beach in

expanding circular "wavelets". Near the shoreline the tracer was observed to move either in the direction of the mean longshore current or opposite to it, depending on the direction of the expanding circular wavelet of the bore at a given location. Under these conditions sand moved rapidly onshore with very little net longshore movement despite the strong current recorded in the deeper region near the breaker line.

In Oarai 82, waves broke mainly as spilling breakers. Little wave energy was expended at the breaker line. The surf zone was unusually turbulent and clouds of suspended sediment were seen at all locations. Table 3 shows that the advection velocity and transport were essentially constant in this four-color experiment, except near the shoreline, where the longshore current was relatively stronger. The slowly rising tide moved the most landward-injected tracer onshore.

(5) Total transport rate (Q; I)

The total transport rates are given in the last row of Table 3. They were calculated by averaging over the products of v_a and b for the respective regions and then multiplying by the width of the surf zone. In order to relate the transport rate to the wave and current conditions, Eqs. 5 and 6 were substituted into Eq. 1, and a planar beach slope was assumed, for which $x_b = h_b/\tan\beta = H_b/(\gamma_b \tan\beta)$, where $\tan\beta$ is the beach slope and γ_b is the ratio of wave height to water depth at the breaking point. An empirical formula is thus obtained,

$$Q = \frac{3.8\ 10^{-4}}{\gamma_b \tan\beta} H_b^2 \bar{V} \qquad (7)$$

which is dimensionally correct. For a given wave height and average longshore current, Eq. 7 states that the transport should be greater on a more gently sloping (wider) beach. The data are plotted in Fig. 7. The dependence of Q on the beach slope is given some support by comparing results for Shimokita (gentle slope) and Hirono (steep slope).

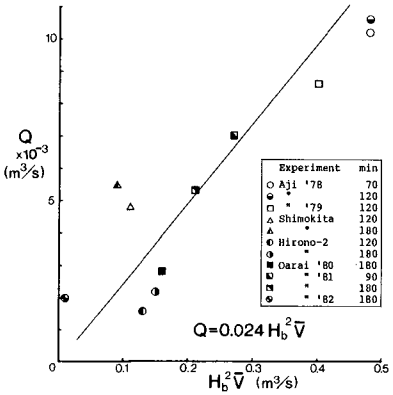

Fig. 7 Volumetric transport rate.

A popular theoretical expression for the longshore current generated by obliquely incident waves (Longuet-Higgins, 1970) contains the beach slope in the numerator and a friction coefficient in the denominator. Substitution of the theoretical average current into Eq. 7 would show Q to be inversely proportional to the friction coefficient, a physically reasonable result. Assuming an average beach slope of 1/50 and a breaking index of 0.8, Eq. 7 becomes

$$Q = 0.024\ H_b^2 \bar{V} \qquad (8)$$

The experimental results for the mixing depth and advection velocity have thus indicated that the combination $H_b^2 \bar{V}$ is a natural quantity on which the total volumetric transport rate should depend. In Fig. 7, the straight line is given by Eq. 8, which also gives the best-fit line through the origin. The data scatter in Fig. 7 is less than that in Figs. 5 and 6. This is because v_a and b are, roughly speaking, inversely related: the sand should move faster when the moving layer is thinner, and conversely, implying more complicated relationships than the simple intuititive functional dependencies given by Eqs. 5 and 6. However, since Q is formed as a product of v_a and b, it should be approximately invariant to the inverse relationship between v_a and b.

It is customary to consider the immersed weight transport rate, I, when correlating measured transport rates with the forcing functions of waves and current. The measured immersed weight transport rate, I_m is related to Q by

$$I_m = (\rho_s - \rho_w)\, g\, (1 - a')\, Q \tag{9}$$

in which ρ_s (ρ_w) is the density of sand (water), g is the acceleration of gravity and a' is the sand porosity.

Bagnold (1963) derived a predictive expression for the immersed weight transport rate in terms of the wave power at the breaker line (breaking wave height) and current velocity, namely,

$$I_p = K' (EC_g)_b \bar{V}/u_m \tag{10}$$

in which E is the wave energy density, C_g is the group velocity, u_m is the maximum orbital velocity and K' is a coefficient which must be empirically determined and which is not expected to be constant.

The well-known Bagnold/Inman/Komar, or CERC, formula is a special case of Eq. 10 in which the transport is due solely to oblique wave incidence (Komar and Inman, 1970). In the case of the Oarai series of experiments, the longshore current was produced by a combination of oblique wave incidence and systematic variation in breaking wave height as a result of diffraction at the harbor breakwater. In fact, in Oarai 80, the direction of the longshore current was opposite to that expected from oblique wave incidence. Due to the complexity of the origin of the longshore current in several of our experiments, and due to the potentially high uncertainty in determining the breaking wave angle, Eq. 10 was used because of its generality. In applications, such as numerical modeling of shoreline change, the burden of the calculation falls on computing the mean longshore current and breaking wave height.

Komar and Inman (1970) found K' = 0.28 on the basis of their fluorescent tracer experiments. The results of the present experiments are plotted in Fig. 8 together with the data of Komar and Inman. A best-fit line through the origin gives K' = 0.21 for the present experiments. In linear wave theory, $u_m = 0.5\, \gamma_b\, C_g$, and therefore Eq. 10 has the same basic dependence on the waves and current as given in Eqs. 7 and 8. It should be noted that the significant wave height was used in obtaining Eqs. 7 and 8, whereas the root mean square wave

height was used in the comparison of I_m and I_p, in order to be compatible with the results of Komar and Inman.

Our results give a lower value of the empirical coefficient K' in Eq. 10 than found by Komar and Inman (1970). This may be due to the strict procedure used in defining the depth of mixing. In contrast, based on results of a trapping experiment, Bruno et al. (1980), in a comparison using the CERC formula, report transport coefficients larger than those of Komar and Inman. We believe that a higher value is at least partially explained by the fact that sand caught by the trap includes a contribution from the longshore transport occurring outside the breaker line, and possible entrapment of onshore transport by the detached breakwater (Sasaki, 1975).

In Ajigaura 79, the two temporal sampling lines extended past the average breaker line. The (orange) tracer for the outer portion of the surf zone was also injected outside the breaker line. Significant quantities of orange tracer were recovered at the two stations outside the breaker line. Thus we can conclude that significant longshore transport of sand can occur immediately outside the breaker line. Interestingly, no tracer of the other two colors injected in the surf zone was recovered outside the breaker line.

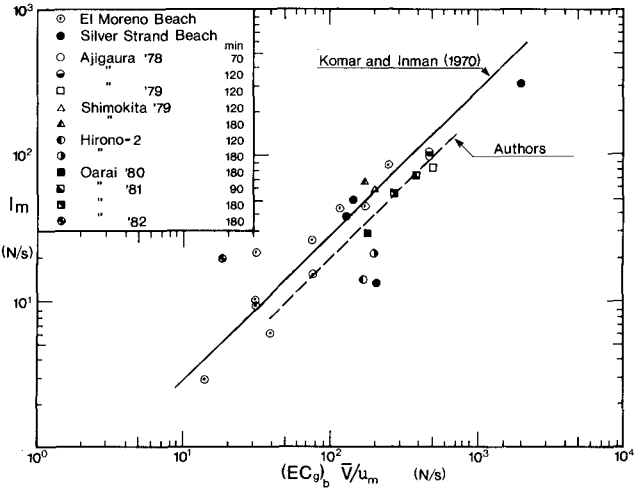

Fig. 8 Measured immersed transport rate plotted against Bagnold's predictive expression.

5. CONCLUDING DISCUSSION

Multicolor tracer experiments were found to be a practical method for obtaining information on the distribution of the sand transport rate across the surf zone. At least three colors are necessary to probe the often distinct transport regions of the swash zone, midsurf zone, and outer surf zone. As a result of these experiments, simple empirical expressions were obtained relating the sediment response (depth of mixing, advection velocity, and transport rate) to the average wave and current conditions. In particular, it was found that Eq. (7) for the total volumetric sand transport rate,

$$Q = (\text{factor})\ H_b^2\ \bar{V} / \tan\beta$$

is consistent with and offers an alternative to presently accepted predictive formulae.

At an increase in expense, refined versions of these experiments should be capable of revealing dependencies of the longshore transport rate on such factors as the beach slope, wave type (wave asymmetry), size and specific gravity of the sand, etc. A fundamental theoretical study of the vertical and horizontal movement of the tracer center of mass should also be made to better interpret such experiments.

ACKNOWLEDGEMENTS

The field work and sample processing in experiments of this size cannot be done without the assistance of many people, both known and anonymous. We would like to thank all of them including Mr. S. Hotta, who kept the 16mm cameras rolling in rain and shine; Messrs. S. Kubota, S. Harikai and S. Katori, who at various times assisted in all aspects of the field work, sample processing, and experiment administration; Dr. R. S. Farinato, who was an early collaborator, and Mr. J. Romeu for assistance with the figures and programming.

The experiments at Shimokita and Hirono were performed to predict beach evolution at the specific sites. The support of the Tohoku Electric Power Co., Ltd., and the Tokyo Electric Power Co., Ltd., is greatly appreciated.

APPENDIX: Governing Equations of Tracer Movement

The derivation is based on considerations of the tracer velocity distribution. It is assumed that the advection velocity of an individual tagged grain is constant during an experiment. The total population of tagged grains will have a continuous velocity distribution, such as sketched in Fig. A1.

For the SIM, the longshore position of the tracer center of mass, Y, at time t_o is given by

$$Y = \frac{\int_{-\infty}^{\infty} y\, N(y, t_o)dy}{\int_{-\infty}^{\infty} N(y, t_o)dy} \qquad (A\text{-}1)$$

$N(y, t_o)$ denotes the number of tracer particles integrated in the vertical and on-offshore directions, and y is the distance alongshore from the injection line (Fig. 2). The path of the line integral in Eq. A-1 is shown as the dashed line in Fig. A2. In order to calculate Y using Eq. A-1, all samples must be taken at the same time.

Instantaneous sampling at all points on a two-dimensional grid is not possible and, in practice, sampling is accomplished by moving systematically alongshore and taking samples simultaneously on each on-offshore line. In such a case, only the number $N(y, t)$ along the solid line in Fig. A-2 is known, where t is the time of sampling on a given line. Therefore, the path of the integral must be converted from the dashed line to the solid line. Then the number of tracer grains in the small interval AB is the same as in A'B' or A'B". Denoting the coordinates of A and A' by (y, t_o) and (y', t), and the differences along the y axis of AB, A'B', and A'B" as dy, dy', and dy", respectively, the following equations can be easily obtained:

$$y = y' \frac{t_o}{t} \qquad (A\text{-}2)$$

$$N(y, t_o)dy = N(y', t)\, dy"$$

$$= N(y', t)(1 - \frac{y'}{t}\frac{dt}{dy'})dy' \qquad (A\text{-}3)$$

Substitution of Eqs. A-2 and A-3 into Eq. A-1 yields

$$Y = \frac{\int_{-\infty}^{\infty} \frac{y't_o}{t} N(y', t)(1 - \frac{y'}{t}\frac{dt}{dy'})\, dy'}{\int_{-\infty}^{\infty} N(y', t)(1 - \frac{y'}{t}\frac{dt}{dy'})\, dy'} \qquad (A\text{-}4)$$

The advection velocity is given by $v_a = Y/t_o$, and it can be seen that v_a is independent of t_o.

The governing equation for the TIM can be obtained as a special case of Eq. A-4 by taking the path of integration from $(y_o, -\infty)$ to (y_o, ∞), where y_o is the fixed location of the sampling line. In this case, as dt/dy' goes to infinity, the term of unity on the right side of Eq. A-4 can be neglected: then by the chain rule, (dt/dy')dy' reduces to dt. This gives

$$Y = \frac{\int_{-\infty}^{t_o} \left(\frac{y_o}{t}\right)^2 N(y_o, t)\, dt}{\int_{-\infty}^{t_o} \left(\frac{y_o}{t}\right) N(y_o, t)\, dt} \qquad \text{(A-5)}$$

The advection velocity is $v_a = Y/t_o$ which is also independent of t_o. Note that the weighting functions of $(y_o/t)^2$ and (y_o/t) in the numerator and denominator differ from expressions found in other work (for example, Lean and Crickmore, 1963; Inman et al., 1980).

LITTORAL PROCESSES IN CAMPELLO COASTS

J.J. DIEZ (*)

M. ARENILLAS (**)

ABSTRACT

The coasts of Campello (fig. 1), just at the North of Alicante, have undergone important erosions in the last few years. A study has been developped for over one year to separate seasonal and permanent variations of the shoreline. The geomorphology and the recent generation of these coasts have been established and the study and wind wave regimes have been defined to evaluate the littoral transports, particularly the longshore ones. The seasonal transversal profiling may show the seasonal changes in the littoral zone and the sieve and mineralogical analysis of the different samples of the beaches have completed the data for the discussion.

Taking into account other studies of the authors in other parts of the East and Southeast coasts of Spain, an hypothesis on the littoral processes has been established, separating the seasonal and the permanent and degradative consequences. Some recommendations to keep at least the present situation of the beaches and to protect the other stretches of the shore are presented as final conclusions.

1 INTRODUCTION

The especial quality of Mediterranean Coasts in Spain has suffered lately somehow because of the concurrence of several circumstances, as the reduction of solid materials apported by the rivers or the inadequate use of the littoral and coastal zones, without the necessary suitable shore protection implementations (COPEIRO, E. 1978; DIEZ, 1982, a). It obeys to a common worldwide phenomenon related to actions badly planned, which ignores the littoral dynamic and its role in the beach formation an evolution.

Particularly, some parts of the coasts of Campello have suffered some apparently critical erosion in recent years. Since 1970 several shore protection systems have been tried without adequate results and, for that reason, a complete study has been developed along 1980-82. Even during the period of this study, while several perpendicular groins were being built, important damages in the village of Campello were produced by winter storms.

This study has been developed following two basic lines of research: a) Analysis of the littoral dynamic to define the littoral processes, and b) Identification of the forms existing in the coastal stretch.

The former has required the knowledge of the maritime winds to establish the accurate wind wave regimes (DIEZ, 1982, b) because sufficient wave register data are not available for this area. Advances in the methods for waves and storms forecasting (SUAREZ BORES, 1970; C.E.R.C., 1975), and the improvement in statistics data (HOGREN and LUMB, 1967; BRITISH ADMIRALTY, 1968) have been regarded.

The latter has been based on the present knowledge of the Geology of the area (MINISTERIO DE INDUSTRIA Y ENERGIA; ALONSO and PEREZ MATEOS, 1959) and on the results of the analysis of the samples obtained from the beaches of this coasts, placed at the South of La Nao cape, in the North end of the Southeastern Spanish littoral. Contributions for understanding the genesis and classification of the coastal formes (SUAREZ BORES, 1974) have been considered.

2 LITTORAL DYNAMIC

The principal and nearly exclusive factor involving the littoral processes in Spanish Mediterranean coasts is the wind wave regime. Winds affect somehow the formation and evolution of dunes and the filling of lagoons, and both surges and tides only modify the level of the wave action. Although changes of mean sea level caused by winds and/or pressure variations must be taken into account because of their incidence in the analysis of both observational data and changes of shoreline and transversal profiles. However this stretch is one of the least affected by them in all the Spanish coasts. The tide is extraordinary lessened here and the storm-surges do not seem to have produced elevations of the mean-sea level over 40 cm.

As in other coasts studied (DIEZ & ARENILLAS, 1982, a and b) no appropriate and sufficient registered or observed data of the sea exist to define the wind wave regime for this coast. Thus a forecasting method arising from wind regimes has been adopted, taking into consideration the criteria developed (DIEZ, 1982, b) which require establishing a wind regime first of all.

In accordance with those criteria the wind regime adopted for these coasts is the one adopted for Santa Pola bay by the authors. Other alternative based on the linnear interpolation is neither too different nor more accurate here because of the position and the general orientation of the coasts of Campello. The dominant sea winds are from E and SE, nearly facing the general shoreline direction. The abundant breezes and other local winds are superfluous with this method because their influence on the littoral processes is weak here.

In the Appendix the wind wave regime is obtained in accordance with all these considerations and an evaluation of the longshore littoral transport is reached by applying the C.E.R.C. formule. The directional wave regime shows clearly the importance of the fetch configuration effect on waves reaching the coast, particularly on the ones from the first quadrant (N, NE, E). The reduction is specially important for N and, in a minor degree, for NE waves. On the other hand the S and SE wind waves are practically saturated when reaching the coast. The seasonal analysis shows that the strongest waves occur in winter -and less frequently at the beginning of springtime-, when the waves from the first quadrant are more dominant.

The evaluation of the longshore littoral transport -also in the Appendix- show a clear dominance of the Southward transport, perfectely noticeable in the direction of the annual average resultant. Independently of the accuracy of the C.E.R.C. formule for these coasts, the method followed in the Appendix may be accepted because its inaccuracy will affect all directions in a similar proportion. The aim of the evaluation method is not to define an accurate annual longshore transport rate, but to establish an average wave incidence direction in relationship with the capacity of the waves to generate the littoral drift. Nevertheless the relative importance of the total transport respect to the net southward transport must be taken into account, especially to understand the genesis of the present San Juan bay.

3 DESCRIPTION AND GEOMORPHOLOGY

This sector of Campello littoral corresponds to a stretch of plain coast placed between two other cliff-stretches: Huertas Cape at the South and an alternating system of cliffs and "calas" at the North, from the Freu pass. From a point of view based on the longshore transport, this stretch cannot be considered as an isolated one, that is, as a physiographic unit because not even the Cape is a total barrier for the littoral drift. Nevertheless it constitutes a particular subunit, a little appart off the littoral transport and fundamentally fed by a singular source of materials; therefore it admits an individualized study.

From "San Antonio" and "La Nao" Capes southward, Spanish coast shapes in accordance with the general geological system of the

Betic chaines, which direct their aligrements from the Peninsular South to the capes and farther under the sea, emerging again in Pitiusas and Mallorca Isles. Prebetic and Subbetic chaines, at the North, and the actual Betic ones, at the South, close a wide Oval framing the coastal area between "La Nao" and "Palos" capes. The different chaines reach the sea transversally to the Coast in a wide and high montainous arc and in other minor sierras and spurs. They structure a series of bays and coves opened to the second quadrant and filled with Neogenic and Quaternary sediments forming the present coastal plains. Within this frame, the Campello coastal area is placed between the Paleogenic sierras of Bonalba and Ballestera, at the North, and the Miocene of Huertas Cape, at the South, and constitutes an important Quaternary deposit between the mountains and the sea.

The Prebetic formations of the interior area may be easily characterized as Mesozoic or Low-Tertiary ones; but the characterization of the carborated Jurassic and Cretaceous Subbetic formations offer many difficulties because of their strong tectonic in nappes and scales. The dominant materials in the plain are carbonates and detritus from the Prebetic and Subbetic Mesozoic, which, removed in different stages, have constituted most of the Tertiary and Quaternary sediments. Minor quantitative importance have the numerous Triasic and Jurassic outcrops from volcanic or subvolcanic origin (however some of their constituent mineral anpear in the beaches). The river Seco of Campello and its tributaries have principally canalized those materials towards the shore since the Pliocene. But other minor streams have colaborated in the drain of the generally intermitent run-off generating numerous aluviar cones and glacis between the mountains and the shoreline. So, three geological ensambles define this area: Betic chaines, the other minor Neogenic formations and the Quaternary fillings. These elements and the littoral dynamic have imposed the posterior evolution of the shore.

There are enough indicators of a progression of the shore in most of the points of this Spanish littoral since the final Tertiary in relationship with the variations in the Quaternary climatology and the tectonic factor afecting this zone; and the generation and posterior evolution of the lagoons of this area supports that hypothesis. Presently the human factor has introduced some incidences in the process.

The littoral of Campello may be considered divided in two stretches by the delta of the Seco river, but, initially, its shoreline should have been one only cordon-stretch, double-supported on the cliffs at the North, and on the Huertas Cape, at the South, and with an important massive singularity constituted by the river materials; its importance has led to the formation of an actual geometric singularity dividing the stretch. The evaluations of the average volume of materials dragged by the river entablish it in $2 \cdot 10^6$ ton/year. At present, however, this volume

must be reduced because of the industrial use of the materials as aggregates and the reduction and control of the water streams.

Southward from the delta a cordon-beach has closed an old lagoon up to the cape. Behind the beach and the berm, all along the cordon, one or several chaines of dunes advance towards the plain which once before was the lagoon. The more towards the south the wider and flatter the beach is, the less pebbles appear and the thicker the dunes are, though different buildings bumper that observation at present. At the North of Muchavista all the beach is constituted by pebbles which desappear in the middle of San Juan beach. All together it looks like a double-supported, though somehow onen beach, due to its length.

At the North of Seco river, along of "Carrer del Mar" the shore deposits look different. They are at the foot of a "rasa" of a gradually increasing level to reach the cliffs which shows both deltaic and littoral influence. All the up-beach shows a thick layer of large gravels, even cobbles, in spite of the sandy bottoms of the onshore zone.

4 STUDY OF THE SHORE MODIFICATIONS

The erosion of the beaches of Campello is noticeable for several years now, after their inhabitants observations, though no accurate documentation permits to define it. Inversely to other places like Denia, neither historical nor recent chartography has been available as a suitable reference. At the North of the old pass of the Freu, the sandy little beaches seem to show some regression for about 30 years now. Between the Freu and the delta ("Carrer del Mar") the erosion seems to have been obvious since the pass was closed, after some inhabitants, though others say that it began after the construction of the first groin (Fig. 2).

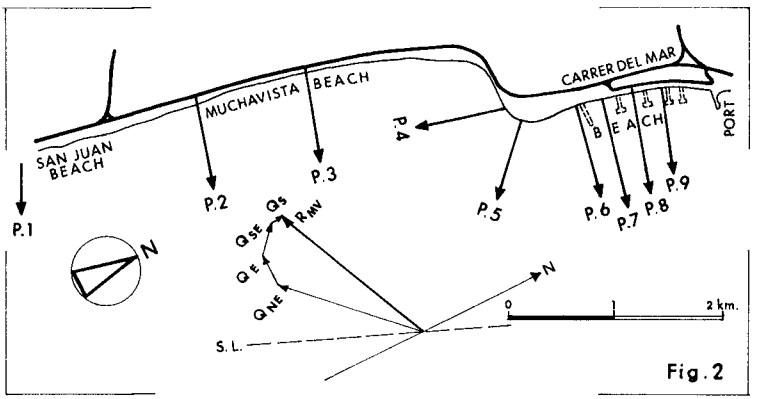

Fig. 2

Actually the seawall must not have had a good performance as a protector and afterwards the beginning of other T-groins has accelerated the erosive process destroying the revetment in both 1979-80 and 1980-81 winters.

In the San Juan bay, Muchavista beach is undergoing a slow but continuous process of regression which affects the promenade every winter for some years now; (it probably has begun just after the last Seco's flood and subsequent advance of the delta, about 20 years ago). The erosion has been spreading southwards and, in the two last winters, has reached even most of San Juan beach.

Nine transversal profiles (P.1 - P.9) have been determined twice a year, considering the experience in other studies of this area, which show not more than two different seasonal profiles. The profiles P.4 - P.5 - P.6, and even P.7, show their deltaic nature. The mean slopes are smaller at the South (P.1 - P.3). In general, the variations of the different profiles between February and October correspond to typical transformation from bar (storm) to berm profiles (Fig. 3). P.1 shows, besides, a loosing of sands and some retreat of the shoreline, increasing its mean slope. P.2 and P.3, on the contrary, show some accretion and an advance of the shoreline, decreasing their mean-slope. Their pebbles were practically covered by sands. The deltaic front (P.4 - P.6) shows some erosion. The accretion in P.7 seems to show a dominant southward transport during spring and summer times. P.8 and P.9 do not show any recovery after the winter erosions.

As a whole the erosions seem to dominate in spite of the seasonal quietness. During winter the products of the erosion in both the delta and Muchavista beach may reach San Juan beach (P.1); during summer the materials of the delta reach Muchavista beach, because of a more perpendicular incidence of the waves. Also during summer eolic action takes the sands upwards to the berms and dunes in San Juan. The eolic circulation of the sands is easily noticeable in the bay all the year round though at present it is almost totally interrupted because of the wall of buildings, which border all San Juan beach. The orientation of the shoreline in P.1 and the incidence of the summer waves may permit also some transport towards P.2.

In the very nine profiles several sand samples have been taken from the beach and from several points of the bottom surface of nearshore zone, principally from onshore zone. All the "Carrer del Mar" and nearly all the Muchavista beach have a cap of pebbles which the nearer the delta the thicker and wider is, showing its deltaic origine. The visual survey of the sections of beaches in depth did not show variability but in the distribution of grain sizes. The samples were analyzed in their size distribution (after eliminating the organic material) and in their mineralogical nature. These latter analysis have only looked for the rate of the most abundant fractions and, in case, the roundness degree of the grains.

Fig. 3

The rarer weight minerales had been studied (ALONSO & PEREZ MATEOS, 1959) and in this work it has been searched quartzs -white, grey and red-, tourmaline, circon, micas, lime organic rest and some meaning opaque one (particularly illmenita which is brought by Seco river from an ophitic outcrop).

Apart from the meaning of the mineralogical data, the influence of the deltaic materials in the formation of these beaches is well shown in the grain size distribution (Fig. 4) of some samples (change of concavity in P.4 - 150 m.; or variation of the slope around the nº 70 A.S.T.M. sieve size, in P.1, P.3 - 100 m. or P.7 - 200 m.). (Samples are named after the corresponding profile. If it is followed by a distance in meters it means that the sample has been taken at this distance from the shoreline; otherwise, the sample was taken at the beach).

The influence of the cap of pebbles in the formation of the beaches is shown, in turn, in the noticeable inflexion shown by several samples (P.9 - 100 m., P.8 - 50 m. and 100 m., P.2 - 100 m, P.3 - 300 m. and P.2 - 400 m.) about the nº 100 A.S.T.M. sieve size.

The uniformity of the size distributions of other samples must be due to the role of the littoral dynamic, and it is also noticeable that silts are more abundant at the North, and the farther from the shoreline the samples have been taken.

On the other hand, comparing the size distributions of all these samples to the ones of Santa Pola and Denia it seems that they are coarser here, the proportion of silts being minor.

The results obtained from the nature analysis are outlined in Fig. 5 in which the variation of the components along the shoreline is shown. The grey quartzs have abundant inclusions, which are not frequent in the other varieties of the quartz; this circumstance has not been found in the other areas studied in this littoral (Denia, Santa Pola). All but particularly the red quartzs show generally the crystalline faces of their grains, even the rounded ones, indicating a relatively short transport length. Tourmaline is especially angular. Carbonates are dominant in all fractions, constituting about 80% of the sands and the small grains show their shell nature; their source is here principally the cap of pebbles, which are rounded fragments of limestones.

The contains of organic material is minor than in other areas, being minima in the beaches (except in the beach of "Rincón", probably because some organic pollution), and maxima on the bottom of the deltaic front.

The lime fraction of sands varies very little either along shoreline or transversally. Quartzs are rather constant also: a) The roundness degree is higher at the South than at the North of the delta and in the nearshore than in the beach; b) the red quartz

outnumbers the grey one, unlike in other areas of this littoral (Denia, Santa Pola), but it diminishes in front of the delta. There are grains (rather sharp) of illmenita only at the South of the delta (but for a small quantity in P.6), probably in relation ship with the dominant longshore transport. There are circon and tourmaline in San Juan beach (P.1) but not in Muchavista (P.2 and P.3); they seem to be in relationship with the quarrystones of the groins, in accordance with the studies of Denia and Santa Pola.

CONCLUSION

The study of the littoral dynamic shows a more or less pronounced dominance of the southward longshore transport. The results of the mineralogical analysis keep the same hypothesis. Nevertheless it is not possible to ignore the relevance of the longshore transport in both directions and the importance of the transversal dynamic. On the other hand a certain reduction of the available materials in the littoral zone is obvious and even the Seco river has diminished its activity lately. The present erosion of the deltaic front is therefore normal and, shomehow, does not present any cause of worry. The situation is different, however, in the beaches.

In the "Carrer del Mar", at the North of the delta, the reduction of materials has become practically total because of the clossure of the Almadraba pass, first of all, and of the construction of the first long groin, sometime later. The resultant physiographical pattern practically hampers any part of the littoral drift to reach the beach all along this stretch. Therefore the other shore protection messures adopted up to now could not be succesful. But, on the contrary, the weak vertical sea wall firstly constructed as shoreline revetment should only accelerate the process, by recycling itselt (The erosion takes the sandy materials off; consecquently the slopes grow up, particularly in the surf zone; the breaking waves become higher also and their action increases over the pebbles and, usinig them, over the wall). At present the process have led to a mean slope of the surf-zone between 6-8%, which is rather significant though it has not reached the extraordinary values of some other coasts like almazora's (up to 25% in several stretches).

The posterior construction of three T-groins was badly developped, being simoultaneously constructed their perpendicular branches and postponing too long the construction of their parallel ones which should constitute the actual and efficient protection. The pressence of perpendicular elements of the groins have accelerated the erosion even more.

In San Juan bay the erosion had begun in Muchavista beach but have reached now the very San Juan beach. The data of previous chapter seem to show an easier natural nourishment of the South of the bay from the nearshore, receiving directly the materials

from both the deltaic front and the littoral drift from the NE. The nourishment of the North of it, from the South, is humper by the asymetric bottom structure of the deltaic front (P.4), which is due to the dominance of the southward littoral dynamic. This funtional scheme must be completed with the eolian activity which permits sand to move in a cycle and to nourish the North of the bay (Muchavista beach) from the land. This hypothesis is perfec tly compatible with all the results of the observation and analy sis. The sands accumulated nearshore of San Juan beach during the winter, due to the NE and E waves, may reach the shore and backshore during the summer under the action of the winds perpen dicular to the coastline. During the autumn the dunes move northwards and the sands spread on the plain in the same way they have filled the lagoon; part of them reach the extreme North of the bay and renourish Muchavista beach, closing the cycle: Sands move southward in the bay and northward along the backshore. The latter parts of the cycle is obstructed at pre-sent by the presence of an inadequated wall of constructions, which have destroyed and substituted the dunes. Therefore the erosion appears rather advanced in Muchavista and only seems to begin in San Juan, but an increasing of the regression of the latter beach is foreseable.

As conclusions it is possible to establish the following state-ments:

1.- This stretch cannot be considered a physiographical unit since not even Huertas cape is a total barrier to the longshore transport. Nevertheless its most important source of material is interior to the very stretch (Seco river), being more diffi-cult for the general littoral drift to reach its beaches, parti-cularly that one of "Carrer del Mar" after closing the Freu pass. This difficulty is increased by the very presence of the delta which as counterweight is undergoing an appreciable regressive process, such as it has been noticed even during calm weather season.

2.- The littoral dynamic has an important transversal component. Its longshore component is alternating and significant in both directions though the southward transport is dominant along the mean year. This general consideration must be in accordance with the particular orientation of the shoreline in each point which may modify the direction of transport. So are the cases of the south end of San Juan bay and the north bord of the delta: south ward of a certain point in each of them only northward transport occurs in the surf-zone.

3.- The importance of the total longshore transport and the del-ta activity all along has permited the development of the presen-te plain through the formation of one or several successive ba-rriers and the posterior filling of the littoral lagoons. This evolution of the shore has been favoured besides by the progre-

ssion of the point delta, which acted as support of the barrier, and by the eolian activity, which accelerated the filling. During this period all this stretch, between Huertas cape and the cliffs of the North, behaved as a sink for total longshore drift in both directions.

4.- At present, however, the relative position of the deltaic front respect to the cliffs and the clossure of the Freu pass avoids practically any nourishment of the "Carrer del Mar" beach from the littoral drift. The erosion has begun to dominate and afterwards, to increase by the inadequacy of the succesive works for shore protection.

5.- The present dimensions of the San Juan bay, between the delta and Huertas cape, would be adequate, however to permit a sufficient nourishment, if the eolian migration of sandy cycle were not cut. Therefore the erosion has begun in the North of the bay as it always hapens leeward of a geometric singularity (the delta itself), but it is spreading riskibly southward and will reach the very San Juan beach.

6.- In order to implement some important harbour facilities for pleasure or a marina, within the district of Campello the very deltaic cone would be the best place since it would be planned without producing negative changes in the littoral processes. The port should be interior and especial cares should be taken to permit the evacuation of the floods and to avoid the entering of the sands.

RECOMMENDATIONS TO ACT

Considering the conclussions above some recomendations may be proposed. Apart from the delta, which would admit an interior port of pleasure, two sub-stretches will be distinguished:

a) The "Carrer del Mar" is very undernourished now from both directions and the transversal dynamic acts efficiently over it. Only some offshore system of protection, preferably complemented by an artificial replenishment might be suitable. The designed T-groins would likely have been succesful if the parallel breakwaters had been constructed quickly after beginning each T-groin; it had obliged to construct one after the other instead of simultaneously. Besides, some other breakwater will be necessary northward of the last one and related to the little haven. In any case, an important artificial replenishment will be necessary to get a suitable beach, but a reduction of the amount of sands would be possible employing material from the delta in the deep and back layers.

b) In Muchavista the undernourishment is more endemic but it would be less severe if the eolian feeding were not so diminished now. Any construction in this bay would affect its present aes-

thetic quality. Only the artificial nourishment in the north end of the bay might be effective. Nevertheless a suitable revetment with a soft slope will be necessary immediately to protect the promenade.

APPENDIX: LITTORAL DYNAMIC EVALUATIONS

The sectorial definition of the Fetch for a point placed in front of the Seco delta and in deep waters is shown in Fig. 6. The number of sectors is enough and the limits between each couple are placed so as to adequate it to the real Fetch.

The parameters of the sectors are shown in TABLE A.1. The directional wind wave regime obtained is shown in Fig. 7. From these regimes a valuation of the longshore littoral transport has been obtained by applying the C.E.R.C. longshore transport rate formule (in decimal units):

$$Q\ (m3/year) = 2.045 \cdot 10^3 \cdot f \cdot H_o^{5/2}\ (m) \cdot F\ (\alpha_o)$$

and following the method developped in other previous woks to obtain an annual average resultant wave.

In it, $f = (1-F_x) \cdot K_o \cdot K_f$, with

$$K_o = \frac{\text{nº of observations in the octant (sector)}}{\text{total nº of observations} = 1072}$$

TABLE A.1.

K_f = 1 for all directions (sectors) because the general direction of the shoreline coincides, in this case, with the N.NE - S.SW direction.

F_x may be obtained from the Fig. 7, where the regime of each direction must be considered shortened by the $(H_o)_{max}$ corresponding to the rerpective top wind speed observed.

The α_o value of each direction is the average of the two extreme α_o of the correspondent sector (octant).

The values of these variables for the four established directions are as follows:

a) NE direction: α_o = av (90º, 45º) = 67,5º
K_o = 162:1072 = 0,1511 ; $(H_o)_{max}$ = 3,51 m.

b) E direction: α_o = av (45º, 0º) = 22,5º
K_o = 222:1072 = 0,2071 ; $(H_o)_{max}$ = 5,56 m.

c) SE direction: α_o = av (0º, -45º) = -22,5º
K_o = 56:1072 = 0,0522 ; $(H_o)_{max}$ = 5,04 m.

d) S direction: α_o = av (-45º, -90º) = -67,5º
K_o = 81:1072 = 0,0737 ; $(H_o)_{max}$ = 3,72 m.

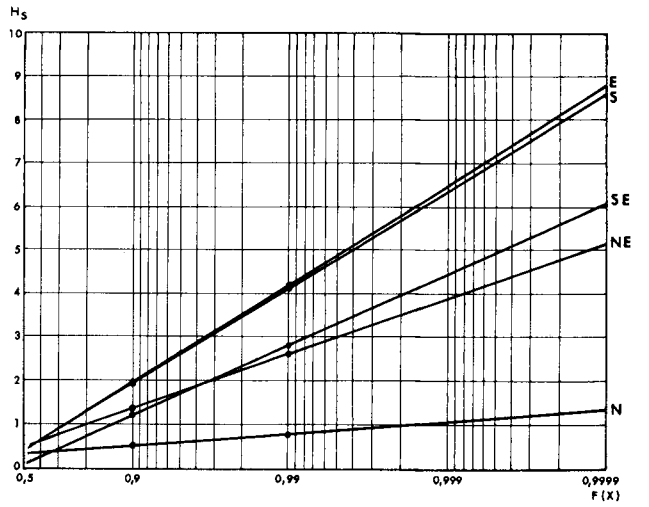

Fig.7

where sign (+) means southward longshore dynamic and sign (-) means northward longshore dynamic.

With these data the respective longshore transport rate induced are obtained in TABLE A.2.

The results show a clearly dominant southward transport though both the resultant total (Q_T = 1.071.404 m3/year) and net (Q_N = 593.158 m3/year) annual longshore transport rates are not to be considered as accurate ones.

Adscribing to each direction a vector defined by de α_o value and the particular Q value obtained from TABLE A.2. an average (equivalent) annual wave direction (A.V.) may be established (Fig. 2).

BARRIER BEACH FEATURES OF CALIFORNIA

Hugh Converse 1/

INTRODUCTION

Remarkable near-continuous examples of barrier beach features are found in many coastal areas, worldwide. The most notable North American examples are the margins of North America along the Atlantic and Gulf of Mexico, where barrier islands are found along more than 60 percent of the coastline. There are, in fact, 280 large-scale individual barrier features, 70 of which are highly developed and 100 more are being developed (Hobson, et al, 1980). These barriers have been built out of the enormous volumes of sediment available from the extensive watersheds of eastern and central North America and, through the ages, appear to have migrated long distances across a wide continental shelf in response to the interplay of waves and tidal currents, eustatic sea level fluctuations and sand supply.

Barrier features are less in evidence on the west coast of North America though they are by no means absent. For example, along a 60-mile reach of the Oregon-Washington coast adjacent to the Columbia River mouth, impressive barrier spits have straightened the coast by blocking the bays and headlands. These are black-sand beaches, formed from the large sediment supply of the extensive inland basin of the Columbia (Bascom, 1980; Cooper, 1967), which has the 29th-largest discharge of the world's rivers (Inman and Nordstrom, 1971). The longest spit in this reach is about 19 miles long. The North Pacific coast is a high-energy wave environment, and these spits are continually shifting. Indeed, one of the most outstanding examples of continuing shore movement in North America is found at Cape Shoalwater at the north side of Willapa Bay, Washington where the inlet has migrated about 2.5 miles northward in the last 95 years across homesites, a cemetery and a lighthouse (Terich and Schwartz, 1981; US Corps of Engineers, 1971a).

CALIFORNIA BARRIER BEACH FEATURES

The barrier beach features of California, which are principally composed of quartz and feldspar sands, are proportionally less extensive, but are more common than is generally recognized. Out of an open mainland coastline of 1,073 miles, approximately 210 miles, or about 20 percent may be termed barriers. (By comparison, all sand beaches on the coastline total about 550 miles - U.S. Corps of Engineers 1971b; these figures exclude offshore islands.) This figure is based on barrier features identified during a reconnaissance-level review of existing base maps, aerial photography, historical reports, narrative coastal inventories, and limited on-site inspections. (Especially valuable were U.S. Geological Survey quadrangles, and the file of low-level 35mm photography of the entire California coastline maintained by the State of California Department of Boating and Waterways.)

1/ Civil Engineer, USAE Div., South Pacific, San Francisco, Calif.

In all (see Figure 1), 181 separate barrier beach features were identified in California. Of these, 29 are highly developed with works of man, and 42 are partially developed. Of the total number, about 16 may be considered as major geological features with a length greater than three miles: these are commonly bay-mouth barriers and spits. The distribution of barrier length is shown in Table 1. The other features are generally small creek or bay-mouth barriers: some of which are to be found as an uncommon and analomous features on an otherwise rocky and precipitous coast and without sufficient drainage area to produce more than a relative modicum of sand. Barrier identification generally follows definitions by Shepard and others (Shepard, 1973; Putnam, et al, 1960) with a specific primary criterion that a coastal lagoon or inlet, marsh or permanent or semi-permanent wetland or water-body exists (or historically existed) behind part of the barrier; the barrier may be closed seasonally or permanently - as in the case of certain freshwater or brackish lagoons and lakes which have long been separated from the ocean. (The sheltered coastline of San Francisco Bay is excluded from this analysis.)

From north to south in California, a partial list of notable coastal barrier features include Big Lagoon; Humboldt Bay - the largest lagoon on the California coast (Shepard, 1973); Bodega Harbor; portions of Monterey Bay; Morro Bay; Los Angeles-Long Beach Harbor to Newport Bay; the Oceanside area, and San Diego Bay. Several of these are discussed below as case histories, with San Diego Bay being treated in more detail. Cenerally, it is true that these features owe their existence to plentiful present, or past, supplies of sediment and that extensive coastal wetlands and marshes with important wetland values are, or were, present in association with them. With the notable exception of the Los Angeles Harbor to Newport barriers which have been greatly modified, most California barriers still approximate their natural state insofar as coastal processes are concerned. However, the associated coastal marshes and wetlands have been greatly reduced by dredging, filling, and other urban activities, and many are also severely threatened by natural and man-induced sedimentation from upland runoff.

FIG. 1 (Cont)

Most of the major barriers have remained essentially stable in shape and location during their recorded history, although some structures built on barrier beaches have been damaged during cyclic winter storms, and significant amounts of sand have artificially been placed on certain southern California barriers.

COASTAL ZONE MANACEMENT

Today, further building and development on California barriers, and beaches in general, is now constrained by strict State coastal zone management policies, which include regulations to protect recreational beaches and environmentally-sensitive habitat areas - such as barrier-associated coastal wetlands and marshes; and coastal hazard regulations which generally require that coastal structures be set back sufficiently from the shore so as not to be endangered by cyclical erosion (State of California, 1976).

The California Coastal Act of 1976, though of Statewide application, calls for the separate development and administration of Local Coastal Programs (LCP's) by local entities, consisting of land use plans and zoning regulations for upland areas (above mean high water). These programs are currently in process; to date about one-quarter of them have been approved by the State Coastal Commission (California Coastal Commission, 1979 and 1982), which still retains control of tidal and submerged lands below mean high water, including coastal wetlands and lagoons. In all, the 181 barriers identified in this review are variously located in many different jurisdictions. Within California there are a total of about 120 LCP's divided between 67 counties and cities, one university, and four ports.

Despite local differences in application, the net effect of these regulations will be to strictly limit development along California beaches, including the coastal barriers. Although it is yet too early to be completely sure, it appears that, under Coastal Commission and other State policies, major coastal structures are precluded except in port areas, or where an evident, water-dependent, public need, without a feasible alternative, can be demonstrated (California Resources Agency, 1978).

CASE HISTORIES

Long reaches of the California coastline are bordered by cliffs: either the steep faces of elevated marine terraces or the precipitous slopes of coastal hills or mountains. The open ocean coastline is, as indicated previously, fronted by sand beaches for about half of its length; many of these beaches are little more than a narrow strand along a steep or rocky backshore; wide, extensive sand beaches are generally only to be found where sizable streams or intermontane valleys come to the shore. Small barrier features may be found blocking small streams in many areas of the coastline, but longer, larger barriers are, of necessity, associated with more plentiful sand supplies from larger watercourses and drainage basins. Many barriers are also associated with hook-shaped bays which are an important and recurring feature of the California coast. These latter features occur in many areas of the world where a particular

wave direction acts obliquely on the coastline over eons, resulting in indented hooked or crenulate-shaped bays in the lee of prominent headlands (Silvester 1974).

The following case histories (see Figure 3 - Note: Figure 2 deleted) include Humbolt Bay where protective barrier beaches occur along a long straight reach of sandy coastline. By way of contrast, barrier spits at Bodega Harbor, Bolinas Lagoon and the elongated barrier at San Diego Bay have been built by wave-induced currents acting in the lee of prominent headlands; these features follow the hooked form.

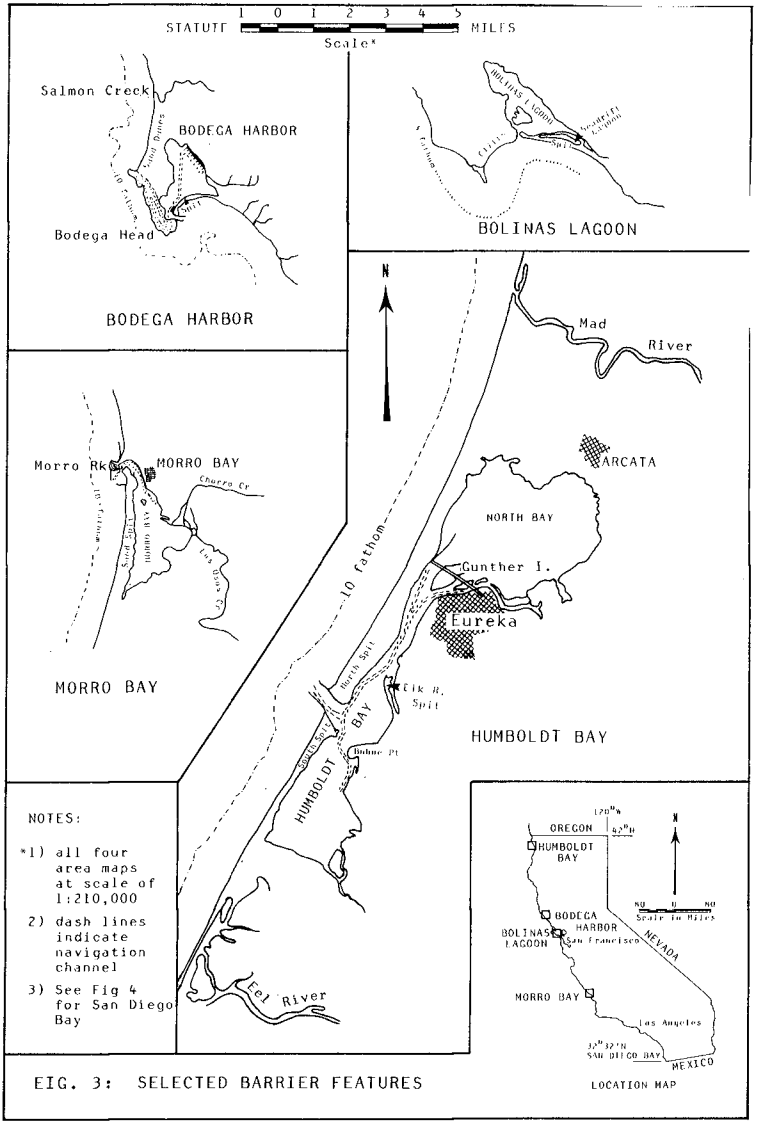
Humboldt Bay

This brief review of case histories of selected California barriers begins with Humboldt Bay, a shallow tidal estuary 230 miles north of San Francisco. The bay, with a high tide area of about 25 square miles, is separated from the ocean by two long barrier spits which in turn are separated from each other by a jettied entrance channel with a maintained 40-foot depth. A treacherous, shoaling submerged bar at the entrance requires large volumes of regular dredging. Both spits, especially the north, have active dunes. The north spit is about 8 miles long, and averages about 3,000-4,000 feet in width. Although largely open space, there are industrial and residential areas along the bayward side, as well as numerous roads. The south spit is about 4 miles long and narrow, ranging from 600-1,500 feet in width; it is maintained as undeveloped open space. The likely sources of material for these features are modern and prehistoric sands from the nearby Mad and Eel Rivers: the latter stream being a prodigious sediment carrier during flood periods (Welday, 1970). Overall, since the entrance was fixed by jetty construction in 1890, the north and south spits have advanced seaward (Noble, 1971; Kieslich, 1981; Shapiro, 1979); at present, the spits are in a state of dynamic equilibrium. Fixing of the jetties and subsequent deepening of the entrance channel concentrated wave energy on an elevated bluff area bordering the bay inside and opposite the entrance. As an apparent result, the area has retreated up to 1,600 feet since 1854, almost obliterating the bluff area, and lengthy stretches of the shoreline have been armored (Tuttle, 1982; Shapiro, 1979). Also, two relatively small laterally-moving spits have been created inside the bay, one to the north and one to the south, continually extended by materials moved by wave energy coming through the entrance.

The applicable Local Coastal Program of Humboldt County emphasizes protection of the spits as valuable open space and habitat area. This fact, coupled with their essential stability, indicates that the barriers will remain relatively unchanged over the next several years.

Bodega Harbor

Bodega Harbor is a small triangular-shaped coastal lagoon 55 miles northwest of San Francisco. The water area at high tide is about 1.3 square miles. The lagoon is located directly on the San Andreas fault zone and is separated from the Pacific on the west by a wide (2,500' wide and greater) tombolo-like sand barrier which links the



EIG. 3: SELECTED BARRIER FEATURES

mainland with Bodega Head, a rocky promontory to the west. To the south, the harbor is separated from the ocean by a much narrower curved barrier spit (600 feet or more in width), 1.6 miles long, with a jetty-protected entrance at the west end. The principle sources of the barrier sands are Salmon Creek and the Russian River, both to the north (Zeller, 1962). The entrance requires very little maintenance as the tidal prism balances the effects of wave attack. Past overgrazing had denuded the north barrier, resulting in movement of sand dunes and large volumes of sand blowing into the interior channels. In recent years, replanting of vegetation has stabilized the dunes resulting in lessened maintenance dredging. Filling of the harbor by landfills has also been halted.

The harbor area is an important recreational and commercial fishing center but developmental pressure is relatively low. The Local Coastal Program of Sonoma County provides for continuance of the barrier area as protected open space. The northern dune area is part of a State park and the curved barrier spit adjacent to the entrance is a County Park. Since both barriers are essentially stable, important physical changes are not expected in the foreseeable future.

Bolinas Lagoon

Like Bodega Harbor, Bolinas Lagoon is a triangular-shaped coastal inlet and is similarly located directly on the San Andreas fault zone, 15 miles northwest of San Francisco. The lagoon area is about 2.2 square miles. The lagoon is about 3.5 miles long by 1.5 miles wide and is separated from the ocean by a curving sand spit 700 to 1,500 feet wide and 2 miles long. An uncontrolled entrance to the lagoon is at the west end of the spit and is naturally maintained by the tidal prism of the inlet, though at a shoal depth. The tidal prism of the lagoon has been greatly diminished over the last century as agricultural and urban land use have resulted in accelerated sedimentation. Without watershed control of sediment loads, and possibly remedial dredging, the inlet will close and the lagoon will eventually become a meadow (Johnson, 1974). (As noted earlier, this is a general problem facing many lagoons in California.)

The primary source of material for the spit is northwest drift of material from the submerged bar (San Francisco Bar) offshore the Colden Cate and the cliffs to the west of the inlet entrance which are actively eroding (Wilde and Yancey, 1970). Most of the spit is privately owned above the mean high tide line and has been almost completely developed during the last 20 years with expensive single family dwellings. The spit has also been extensively reshaped on the inlet side and a sizable artificial lagoon has been created entirely within the spit.

Like most California beaches exposed to open ocean influence, the beach width on the Bolinas spit varies seasonally, narrowing in the winter due to storm erosion and widening again in the summer. The average seasonal variation is about 100 feet (Johnson, 1970). Unfortunately, however, since this figure is an average, extreme storm conditions can threaten the private homes, many of which are close to the beach. In 1977-78, nine homes were nearly undermined by erosion of the beach and adjacent low dunes during a combination of

high wave conditions superimposed on high tides. Temporary sandbagging and placement of a Longard tube was undertaken and some rock revetment was later placed (Domurat, 1978: Moore, 1978).

Despite a proper concern for the houses, there is no particular threat to the barrier spit as a geological feature while it remains in state of dynamic equilibrium. No significant amount of new construction nor intensification of use is likely under the applicable governmental policies.

Morro Bay

Morro Bay is a shallow natural harbor located about 200 miles south of San Francisco. The lagoon, which has an area at high tide of about 3.2 square miles, is separated from the open ocean by a barrier spit about 4 miles long and 1,700 feet wide, and is ridged with both active modern dunes and heavily vegetated dunes of intermediate and ancient age. The primary sources of sand are sediments from the Chorro Creek and Los Osos Creek drainages which continue to slowly fill the inlet (Shepard and Wanless, 1971; Cooper, 1967).

The natural entrance to the lagoon has been greatly modified for small craft navigation. The entrance, which is at the north end of the harbor and skirts the north end of the spit, is in the lee of Morro Rock, a large granitic monolith which is connected to the mainland by a tombolo-like formation. Formerly, the rock was an island with a sand bar in its lee dividing two separate shallow channel entrances into the bay - around the north the south side of the rock, respectively.

Harbor improvements constructed in the early 1930's cut off the north channel. Because of continuing shoaling, two converging breakwater - jetties were constructed to protect the entrance, one from the south side of Morro Rock and another from the barrier spit. Shoaling of the entrance remains a problem, however; and an average of about 120,000 cubic yards per year of material must be removed to keep the channels at a depth of 16 feet. Sand moves both ways but the net drift appears to be to the north; most of the shoaling is due to littoral movement though some material does blow off the spit into the interior channels. Spoil disposal has generally been on adjacent beaches. The harbor improvements have resulted in an accretion north of Morro Rock and readjustment of the position of the tip of the barrier spit; however, in general, the barrier is in a state of dynamic equilibrium. The most notable natural change in recent times would appear to be continued dune building and advance of dunes into the tidal flats and shallow water behind the spit (Cooper, 1967). The tip of the spit adjacent to the entrance is open space which will be protected by the City of Morro Bay's Local Coastal Program; the balance of the spit is a protected State park. The entire spit is without road access and is otherwise undeveloped. Its continued preservation seems assured.

San Diego Bay

San Diego Bay (Figure 4) is an elongated, crescent-shaped embayment of variable width with a high tide area of about 16.6 square miles. It is separated from the Pacific by a narrow sand barrier which

FIG. 4: SAN DIEGO BAY

connects with Coronado Island and North Island adjacent to the bay entrance at the north end of the bay. The bay entrance, which is partly protected by the sheltering headland of Point Loma to the west, is self-scouring to a natural controlling depth of about 25 feet; but is maintained at a much greater depth (up to 42 feet) to allow deep draft access to the bay, which is one of the finest natural harbors in the world. Tidal scour has been assisted by construction of a training jetty, on the barrier side of the channel, completed in 1904. Dredging maintenance requirements are low.

The bay appears to be a drowned, possible faulted valley, and the barrier grew by northerly currents moving sand from the Tijuana River and Otay River deltas (Shepard and Wanless, 1971) to the south (continued supply has been from the Tijuana in recent times). The narrow part of the barrier, or strand, is about 7 miles long and in its natural state had a variable width of about 500-700 feet. The beach was backed by low-active dunes averaging about 10 feet high which tend to encroach into the bay locally widening the strand considerably (Inman, et al, 1974). Although occasionally breached during high wave conditions, the barrier has always been continuous in historic times (Hertlein and Grant, 1944; Herron, 1980). North Island and Coronado Island were joined into one in 1944 by hydraulic filling with dredge material; the combined "island" feature is about 3 miles long and 2 miles wide. Hydraulic filling continued apace in the area from about 1910 to the 1970's; the northern and eastern margins of the bay were greatly reshaped and the barrier was widened at several places. The period of greatest activity was in war years of the 1940's when the bay was deepened extensively for the Navy, generating large volumes of spoil; over 28 million cubic yards of excess sand was placed on the seaward side of the barrier between 1940-46 (with smaller fills since), greatly widening the beach (Inman, et al, 1974). Despite slope readjustments, beach recession, and littoral movement, some of this sand remains in the area.

The barrier (or Silver Strand as the narrow portion is known) is remarkable for the diversity of the land uses - both military and civilian. At the north is the North Island Naval Air Station, while Coronado is an incorporated city with residential, commercial structures, and a wide recreation beach; further south, a four-lane highway backs a wide beach and continues south along the barrier; naval housing areas behind the highway contrast with a reach with several multi-story condominiums on the seaward side of the highway, some close to the beach and protected with a rubble seawall; near the south end, a former widened dune area has been dredged and reshaped on the bay side to create a residential marina community. About two miles on the beach serve as popular State beach recreation area; several more miles are reserved for the Navy as an amphibious training area. Further to the south where the barrier widens to join the Tijuana and Otay floodplain, is a large Naval radio station. In the past, a railroad spur extended for the length of the barrier but has now been abandoned. Detailed engineering studies of a second bay entrance crossing the barrier have also been made but are presently inactive.

A sandy beach fronts the floodplain for several miles further south to the Mexican frontier, bordering the residential community

of Imperial Beach, and is breached by the mouth of the Tijuana River. At the river mouth the beach consists of two narrow spits backed by a lagoon and marsh with an area of about 1.7 square miles, managed as a wildlife refuge.

In recent years, concern has grown about the maintenance of sand supply to the sand barrier primarily because the 1,730 square mile drainage of the Tijuana River, most of which is in Mexico, is now 72 percent controlled by dam construction (Phillips, et al, 1979). Previous to control, which was essentially completed at its current level about 1940, periodic floods supplied an annual average of about 700,000 cubic yards to Silver Strand beaches (Inman et al, 1974).

Littoral movements in the vicinity of the Tijuana River mouth are divided between north along the strand and south into Mexico. Physical evidence (movement of past fills, etc.) strongly supports a net northward movement along the strand. (Longshore transport calculations are not fully consistent in this matter although they indicate large transport to the north in the winter and to the south in summer.) It is known, however, that sand is moving along the barrier to the tip of North Island. Some of the material is accreting at the Zuniga Schoal area adjacent to the jetty along the east side of the entrance. Large amounts, however, are also moving into the entrance channel and are flushed offshore to a depositional area in depth of 50 to 110 feet. This latter volume is estimated at 2 million cubic yards per year, based on comparative bathymetric surveys (Inman, et al, 1974), but the estimate may need further investigation.

Therefore, since the natural sand source of the Tijuana River has been cut off, a continuing sand supply to balance losses at the northern end of barrier is no longer available and long-term recession of the beach can be expected without artificial protection or nourishment.

As might be expected, this problem should first become evident nearest the former source area. This hypothesis appears to be confirmed at Imperial Beach, just north of the Tijuana mouth, where erosion of the beach and damage to structures have occurred (U.S. Corps of Engineers, 1975). Due to the presence of a remnant delta of the Tijuana River, this area is a zone of wave energy convergence, which would tend toward increased erosion. The erosion has been countered by groin construction (which proved ineffective) and periodic beach nourishment; more permanent solutions such as an offshore submerged breakwater and fill are under consideration by the Corps of Engineers and the State of California.

Overall, the cutoff of sand from the Tijuana basin has resulted in a narrowing of the southern part of the barrier; however, at the north, the strand and North Island remain considerably widened over natural conditions due to past fills despite continued losses of material to Zuniga Shoal and the offshore sediment-deposition zone. Typical long-term changes, through the mid-1950's are as follows: Tijuana River and U.S. Naval Radio Station; average rate of change -2.3 feet per year (period of record 1889-1954); Silver Strand and North Island; average rate of change: +8.2 feet per year (period of record: 1856-1956). (May, et al, 1982)

Long-term stability of the barrier will require remedial human intervention and management. Artificial nourishment is a preferred

solution as long as sources of fill can be readily obtained. A recent (1978) Corps of Engineers channel deepening in the bay provided an additional 6 million cubic yards of sand for Imperial Beach and the Silver Strand; although disposal of such dredging cannot be regarded as a permanent solution, significant amounts of suitable beach can be obtained in this way. Possible long-term solutions might involve, for example, recycling of sand now transported north to Zuniga Shoal and/or the adjacent offshore sediment sink (possibly with added structures in the area to accrete sand in the shoal for recycling before it is lost to the sediment sink). Alternatively, extensive "hard" structures - such as an artificial headland or series of headlands - might be considered for all or part of the entire littoral cell between the Tijuana River and the harbor entrance. However, this would be expensive and require a great deal of planning and investigation to minimize adverse effects on adjacent areas. In any case, improved monitoring of the wave climate and beach changes will be necessary so that future engineering decisions will be based on accurate knowledge of coastal processes. (Monitoring measures now being considered are discussed subsequently.)

Management jurisdiction for the barrier is divided between the Local Coastal Programs of San Diego County and the cities of San Diego, Coronado and Imperial Beach, as well as the Navy - whose upland jurisdiction is generally exempt from the California Coastal Plan. The application of current Coastal Act guidelines and Navy policy will prevent further encroachments on the beach side of the barrier. (For example, construction of additional large multi-story condominiums, similar to those noted above at Coronado, would probably not be allowed.) Preservation of the barrier spits which front the Tijuana River Marsh is also indicated under the applicable governmental policies.

In summary, human activities to date have greatly modified the barrier between the Tijuana River and the San Diego Bay entrance with considerable enlargements at the north, by dredged fills and beach nourishment, counterbalanced by upstream control of the Tijuana River, the likely principal sand supply to the strand. Recognizing the high level of development of the barrier, continued and intensified management will be necessary to protect its physical form and the multiple uses it sustains.

OTHER BARRIERS

Los Angeles Basin

A notable series of barrier features (Figure 5) exist along about 22 miles of the 30-mile long segment of coastline bordering the southern side of the Los Angeles Basin. The basin is essentially a large alluvial plain formed by deposits of sediment carried by the San Gabriel, Santa Ana and Los Angeles Rivers which, even in historical times, frequently changed location during flood periods and inundated vast areas (Shepard and Wanless, 1971). Until this century, six well-developed bay-mouth barriers breached by tidal inlets or associated with river mouths, and backed by about 25 square miles of marshlands, existed in this area (Speth, et al, 1976; Cooper, 1967).

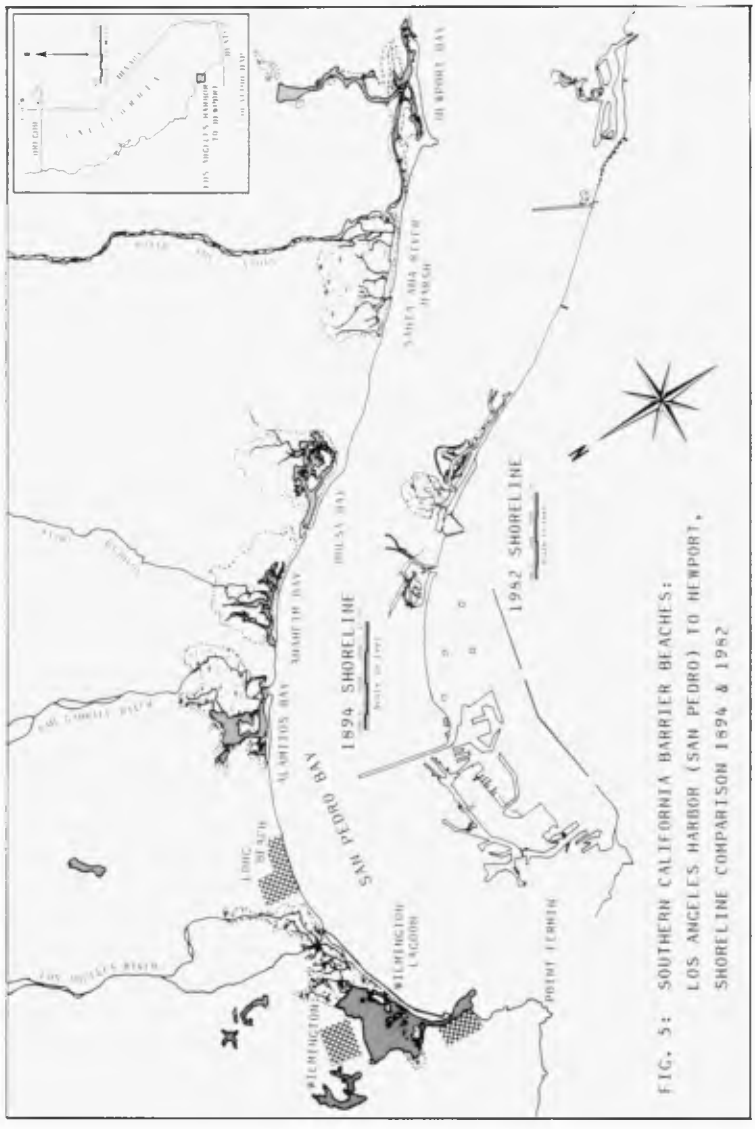


FIG. 5: SOUTHERN CALIFORNIA BARRIER BEACHES: LOS ANGELES HARBOR (SAN PEDRO) TO NEWPORT, SHORELINE COMPARISON 1894 & 1962

Today most of the area and the entire region has been utterly transformed by industrial and urban development. The Rattlesnake Island (or Terminal Island) barrier adjacent to the mouth of the Los Angeles River has become the center of a great port complex, almost totally reshaped and enlarged by dredging and filling, backed by intensive industrial, commercial and residential facilities, separated by the river by channelization and from the open ocean by three segments of Federal breakwater, with a total length of 8 miles (Parker, 1971)

Enlarged by fills, armored and bulkheaded, and in the wave shadow of the breakwater, the stability of the former natural barrier is no longer dependent on the usual coastal processes. The nearby barrier at Los Alamitos Bay adjacent to the mouth of the San Gabriel River lies just at the edge of the wave shadow of the breakwater; further downcoast are bay and river mouth barriers at Anaheim Bay, Bolsa Chica, Santa Ana River and Newport Bay. All of these areas (and intervening reaches) have suffered to some degree from beach erosion due to diminution of the sand supplied to the beach, notably at Surfside-Sunset (Anaheim Bay barrier) and at Newport which have residential areas close to the beach. Many factors have been advanced as contributing causes (Habel and Armstrong, 1977): diminished supply of sand from upland sources due to construction of dam and debris basins; sand and gravel mining from river channels; prolonged drought conditions in Southern California which act to limit supplies of sediment to the coast; jetty construction at Anaheim Bay; and losses to the submarine canyon at Newport Beach. In any event, it has been necessary to nourish most of the entire reach periodically with sands trucked from river beds or other inland sources, and more recently, dredged from an offshore borrow site. In addition, nine groins have been built along the west portion of the Newport barrier to retain beach fill.

Most of this coastline consists of sandy beaches, intensively used for public recreation and backed by a four-lane highway; the largest beach protection investments have been made in areas where residences and park facilities are on or close to the beach, in front of the highway or other roads. Under the Local Coastal Program policies of Orange County, and the cities of Seal Beach, Huntington Beach, and Newport Beach, the land uses should remain largely unchanged. Continued beach nourishment will probably be required.

Oceanside and Vicinity

A twenty-five mile segment of the coast southward from the vicinity of Oceanside, 65 miles south of Los Angeles Harbor, is of especial interest because of persistent beach and cliff erosion. The shoreline is bordered by elevated marine terraces fronted by generally narrow sandy beaches. At intervals, the terraces are interrupted by stream valleys containing brackish or saltwater lagoons and marshes which are separated from the ocean by narrow sand barriers. In all, nine such lagoon-marsh-barrier complexes are present in this reach.

Several communities lie along the marine terraces and border the lagoons. A particularly complicated situation exists at the town of Oceanside where breakwater-protected military and civilian small

craft harbors, with a common entrance and landfills, have been constructed (1940's-1970's) in marshy areas behind barriers adjacent to the San Luis Rey and Santa Margarita Rivers. With seasonal reversals in littoral drift, shoaling problems have been severe in the entrance, which tends to act as a sand trap. Concurrently, severe erosion has occurred on the 2.2-mile reach of beach immediately south of the harbor in front of the city of Oceanside, stripping off sand, leaving cobbles on the beach and threatening roads and homes. This reach has required repeated nourishment with sand dredged from the small-craft harbor and truck-hauled from inland sources. Numerous studies and remedial actions have been undertaken by the U.S. Corps of Engineers regarding this problem.

There are also concerns about the effects of the harbor interrupting sand supplies to the beach. However, the entire 25-mile reach, which - as noted - is primarily bordered by cliffs (marine terraces), appears to be retreating. Primary causes cited include diminution of sand supply to the coast by upstream controls and due to the prolonged drought period (1948-1978): these causes being preparatory to episodic erosion of the cliffs during high wave conditions. Cliff erosion is also worsened by changes in groundwater and drainage of the bluffs due to urban development (Kuhn and Shepard, 1980).

The problems of most concern to the affected communities do not involve critical erosion on the barrier beaches which front the lagoons (barriers occupy about 8 miles of the 25-mile reach and several are protected by revetments, seawalls and periodic nourishment, Habel and Armstrong, 1977); but, the general problem has prompted initiation of a major coastal processes monitoring and investigative effort by the Corps of Engineers which emphasize this particular area. The study will be expanded to include the Orange County and San Diego coastlines between Dana Point near San Juan Capistrano, and the Mexican border. (This Congressionally-authorized study known as the CCSTA: Coast of California Storm & Tidal Action study, will ultimately include additional areas of California.) Monitoring and investigation of barrier features, though not separately distinguished as such, will be contained within the CCSTA, as part of studies of the larger coastline.

THE COAST OF CALIFORNIA STORM AND TIDAL ACTION STUDY (CCSTA)

Before concluding this paper it might be useful to discuss the CCSTA. The study plan is still being formulated by the Corps of Engineers, Los Angeles District; a multi-year program is envisioned initially emphasizing gathering of basic data, including expansion of an existing state-of-the-art wave gaging network, and recurring beach profiling and sediment sampling. Study planners are considering inclusion of field and office studies of wave hindcasting; quantification of sediment sources (streams, cliffs, coastal longshore drift, fills) and sediment sinks (submarine canyons and offshore deposition zones); historical shoreline changes; sea level fluctuations; and, climatic changes.

Data gathered would be analyzed in order to evaluate present conditions, predict impacts of proposed changes and aid in formulation of local and regional solutions.

Although, as noted, this overall plan is still being developed, data collection for the CCSTA and related program has already begun; the existing Corps of Engineers wave gaging network (Domurat and Pirie, 1980) is being expanded to include directional wave gages at additional locations in the San Diego region, and beach profiles which will ultimately cover 100 ranges over the 85-mile reach from Dana Point to Mexico.

One directional gage (Seymour and Higgins, 1978) is being planned for installation at Imperial Beach at the south end of the Silver Strand, and at least one other gage further north along the barrier is under consideration. If carried out, this would be an important step toward better quantification of coastal processes between the Mexican border and Zuniga shoal.

SUMMARY OBSERVATIONS AND CONCLUSIONS

In summary, though of secondary importance, barrier beach features are widespread in California. As indicated in the above case histories, most California barriers have been essentially stable in historic times. Those subject to erosion have been maintained in place by artificial beach nourishment or other protection. Although present management practices will probably continue to be satisfactory, human intervention with beach nourishment and structures may be necessary in some areas. However, such intensified solutions will have to be based on more complete data on coastal processes, in order to respond to tightened State and local coastal management policies.

As recognized by various observers, the coast of California is readily characterized as one of cliffs and bluffs; the cliffs commonly being elevated marine terraces (Kaufman and Pilkey, 1979; Shepard and Wanless, 1971). Barriers are less extensive in California than in many other areas due in part to lesser sediment supplies from restricted drainage areas. Still, as noted, a sizable portion of the California shore is bordered by barriers; and as case studies indicate, their protective functions can be quite important. Some of the barriers are small-scale features occurring at the mouths of streams which breach long reaches of coastal cliffs or mountains. Others are sizable features, often associated with larger geologic elements such as intermontane valleys or alluvial plains - the Los Angeles Basin is an example - which adjoin the coast. Of the barrier beaches examined: Humboldt, Bodega, Bolinas, Morro Bay (and the large majority of smaller barriers identified) have remained essentially stable throughout historic times, despite varying degrees of human activity. Southern California barriers between Los Angeles and Newport and at San Diego have generally been subjected to erosion by interruptions to sand supplies - in part because of urban development. However, the barriers - some of which are no longer recognizable, have either been stabilized by protective works or artificial sand nourishment. In the Oceanside area, erosion problems at the several barriers have been dealt with by localized protection; however, a more general condition of beach and episodic cliff retreat continues along a 25-mile reach.

The latter case, and that of the San Diego Bay barrier (whose sediment supply is now dependent on a dam-truncated watershed), give

evidence that barriers are part of larger systems which should be better understood if intelligent coastal management is to be carried out. Regional studies of wave regimes, shoreline changes and related coastal and watershed processes are desirable to understand what is happening to the shore and to evaluate any prescribed actions, which might range from continuing current practices of incremental protection, through large-scale beach nourishment and engineered coastal stuctures.

Ultimately, some beaches and coastal barriers - especially in southern California - will need protection. Although artificial nourishment remains the favored technique, economic considerations may necessitate combining nourishment with structures to reduce losses of beach material. Certain barrier-associated coastal lagoons could also benefit from limited dredging to remove excessive sedimentation which threatens their continued existence. (This is, however, a controversial issue.)

This observer believes that State and local coastal plans, although strict, will prove flexible enough to allow necessary improvements, provided they are presented and justified on a rational and technically-sound basis. In this regard, expanded study, monitoring and evaluation of the impacts of coastal and related processes on barriers and other shoreline features such as those planned for the CSSTA study should prove useful.

ACKNOWLEDGEMENTS

The aid of personnel from the San Francisco and Los Angeles Districts of the U.S. Army Corps of Engineers is gratefully appreciated. Also, special thanks is due Ceorge A. Armstrong for aid in reviewing the remarkable file of aerial coastline photographs which he has taken for the California Department of Boating and Waterways.

The views of the author do not purport to reflect the position of the Corps of Engineers or the Department of Defense.

CHANGES IN THE COASTAL MORPHOLOGY OF VRACHATI, GREECE

by
C.I. Moutzouris*
A.J. Rogan**, M. ASCE

ABSTRACT

The coastal morphology of Vrachati, which lays on the southeastern coast of the Corinthiakos Gulf, has considerably changed since the construction of two successive coastal structures. The present paper describes these changes and attempts to estimate the rate of longshore drifting sediment load. The description of the changes and the estimation of the rate are based on observations of aerial photographs of the area and on extensive bottom sediment sampling.

1. INTRODUCTION

The Corinthiakos Gulf lays between Peloponnesos and the mainland of Greece (see Fig. 1). According to Piper et al., 1980, it is a major late Cenozoic graben with maximum depth of 860m in its eastern part. It communicates with the Patraikos Gulf through the Rion Straits and with the Saronikos Gulf through the Canal of Corinthos. Beaches are coarsest and steepest where exposed to the prevailing winds.

Vrachati lays on the southern coast of the southeastern part of the Corinthiakos Gulf (see Fig. 2). The coast there has a mild slope mostly due to prodelta platforms from torrents draining into the sea and to accumulation of sediments. Cir-

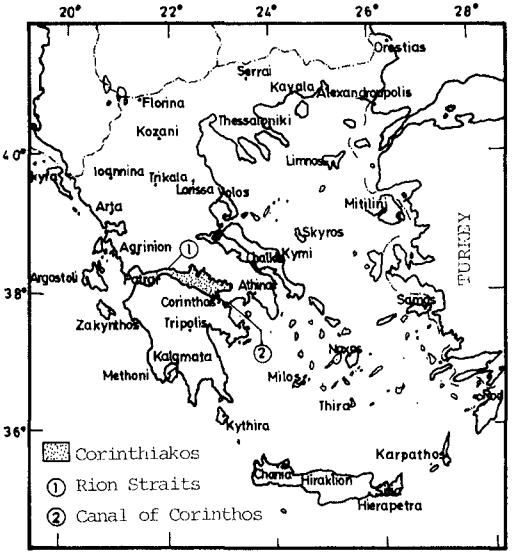

Fig. 1. -Map of Greece and the Corinthiakos Gulf

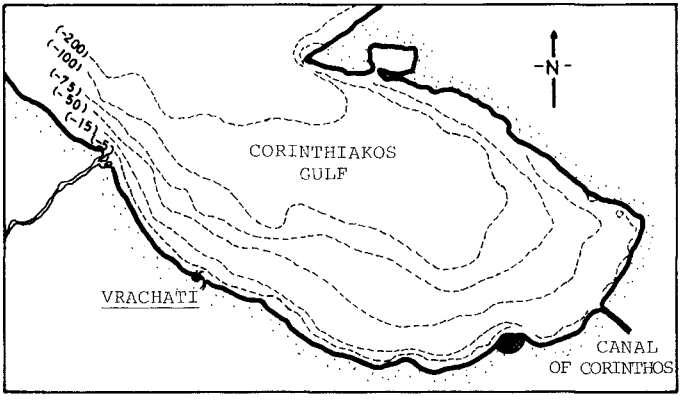

Fig. 2. -Southeastern part of the Corinthiakos Gulf

culation is mostly wind-driven. The tidal current through the Canal of Corinthos is rather weak and does not really affect the circulation in the Vrachati coast. Mean tidal range in the area is very small, locally less than 20 cm. There is an almost bimodal wind pattern from eastern and western directions, but longshore circulation is dominated by waves and wind-driven currents mostly from the W, due to their higher frequencies of occurrence.

A breakwater was built at Vrachati in 1939 in order to provide protection to small fishing vessels. The presence of the breakwater disturbed the nearshore circulation pattern and resulted in intense modifications of the coastal morphology. For this reason, a groin was built in 1967 upstreams of the breakwater. The groin only decreased the rate of coastal modifications. Even today considerable quantities of sediments are locally deposited, as it can be seen in Fig.3.

Fig. 3. -The coast of Vrachati

The effort at the Civil Engineering Department (CED) of the National Technical University of Athens (NTUA) has focused on the nearshore processes at the southern coast of the Corinthiakos Gulf, and more specifically at the Vrachati coast, for three main reasons :

- This coast suffers from extensive erosion and accretion. Efforts are being made now to deal with this problem : the latest one is a comprehensive study which is about to be assigned by the Ministry of Public Works.
- The existence at Vrachati of the breakwater and the parallel groin combined with the simultaneous existence of ae-

rial photographs taken regularly during the same period permit the study of the evolution of the shoreline. The system of the two structures acts as a trap and allows the study of longshore drifting small-sized sediments.

The first part of the present paper describes the evolution of the shoreline at Vrachati due to the construction of the two coastal structures. Then an estimation of the rate of longshore drifting sediments is made.

2. EVOLUTION OF THE SHORELINE

The shoreline of Vrachati was straight before the construction of the breakwater, which was built in 1939 perpendicular to the shoreline (see Fig. 4). Its total length is 189 m. Intense accretion to its left and right occurred after the construction of the breakwater. The zone of accretion to the left had a length of approximately 750m. Longshore drifting sediments were deposited there, due mainly to the presence of the breakwater which was a form of littoral barrier. The zone of accretion to the right was extending up to a torrent draining to the sea and had a length of approximately 330 m. Sediments were accumulating there mainly from the torrent. A part of the load deposited there is believed to have its origins also from the longshore drifting load. The general shape of accretion around the breakwater indicates that the main direction of drift of longshore sediments past the Vrachati coast is from left to right.

In order to protect the coast from the aforementioned accretion, a groin of 135m was built in 1967 perpendicular to the shoreline at a distance of 158m to the left of the breakwater. As a result, further accretion occurred to the left of the groin, because the longshore drifting sediments were now obstructed by the new littoral barrier. The shoreline started to retreat in the zone between the two structures. This is due to the decreased quantities of longshore drifting sediments by-passing the groin and being deposited in the zone. The evolution of the shoreline to the right of the breakwater has not shown any clear tendencies. A remarkable difference between the two beaches upstreams and downstreams of the two structures is noted here : the upstream beach is made of pebbles, while the downstream beach is made of fine sand.

Long observations in-situ under wave attack conditions led the writers to the conclusion that the longshore drift of sediments is partially interrupted by the groin. The groin is a classical partial littoral barrier. Most of the suspended load by-pass the groin and are partially deposited in the zone between the groin and the breakwater and in the zone protected by the breakwater. If there were only the

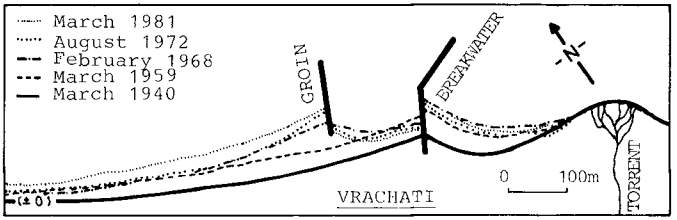

Fig. 4. -Evolution of the shoreline at Vrachati

groin, an erosion would have occurred downstream of the groin. Because of the presence of two successive structures (groin, breakwater), part of the suspended load is trapped in-between. The above qualitative observations are confirmed also by the grain-size analysis of the sediments, as it is analysed later.

3. MODEL APPLIED

It is commonplace to state that the second best method for estimating the rate of longshore drifting sediments, in cases where no data exist, is to study in detail the shoreline evolution as well as the sediments accumulated in the area. Following the above statement and according to the visual observations reported previously, the model chosen to apply for the estimation of the total rate of longshore drifting sediments was based partially on the shoreline evolution and partially on the sediment sizes (see Fig. 5). This model is somehow consistent with the Baker "two line theory" on partial transport blockage. The net total longshore drifting load S is composed of two components :

(1) $S=S_b+S_s$

S_b is the net bedload and S_s is the net suspended load. By definition, the grains of S_s are finer than those of S_b.

The bedload is estimated according to the shoreline evolution on the upstream sides of the two structures, because the structures act as littoral barriers and the accreted shoreline has not yet reached their heads. In order to apply the Pelnard-Considère method, as presented by Bijker, 1972, two time periods have been selected :

- period_a (1939-58), when only the breakwater existed.
- period_b (1967-81), when both structures existed.

The suspended load is estimated according to the size of sand sediments, which are deposited in the zone between the two structures. This zone is a natural trap for fine grains, because of decreased current action.

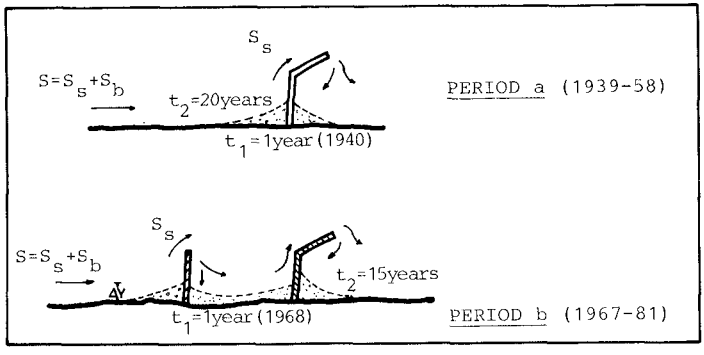

Fig. 5.- Model applied for the estimation of S

4. TECHNIQUES USED

The following techniques have been used for the application of the model : analysis of successive aerial photographs, sediment sampling and analysis and wave hindcasting.

4.1. Aerial photographs

Many sequences of aerial photographs were examined. They had been taken in successive years by the Directorate of Aerial Photographing, Ministry of Regional Planning, Housing and Environment. The examination permitted to follow the shoreline evolution as function of time and presence of coastal structures.

It was found that the shoreline progressed as follows (see Fig. 5) :

ΔY=35m during period a (upstreams of the breakwater)
ΔY=27m during period b (upstreams of the groin)

4.2. Sediment sampling and analysis

Many spot samples have been collected from various locations in the surf zone along the coast, because spot samples are

usually representative of one sedimentation unit (see Fig. 6). For comparison reasons, some of the samples have been collected from on-shore. In order to check the influence of the changing wave climate, samples have also been collected in summer and autumn times.

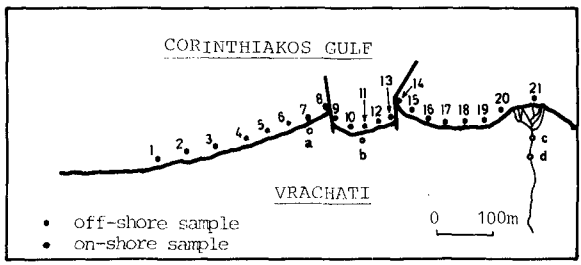

Fig. 6.- Sites of sampling along the coast

The samples were prepared for grain-size analysis and then analysed in the laboratory of the Chair of Foundations, CED/NTUA. Size distribution was determined by standard sieve analysis techniques. The size analysis data were plotted as cumulative curves with arithmetic ordinate, which is a commonly used method of graphic presentation (see Constantinidis and Mavromatos, 1982, and Markoulidis and Zissis, 1983). The material was found to range mainly from fine sand to gravel. The particle sizes and statistical parameters of the samples were found to change along the coast. The grain-size cumulative curves may be classified into 5 families :

Samples 1, 2, 3, 4, 5, 6, 7 (see Fig. 7)

They are coarse grained because they come from the exposed coast upstreams of the structures. Large quantities of the material existed there even before the erection of the structures : particles with diametres as big as 40mm cannot be transported by wave-induced currents. The population of these samples characterises most of the exposed beaches of Corinthiakos : it is a poorly sorted beach with strongly fine-skewed and mesokurtic population.

Samples 8, a, b (see Fig. 7)

They are characteristically bi-modal, because fine grains were trapped by the groin. Curve 8 is met in almost every samples from the zone upstreams of a littoral barrier.

Samples 9, 10, 11, 12, 13 (see Fig. 7)

They are fine grained because of extensive accretion in this area of reduced wave and current action. They characterize a moderately sorted beach with coarse-skewed and leptokurtic population.

Samples 14, 15, 16, 17, 18, 19, 20 (see Fig. 8)

They range from fine-grained (in the protected zone) to median-grained (in the zone of restored current action). Samples 14 and 15 are well sorted with coarse-skewed and platykurtic population.

Samples 21, c, d (see Fig. 8)

They are very coarse-grained, due to the contribution of the torrent.

No significant seasonal change has been detected in the size distribution curves of the samples, especially in the protected zones (see Fig. 9).

4.3. Wave hindcasting

Wave data do not exist in the area under examination. For this reason wave characteristics in deep sea were computed according to the SMB method. Wind data are regularly taken in the area by the National Meteorological Service (EMY). Annual frequencies of occurrence of winds, which generate waves in the Vrachati area, are shown in Table 1. The effective fetch F_{ef} from these directions and the corresponding wave heights H_o and periods T are given in Table 2.

Refraction diagrams for the most frequent waves from E, NE, N and NW were computed according to a numerical method used at the Chatou Research Center-CREC (see Lepetit, 1964). According to this method the refraction coefficient is analysed in two partial coefficients. The first is related to the variation of distance between the orthogonals. The second depends on the modification of the phase velocity. The data introduced for the numerical analysis of the differential equation were the bottom topography, the deep sea characteristics of the monochromatic waves and the phase velocity of the waves. The equation was solved numerically by computer (see Petridis, 1982). Resulting refraction diagrams for waves from E and NE are shown in Fig. 10.

5. RESULTS

5.1. Bedload

The net load S_b was evaluated from the measured progression ΔY of the shoreline during a certain number of years. According to results reported earlier, the shoreline progressed 35m in 19 years (period a) and 27m in 14 years (period b). Surveys made in-situ indicated that the depth of active

sediment transport h is of the order of only 3m.

The angle of incidence α of each monochromatic wave is defined as the angle between the wavecrests and the shoreline. α_o is the value of α in deep sea. The average angles $\bar{\alpha}_d$ of wave incidence from each direction at the depth contour of -3m were evaluated from the refraction computations and are presented in Table 3. Positive (negative) values of a indicate incidence from the left (right) to the right (left) of Fig. 4. The average angle $\bar{\alpha}$ of wave incidence from all directions at the depth contour of -3m was evaluated according to the frequencies of occurrence of Table 1. $\bar{\alpha}$ was found equal to +1.21°.

DIRECTION	FREQUENCY	$\bar{\alpha}_o$ (°)	$\bar{\alpha}_d$ (°)
NW	0.0502	+67.5°	+33.50
N	0.0354	+22.5°	+12.92

Table 3.- Average angles of wave incidence at -3m

After introducing the above values to the equations of Pelnard-Considère, it was found that :

$S_b = 36.5 \times 10^3 m^3/year$ during period a

$S_b = 31.8 \times 10^3 m^3/year$ during period b

As it can be seen S_b was higher in period a than in period b, due to the obstruction from the groin.

The above method of estimation of S_b has several weak points. But it is undeniable that most existing data of longshore drifting sediments quantities have been gathered from surveys of the accumulated material in littoral barriers (Bruun, 1976).

For comparison reasons, S_b was next computed according to a second method. In a very recent paper Hallermeier, 1982, proposed a method of computation of bedload, which accounts for the sediment sizes, the bottom slope and configuration, the wave diffraction, etc. According to this approach, S_b depends upon some characteristic parameters : the wave height H_e, length L_e and angle α_e at the seaward limit to littoral zone, the water depth d_e at the same limit, the parameter Θ ($=d_e/H_e$), the median sediment grain diameter M_D, the wave reflexion and the bottom angle. Table 4 presents the analytical computations of S_b according to Hallermeier for each monochromatic wave given in Table 2. Local surveys indicated that the average bottom angle in the area is of

Table 4.- Computation of bedload according to the Hallermeier equation

the order of 2°. The corresponding average wave reflexion coefficient is of the order of 3%. For the evaluation of the median diameter it was considered that the samples 18, 19 and 20 are the most representative : their grain-size cumulative curves agree well with the corresponding curves of samples from undisturbed areas. For this reason, M_D was taken equal to 0.3mm.

According to the computations in Table 4 the gross loads are as follows :

$S_b' = 57.8 \times 10^3 m^3/year$ from left to right

$S_b'' = 15.5 \times 10^3 m^3/year$ from right to left

The net bedload is :

$S_b = 42.3 \times 10^3 m^3/year$ from left to right

The load according to Hallermeier apparently represents the net bedload during the last years, because the estimation was based on recent field data.

5.2. Suspended load

For the computation of the net suspended load S_s which is transported along the coast, information was needed on the

grains trapped between the two structures. Finally it was assumed that the graphic mean diameter M_z, as defined by Folk, 1974, is representative of the diameters ensemble :

$$(4) \quad M_z = \frac{\phi_{16} + \phi_{50} + \phi_{84}}{3}$$

ϕ is the grains diameter expressed in the phi-scale. The average M_z for the samples 9, 10, 11, 12 and 13 is computed from equ. (4) and Fig. 7 :

$$(5) \quad M_z = 0.14\text{mm}$$

An equation proposed by the Laboratoire Central d' Hydraulique de France-LCHF was the computation of S_s (see Leclerc et al., 1976) :

$$(6) \quad S_s = KgHLTf(\alpha)$$

g is the gravitational acceleration, H and L are the wave height and length at a water depth of 15m, α_{15} is the angle of incidence at the same depth, $f(\alpha)$ is a function of the angle α_{15}. The coefficient K is given by equ. (7) :

$$(7) \quad K = 0.18 \times 10^{-5} \; D^{-05}$$

D is the grain diameter ($\leq$1mm). In the present study it is considered that the average graphic mean diameter of the samples corresponds with D.

The computations of suspended loads for each monochromatic wave given in Table 2 are shown in Table 5. The gross loads are as follows :

$S_s' = 2.2 \times 10^3 m^3/year$ from left to right

$S_s'' = 0.7 \times 10^3 m^3/year$ from right to left

The net suspended load is :

$S_s = 1.5 \times 10^3 m^3/year$ from left to right

5.3. Total load

The net total sediment load drifts from left to right past Vrachati and is equal to :

$S = 38.0 \times 10^3 m^3/year$ during period a

$S = 33.3 \times 10^3 m^3/year$ during period b

The computation of S was based on a wide range of data : wind, sediment, bottom and shoreline progression data.The difference between period a and b is due to the different

Table 5.- Computation of suspended load

rates of shoreline progression during these periods.

For comparison reasons S was then computed according to the well known method of the Coastal Engineering Research Center CERC, as it is presented in the Coastal Protection Manual, 1976. This method ignores the sizes of the transported sediments and the bottom slope. The rate of longshore transport is proportional to the longshore wave energy flux. In other terms, the transport depends exclusively upon the wave climate in the area. The computation of S according to this method is shown analytically in Table 6. The gross loads are as follows.

$S' = 51.7 \times 10^3 m^3$/year from left to right

$S'' = 12.3 \times 10^3 m^3$/year from right to left

The net load S is :

$S = 39.4 \times 10^3 m^3$/year from left to right

The above value refers to time periods a and b, because it was computed from wind data covering both periods.

6. CONCLUSIONS

The adopted method of estimation of the net longshore drifting load is the second best to direct measuring the load, because it is based on a wide range of data:wind, sediment, bottom, shoreline progression data. It can be applied when time presses, although many parameters are neglected. This method gives results averaged in time, while measurements of only one year or less may give very erroneous results.

The research described in the present paper will be continued with load measurements, in order to check the accuracy of the results.

COMPUTATIONAL ALGORITHM FOR LONGSHORE ENERGY FLUX INCORPORATING FRICTION

by

T.L. Walton, Jr.[1], M. ASCE
J.R. Weggel[2], M. ASCE

Introduction

The calculation of longshore sand transport on beaches is a significant coastal engineering problem with application to various areas of coastal structure design (i.e., jetties, groins, and offshore breakwaters), and inlet navigation channel design (i.e., studies of required maintenance dredging). Longshore sand transport as a first approximation is linearly related to longshore energy flux (see Bruno, et al. (1981)), hence, this paper simply presents a method for computing longshore energy flux as a means of determining longshore sand transport.

The approach used herein for calculating longshore energy flux includes an analytical method for incorporating frictional wave energy dissipation. The method is simple enough to program on a hand-held programmable calculator. It therefore provides a method by which rapid calculations can be made for a site at which offshore wave data exist. If offshore directional random wave data are available (i.e. directional wave spectra) then more advanced techniques should be used (see Walton and Dean (1981)).

Computation of the longshore energy flux factor P_{ls} is in accordance with the Shore Protection Manual (1977) equation (4-28)

$$P_{ls} = \frac{\rho g}{16} H_b^2 C_{gb} \sin 2\alpha_b \qquad (1)$$

[1]Hydraulic Engineer, U.S. Army Coastal Engineering Research Center, Fort Belvoir, VA 22060

[2]Chief, Evaluation Branch, U.S. Army Coastal Engineering Research Center, Fort Belvoir, VA 22060

in which P_{ls} is the longshore energy flux, ρ is the mass density of the fluid, g is the acceleration of gravity, H_b is the breaking wave height, C_{gb} is the wave group velocity at the point of wave breaking, and α_b is the angle the breaking wave crest makes with the shoreline, where the subscript "b" denotes breaking wave conditions. The quantity P_{ls} is not truly a longshore energy flux as Longuet-Higgins (1972) has noted, but since this terminology has been widely used (see Shore Protection Manual (1977)), this paper will not deviate from this usage.

Equation 1 can also be written as

$$P_{ls} = E_b C_{gb} \cos \alpha_b \sin \alpha_b \tag{2}$$

where E_b is the wave energy density at breaking given by,

$$E_b = \frac{\rho g}{8} H_b^2 \tag{3}$$

From conservation of energy considerations, for waves approaching shore over straight and parallel bottom contours,

$$E_i C_{gi} \cos \alpha_i = E_b C_{gb} \cos \alpha_b \tag{4}$$

if no energy dissipation has occurred from a given offshore site (represented by the subscript "i") to the breaker location (See Ippen (1966)). If energy dissipation is included, equation (4) must be modified to the following

$$K_e^2 E_i C_{gi} \cos \alpha_i = E_b C_{gb} \cos \alpha_b \tag{5}$$

where the factor K_e^2 accounts for energy reduction due to dissipation by bottom friction, percolation, or other dissipative mechanisms between the offshore site and the breaker location.

Equation (1) with frictional dissipation included can be rewritten as,

$$P_{ls} = K_e^2 \, (EC_g \cos \alpha)_i \sin \alpha_b \qquad (6)$$

where offshore wave data can be used directly to evaluate the term in brackets.

The values of K_e and $\sin \alpha_b$ can be found from linear wave theory transformation processes and a breaking wave height to water depth ratio which is dependent on bottom slope and offshore (deep water) wave steepness.

In this paper the energy dissipation is assumed to be due only to bottom friction; percolation is neglected. From a practical standpoint, the importance of percolation in wave energy dissipation is questionable since in many offshore areas sand is underlain by mud and/or rock. Also, the top layer of sand often has mixed within it organic material and very fine silts that reduce the permeability of this layer.

Bretschneider and Reid (1954) developed equations for the friction coefficient K_f (where $K_f = K_e$ in the case of no percolation) for both constant bottom slope and constant depth cases. Their method of estimating wave height decay requires numerical integration for the case of a constant bottom slope. In the absence of refraction, a chart with solutions has been presented for various values of parameters T^2/d and $\frac{fH_o}{md}$; where T is the wave period, d is the water depth, m is the offshore slope, H_o is the deepwater wave height, and f is a friction factor.

The present approach simplifies the constant slope equation by invoking the shallow water assumption and provides an analytical solution. Over much of the range of the parameters T^2/d and $\frac{fH_o}{md}$, the analytical solution provides answers that are within 5% of the more involved numerical integration solution. The analytical solution of the friction coefficient K_f allows computation of

K_f and P_{ls} on most hand-held programmable calculators. This simplified solution of K_f assumes straight and parallel offshore bottom contours.

The analytical solution for the friction coefficient, K_f, integrated from deep water to a shallow water depth d is:

$$K_f = \left(1 + \left(\frac{fH_o}{md}\right)(\cos \alpha_o)^{\frac{1}{2}}\, 0.12(k_o d)^{-\frac{1}{4}}\right)^{-1} \tag{7}$$

The derivation of equation 7 is given in Appendix A. For values of $\frac{L_o}{d} \geq 15$, and $\frac{fH_o}{md} \leq 1.0$, equation 7 estimates K_f with less than 5% error. Since in most practical applications the friction coefficient f is rarely known with any accuracy, this approximate K_f is believed satisfactory for most engineering purposes.

The method for solving sin α_b is as follows: (1) determine explicitly the breaking wave height using linear wave theory, and the ratio of breaker wave height to water depth (dependent on bottom slope m and deepwater wave steepness) by assuming breaking occurs in shallow water; (2) determine the breaking wave depth from breaker height to water depth ratio; and (3) solve for α_b, the breaking wave angle, using Snell's Law of Refraction. This approach is detailed in Appendix B. The equation used to find the breaking wave height is

$$H_b = \left[\left(\frac{\kappa}{g}\right)^{\frac{1}{2}} K_f^2\, H_i^2\, C_{gi} \cos \alpha_i\right]^{0.4} \tag{8}$$

where K_f represents a spatial average friction coefficient between the site where the wave data observations are available and the breaker site. The breaker depth is given by

$$d_b = H_b/\kappa \tag{9}$$

where

$$\kappa = 1.16\left[m(H_o/L_o)^{-\frac{1}{5}}\right] 0.22 \qquad (10)$$

Equation 10 is from the work of Singamsetti and Wind (1980) who reviewed various equations for the breaking wave height to breaker depth ratio using Battjes (1974) data.

As the friction coefficient K_f of equation 7 depends on the ratio of deep-water wave height to breaking depth $\frac{H_o}{d_b}$, the solution technique used assumes that $H_o \simeq H_b$ to a first approximation for directly computing K_f in equation 7.

The friction factor used is that defined by Bretschneider and Reid (1954) in which the bottom shear stress is defined by a shear stress equation given by

$$\tau_b = \rho f |U_b| U_b \qquad (11)$$

where U_b is the bottom orbital velocity given by linear wave theory. Values of the friction factor f for oscillatory flow have been given by Kamphuis (1975) and Vitale (1979), where f is defined as a function of the relative roughness parameter $\frac{k_e}{\zeta_b}$ and an oscillatory Reynolds number $\frac{U_b \zeta_b}{\nu}$, with k_e = the equivalent sand grain size on the bed, ζ_b = the total horizontal excursion of the water particle motion at the bottom in the absence of a boundary layer, and ν = the kinematic viscosity of sea water.

Kamphuis (1975) notes that k_e can be related to the size distribution of the sand on the bottom by

$$k_e = 2d_{90}$$

where d_{90} is the sand grain diameter such that 90% is finer. Using a Moody-Stanton-type diagram (as is used to present pipe friction factors), Kamphuis (1975) has presented his friction factor, f_k, as a function of Reynolds number

and relative roughness. Since Kamphuis used an alternative definition for his friction factor, the relationship between the friction factor used in this paper and Kamphuis' f_k is $f = \frac{f_k}{2}$.

Comparison of Measured and Predicted Breaking Wave Angles

The major error in calculating longshore energy flux involves predicting the breaking wave angle. The present algorithm for calculating breaking wave angle was compared to three sets of breaking wave data taken in three-dimensional laboratory wave basins. Two of these data sets (Shay and Johnson (1951), and Vitale (1981)) were obtained with movable bed models. The objective of their studies was to measure longshore sand transport and correlate transport rates with wave properties. The movable bed model tests had a large variation in breaking wave angle due to shoreline adjustment during the testing. Also, in the movable bed models, the breaking wave angle (defined to be the angle between the breaking wave and the shoreline) is more difficult to measure since the shoreline position is dynamic and difficult to define. The third set of data (Galvin (1965)) were from a fixed bed model. Observations of breaking wave angles had minimal variation and were averaged for each test to provide a good measure of the breaking wave angle. The friction factor used in the calculations (for all data) was assumed to be $f = 0.1$. This value appeared reasonable for the range of wave heights, periods, water depths, and bottom roughness for the laboratory tests. Results of the calculations were not sensitive to friction. Values of f ranging from 0 (no friction) to 0.1 did not change the correlation coefficients relating the calculations to the data by more than 5%, suggesting that frictional effects in the data are negligable relative to the overall scatter of the measurements and other difficulties inherent in measuring breaking wave angle.

In all laboratory tests the wave generators were in transitional water depths ($1/20 \leq d/L \leq 1/2$) and wave parameters in deep water were calculated using linear wave theory to provide input to the calculations.

The comparison between calculated and observed breaking wave angles is shown in Figure 1, along with the range of the variables and the correlation coefficient for each of the three data sets.

The best data for comparison (i.e., the least scatter for individual tests) was Galvin's (1965). This data set gave a correlation coefficient of $r = 0.97$.

Summary and Conclusions

A technique has been presented for calculating longshore wave energy flux which can be used in areas where offshore wave data are available and the offshore bottom contours are nearly straight and parallel. This method incorporates a simplified analytical technique for computing wave energy dissipation by bottom friction and can be applied with minimal computational effort using a hand-held programmable calculator.

Results for computation of breaking wave angles have been compared to existing laboratory data and found to provide good correlation in one set of tests and reasonable correlation (in view of laboratory data scatter) in two other sets of tests. It is felt that this method of computing longshore energy flux will find many useful applications in view of the simplicity of the algorithm developed.

Collection Methods and their Engineering Applications Work Unit, Shore Protection and Restoration Program, Coastal Engineering Area of Civil Works Research and Developmemt, U.S. Army Corps of Engineers. Permission was granted by the Chief of Engineers to publish this information.

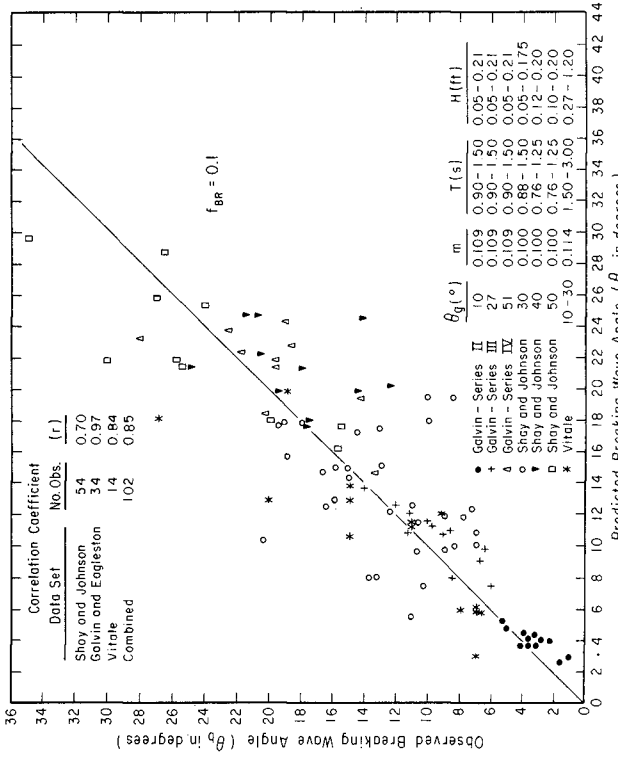

FIGURE 1 - Comparison of Observed and Predicted Breaking Wave Angles

APPENDIX A

Simplified Solution of Friction Coefficient K_f for Constant Bottom Slopes

Bretschneider and Reid (1954) have provided a numerical integration type solution for the friction coefficient K_f as given in equation (B-4a) of BEB TM 45. This solution is as follows:

$$K_f = \left(1 + \left| \frac{fH_o}{mT^2} \int_{\infty}^{d/T^2} \phi_f K_r \, \delta(d/T^2) \right| \right) \qquad (A\text{-}1)$$

where

$$\phi_f = \left(\frac{64\pi^3}{3g^2}\right)\left(\frac{K_s}{\sinh kd}\right)^3$$

and

K_r = refraction coefficient

K_s = shoaling coefficient

as normally defined in linear wave theory (see Ippen (1966)).

Equation A-1 can be nondimensionalized in terms of the deep water dimensionless wave number $k_o d$ and the site dimensionless wave number kd to be

$$K_f = \left(1 + \left| \frac{fH_o}{md}\left(\frac{4}{3\pi}\right) \int_{\infty}^{k_o d} \left(\frac{K_s}{\sinh kd}\right)^3 K_r \, \delta(k_o d) \right| \right)^{-1} \qquad (A\text{-}2)$$

Assuming that offshore bottom contours are straight and parallel, Snell's Law of Refraction can be applied from deep water to the site of interest where

$$K_r = (\cos \alpha_o / \cos \alpha)^{0.5} \qquad (A\text{-}3)$$

which can be reduced to the following for shallow water depth d to

$$K_r = (\cos \alpha_o)^{0.5} \left[(1 - (\sin^2 \alpha_o) k_o d\right]^{-0.25} \qquad (A\text{-}4)$$

As $(\sin\alpha_o)^2 k_o d$ is small over most of the wave transformation zone, Equation A-4 is simplified to

$$K_r \simeq (\cos\alpha_o)^{0.5} \tag{A-5}$$

Again assuming depth d is in shallow water

$$K_s \simeq (2kd)^{-0.5} \tag{A-6}$$

Upon applying the above assumptions to the integral term of equation A-2 the integral becomes

$$I_1 = \int_{\infty}^{k_o d} \frac{X^{-9/4}}{2^{3/2}}\, dX = \frac{1}{2^{3/2}} \left(-\frac{4}{5} X^{-5/4} \right) \Bigg|_{\infty}^{k_o d}$$

$$\simeq \frac{\sqrt{2}}{5} (k_o d)^{-5/4} \quad (1 - (k_o d/\infty)^{5/4}) \tag{A-7}$$

$$\simeq \frac{\sqrt{2}}{5} (k_o d)^{-5/4}$$

Applying the above integration to equation A-2 the simplified friction coefficient (from deep water to shallow water depth d) becomes

$$K_f = \left[1 + \left(\frac{4\sqrt{2}}{15\pi} \right) \left(\frac{fH_o}{md} \right) (\cos\alpha_o)^{0.5} (k_o d)^{-0.25} \right]^{-1} \tag{A-8}$$

For the case of no refraction ($\alpha_o = 0^o$ or $K_r = 1.0$) the equation becomes

$$K_f = \left[1 + 0.12 \left(\frac{fH_o}{md} \right) (k_o d)^{-0.25} \right]^{-1} \tag{A-9}$$

which can be compared to the values given by the Bretschneider and Reid (1954) complete solution, Equation A-2. The present solution and the percent error between the present solution and that of Bretschneider and Reid are given in Table A-1 and presented in Figure A-1 where the error E is defined as

$$E = \frac{K_f \text{ (Bretschneider-Reid)} - K_f \text{ (eq. A-9)}}{K_f \text{(Bretschneider-Reid)}} \qquad \text{(A-10)}$$

APPENDIX B

Development of Equation for Breaking Wave Angle

The conservation of energy equations from offshore to the breaker location for waves refracting over straight and parallel offshore bottom contours in the case of energy losses to bottom friction can be written as

$$\frac{\rho g}{8} H_i^2 C_{gi} \cos \alpha_i = \frac{\rho g}{8} H_b^2 C_{gb} \cos \alpha_b + \text{losses} \tag{B-1}$$

where the losses can be expressed in terms of a friction coefficient K_f as

$$\text{losses} = (1 - K_f^2) \frac{\rho g}{8} H_i^2 C_{gi} \cos \alpha_i \tag{B-2}$$

Upon combining equations B-1 and B-2, and canceling like terms it can be found that

$$H_b^2 C_{gb} \cos \alpha_b = K_f^2 H_i^2 C_{gi} \cos \alpha_i \tag{B-3}$$

Assuming breaking occurs in shallow water

$$C_{gb} = (g d_b)^{0.5} \tag{B-4}$$

Now assuming $\kappa = \frac{H_b}{d_b}$ is known (see equation 10 in text) equations B-3 and B-4 can be solved as

$$H_b = \left[\left(\frac{\kappa}{g} \right)^{1/2} K_f^2 H_i^2 C_{gi} \cos \alpha_i \right]^{0.4} \tag{B-5}$$

Using Snell's Law of Refraction and the shallow water assumption

$$\sin \alpha_b = \left(\frac{g H_b}{\kappa} \right)^{0.5} \left(\frac{\sin \alpha_i}{C_i} \right) \tag{B-6}$$

which can then be solved for α_b.

BREACH/INLET INTERACTION AT MORICHES INLET

E.J. Schmeltz,[1] A.M.ASCE, R.M. Sorensen,[2] M.ASCE
M.J. McCarthy,[3] A.M.ASCE, G. Nersesian,[4] M.ASCE

ABSTRACT

Moriches Inlet is located on the south shore of Long Island, New York, approximately 45 miles (72 kilometers) west of Montauk Point and 80 miles (130 kilometers) east of New York City. The inlet forms the primary outlet through the barrier island between Moriches Bay and the Atlantic Ocean. The inlet is protected and stabilized by two stone jetties approximately 800 feet (245 meters) apart .

During January, 1980, a severe northeast storm resulted in the breaching of the barrier island immediately to the east of the existing Moriches Inlet. By the fall of 1980, the breach had expanded to nominally 2900 feet (885 meters) in width with a maximum depth of around 10 feet (3 meters) and the U.S. Army Corps of Engineers was requested to affect its closure. The method adopted by the Corps consisted of the placement of beach fill in the opening to develop a cross-section with a centerline elevation of +13.25 feet (4 meters) MLW and side slopes of 1V:25H. Initiated in October 1980, the closure operation was succesfully completed in February, 1981.

The formation of a significant breach immediately adjacent to the existing inlet and the artificial closure of the opening afforded a unique opportunity to study the dynamics of a tidal inlet under the influence of relatively rapid changes in tidal prism and cross sectional area. The purpose of this paper is to present the results of a field measurement program and subsequent analyses of the dynamics of the inlet/breach system. The analyses were based on data obtained before, during and after closure of the breach.

DESCRIPTION OF THE STUDY AREA

The eastern 33 miles (53 kilometers) of the south shore of Long Island has eroding headlands that contribute sediment to the net littoral drift to the west along most of the south shore. Generally narrow beaches cut by six inlets (from east to west: Shinnecock, Moriches, Fire Island, Jones, East Rockaway and Rockaway) occupy the remaining 87 miles (140 kilometers) of the south shore. A vicinity map is shown in Figure 1.

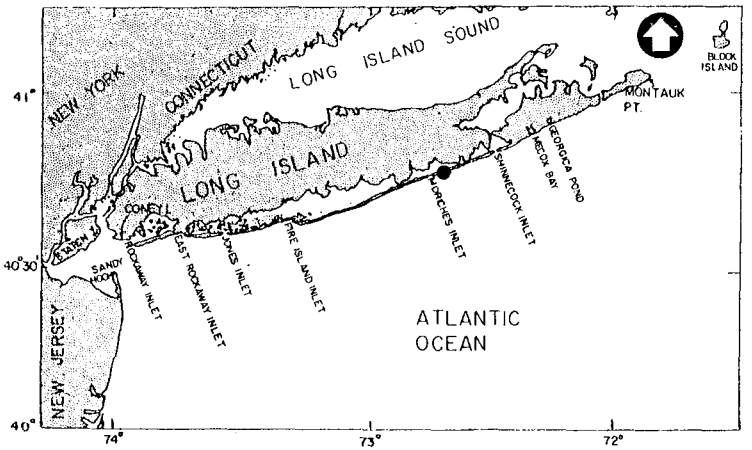

Figure 1 - Vicinity Map

Moriches Inlet, located about 80 miles (130 kilometers) from the western end of the island, connects Moriches Bay to the Atlantic Ocean. Moriches Bay extends about 13 miles (20 kilometers) along the coast and has a width of one to two miles in the vicinity of the inlet (Figure 2). The Bay, which is generally less than six feet (1.8 meters) deep, is open via narrow connections to Shinnecock Bay on the east and Great South Bay on the west. There is a small net flow through these connections into Moriches Bay which augments the ebb flow through Moriches Inlet. This system is crossed by the intercoastal waterway (ICWW) which is dredged to a depth of six feet (1.8 meters).

Inlet migration and offset patterns, sediment entrapment at groins and inlet structures, wave hindcasts, and grain size and trace mineral variations all indicate a strong net longshore transport to the west (Reference 1). Taney (Reference 2) estimated this drift in the vicinity of Moriches Inlet to be 300,000 cubic yards (230,000 m^3) per year; Panuzio (Reference 1) presents an estimated net rate of 350,000 cubic yards (269,000 m^3) per year. The longshore transport is consistently to the west except for the summer months when short term reversals can occur (Reference 3).

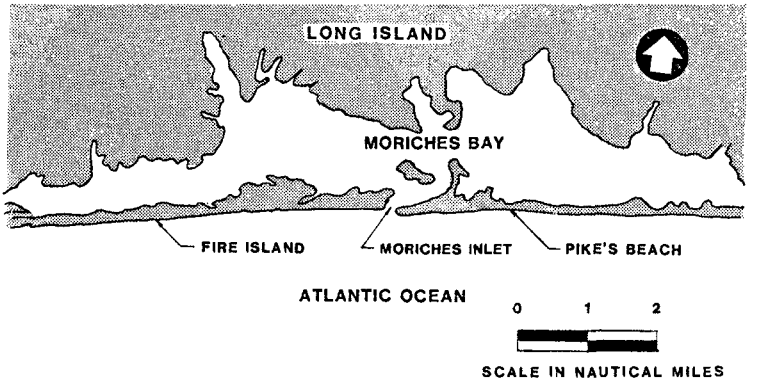

Figure 2 - Bay System (Local) Map

The history of Moriches Inlet has been treated by a number of investigators (Reference 4, 5, 6) and is summarized here only briefly. In 1828, there were two inlets to Moriches Bay, but both closed by 1838. The Bay remained landlocked for nearly a century until March, 1931, when a storm cut a new opening to the Atlantic Ocean. By 1949, this inlet had migrated 4000 feet (1220 meters) to the west and by May, 1951 it was again closed. In 1952-53, a pair of jetties was constructed in the dry at the location of the old inlet. Dredging was then initiated to cut a channel between the new jetties when a minor storm in September, 1953 completed the opening. Figure 3 shows the layout of the jetties and the pattern of adjacent channels in 1967. The jetties are spaced about 800 feet (245 meters) apart.

Further dredging was undertaken at Moriches Inlet in 1958, when a 10-foot (3 meter) deep, 200-foot (60 meter) wide channel,the Bay Channel, was cut from a point just inside the inlet to the northeast and then back to the ICCW (see Figure 3). This channel was widened to 300 feet (90 meters) in 1963. A second channel, the Northwest Channel, was dredged in the northwest direction back to the ICCW in 1966.

In 1956, just after the inlet was opened, the throat cross-sectional area was 6,500 square feet (600 m^2). The area increased to over 12,000 square feet (1,115 m^2) by 1975 as channel erosion assisted by the dredging caused the entrance cross sectional area to grow toward the estimated (Reference 4) stable value of about 18,000 square feet (1,675 m^2). The mean tide range in the bay increased from just under 0.5 feet (0.15 meters) in 1956 to about 2.0 feet (0.6 meters) in 1975. In the ocean, the mean range is 2.9 feet (0.9 meters) and the average spring tide range is 3.5 feet (1.06 meters). A photograph of Moriches Inlet as it appeared in 1973 is shown in Figure 4.

The ebb tidal flow through the Northwest Channel from the ICCW to the inlet is directed at Pikes Beach (see Figure 3). With increased flow, owing to increased inlet throat area, channel dredging and the ebb flow pattern in the main channel, the bay side of Pikes Beach adjacent to the east jetty underwent significant erosion from 1955 on. Czerniak (Reference 4) in a study of the inlet conducted for the U.S. Army Engineers, New York District identified the possibility of the formation of a breach in that area on the basis of existing flow patterns.

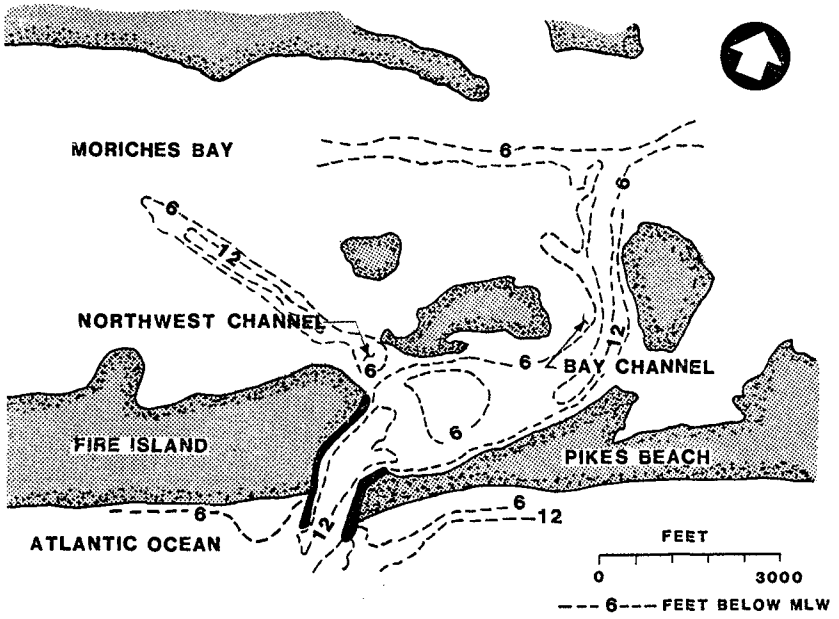

Figure 3 - Plan of Inlet and Adjacent Channels

The main (Bay) channel from the inlet to the ICCW developed a deep section adjacent to Pikes Beach (see Figure 3). Ebb flow concentrates in this section as it is deflected from a southerly to southwesterly direction. This, possibly assisted by the ebb flow from the Northwest Channel, was the likely cause of the severe erosion of the bay side of Pikes Beach adjacent to the inlet. The resulting necking of Pikes Beach is demonstrated by a photograph taken in January 1978, shown in Figure 5. Suffolk County had dredged sand from the bay to build up Pikes Beach to resist the necking of the beach but, as the photograph demonstrates, the reduction in beach width adjacent to the inlet was still quite significant.

Figure 4 - Moriches Inlet Viewed From the South (September 1973)

DEVELOPMENT OF THE BREACH

A severe Northeast storm on January 14-16, 1980 caused the formation of a breach through Pikes Beach, at the narrowest section about 1000 feet (305 meters) east of the east jetty. Figure 6 is a photograph taken soon after the breach occurred. Apparently, wave action and stronger ebb tidal currents in the bay resulting from the stronger winds and higher water levels during the storm caused excessive erosion on the bayside and washover of the barrier island from the ocean side.

The initial width of the breach when first observed on January 16 was estimated to be on the order of 300 feet (90 Meters) and the depth was estimated at about 2 feet (0.6 meters). A hydrographic survey on January 20 indicated the breach to be 700 feet (215 meters) wide and an average of 3.3 feet (1 meter) deep below Mean Low Water (Reference 7). By May 1980 the fillet between the breach and East Jetty was entirely removed and by October 1980 the breach was nominally 2900 feet (885 meters) wide. Figures 7 through 9 provide a photographic history of the development of the breach. Comparative shorelines indicating the necking of Pikes Beach and the subsequent breach development are shown on Figure 10.

Figure 9 - Breach Development - September 21, 1980

As a result of concerns expressed by local interests regarding increased exposure to storm induced flooding in the backbay areas and the impact of possible changes in bay salinity on the shellfish industry, the U.S. Army Corps of Engineers was requested to effect closure of the breach. It was intended that construction be completed prior to the winter storm season of 1980 - 1981 which essentially allowed for a six month construction period.

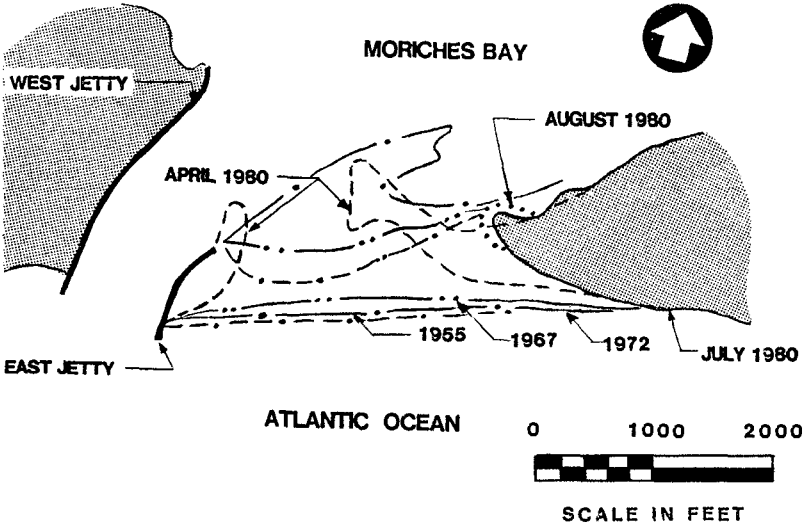

Figure 10 - Comparative Shorelines East of Moriches Inlet

The construction of the closure works and development of the methodology are treated by McCarthy, Schmeltz and Lehan (Reference 8). Briefly the design developed by the Corps of Engineers called for the placement of 1.2 million yds^3 (980,000 m^3) of beach fill in the opening to develop a cross-section with a centerline elevation of +13.25 feet (+4 meters) MLW and side slopes of 1V:25H.

For the construction, temporary steel sheetpiling was driven on the bayside of the breach essentially parallel to the original water line. The sheeting served to provide access for land based construction equipment and to "pinch off" flow in the newly formed channel. Construction proceeded from the easternmost point of the breach to the East Jetty of Moriches Inlet. Following placement of the fill the sheeting was removed and the material graded to the desired section.

Construction activities began in October 1980 and closure of the breach with the sheeting was effected in December 1980. The filling operation was completed to the final desired cross-section in February 1981. It is worthy of note that erosion of the bay side of Pikes Beach recurred after the closure. In order to stabilize this area 1600 feet (490 meters) of stone revetment was placed by Suffolk County (Reference 9) in April, 1982.

FIELD MEASUREMENTS

Prior to the startup of construction activities, a field measurement program was initiated in order to obtain data on the inlet/breach system. It was intended to collect information before, during and after closure of the breach. The program included the following measurements:

- Breach and Inlet cross-sections
- Velocity measurements as a function of breach closure and tides
- Tidal readings inside and offshore of the inlet

Data was obtained over a six month period. Systematic aerial photographs were also initiated by the Corps of Engineers in order to document the development of the breach from initial formation and continuing 15 months after closure.A chronology of activities related to the breach, closure operations and measurement program is presented in Table 1.

TABLE 1
MORICHES INLET/BREACH CHRONOLOGY

• Mid January, 1980	- Breach Opens Initially 300 Feet (90 meters)
• October 1, 1980	- Closure Operations Begun Breach 2900 Feet (885 meters)
• October 3, 1980	- Bay Tide Gauge Installed
• October 4, 1980	- 1st Current Profiling
• October 20, 1980	- Ocean Tide Gauge Installed
• October 21, 1980	- 2nd Current Profiling
• December 15, 1980(Apprrox.)	- Breach Closed
• December 19, 1980	- 3rd Current Profiling(Partial)
• January 19/20, 1981	- 4th Current Profiling
• January 31, 1981(Approx.)	- Construction Completed
• March 24/25, 1981	- 5th Current Profiling Removal of Tide Gauges
• April, 1982	- Stone Rip-Rap Protection Placed on Bay Shoreline

Cross sections of both Moriches Inlet and the breach were obtained at the locations shown on Figure 11 for each period of measurement. Depth measurements were made with a Raytheon DE 719 precision depth recorder. Profiles were obtained by piloting the vessel along a predetermined track at constant speed utilizing existing rangemarks and fixed objects to maintain alignment.

Results of the depth profiling were utilized at each measurement period to delineate segments of the inlet and breach for velocity profiling. The intent of the current measurements was to allow a volumetric analysis of flow through the respective channels. A representative sample of the segments utilized for one survey is shown in Figure 12.

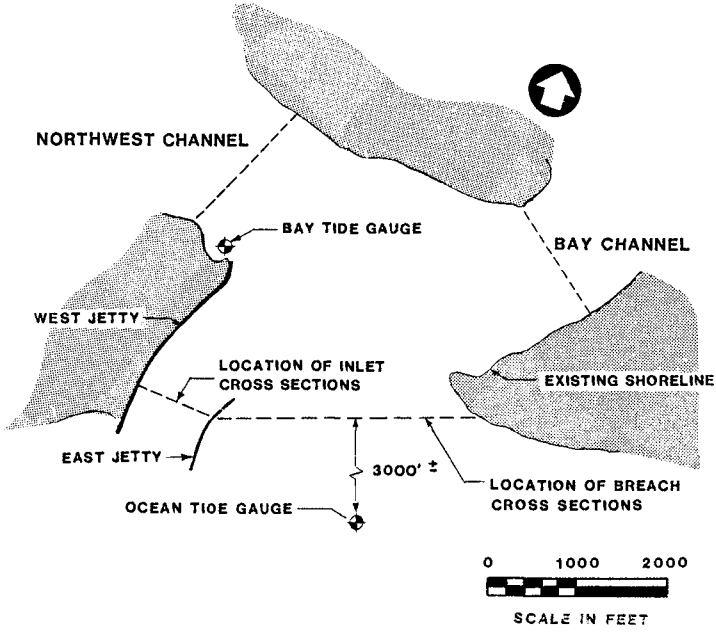

Figure 11 - Inlet Cross-Section and Tide Gauge Locations

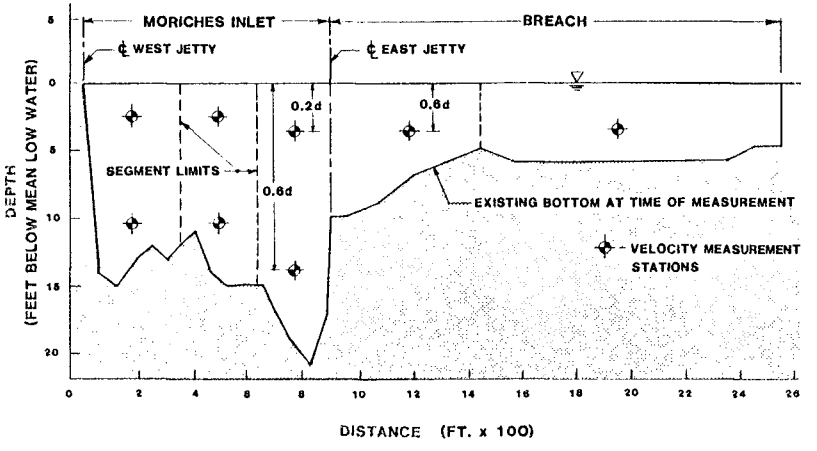

Figure 12 - Current Profiling Station Locations

Current measurements were obtained at each station at 0.2 and 0.8 of the average depth in the segment at the time of measurement. In cases where the depth was not sufficient to permit dual measurements, a single reading at 0.6 of the depth was obtained to reflect the average current in the segment. Measurements were made utilizing over the side current meters with directionality inferred from the surface currents. Readings were obtained atapproximately 1 hour intervals at each point of interest. Each monitoring period covered a minimum of 13 hours, sufficient to fully define a tidal cycle.

Cross-section data and velocity profiles were obtained on four occasions at approximately the following stages of construction of the breach closure:

- Profiling A - October 4, 1980 Prior to initiation of construction
- Profiling B - October 21, 1980 Breach half closed
- Profiling C - January 19 and 20, 1981 Closure complete
- Profiling D - March 25,1981 One month after completion of construction

Two recording tide gauges were installed on site, one inside and one outside of the inlet as shown on Figure 11. The inside or "bay" gauge was installed on October 3, 1980. This gauge was located at the base of a tide staff on the north end of the West Jetty. Initially it was intended that the "ocean" wave gauge be installed on a crib at the southern end of the West Jetty. However, due to hazardous conditions at this location the gauge was finally installed slightly east and offshore of the inlet as shown on Figure 11. This location was chosen in order to avoid the shoals offshore of the inlet and breach and to reduce the possibility of the gauge being buried by sediment transported away from the fill operations. The ocean gauge was installed on October 20, 1980.

Both of the tide gauges were bottom mounted pressure recording units set to record water levels at 10 minute intervals. Essentially concurrent readings were obtained both in the bay and in the ocean. During periods of current monitoring, tidal measurements were also obtained from tide staffs located adjacent to the north end of the inlet. Visual readings were obtained during on-site operations at 30 minute intervals.

DISCUSSION OF RESULTS

Breach and inlet cross sections obtained at various times prior to, during and after construction are shown in Figure 13 along with the relative locations of the temporary sheetpile closure structures. Cross section data is presented in tabular form in Table 2 for the breach, inlet and system total.

Initially, the inlet profile consisted of a relatively shallow channel on the west bank and a deep channel near the East Jetty. The breach was relatively flat and shallow until just east of the jetty where a small channel is apparent. As can be seen in the figure, both the inlet and breach began to deepen as closure was carried out. Examination of aerial photos also indicate significant shoaling in the ebb and flood tidal deltas. Overall the pinching off of the breach by the sheet pile retaining structure, however, resulted in a shift in tidal flow from the breach to the inlet with a commensurate increase in cross sectional area of the original channel.

NOTES:

1. Construction initiated approximately 10/9/80, sheet pile closure effected 12/80.
2. Breach approximately 1/2 closed as of 10/20/80.
3. N.A. indicates data not available.

Measurements obtained in July and September 1980, both prior to construction indicate that the cross sectional area of the inlet was decreasing, implying a possible instability towards closure of the inlet. It is, however, interesting to note that the gross cross-sectional area of the inlet and breach from the first available data in July 1980 through late October, 1980 (shortly after construction began) remained relatively constant near 23,000 ft^2 (2100 m^2). From the July measurements the gross area was divided roughly equally between the breach and inlet. As a result of the apparent consistancy of the gross cross-sectional area of the inlet/breach during this period, the cross-sectional areas of the Bay and Northwest channels were evaluated from the July 1980 data. The location of the lines is shown on Figure 11. These computations indicate a combined cross-section in these channels of approximately 22,500 ft^2 (2040 m^2). The inference, than, is that a secondary control may have existed in the form of these channels.

As closure progressed, the channel in the breach adjacent to the East Jetty initially deepened in response to the decrease in width, but eventually closed. Concurrently, the inlet cross section enlarged. After closure, the inlet became deeper and began to change to a single channel more centrally located between the jetties.

The cross-section of the inlet decreased from July to late October. Subsequently the inlet cross-sectional area shows a persistant increase reaching a maximum in December shortly after closure was completed with the sheet pile walls. Subsequent measurements indicate a slight decrease in the inlet cross section which may correspond to an increase in hydraulic efficiency as the inlet moved towards its more stable, prebreach condition. Data on variations in inlet and breach cross section as a function of time are plotted in Figure 14. Data prior to the breach were obtained from reference 4.

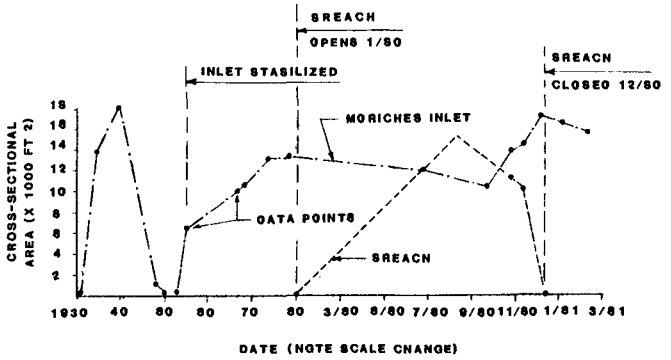

Figure 14 - Inlet/Breach Cross-Sectional Area Changes

It is interesting to note that earlier estimates by other investigators (References 4, 5) indicate a stable cross section of the inlet ranging from 16,000 ft^2 (1500 m^2) to 20000 ft^2 (2100 m^2). The latest available measurements of the cross section of Moriches Inlet prior to the breach, obtained in April, 1978, indicated an area of approximately 12500 ft^2 (1860 m^2). It appears, then, that the inlet was probably moving towards its prebreach condition at the time of the final measurements in this program.

Velocity measurements in the inlet and breach were utilized to assess variations in tidal prism at the time of measurements. Peak measured velocities, provided as an indication of the relative flow, during each measurement period are presented in Table 3. Tide ranges based on measured data from the "ocean" and "bay" as well as predicted tides in the ocean at the time of measurement (Reference 10) are also provided .Tidal prisms computed on the basis of field measurements are shown in Table 2.

TABLE 3
TIDE RANGES AND CURRENT VELOCITIES

DATE	TIDE TABLES (ft)	MEASURED TIDES (ft)		MAX. CURRENTS (ft/sec)	
		OCEAN	BAY	BREACH	INLET
10/4/80	3.3	n.a.	2.2	2.0	3.5
10/20/80	3.7	3.7	2.8	1.5	2.5
1/20/81	4.0	4.4	3.3	CLOSED	6.8
3/25/81	3.0	3.3	1.8	CLOSED	4.2

As shown in Table 3, measured ocean tide ranges varied during the measurements from 4.4 feet (1.3 meters) to a low of 3.3 feet (1 meter) and compare favorably with the predicted tide ranges. Tidal differentials and maximum current velocities in the inlet, show a marked increase as the closure was effected.

Considering the variations in the ocean tides experienced during the measurement periods, it appears that the tidal prism decreased slightly after closure was completed. However, considering that the cross section with the breach was nearly twice as large as the pre and post breach inlet sections, the change in flow quantity is relatively minor varying from a maximum of 7.3×10^8 ft^3 (2.07×10^7 m^3) with the breach open to 5.9×10^8 ft^3 (1.67×10^7 m^3) after closure. The maximum values are also substantially below the "potential" tidal prism determined by Mehta and Hou (Reference 5) of 1.5×10^9 ft^3. Note that both measurements sets were obtained with an ocean tide range of 3.3 feet (1 meter). Bay tide ranges, also decreased from 2.2 feet (0.67 meters) to 1.8 feet (0.55 meters) on the bay side of the inlet. These results should, however, be viewed with caution due to the limited nature of the available data and the effect of

secondary controls of the Bay and Northwest Channels on tide readings obtained immediately adjacent to the northern limit of the inlet.

In any case, the level of change in the tidal prisms with and without the breach seems to provide further substantiation of the secondary control of the Bay and Northwest Channels while the breach was open.

As a gross indicator of the overall stability of the system, O'Brien's Area/Tidal Prism relationship (Reference 11) was utilized with the measured tidal prisms to determine "stable" areas. The values determined in this evaluation are provided in Table 2. As seen in the table the values vary, as a function of the measured prism, from 10,800 ft^2 (1000m^2) to a high of 22,800 ft^2 (2120 m^2). Based on the measured prisms after construction, O'Brien's method yields a stable cross-sectional area of the inlet of nominally 12,000 ft^2 (1115 m^2) , close to the measured values in April 1978.

Overall the comparisons indicate that measured cross sections prior to closure were larger than could be sustained given the available tidal prism. Measurements after closure, in March 1981, show a closer agreement with computed values although it appears that a further reduction in area of the inlet is possible.

CONCLUSIONS

Prior to closure of the breach, the tidal prism determined from velocity measurements appears to have been inadequate to maintain the cross sectional area of the inlet/breach system, i.e. the system was probably unstable towards closure. However, the inlet was undergoing migration beyond its control structures which may have resulted in closure of the original inlet replaced by an uncontrolled, migratory channel. Based on previous experience with inlets at this location, the ultimate result may have been complete closure of the connection between Moriches Bay and the Atlantic Ocean.

The gross cross sectional area of the inlet/breach system, prior to the beginning of the closure operations, was on the order of 23,000 ft^2 (2140 m^2) divided roughly equally between the original inlet and the breach. During construction the cross-sectional area of the original inlet increased by nominally 25% relative to the pre construction condition to approximately 15,000 ft^2 (1390 m^2). The post construction cross section of nominally 12,000 ft^2 (1115 m^2) correlates well with measurements obtained before the breach. This seems to indicate that the channel was returning to its prebreach configuration as of the conclusion of the measurement program.

Both observations and measurements indicate that as the breach was "pinched off" by the temporary sheet pile structures, flow was shifted from the breach to Moriches Inlet. Both currents and tidal differentials showed a marked increase as construction progressed. Although the data are limited, tidal prisms appear to have decreased slightly after the closure was completed.

The magnitude of change in tidal prism, however, appears somewhat smaller than might have been expected. The Bay and Northwest channels which exist behind

the inlet may have exerted a secondary control on the system. The result of the influence of these channels could have been to minimize, at least temporarily, further increases in both the cross sectional area and flow through the inlet/breach system.

ACKNOWLEDGEMENTS

Some of the data described in this document were collected under the Civil Works Research and Development Program of the U.S. Army Corps of Engineers. Permission to publish this paper is appreciated. The findings of this paper are not to be construed as official Department of the Army position unless so designated by other authorizing documents.

The authors would also like to express their appreciation to Lizza Industries, Roslyn, NY and Ocean Surveys, Inc, Old Saybrook, CN for their invaluable assistance in the collection of the data utilized in these investigations; and to the Coastal Engineering Research Center for access to the aerial photographs of the site.

SHORE PROTECTION AT VENICE: A CASE STUDY

A. Muraca (*)

ABSTRACT

The lagoon of Venice (N. Adriatic) is the most important in Italy (Fig. 1). Between 1840 and 1933 the tidal entrances facing the lagoon were controlled by six large jetties, after the construction of which more evident erosion phenomena appeared in some tourist resort beaches near the inlets. Detailed historical, movable bed models, and field studies have recently been conducted with the aim of defining a proper defence system for these beaches. The results of these studies are reported here.

HISTORICAL REPORTS

The lagoon of Venice originated nearly 6,000 years ago as a result of slow invasion by rising sea-water over a wide alluvial zone, faced by a large dune system whose position has not significantly changed in time.

The first detailed historical reconstruction of the lagoon describes the site as it was about 1,000 years ago (Filiasi [2]). At that time the lagoon was connected to the sea by nine different mouths, called "ports", i.e. from NE to SW, Jesolo, Lio Maggiore, Treporti, S. Erasmo, S. Nicolò, Malamocco, Porto Secco, Chioggia and Brondolo (Fig. 2).

The following evolution of the northern lagoon area is shown in Fig. 3. In the 16th century five inlets were still present on this side, i.e. Jesolo, Lio Maggiore, Treporti, S. Erasmo and S. Nicolò. One century later, as a consequence of large deposits of river sediment, the port of Jesolo became a branch of the Piave river and that of Lio Maggiore an internal channel called "Pordelio". Sediment deposits continued in front of the Pordelio channel.

Finally, as a consequence of the construction of two big jetties between 1882 and 1910, Treporti, S. Erasmo and

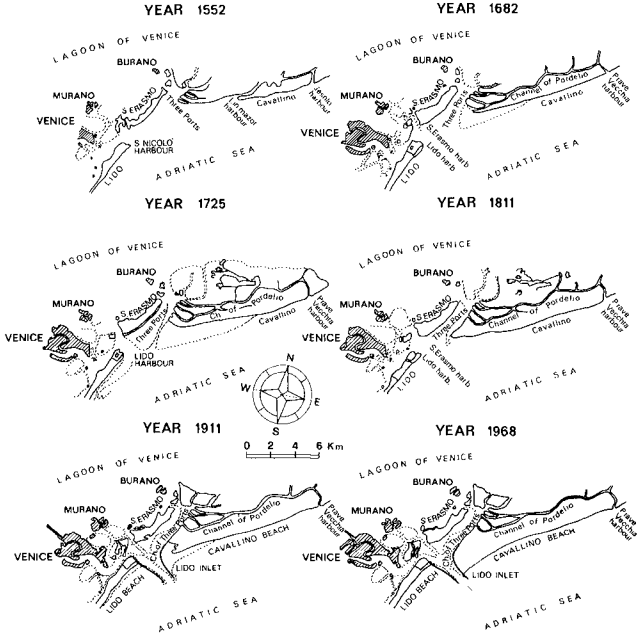

FIG. 3 : Topographic change of N-E lagoon area (after Miozzi [3])

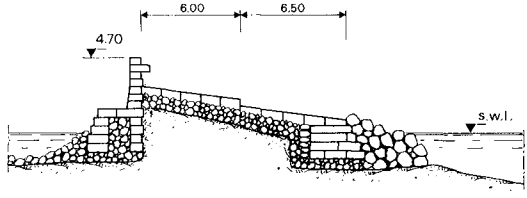

FIG. 4 : Seawall built between 1744 and 1782

the Lido (S. Nicolò) were united to form the Lido inlet. In the meanwhile, fewer modifications took place on the southern side of the lagoon, where the sediment supplied by river floodings had the effect first of closing the Porto Secco inlet and then of confining the Brondolo inlet to the border of the lagoon itself.

From the beginning of the 13th century, man's contribution became gradually more important. The Venetians generally followed three main directions while aiming at preserving the singular aspect of their lagoon:

1) they avoided large river sediment deposits inside the lagoon and preserved the activity of the inlets;
2) they favoured predominance of salt water over fresh in the lagoon;
3) they assured an efficient shore defence system to the islands composing the littoral belt.

To satisfy the first two needs (points 1 and 2), from the 14th century onwards, the main rivers formerly entering the lagoon were diverted outside it. Longshore sediment supply consequently increased at the borders of the lagoon.

Shore defence had been important since the 11th century, when the first artificial sand movements were performed, whereas the first structures were built around the 14th century. These consisted of groins and sea-walls, built of several lines of generally transversally connected wooden piles. Stones were also placed between the lines of the groins and at the foot of the sea-walls. The effect of these structures was, however, often unsatisfactory and the Venetian government was frequently obliged to remove or modify them. Between 1774 and 1886, about 20 km of large sea-walls were built. The first 5 km were built between 1774 and 1782 to protect positions between the Malamocco and Brondolo inlets, where beach extension was insufficient to avoid flooding during heavy storms. Although these structures, where concrete was used to increase the stability of the stones, represent an incredible technological level for those times (see Fig. 4), they underwent serious damage and the bottom erosion rate increased in front of the sea-walls. Parts of these structures were destroyed in November 1966, during a storm in which the sea rose approx. 2 m above normal levels. On that occasion, it was noticed that, two hundred years after their construction, damage to the sea-walls was mainly due to cavities which had formed under the stone covering, rather than to structural weaknesses.

EFFECTS OF JETTY CONSTRUCTION

Between 1840 and 1933, both to improve navigation facilities and to increase sea/lagoon water exchange, six large jetties were built, thus causing the present configuration of the lagoon. Fig. 5 shows this configuration: of the nine tidal inlets active 1,000 years ago, only three still remain. They are:

- the Lido, whose jetties were built between 1882 and 1910. The N jetty is 3,635 m long, the S one 3,155 m; the inlet channel is 900 m wide;
- Malamocco inlet, whose jetties were built between 1840 and 1872. The N jetty is 2,120 m long, the S one 930 m. This inlet is 470 m wide and separates the littoral of the Lido from that of Pellestrina;
- Chioggia inlet, whose jetties were built between 1911 and 1933. The N jetty is 1,800 m long, the S one 1,500 m; the inlet channel is 550 m wide.

To analyze the effects produced by the long jetties on the adjoining beaches, bathymetric charts up to 1810 have been collected and compared with the present situation.

As Figs. 6 and 7 show, large offshore bars were present in front of Malamocco and the Lido inlets before jetty construction: their orientation testifies to a net southward littoral drift. These bars were quickly eroded as a result of jetty construction and steady deepening of the bottom appeared in the central parts of Pellestrina and the Lido beaches.

Long-term profile changes (Fig. 8) show this behaviour (for location, see Fig. 5). The evolution of section 16 clearly reveals the process of bar destruction, while more gradual bottom erosion is seen in section 21. In profile 29, surveyed at the middle of Pellestrina beach, erosion actually increases at a slower rate, probably due to the presence of a steeper slope resulting from the construction of the sea-walls since the 18th century. However, the long-term trend of bottom evolution shows strongest erosion occurring between the 3- and 10-m depth contours in the central part of the Lido.

It is worthy of note that, while generally accretion or stability of the submerged beach has been noticed close to the jetties, clear-cut erosion has developed to the SE, close to the Malamocco inlet: this phenomenon may be partly ascribed to the limited extent of the jetty, which is the smallest of all.

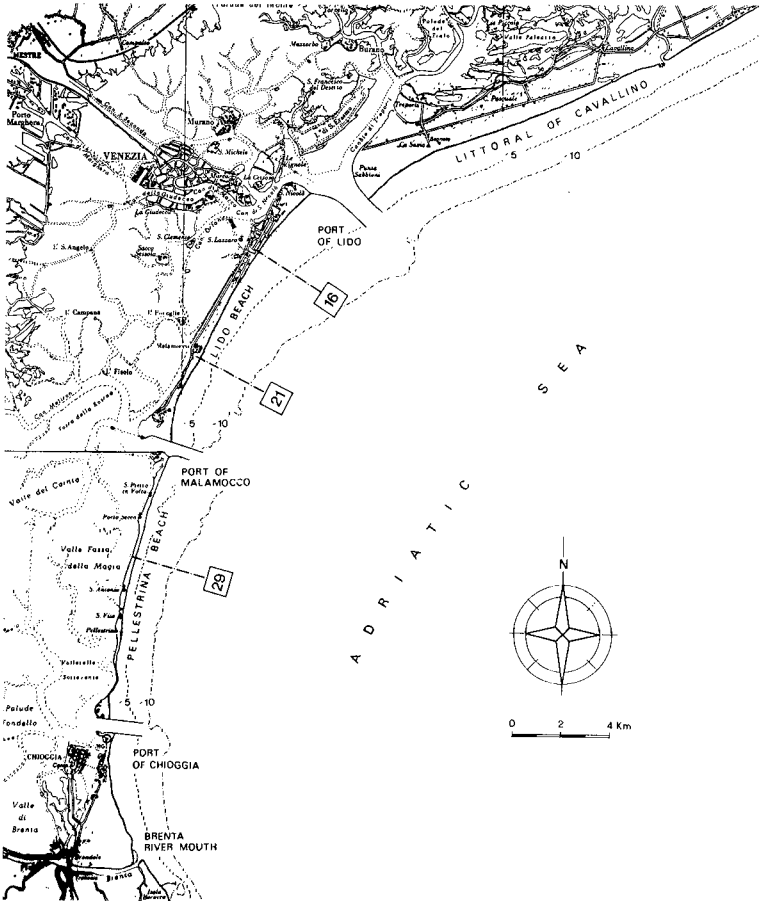

FIG. 5 : Venice coastline and profile location

FIG. 6 : Shoal orientation in front of Malamocco

FIG. 7 : Shoal orientation in front of Lido

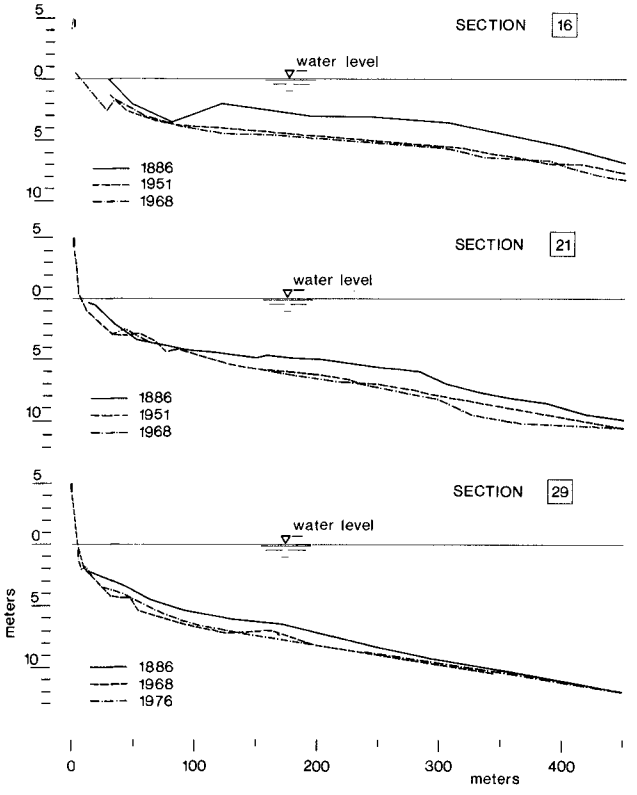

FIG. 8 : Beach profile changes in front of Lido and Pellestrina islands

Shoreline variations are shown in Fig. 9. Shoreline advance is evident close to the updrift jetty of the Lido inlet and reveals a southward net littoral drift. From the beginning of this century the average rate of shoreline advance (updrift side of jetty) was more than 10 m a year; the interrupted littoral drift has been evaluated between 350,000 and 400,000 cubic metres a year. Thus, this area represents a potential borrow site from which large quantities of sand could be dredged. Between the Malamocco and Lido inlets, net littoral drift was probably southward before jetty construction (see Figs. 3 and 6): shoreline variations show that sand tends to accumulate close to both updrift and downdrift jetties, while no variations are logically present in front of those stretches protected by sea-walls. Between Malamocco and Chioggia inlets, sand accumulates again close to both jetties, but this behaviour is less evident due to the great length of the sea-walls.

South of Chioggia inlet, both shoreline advance and orientation of the mouth of the Brenta river clearly show northward net littoral drift. The opposite net littoral drift direction existing at both extremities of Pellestrina leads to the hypothesis that an inversion of net longshore transport probably occurs along this shoreline. If this had also taken place in the past, due to the particular direction of the stretch of coast in question, the consequent sand transport deficit would explain the great "thinning" in time of this area compared with nearby stretches like the Lido.

SHORE DEFENCE PROJECT

In the last century, the Lido has become a very important tourist resort. In order both to arrest bottom erosion and to satisfy the need for improved tourist facilities, artificial beach nourishment represents the proper solution. As mentioned above, the area close to the updrift jetty of the Lido inlet represents a suitable borrow site, and a quantity of sand could be dredged from it sufficient to renourish the whole of the Lido. Moreover, the presence of the two jetties at the ends of the beach would assure good stability with respect to longshore transport: as a consequence, both in order to reduce the initial quantity of fill material and to increase its stability, a perched beach scheme was first considered.

Studies were conducted in a two-dimensional movable bed model to investigate the behaviour of different types of submerged structures (ref. [1]). Scale ratios for crushed

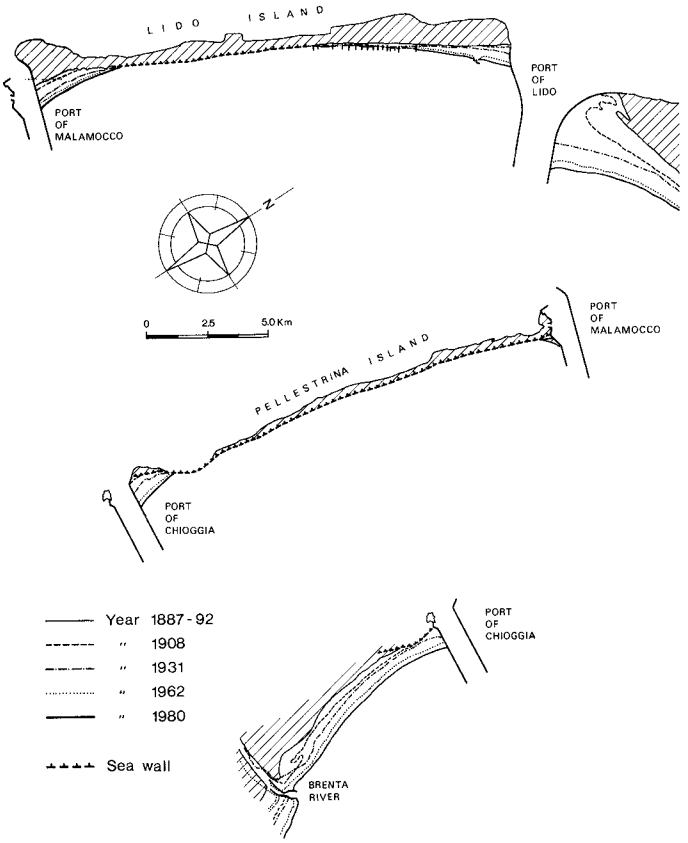

FIG. 9 : Shoreline changes (after Zunica [5])

bakelite as model material were first determined as reported by Noda [4] and applied as follows:

horizontal scale = 1:30
vertical scale = 1:20
median diameter of bakelite = 0.75 mm.

In order to calibrate the model, the initial nearshore slope was changed until an equilibrium profile similar to the natural one was experimentally achieved.

Different configurations of piled sandbags plus a concrete obstacle (see Fig. 10) were tested and summer and winter equilibrium beach profiles were reproduced in the laboratory. These experiments proved that piled sandbags were more stable and allowed less fill material to be transported offshore during winter wave attack. It was also found that the problem of scouring on the landward side of the obstacle could be successfully solved if one or two extra lines of bags were placed on the bottom (Fig. 10; configurations B and D). On a distorted scale, Fig. 11 shows the laboratory behaviour of the submerged structure with and without two extra lines of sandbags (Fig. 10; confs. C and D). The scouring phenomenon on the landward side of the obstacle clearly decreases if configuration D is applied.

Finally, the perched beach solution was tested in prototype conditions. Artificial nourishment stopped by a submerged obstacle was placed at Albarella, a partly eroding tourist beach close to Venice (Fig. 1).

One hundred cubic metres of fill material were placed along a 700-m segment of shoreline and a piled sandbag barrier was placed about 170 m offshore, at an average depth of 1.8 m. A groin of piled sandbags was also placed at the SE extremity to increase the stability of the fill material (Fig. 12). The size of typical filled bags was approx. 2.2 x 1.5 x 0.25 m. They were carefully placed on the bottom by a crane working from a pontoon; divers checked the crane's manoevers.

A comprehensive engineering analysis of the behaviour of the perched beach was carried out. Data evaluated include repetitive beach profiles, bathymetric surveys, visual observation of sea state, wave gage records, aerial photography, and refraction studies.

Unfortunately much of the fill material was removed, especially northwards, during the winter.

Analyses indicate that this behaviour was mainly due to the limited extent of the fill area: as a consequence, the

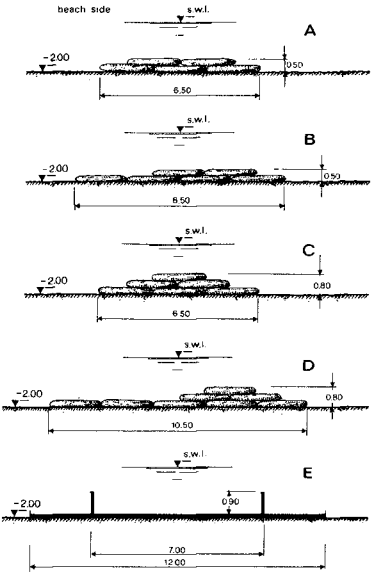

FIG. IO : Submerged structures tested in the model (prototype dimensions)

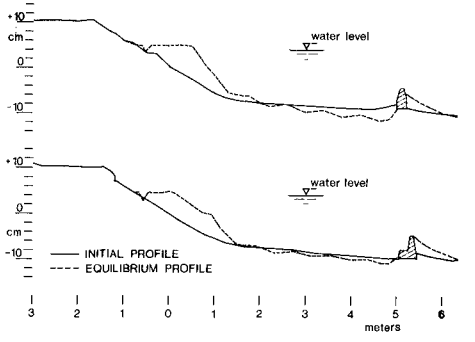

FIG. II : Comparison of equilibrium profiles (confs. C and D)

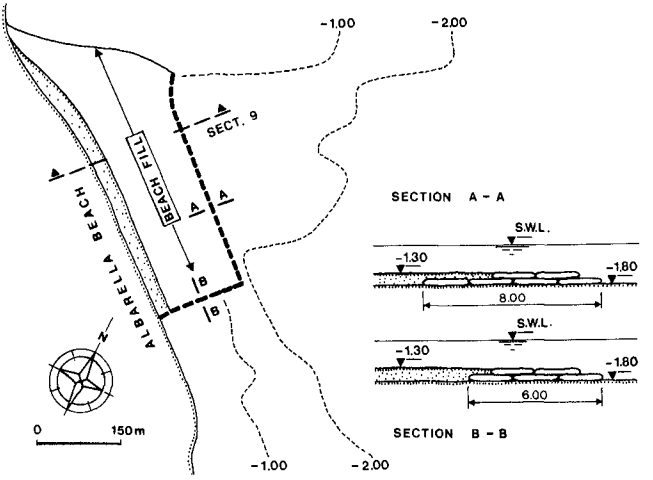

GENERAL MAP OF PROJECT LOCATION

SECTION 9

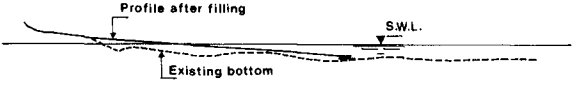

FIG. I2 : General features of perched beach construction

effect of both longshore littoral drift and lateral spreading of artificial sand prevailed, and the submerged obstacle did little to increase fill stability.

However, two years after construction of the artificial beach, the piled sandbags showed satisfactory behaviour: no sinking of the submerged structure was observed and no scouring occurred on the landward side, but sand tended to accumulate on the seaward side.

In any case, the above prototype experiment cannot be considered completely significant for the beaches of Venice: in fact, in front of the Lido, the fill area will be much larger and the long jetties bordering the shoreline will probably reduce the influence of longshore littoral drift. For these reasons, some doubts remain regarding the suitability of using submerged obstacles. Further three-dimensional laboratory studies will be conducted.

SUMMARY AND CONCLUSIONS

After jetty construction, the beaches situated between the three Venice tidal inlets have shown two main types of beach behaviour:

1) deposit of sand close to both updrift and downdrift jetties;
2) large-scale erosion of the bottom, with the rapid removal of offshore shoals.

Artificial beach nourishment is considered to be the proper solution both for the problems of bottom erosion and increased tourist facilities, and a perched beach scheme was tested both in the laboratory and in situ. Further research is still needed to evaluate the opportunity of complementary structures to increase the stability of the fill material.

If a submerged obstacle is to be used, a structure composed of piled sandbags has shown itself to be stable, both in the laboratory and in situ.

ACKNOWLEDGEMENTS

SEDIMENT BYPASSING AT MIXED ENERGY TIDAL INLETS

Duncan M. FitzGerald

ABSTRACT

Inlet sediment bypassing, through the previously recognized mechanisms of stable inlet processes and ebb-tidal delta breaching, has been documented at six mixed energy (tide-dominated) coasts around the world including the coasts of: central South Carolina, Virginia, southern New Jersey, New England, the East Friesian Islands, and the Copper River Delta in Alaska. Regardless of the mechanism, the end product of the bypassing process is the formation of a large bar complex that migrates onshore and attaches to the downdrift inlet shoreline. Thus sediment bypassing is a discontinuous process at mixed energy tidal inlets.

The morphology of the bar complexes is highly variable with widths ranging from 40-300m and lengths from 300 to over 1500m. Generally, the size of the bar complexes increases as inlet size increases and as the rate of longshore sediment transport increases. The frequency of bar welding events at mixed energy inlets varies from 3-7 years. The location where the bars attach to the downdrift beach and length of shoreline that is affected by the bar welding process is dependent on inlet size, orientation of the main ebb channel and wave versus tide dominance of the shoreline.

INTRODUCTION

Tidal inlets represent an interruption in the longshore sediment transport system. The manner in which inlets bypass sand on their ebb-tidal shoals controls the rate and location of sand nourishment to the downdrift barrier island. This paper will discuss how sediment moves past non-structured tidal inlets and the factors that influence this process along mixed energy (tide-dominated) depositional shorelines (Hayes, 1979; Nummedal and Fischer, 1978). Mixed energy coasts, as Hayes (1979) has described, are characterized by short stubby barrier islands, numerous tidal inlets with well developed ebb-tidal deltas, and a marsh and tidal creek system that separates the barriers from the mainland. The central South Carolina coast (Fig. 1) which has a 1.5m mean tidal range and 0.6m average wave height, is an example of such a coast. Other mixed energy (tide-dominated) shorelines that will be discussed in this paper are listed in Table 1. The wave and tidal energies of these coastlines are shown graphically in Figure 2.

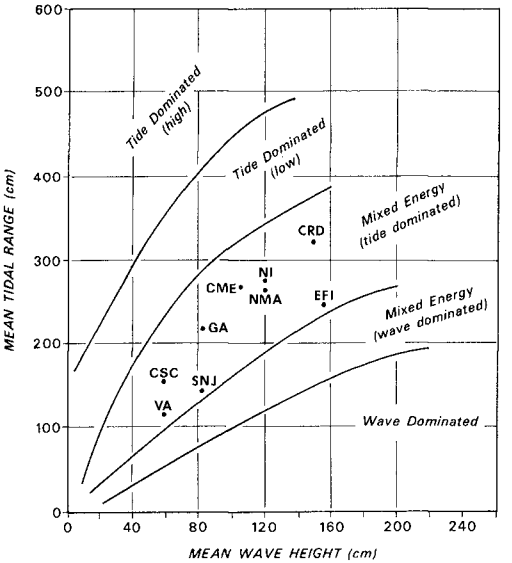

Figure 2. Coastal classification (after Hayes, 1979; Nummedal and Fischer, 1978). Mixed energy (tide-dominated) inlet shorelines where bar complexes weld to beach include: CRD - Copper River Delta, Alaska; EFI - East Friesian Islands, West Germany; NI - New Inlet, Massachusetts; NMA - northern Massachusetts, CME - central Maine; GA - Georgia (note that bar complexes do weld to these inlet shorelines as they do in other mixed energy coasts); CSC - central South Carolina; SNJ - southern New Jersey; VA - Virginia.

INLET SEDIMENT BYPASSING

Inlet sediment bypassing is defined as a process whereby sand is transported from the updrift side of the tidal inlet shoreline to the downdrift side. In a pioneering paper by Bruun and Gerritsen (1959) they described three methods by which sand moves past tidal inlets: 1) through wave induced sand transport along the periphery of the ebb delta (terminal lobe), 2) through the transport of sand in channels by tidal currents, and 3) by the migration of tidal channels and sand bars. They also showed that the type of bypassing process that occurs at an inlet could be determined using the following expression:

$$r = M_{mean}/Q_{max} \qquad (1)$$

where: (r) equals the ratio between the longshore sediment transport rate (M_{mean} in cubic yards per year) and the maximum discharge at the inlet under spring tidal conditions (Q_{max} in cubic yards per second). Inlets with high ratios (r>200-300) bypass sand by wave action along the terminal lobe and inlets with low values (r<10-20) bypass sand by the other two methods.

FitzGerald et al (1978) in a study of central South Carolina tidal inlet processes found that sediment bypassing occurs by the migration of tidal channels and/or sand bars (method #3). They presented two models which detailed the mechanics of sand bypassing at non-migrating inlets: bypassing by stable inlet processes and by ebb-tidal delta breaching (Fig. 3). The r values for these inlets range between 50 and 150 and thus it would seem that Bruun and Gerritsen's (1959) third method of inlet sediment bypassing may not be characteristic of tide-dominated inlets but rather a process that occurs at mixed energy inlets. In later papers by FitzGerald and Hayes (1980) and FitzGerald (1982) the models depicted in Figure 3 were shown to be applicable to other mixed energy tidal inlets (Table 1).

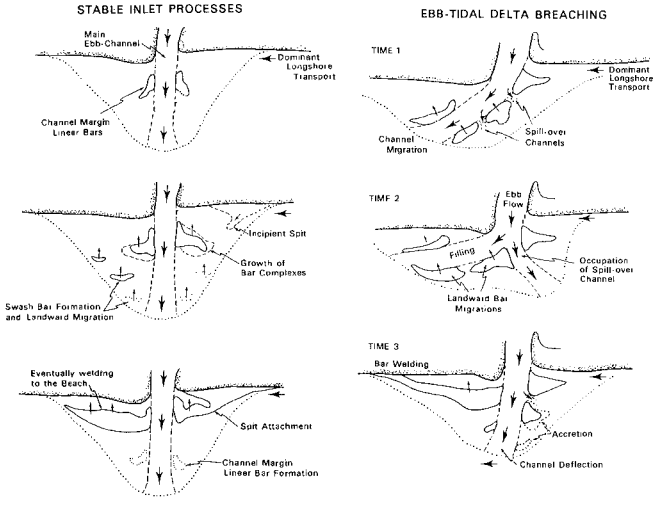

Figure 3. Models for inlet sediment bypassing at mixed energy (tide-dominated) coasts (from FitzGerald et al, 1978). Note that large bar complexes migrate onshore along the downdrift inlet shoreline in both cases.

Stable Inlet Processes

Stable inlets are defined as having a stable inlet throat (non-migrating) and a stable main ebb channel position through the ebb-tidal delta (Fig. 3). The pattern of sand circulation at mixed energy inlets has been described by a number of researchers including Oertel (1972), Hine (1975), FitzGerald et al (1976), Davis and Fox (1980) and Nummedal and Penland (1981).

The bypassing of sand at these inlets occurs through the formation, landward migration and attachment of large bar complexes to the downdrift inlet shoreline. The development of the bar complexes results from the stacking and coalescing of swash bars on the ebb tidal delta platform. Swash bars are wave built accumulations of sand (Hine, 1975) that form in the distal portion of the ebb delta from sand that is transported seaward in the main ebb channel. The swash bars move onshore due to the dominance of landward flow over the swash platform. As illustrated in Figure 4 waves breaking across the terminal lobe create bores of water that retard the ebb-tidal currents but that enhance the flood-tidal currents. Thus, there exists a net landward transport of sand on both sides of the main ebb channel. The net movement of sand onshore has also been attributed to increased wave suspension during the flood cycle than during the ebb cycle (Oertel, 1972; Hubbard et al, 1977; FitzGerald and Levin, 1981).

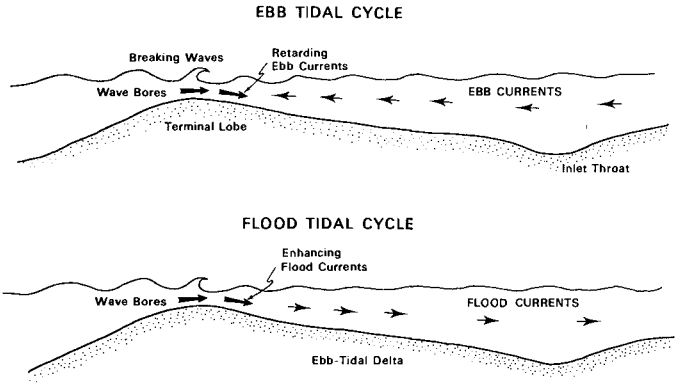

Figure 4. Wave swash model. Wave bores retard ebb tidal currents on the swash platform while they enhance the flood tidal currents. Net landward sediment transport results on both sides of the main ebb channel.

The stacking and coalescing of swash bars results from a decrease in the rate of their onshore migration. As swash bars migrate up the shoreface they gain a greater and greater intertidal exposure and thus wave swash, which causes their onshore movement, operates over an increasingly shorter period of the tidal cycle (Fig. 5). This developmental process is exemplified in the sequential sketches made of Price Inlet, South Carolina from aerial photographs taken between

1973 and 1977 (Fig 6). A photograph taken of the bar complex welding to the downdrift shoreline at Price Inlet in 1977 is shown in Figure 7.

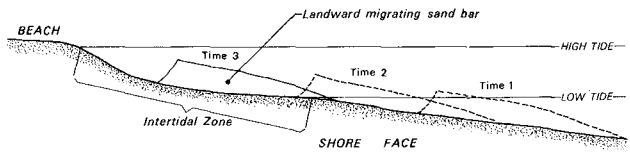

Figure 5. Model of bar migration up the shoreface. Note that the bar attains a greater intertidal exposure as it moves closer to shore. This will cause an increasingly shorter period of the tidal cycle in which wave swash operates. Thus onshore bar migration slows with time resulting in a stacking of swash bars.

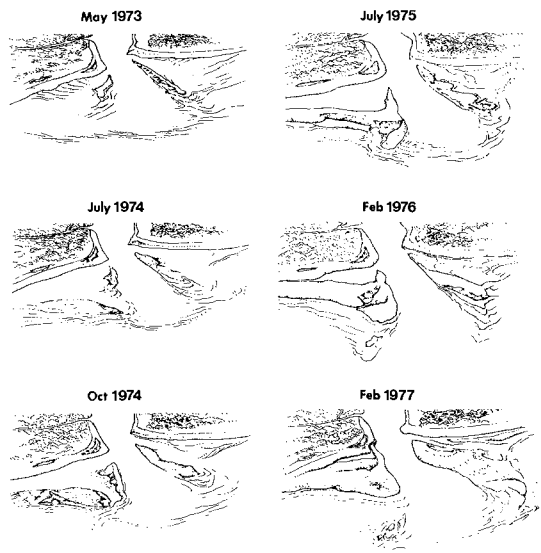

Figure 6. Sequential sketches of Price Inlet, South Carolina, drawn from aerial photographs. Note the bar complex development and its onshore migration.

Figure 7. Oblique aerial photograph of Price Inlet, South Carolina showing a bar welding event. Downdrift shoreline is in the foreground.

Ebb-Tidal Delta Breaching

Inlets that bypass sand through ebb-tidal delta breaching have stable inlet throat positions but their main ebb channels migrate (Fig. 3). The dominant direction of longshore sediment causes preferential deposition on the updrift side of the ebb-tidal delta. This results in a downdrift migration of the main ebb channel such that it will tend to parallel the downdrift inlet shoreline (Bruun and Gerritsen, 1959). This channel configuration produces a circuitous pathway for tidal exchange between the ocean and backbarrier area. Consequently, ebb flow in the main channel will breach a new channel through the ebb delta. This process may occur gradually during a six to twelve month period or it may happen catastropically during a single storm when tidal currents are stronger. A 1963 vertical aerial photograph of Breaches Inlet, South Carolina (Fig. 8) shows the breaching process in a stage of near completion. The old channel position is being abandoned.

Once the breaching process is completed, most of the water entering and leaving the inlet flows through the new channel. Because of the smaller volume of flow in the abandoned channel, scour by tidal currents decreases and the channel is gradually filled with sediment. The processes that cause this infilling include ebb and flood-tidal

currents, wave induced sediment transport on the swash platform and finally the landward migration of swash bars.

Ebb-tidal delta breaching results in the bypassing of a large proportion of the ebb delta sand. Some of this sand fills the abandoned channel while the rest forms a large bar complex similar to the bar complex described in the stable inlet processes section. These bars migrate onshore and attach to the landward beach. An example of a large bar complex that formed after delta breaching at Breaches Inlet, South Carolina is shown in Figure 9.

Figure 8. Vertical aerial photograph of Breaches Inlet, South Carolina showing that a new channel has recently been breached through the ebb-tidal delta. The abandoned channel is being filled with sediment at this time.

Figure 9. Oblique aerial photograph of the downdrift shoreline of Breaches Inlet, South Carolina. The large bar that has partially attached to the Isle of Palms formed after the ebb-tidal delta had been breached.

BAR MORPHOLOGY AND BEHAVIOR

Along mixed energy (tide-dominated) coastlines (Table 1) regardless of how sand bypasses the inlet, whether it be through stable inlet processes or ebb-tidal delta breaching, the end product is the formation of a large bar complex. These bars have been recognized and measured at many tidal inlets too numerous to mention. They are normally aligned parallel to shore and are cuspate in shape. Their lengths and widths are highly variable but an average range would be: length = 300-1500m and width = 40-300m. They are fronted by a .5 to 1.5m high slipface. Bar complexes associated with inlet sediment passing should not be confused with ridge and runnel systems that have been described by Hayes and Boothroyd (1969) and Davis and Fox (1972). They are normally much larger features and add a much greater volume of sand when they weld to the beach than do ridge and runnel systems.

As the bars migrate onshore they gain a larger and larger intertidal exposure. This is due to a combination of the bar's moving up the shore face and the continued welding of swash bars to its seaward side. The rate of landward migration of bar complexes is dependent on tidal range, wave energy and height of the bar with respect to mean low water. Bar migration rates have been measured at Price Inlet, South Carolina to be 110m/yr (FitzGerald, 1976) while in the East Friesian Islands, West Germany they migrate over 400m/yr (Nummedal and Penland, 1981). The greater migration rate in the Friesian Islands compared to that of Price Inlet is due to greater wave energy along the German coast (Fig. 2). Larger waves produce stronger wave swash and thus, a greater onshore sediment transport rate. Tidal range affects bar migration rates by controlling the period of time in which wave swash will be an active process.

When the bar welds to the intertidal beach its cuspate nature usually results in a small ponded water region being formed in front of the bar. The rate of migration of the bar up the beach is slow and highly dependent on the high tide level and wave energy. Migration is the greatest when spring tides coincide with large wave heights. The rate of migration also increases during moderate storms. During these events, although some of the lower bar sands may be eroded and move along shore or offshore, the large waves and storm surge cause increased wave swash and higher portions of the beach to be affected by this process. The final welding of the bar to the beach above mean high water occurs during a large spring tide with high wave activity. It could also happen during a storm.

OCCURRENCE OF BAR COMPLEXES

Remarkably similar shoreline morphologies found among mixed energy (tide-dominated) coasts throughout the world (Table 1), which presumeably is the result of similar ratios between wave and tidal energies (Fig. 2), would suggest that inlets along these shorelines should exhibit similar sand bypassing mechanisms. One indication that this is true is the documentation of landward migrating bar complexes along most of these coastlines. Examples from

five regions around the world will be used to corroborate this.

It has already been demonstrated that inlet sediment bypassing at central South Carolina inlets occurs through the attachment of large bar complexes to the downdrift beaches (Figs. 7 and 9) and therefore, further evidence will not be supplied. However, for a more detailed discussion of sand bypassing along this coast consult FitzGerald et al (1978) and Sexton and Hayes (1982).

On the New England coast, mixed energy barrier systems exist along parts of Cape Cod, Massachusetts, along a 30km stretch of shoreline between Boars Head, New Hampshire and Cape Ann, Massachusetts, and along sections of the central and southern coast of Maine. For the barriers north of Cape Ann northeast storms cause a net southerly longshore transport direction along the coast. Inlets of this region bypass sand by ebb-tidal delta breaching (Parker River Inlet, Fig. 10) and through stable inlet processes (Essex River Inlet, Fig. 11). In Figure 11A note that a bar has recently welded to the high beach and that another bar is developing on the swash platform. Nauset Inlet located on outer Cape Cod transfers sand to the south by both bypassing processes (Fig. 12).

Figure 10. Oblique aerial photograph of Parker River Inlet, Massachusetts. Note that the main ebb channel abuts the downdrift beach and that the bulge in the downdrift shoreline coincides with bar welding.

Along the central Maine coast most of the beaches occur in pockets between protective headlands or they are found at mouths of major river systems. The sand comprising the barriers in the latter setting are believed to have been derived from sediment that was discharging out of the rivers during deglaciation. The sand circulation pattern at one of these localities is illustrated in a diagram of the Popham Beach-Kennebec River system (Fig. 13). FitzGerald and Fink (1981) have described the exchange of sand between the beach and river as follows. Sand is transported seaward in the channel between Wood and Pond Islands by dominant ebb-tidal currents. It is deposited in the shallow water region between the

6 and 12 foot contours. Wave attack coming from a southeasterly direction drives the accumulating sand in an onshore direction toward Fox Island. Swash bars stack at this location, forming a large landward migrating bar complex over 1.5km in length. A bar complex welds to Popham Beach at a frequency of about once every five to seven years. An example of one of these bars is shown in Figure 14. As the bar migrates onshore it extends toward the Kennebec River and thus when it attaches to the shore a large portion of Popham Beach is affected. The sediment gyre is completed by flood and wave-generated currents that transport sand east along the beach and into the Kennebec River channel.

Along the southern New Jersey coast the transfer of sediment past inlets has been reported by Halsey et al (1981) and FitzGerald (1981; 1982). The dominant direction of longshore sediment transport on this coast is to the south. The updrift inlet shorelines are commonly formed by southerly accreting spits. The southerly downdrift inlet shorelines are sites of deposition. At Absecon Inlet and Great Egg Inlet on the New Jersey coast the dominant mechanism for inlet sediment bypassing is through ebb-tidal delta breaching. As a consequence of this process bars measuring between 500-1500m have moved onshore to the downdrift inlet shorelines of Atlantic City Beach and Ocean City Beach, respectively (FitzGerald, 1981; 1982). Two sequential U.S. Coast and Geodetic Survey bathymetric maps of Absecon Inlet illustrate the breaching process (Fig. 15). Note the deflection of the main ebb channel in 1864 and its straight seaward course in 1881. The sand that was bypassed during the delta breaching process moved onshore and had formed a large bar that had partially attached to the Atlantic City shoreline by 1881.

Inlet sediment bypassing on the Virginia coast has been discussed by Rice et al (1976) and FitzGerald (1982). Rice and others have described the historical migration of channels and the formation

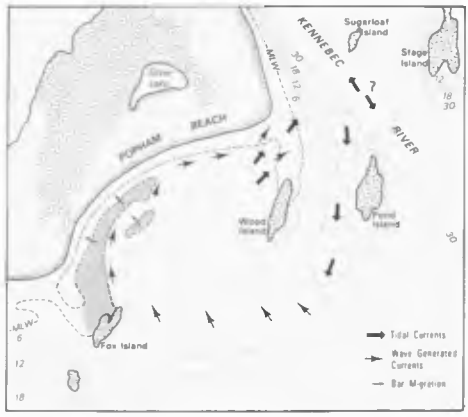

Figure 13. Sand circulation at Popham Beach, Maine (from FitzGerald and Fink, 1981). A sediment gyre is developed by: seaward transport by ebb-tidal currents, onshore transport by wave action, and northeast sand movement by flood-tidal and wave-generated currents. Bar complexes along this shore are over 1km long and weld to the beach every five to seven years.

Figure 14. Oblique aerial photograph of Popham Beach, Maine illustrating a bar welding event (photograph by Fink).

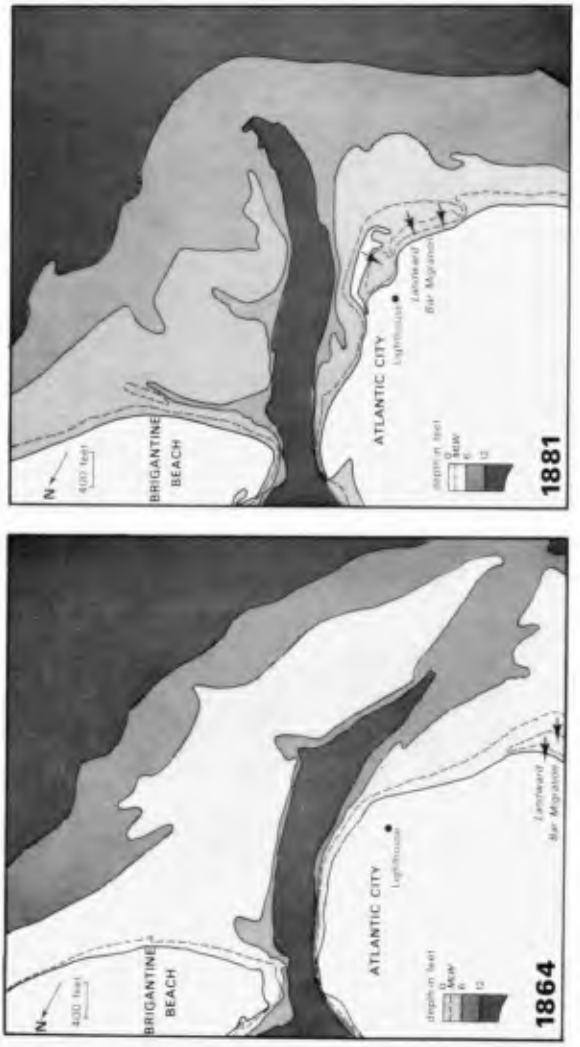

Figure 15. Bathymetric maps of Absecon Inlet, New Jersey redrawn from the 1864 U.S. Army Corps of Engineers survey and the 1881 U.S. Coast and Geodetic Survey coastal chart. The process of ebb-tidal breaching has been responsible for bar formation off northern Atlantic City Beach.

of bar complexes while FitzGerald has documented the landward migration and attachment of these bars to the downdrift inlet shoreline. Oblique aerial photographs (1971) of northern Parramore and Hog Islands illustrate different bar morphologies as they weld to the downdrift inlet shorelines of Wachapreaque and Quinby Inlets, respectively (Fig. 16).

Figure 16. Oblique aerial photographs of a. northern Parramore Island, Virginia and b. northern Hog Island, Virginia (photographs by Sue Halsey).

The East Friesian Islands are a chain of barriers located along the West German North Sea coast (Fig. 17). The pattern of inlet sediment bypassing along these islands has been studied by Nummedal and Penland (1981). Generally, sand is moving in an easterly direction along the coast due to the strong component of easterly wave energy flux. Sand bypassing occurs in the form of migrating swash bars (Nummedal and Penland, 1981). Tracks of bar movement at Norderneyer Seegat over a 31 year period of time are given in Figure 18. The tracks illustrate that bars migrate in a semi-circular pathway along the ebb delta periphery. As they move close to shore they tend to stack, forming large bar complexes which may

extend along the beach up to a 1km or more. Photographs of bar complexes migrating toward the updrift barrier shorelines of Langeoog and Spiekeroog are shown in Figure 19.

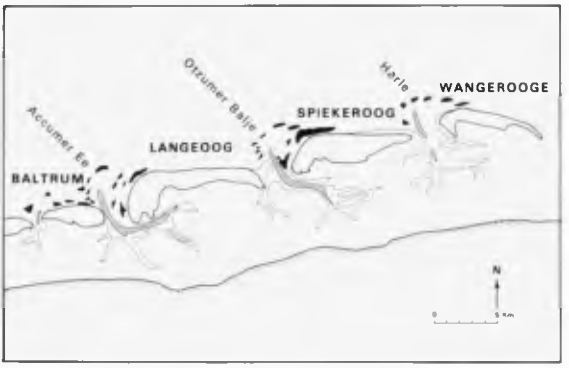

Figure 17. Map of the eastern two thirds of the Friesian Islands, West Germany. Note that the bulbous portion of these barriers coincides with the location where bars are attaching to the beach.

a.

b.

Figure 19. Oblique aerial photographs of a. Langeoog and b. Speikeroog. These bars are over a kilometer in length.

The chain of barriers that fronts the Copper River Delta in the Gulf of Alaska is an unusual type of shoreline morphology to occur along a collision coast. Sediment discharged from the river has undoubtably been responsible for the existence of these islands. As Hayes et al (1976) have described, the barriers of this group have bulbous updrift ends (Fig. 20). They have attributed this barrier morphology to the uplift that occurred to this region in March 1964 and as a result of wave refraction around the ebb-tidal delta which produces a longshore transport reversal along the downdrift inlet shoreline. An oblique aerial of Egg Island, Alaska (Fig. 21) from Hayes et al (1976) reveals that progradation of the updrift end of the barrier may also be a product of the onshore migration of bar complexes.

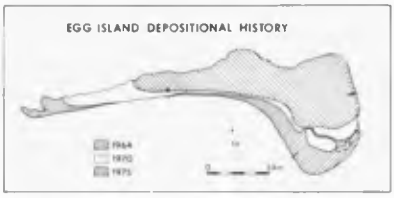

Figure 20. Depositional history of Egg Island, Alaska. The progradation of the eastern end of the island has, in part, resulted from the welding of bar complexes to the beach (from Hayes et al, 1976)

Figure 21. Oblique aerial photograph of Egg Island, Copper River Delta, Alaska. Note the bar (arrow) that is migrating onshore to the downdrift inlet shoreline. (from Hayes et al, 1976)

The Georgia coast fits well into the mixed energy (tide-dominated) coastline classification of Hayes (1979) and Nummedal and Fischer (1978) (Fig. 2). Although it has very similar coastal morphology, including inlet size and barrier island length, compared to that of the East Friesian Island coast, bar complex development does not appear to be an active process at the sounds along this coast. The reason for this is most likely related to the large tidal prisms (10^9-10^{10} m^3, Jarrett, 1976) and small wave energies (wave height = 80 cm, Thompson, 1977) of the Georgia coast. The

large ebb tidal deltas associated with these sounds extend 6-8km offshore where the depth is 5-6m. The low gradient slope (1:1200) created by the ebb deltas results in a gradual attenuation of the wave energy over the swash platform. Consequently, the formation of swash bars and their subsequent landward migration is not a large scale process on the ebb deltas. Oertel (1977) has shown that most of the transfer of sand from delta to the beach occurs very close to the inlet (200m) and affects a very small section of shoreline compared to the size of the inlet (width 1.5-6km) and the ebb tidal deltas. The presence of large landward migrating bar complexes along the East Friesian Island coast undoubtably is due to much greater wave energy of this shoreline compared to that of the Georgia coast.

LOCATION OF BAR WELDING

In the previous section it was shown that inlet sediment bypassing along mixed energy (tide-dominated) coasts occurs through the attachment of bar complexes to the downdrift inlet shoreline. From the time of bar's formation to the time that they weld to the beach can take anywhere from 3 to 7 years. The position where the bars come onshore has particularly important influence on the erosional-depositional patterns along the barrier island. A case has been made by FitzGerald et al (1982) that the location of bar attachment can significantly influence barrier island morphology. Notice in Figure 17 of the East Friesian Islands and Figure 20 of Egg Island that the bulbous portion of the barrier coincides with the site where bar complexes weld to the beach.

The location where the bar complexes move onshore and the length of barrier island shoreline that will be directly affected by the process is controlled by: 1) inlet size, 2) wave versus tide dominance, and 3) channel orientation (Fig. 22). There exists a fairly good correlation between inlet size and the size of the bar complexes that form on the ebb delta. Generally, larger inlets have larger bar complexes. The size of the bar complexes that are formed during the bypassing process is also strongly influenced by the net long shore sediment transport rate. The greater the rate of sand movement along the coast the greater is the volume of sand that must bypass the inlet. This would suggest that inlets that occur along coasts with high longshore sediment transport rates should have relatively large bar complexes. In support of this contention are the bar complexes that are found along the East Friesian Islands. Here the longshore transport rate is about 270,000m^3/yr and the bar complexes are over a kilometer in length (FitzGerald et al, 1982).

The dominance of wave action versus tidal currents at an inlet has been shown by Bruun and Gerritsen (1959) and Hubbard (1977) to control the manner in which sand bypasses the inlet. At wave dominated inlets sand is continuously transferred around the inlet by wave action on subtidal or intertidal bars (Fig. 22). At tide dominated inlets sand is bypassed in packets in the form of bar complexes welding to the beach.

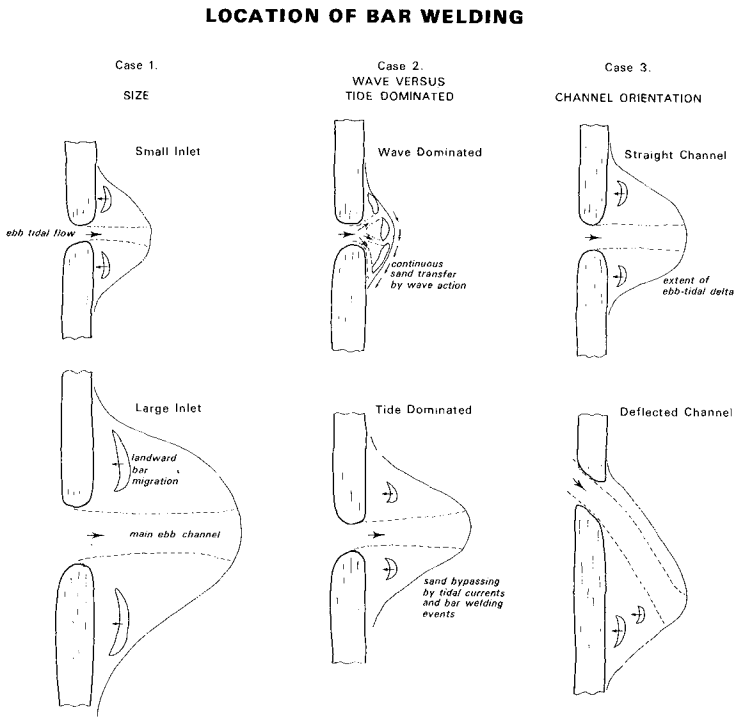

Figure 22. Model of the factors affecting the type of inlet sediment bypassing and where the bar complexes weld to the downdrift shoreline.

The orientation of the main ebb channel controls the distance away from the inlet that bar complexes attach to the shoreline (Fig. 22). If the channel has a straight seaward pathway out of the inlet then the bar complexes will attach to the beach relatively close to the inlet. A deflected channel position, downdrift deflection is most common, will result in bar complexes welding to the beach some distance away from the inlet. The deflected position of the main channel can be caused by preferential addition of sand to one side of the ebb-tidal delta or it may result from backbarrier tidal creeks approaching the inlet mouth at an angle. Prior to being jettied, Murrells Inlet on the South Carolina coast had a deflected main ebb channel due to both of these factors (Fig. 23). Parker River Inlet in Massachusetts (Fig. 10) is another example of an inlet that has a deflected main ebb channel. At this inlet

the dominant southerly longshore transport direction combined with northerly approach of the Parker River produce a main ebb channel that hugs the downdrift barrier. Along the downdrift barrier there is a distinct bulge in the shoreline where bar complexes weld to the beach.

Figure 23. Oblique aerial photograph of Murrels Inlet, South Carolina. Inlet sediment bypassing at this inlet occurred through ebb-tidal delta breaching prior to being jettied.

CONCLUSIONS

1. Two mechanisms, referred to as stable inlet processes and ebb-tidal delta breaching, account for most of the sand bypassing that occurs at mixed energy (tide-dominated) tidal inlets. These processes result in the formation of large bar complexes that migrate landward and attach to the beach. This means that along mixed energy (tide-dominated) coasts sand is not continuously transferred past inlets but rather it is added to the downdrift shoreline in discrete packets. This mode of inlet sediment bypassing comprises a separate class in Bruun and Gerritsen's (1959) scheme of sand bypassing with "r" values between their wave-dominate (r>200-300) and tide-dominated (r<20-30) classes.

2. Bar complexes are much larger features than the ridge and runnel systems of a constructional beach. Their morphology is highly variable with widths ranging from 40 to 300m and lengths from 300 to over 1500m. The size of the bar complexes appears to increase with increasing inlet size and volume of sand that is bypassing the inlet. An exception to this trend is the Georgia coast.

3. The location where the bar complexes move onshore and the length of coastline that experiences progradation directly from this bar welding process is dependent on: 1) inlet size, 2) wave versus tide dominance of the inlet and 3) orientation of the main ebb channel. The last factor is controlled by the configuration of the backbarrier tidal channels, dominant longshore sediment transport rate and direction, and bank stability of the main ebb channel.

ACKNOWLEDGEMENTS

The author's understanding of tidal inlet processes has benefitted greatly from discussions with Miles Hayes, Dag Nummedal, Dennis Hubbard and Shea Penland as well as from the pioneering work of Dr. Per Bruun. Drafting in this paper was done by Eliza McClennan, University Cartographer, Boston University Cartographic Services Laboratory. Some of the photographs and diagrams were supplied by Miles Hayes, Dag Nummedal, Sue Halsey and Ken Fink.

HARBOUR SEDIMENTATION - COMPARISON WITH MODEL

B.D. Pratte, D.H. Willis and J. Ploeg[1]

ABSTRACT

A mobile-bed model study of Pointe Sapin Harbour, in the Gulf of St. Lawrence, resulted in construction of a detached breakwater and sand trap to prevent harbour entrance infilling. The sand trap is filling in at a faster rate than predicted from the model. This is partly due to incomplete modelling of the wave climate; partly to incorrect modelling of distribution of alongshore sand transport; and partly to a complex sand supply at the site. Nevertheless, the sand trap solution is performing well.

POINTE SAPIN HARBOUR

Pointe Sapin Harbour is a small fishing harbour on the Gulf of St. Lawrence, see Figs. 1 and 2. Records show that the first wharf was built there in 1913 on a soft sandstone coast. The situation quickly changed however, for aerial photographs taken between the World Wars clearly show a sandy coast, and what is worse, sedimentation in the harbour berths. Then began the familiar extensions of the structures seaward in an attempt to block the transport of sand into the harbour.

By the mid-1970s it was time for another extension. During northeast storms, two or three times a year, the harbour entrance would completely fill in to above Low Water within 12 hours, see Fig. 3. The danger in this is obvious: vessels were caught in open water by the storm, with no refuge; and they were trapped in the harbour after the storm, unable to see to their traps and nets until the entrance could be dredged.

THE CAUSE

The cause appeared to be alongshore transport of beach sand by waves. As shown in Fig. 1, Pointe Sapin Harbour is sheltered by Prince Edward Island from waves from the southeast. To the northeast however, the available fetch is 225 km and from this direction come storms with significant wave height, H_s, of 3 m and peak period T_p, of 8 s. The result is an overwhelmingly predominant northeast-to-southwest transport of beach sand.

How much transport is a matter for debate. This is due to all the usual reasons, plus:

[1]Hydraulics Laboratory, Division of Mechanical Engineering, National Research Council Canada, Ottawa, Ontario K1A 0R6, Canada.

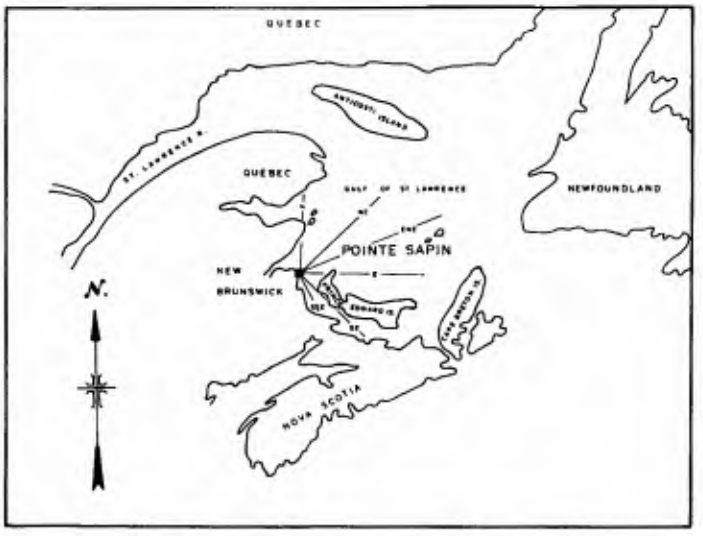

Fig. 1 Location of Pointe Sapin

Fig. 2 Harbour before sand trap construction

1. Sand supply is limited, there being a maximum of only a metre of sand overlying sandstone and till.

2. The profile is very shallow. The surf zone under the northeast storm waves can be as much as 1 km wide.

Estimates of the net northeast-to-southwest transport ranged from 120,000 m^3/yr (Pratte and Willis 1979) to 205,000 m^3/yr (Hydrotechnology Ltd. 1980). The only two fairly firm facts are: that 10,000 to 30,000 m^3 needed to be dredged annually from the harbour entrance; and that it took approximately 12 hours to fill in the entrance during storms.

THE MODEL

A physical model of Pointe Sapin Harbour was built in the Hydraulics Laboratory of the National Research Council Canada to seek engineering solutions to the infilling problem, see Fig. 4. The horizontal scale was 1:100 to fit into the available wave basin. Flume tests indicated a vertical scale of 1:30 (i.e. a distortion of 3:33) and a grain size of 260 μm would correctly model the beach slope under typical northeast storm conditions, wave height 3 m and period 8 s. An almost uniform silica sand of this size was used in a mobile bed 50 mm (1.5 m full scale) thick in the model.

Initial tests reproduced the observed infilling of the harbour entrance by running 90 minutes of the northeast storm waves. Assuming this corresponded to 12 hours full scale, an approximate sedimentological time scale of 8 was determined. However, since bedload transport

Fig. 3 Sand deposition in harbour entrance

Fig. 4 Sand deposition in model harbour entrance

on the model was being used to simulate suspended load transport in real life, it was recognized that the actual sedimentological time scale would be a function of the wave conditions and location in the model.

THE SOLUTION

The most obvious solution would have been to simply live with the existing entrance infilling and to make available a dredge on a permanent basis. This was not acceptable since Public Works' dredges were required to be mobile and serve many harbours. A second obvious solution, but one which we were determined to avoid, was buying a little more time for the harbour by extending into (temporarily) deeper water. Some such schemes were tested on the model of course, but so were more radical schemes attempting to achieve natural sand bypassing.

In the end, we proposed the solution shown in Fig. 5. This consists of a sand trap updrift of the entrance, protected by a detached breakwater. The breakwater not only provided calmer water to encourage settlement of the sand, but also created a sheltered area from which a dredger could clean out the trap and pump the sand across the entrance to the downdrift side of the harbour.

THE FULL-SIZE MODEL

At this point (1979) something rather unusual happened: the full-sized harbour was actually modified exactly as proposed by the model

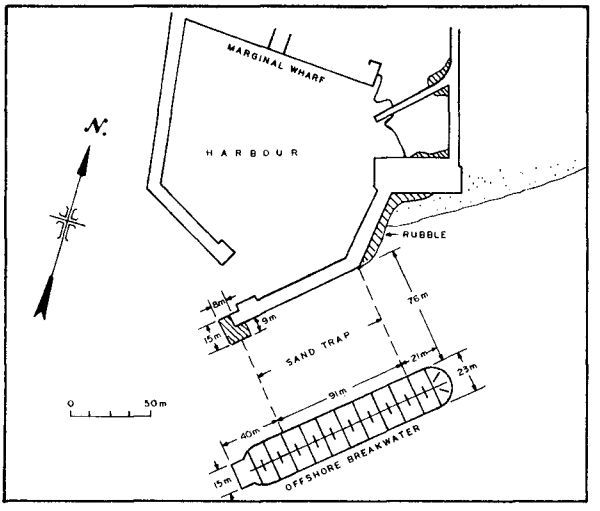

Fig. 5 Sand trap as built

study. This provided a rare opportunity to check the performance of a mobile-bed model.

Beginning in the spring of 1980 just before completion of the offshore breakwater, the National Research Council commissioned a time series of aerial photographs to be taken of the harbour. Five complete sets were obtained: May, August and November 1980, and May and November 1981. The similarities between model and nature are quite striking, as shown in Figs. 6 and 7.

However, the model considerably underestimated the rate at which the sand trap filled.

COMPARISON OF TRANSPORTS

To a certain extent, this underestimate could be explained by "model effect". For example, only the most severe annual storms were simulated on the model, whereas the real harbour was also exposed to every-day waves which contributed sand to the trap. We did attempt to compensate for this in analysing the model results, but perhaps that compensation was not enough.

Another model effect has already been mentioned: the representation of full-size suspended load by model bed load transport. As discussed above, our calculated sedimentological time scale of 8 could at

Fig. 6 Build-up in model sand trap

Fig. 7 Build-up in full-size sand trap

best be correct only within a narrow range of water depths close to the entrance. Expressed another way, the distribution across the beach profile of alongshore transport was incorrectly modelled.

In 1980, the opportunity presented itself to examine these two effects in greater detail. The Small Craft Harbours Directorate of Fisheries and Oceans Canada commissioned a 10-year hourly hindcast of breaking waves for several New Brunswick harbours (Hydrotechnology Ltd., 1980), one of which was Pointe Sapin. Palmer (1980) used this data to produce alongshore current statistics, including distribution, for Pointe Sapin from the method described in Willis (1978). These were converted to alongshore transport statistics, still including offshore distribution, following Willis (1979).

Fig. 8 presents the average annual transport rate distributions for the ten years of data. The approximate position of the breakwater is also shown. What is clear is that the major portion of the transport, 60%, is contained between the breakwater and the shore, in the sand trap in other words. By contrast, considerable transport had been noticed seaward of the breakwater in the model. Clearly, the use of only storm waves as well as the incorrect modelling of transport distribution were factors in the model underestimating trapping rates.

A third factor has come to light just this year, 1982: the complex distribution of sand sources at Pointe Sapin. The Canadian Coastal Sediment Study undertook two field surveys of the area as part of the process of choosing a site for a comprehensive investigation of

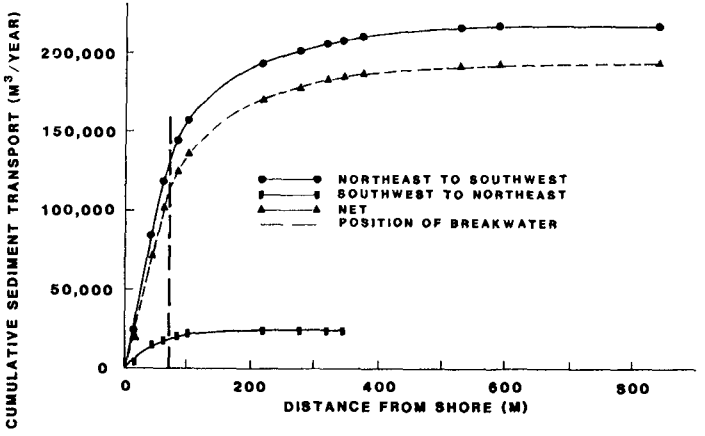

Fig. 8 Cumulative Sediment Transport

nearshore sand transport. These surveys found a predominantly soft sandstone nearshore seabed, with a thin sand layer only within 100 m from shore, see Forbes (1982). Forbes also found a second sand accumulation built up against a sandstone scarp farther offshore but still in relatively shallow water. It seems likely that some of this offshore material finds its way onshore and into the trap during storms.

CONCLUSIONS

Whatever the cause, the result remains that more sand than expected is accumulating in the Pointe Sapin trap, approximately 110,000 m^3/yr as compared to the previous dredging requirement of up to 30,000 m^3/yr. More dredging is required, and plans for a permanent dredging plant are being discussed. Nevertheless the main aim of the scheme has been attained, in that since the construction of the breakwater the harbour has remained open.

Meanwhile, the Canadian Coastal Sediment Study has chosen the Pointe Sapin site for its study of nearshore sand transport in the coming year. Pointe Sapin promises to be the most studied beach in Canada.

MODELING COASTAL CURRENTS AND SEDIMENT TRANSPORT

by

Y. Peter Sheng[1]
and
H. Lee Butler[2]

ABSTRACT

An efficient three-dimensional model of coastal currents and sediment transport has been developed. Simulations of tide- and wind-driven currents and sediment transport in the Mississippi Sound are presented. Results of a laboratory study on settling, resuspension, and deposition of sediment are briefly described. Wave effect on sediment resuspension is also addressed.

INTRODUCTION

Sediment transport in shallow coastal waters is an important coastal engineering problem. Many coastal waters, e.g. the Mississippi Sound, are receiving greater environmental concern due to increasing utilization of their resources, including dredging of shipping channels and disposal of dredged materials. To develop a regional plan of dredged material disposal alternatives, one should not only be concerned with the short-term fate of dredged material at specific sites, but more importantly the subsequent resuspension, transport, and deposition of sediment due to combined current and wave actions, particularly during the sporadic high-energy events.

The various physical processes that can affect the distribution of sediment in a coastal environment are shown in Figure 1. Definitive quantitative understanding of the various processes is crucial to the success of any large-scale model. Recent improvements in numerical estimation of currents and waves and the increased availability of field data and satellite imageries has made it feasible to carry out meaningful large-scale simulation studies of sediment transport events (e.g. Sheng and Lick, 1979; Sheng, 1980). In this paper, we highlight a systematic study of the sediment transport in the shallow coastal waters of the Mississippi Sound and adjacent continental shelf waters in the Gulf of Mexico.

In the following, a three-dimensional hydrodynamic model will be presented first, followed by a realistic simulation of tide- and wind-driven currents in the Mississippi Sound and adjacent shelf waters. Transport, resuspension, and deposition of cohesive sediments are then discussed, followed by a discussion on the bottom boundary layer and wave effect.

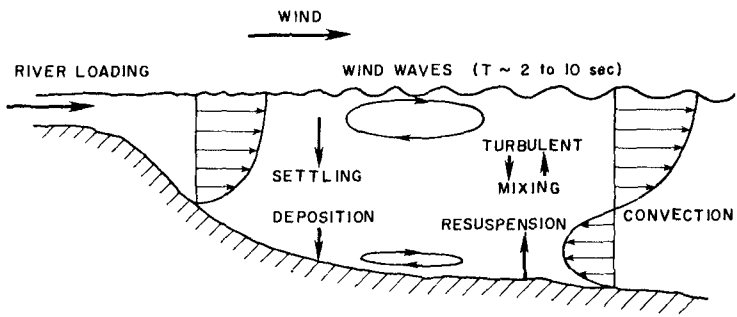

Figure 1. Schematics of Dominant Mechanisms Affecting Sediment Distribution in Shallow Coastal Waters.

A THREE-DIMENSIONAL NUMERICAL MODEL OF COASTAL CURRENTS

In order to study the dynamic response of coastal waters to tides, winds, and meteorological forcing, a three-dimensional, free-surface, time-dependent model is often desired. In addition, stratification and complex topography have to be properly resolved. For relatively long-term application, computational efficiency of the model is extremely important. Traditional three-dimensional, free-surface models (e.g., Leendertse and Liu, 1975) require an exceedingly small time step (associated with the propagation of gravity wave over the distance of a horizontal grid spacing), and hence require extraneous computational costs.

Special features of the present model include (1) a "mode-splitting" procedure which allows efficient computation of the vertical flow structures (internal mode), (2) an efficient ADI scheme for the computation of the vertically-integrated variables (external mode) (3) an implicit scheme for the vertical diffusion terms, (4) a vertically and horizontally stretched coordinate system, and (5) a turbulence parameterization which requires relatively little tuning.

Governing Equations and Boundary Conditions

The basic equations describing the large-scale motion in a large body of water consist of a continuity equation, momentum equations, conservation equations of heat and salinity, and an equation of state. For simplicity here, the last three equations have been combined into an equation for the density. Inherent assumptions are: (1) pressure

distribution is hydrostatic in the vertical direction, (2) Boussinesq approximation is valid, and (3) non-constant eddy viscosities and diffusivities are used to describe the turbulence. The resulting equations are as follows:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \tag{1}$$

$$\frac{\partial u}{\partial t} = -\left(\frac{\partial u^2}{\partial x} + \frac{\partial uv}{\partial y} + \frac{\partial uw}{\partial z}\right) + fv - \frac{1}{\rho_o}\frac{\partial p}{\partial x} + \frac{\partial}{\partial z}\left(A_v \frac{\partial u}{\partial z}\right) + \nabla_H \cdot (A_H \nabla_H u) \tag{2}$$

$$\frac{\partial v}{\partial t} = -\left(\frac{\partial uv}{\partial x} + \frac{\partial v^2}{\partial y} + \frac{\partial vw}{\partial z}\right) - fu - \frac{1}{\rho_o}\frac{\partial p}{\partial y} + \frac{\partial}{\partial z}\left(A_v \frac{\partial v}{\partial z}\right) + \nabla_H \cdot (A_H \nabla_H v) \tag{3}$$

$$\frac{\partial p}{\partial z} = -\rho g \tag{4}$$

$$\frac{\partial \rho}{\partial t} = -\frac{\partial u\rho}{\partial x} + \frac{\partial v\rho}{\partial y} + \frac{\partial w\rho}{\partial z} + \frac{\partial}{\partial z}\left(K_v \frac{\partial \rho}{\partial z}\right) + \nabla_H \cdot (K_H \nabla_H \rho) \tag{5}$$

where x and y are the horizontal coordinates; z is the vertical coordinate pointing vertically upward to form a right-handed coordinate system with x and y; u, v, and w are the three-dimensional velocities in the x, y, and z directions; t is time; f is the Coriolis parameter; g is the gravitational acceleration; p is the pressure; ρ is the density; A_H, and K_H are the horizontal eddy coefficients; A_V and K_V are the vertical eddy coefficients; and

$$\nabla_H \cdot (A_H \nabla_H E) = \frac{\partial}{\partial x}\left(A_H \frac{\partial E}{\partial x}\right) + \frac{\partial}{\partial y}\left(A_H \frac{\partial E}{\partial y}\right) \tag{6}$$

At the free surface, the appropriate boundary conditions are: (a) the wind stress is specified,

$$\rho_o A_v \left(\frac{\partial u}{\partial z}, \frac{\partial v}{\partial z}\right) = (\tau_{sx}, \tau_{sy}) = \rho_a C_{da} (u_w^2 + v_w^2)^{1/2} (u_w, v_w) \tag{7}$$

where τ_{sx} and τ_{sy} are the wind stresses in the x and y directions respectively, ρ_a is the air density, C_{da} is the drag coefficient and (u_w, v_w) are the wind velocities at a certain height above the surface; (b) the kinematic condition is satisfied,

$$w = \frac{\partial \zeta}{\partial t} + u\frac{\partial \zeta}{\partial x} + v\frac{\partial \zeta}{\partial y} \tag{8}$$

where ζ is the elevation of the free surface; (c) the dynamic condition is satisfied, i.e., $p=p_a$, where p_a is the atmospheric pressure; and (d) the density flux, i.e., the heat flux and the salt flux, is specified.

At the bottom, the boundary conditions are: (a) a quadratic stress law is valid:

$$\rho_o A_v \left(\frac{\partial u}{\partial z}, \frac{\partial v}{\partial z}\right) = (\tau_{bx}, \tau_{by}) = \rho C_d \, (u_1^2 + v_1^2)^{1/2} \, (u_1, v_1) \tag{9}$$

where τ_{bx} and τ_{by} are the bottom shear stresses, C_d is the skin-friction coefficient, and (u_1, v_1) are the velocities at the first grid point above the bottom, and (b) heat flux (or temperature) and the salt flux are specified.

Grid Structure

Anticipating appreciable variation of bottom topography in the horizontal direction, the x,y,z coordinate system is vertically-stretched to a x,y,σ coordinate system, such that an equal number of grid points exist in the shallow coastal and the deep offshore areas (Figure 2a). The transformation takes the form:

$$\sigma = \frac{z - \zeta\,(x,y)}{h(x,y) + \zeta(x,y)} = \frac{z-\zeta}{H} \tag{10}$$

where h (x,y) is the local water depth and $\zeta(x,y)$ is the free-surface

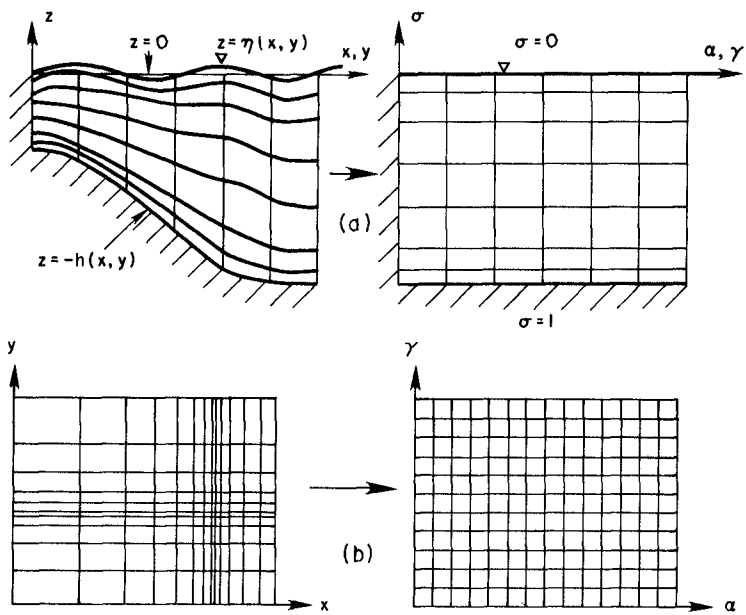

Figure 2(a). Vertical Stretching of the Coordinates,
(b). Horizontal Stretching of the Coordinates.

elevation. Such a transformation leads to (1) the same order of numerical accuracy in the vertical direction at all horizontal locations, and (2) a smooth representation of the bottom topography. Although additional terms are introduced by this transformation, the advantages warrant its application. Models using regular rectangular grid in the vertical direction cannot accurately resolve the shallow coastal area unless a large number of grid points is used in the deeper offshore area. In addition, if the bottom is approximated by a series of rectangular steps, estimate on bottom stress may be distorted and hence is not suitable for studying sediment transport problems.

To better resolve the complex shoreline geometries and bottom features, a non-uniform grid is often required in the x and y directions (Butler and Sheng, 1982). To allow ease in numerical analysis and as shown in Figure 2b, this non-uniform grid (x,y,z) is further mapped into a uniform grid (α,γ,σ):

$$x = a_x + b_x \alpha^{c_x} \quad ; \qquad y = a_y + b_y \gamma^{c_y} \tag{11}$$

The transformed three-dimensional equations of motion in α,γ,σ grid system are rather complex. Detailed equations and boundary conditions in non-dimensional form can be found elsewhere (Sheng, 1981). Staggered numerical grid is used in both the horizontal and vertical directions.

External Mode

In the present study, numerical computation of the vertical flow structures (internal mode), which are governed by slower dynamics, are separated from the computation of the vertically-integrated variables (external mode). This so-called "mode splitting" technique resulted in significant improvement of the numerical efficiency of a three-dimensional hydrodynamic model for Lake Erie (Sheng et al., 1978). It allows for computation of the three-dimensional flow structures with minimal additional cost over computation of the two-dimensional flow with a vertically-integrated model.

The external mode is described by the water level (ζ) and the vertically-integrated mass fluxes $(U,V) \equiv \int_{-1}^{0} (u,v)\, Hd\sigma$. Performing vertical integration of the transformed three-dimensional equations of motion, and rewriting (α,γ) as (x,y) for simplicity, we obtain:

$$\frac{\partial \zeta}{\partial t} + \frac{1}{\mu_x}\frac{\partial U}{\partial x} + \frac{1}{\mu_y}\frac{\partial V}{\partial y} = 0 \tag{12}$$

$$\frac{\partial U}{\partial t} = -\left[\frac{1}{\mu_x}\frac{\partial}{\partial x}\left(\frac{U^2}{H}\right) + \frac{1}{\mu_y}\frac{\partial}{\partial y}\left(\frac{UV}{H}\right) + H(u\omega)_{\sigma=0}\right] - fV - \frac{gH}{\mu_x}\frac{\partial \zeta}{\partial x} + \frac{1}{\rho_o}(\tau_{sx}-\tau_{bx})$$

$$- \frac{1}{\rho_o \mu_x}\int_{-1}^{0}\left[gH\int_{\sigma}^{0}\frac{\partial \rho}{\partial x}\,d\sigma + g\frac{\partial H}{\partial x}\left(\int_{\sigma}^{0}\rho\, d\sigma + \sigma\rho\right)\right]Hd\sigma + (H.D.)_x \tag{13}$$

$$\frac{\partial V}{\partial t} = -\left[\frac{1}{\mu_x}\frac{\partial}{\partial x}\left(\frac{UV}{H}\right) + \frac{1}{\mu_y}\frac{\partial}{\partial y}\left(\frac{V^2}{H}\right) + H(v\omega)_{\sigma=0}\right] + fU - \frac{gH}{\mu_y}\frac{\partial \zeta}{\partial y} + \frac{1}{\rho_o}(\tau_{sy}-\tau_{by})$$

$$-\frac{1}{\rho_o \mu_y}\int_{-1}^{0}\left[gH\int_{\sigma}^{0}\frac{\partial \rho}{\partial y}d\sigma + g\frac{\partial H}{\partial y}\left(\int_{\sigma}^{0}\rho d\sigma + \sigma\rho\right)\right]Hd\sigma + (H.D.)_y \tag{14}$$

where $\mu_x \equiv dx/d\alpha$ and $\mu_y \equiv dy/d\gamma$ are the stretching coefficients, $\omega \equiv d\sigma/dt$ is the vertical velocity in the stretched coordinate, and $(H.D.)_x$ and $(H.D.)_y$ are the horizontal diffusion terms. Notice that the bottom stresses (τ_{bx}, τ_{by}) are determined from the latest three-dimensional velocity profiles available from the internal mode computation, and hence are more accurate than the traditional vertically-integrated models which assume the bottom stress is proportional to the local vertically-integrated velocity or its square.

Treating implicitly all the terms in the continuity equation, while only the time derivatives and the surface slopes in the momentum equations, one can obtain the following finite-difference equations:

$$(1+\phi\lambda_x+\phi\lambda_y)W^{n+1} = [1+(1-\phi)\lambda_x+(1-\phi)\lambda_y]W^{n} + \Delta t D^{n} \tag{15}$$

where

$$\lambda_x = \frac{A\Delta t}{\mu_x \Delta x}\delta_x; \quad \lambda_y = \frac{B\Delta t}{\mu_y \Delta y}\delta_y;$$

$$A = \begin{pmatrix} 0 & 1 & 0 \\ gH & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}; \quad B = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ gH & 0 & 0 \end{pmatrix}; \quad D = \begin{pmatrix} 0 \\ D_x \\ D_y \end{pmatrix}; \quad W = \begin{pmatrix} \zeta \\ u \\ v \end{pmatrix} \tag{16}$$

where $(\Delta x, \Delta y)$ are the spatial grids, Δt is time step, D_x and D_y are terms in Eqs. (13) and (14) excluding the time derivatives and the surface slopes, superscripts n+1 and n indicate present and previous time step of integration, δ_x and δ_y are central difference spatial operators, and ϕ is a weighting factor, $0<\phi\leq 1$. If $\phi=0$, Eq. (15) reduces to a two-step explicit scheme. If $\phi>0$ the resulting schemes are implicit, with $\phi=1/2$ corresponding to the Crank-Nicholson scheme and $\phi=1$ corresponding to the fully implicit scheme. Eq. (15) can be factorized such that solution can be obtained by consecutive tridiagonal matrix inversions in the x-direction and y-direction. Further, we employ a method that solves only two variables during each sweep. This method allows very large time step to be used and has been found to be more stable than the traditional ADI method. Courant number based on the maximum propagation speed of surface gravity wave, $(gH_{max})^{1/2}\Delta t/\Delta x$, may now be as large as 100, compared to the limit of 1 for the explicit method. The maximum step is now governed by the CFL condition based on vertically-averaged advection speed in the system.

In the full three-dimensional model, the external mode computation

is carried out in conjunction with the internal mode computation. Depending on the problem of interest, the internal mode may be computed every so often with a time step equal to or greater than the external time step.

Internal Mode

The internal mode of the flow is described by the vertical flow structures and the density. Defining perturbation velocities as $u' \equiv u - U/H$ and $v' \equiv v - V/H$, the equations for the internal mode are obtained by subtracting the vertically-averaged momentum equations from the three-dimensional equations:

$$\frac{1}{H}\frac{\partial Hu'}{\partial t} = B_x - \frac{D_x}{H} + \frac{1}{H^2}\frac{\partial}{\partial \sigma}\left[A_v \frac{\partial}{\partial \sigma}\left(\frac{Hu'+U}{H}\right)\right] \tag{17}$$

$$\frac{1}{H}\frac{\partial Hv'}{\partial t} = B_y - \frac{D_y}{H} + \frac{1}{H^2}\frac{\partial}{\partial \sigma}\left[A_v \frac{\partial}{\partial \sigma}\left(\frac{Hv'+V}{H}\right)\right] \tag{18}$$

where B_x and B_y represent all terms in the transformed three-dimensional momentum equations except the surface slopes and the vertical diffusion terms, and D_x and D_y are defined in Eq. (16). Notice that the above equations retain the three-dimensionality and hence are different from the model of Nihoul and Ronday (1983) which is actually a superposition of a two-dimensional model and a vertical one-dimensional model.

The above equations do not contain the surface slope terms and hence a large time step may be used in the numerical computation. In the present model, a two-time-level or three-time-level scheme with a vertically implicit scheme is generally used. The bottom friction terms are also treated implicitly to ensure unconditional numerical stability in shallow waters. Care must be taken to ensure that the vertically-integrated perturbation velocities at each horizontal location (i,j) always equal to zero.

Once the equations for (u',v') are solved, and (u,v) obtained, vertical velocity ω and density ρ may be computed. As mentioned before, the internal mode may be computed as often as the external mode or as desired and as dictated by the problems of interest. The numerical time step for the internal mode is limited by the CFL condition based on the advection speed. In the present study, the drag coefficient C_d in the quadratic bottom stress law Eq. (9) is generally specified as a function of the bottom roughness (z_0), the distance above the bottom (z_1), at which (u_1,v_1) is computed, and the stability function of the bottom flow (ϕ_s):

$$C_d = k^2 \left(\ell n \frac{z_1}{z_0} + \phi_s\right)^{-2} \tag{19}$$

where k is the von Karman constant. It can be shown that the stability may increase (unstable case) or decrease (stable case) the drag

coefficient by as much as 40% (Sheng, 1980).

Turbulence Parameterization

A semi-empirical theory of vertical mixing is used in this study. The effect of stratification, as measured by the Richardson number, Ri, on the intensity of vertical turbulent mixing is parameterized by a number of empirical stability functions:

$$A_v = A_{vo}\,\phi_1(Ri);\quad K_v = K_{vo}\,\phi_2(Ri);\quad Ri = \frac{-g}{\rho}\frac{\partial \rho}{\partial z}\left[\left(\frac{\partial u}{\partial z}\right)^2 + \left(\frac{\partial v}{\partial z}\right)^2\right]^{-1/2} \qquad (20)$$

where A_{vo} and K_{vo}, are the eddy coefficients in the absence of any density stratification and ϕ_1 and ϕ_2 are stability functions. Traditionally, these stability functions have been determined empirically by comparing model output with measured data. As shown in Figure 3a, great discrepancy exists among the various empirical forms of the stability functions. In addition, the critical Richardson numbers, at which turbulence is completely damped by buoyancy, given by these formulas are much too high (10) compared to the measured value of 0.25 (Erikson, 1978). To unify this discrepancy, stability functions may be determined from a second-order closure model of turbulence. Assuming a balance between turbulence production and dissipation, i.e., the so-called "super-equilibrium" condition (Donaldson, 1973), we can obtain a simpler set of algebraic relationships between the turbulent correlations and mean flow gradients. As shown in Figure 3b, such a stability function leads to a

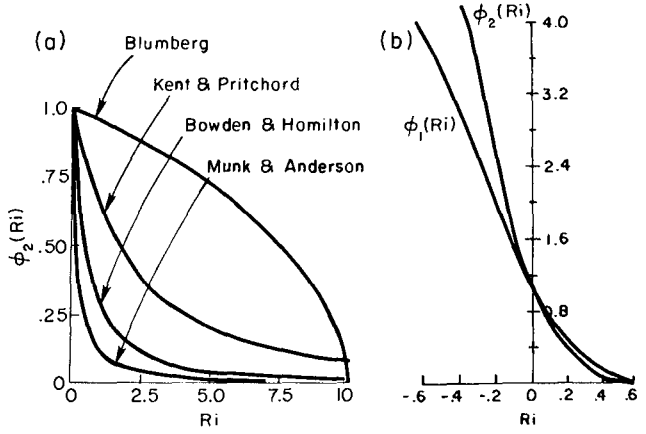

Figure 3. Stability Function vs. Richardson Number:
(a). Empirical Formulations,
(b). "Superequilibrium" Formulation Derived from Reynolds Stress Model.

critical Richardson number much closer to 0.25. In addition, such a formulation allows the definition of finite eddy coefficients in the unstable range (Ri < 0). In order to utilize these relationships, a turbulence length scale which varies with depth and Richardson number has to be prescribed empirically.

SIMULATION OF TIDE- AND WIND DRIVEN CURRENTS

The three-dimensional numerical model of coastal currents has been applied to simulate the tide- and wind-driven currents in the Mississippi Sound and adjacent continental shelf waters of the Gulf of Mexico. As shown in Figure 4, the horizontal grid is composed of 116 grid points in the y-direction and 60 grid points in the x-direction. The smallest grid spacing in the computational domain is on the order of 1 km. The water depth varies from only a few meters within the Mississippi Sound and the Mobile Bay to over 1000 m along the southern boundary.

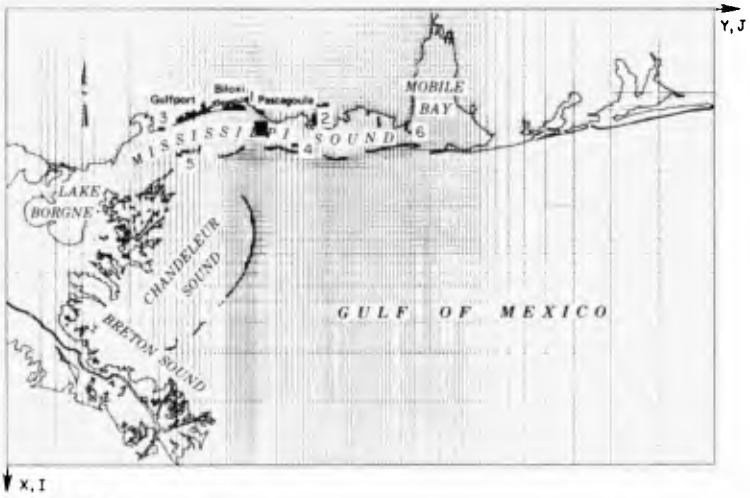

Figure 4. Computational Grid for Mississippi Sound Simulation.

Tides in the Gulf of Mexico

Gulf tides differ from tides in most other places in the world due to the dominance of the diurnal components K1, O1 and P1 collectively over the semi-diurnal components M2 and S2, except along the west Florida coast. Reid and Whitaker (1981) developed a numerical tide model for the Gulf based on the vertically-integrated, linearized tidal equations to portray the barotropic response of the Gulf to tidal forcing. Forcing at ports was also included with an impedance type condition. Detailed data from 20 tidal gages located in open coastal

waters of the Gulf were used for the fine tuning of their model. Their study confirmed that diurnal tide in the Gulf is primarily a co-oscillating tide driven by adjoining Atlantic Ocean and Caribbean Sea.

The water level response for a given tidal constituent is usually expressed in terms of the surface displacement ζ (Schureman, 1941):

$$\zeta = F(t)\, A(\lambda,\Phi) \cos [\, \omega_0 t + \chi - G\,(\lambda,\Phi)] \qquad (21)$$

where λ is the longitude, Φ is the latitude, A is the mean amplitude over 18.6 years and G the Greenwich phase or epoch at given position (λ,Φ), ω_0 is tidal frequency, χ is the astronomical argument, while F is the nodal factor, a slowly varying function of time. Tides at particular stations are characterized by A and G for individual constituents. In our study, A's and G's for 5 constituents (O1, K1, P1, S2 and M2) along the open boundaries of our grid are supplied from Reid and Whitaker's model. Surface displacements at the open boundary stations are determined from a linear combination of those due to the five tidal constituents.

Tidal Currents off the Mississippi Coast

As a first example, tides during 20 Sept. to 25 Sept. 1980 are computed with our three-dimensional model. The surface displacements at four stations (see Figure 4 for locations) within the Mississippi sound are compared with measured data in Figure 5. Notice that the measured data have been filtered such that variations due to short-period oscillations on the order of a few hours or less are not included. Initially, the diurnal tides are predominant. Towards the end of the five-day period, the diurnal tides become somewhat less predominant while the semi-diurnal tides became gradually more apparent. Good agreement is found at all stations.

In this simulation, a relatively large time step of 12 minutes was used for both the external and the internal modes. Seven grid points are used in the vertical direction. A relatively smooth bottom with a roughness length, z_0, of 0.1 cm was assumed. A parabolic length scale, Λ, was assumed in the vertical direction.

The tide-driven horizontal currents at mid-depth are shown in Figure 6 for two stations in the Mississippi Sound. Currents on the order of 30 cm/sec exist at both stations. Again, reasonable agreement is found between data and model results.

The horizontal velocity field at 1 m depth, after 3 days of simulation, is shown in Figure 7. Relatively large currents exist at the various tidal inlets and in the area between the Ship Island and the Chandelier Island. Except in these areas, at this instant of time, bottom shear stress generated by the tidal currents are generally less than 0.8 dyne/cm^2. Hence little sediment resuspension is expected. However, during strong spring tides, such as those during the period of 12 June to 16 June, 1980, relatively stronger currents and bottom shear stresses in excess of 0.8 dyne/cm^2 could prevail within the tidal

inlets and other shallow areas. Resuspension of cohesive sediment in these areas might occur and leave behind the coarser non-cohesive sediment.

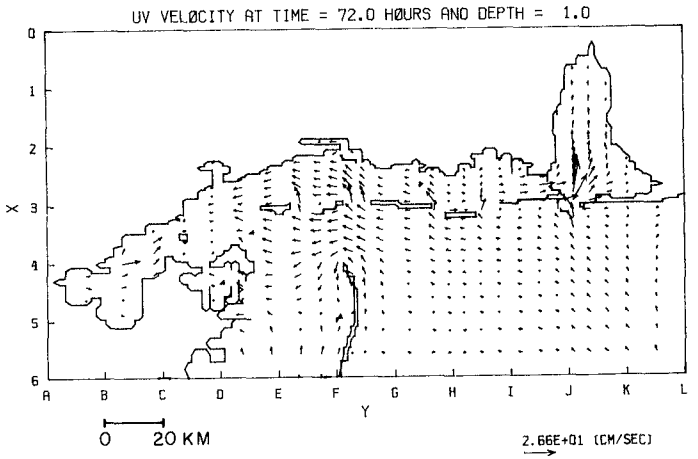

Figure 7. Tide-Driven Horizontal Velocities at 1 m Depth in the Vicinity of the Mississippi Sound at 0 hr, 23 Sept., 1980.

Wind-Driven Currents off the Mississippi Coast

The results presented in the above did not contain any wind-driven effect. During our study, wind data were collected at several meteorological stations surrounding the Mississippi Sound. The wind during the 5-day period was generally quite mild ($\lesssim$ 5 m/sec) from the Southeast. To examine the effect of wind on the currents, we carried out a three-day simulation from 20 Sept., using a uniform wind stress of 1 dyne/cm^2 from the Southeast. The southeasterly wind caused water to pile up within the Mississippi Sound, with a set-up on the order of 12 cm along the Northern shore, and only 6 cm behind the barrier islands.

The influence of wind on the current also depends on the location. Figure 8 shows the along-shore velocity at 2 locations over the 3-day period. At Station 5, off Cat Island, the presence of the wind did not have appreciable effect on the tidal current. At Station 6, within the pass between the Mississippi Sound and the Mobile Bay, the wind caused significant flow from the Mobil Bay into the Sound. This resulted in a significantly larger bottom shear stress which leads to the reduction in the amplitude of the tidal currents.

Wind-driven currents in the Mississippi Sound depend strongly on the wind direction. For example, assuming a uniform wind stress of 1 dyne/cm^2 from the West, our model results showed relatively stronger currents in the along-shore direction (Figure 9). Notice the near-surface and near-bottom velocities differ not only in magnitude but also in direction at some locations. This is partially associated

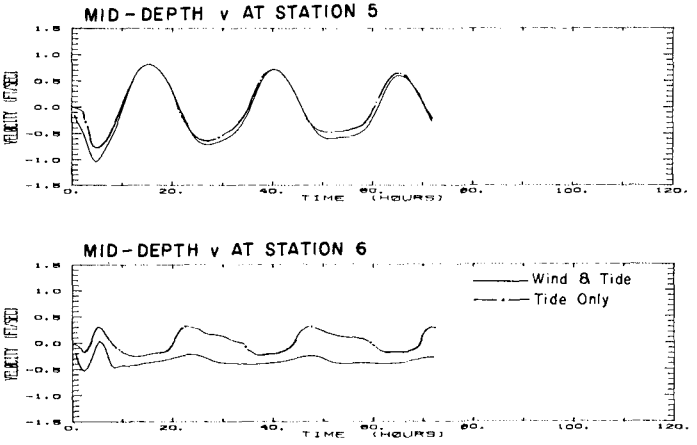

Figure 8. Mid-Depth Along-Shore Velocity at Stations 5 and 6 from 20 Sept. to 23 Sept., 1980. Tide and Wind Forcings.

with the pressure gradient caused by the wind set-up, which is on the order of 20 cm across the Mississippi Sound. According to a laboratory flume study on the erodibility of the Mississippi Sound sediments (Sheng, 1981), it is expected that the bottom shear stress generated by the strong Westerly wind in winter may cause significant resuspension of sediments.

TRANSPORT, RESUSPENSION, AND DEPOSITION OF COHESIVE SEDIMENTS

Transport Modes

The transport of cohesive sediment in the water column can be described by a conservation equation, similar to the heat or salinity equation, for the suspended sediment concentration. An equation similar to Eq. (5) can be written for the sediment concentration C. However, the vertical velocity in the sediment concentration equation should be composed of the sum of the fluid velocity (w) and a settling speed of the particles (w_s). In fresh water, the settling speed of cohesive sediment from a coastal environment shows a relatively flat spectral distribution. As the salinity increases, the sediment particles form aggregates and the spectral distribution becomes much sharper (Fig. 10). In this study, for simplicity, we assume the cohesive sediment in the Mississippi Sound can be described by one single settling speed. The settling speed of bottom sediment samples from the Sound was measured in laboratory, without adding dispersant to the samples, and a median settling speed determined.

The behavior of sediment in the water column depends on the

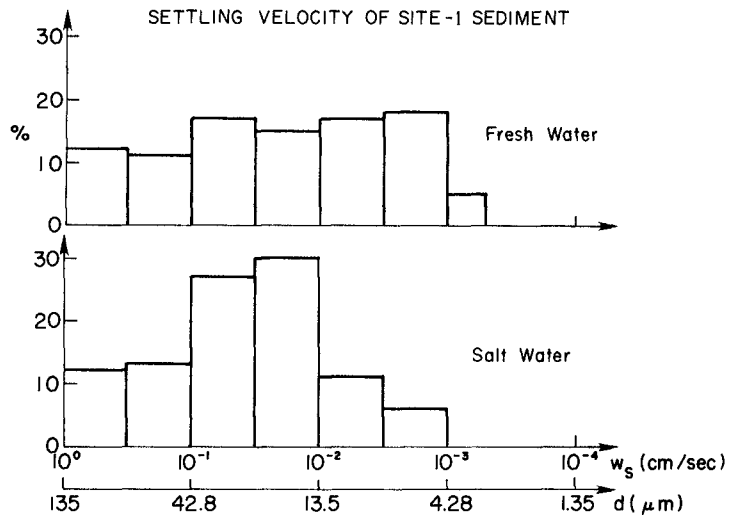

Figure 10. Settling speed of Mississippi Sound Sediments in Fresh and Salt Water.

cohesion and collision of sediment particles. Clay mineralogy and other chemical parameters determine the cohesion of sediment particles. However, in coastal waters where flow is generally turbulent, collision between particles play a more dominant role than cohesion in determining the state of flocculation. The frequency of collision between various groups of particles depends on the turbulent shearing rate on the dissipation scale and differential settling. Although our hydrodynamic model is capable of computing the small-scale turbulent shearing rate, there is insufficient data at this time to allow for precise determination of model coefficients for the flocculation model.

Resuspension and Deposition Modes

Resuspension and deposition of sediment at the sediment-water interface play important roles in the distribution of suspended sediment concentration. In general, resuspension and deposition depend on (1) the hydrodynamic forces generated at the bed within the turbulent bottom boundary layer; (2) bed properties such as sediment composition, water content, bed preparation (settling) time, and organic matter, bacteria, and benthos; and (3) fluid properties including salinity, temperature, and pH of pore water and overlying water.

Effects of dominant parameters (shear stress, water content, bed preparation time, and salinity) on resuspension and deposition were

investigated in a laboratory flume (Sheng 1981; Sheng et al. 1982). To prepare the bed, sediments are introduced into the flume, resuspended, and allowed to settle for a period of 1 to 10 days. A given bottom shear stress is then applied and the time history of sediment concentration recorded until an equilibrium concentration is reached, at which the resuspension balances the deposition. As shown in Figure 11, resuspension as indicated by the equilibrium concentration depends strongly on the applied shear stress. More than an order of magnitude increase in equilibrium concentration can be expected when the shear stress is increased by a factor of 5. Salinity affects the aggregation of particles and hence the erodability of the

(b). Effect of Salinity,
(c). Effect of Time History of the Bed, and
(d). Resuspension Rate as a Function of Time History of the Bed.

bottom sediments. The sediment becomes harder to erode at higher salinity, with most variation occurring between 0 and 15 $^{o}/_{oo}$. The sediment also becomes harder to erode as more time is allowed for the preparation of the bed. From the laboratory flume data, proper bottom boundary conditions for the sediment transport model can be derived in terms of the rate of resuspension (E) and deposition (V_dC) (Sheng, 1981). The bottom boundary condition for the sediment concentration (C) equation can be written as:

$$\text{Net Upward Flux} = w_sC - K_v \frac{\partial C}{\partial z} = E - V_dC \qquad (22)$$

where the deposition velocity $V_d > 0$ while the settling velocity $W_s < 0$.

Sediment Movement in the Mississippi Sound Due to a Westerly Wind

As an example to illustrate the important role of resuspension and deposition, we performed a 1-day simulation of sediment movement due to a Westerly wind.

Initially, the background concentration is assumed to be zero everywhere except within a square area (shown in Figure 12) where the concentration is 500 mg/l (newly introduced sediment). The sediment concentration is then computed with three different bottom boundary conditions: (1) zero net flux and zero settling speed, (2) with deposition and resuspension, but no resuspension of old sediment (vs. the newly introduced sediment) is allowed, and (3) deposition and resuspension allowed at all locations. For (2) and (3), a settling

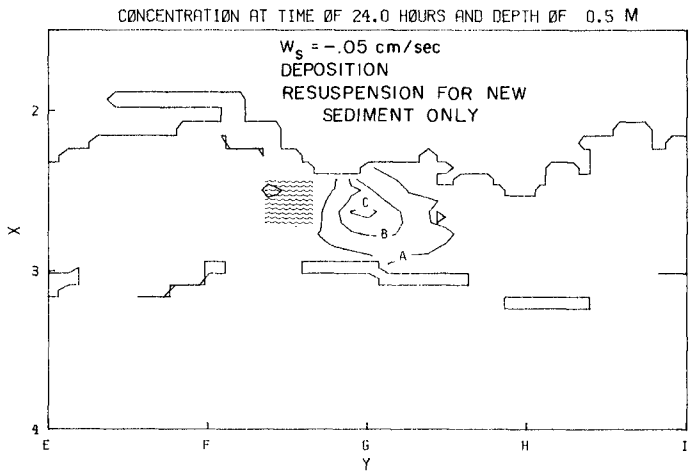

Figure 13. Same as Figure 12 except that w_s = -0.05 cm/sec; Deposition but no Resuspension for Old Sediment.

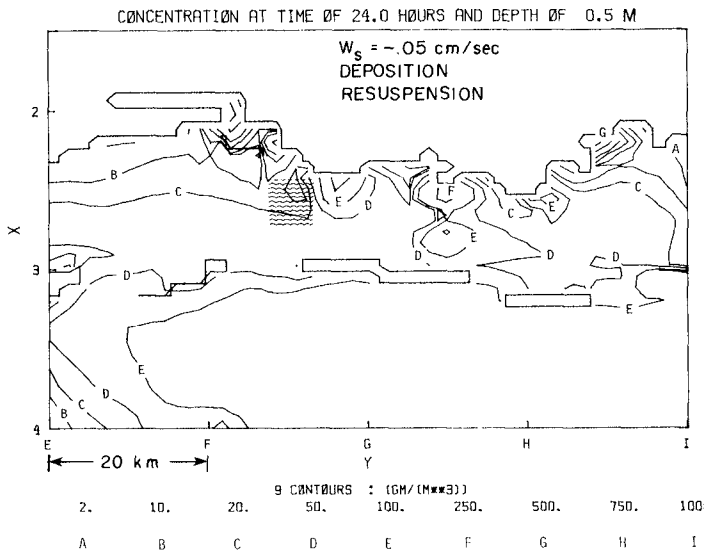

Figure 14. Same as Figure 12 except that w_s = -0.05 cm/sec; Deposition and Resuspension.

speed of 0.05 cm/sec was used. The results at 0.5 m depth at the end of one-day simulation are shown in Figures 12, 13 and 14. It is clear that resuspension of sediment plays a dominant role in redistributing sediment. The difference in results for (2) and (3) reflects the importance of quantifying the time history of bottom sediments, which strongly affects the erodability as shown in Fig. 11.

BOTTOM BOUNDARY LAYER AND WAVE EFFECT ON SEDIMENT RESUSPENSION

The wave climate during the September period of 1980 was studied by means of a spectral wave hindcasting model modified for shallow water. The blockage effect of the barrier islands allows us to assume that most of the wave energy in the Mississippi Sound was derived from the wind fetch within the Sound. From 20 to 25 Sept., wind was generally from the Southeast at about 5 m/sec. Results of the wave model indicate wave height generally under 30 cm and wave period under 3 sec. At a station off Gulfport (Station 17), the wave-induced bottom stress was the highest among all stations and on the order of 5 dyne/cm^2 during the first day (Fig. 15a). However, wave-induced stress over most of the sound was generally not very strong, as can be seen in Fig. 15b, the bottom stress at a station off the Biloxi channel (Station 10) was generally less than 1.3 dyne/cm^2. These findings are consistent with the sediment concentration data collected during this time period, which showed a slight initial increase in concentration followed by primarily depositional events. We also found that linear wave theory and empirical bottom stress formula tend to overestimate the wave-induced bottom stress within an oscillatory boundary layer.

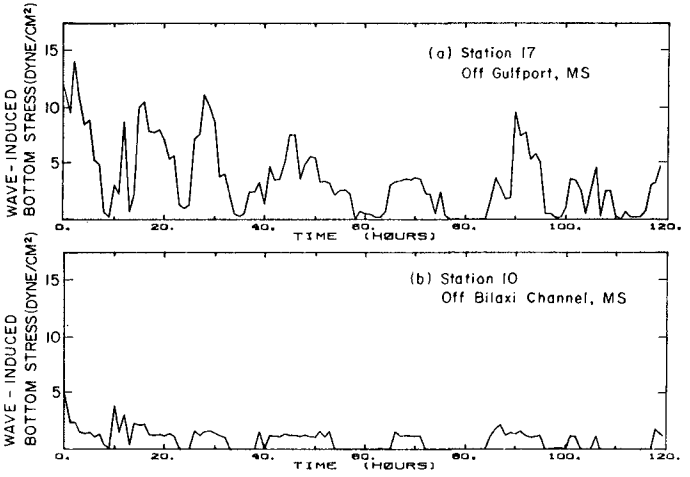

Figure 15. Wave-Induced Bottom Stress at two Locations in the Mississippi Sound from 20 to 25 Sept., 1980.
(a). Station 17 off Gulfport, MS.
(b). Station 10 off Biloxi Channel.

Oetailed turbulent dynamics of the bottom bounday layer under a pure wave (Sheng, 1982) and current-wave interaction (Sheng and Lewellen, 1982) have also been studied using a Reynolds stress model. Contrary to the general belief, the presence of the wave was found to not always enhance the current-induced stress.

CONCLUSIONS AND RECOMMENOATIONS

An efficient three-dimensional numerical model of coastal currents has been developed and is operational. The model is suitable for detailed short-term simulations as well as longer-term simulations. Currents in Mississippi Sound and adjacent offshore waters have been computed with the three-dimensional model. Results obtained during a five-day period in September 1980 agree very well with the measured data. Large spatial and temporal variation of bottom shear stresses exist within the area. Rate of resuspension of the Mississippi Sound sediments (primarily Smectite) has been determined experimentally and was found to increase with increasing shear stress, decreasing salinity, and shorter time-history of the bottom sediment. Studies are needed to elucidate the effect of turbulence on flocculation, the current-wave interaction within the bottom boundary layer, and the inclusion of sediment time-history as a parameter in the mathematical model.

MODELLING OF SEA-BED EVOLUTION UNDER WAVES ACTION

by

Y. COEFFE (1) and PH. PECHON (2)

ABSTRACT

This paper presents a numerical model computing sea-bed evolution due to longshore currents, which has been developed at the Laboratoire National d'Hydraulique.

This model has been applied to a schematic semi-circular bay. The computation of sand sea-bed modifications reveals two main tendencies : a marked accretion in the "up-stream" zone of the bay and a marked erosion in the "down-stream" zone of the bay, as far as longshore currents are concerned.

1. INTRODUCTION

The action of waves is the predominant factor of sea-bed changes in the surf zone. The currents induced by breaking waves can be rather important, and their action is reinforced by the turbulent effects which appear in the breaking zone.

The model presented is able to predict longshore currents and sand transport field, and can deduce sea-bed evolutions under wave action for any bottom shape.

A mathematical model to compute longshore currents has been available at the Laboratoire National d'Hydraulique since 1977. In the numerical solution, energy transfers are simulated by introducing additional terms, derived from the Longuet-Higgins formulation, in the long wave equations.

(1) Head of the Maritime Hydraulics Division, Laboratoire National d'Hydraulique, E.D.F, Chatou, France.
(2) Research engineer, Laboratoire National d'Hydraulique, E.D.F, Chatou, France

This model has been applied to the simplified case of a semi-circular bay, the refraction of a monochromatic wave being computed with an other model, to estimate wave height, crest incidence and shoaling number in the domain. Recently, the introduction of a solid transport formula into the numerical model made it possible to estimate changes of the sea-bottom resulting from the longshore currents. Bijker formula has been selected because it takes into account the coupling of the average current over a vertical line and the wave orbital velocity. It is used to calculate bed and suspended load transport.

Once the quantities of transported materials are known, erosion and accretion can be calculated. The interaction between the modification of the sea-bed and wave induced currents is taken into account by adjusting the wave propagation after each significant change of the bathymetry and a new longshore current field is then deduced.

The modelling principles are summed up on figure 1. The numerical model includes at first a wave propagation model, then a current model and a bed evolution model ; this paper presents each part and the application to the schematic bay.

2. WAVES PROPAGATION MODEL

A classical pure refraction model is used, assuming linear wave theory, neglecting diffraction effects and using Snell's law.

The breaking of waves is considered. The method used here is to follow a wave orthogonal and to test in each point if breaking is occuring or not. The Battjes' criterion is used : the wave breaks at a place of depth d if the wave height H verifies

$$H \geqslant jd$$

where j is an experimental coefficient, function of bottom slope and local wave steepness, which determines the wave breaking evolution.

So, wave height incidence and shoaling number are estimated over the entire domain of interest.

This model has been applied to the schematic semi-circular bay, the characteristics of which being (fig 2) :

- radius of the bay = 260 m
- off-shore depth = 7,5 m

The off-shore wave conditions considered are :

- monochromatic wave
- height : 3 m
- period : 10s

The refraction diagram is shown on figure 3.

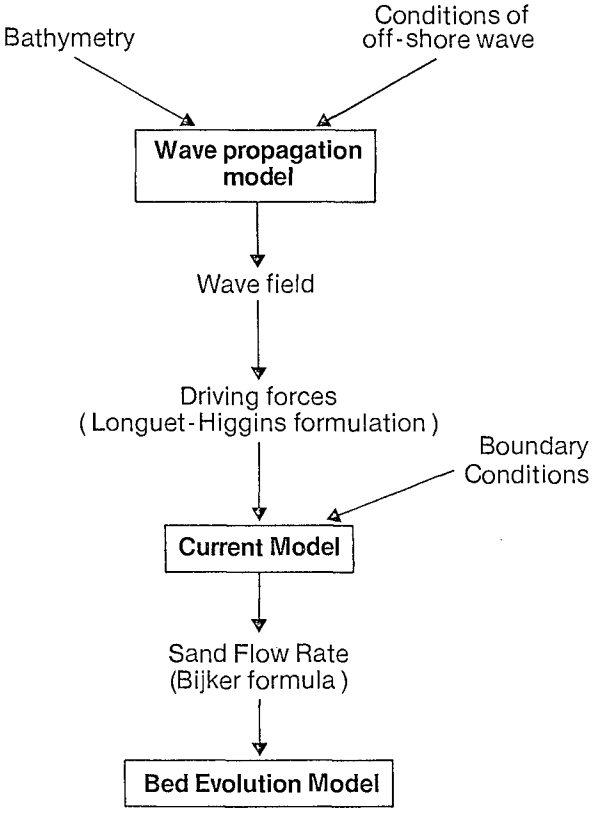

Fig.1 Modelling Principles

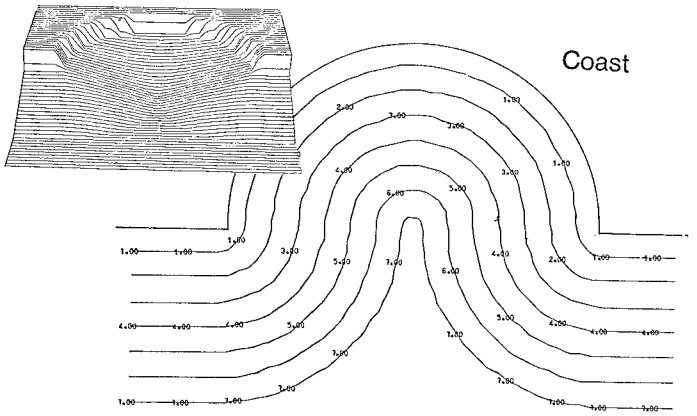

Fig.2 Initial Bathymetry of the Bay

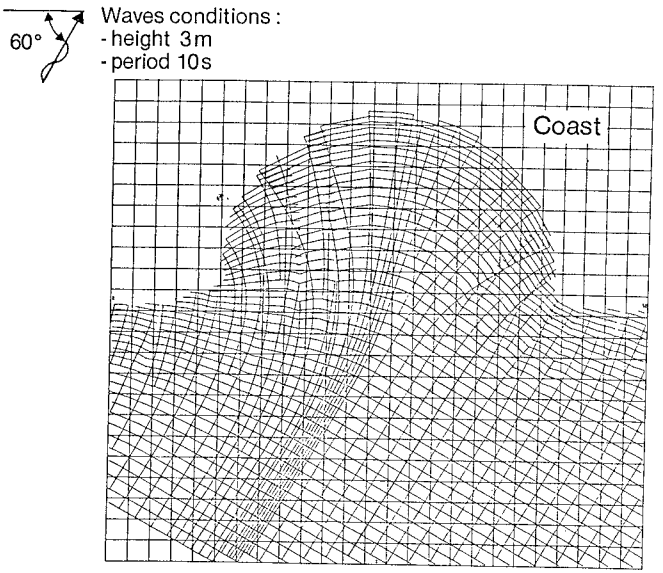

Fig.3 Refracted Waves Diagram

3. LONGSHORE CURRENT MODEL

3.1. Description

The assumptions of the longshore current model are :

- incompressible fluid
- linear Stokes waves
- the vertical component of the current is neglected
- for the calculation of waves currents, the variations of sea surface elevation are neglected compared to the total depth.
- the mass current is assumed to be constant over the depth
- wind action is neglected

With these assumptions, the Navier-Stokes equations can be integrated over the total depth and time averaged over a wave period. That leads to long waves equations in which appears a radiation stress tensor $\bar{S}$, representing the extra terms coming from averaging non linear terms involving velocities

The wave driving forces can be defined as follows :

$$\vec{\tau} = -\frac{1}{\rho} \operatorname{div} \bar{S}$$

Using Longuet-Higgins formulation, the tensor $\bar{S}$ is written :

$$\bar{S} = E \begin{bmatrix} (2n - \frac{1}{2}) \cos^2\alpha + (n - \frac{1}{2}) \sin^2\alpha & n \sin\alpha \cos\alpha \\ n \sin\alpha \cos\alpha & (2n - \frac{1}{2}) \sin^2\alpha + (n - \frac{1}{2}) \cos^2\alpha \end{bmatrix}$$

where $E = \frac{1}{8} \rho g H^2$ is the wave energy

n is he shoaling number

α is the wave incidence

The bottom friction has been assumed proportional to the squared velocity, taking into account the orbital velocity in the following form :

$$\vec{\tau}_b = -\frac{\rho g}{C_s^2} \vec{u} \, \| \vec{u} + \vec{u}_{orb} \|$$

where $\vec{u}$ = mean velocity

$$\vec{u}_{orb} = \frac{2H}{T} \frac{1}{\operatorname{sh}\left(2\pi \frac{d}{CT}\right)} \begin{bmatrix} \cos\alpha \\ \sin\alpha \end{bmatrix}$$

3.2. Application

The longshore current model has been applied to the semi-circular bay. Using the propagation model results, driving stresses are calculated. Then the wave height field is smoothed (fig. 4) to get a more regular radiation stress tensor. Then induced currents are computed.

The boundary conditions along the left side of the grid are coming from the application of the model to a rectilinear shore, with a bathymetry similar to the incoming part of the semi-circular bay. For this last case, the water flow obtained at the left boundary is transfered at the right one in order to get the stationary solution of an infinite shore.

At the right open boundary, a free exit of the current is imposed.

The obtained velocity pattern is shown on figure 5. Strong velocities appear in the breaking zone and an eddy takes place in the right part of the bay. The maximum velocities reach about 1,4 m/s, in the rectilinear part.

4. SEDIMENT TRANSPORT CALCULATION

4.1. Transport formula

A sediment transport formula was added to the current model. The chosen transport law is Bijker's formula which takes into account the coupling of the averaged current and the wave orbital velocity. The mean bed shear resulting of the combination of waves and longshore current is hold responsible for the stirring up of the material. Once the material is stirred up, it is transported by the normal current. For the bed load part this transport law is written as :

$$T_b = 5D\ (\mu\tau c/\rho)1/2\ \ e^{-0,27\ \frac{\Delta D\rho g}{\mu\ \tau_r}}$$

Δ : relative apparent density

D : grain size

μ : ripple coefficient

τ_c : bed shear due to mean current

τ_r : bed shear due to mean current and waves

Tb : bed load transport.

The suspended load is evaluated by assuming a logarithmic velocity distribution

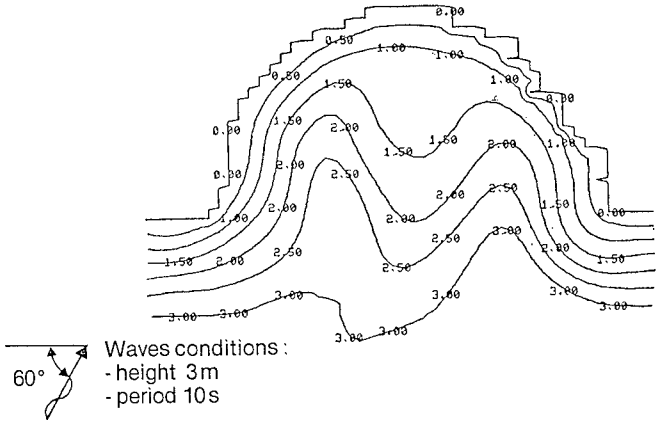

Fig.4 Contour-lines of Smoothed Wave Height

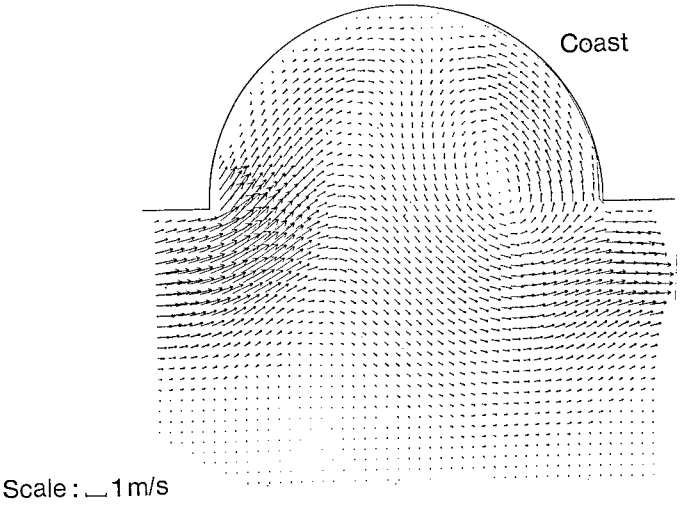

Fig.5 Velocity Field

The concentration c(z) is written as :

$$\frac{C(z)}{Ca} = \left[\frac{h - z}{z} \times \frac{a}{h - a}\right]^Z \quad \text{in which } Z = W/Kv*$$

Where W = fall velocity of the particles

K = Karman constant

v* = stress velocity due to wave and mean current

C_a = concentration of suspended load immediately above the bed

4.2. Application

The transport flow rate resulting from the velocity field in the bay is presented on figure 6, for a 0,5 mm grain size.

The total sand transport going through a section of the left rectilinear shore near the bay has been compared with the CERC formula and the formula of Larras and Bonnefille :

- formula of the CERC :

$$Q = 6{,}5\ 10^{-2}\ H^{5/2} \cos^{1/4} \alpha \sin 2\alpha$$

- formula of Larras et Bonnefille :

$$Q = K(H/L, D)\ \frac{H^3}{T} \sin \frac{7\alpha}{4}$$

where H is the wave height, α is the wave incidence, T is the period and D is the sand diameter.

The transport flow evaluated with the first formula is equal to 0,8 m^3/s whereas the second one gives 0,1 m^3/s. The difference between these two valuations comes from the difficuties of mesuring sand transport flow in the surf zone. The computation gives for this section (fig 7) Q = 0,3 m^3/s which is in the range of these formulae.

5. EVOLUTION OF THE SEA-BOTTOM

5.1. Description of the method

Continuity equation applied to the sediment transport gives the bed evolution :

$$\frac{\partial Z_F}{\partial t} + \text{div } \vec{T} = 0$$

where $\vec{T}$ is the sediment transport flow rate, and Z_F the bed level.

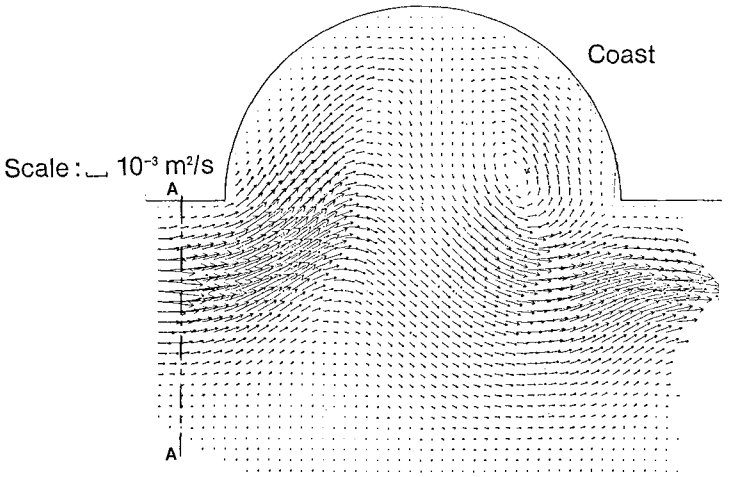

Fig.6 Sediment transport field

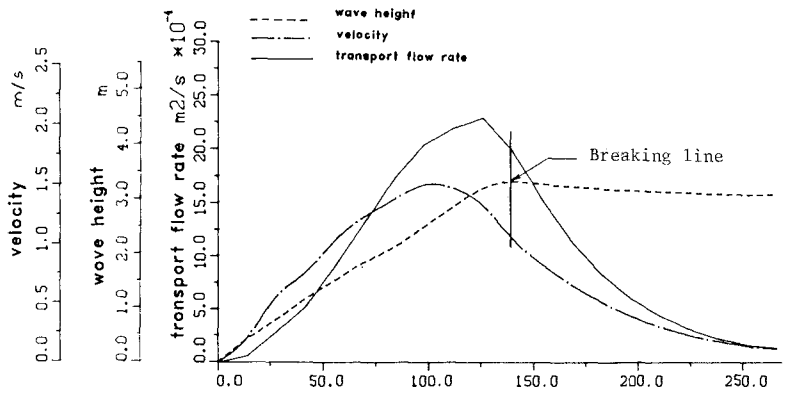

Fig.7 Velocity,wave height and transport distribution along A–A section

The bed evolution modifies progressively the waves propagation and the current field. It is very important to take this coupling into account, and to update the longshore currents according to new water depth. However the sedimentological time scale being much greater than the velocity time scale, the sea-bottom and water flow changes are calculated by doing two loops as shown on the following diagram :

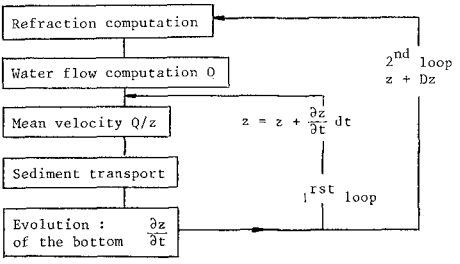

Fig.8 Modelling principles of bed evolution calculation

The first loop takes into account the interaction of the velocity field and the sea-bottom evolution for a constant water flow field, by the following way :

- sand transport calculation using Bijker's formula
- calculation of $\frac{\partial Z_F}{\partial t} = -\operatorname{div} \vec{T}$
- modification of sea-bottom $\frac{\partial Z_F}{\partial t}$ dt. The time step dt is chosen so that the water depth is changed of 5 % at most in the domain.
- adjustement of the velocity, considering a constant water flow rate and return to the first step.

When the modifications of the bathymetry are big enough, the waves characteristics in the domain are re-evaluated. The new driving forces and the induced longshore currents are computed again with the wave propagation model.

5.2. Results

In the case of the semi-circular bay, the comparison between the initial topography and the topography after 100 hours storms reveals the main following tendencies (fig 9) :

- large accretion in the left side of the bay due to incoming littoral transport
- large erosion of the beach in the right side of the bay due to reconstitution of littoral transport
- erosion of the area close to the left cape at the entrance of the bay and accretion just behind the cape
- general filling of the beach of the bay.

These changes agree with some natural tendencies but the obtained values need to be checked over real cases or physical model experiments.

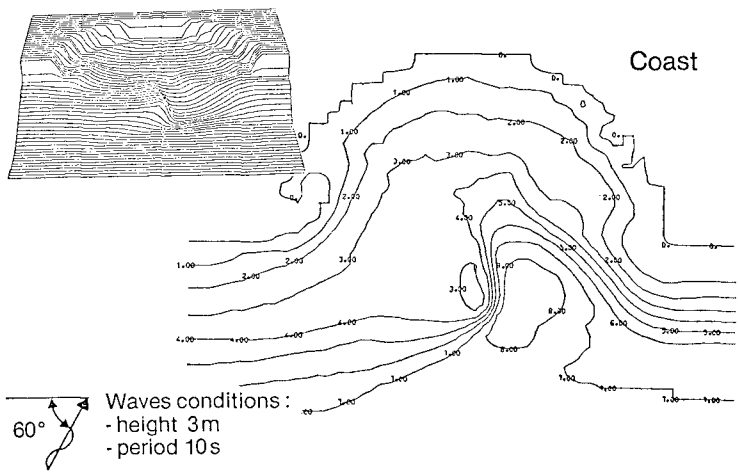

Fig.9 Bathymetry after 100 hours storm

6. CONCLUSION

The first results obtained by the mathematical model show that the modelling of sea bed evolution under the action of waves is no more a domain restricted to physical models.

The presented bidimensional model is able to compute longshore currents induced by breaking waves and to simulate bathymetry modifications, considering the interaction between sea-bed changes and velocity field. The application to a schematic semi-circular bay has given reasonnable results in agreement with known natural tendancies. However the developement of this model requires more accurate comparisons with scale model results or real cases. This work will be planned in the near future.

7. AKNOWLEDGEMENT

This study has been done as part of a joint research programm of EDF-LNH and the "Ministère de la mer".

DESIGN AND CALIBRATION OF FALSE BAY SEDIMENT MODEL

by

J S Schoonees* and J P Möller**

1. INTRODUCTION

False Bay is situated near Cape Town in the Republic of South Africa. The National Research Institute for Oceanology (NRIO) of the Council for Scientific and Industrial Research (CSIR) was commissioned to undertake studies on a recreational scheme in the Strandfontein area of False Bay. A tidal pool was built as phase 1 of this project. Phase 2 is a bathing improvement scheme (see Figures 1 and 2).

The aim of the bathing improvement scheme which consists of a number of structures, is to provide bathing facilities for the Mitchell's Plain community. At present the major part of the coast is rather unsafe for bathing mainly because of very steep beach profiles. Conditions were laid down to ensure safe bathing, e.g. a uniform flat beach slope and the absence of rock and rip currents. Further requirements were that a safe bathing beach must be formed soon after completion of the structures and that the adjacent coastline must not be adversely affected in the long term. This paper deals with the design and calibration of a sediment model which was chosen to evaluate and optimise the design of the proposed T-groyne and the system of detached breakwaters shown in Figure 3.

2. DESIGN OF THE MODEL

2.1 Design Philosophy

The basic prerequisite of a sediment model is to reproduce sediment motion correctly. This can be achieved by

* J S Schoonees, Sediment Dynamics Division, Coastal Engineering and Hydraulics, National Research Institute for Oceanology, South African Council for Scientific and Industrial Research, Stellenbosch.

** J P Möller, Sediment Dynamics Division, Coastal Engineering and Hydraulics, National Research Institute for Oceanology, South African Council for Scientific and Industrial Research, Stellenbosch.

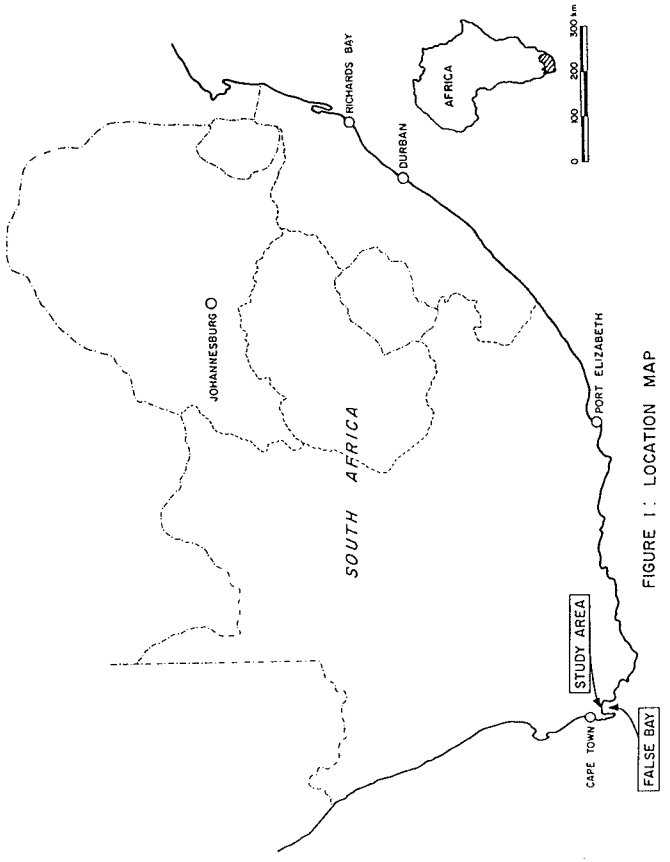

FIGURE 1: LOCATION MAP

FIGURE 2: STUDY AREA

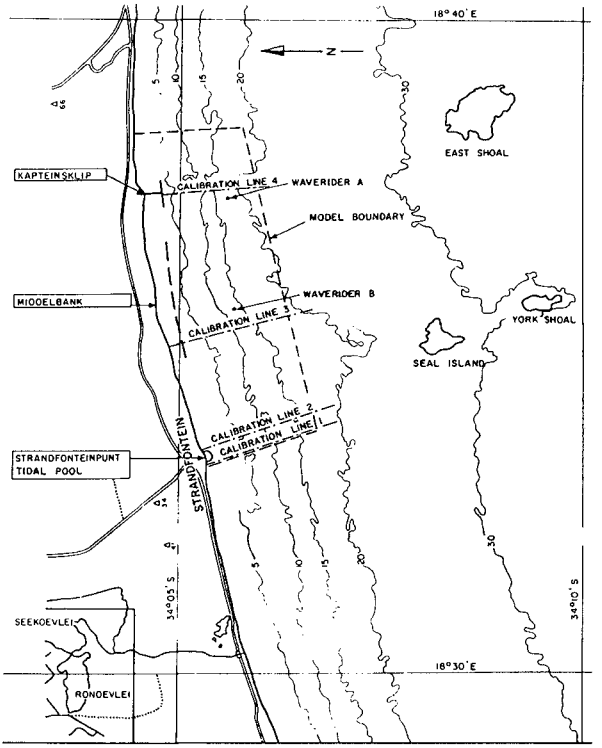

FIGURE 3: THE BATHING IMPROVEMENT SCHEME

modelling the on-offshore and longshore transport rates accurately. Inherent in this approach is the fact that the sedimentological time scale must not vary from place to place in the model. The time scale must also be constant in time, that is, as the experiment progresses. It will be shown that the selection of the bed material and the determination of the horizontal and vertical scales after model boundaries have been chosen, will ensure that sediment motion is correctly modelled and that a constant sedimentological time scale is obtained.

2.2 Choice of the Bed Material

Sand instead of lightweight material was chosen as the most suitable sediment for the model for the following reasons:

(a) To obtain the most accurate simulation of longshore transport the functional relationship between the transport and the driving forces should be examined. This relationship can, for most practical purposes, be approximated as:

$$S_x = a(v_* - v_{*c})^b \qquad (1)$$

where a, b = coefficients dependent on the grain size
v_* = shear velocity
v_{*c} = critical shear velocity at initiation of particle motion
S_x = longshore transport rate.

The best comparison between transport rates in model and prototype is obtained when v_{*c} and b are scaled 1 to 1. This can be done only by using sand for model material with approximately the same grain size as in prototype because v_{*c} and b are dependent on the grain size. The scale of v_* depends on the velocity scale and the hydraulic roughness scale. Bedforms are exaggerated in the model relative to prototype; this results in a roughness scale which is closer to unity than to the vertical scale. Consequently, more material is entrained on scale, due to higher turbulence close to the bed, than in prototype. The scaling process for longshore transport is completed by choosing a scale for the longshore current velocity which yields a velocity greater than that which would have been obtained from the Froude velocity scale in order to ensure a constant time scale. This is similar to the concept of an "ideal velocity scale" introduced earlier by Bijker (1967).

(b) It has been shown (Swart, 1974) that the geometric shape of the dynamic beach profile depends strongly on the grain size, wave height and wave steepness. Lightweight material, scaled according to the submerged weight, will be relatively too heavy out of the water, resulting in very steep (almost vertical) beach slopes near the water line. Therefore, to ensure the same breaker type in the model and

prototype and consequently also similar longshore current profiles, sand with the same grain size as the prototype material should be used.

The empirically derived relationship (Swart, 1974) for the equilibrium beach slope of sandy beaches is as follows:

$$m_r = 1{,}51 \times 10^{3}\left(\frac{H_o}{L_o}\right)^{-1}\left[H_o^{0{,}132}\, D_{50}^{-0{,}447}\left(\frac{H_o}{L_o}\right)^{-0{,}717}\right]^{-2{,}38} + 0{,}11 \times 10^{-3}\left(\frac{H_o}{L_o}\right)^{-1} \qquad (2)$$

where m_r = schematized equilibrium beach slope at the still water level
H_o = deep-water wave height
L_o = deep-water wave length
D_{50} = median sediment particle diameter.

(c) Porosity is normally greater at the grain sizes needed to model sedimentary processes with lightweight material than in prototype. Therefore substantial wave energy losses occur due to percolation. The correct modelling of the breaker characteristics and longshore water and sediment movement becomes extremely difficult to achieve in practice.

2.3 Selection of the Model Boundaries

The study area stretching from a slightly curved beach to the 22 m contour, is naturally bounded by two easily distinguishable features, namely, the tidal pool at Strandfonteinpunt and the rocks of Kapteinsklip - see Figure 3. Both of these form a partial obstruction to the longshore transport. The natural choice for the model boundaries is therefore as follows:

(a) From Strandfonteinpunt to approximately 1 km beyond Kapteinsklip. It was necessary to extend the model to the east of Kapteinsklip because the proposed scheme incorporates a groyne at Kapteinsklip.

(b) The depth at the offshore limit of the model is 22 m relative to mean sea level (MSL) but the movable bed terminates at the 16 m contour. This is safely beyond 8 m, the depth of significant sediment movement found in a theoretical analysis of longshore transport in a feasibility study.

2.4 Determination of the Horizontal and Vertical Scales of the Model

Swart (1974) devised a method to calculate the on-offshore transport that is based on the equilibrium beach profile concept. According to Swart (1974) the on-offshore trans-

port is directly proportional to the difference in configuration between the existing and equilibrium profiles. Therefore to model on-offshore transport correctly, the distortion of the model (ratio between the vertical and horizontal scales) must be equal to the ratio between the equilibrium beach slope in the model and that in prototype. This method was proposed by Bijker (1967) as well as Fan and Le Méhauté (1969). The Swart (1974) procedure for the calculation of the equilibrium beach slope was used. If the above-mentioned criterion is not met, additional on-offshore transport will take place in the model because of the incorrect distortion of the model - something that does not happen in prototype.

A horizontal scale of 1 in 120 was chosen to fit the model of the study area into the available model basin. From the results of the feasibility study the representative wave condition is: wave period = 10 s; deep-water significant wave height (H_S) = 2 m. The vertical scale was computed to satisfy the previously mentioned criterion as follows:

(a) Determine the prototype equilibrium beach slope:

From (2) $m_{r,p\infty} = 0{,}0240$ with $D_{50,p} = 450$ μm and $L_o = \frac{gT^2}{2\pi} = 156$ m (linear theory).
(g = gravitational acceleration; T = wave period; subscripts: m = model; p = prototype; ∞ = infinitely long time, that is, equilibrium conditions.)

(b) Select a vertical scale, say, 1 in 40.

(c) Calculate the equilibrium beach slope in the model with:

$H_{s,m} = \frac{1}{40} \times 2 = 0{,}05$ m

$L_{o,m} = \frac{1}{40} \times 156 = 3{,}90$ m (the wave length must be scaled with the vertical scale in order to model refraction correctly).

$D_{50,m} = 450$ μm (D_{50} must preferably be as close as possible to $D_{50,p}$, except for very coarse prototype material. For $D_{50,p}$ large, $D_{50,m}$ must be chosen such that $D_{50,m} < D_{50,p}$ or problems with the initiation of sediment movement will occur.

From (2): $m_{r,m\infty} = 0{,}0491$

(d) Check whether the slope ratio $(\frac{m_{r,m\infty}}{m_{r,p\infty}})$ is equal to the distortion factor (DF).

$$DF = \frac{1}{40} / \frac{1}{120} = 3,0$$

$$\frac{m_{r,m^\infty}}{m_{r,p^\infty}} = \frac{0,0491}{0,0240} = 2,04 \neq DF.$$

Choose a new vertical scale and repeat the procedure until $\frac{m_{r,m^\infty}}{m_{r,p^\infty}} = DF$. The result of this iteration process was a vertical scale of approximately 1 in 50. It must be added, because (2) is applicable only to sandy beaches, that the sediment in the model must be sand to permit the use of this method.

(f) Check that a realistic vertical scale is obtained by quantifying the internal friction and surface tension effects. If not, change the horizontal scale and repeat the iteration process.

Because it is a distorted model with the beach slope being steeper than in prototype, the breaker index will be influenced in such a manner that the breaker line will move inshore. To compensate for this effect, the wave height was increased to scale the width of the breaker zone correctly. This increase was, however, not significant enough to conflict with the requirements described in previous paragraphs.

3. DATA ACQUISITION AND CALIBRATION

3.1 Waves

Datawell Waveriders (accelerometer buoys) were deployed at the site to measure the wave heights and periods. Partly because of the complex bathymetry (see Figures 3 and 4) of the bay which caused unreliability of the theoretical refraction method used, and partly to obtain the best possible coverage in the limited recording period available (one year only - April 1980 to March 1981), recordings were made at two separate locations in a water depth to mean sea level (MSL) of approximately 20 m (see Figure 3 for the positions of the Waveriders). The results are summarized in Figures 5 and 6. Simultaneously a year-long exercise was undertaken during which aerial photographs were obtained of the study area approximately every second day. By orientating the individual photographs taken during each flight with the aid of a template, photographic strips of the coastline were obtained. The wave directions along the 6 m depth contour were then read off from these strips, thus acquiring a wave direction distribution along the coastline for every flight. The accuracy of this method, obtained from successive flights on two occasions (total number of repetitions: 48 flights) is 3,8°.

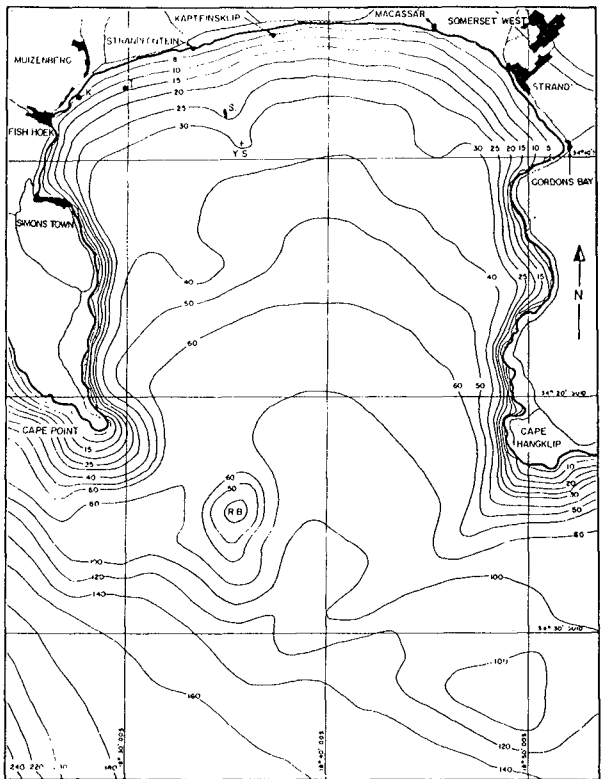

FIGURE 4: BATHYMETRY OF FALSE BAY

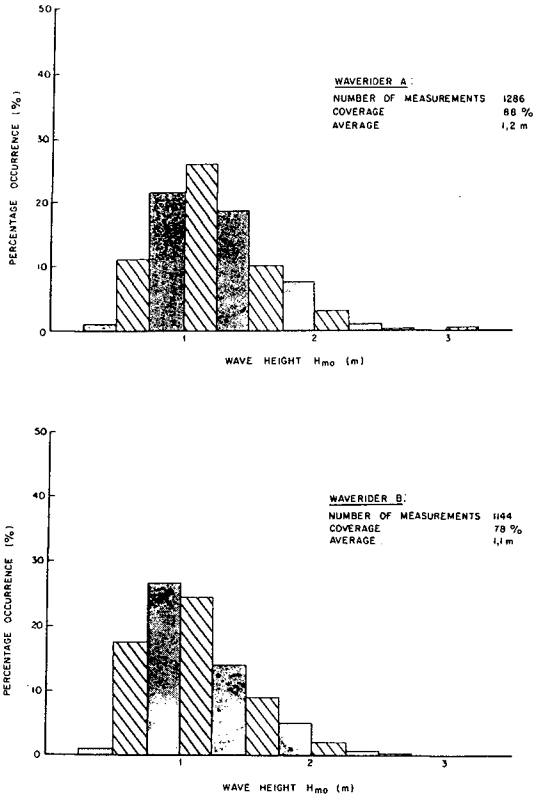

FIGURE 5: WAVE HEIGHT HISTOGRAMS

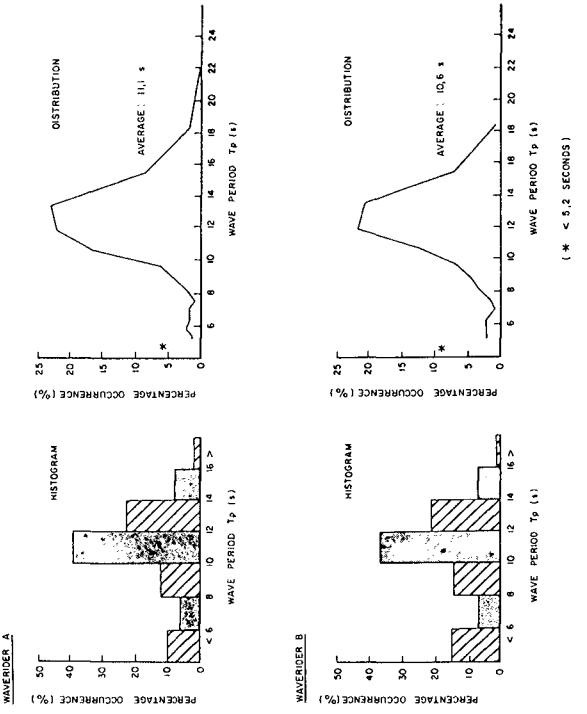

FIGURE 6: WAVE PERIOD OCCURRENCE

Deep-sea wave directions during the (Waverider) recording year (see Figure 7) were obtained from voluntary observing ships. The wave direction distribution along the 6 m depth contour was then compared with the distribution obtained from the theoretical wave refraction exercise. The measured wave patterns proved the theoretically-predicted tendencies.

Deep-sea ship observations also provided the wave climate over a period of 20 years (1960-1979). Equivalent deep-sea instrument (Waverider) data were computed for the 20-year period by using the relations (CSIR, to be published in 1982):

$$H_s \text{ (Waverider)} = 1{,}0 + 0{,}55\ H_s \text{ (ship)}$$

$$T_p \text{ (Waverider)} = 4{,}1\ T^{0\ 55} \text{ (ship)}.$$

By shoaling and refracting each of these observations the shallow water wave climate at the position of waverider A (see Figure 3) was determined, thus making it possible to see how representative the year's recorded data were. The wave height exceedance curves are shown in Figure 8, which indicates a relatively calm recording year.

The wave climate was divided into two parts, that is, westerly waves (causing eastbound longshore transport) and easterly waves (causing westbound longshore transport). For example, the westerly waves include waves from the WSW, SW, etc. As the wave energy is proportional to the product of the peak energy wave period (T_p) and the square of the significant wave height (H_s), it was possible to calculate $\overline{T_p}$ and $\overline{H_s^2 T_p}$ for easterly and westerly waves (the bar denotes mean values). Thus a representative wave that has the average wave energy is one with $H_s = (\overline{H_s^2 T_p}/(\overline{T_p}))^{1/2}$. This was done for both easterly and westerly waves, resulting in:

$$H_{s,east} = 1{,}0 \text{ m};\ T_{p,east} = 10{,}7 \text{ s}$$

$$H_{s,west} = 0{,}8 \text{ m};\ T_{p,west} = 12{,}2 \text{ s}.$$

The wave directions along the model boundary were measured from refraction diagrams for all possible wave directions and wave periods and weighted mean directions along the boundary obtained by using the deep-sea wave climate. However, irregular waves are preferred to regular waves due to the fact that in prototype the breaker line is continually shifting, as opposed to the stationary breaker line resulting from regular waves. Furthermore, irregular waves in the model will also reduce secondary wave generation effects. By using a period variator the periods were randomly altered around the calculated peak wave period according to a normal distribution with a standard devia-

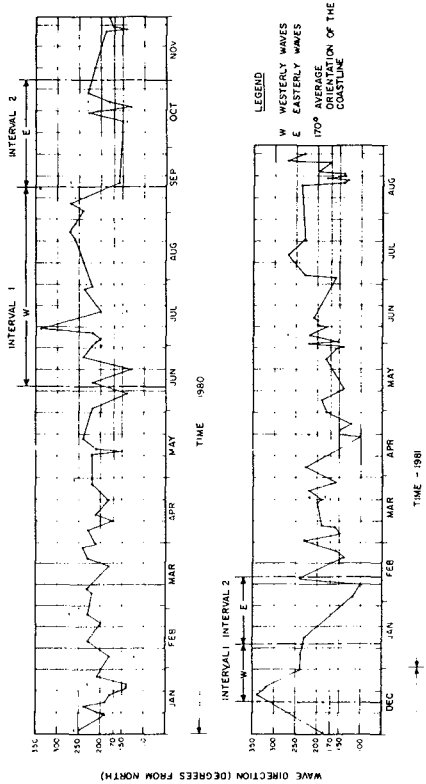

FIGURE 7: DEEP SEA WAVE DIRECTIONS (SHIP DATA)

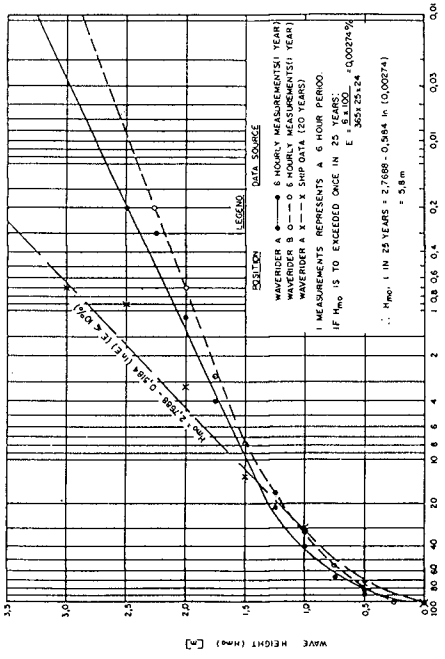

FIGURE 8 : WAVE HEIGHT EXCEEDANCE CURVES

tion of 0,2 s. At the same time the wave height was changed in a cyclic manner, resulting in quasi-irregular waves. A series of measurements were taken to ensure the correct reproduction of the input wave variables.

Because the calculated wave characteristics and the model sediment size differ from the original values, the vertical scale was recalculated. The discrepancy between these two vertical scales was insignificant.

3.2 Tides

The tides in the False Bay area are semi-diurnal with a mean range of about 1,6 m. Because tidal currents are negligible in this area (Atkins, 1970) the other tidal effects, that is, exposure of a steeper part of the beach profile to wave action, as well as causing the breaker line to change position, were modelled by testing 0,5 m above MSL and using quasi-irregular waves.

3.3 Sediment

Sediment samples were taken monthly at fixed positions along the beach. The particle size and distribution were determined in a settling tube. The median particle diameter for the 8 km stretch of coastline (upper and lower foreshore combined) from February 1980 to November 1981 was 450 μm. The beach between Strandfonteinpunt and Kapteinsklip is a moderately protected beach with little net sediment movement. Therefore it was difficult to acquire calibration data because quarterly hydrographic surveys showed beach and nearshore profile changes of less than 0,3 m (which approaches the measuring accuracy of the surveys). Figures 9 and 10 show typical beach and nearshore profiles. Daily aerial photographs used for determining the wave direction provided profile growth and recession rates at four places (see Figure 3 for the four calibration lines) along the coastline. After the scales of the photographs had been determined, the distances between the waterline and arbitrarily chosen beacons were measured. Tidal corrections, deduced from the beach profiles and the tidal heights at the time that the photographs were taken, were then applied to give the growth and recession of the waterline with time. Four distinct time intervals were identified from Figure 7, two for easterly and two for westerly waves. These, together with the corrected growth and recession rates are shown in Figures 11, 12 and 13. The rates of waterline movement were averaged for easterly and westerly waves at each of the calibration lines.

In order to model the prototype conditions, it was necessary to introduce and extract a longshore current as well as longshore sediment transport at the sides of the model.

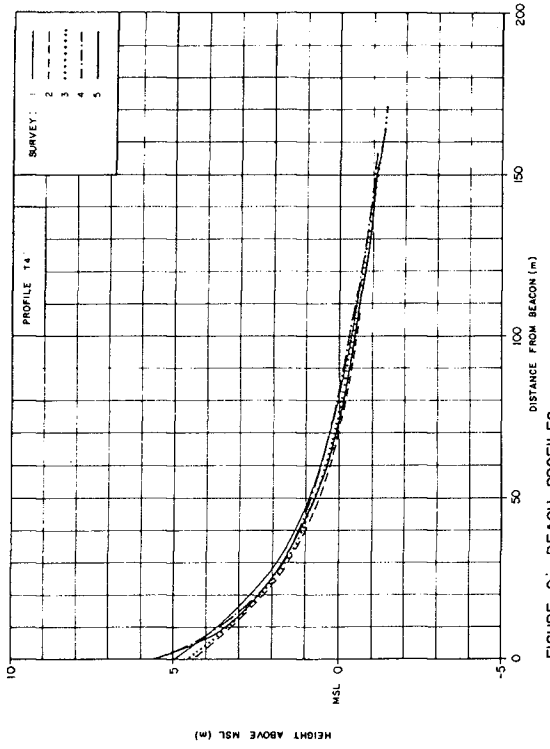

FIGURE 9: BEACH PROFILES

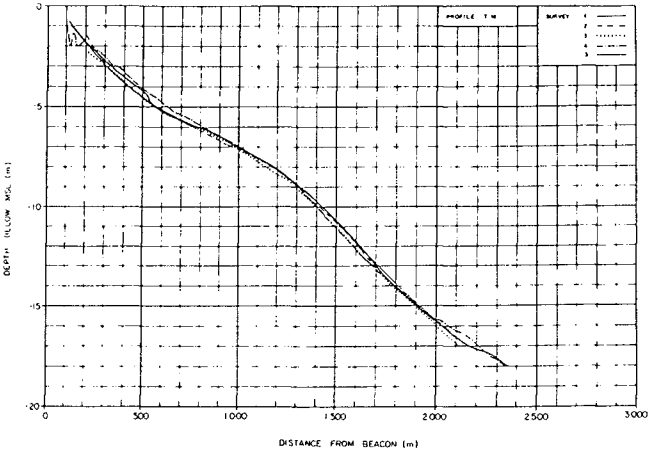

FIGURE 10: NEARSHORE PROFILES

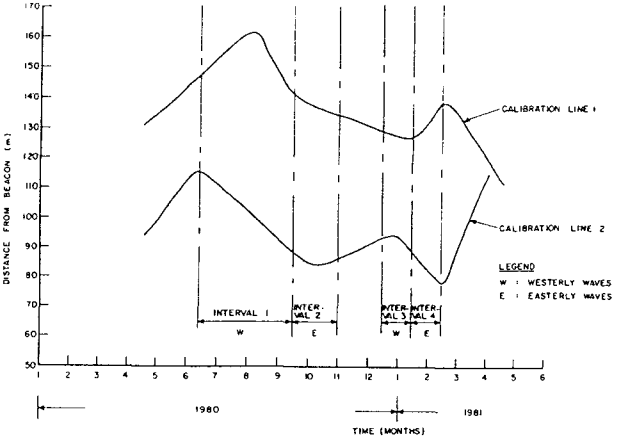

FIGURE 11: WATERLINE MOVEMENT AT STRANDFONTEINPUNT

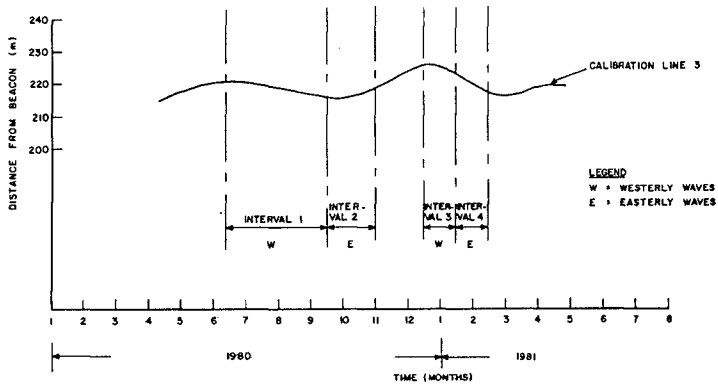

FIGURE 12: WATERLINE MOVEMENT AT MIDDELBANK

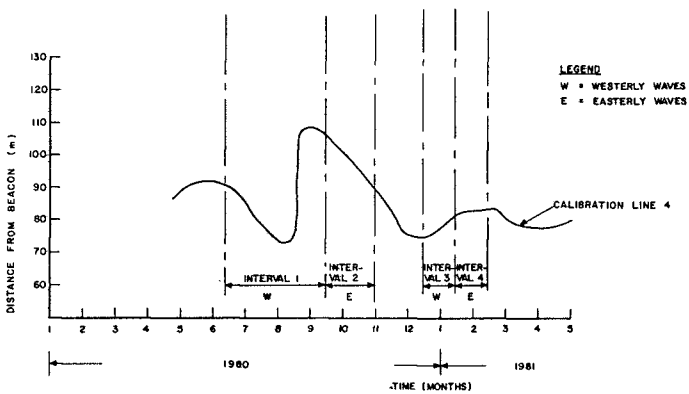

FIGURE 13: WATERLINE MOVEMENT AT KAPTEINSKLIP

Therefore the entrance/exit conditions had to be calibrated for both the easterly and westerly waves.

The overall water circulation pattern was monitored using a dye tracer to ensure the correct reproduction of the magnitude of the longshore current. The correct distribution of the longshore current (as predicted by Longuet-Higgins (1970)) relative to the average breaker line was obtained with a set of baffles. The sand feeding rate was determined by a trial and error process. It was found that because of the relatively slow longshore sediment movement, the feeding had to be intermittent. After these variables had been calibrated, verification tests were executed to determine the sedimentological time scale. The prototype tendencies of growth and recession were matched in the model except for calibration line 1. The proximity of this line to the edge of the model prevented its use during calibration procedure.

The distribution of the shallow-water wave climate according to wave direction, is as follows:

(i) westerly waves: 46,9%,

(ii) easterly waves: 13,2%,

(iii) calm periods (includes deep water waves moving away from the land): 36,5%, and

(iv) waves perpendicular to the coastline of the study area (for the 5° interval of 168° - 172°): 3,4%.

By taking this distribution into account, the following sedimentological time scale was obtained: 24 hours (model) ≡ 1 year (prototype). One year in prototype is therefore represented by five cycles, each comprising 3,75 h westerly and 1,05 h easterly waves.

4. CONCLUSIONS

A procedure is outlined for the design of movable bed coastal models, which uses the scales of the longshore and on-offshore transport instead of only longshore transport, as is common practice. This method indicates that sand is preferable to lightweight material for a movable-bed model.

Although the outlined iteration procedure results in large models, the verification is more easily accomplished.

In areas with low sediment transport, it is often possible to acquire good calibration data for a sediment model only if the model includes structures or coastal features that at least partially obstruct the longshore sediment movement. An alternative would be to undertake hydrographic

surveys before and after storms. This, however, can be very costly.

The use of aerial photography for the determination of wave direction provided useful additional coastline data. In this case the photographs were used to identify rocky areas and to obtain waterline growth and recession rates. The main disadvantage of this method is the impossibility of collecting data during stormy periods.

The utilisation of quasi-irregular waves nearly eliminated the formation of beach cusps due to secondary wave effects.

BLOWN SAND ON BEACHES

by

Susumu Kubota[1], Kiyoshi Horikawa[2]

and Shintaro Hotta[3]

ABSTRACT

The blown sand transport rate and the vertical and shore-normal distributions of the wind speed were measured simultaneously on a windy beach. The sand transport rate was measured with conventional total quantity-type traps and with a large trap in the form of a trench. The vertical distribution of the wind speed was measured using an ultrasonic anemometer array consisting of six meters. The distribution of wind speed at a height of 1 m in a section normal to the shoreline was measured with five ultrasonic anemometers. A logarithmic law for the vertical distribution of the wind speed was satisfied, and the wind speed in the section normal to the shoreline was almost constant. The Kawamura and Bagnold formulae were found to predict well the sand transport rate. The trench trap and conventional traps gave empirical coefficients of 1.5 and 1.0, respectively, for the sand transport rate averaged over a section normal to the shoreline. The lower value determined with the conventional traps (1.0) is attributed to their inefficiency compared with the trench trap. In order to obtain data at high shear velocities, a wind tunnel experiment was carried out. This experiment showed that both the Kawamura and Bagnold formulae were valid in the range between 60 to 300 cm/s in the wind shear velocity. The empirical coefficient in the laboratory experiments was 1.0: the difference between the field result with the trench trap and the wind tunnel experiment is attributed to the fluctuations in natural wind.

1. INTRODUCTION AND OBJECTIVES

From the viewpoint of coastal zone management in Japan, up to about 30 years ago the prevention of river mouth closure and the protection of cultivated land from intruding blown sand were important subjects for agricultural civil and coastal engineers. At that time there were rich sandy beaches. However, characteristics of the coast have changed in this country since then. Flood control systems for inland rivers brought about new serious problems of coastal erosion, and engineers

1. Research Engineer, Nearshore Environment Research Center, 1202 Famille Hongo Building, 1-20-6 Mukohgaoka, Bunkyo-ku, Tokyo 113, JAPAN
2. Professor, Department of Civil Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113, JAPAN.
3. Research Associate, Department of Civil Engineering, Tokyo Metropolitan University, 2-1-1 Fukazawa, Setagaya-ku, Tokyo 158, JAPAN

have become intensely occupied with this challenge. As a result, it seems that the topic of blown sand was left behind as a field of engineering interest. However, blown sand can be an important factor affecting beach change where a strong seasonal wind is predominant. In such situations, sand transport by wind should be included in the sand budget. Therefore, the authors initiated comprehensive field investigations and laboratory studies to establish calculation methods for the transport of sand by wind on beaches. As a first stage of this study, the main effort was concentrated on calculating the total sand volume transported through a section normal to the shoreline (Horikawa, Hotta, Kubota, and Harikai, 1981; Horikawa, Hotta, and Kubota, 1982a).

Several formulae for predicting the total sand transport rate by wind have been presented (O'Brien and Rindlaub, 1936; Chepil, 1945; Kawamura, 1951; Bagnold, 1954; Zingg, 1952; Kadib, 1966; Hsu, 1974). A characteristic of the above formulae, with the exception of Kadib's, is that the total sand transport rate is proportional to the third power of the shear velocity (i.e., the wind speed) at a certain height. A number of detailed discussions of the above formulae have been given (e.g., Horikawa and Shen, 1960; Nakamura, 1971; Phillips and Willetts, 1978). These studies indicate that the various predictive expression can give relatively good results if the empirical coefficients in the formulae can be determined with reasonable accuracy. The two formulae most commonly employed for estimating the total transported sand volume by wind, and for comparison and discussion of experimental results, are those of Bagnold and of Kawamura. They are

$$q = B\sqrt{\frac{d}{D}}\,\frac{\rho}{g}\,u_*^3 \qquad \text{Bagnold (1954)} \qquad (1)$$

$$q = K\,\frac{\rho}{g}\,(u_* - u_{*c})\,(u_* + u_{*c})^2 \qquad \text{Kawamura (1951)} \qquad (2)$$

where q is the sand transport rate (unit weight/unit time/unit width), u_* is the shear velocity, u_{*c} is the critical shear velocity of sand grain movement, ρ is the density of air, g is the acceleration of gravity, D is the standard sand grain diameter (0.25 mm), d is the sand grain diameter forming the sand bed, and B and K are nondimensional empirical coefficients.

2. FIELD OBSERVATION

Two field observations were carried out. The first was conducted between January 7 and January 12, 1981, and the second between January 7 and 17, 1982. The observation site was Yonezu Beach on the west side of the Tenryu River in the middle part of the main island of Japan (Fig. 1). During winter, sand is continually in motion at this site due to the strong seasonal wind from the west, blowing parallel to the shoreline. The sand grain size on this beach ranges between 0.1 to 0.8 mm, and its median diameter is 0.4 mm. The sand is well sorted. During the experiments, dune configurations 20 to 50 cm high and 20 to 30 m long existed on the beach normal to the shoreline and normal to the predominant direction of the wind.

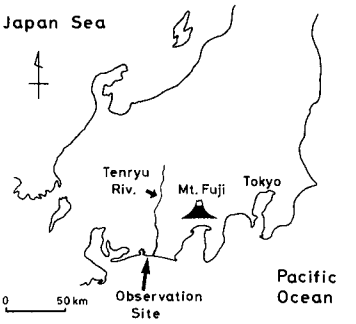

Fig. 1 Location map of the site.

2.1 Experiment Background

The wind speed was measured by an anemometer array consisting of six ultrasonic Doppler shift-type anemometers (Photo 1). An ultrasonic anemometer has the distinguishing merit that the wind speed can be measured precisely at high frequency, because the ultrasonic beam is emitted at 10 Hz. However, this instrument has a drawback for the present application. Data can be lost if a flying sand grain intersects a beam or hits the emitting probe. Therefore, this instrument is not suitable for measuring the wind speed near the beach surface where high concentrations of blown sand can appear. The lowest elevation used for the wind speed measurement was 10 cm. At this elevation noise sometimes appeared, but the frequency of occurrence was small and the noise could be excluded in the computer analysis.

Two kind of traps were used for measurement of the blown sand transport rate. One was a conventional total quantity-type trap and the other was a trench trap. The former was patterned after the traps used by Horikawa and Shen (1960), with some modifications based on field experience. Photo 2 shows a trap in operation. The mouth of the trap was 10 cm by 200 cm. In Photo 2, it is seen that local scour did not take place around the trap. Normally, local scour will appear around an object. Because of this, irregular trapping of the blown sand occurs during progress of the scour. To prevent the generation of scour, several procedures were attempted. We finally succeeded by spraying water around the trap during its setting. The sprayed surface resists erosion and no scour takes place. For the first few minutes, dried sand grains transported from upstream adhere to the wetted surface. Thereafter, a dry sand surface with no scour forms (as seen in Photo 2).

The other trap used for measurement of the blown sand transport rate is a trench-type trap. The idea of such a trap was suggested from previous studies. It is commonly known that the travel distance of a sand grain in saltation or in suspension is in the range of a few centimeters to a few meters. The experiment by Ishihara and Iwagaki (1952) showed that 97% of the total blown sand from upstream fell within 4 m of the waterline in the case of a pond or a stream. Iwagaki (1950) also reported that by utilizing the above information and constructing a

Photo 1 Ultrasonic anemometer array.

Photo 2 Total quantity type trap.

stream a few meters wide, cultivated land could be protected from intruding blown sand. This measure was implemented at Tottory beach in Japan. From the preceding results, the authors concluded that the entire quantity of blown sand could be trapped by a trench of width more than a few meters. A trench trap 8 m wide, 1 m deep, and 50 m long was therefore used.

Photo 3 shows the trench in the first observation: (a) at the beginning of the observation, and (b) at the same location after four days. The photo shows the upstream side slope, and indicates that the slope advanced while maintaining the rest angle of the dry sand. We can estimate the total amount of blown sand trapped by the trench given the width of the accumulated sand and the depth of the trench.

(a) Beginning of the observation. (b) End of the observation.

Photo 3 Trench trap.

2.2 Experiment Procedure

Figure 2 shows the beach profile and the arrangement of the instrumentation for the first observation. Symbols A to F indicate positions of the total quantity traps (arranged across a section normal to the shoreline). The open squares indicate locations where the vertical distribution of the wind speed was measured. Together with measurements of the vertical wind speed distribution at each position on the beach, blown sand was collected by the total quantity traps on January 8, 9 and 10, 1981. The sampling period for the transport rate was 10 minutes.

Survey poles with measurement scales were installed in the trench at 1-m intervals in the direction of the wind, and at 2-m intervals in the direction normal to the wind (See Photo 3). The change in the sand surface was measured from differences in distance from the tops of the poles to the sand surface. Measurement of the sand surface change in the trench was carried out around 9:00 am and 5:00 pm from January 8 to January 12.

Figure 3 shows the beach profile and the arrangement of the instruments for the second observation. Letters A to F give positions of the total quantity traps. Numbers 3 to 7 give the positions of the anemometers. While measuring the wind speed distribution continuously, the distribution of the sand transport by wind in a section normal to the shoreline was measured by total quantity traps on January 13 and 14, 1982. As in the first observation, the sampling period was ten minutes.

The trenches were dug as sbown in Fig. 3. The sand transport rate was measured at the most-upstream trench, TC. Tbe region S between the two downstream trenches TB and TA was used in an attempt to check the sand budget. The trench TB stops the blown sand from the upstream side, while the downstream trench TA collects the blown sand originating from region S. If we know the total sand volume which moved from region S, we can compare this amount with that collected in trench TA. To determine the total sand volume moved from region S, small steel pipes 12 mm in diameter and 1 m in length were hammered into the surface

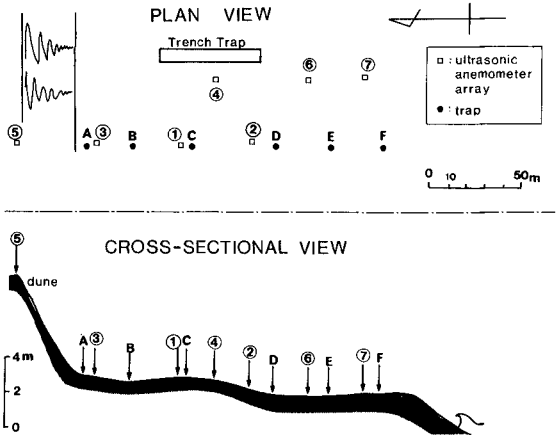

Fig. 2 Beach profile of the site and arrangement of instrumentation (first observation).

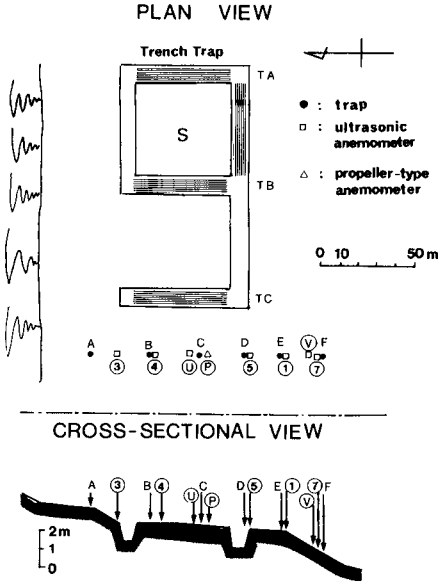

Fig. 3 Beach profile of the site and arrangement of instrumentation (second observation).

to form a grid with a 2 m by 2 m mesh. The distance between TB and TA was 50 m. A width of 50 m was choosen for the measurement. A total of 676 pipes were installed.

The region between TC and TB was used in an experiment of the drying process of the sand surface. Details of this experiment have been described elsewhere (Horikawa, Hotta, and Kubota, 1982b).

The circled letters U and V indicate the positions where the vertical distribution of the wind speed was measured on January 15 and 16, 1982. The ultrasonic anemometer has been rather recently developed. To discuss and compare results of our field observations relative to previous studies, one needs to know the characteristic difference, if any, between the ultrasonic anemometer and conventional anemometers such as the propeller-type, cap-type and so on. For this purpose, the wind speed at a height of 5 m was measured with a propeller-type anemometer at position P in Fig. 3. The statistical characteristics and 10-min averages of the two types of instruments were found to be essentially the same. The wind speed was recorded on an open-wheel recorder for both experiments, and the data were averaged in intervals of 10 minutes.

3. RESULTS

3.1 Sand Characteristics

The grain size distribution and the median diameter of the sand are important parameters governing the blown sand transport. Table 1 gives examples of the median diameter and the uniformity coefficient based on sieve tests of the sand trapped by the total quantity traps in the first observation. Here d_{50} is the median diameter, and the uniformity coefficient is $U_c = d_{60}/d_{10}$. In Table 1 is also given the median diameter (0.4 mm) and uniformity coefficient (1.75) of the surface layer sand to about 0.5 cm in depth, which was removed from the neighborhood of point C on January 10, 1981

Table 1 Median diameter of blown sand and uniformity coefficient.

Location (Fig. 2)	10 Jan 81		9 Jan 81		8 Jan 81	
	d_{50}	U_c	d_{50}	U_c	d_{50}	U_c
A	0.31	1.50	0.25	1.47	0.27	1.58
B	0.31	1.50	0.27	1.50	0.28	1.55
C	0.31	1.52	0.28	1.58	0.27	1.50

F	0.26	1.61	0.25	1.53	0.24	1.44
surface	0.4	1.75				
u_*	37.6 (cm/s)		39.5 (cm/s)		30.0 (cm/s)	

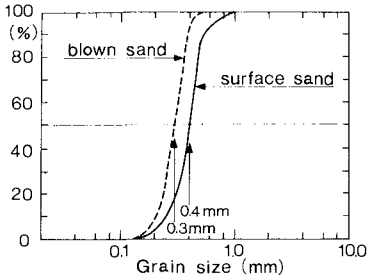

Fig. 4 Grain size accumulation curves of blown sand and surface sand.

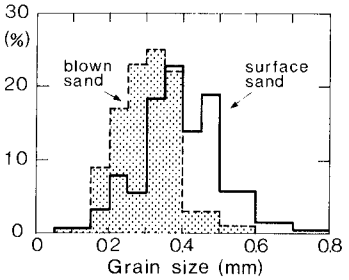

Fig. 5 Grain size distribution of blown sand and surface sand.

Figure 4 shows the particle size accumulation curves of the surface sand and a sample of the trapped sand at point C on January 10 (as listed in Table 1). Figure 5 shows the sand grain size distribution of both sand samples. The median diameter of the trapped blown sand is about 0.3 mm and the uniformity coefficient is around 1.5 (well sorted). Both the median diameter and the uniformity coefficient of the trapped sand are smaller than those of the surface sand. Larger grain sizes in the blown sand are seen to be limited in number (Fig. 4). It is therefore a difficult problem to determine the median diameter which represents the blown sand.

3.2 Wind Speed Distributions

To calculate the blown sand transport by Eqs. (1) and (2), the shear velocity u_* as an external force must be given. The shear velocity can be obtained as the gradient of a straight line on semilog paper, if the logarithmic law for the vertical distribution of wind speed is valid. That is,

$$u = 5.75\, u_* \log_{10} \frac{z}{z_o} \tag{3}$$

where u is the wind speed at a height z, the roughness of the sand surface is z_o, and u_* is the shear velocity. Equation (3) holds under the condition that the wind speed is not sufficiently large to move the sand grains. However, the distribution of the wind speed will be affected by the moving sand grains if the wind speed is greater than the critical wind speed and sand grains begin to move. Then Eq. (3) should be replaced by

$$u = 5.75\, u_* \log_{10} \frac{z}{z'} + u' \tag{4}$$

where (z', u') defines the "focal point" according to Bagnold (1954). Therefore, on semilog paper, all lines expressing the vertical distribution of wind speed converge to the focal point.

Figure 6(a) shows examples of the vertical distribution of wind speed observed on January 7 and 8 in the first observation. We can conclude that Eq. (4) is satisfied. Equation (4) was also satisfied at other observation points on the flat portion of the beach, except in the vicinity of a coastal dune located parallel to the shoreline.

The focal point observed in the first observation ranged between $u' = 130$ to 250 cm/s, and $z' = 0.11$ to 0.3 cm. Zingg (1952) suggested the following empirical equations for the focal point:

$$u' = 20\ d \quad \text{(mile/hr)} \tag{5}$$

$$z' = 10\ d \quad \text{(mm)} \tag{6}$$

Here d is the diameter of the sand in mm. We shall compare the observed results with Zingg's equations. If the diameter of the sand grains is taken as 0.4 mm (the median diameter of the sand bed), then

$$u' = 8.8 \cdot 10^2\ d = 358 \text{ cm/s} \quad \text{and} \quad z' = 10 \cdot 0.4 = 0.4 \text{ cm}$$

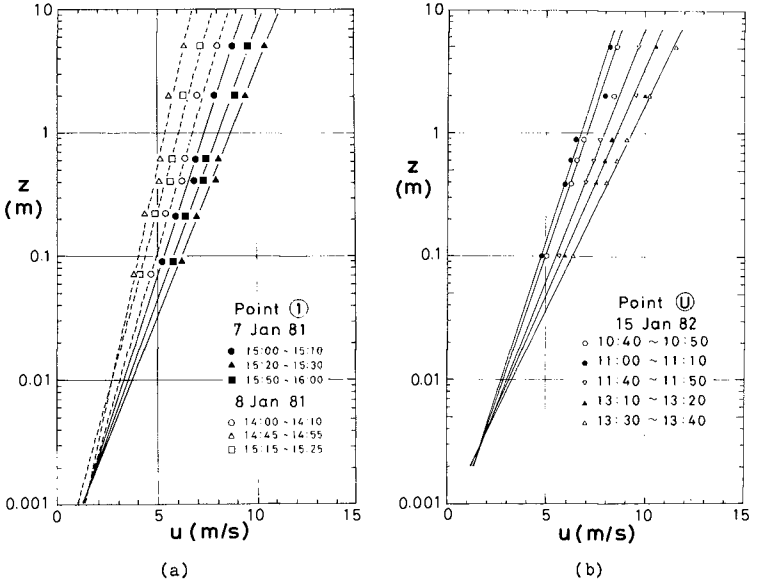

Fig. 6 Examples of vertical distribution of wind speed.

If d is 0.3 mm, the median diameter of the trapped blown sand, then

$u' = 264$ cm/s and $z' = 0.3$ cm.

For the first observation, Zingg's formulae agree with the upper limits from the field measurements.

In the second observation, the vertical distribution of wind speed was observed on January 14 and 15 (Fig 6(b)). Equation (4) was satisfied, but the focal point took on somewhat different values from the first observation. That is, u' was around 220 cm/s, and z' was around 0.6 cm, about twice that of the first observation. The value $z' = 0.6$ cm is somewhat larger than that predicted by Zingg's equation. To evaluate the utility of Zingg's equations, further observations are needed.

Another way to determine the shear velocity is to establish a relationship between the shear velocity and the wind speed at some specified elevation. Horikawa and Shen (1960) gave the following equations to calculate the shear velocity from the wind speed at heights of 1 m and 4.465 m. They are

$$u_* = 0.0690\, u_{100} - 18.4 \quad \text{(cm/s)} \tag{7}$$

$$u_* = 0.0548\, u_{446.5} - 14.7 \quad \text{(cm/s)} \tag{8}$$

Here u_{100} and $u_{446.5}$ are the wind speed at heights of 100 cm and 446.5 cm respectively. These equations are based on four assumptions; 1) Eq. (4), 2) Zingg's empirical formulae for the focal point, 3) the diameter of sand grain is 0.3 mm, and 4) the Karman constant is equal to 0.4. Assuming the same conditions, but directly inserting the measured average focal point ($u' = 200$ cm/s and $z' = 0.20$ cm), we obtain the following two equations:

$$u_* = 0.0644\, u_{100} - 12.9 \quad \text{(cm/s)} \tag{9}$$

$$u_* = 0.0511\, u_{500} - 10.2 \quad \text{(cm/s)} \tag{10}$$

Thus the shear velocity can be calculated from the wind speed at heights of 1 m and 5 m. Figure 7 shows a comparison of the shear velocity given by Eqs. (9) and (10) with the field data. The equations are seem to provide a good prediction.

Figure 8 shows an example of the ten-minute average wind speed at a height of 1 m across a section normal to the shoreline in the second observation. The data show that the wind speed was almost constant on the beach surface. Therefore, we can assume that the shear velocity acting on the sand surface was also constant.

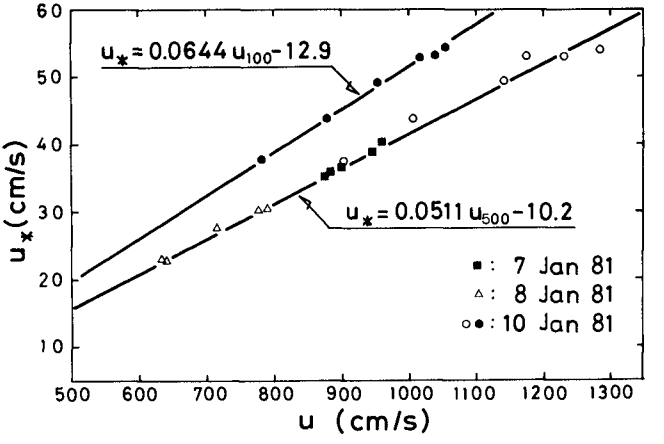

Fig. 7 Relationship between shear velocity and wind speed at heights of 1 m and 5 m.

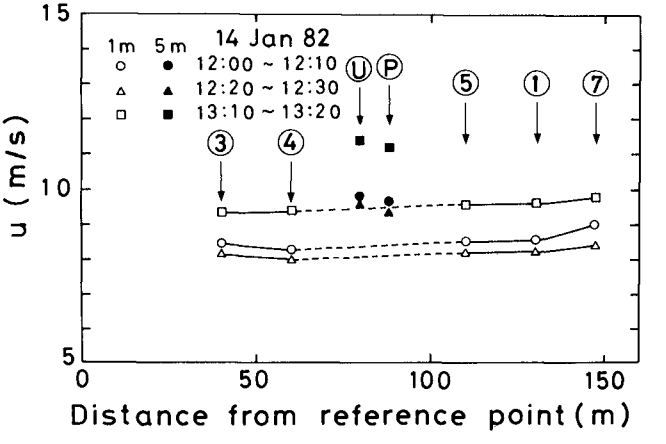

Fig. 8 Wind speed distribution at 1 m height in a section normal to the shoreline.

3.3 Sand Transport Rate

(1) Conventional trap

Figure 9 shows the distribution of the blown sand transport rate in a section normal to the shoreline on the first observation. Figure 10 shows a plot of the sand transport rate against the shear velocity at the measurement point C obtained from vertical distribution of wind speed measured simultaneously at the same point. In this figure, the curves calculated by the Bagnold and Kawamura formulae with empirical coefficients of 1.0 and 2.0 are also drawn. It is clear that both the Bagnold and Kawamura formulae agree well with the field data if the empirical coefficients are chosen to be about 1.0.

Figure 11 shows the sand transport rate distribution during the period in which the wind speed distribution was measured on the second observation. The sand transport rate was not constant in the section, although we had inferred that the shear velocity was constant on the beach (last paragraph of Subsection 3.2). We carefully observed the sand surface to resolve this problem. The surface consisted of a dune configuration about 30 to 50 cm high and about 15 to 20 m long. The dried sand layer was thick at the crest and thin at the trough. Sand was actively blown at the crest but not at the trough. We finally realized that the quantity of sand caught by the trap was dependent on the location of the trap. That is, a large amount of blown sand was trapped if a crest was located in front of the trap, whereas the amount collected was small behind a trough.

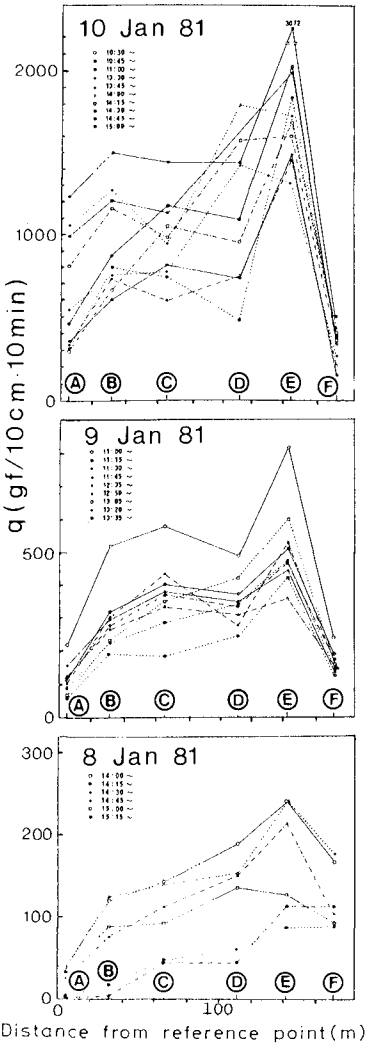

Fig. 9 Blown sand transport rate distribution in a section normal to the shoreline (first observation).

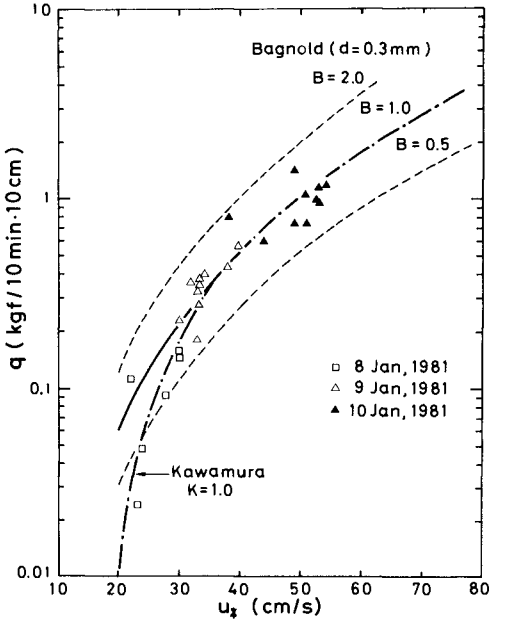

Fig. 10 Blown sand transport rate at point C (first observation).

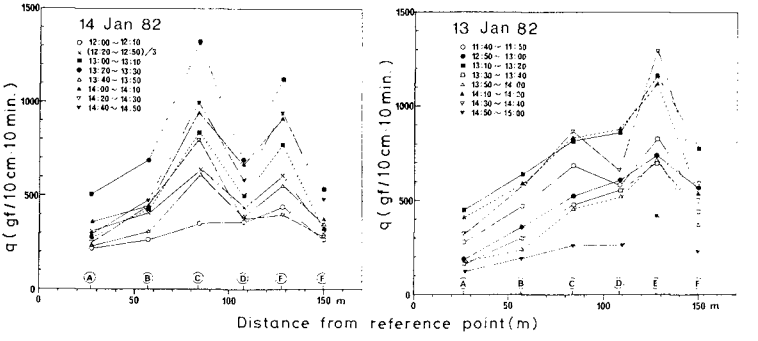

Fig. 11 Blown sand transport rate distribution in a section normal to the shoreline (second observation).

We found that the sand was not actively blown on the landward side of the beach which had been covered by dirt deposited by a storm. There was also very little sand blown in areas of dense coastal vegetation (e.g., measurement point A). We therefore can expect that a plot of the transport rate measured by point sampling against the shear velocity will show great scatter. However, for engineering purposes, it is more important to evaluate the average sand transport than to evaluate the local transport.

Figure 12 shows the average transport rate in the section A to F for the two observations. The shear velocity was calculated from the vertical distribution of wind speed for the first observation, and from Eq. (9) for the second observation. Both the Kawamura formula and the Bagnold formula agree well with the data when the empirical coefficient is 1.0. The Kawamura formula gives a particulary good result for the sand transport under shear velocities lower than 33 cm/s because it accounts for the critical shear, as was pointed out by Horikawa and Shen (1960).

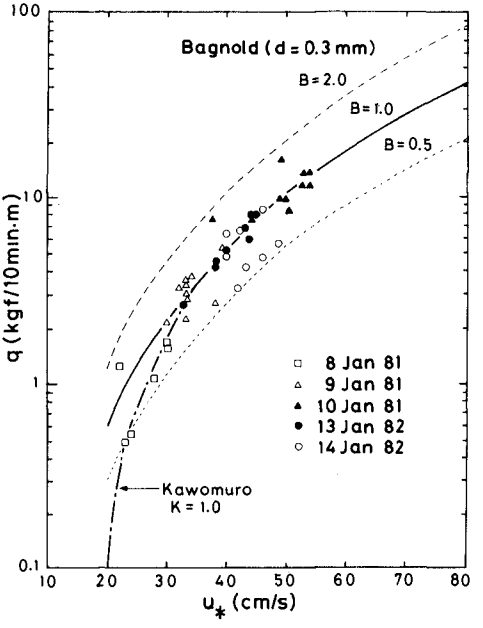

Fig. 12 Average sand transport rate (both observations).

(2) Trench trap

In Table 2, columns 1 to 3 list the times when sand was effectively blown, and the accumulated sand volume during the respective period. The measured sand volumes in the second observation were almost the same for trenches TC and TA (Fig. 3). The fourth column in Table 2 shows accumulated sand weights calculated assuming the dry sand has a weight density of 1650 kgf/m^3. The fifth and sixth columns indicate the estimated blown sand volume using Eqs. (1) and (2) for the transport rate, and (9) and (10) for the shear velocity. In the estimation, the following parameters were assumed: an empirical coefficient of 1.0 in the Bagnold and Kawamura formulae; a sand grain diameter of 0.3 mm in the Bagnold formula; u_{*c} of 20 cm/s in the Kawamura formula, and finally $\rho/g = 1.25 \cdot 10^{-6}$ (gf·s^2/cm^4).

The last two columns show the ratio of the measured blown sand volume to the estimated volume. The measured volume from the trench is greater than the estimated volume, about 1.25 (1.5) times the estimated amount for the first (second) observation. It is not clear why this difference appears, although it is reasonable to attribute it to experimental error. In Subsection 3.3 (1), it was found that the empirical coefficients for both formulae based on measurements by the conventional trap have a value of about 1.0. The difference in results most likely is due to the lower efficiency of the conventional traps. From this consideration, the efficiency of the conventionl trap is given by the reciprocal of the ratio of the measured sand volume to the estimated volume. The range in efficiency is about 0.65 to 0.8.

Accordingly, we conclude that the empirical coefficients for Eqs. (1) and (2) should be about 1.5.

Table 2 Blown sand measured by trench trap.

Date	Time	Observed sand volume		Estimated sond volume		Ratio of observed to estimated vol.	
		(m^3/m)	(Kgf/m)	Bagnold	Kawamura	Bagnold	Kawamura
1981							
Jan. 9	9:00 ~ 16:00	0.071	117	102	92	1.15	1.27
10	9:00 ~ 15:15	0.314	518	425	452	1.22	1.15
11	9:00 ~ 15:40	0.171	282	218	222	1.29	1.27
12	9:00 ~ 15:00	0.186	306	222	232	1.37	1.33
1982 Jan. 13, 9:00 ~ Jan. 14, 17:00		0.60	990	661	641	1.50	1.54

Now we will discuss the sand budget for region S and trench TA in the second observation. The sand volume blown off region S was about 1 m^3 per unit width in the period when effective blown sand took place, as listed in Table 2. If the weight density of the sand is 1650 kgf/m^3, the weight of sand blown off the region per unit width is 1650 kgf/m. This value is much larger than that caught in trench TA (or TC, Table 2). If this value is correct, it implies that trench TA did not stop the entire volume of blown sand from upstream. However, we observed

that only a very small volume of blown sand in suspension crossed over the trench. Therefore, it seems that the overestimation of the sand volume blown off region S was due to insufficient accuracy in the measurement of the sand surface change with the rods.

(3) Laboratory experiment

Measurements of the sand transport by wind obtained from this field study were limited to rather low shear velocities as seen in Fig. (11). The maximum shear velocity obtained in our field observations was around 60 cm/s. If we evaluate the wind strength at the height of 5 m, a shear velocity of 60 cm/s is equivalent to a wind speed of around 12 to 13 m/s for a ten-minute average, and around 18 to 20 m/s for a momentary maximum wind speed. It often happens that the wind speed is higher than the above values. It was, however, difficult for us to wait for such a condition to occur during the field investigation because of economic considerations. Therefore, we conducted a simple laboratory experiment on the sand transport rate by wind under a high wind speed. The results are now briefly described.

The experiments were carried out using a blowoff-type wind tunnel specially designed for studying blown sand. The wind tunnel is 1.1 m high, 1 m wide, and 20 m long. The bottom is tapered with a gradient of 1/10 at both ends. The cross section of the tunnel on which sand can be placed to a thickness of 10 cm is 1 m by 1 m. The wind speed can be varied from 3 to 30 m/s. The wind speed was measured by an array of four hot-film anemometers. The experimental facility is described by Horikawa, Hotta, and Kubota (1982b).

Sand from Yonezu beach (site of the field study) was used in the experiments. The vertical distribution of wind speed was measured, and the shear velocity was calculated from the distribution. The anemometers were placed 1, 5, 10, and 20 cm from the sand surface. Equation (4) was satisfied in this experiment, although the wind speed at the 1-cm height deviated somewhat from the straight line formed by the other measurement points (when the shear velocity was higher than around 180 cm/s). The sand passing the downstream end of the test section was considered to be the sand transported by wind. The time interval for applying the wind varied from two minutes to ten minutes, depending on the speed. Figure 13 shows that the Kawamura and Bagnold formulae agree well with the experimental results even at high shear velocities, with the empirical coefficient determined to be about 1.0.

4. DISCUSSION AND CONCLUSIONS

From results of the field study, we concluded that the empirical coefficient for the Bagnold and Kawamura formulae should be about 1.5. However, the laboratory experiments with high shear velocities indicate that the these coefficients should be about 1.0. Horikawa and Shen (1960) also found that the coefficient in the Kawamura formula is approximately 1.0 from their laboratory experiments using well-sorted sand of medium diameter 0.2 mm.

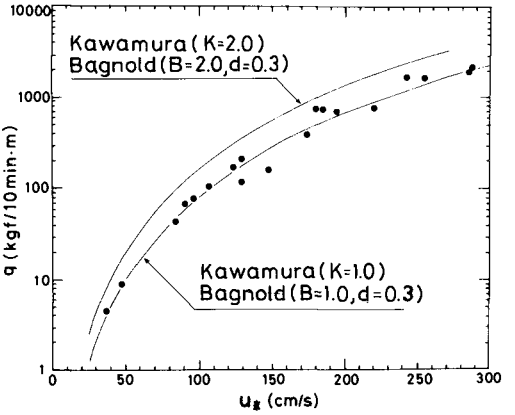

Fig. 13 Blown sand transport rate at high shear velocities.

The coefficients based on the field data are therefore larger than those obtained from the laboratory experiments. This may be due to a difference in characteristics between natural wind and latoratory wind. Usually a constant wind speed is maintained in laboratory experiments. However, the speed of natural wind varies, and a ten-minute average is ordinarily used in correlations. The blown sand transport rate is proportional to the third power of the wind speed, or of the shear velocity. A short interval of high speed wind is then efffectively equivalent to a longer interval of constant lower wind speed.

The value of 1.5 for the empirical coefficients in the Bagnold and Kawamura formulae found in the second field experiments fortuitously agrees with the result of Bagnold from laboratory experiments using well-sorted sand with median diameter of 0.25 mm. The reliability of the coefficient is increased by this field study. We consider both of the Bagnold and Kawamura formulae valid to estimate the total sand transport rate by wind. Both are equivalent at high shear velocities, but the Kawamura formula is recommended for low shear velocities.

Finally, we mention the fact that the total sand transport rate is strongly affected by the moisture in the sand layer. However, we have just begun to study this effect. An intense effort is necessary to clarify the role of moisture in the sand layer.

ACKNOWLEDGEMENT

The authors would like to express their appreciation to Mr. M. Nakura, head of the Management Department, Hamamatsu Construction Works Branch, Shizuoka Prefecture, for his considerable assistance. We also thank Dr. N. C. Kraus for proofreading, and Misses T. Kohno and K. Suzuki for typing the manuscript. The support of the Central Research Institute of Electric Power Industry over the course of this work is greatly appreciated.

CHANNEL SHOALING PREDICTION: A METHOD AND APPLICATION

R. B. Harley,[1] Member, ASCE and R. G. Dean,[2] Member, ASCE

ABSTRACT

Due to concerns of possible shoaling problems, an extensive field survey program was carried out at the site of the proposed Cerrejon coal port on the Caribbean coast of northeast Colombia. The program yielded considerable data on winds, waves, currents, and sediment factors. Techniques for the primary measurement of sedimentation-related tendency included dredged test pits, scour crosses, and suspended sediment samplers.

The port plan includes dredging a 4.6 kilometer long channel varying from 12 to 21 meters in depth. In order to assess the magnitude of maintenance dredging and related problems, a method was developed for incorporating the sediment response measurements into predictions of the areal and seasonal distributions of bed load and suspended sediment deposition.

Offshore test pits were monitored for rate of filling and character of the material being deposited. Suspended sediment samplers were similarly observed and also provided data on concentration versus depth.

The procedure which was developed for analysis and interpretation of the data included extrapolation of suspended sediment data to the seabed, investigation of correlations between wind activity and deposition rates, application of test pit data to a channel of larger dimensions, and testing of hypotheses regarding transport mechanisms. The procedure concluded that average annual shoaling would be approximately 300,000 m^3 and predicted areal and seasonal variation of deposition rates.

BACKGROUND

A 15 million ton per year coal export terminal is being

---

(1) Engineering Associate, Exxon Research and Engineering Company, Florham Park, New Jersey 07932.

(2) Graduate Research Professor, Department of Coastal and Oceanographic Engineering, University of Florida, Gainesville, Florida 32611

developed on the Caribbean coast in the northeast of Colombia (see Figure 1). The terminal is the outlet for coal received by rail from a mine being opened approximately 150 km inland. The mine, railroad, port and associated facilities are being developed by partnership of International Colombia Resources Corporation, an affiliate of Exxon Corporation, and Carbocol, a company owned by the government of Colombia.

The terminal is being designed to accommodate vessels up to 150,000 dwt. A site selection investigation identified Bahia Portete, a large natural bay near the tip of the Guajira Peninsula, as the optimum port site (see Figure 2). Further optimization studies resulted in a plan, shown in Figure 3, to dredge a 4.6 kilometer long channel extending from just within the mouth of the bay to the 21 meter contour. The channel varies in depth from 12 to 21 meters. The plan resulted from estimates of the relative cost for dredging versus trestle structures, assessment of wave conditions at the coast and further into the bay, and consideration of possibilities for future development of Bahia Portete.

Early site investigations noted the presence of a plume of turbid water flowing to the southwest along the coast of the peninsula and past Bahia Portete. Depending on the tide, the plume was periodically diverted into the bay. At the inside of the east headland of the bay entrance, a sand spit approximately 800 meters long extended into the bay. These conditions gave rise to concern over possible shoaling problems in the channel. As a result, a coordinated field survey program and analytical method were developed to provide predictions of shoaling in the proposed channel.

SITE CONDITIONS

Wind and Wave

The site is located in the tropical trade wind zone at approximately 12 degrees north latitude. As shown in Figure 2, the port will be situated near the northern tip on the leeward side of the Guajira Peninsula. Most wave activity in the area is generated by the easterly trade winds and passes the site farther offshore, north of the tip of the peninsula. Wave activity in the lee of the peninsula includes that which is diffracted around the peninsula and that which is generated by the northeasterly component of the wind regime (parallel to the coast). Little swell activity was observed or recorded during the field survey.

In addition to the protection afforded by the coastline orientation, waves approaching the site are further attenuated by refraction. Wave approach is primarily from the northeast and parallel to the coastal contours. While offshore waves exceed 2 meters 35 percent of the time, waves at the coast are rarely more than 1 meter (only 5 percent of the year). Between the end of the

FIGURE 1 - PROJECT LOCATION

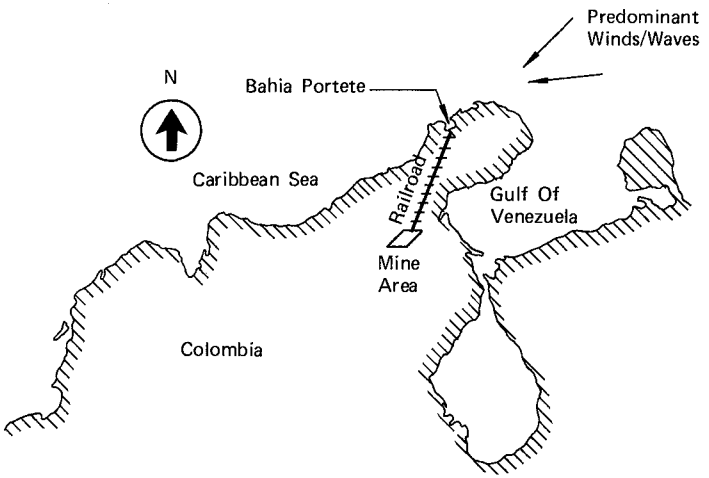

FIGURE 2 - PROJECT AREA

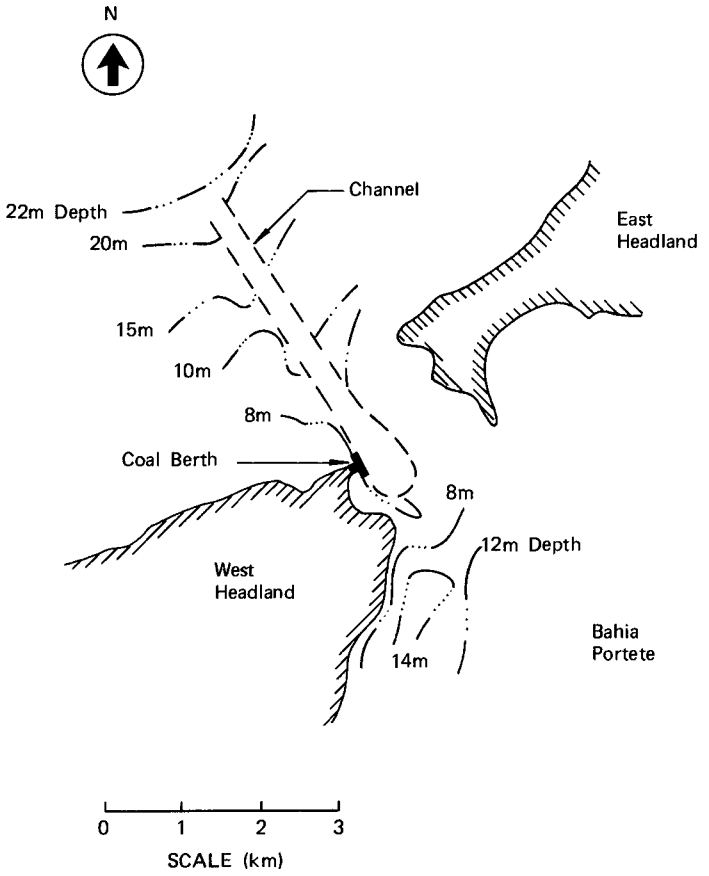

FIGURE 3 - PORT LAYOUT

channel (21 m depth) and the bay entrance, the prevailing waves change direction by up to 45 degrees.

Short wave activity (2-4 secs.) is also generated across the 10-15 kilometer fetch of the bay itself, primarily out of the east and southeast. Typically 0.3 - 0.5 meters in height, these waves can approach directly to the port area from across the bay.

Warm tropical winds persist at 20 to 30 knots for much of the year with June - August and January - April the more severe seasons. Field measurements of both winds and waves, and of sediment deposition rates, encompassed portions of both of these periods.

Climate and Topography

At the site, the Guajira Peninsula is predominantly dry, arid, and flat. There is little vegetation or runoff, and the area is sparsely populated. The shoreline is generally steep and rocky except in the inner reaches of the bay. At the headlands, the shoreline rises nearly vertically to elevations of 5 - 20 meters, except for a few pocket beaches. The face of the cliff-like shoreline is composed primarily of hard sandstone overlaying stiff clays. There is some evidence of shoreline erosion on the west headland, which is subjected to direct attack from offshore waves and those generated across the bay. Upcoast (windward) from the site, however, there is little sign of coastal erosion as the hard sandstone appears to resist the significantly attenuated waves. As such, the site appears to be sand starved, with pocket beaches that are not filled and no trace of an offshore deposit extending from the eastern headland of the bay entrance.

The seabed characteristics vary between the offshore and bay areas. Offshore and in the entrance, the seabed is largely a layer of silty sand up to 12 meters thick overlaying stiff clays and limestone. The entrance is only 3-8 meters deep but there is a natural trough in the entrance and a depression in the seabed offshore that indicate a lack of deposition, either through continued suspension by currents, or lack of a sediment source, or both. In the bay, the depth averages 10 meters and the seabed is very fine, mucky silt that is easily suspended.

There is a sand spit which extends into the bay from the inside of the east headland. The spit appears to be due to a relatively small sediment supply as compared to the transporting capacity of the waves. Thus, the sediment is driven into the bay where equilibrium is found between the Caribbean swell propagating into the bay and the short, locally-generated waves from the east within the bay.

Current and Tide

The tidal range is small, with a maximum range of only 0.5 meters. Runoff is negligible due to the arid nature of the

region. Nevertheless, the current regime is complex, consisting of alongshore coastal currents, tidal currents in the bay entrance, and density currents. Offshore of the entrance, currents vary from 0.3 to 0.6 knots, varying in direction with the tidal flow in and out, but generally running to the west. In the entrance, currents reach up to 1.5 knots in order to empty and fill the large area of the bay on spring tides. Also in the entrance, an outward flow exists near the bottom in the form of a warm, relatively dense turbid layer. This turbidity is interpreted to result from the densifying of water in Bahia Portete through evaporation, subsequent sinking, and outflow as a warm bottom layer with fine material in suspension. The material itself possibly results from suspension of fine sediments from the bottom of the bay, some erosion of the western headland, or diversion of alongshore drift into the bay by the incoming tide.

FIELD MEASUREMENT PROGRAM

Physical Factors

The site conditions were established through a nominal one year field survey program. The program included measurements of winds, waves, currents, tides, salinities, water temperatures, water density, and bathymetry.

The wave measurement program utilized both pressure gauges and waverider buoys. The instruments were situated at five different locations during the course of the survey, being moved to avoid repeated incidents of damage by vessels or vandalism, and to optimize the applicability of the data as site phenomena were established and the sediment monitoring progressed. One instrument remained in "deep water" at approximately the 21 meter depth contour for measurement of unmodified waves and correlation to deep water hindcast data. Wave direction was established by instrument aided observation in the offshore area and aerial observations.

The current measurement program included permanent installations of taut line moorings for varied periods at three locations. Two offshore locations, one closer to the entrance than the other, and a location at a proposed berth site in the bay, were monitored. Since the permanent installations included only one meter at a single elevation, vertical profiles were also established through measurements from a survey vessel at six different elevations through four daily tidal cycles in the bay entrance. Diver evaluation of current flows through observation and use of hand held meters were also included.

Bathymetric data were collected over an area including the bay entrance and areas extending 3 kilometers into the bay and 8 kilometers offshore. The data were taken by side-scan sonar and echo sounding on tracks sufficient to define seabed contours for estimates of dredging and more than sufficient for sediment study purposes.

Wind measurements were taken at the point of the west headland, which has good exposure to overwater conditions. Recordings were taken at one hour intervals for the duration of the field survey program.

Tidal data were continuously recorded for four months of the program and correlated to existing data at Cristobal, Panama for establishment of generalized relationships.

The salinity, temperature, and density measurements were concentrated in the entrance where the warm, turbid layer of density current was most evident. The data confirmed diver observations that a significant gradient exists at 1-2 meters above the seabed, below which the flow is warmer, denser, and more saline.

Sediment Monitoring

During the course of the survey of site conditions, suspended and bed load sediment activity were also monitored, primarily through the use of dredged test pits and time integrated sediment samplers (TIS's). Spot sampling of the seabed and suspended sediments; surf zone sampling and current measurements; aerial, coastline, and seabed reconnaissance; and motion pictures were also used to establish qualitative data described herein.

The test pits monitored the deposition of both suspended and bed load sediments at two locations along the proposed channel - one at the projection of the coast across the bay entrance (9 m depth), and a second at the mid-point between the first and the offshore end of the channel (14 m depth). The pits were 12 meters square with a nominal depth of 1 meter. Filling of the pits and scour around them were monitored over a period of 9 months, including the most severe weather periods, and the character of the deposited sediment was established. The intended purpose was primarily to establish the effects of sediments transported alongshore on potential channel filling, although all material being deposited was obviously included.

To facilitate measurement of the filling rates, a total of 21 metal rods were driven into the bottom, extending across and outside the pits (see Figure 4). At approximately monthly intervals, divers measured the distance from the top of each stake to the seafloor. In addition, underwater observations of bottom character and sediment motion were made and cores were taken and analyzed to document the character of material filling the pits.

All along the channel and especially through the bay entrance and adjacent to the test pits, the contribution of suspended sediments to deposition were monitored through collection of material falling through the water column in Time Integrated Samplers (TIS's). Vertically mounted sediment cups on a taut line mooring were open at the top to collect falling material. Six strings with cups located at 10, 20, 30 and 70 percent of the depth

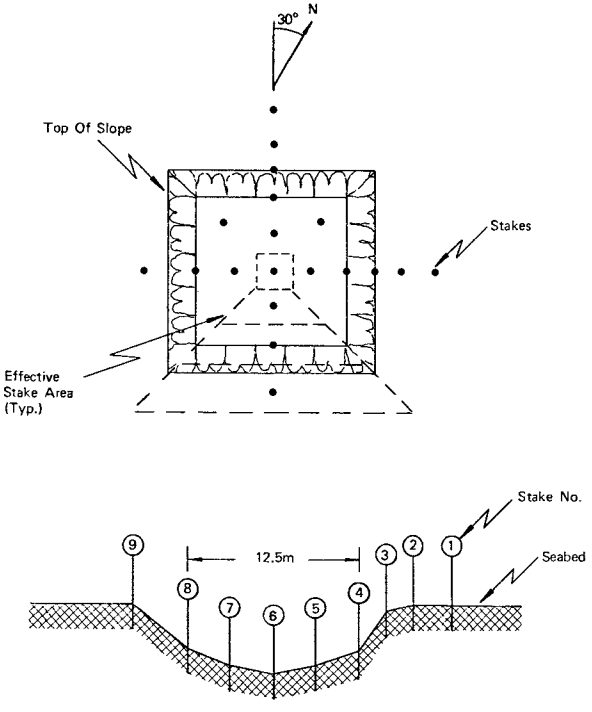

FIGURE 4 - DREDGED PITS PLAN AND PROFILE

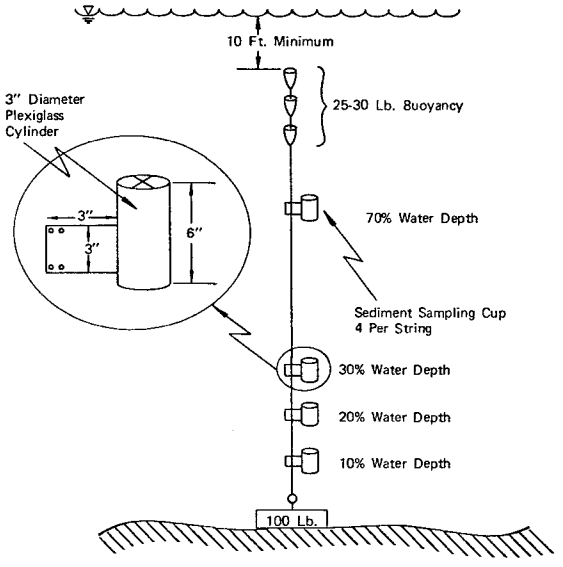

FIGURE 5 - TIS STRING

above the bottom were used (see Figure 5). Cross vanes inside the top of each cup served to reduce turbulence and any tendency for material deposited in the cup to be resuspended. The monthly servicing of these strings by a diver involved first capping each cup to avoid loss of sediment and then retrieving the entire string for fitting of clean collection cups. The dry weight of sediment in the cup was established later in the laboratory and, together with saturated density and porosity characteristics, used as a basis for calculating actual deposition rates in terms of centimeters per day of material added to the bottom.

FIELD DATA

Dredged Test Pits

Data reported from the monitoring of the offshore test pit is shown on Figure 6. The data shows that in spite of its narrow width relative to the proposed channel, the pit did not fill more than 0.5 meters in 27 weeks, and on the average much less than that. Most of the filling (up to 0.3 m) took place between the 18th and 21st week measurements - a period of only 3-4 weeks, but when the wind/wave environment was most severe.

As expected, the pit nearer shore filled somewhat more quickly than the offshore pit, becoming nearly full after 21 weeks. Again, the most rapid filling related only to the most severe wind/wave conditions, in an apparently non-linear manner. More than half of the filling occurred in a period of four of the 21 weeks. Practical assessment of the effect of rapid filling on actual channel shoaling predictions is discussed under "ANALYSIS OF SEDIMENTATION DATA."

In assessing the volume of material deposited in the pits, it was also necessary to consider the effective area of the pits and stake coverage as they bore relation to actual filling rates. Since slumping of the sides occurred and because the more fluid suspended load filled the deep center of the pits more rapidly, the average change in elevation was sensitive to the area considered. In general, the average decreased as greater area was considered. In order not to underestimate deposition, a reduced effective area was established based on analysis of the sensitivity and incorporating, for the most part, only the deeper and more rapidly filled portions of the pits.

Attention was also given to the fact that the deeper deposition at the stakes in the center of the pit represented a lesser area of the pit, due to the square plan of the pit and the pattern of stake placement (refer to Figure 4). Sub-dividing the pit into areas of individual stake coverage, the center stakes became less weighted in calculating the average rate of filling.

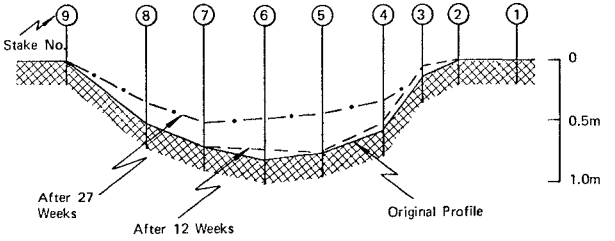

FIGURE 6 - DREDGED PIT DATA

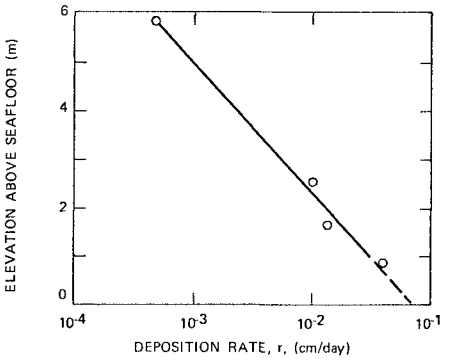

FIGURE 7 - TIS DATA

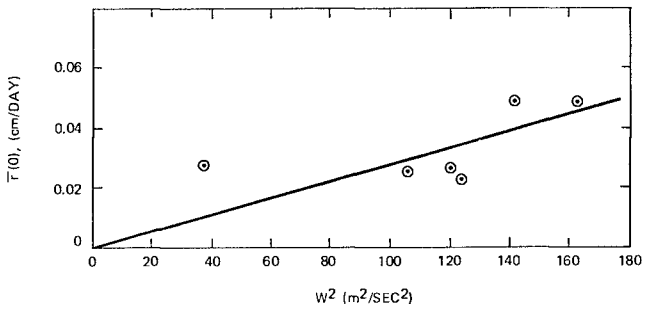

FIGURE 8 - CORRELATION OF SUSPENDED SEDIMENT DEPOSITION RATE, $\bar{r}(0)$, WITH MEAN WIND SPEED SQUARED, TIS 4

T1S Strings

A sample of data reported for one monitoring of a T1S string is shown on Figure 7. The graph shows the variation of material collection rate versus the elevation of the TIS cups above the seafloor. The collection rate was established from the laboratory measurements of the weight of material collected over the sampling interval. As shown, the graph is used to extrapolate collection rates to estimates of material deposited on the seafloor based on an exponential relationship.

Considering: (1) the material in suspension to be of uniform diameter and density and (2) the vertical eddy diffusivity, ε, to be uniform, the concentration, $C(z,t)$, of sediment is

$$C(z,t) = C_o(t)\, e^{-\frac{w}{\varepsilon(t)} z} \tag{1}$$

in which C_o is the concentration at the seafloor, and w is the fall velocity of the sediment. The seafloor concentration, $C_o(t)$, is related in an unknown way to the forcing factors (waves, winds, etc.). lt is noted that if there were N components of suspended sediment characteristics, Eq. (1) could be generalized to

$$C(z,t) = \sum_{n=1}^{N} C_{o_n}(t)\, e^{-\frac{w_n}{\varepsilon} z} \tag{2}$$

Returning now to the representation for a single sediment characteristic (Eq. (1)), the sedimentation cups are considered to result in a sheltered environment in which the sediment settles and is collected. ln this regard, it is noted that Gardner (1977) has conducted laboratory and field studies of the trapping efficiency of samplers of various geometries in steady currents. For cylinders of the aspect ratio used in this program, the "collection efficiency" is approximately unity. If the sedimentation cups perform as discussed above, the average depositional rate $\bar{r}(z)$ over a time, T, is

$$\bar{r}(z) = \frac{1}{T} \int_{t}^{t+T} wC(z,t)dt \tag{3}$$

and considering the average concentration to have the same form as Eq. (1), the average deposition rate can be expressed in the form

$$\bar{r}(z) = \bar{r}(0)e^{-Kz} \tag{4}$$

and taking the logarithm of both sides of Eq. (4)

$$\ln \bar{r}(z) = \ln \bar{r}(0) - Kz \qquad (5)$$

Thus, by plotting on semilogarithmic paper the average depositional rate at four elevations, it is possible to extrapolate to determine the deposition rate to be expected at the seafloor. Recalling the presence of the warm turbid layer of bottom water and the possible contributions from more than one sediment type component, it is important in cases where deviation from a straight line occurs to weigh the lower two measurements more heavily than the upper two in extrapolating to the seafloor.

Other Measurements

The observations and spot samples taken on site were used primarily to confirm the interpretation of the more quantitative data and to relate it to assessments of the overall seafloor processes. The lack of filled pocket beaches, for example, relates to the fact that the pits did not fill rapidly, attesting to the lack of a substantial sediment source. The presence of the seabed trough in the bay entrance is also indicative of either the sediment-starved nature of the area, or of the existence of a sufficient flushing mechanism (e.g. the density and tidal currents). The discovery of the density current at the seafloor supports a correlation of the sedimentation data to wind phenomena on the basis of evaporation (see the following section). The spot sediment samples indicated a generally exponential distribution of sediment concentration in the water column, confirming the TIS data shown in Figure 7.

ANALYSIS OF SEDIMENTATION DATA

An attempt was made to correlate the sedimentation data collected in the suspended sediment samplers and the test pits with relevant measured wind and wave characteristics. The final method developed includes a correlation between the seafloor extrapolated suspended sediment deposition and wind data. This relationship is then utilized to determine the portion of the trapped material in the test pits that is due to bed load transport (total deposition less suspended sediment deposition). These results are then applied to the prediction of shoaling in the navigation channel.

Correlation of Measured Suspended Sediment Deposition Rates With Winds and Waves

A reasonable index of the potential of the waves to cause suspended material sedimentation is the rate at which the waves dissipate energy on the bottom sediments. The average rate of wave energy dissipation is

$$\bar{\dot{e}} = \frac{1}{T} \int_{t}^{t+T} \tau_b U_b dt \quad \alpha \quad \frac{1}{T} \int_{t}^{t+T} |U_b|^3 dt \tag{6}$$

in which U_b is the magnitude of the wave-induced water particle velocity at the bottom. From linear wave theory

$$|U_b| = \frac{H}{2} \sigma \frac{1}{\sinh kh} \tag{7}$$

in which H is the wave height, h is the water depth, and σ and k are the wave angular frequency and wave number, respectively:

$$\sigma = \frac{2\pi}{T} \tag{8}$$

$$k = \frac{2\pi}{L} \tag{9}$$

with the wave length, L, and wave period, T, being related by the well-known dispersion equation

$$L = \frac{gT^2}{2\pi} \tanh kh \tag{10}$$

The values of $\bar{\dot{e}}$ were calculated and summed for all periods over which the TIS strings were emplaced. For this purpose, the local depth at the TIS string of interest was taken into account as was the transformation of wave height from the wave measurement location to each particular TIS location. For periods with less than 80% wave data return, the results were not included in the analysis.

The effect of the wind on shoaling rates at Bahia Portete is believed to be somewhat unusual due to the interrelationship between wind evaporation rates, densification and sinking of water in Bahia Portete, and the ultimate outflow of warm, dense and turbid water in the lower layers from Bahia Portete. The wind also contributes to shoaling through generation of local waves in Bahia Portete which then attack and erode the cliffs on the western side of the bay. The effect of the wind was characterized through the wind stress, or more simply, by the square of the wind speed, W^2. Since local monthly measurements of wind speed were available by percentages Δp_n in various class intervals, the monthly mean square wind speed was approximated by

$$\overline{W^2} = \sum_{n=1}^{N} \overline{W_n^2} \, \Delta p_n \tag{11}$$

where W_n is the magnitude of the wind speed associated with the n^{th} speed category. Table 1 summarizes values of extrapolated seafloor

deposition rates, the wave energy dissipation factor, $\overline{\dot{e}}$, and $\overline{W_j^2}$, for each TIS string and each intersurvey period.

The monthly mean seafloor deposition of suspended sediments was correlated with the monthly mean wave energy dissipation factor and the monthly mean square wind speed in the linear form

$$\overline{r}_j(0) = K_1 \overline{\dot{e}}_j + K_2 \overline{W_j^2} \tag{12}$$

using the method of least squares. In addition, the goodness-of-fit parameter, μ , was calculated for each TIS string, where

$$\mu \equiv \frac{\sqrt{\sum_j \delta_j^2}}{\sqrt{\sum_j [\overline{r}_j(0)]^2}} \tag{13}$$

in which

$$\delta_j \equiv \overline{r}_j(0) - (K_1 \overline{\dot{e}}_j + K_2 \overline{W_j^2}) \tag{14}$$

To provide insight into the interpretation of μ values, if Eq. (12) provided a perfect fit to the measured data, then μ would be zero. The maximum value of μ if no correlation existed would be unity as would be obtained by $K_1 = K_2 = 0$.

The results of the least squares procedure showed, somewhat surprisingly, that the sedimentation rates were very poorly correlated with the waves. However, there was quite good correlation with the wind. There are several possible explanations for wind appearing as an important causative factor. Wind is related to the local waves and, due to the predominant direction, the wind contributes to the westerly current which carries sediment from the shores located to the east of Bahia Portete. As noted previously, wind also causes evaporation of the water in Bahia Portete, thereby creating dense water which outflows as a turbid bottom current.

Because waves did not prove to be a strong correlative factor, the least squares procedure was again carried out with W^2 (which is proportional to wind stress) as the only correlation factor. The results are presented in Table 2 and an example given in Figure 8. Some of the fits are extremely good (TIS 1 and 2), whereas one is poor (TIS 3 - based on only two data points), and the others are reasonable and considered to provide a good basis for calculating the deposition rates due to suspended load.

Correlation of Bed Load

Deposition of material transported as bed load depends on the available energy to transport the material and the availability of such material to be transported. Since there were available

TABLE 2

SUMMARY OF BEST FIT COEFFICIENTS, K, AND NORMALIZED STANDARD DEVIATIONS, μ , FOR SUSPENDED SEDIMENT DEPOSITION RELATIONSHIP TO WIND STRESS

TIS No.	No. of Data Points	K $(cm\ sec^2)/(day\ m^2)$	μ

6	1	Insufficient Data	

results from only two test pits, as compared to meaningful results from five TIS strings, and since the test pits are judged to remain effective in trapping over only eight months or so, the correlation for the pits is necessarily relatively less comprehensive. Fortunately, in the prediction results to be presented later, the bed load component constituted only 20% of the total deposition.

As noted previously, the bed load component in the test pit deposition was estimated from the total deposition as the complement of the suspended load as determined by extrapolation of the TIS data to the sea floor. (It is noted that a TIS string was located in proximity to each of the test pits.). The bedload was found to correlate best with the wave energy dissipation index (Eq. (6)) and that correlation was employed in the later predictions of shoaling rates in the navigational channel.

PREDICTION METHOD FOR CHANNEL SEDIMENTATION RATES

The two basic premises for prediction of deposition rates in the navigation channel are: (1) the test pits and TIS units accumulated representative measures per unit area of the suspended sediment that will occur in the channel and (2) per unit length, the test pits entrap the same bed load amount as would the channel.

The average daily total sedimentation rate, r_t, per unit area is expressed as the sum of the bed and suspended load components

$$r_t = r_B + r_S$$

which applies to both the test pits and to the navigation channel and in which the subscripts "t", "B" and "S" denote total, bed load and suspended load, respectively. Since the suspended sediment deposition rate is the same in the test pits and the navigation channel

$$(r_S)_{NC} = (r_S)_{TP} \tag{16}$$

where "NC" and "TP" denote "navigation channel" and "test pits," respectively. Since it is assumed that the bed load sediment deposition rate per unit channel length will be the same for both the navigation channel and test pit, it follows that

$$(r_B)_{NC} = (r_B)_{TP} \frac{W_{TP}}{W_{NC}} \tag{17}$$

in which W_{TP} and W_{NC} denote the respective widths of the test pit and navigational channel. The average daily total deposition rate for the navigational channel is then

$$(r_t)_{NC} = (r_t)_{TP} \frac{W_{TP}}{W_{NC}} + \left(1 - \frac{W_{TP}}{W_{NC}}\right) (r_s)_{TP} \qquad (18)$$

These concepts were applied using the correlation between wind and deposition rate to predict total seasonal deposition rates and annual deposition rates along the channel length.

RESULTS

The results of the correlation and prediction methods described in the previous section were applied to the estimation of: (1) total annual shoaling rate, (2) distribution of annual shoaling rate along the navigation channel, (3) seasonal distribution of total shoaling rates, and (4) shoaling due to extreme events.

The total annual shoaling rate was estimated at 306,000 m^3. The associated depositional distribution along the channel is presented in Figure 9. The monthly variation of shoaling is shown in Figure 10 and is reasonably constant due to the fairly steady winds which cause the dominant suspended sediment shoaling components.

SUMMARY AND CONCLUSIONS

A method has been developed and applied for predicting sedimentation in a reasonably deep dredged navigation channel. The procedure requires a substantial field component including measurement of suspended sediments and sedimentation in dredged test pits. Additionally, measurements and/or hindcasts are required of the potential causative factors: winds, waves, and currents.

In application of the method to a coal loading terminal at Bahia Portete, Colombia, which will require a 21 meter channel, the strongest correlation for suspended sedimentation rates occurred with wind speed squared rather than a measure of wave energy dissipation. The bed load deposition correlated best with the wave energy dissipation. Considering suspended and bed load deposition in the navigation channel to be plan area and perimeter dependent, respectively, predictions were made of seasonal, areal and total annual deposition rates.

The predictions are believed to slightly overpredict sedimentation due, in part, to the rather small size and equal plan dimensions of the test pits which results in the tendency to trap and weight equally the two orthogonal components of bed load whereas the navigational channel would entrap only that component perpendicular to the channel axis. The model does not account directly for density currents that result from high concentrations of suspended load near the bottom. This phenomenon would result in

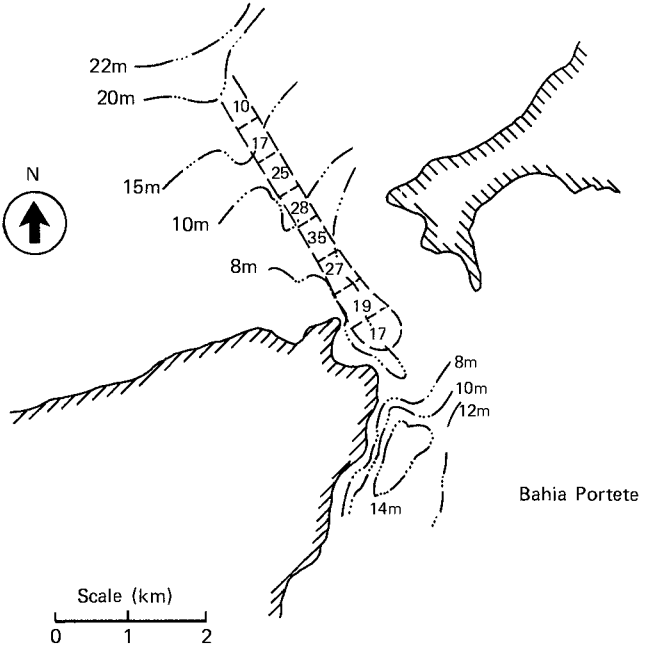

FIGURE 9 - ESTIMATED ANNUAL DEPOSITION RATES (IN cm/YR) FOR EACH ONE-HALF KILOMETER OF CHANNEL LENGTH

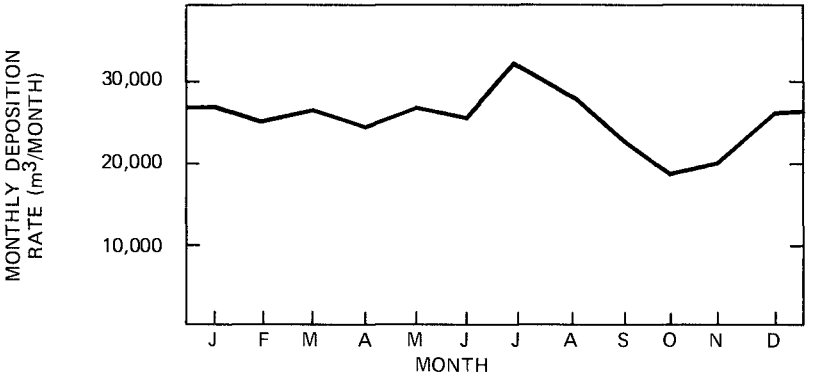

FIGURE 10 - AVERAGE MONTHLY DEPOSITIONAL RATES

greater deposition in deep channels than in shallow channels. Although this mode of transport (density currents) can dominate in some locations where very high turbidity exists, it is not believed to be a major factor at Bahia Portete.

As an overall summary statement, a qualitative assessment is that the uncertainties in the methodology and data are such that the shoaling predictions are somewhat excessive (say 10 - 15%). The coal exporting facility is now being constructed and it will be of interest to compare future maintenance dredging requirements with the predictions presented here.

ACKNOWLEDGEMENTS

Collection of the field data required for the shoaling analysis was accomplished by the combined efforts of Frederic R. Harris Engineering Corporation, Lake Success, New York; Hidrotec Ingenieros Consultores, Bogota, Colombia; Dames and Moore, Cranford, New Jersey; and T. L. Roscetti, Senior Staff Engineer, Exxon Research and Engineering Company.

CONSTRUCTION OF A BREACH CLOSURE IN A BARRIER ISLAND

M.J. McCarthy, A.M. ASCE[1], E.J. Schmeltz, A.M. ASCE[2],
G.R. Lehan, M.ASCE[3]

ABSTRACT

A breach was opened in the barrier beach along the south shore of Long Island, New York during a winter storm in January, 1980. Due to public safety and environmental concerns, a contract to close the breach using sand fill was awarded to a local contractor. This paper discusses the evolution of the construction procedures developed to allow the contractor to successfully complete the project on schedule and on budget.

1.0 INTRODUCTION

Moriches Inlet is located on the south shore of Long Island, approximately 130 kilometers (80 miles) east of New York City as shown on Figure 1. The inlet, which forms the primary outlet through the barrier island between Moriches Bay and the Atlantic Ocean, is stabilized by two stone jetties approximately 245 meters (800 feet) apart.

During January 1980, a severe northeast storm resulted in the breaching of the barrier island immediately to the east of the inlet. The breach, initially 90 meters (300 feet) in width, was probably the result of excessive erosion/washover from the bayside of the barrier island coupled with high waves and tides on the oceanside.

Tidal currents and wave action in the area resulted in the rapid growth of the breach until the fall of 1980 when, due to local concerns regarding exposure to storm induced flooding and effects on shellfish beds, construction was begun to effect it's closure. At that time, the breach, shown in Figure 2, had expanded to nominally 885 meters (2900 feet) in width with an average depth of 3 meters (10 feet). The plan selected for the closure consisted of the placement of 1.2 million cubic yards of beach fill with a final crest elevation of +4 meters (+13.25 feet) MLW and side slopes of 1:25.

2. Manager, Coastal Engineering, PRC Harris, 3003 New Hyde Park Road, Lake Success, N.Y.
3. George R. Lehan, Consulting Engineer, 95 Claydon Road, Garden City, N.Y.

The purpose of this paper is to discuss the development and implementation of construction proceedures utilized to close the breach given the following criteria:

- minimize the loss of fill material placed in the breach
- minimize the time required to complete construction (maximum 6 months)
- allow construction to be accomplished primarily with land plant
- complete construction without creating any permanent structural modifications in the area

Monitoring of the inlet and breach area was conducted during construction activities to insure that these areas were reacting to the closure operations as expected. Several design modifications were instituted during construction as a result of these monitoring operations which contributed to the successful closure of the breach.

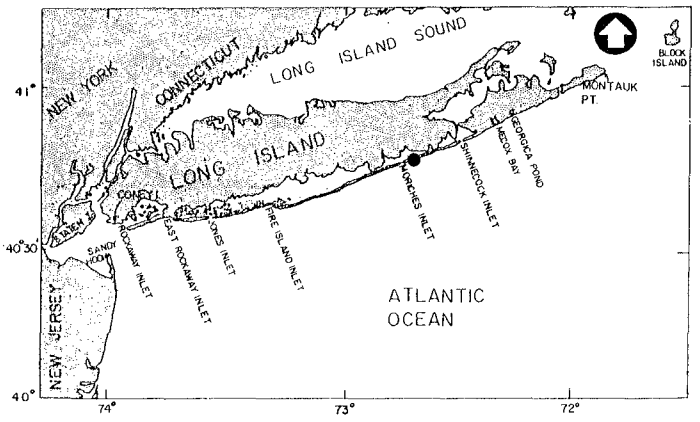

Figure 1 - Site Location

Figure 2 - Breach Immediately Prior to Closure (7/12/80)

2.0 SITE DESCRIPTION

Moriches Inlet is one of the five inlets through the barrier beach along the south shore of Long Island. Although the inlets and bays are interconnected, each inlet system functions relatively independently. Moriches Inlet primarily drains Moriches Bay from the Quantuck and Quogue Canals to the east to Narrow Bay to the west as shown on Figure 3.

Moriches Inlet has been opened and closed numerous times over the period in which records have been maintained (Reference 1). The present inlet was formed in 1931 as a result of a March storm. Between 1931 and 1947, the inlet migrated westward about 1220 meters (4,000 feet). A stone jetty was constructed along the west side of the inlet in 1947, in an attempt to stabilize it, however the inlet closed again during a storm in May, 1951.

The present stone jetties were constructed during 1952 and 1953, and extended in 1954. Despite the presence of the jetties, navigation through the inlet has been considered unsafe due primarily to the shifting shoals offshore of the inlet. The stabilized inlet has also experienced progressive erosion along the bay shoreline to the east of the jetties, as shown in Figure 4. This erosion was noted in a 1958 U.S. Army Corps of Engineers review of the inlet and has been described numerous times since then as the erosion became more pronounced, culminating in the breach during the January, 1980 storm.

Environmental conditions along the ocean shoreline in the vicinity of Moriches Inlet are typical of the entire south shore of Long Island. Nearshore wave heights average nearly 0.7 meters (2.3 feet) with maximum heights of approximately 4.1 meters (13.5 feet) (Reference 2). The lowest wave conditions occur during the months of May through September. Peak wave heights typically occur in February and March. Wave periods typically average between 4 and 7 seconds.

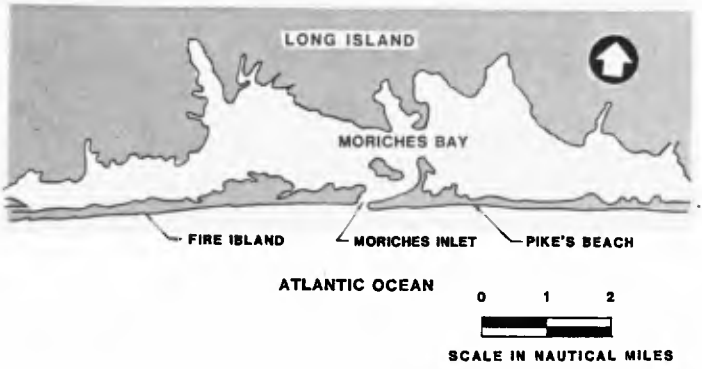

Figure 3 - Site Plan

Figure 4 - Erosion Along Pikes Beach (2/70)

Current velocities in the breach were estimated to be up to 5 feet per second prior to the start of closure operations. Current and bathymetric conditions were monitored during closure operations to assist in the development of the final closure procedures. The monitoring program and an analysis of inlet and tidal prism changes are the subject of a separate paper (Reference 3). Current velocities measured during closure operations ranged from zero during slack tide to over 1.7 meters (5.5 feet) per second at peak conditions.

Longshore transport in the inlet area is predominantly from east to west. The littoral transport rate averages over 300,000 cubic yards per year.

3.0 ALTERNATIVES CONSIDERED

A number of alternative procedures were considered to effect closure of the breach within the constraints identified above. Additional constraints considered in evaluating alternatives included:

- material sources were 600,000 cubic yards from bay dredging and 600,000 cubic yards from an upland source
- the contractor had a considerable quantity of PZ-27 steel sheet pile in varying lengths available for use

Preliminary options investigated included:

- placement of fill with no temporary retaining structures
- use of concrete pipe temporary retaining structures
- use of barges to retain the fill temporarily
- use of steel sheet pile temporary retaining structures

The initial option of placement of the sand fill with no temporary retaining structures included placement of the upland fill material along the ocean and bay sides of the breach to act as retention dikes for the dredged sand. The intent of this placement procedure was to provide protection for the dredged sand from severe erosion while it was in a slurry state. This option was discarded due to the expected high loss of fill even considering the special placement of materials proposed.

The second option evaluated for closure involved the use of scrap concrete pipe as a temporary retention dike for the sand fill. The concrete pipe was available in lengths ranging from 2.4 to 3.6 meters (8 to 12 feet) and diameters to 1.5 meters (60 inches). Several alternatives were developed to effect closure using the concrete pipes including placement in horizontal and vertical configurations to retain the sand fill. An additional alternative called for placement of the concrete pipes parallel to the currents and was intended to reduce the potential scour of the bottom as the breach was closed by providing culverts for the flow and scour protection. A controlled cutoff of the flow could then be effected by placing pipes to close off the culverts providing a quiet area to place fill. All alternatives involving the use of concrete pipes were ultimately discarded due primarily to the cost of transporting the pipes to and from the project site.

A third option evaluated consisted of sinking barges in the breach area to stop the current flow and allow placement of the sand fill. This option was discarded primarily due to the shallowness of the breach area which would require dredging to move the barges into position. In addition, due to the scouring of the bottom causing settlement of the barges as well as placement of fill along one side, it was felt that difficulties would be experienced in raising the barges at the conclusion of the project.

The fourth option investigated was the use of steel sheet piles driven to act as a retention wall for the fill during placement. Two basic alternative schemes utilizing the steel sheeting were developed and evaluated. The first, consisted of two single rows of sheet piles driven along the ocean and bay sides of the breach to effectively seal off the fill. Several potential problems were envisioned which caused this alternative to be discarded. These were:

- exposure of the sheet pile wall to ocean waves causing stability problems and scour at the toe
- scour of the sand fill placed between the widely separated walls due to currents moving around the ends of the sheet pile walls and by direct wave attack from the southwest

In response to these concerns, a second sheet pile alternative was developed. This alternative , shown in Figure 5, consisted of two parallel rows of sheet pile driven approximately 30 meters (100 feet) apart along the bay side of the breach. The advantages of this alternative were felt to include:

- control of tidal currents in the fill area
- potential for trapping a portion of the predominantly westward littoral drift
- protection for most of the retaining structure from wave attack
- protection against complete loss of the placed fill material in the event of a storm during construction

This alternate was eventually selected for use in the closure operation.

In an effort to further minimize fill loss it was decided to place the fill material from upland sources between the sheetpile dikes and along the ocean side of the breach. Dredge fill would then be placed between these two protective arms forming the center of the closure.

During final selection of the construction alternative, concerns over the stability of the cantilever sheet pile retaining walls under construction loads and the effects of scour along the bayside were addressed. Stability calculations were made to determine minimum setback distances for equipment operating within the sheet pile walls as well as the maximum tolerable scour along the bayside. In an effort to control this scour and enhance the stability of the retaining wall, short sheet pile "spurs", as shown on Figure 5, were proposed to be driven at right angles to the main wall on the bay side.

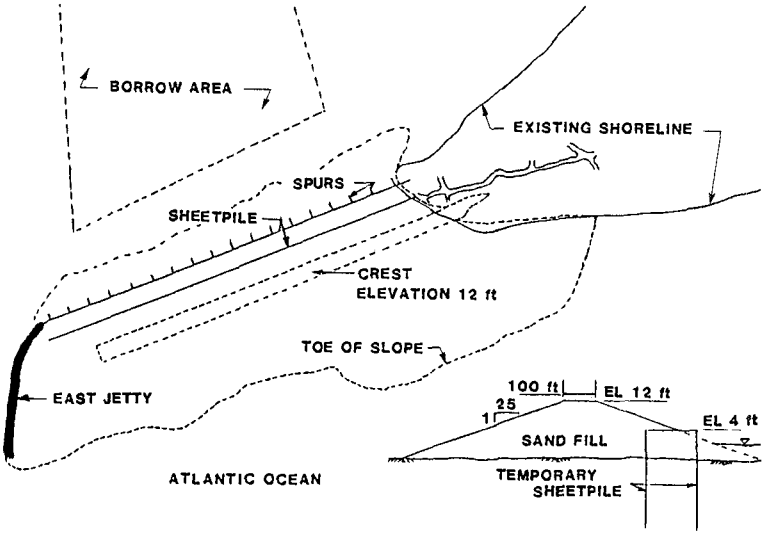

Figure 5 - Selected Construction Plan

4.0 CONSTRUCTION PROCEDURES/MONITORING

Construction operations began in early October ,1980. Initial operations consisted of cutting and stabilizing a haul road over the dunes leading to the construction site and moving in equipment and sheet piles. Placement of fill material from upland sources and driving of sheet pile walls commenced on October 10. Figure 6 is an aerial view of the construction site made on October 12, showing a short section of the sheet pile wall in place and the beginning of a sand bar along the ocean side of the closure. This bar was in evidence throughout the closure operations and seemed to be due to the entrapment of the westward littoral transport. In any event, the bar migrated westward as closure operations progressed and provided addtional protection from the ocean waves to both the fill material and the exposed portions of the sheet pile wall.

Placement of the sheet pile walls was accomplished using a Link Belt 138, 70 ton crane fitted with a vibratory hammer as shown on Figure 7. Construction operations were able to be continued during most weather and sea conditions although at several times the safety of the construction crew guiding the sheet piles into position required shutdown of these activities as shown on Figure 8.

Monitoring of the closure operations was conducted based on periodic field surveys as well as reports from construction foremen onsite. Of primary concern were the stability of the bayside sheet pile wall, reaction of the open portion of the breach as closure operations progressed and stability of the exposed east jetty. As shown on Figure 9, a deep channel began to form adjacent the east jetty as the closure was affected. Current measurements obtained during this period idicated that the primary flow was being shifted back to the original inlet, however significant currents were still being experienced in the breach. As discussed below, the changes in this section were closely monitored to attempt to prevent any further deterioration of the east jetty.

Additional concerns were identified during soundings made along the bayside of the sheet pile wall by the construction crew, indicating significant scour occurring along one section of the wall. A site visit by the engineers indicated that the sources of the problem were twofold involving both the spacing of the sheet pile spurs and the location of the sand bar on the bayside of the wall. As shown in Figure 10, the sand bar was causing flow from the Bay Channel to pass along the sheet pile wall. To alleviate this problem. the dredge was instructed to cut a channel through the sandbar to allow flow from the Bay Channel to move into the old inlet and spacing of the spurs was reduced in this area.

Final closure operations were begun in the beginning of December. As shown on Figure 11, the tidal currents were primarily moving in and out of the bay through the old inlet, due in part to the cut made by the dredge through the sand bar. To further channel the flow into the inlet a long spur was constructed to deflect the ebb tide away from the breach. These procedures worked as sand began to naturally accumulate in the remaining breach opening and closure operations were completed with no further difficulties on December 15.

Figure 10 - Construction Progress (12/4/80)

Placement of sand from upland sources and by dredging continued until mid January, 1981. The sheet pile walls were also removed during this period and all construction activities were completed by the beginning of February 1981.

5.0 CONCLUSIONS

As a result of the construction procedures developed in this study, the breach in the barrier island was closed utilizing primarily land based plant supported by dredging conducted in relatively protected areas. Despite working during a typically stormy portion of the year, constuction delays due to weather were minimal. The closure of the breach was effected nominally 2 months after startup of construction and the overall project was completed within 5 months of startup.

Losses of material were limited to approximately 15 percent of the gross volume of material placed at the site. These losses included those experienced during a storm which occurred several weeks after closure operations began. This storm had a return period of slightly over two years and caused some damages to the exposed sheet pile walls as well as loss of fill. Most observers agreed, however, that without the sheet piles, the majority of the fill placed would have been lost.

Close cooperation between the engineers and contractor allowed procedural and design changes to be made as site conditions changed. This cooperation contributed to the timely and succesful completion of the project within the constraints of the owner and the contractor.

6.0 ACKNOWLEDGEMENTS

Cooperation of the officials and field personnel of Lizza Industries during the conduct of these studies is gratefully acknowledged. In addition the authors would like to acknowledge the assistance of personnel from Ocean Surveys, Inc.in the conduct of field monitoring and the U.S. Army Corps of Engineers, New York District for their cooperation.

HYDROSEDIMENTOLOGICAL STUDIES IN BAHIA BLANCA

BY

Petroni R.V.[1], Serman D.D.[2] and Escalante R.S.[3]

1. INTRODUCTION AND SUMMARY

The increasing international grain trade make it necessary to have more deep facilities for large draught ships.

Within the areas of major agriculture developments, Bahía Blanca harbour complex, is one of the most important and consequently also its improvement. In order to achieve this improvement a deeper and wider navigation channel has to be designed.

The actual channel, 100 km. long is limited to bulk carriers up to 37 ft. draught. It is developed along a sandy and silty coast with large bars and islands. Bahía Blanca is located at the southwest of the Buenos Aires Province, within a Bay of trapezoidal shape, where the mean tidal range changes from 3,5 m in the inner part to 1,8 m in the outer part. Trying to improve a so long channel in a complex sedimentological area imply a rather difficult task, which requires a fully investigation programme to achieve an economical and technical solution. To this end, extensive field and desk studies were carried out covering all the influence area and testing different alternatives.

One of the major problems to solve is the sedimentological stability of the channel due to the action of currents and waves.

The use of mathematical models and of large and reliable field surveys, together with a pilot test dredging used as a one to one model for the calibration of the transport formulas, looks as the most suitable method to attack such problems.

The results of this study are part of the navigation channel project carried out by the firm NEDECO-ARCONSULT for the Argentine Government.

2. SITE DESCRIPTION

PHISIOGRAPHIC CHARACTERISTICS

From the phisical point of view, Bahía Blanca is characterized by sandy and silty coasts with large bars and islands which show the result of a dentrictic shape. Fig. 1.

One of the most important physical factors of the area are the tides, which in the range up to 4 m. flood large part of those bars spreading the water surface from 745 Km2. in low water to aproximately 1.880 Km2 in high water; showing at this stage a unique water surface with a few islands.

This means that the difference between low water and high water is of about 1.135 Km2. of land, that is covered with water alternatively within 6 hours and a half.

This behavior has an important influence in the hydrosedimentological aspects of the area.

Other important picture of the area is that there is no fresh water supply, because only small creeks discharge on it.

It is a windy area with a dry climate. The reason of that is due to the fact that the most frequent winds are from the West and North, which induce a typical continental weather.

Eventhough, when this situation is reversed the winds from the South-East produce changes in the Bay behavior with wind set up and ocean waves conditions.

Due to the continental weather and the low depth, the water temperature is affected by the air temperature, making its variation from a maximum of 26°C and a minimum of 9°C.

HYDROOCEANOGRAPHIC CHARACTERISTICS

The Principal Channel has an extention of about 100 Km. long.

This is a natural channel, part of which has a depth of more than 60 feet. But there are other areas where the navegation is restricted by depth of about 30 feet, which imply a yearly mantainance dredging and also to make use of the tide to go in and out of the channel.

Those areas of shallowness are principally located on the outer zone, where, the sand bars movement are due to the combined action of currents and waves.

As a general feature of the channel, we can divide it in three different sections each of them with different geomorphological characteristics.

The inner part, is extended from Galvan Port to Belgrano Port

with aproximately 30 Km. Here we find soft rocks on the bed and therefore a very stable situation. On the other hand the flats are muddy convered, and due to the tidal action and wind induced turbulence we find in the water large amount of suspended sediment, getting from the tidal flats.

From Belgrano Port up to an extention of about 20 Km. the channel bed is of fine sand and silt. Here is where largest depth is found.

Out of this area, the channel becomes erratic and shallow. Rather than one defined channel we find several branches which also change in shape and depth due to storm conditions.

As it was said before, the tide characterizes the flow conditions in the area, generating reversible currents in the natural channels of about 0,3 to 1,3 m/s.

These currents induce the movement of large amount of sediment inward and outward the bay during flood and ebb. It can be said that the sediment transport induced by tidal currents has an almost zero net drift.

However under storm conditions, where wind driven currents and waves are present, the dynamic stability is broken.

Particulary in the outer area, the wave climate has a very important role in the sedimentation mechanisms.

Two wave systems are presented, the ocean waves coming from the S and SE and the localy generated wave by anshore winds.

The first one have waves up to 5 m. height and period of 12 seconds, which are strongly effected by the shoals and the second one goes up to 4 m. height but in the period of 7 to 8 seconds.

3. HYDROSEDIMENTOLOGICAL PROBLEM
