At the present time sea wave is described by means of two theoretical models, the first is based on regular waves, components of which do not change in time and space, and the second model is based on irregular waves, components of which are randomly changed. The latter coincides to the greater extent with the rolling sea, but even this model does not characterize it to the full. Taking sea wave for a random process, the model of irregular waves does not take into account the sequence of their alternation. From the point of view of probability, on which the model of irregular waves is based, the maximum wave may be followed by the minimum wave, and the greater period may be followed by the smallest one. The real sea wave, especially in shore zone, where the main engineering constructions are placed, is characterized by clearly expressed group structure, which includes alternation of a number of great and small waves and the maximum wave is always followed by the wave having almost the same parameters. Moving through the pointed measuring section, and also depending on the wave generating condi-

^{xx} Candidate of technical sciences. Vice-Director of All-Union Research Institute for Transport, Construction, Moscow, USSR.

tions, the number of waves in the group is changed.

There is a tale about "the 9-th bar" - the greatest wave in the group consisting of nine waves, which coincides to a certain extent to the observations in situ. According to the linear potential theory, simple wave group may be obtained by means of addition of two sinusoidal waves with different but almost the same wave numbers and frequencies. In nature it is much more complex, but the nature of wave group structure is the same and is based on the existence of the several systems of quasi - regular waves in the field of the wind irregular waves which are characterized by their own frequencies, that the main energy of this system is concentrated on. These systems, interacting with each other, form groups of waves, and the spectrum of such wavering, when the peaks of the energy maxima of wave systems are widely distributed in their frequencies, is multimodal.

The main energy maximum of the spectrum has the least angular frequency (rad/sec), and the rest are placed in order of energy level decreasing according to increasing frequencies. The energy of spectrum components with the frequencies greater than the frequency of the third maximum, as a rule, is very small in general energy balance. The example of such energy spectrum of waves in the area Sheskhari (the Black sea) is shown in fig.1 (the angular frequency in rad/sec is presented on the X-axis and the spectrum density, normalized on the dispersion - sec, is on the Y-axis).^x

^x The existence in the wind wave field several systems of waves, characterized by their own wave length (phase speed) is mentioned in the works by L.F.Titov, Newman, Physical explanation of such wave field structure is presented in paper [1].

In this area the wave properties and also pressures on the breakwater of vertical type were measured. Waves near the vertical wall were characterized by narrow spectrum of directions and thus, data on pressure measured in situ should be referred to the wave interaction when they frontally approached the wall. The waves parameters were measured outside of the interference zone and also just near the wall. The pressure was registered on seven subsurface levels. The number of waves in one oscillogram was about one hundred. The storms with maximum wave height from 1,0 to 2,5 m were registered. The loads acting on the wall were defined according to the pressure values. The object was to compare the values measured in situ with the values calculated by theoretical formula. With this aim the maximum wave from one hundred registered waves (1% provision in the wave system) was chosen in the oscillogram. The calculations were made by the following formula:

$$\frac{p}{\gamma} = Z - \eta(t) - h r \sin \delta t [ch \varphi - ch a (H-Z)] + \quad (1)^x$$

$$+ a h^2 m [ch 2 \varphi - ch 2 a (H-Z)]$$

where $\frac{p}{\gamma}$ - pressure in the point defined by the coordinate Z ;
 h - the incident wave height;
 $\eta(t)$ - position of the free water surface at the wall in respect to the calm water level;
 $\delta = \frac{2\pi}{T}$ - angular frequency;
 $a = \frac{2\pi}{\lambda}$ - wave number;
 T - wave period;
 λ - wave length;
 H - water depth near the wall.

^x The results of calculation according to the formula (1) coincide with the calculations made with the help of charts, given in the Construction Codes of the USSR (SNiP 11-57-75).

$$\alpha = a h$$

$$\beta = a H$$

t - time

$$\varphi = a (H - \eta)$$

$$n = \frac{1 + 2\alpha \sin \beta t}{ch \beta \cdot \ell^{(\varphi - \beta)}} \quad ; \quad m = \frac{\cos^2 \beta t}{2 \operatorname{sh} 2\beta \cdot \ell^{(\varphi - \beta)}}$$

The intercepting point of the coordinates is situated on the calm water level and the axis O-Z is directed downward.

The formula (1) was preliminarily checked in the laboratory conditions on the regular wave and provided the coincidence with the experimental data within 10%.

Comparison of calculations made with the help of formula (1) with the data obtained in situ showed that the calculated load values were 30% greater than measured values (in some cases - 50%). In connection with that the assumption was made that there is some influence of group wave structure on pressure values and the mathematical model of wavering process near the vertical wall was as:

$$\eta(t) = \sum_K^k h_i \sin \delta_{i0} [1 + f(t)] t \quad (2)$$

where K - the number of wave systems (within 3)

which is defined according to the number of characteristic energy maxima of frequency spectrum;

δ_{i0} - the main frequency of system;

h_i - equivalent wave height of the system.

Wave heights h_i were derived from the assumption that maximum wave height according to the given realization (h_{max}) is the result of addition of equivalent system wave heights and also according to the fact that the energy is proportional to the square wave height. For the three wave systems the equations of connection will be following:

$$h_{max} = h_1 + h_2 + h_3 \quad (3)$$

$$\frac{h_1}{h_2} = \sqrt{\frac{S(\beta_{1,0})}{S(\beta_{2,0})}}; \quad \frac{h_1}{h_3} = \sqrt{\frac{S(\beta_{1,0})}{S(\beta_{3,0})}}; \quad \frac{h_2}{h_3} = \sqrt{\frac{S(\beta_{2,0})}{S(\beta_{3,0})}} \quad (4)$$

$S(\beta_{1,0})$, $S(\beta_{2,0})$, $S(\beta_{3,0})$ - the values of spectrum density maxima at frequencies $\beta_{1,0}$, $\beta_{2,0}$, $\beta_{3,0}$ (fig. 1).

With the help of the in situ occillograms it was shown, that it is possible to select a periodical function:

$$f_i(t) = A \cos Bt \quad (5)$$

with which on definite t (the interval of order 100 waves), the function $\eta(t)$, computer calculated according to (2), has a group structure, and its statistical and spectral characteristics are close to the natural irregular process. In the expression (5) B - the frequency of wave groups appearance - rad/sec (under suggestion of A. I. Kuznetsov).

Euler's equation was used to determine the pressure (on axis OZ).

$$\frac{\partial V_z}{\partial t} + \frac{\partial V_z}{\partial z} V_z = g - \frac{1}{\rho} \frac{\partial P}{\partial z} \quad (6)$$

In the course of its integration the value of vertical speed component according to the linear wave theory was written down as follows:

$$V_z = -\sum_1^3 \frac{\beta_i h_i \operatorname{sh} \beta_i (H-z)}{\operatorname{sh} \beta_i} \cos \beta_i t \quad (7)$$

As a result of integration (6) the formula for pressure value in the point of ordinate Z (with 3 components of wave field) was obtained:

Fig.1. Example of wave oscillations spectrum in the area of Sheskhari

$$\begin{aligned}
 \frac{P}{\gamma} = & Z + \eta(t) - \sum_1^3 h_i \cdot m_i \cdot \sin b_i t [ch \varphi_i - ch a_i (H-Z)] + \\
 & + \sum_1^3 a_i h_i^2 m_i [ch 2\varphi_i - ch 2a_i (H-Z)] - \\
 & - 2h_1 h_2 \sqrt{\frac{a_1 \cdot a_2}{sh 2\beta_1 \cdot sh 2\beta_2}} [sh \varphi_1 \cdot sh \varphi_2 - sh a_1 (H-Z) \cdot sh a_2 (H-Z)] \cdot \cos b_1 t \cdot \cos b_2 t \\
 & - 2h_1 h_3 \sqrt{\frac{a_1 \cdot a_3}{sh 2\beta_1 \cdot sh 2\beta_3}} [sh \varphi_1 \cdot sh \varphi_3 - sh a_1 (H-Z) \cdot sh a_3 (H-Z)] \cdot \cos b_1 t \cdot \cos b_3 t \\
 & - 2h_2 h_3 \sqrt{\frac{a_2 \cdot a_3}{sh 2\beta_2 \cdot sh 2\beta_3}} [sh \varphi_2 \cdot sh \varphi_3 - sh a_2 (H-Z) \cdot sh a_3 (H-Z)] \cdot \cos b_2 t \cdot \cos b_3 t
 \end{aligned}$$

Notations in (8) are similar to those of (1).

By means of integrating (8) in the limits from $\eta(t)$ to H the load on the wall was determined.

All calculations were performed with the help of a computer.

As could be seen from the formula (8), besides members, which characterize each wave system separately, the pressure value is influenced also by cross members, which reflect the interaction of wave field components (the last three members of formula (8)). This expresses the influence of the group wave structure on the value of wave pressure. When $h_2 = h_3 = 0$ and $A = 0$ we have a system of regular waves and formula (8) is transformed into (1). The influence of the group wave structure on the pressure and loads values was checked according to the data obtained in situ in the course of several storms. Here are the results for the case of the greatest deviation of in situ data from calculated with the help of formula (1) at the maximum wave of 1% provision. Wave actions were characterized

by the average wave height $h = 0,75$ m, and the wave height of 1% provision $h_{1\%} = 1,8$ m. The spectral density function of the wavering had three sufficiently spaced maxima (fig. 2-a), from which those situated at high frequencies, were smoothed at the load spectrum, and especially at the wave pressure spectrum near the bottom at point with coordinate 11,2 m (fig. 2-b, 2-c). The mathematical model of the process was described by means of three wave systems with equivalent heights $h_1 = 0,78$, $h_2 = 0,54$, $h_3 = 0,48$ m and with frequencies respectively $b_{1,0} = 0,65$, $b_{2,0} = 1,10$, $b_{3,0} = 1,47$, parameter $A = 0,03$ and group frequency $B = 0,1$. Fig. 3 shows one of the most characteristic areas of in situ oscillogram of wave and wave pressures. The model of this recording together with the chronogram of the loads calculated by means of a computer according to formula (8) are presented at fig. 3-b and 3-c.

It could be seen from the comparison that the recording model somewhat lacks high frequency oscillations, but the group structure character in model and in situ are similar. In the course of comparison it should be kept in mind that the scale factors for models and for experiments performed in situ are quite different. The functions of spectrum density obtained by means of calculations illustrate the coincidence of energy distribution in accordance with frequencies in situ and in model (see fig.2 - dashed line). Finally, for the given example there is a comparison of wave pressure diagrams from the wave of 1% provision obtained in situ and also calculated considering (formula 8) and without consideration (formula 1) of the group wave structure, fig. 4. This comparison shows that pressure and load calculations without considering the group structure according to the theory of regular waves provide sufficient and sometimes excessive margin. Consideration of group structure of waves in the analytical description of the process makes it possible to draw closer in situ and computed data. But formula (8) could not be considered as a formula for

calculations, but only as a proof of the influence of wave group structure on the pressure and load values.

At present time according to the results of modelling wave actions on the constructions in wave tank with irregular waves, there is some information that hydrodynamic pressure and reactions in the elements of constructions (for pile structures) under the action of waves with group structure according to the intensity of action, depending on the number of waves in the group, take the intermediate position between regular and purely random waves.

The regular waves produce maximum pressure and reaction values and the irregular-minimum [2]. Above mentioned consideration of group structure draws the calculations quite close to the data obtained in situ that is why modeling of wave action on the constructions with regard to actions of only irregular waves without considering their group structure, could lead to the too low results.

Consideration of group structure in the course of wave loads calculation and wave modelling needs further investigation.

IMPACT WAVE FORCES
ON VERTICAL AND HORIZONTAL PLATE

by

S.R. Massel ¹, M. Oleszkiewicz ², W. Trapp ³

INTRODUCTION

The hydrodynamic impact problem is a very difficult problem because the physics of what actually happens during the instant of impact are not understood. Despite of fact that a large number of references exist on the subject, many questions are left unanswered.

The object of this research is to investigate the problems of hydrodynamic impact associated with the water waves impacting on the vertical and horizontal plates. Of particular interest are the impact forces, their relation to the incident wave parameters and scale effect problems.

VERTICAL WALL BREAKWATER

Consider first the case of the vertical plate which can simulates easily the breakwater wall. The prediction of shock-pressures exerted by breaking waves is the most important thing to be known for the design of breakwaters. However due to great difficulties in the experiments, very little information is available in regard to the practical data of the shock pressures on the prototype objects. On the other hand, during the recent decades a large number of model investigations of shock pressures have been undertaken. They indicate that the configurations of breaking waves at breakwaters vary in a wide range depending upon the type of breakwaters, the characteristics of breakwaters, the characteristics of incident waves, the ratio of the depth of water in the front of the breakwater to the height of the incident wave.

In the previous research undertaken for example, by Nagai [7], Mitsuyasu [6], Hayasi [3], Rundgren [9], Richeart [8], Loginov [5] and others, the shock pressures at particular points of the vertical wall were considered. The results of these investigations give a very ambiguous picture of the problem; often they are contradictory and have been presented in a different way. Thus, it is extremely difficult to compare the results by different authors. The value of pressure depends very strongly on the position of the air cushion. Moreover, the considered wave is usually disturbed by the preceding wave, so it

¹ Assist. Prof., ² Res. Eng., ³ Sen. Res. Ass.
Institute of Hydroengineering of the Polish Academy
of Sciences, Gdańsk, Poland.

loses part of its energy before it reaches the wall. These factors are, to some extent, a random factors.

In order to predict the effective forces on the vertical wall and to avoid the influence of the air cushion configuration on the impact forces, in the present study, the total force on the breakwater wall will be considered. The vertical plate with two degrees of freedom (horizontal displacement and rotation around the horizontal axis) simulates the breakwater wall (Fig.1). The wave breaking is forced by the composite-type bottom on which the test wall is situated. The displacements of the two points are measured simultaneously by the Phillips' capacitive sensors. The deflection of the supporting rings is in the elastic range, therefore the forces at the two measuring points are related to the displacements by Hooke's law.

Numerous experiments indicate that, if for certain wave height, the breaking wave front is approximately plane and if it creates a very thin air cushion, the pressure peak reaches a maximum value. If the wave height is only slightly smaller, the wave front will be sloping backwards. On the other hand, if the wave height is larger, the air cushion will be thicker and the wave breaks further from the wall. Therefore, for a given wave period and a given depths h_1 and h_2 , it is only one wave height that is associated with the max. force.

The first series of experiments were carried out in the wave tank being 10 m long and 25 cm width for three various wave periods. For each period, the wave height corresponding max. force was chosen.

As was mentioned above, the max. impact forces may be treated as a random variables. In order to obtain a set of data which is sufficient for statistical analysis, the experiments were repeated many times.

Since the extension of model shock pressure into prototype scale is of particular interest for engineers, various model scales were also considered. Taken as a prototype was the breakwater on 6 m water depth subjected to the wave dimensions being 2,5 m height and 5-6 s period. Laboratory tests were conducted in the five scales $1/20$, $1/30$, $1/40$ and $1/50$. It means, that considering the scale $1/20$ as a reference scale, we obtain a set of experiments in the scales $1/1$, $1/1.5$, $1/2$ and $1/2.5$.

In the various scales, the corresponding wave parameters and water depths were calculated in accordance with the Froude's law. At the same time, the mechanical device for the impact force measurement has not been changed.

From the numerous laboratory tests we found that

Fig.1 Vertical and horizontal plates.

probability density functions $f\left(\frac{R_1}{\bar{R}}\right)$ and $f\left(\frac{R_2}{\bar{R}}\right)$ (\bar{R} - mean value of the impact force R) are of the Weibull type

$$\left. \begin{aligned} f(x) &= ab \cdot x^{b-1} \exp(-ax^b) & \text{for } x > 0 \\ f(x) &= 0 & \text{for } x \leq 0 \end{aligned} \right\} \quad (1)$$

$$\text{where: } x = \frac{R_1}{\bar{R}_1} \quad \text{or} \quad x = \frac{R_2}{\bar{R}_2}$$

From Eq.1, it immediately follows that the probability distribution function $F(x)$ takes the form

$$F(x) = 1 - \exp(-ax^b) \quad (2)$$

Taking the derivative of Eq.2 gives

$$Y = \ln a + bX \quad (3)$$

$$\text{where: } Y = \ln \{-\ln [1 - F(x)]\}, \quad X = \ln\{x\} \quad (4)$$

Thus, the representation of the Eq.3 in the logarithmic scale is the straight line. In the Fig.2 the theoretical formula (3) is checked against the experimental data for the impact force R and various model scales. The agreement is quite satisfactory. However, for various scales the distribution parameters a and b takes a different values. When the parameters a and b are found from the Fig.2, the corresponding probability density functions can be easily calculated (see Fig.3).

The wave forces were measured in two points of the vertical plate. One supporting ring was approximately situated at the SWL (for wave force R_1 - point B), the other was above SWL (for wave force R_2 - point A). Fig.4 shows the example of the correlation between the force R_1 and R_2 . In each calculated cases the correlation coefficient was greater than 0.8.

As the mechanical measuring device was not scaled, it is difficult to say how much wave momentum is associated with the pulse and how much is dissipated by the mechanical and hydrodynamic dumping.

In order to give the answer on that question we considered the very simple model. In the first place, by way of experimental verification we found that the horizontal motion of the plate predominates over the rotation motion; in the record it is only one frequency that is visible. So we can state that the two degrees of freedom system is approximately equal to the two systems having one degree of freedom (Fig.5). The unknown characteristics of the measuring systems are defined by the special calibration tests.

The equation of motion of any single-degree-of-freedom system can be reduced to the equation of motion of a simple spring-mass system with damping

Fig.2 Probability distribution for max. forces in the logarithmic scales.

Fig.3 Probability density functions for max. forces.

Fig.4 Correlation between forces.

Fig.5 Equivalence of the measuring systems.

$$(m + m_a) \frac{d^2 u}{dt^2} + (C + C_a) \frac{du}{dt} + k \cdot u = P(t) \quad (5)$$

in which: u - displacement of the plate,
 m - mass of the vibrating part of system,
 m_a - added mass of the water participating
in vibration,
 C - mechanical dumping,
 C_a - hydrodynamic dumping,
 k - stiffness of the system,
 P - impact force.

As we know displacement u , the impact force $P(t)$ is given by the Volterra type integral equation

$$u(t) = \frac{1}{(m + m_a)\omega} \int_0^t P(\tau) \cdot e^{-h(t-\tau)} \sin \omega(t-\tau) d\tau \quad (6)$$

From numerical solution of the Eq. 6 follows that, the rise time of the impact force is less than or equal to $1/4$ of the natural period of the measuring system $T_n \approx 0.003 \div 0.005$ s. Moreover, only $\sim 40\%$ of the wave momentum is associated with the plate displacement; almost 60% of the momentum is dissipated due to mechanical and hydrodynamic dumping and added mass generation. It means, that the real maximum impact force is about 2.5 times greater than the force calculated simply from the displacement u by Hooke's law.

We consider now the problem of the force scaling. Usually, for the gravity wave phenomena, we use the Froude law of similarity. Thus for the mean wave force we have

$$\frac{\bar{R}_p}{\bar{R}_\lambda} = \lambda^3 \quad (7)$$

in which: \bar{R}_p - mean wave force for prototype,
 \bar{R}_λ - mean wave force in the scale $1:\lambda$.

At present we assume that in model experiments (scale $1:\lambda$) we obtain the wave force which is equal to \bar{R}_M . When no scale effect, the following relation becomes

$$\bar{R}_M = \bar{R}_\lambda \quad (8)$$

When it is not that case, we define the scale effect coefficient in the form

$$\eta_\lambda = \frac{\bar{R}_\lambda}{\bar{R}_M} \quad (9)$$

thus

$$\bar{R}_p = \bar{R}_\lambda \cdot \lambda^3 = \bar{R}_M \cdot \lambda^3 \cdot \eta_\lambda \quad (10)$$

Applying the above definition of the scale effect coefficient to the mean maximum forces we obtain the distribution of the η value as shown in Fig. 6. It should be noted that the experiments in the scale $1:20$ serve as a reference experiments. If we reduce model scale twice (from $1:1$

Fig.6 Scale effects coefficient for mean max. impact force.

to 1:2), the mean impact force at the model decreases less than it follows from Froude law for period $T=1s$. It means that $\bar{R}_M > \bar{R}_\lambda = \frac{1}{8} \bar{R}_P$ or $\bar{R}_M / \bar{R}_P > \sqrt[1]{2^3} = \frac{1}{8}$

Therefore, the prediction of the prototype forces basing on the model test (in this case) overestimates the real force. Thus, the scale effect coefficient $\eta_\lambda < 1$ has to be included (see Fig.6).

The scale effect concept can be extended to the maximum impact force with arbitrary probability of occurrence. From the calculations (not indicated here) follows that the relatively high scale effects may be expected for very low and very high probabilities.

The work reported in this part of paper is the first phase of a project intended to develop insight into breaking wave forces acting on breakwaters and the more efforts are needed towards better understanding of these sophisticated phenomena. First of all, the amount of the air content in the breaking wave is still not good defined. However, the air in the water influences strongly on the added mass vibrated with the plate.

HORIZONTAL PLATE IN THE SPLASH ZONE

An important class of forces for which there is not a large extensive history of study are the impact forces that act on horizontal members in so called "splash zone" [1,2,4,10]. The splash zone is a region wherein the particular horizontal members of the maritime structure are not usually considered to have continuous contact with the waves, but which are located at a height relative to the mean water surface, so that only occasional contact with the water will occur. The nature of the forces that occur during such contacts is essentially impulsive.

In order to provide some knowledge of the pressure distribution on the underside of horizontal members a laboratory study was made. The particular problem considered here is treated by the impact force measurements for a horizontal rigid plate, assuming that the wave system propagates in a direction of longitudinal axis of the plate. A illustration of the situation being analyzed is shown in Fig.7 for the progressive wave and in Fig.8 for the standing wave; the height of the plate (1 m length) above the mean water level is equal to S , H is the incident wave height and h is the water depth. The six electro-kinetic type pressure gauges are installed along the plate axis. The working frequency band for the pressure gauges is equal to $10^{-2} - 10^4$ Hz.

The records taken from the experiments illustrate the impulsive character of pressure. Sometimes due to disturbances underneath the platform, the peak pressure

Fig. 11 Impact pressure as a function of Ursell's number

Fig.12 Notation for the impact pressures standing waves .

Fig. 13 Impact pressure as a function of Ursell's number.

is not so clearly pronounced. In order to classify the impacts induced by the progressive waves we use the notations given in Fig.9, in which p_i - peak pressure, p_s - slowly varying pressure and p_m - maximum pressure when no impact occurs.

The incident wave were Stokes' waves $2 \leq \frac{L}{h} \leq 8$ (L - wave length, h - water depth).

In Figs.10 and 11 the normalized wave induced pressure is plotted against the Ursell's number

$U = \frac{H}{L} \left(\frac{L}{h} \right)^3$ for nondimensional clearance $\frac{S}{\frac{H}{2}} = 0, \frac{1}{3}, \frac{2}{3}$
(S - clearance between the bottom of the horizontal plate and the still water level).

The data points are the results of the averaging of numerous experiments. Moreover, the standard deviation from the mean value is also indicated. The slowly-varying pressure p_s is almost constant in the considered range of Ursell's number. The highest value p_s is obtain when the plate is at the still water level ($S=0$).

The maximum pressure p_m (when no impact) is slowly-varying function of Ursell's number with max. value at $U \sim 10-15$. The same tendency for the peak pressure p_i is observed. In Figs.10 and 11 the best fittings of the experimental data are indicated by the solid and dashed lines.

When the standing waves are considered, it is hardly to distinguish the various types of pressure.

According to Fig.12 the analysis of the experimental data is restricted to the maximum pressure value p_m . The example of the result is given in Fig.13. The pressure p_m is also the slowly varying function of the Ursell's number.

CONCLUSIONS

With respect to measurement of the impact forces at the vertical wall due to breaking wave it was found that the maximum force can be treated as a random variable with the probability distribution of the Weibull type. The amount of the air entrapped into breaking wave produce some inconsistency with Froude scaling law. Thus, the statistical concept of the scale effects was introduced.

The preliminary study of the wave impact on the horizontal plate suggests that the peak pressure and the slowly-varying part of pressure are functions of the Ursell's number.

It should be pointed out that the more efforts are needed to better describing of these complicated phenomena.

CHAPTER 142

WAVE PRESSURES ON SLIT-TYPE BREAKWATERS

by

Shoshichiro Nagai¹, F.ASCE and Shohachi Kakuno²

ABSTRACT

For severe storm waves with periods of 7.0 sec to 14.0 sec and heights of 6.3 m to 9.0 m, it was proved that the resultants of the maximum simultaneous pressures exerted by breaking waves on the slit-type breakwaters with the optimum relative chamber width of $l/L = 0.05$ to 0.07 were in most cases less than 70 per cent of those exerted on the conventional composite-type breakwaters.

INTRODUCTION

The experimental results in the previous study (2) showed that the resultants of the maximum simultaneous pressures exerted on the slit-type breakwaters by breaking waves with periods of 6.0 sec and 7.0 sec and heights of 3.3 m to 4.3 m were less than about 60 per cent of those exerted on the conventional composite-type breakwaters, while the resultants of the maximum simultaneous pressures exerted on the slit-type breakwaters by non-breaking or standing waves were a little less than or approximately equal to those on the conventional composite-type breakwaters.

For more severe storm waves with periods of 7.0 sec to 14.0 sec and heights of 6.3 m to 9.0 m, the resultants of the maximum simultaneous pressures exerted on the slit-type breakwaters located at a water depth of 16.0 m by breaking and non-breaking waves are presented herein, compared with those on the conventional composite-type breakwaters. Finally the optimum relative chamber width, l/L , for the slit-type breakwater is shown.

EXPERIMENTAL EQUIPMENT AND PROCEDURES

The experiments were carried out at a scale of 1/25 in a 100 m-long wave channel of 2 m-height and 1.2 m-width with a wind blower at the Harbor and Coastal Engineering Laboratory of Osaka City University.

Cross-Sections of Breakwater Model. — As the basic cross-section of the breakwater models used in the experiments, the south breakwater in the Port of Kashima (1) was selected, as shown in Fig. 1. The breakwater, 2,900 m in overall length, was constructed in 1969 at water depths from about 9 m to 20 m below the Datum Line (D.L.), and was severely hit by storm waves in January of 1970, the characteristics of which were hindcast to be $H_{1/10} = 10$ m and $T_{1/10} = 10$ sec to 12 sec. The vertical walls of reinforced concrete caisson were slid toward harbor-side by 0.24 m to 1.81 m. The experiments (1), which were conducted at a scale of 1/25 at the same wave channel as used at this experiment, showed that the maximum resultant pressure of $P_e = 193$ t/m was exerted by a wave with $H = 9.6$ m and $T = 8$ sec, and the value was confirmed by the maximum resultant pressure of $P_{cal} = 202$ t/m which was obtained by the wave-pressure formula (1).

FIG. 1.- Cross-Section of Kashima South Breakwater

The five cross-sections of breakwater model were used in the experiments, as shown in Figs. 2 to 6 and Table 1. As known from Figs. 2 to 6 and Table 1, the width of wave chamber, l , was changed to be 6 m and 10 m. Fig. 7 shows the profile of the model sea bed and the position of a wave recorder for offshore waves.

Void Ratios of the Slit-Type Box Wave Absorber. — The void ratios of the slotted vertical front-wall and slotted horizontal bottom-wall of the wave absorber were constant $\lambda = 0.24$ and $\lambda' = 0.15$, respectively (2).

Conventional Composite-Type Breakwater. — The cross-sections of conventional composite-type breakwater were made by attaching a iron plate to the sea-side of the vertical front-wall of the slit-type breakwater from the top to the bottom.

EXPERIMENTAL RESULTS AND ANALYSIS

Maximum Simultaneous Wave Pressure and Maximum Wave Pressure Intensity for Breaking Waves. ——— Wave pressures exerted on five points of the slotted vertical front-wall (shown by F1 to F7 in Fig. 9) and on five points of the vertical solid back-wall (caisson) (shown by B1 to B7 in Fig. 9) were simultaneously measured. The maximum simultaneous wave pressures exerted on the slotted vertical front-wall and those on the solid back-wall do not simultaneously occur, and the former always occurred earlier than the latter. However, when the intensity of the wave pressure was small, the change of the maximum simultaneous pressures in a short time was so little that both maximum simultaneous pressures may be approximately considered to simultaneously occur. Therefore, for such cases the sum of both maximum simultaneous pressures was taken as the maximum simultaneous pressure exerted on the slit-type breakwater, as denoted by $P_{e \max}(\text{slit})$ (2).

When wave pressures are so strong as in the cases of this experiment, however, the maximum simultaneous pressures change rapidly even in a short minute. The experiment showed that the resultant of the maximum simultaneous pressures exerted on the slit-type breakwater, $P_{e \max}(\text{slit})$, was the sum of the resultant of the maximum simultaneous pressures exerted on the solid back-wall (caisson) and the resultant of the pressures simultaneously exerted with those of the back-wall on the slotted front-wall. Figs. 10 to 14 show the vertical distributions of the maximum simultaneous pressures exerted by strong breaking waves on the slit-type breakwaters with the cross-sections of I to V and those on the conventional composite-type breakwaters with the same cross-sections as I to V for comparison, respectively.

The resultants of the maximum simultaneous pressures on the slit-type breakwaters, $P_{e \max}(\text{slit})$, and those on the conventional composite-type breakwaters, $P_{e \max}(\text{compos.})$ are summarized in Tables 3 to 7 for the breakwaters with the cross-sections of I to V, respectively. These tables also show the resultants of the maximum simultaneous pressures obtained by the wave pressure formulas for conventional composite-type breakwaters, $P_{c \max}(\text{compos.})$ (3). The wave pressure formulas used for breaking waves were those for composite-type breakwaters with low rubble-mounds such as $0.40 \leq h_1/h_2 < 0.75$, and the resultants of the maximum simultaneous pressures for standing waves were calculated by use of P_A' and P_A (4).

Figs. 15 and 16 summarize the ratios of $P_{e \max}(\text{slit})$ over $P_{e \max}(\text{compos.})$ and $P_{e \max}(\text{slit})$ over $P_{c \max}(\text{compos.})$ for breaking waves. It may be stated from these figures that the ratios of $P_{e \max}(\text{slit})/P_{e \max}(\text{compos.})$ for breaking waves are within 0.48 to 0.81 in Fig. 15 and the ratios of $P_{e \max}(\text{slit})/P_{c \max}(\text{compos.})$ are 0.44 to 0.77 in Fig. 16, and in most of the cases of breaking waves both the ratios are less than 0.70.

According to Figs. 10 to 14, the maximum wave pressure intensities on the slotted front-walls and the solid back-walls of the slit-type breakwaters reduce to less than 60 % of those on the conventional solid caissons of composite-type breakwaters, and the reduction of the

pressure-intensity becomes larger as the intensity of shock pressure exerted on the caisson of composite-type breakwater becomes higher.

Effect of the Width of Wave Chamber. — Comparison among the values of $P_{e \max}(\text{slit})$ in Tables 3 (for cross-section I with $l = 10$ m), 4 (for cross-section II with $l = 6$ m) and 5 (for cross-section III with $l = 6$ m) shows that the width of the wave chamber, l , has no definite and noticeable effect on the resultant of the maximum simultaneous pressures of the slit-type breakwater. Figs. 10 and 12 also show that the width of the wave chamber has a slight effect on the vertical distribution of the maximum simultaneous pressures of the slit-type breakwater.

Effect of the Top-Width of Base-Rubble-Mound. — Effect of the top-width of the base-rubble-mound of the slit-type breakwater, B , on the wave pressures was tested by changing $B = 6.0$ m (section V), $B = 8.0$ m (section III) and $B = 12.0$ m (section IV). The experimental results are listed in Tables 7, 5 and 6, respectively. According to Tables 5 to 7, it may be stated that the top-width, B , has little effect on wave pressure for the slit-type breakwater, while the effect is remarkable for the conventional composite-type breakwater.

Maximum Simultaneous Wave Pressure for Standing Waves. — The maximum simultaneous wave pressures exerted on the slit-type breakwaters by standing waves and partial standing waves were almost same as or a little less than those for conventional composite-type breakwaters, when the heights of the top of vertical wall of composite-type breakwater from the still water level, H_c , were 2.5 m to 5.6 m which were comparable to the heights of incident waves, $H = 3.3$ m to 4.3 m (2). However, in the cases where the heights of incident waves were so large as $H = 7.0$ m to 9.0 m, compared with $H_c = 5.0$ m (constant), there was caused a large quantity of wave-overtopping over the vertical walls of the composite-type breakwaters, which resulted in reduction of the resultant of the maximum simultaneous pressures, $P_{e \max}(\text{compos.})$. Therefore the values of $P_{e \max}(\text{compos.})$ measured in these cases were less than $P_{c \max}(\text{compos.})$ calculated by the wave pressure formulas of P_A' and P_A (4). Since the heights of composite waves generated at the sea-side of the slit-type breakwaters were smaller than those generated at the sea-side of the conventional composite-type breakwaters, the quantity of wave-overtopping over the slit-type breakwaters was smaller than that in the composite-type breakwaters. This fact results in some cases where $P_{e \max}(\text{slit})$ were a little larger than $P_{e \max}(\text{compos.})$ and nearly same as or slightly smaller than $P_{c \max}(\text{compos.})$ calculated by the formulas of P_A' and P_A , as shown in Tables 3 to 7.

Upward Pressure on the Slotted Bottom-Wall. — The upward pressures exerted on the slotted horizontal bottom-wall by the waves transmitted underneath the wave absorber were as large as $p_u = 4.0$ t/m² to 8.0 t/m² which were nearly same as the intensities of the horizontal wave pressures exerted at the same level as the slotted bottom-wall on the solid back-wall. However, when the trough of a receding wave came considerably down below the bottom-wall, the wave severely hit upward on the bottom-wall at the time of upward moving, and the intensities of the upward pressures reached up to $p_u = 9.3$ t/m² to 13.4 t/m² which were much larger than the intensities of horizontal wave pressures

exerted at the same level on the solid back-wall. However, when the slotted bottom-wall was installed so as to be located a little lower than the lowest trough of the design wave, the intensities of the upward pressures reduced to $p_u = 8.5 \text{ t/m}^2$ to 7.2 t/m^2 , respectively. These experimental results are shown in Table 8.

OPTIMUM CHAMBER WIDTH FOR WAVE PRESSURE

As has already been mentioned, it was proved that the change of the width of wave chamber from $l = 6.0 \text{ m}$ to 10.0 m had no definite and noticeable effect on the intensities and their vertical distributions of the maximum simultaneous wave pressures exerted on the slit-type breakwaters by breaking waves and non-breaking waves.

As known in Tables 3 to 7, all of the largest breaking wave pressures for the slit-type breakwaters with cross-sections I to V were exerted by breaking waves with periods of 8.0 sec to 10.0 sec , which had wave-lengths of $L = 83 \text{ m}$ to 112 m . Therefore, for the width of wave chamber $l = 6.0 \text{ m}$, the ratios of l/L , which was designated as relative wave chamber width, were 0.07 to 0.05 . In the previous experiments (2), largest breaking wave pressures were exerted by breaking waves with a period of 7.0 sec , which had wave lengths of $L = 61 \text{ m}$ to 66 m . Since there were no noticeable differences between the maximum simultaneous pressures exerted on the slit-type breakwaters with different widths of wave chamber, $l = 3.75 \text{ m}$ and 5.50 m , the wave chamber width was decided $l = 3.70 \text{ m}$ for the slit-type breakwater in the Port of Osaka, which has been under construction since 1977. As the period of the design wave is 7.0 sec , and its wave lengths are $L = 61 \text{ m}$ to 66 m , the ratio of l and L is about 0.06 .

Therefore it may be stated that the optimum relative wave chamber width, $(l/L)_{\text{opt}}$, is 0.05 to 0.07 , on an average 0.06 , for slit-type breakwaters. More definitely and clearly speaking for the purpose of practical design, the optimum wave chamber width, l , would be 3.70 m or so for moderate waves with heights equal to or less than about 5.0 m and periods equal to or less than about 7.0 sec , and $l = 6.0 \text{ m}$ or so for larger waves with heights larger than 5.0 m till about 10.0 m and periods larger than 7.0 sec till about 15.0 sec .

REFLECTION COEFFICIENT OF SLIT-TYPE BREAKWATER

The heights, H_C , of the composite waves, generated at one to two wave lengths offshore of the slit-type breakwaters and composite-type breakwaters, were measured by visual observation through the glass wall of the wave channel in all the experiments. The coefficients of reflection of both the breakwaters, K_R , obtained from H_C , are shown in Tables 3 to 7. The values of K_R in the slit-type breakwaters are about 0.10 to 0.30 for breaking waves, and about 0.50 to 0.70 for non-breaking waves, while K_R in the composite-type breakwaters are about 0.50 to 0.60 for breaking waves and about 0.70 to 0.80 for non-breaking waves.

Fig. 17 shows relationships between K_R and T as well as K_R and l/L for the cross-section V of breakwater ($l = 6.0$ m) when the incident waves are $H_I = 8.0$ m to 9.0 m. The theoretical curve shown in Fig. 17 was obtained so as to $K_R = 0.20$ at $l/L = 0.15$.

CONCLUSIONS

It may be stated that the most outstanding characteristics of the slit-type breakwater, which denotes a special composite-type breakwater attached a slotted box-type wave absorber to the sea-side vertical wall of the caisson near the still water level, is to be able to reduce the resultants $P_{e \max}(\text{slit})$ of the maximum simultaneous shock pressures exerted by breaking waves to less than 70 % of those exerted on the conventional composite-type breakwaters, $P_{e \max}(\text{compos.})$, or $P_{c \max}(\text{compos.})$ which denotes the resultant of the maximum simultaneous pressures calculated by the wave pressure formulas for breaking waves (3). The point of action of these resultant pressures should be taken at the still water surface. The effect of width, l , of the wave chamber of the box-type wave absorber on the wave pressures is not so sensible as the effect on reflection coefficient, and the optimum relative chamber width, l/L , would be 0.05 to 0.07, on an average 0.06. It may be stated, therefore, for practical design that the optimum chamber width, l , would be 3.70 or so for moderate design waves with heights equal to or less than about 5.0 m and periods equal to or less than 7.0 sec, and $l = 6.0$ m or so for larger waves with heights larger than 5.0 m till about 10.0 m and periods larger than 7.0 sec till about 15.0 sec.

For non-breaking waves the $P_{e \max}(\text{slit})$ could be obtained from $P_{c \max}(\text{compos.})$, which denotes the resultant of the maximum simultaneous pressures calculated by the wave pressure formulas for non-breaking or standing waves (3) (4).

The top of the slotted vertical front-wall of the slit-type breakwater should be taken at the same level as the crown of the solid caisson wall for ordinary cases, and the slotted horizontal bottom-wall be installed at such a level as a little lower than the lowest trough of the design wave at the slit-type breakwater to avoid high upward pressures exerted from underneath the bottom-wall.

The void ratio of the slotted vertical front-wall should be $\lambda = 0.24$ or so and that of the slotted horizontal bottom-wall be $\lambda' = 0.15$ or so.

The coefficients of reflection, K_R , of the slit-type breakwaters which have the optimum chamber width, l , as described here, and the void ratios of $\lambda = 0.24$ and $\lambda' = 0.15$ are about 0.10 to 0.30 for breaking waves and about 0.50 to 0.70 for non-breaking waves. These values of K_R are smaller than about 0.50 to 0.60 for breaking waves and about 0.70 to 0.80 for non-breaking waves in the conventional composite-type breakwaters.

CHAPTER 143

DYNAMIC BEHAVIOR OF VERTICAL CYLINDER DUE TO WAVE FORCE

Toru Sawaragi* and Takayuki Nakamura**

ABSTRACT

This paper describes the dynamic behavior of a fixed cylindrical pile due to both the in-line or longitudinal force and lift or transverse force in regular waves. Resonant response of the pile due to the lift force in the direction normal to the wave propagation direction is discovered at the period ratios of $T_w/T_n=2,3,4,5$ and 6 (T_w : the wave period, T_n : the natural period of the pile). Furthermore, the resonant responses in the wave propagation direction due to the in-line force also appear at the same period ratios, in addition to the well known resonance point of $T_w/T_n=1$. Moreover, dynamic displacements of the pile in the direction normal to the wave propagation direction are longer than those in the wave propagation direction when the period ratio is longer than 1.6 and Keulegan-Carpenter number is larger than 6.

Next, for the purpose of the ocean structural design, the methods of estimating the dynamic displacements in both directions and of estimating the dynamic displacements considering both are derived by using Morison's equation and lift force equation formulated by the authors. The displacements calculated are compared exactly with the experimental results to investigate the validity of the proposed method.

INTRODUCTION

In recent studies of wave force on a cylindrical pile, it has been discovered that a lift force acts on the pile in the direction normal to the wave propagation direction, in addition to a in-line force acting on the pile, as described by Morison's equation, in the wave propagation direction.

It was pointed out by Bidde¹⁾, Sarpkaya²⁾ and the authors³⁾ that the lift force has a magnitude as large as the in-line force, and that the frequency of the lift force is higher than that of the wave and the in-line force. On the other hand, considering the fact that the natural frequency (f_n) is generally higher than the wave frequency (f_w), the lift force may be important when the resonance response of a fixed off-shore structure in waves is examined. In fact, Wiegel et al⁴⁾ reported that 2-foot pile vibrates largely with the vibration period of 2.5 seconds in the direction normal to the wave propagation direction due to the alternate breaking of the large vortices under the large wave condition with the wave period being about 13 seconds. And they also reported that the test pile was broken by the lateral vibration described above.

With the above-described background, first, in this paper, the influence of lift force on the dynamic response of a cylindrical pile of cantilever type was investigated by experiments, and the effects of a period ratio (T_w/T_n) or a frequency ratio (f_w/f_n) and Keulegan-Carpenter number for the dynamic response are discussed. (T_w : the wave period and

*Professor, Department of Civil Engineering, Suita, Osaka, 565, Japan

**Assistant Professor, Department of Ocean Engineering, Ehime, Japan

equal to $1/f_w$, T_n ; the natural period of the pile and equal to $1/f_n$).

Secondly, in order to estimate the dynamic response in the in-line and normal direction, equations on dynamic displacements in two directions are derived by using the Morison's equation on the in-line force and the lift force equation formulated by the authors. Furthermore, the combined dynamic displacement is calculated, and these calculated results are compared with the experimental results.

EXPERIMENT

The wave tank used in this experiment was a 0.7m wide, 0.95m deep and 30m long wave channel at the Hydraulics Laboratory of Civil Engineering, Osaka University. A flap type wave generator was located at one end of the wave tank and a pebble beach was installed at the other end of the wave tank to absorb the wave energy.

Model cylinders used in this experiment were two kinds of cantilever type structure with a concentrated mass at its top as shown schematically in Fig. 1(A) and (B). Each model pile consisted of three parts, i.e., a concentrated mass, a circular cylinder and a spring bar. The mass was made of steel and had the same diameter as that of the cylinder. The spring bar was also made of steel and had a circular cross section with diameter of 5.5mm for the model pile of Fig. 1(A) and 5.9mm for that of Fig. 1(B). The model pile of Fig. 1(A) was fixed on the shelf in the square box made of steel with the same height as that of the horizontal flat bed. In this case, a 2.5cm cylinder made of acrylicresin was used for a circular cylinder and the water depth was kept constant at 35cm above the horizontal bed. On the other hand, the model pile of Fig. 1(B) was fixed on the channel-shaped steel having a height of 5cm that was rigidly connected to the bottom of the wave tank. In this case, a 3cm cylinder was used and the depth of the water was kept constant at 65cm above the bottom of the wave tank. The model pile of Fig. 1(A) was used only for the purpose of measuring the dynamic response in the comparatively small ranges of T_w/T_n and the one of Fig. 1(B) was used for that of T_w/T_n being large.

In this experiment, five kinds

of concentrated mass were mounted on these model piles, considering the efficiency of the wave generator and values of period ratio(T_w/T_n). The values of these masses are tabulated in Table 1(A) and (B) for the model pile of Fig. 1(A) and (B) respectively. In this table, the natural period T_n and the natural frequency f_n of the pile measured from the experiment of free vibration in water, and the logarithmic decrement δ measured from the experiment of free vibration in air are also tabulated for each mass.

In order to clarify the effects of Keulegan-Carpenter number and the period or frequency ratio on the dynamic response of the model pile, the region

Fig. 1 Structural model of experimental cylinders

of the model ratio (T_w/T_n) wave fixed between 0.8 and 7.5, and the range of rmsK-C number (rms K-C), which is the root mean square value of Keulegan-Carpenter number at each vertical elevation of the cylinder, was from 2 to 20. The range of rms Reynolds number (rmsRe), which is the root mean square value of Reynolds number at each vertical elevation of the cylinder, was from about 2000 to 8000.

The wave condition used in this study was as follows, the wave height was fixed between 2cm and 16cm, and that of the wave period was 0.6sec to 2.3sec.

In this experiment, a 16-mm cine-camera was located right above the pile to measure the dynamic displacement at the top of it. Also the strain gages were mounted near the fixed end of the cantilever to measure the dynamic overturning moment in both directions. The wave gage used was a parallel-wire resistance type and was installed at the side of the model pile. Furthermore, in order to synchronize the 16mm-movie record with records of water surface elevation and dynamic moment, pulse signals of 10 Hz were utilized. The movie records were analyzed with an electronic graph-pen system, and then locus of the top of the model pile was reproduced with a graphic display system.

Table 1 Dynamic characteristic of the model pile

DYNAMIC BEHAVIOR OF THE MODEL PILE

1) DYNAMIC LOCUS OF THE MODEL PILE

Typical loci of the top of the model pile during one wave cycle of the incident wave (except (B-1)) are shown schematically in Fig. 2 with the frequency ratio as a parameter. In Fig. 2, the X-axis is the direction of the wave propagation direction and Y-axis is the direction normal to the wave propagation direction. From this figure, the following results are appeared. (A) : In the range of frequency ratio (f_w/f_n) larger than 0.9 (Fig. 2 (A-1) ~ (A-3)), the displacement of the top of the pile in the X direction is predominant in comparison with that in the Y direction and the locus shows a nearly straight line in the X direction. Because of the well-known resonance at $f_w/f_n=1$ due to the in-line force, the pile vibrates largely in the X direction. In this case, the frequencies of the displacements in both directions possess the wave frequency as shown in Fig. 3 (A). Here, Fig. 3 shows the time histories of the displacements in both directions and corresponds to the locus shown in Fig. 2, respectively. (B) : In the range of frequency ratio ranging from 0.6 to 0.9, the locus looks like a letter of infinity sign (∞), as shown in Fig. 2 (B-1) and (B-2). In this case, the Y-displacement has the second harmonic frequency, as shown in Fig. 3 (B), but the X-displacement has only the wave frequency. (C) ; When the frequency ratio ranges from 0.4 to 0.6, the locus is nearly a double ellipse as shown in Fig. 2 (C-1) and (C-2). In this case, the Y-displacement is much greater than the X displacement,

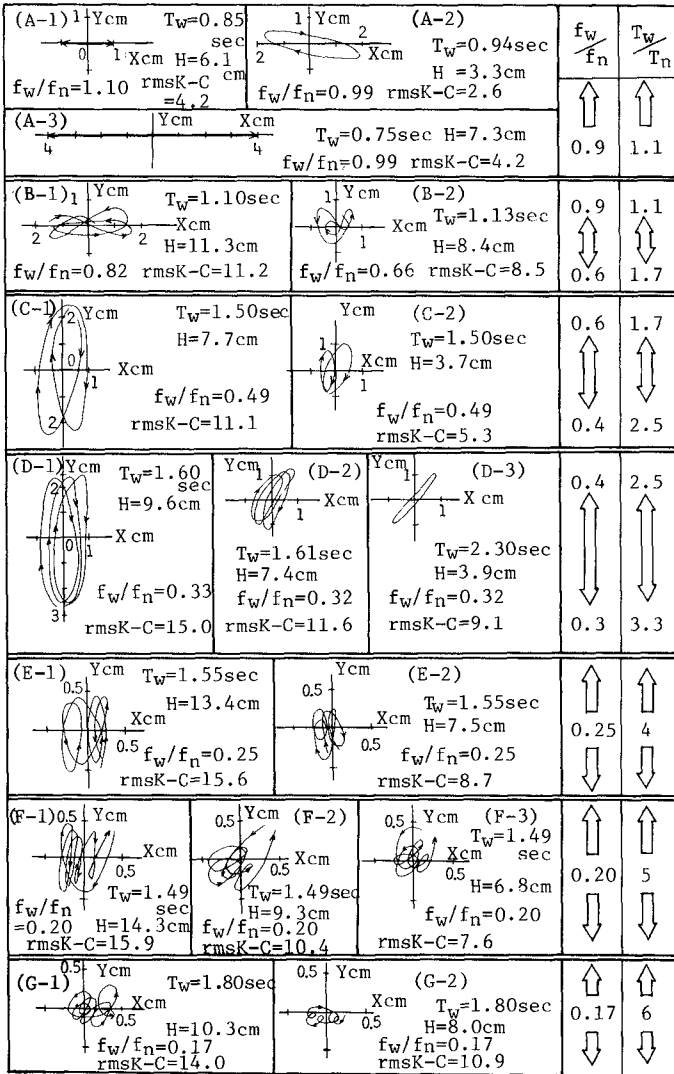

Fig.2 Loci of dynamic displacements at the top of the cylinder

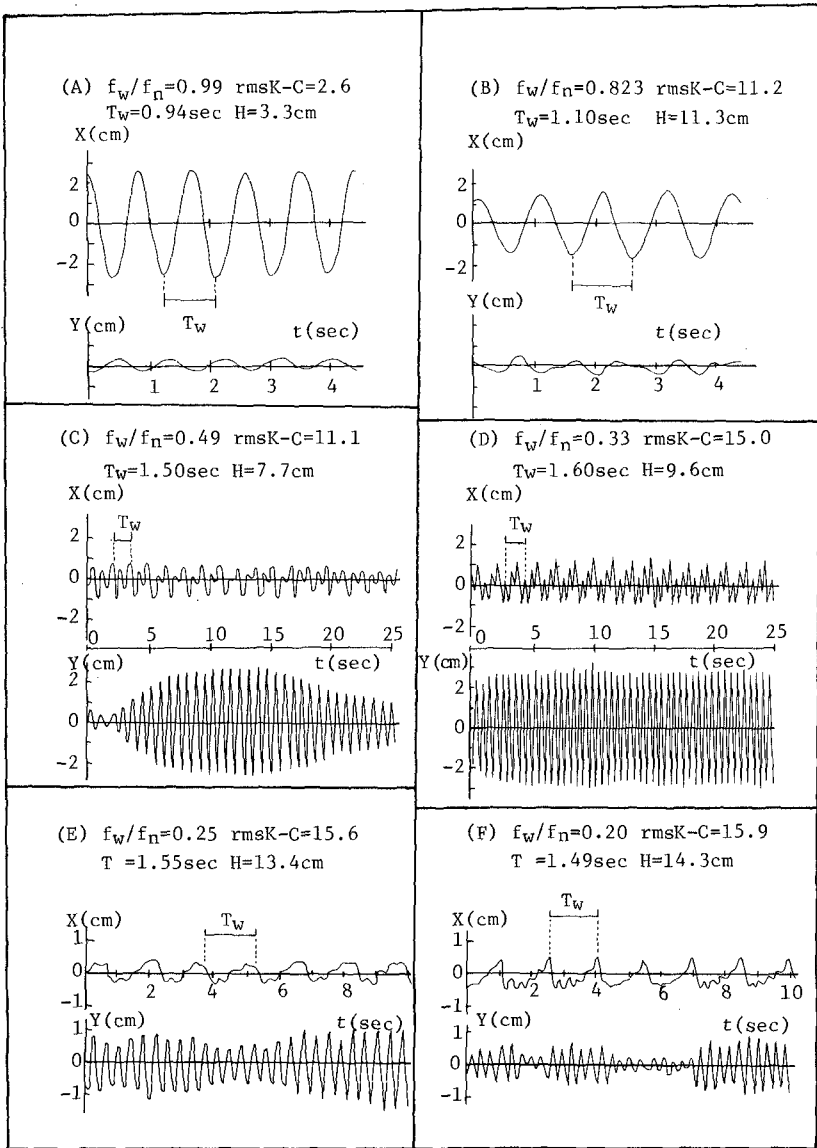

Fig. 3 Time history of the X and Y displacement

because the pile is resonated by the lift force component with the frequency two times as large as the wave frequency. Consequently, the Y displacement vibrates largely with the second harmonic frequency of the wave as shown in Fig. 3 (C). On the other hand, the X displacement has both the wave frequency and the second harmonic frequency of the wave. Since the characteristics of the lift force frequency will be given later, readers may want to refer to Fig. 6. (D) : With a frequency ratio ranging from 0.3 to 0.4 the locus shows a long ellipse and a triple ellipse as shown in Fig. 2 (D-1), (D-2) and (D-3). In this case, the pile is resonated at $f_w/f_n=1/3$ by the lift force component which corresponds to the third harmonic frequency of the wave. Therefore, the Y displacement vibrates largely with the frequency as shown in Fig. 3 (D). From this figure, it can be seen that the X displacement has also the third harmonic frequency of the wave in addition to the wave frequency, and like the case of (C), the Y displacement is larger than the X displacement. (E) : When the frequency ratio is nearly equal to 0.25, the locus is similar to the figure of a tetra ellipse and the Y-displacement has also the more significant magnitude compared with the X displacement (see Fig. 3(E)). Furthermore, the smaller the value of the frequency ratio, as shown in Fig. 2 (F-1), (F-2), (F-3), (G-1) and (G-2), the more complicated the dynamic locus becomes owing to the appearance of higher harmonic frequency components in both displacements, and in the range of frequency ratio nearly equal to $1/5$ and $1/6$, it can be seen that the Y displacement cannot be neglected in comparison with the X displacement. Here, the effect of rmsK-C on the locus is not clearly distinguishable, but the following features may be pointed out: when the frequency ratio nearly equals 1, the Y displacement appears only at comparatively small values of rmsK-C, and in the range of frequency ratio smaller than 0.9, the Y displacement decreases with decreasing values of rmsK-C and the Y displacement is equal to or smaller than the X displacement when the value of rmsK-C is comparatively small.

The reason for the higher harmonic frequency of the wave of the X displacement will be presented later.

2) RESONANT CHARACTERISTICS OF THE PILE

In order to examine the resonant characteristics of the pile due to the in-line and lift forces, the resonant curves in both directions were obtained. Fig. 4 and Fig. 5 show the resonant curves in the X and Y directions respectively with rmsK-C as a parameter. In these figures, the abscissa is the period ratio ($1/(f_w/f_n)$) and the ordinate is the so-called amplification ratio, i.e. the ratio of the dynamic displacement to the static displacement due to the wave forces. Here, the static displacements, X_s and Y_s , are calculated by means of the structural model shown in Fig. 9, and by using the Morison's equation on the in-line force and the lift force equation (Eq. 7) derived by the authors on the lift force. The linear wave theory is also used. The wave force is integrated from the bottom of the circular cylinder to the elevating water surface as a sinusoidal wave. In these figures, $X_{p/10}$ and $Y_{p/10}$ are measured one-tenth maximum dynamic displacements of X and Y respectively, since the Y displacement was irregular in regular waves as shown in Fig. 3.

From Fig. 4, it is clear that the resonant response due to a in-line

Fig. 4 amplification ratio in X-direction

Fig. 5 Amplification ratio in Y-direction

lar cylinder in waves during one wave cycle. Here F_x and M_x are calculated by using the Morison's equation and the linear wave theory. Table 2 (I) is the result of the consideration of the effect of the finite amplitude nature, the wave force still being considered as a sinusoidal wave, i.e. the integral region of the wave force is from the bottom of the circular cylinder to the elevating water surface. On the other hand, Table 2 (II) indicates the result of neglecting the above-described effect. It is seen that F_x and M_x have higher harmonics than the wave frequency as shown in Table 2 (I) and (II). Moreover, it is clear that these components with the second harmonic frequency of the wave differ significantly between (I) and (II), but this significant difference between (I) and (II) cannot be seen when $n=3$. The non-linearity of the

force appears at the period ratios $T_w/T_n = 1, 2, 3, 4, 5$ and 6 , but there is no response at the period ratio $T_w/T_n = 7$. Among these resonances, the well-known resonance at $T_w/T_n=1$ is the most predominant, but the resonance at the period ratio $T_w/T_n = 2$ and 3 are also comparatively large.

The reason for the appearance of the response at $T_w/T_n=2$ and 3 may be due to the fact that the in-line force (F_x) and the over-turning moment (M_x) caused by the in-line force have higher frequency components than the wave based on the non-linearity of the drag force and the finite amplitude nature of the water wave. A good example illustrating this fact is presented in Table 2. This table shows the result of a harmonic analysis of F_x and M_x acting on a vertical circu-

	nf_w	(I)	(II)
F_x	n=1	18.46×10^{-3} (Kg)	18.38×10^{-3} (Kg)
	2	1.63	0.10
	3	2.13	2.08
	4	0.06	0.10
	5	0.31	0.31
	6	0.08	0.10
M_x	n=1	353.63×10^{-3} (Kg cm)	348.25×10^{-3} (Kg cm)
	2	56.03	1.89
	3	43.96	40.98
	4	3.76	1.89
	5	5.84	6.15
	6	1.29	1.89
T=1.5sec H=8cm rmsK-C=11.53 D=2.5cm			

Table 2 Harmonic analysis of F_x and M_x at $T_w/T_n=2$ and 3 are the most predominant in case of rmsK-C being larger than 3. It may be considered that these facts have a close relation with the frequency characteristics of a lift force and the magnitude as shown in Fig. 6 and 7. Fig. 6 shows the variation of the predominant non-dimensional lift energy ($S_L(nf_w)\Delta f/\sigma_L^2$, n=1-4) for each harmonic component of the wave frequency with rmsK-C. This figure was obtained by using the experimental result of the wave force on a rigidly supported vertical circular cylinder and was presented in Ref.(3), too. Here, $S_L(nf_w)\Delta f$ is the lift energy for the n-th harmonic of the wave frequency, and σ_L^2 is the variance of the lift force. From this figure, it can be seen that the predominant lift frequency equals the wave frequency in the range where rmsK-C is smaller than 3 approximately, corresponds to the second harmonic frequency of the wave in the rmsK-C range of 6 to 12, and equals the third harmonic frequency of the wave in the range of rmsK-C larger than 13, and the rest is the transition region from f_w to $2f_w$ and from $2f_w$ to $3f_w$. Fig. 7 shows the ratio of the one-tenth maximum lift force ($F_{L1/10}$) to the mean value of the maximum in-line forces (F_{Tm}) with rmsK-C as a parameter, and this figure was obtained by using the same experimental results described above. Furthermore, the experimental results of Sarpkaya⁵⁾, using the U-shaped water-tunnel, are given by the dotted line in Fig. 7. From this figure, the magnitude of the lift force increases rapidly as compared with the in-line force as rmsK-C increases (from 5 to 10) and it reaches the maximum value of 1.1 times the in-line force at rmsK-C=10.

Therefore, from the characteristics of the lift force described above, it can be considered that the resonance at $T_w/T_n=1$ in the Y-direction appears only when rmsK-C is lower than 3, due to the predominant lift force component having the waver frequency (see Fig. 6). However, this resonance can be neglected as shown later, because the magnitude of the lift force is comparatively smaller than that of the in-line force when

drag force and the effect of the finite amplitude nature of the water wave on the dynamics of the pile will be described later on in detail.

From Fig. 5, it is evident that the resonant response due to the lift force appears at the same period ratios as those in the X direction. In this case, however, the resonant condition depends on rmsK-C, i.e. the resonance at $T_w/T_n=1$ is predominant for values of rmsK-C smaller than 3, and the resonances

rmsK-C is smaller than 3 as shown in Fig. 7, and the dynamic displacement in the Y-direction is very small compared with that in the X-direction at this period ratio. Furthermore, at $T_w/T_n=2$, the resonant response appears only when rmsK-C is larger than 3, due to the predominant second harmonic frequency shown in Fig. 6. From the investigation described above, it can be concluded that the resonant characteristics of the pile due to both the in-line and the lift force have a close relation to the characteristics of the wave forces, including the frequency and magnitude of the wave force.

Fig. 6 Predominant lift energy versus rmsK-C

Fig. 7 Ratio of maximum one-tenth lift force to in-line force versus rmsK-C

X-displacement is predominant when the period ratio is smaller than 1.5 approximately. On the other hand, the Y-displacement is predominant in the range where the period ratio is larger than 1.5 and especially the predominance of the Y-displacement is conspicuous near the resonance points described above except at $T_w/T_n=1$, when rmsK-C is larger than 6. This reason can be given by the characteristics of the lift force as shown in Fig. 6 and Fig. 7.

Therefore, from the above-mentioned experimental results, it can be pointed out that rather than a in-line force, a lift force is the more significant force when the natural period of the structure is lower than the wave period and rmsK-C is higher than 6.

ESTIMATION OF DYNAMIC RESPONSE

Fig. 8 Ratio of Y-displacement to X-displacement versus period ratio

3) MAGNITUDE OF THE Y-DISPLACEMENT

From the practical point of view, it may be important to know the magnitude of the Y-displacement in relation to the X-displacement. Fig. 8 shows the variation of the ratio of the Y-displacement to the X-displacement in terms of T_w/T_n . Here, the one-tenth maximum displacements in both directions are used. From this figure, it is clear that the

1) FORMULATION OF THE LIFT FORCE EQUATION

As mentioned above, the computation of a lift force is necessary in order to estimate the dynamic response of a structure due to it. However, it is difficult to formulate the lift force equation which can express the time variation of the lift force, because the lift force is generated by the alternate breaking of the eddies and it is irregular even in regular waves. Therefore,

Fig. 9 Phase angle of the n-th harmonic lift force

the formulation of the lift force is performed empirically based on the experimental result of wave forces on a rigidly supported vertical circular cylinder.

It may be assumed that the formula is expressed by the superposition of each predominant frequency component of the lift force as shown in Fig. 6, given by Eq.(1).

$$f_L(t) = \sigma_L \sum_{n=1}^4 \frac{\sqrt{2S_L(nf_w)\Delta F}}{\sigma_L^n} \times \cos(2n\pi f_w t - \epsilon_n) \quad (1)$$

Here, $f_L(t)$: the lift force per unit length; $S_L(nf_w)$: the variance of the lift force; and ϵ_n : the phase angle between the n-th harmonic lift force component and the incident wave. The spectral energy of the n-th harmonic lift force may be given by the experimental result of Fig. 6. In this study, the non-dimensional n-th harmonic lift force energy is given by the empirical formula which is specified at the right side of Fig. 6, and it is shown by the solid line in this figure. Further, the phase angle was obtained by using the result of harmonic analysis of both the measured lift force and wave records. The change of phase angle with rms K-C is shown in Fig.9, in which

the predominant region of the n-th harmonic lift force is also shown by an arrow mark. The scattering of the experimental results is relatively large, but if attention is focussed on each predominant region ϵ_n may be considered as a constant value, i.e. $\epsilon_2/2 = 25^\circ$, $\epsilon_3/3 = -15^\circ$ and $\epsilon_4/4 = 0^\circ$. However, as ϵ_1 is scattered from 60° to 120° in the predominant region of f_w frequency, it seems to be quite all right to consider that the average value of ϵ_1 is 90° , because the magnitude of the lift force is quite small in comparison with the in-line force in the region where rmsK-C is smaller than 5, as shown in Fig. 7.

On the other hand, Chakrabalti et al⁶⁾ have presented the lift force as shown in Eq. 2.

$$f_L(t) = -\frac{1}{2} \rho D U_m^2 \sum_{n=1}^4 C_{L_n} \sin(2n\pi f_w t - \sigma_n) \quad (2)$$

Here, U_m : the maximum horizontal water particle velocity; C_{L_n} : the lift coefficient for the n-th harmonic lift force; D : the diameter of a circular cylinder; and ρ : the density of water.

Since the lift force in regular waves is irregular, $f_L(t)$ is considered as a random function of time. With the exception of C_{L_n} , the terms on the right hand side of Eq. (2) are the regular functions or constants.

Therefore, C_{Ln} must be a random variable. On the other hand, the distribution of the peak lift force is similar to the Rayleigh distribution from the authors' experiments³⁾. Fig.10 shows an example of the relation between the ratio of the significant value of the lift force and its mean value and rmsK-C. The theoretical value of this ratio based on the Rayleigh distribution is 1.637, and it is shown by a

Fig. 10 Ratio of significant lift force to mean lift force versus rmsK-C

straight line in Fig.10. As seen in this figure, the experimental values are scattered around the theoretical value independent of rmsK-C.

Moreover, the lift force spectra in the predominant region of each harmonic lift force component can be considered to be a narrow-band spectra^{3), 6)}. From the above investigations, the lift force can be assumed to be a random variable of the narrow-band Gaussian random process.

Thus, the variance of the lift force can be given by Eq. (3)⁷⁾,

$$\sigma_L^2 = E[f_L^2(t)] = \left(\frac{1}{2} \rho DU_m\right)^2 \frac{1}{2} E[C_L^2] \quad (3)$$

Here, C_L is the lift coefficient of the peak lift force and is a random variable of Rayleigh distribution. Therefore, using the following relation,

$$(C_L)_{rms} = \sqrt{E[C_L^2]} = C_{L1/10} / 1.8$$

σ_L is given by Eq. (4) from Eq. (3).

$$\sigma_L = \frac{1}{2} \rho DU_m^2 \left(\frac{C_{L1/10}}{1.8\sqrt{2}}\right) \quad (4)$$

The validity of Eq.(4) is examined by investigating Eq.(5) deduced from Eq.(4).

$$\sigma_L / \left(\frac{1}{2} \rho DU_m^2\right) = C_{L1/10} / (1.8\sqrt{2}) \quad (5)$$

Here, we express the value of the left-hand side of Eq.(5) as ξ , and that of the right-hand side of this equation as ξ' . The value of ξ can be calculated by the standard deviation of the lift force obtained from the measured lift force records. On the other hand, the value of ξ' can also be calculated by using the one-tenth maximum lift coefficient obtained semi-empirically by the authors³⁾ and is given by Eq. (6) :

$$C_{L1/10} = \begin{cases} 0.245[\text{rmsK-C}] + 0.245 & , 0 < \text{rmsK-C} < 9 \\ -0.155[\text{rmsK-C}] + 3.85 & , 9 < \text{rmsK-C} < 18 \end{cases} \quad (6)$$

If Eq.(4) is valid, ξ and ξ' have to agree with each other. This agreement of ξ and ξ' is shown in Fig. 11, from which it can be seen that ξ and ξ' agree well regardless of rmsK-C. Therefore, the lift force equation can be expressed as Eq.(7) from Eq.(2) and Eq.(4),

$$f_L(t) = \frac{1}{3.6} CL_{1/10} \rho DU_m^2 \sum_{n=1}^k \frac{S_L(nf_w)\Delta f}{\sigma_L^2} \cos(2n\pi f_w - \theta_n) \quad (7)$$

Fig.11 Comparison ξ and ξ' versus rmsK-C

placements of the top of pile, X and Y (X and Y are for the X and Y directions respectively), are given by the horizontal displacements at the bottom of the circular cylinder, x and y, and the rotation angles of the circular cylinder, θ_x and θ_y respectively. Furthermore, assuming $\sin\theta \approx \theta$, X and Y are given by Eq. (8).

$$\begin{aligned} X &= x + L \theta_x \\ Y &= y + L \theta_y \end{aligned} \quad (8)$$

Here, L : the distance from the bottom of the cylinder to the top of the pile.

In this study, the mass of the spring bar and the wave force on this bar are assumed to be negligible, because these values are very small. On these assumptions, the equation of motion of the pile in the X direction due to the in-line force may be given by Eq. (9) and Eq. (10). On the other hand, that in the Y direction may be given by Eq. (11) and Eq. (12). In these equations, it was assumed that the mutual influence between the vibrations of X and Y can be neglected.

$$\begin{aligned} (m+m_V) \frac{d^2x}{dt^2} + (m+m_V) G \frac{d^2\theta_x}{dt^2} + X \frac{dx}{dt} + G_A C \frac{d\theta_x}{dt} \\ + \frac{6EI}{l^3} (2x - l\theta_x) \end{aligned}$$

2) EQUATION OF MOTION OF THE PILE

In order to estimate the dynamic response of a single pile structure (see Fig. 1), the pile was idealized by a two-degree of freedom equivalent spring-mass system with a viscous damper as shown in Fig. 12. The idealization is based on the assumption that the rigidity of the cylinder section on Fig. 1 is much larger than that of the spring bar section, allowing to assume the circular cylinder and the concentrated mass to be a rigid body. In this case, the dis-

$$= \frac{1}{2} C_D \rho D \int_{z_L}^{h+\eta} (u - \frac{dx}{dt} - z^* \frac{d\theta_x}{dt}) | u - \frac{dx}{dt} - z^* \frac{d\theta_x}{dt} | dz + \int_{z_L}^{h+\eta} C_M \rho \frac{\pi D^2}{4} \frac{\partial u}{\partial t} dz \tag{9}$$

$$\begin{aligned} & (m + m_v) G \frac{d^2 x}{dt^2} + [I_G + I_{Gv} + (m + m_v) G^2] \frac{d^2 \theta_x}{dt^2} + G_{AC}^2 \frac{d\theta_x}{dt} + \frac{2EI}{\ell^3} (2\ell \theta_x - 3x) \\ & = \int_{z_L}^{h+\eta} z^* [\frac{1}{2} C_D \rho D (u - \frac{dx}{dt} - z^* \frac{d\theta_x}{dt}) | u - \frac{dx}{dt} - \frac{d\theta_x}{dt} | \\ & \qquad \qquad \qquad + C_M \rho \frac{\pi D^2}{4} \frac{\partial u}{\partial t}] dz \\ & + [mgG_A - \frac{\rho g \pi D^2 (h + \eta - z_L)^2}{8}] \theta_x \tag{10} \end{aligned}$$

$$\begin{aligned} & (m + m_v) \frac{d^2 y}{dt^2} + (m + m_v) G \frac{d^2 \theta_y}{dt^2} + C \frac{dy}{dt} + G_{AC} \frac{d\theta_y}{dt} + F_D \\ & \qquad \qquad \qquad + \frac{6EI}{\ell^3} (2y - \theta_y) = \int_{z_L}^{h+\eta} f_L(z) dz \tag{11} \end{aligned}$$

$$\begin{aligned} & (m + m_v) G \frac{d^2 y}{dt^2} + [I_G + I_{Gv} + (m + m_v) G^2] \frac{d^2 \theta_y}{dt^2} + G_{AC} \frac{d\theta_y}{dt} \\ & \qquad \qquad \qquad + G_{AC}^2 \frac{d\theta_y}{dt} + M_D + \frac{2EI}{\ell^3} (2\ell \theta_y - 3y) \\ & = \int_{z_L}^{h+\eta} z^* f_L(z) dz + [mgG_A - \frac{\rho g \pi D^2 (h + \eta - z_L)^2}{8}] \theta_y \tag{12} \end{aligned}$$

Here, G : distance from the lower end of the cylinder to the center of gravity including the added mass of the cylinder ; G_A : distance from the lower end of the cylinder to the center of gravity minus the added mass of the cylinder ; EI : flexible rigidity of the spring bar ; C : structural damping coefficient ; ℓ : length of the spring bar ; h : still water depth ; η : water surface elevation ; I_G : moment of inertia about the center of gravity due to the total mass minus the added mass of the cylinder ; I_{Gv} : moment of inertia about the center of gravity due to the added mass of cylinder ; C_D : drag coefficient ; C_M : mass coefficient ; u : horizontal water particle velocity ; m : total effective mass minus the added mass ; m_v : added mass of the cylinder given by Eq.(13).

$$m_v = C_v \pi \rho D (h + \eta - z_L) / 4 \quad (13)$$

In Eq.(13), C_v is the coefficient of added mass ($C_v = C_M - 1$); z_L : distance from the bottom of the water to the lower end of the cylinder; z^* : $z - z_L$; F_D and M_D are the fluid damping force and moment in the Y direction respectively, and these are given by Eq. (14) and (15).

$$F_D = \int_{z_L}^{h+\eta} \frac{1}{2} C_D \rho D \left(\frac{dy}{dt} + z^* \frac{d\theta_y}{dt} \right) \left| \frac{dy}{dt} + z^* \frac{d\theta_y}{dt} \right| dz \quad (14)$$

$$M_D = \int_{z_L}^{h+\eta} \frac{1}{2} C_D \rho D z^* \left(\frac{dy}{dt} + z^* \frac{d\theta_y}{dt} \right) \left| \frac{dy}{dt} + z^* \frac{d\theta_y}{dt} \right| dz \quad (15)$$

In this analysis, it is assumed that the lift force can be calculated by Eq.(7), and the values of drag and mass coefficients, C_D and C_M , assumes the following values, i.e. $C_D=1.5$ and $C_M=2.2$, based on the experimental results of the authors³⁷.

Since the equations of motion described above are nonlinear differential equations, no exact solution can be obtained. Hence, only approximate solutions can be obtained by using the numerical techniques. In this calculation, Newmark β -method⁸⁾ is used to solve the equation of motion. The value of β is selected as 1/6, which is equivalent to a linear acceleration method. The time interval, Δt , is taken as 0.005 sec, because the natural frequency of the second mode of the vibration model ranged from 31 to 35.5Hz for the five kinds of masses shown in Table 1. Taking a stationary response condition into account, the calculation time was as 15 seconds for each case.

3) CALCULATION RESULT

At first, the dynamic displacement in the X direction was computed to investigate the estimation described above (refer to Table 2). Fig. 13 shows a few examples of computation results in the X direction due to the in-line force for values of period ratio about 2 or 3. In this figure, the solid line indicates the calculated result by the method (I), which considers the effect of the finite amplitude nature of the wave, the latter being considered as a sinusoidal wave, on the in-line force, and the dotted line indicates the calculated result by the method (II), which neglects the above-mentioned effect on the in-line force. In other words the integral region of the wave force on the pile is from the lower end of the cylinder to the still water level; η in Eqs.(9) and (10) is assumed to be 0. The measured results are also shown in this figure by small circles.

From this figure, it can be seen that the calculated results by means of method (I) agree well with the measured results. On the other hand, there is much discrepancy in the frequency and magnitude of the displacement between the calculated results by method (II) and the measured results at the period ratio $T_w/T_n=2$, as shown in Fig. 13 (A) and (B). However, there is little difference between the results of methods (I) and (II) at $T_w/T_n=3$, as shown in Fig. 13 (C). From this fact, it can be considered that the resonance in the X direction at $T_w/T_n=2$ is caused by the finite amplitude nature of waves and that at $T_w/T_n=3$ is caused by the non-linearity of the drag force. Moreover, the dynamic displacement in

Fig. 13 Calculation results of cylinder displacement in the X direction

Fig. 14 Calculation results of cylinder displacement in the Y direction

the X direction for other ranges of the period ratio were computed by method (I). As a result, it was confirmed that the dynamic response in the X direction can be calculated by Eqs. (9) and (10) based on method (I) in the range where the period ratio is smaller than 6.5.

Next, the dynamic displacements in the Y direction due to the lift force were also computed by Eqs. (11) and (12) based on method (I) described above. Some examples at the resonance points in the Y direction are shown in Fig. 14. The solid line shows the calculated result and small circles denote the measured result. In this case, as the Y displacement is not regular, the displacement nearly equal to the maximum value is plotted for both the experimental and calculated results.

This figure indicates that the calculated results agree well with the measured results for each resonance point including the properties of the frequency and magnitude of the Y displacements. Therefore, it is concluded that the dynamic response in the Y direction due to the lift force can be calculated by Eqs. (7), (11) and (12).

Finally, the combined dynamic displacements of the pile were computed by composing the calculated displacements in two directions, because the maximum dynamic displacement considering both displacements is desired for an engineering design. Furthermore, comparison between the computed and measured combined dynamic responses gives the whole judgement for the validity of the estimation method of the dynamic responses in both directions. Fig. 15 shows this comparison, and the right-hand side of this figure is the calculated result while the left-hand side indicates the measured result. As in Fig. 2, the X-axis is the direction of the wave propagation direction and the Y-axis is the direction normal to the wave propagation direction. Because of the irregularity of the Y displacement, the combined dynamic displacements during one wave cycle in which the maximum combined displacement appears are plotted in Fig. 15. It is apparent that the period ratio gradually increases from (A) of $T_w/T_n \approx 1$ ($f_w/f_n \approx 1$) to (G) of $T_w/T_n \approx 5$ ($f_w/f_n \approx 1/5$). A little difference between the measured and calculated locus is observed in the case of (G), in Fig. 15. However, taking into consideration the irregularity of the Y displacement, the calculated results can safely be said to have good agreements with the experimental results. It is concluded that the combined dynamic displacement can be calculated by Eqs. (7), (9), (10), (11) and (12).

CONCLUSION

The dynamic behavior of a fixed circular pile due to the in-line and the lift forces is investigated from the theoretical and experimental stand point of view. It enabled us to arrive at the following conclusions.

First, the resonant responses of a single circular pile due to the lift force in the direction normal to the wave propagation direction are found to take place at the period ratios of $T_w/T_n = 2, 3, 4, 5$ and 6, when $rmsK-C$ is larger than 3. Furthermore, the resonant responses in the wave propagation direction due to the in-line force also appear at the same period ratios as the former case, in addition to the well known resonance at $T_w/T_n = 1$. Moreover, dynamic displacements of the cylinder due to the lift force in the direction normal to the wave propagation direction are larger than those in the wave propagation direction due to the in-line force at the above-mentioned resonance points except at $T_w/T_n = 1$, when $rmsK-C$ is

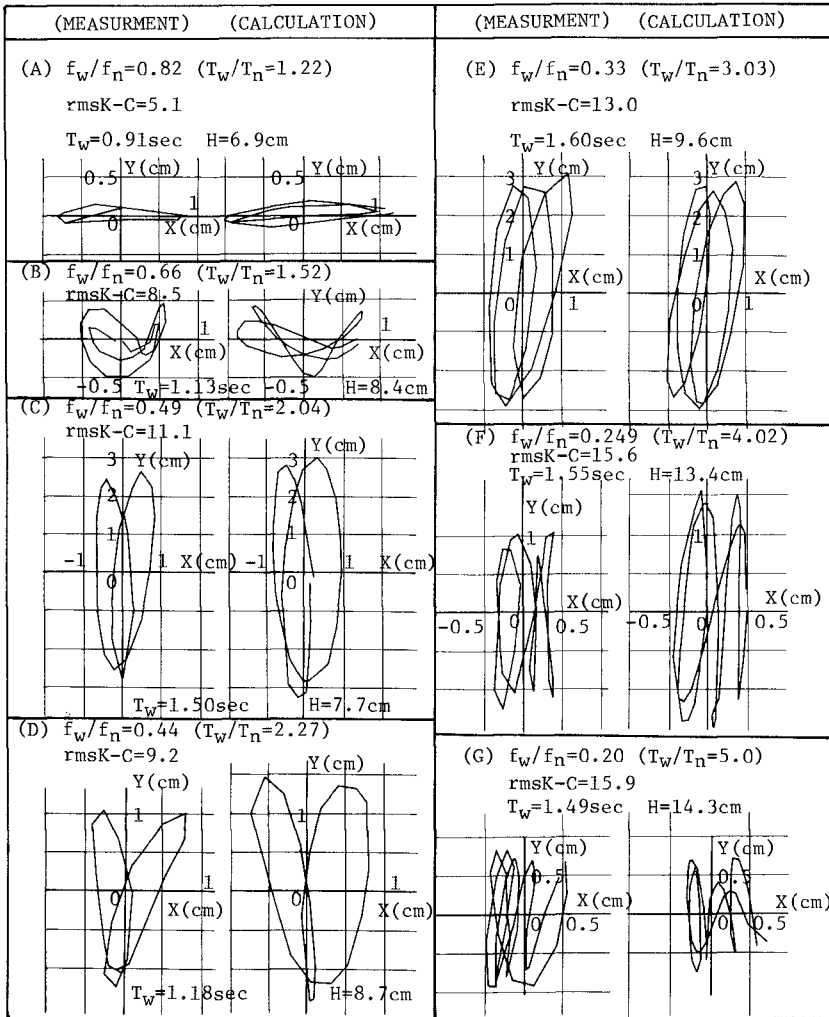

Fig. 15 Calculation results of dynamic loci

larger than 6. Therefore, the lift force is more significant than the in-line force when the natural period of the structure is smaller than the wave period and $rmsK-C$ is comparatively large.

Secondly, the dynamic displacements in both directions and the combined dynamic displacement can be calculated by applying the Morison's formula and the lift force equation to the equation of motion in each direction.

CHAPTER 144

WAVE FORCES INDUCED BY IRREGULAR WAVES ON A VERTICAL CIRCULAR CYLINDER

ABSTRACT

In order to examine the irregular wave forces on a small diameter cylinder, laboratory experiments have been conducted on water particle velocities and wave forces with various kinds of irregular waves. As the results, it is indicated that the time variation and the spectral distribution of wave forces can be calculated adequately from the water level variations by using the methods proposed by Reid¹⁾ and Borgman²⁾ respectively.

Moreover, with respect to the irregular wave forces on a large diameter cylinder, a new calculation method was shown by means of applying Reid's linear filters¹⁾ to MacCamy and Fuchs's diffraction theory³⁾.

INTRODUCTION

A number of studies have been done with respect to wave forces induced by periodic waves on marine structures, especially on a circular cylinder. Considering the irregularity of waves in the fields, however, it is very important to investigate the irregular wave forces systematically. In the case of periodic waves, Morison's equation and MacCamy and Fuchs's diffraction theory have been employed to estimate the wave forces respectively on a small and on a large diameter cylinder. Therefore, in the case of irregular waves, it is reasonable to investigate the wave forces by using these two methods in the same way.

Formerly, Reid has studied of the correlation of water level variations with wave forces on a circular cylinder for nonperiodic waves from the viewpoint of their time variations and indicated a method of calculation for the drag and inertia coefficients in Morison's equation. On the other hand, Borgman has shown a method of calculation for the wave force spectrum from the water level spectrum. These methods, however, have

been supported by experiments not sufficiently. As for the irregular wave forces on a large diameter cylinder, few studies have been presented till now.

Therefore, the authors have studied firstly the water particle velocities⁴⁾ in irregular waves, which play an important role in Morison's equation, and secondary the wave forces on a small diameter cylinder from the standpoints of the time variation and the power spectral distribution. Finally we show the method of calculation for irregular wave forces on a large diameter cylinder.

VELOCITIES AND ACCELERATIONS IN IRREGULAR WAVES

1-(1). Experiments

In order to investigate the water particle velocities and accelerations in irregular waves, laboratory experiments were carried out at the Department of Civil Engineering, Kyoto University.

The sketch of this experimental apparatus are shown in Fig.1. The dimension of the wave tank is 50cm wide, 70cm high and 27m long. The generator of irregular waves is installed at the end of the tank. A probe of the ultrasonic current meter shown in Photo.1 and a wave gauge were set 8m apart from the wave plate. At another end of the tank, the wave absorber was installed. The generator of irregular waves has fifteen band-pass filters which divide the frequency range $0.2 \sim 5.0$ Hz every $1/3$ oct., and therefore, irregular waves having various kinds of spectral distributions can be generated by regulating the output of each filter.

Fig.1 Schematic of experimental apparatus in the case of water particle velocity.

Photo.1 Probe of ultrasonic current meter.

1-(2). Analysis

Let the position of a wave gauge across the still water surface be taken as the origin of the coordinates, the direction of wave propagation as X-axis, and the vertical direction upward as Z-axis, respectively. If the water surface elevation of irregular waves at the position of a wave gauge is represented as

$$\eta(t) = \int_0^\infty M(\omega) \cos(\omega t - \theta(\omega)) d\omega, \dots\dots\dots (1)$$

the horizontal velocity u and vertical velocity w of a water particle, and the horizontal and vertical acceleration, \dot{u} and \dot{w} , are represented as follows¹⁾ by using the small amplitude wave theory:

$$u(t) = \int_0^\infty R_u(\omega) M(\omega) \cos(\omega t - \theta(\omega)) d\omega, \dots\dots\dots (2)$$

$$w(t) = - \int_0^\infty R_w(\omega) M(\omega) \sin(\omega t - \theta(\omega)) d\omega, \dots\dots\dots (3)$$

$$\dot{u}(t) = - \int_0^\infty \omega R_u(\omega) M(\omega) \sin(\omega t - \theta(\omega)) d\omega, \dots\dots\dots (4)$$

$$\dot{w}(t) = - \int_0^\infty \omega R_w(\omega) M(\omega) \cos(\omega t - \theta(\omega)) d\omega, \dots\dots\dots (5)$$

in which ω is the angular frequency, θ is the initial phase, $M(\omega)$ corresponds to the amplitude spectrum, and $R_u(\omega)$ and $R_w(\omega)$ are given by

$$R_u(\omega) = \frac{\omega \cosh k(h+z)}{\sinh kh}, \dots\dots\dots (6)$$

$$R_w(\omega) = \frac{\omega \sinh k(h+z)}{\sinh kh}, \dots\dots\dots (7)$$

$$\omega^2 = gk \tanh kh, \dots\dots\dots (8)$$

in which h is the water depth and k is the wave number.

Eqs. (6) and (7) give the theoretical frequency response functions of u and w to η , while experimental values of them are calculated from

$$R_u = \sqrt{\frac{S_u(\omega)}{S_\eta(\omega)}}, \dots\dots\dots (9)$$

$$R_w = \sqrt{\frac{S_w(\omega)}{S_\eta(\omega)}}, \dots\dots\dots (10)$$

in which $S_\eta(\omega)$, $S_u(\omega)$ and $S_w(\omega)$ are the power spectra of η , u and w respectively.

In order to calculate the time variations of u and \dot{u} from η , Reid proposed the following symmetrical and asymmetrical linear filters¹⁾:

$$G_s[y(t)] = a_0 y(t) + \sum_{n=1}^N a_n [y(t+n\tau) + y(t-n\tau)], \dots\dots\dots (11)$$

$$G_a[y(t)] = \sum_{n=1}^N b_n [y(t+n\tau) - y(t-n\tau)], \dots\dots\dots (12)$$

in which a_n and b_n are Fourier coefficients of their frequency response functions. Substituting $\eta(t)$ of Eq.(1) into $y(t)$ in Eqs.(11) and (12), they are deduced as follows:

$$G_s[\eta(t)] = \int_0^\infty [a_0 + 2 \sum_{n=1}^N a_n \cos n\omega\tau] M(\omega) \cos(\omega t - \theta(\omega)) d\omega, \dots\dots\dots(13)$$

$$G_a[\eta(t)] = - \int_0^\infty [2 \sum_{n=1}^N b_n \sin n\omega\tau] M(\omega) \sin(\omega t - \theta(\omega)) d\omega \dots\dots\dots(14)$$

Comparing Eq.(1) with Eqs.(13) and (14), it is found that G_s produces no phase change and has the frequency response function $[a_0 + 2 \sum_{n=1}^N a_n \cos n\omega\tau]$, and that G_a changes the phase by $\pi/2$ and has $[2 \sum_{n=1}^N b_n \sin n\omega\tau]$ as the frequency response function. It is also seen by comparing Eqs.(2) to (5) with Eqs.(13) and (14) that the time variations of required variables can be calculated from the water level variation $\eta(t)$ by selecting one of the frequency response functions and filters as shown in Table 2. In the calculation, $\tau=0.08$ sec and $N=25$ were adopted.

As the acceleration can not be measured directly, \dot{U} and \dot{W} are estimated by differentiating measured U and W with respect to time t . However, since the direct differentiation may enlarge errors due to noises more or less contained in measured U and W , they are differentiated after being passed through the following low-pass filter:

$$F_c(\omega) = \begin{cases} 1: \omega \leq 2\pi f_c \\ 0: \omega > 2\pi f_c \end{cases} \dots\dots\dots(15)$$

In actual calculations, this operation was carried out by using the filter G_s which has the frequency response function $\omega F_c(\omega)$. In the calculation, $f_c=4.0$ Hz, $\tau=0.08$ sec and $N=40$ were used.

Table 2 Correspondence of input, frequency response function and linear filter to output.

Input	Frequency response function	Linear filter	Output
Measured $\eta(t)$	$R_u(\omega)$	$G_s[\eta(t)]$	$u(t)$
	$\dot{R}_w(\omega)$	$G_a[\eta(t)]$	$w(t)$
	$\omega R_u(\omega)$	$G_s[\eta(t)]$	$\dot{u}(t)$
	$-\omega R_w(\omega)$	$G_s[\eta(t)]$	$\dot{w}(t)$
Measured $u(t)$	$\omega F_c(\omega)$	$G_a[u(t)]$	$\dot{u}(t)$
Measured $w(t)$		$G_a[w(t)]$	$\dot{w}(t)$

1-(3). Results and discussions

As an example, the results of Case I-10 are shown in Figs.2 through 9. In Fig.2, the power spectral densities S_η , S_u and S_w of η , u and w respectively are compared. In the frequency range for the large value of S_η , three power spectra resemble each other in shape. However, in the high frequency range (>1.5 Hz), the values of S_w become larger than those of S_u . This trend is seen in all cases. In the range of higher frequency than 2 Hz, the accuracy of the current meter becomes poor, so that the noise of the current meter can not be separated from the power of U and W .

Therefore, more detailed discussion on the characteristics of the high frequency components of u and w has no meaning.

In Figs. 3 and 4, experimental values of the frequency response functions calculated from Eqs. (9) and (10) are compared with the theoretical values by Eqs. (6) and (7) based on the small amplitude wave theory. In the low frequency range (<1.5 Hz), the experimental values agree well with the theoretical curves, but in the high frequency range (>1.5 Hz), the former becomes larger than the latter.

Fig. 5 shows an example of the time variation of measured η of irregular waves. Calculated values of u , w , \dot{u} and \dot{w} obtained by using measured η as an input to each linear filter (in Table 2) are plotted in Figs. 6 through 9. Fig. 6 shows the comparison between time variations of the measured u and the simultaneously calculated one. Both are in good agreement, but the measured value is slightly larger than the calculated one near the crest and trough. In Fig. 7, the time variation of measured w is compared with that of the simultaneously calculated one. In the vicinity of the trough the measured value is larger than the calculated one. Also the level of noise of the current meter in w is higher than that in u .

Fig. 2 Power spectral density distribution of η , u and w of irregular waves.

Fig. 3 Frequency response function of u to η under irregular waves.

Fig. 4 Frequency response function of w to η under irregular waves.

Fig. 5 Time variation of η of irregular wave.

Fig. 6 Time variation of u in irregular wave.

Fig. 7 Time variation of w in irregular wave.

Fig. 8 Time variation of \dot{u} in irregular wave.

Fig. 9 Time variation of \dot{w} in irregular wave.

Fig.8 shows the comparison of the time variation of \dot{U} between that calculated from the time variation of η and that calculated from the measured U by passing it through the filter which has the frequency response function $\omega F_C(\omega)$ shown in Table 2. Both are in fairly good agreement, and however, since the measured U contains some noises, high frequency disturbances are seen in the curve of \dot{U} calculated from the measured U , even though it is passed through the low-pass filter $F_C(\omega)$. Fig.9 also shows the comparison of the time variation of \dot{W} between calculated from the measured η and calculated from the measured W . Higher level noises are contained in this case than in the case of U , so that the high frequency vibration in \dot{W} calculated from W is larger than that in \dot{U} calculated from U .

The discussion mentioned above is only for Case I-10. Now considering all cases of the irregular waves shown in Table 1, the following facts are obtained:

Regardless of the shape of power spectrum of water level variation, the measured value of frequency response function for the water particle velocity agrees well with the theoretical value based on the small amplitude wave theory in the low frequency range where the value of S_η is large. On the other hand, in the high frequency range, the measured value of the frequency response function becomes larger than the theoretical value. This trend is remarkable for W . This may explain the experimental fact that absolute values of measured time variations of U and W near the wave crest and trough, where the effect of high frequency components will appear, become larger than those calculated by the linear filters.

In the water particle accelerations, \dot{U} and \dot{W} , calculated from the measured U and W , there are bigger high frequency disturbances than in the case of \dot{U} and \dot{W} obtained from η . This is due to noises originally contained in measured U and W . However, relatively low noise level in U makes the difference between \dot{U} calculated by the two methods small, while the difference is big in the case of \dot{W} because of higher noise level.

The cut-off frequency of the low-pass filter, f_C , was 4.0 Hz in the calculation of Eq.(15). If we select a smaller f_C , noises are expected to be reduced. However, since the cause of the noise is a defect of the current meter itself, only the improvement of the current meter in future can solve this problem.

IRREGULAR WAVE FORCES ON A SMALL DIAMETER CYLINDER

2-(1). Experiments

In order to estimate irregular wave forces on a small diameter cylinder by using Morison's equation, laboratory experiments were carried out for 22 kinds of irregular waves in the same wave tank as mentioned in 1-(1).

The disposition of the experimental apparatus are also shown in Fig. 10. A wave gauge, the current meter and a circular cylinder were set 6m apart from the wave plate. The cylinder is 6cm in diameter and constructed of three parts, the upper and the lower cylinder and the segment with length of 4cm, as shown in Fig.11.

The data on wave forces on the segment are obtained by using the two strain gauges attached to the plate spring which suspends the segment from the upper cylinder. The natural frequency of this system in the still

water was 19.2 Hz. This frequency was so high as to avoid the experimental error caused by interactions of the segment to the waves.

In the experiment, the water depth was 45cm, and the depth of measuring point of wave forces were 10cm, 15cm and 20cm below the still water level. All of experimental data were recorded by the analog data recorder with 0.08 sec and 0.02 sec time interval.

Fig.10 Schematic of experimental apparatus in the case of wave force.

Fig.11 Schematic of circular cylinder.

2-(2). Analysis

The method of calculation for the time variation of irregular wave forces has been also shown by Reid as described below¹⁾:

Irregular wave forces as well as periodic ones can be expressed by the following Morison's equation:

$$F(t) = C_D \cdot \frac{\rho}{2} D u(t) |u(t)| + C_M \cdot \rho \frac{\pi D^2}{4} \dot{u}(t) \quad , \quad \dots\dots\dots(16)$$

in which ρ is the density, D is the diameter of cylinder, C_D and C_M are the drag and inertia coefficients respectively, and $u(t)$ and $\dot{u}(t)$ can be calculated from the following Eqs.(17) and (18):

$$C_D = \overline{F^*(t) \cdot F_1(t)} / \overline{F_1(t)^2} \quad , \quad \dots\dots\dots(17)$$

$$C_M = \overline{F^*(t) \cdot F_2(t)} / \overline{F_2(t)^2} \quad , \quad \dots\dots\dots(18)$$

These equations have been obtained by using the condition that the value of the variance between the measured wave force $F^*(t)$ and $F(t)$ of Eq.(16) is made least, in which $F_1(t)$ and $F_2(t)$ are respectively the drag and the inertia wave force in Eq.(16), and $\overline{\quad}$ indicates to take the average with respect to time t . The degree of differences between $F^*(t)$ and $F(t)$ can be known from their correlation coefficient r shown by the following equation:

$$r = \sqrt{1 - [\overline{\{F(t) - F^*(t)\}^2} / \overline{F^*(t)^2}]} \quad . \quad \dots\dots\dots(19)$$

This Reid's method was applied to all of experimental cases to obtain the values of C_D and C_M , and moreover, these values were employed to Eq.(16) to compare with $F^*(t)$ from the viewpoint of time variation. In the calculation, $\tau=0.02$ sec and $N=40$ were used.

On the other hand, the spectral distribution of wave forces, $S_F(f)$, can be calculated from the spectrum of water level variation, $S_\eta(f)$, by using the following equations obtained by Borgman²⁾:

$$S_{F1}(f) = \frac{8 d^2 \sigma^2}{\pi} S_u(f) + m'^2 S_{\dot{u}}(f) \quad , \quad \dots\dots\dots(20)$$

$$S_{F2}(f) = \frac{d^2 \sigma^2}{\pi} \left[\frac{8}{\sigma^2} S_u(f) + \frac{4}{3 \sigma^6} [S_u(f)]^{*3} \right] + m'^2 S_{\dot{u}}(f) \quad , \quad \dots\dots\dots(21)$$

$$\left. \begin{aligned} d &= C_D \cdot \frac{1}{2} \rho D \quad , \quad m' = C_M \cdot \frac{1}{4} \rho \pi D^2 \quad , \quad \sigma^2 = 2 \int_0^\infty S_u(f) df \quad , \\ [S_u(f)]^{*3} &= \int_{-\infty}^\infty [S_u(g)]^{*2} S_u(f-g) dg \quad , \\ [S_u(f)]^{*2} &= \int_{-\infty}^\infty S_u(g) S_u(f-g) dg \quad , \end{aligned} \right\} \dots\dots\dots(22)$$

in which f is the frequency, and $S_{F1}(f)$ and $S_{F2}(f)$ are respectively the first and the second approximation of wave force spectrum.

These equations were also applied to all of experimental cases and compared with the spectra, $S_{F*}(f)$, obtained from the measured wave force F^* . In the calculation of S_{F1} and S_{F2} , it is necessary to give the values of C_D and C_M , and therefore, the values obtained from Eqs.(17) and (18) were employed. As for the calculation of S_{η} and S_{F*} , the data with time interval 0.08 sec were used.

2-(3). Results and discussions

Table 3 shows the experimental cases of irregular wave forces, in which Z_p is the depth of the measuring point, (Wave freq.(Hz)) is the frequency range of band pass-filters employed to generate the waves, and C_D , C_M and r are respectively the drag, the inertia and the correlation coefficients calculated from Eqs.(17), (18) and (19) respectively. The values of C_D and C_M are respectively from 5.60 to 1.45 and from 2.30 to 1.51, and seem to become larger in both cases that Z_p is closer to the water surface and that the generated waves shown by (Wave freq.(Hz)) contain higher frequency component waves more powerfully. In irregular waves, as the measuring point become closer to the water surface, high frequency components of water particle velocities increase even if the frequency components of surface waves are not changed. Therefore, this trend may be generalized by the statement that the values of C_D and C_M increase according to increase in high frequency components of water particle velocities.

Table 3 Values of C_D , C_M and r in each experimental Case.

$h = 45 \text{ cm}$					
Case	z_p (cm)	Wave freq. (Hz)	C_D	C_M	r
1	-10	(0.5)	1.74	1.98	0.948
2		(0.8)	2.74	2.15	0.965
3		(1.0)	3.94	2.15	0.971
4		(1.25)	4.85	2.27	0.977
5		(0.2~1.0)	2.33	2.03	0.960
6		(0.8~1.25)	4.10	2.13	0.956
7		(0.5~1.6)	4.21	2.30	0.947
8		(0.4~2.5)	5.60	2.29	0.955
9		(0.2~5.0)	2.66	2.08	0.945
10	-15	(0.8)	2.70	1.92	0.971
11		(1.0)	2.74	1.94	0.980
12		(0.2~1.0)	2.19	1.95	0.966
13		(0.8~1.25)	2.60	2.04	0.975
14		(0.5~1.6)	2.56	2.02	0.961
15		(0.4~2.5)	2.26	1.88	0.962
16		(0.2~5.0)	2.62	1.99	0.967
17		(0.8)	1.46	1.57	0.958
18	(0.2~1.0)	1.85	1.53	0.959	
19	-20	(0.8~1.25)	2.06	1.64	0.966
20		(0.5~1.6)	2.38	1.63	0.962
21		(0.4~2.5)	1.71	1.51	0.958
22		(0.2~5.0)	1.45	1.57	0.956

The reasons why such tendencies appear are not necessarily clear now, but some discussions can be made as follows⁵⁾:

When the water particle velocities increase in high frequency components, each wave in one series of irregular waves tends to decrease the value of Keulegan-Carpenter's number⁶⁾ because smaller period of each wave is more possible. In such a case, the values of C_M become relatively larger because the reduction of the inertia force by wake vortices become smaller. Under such fluid conditions, the drag force may not become so large as to matter in practical application even if the values of C_D become large.

On the other hand, when the increase in high frequency components of velocities is caused by the increase in any nonlinearity not to be expressed by the superposition of small amplitude waves, the velocities and accelerations calculated from η by Reid's method may become a little smaller than actual ones, which may involve some risk of providing larger values of C_D and C_M . Therefore, the characteristics of C_D and C_M in irregular waves are still to be investigated.

As examples of the time variation of irregular wave forces, the results of Cases 5, 14 and 19 (in Table 3) are respectively shown in Fig.12 (a), (b) and (c). The calculated wave forces F shown in chain lines agree fairly well with the measured values F^* shown in solid lines, which is also recognized from the fact that almost values of r in Table 3 are close to 1. Strictly speaking, however, F^* is slightly larger than F near the crest and trough as well as the velocity and acceleration. The difference of F from F^* is caused by not only the differences of calculated u and \dot{u} from their measured ones but also the method of calculation such that C_D and C_M are fixed to certain values over one series of irregular waves.

(a) Case 5

(b) Case 14

(c) Csaе 19

Fig.12 Time variation of wave forces, F^* and F , on small cylinder.

As examples of power spectral density distributions of wave forces, the results of Cases 3, 7, 14 and 19 (in Table 3) are shown in Fig.13(a), (b), (c) and (d) respectively. In each figure, the spectrum of the measured wave force, S_{F^*} , are shown in solid line, and the first and second approximations of theoretical spectrum, S_{F_1} and S_{F_2} , calculated from S_η by using Eqs.(20) and (21) respectively are shown in dotted lines.

S_{F_2} contains the effect of nonlinear interactions of component waves with each other, but S_{F_1} and S_{F_2} are not so different from each other, and agree well with S_{F^*} .

Then, considering the results of all experimental cases shown in Table 3, the following facts are obtained:

The time variations of wave forces calculated from Reid's method are in fairly good agreement with the measured wave forces, and the spectral distributions of forces calculated from Borgman's method also agree well with ones obtained from the measured wave forces.

IRREGULAR WAVE FORCES ON A LARGE DIAMETER CYLINDER

3-(1). Theory

The coordinate system is taken in the same way as mentioned in 1-(2), and moreover, the center axis of a cylinder is at $X=0$.

When the water level variation at $X=0$ is monochromatic as shown in Eq.(23), the induced wave force is represented as shown in Eq.(24) by MacCamy and Fuchs's diffraction theory³⁾:

$$\eta(t) = a \cos(\omega t - \delta) \quad , \quad \dots \dots \dots (23)$$

$$\begin{aligned}
 F(t) &= \text{Re} \left\{ 4 \rho g \frac{\cosh k(h+z)}{k \cosh kh} \frac{1}{H_1^{(W)}(kR)} a e^{-i(\omega t - \delta)} \right\} \\
 &= 4 \rho g \cdot C_1(\omega) \cdot a \cos(\omega t - \delta) \\
 &\quad - 4 \rho g \cdot C_2(\omega) \cdot a \sin(\omega t - \delta) \quad , \quad \dots \dots \dots (24)
 \end{aligned}$$

in which a is the amplitude, δ is the initial phase, g is the acceleration of gravity, $H_1^{(1)'}$ is the derivative of Hankel function of first kind of order 1, and C_1 and C_2 can be deduced as Eqs.(25) and (26) respectively, which become frequency response functions of wave forces to water level variations:

$$C_1(\omega) = \frac{\cosh k(h+z)}{k \cosh kh} \frac{J_1'(kR)}{J_1'^2(kR) + Y_1'^2(kR)} , \dots\dots\dots (25)$$

$$C_2(\omega) = \frac{\cosh k(h+z)}{k \cosh kh} \frac{Y_1'(kR)}{J_1'^2(kR) + Y_1'^2(kR)} , \dots\dots\dots (26)$$

in which R is the radius of the cylinder and J_1' and Y_1' denote the derivatives respectively of Bessel function of order 1 and of Neuman function of order 1.

In the next place, when the water level variation is irregular as shown in Eq.(27), the induced wave force is represented as Eq.(28) within the range of small amplitude wave theory:

$$\eta(t) = \int_0^\infty M(\omega) \cos(\omega t - \delta(\omega)) d\omega , \dots\dots\dots (27)$$

$$F(t) = 4\rho g \int_0^\infty C_1(\omega) \cdot M(\omega) \cos(\omega t - \delta(\omega)) d\omega - 4\rho g \int_0^\infty C_2(\omega) \cdot M(\omega) \sin(\omega t - \delta(\omega)) d\omega . \dots\dots\dots (28)$$

The first term in the right hand side of Eq.(28) has the same phase as Eq.(27) and the second term has the changed phase by $\pi/2$ from Eq.(27). Therefore, the time variation of wave forces can be calculated from the simultaneous water level variation by using both the symmetrical linear filter G_S which has the frequency response function $C_1(\omega)$ and the asymmetrical one G_a which has $C_2(\omega)$, as follows:

$$F(t) = 4\rho g G_S[\eta(t)] + 4\rho g G_a[\eta(t)] . \dots\dots\dots (29)$$

The validity of this calculation method were discussed by using the wave force data obtained in the experiment with the small diameter cylinder shown in 2-(1).

3-(2). Results and discussions

Figs.14 and 15 show the results obtained by applying the method shown in 3-(1) to Cases 3 and 7 shown in Table 3 respectively, in which, (a) shows the water level variation η used as the input data, and (b) shows the comparison between the measured wave force F^* and the calculated one F obtained as the output data. It is recognized from Fig.14(b) that the calculated wave force shown in chain line agrees well with the

Fig.14 Time variation of wave forces on large cylinder (Case 3)

Fig.15 Time variation of wave forces on large cylinder (Case 7)

experimental one shown in solid line. This reason is considered that since the waves of Case 3 have the narrow band spectrum of which predominant frequency is relatively high value 1.0 Hz as shown in Fig.13(a), the drag force can be ignored. In another words, the difference between these two curves shows the drag force because the wave force calculated from the diffraction theory expresses only the inertia force.

On the other hand, Fig.15(b) indicates that the calculated wave force is fairl different from the experimental one because of the larger drag force. The reason of the increase in drag force may be understood from its wave spectra shown in Fig.13(b).

Now, considering the results of not only Cases 3 and 7 but also another cases, the following fact is obtained:

When the cylinder is so large in diameter that the inertia wave force is predominant to the drag one, the irregular wave forces can be estimated from only the water level variation by using this method.

CONCLUSION

The time variation of the horizontal and vertical velocities and accelerations of water particles can be predicted fairly well from the water level variation by using Reid's linear filters based on the small amplitude wave theory. Consequently, the time variation of the irregular wave forces can be adequately calculated from the water level variation by using Morison's equation in the case when the values of drag and inertia coefficients can be estimated. In such a case, also the spectral density distribution of wave forces can be calculated adequately from the spectrum of water level variation by using Borgman's method. In order to put these methods into practical application, however, the characteristics of the values of drag and inertia coefficients should be investigated from the standpoint, for example, of comparing with the results already obtained under periodic waves.

On the other hand, in such a case that each wave steepness in irregular waves becomes so large that the nonlinear characteristics can not be ignored, the linear filters may provide a little smaller values of the velocities and accelerations than the actual ones, which involve some risk of providing larger values of drag and inertia coefficients. Therefore, a certain nonlinear filters should be investigated in futuer.

Moreover, when the inertia wave force is predominant to the drag one, irregular wave forces on a cylinder can be calculated from only the water level variation by the method of applying Reid's linear filters to MacCamy and Fuchs's diffraction theory as presented in this paper.

ACKNOWLEDGEMENT

The authors wish to express their gratitude to Mr. Tetsuo Sakai, Mr. Tetsuo Senda and Mr. Yoshiteru Dobashi for their assistance through the experiments and data analysis. This work was partly supported by Scientific Research Funds from the Ministry of Education, Japan.

CHAPTER 145

LOADING AND RESPONSE OF CYLINDERS IN WAVES

by G N Bullock¹, P K Stansby¹ and J G Warren²

1. Introduction

The nature of the wave-induced flow around a circular cylinder is to a large extent determined by the ratio of water-particle orbit size to cylinder diameter, characterized in regular waves by the Keulegan-Carpenter number KC (see Appendix II for definitions). When $D/L > 0.2$ wave scattering effects are negligible and it is conventional to describe the fluid loading in terms of drag and inertia forces in-line with the direction of wave propagation plus a transverse 'lift' force.

The idealised two-dimensional situation of a cylinder normal to planar sinusoidal flow has been investigated in U-tubes by Sarpkaya (10, 11). As KC advances above 2 vorticity starts to be shed and produces forces in addition to the inertia force which would result from the undisturbed fluid acceleration. The vortex-induced forces become more important as KC increases. Defining the drag force as the component of the in-line force in phase with the fluid velocity and the inertia force as the component in phase with the acceleration, it is found that the drag, inertia and lift can have comparable magnitudes when KC is between 8 and 25. This paper is concerned with the corresponding regime in waves.

In the idealised situation vortex shedding is almost perfectly correlated along the length of the cylinder but generally this will not be the case in waves. Here the degree of vortex coherence will influence the vortex-induced forces particularly the lift which is strongly dependent on history effects. Although the forces on fixed vertical cylinders have been measured, little is known about the loading on cylinders in general orientation in either unidirectional waves or planar flows. Real seas are further complicated by being random and multidirectional with the possibility of superimposed currents. The interaction of cylinder vibration with vortex shedding can be highly non-linear in currents, e.g see (12), but again little is known about what happens in waves.

Although scale influences the magnitude of forces when vortex shedding is important, small-scale experiments can qualitatively represent full-scale flows. Thus, the interrelation between the various parameters which influence wave loading may be studied in the relatively controlled environment of a laboratory channel. Furthermore, analysis techniques which have been justified on the model scale can then be applied with greater confidence to full-scale situations.

1. Civil Engineering Department, University of Salford, England
2. Taylor Woodrow Construction Ltd. London, England.

In this paper we consider the loading and response of small-diameter flexible cylinders with natural frequencies of vibration in excess of the dominant wave frequency. The way in which vortex shedding generates loading is illustrated by results from a mathematical model (13) and a brief review of experimental studies using fixed cylinders. This is followed by a description of an investigation in which flexible cylinders were mounted as vertical cantilevers in a laboratory wave channel. Both regular and 'random' waves were generated while structural frequencies were tuned through a range of values. Methods of predicting the in-line response are tested and the cross-flow response is evaluated.

With the test cylinder in regular waves, in-line and transverse displacements at still water level, x_0 and y_0 , depend upon

$$f_w, D, \rho, \mu, f_n, S_n, \bar{m}, \delta, t, k, d$$

Dimensional analysis gives

$$\frac{x_0}{D}, \frac{y_0}{D} = f\left(KC, Re, kd, \frac{S_n}{d}, \frac{t}{T}, \delta, \frac{\bar{m}}{\rho D^2}, Fr\right)$$

where the Reynolds number (Re) is effectively a scale parameter. In planar oscillatory flows the parameter kd , which indicates the degree of particle motion attenuation with depth, and S_n/d , which indicates the degree of wave non-linearity, both disappear.

2. Vortex Shedding in Planar Oscillatory Flows

A mathematical model of two-dimensional vortex shedding from the circular cylinder has been developed (13). Principles of potential flow are used and the separating shear layers are represented by discrete vortices. Fixing separation on the line through the cylinder centre normal to the incident velocity gives forces which are in reasonable agreement with experiment (11) at very high Reynolds numbers for $KC > 12$ (approx.). Fig. 1 shows the variation of non-dimensional in-line and lift force, $C_x(t)$ and $C_L(t)$, with time for $U = U_0 \cos(2\pi t/T)$ and $KC = 12.5$ and 18.4 . The in-line force is closely predicted by Morison's formula, $\frac{1}{2}\rho DU|U|C_D + \frac{1}{2}\rho\pi D^2 \dot{U}C_M$ with $C_D = 0.7$ and $C_M = 1.4$, even though there are complex asymmetric vortex motions which cause lift fluctuations at higher frequencies than the incident flow frequency. These vorticity patterns are sketched in Fig. 2 for $2.25 < t/T < 2.75$. The vorticity is concentrated in areas rather than at points.

The lift variations are not repetitive for the examples shown although nearly periodic forms have been observed in certain cases. This is in keeping with experimental studies at low Reynolds numbers (8). Fig. 2 shows that for $KC = 12.5$ the strong positive vortex shed in the previous half cycle moves towards the cylinder generating positive lift at $t/T = 2.25$ and 2.35 . At $t/T = 2.45$ positive vorticity rolling

Fig. 1. Time histories of $C_x(t)$ and $C_L(t)$ from mathematical model

Fig. 2. Sketches of vortex movement to demonstrate generation of forces.

up close to the cylinder generates negative lift. At $t/T = 2.55$ and 2.65 negative vorticity rolling up close to the cylinder generates positive lift. By $t/T = 2.75$ two lumps of vorticity have been shed corresponding to those at $t/T = 2.25$. For $KC = 18.4$ the situation is similar, the four vortices shed causes four peaks in lift with an initial peak from the returning vorticity of the previous half cycle. The vorticity from earlier half cycles appears to have little effect. The rule that the ratio of lift frequency to flow frequency is $N + 1$ where N is the number of vortices shed per half cycle is thus demonstrated. However the rule does not always apply, particularly when N is large and the shed vortices vary considerably in strength.

3. Fixed Vertical Cylinder in Waves

Various investigators have measured wave forces on fixed vertical cylinders in laboratory wave channels. C_D and C_M have been calculated (using horizontal water-particle motions from third order wave theory) for a section close to the surface (9) and C_D values were found to be slightly greater than for planar oscillatory flows (10) with $10 < KC < 25$. Other tests (14) indicate that the use of C_D and C_M from U-tube experiments will give a good representation of local in-line forces.

Local lift forces have also been measured (2) and their Fourier components were found to be dependent on spanwise position. A non-uniform velocity distribution has been investigated in detail for a steady flow approaching a circular cylinder (7). The linear spanwise velocity variation caused vortex shedding, and hence lift frequencies to be roughly proportional to local velocity although these frequencies would be unchanged for several diameters as vortices were shed as distinct 'cells'. Thus vortex lines were not continuous throughout the depth. Such incident flows contain vorticity normal to the cylinder axis while waves are essentially irrotational. But a uniform, and hence irrotational flow incident on a tapered cylinder also produced cells of different frequency (4). It seems likely that incoherent cell structure will also occur in waves, at least when several vortices are shed per half cycle.

Lift fluctuating mainly at the wave frequency has been measured for $KC < 5$ (2) and this has not been observed in planar or other wave flows (to the writers' knowledge). This could however be due to wave non-linearity effects as vortex patterns due to the passage of a wave crest can be very different from those due to the passage of a trough (16). Local C_D and C_M values were also calculated in (2) and the high degree of scatter could in part be due to the use of linear wave theory. For $6 < KC < 14$ lift at almost entirely twice the wave frequency is in agreement with Isaacson and Maull (5) who measured the total force on the cylinder. However differences in magnitude may again be due to different non-linearity effects. For $KC > 16$ the rms lift has decreased (5) and contains several Fourier components of similar magnitude.

4. Flexible Vertical Cylinder in Waves

The present investigation was conducted in a 1.25m wide x 0.8m deep x 40m long laboratory channel with a computer-controlled, piston-type paddle at one end and a gently sloping, 10m long, 'beach' at the other (Plate 1). The beach was estimated to have a reflection coefficient that varied from 2.8% up to 5.0% over the range of wave frequencies considered. The temporal variation in water surface elevation was measured by capacitance-type wave gauges linked to the computer which was used for data collection and some analysis.

When regular waves were required the computer was programmed to adjust a sinusoidal paddle motion until waves with a specified frequency and standard deviation of water surface elevation were generated at the test section. A system was developed whereby data of the type presented in Fig. 3 could be automatically collected for up to 48 different wave conditions. 'Random' waves were generated by the use of an algorithm (3) in which pseudo-random noise is produced by feedback in a shift register and passed through a digital filter to give the paddle motion for the desired wave spectrum. Because this technique produces a deterministic time series it is possible to conduct a series of tests in nominally identical wave conditions.

Four 0.8m long cylinders with diameters ranging from 21mm to 54mm were used in the investigation (see Table 1). When a particular cylinder was under test it was mounted on the bottom of the channel in a 0.6m depth of water to form a vertical surface-piercing cantilever. The required degree of flexibility was achieved by fabricating each cylinder from Polypropylene tube (Young's Modulus of 700 MN/m^2) and the resonant frequency was controlled by use of a variable tip mass. Vibration was measured by means of two pairs of strain gauges positioned 25mm above the base and displacements were estimated on the basis of the first mode shape. Negligible motion was detected at frequencies associated with any higher mode.

The logarithmic decrements of structural damping were determined in free vibration tests to be between 0.18 and 0.22. The mass of each structure was generalised by use of an equivalent mass (\bar{m}) defined in the way that has become standard for estuarial structures. Thus \bar{m} is the mass/unit length of a uniform cylinder extending to mean water surface level which vibrates with the same energy, resonant frequency and mode shape as the original structure. Values of f_n were determined in still water tests. A particular test structure was then defined by means of the dimensionless parameters Fr , δ and $\bar{m}/\rho D^2$.

Regular Wave Tests

These tests were carried out with intermediate depth waves ($0.5 < kd < 3.0$) at surface Re between 4.6×10^3 and 17×10^3 and KC up to 28, all values calculated using linear theory.

Plate 1. General view of experimental equipment.

Plate 2. Oscilloscope traces of the temporal variation in x_0 and y_0 during series A test with $Fr = 2.0$ and $KC = 17$.

Fig. 3. Typical results for the variation in root-mean-square x_0/D and y_0/D against various parameters for regular waves.

Fig. 3 shows three typical sets of results for the variation in rms x_0/D and y_0/D against Fr , KC and kd . Additional parameters for these and other similar tests are given in Table 1. Because cross-flow response was often quite different from one wave cycle to the next, each point in Fig. 3 is based on 19,600 readings taken at 0.06 sec intervals (350 to 1300 wave cycles) to give sensible statistical estimates. For the range of parameters considered the cross-flow response can be much greater than the in-line response and both motions tend to increase as Fr approaches an integer value. The wave height for the runs in Fig. 3 was unchanged at 113mm. (The low level of reflection is considered to have little influence on the results).

The in-line response followed a very similar pattern in each wave cycle of a particular test but the form of the pattern depended upon the prevailing test parameters. Several attempts were made to predict the observed behaviour. In these the cylinder was divided into segments and the horizontal water-particle motion at the centre of each segment was calculated from simple theory. Local KC values were used in conjunction with data from U-tube experiments (10) to assign values to C_D and C_M in the Morison equation and hence to estimate the bending moment at the cylinder base. Wave-induced motion was predicted by assuming that the cylinder formed part of a linear, single-degree-of-freedom system and feeding a time series of base bending moments into a finite difference scheme based on the appropriate equation of motion. The best results were obtained when the Morison equation was extended to include relative motion terms, when some account was taken of the variation in water-surface elevation and when second order rather than first order wave theory was used. Fig. 4 shows a comparison of measured and predicted time-histories for base strain while Fig. 5 shows a more general comparison of rms x_0/D values. The predictions were good except when $Fr \approx 2$ and the experimental cylinder was subjected to strong transverse bending moments that varied at twice the wave frequency. In these circumstances, which occurred when the surface KC was around 13, the observed in-line motion was seriously underestimated.

The general success of the extended Morison equation when used with coefficients obtained with stationary cylinders suggests that the vorticity shed in a wave cycle is mainly dependent on the relative in-line fluid motion. However, in these experiments the cylinder motion was always small in comparison with the fluid motion. If we assume that the vorticity shed was largely independent of response, because vorticity was mainly responsible for in-line motion and entirely responsible for cross motion, it is reasonable to expect rms $y_0/rms x_0$ to be sensibly constant for situations with the same Fr , KC and kd . Further specification by $\bar{m}/\rho D^2$ and δ is conveniently avoided as they affect only the magnitude of the responses and S_n/d was the same in most tests. In the present case KC was a more important parameter than kd , so ratios of rms $y_0/rms x_0$ were calculated from the experimental results and plotted against Fr and KC . This produced a chart similar to Fig. 6 in which each dot indicates the location of a

result from the series of tests A to M detailed in Table 1. (In each test k_d decreased from about 2.5 to 0.75 with increasing KC). The scatter in the values of $\text{rms } y_0 / \text{rms } x_0$ found within a given region of the chart was small enough (15) to justify the sketching of contours as shown. Values in excess of 3 were obtained only in the sensitive area around $Fr = 2$ and $KC = 13$ where the vorticity shed in a wave cycle was probably markedly dependent on response (see § 5).

Unlike the in-line motion, the transverse response tended to be very erratic with intermittent bursts of activity that varied in both magnitude and duration. However, during tests in which f_n was close to the frequency of a major component in the transverse bending moment, y_0 would occasionally follow repetitive patterns which could persist for many wave cycles. The most stable responses were generally associated with the sensitive area around $Fr = 2$ and $KC = 13$. When these broke down either the same pattern or its mirror image in the in-line plane was quickly re-established (Plate 2).

Some characteristics of the different types of motion are illustrated by the probability density histograms shown in Fig. 7, the right hand pair being for the conditions of Plate 2. The in-line histograms are asymmetric, mainly due to the different loading produced by the passage of wave crests as opposed to troughs, whereas the transverse histograms are symmetric. Because the cross motion varies from the very erratic to the near sinusoidal oscillations associated with a repetitive pattern, the corresponding probability density histograms are a combination of the 'bell-shaped' Gaussian and two-peaked, sine-wave density functions. The relative magnitudes of these forms within a particular histogram give an indication of the periods over which the different conditions were prevalent. Spectral analyses of both the in-line and transverse response show the variance to be mainly at harmonics of f_w , significant dynamic magnification occurring whenever f_n was close to a wave harmonic. A fair proportion of the in-line response always occurred at f_w but this was not true of the transverse motion.

Time-histories of in-line and transverse base bending moments were calculated from strain data for 82 seconds of selected tests. As would be expected spectral analyses reveal that most of the variance in the in-line moment occurred at f_w whereas the largest harmonic in the transverse moment depended upon the prevailing test parameters. An indication of the regions over which various harmonics predominate is shown in Fig. 8 which suggests that the boundary between adjacent regions moves towards higher KC as k_d increases. This is doubtless due to the increasingly non-uniform velocity distribution as one moves towards a condition of 'deep-water' waves. In these circumstances the local value of KC reduces with depth and it is quite possible for the dominant harmonic in the transverse loading near the surface to have higher frequency than that of the dominant harmonic in the loading further down (2).

Fig. 8. Predominant harmonic in transverse moment or force

Random Wave Tests

During these tests the waves had a Pierson-Moskowitz spectrum with $S_{\eta} = 32\text{mm}$ and the variation in water-surface elevation was approximately Gaussian. Spectra for in-line and transverse response of the 28mm diameter cylinder when tuned to various f_n above the frequency of the wave spectral peak are shown in Fig. 9.

In most tests the in-line motion was dominated by vibration at the natural frequency although there was always significant response at frequencies associated with the peak of the wave spectrum. The spectral peak at f_n rapidly diminished as f_n was increased.

Predictions of in-line response were made in the frequency domain by applying transfer functions to the measured wave spectrum. The effects of structural movement were ignored so that base bending moment spectra could be calculated by use of linear wave theory and a linearised drag term in the Morison equation as proposed by Borgman (1). Guidance in the choice of values for the Morison coefficients was sought by calculating surface KC values for a regular wave with the same S_{η} as the wave spectrum and a frequency equal to that of the spectral peak. For the situation of Fig. 8 this gave $KC = 14$. U-tube experiments (10) indicate that around this value $C_D \approx 2$ and $C_M \approx 1$ and for simplicity these values were assumed to apply throughout the water depth. The response spectra obtained from the bending moment spectra by use of appropriate dynamic admittance terms were in remarkably close agreement with the experimental results (e.g Fig. 9). This is perhaps surprising as the calculations were drag-dominated and suggests that the errors inherent in the assumptions must at least partially cancel each other out. Refinement of the present calculations was not justified and new tests will be carried out to investigate this matter further.

The transverse response was of comparable magnitude to the in-line response but occurred only at frequencies near f_n . It was highly irregular and tended to be dominated by short bursts of above average motion which appeared to be either caused by the passage of a single wave or built up by a sequence of waves. Short bursts of high response at f_n also occurred in the in-line direction but did not necessarily coincide with those in the cross mode. Examination of the limited number of spectra obtained for the transverse response indicated that the variance did not always decline when f_n was increased. Instead there was a suggestion that the response increased when f_n was near an integer multiple of the dominant wave frequency in a manner reminiscent of the regular wave tests. It is interesting to note that the situation with $KC = 11$ and $Fr = 3.8$ occurred in both regular and random waves and the rms y_0 values were very similar (KC and Fr for random waves were calculated on the basis of a sine wave as previously described).

5. Analysis

The experiments were primarily concerned with the evaluation of response

Fig. 9. Response of 28mm diameter cylinder in random waves.

Fig. 10. Comparison of experimental results with results from the two-dimensional mathematical model

due to vortex shedding in waves. In regular waves definition of water-particle motions in an accepted manner together with the use of Morison's equation with relative motion terms and coefficients for fixed cylinders usually gave a good prediction of in-line response. This prediction was not disrupted by cross response which was often greater than the in-line response. An equivalent prediction method does not exist for cross motion and $\text{rms } y_0/D$ should ideally be defined by all the stated non-dimensional groups. To avoid this an approximate argument, which assumes that vorticity shed in a wave cycle is independent of the response which it generates, allows $\text{rms } y_0/\text{rms } x_0$ to be defined in terms of Fr , KC and kd . The contour plot of Fig. 6 is itself a justification for its method of presentation. The influence of kd is however omitted and Fig. 9 shows its effect on the dominant frequency of lift moment. This will affect the dependence of cross response on KC . It may be possible to weight KC through kd to overcome this.

The in-line response is underestimated by the above prediction for parameters approximately given by $1.8 < Fr < 2.2$ and $10 < KC < 17$. The area acceptably fits the contour plot and $\text{rms } y_0/\text{rms } x_0$ attains a maximum of 3. Lift moment is predominantly at twice the wave frequency and cross response and moment are at their most repetitive. Because drag and lift are vortex-induced it seems likely that the strength of the one vortex shed per half cycle is usually magnified by the response. This is analogous to the situation in currents where cross motion increases the vortex-induced forces which then increase the response in a feedback loop until equilibrium is reached, e.g see (12). The lift also 'locks-on' to the cylinder motion. However in waves, outside the sensitive area, cross response appears to have little influence on the vortex-induced forces in a permanent or long-term sense. Experiments with a linear mode response (6), which covered a range of δ , support this although the sensitive area was not found.

Cross response never defines the lift moment frequency and without this stabilising influence apparently stable patterns will always break down. In general cross response and moment are irregular and their fine structure is obviously interactive. Such patterns are shown in Fig. 10 and compared with the two-dimensional mathematical model. The potential-flow calculation accommodates cylinder velocities but only very small responses are considered because of the assumption of fixed separation. The KC of the high Reynolds number simulation is adjusted to give the same lift frequencies as the surface KC in waves. The different $\bar{m}/\rho D^2$ cause the model response to be roughly 1/10 of the experimental response but the interaction is similar for both. Lift acting against the motion reduces response while lift acting with the motion increases it. For the mathematical model the peak lift was greater than on the fixed cylinder but rms values were similar. It is important to note that in the experiment the small lift moment causes a greater response than the much larger in-line moment. The peaks in lift moment are considerably smaller than would be obtained by dividing the span into segments and summing the influence of lift maxima obtained from U-tube experiments through the associated KC values.

Extension of these results to other situations requires an interpretation of the physical processes involved. Magnification of vortex-induced forces by response is most likely when forces and response are nearly sinusoidal and at the same frequency (the situation of locking-on in steady currents). When the force is complex with spectral analysis indicating several harmonics of similar magnitude, feedback through a response at around the natural frequency would have to have a remarkable form to magnify the force in a permanent way.

Random waves will further reduce the possibility of permanent magnification and rms cross response can be as large in random waves as it is in regular waves for the same S_n and KC . The prediction of in-line response in the frequency domain by making several assumptions was remarkably good. However the validity of each assumption should be checked in isolation.

CHAPTER 146

WAVE FORCES ON A ROW OF CYLINDRICAL PILES OF LARGE DIAMETER

by

J.C.W. Berkhoff* and J. v.d. Weide**

Abstract

In order to determine wave forces on a row of three cylindrical piles (Figure 2), a numerical computation procedure was applied using a solution of the Helmholtz equation, in which the scattered wave field is described as the result of a series of singular sources located along the circumference of the pile [Berkhoff, 1976, reference 1]. Results of the computations were verified by means of model experiments, using both regular and irregular waves.

It is shown that for the two pile geometries, included in the study, strong mutual interference will occur, resulting in transverse forces which are much higher than those found for single piles.

1 Introduction

In order to protect the low-lying hinterland of the lower Rhine delta against flooding, the Dutch have developed the Delta scheme, which involves the closure of a number of estuaries and the construction of three storm-surge barriers, the largest of which is currently being designed. This structure will be located in the Eastern Scheldt and will consist of a group of three sluices, each consisting of a number of gates with a span of approximately 40 m. Gates are suspended between piers founded at the seabed, which locally has a depth of 38 m below sealevel.

For the construction of the piers, cylindrical cofferdams were envisaged, due to time constraints three of these cofferdams had to be used simultaneously. Due to the large dimensions of these structures a strong mutual interference had to be expected which might adversely effect current and wave forces. Therefore, a study was performed to determine wave forces on a row of cylindrical piles. Results of this study are presented in this paper.

2 Theoretical considerations

Wave forces have been the subject of many studies, resulting in a number of theories and computation techniques. Each of these has its own distinct field of application as may be demonstrated with the help of Figure 3.

For objects which are small with respect to the wave length ($D/L < 0.1$) it is assumed that the local flow field is only marginally affected by the presence of the object.

Consequently orbital velocities and accelerations within the fluid are computed for the undisturbed condition using conventional wave theories. Once local accelerations and velocities are known corresponding wave forces may be computed. In this respect two limiting conditions may be considered

H = wave height
 L = wave length
 D = characteristic length of object

FIG. 3 CHARACTERISTIC WAVE PARAMETERS

FIG.: 4 NOTATIONS

characterized by large and small values of the Keulegan Carpenter number

$$\frac{U_{\max} T}{D}$$

which, for deep water, is proportional to the ratio of wave height (H) over pile diameter (D).

For large value of H/D, drag forces are most important whereas for small values of H/D inertia forces predominate. In view of the dimensions of the cofferdam, the latter conditions applies for the present case. However, the ratio of the pile diameter over the wave length is such, that the effect of the structure on the local flow field can no longer be neglected. Resultant forces have to be derived, therefore, from a description of the local wave field which takes into account both the effect of the incident and the scattered waves.

Values of H/D and D/L are such that they fall within the hatched area bounded by the limiting wave steepness in deep water ($H/L = 0.1$) and the line $H/L = 0.03$, indicating roughly the limit beyond which shallow water effects strongly manifest themselves. In this area linear wave theory may be applied to describe the wave field. Mathematically the problem is then described as the solution of the Laplace equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} = 0 \quad (1)$$

which satisfies the following boundary conditions

$$\text{free surface: } \frac{\partial^2 \phi}{\partial t^2} + g \frac{\partial \phi}{\partial z} = 0 \quad (2)$$

$$\text{horizontal bottom } \frac{\partial \phi}{\partial z} = 0 \quad (3)$$

$$\text{surface of the pile } \frac{\partial \phi}{\partial n} = 0 \quad (4)$$

Furthermore the well known Sommerfeld condition should be fulfilled, stating that the scattered wave vanishes with increasing distance from the object.

In general, the solution of equation (1) is written as

$$\Phi = \phi_i + \phi_d \quad (6)$$

where

ϕ_i = potential of incident wave

ϕ_d = potential of scattered wave

The potential ϕ_i is expressed as

$$\phi_i = \frac{H g}{2 \omega} \frac{\cosh k(d+z)}{\cosh kd} e^{i(\omega t - mx)} \quad (7)$$

which satisfies condition 2 and 3, provided the dispersion relationship is valid, stating

$$\omega^2 = gk \tanh kd \quad (8)$$

The potential ϕ_d may be expressed as

$$\phi_d = \frac{H g}{2 \omega} \cdot \frac{\cosh k(d+z) \cdot F(x,y) \cdot e^{i\omega t}}{\cosh kd} \quad (9)$$

which also satisfies condition 2 and 3.

Substitution of (9) in (1) results in the well known Helmholtz equation

$$\frac{\partial^2 F(x,y)}{\partial x^2} + \frac{\partial^2 F(x,y)}{\partial y^2} + k^2 F(x,y) = 0 \quad (1')$$

The problem is defined now as a solution of equation (1'), which satisfies the boundary condition (5) and the Sommerfeld condition.

As early as 1954 McCamy and Fuchs [3] have solved this problem analytically for a single circular pile, by using a series of Bessel functions. Using the same procedure Spring and Monkmeyer [5] derived a solution for an array of two circular piles of arbitrary diameter and solved the problem for an infinite row of equally spaced equal cylinders exposed to perpendicular wave attack. The solution has been extended to waves from arbitrary direction of incidence by Massel [4], who presented an approximate solution. Recently, Chakrabarti [2], using the solution of Spring and Monkmeyer determined a solution for any arbitrary size at arbitrary angles to the incident wave. However, for an array of cylindrical piles of arbitrary cross-section no analytical solutions are available. Recourse had to be taken to a numerical technique, therefore, as described by Berkhoff. [1]

This was done by assuming that the scattered wave field may be considered as a result of a series of singular sources located along the circumference of the pile. Denoting the strength of the source distribution by $\alpha(\xi, \zeta)$ (see Figure 4) and the source potential function by $G(x, y, \xi, \zeta)$ the following expression is obtained for $F(x, y)$

$$F(x, y) = \int_S \alpha(\xi, \zeta) G(x, y, \xi, \zeta) ds$$

where

S = circumference of the piles

(ξ, ζ) = coordinate of the source point located at the object

A source potential function which is a solution of the Helmholtz equation (1') and which satisfies the Sommerfeld condition is found as

$$G(x, y, \xi, \zeta) = \frac{1}{2i} H_0'(k_0 r)$$

where

$$r = \sqrt{(x - \xi)^2 + (y - \zeta)^2}$$

and

H_0' = Hankel function of first kind and zero order.

The source strength $G(\xi, \zeta)$ is found from the boundary condition at the pile surface by putting

$$-\frac{\partial \phi_i}{\partial n} = \frac{\partial \phi_d}{\partial n}$$

which results in the integral equation

$$-\left[\frac{\partial e^{-imx}}{\partial n}\right]_{x_0, y_0} = \alpha(x_0, y_0) + \int_S \alpha(\xi, \zeta) \cdot \frac{\partial}{\partial n} \left[\frac{1}{2i} H_0^{(1)}(k_0 r) \right]_{x_0, y_0} ds$$

Where x_0, y_0 are the coordinates of an arbitrary point at the circumference of the object.

Once the wave potential is known, the pressures may be obtained from the Bernoulli equation

$$p = -\rho \frac{\partial \phi}{\partial t}$$

Integration of the pressures along the circumference of the pile yields the total wave force.

3 Results for circular piles

3.1 Introduction

In order to compare the results of the present theory with previous studies interaction effects were first studied for a row of 3 circular piles with a diameter of 18 metres, located 40 m apart. Results are given in a dimensionless form using the force coefficients

$$C_{F_x} = \frac{F_x}{\rho g H \operatorname{tgh} kd \cdot \frac{\pi D^2}{4}} \quad \text{and}$$

$$C_{F_y} = \frac{F_y}{\rho g H \operatorname{tgh} kd \cdot \frac{\pi D^2}{4}}$$

with

$F_{x,y}$ = maximum force in x or y direction respectively

ρ = density of water

g = acceleration of gravity

H = wave height

d = water depth

k = $2\pi/L$ with

L = wave length

D = pile diameter

Resultant forces were first computed by means of the theory described in section 2. In order to verify these results, model tests have been performed subsequently. These tests have been carried out in a model basin with dimensions 11 x 25 m², using a linear scale of 1 : 64. Both regular and irregular waves have been applied to determine the transfer function between wave heights and wave forces.

Finally, for a selected number of pile geometries, the effect of the distance between the piles has been studied experimentally.

3.2 Results of computations

Longitudinal and transverse force coefficients C_{F_x} and C_{F_y} are shown on Figures 5 and 6. Forces have been computed for each individual pile, using wave periods between 4 and 12 seconds and directions ranging from 0° to 30° . (0° corresponding to a direction perpendicular to the centerline of the pile array). It appears that results for a single pile are in good agreement with the analytical solution obtained by McCamy and Fuchs. Individual piles of a row of three piles may experience higher forces than single piles, due to mutual interference. These effects are most pronounced for transverse forces and are clearly shown for wave periods of 5 - 6 seconds.

3.3 Experimental verification

Results of computations have been verified experimentally, for the most critical position of the pile as shown on Figure 7. It appears that results for both regular and irregular waves are in good agreement with computed values.

Experiments have been repeated for various distances between the piles. As may be inferred from Figure 8 interference effects are most pronounced for l/D values in the order of 2. For higher values the effect of the mutual interference vanishes. Transverse forces for all tested arrangements were still higher than those for single piles, however.

4 Results for an array of cofferdams

4.1 Introduction

Forces on the array of cofferdams shown on Figure 2, have first been computed. It should be noted that the same dimensionless force coefficients have been used as for circular piles, which explains the high values of these coefficients in the graphs. Subsequently computed values were verified using the same experimental set up as described in section 3.1.

4.2 Results of computations

Longitudinal and transverse force coefficients C_{F_x} and C_{F_y} are shown on Figures 9 and 10. Forces have been computed for each individual pile, using wave periods between 4 and 12 seconds and directions ranging from 0° to 30° . It appears that for wave periods between 5..6 seconds, similar interference effects are observed as for circular piles. However, these effects are small compared to another strong interference, observed for a period of 10 seconds, which again is more pronounced for transverse forces. Plots of wave-heights around the piles show a strong amplification of wave-heights between the piles for this wave periods, as a result of interference between scattered and incident waves.

4.3 Experimental verification

Results of computations have been verified experimentally for the most critical position of the pile, as shown on Figure 11. Again computed results agree with experimental data, although transfer functions for C_{F_y} obtained by means of irregular wave show a less distinct amplification for 10 seconds, due to poor resolution of the spectral analysis in this range.

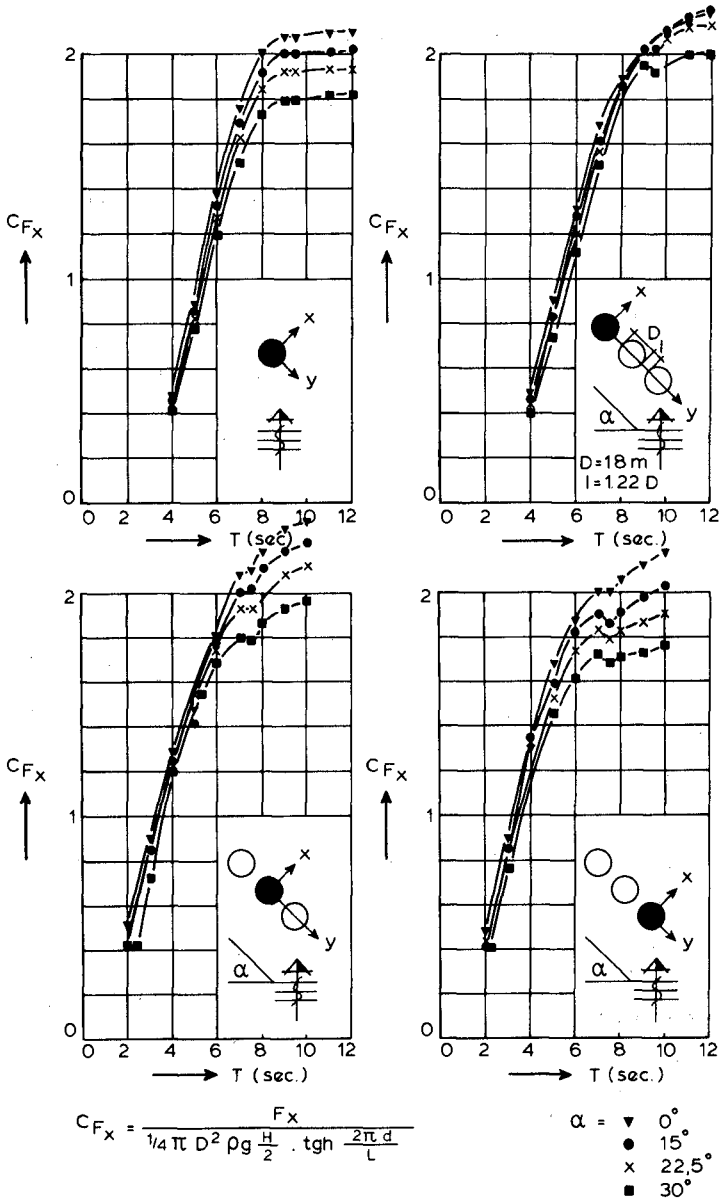

FIG. 5

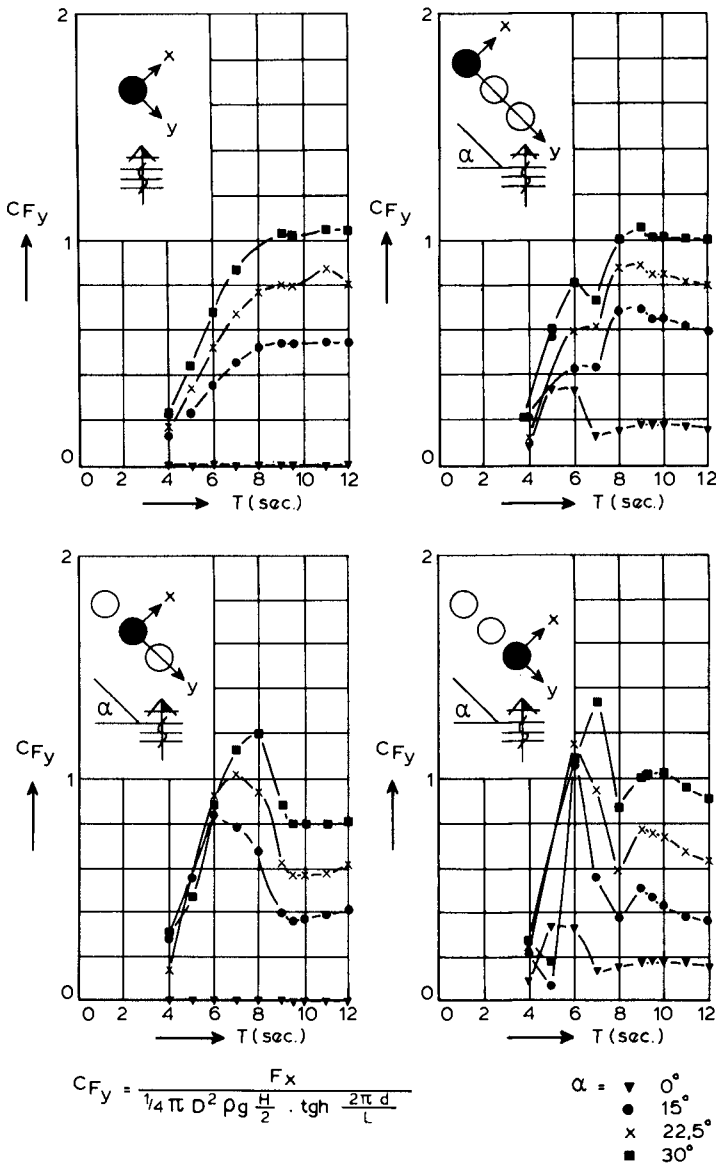

FIG. 6

FIG. 7

FIG. 8

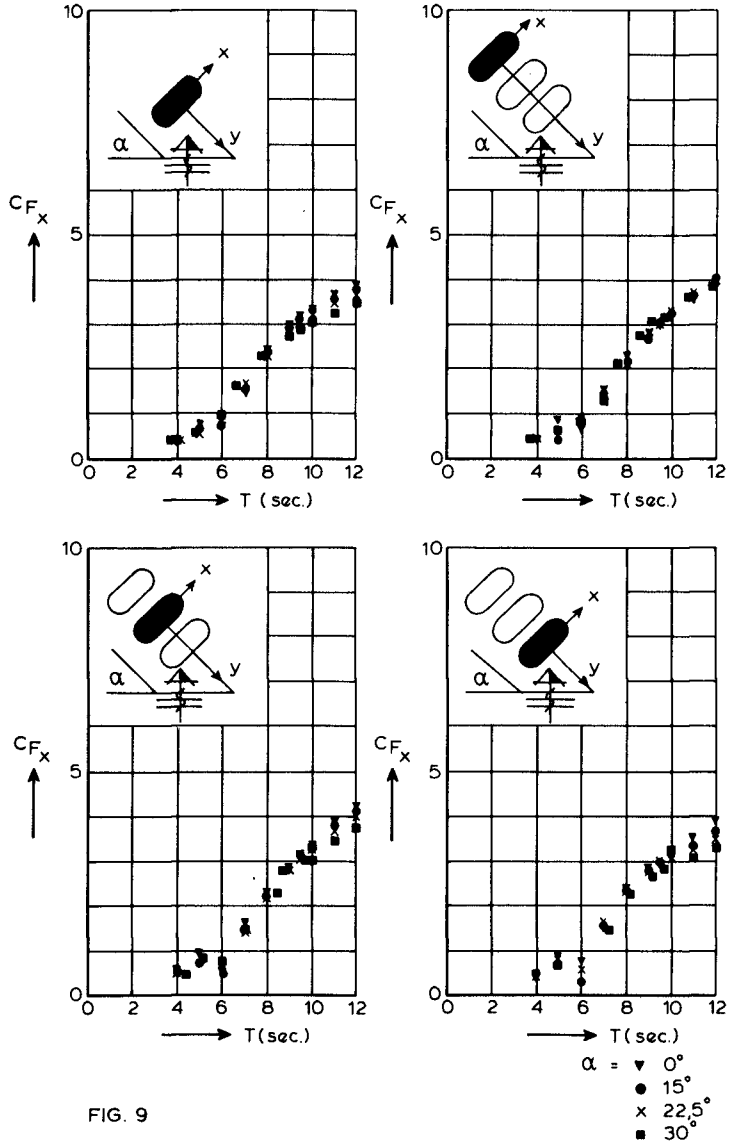

FIG. 9

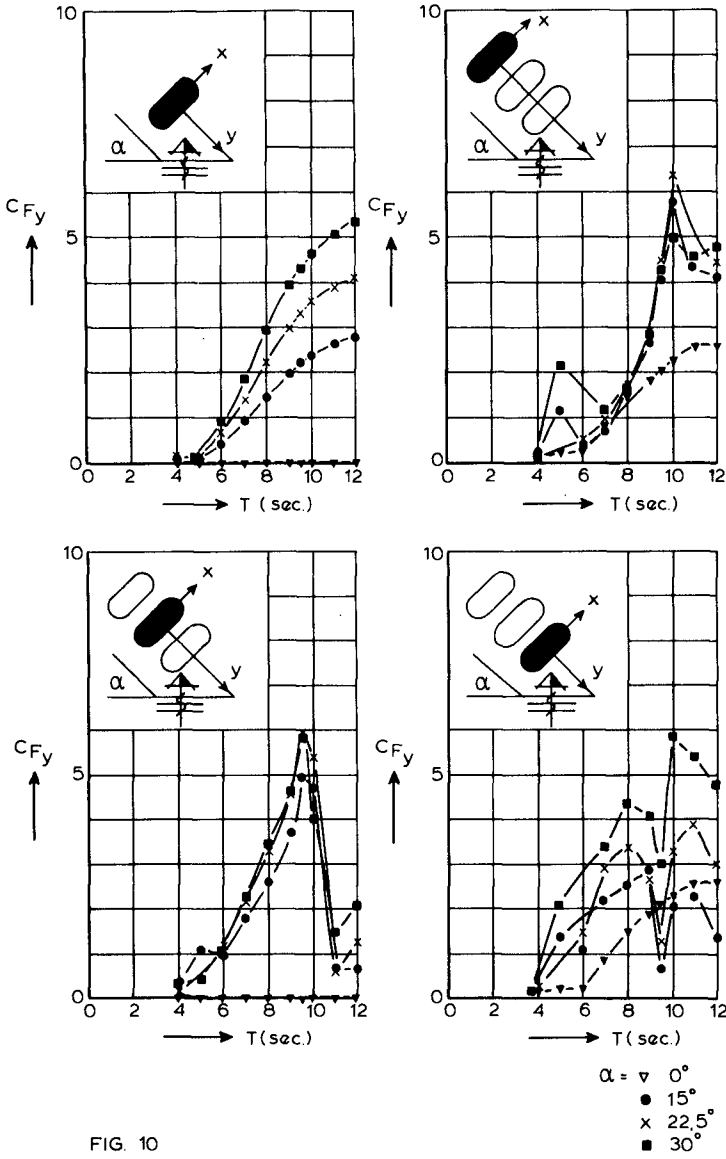

FIG. 10

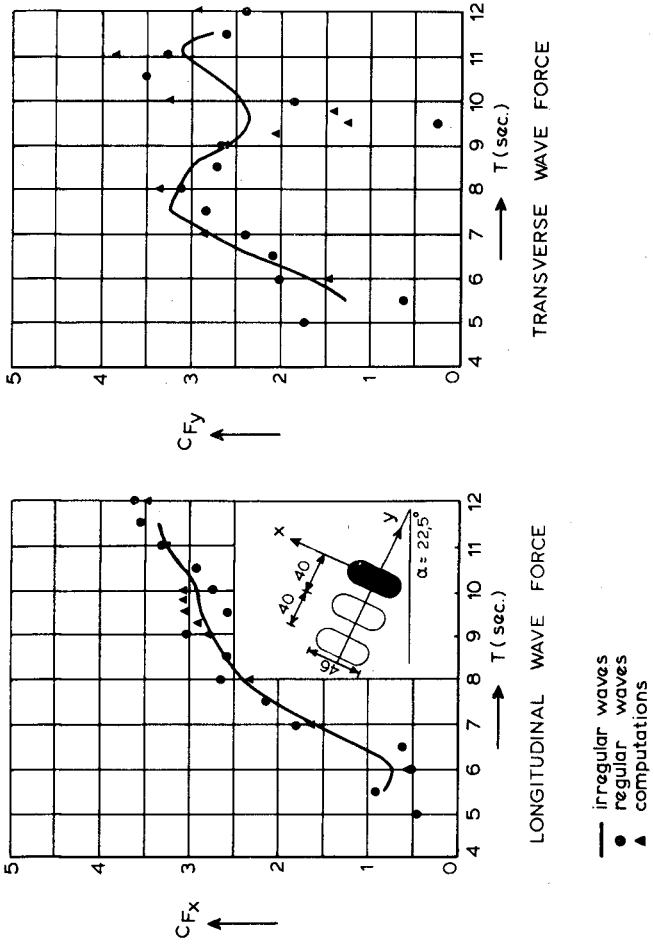

FIG. 11

FIG. 12

Transverse forces measured for different distances between the piles (Figure 12), show highest amplification for closely spaced piles ($1/D=1.22$), values decrease with increasing distance between the piles. Obviously, critical wave periods causing maximum amplification are also shifted. Maximum forces for all configurations are, however much higher than those found for the individual piles.

WAVE LOADS ON HORIZONTAL CYLINDERS

by

P. Holmes¹ and J. R. Chaplin²INTRODUCTION

The problem of predicting wave induced loads on cylinders is an enormously complex one. It is clear from the scatter present in most experimental determinations of force coefficients that there are many individual factors which influence the mechanisms of flow induced loading. Among these are some, for instance Reynolds number, separation and periodic vortex shedding, which are inter-related and whose influences cannot be studied in isolation. Others, such as shear flow, irregular waves and free surface effects, can at least be eliminated in the laboratory, in order to approach an understanding of the more fundamental characteristics of the flow.

A vertical cylinder in uniform waves experiences an incident flow field which can be described in terms of rotating velocity and acceleration vectors, always in the same vertical plane, containing also the cylinder axis, whose magnitudes are functions of time and of position along the length of the cylinder. Some of the essential features of this flow can be studied under two-dimensional oscillatory conditions, in which either the cylinder or the fluid is oscillated relative to the other along a straight line (planar oscillatory flow). The incident velocity and acceleration vectors are then always concurrent, normal to the cylinder axis, and oscillating in magnitude with time.

According to Morison's equation (1), the total force per unit length on the cylinder in line with the velocity and acceleration vectors in this context, is the sum of the drag and inertia components:

$$F = F_d + F_i = C_d \frac{1}{2} \rho d U|U| + C_m \frac{\pi d^2}{4} \rho \frac{dU}{dt} \quad (1)$$

where C_d and C_m are the time-independent drag and inertia coefficients, U the instantaneous flow velocity, ρ the fluid density and d the cylinder diameter. From experiments in planar oscillatory flow around smooth cylinders, Sarpkaya (2, 3) found that C_d and C_m are functions of the Keulegan Carpenter number, $K_C = U_{\max} T/d$, where T is the period of oscillation, and of the Reynolds number, $Re = U_{\max} d/\nu$, when it is

1. Professor of Maritime Civil Engineering, University of Liverpool, U.K.
2. Lecturer in Civil Engineering, University of Liverpool, U.K.

greater than about 2×10^4 . Sarpkaya derived C_d and C_m from force records by a Fourier-averaging procedure.

Very much less attention has been given to wave loads on horizontal cylinders, although many characteristics of the flow are qualitatively different from those relating to vertical cylinders. Most of the investigations on horizontal cylinders have concentrated on the effects of proximity of the ocean bottom (4, 5, 6), so that particle orbits in the region of the cylinder were fairly flat ellipses. In some cases the flow is assumed to be planar oscillatory as described above. Mauli and Norman (7) measured wave forces on horizontal cylinders where particle orbits were almost circular and analysed the results in terms of horizontal and vertical load components. It is more instructive, however, to study the load components which are in line with the velocity and acceleration vectors respectively, since the drag and inertial contributions are then more readily distinguished. In the particular case when particle orbits in the region of the cylinder are circular, the incident flow around the cylinder is represented approximately by uniform flow described by a rotating velocity vector of constant magnitude. The actual flow deviates from this uniform condition as a result of the phase differences in the direction of wave propagation between particle motion on adjacent orbits, and because of the exponential decay of particle velocities with depth. However, providing the diameter of the cylinder is small compared with the wavelength the assumption of uniform ambient flow is a reasonable one. The undisturbed flow conditions around the cylinder can then be specified very simply. As in the case of the idealisation of flow around vertical cylinders in waves by planar oscillatory flow, some of the essential features of horizontal cylinders in waves can be represented in isolation. The ambient flow consists of a body of water moving without distortion or rotation around a circular orbit at the centre of which is the axis of the cylinder. The incident velocity and acceleration vectors are now of constant magnitude, rotating with constant angular velocity once in every wave period, with the latter leading the former by 90° . In this context the components of Morison's equation for force per unit length may be written:

$$F_d = \rho C_d \frac{1}{2} \rho d \Omega^2 R^2 \quad (2)$$

$$\text{and } F_i = C_m \frac{\pi d^2}{4} \rho \Omega^2 R \quad (3)$$

where F_d and F_i are respectively drag and inertia load per unit length, Ω is the wave angular frequency and R the radius of the particle orbit. The components F_d and F_i act in the directions of the velocity and acceleration vectors respectively and are thus now orthogonal. It is worth noting that viewed from a frame of reference centred on the axis of the cylinder and rotating with the wave frequency, the ambient flow, but for the re-cycling of the previously generated wake, is steady. Moreover, fluctuations with time in F_d and F_i can be caused only by this disturbed incident flow resulting from the previously generated wake, and by vortex shedding.

Like planar oscillatory flow, this simplified model of circular irrotational ambient flow around a cylinder can be used in the laboratory to reproduce some features of wave loading, in the absence of others which normally add to the complexity of interpreting experimental data. It is perhaps closer to the widely studied case of steady uni-directional flow around cylinders since the interference of the wake on the incident flow is less pronounced, and the magnitude of the velocity is steady. The analytical methods used to investigate separated flow around cylinders, such as the finite difference solution for the time-dependent Navier-Stokes equations (8), or the discrete vortex model (9), may be used also in this context without fundamental changes. However, they remain restricted or incomplete, and require experimental data for verification.

The purpose of this paper is to describe an experiment in which circular irrotational ambient flow around a cylinder was modelled by moving a cylinder without rotation around a circular orbit in initially still water. Allowing for the changed frame of reference, the motion of the fluid is identical in the two cases. However, forces experienced by the cylinder differ due to the presence of a pressure gradient in the fluid on the one hand and to the inertia of the cylinder itself on the other. The difference may easily be calculated, as shown below. Forces experienced by the cylinder were monitored continuously with time for Reynolds numbers in the range 0.4×10^5 to 2.4×10^5 and for Keulegan Carpenter numbers of 12.8, 24.0 and 35.7.

APPARATUS

The tests were carried out in a tank about 5m. square in plan, in a water depth of 90cm. The cylinder was supported with its axis vertical from an arm which rotated above the water surface about a central pivot. The apparatus is shown in Fig. 1. A one horsepower variable speed motor provided the drive to the central shaft and was mounted on the side of the tank to minimise vibrations in the cylinder support. In order that the cylinder should pass around its orbit without rotation, a secondary drive belt was provided between its axial support and a fixed central pulley. A number of alternative interchangeable belts facilitated different orbital radii. The use of toothed rubber timing belts throughout ensured perfectly synchronous rotation between the motor, the central drive shaft and the cylinder itself. A simple potentiometer with its end stops removed was connected to the motor and acted as an angular displacement transducer, from the output of which also the angular velocity of the arm could be derived.

The cylinder was mounted axially on a 5cm. diameter hollow alloy tube, cantilevered vertically downwards from the rotating arm, instrumented near its upper end with orthogonal pairs of strain gauges. Since the cylinder and its support did not undergo rotation the cable to the gauges was not subject to any overall twisting and could be connected directly to the conditioning instruments. The cylinder was made out of 15cm. diameter perspex tube of 10mm. wall thickness, and was airtight to minimise its mass. Its natural frequencies in air and water were respectively 14 Hz. and 9 Hz. End discs of diameter 25cm. were mounted on the cylinder as shown in Fig. 1. At its upper end a larger disc of diameter 60cm. was mounted on the fixed cylinder to minimise free surface interference on the instrumented cylinder.

FIGURE 1
Rotating Arm Apparatus

Experiments were run on-line to a Data General Nova Computer which sampled the unfiltered outputs of the strain gauge amplifiers and angular displacement transducer at a frequency of 100 Hz. With the available core, maximum run time was about 40 seconds. The data was processed immediately after each test to provide radial and tangential load components (since the orientation of the gauges rotated with respect to the radial direction during each rotation) and velocities. Besides further digital processing the data was then available for conversion back to analogue form for plotting at a reduced speed on a pen recorder.

Initial strain gauge calibrations were carried out by loading the cylinder at its centre from weights hung over a pulley at the side of the tank. From subsequent tests in air, the effective mass of the cylinder and its support was determined from the outputs of the gauges responding to centrifugal forces. A more rapid method of calibration was then possible, since during each revolution of the apparatus in air, the strains in the cylinder support tube oscillated about zero. A sinusoid was fitted by least squares to the output of each pair of gauges from which their sensitivities and absolute orientations were derived. This method of calibration was applied before and after each series of tests, and in every case the stability of the gauges and instruments was found to be satisfactory. The effective mass of the cylinder and support was 5.47 kg.

RESULTS AND DISCUSSION

According to Morison's equation, the forces per unit length experienced by a cylinder passing around a circular orbit in otherwise still water are:

$$F_d = C_d \frac{1}{2} \rho d \Omega^2 R^2 \quad (4)$$

$$\text{and } F_i = C_a \frac{\pi d^2}{4} \rho \Omega^2 R + M \Omega^2 R \quad (5)$$

where R is the orbit radius, M the mass per unit length of the cylinder. The added mass coefficient C_a is given by $C_a = C_m - 1$. The primary object of the experiments described here was to investigate C_d and C_a as functions of the Reynolds number R_e and the Keulegan Carpenter number K_c . The components F_d and F_i correspond to the mean tangential and radially outward forces respectively measured on the cylinder. The derived values for C_d and C_a are time averaged; it is worth noting that since F_d and F_i are orthogonal, C_d and C_a can be derived independently.

In an ideal fluid $C_a = 1$. Although this result is normally derived in the context of concurrent velocity and acceleration vectors, it applies to all cases, whatever their relative orientations.

Tests were carried out with the 15cm. diameter cylinder located at three different radii on the rotating arm: 0.306m, 0.572m. and 0.852m. Since the Keulegan Carpenter number is given by:

$$K_c = \frac{2\pi R}{d} \quad (6)$$

its value is independent of the speed of rotation, by which the Reynolds number is determined:

$$R_e = \frac{\Omega R d}{\nu} \quad (7)$$

The three radii used in the tests correspond to K_c values of 12.8, 24.0 and 35.7, respectively. The appearance of K_c and R_e directly as the independent parameters of the experiment is an advantage, since the flow-induced loads are expected to be functions of them only for rigid smooth cylinders.

Fig. 2 presents typical records of tangential and radial loads derived from the strain gauge outputs. In both cases the cylinder was accelerated from rest at the beginning of the record to a constant angular velocity. The first revolution of the cylinder around its orbit is characterized by abnormally high drag and oscillating lift associated with strong vortex shedding. Subsequently the cylinder passes into its own wake and the disturbances present result in a reduction in drag and oscillating lift. After two or three revolutions the mean drag and inertial loads stabilise and show very little variation with time. It is worth noting that the motion of the cylinder resulted in little overall rotation of the water in the tank, which would have caused a progressive reduction in flow-induced forces owing to reducing relative incident velocities. It is reasonable to assume that the cylinder does not stir the tank appreciably for the following reasons. Firstly, its dimensions are small compared with those of the tank itself. Secondly, the cylinder does not rotate; disregarding preferential decay of vorticity of one sense of rotation there is therefore no net addition of vorticity to the water in the tank from the motion of the cylinder.

Radial force records show fluctuations of irregular magnitudes at a frequency corresponding to a Strouhal number of about 0.2. Drag and added mass coefficients are presented in Fig. 3 as functions of R_e and K_c . Each point is derived from the mean radial and tangential force components recorded over a period of about 40 seconds. In each case three or four revolutions were completed before the recording was begun. Fig. 3 clearly shows that with increasing R_e , there is a reduction in C_d and an increase in C_a , depending also on K_c . Although it is clear that the reduction in C_d follows the expected behaviour close to transitional R_e , it is not easy to account for the equally dramatic change in C_a . In contrast to uniform or planar oscillatory flow around a cylinder, in the present case the orbital motion must result in asymmetry of the time-averaged characteristics of the wake. Although the rates at which vorticity is shed in the two shear layers are equal, the outer shear layer must be weaker since its separation point is moving away through the fluid more rapidly than that of the inner shear layer. This causes the vortex shedding to be an asymmetrical process, with unequal proportions of the shed vorticity finding its way into the major

FIGURE 3

Drag Coefficient and Added Mass Coefficient as Functions of Reynolds Number at Keulegan Carpenter Numbers

vortices of alternate senses of rotation. Possibly modification of this mechanism at transitional Reynolds numbers causes the observed changes in C_a .

However, despite the obvious differences in flow conditions, it is interesting to compare the present results with those obtained by Sarpkaya (3) for planar oscillatory flow around a cylinder. Lines fitted to the data have been re-plotted with Sarpkaya's results in Figs. 4 and 5, where it is shown that there exists at least some qualitative agreement between the two sets of data. Agreement between inertia coefficients would suggest that the added mass of the cylinders were independent of the relative orientations of the velocity and acceleration vectors. As mentioned previously, this would be the case in an ideal fluid, but in a real fluid it is reasonable to expect that the effects of viscosity and the history of the flow would make contributions to the added mass. Qualitative agreement between the two sets of data would also suggest that a conceptual explanation of the observed changes at transitional Reynolds numbers must be sought in terms of the features common to both cases.

CONCLUSIONS

Circular orbital flow around a cylinder has been modelled experimentally by moving a cylinder around a circular path in otherwise still water. The nature of the resulting flow warrants further investigation since it displays many of the essential features present in wave-induced flow around cylinders, and yet is specified very simply.

With increasing Reynolds number over the range 0.4×10^5 to 2.4×10^5 the drag coefficient was found to fall from about 0.9 to 0.4, depending also on Keulegan Carpenter number. Simultaneously the added mass coefficient increased, becoming positive only for higher Reynolds numbers. In both respects the present results are in qualitative agreement with those of Sarpkaya (3) for planar oscillatory flow.

CHAPTER 148

NON-BREAKING AND BREAKING WAVE LOADS ON A COOLING WATER OUTFALL

by

G.R. Mogridge* and W.W. Jamieson**

ABSTRACT

Cooling water from a power generating station in Eastern Canada is pumped to an outfall and distributed into the ocean through discharge ports in the sidewalls of a diffuser cap. The cap is essentially a shell-type structure consisting of a submerged circular cylinder 26.5 ft in diameter and 14 ft high. It is located in 25 ft of water at low water level and 54 ft at high water level. Horizontal forces, vertical forces and overturning moments exerted by waves on a 1:36 scale model of the diffuser cap were measured with and without cooling water discharging from the outfall. Tests were run with regular and irregular waves producing both non-breaking and breaking wave loads on the diffuser cap.

The overturning moments measured on the diffuser cap were up to 150 percent greater than those on a solid submerged cylinder sealed to the seabed. Unlike sealed cylinders, all of the wave loads measured on the relatively open structure reached maximum values at approximately the same time. The largest wave loads were measured on the diffuser structure when it was subjected to spilling breakers at low water level. For a given wave height, the spilling breakers caused wave loads up to 100 percent greater than those due to non-breaking waves.

INTRODUCTION

A power generating station, located on the east coast of Canada, disposes of cooling water through a 12 ft diameter tunnel a distance of approximately 300 ft offshore, where it rises vertically to a diffuser structure which distributes the water through a number of discharge ports into the Bay of Fundy. The large arrows, in the schematic representation of the cooling water outfall in Fig. 1(a), indicate the flow direction of the warm water through the tunnel, into the diffuser cap and out of the discharge ports. The diffuser cap is a shell-type structure consisting basically of a submerged concrete circular cylinder with a solid top, an open bottom and a number of 5.5 ft square openings in the sidewalls. It is 26.5 ft in diameter, 14 ft high and is held in place by rock anchors. The bottom of the cap does not make a perfect seal with the seabed because of numerous gaps between the bottom of the structure and the seabed around its circumference. The cooling water outfall is located in a water depth of 25 ft at low water level (LWL), 39 ft at mean water level (MWL) and 54 ft at high water level (HWL). Since waves up to 50 ft high are expected at this location, the structure is exposed to breaking waves. The five arrows radiating outward from the diffuser cap in Fig. 1(b) show the direction of cooling water discharge in

*Associate and **Assistant Research Officers, Hydraulics Laboratory, Division of Mechanical Engineering, National Research Council of Canada, Ottawa, Ontario, Canada, K1A 0R6.

FIG.1 COOLING WATER OUTFALL

relation to the direction of wave propagation. The three shaded arrows indicate the present requirements of the power generating station, which call for 3 discharge ports ($N=3$) and a cooling water discharge Q of 300,000 gpm (US). In the near future, the cooling water outfall will be required to handle a discharge of 450,000 gpm (US) with five discharge ports ($N=5$) in operation as indicated by the five arrows in Fig. 1(b). After being damaged during a storm in February 1976, the anchoring system had to be redesigned to secure the diffuser cap to the seabed. The loads exerted by ocean waves and cooling water discharge were required to permit a safe design of the structure and its rock anchors.

Various methods, which use linear wave theory and neglect viscous effects, are available for predicting wave loads on large submerged structures resting on the seabed. For example, Garrison and Chow (6), and Hogben and Standing (10) have published linear numerical diffraction theories which use a source distribution over the immersed surface of a structure for the prediction of wave loads. For ease of computation, these methods have been simplified by Black (1), Garrison and Stacey (8), Fenton (4) and Isaacson (11). Gran (9) has presented an analytical method which does not satisfy all the boundary conditions but provides an approximate solution at minimum cost. Black, Mei and Bray (2) have presented a semi-analytical method using variational calculus while Yue, Chen and Mei (14) have proposed a method that they refer to as a hybrid element method which combines the use of variational principles and finite element techniques. All of these methods assume that structures, which sit on a flat bottom, are both solid and sealed to the seabed. For structures raised slightly above the seabed, both experimental and theoretical results have been presented by Gran (9) for cylinders, and by Chakrabarti and Naftzger (3) and Garrison and Snider (7) for hemispherical shells. To the authors' knowledge, no information is available in the literature concerning the calculation of wave loads on a relatively large shell-type structure such as the diffuser cap, which is not only raised above the seabed but has large openings in the side-walls. The prediction of the maximum design loads on the diffuser cap is further complicated by the existence of irregular waves, cooling water discharge and critically steep waves that result in spilling breakers in the vicinity of the outfall during storm conditions.

Since reliable theoretical methods were not available for predicting the wave loading on such a complex structure, it was necessary to perform model tests. The loading due to non-breaking and breaking waves in regular and irregular wave trains, and the effects of cooling water discharge were measured using a 1:36 Froude model. A digital computer was used for the acquisition, processing, plotting and storage of the experimental data.

EXPERIMENTAL METHOD

The photograph in Fig. 2 shows the 1:36 plexiglass scale model of the diffuser cap which was positioned in the centre of a 12 ft wide wave flume. A semiconductor strain gauge force dynamometer was used to measure the forces and overturning moments on the model. The sign convention (Fig.3) was chosen such that the horizontal force $F_x(t)$ is positive in the direction of wave propagation, the vertical force $F_z(t)$ is positive in the upward direction and the overturning moment $M_y(t)$ is positive in the counter-clockwise direction. The force dynamometer had an overall

FIG. 2 MODEL OF DIFFUSER CAP

FIG. 3 SIGN CONVENTION

accuracy of within plus or minus three percent. It was mounted in a cavity in the floor of the wave flume below a steel base plate which was flush with the bottom. The diffuser cap was connected rigidly to the force dynamometer by four aluminum rods which passed freely through holes in the steel base plate. The discharge pipe, that was used in the model to simulate the prototype cooling water tunnel, did not touch or interfere with the operation of the force dynamometer. The exit of the model discharge pipe can be seen in Fig. 2 through the discharge port in the front of the diffuser cap. The natural frequency of vibration of the total measuring system with the model mounted was approximately 75 Hz when submerged in water, and therefore was sufficiently high to eliminate resonance problems.

In Fig. 4, the elevation and plan views of the wave flume show the experimental setup. Beach slopes, modelled from the prototype contours, were 1:50 offshore of the diffuser cap, 1:5 in the immediate vicinity of the cap and 1:8 onshore. Simulation of the cooling water discharge to the model was accomplished by a 300 gpm (US) pump and measured by a calibrated orifice meter. Water was pumped out of a reservoir at the end of the flume through a 2 in. diameter pipe to the diffuser cap and returned via two 3 in. diameter pipes under the floor of the flume from the area of the wave generator. Wave profiles were measured by two capacitance wave probes located as shown in Fig. 4.

Acquisition of data for forces, moments and wave profiles was accomplished using a digital computer. Force, moment and wave profile data were sampled at a rate of 100 data points per second for an interval of 8 sec. For irregular waves this rate was decreased to 20 data points per second to give total record lengths of 50 sec. The data was analysed and the results were automatically plotted and printed immediately following each test.

EXPERIMENTAL RESULTS

Non-Breaking Waves

To determine the effects of wave period T and water depth d on wave loading, the diffuser cap was subjected to regular non-breaking waves for various wave periods and wave heights at LWL, MWL and HWL. Fig. 5 shows typical test results for time series plots of wave loads and water surface elevations $\eta(t)$ measured at the diffuser cap and upwave of the cap. It may be observed that the phasing of the wave loads and water surface elevation are such that all the loads, $F_x(t)$, $F_z(t)$ and $M_y(t)$, reach maximum positive values near the time of still water level (SWL). Throughout the testing program, the experimental results indicated that the maximum positive magnitudes of the wave loads were always greater than the maximum negative values. Thus, only the magnitudes of the maximum positive loads will be considered in this paper. Fig. 6 shows the experimental measurements for the maximum values of horizontal force F_x , vertical force F_z and overturning moment M_y plotted against wave height H measured at the diffuser cap, for wave periods between 6 and 16 sec. There is only a small variation of wave loads with wave period, although the magnitudes of the wave loads tend to be largest at 10 and 12 sec. A larger variation in wave loading results for different depths of submergence of the diffuser cap as shown in Fig. 7. The largest forces and moments were measured on the diffuser cap when it was located in the shallowest water depth of 25 ft (LWL).

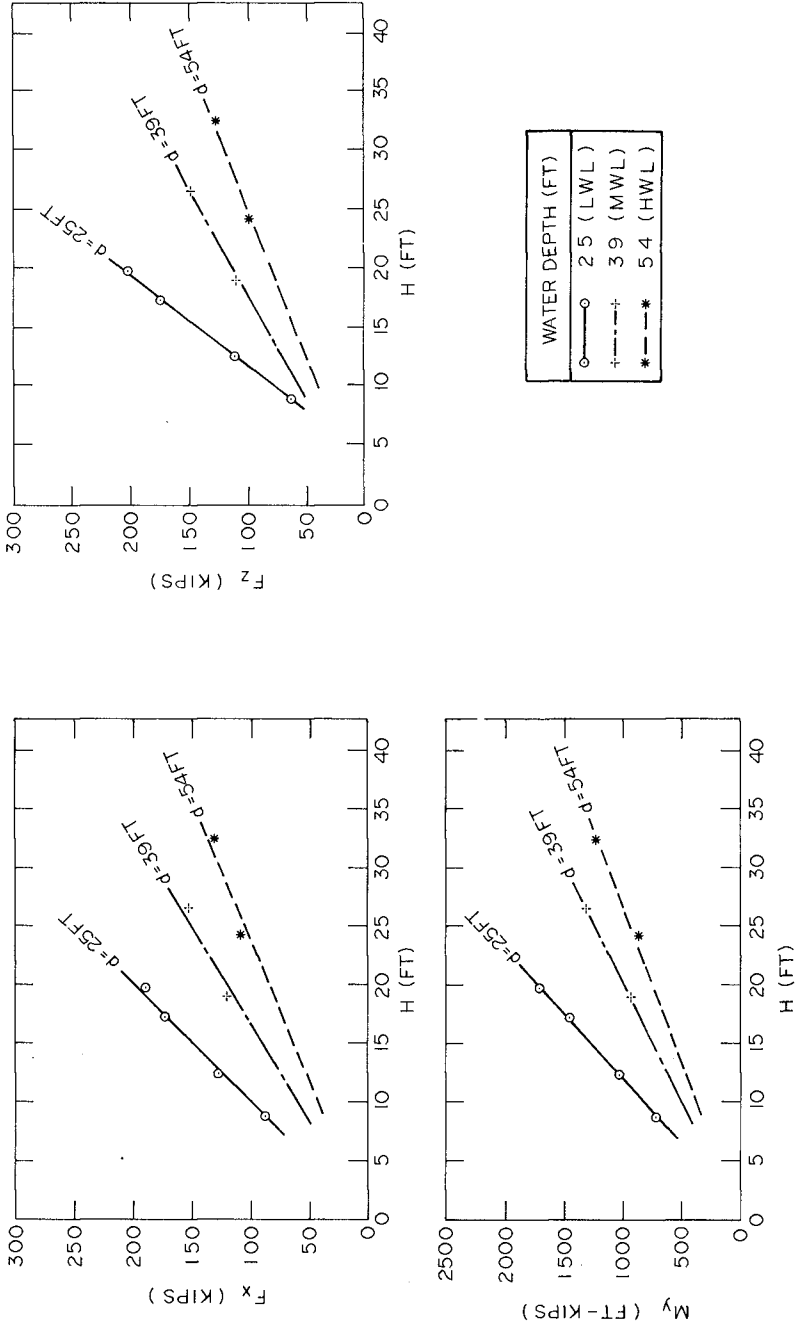

FIG. 7 VARIATION OF WAVE LOAD WITH WATER DEPTH
NON-BREAKING REGULAR WAVES
(N=3, Q=0, T=10 SEC)

A rigorous theoretical method for the prediction of non-breaking wave loads on a relatively open structure such as the diffuser cap does not presently exist. It may be of interest, however, to demonstrate some of the similarities and differences in wave loading between a ported submerged structure, such as the diffuser cap, and a solid submerged structure which is sealed to the seabed. Fig. 8 shows results for a wave period of 12 sec and a water depth of 25 ft for non-breaking regular waves. The wave loading shown for the sealed submerged cylinder, 26.5 ft in diameter and 14 ft high, was calculated using the linear numerical diffraction theory of Hogben and Standing (10).

The horizontal wave forces measured on the diffuser cap are quite similar in magnitude to those on the sealed submerged cylinder. However, it should be mentioned that for some tests, the horizontal forces on the diffuser cap vary as much as plus or minus 25 percent from those on the sealed cylinder. For both structures, F_x occurs approximately at the time of SWL which is indicative of inertial predominant horizontal forces.

The overturning moments on the diffuser cap are significantly larger than those on the sealed submerged cylinder calculated by the diffraction theory and are in fact up to 150 percent larger for some tests. For both the diffuser cap and the sealed cylinder, M_y occurs approximately at SWL.

The vertical forces measured on the diffuser cap are up to 75 percent smaller than those calculated for the sealed submerged cylinder (Fig. 8). The maximum vertical forces for the two cases not only vary significantly in magnitude, but also occur at different times with respect to the wave profile. The maximum uplift forces on the diffuser cap occur approximately at SWL, while those on the sealed cylinder occur near the wave trough. Similar phasing results were obtained experimentally by filling the diffuser cap with styrofoam, which caused the maximum vertical force to occur approximately at the trough; however, when the styrofoam was removed, the phasing reverted back to F_z occurring near the time of SWL. Thus, all the wave loads on the diffuser cap reach maximum values at the same time, resulting in a far more critical loading situation than for the sealed structure where F_z is out of phase with respect to F_x and M_y . The difference in phasing for the diffuser cap is due to the existence of the discharge ports in the offshore side of the cap. Calculations have indicated that if the same magnitude of pressure that exists on the offshore side of the sealed submerged cylinder is allowed to enter through the discharge ports into the diffuser cap, and contributions due to drag are included, a reasonable estimate of the total uplift force on the diffuser cap is possible and it is found to occur approximately at SWL as measured by experiment.

Gran (9) has shown that a gap underneath a solid cylinder causes similar variations in loading. That is, the gap tends to reduce the magnitude of F_z , increase M_y and have little effect on F_x . Garrison and Snider (7), and Chakrabarti and Naftzger (3) have also demonstrated that a substantial reduction in vertical force occurs when a hemispherical shell is held slightly above the ocean bottom, while the horizontal forces remain approximately the same. The analysis of Chakrabarti and Naftzger (3) shows that the pressure inside may be assumed to be uniform for small values of ka and can be approximated by the average pressure at the bottom of the corresponding sealed structure. The force on the raised structure can then be calculated by subtracting this pressure times the

 NON-BREAKING REGULAR WAVES
 ($N = 3, Q = 0, d = 25 \text{ FT}, T = 12 \text{ SEC}$)

area of the base from the force on the sealed structure. The same assumption of uniform pressure inside the structure cannot be made for the diffuser cap, since it has ports on one side causing an asymmetrical pressure distribution. The ports also cause the maximum vertical forces to occur approximately at SWL, whereas for the structures studied by the above authors, maximum values occurred near the trough.

For vertical circular cylinders projecting through the water surface, Mogridge and Jamieson (12) have indicated that there may be some viscous drag effects in the horizontal forces for ka less than 2.8, which for the diffuser cap diameter of 26.5 ft would be for periods greater than 10 sec. However, for the diffuser cap, the horizontal forces are almost entirely inertial, while the vertical forces appear to be due to the combined effects of inertia and drag. In order to substantiate this statement, the F_x and F_z data in Fig. 8 has been replotted in Fig. 9 on a logarithmic scale. Since inertial force is directly proportional to wave height, inertial force can be represented by a straight line with a slope of 1:1. In this plot, the solid line with a slope of 1:1 is fitted through the horizontal force data. A reasonably good fit confirms the existence of inertial predominant horizontal forces. The vertical force data in Fig. 9 lies on a slope greater than 1:1 and thus the force is not solely inertial but is due to the combined contributions of inertial force, drag force and possibly non-linear wave effects. The slope depends on the proportion of drag to inertial force and whether the drag coefficient is constant or a function of wave height.

Breaking Waves

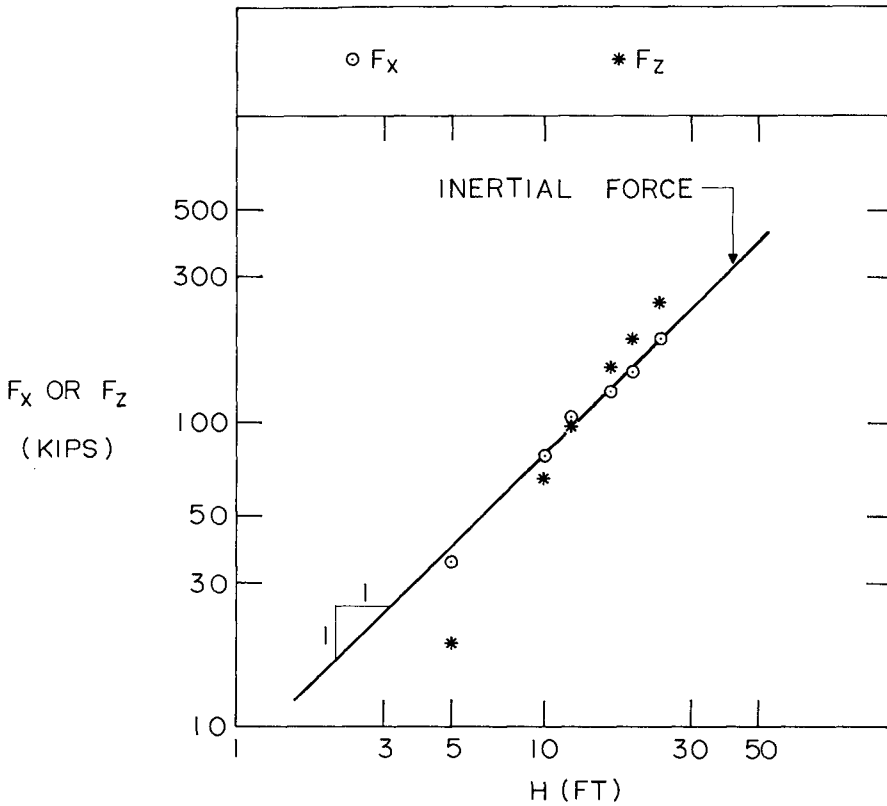

Breaking wave forces were also measured on the diffuser cap. The regular non-breaking wave heights were increased until relatively steep waves were generated at the wave board. The combination of these steep waves and the gentle bottom slope of 1:50 created spilling breakers in the vicinity of the diffuser cap. The magnitudes of the vertical forces due to spilling breakers were always maximum in the positive or upward direction. Occasionally, a plunging wave would break on the diffuser cap; however, this still did not cause the negative vertical forces to be larger than the positive values, possibly because even at LWL there was enough water above the diffuser cap to cushion the force of the breakers.

Non-breaking and breaking wave load data are plotted in Fig. 10 for $N=3$ and $N=5$. For a given wave height, spilling breakers often produce wave loads much larger than those caused by non-breaking waves. The data for the most extreme breaking wave conditions indicate wave loads as much as 100 percent greater than for non-breaking waves.

The breaking waves produce much more scatter in the wave load data than the non-breaking waves. The breaking mechanism apparently affects the period of the waves. Although the periods of the individual waves measured near the wave generator were all approximately 12 sec, at the diffuser cap a range of wave periods were measured. This variation in wave period at the structure probably accounts for some of the scatter of the data. However, most of the scatter is probably due to the variation in the degree of breaking at the structure. Spillage at the crest rapidly reduces the wave height, but does not significantly alter the fluid accelerations or pressures on the structure. Although not

— INERTIAL FORCE ➔ SLOPE = 1:1 ($F \propto H$)

INERTIAL FORCE + DRAG FORCE ➔ SLOPE > 1:1

**FIG.9 LOGARITHMIC PLOT OF F_x AND F_z
NON-BREAKING REGULAR WAVES
($N=3$, $Q=0$, $d=25$ FT, $T=12$ SEC)**

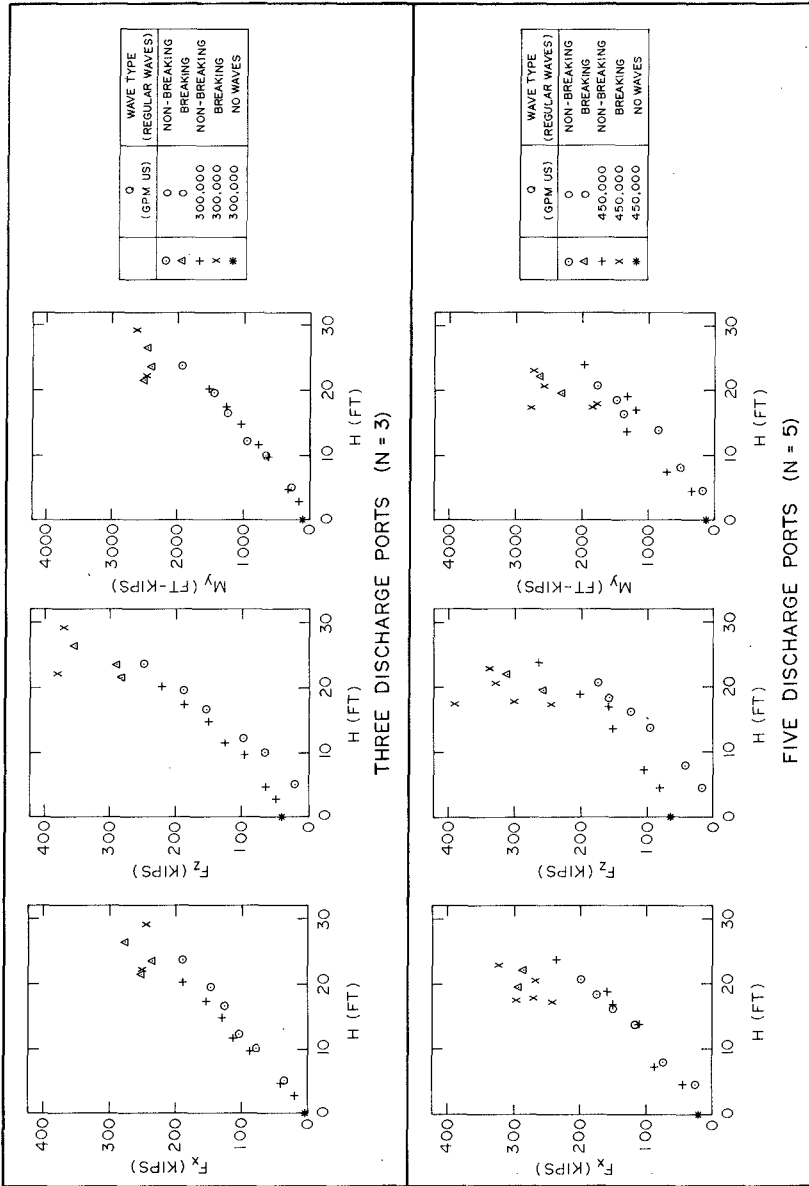

FIG. 10 WAVE FORCES AND OVERTURNING MOMENTS
($d = 25$ FT., $T = 12$ SEC)

shown here, wave loads can be plotted against instantaneous wave slope at the time of maximum loadings as in Mogridge and Jamieson (13) and correlations are somewhat better than plotting against wave height.

The maximum loads due to breaking waves generally occur near the time of SWL as for non-breaking waves, but there is enough of a phase shift in some tests to indicate that higher velocities cause significant increases in viscous drag forces.

Cooling Water Discharge

The effect of cooling water discharge on the wave loading is shown in Fig. 10. The upper plots show the results with a discharge of 300,000 gpm (US) while the lower plots are for 450,000 gpm(US). F_x and M_y show minimal differences in loading due to cooling water discharge for both non-breaking and breaking wave conditions. However, F_z does increase considerably due to discharge, particularly for low wave heights. For breaking waves, the increase in F_z due to discharge is not as well defined as for non-breaking waves because of the considerable scatter in the data caused by the spilling breakers.

Irregular Waves

The time series plot of the water surface elevation for the storm, which damaged the diffuser cap in February 1976, is shown in Fig. 11. This 20 minute prototype wave record, measured in relatively deep water, was reproduced directly in the wave flume at the wave board. That is, a Fourier analysis decomposed the wave record into sinusoidal components described by amplitude and phase angle for each frequency. Predetermined transfer functions, compensating for water depth and wave generator characteristics, were applied to each frequency component to give voltage amplitudes for generation of the required wave amplitudes at the wave board. Then, by means of an inverse Fourier transform, a voltage time series was obtained and used as input to the wave machine for the simulation of the prototype wave profile in the flume. Using this method of irregular wave generation, actual wave records can be reproduced with correct phasing between frequency components, which is important when grouping is present in the wave records. Further details are available in the report by Funke and Mansard (5).

A comparison of the prototype spectrum and the model spectrum measured 54 ft upwave of the diffuser cap at HWL, is shown in Fig. 12. The significant wave heights in the prototype and the model were 18.3 ft and 18.7 ft respectively, while the peak wave period was 13.4 sec in both spectra. This was one of the better fits between the model and prototype spectra because at HWL the water was sufficiently deep in the wave flume to minimize wave shoaling between the wave board and the wave probe.

The irregular waves, generated in the wave flume, produced non-breaking and breaking waves at the diffuser cap. As with regular waves, the wave loads reached maximum values at approximately the time of SWL and the largest wave loadings were measured at LWL. The analysis of the irregular wave data was treated on a wave-to-wave basis; that is, the largest wave loads and corresponding zero up-crossing wave heights were selected over the entire wave height range, disregarding wave period. Fig. 13 shows a comparison of the wave loading results due to the February 1976 storm, and the 10 and 12 sec regular waves. More scatter

FIG.11 PROTOTYPE WAVE PROFILE
(FEBRUARY 2, 1976, 1500 HR)

FIG.12 WAVE SPECTRA

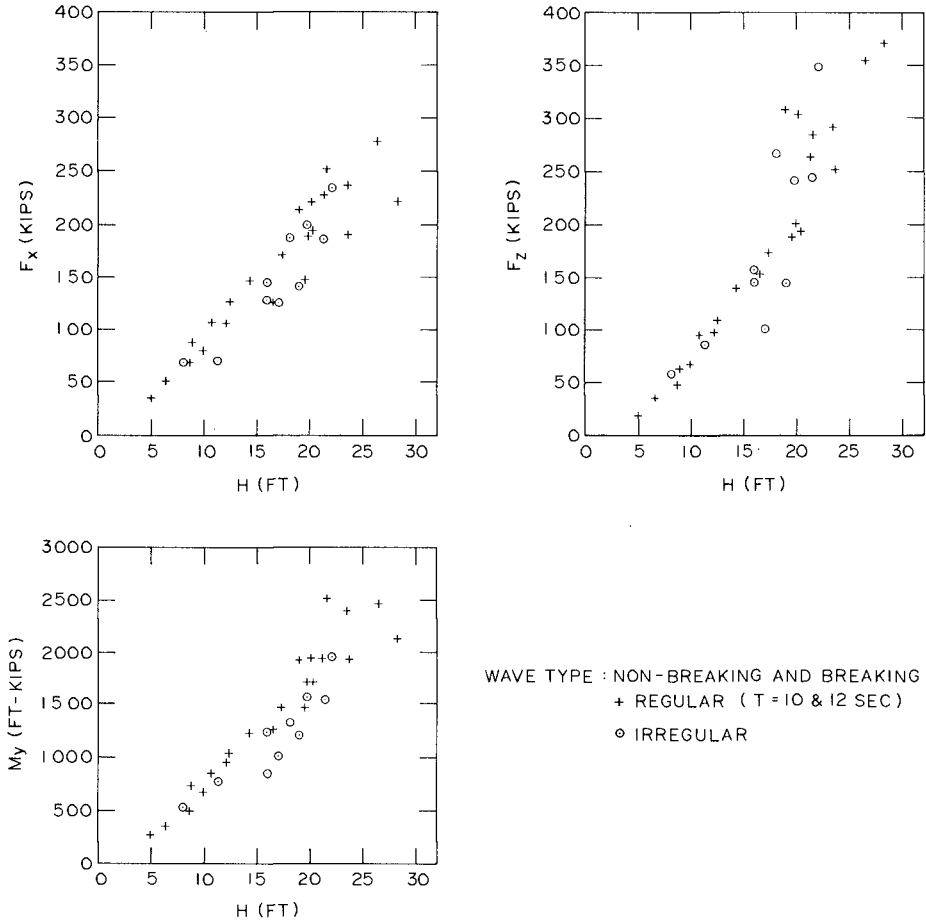

FIG.13 COMPARISON OF RESULTS FOR REGULAR AND IRREGULAR WAVES (N = 3 , Q = 0 , d = 25 FT)

results for the irregular waves because there is a much wider frequency range present than just 10 and 12 sec, and also because there is some breaking of the higher frequency waves even at low wave heights. Based on the limited number of tests analysed, using only one irregular wave record which consisted essentially of non-grouped waves, it appears that irregular wave loads are no more severe than regular wave loads. Negligible differences were also observed (13) between irregular and regular wave loadings when cooling water discharges of 300,000 gpm (US) and 450,000 gpm (US) were used. It should be emphasized that the irregular wave record used for these tests, produced the maximum possible wave heights and steepnesses at the diffuser cap because of the depth limitation. Therefore, it is most unlikely that any other irregular wave record would produce wave loads any higher. This does not mean that in general, wave load tests need not be conducted using irregular waves. On the contrary, it is possible that where wave heights are not limited by water depth, interaction of wave frequencies may produce groups of very high steep waves creating large structural loads. In addition, if it is anticipated that structural fatigue may be a problem, load distribution functions should be measured using irregular waves.

CONCLUSIONS

Horizontal forces, vertical forces and overturning moments on the diffuser cap of a cooling water outfall have been determined. Existing theoretical methods cannot be used to predict the loading on such an open submerged structure as the diffuser cap which is subjected not only to the combined loading of non-breaking waves and cooling water discharge, but also the extreme loadings imposed by breaking waves. A model testing program has resulted in the following conclusions:

1. A large variation in wave period causes only a small variation in wave loading. A larger variation in loading results for different depths of submergence of the diffuser cap. The largest forces and overturning moments, for a given wave height, occurred at low water level for 10 and 12 sec waves.
2. It cannot be assumed that the magnitude of the maximum wave loads on a shell-type structure raised above the bottom with ports in the sidewalls will be similar to those on a sealed structure. For example, the wave loads on the diffuser cap were such that, compared to a sealed submerged cylinder, the horizontal forces were generally within plus or minus 25 percent, the vertical forces were up to 75 percent smaller and the overturning moments were up to 150 percent larger.
3. All of the wave loads on a ported structure, similar to the diffuser cap, reach maximum values at about the same time. This results in a far more critical loading situation than for a sealed structure where the vertical force is approximately 90 degrees out of phase with respect to the horizontal force and overturning moment.
4. For a given wave height, spilling breakers on the diffuser cap caused loads up to 100 percent greater than those due to non-breaking waves. For both the non-breaking and breaking waves, the magnitude of the vertical force was always maximum in the upward direction.
5. Tests performed with simultaneous wave loading and cooling water discharge indicated that for low wave heights, the discharge through the diffuser structure could increase the uplift forces considerably;

however, for high waves and particularly for spilling breakers, the discharge did not significantly affect the magnitude of the wave loads.

6. Based on the limited number of tests using a non-grouped irregular wave train, the magnitudes of the maximum irregular wave loads on the diffuser cap were no more severe than the regular wave loads. This conclusion does not necessarily apply in general to other situations where such factors as wave grouping or fatigue stresses may be important.

ACKNOWLEDGEMENTS

CHAPTER 149

TRIPOD CONCEPT FOR PILE STRUCTURES IN FAST CURRENT

BY

J. Khanna M.ASCE * and J.S. Wood M.ASCE **

ABSTRACT

This paper describes a simple but elegant concept developed for the construction of offshore pile-supported structures in strong current. This tripod concept was developed during design studies for the Carajas Project which required an iron ore terminal at Ponta da Madeira, Sao Marcos Bay, in northern Brazil for mooring ships up to 300,000 DWT in up to 6 knot tidal currents. Experience during the construction of the Immingham oil terminal on the Humber River in England in 1968 had shown that cylindrical steel piles were susceptible to vortex-induced in-line and cross-flow vibrations. The cross-flow vibrations were particularly dangerous and occurred mainly during the construction phase when the individual piles could vibrate as cantilevers.

In the tripod concept all piles for the offshore structures, such as mooring and berthing dolphins, working platforms, approach trestle etc. are driven in groups of three from a working platform and immediately connected at the top to form a stable tripod module. The construction of the tripod module prevents the piles from vibrating in the dangerous cross-flow swaying mode. Some bow-string modes of vibration due to in-line and cross-flow excitations are still possible but these can be reduced by appropriate choice of pile diameter, pile slope and cap mass. If further attenuation of vortex-induced vibrations is necessary, then perforated shrouds over 20% of the pile-wetted length may be used.

This paper presents some results of the analysis, and hydro-elastic model testing carried out at the British Hydromechanics Research Association at Cranfield (U.K.) during 1975-76 which validated the efficacy of the tripod concept. Also presented are illustrations of the use of the concept, and design criteria for the design of tripod structures for locations where fast currents may be a problem.

** Assistant Manager - Vancouver Office, Swan Wooster Engineering Co. Ltd. - Vancouver, Canada, formerly Deputy Project Manager, PROMON/HOWE-SWAN WOOSTER Consortium, for the Carajas Iron Ore Project, Rio de Janeiro, Brazil.

INTRODUCTION

During 1974-77, a consulting engineering consortium PROMON/HOWE - SWAN WOOSTER composed of PROMON ENGENHARIA, S.A. of Brazil, HOWE INTERNATIONAL LTD and SWAN WOOSTER ENGINEERING CO. LTD. of Canada was retained by AMAZONIA MINERACAO S.A. to carry out design studies and detailed design for the marine terminal for the Carajas Project. An iron ore shipping terminal was required at Ponta da Madeira in Sao Marcos Bay in northern Brazil for mooring ships up to 300,000 DWT. The site was protected from wind and waves, but was exposed to very strong tidal currents which for design purposes were estimated to be 6 knots.

The effect of these fast flowing currents created one of the most difficult design problems on the project. It was known that cylindrical steel piles in fast flowing current were susceptible to oscillations due to in-line and cross-flow excitations created by the shedding of vortices in the wake of the piles. This problem had surfaced acutely during the construction of the Immingham Oil Terminal on the Humber River in England in 1968, where ebb tidal currents reach a velocity of 5.5 knots. It was found (1)* that if any pile was left as a cantilever and allowed to oscillate across the flow, then the movements became so violent that 750 mm cylindrical steel piles, 12 mm wall thickness, would reach an amplitude at the top of + 1 m and snap off at the sea bed. Therefore each pile that was driven had to be instantly restrained by some temporary device such as wires and timbers to a stable part of the work. The restrained piles were, however, not immune to vibrations. These restrained piles and even completed structures were subject to in-line oscillations for several hours during the tidal flows. Extensive additional bracing was subsequently added to the Immingham terminal pile structures in order to ensure safety.

During the design studies at the Ponta da Madeira Terminal, a design concept evolved in which all the piles for the various structures would be driven in groups of three from a working platform and connected at the top to form stable tripods. At a later stage in the construction, the tripods would be capped to form the decks of the various terminal structures. Figure 1 shows the tripod concept during construction. The tripod concept for construction in fast flowing waters is not entirely original. We have recently become aware that native Indian fishermen in Yakima (Washington State) in U.S.A., use tripods in fast flowing streams to form platforms for fishing. (Figure 2).

*Figures in parentheses refer to References.

The construction of a tripod prevents the piles from vibrating in the dangerous cross-flow swaying mode. Some bow-string modes of vibration are still possible due to in-line excitations but these can be reduced by appropriate choice of pile diameter. If further attenuation of the vortex-induced vibrations is necessary, then spoilers in the form of lightweight fibreglass shrouds can be used. The tripod concept was verified by extensive hydroelastic model testing at the British Hydromechanics Research Association (BHRA) Laboratories at Cranfield (U.K.) during 1975-76.

This paper presents the theoretical basis for the tripod concept as well as some results of the hydroelastic model testing carried out at BHRA to validate the tripod concept. Also presented are illustrations of the use of the concept, and design criteria for the design of tripod structures for locations where fast currents may be a problem.

Figure 1 **Tripod concept during construction.**

Figure 2 Yakima fishermen on a platform built on tripods in fast current.

THEORETICAL BASIS

In fast flowing water, pairs of eddies or vortices are formed downstream of a circular section in a regular pattern known as the Karmen Vortex Street (Figure 3.). The eddy shedding causes hydraulic pressure differentials around the circular section resulting in the application of a periodic force to the pile. The frequency of shedding of vortex pairs is given by

$$F = \frac{SV}{D}$$

where F = frequency of shedding of vortex pairs
 S = Strouhal Number
 V = flow velocity
 D = pile diameter

The shedding of each pair of vortices is accompanied by a fluctuation in the lift force across the stream flow. When one of the pile natural frequencies is close to the vortex-pair shedding frequency, resonant amplification occurs leading to the possibility of structural failure. The shedding of each individual vortex creates a fluctuation in the in-line drag force. When one of the pile natural frequencies is close to the frequency of individual vortex-shedding (given by $2F$), the resonant amplification can occur in the in-line direction. The in-line excitation is an order of magnitude smaller than the cross-flow excitation so that in-line forces are not likely to cause swift structural failures due to overstressing but are likely to lead to fatigue failures.

Typical response of an individual pile to flowing water is shown in Figure 4, where, the reduced amplitude, y/D ,

where y = maximum displacement amplitude
 D = pile diameter

is plotted against, the reduced velocity, V/ND ,

where V = flow velocity
 N = pile natural frequency
 D = pile diameter.

Figure 3 Flow around circular pile.

Figure 4 Response of cylindrical piles to flowing water.

In the range of Reduced Velocity from about 1 to 4, in-line vibrations can occur with a maximum displacement of about 20% of pile diameter. In the range of Reduced Velocity, from about 4 to 7, the more dangerous cross-flow vibrations can occur with a maximum response as much as the pile diameter.

The response of a cylindrical pile is also influenced by the damping present in the structural system and the water depth over which the vortex-induced excitation is transmitted to the pile. This influence is represented by King (3) as a stability parameter, K_s , where

$$K_s = \frac{2M_e \delta}{\rho D^2}$$

where

M_e = equivalent mass/unit length

δ = damping log. decrement

ρ = water mass density

For a pile with mass at the top

$$M_e = \frac{M_t Y_t^2 + \int_0^L m y^2 dx}{\int_0^h y^2 dx}$$

where M_t = top mass

Y_t = top displacement

m = pile mass including mass of entrained water and added mass

L = pile length

h = water depth

An example of the influence of stability parameter for the first normal in-line mode (3) is shown in Figure 5 where it is seen that as the stability parameter increases the vibration amplitude decreases. Based on the research on pile vibrations following the Immingham experience (3), King developed vibration limits for a single pile which was used as a basis for the development of design limits for the Ponta da Madeira terminal pile structures as shown in Figure 6.

This criteria, which was subsequently verified by testing at BHRA for completed structures, was used to design the individual tripod modules and the completed structures. In those instances where the structure Reduced Velocity and Stability Parameter were such as to allow in-line vibrations, (Reduced Velocity between 1.2 and 3.5, Stability Parameter less than 1) vortex spoilers in the form of shrouds were envisaged.

Figure 5 Stability parameter influence on in-line cylindrical pile response.

Figure 6 Design limits for single pile.

ANALYTICAL RESULTS

Various design options for the marine terminal structures which would satisfy the criteria given in Figure 6, were analysed. Some of the results of these analyses are shown in Figure 7. These results apply to pile structures in 40 m water depth subjected to a 6 knot current. It can be seen that a 1.5 m cantilever pile lies in the cross-flow maximum response range and would fail. In order to avoid failure, a cantilever pile requires a diameter of 3.5 m, which is an expensive pile to purchase and requires a large costly construction rig for installation. Furthermore, it can be seen that if 1.5 m piles were used as vertical piles to construct a terminal structure such as a mooring dolphin, then in spite of the connection at the top through a pile cap, the structure would still remain vulnerable to damaging cross-flow response at current velocity as low as 3 knots. However, if the same 1.5 m piles were installed as tripods then the dangerous cross-flow vibrations would be completely avoided. Some in-line vibrations might still occur because reduced velocity exceeds 1.2 (See Figure 6) but these could be checked using stability parameter for stress calculations and appropriate remedial steps, such as changing the pile diameter or using spoilers, taken. It can be seen, therefore, that tripods present an attractive solution for pile structures in fast current.

The tripod solution was compared with a conventional vertical pile solution for some of the terminal structures. The comparison for one of the mooring dolphins is shown in Figure 8, where it can be seen that two tripods comprising six 1.5 m piles can perform satisfactorily as a Mooring Dolphin structure, which for a conventional vertical pile design would require the use of four 3.5 m vertical piles, which represents a more expensive solution for the conditions at Ponta da Madeira.

Figure 8 Mooring dolphin- Analytical results.

MODEL TEST RESULTS

The model tests were carried out at BHRA Cranfield. A scale of $1/39.4$ was used to construct hydroelastic models. Two individual tripod models were tested (Figure 9). Tripod 1 had 3 legs inclined at 1 in 2 batter. Tripod 2 had 2 legs inclined at 1 in 2, and 1 leg vertical. The tripods were tested to a scaled velocity of about 6.5 knots. Figure 10 shows tripod 1 in the test flume. The end conditions at the base were altered from pinned to fixed to simulate the construction stage and the completed stage. The end conditions at the top were altered to simulate various methods of holding the piles as tripods. It was found that there was little difference in the overall behaviour with various methods such as horizontal template, and side gusset plates to hold the top, because in each case a pinned condition was simulated at the top of the piles. However, gusset plates along the sides provided an efficient energy transmission path between individual piles making vibration suppression more difficult.

The two tripods essentially behaved as an assemblage of individual piles and structural oscillations recorded were predominantly in the bow-string mode although some coupled vibrations were also observed.

The majority of the tests were carried out with the Type 1 tripod because this was more flexible than tripod Type 2, It was concluded that the tripods could have significant oscillations during the construction stage.

Vortex spoilers in the form of perforated shrouds and radial fins were also tested. The perforated shrouds had a length of 20% of the pile wetted length. The shrouds had a diameter 20% greater than the pile diameter, and a 36% open area. The radial fins had a projection of 20% of the pile diameter and a length of 15% of the pile wetted length. Helical strakes were not tested due to the practical difficulty of installing them either before or after the pile driving.

Typical results for the individual tripod are shown in Figure 11. It can be seen that the tripod piles without any spoilers could develop vibration amplitude as much as 10% of the diameter. Radial fins reduced the amplitude of vibration to less than half the amount without spoilers but still left significant vibrations. However, perforated shrouds caused a reduction of the vibrations to negligible proportions. Some tests were performed with shrouds on a single leg or two legs. In some instance they effectively suppressed the vibrations but these were less effective if the shrouds were clamped on a pile in the wake of a leading pile.

Figure 9 Model tripods tested.

Figure 10 Tripod 1 in test flume.

Figure 11 Tripod 1 test results.

The two tripods were then interconnected by a rigid wooden deck to which masses could be attached to simulate more closely a completed structure. The interconnected model tripods are shown in Figure 12. In this case the stability parameter was computed to about 3. The results of the tests are shown in Figure 13. It can be seen that no significant vibrations were observed. This provided a confirmation of the stability parameter concept.

The model tests verified that the criteria, shown in Figure 6, could be used for the design of the marine terminal structures. Further details of the test program and results are given in Reference 2.

Figure 12 Coupled tripods in flume.

Figure 13 Coupled tripod test results.

CONCLUDING DISCUSSION

This paper has described the evolution and confirmation of the simple tripod concept for use in constructing marine terminal structures of piles in fast flowing current. An example of the final design of one of the berthing dolphins is shown in Figure 14. Based on these studies the following conclusions are drawn:

1. The modular tripod is an effective concept for construction of offshore pile-supported structures in fast current. For structures supporting mainly vertical loads, the pile slopes may be steep such as 1:3. For structures supporting mainly horizontal loads the pile slopes may be less steep such as 1:2.

2. The tripod modules and structures composed of them can be designed on the basis of criteria similar to those developed for individual piles (Ref.2). Using two design parameters, the reduced velocity V_R , and the stability parameter, K_S , where

$$V_R = \frac{V}{ND} \quad V = \text{Velocity, } N = \text{pile nat. freq.} \\ D = \text{pile dia.}$$

$$K_S = \frac{2M_e \delta}{\rho D^2} \quad M_e = \text{equiva.mass/unit length,} \\ \delta = \text{log. dec. of damping,} \\ \rho = \text{mass density}$$

safety against vortex-induced vibrations is ensured if the following conditions are satisfied:

1. $V_R < 1.3, K_S$ any value (no significant vibration)
 2. $1.3 < V_R < 3.5, K_S > 1$ (no significant in-line vibration)
 3. $V_R > 3.5, K_S > 17$ (no significant cross-flow vibrations)
3. The design parameters V_R and K_S can be varied by changing pile diameter, R , pile slope and cap mass.
4. The tripods should be designed so as to definitely eliminate cross-flow bowstring vibrations. If in-line bowstring vibrations cannot be eliminated then the use of vortex-spoilers should be considered. Shrouds over 20% of the wetted lengths are adequate to control the vibrations and are omni-directional. Radial fins are not as effective as shrouds.

ACKNOWLEDGEMENTS

The tripod concept was developed during design studies for AMAZONIA MINERACAO S.A., BRAZIL by a consulting engineering consortium PROMON/HOWE-SWAN WOOSTER composed of PROMON ENGENHARIA S.A. of Brazil, HOWE-INTERNATIONAL LTD and SWAN WOOSTER ENGINEERING CO. LTD. of Canada. The hydroelastic model testing was carried out at B.H.R.A., Cranfield, (U.K.). The assistance of Mr. P.P.Barreto of PROMON, and of Mr. N. Allyn of SWAN WOOSTER, in the analytical assessment, is gratefully acknowledged. Acknowledgement is also due to Sisse Briemberg for the photograph of Yakima fishermen.

CHAPTER 150

New Dike Design Criteria Based on Wave Spectra

by

Dr.-Ing. Hans Kaldenhoff +

Dr.-Ing. Suhan M. Gökcesu ++

1. INTRODUCTION

The subject of this paper is the research upon the wave run up on even slopes under random wave conditions. This project was performed in order to get additional tools for dike designing questions.

Earlier works for this subject were performed under the basic idea that the sea can be represented by regular waves and a significant wave height. But the random sea is the result of the superposition of waves with different periods, lengths and amplitudes and they are even progressing in different directions. The values of all these parameters are random distributed. It seems questionable whether the results of former research using regular waves are sufficient especially for problems of wave and structure interactions. Severe damages on structures do force us to develop better design criteria.

2. PHYSICAL BACKGROUND

It is not possible to describe the complex properties of wind waves, the nonlinearity and irregularity of their variables by hydrodynamic laws. Thus it is necessary to use statistic laws and take the topography and the climatic conditions into consideration.

A well-known method is to regard the energy spectra of waves that is the energy density as a function of frequency. A second method describes the probability

+ Professor, Technical University of Berlin, Germany

++ Professor, University of Dar es Salaam, Tanzania

of wave amplitude and frequency with a distribution function and that allows to calculate directly the necessary wave parameters for any dimensioning procedure. That is one of the reasons why engineers favor this method as we did too. The Rayleigh-distribution is often used as it corresponds very well with normalized wave heights and normalized wave periods as well in deep as in shallow areas. This distribution function is steady and one-dimensional. It is used in the following form to describe the normalized wave height $\eta = H/\bar{H}$ and the normalized period $\tau = T/\bar{T}$.

$$F(\eta = \frac{H}{\bar{H}}) = 1 - \exp(-\frac{\pi}{4} \eta^2)$$

$$F(\tau = \frac{T}{\bar{T}}) = 1 - \exp(-\frac{\pi}{4} \tau^2)$$

These waves are progressing to the shore or other barricades. They become reflected and/or refracted, they even produce some kind of mass transport. This resulting motion on slopes is called run up and includes run up with breaking and without breaking. Depending on the wave and slope parameters different behavior of the run up and wash down is to be seen. Their terms are shown in figure 1.

R_{ZR} = height between the run up (upper turning point) and the following lowest wash down (lower turning point)

R_{ZA} = height between the wash down and the following run up

S_z = height between SWL and lower turning point (positive or negative referred to SWL)

The run up is the most important height, especially for designing purposes. Unfortunately there is no useful physical description of the run up and wash down depending on the producing waves. But it seems to be possible to refer the statistical behavior of the run up oscillation to the wave spectra.

figure 2

figure 4

figure 1

figure 3

As the random sea can be described by the statistical distribution of its parameters (in here the Rayleigh-distribution), we postulated the possibility to describe the run up oscillation parameters by the Rayleigh-distribution too.

3. MODEL TESTS AND RESULTS

To prove the postulate, physical model tests became necessary and the equipment of the laboratory allowed to produce any kind of a random sea in a free surface channel and to build any kind of slope in a large scale (1 : 10 to 1 : 5). The distribution function of the wave parameters are basically referred to the wave spectra of the German North Sea where measurements were being performed since 10 years by the research group Neuwark and their results are statistically analyzed in the above mentioned way. The exponents of the distribution functions of the wave heights are given in figure 2 as a function of the normalized significant height $C_{1/3}$.

The physical experiments were conducted by varying the following parameters:

- exponents of the distribution function of the normalized wave height, mean wave height and mean significant wave height
- water depth
- constant slope 1 : 3, 1 : 4, 1 : 6
- broken slope and berms

The whole program was coordinated that way, that the run up could be described by a one-dimensional distribution function for different parameters and it should be used as a designing tool.

The test channel is 90 m long, 4 m wide, 2 m deep and it is possible to generate 0.6 m high waves. The wave gauges are of the resistant type and their linearized signals were evaluated by a computer in on-line technics.

A special procedure was developed to generate the random sea. This procedure used different wave groups, the arrangements of which could be changed

to generate different wave trains. All of those trains had the same probability density function and their parameters agreed very well to the prototype conditions. Additionally the normalized wave height was varied. From all of those possible wave trains, which all fulfilled the prototype conditions, only six were chosen to run the tests with. For the tests three different water depths (1.0; 1.25; 1.50 m) were used.

Figure 3 gives an overall idea of the oscillation of the wave generator (upper curve), the water surface in front of the slope (middle curve) and the run up (lower curve). The parameters noticed in figure 3 were evaluated by the computer, directly using the following assumptions and equations.

- a. The normalized run up height ζ^* is Rayleigh-distributed if the normalized wave height follows the same distribution function.

$$F(\eta = \frac{H}{H}) = 1 - \exp(-\frac{\pi}{4} \eta^2)$$

$$F(\zeta^* = \frac{R_{ZA} + S_Z}{R_{ZA} + S_Z}) = 1 - \exp(-\frac{\pi}{4} \zeta^{*\phi_{(R_{ZA} + S_Z)}}$$

- b. According to the wave statistics it is assumed that the exponents of the run up distribution function are a function of their $C_{1/3}$ values.

$$\phi_{(R_{ZA} + S_Z)} = f(C_{1/3(R_{ZA} + S_Z)} = \frac{(R_{ZA} + S_Z)^{1/3}}{R_{ZA} + S_Z})$$

- c. All the distribution functions of the normalized run up and the wave parameters have each the same function value regarding their $C_{1/3}$ values, even if their exponents are different; see figure 4.

Assuming a. to c., it becomes possible to calculate the ϕ -exponent of the Rayleigh-equation for

the run up variables using the \emptyset -exponent of the Rayleigh-equation for the sea and their known $C_{1/3}$ values as well as the $C_{1/3}$ values of the run up tests.

$$\Phi_{(R_{\gamma_A}, S_{\gamma_A})} = \Phi_H \left(\frac{\ln C_{1/3(H)}}{\ln C_{1/3(R_{\gamma_A}, S_{\gamma_A})}} \right)$$

- d. We furthermore expected the mean values of the run up heights to be a function of the mean values of the wave heights and the structure parameters as well as the water depth.
- e. The assumption is made that it is possible to correlate the mean values of the wave heights and run up heights to the mean values of their $C_{1/3}$ values for constant water depths.

The above mentioned assumptions have been proved by using methods of the mathematical statistics such as the χ^2 - and Kolmogorov test with different significance levels to test the parent population or the correlation and regression analysis to find the function values. The probability of errors was better than 5%. This immense evaluation, test and calculation program could only be done by using computers. For the practical use, graphics were developed with dimensionless parameters.

The first results showed already that all the assumptions are right and useful. The relation between the dimensionless significant wave height and the dimensionless mean wave height is shown in figure 5. The correlation factor is 0.9729 which proves the linear correlation between those parameters for the chosen six parent populations. The regression curve goes through the origin and proves the physical background of this relation and the quotient of $\bar{H}_{1/3}/\bar{H} = 1.587$ differs only slightly from the theoretical value 1.598, calculated by Longuet - Higgins.

figure 5

figure 6

Figure 6 shows the relation between the exponent of the wave height distribution function and the $C_{1/3}$ value of the six different wave trains. The correlation is not linear and the correlation factor of 0.9913 proves the excellent correlation of the exponents and underlines that the distribution exponent is a function of the $C_{1/3}$ value.

The relation between the mean dimensionless wave heights and their mean dimensionless run up heights is shown in figure 7. This result again proves the above mentioned assumption that the mean run up correlates to the mean wave heights depending on the slope. Moreover the diagram proves the tendency predicted by Webber and Bullock, but the actual results differ significantly. The linear relation between the run up and the significant run up is also to be seen from figure 7 and shows a correlation factor of 0.9715.

Finally the relation between the exponents of the distribution function and the run up and their $C_{1/3}$ values is drawn in figure 8. The measuring points show a parabolic curve with the high correlation factor of 0.9766.

Summarizing it should be stated that the basic assumption is proved and the relation between the wave heights and the run up could be found. Designing charts basing on this procedure with more parameters and broken slopes will be developed.

CHAPTER 151

BLANKET THEORY & LOW COST REVETMENTS

BY C. T. BROWN*

Summary : This paper seeks to demonstrate that Hudson's equation for the stability of Rubble-mound armour- units is a particular solution of a more general theorem, for the particular case of discrete units of fixed geometric form. By re-developin the general theorem it is proposed that a linear relationship exists between the momentum of an incident wave and the slope-normal surcharge required for stability. From this concept, a new suite of armour units has been developed which discard the concept of minimum mass in favour of a minimum slope-normal dimension. In addition it is possible that the term in Hudson's equation, $\cot \alpha$, might be replaced by the term $\cos \alpha / \sin(\alpha + \beta)$, where β is the tangent to the breaker centreline.

Introduction

Contemporary breakwaters and revetments when suitable rock is economically unavailable use discrete armour units such as tribars, dolosse etc. which are generally characterised as being massive and of complex geometric form. Each armour unit is presently considered to be of fixed form, and hence there tends to be a unique relationship between the design conditions and the required unit size, larger units utilising more material than is required, smaller units having a sub-minimal factor of safety.

This fixed geometric relationship has operated against a flexible design approach, leading designers to specify a particular geometric form of specified mass for their design. It is questioned if this procedure allows contractors sufficient flexibility to optimise their construction methods to produce a low cost revetment. Examination of the current design formulae suggests that this rigidity is not necessary.

Theory

As any student of literature will report, there are any number of formulae for the design of rubble mound breakwaters. Accepting that at the most critical condition, there is a linear relationship between H and L, these equations are all of the form $W = K \gamma r \frac{H^3}{\phi(\alpha) \phi(\delta_s \delta_w)}$.

The most widely accepted of these formulae is that put forward by Hudson, namely $W = \frac{H^3 \gamma r}{K_D \cot \alpha (S_r - 1)^3}$.

* Consulting Engineer, Sydney, New South Wales, Australia.

(Note: It is always assumed that the mass density of the water in the slope is the same as that in the jet. For several reasons, it may be that the apparent density of the fluid is not that of water at rest. Thus, the relative density function might be better written in the form

$$\phi(\gamma) = \left(\frac{\gamma_r - \gamma_f}{\gamma_w} \right) \text{ where } \gamma_f \text{ is the density of the fluid in the revetment.}$$

For a properly designed armour layer, ultimate failure will entail the wholesale movement of the armour, then this relationship could be considered to apply to an overall, 'blanket', revetment.

$$\text{Putting } W = V \gamma_r = K_v \cdot l^3 \cdot \gamma_r$$

$$H = l \cdot (S_r - 1) \cdot (K_v K_D \text{Cot} \alpha)^{1/3}$$

i.e. armour stability is a linear relationship to material thickness and submerged density, for a given armour geometry described by $(K_v K_D)^{1/3}$.

This form of equation suggests that $K_v K_D$ is a constant. The corollary is that K_D can be designed by appropriate choices of K_v .

Returning now to the preliminary concepts, a number of mechanisms have been postulated for failure of rubble mound slopes - in particular slopes armoured with rock of oblate form.

There are two main classes of attack, the first with breaking, or broken, waves, the second where the wave has not broken.

In the first, the wave breaks on the slope, so destroying part of the energy, the wave running up the slope until the energy is either destroyed in the slope, reflected, or converted to potential energy, the flow then reversing and the potential energy, less losses, being returned seawards as a varying flow of water. In the non-breaking case, there is no energy loss due to breaker turbulence, so the potential energy (run-up) should be a greater proportion than before.

Imagining an armour layer which applies a slope normal surcharge and restrains the surface particles of the underlayer from motion, the hydrodynamic behaviour described above will result in a head loss across the structure.

FIGURE 1.

REVETMENT - DEFINITION SKETCH

$$\Phi_n \alpha = \left(\frac{\cos \alpha}{s_i \alpha + \beta} \right) / \cos 46 \text{ vs } \beta$$

FIGURE 2a.

FIGURE 2b: RELATIVE VARIANCE OF WAVE FUNCTIONS

Allowing the surcharge to have a porosity p , consider the pressure sensed at a point on the under-layer. At 0 porosity no water will flow through the slope, and the static pressure will be that of the surcharge $(\frac{W \cos \alpha}{A})$. Under the

wave impact, a pressure $p = K_1 \rho g H_b$ will be induced. If the slope has a porosity of 100%, the underlayer some lower value, then the shock pressure will be some lesser value, occurring at the interface.

FIGURE 3.

On the drawdown, the position is reversed. For a 0% porosity cover, the head across the armour layer will maximise, and for 100% it will be zero. Efflux from the slope can be considered as a reverse jet.

The function of the armour layer is to surcharge the embankment at any level so that a positive interparticle reaction occurs, so keeping the slope stable. Thus a family of curves such as Fig. 3 could be drawn.

By inspection, it can be seen that an economic minimum can be expected for the slope-normal porosity. Examining the failure case, providing the unit area is not too large, it would appear that the safe unit has a porosity of less than optimum, so that loss of a single unit tends to the optimum condition by increasing the local porosity.

Apart from these structural performance effects, the porosity of the slope also affects both run-up and reflection. The effect on run-up is well known and documented in many standard works.

With regard to reflection, Sawaragi (1966), in his experiment on scour, demonstrated a relationship between reflection and slope-normal porosity of a permeable face. This effect seems mainly related to the damping due to the porous face, as the face appears to be thin compared to the three-dimensional porous core behind. Nevertheless, his experiment showed reflection as low as 20% for 20° slopes with surface porosity of 30%.

FIGURE 4.

FIGURE 5a.

Referring to the definition sketch, it can be seen that, at maximum run-up, the wave can be typified by two domains, the part outside the slope, and the part within. Intuitively, it could be imagined that the first part will be reflected as if it were on a smooth impermeable slope. Ideally, the water within the slope would be released at a constant rate, i. e. a critically damped wave.

Thus maximising the internal voids and the adoption of the optimum slope face porosity should minimise both run-up and reflection.

By using an armour unit whose geometry may be altered along logical paths, it should therefore be possible to design a revetment for all three criteria, i. e. stability, run-up and reflection.

Using the concept of an armour layer 'veefaced' to the slope, a further examination of the forces is warranted.

Fig. 4 shows a water mass impinging upon the slope at an angle to the horizontal. The momentum flux of the jet normal to the surface is $F_i = \rho u^2 \sin(\alpha + \beta)$. At a depth L normal to the surface of the slope, a pressure P_L is induced, where $P_L = K_1 \rho_w u^2 \sin \theta$. Now

in shallow water $u^2 \simeq g d_b = K_2 \cdot g \cdot H_b$. Hence $p_i = K_1 \cdot K_2 \cdot \rho_w g H_b \sin \theta$

The resisting force due to the layer thickness L (ignoring for the moment any shear forces) is $F_a = (\rho_r - \rho_f) \cdot g \cdot L \cdot (1-p) \cdot \cos \alpha$.

Hence, at 'lift-off',

$$K_1 K_2 \rho_w \cdot g \cdot H_b \cdot \sin \theta = (\rho_r - \rho_f) \cdot g \cdot L (1-p) \cos \alpha$$

$$\text{or } L(1-p) = K \cdot \frac{H}{\left(\frac{\rho_r - \rho_f}{\rho_w}\right) \frac{\cos \alpha}{\sin(\alpha + \beta)}}$$

Plotting the function $\cos \alpha / \sin(\alpha + \beta)$ for values of α and β , a family of curves is obtained. The normalised values are shown in Figure 2a. It can be seen that the minimum values of the curves are close to the value for $(\cot \alpha)^{1/3}$, Hudson's empirical angle function.

The effects of wave steepness and reflection will be found in the values of K_2 and β .

Now the rise of water in the core voids is a time integral of the driving force above, it is a reasonable assumption that the outflow velocity is a scalar function of the inflow velocity. Hence the uplift pressure during downrush $\propto p_i$, and the above expression holds.

The component of force parallel to the slope may cause a sliding failure if too close to the crest or toe. For squat units, or poorly interlocked designs, the surface drag force can exercise an overturning moment, rotating the unit on the slope. This will often lead to positive feedback, and the element will become unstable and leave the slope.

Damage Behaviour

The literature contains a great deal of information concerning the behaviour of armour systems after damage.

In applying the damage criteria to any revetment, careful consideration must be given as to what is causing the damage. In coastal engineering, it is customary to present the damage history as shown in Fig. 5 a. A different perspective is shown by plotting instead the rate of damage as in Fig. 5 b, which is the typical way for production engineering.

Part A of the curve shows the initial rate of failure due to production faults etc. (i. e. poor placement), which rapidly falls too close to zero as the faulty items are discarded. A stable, near zero rate is then achieved, which represents the useful working life of the product. After this, wear, decay etc. begin to take their toll and the damage rate increases.

FIGURE 5b.

UTILITY OR DAMAGE CURVES

Now a product which can be produced to a high standard may have no apparent element 'A' to its utility curve.

Looking at revetment construction, if random placement is used, it must be expected that a statistical proportion of the units will be unstably placed and will be removed in the initial 'settling in' phase. It is important that the removal of these units does not cause any consequential damage, such as mechanical damage to adjacent units, other than that implied by the actual unit loss.

If a disciplined procedure for placement is adopted, utilising a unit deliberately designed to facilitate disciplined (pattern) placement, (such as a right prism), it can be anticipated that placement errors can be eliminated so that the utility curve is represented by sections B and C only.

The difference must be made here between disciplined (pattern) placement and uniform (undisciplined) placement. In uniform placement, units (e.g. Tribars) are placed randomly in a planar array. In pattern placement, randomness is almost non-existent, only being measurable in the tolerance measurements.

The advantages of pattern placement as against uniform or random placement are well shown in the case of Tribars.

Table 1 Stability Factor for Modes of Placement of Tribars

Placement	No. of Layers	k	Porosity %	Damage Criteria	K _D		Source
					K _D	K _D /n	
Pell-mell	2	1.0	54	1%	12	6	Hudson 9/60
Uniform	1	1.1	47	1%	25	25	Hudson 9/60
Uniform	1	1.0	-	-	15(25)	15	Jackson/68
Uniform	1	1.0	-	6%	12	12	Gordon/73
Uniform	1	1.0	-	-	25	25	Hudson/74
Pattern	1	1.0	-	2%	70	70	Gordon/73
Pattern	1	1.0	-	.1%	25	25	Gordon/73

Thus, pattern placement has reduced the unit mass by a factor of 4, the material usage by 37%, and damage rate reduced by a factor of ten.

In his observations, Gordon remarked that both pattern and uniform Tribars exhibited 'plateau' behaviour, such that finite amounts of damage occurred for short duration, followed by long periods of apparent stability. He did not observe the cause of the sudden instabilities, but I would venture that it was due to rearrangement of the underlayer, 'springing' the point or line contact between units, and so breaking the pattern. Use of planar contact faces prevents this catastrophic failure.

Practical Applications of Blanket Theory

Of the multitude of armour units and systems available for consideration, a reasonable number exist which can be assessed according to the 'linear' blanket theory outlined above. These systems include both free-standing armour units and interconnected systems.

The results of asterisked units have been reworked in accordance with the 'linear' theory outlined below, and used to demonstrate, where possible, the effect of porosity and/or interconnection.

Careful examination of the references indicates that the value of interconnections is only appreciable for very squat units, i. e. units where the eccentricity of disturbing motion can rotate the unit from the slope. This may be due either to high surface drag or to eccentric slope normal forces - probably the former. (This is a characteristic failure mode of random units. Indeed, some units, such as the dolosse, seem deliberately contrived to generate maximum drag at a maximum lever arm to the centre of gravity).

Gabions	2.67	1.67	1.26	35	9	4.3 *

¹ 15% of units removed from slope (face centre unit of each group of seven units) without inducing failure

* Failure in the case of gabions denotes pronounced departure from the as-built profile due to pumping. Due to multiplicity of redundant active bonds, structure fails by breakdown of

underlayers, or long term wear on wire cage.

The Seabee

The Seabee is an armour unit designed with the above arguments in mind, namely:-

1. Slope height is independent of area .
2. Porosity is variable.
3. Pattern is easily laid, and is unharmed by loss of any individual unit .
4. In plane forces are spread in a 120° form by face to face contact.
5. Each unit is in frictional contact with four adjacent units, and the units are thus in a zero, or compressive stress situation.
6. The major water paths are coaxial and disturbing forces thus have low moment generating capacity.

Because of its simple form, the Seabee allows for economical, rapid manufacture from a variety of materials and in any size. Due to the separation of water passages from contact faces, inter unit contact is maximised and drag force eccentricities minimised. By utilising high aspect ratios, the surface drag force due to uprush and downrush is of little consequence in armour element mechanics. By utilising the variable porosities available, the best combination of stability, reflection and run-up can be attained.

Plates 1 and 2 show views of an ocean front revetment at Wamberal, N.S.W. during and after construction.

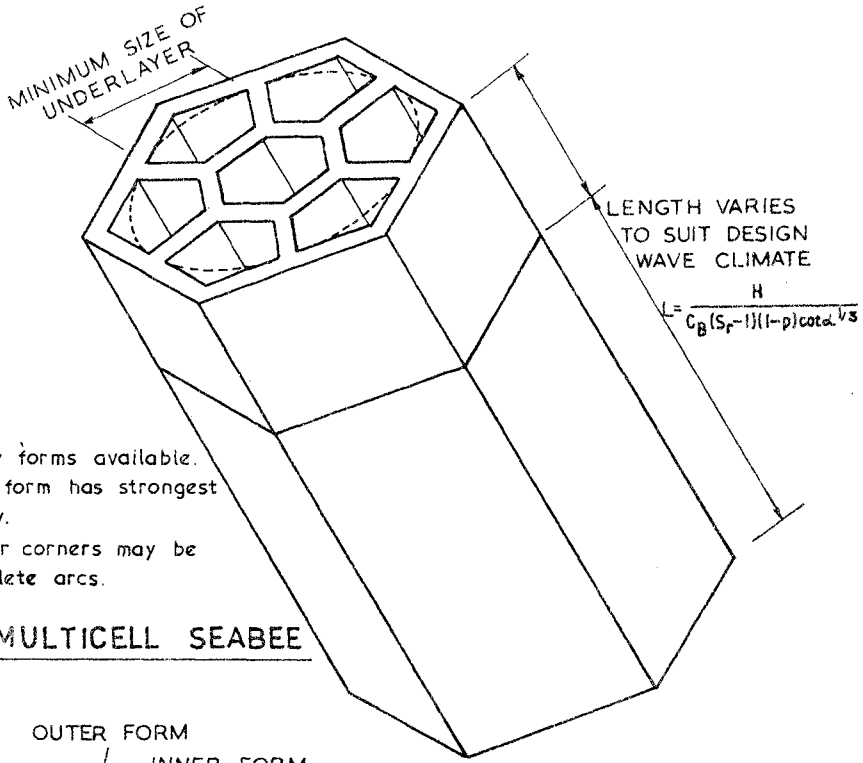

It should be noted that worldwide patents in respect of the Seabee system have been applied for and/or are pending.

Conclusions

A re-examination of Hudson's well known equation allows the proposition, that for a given material, $\frac{H}{L_0} = K \cdot \phi(\alpha)$ where K is a constant associated with the unit geometry[†]

Many experiments have shown that Hudson's empirical angle function, $(\cot \alpha)^{1/3}$, describes to a reasonable degree the effect of the slope angle. Others have demonstrated the variability due to variations in H_0/L_0 . By considering the mechanics of the wave 'thrust' or jet, an alternate possible function is proposed:

$$\phi(\alpha) = \frac{\cos \alpha}{\sin(\alpha + \beta)}, \quad = \tan^{-1} \sqrt{\frac{d}{K H}}$$

PLATE 2 PRACTICAL COMPLETION AT WAMBERA BEACH
(TOTAL COST = \$110 PER FOOT RUN)

Variations in β give rise to a curve similar for that shown for waves of various steepness. A full justification has not been made for this new function, and it is proposed that this concept provides instead a justification for accepting Hudson's angle function as being a reasonable shorthand for the minimum stability case.

A corollary of this proposition is that the arbiter of both stability and economic worth is the value C_B and the ability of the form to maintain its properties through large changes in aspect ratio. Hudson's K_D is shown to be a relative stability factor only, applying only to fixed geometric forms.

Two basic routes apply, the first being the use of active mechanical bonding (e.g. reno mattresses, gobimats, rodded Nami rings). The second is to design the joint planes so that failure is only possible along the minimum force vector.

The Seabee is a unit designed in accordance with these principles. Laboratory units have been tested to K_D values of greater than 400, some units being too stable a size to determine their relative stability parameter. This unit allows full capability for post-design geometry changes, and highlights the need for alternative armour system specifications. Units of minimum mass or maximum weight may or may not be the most economic to construct.

Thus contracts might better be written about a number of alternate armour units or, in the case of suitable units, by specifying the required porosity and the minimum submerged surcharge, and prompting the tenderer to determine his own optimal unit size and type. This will not relieve the design engineer of his responsibilities but it should encourage a more aware approach by all parties.

Reference to the definition sketch shows that the volume of the wave (H, L) can be considered to be stored within the hysteresis loop of the water surface envelope. In permeable cores of suitable characteristics, this envelope passes through a single point at the surface of the (semi-)permeable core, where it is increasingly common to find a filter-cloth. For thinner underlayers, the envelope subtends a line at this surface, centred on the phreatic surface in the core, pumping the local filter-fabric/core formation. In such circumstances, cheap filter-cloths are a false economy. It might also be expected that the disturbing pressure drop across the armour layers could be related to the volume of the hysteresis loop and the elevation of the inner node. Before closing, it should be further noted that irregular or periodic wave trains cause the phreatic level to vary, so developing a secondary hysteresis effect.

Appendix: The value of β

the value of β can be approached as follows. Considering the wave

motion immediately prior to impact, the wave has a horizontal velocity

$$c = \frac{1}{2} \cdot \frac{L}{T} \sqrt{1 + \frac{4\pi d/L}{\sinh(4\pi d/L)}}$$

at impact, the vertical component of velocity is due to the loss in potential energy in falling from the wave crest to the point of impact, thus

$$w = \sqrt{g\Delta h}, \quad v = \sqrt{w^2 + c^2}$$

for shallow water

$$c \approx \sqrt{gd}, \quad v = \sqrt{g(d + \Delta h)} \approx \sqrt{K_2 g H}$$

Now

$$\begin{aligned} \beta &= \tan^{-1} c/w \\ &= \tan^{-1} \sqrt{d/\Delta h} \approx \tan^{-1} \sqrt{d/KH} \end{aligned}$$

Unfortunately there has not yet been time to check this relationship to see if it does indeed hold. But it is a concept that is easily grasped and gives values intriguingly close to those of both Hudson and Per Bruun.

CHAPTER 152

EFFECTIVENESS OF SEADIKES WITH ROUGH SLOPE

Osamu Toyoshima
Public Works Research Institute
Ministry Of Construction, Japan

ABSTRACT

The length of the coastline of Japan is very long, and it exceeds 31000 kilometers. In which, about 19000 kilometers are remained as natural coast, but 8000 kilometers are protected by the seadikes (inclusive of seawalls).

Before 1965, there were about 5900 kilometers of seadikes. Then, we have constructed more than 2100 kilometers of seadikes during the past ten years.

In Japan, sea and shore are all under the control of the Government, and 8000 kilometers of coastal structures have been constructed or improved as the Public Works. Before 1945, however, most of seadikes, though their length were not so long in that age, were constructed as reclamation works by private, and after the War, these private reclamation seadikes were changed to the government management and have been improved as the public works. These former seadikes were almost for the storm surge.

Since the early 1960's, beach erosion in Japan has become increasingly severe, and many seadikes have been constructed for measures against beach erosion. Because of customs of long standing and low cost, most of seadikes in that time were vertical type ones and made of concrete. Several years after construction, some of those seadikes were destroyed by the scouring at the toe of the seadikes due to the reflected waves. For the prevention of scouring, it is essential to dissipate wave energy and decrease the return flow on a dike face.

One of the measures is to make the face rough and permeable. Several inclined slope type seadikes with rough and permeable face were proposed by the author. Thirty or more experimental works of these new type seadikes have been carried out on every place where each conditions of wave and beach were respectively diverse. In parallel with constructions, numerous field investigations have been carried out under guidance of the author.

The effects were evaluated after the field investigations for more ten years, and most of these experimental works were effective.

TRANSITION OF SEADIKES STRUCTURE

Before 1940's, seadikes were constructed as the reclamation dikes under the private management and made of stone masonry as showed in Figure 1.

Fig.1 Former vertical type seadikes for storm surge

After the War the first improvement works were concrete facing of these masonry seadikes. In that time, the thickness of concrete facing was ordinary 30 cm.

Fig.2 Concrete facing works after the War

On September 26, 1959 a extra-large typhoon attacked the Ise Bay. More than 5000 people died, and 680 kilometers of seadikes were destroyed. Damaged seadikes were restored as the concrete face inclined type seadikes as showed in Figure 3. The thickness of concrete were 50 cm in front and 20 - 25 cm in rear facing.

Fig.3 Typical seadikes after the "Ise Bay Typhoon"

After the "Ise Bay Typhoon", this inclined type seadikes had been used many coasts not only for storm surge but also as prevention works for beach erosion. Seadikes for storm surge had been constructed generally at the bottom of bays with very shallow water. Tidal ranges of these area are pretty large, and bed material are usually silt or fine sand. There have been almost no problems about the beach erosion and scouring at the toe of the seadikes.

Meanwhile, since the 1960's, beach erosion has become severe and many seadikes for beach erosion were constructed. Seadikes at that time were almost vertical type ones showed in Figure 4 or the inclined type ones such as shown in Figure 3.

Fig.4 Vertical type seadikes in the 1960's

Different from the seadikes for storm surge, seadikes for beach erosion had been constructed on the sandy beach with pretty steep near shore. After the construction some of these seadikes have suffered considerably damage in every coasts.

From the first, the mechanism of beach erosion had not exactly been known yet in those days. In order to prevent the erosion of sand dunes and regression of shore line, seadikes had been constructed without considerable studies.

The incident waves were violently reflected on the steep front slope of seadikes. Forshore and the toe of seadikes were washed out with the reflected waves. Then, contrary to expectation, these seadikes encouraged the beach erosion.

EXAMPLES OF DAMAGED SEADIKES

Example (1)

The shore line had been receding gradually and the uprush had broken into the houses. Then, new seadikes were constructed.

Fig.5

However, the incident waves were violently reflected on the front slope foreshore and the toe of seadikes were washed out with reflected waves.

Contrary to expectation only one year after the construction, the seadike were destroyed and beach erosion has encouraged.

As the measure for wave overtopping and against scouring at the toe of the sea dikes, armour units had to be installed.

Lost beach have never reappeared.

Example (2)

This coast had been a stable bathing beach for long time.

On July 1970, a middling typhoon attacked the coast

Six monthes after, on January 1971, the shore-line greatly receded.

On July 1972, the beach have entirely vanished.

Example (3)

On March 1969, the shoreline was slowly receding, and gentle slope dune changed into the bluff

Seawalls had been built at the toe of the bluff until March 1972. However, on January 1973 the beach vanished.

Then we had to install armour units as the wave defence works.

PROPOSAL OF NEW TYPE SEADIKES

As the countermeasures against the foreshore erosion and the scouring at the toe of seadikes, the toe protection works, made of rip-rap or armour units, or underpinning works, made of cut-off wall or steel sheet pile, were constructed. Some of them were success, but another were ineffective.

Then, the author proposed the "Detached Breakwater System" at that time for these destructed coast. However, there had been many natural beaches needed some useful and effective seadikes. Then the author proposed some new type seadikes.

After many field experiences such as above-mentioned examples, the author thought that, points of attention and problems to be consider for the new seadikes were to be as follows:

- 1) Decrease the reflected waves from the front of seadikes as little as possible.
- 2) Make the front face more rough.
- 3) Make the front face permeable if possible.
- 4) Some partial collapses should be allowed, but never be destroyed the whole body of the seadikes.
- 5) Repair and reinforcement to be easy.
- 6) Structure to be simply and low cost.

The first new type seadikes the author proposed was a "Block faced seadike" covered the front slope with some artificial concrete blocks such as armour units.

Fig.14 Block faced seadike

Fig.15 Hollow square block

The above shows a example of block faced seadikes used the "Hollow square block" which is used generally in Japan.

These block faced seadikes were constructed at more than ten sits in Japan, and most of them have been quite effective.

Fig.16 Block faced seadike

The above was constructed on 1966. The armour units are installed on the rip-rap.

Even now, they have been in existence without any accident.

In the same way, the next example is block faced seawall. This seawall has been constructed on 1977 as the restoration works of the former vertical type seawall.

A respectable wave attacked the coast on July 1978. Neighboring seawalls were destroyed about 100 meters in length, but this block faced seawall has been in existence without a change.

Fig.17 Block faced seawall

Fig.18 Cross section

The second new type seadikes the author proposed was a "Lattice type seadikes".

It is covered the front slope with lattice works filled with rip-rap, cobbles, concrete blocks, armour units and soddings etc.

The first lattice type seadikes was constructed on 1967. The lattice has a 2 meters square and its member is made of concrete of a 40 by 50 cm section.

The compartment filled with rip-rap is showed in Figure 19, and filled with cobbles in Figure 20 and 21.

These were constructed on 1968 and 1976. The former has experienced several times violent waves during the past ten years. Fortunately,

Fig.21 Cross section of the Lattice type seadikes

Fig.22 A example of partially collapsed seadike

The above seadike was partially collapsed at the low side compartments. However, the lattice were undamaged and the destruction did not amount to the whole body of the seadike.

If heavy storms attacked the front slope, the fills of the compartments will be collapsed. Then, the lattice should be designed strong enough to stand alone.

In the above, (1) is the section of before construction, (2) is just after the destruction, and (3) is several days after the destruction. Run off sand came back again of itself, and the beach was restored passably.

It is easy to repair this kind of seadikes collapses compared with reconstruct vertical type seadikes.

On the gentle and permeable slope, run up waves dissipate and percolate. Then, after the storms the quitted sand frequently come back to the fore shore, we can easily repair and restore the seadikes.

The next example also is the lattice type seadike. The compartment of the lattice is filled with concrete blocks, cobbles and grass. It was constructed on 1967 succeeding next to the existing vertical type seadike.

The change of the type of seadike was carried out according to the proposal of the author. Because, the fore shore in front of the existing vertical type seadike had begun to show a distinct tendency to the beach erosion.

Fig. 23 Lattice seadike

Fig.24 Cross section of the above seadike

Three years after the construction, the vegetables on the front slope have grown thick, as showed in Figure 25. And, these lattice type seadikes have been in existence without any damage.

Fig.25 Vegetables grew thick on the lattice slope

However, the fore shore in front of the vertical seadike has become narrow, and on 1975 the vertical seadike was partially destroyed by the middling waves. (Arrow mark in Fig.26)

Fig.26 Vertical seadike was partially destroyed

These proposed permeable and rough slope seadikes show that they are appropriate methods of the dune protection. The distinctive features of these new seadikes are not the non-destruction, but the easy restoration and don't encourage the beach erosion.

And, the proper countermeasures against beach erosion should depend on groins, detached breakwaters, nourishments and etc. (END)

CHAPTER 153

SCOURING AT THE TOE OF A SEAWALL DUE TO TSUNAMIS

by

Hitoshi Nishimura*

Akira Watanabe**

and

Kiyoshi Horikawa***

ABSTRACT

In this paper, the general features and mechanism of scouring at the toe of a seawall due to tsunami invasion are discussed based upon the results of two-dimensional experiments. The effects of the various slopes, bed material, water depth and wave conditions are separately investigated. After some consideration of the scouring mechanism, a critical condition for the occurrence of scouring is given in terms of two important parameters, namely, the rate of return flow from the land and water layer thickness in front of the seawall. These findings lend perspective towards the quantitative prediction of the total amount and pattern of scouring.

INTRODUCTION

Coastal structures on the Pacific coasts of Japan are continuously exposed to violent tsunamis and, as is well-known, damage to such structures is often caused by scouring at their toe. Although this is a serious problem in the field of coastal engineering, it is extremely difficult to analyze the whole process of tsunami deformation over a movable bed, which includes shoaling, breaking, reflection, overtopping, runup, and return flow. Furthermore, hydraulic phenomena have to be related to the amount of sand movement. And finally, for this phenomenon field data are lacking and difficult to obtain.

Herein, a series of two-dimensional experiments are described which were carried out under simplified conditions in order to clarify the scouring mechanism due to tsunamis.

DESCRIPTION OF EXPERIMENT

The model installed in a wave flume consists of a seawall with a sloping face, sloping sea bottom, and sloping land surface connected to the crown of the seawall as shown in Fig. 1. For each experimental run, a solitary wave simulating a tsunami wave was generated by allowing a mass of water from the head tank into the flume. The air valve is automatically operated to pump up the prescribed amount of water into the tank or to release it into the flume. Capacitance wave gages and a propeller current meter were used for the measurements. Deformation of the incident waves and bottom topography were recorded by a VTR system and a motor-driven camera.

Experimental conditions are given in Table 1, where underscoring indicates the standard conditions. Effects of each factor on the amount and the pattern of scouring were systematically investigated by shifting individual conditions from the standard condition.

Fig. 1. Experimental installation.

Face slope of the seawall:	90°, 60°, 45°		
Land slope (fixed bed):	1/15, 1/30, 1/60, 1/120		
Bottom slope (movable bed):	1/5, 1/10, 1/15, 1/30		
Water depth at the toe:	15 cm, 10 cm, 5 cm, 0 cm		
Crown height of the seawall:	10 cm, 5 cm, 0 cm		
Incident wave height:	35 cm, 30 cm, 25 cm		
Bed material	<u>Mesalite</u>	Sand(A)	Sand(B)
Specific gravity:	1.65	2.65	2.65
Median grain size:	0.25	0.20	0.70

Table 1. EXPERIMENTAL CONDITIONS

EXPERIMENTAL RESULTS

A single incident solitary wave was caused to break on the slope, collide against the sea wall, overtop, and run up on the land slope as illustrated in Fig. 2. During these processes, only minor scouring if any takes place. Then the mass of water stored temporarily on land starts to flow back and this return flow is the significant contribution to scouring. Figure 3 is a brief description of general features of the present phenomena. The position and the amount of scouring at a given moment are controlled mainly by the instantaneous rate or velocity of the return flow and the thickness of the water layer receiving the flow. The influence of scouring is fed back to the water depth as well as to the wave behavior.

The effects of each factor on scouring found through the experiments are summarized as follows:

Fig. 2. Sketch of wave deformation and scouring processes.

- (1) A decrease of incident wave height or an increase of the crown height reduces the amount of the wave overtopping and scouring, but these factors are not necessarily advantageous for protection of the structure since the area of serious scouring approaches the toe in such cases.
- (2) When the face slope is mild, the amount of scouring is large and it occurs exactly at the toe.
- (3) The amount of scouring decreases considerably as the water depth in front of the seawall increases.
- (4) A milder land slope causes a larger amount of wave overtopping and a smaller return flow rate. The total amount of scouring depends on the instantaneous water depth when the return flow strikes the bottom.
- (5) The influence of the bottom slope is comparatively small.
- (6) The use of bed material with smaller specific gravity leads to much greater scouring, while the effect of grain size is not too significant (Fig. 4).
- (7) When waves are applied repeatedly, much less scouring is caused by each successive wave.

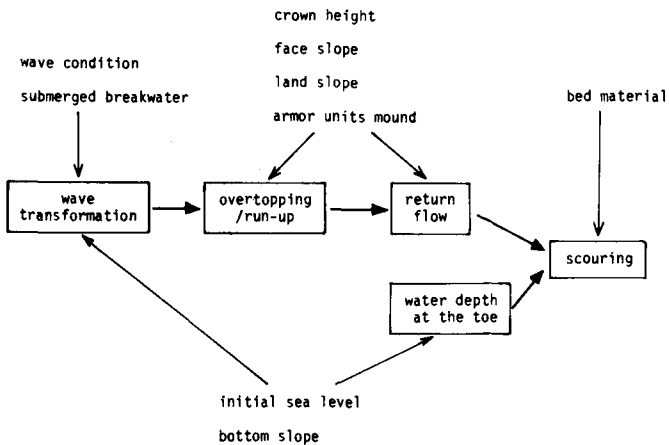

Fig. 3. Description of the wave deformation and scouring phenomena.

Fig. 4. Resultant scouring patterns.

DETAILED DISCUSSION OF SCOURING PHENOMENA

The amount of scouring cannot be simply related to the amount of wave overtopping or the maximum rate of return flow, since the water depth in front of the seawall is another important factor controlling the phenomena as was mentioned in the previous section. It effectively works as a buffer when the flow hits the sea bottom. For the discussion of this essential part of the total mechanism, some sets of experimental data with the vertical seawall and the sea bottom of standard sand (A) are selected here.

When the flow rate is large, the hydraulic phenomena near the seawall are extremely complicated and by no means easy to analyze. Therefore, it is more practical to define the water depth by taking the ambient sea level as the reference level. Assuming that there is no water in the flume and that the mass of water flows from the land slope to the sea bottom with the initial velocity measured at the crown, then the instantaneous shape of the nappe is easily calculated. Such a parabolic nappe actually appears when the sea level is lower than the crown. The outer end of the assumed nappe is almost always very close to the point of most intense scouring at that moment. As illustrated in Fig. 5, d_0 is the water depth measured from the reference sea level to the initial sea bottom at the end of assumed parabolic nappe. Now the value of d_0 is determined from the return flow velocity and the ambient sea level.

Figure 6 shows the measured variation of the return flow velocity v and the water depth d_0 for a particular case. As the scouring takes

Fig. 5. Definition sketch.

Fig. 6. Variation of the flow velocity and the reference water depth.

place, the bottom profile changes, adding some depth. The measured variation of the additional depth $d-d_0$ at the end of the nappe is also plotted in the same figure.

The flow velocity is replotted to the reference depth in Fig. 7. The dashed line shows the relationship between v and d_0 corresponding to the data in Fig. 6. The water depth is almost at its maximum when the return flow is initiated, and it decreases as the flow velocity increases. Then the water depth slightly increases because the end of the nappe is shifted by the increase of the velocity of the return flow. In this case, the water depth reaches its minimum value when the return flow terminates. The intense flow strikes the thin water layer and scouring results in the region of large flow velocity. Consequently, the process of the flow and depth variation is shifted in the figure in terms of the substantial water depth d as shown by the solid line.

Fig. 7. Variation of the flow velocity to the reference water depth.

The solid circles on the line indicate the active motion of bed material and the half solid circles correspond to the less active motion of sand.

Similar plots are shown together in Fig. 8 for several cases for different conditions of land slope, bottom slope and initial sea level. It seems that there exists a critical condition for movement and non-movement of bed material. When the flow-depth variation is traced in the v - d plane, scouring begins immediately after crossing the dashed line and advances in such a way that the flow-depth combination follows the line. In principle, this curve can be used to predict the scouring pattern from a given variation of flow velocity and sea level. However, more careful investigation is necessary for the actual use of the curve. The circles connected by the solid line in Fig. 8 are the plot for the case of a steep land slope. Under such a conditions, the increase and decrease of the velocity of the return flow is comparatively rapid and the time duration of high velocity is not enough for completion of scouring. The space between the solid and dashed lines is to be filled by successive

Fig. 8. Critical condition for sand movement.

waves. To conclude, the dashed line in Fig. 8 is considered to represent the ultimate profile under repeated action of tsunami waves.

Scouring phenomena due to tsunamis were investigated from various points of view in this study. It is noted, however, that further studies on similarity laws are indispensable for the quantitative prediction of scouring on actual coasts.

CHAPTER 154

SIMULATION OF WAVE/WIND FORCED HARBOR OSCILLATION

S. K. Liu,¹ H. S. Hou,² and C. C. Chang³

INTRODUCTION

This paper describes the methods used in an investigation of the response characteristics of a large man-made harbor under construction. In the investigation a three-dimensional finite difference model is applied in conjunction with physical models and field observations to assist in determining criteria for design and operation. In the modeling investigation, the dynamic response of the harbor system induced by tide, incoming short/long waves, wind stress and bottom dissipation are considered simultaneously. Particular emphasis of the study has been on the wave- and strong monsoon-induced oscillations that match the range of the resonant period of ships and mooring systems expected to operate in the harbor. The resolution required to handle short-period oscillation and wind stress precludes the possibility of using methods involving the inversion of extremely large matrices.

The results of the numerical simulation at important localities within the harbor system are later analyzed by spectral and cross-spectral methods. The same methods can then be used to study ships' responses at these localities with the predicted water level and three-dimensional current components.

THE HARBOR SYSTEM

Taichung Harbor (Fig. 1) is located on the west coast of Taiwan, facing Taiwan Strait, approximately 100 miles from the mainland. The harbor has been under construction for five years. At its completion, the harbor complex will be 9.5 kilometers long in the NNE-SSE direction. One of the major considerations in the design and planning process is the possible seiche motion induced by the persistent wind field in line with the main channel during the monsoon season usually lasting several months each year. Also of concern is the possible presence of short-period oscillations at facilities serving container ships, whose loading and unloading operations are sensitive to these oscillations, particularly when the oscillation period matches the natural frequency of the mooring system. To this end, it has been decided to develop a numerical model in conjunction with the physical model of the harbor system which will be capable of simulating tidal flow, wind-driven circulation and harbor oscillations.

² Taichung Harbor Bureau. Present address: Director, Graduate Institute of Rivers and Oceanography, Taiwan Institute of Oceanography, Taiwan, Republic of China

³ Chief Engineer, Taichung Harbor Bureau, Taiwan, Republic of China

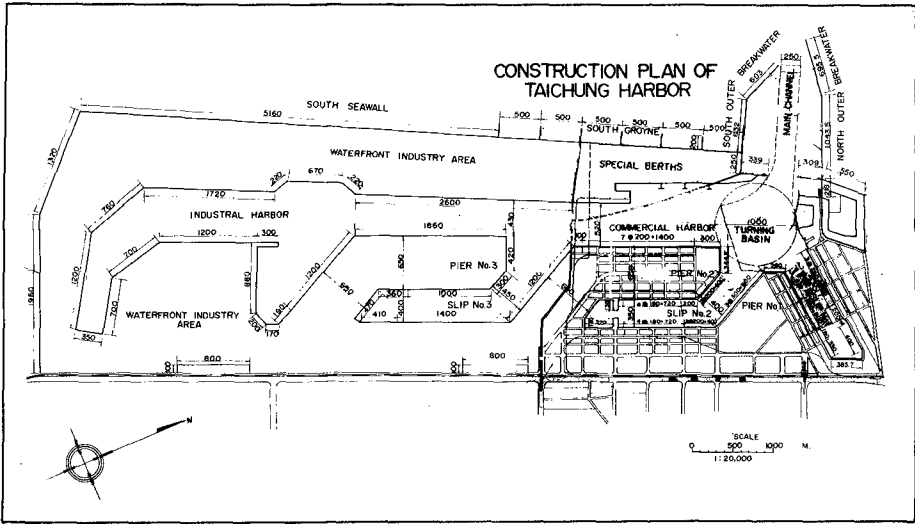

Figure 1

Figure 2

After evaluating existing numerical models in the public domain, the computational method described in Ref. 1 was adapted and simplified for this specific application. An explicit multilayer model was selected for the following reasons:

- (1) For harbor oscillation studies, due to the required temporal resolution for representing incoming waves with periods ranging from 9 seconds to 30 minutes, the size of the time integration is smaller than that required for maintaining the courant stability condition associated with the explicit solution method. Because of this requirement, the benefits associated with the implicit scheme cannot be realized yet for each integration step. Approximately twice as many numerical operations have to be performed as in an explicit scheme.
- (2) For studies involving wind drift and return currents, a multilayer model gives more accurate results than a vertically integrated model.
- (3) For investigating a harbor's dynamic behavior induced by wind stress, incoming waves, bottom stress, and the nonlinear advective acceleration, a model must include these essential terms in the computation.
- (4) In addition to the harbor's basic modes, higher modes generated by the aforementioned dynamic effects falling within the 20- to 40-second range are also of great importance to the operation of container ships. This condition precludes the possibility of using any method involving the inversion of extremely large matrices. Due to the size of the harbor system, in order to resolve oscillations within the range of interest, matrices of the size 450×450 would have to be inverted.
- (5) Velocity components in three directions as derived from a three-dimensional computation form a good basis for establishing a prediction method for responses of moored ships. This can be achieved by linking the computed water velocity components in three dimensions to the ship's response characteristics at a particular location according to experiments on ships' response in a physical model basin, which can be conducted separately.

From these considerations, a numerical model was established according to the basic scheme developed at the Rand Corporation to solve the following dynamic equations:

$$\frac{\partial u}{\partial t} + \frac{\partial(uu)}{\partial x} + \frac{\partial(uv)}{\partial y} + \frac{\partial(uw)}{\partial z} - fv + \frac{1}{\rho} \frac{\partial p}{\partial x} - \frac{1}{\rho} \left(\frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} \right) = 0 \quad (1)$$

$$\frac{\partial v}{\partial t} + \frac{\partial(vu)}{\partial x} + \frac{\partial(vv)}{\partial y} + \frac{\partial(vw)}{\partial z} + fu + \frac{1}{\rho} \frac{\partial p}{\partial y} - \frac{1}{\rho} \left(\frac{\partial \tau_{yx}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{yz}}{\partial z} \right) = 0 \quad (2)$$

where x , y and z are Cartesian coordinates, positive eastward, northward and upward, respectively; u , v and w denote the respective components of velocity; f represents the Coriolis parameter; ρ is the density of water; τ_{xx} , τ_{xy} , τ_{xz} , etc. are components of stress tensor.

For the present study no correction has been made to account for the effect of vertical acceleration because the ranges of wave period in the investigation of hydrostatic pressure distribution are considered to be valid. For shorter wave studies in the future, Boussinesque terms of the form, if H and ζ denote depth and surface elevation, follow:

$$\frac{\partial^3 \zeta}{\partial t^2 \partial x} \left[\frac{(H + \zeta)^2 - \zeta^2}{2(H + \zeta)} \right] \quad \text{and} \quad \frac{\partial^3 \zeta}{\partial t^2 \partial y} \left[\frac{(H + \zeta)^2 - \zeta^2}{2(H + \zeta)} \right]$$

would have to be added to the momentum equations in the horizontal direction (Eqs. 1 and 2). In that case, a four-level time integration scheme has to be used instead of the three-level scheme employed presently. For waves of present concern, the hydrostatic principle applies:

$$\frac{\partial p}{\partial z} + \rho g = 0 \quad (3)$$

For incompressible fluids, the continuity equation is:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (4)$$

The basic numerical scheme for solving this set of equations and the treatments at open and closed boundary conditions can be found in Ref. 1.

BOUNDARY SPECIFICATIONS

In order to analyze the response of a harbor system under possible future conditions, wave energy with periods from 9 seconds to tidal frequencies were used to drive the system at the harbor's entrance. The spectral input was derived from long-term field data, including long-period oscillations induced by typhoons and reflected waves within Taiwan Strait originating from offshore areas.

The line spectrum for simulation input is shown in Fig. 2. This input line spectrum is applied for the majority of simulation runs. On several occasions, when the inner harbor entrance was used as the model's open boundary, for more efficient use of machine storage capacity, this input spectrum was multiplied by a set of wave sheltering coefficients obtained by physical model tests.

Because the length ratio between the harbor's boundaries and the entrance is approximately 100 to 1, the scheme of radiative open

boundary was not applied. The bottom stress coefficient used for computation was $55 \text{ m}^2/\text{sec}$. This value was derived from tests using the alluvial sediment which is homogeneously distributed in the construction area. The general composition of bed material is not expected to change in the near future.

The direction and speed of winter monsoons used for the simulation were derived from local weather statistics. The speeds have varied from 20 to 35 knots with run-in periods for different simulations. The time step size selected for different simulation tests ranged from 1.0 to 2.0 seconds for various temporal resolutions. The horizontal grid size ranged from 50m to 100m; the vertical layer thickness ranged from 3.0 to 14.0m, depending on different stages in the construction phase. A typical simulation period is 2.5 hours.

SIMULATION RESULTS

With the specified boundary and initial conditions a set of simulations was carried out for several system configurations representing different stages in the master construction plan. Results of the computation at important locations were recorded for further analysis and future restart. Figures 3 through 5 show the time histories of water level variation at several key locations.

The water level at the harbor's inner entrance, which contains the energy input at the open boundary, is shown in Fig. 3 as curve A. At this location, longer waves are not damped. On the other hand, within the fisherman's harbor (curve B of Fig. 3) shorter waves were damped. An oscillation of approximately 30 seconds is evident. As a consequence of wind stress, a negative setup of 25 cm occurred at this end of the harbor system. At locations in the main harbor system (Fig. 4), nonlinear effects become more pronounced. As shown by curves C and D in Fig. 4, water level variations contain waves of higher orders as the interaction between horizontal advective mechanisms and bottom and surface stress terms gives rise to a complicated pattern.

At the other end of the harbor system, patterns of oscillation become equally complicated, superimposed on the wind-induced setup of roughly 30 cm above the reference level. Because of its location, the water surface at station 9 contains more shorter-period oscillation than that found at station 10.

The spatial variation of water level elevation within the harbor system for the 10-year plan is illustrated in Fig. 6. Boundary effects on wave propagation are evident in this figure. To show the propagation and modifying process of longer period waves, the water levels at the entrance and at station 6 are plotted in Figs. 7 and 8 for a longer period of time. This section of 54 minutes was abstracted from the end portion of a 2.5-hour simulation. During this period, the water level at station 6 contains not only the basic mode of 12 minutes, but also modes induced by the nonlinear interactions.

Figure 6

Figure 7

Figure 8

When the computed results are analyzed in the frequency domain (Figs. 9 and 10), the computed line spectra reveal distinct peaks at 52 seconds, 60 seconds, 120 seconds, and the basic mode at 12.5 minutes ($f = .08 \text{ min}^{-1}$). In the amplitude of the frequency response function (Fig. 11) which is the square of the amplitude ratio, it is shown that the 52-second oscillation is the most significant one. However, oscillations at other frequencies are also important, depending upon the type of ships operating in the vicinity. This graph also indicates that significant amplification would result if incoming waves contained periods from 50 seconds to 100 seconds: Phase differences from the harbor entrance to station 6 are presented in Fig. 12. Certain negative phase lags indicate that these oscillations are generated within the harbor system and are therefore not correlated with those entering from the harbor entrance.

Figure 13 is the amplitude ratio between the inner harbor entrance and the fishing harbor. A distinct peak at 30 seconds is the basic mode for that basin. For waves of shorter period, the ratio approaches 0.16, which agrees with the wave sheltering coefficient as obtained by means of wave tank tests.

The smallest basin in the harbor system is the workshop's basin situated next to the fisherman's harbor. The amplification factor in that basin is plotted in Fig. 14. The highest amplification factor is found at frequency 0.066 sec^{-1} , which corresponds to a period of 15 seconds.

The previous analyses in the frequency domain are computed using the direct Fourier transformation technique. If the computed results are compared with observed data, which unavoidably contains errors, spectral and cross-spectral density functions would have to be used.

Spectral density functions at station 6 are plotted in Fig. 15. The predictive impulse response function [2], as derived from spectral densities between the harbor's inner entrance and the fisherman's harbor, is presented in Fig. 16. The impulse response function has certain significance during time domain prediction if one wishes to compute water level oscillation within the harbor system from a future given wave climate at the harbor's entrance. This can be achieved by means of numerical convolution [2] without having to perform the simulation anew. It also has a definite advantage over its frequency domain equivalent, the frequency response function, because when a new data point is added to the input series, the output series can be readily obtained by the convolution scheme which involves only a limited number of computational operations. Unlike the frequency response function, in order to obtain the predicted new series, the new data series has to be transformed back and forth from time to frequency, then back to time domain. This would involve several orders more operations in the computation.

CHAPTER 155

MIXING OF HEATED WATER DISCHARGED IN THE SURF ZONE

Kiyoshi Horikawa¹, Ming-Chung Lin² and Tamio O. Sasaki³

ABSTRACT

In this paper, a description is given on the mixing processes of heated water discharged into the surf zone, based on the field investigations.

In accordance with the flow characteristics observed, the flow region can be classified into three parts, namely the jet flow region, nearshore current region and coastal current region. In the jet flow region, the flow characteristics are expressed well by the two dimensional turbulent jet flow model and strongly influenced by the cusped bottom configuration formed under the interaction between the jet flow and nearshore currents. It is realized that the decay of plume centerline temperature is slower than the other cases owing to the influence of bottom slope, water depth and the direction of jet axis. By the dye tracer studies, in the nearshore current region the variance increases approximately with time at a power of 1.72 for longitudinal and of 1.95 for lateral respectively, while the diffusion coefficient increases with diffusion scale at a power of 1.43 for longitudinal and of 1.71 for lateral respectively. In the coastal current region, the representative isotherms are mainly in appearance either of the southerly alongshore or northerly stretch, possibly caused by some fairly long period waves.

The cloud of heated water was always confined within a certain strip of nearshore zone, likely in response to the existence of a turbulent boundary layer phenomena appeared in parallel to the coastline. Quantitative modelling of this resulting plume is then made. In addition, some pulsation patterns of isotherms were also observed. Finally, a graphical representation of the functional relationship between the relative temperature difference and the area within the specified isotherm is shown.

INTRODUCTION

It was more than ten years ago when the heated water discharged from power stations was recognized as environmental pollutant. In accordance with the expansion of national economical activities in Japan, the facilities for electric power generation have been consolidated during the last twenty years by the extensive efforts of electric power industries. Figure.1 indicates the past growth tendency of electric power generated and supplied in Japan. From this diagram it is realized that the principal medium for electric power generation has changed drastically from hydraulic power to fossil-fuel power. The growth rates of hydraulic power and fossil-fuel power during the period of 1960 to 1975 were two and eight times respectively. Therefore the share of hydraulic power dropped from 60% to 22%, while that of fossil-fuel power increased from 40% to 72%. Another thing which should be mentioned is that the growth rate of nuclear power during the same period was surprisingly large, although its share was as small as 6% in 1975.

At any rate the thermal power, that is fossil plus nuclear fueled power plants, are playing a greater important role of electric energy supply to the Japanese society at present. It means that the operation of cooling water system consisting of intake and outlet structures is throwing into the society the various environmental problems which are still unsolved. It is generally said that the necessary amount of cooling water is 3 to 5 m³/sec per 100 MW of fossil-fuel power plant or 6 to 8 m³/sec per 100 MW of nuclear power plant. Therefore the amount of about 4000 m³/sec of cooling water is at present taken from bays as well as from open sea, and the same amount of heated water is discharged to the sea water region. Especially the nuclear power plants has normally been constructed in Japan on the coast facing the open sea.

As a typical setup for the cooling water system in Japan, the layout of the Fukushima Nuclear Power Plant No.1 of the Tokyo Electric Power Company will be shown in Fig.2. The cooling water is taken from the sheltered basins and the heated water is discharged into the surf zone on the open sea coast through the outlets installed at the roots of the breakwaters.

In order to predict the isotherm, say 1°C above the ambient water temperature, a simulation model established by Wada at the Central Research Institute for Electric Power Industries has been widely used in Japan [Wada, 1966]. In this model the existence of surf zone was completely eliminated. This assumption may hold good for heated plume discharged into a bay area where the short period wave action is negligibly small. On the other hand, in the case of heated water discharged into the surf zone, which is very common in Japan especially for nuclear power plants, the interaction between the discharged flow and the nearshore currents induced by breaking waves should be taken into consideration in the isotherm prediction. The senior author expressed the above opinion at a certain specified committee meeting in Japan about ten years ago.

Fig.1 The tendency of electric power supply in Japan.

Fig.2 Configuration of Fukushima Nuclear Power Plant No.1.

During the last several years, we have had an opportunity to continue the field observations at the Fukushima Nuclear Power Station No.1, which is located at the northeastern Pacific coast of the Honshu Island in Japan. The first unit of 460 MW was installed and started to operate in 1971. The capacity of this plant increased gradually to 1244 MW in 1974, 2028 MW in 1976, and 2812 MW in 1978. According to the construction plan, the final total capacity of 4696 MW will be established in 1979. Following the above processes, the amount of heated water was 25 m³/sec initially, then increased to 69 m³/sec and is at present 159 m³/sec. After completing the construction works, the total discharge may reach to the amount more than 270 m³/sec.

SUBJECTS OF FIELD OBSERVATIONS

The subjects and measuring techniques of the present field observations are given in Table 1. The wave characteristics, current velocity and temperature in offshore region have been recorded continuously during the last several years by the efforts of the Tokyo Electric Power Company. Therefore we devoted our efforts mainly to grasp the relatively short term characteristics of flow pattern and temperature distribution induced by heated water discharge in the nearshore area.

In order to obtain the data of flow characteristics especially in the vicinity of outlets, dye and float tracing techniques were employed with the Balloon-borne Camera System. The dye used for the present tests was fluorescent sodium. On that occasion the Stereo Balloon-borne Camera System was applied to get any information on the complicated water surface configuration induced by the interaction between the incoming waves and jet flow.

For the latter subject, namely the water surface temperature distribution, the thermister or thermometer as well as the infrared photography were applied. Here we will explain the outline of the infrared photographic method. Figure 3 is the schematic diagram of the measuring instrument Fujitsu IRA-301, and Table 2 gives the main characteristics of the present instrument.

CLASSIFICATION OF FLOW REGION

Looking at the flow characteristics, the flow region seems to be classified into the following three parts as shown in Fig.4; namely the jet flow region, nearshore current region, and coastal current region. In the first region, the jet flow of heated water is predominant, while in the second region the interference between the discharged flow and nearshore currents must have an important role on the flow pattern as well as the temperature distribution. Beyond these two regions, the coastal current seems to play a primary role on the diffusion and dispersion processes.

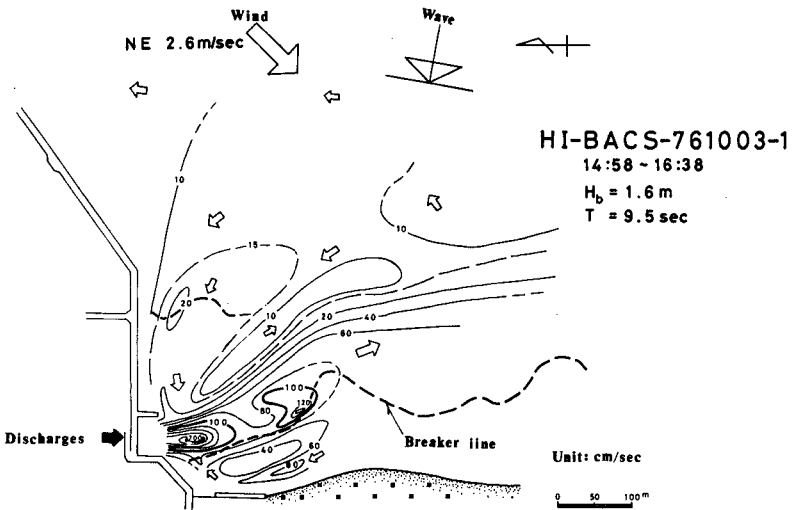

Fig.5 Typical example of surface current velocity distribution in the high tide.

CHARACTERISTICS IN EACH REGION

Jet Flow Region

Figures 5 and 6, obtained in the high tide and low tide respectively, illustrate two typical examples of surface current velocity distributions, from which the jet flow characteristics can be investigated.

Although the outlet flow was discharged in the alongshore direction, the axis of jet flow was shifted toward offshore. Through these investigations, we recognized that the shoreline configuration was deformed by the interaction between the jet flow and the nearshore currents especially the alongshore current. Figure 7 illustrates the situations stated above. That is to say, the nearshore bottom configuration seems to relate with the jet discharge and the longshore current velocity. Such cusped bottom configuration must have strong influence on the jet flow direction especially under the lower tide condition. When it is high tide, such influence will be diminished by the increase of water depth.

The above fact is also demonstrated in the alongshore temperature distribution patterns. Figure 8 gives some examples of the above patterns, from which it is realized that the alongshore decrease of water temperature is relatively small except in one case. The exceptional case was observed under the low tide condition. This result consists with the fact that the cusped pattern influences strongly on the jet flow direction when tide is low.

Now let us analyze the jet flow characteristics. By using the jet flow data obtained by the Balloon-borne Camera System, the axial variations of the maximum speed U_{max} and the width of jet flow b were read and plotted as shown in Figs. 9 and 10. The tendencies agree fairly well with those in the two-dimensional turbulent jet flow. Hence the eddy coefficient ϵ was evaluated by using the following equation based on the two-dimensional turbulent jet flow assumption (Schlichting, 1968) :

$$\epsilon = 0.037 b_{1/2} U_{max} \quad (1)$$

where $b_{1/2}$ is the half width of jet flow. The axial variation of ϵ was plotted as shown in Fig.11, where x is the distance measured along the jet axis from the outlet. From these results, it may be concluded that the actual jet flow can be simulated by the two-dimensional turbulent jet flow in spite of the complicated situations. The order of ϵ is of $10^4 \text{cm}^2/\text{sec}$.

Next the temperature distribution along the jet axis will be investigated. Figure 12 indicates the comparison of the present cases with other previous investigation data. From this comparison, it is realized that the temperature decrease seems to be smaller than the others owing to the influences of bottom slope, water depth and the direction of jet axis.

As a reference the water surface configuration in the vicinity of the outlet is demonstrated in Figs.13 and 14.

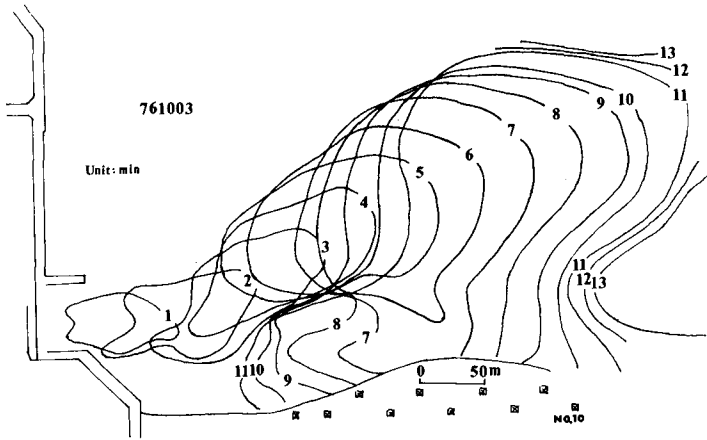

Fig.15 Typical example of dye tracer pattern.

Nearshore Current Region

In order to evaluate the global diffusion coefficient, we released dye at the outlet and took pictures of the dye cloud successively at a certain time interval from air by using the Balloon-borne Camera System. Figure 15 gives one example of the variations of dye diffusion pattern. Assuming that the dye concentration is expressed by the normal distribution, we evaluated the longitudinal and lateral variances of dye diffusion. Figure 16 shows the calculated results, in which the ordinate is the variance and the abscissa is the time elapsed since the dye was released. The exponents of t are 1.72 for longitudinal and 1.95 for lateral respectively. That is, the diffusion process of the present case is not expressed by the Fickian type, and is also different from the diffusion of inertial subrange in the isotropic turbulence. The order of the diffusion coefficient K is approximately equal to that of ϵ .

The relationship between the diffusion coefficient K and the scale of diffusion ℓ was investigated as shown in Fig.17. The exponents of ℓ are 1.43 for longitudinal diffusion and 1.71 for lateral diffusion respectively. At any rate the 4/3 power law may not be applicable to the present case. Okubo (1971) analyzed the numerous data of circular dye patch in the ocean and found that the variance σ^2 is proportional to $t^{2.34}$ as well as that the diffusion coefficient K is proportional to $\ell^{1.15}$. Comparing the Okubo results with the present ones, we can realize that the diffusion phenomena in the nearshore area is completely different from that in the ocean. This fact seems to be quite natural.

Coastal Current Region

Representative isotherms are illustrated in Fig.18. Type 1 is the southerly alongshore stretch of isotherms. Type 2 is the northerly stretch of isotherms along the breakwater. Finally, Type 3 is of intermediate between Types 1 and 2. The last type could be observed when the discharge of heated water was as small as 25 m³/sec, therefore at present Types 1 and 2 can only be seen due to the larger amount of heated water discharge.

It is quite interesting and important from the engineering view point to find out the real reason why such isotherm patterns as Types 1 and 2 are produced. At the present stage, we have not yet fully verified the following hypothetical explanation. According to the results of current measurement in the offshore region, we can observe clearly the alternating current in parallel to the coastline with the period of 1 to 2 days (Nakamura and Horikawa, 1977). The current amplitude is about 10 to 30 cm/sec and the current pattern is rather rectangular instead of sinusoidal. Such fairly long period waves may cause the alternating patterns of isotherms, that is from Type 1 to Type 2, and vice versa. At the present stage our collected data are still not enough to define the long period oscillations. The continental shelf wave may be one of the possible waves.

Fig.17 Dispersion coefficient versus scale of diffusion.

Fig. 18 Classification of three types of thermal plume at the Fukushima Nuclear Power Plant No. 1.

Fig. 19 Surface isotherms obtained by infrared scanner.

CHARACTERISTICS OF ISOTHERMS

The infrared photograph must be one of the most effective measures for surveying the surface water temperature distribution in a wide area. Figure 19 shows a part of results obtained by analyzing the infrared photographic image which was taken from the altitude of 1200 m above the sea level. The cloud of heated water extended southerly as far as 4.6 km from the outlet of the power station, and was confined within a certain strip of nearshore zone, whose width was about 600 m. The last fact is quite interesting and raises up a question why such a phenomenon was observed. One possible explanation is the existence of a turbulent boundary layer phenomena appeared in parallel to the coastline. Outside the boundary layer, that is in the offshore region, the diffusion is normally very weak, but inside the boundary layer the turbulent mixing is predominant. In order to clarify the above concept it is necessary to carry out the long-term simultaneous measurement of current velocities at various locations on a line perpendicular to the shoreline.

Let us look at the detailed structure of isotherms, from which pulsation patterns of isotherms are observed. To explain such phenomena, we may be able to point out the following factors. These are (1) the oscillation of water surface in the harbor basin, (2) the oscillatory pump regulation for supplying a constant amount of cooling water, (3) the undulatory internal jump formed just outside of the outlet, and (4) an alongshore long period oscillation in the nearshore area. The alongshore distance between two successive isotherm fronts at 22.7°C is evaluated as about 800 m. Here we will assume the front speed being 60 cm/sec which gives a rather moderate value. Then the period of pulsation is estimated to be about 22 min, which is approximately equal to the observed natural oscillation period of harbor basin.

In order to investigate more fine structure of temperature distribution, the closed up view of isotherms is shown in Fig.20. From this diagram we can see really complicated patterns caused by the interference between the jet flow and the nearshore currents, especially the rip currents.

By using these data, we drew in Fig.21 a diagram which shows the functional relationship between the relative temperature difference $(T - T_a) / (T_0 - T_a)$ and the area A covered by the isotherm of a specified temperature T . Here T_0 is the temperature at the outlet, and T_a at the ambient water. Table 3 illustrates the oceanographical and meteorological conditions under which these data were obtained. Figure 21 indicates that the area within the isotherms generally increases exponentially with decreasing relative temperature difference; that is

$$A = k_1 \exp(-k_2 T_r) \quad (2)$$

in which k_1 and k_2 are constants. In general the constants k_1 and k_2 must be a function of heated water discharge. The covered area for +1°C isotherm obtained by using the present relationship seems to be larger than that predicted by the Wada model. In order to get a more precise family of

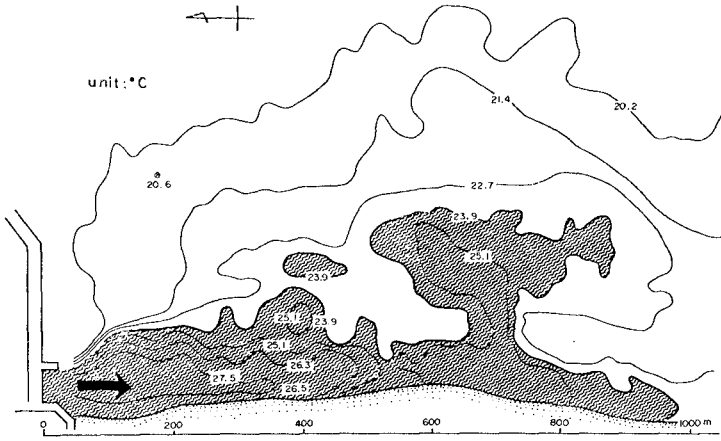

Fig.20 Surface isotherms in the vicinity of power plant showing the effects of nearshore current.

* Measured clockwise from the east.

prediction curves, we have to accumulate more data under the various conditions of discharge. We evaluated the alongshore distance of the isotherm front under some appropriate assumptions by following the treatment of Csanady (1970) and obtained the value of 4 km which is fairly close to the actual distance of 4.6 km. The detail of the above computation will be given in Appendix of this paper.

CONCLUSION

Although the present investigations on heated water dispersion are only the preliminary ones, the observation data and the analyzed results seem to be quite valuable to get an insight into the real phenomena of heated water mixing in the nearshore area. The main conclusions are :

(1) The jet flow characteristics are expressed well by the two dimensional turbulent jet flow model.

(2) The jet flow direction and the alongshore temperature distribution are strongly influenced by the cusped configuration formed under the interference between the jet flow and nearshore currents.

(3) The eddy coefficient of jet flow was evaluated by using the jet flow characteristics. While the diffusion coefficient in the nearshore current region was evaluated by using the dye diffusion patterns.

(4) The detailed discussion on isotherm patterns was made from the various view points.

(5) A functional relationship between the relative temperature difference and the area covered by the specified isotherm was presented.

ACKNOWLEDGEMENTS

The present investigation was partly supported by the Scientific Research Fund of the Ministry of Education in Japan. The writers are deeply indebted to the personnel of the Coastal Engineering Laboratory, University of Tokyo, and of the Nearshore Environmental Research Center for accomplishing the field observations. The writers' thanks are also due to the people at the Tokyo Electric Power Company, who kindly forgave the writers' group to carry out the present investigations.

< APPENDIX >

A COASTAL ENTRAPMENT MODEL OF HEATED WATER

In order to formulate the present phenomena, the following assumptions are made (see Fig.A) :

- (1) Steady state Phenomena,
- (2) Line source of heated water discharge,
- (3) Diffusion coefficient in y direction K_y being independent of y ,
- (4) Uniform water depth, and
- (5) Diffusion coefficient in x direction K_x being negligible,

Fig. A Definition sketch.

Hence the basic equation is given by

$$U \frac{\partial T_{*}}{\partial x} = K_y \frac{\partial^2 T_{*}}{\partial y^2} \quad (1)$$

where $T_{*} = (T - T_a) / (T_0 - T_a)$, x and y are the axes taking along and perpendicular to the shoreline as shown in Fig.A, and U the uniform coastal current velocity. The boundary conditions are

$$T_{*} = \begin{cases} T_{*0}, & \text{at } x=0 \text{ and } b \geq y \geq -b \\ 0, & \text{at } x=0 \text{ and } |y| > b \end{cases} \quad (2)$$

Considering the condition of $x = Ut$, we can express the diffusion coefficient K_y by the next equation

$$K_y = \frac{1}{2} \frac{d\sigma_y^2}{dt} = \frac{U}{2} \frac{d\sigma_y^2}{dx} \quad (3)$$

where σ_y^2 is the variance in y direction. Then the solution of Eq.(1) is given by

$$\begin{aligned} T_{*}(x, y) &= \frac{T_{*0}}{\sqrt{2\pi} \sigma_y} \int_{-b}^b \exp\left\{-\frac{(y-y')^2}{2\sigma_y^2}\right\} dy' \\ &= \frac{T_{*0}}{2} \left[\operatorname{erf}\left(\frac{b-y}{\sqrt{2}\sigma_y}\right) + \operatorname{erf}\left(\frac{b+y}{\sqrt{2}\sigma_y}\right) \right] \end{aligned} \quad (4)$$

where T_{*0} is the initial temperature as shown in Fig.A.

On the basis of the two-dimensional jet flow, we assume

$$\sigma_y = p x \quad (5)$$

where p is an appropriate constant. Therefore Eq.(4) is rewritten as follows ;

$$T_{*}(x, y) = \frac{T_{*0}}{2} \left[\operatorname{erf}\left(\frac{b-y}{\sqrt{2} p x}\right) + \operatorname{erf}\left(\frac{b+y}{\sqrt{2} p x}\right) \right] \quad (6)$$

The relative temperature difference at the shoreline $y=0$, T_{*s} , is expressed by

$$\begin{aligned} T_{*s}(x) &= T_{*}(x, 0) = T_{*0} \operatorname{erf}\left(\frac{b}{\sqrt{2} p x}\right) \\ &\xrightarrow{x \rightarrow \infty} \frac{\sqrt{2}}{\pi} \frac{b}{p x} \end{aligned} \quad (7)$$

Given conditions for the present case are $b=30$, $T = 27.9^{\circ}\text{C}$, $T = 19.7^{\circ}\text{C}$, $T = 20.2^{\circ}\text{C}$, and the value of p is assumed to be 0.1 referring the value for lakes given by Csanady (1970). Therefore

$$T_{*s} = (20.2 - 19.7) / (27.9 - 19.7) = 0.06$$

$$x = \frac{\sqrt{2}}{\pi} \frac{b}{p} \frac{1}{T_{*s}} = \frac{\sqrt{2}}{3.14} \frac{30}{0.1 \times 0.06} \approx 4000 \text{ m} = 4 \text{ km}$$

The p value seems to vary depending on the discharge of heated water.

OUTFALL DIFFUSION MODELS FOR THE COASTAL ZONE

D. C. L. Lam and C. R. Murthy

Applied Research Division, National Water Research Institute,
Canada Centre for Inland Waters, Burlington, Ontario, Canada

Abstract Two approaches for developing outfall diffusion models for the coastal zone are discussed. The statistical model combines a simple Gaussian analysis with the time-series records of flow measurements to elucidate the dispersion patterns in a shore-parallel, a current-reversal, and stagnation flow regimes. The deterministic model explores the more complex characteristics of a plume in an advection-dominant situation. The cases of Fickian diffusion, shear diffusion, and inertial subrange hypothesis are studied. It is shown that a previously derived semi-empirical relationship produces an agreement at least as good as the optimized results of these theoretical models. These models are quite useful for site specific evaluation of potential continuous discharges of effluents into the coastal zone.

INTRODUCTION

The recent increase of industrial and energy development in the Great Lakes basins has created considerable concern in the capability of the coastal waters as intermediate buffer zones for receiving the waste effluents and subsequent mixing of the materials with offshore waters. The physical dynamics of the transport and dispersion mechanics in these zones are complex. At the present stage, the existing knowledge has largely been drawn from long term observational research programs conducted in the lake environment. The direct application of this information for site specific evaluation must require indepth interpolation and further tests for generality. One approach to explore the observational results is to develop deterministic and stochastic models, incorporating the empirical results.

The environmental data base has been established at our institute for the past ten years, and consists of statistical and climatological summaries of currents, temperature, diffusion parameters in several coastal sites of the Great Lakes. The flow regimes are fundamental in defining the types of dynamics encountered in this coastal area. The temperature data provide information about upwelling and downwelling episodes, internal wave characteristics and thermal plume structure near outfalls. The dye diffusion data have resulted in a series of eddy diffusion diagrams which relate the turbulent diffusion coefficients to the plume properties. This provides the background information to develop a package of computer programs designed to have a certain degree of predictive capability of the transport and dispersion characteristics for the nearfield and farfield zones. Recognizing the need for generality and flexibility in such a package, we have developed a number of models which can be applicable for different site situations and management problems. This paper describes two examples of these. While

both of them are designed for simulating the transport and dispersion of a conservative substance, they can be extended to include the simple decay or growth kinetics of nonconservative substances.

STATISTICAL MODEL

Strong shore-parallel currents within a few kilometres from the coast dominate organized flow patterns in the Great Lakes. These currents are of practical concern owing to their capability to transport pollutants introduced at the shoreline. Under conditions of steady shore-parallel currents, a continuous pollutant source located within the coastal zone would result in a quasi-steady state plume. Mean concentration distributions constructed from repeated instantaneous concentration profiles of a steady state plume approximates a Gaussian distribution (see Figure 1). For this reason, Gaussian diffusion models have been extensively used for quantitative modeling and dilution estimates of continuous effluent plumes.

Gross estimates of diffusion of effluent sources at a particular site can frequently be made by judicious application of coastal zone climatological data. These climatological data include statistical summaries of coastal currents and dispersal processes and are considered to be representative of the site in question.

In order to develop a statistical model, we have integrated the coastal zone climatology with a steady state Gaussian plume model following the approach of "air pollution" meteorology to estimate probable concentration of pollutants discharging from industrial stacks.

A depth integrated two dimensional cross-plume Gaussian distribution of concentration forms the basis of our calculations,

$$\bar{\chi}(x,y) = \frac{q}{2\sqrt{2\pi}\sigma_y hU} \text{Exp}\left(-\frac{y^2}{2\sigma_y^2}\right) \quad (1)$$

where

- x = direction of the mean current, U
- y = perpendicular to the mean current
- q = source strength
- σ_y = cross-plume standard deviation, related to eddy diffusivity $K_y = \sigma_y^2/2t$
- t = x/U
- h = depth of water

Introducing $q = \chi_s D$ (χ_s is source concentration and D is source discharge rate), a dilution factor $\eta = \frac{\bar{\chi}}{\chi_s}$ can be defined. From (1)

Figure 1: Gaussian Profile vs Observed Profile

Figure 2: Simulated Results for a Shore-Parallel Current Regime

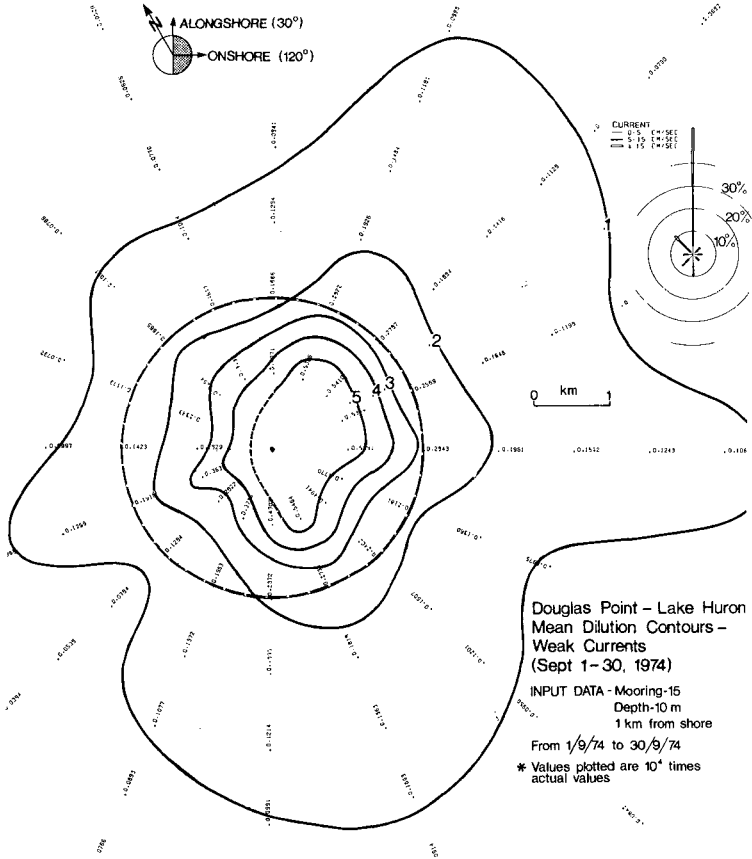

Figure 4: Simulated Results for a Weak Current Regime

we have

$$\eta = \frac{D}{2\sqrt{2}\pi\sigma_y hU} \text{Exp}\left(-\frac{y^2}{2\sigma_y^2}\right) \quad (2)$$

Under steady state conditions, the key parameters controlling the dilution ratio are (1) the mean current U and, (2) the eddy diffusivity K_y .

Over a period of time, the direction of the coastal current shifts. The current rose, which gives the joint current speed and direction frequency distribution, is a useful indicator of the flow characteristics. We will calculate the mean dilution over a period that is very long compared with that over which the mean current is computed.

To estimate cross-plume eddy diffusivity, we fall back on experimental data obtained from extensive dye plume diffusion experiments in the coastal zone of the Great Lakes (Murthy and Kenney, 1974).

An integrated computer program was developed incorporating the coastal current climatology data to the steady state Gaussian plume model given by Eq. (2).

Coastal climatological data on currents were divided into "episodes" describing the general characteristics of the flow such as (1) steady shore-parallel currents, (2) steady shore-parallel currents followed by frequent current reversals, etc. These "episodes" generally range from a few days to a month.

Using this model we have calculated mean dilution contours for two typical climatological "episodes" for the Douglas Point region in Lake Huron where a large nuclear power complex is currently under construction. Figure 2 shows a typical plot of mean dilution contours calculated for a shore-parallel current regime. Figure 3 on the other hand is for a case where the currents reversed quite frequently but essentially maintained a shore-parallel current regime (bimodal character). Figure 4 shows a case of weak currents interspersed between shore-parallel currents.

DETERMINISTIC MODELS

The simple Gaussian model as given by Eq. (1) represents a first order approximation of the cross-plume distribution of mean concentration. It corresponds to the simplest form of deterministic models namely the Fickian diffusion model, in which the eddy diffusivity is assumed to be a constant. While this simplification makes the statistical evaluation of the mean distribution quite practical, some of the more complex characteristics of a quasi-steady state plume cannot be simulated. There exists in the literature (e.g., Okubo, 1971) a number of turbulence models which relate the eddy diffusivity to the mean concentration itself, and are purported to include the effect of the

growth of the eddy size. In general, the cross-plume eddy diffusivity, K_y , in these models can be expressed in the following form,

$$K_y = c \sigma_y^n \tag{3}$$

$$\sigma_y = \left\{ \int_{-\infty}^{\infty} \bar{x}y^2 dy / \int_{-\infty}^{\infty} \bar{x} dy \right\}^{1/2} \tag{4}$$

where n and c are constants or parameters of the model, and σ_y is the cross-plume standard deviation. For certain choices of the constants n and c , the eddy diffusivity, K_y , as given by Eq. (3) has a specific meaning. Table 1 summarizes their theoretical significance.

n	c	Diffusion Law	Diffusion Parameters	Diffusion Model
0	$c \sim K_a$	$K_y = K_a$	K_a , Apparent Diffusivity	Fickian Diffusion
1	$c \sim q_s$	$K_y \sim q_s y$	q_s , Diffusion Velocity	Shear Diffusion
4/3	$c \sim \epsilon^{1/3}$	$K_y \sim \epsilon^{1/3} y^{4/3}$	ϵ , Energy Dissipation Parameter	Inertial Surbrange Diffusion

Table 1. Theoretical Significance of the Constants n and c

By means of statistical analysis of large volumes of ocean and lake dye diffusion data, Okubo (1971) and Murthy and Kenney (1974) have concluded that the actual environment does not always conform to any one of these theoretical models. For example, for the Great Lakes, the following semi-empirical seems to be more appropriate, (Murthy and Kenney (1974)).

$$K_y = .075 \sigma_y^{1.2} \tag{5}$$

During the period of 1972-1973, a new set of dye diffusion measurements were conducted in Lake Ontario. The information obtained from these measurements has not been included in the statistical analysis for estimating the diffusion law given in Eq. (5). Hence, this set of data serves the purpose as an independent check on the semi-empirical relationship as given in Eq. (5). In order to compare the effect of using the semi-empirical law and that of using the theoretical models in Table 1, a deterministic approach has been adopted. In this approach, as a contrast to the statistical analysis in Murthy and Kenney (1974), a numerical solution is sought for the steady state two-dimensional advection-diffusion equation,

$$U \frac{\partial \bar{X}}{\partial x} + V \frac{\partial \bar{X}}{\partial y} = \frac{\partial}{\partial x} (K_x \frac{\partial \bar{X}}{\partial x}) + \frac{\partial}{\partial y} (K_y \frac{\partial \bar{X}}{\partial y}) \tag{6}$$

where U and V are the mean flow velocities. To limit the scope of this analysis and to reduce the dimensionality, we have purposely selected one particular set of experiments in which the flow is predominantly shore-parallel and reasonably steady. This simplifies Eq. (6) to

$$U \frac{\partial \bar{\chi}}{\partial x} = \frac{\partial}{\partial y} (K_y \frac{\partial \bar{\chi}}{\partial y}) \quad (7)$$

because the mean flow can be aligned with the x coordinate (down-stream direction) so that the cross-plume velocity, V , and the diffusivity, K_x , can be omitted in the presence of the strong advection term in the x -direction on the left hand side of the equation.

To accommodate different models for K_y , and to avoid numerical dispersion (Lam, 1976), Eq. (6) is solved by an implicit finite difference scheme. In this scheme, the x -coordinate is identified as the marching direction, analogous to the time-coordinate in the simple heat conduction equation, so that the conventional Crank-Nicolson (central differencing) scheme can be used to update the cross-plume concentration for each increment of Δx in that direction. For the nonlinear forms of the eddy diffusivity in Eq. (3), i.e., for the cases in which $n \neq 0$, each update step will involve an internal iterative procedure. Specifically, for a fixed value of x , the standard deviation, σ_y , as defined in Eq. (4) is calculated numerically by using the known values of $\bar{\chi}$ along the y -direction. This value of σ_y will then prevail in the cross-plume direction at this value of x .

To proceed to the next interval at $x+\Delta x$, a new σ_y is needed, and is approximated by an appropriate guess. This guess will give rise to a solution of $\bar{\chi}$ at $x+\Delta x$ by the Crank-Nicolson procedure. Then, a new guess of σ_y is made by substituting this $\bar{\chi}$ into Eq. (4).

The process can be repeated iteratively, until some degree of consistence is reached between $\bar{\chi}$ and σ_y . It must be pointed out that under certain assumptions, such as constant flow velocity, it is possible to express σ_y in terms of the independent variable x or other length scales, so that the iteration procedure may not be necessary. However, Okubo (1976) has demonstrated the danger of applying such simplification, which may result in an eddy diffusion almost an order of magnitude too high.

Figure 5 shows the locations of the three measured profiles during an experiment conducted in Lake Ontario on June 16, 1972 (Murthy and Miners, 1977). Each of the profiles has been sampled several times in the cross-plume direction and at three different depths of 1m, 3m, and 6m beneath the water surface. To simplify the computation, these profiles have been averaged horizontally and also integrated vertically to provide the observational mean values, χ_0 , of concentration. In particular, the profile at the section ($x = 280$ m) close to the outfall is used as the initial condition for Eq. (7). The remaining two profiles are used to establish the least-square error, E , between the observed value χ_0 and the computed value $\bar{\chi}$,

Figure 5: Locations of Measured Profiles

$$\text{i.e., } E = \sum_{x=790\text{m}} \{ \bar{\chi}_o(x,y) - \bar{\chi}(x,y) \}^2 + \sum_{x=1260\text{m}} \{ \bar{\chi}_o(x,y) - \bar{\chi}(x,y) \}^2 \quad (8)$$

For a given choice of n in Eq. (3), it is possible to choose an optimal value of c so that the least-square error is a minimum, i.e., $E = E_{\min}$. There are many computational techniques for solving this optimization problem. We have used the conjugate direction method (Powell, 1964) and the quasi-Newton method (Spath, 1967). Both of these methods gave practically the same results. Table 2 summarizes the results for the different cases of n . Instead of providing the optimized values of c in each case, we have calculated the corresponding diffusion parameters as explained in Table 1 by eliminating the proportionality constants in c (Okubo 1971) so that they can be compared directly to the measured range of these parameters. We have also included the least-square error associated with the computed results of the semi-empirical relationship, Eq. (5), in which case optimization is not necessary since both n and c are given.

From Table 2, based on the least-square errors, it can be seen that the semi-empirical model appears to produce the best fit to this particular set of data, and the constant diffusivity gives the worst case.

n	Diffusion Law	Diffusion Model	Optimized Diffusion Parameters	Observed Range (Ocean and Lake Data) (Okubo 1971, Sullivan 1971)	E or E_{min} (Errors as defined in Eq. (8))
0	$K_y = K_a$	Fickian Diffusion	Apparent Diffusivity $K_a = 5.9 \times 10^3 \text{ cm}^2/\text{s}$	$10^3 - 10^5 \text{ cm}^2/\text{s}$	1138 (E_{min})
1	$K_y \sim q_s \sigma_y$	Shear Diffusion	Diffusion Velocity $q_s = 0.32 \text{ cm/s}$.1 - .5 cm/s	995 (E_{min})
4/3	$K_y \propto \epsilon^{1/3} \sigma_y^{4/3}$	Inertial Subrange Diffusion	Energy Dissipation $\epsilon = 3. \times 10^{-3} \text{ cm}^2/\text{s}^3$	$2 \times 10^{-3} - 5 \times 10^{-3} \text{ cm}^2/\text{s}^3$	974 (E_{min})
1.2	$K_y = 1.2 \cdot .075 \sigma_y$	Semi-Empirical Model	-	-	958 (E)

Table 2: Comparison of Optimized Diffusion Parameters and their Observed Range

However, it must be emphasized that such comparison of E_{min} does not lead to a more definite conclusion, nor can it be used to discriminate models. Rather, the optimization procedures are merely used here as a tool to search for the best solution for each case of diffusion models. Indeed, the fact that the optimized diffusion parameters are within the range of the observed range shows that each of these theories can be applicable to the set of observations, provided that the values of c are chosen correctly. Since we have used equally successfully the semi-empirical relationship without any further adjustment of the value of c , we consider this quite a remarkable result in the verification of the semi-empirical law.

Figure 6 shows the computed profiles of using this law and other models as compared to the observed data. Figure 7 shows the centre line of the plume as computed by different models. The nonlinear models including that of Eq. (5) give practically the same kind of agreement with the data, whereas the constant diffusivity result, though quite acceptable, is not as accurate. This is consistent with the results in Table 2..

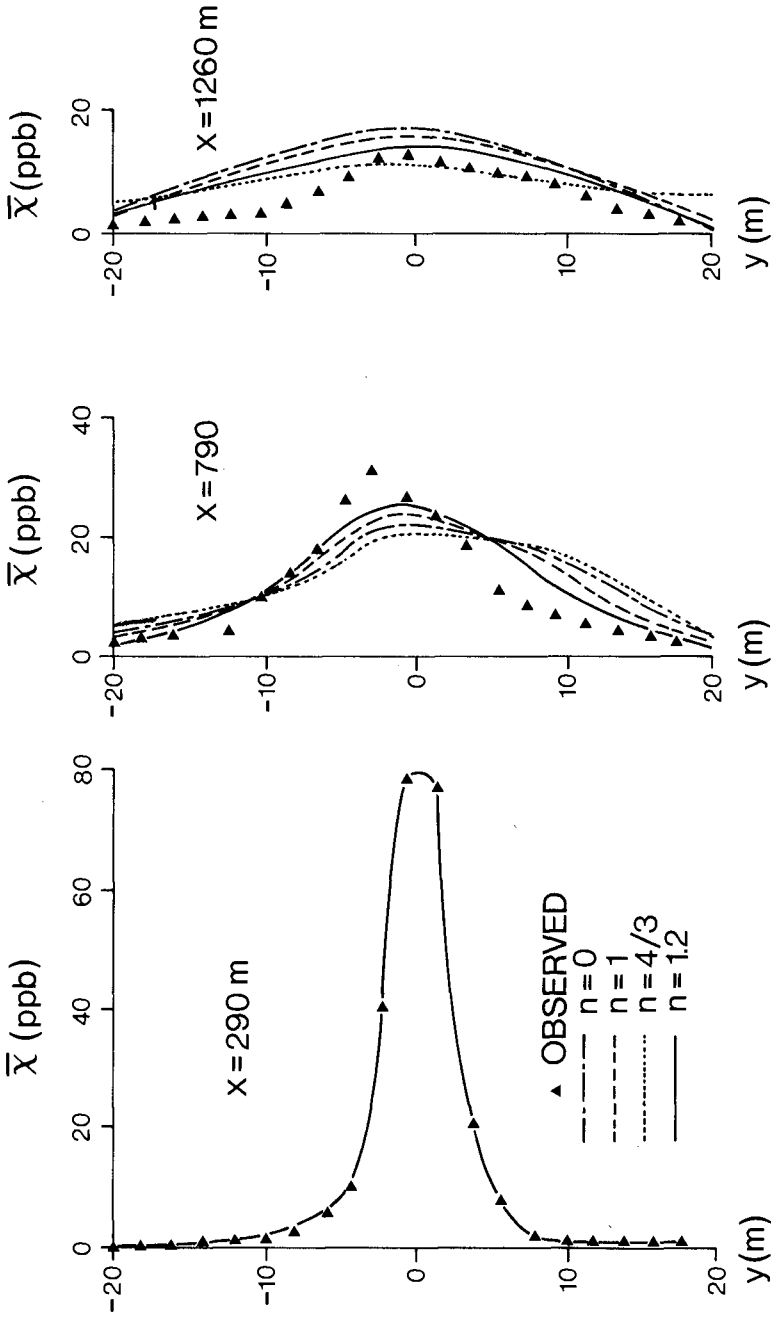

Figure 6: Computed and Observed Cross-Plume Profiles. The lines ($n = 0, 1, 4/3, 1.2$) represent computed results and the triangles represent the observed data.

The symbols are the same as in Figure 6.

CONCLUSION

It has been demonstrated that it is possible to use a simple Gaussian statistical model for making first order estimates of the distribution of the mean concentration near an outfall in the far-field for different coastal flow regimes. A more rigorous examination of the second-order effects by means of numerical modeling and optimization methods reveals that the previously derived semi-empirical relationship produces at

least equally acceptable results as some of the well-tuned, nonlinear, theoretical models. Further analysis on a larger set of observed data and more general flow conditions is needed to establish the applicability and limitation of these models. This is being done at the National Water Research Institute, Canada, as part of an ongoing project to develop simulation models for the coastal zone systems.

CHAPTER 157

LARGE SCALE TURBULENCE IN TIDAL CURRENTS

by John B. Hinwood¹

1. INTRODUCTION

Aerial photographs of tidal inlets sometimes show an orderly pattern of large eddies or cells aligned in long rows along the mean streamlines. The cells have only been observed where the velocity is high and have not been observed during strong winds. The observations of cells are described but their complete structure and origin are not yet known, however it has been established that density variations are not a factor.

2. OBSERVATIONS OF CELLS

Occurrence of Cells: The initial observation of the cells was made in Western Port, a large tidal inlet near Melbourne, Australia. Fig. 1 is taken from a colour transparency made by Pollock in 1973 and shows a 200 m × 300 m section of the channel in Western Port, completely occupied by cells. In this case the wind speed was less than 3 km/hr and was just sufficient to ruffle the water surface after a fetch of about 4 m. The cells are visible in the photograph because of the contrast between the unruffled water rising at the centre of the cells and the darker ruffled water descending at the edges of the cells. Individual cells could be followed for as long as 30 minutes.

Other tidal inlets where the same type of pattern has been found on aerial photographs are Delaware Bay, U.S.A. and Corner Inlet, Lakes Entrance, and Port Phillip, all near Melbourne.

In the last case the cells are visible because the rising columns of water entrain fine sand from the bed which settles out as this water flows outwards towards the descending edges of the cells.

At the location shown in Fig. 1, cells have been observed on about 10 occasions and have been shown not to be present on about the same number. In Port Phillip there have been 5 observations of cells in 20 sets of observations. The frequency of success in these observations was biased by making the later observations at supposedly favourable times. While the occurrence of cells cannot yet be predicted, they have only been observed around the times of peak ebb or flood current, usually near spring tide, and never in current velocities less than 0.8 m/s. They have not been observed under windy conditions.

Monash University, Melbourne, Australia

In the absence of natural indicators the presence of cells may be shown by dye traces, and this has been done in most of the observations described here. More importantly the dye traces reveal details of the flow field.

Fig. 1 Aerial Photograph of Cells and Dye Trace (black) in Western Port

Size of Cells: The cells observed in Western Port were in a region of the channel in North Arm, where the water depth ranges from 14 to 18 m and averages 16 m. The typical width of the largest cells measured on Fig. 1 was 20 m. The cell length was much less regular, and was about one to two times the cell width.

In Port Phillip the cells observed in the flow around the northern end of Swan Island were measured. The sea bed slopes smoothly up towards the island, and the flow was of uniform speed and was more or less parallel to the depth contours. The cell width increased from 3.5 m to 14 m as the depth increased from 4 m to 9 m.

3. ORIGIN OF THE CELLS

Density stratification has been eliminated as a possible mechanism as detailed measurement has shown no stratification in Western Port and Port Phillip near Swan Island. Vertical profiles of temperature and salinity were measured using a Hamon T/S meter reading to 0.1°C and 0.01‰. Additional surface readings were taken in a bucket which was carefully filled from the top centimeter of the water. Differences in temperature and salinity over the depth were less than the limit of reading.

The cells have not been observed in strong wind and have been observed in calm conditions. Furthermore the cells shown in Fig. 1 distorted rapidly when a light cross-wind sprang up, and lost their regular alignment in rows.

The possibility of wave/current interactions can also be eliminated. Cells forming on the ebb tide, inside the bays under calm conditions are not subject to either ocean waves or local wind chop. In several cases local wind chop appears on the photographs at an angle to the cells and with a much smaller wave length.

At bends in a canal or river, a secondary flow is produced, and may persist downstream as a helix with its axis parallel to the direction of flow.

The observations of cells near Swan Island were in curvilinear flow, but those in Western Port were in a long straight reach of channel. Nevertheless, the influence of a distant upstream bend might have persisted, and it is not possible to eliminate this mechanism as a possibility.

The interaction between the flow and the bed forms is another possible mechanism. There are 2 m dunes both upstream and downstream of the area shown in Fig. 1, although the area itself has a plane bed, and there are sand waves in Port Phillip. In the lee of a dune there is a flow separation which may become unstable producing weak vortices with axes aligned parallel to the flow. Nakagawa and Hinwood [1] discuss this mechanism further, but do not explain how the vortices transform into cells.

The analyses of flow over a wavy bed by Kennedy [2] and later workers have shown that a secondary flow is generated above a wavy bed. The three dimensional cellular flow would be the result of an array of dunes with crests parallel to the flow combined with an array perpendicular to the flow.

Side-Scan sonar traces were made of the sea bed in Western Port [3]. These traces did not show any marked variations in dune height in the transverse direction but did show dunes with crests perpendicular to the flow upstream of the zone of cellular flow. There must remain a possibility that these dunes are producing a secondary flow which gives rise to the cellular flow further downstream.

4. CONSEQUENCES OF CELLULAR FLOW

Over length scales smaller than a few cell dimensions, processes dependent upon turbulent transport will be affected by the discrete, and not continuous, nature of the turbulence. At greater length scales, the sum of effects of many discrete steps is indistinguishable from the effects of continuous processes.

In particular, the lateral mixing of a passive pollutant will approximate a binomial distribution after spreading over a few cell dimensions, but tends towards a normal distribution after spreading over many. At very small scales, the pollutant will be moved by the cellular eddies with very little mixing as shown in Fig. 1. Hence near the source higher peak pollutant concentrations are possible in a cellular flow.

For vertical transport of pollutant or momentum, the mixing length model of turbulence appears to be justified with a mixing length equal to the cell height — i.e. the total depth. Conditions very near the bed are likely to be dominated by the smaller inter-cellular scales and would require a different approach.

5. CONCLUSIONS

A highly ordered — "cellular" — structure of turbulence has been observed in strong tidal currents. The cell dimensions are in the order of the water depth and velocities about one-tenth those of the main current. The origin of the cells is not known, but cannot be attributed to density variations or to wind, and indeed wind disrupts the pattern.

The existence of the cells suggests that mixing could be described by a mixing length model using the typical cell dimensions. Near a source discharging into the flow, peak concentrations would be high, but far from the source the effects of action by many cells is likely to produce concentration patterns indistinguishable from those in other kinds of flow.

CHAPTER 158

3-D CURRENT MODEL WITH DEPTH VARYING EDDY VISCOSITY

by

Bryan R. Pearce¹, Cortis Cooper², and Susan Nelson³

Introduction

The ability to quickly and accurately predict the three dimensional velocity field in a water body of variable lateral and vertical extent remains elusive. Yet the practical need for a predictive model has become more pressing due in part to increased public concern for the environment and the expanded search for offshore resources. For example, a 3-D⁴ velocity model could serve as the basis for predicting storm-induced current forces on offshore oil-production platforms.

Another application for 3-D circulation models is in the area of pollution control and in particular in predicting the trajectory of a surface pollutant such as oil. The state-of-the-art for predicting the advection of oil slicks is the "fixed wind factor" approach. The method consists of simply taking the center of mass movement to be a fixed percentage of the wind speed. When the factor is taken as 3%, as is commonly done, the procedure is known as the "3% rule". The Coriolis "force" is sometimes accounted for by deflecting the surface current a constant angle to the right of the wind velocity. This angle is the deflection angle.

Oil spill modelers usually justify the fixed wind factor approach by referencing a number of previous field and laboratory studies investigating the wind factor. Stolzenbach et al. (1977) compiled the results of the most often quoted experiments (Table 1). Note that the supposedly constant wind factor varies by a factor of five between investigators and that large variations occur even within an individual data set as shown by the standard deviations in Table 1.

Ekman (1905) was one of the first to effectively address the problem of modeling the vertical structure of the horizontal velocities. One of his simplest models considers wind-induced drift only and is derived by simplifying the Navier-Stokes Equations to achieve a balance between the Coriolis "force" and the frictional force between water layers. The solution to the Ekman problem is:

$$u = V_0 e^{-(\pi/D)z} \cos\left(\frac{\pi}{4} - \left(\frac{\pi}{D}\right)z\right)$$

$$v = V_0 e^{-(\pi/D)z} \sin\left(\frac{\pi}{4} - \left(\frac{\pi}{D}\right)z\right) \quad (1)$$

$$D = \pi \sqrt{\frac{2N_v}{f}} \quad (2)$$

$$V_0 = \frac{\tau_{sy}}{\rho N_v a} \quad \text{and} \quad (3)$$

N_v = the vertical eddy viscosity coefficient

$$a = \sqrt{\frac{f}{N_v}}$$

and where z, u, v, τ_{sx} and τ_{sy} are defined in Figure 1

At $z = D$, the depth of frictional influence, it can be seen from Equations 1 that the velocity has been reduced to 1/23 of V_0 . The result of plotting Equations 1 is the classic Ekman "spiral". For infinitely deep water the surface current is aligned at 45° to the right of the wind.

For the case of finite depth Ekman carried out a similar analysis. In general, the "shallow water" solution will yield surface currents of both less magnitude and deflection than the infinitely deep case. However, for the case when the water depth is greater than 1/2 the frictional depth, the surface current no longer "feels" the effect of the bottom and behaves as if the water were "deep".

There are several characteristics of the Ekman approach which are unrealistic. For example, the Ekman-type solution predicts a deflection angle of 45° in deep water. Yet, as Madsen (1977) points out, surface drift experiments (Table 1) indicate the deflection angle to be much smaller (of the order 10°). Most of these experiments were performed in relatively shallow water and hence one might argue that the surface deflection would have been reduced due to the influence of the bottom. This does not appear to be the case. For example, consider the field experiment performed by Teeson et al. (1970). It is possible to establish the extent of bottom influence for these experiments if some value for the vertical eddy viscosity is specified. Since the value of N_v is not well known, it will be assumed that the 3% rule is roughly correct. This assumption allows an approximate evaluation of the vertical eddy viscosity using Equation 3. Plugging this value for N_v into Equation 2 yields a frictional depth for Teeson's experiments of

approximately 20 meters. Hence for the bottom to have significantly effected the surface current in Teeson's experiments, the water depth would have had to have been about 10m or less. In fact, Teeson's experiments were performed in water depths well above that -- in the range of 20 to 30 meters. Unsteady effects were also examined and rejected as the cause for the discrepancies (Cooper and Pearce(1977)). To understand why Ekman's Model apparently yields deflection angles which are too high, examine the assumption that the vertical eddy viscosity is constant in the vertical.

Ekman used the laminar analogy to write the interfacial frictional stresses as a function of the turbulent eddy viscosity coefficient, N_v , which in terms of the turbulent component of the velocities can be written as:

$$\begin{aligned}\tau_{xz} &= -\rho \overline{u'w'} = \rho N_v \frac{\partial u}{\partial z} \\ \tau_{yz} &= -\rho \overline{v'w'} = \rho N_v \frac{\partial v}{\partial z}\end{aligned}\quad (4)$$

where u' , v' , and w' are the turbulent components of the velocity in the x, y, and z direction respectively, (see Figure (1)).

It is clear that w' will be zero near a solid boundary and since $\partial u/\partial z$ (or $\partial v/\partial z$) will, in general, not be zero near a boundary, it follows from Equations 4 that N_v must be zero near that boundary. It is concluded that a realistic variation for N_v would be a shape with N_v near zero at the surface and the bottom and a maximum somewhere in between.

The above argument can be partially substantiated when one examines the effect of including a varying vertical eddy viscosity in the Ekman-type formulation. Madsen (1977) solved an unsteady form of the Ekman formulation. He assumed the vertical eddy viscosity to be zero at the surface and to increase linearly with depth. For steady state, his results indicate a deflection angle of approximately 10° at the surface-- a value consistent with the field observations in Table 1. Other aspects of Madsen's Model remain comparatively similar to Ekman's Model including the magnitude of the surface current and the total mass flux.

Another situation in which a vertical variation of the eddy viscosity results in more realistic flow patterns is for the case of flow in an infinitely long channel of finite depth with a wind blowing in the axial direction (i.e. 1-Dimensional flow). For this situation, an analytic solution assuming a constant vertical eddy viscosity yields a linear velocity profile. If instead, it is assumed that N_v varies parabolically (zero at the surface and the bottom) then the solution for the velocity is a logarithmic profile near the surface and the bottom. Intuitively this latter solution seems much more correct, since one would expect the velocity to exhibit a logarithmic profile near the surface and the bottom. This intuition is substantiated by laboratory experiments performed by Shemdin (1972).

Figure 2: Plot of Prescribed Functions vs. Depth

Figure 3: Functional Form for the Vertical Variation of N_v

Figure 1: Definition of Variables Used in the Model

It is concluded that in order to realistically model the velocity profile, a vertical variation in the vertical eddy viscosity should be incorporated into a realistic 3-D model. Several modelers in the past, besides Madsen, have included a vertical variation in N_v .

Heaps (1972, 1974) has recently developed numerical models using a weighted residual technique. The outstanding features of these models include: (1) a relatively simple formulation, 2) reasonable computer-time requirements, and 3) a continuous functional form for the velocity profile.

Model Formulation

Thus, the modeling approach chosen by the authors has been to develop a 3-D model utilizing the Galerkin technique and incorporating a varying vertical eddy viscosity. The model is based upon the 3-D Momentum Equations with the following simplifying assumptions: i) vertical velocities are neglected and, ii) the laminar analogy is incorporated thus allowing the expression of the turbulent shear stresses in terms of the eddy coefficients. Thus the Momentum Equations become:

$$\begin{aligned} \frac{du}{dt} &= -g \frac{\partial \eta}{\partial x} + fv + \frac{\partial}{\partial x} (N_H \frac{\partial u}{\partial x}) + \frac{\partial}{\partial y} (N_H \frac{\partial u}{\partial y}) + \frac{\partial}{\partial z} (N_v \frac{\partial u}{\partial z}) \\ &\quad - \frac{1}{\rho} \frac{\partial P_a}{\partial x} - \frac{g}{\rho} \int_0^z \frac{\partial \rho}{\partial x} d\zeta \\ \frac{dv}{dt} &= -g \frac{\partial \eta}{\partial y} - fu + \frac{\partial}{\partial x} (N_H \frac{\partial v}{\partial x}) + \frac{\partial}{\partial y} (N_H \frac{\partial v}{\partial y}) + \frac{\partial}{\partial z} (N_v \frac{\partial v}{\partial z}) \\ &\quad - \frac{1}{\rho} \frac{\partial P_a}{\partial y} - \frac{g}{\rho} \int_0^z \frac{\partial \rho}{\partial y} d\zeta \end{aligned} \quad (5)$$

Conservation of mass yields an additional governing equation. The appropriate form of the continuity equation for an incompressible fluid is:

$$\frac{\partial \bar{U}}{\partial x} + \frac{\partial \bar{V}}{\partial y} = \frac{\partial \eta}{\partial t} \quad (6)$$

where \bar{U} and \bar{V} are the mass flux per unit length in the x and y directions respectively.

The surface boundary condition is:

$$\tau_{sx} = -\rho_s N_v \frac{\partial u}{\partial z} \quad \tau_{sy} = -\rho_s N_v \frac{\partial v}{\partial z} \quad @ \quad z = -\eta \quad (7)$$

where τ_{sx} and τ_{sy} are the surface shear stresses induced by the wind in the x and y direction, respectively and ρ_s is the density of water at the surface. Where τ_{sx} and τ_{sy} can be determined from the windspeed. A no-slip boundary condition at the bottom is assumed, or:

$$u = v = 0 \quad @ \quad z=H \quad (8)$$

The effect of bottom roughness can be included by varying the eddy viscosity near the bottom. For the case of an ideally smooth bottom, N_v will theoretically approach the value of the kinematic viscosity of water

near the bottom. As the bottom roughness increases, the value for N_V at the bottom can be expected to rise.

Thus, a set of governing differential Equations (5 and 6) and boundary conditions in the vertical (7 and 8) have been derived. The horizontal boundary conditions about the perimeter of the water body need not be introduced yet.

Application of a weighted residual technique begins by assuming a generalized functional relationship to approximate the true solution, or

$$\hat{u} = u_0 + \sum_{I=1}^{I'} c_I \Omega_I \quad \hat{v} = v_0 + \sum_{I=1}^{I''} d_I \Omega_I \quad (9)$$

where u and v are the "trial functions", c_I and d_I are the undetermined parameters, I' and I'' are the number of terms needed to reach the required degree of accuracy and Ω_I 's are prescribed functions. In theory, the only restriction in choosing the Ω_I 's is that they must satisfy the vertical boundary conditions when combined with the leading terms, u_0 and v_0 . In practice, however, they are chosen so as to approximate the true solution with as few terms as possible

The leading terms, u_0 and v_0 , are also somewhat arbitrary and may not have the same functional form as that assumed for the prescribed functions. These terms, however, when combined with the summation terms, must meet the necessary vertical boundary conditions. Using cosines, the trial functions can be written:

$$\hat{u} = u_0 + \sum_{I=1}^{I'} c_I \cos\left(\frac{a_I z}{H}\right) \quad \hat{v} = v_0 + \sum_{I=1}^{I''} d_I \cos\left(\frac{a_I z}{H}\right) \quad (10)$$

where a_I are prescribed constants.

To evaluate u_0 , v_0 , and the a_I 's the boundary conditions at the surface and bottom are utilized. It is found through trial and error that a sinusoidal function of the form.

$$u_0 = -\frac{H^T s_X}{\pi \rho N_V} \sin\left(\frac{\pi z}{H}\right) \quad v_0 = -\frac{H^T s_Y}{\pi \rho N_V} \sin\left(\frac{\pi z}{H}\right)$$

fits the required b.c. at the surface.

At the bottom boundary, u_0 and v_0 go to zero. Then, in order to meet the bottom b.c. (Equation 8) the a_I 's must be odd multiples of $\pi/2$ (i.e. $\pi/2, 3\pi/2, 5\pi/2, \dots$). Thus the trial functions can be written in final form:

$$\hat{u} = \frac{-H^T s_X}{\pi \rho N_V} \sin\left(\frac{\pi z}{H}\right) + \sum_{I=1}^{I'} c_I \cos\left(\frac{a_I z}{H}\right)$$

$$\hat{v} = \frac{-H^T s_Y}{\pi \rho N_V} \sin\left(\frac{\pi z}{H}\right) + \sum_{I=1}^{I''} d_I \cos\left(\frac{a_I z}{H}\right) \quad (11)$$

Figure 2 is a plot of the first three Ω_I terms.

Now that the trial functions have been specified, they can be substituted into the Momentum Equations (5). In general, there will be an error associated with this substitution, since the trial functions are not the exact solutions to the Momentum Equations. This error is commonly referred to as the "residual". Performing this substitution yields:

$$R = \frac{d\hat{u}}{dt} + g \frac{\partial \eta}{\partial x} - \frac{\partial}{\partial x} (N_H \frac{\partial \hat{u}}{\partial x}) - \frac{\partial}{\partial y} (N_H \frac{\partial \hat{u}}{\partial y}) - \frac{\partial}{\partial z} (N_V \frac{\partial \hat{u}}{\partial z}) - f\hat{v} + \frac{1}{\rho} \frac{\partial P_a}{\partial x} + g \frac{1}{\rho} \left(\int_0^z \frac{\partial \rho}{\partial x} dz \right) \neq 0 \quad (12)$$

For the sake of brevity, only the residual in the x direction is shown.

The error is minimized by specifying that the integral of the residual times a weighting function over a region be zero. For the case of interest, it is convenient to minimize the residual over a water column which yields:

$$\int_{-z}^H R W dz = 0 \quad (13)$$

W is specified as the prescribed function Ω_I (the Galerkin Method). Application of the Galerkin technique utilizes the orthogonality properties of Ω_I (i.e. $\cos(a_I z/H)$).

Taking $W = \Omega_I$ and substituting Equation 12 into Equation 13 yields:

$$\int_0^H R \Omega_J dz = \int_0^H \frac{d\hat{u}}{dt} \Omega_J dz + \int_0^H g \frac{\partial \eta}{\partial x} \Omega_J dz - \int_0^H \left(\frac{\partial}{\partial x} (N_H \frac{\partial \hat{u}}{\partial x}) + \frac{\partial}{\partial y} (N_H \frac{\partial \hat{u}}{\partial y}) \right) \Omega_J dz - \int_0^H \left(\frac{\partial N_V}{\partial z} \frac{\partial \hat{u}}{\partial z} \right) \Omega_J dz - \int_0^H N_V \frac{\partial^2 \hat{u}}{\partial z^2} \Omega_J dz - \int_0^H f \hat{v} \Omega_J dz + \int_0^H \frac{\partial P_a}{\partial x} \frac{\Omega_J}{\rho} dz + g \int_0^H \frac{1}{\rho} \left(\int_0^z \frac{\partial \rho}{\partial x} dz \right) \Omega_J dz \quad (14)$$

where J and I are both counters which are used interchangeably, and where the N_V term has been differentiated and conveniently separated into two terms. There is an equivalent Galerkin statement for the y direction.

Observe that the lower limit on the integration in Equation 14 has been moved from $z=-\eta$ to $z=0$. In order for this approximation to be valid, η must be much less than the still water depth, H . If this assumption was not made, then the integrals in Equation 14 would have to be continually reevaluated in time, since η is a function of time. This reevaluation would be computationally prohibitive.

In order to evaluate the integrals, a functional form for the vertical variation of the vertical eddy viscosity must be specified. This is done by approximating N_V with a series of linear segments as shown in

Figure 3. The slope (α_k), the intercept (β_k), and the number of segments (k') must be input by the model user. This linear approximation scheme has several obvious advantages. For instance, it is reasonably simple to integrate and it can approximate very complex forms.

Carrying out the integrations, yields:

$$0 = \frac{H}{2} \frac{\partial c_J}{\partial t} + HB_J \frac{\partial \eta}{\partial x} - \epsilon \frac{Hc_J}{2} + \tau'_x A_J - \sum_{I=1}^{I'} c_I \bar{\delta}\sigma_{IJ} + \tau'_y \frac{Hf}{\pi} \Gamma_J - f \frac{H}{2} d_J + \Delta P_{xJ} \tag{15}$$

where: $B_J, A_J, \bar{\delta}\sigma_{IJ}, \Gamma_J$ are constants which arise from the integration,

$$\tau'_x = \tau_{sx}/\rho ; \tau'_y = \tau_{sy}/\rho ;$$

ΔP_{xJ} is do to the surface pressure gradient and density gradients; ϵ is a parameter such that $\epsilon u = \partial/\partial x (N_H \partial u/\partial x) + \partial/\partial y (N_H \partial u/\partial y)$.

Equation 15 and its equivalent in the y-direction can be conveniently thought of as the governing Momentum Equations for a water column. All parameters are specified except the unknowns $c_J, d_J,$ and η . The Momentum Equations represent a set of $2I'$ equations with $2I' + 1$ unknowns. To solve for the unknowns, one more equation linking the c_J 's and d_J 's to η must be specified. This is accomplished using the Continuity Equation (6). With some manipulation, the mass fluxes, \bar{U}, \bar{V} , can be written in terms of the undetermined parameters.

Thus the original second order, nonlinear, Momentum Equations, along with the nonhomogeneous vertical boundary conditions have been reduced to a set of $2I'$ equations which are linear, first order PDE's. These $2I'$ equations coupled with the Continuity Equation and the boundary conditions about the horizontal perimeter of the water body, constitute a set of equations with a unique solution for the unknown variables $c_J, d_J,$ and η . Once the c_J 's and d_J 's are determined, then the velocities, u and v , can be found using Equation 11.

The governing differential equations can be solved using a variety of methods. It was decided to use the so called "split-time", finite difference scheme in the initial modeling. The method has been used with success by many numerical modelers in the past, such as Pearce (1972) and Reid et. al. (1968) and will not be described in detail here.

To apply the method, the water body is discretized in the manner shown in Figure 4. Note the subscripts ℓ and m , are spatial location counters which are associated with the x and y directions respectively. The time counter is n . There will be ℓ' grids in the x direction, m' grids in the y direction, and n' total time steps.

The next step is to apply the discretization to the governing differential equations, for example, Equation 15 yields.

Figure 4: Finite Difference Discretization Scheme

$$c_j(\ell, m, n+1) = c_j(\ell, m, n) * \epsilon'(\ell, m, n) - B_j'(\ell, m, n) * \bar{\eta}_x - \bar{\tau}_{xj}(\ell, m, n) + C_3(\ell, m) *$$

$$\sum_{I=1}^{I'} c_I(\ell, m, n) * \bar{\delta}\sigma_{Ij}(\ell, m, n) + C_2 * d_j(\ell, m, n) - \Delta P_{xj}'(\ell, m, n) \quad (16)$$

where ϵ' is a constant associated with the horizontal eddy viscosity, C_2 is a constant associated with the Coriolis parameter, $\bar{\tau}_{xj}$ and $\Delta P_{xj}'$ are constants associated with the surface shear stress and pressure gradient, respectively and B_j' and C_3 are constants arising from the integrations.

$$\bar{\eta}_x = \eta(\ell, m, n + \frac{1}{2}) - \eta(\ell-1, m, n + \frac{1}{2})$$

Observe that Equation 16 explicitly expresses the "new" c_j 's at time $(n+1)$ in terms of the "old" c_j 's at time n . Also note that the "old" η 's are evaluated at time $n + 1/2$ instead of time n . This characteristic is the basis for the name "split-time". Similar manipulation yields the y equivalent to Equation 16.

Applying the discretization scheme to the Continuity Equation yields:

$$\eta(\ell, m, n + \frac{3}{2}) = \eta(\ell, m, n + \frac{1}{2}) + \frac{\Delta t}{\Delta L} (\bar{U}(\ell, m, n + 1) - \bar{U}(\ell+1, m, n + 1) + \bar{V}(\ell, m, n+1) - \bar{V}(\ell, m+1, n+1))$$

Verification

In order to check the convergence of the formulation as well as the program coding, the model was checked against several simple problems for which analytic solutions are available. The strategy was to start with the most simple case and then examine progressively more sophisticated cases.

The case of wind blowing along an infinitely long channel with a constant N_v was examined first. Figure 5 shows the various physical characteristics of the idealized channel which was used. The effect of the earth's rotation and the lateral shear stresses were neglected and the water density was assumed homogeneous.

The model was run to steady state which took approximately 8000 seconds to reach. Two cases were tried: one with $J' = 3$ and the other with $J' = 5$.

A comparison of the velocity profile from the model and the analytic solution is shown in Figure 6. The comparison is excellent for $J' = 3$ and $J' = 5$.

The model was next tested for a 1-D infinitely long channel

Figure 6: Comparison of Steady State Velocity Profile for the Case of a 1-D, Infinitely Long Channel with Constant N_v . ($N_v = 0.0465 \text{ m}^2/\text{sec}$)

Figure 5: Physical Characteristics of the 1-D Channel

Figure 7: Linear Variation of N_v

identical to that described above except that N_v was no longer considered to be a constant but rather varied linearly as shown in Figure 7. The comparisons between the analytic and the model solutions shown in Figure 8 are poor. It was noted that the analytic solution displayed a very steep gradient near the bottom and it was suspected that more cosine terms were needed in order to approximate this steep gradient. Consequently, the number of terms was increased to eight. Though an improvement has been made by increasing the number of terms, that improvement is small when compared to the discrepancy which remains between the model and the analytic solution.

Spot checks of the computer results yielded no errors, nor did a thorough review of the model formulation. It was estimated that for reasonable values of N_v , the number of cosine terms needed in the model to achieve an acceptable approximation of a realistic velocity profile would be on the order of 20 terms. This poses problems for application of the model in its present form to real-world problems, since the computer time/storage requirements are unrealistic when more than 5 to 10 terms are required.

The future for a 3-D model using the Galerkin approach and a varying vertical eddy viscosity is, however, not as bleak as one might think. The problem with the formulation presented is simply that the trial function chosen, while very effective when dealing with the mild and unrealistic velocity gradients inherent to the constant N_v case, cannot cope effectively with the more realistic, logarithmic velocity profiles which can be created when N_v is allowed to vary with depth.

The poor convergence characteristics of the trial function used in the model can be traced to the choice of the u_0 component of the trial function (Equations 10 and 11). Recall that for the case of 1-D flow in an infinitely long channel with N_v small at the bottom, the u_0 term reaches a negative maximum near the bottom and has relatively sharp positive gradient between the maximum and the bottom (dashed line in Figure 8). Thus the function which must be simulated with a cosine series will have a steep negative gradient near the bottom. Such a function is very difficult to match using simple cosine functions which become zero at the bottom. A similar problem occurs when N_v becomes small near the surface.

Fortunately one can effectively eliminate this strong gradient near the surface by selecting an appropriate u_0 term. This means that the remaining portion to be simulated by the series of cosines will have a much milder slope and hence convergence will be much more rapid.

The choice of the functional form of u_0 depends a good bit upon which functional form one believes to most adequately represent the vertical variation of the vertical eddy viscosity. For the case of a linear variation one possible form of u_0 is.

$$u_0 = \frac{\tau_{sx} z^2 (z H)}{\rho H^2 N_{vb}} + \frac{\tau_{sx}}{\rho \alpha_1} \ln \left(\frac{N_{vb}}{N_{v1}} \right)$$

where: $N_{vb} = \alpha_1 H + \beta_1$ and $N_{v1} = \alpha_1 z + \beta_1$

Figure 9: Comparison of Steady-State Velocity Profile from Revised Galerkin Model and Analytic Solution for 1-D Channel of Infinite Length with $C_b = \infty$

Figure 8: Comparison of Steady-State Velocity Profiles for 1-D Channel of Infinite Length. ($\alpha \bar{z} = 0.01414$ m/sec. and $\beta = 0.1417$ m²/sec)

Note that u_0 is composed of two parts. The second part is the analytic solution for a 1-D, infinitely long channel with a single, linear variation in N_V . This function will serve to moderate the velocity slope near the surface and thus hasten convergence. The first term of u_0 is needed to satisfy the boundary conditions and has a mild slope so as not to adversely affect convergence.

Steep gradients near the bottom are not so easily dealt with. This arises from the fact that one does not know the direction of flow near the bottom beforehand (unlike the situation at the surface). Hence it is seemingly impossible to pick a u_0 term which can help eliminate the sharp gradients near the bottom and thus hasten convergence. Our solution was to avoid these gradients by incorporating a slip velocity at the bottom similar to that used by Heaps (1972).

The Galerkin Model was then reformulated with the new u_0 and v_0 functions. Figure 9 compares the steady state analytic solution for a linearly varying eddy viscosity ($\alpha = .014$ m/sec, $\beta = .00093$ m²/sec) to that from the revised model. The 1-D channel was assumed very long and a no-slip bottom boundary condition was used by taking $C_b = \infty$. The figure indicates an excellent comparison using only three cosine terms.

The case with a slip velocity was examined next. Figure 9 indicates that the model compared very well with the analytic solution. Again this is not surprising, given the fact that the second part of u_0 nearly satisfies the analytic solution by itself.

Final verification is for a sea with an infinite lateral extent, with a linearly varying N_V and with a slip velocity at the bottom. The governing equations and the details of the analytic solution are shown in (Pearce, et al, 1978)

Figure 10 shows a comparison between the numerical, Galerkin Model and the analytic solution. The comparison between the analytic and numerical models is quite good.

Figure 11 shows a comparison for the case of constant eddy viscosity. The analytic model is the Ekman solution for a sea of infinite horizontal extent and finite depth. The comparison is not as good as in the previous figure. The reason for this is because in the case of constant N_V , the second term of the trial function (u_0) becomes linear, reaching a maximum at the surface and no longer aids the convergence.

The comparison for the constant N_V case can no doubt be improved by taking more cosine terms (only 3 cosine terms were used in the results shown in Figure 11). In any event, it must be remembered that the new formulation does fit the varying N_V case, which is more physically realistic than the constant N_V case. Future research will compare model results to prototype data.

CHAPTER 159

MIXED LAYER MODELS FOR COASTAL WATERS

by

Wm. J. Wiseman, Jr., L. J. Rouse, Jr., and O. K. Huh

Coastal Studies Institute, Louisiana State University

Baton Rouge, Louisiana 70803

Abstract

The applicability of oceanic mixed-layer models to the case of wind mixing in a coastal region dominated by river runoff is explored. Two-dimensional effects and the propagation of internal-inertial waves out of the mixed layer are seen to be extremely important. Modification of the boundary conditions changes the appearance of the solutions as well. Further field work will be necessary to determine if additional terms, ignored in the oceanic models, might become important in the coastal region.

Introduction

The regions of strong haline stratification downdrift of the world's major river mouths account for only a small portion of the world's continental shelves, but they are extremely important because of the suspended sediment, nutrients, and pollutants these rivers carry. In order to properly manage such coastal zone areas, it is necessary to understand the mechanisms by which the freshwater, riverine effluent

mixes with the ambient shelf waters. Unfortunately, the space and time scales of the dynamics in these regions do not lend themselves to easy study by classical oceanographic methods. Cruises are not sufficiently synoptic to resolve the temporal scales of interest, and moorings generally are not sufficiently numerous to resolve the spatial scales.

For a number of years we have been investigating the applicability of remote sensing techniques to the study of coastal problems. In the case of mixing between fresh and salt water, a salinity sensor would seem optimal, but routinely available airborne or satellite-borne salinity sensors do not yet appear to have the necessary accuracy, e.g., Thomann (1973). We therefore have stressed the use of thermal sensors. Justifications for this are that over short time scales temperature may be considered as a quasi-conservative parameter, sensor technology is good, and, in the region of interest, temperature is relatively unimportant dynamically. For example, Figure 1 shows four traces of temperature and salinity versus depth from the same station. While the fresh-water inflow from the coast maintains a strong pycnocline all year, during summer the temperature structure reinforces the haline stratification and during winter tends to counteract it. The changeover occurs around April and November. In all cases, the basic density structure is two layered.

Following atmospheric cold-front passages, conditions are often excellent for thermal remote sensing. In Louisiana, such cold fronts occur with a 3- to 10-day recurrence interval from October through April when pulses of cold, dry polar continental air flow down the Mississippi River valley and out over the Gulf of Mexico (Fernandez-Partagas and Mooers, 1975;

Figure 1. Temperature and salinity profiles from a station west of the Mississippi River delta.

Leipper, 1954; Huh et al., 1978). These cold-air outbreaks cool the surface waters of the coastal zone and form sea-surface temperature fronts (Huh et al., 1978), which are later distorted by mesoscale circulations on the shelf, e.g., Figure 2. It is images such as these that we hope eventually to couple with the output of a good oceanic mixed-layer model to hindcast the subsurface structure of coastal waters.

Oceanic Mixed-Layer Models

The influence of the oceanic mixed layer on weather has prompted numerous recent modeling efforts. An excellent model, which incorporates most of the successful aspects of previous models, has recently been published by Niiler (1975). The model assumes distributions observed in nature and then derives a set of equations consistent with these distributions. In the model, temperature is assumed to be the dominant density parameter and heat to be supplied by solar radiation at the sea surface. Mean temperature and mean horizontal momentum are assumed to be uniform throughout the

Figure 2. NOAA-5 thermal IR image of the northern Gulf of Mexico following a cold-front passage (26 January 1977). Colder waters are denoted by the lighter colors.

mixed layer except for two thin shear layers at the sea surface and at the bottom of the mixed layer. The surface layer is a wave-driven shear layer, while the lower shear layer separates the mixed layer from the quiescent fluid below. There exists a finite flux of heat and horizontal momentum into the top of this latter shear layer, but none out the bottom. These fluxes are used to bring fluid entrained from below up to the temperature and mean horizontal velocity of the mixed layer. The fluid is assumed to be incompressible, hydrostatic, and Boussinesq. At the scales of interest, both mean quantities and turbulent correlations are assumed to be horizontally homogeneous.

To determine the mean temperature, mean horizontal velocity and mixed layer depth, mean momentum, and heat are conserved, as well as turbulent kinetic energy. When there exists an excess input of energy from the wind, above and beyond that needed to mix the incoming heat through the mixed layer and to account for background dissipation, fluid is entrained from below. Other than this entrainment, though, the lower fluid is decoupled from the mixed layer. Dissipation of mean horizontal momentum in the mixed layer is accounted for by a quadratic friction law such as used by Pollard and Millard (1970). The model works extremely well in the situations for which it was designed and reproduces many of the observed features of the oceanic mixed layer.

Such a model may not, though, be useful for describing a strongly haline stratified coastal region, and it is therefore important to identify the necessary modifications to make it applicable to such a situation. Many of these will be points which Niiler has already identified as potential additions to his model. Whereas in the deep ocean, though, they may only be aesthetic improvements to an already good predictive model, in the coastal zone they contain the dominant physics.

It is apparent that, in the regions we are discussing, salinity must be included in the equation of state. As a very good first approximation we may even permit salinity to be the sole density parameter and consider temperature to be a dynamically passive contaminant. One consequence of this is that the dominant buoyancy flux is now no longer a distributed source at the sea surface but rather an isolated source at the lateral boundary of the study area. Niiler has also chosen to ignore evaporation minus precipitation as an important source

term and, to a first approximation, it is probably still negligible within the coastal zone. We estimate that the buoyancy flux across the sea surface (caused by sensible and latent heat loss and mass loss) due to a strong cold-front passage, e.g., Nowlin and Parker (1974), is only 20% to 25% of the buoyancy flux due to runoff during the same period and the two fluxes have opposite signs. One might argue that the time necessary for the freshwater input into the coastal boundary layer to mix across the region of interest is large compared to the time necessary for the buoyancy flux out of the sea surface due to a cold-front passage. If this be the case, then indeed it might be necessary to consider evaporation minus precipitation as important over short time scales at the offshore regions of interest.

The vertical distributions of mixed-layer properties for the coastal situation are similar to those for the open-ocean case. The surface shear layer, though, may need to be considered a bit more carefully since, if long waves are propagating into the area from the sea, then the wave-driven shear layer thickness may not be small compared to the mixed-layer thickness. In the coastal zone the mixed layer is only of the order of 10 meters thick rather than 100 meters, as in the oceanic case. Furthermore, the assumption of vertical homogeneity of mean horizontal momentum must be reconsidered. If the mean horizontal momentum is independent of depth, then over most of the mixed-layer depth generation of turbulent kinetic energy by the working of the Reynolds stresses against the mean shear may be ignored. In the oceanic case a mean horizontal velocity change of 10 cm/sec across the mixed layer is necessary for this term to become of the same order of

magnitude as the other retained terms in the turbulent kinetic energy equation (Niiler, 1975). In the case of the thinner coastal zone mixed layer, the mean horizontal velocity change must be only of the order of 1 cm/sec. Our measurements are not sufficiently accurate to resolve whether the mean horizontal velocity change is of this order of magnitude or not and therefore, in the interest of mathematical simplicity, we will initially ignore this term.

Niiler (1975) has also ignored the downward-propagation of internal-inertial wave momentum through the base of the mixed layer. In the conservation equation for mean momentum the loss of momentum by downward propagating internal-inertial waves is modeled by the frictional dissipation. If this momentum is transported to infinity, as it would be in an infinitely deep lower layer that is a good approximation to the deep ocean, then there is no further effect. If, however, the momentum is trapped in a shallow lower layer, it could significantly change the shear across the lower boundary of the mixed layer and thus affect the turbulent kinetic energy equation and the calculated mixed-layer depth. It is conceivable that such a situation could arise when the lower layer is extremely thin, as might be the case in a mixed layer lying over a broad, shallow shelf such as we find in the northern Gulf of Mexico.

Finally, the assumption of horizontal homogeneity must be relaxed. There will be horizontal density gradients imposed by the buoyancy flux at the coast. Coastal Ekman divergences will cause upwelling and downwelling. Also, one would assume that if lateral turbulent mixing is important, then the mixing length will become a function of the offshore distance as well.

As a first step to an understanding of the effects of cold-front passages on the mixed layer in the coastal zone, we have looked at the effects caused by the coastal boundary in an extremely simplified version of Niiler's model. The model has been extended to two dimensions; it is a two-layered model with offshore variation of the properties within the surface mixed layer. We have replaced the heat conservation equation with an equation for the conservation of salt so that our three equations are now

Conservation of mean horizontal momentum:

$$\frac{\partial \bar{u}}{\partial t} + \bar{k} \times \bar{u} = \frac{\bar{\tau}_o}{\rho_o} - \frac{C_D}{h^2} \bar{u} |\bar{u}| - gh \frac{\partial [(\rho_o - \rho) h / \rho_o]}{\partial x} \bar{i} \quad (1)$$

Conservation of salt:

$$h \frac{\partial s}{\partial t} + \bar{u} \frac{\partial s}{\partial x} = (s_o - s) \frac{\partial h_e}{\partial t} H \left(\frac{\partial h_e}{\partial t} \right) \quad (2)$$

Equation used to compute mixed layer depth:

$$\frac{\partial h}{\partial t} = \frac{2m_o \bar{\tau}_o / \rho_o^{3/2} h^2}{[gh^3 (\rho_o - \rho) / 2 - \bar{u} \cdot \bar{u}]} - w_E = \frac{\partial h_e}{\partial t} - w_E \quad (3)$$

where

$$\rho = 1 + bs \quad (4)$$

The variables in equations (1) - (4) have all been normalized. The symbol \bar{u} is mean horizontal transport, t is time, $\bar{\tau}_o$ is horizontal wind stress, ρ is density, ρ_o is a reference density, g is gravity, h is mixed-layer depth, x is the offshore coordinate in the direction of the unit vector \bar{i} , \bar{k} is the unit vector in the vertical direction, s is salinity, s_o is the reference salinity corresponding to ρ_o , h_e is the mixed-layer depth increment due to entrainment, $H(\cdot)$ is the Heaviside function, w_E is the vertical velocity at the base of

the mixed layer due to Ekman divergence (calculated from the continuity equation), and b is a constant. The term m_0 is a constant that determines the amount of energy available for entrainment, for which we have assumed Niiler's value. C_D , the friction coefficient used to model dissipation within the mixed layer, was taken from Daddio et al. (1978).

The mean horizontal momentum equation is linearized and driven by wind stress and a minor momentum source at the coast associated with the riverine influx. Crude, order of magnitude analyses suggest that lateral diffusion is less important than lateral advection of salt, and so the salt balance has no lateral diffusion term. It does, though, include an entrainment term. The equation for mixed-layer depth contains two terms; one is due to the Ekman divergence at the coast and the other is due to the entrainment prescribed by the conservation of turbulent kinetic energy. This latter allows entrainment when the bulk Richardson number

$$Ri = \frac{-g}{\rho_0} \frac{(\rho - \rho_0) h^3}{2 u^2} \quad (5)$$

is less than 1, but does not require the Richardson number to be equal to 1, as did Pollard et al. (1973) in an earlier model.

Initial conditions assumed for the model are an infinitely deep lower layer of 35 ‰ and a mixed layer with salinity of 25 ‰ at the coast, a linear gradient to 33.5 ‰ at 95 km offshore, and constant salinity thereafter. The initial mixed layer depth is 10 meters at 95 km from the coast and specified such that there does not exist a horizontal pressure gradient initially. The boundary conditions are a constant inflow of 25 ‰ water at the coast of a magnitude represent-

ing low river stage in the Mississippi River and a horizontally uniform time-varying, north-south wind stress (shown in Fig. 5).

Results

A plot of mixed-layer depth calculated by the model as a function of time and offshore distance is shown in Figure 3. The initial onshore wind stress tends to depress the pycnocline near the coast and entrain heavier fluid from below as the stress increases. When the stress shifts to an offshore direction, the pycnocline tends to rise to the surface. This tendency is initially overpowered by the entrainment due to the strength of the stress. As the wind decays, though, the Ekman divergence at the coast causes the pycnocline to rise. When the wind is turned off, an unbalanced pressure gradient exists at the coast. As this relaxes, internal-inertial waves propagate seaward.

Some inertial oscillations undoubtedly are also driven by the near-impulsive wind shift, but they seem to be less important. If a more realistic model of the vertical stratification were introduced, vertically propagating internal-inertial waves should result. Indeed, field data from the area during the period of frontal passages indicate the importance of these motions. The time series in Figure 4 shows such oscillations in the salinity structure and the speed time series. The slope of the isotachs suggests downward propagation in the lower layer. With the internal-inertial waves modeled properly, the shear across the base of the mixed layer would change and the entrainment probably would also be altered. The variations of pressure at the base of the mixed layer can be seen in Figure 5, where we have plotted only the

Figure 3. Contours of mixed-layer depth in meters as a function of time and offshore distance for the model conditions described in the text. The wind stress history is shown in Figure 5.

product of the normalized mixed-layer depth and the normalized salinity. This product is proportional to the desired pressure. It can be seen that, after the cessation of the wind stress, a strong onshore pressure gradient builds up in response to the continued input of fresh water at the coast, the only driving force for the model at this time. An alongshore geostrophic current develops to balance this pressure gradient in the model. Such a current does not, though, appear to develop to any great extent during the summer, when winds are light. It would appear that either horizontal mixing is important in practice or the full three-dimensional field of motion is necessary to describe the region, i.e., over the time scales with which we are dealing, the alongshore gradients of properties must also be considered or, most probably, frictional effects become extremely important (Crout and

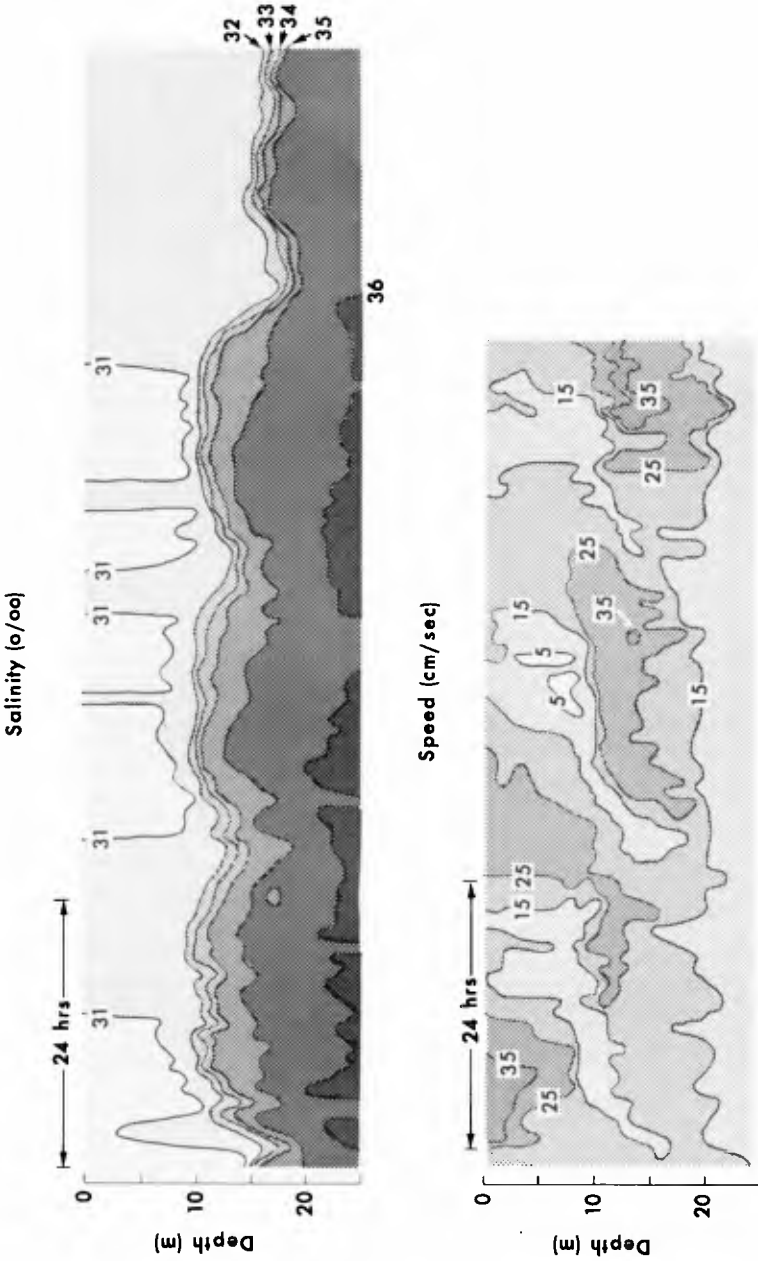

Figure 4. Contours of salinity (upper) and horizontal current speed (lower) as a function of time and depth for a station west of the Mississippi River delta. The data were collected in early October 1975, a period of moderate cold-front passages.

Figure 5. (Upper) Wind stress history for the model. (Lower) A pressure parameter (normalized mixed-layer depth x normalized salinity) at the base of the mixed layer, for selected offshore distances, as computed by the model.

Murray, 1979).

The next steps in the development of the model will be the incorporation of a more realistic wind stress, bottom topography, a realistic stratification in the lower layer and vertical propagation of internal waves, and, finally, addition of a conservation of heat equation. This will then permit interaction of the remote sensing and modeling capabilities.

CHAPTER 160

SOME DESIGN CRITERIA FOR OTEC INSTALLATIONS FOR KEAHOLE POINT, HAWAII

Frederick C. Munchmeyer¹ and Charles L. Bretschneider²

ABSTRACT

Ocean Thermal Energy Conversion, called OTEC, is presently getting much serious support for continued studies. Presently, there are potential OTEC sites off Punta Tuna, Puerto Rico; West Coast of Florida; New Orleans, Louisiana; and Keahole Point, Hawaii, the latter of which is the theme of this paper. The paper gives a summary of the early history of OTEC and its present status at Keahole Point, Hawaii, including design criteria. Any OTEC plant must operate throughout the normal environment, i.e. operational design sea state, including winds, waves and currents. The plant must be designed for the extreme environmental conditions, such as associated with hurricanes. The selection of an OTEC site depends on the availability of the resource, particularly associated with the temperature difference between the surface waters and the deep water. The change in the environmental parameters, and the consequences of any anticipated changes, are subjects of an environmental impact statement, the subject of which has been studied but is not reported here as part of this paper.

INTRODUCTION

The first successful OTEC plant was constructed by Georges Claude in Matanzas Bay, Cuba, in 1930. He was acutely aware of the design problems and made a number of qualitative statements concerning them (Claude, 1930). The second successful OTEC plant has not yet been built; however, early efforts to design such a plant face the same natural problems that Claude recognized and experienced. In Hawaii, where OTEC efforts have been active since 1972 and are accelerating, a number of OTEC design criteria have been studied at a site which is named Keahole Point. We present some of those data here, but before doing so it is instructive to review Claude's 1930 lecture.

He spoke to the American Society of Mechanical Engineers in New York on October 22, 1930, only a few weeks following his OTEC success in Cuba. Six months previously he had been awarded that Society's Fiftieth Anniversary Medal.

The editors of Mechanical Engineering remarked on his prior contributions "...especially the liquefaction of air and of oxygen and hydrogen, the production of nitrogen and ammonia [and]...the process in which

¹ Associate Professor, Department of Mechanical Engineering,
University of Hawaii

² Chairman and Professor, Department of Ocean Engineering,
University of Hawaii

acetylene is dissolved and stored under pressure in acetone..." This was the background of the man about whom the editors remarked further: "At the present time he is engaged in investigations relating to the industrial extraction of thermal energy from the sea..."

In his ASME lecture, Claude said that his "...dear master and friend, D'Arsonval, as far back as 1882..." observed that it is possible to utilize the difference in temperature between the surface of the tropical seas and the deep-sea water to generate power.

Italian and American inventors, between 1882 and 1930, had proposed closed cycle OTEC plants. Claude designed an open cycle plant because "...[the closed cycle] is burdened by...the necessity of transmitting enormous quantities of heat through the inevitably dirty walls of immense boilers with such a small difference in temperature."

He said that vocal critics of his ocean thermal energy ideas abounded, among them "Others [who] declared that it would be impossible to prevent the deep sea water from warming up too much during its ascent..."

In these extracts he also said: "It remained to be determined, however, whether the idea of procuring cold water from the bottom of the sea was chimerical or not.

"In a matter of this kind there is no precedent; all is unknown; theory no longer guides us, and we have to face that terrible adversary, the sea..."

"...a very large and expensive pipe would be needed to feed [the 60 kw] turbine...if the pipe had only the size required to feed the turbine, that is, not larger than 2 ft. in diameter, it would not be possible to insulate it sufficiently...For this reason it would be necessary to use a pipe 2 meters in diameter..."

"Various considerations, especially the proximity of deep water, led me to choose the island of Cuba...[however, bottom surveys] brought...disappointment...the existence of a high submarine cliff almost entirely around the island...The pipe, instead of lying all along its length...on the bottom of the sea...would have to drop down from the cliff into the abyss..."

"Anxious to avoid subjecting the tube to the pressure of the submarine current - much dreaded on those shores swept by the Gulf Stream, I was led to locate the plant in Matanzas Bay...However, the protection afforded here proved to be little or nothing...One day...[during his first efforts in August, 1929] these supposedly quiet waters got angry and sent to the bottom some hundred meters of [2 meter diameter steel] tubing."

Eventually, Claude assembled his mile long steel tube, in a river, and attempted to tow it to the ocean shore site. Bad weather and bad communications led to disaster; his first pipe sank in deep water.

"...I had gained in the [1929] struggle...a precious experience..."

In June 1930 his second tube also sank in deep waters when some of his crew proceeded against orders during the delicate maneuver of laying the pipe. On September 7, 1930 his third attempt to lay the mile long pipe succeeded. Pumping began as soon as all connections were made. The discharge water temperature "...finally...reacted 13 deg. cent. - a good result assuming that the temperature at the lower end of the tube was probably around 11 deg. cent." The system was completed and the turbine was started. "I got 12.5 kw. with warm water at 27.5 deg. cent. and cold water at 17 deg. cent., which increased to 22 kw. with temperatures of 27 deg. and 13 deg., respectively. These variations in the cold-water temperature were due partly to curious fluctuations of the Gulf Stream, and partly to a leak in the tube near the shore..."

Claude concluded his 1930 lecture by expressing "...most complete confidence in the future of this process..." and "certainty that... industries will never lack the precious energy that actuates them."

The data collection and analysis preceding the first OTEC plant at Keahole Point, Hawaii, follows closely Georges Claude's experiences. These efforts recognize more than one possible plant, one on shore as in Cuba and a few floating plants one mile seaward of the Point. We present data on five of Claude's subjects:

- "...the inevitably dirty walls of immense boilers,
- "the deep sea water...warming up...during its ascent,
- "...the pipe...lying all along its length...on the bottom of the sea...
- "...that terrible adversary, the sea, and
- "...the pressure of the submarine current."

Before reviewing these data, the Keahole site is described briefly.

KEAHOLE POINT

Keahole Point is on the west coast of the Island of Hawaii; latitude 19° 45' N, longitude 156° 05' W; see Figure 1. The land area was formed by a prominent lava flow. A 340 acre site has been dedicated to the Natural Energy Laboratory of Hawaii for development of OTEC and other energy concepts. A zone extending one mile into the sea, having a width of one-half mile has been reserved for research purposes. The data that follow pertain to this site.

BIOFOULING OF HEAT EXCHANGERS

The second successful OTEC plant will almost certainly be a closed cycle design, unlike Claude's open cycle. Thus it will utilize heat exchangers and be subject to "...the inevitable dirty walls." Figure 2

FIG. 1 LOCATION MAP OF HAWAIIAN ISLANDS

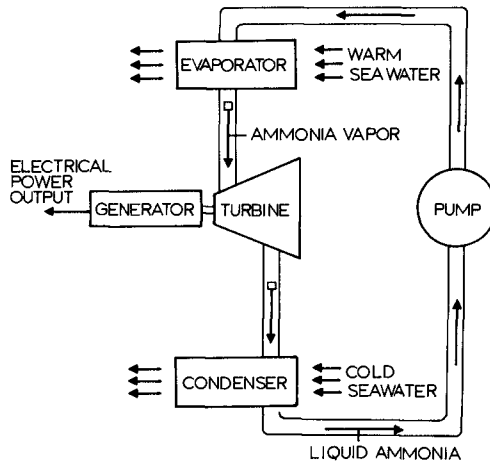

FIG. 2 OTEC CLOSED-CYCLE SYSTEM

describes the closed cycle system. In OTEC, the dirty walls are those exposed to sea water; the dirt is bacterial slime. The first field experiments probing this biofouling of heat exchangers were conducted at sea off Keahole. The primary results measure R_f , the resistance to heat transfer due to fouling, and also the effects of mechanical cleaning after fouling has reached significant levels.

Preliminary tests show that, after R_f has been allowed to grow 50 percent of clean tube resistance, moderate brushing will reduce R_f immediately to zero. After brushing, R_f grows back to the 50 percent level in approximately one month.

All recent experiments have been conducted *in situ*; small heat exchangers are positioned 300 m seaward of Keahole Point and 15 m below the surface. Tube materials and water flow velocities have been changed. No significant differences in the rate growth in R_f have been attributed to these two parameters. The experiments attempt to measure relatively small changes; the design maximum R_f may be in the order of 5 percent of clean tube resistance. A typical set of results is reported by Fetkovich, et al. (Fetkovich, 1977).

This problem will be common to OTEC plants ashore and afloat. A potential design is to control biofouling by brushing; the optimum brushing interval which will be measured in hours or days, cannot yet be predicted.

COLD WATER PIPE THERMAL DESIGN

An unpublished Master's thesis (Wong, 1978) shows that "the deep sea water...warming up...during its ascent" is not a problem for the floating plant at Keahole Point. For any reasonable floating plant pipe design and for power levels as low as 25 RW, the temperature rise of the deep sea water will be less than 1°F. This rise will decrease in magnitude at higher power levels.

The cold water ascending to an OTEC plant ashore may warm up by as much as 1°F. This would occur if the flow is slow or if the pipe diameter is small. Wong's study employed a characteristic temperature profile (Bathen, 1977) at Keahole Point, Figure 3, and the bottom profile (Noda, 1978), Figure 4. The normal current profile (after Merchant, 1975, and Bretschneider, 1978) is shown by curve A of Figures 5 and 6. Curves B and C include the Ekman wind driven current for wind speeds corresponding to Sea States 5 and 6 respectively. Curves D and E are design current profiles during hurricane conditions and are discussed later. The design current profiles were determined by Bretschneider (1978). He also showed that the annual variation in discharge temperature for a typical design would be less than 0.4°F. This estimate is due to changes in surface water temperatures; the inlet temperature is expected to remain more nearly constant.

A useful result of Wong's work is a relatively simple equation that predicts the rise in temperature with precision over a wide range of design variables. That equation is:

FIG. 3 AUTUMN SEAWATER TEMPERATURE PROFILE AT KEAHOLE POINT

FIG. 4 BATHYMETRY PROFILE OFF KEAHOLE POINT IN A TRUE DIRECTION OF 175°

$$\Delta T = 3.57 \left[\frac{4}{\pi} \frac{\dot{Q} \ln (D_3/D_2)}{k} \right]^{-0.98}$$

In that equation:

- ΔT is temperature rise, °F;
- \dot{Q} is volumetric flow through the pipe, cubic feet per second;
- D_2, D_3 are inside and outside pipe diameters, feet;
- k is pipe wall conductivity, BTU/hour-foot-°F.

The equation holds for a bottom laid pipe extending one mile seaward of the point and for these ranges of the design variables:

- plastic and concrete pipes;
- nominal diameters from 1.0 to 8.0 feet;
- nominal flow velocities from 0.25 to 10.0 feet per second.

Wong's analysis shows a range of practical solutions to a specific design problem in which 3000 gallons per minute of deep sea water are required with a warming up during its ascent of 1°F or less.

THE BOTTOM PROFILE

"In matters of this kind there is no precedent...", said Claude. That statement still holds for many aspects of OTEC and particularly for the design of a large diameter pipe that reaches a mile to seaward and a half-mile down.

Claude wished for "the pipe lying all along its length on the bottom of the sea." Such a design could be attained at Keahole Point according to an unpublished survey (Noda, 1978). The slope on one possible pipe line path is shown in Figure 4.

This survey gives precise information about the bathymetry seaward of the point. It also gives the results of a visual survey by submarine along a probable pipeline path. The bottom is a smooth basalt slope, except for outcroppings at the 450 foot level, and channels through the outcrop.

EXTREME WAVE CONDITIONS FOR DESIGN

The design wave criteria can be obtained by a statistical analysis of recorded data, wave observation, or wave hindcasting. In a report, Rocheleau (1977) did a statistical analysis of U.S. Navy (SSMO data) Summary of Synoptic Meteorological Observations, and two sets of wave hindcasts of severe storms, one set of eleven storms from U.S. Army Corps

of Engineers (1968) and the other set of ten storms from Marine Advisors (1973). The statistical analysis of the hindcasts were based on four methods, and are discussed in another paper presented at the 1978 Coastal Engineering Conference by Bretschneider and Rocheleau (1978). Therefore, we will not go into the details.

Many potential OTEC plants will be located in the tropics, and where hurricanes occur, one will find that the design wave is of hurricane origin. Potential OTEC plants are considered for locations in the Gulf of Mexico, off Puerto Rico, and off Keahole Point, Hawaii, and in all cases are subjected to hurricanes. Figure 7 shows the paths of hurricanes and other tropical cyclones prior to 1925 (see Visher, 1925), and Figure 8 shows the paths of more recent hurricanes, all for the Hawaiian waters. The closest to Keahole Point seems to be Hurricane DOT, of August, 1959, the center of which was about 80 nautical miles to the southeast of the potential OTEC site. There is no reason to believe that some future hurricane will not come much closer to Keahole Point. Figure 9, from Bretschneider and Tamaye (1976), is based on the model hurricane of Bretschneider (1972a) using the hurricane parameters estimated from the hurricanes on record. This hurricane is estimated to be the one in one hundred year hurricane for the Keahole Point area. The design wave heights are also close to those obtained from the hindcast study of Rocheleau (1977) which includes two hurricanes.

It is believed that the model hurricane is an excellent means of obtaining the 100-year design hurricane waves. The model hurricane of Bretschneider (1972) was applied to all U.S. Weather Service standard project hurricanes for the Gulf of Mexico and the U.S. East Coast. The results of the maximum values of the significant waves were given in a report by Bretschneider (1972b). The model hurricane was applied to the parameters of Hurricane Camille, August 1969, as reported by Cardone, Pierson, and Ward (1976) three years after the model hurricane was published. It is of interest to note that the agreement between the measured wave heights and those of the model hurricane was quite good, particularly since the hurricane model was not calibrated by use of any hurricane data.

The parameters of Hurricane Camille, 1969, were: radius of maximum wind $R = 10$ nautical miles, forward speed $V_F = 10$ knots, central pressure from normal pressure $\Delta P = 3.1$ inches of mercury, and latitude $\phi = 29$ degrees. This corresponds to a medium size hurricane slightly greater than the standard project and slightly less than the probable maximum hurricane for the south coast of Louisiana, and the wave heights are comparable to those measured during Hurricane Camille. Thus the standard project and probable maximum hurricanes are also the basis of OTEC design criteria for the U.S. Gulf Coast and the U.S. East Coast. This then allows also a consistent method for comparing the Keahole Point OTEC hurricane design criteria with the other OTEC sites in the Gulf of Mexico and the east coast of U.S.A.

The design wind speed cannot be determined consistently from the statistical hindcasts of the waves, because the maximum wind is not

necessarily associated with the maximum significant wave height, which in general is also fetch dependent. However, the model hurricane does give the design wind speed in terms of the 10-minute 10-meter anemometer wind level. The design gust speed is taken as 1.45 times the 10-meter level. Thus the design hurricane wind speed occurs almost simultaneously with the design wave.

The 10-minute average wind speed was the basis for calculating the wind drift by use of the Ekman theory. However, the drag coefficient was modified by $\frac{1}{2}\sqrt{2}$ to take into account that the wind stress diagram through the maximum waves was considered to be represented by a triangular wind stress distribution.

There may be some criticism in determining the wind drift current in this manner, and perhaps the steady state Ekman transport equations do not really apply. Anyway, it will be difficult to measure the surface drift during a hurricane at the time of maximum wave generation.

It is interesting to note, however, that the Ekman wind drift current component in the direction of the design wave is very nearly equal to the wave mass transport velocity determined from the wave spectrum using Stokes second order theory for wave mass transport velocity. This is not true at all depths because the wave mass transport attenuates with depth somewhat more rapidly than the component of the Ekman wind drift in the direction of the wind.

The problem presently under investigation is to determine the proper resultant velocities, i.e. the coupling of the wave orbital velocities with the steady current profiles shown in Figures 5 and 6. The wave mass transport velocity is included in the Ekman wind drift by the very nature in which the wind stress and drag coefficients are determined. Therefore, one should subtract the wave spectrum mass transport velocity from the component of Ekman wind drift in the direction of the wind. If this is not done prior to coupling current and wave orbital velocities, too much wave mass transport in fact will be included. The wave mass transport velocity of the wave spectrum is less than that associated with the individual maximum design wave.

Along with the Keahole Point OTEC deep water facility, there will be shore-based facilities. In this case, the waves will break close to the coastline because the continental shelf is narrow and steep, as shown in Figure 4. The coastal facilities must be designed against the maximum breaking waves on the structure. There will be a slight increase in water depth near the coast due to storm surge and wave set-up, and these factors must be taken into account when selecting a particular shore-based facility. This includes the effect of wave refraction and the design depth should include the maximum tides.

Calculations were made by Rocheleau (1977) to obtain an estimate of the maximum run-up on the coast, and he found up to 16.5 feet above MLLW. This can only be preliminary design run-up until one determines the face and slope of the coastal protection for the shore-based facilities.

ACKNOWLEDGEMENTS

Some of the material and figures given in this paper were obtained from various reports prepared under U.S. Federal grants, including the Department of Energy (D.O.E.), the National Oceanographic and Atmospheric Administration (NOAA) Sea Grant Office, and the State of Hawaii.

INTRODUCTION

The Seto Inland Sea is a national park of Japan whose complicated topography offers a much cherished scenic view. In recent years, however, it has been receiving increasing amount of both industrial and city sewage resulting in worsening of water pollution.

Investigation on the mass transport in near-shore region has been carried out by means of field observation, theoretical analyses, numerical analyses and hydraulic model studies by numerous researchers. One of the advantages of both numerical and hydraulic models is that the natural topography is modeled. Therefore simulations of diffusion have been made in various scales or under various parameters, and the mass transport mechanism have been studied. A hydraulic model reproduces the tidal level and volume transport on the basis of the Froudian law. The similarity of the velocity profile and diffusive phenomenon, however, is not guaranteed by this law on account, at least partly, of shortage of the field data. Among these phenomena tidal residual flow defined constant constituent in tidal current system is often observed in the hydraulic model, of which the existence is not so clear in the field, though it seems to play an important role on the large-scale diffusion.

In this paper, we present a comparative study of two hydraulic models of the Seto Inland Sea in order to better understand the effect of the scale effect of the hydraulic model. The larger model is built with scale ratio of 1 to 2000 and 1 to 159 in horizontal and vertical directions respectively (constructed by Chugoku Institute of Industrial Technology in 1974). The smaller model has scale ratio of 1 to 50000 and 1 to 500 in horizontal and vertical directions respectively (constructed by Disaster Prevention Research Institute, Kyoto University, in 1975). The experimental data of this comparative study are concerned with tides, tidal current and diffusions.

DESCRIPTION OF TWO MODELS

The both hydraulic models are mortared and the generating force of fluid motions is only tide propagated from the open ocean. In Fig. 1 is shown a plan view of the larger model which has three tide generators (Ref. 1). Fig. 2 shows a plan view of the smaller model which has only one tide generator producing the tide of Kii and Bungo channels. There is no tide generator at Kanmon strait in this model because the volume transport through this strait is very small compared with the

other two openings. Table 1 shows scale ratios of hydraulic factors in both models. The hydraulic factors except horizontal length and depth are based on the Froudian law. The hydraulic factors except horizontal length and depth are based on the Froudian law. The model tide we used was the semi-diurnal M_2 tide, which is a dominant constituent in the Seto Inland Sea. By the way, hydraulic values in this paper is expressed by prototype value.

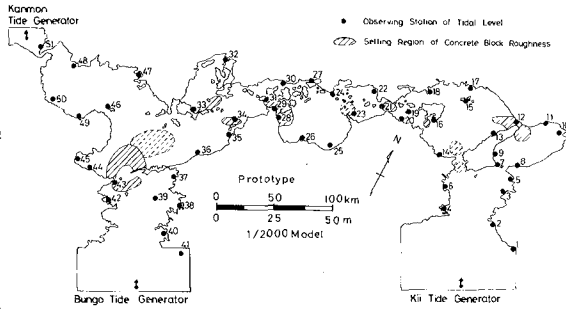

Fig. 1. Plan view of the larger model

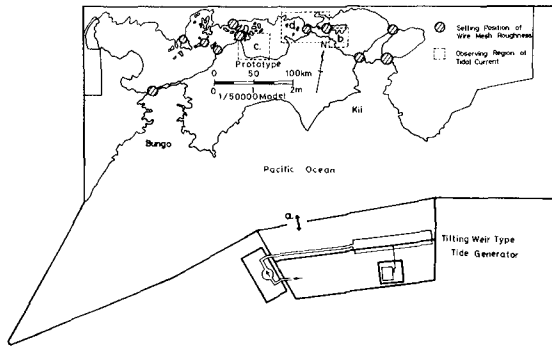

Fig. 2. Plan view of the smaller model

EXPERIMENTAL RESULTS

At first, adjustment of both models was done verifying amplitude and phase of tides at Kii and Bungo channels. Amplitude in the central region is twice as large as that in the open boundary in the prototype. Both models showed the tendency of producing greater tidal amplitude first. The difference has been corrected placing concrete blocks of various sizes in the larger model and wire mesh in the smaller model around the narrow straits.²⁾ Fig. 3 shows the distribution of the amplitude of M_2 constituent obtained by harmonic analyses. A solid line shows a distribution of prototype values. In this figure, filled circles and open circles show a distribution of the tidal ranges without roughness and with roughness respectively. Exaggerated roughness around narrow straits

Hydraulic factors	1/2000 model	1/50000 model	Ratio
Horizontal length	1/2000	1/50000	1/25
Depth	1/159	1/500	1/3.1
Period	1/159	1/2236	1/14.2
Horizontal velocity	1/12.6	1/22.4	1/1.8
Horizontal diffusivity	$1/2.5 \times 10^4$	$1/11.2 \times 10^5$	1/44.8
Discharge	$1/4 \times 10^6$	$1/1.56 \times 10^9$	1/140

Table 1. Hydraulic factors in both models

is so effective that it leads to the correct tidal range in the region away from the ocean as shown in this figure. M_2 -phase in the models agreed with that in the prototype which lags as much as 150 degrees in central region compared with the open boundary.

With the verified models, tidal current was measured. Floats on the sea surface were photographed and loci of their movement in the smaller model are shown in Fig. 4. From this figure the Seto Inland Sea can be classified into two areas. Area I is bays and sounds, which have a weak tidal current with a relatively strong residual component. And area II is narrows and straits, which is dominated by strong oscillatory current. In Fig 5 is shown distribution of the tidal residual circulation in both models so as to understand the outline of area I. The two patterns resemble each other but the smaller model has about twice stronger velocity of circulation than the larger one.

In order to investigate the tidal current in detail, we analyzed the tidal current distribution in the Eulerian manner at the b-region and the c-region in Fig. 2 which are representatives of area I and area II respectively. Values of tidal current were obtained at each fixed station by following numerous floats and the data was analyzed by harmonic method. Fig. 6 shows the amplitude of M_2 -component in the b-region. Direction of M_2 -current is about the same in both models, whereas larger amplitudes are recognized in the smaller model. Fig. 7 shows phase lag distribution of M_2 -component. Phase lag gradient in this region is steeper in the smaller model. In Fig. 8 is shown the Eulerian constant component called the tidal residual flow in tidal hydraulic model. In both models appear large circulations with the

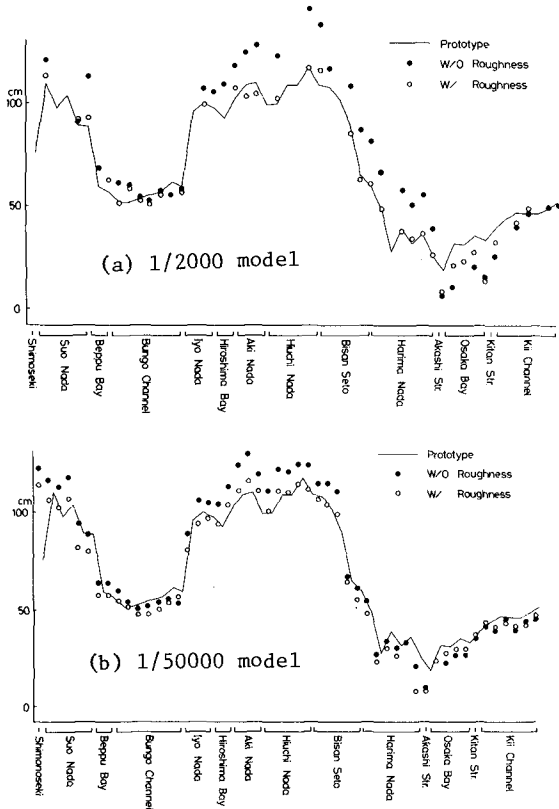

Fig. 3. Distribution of M_2 -amplitude of tidal range

Fig. 4. Tidal loci for 5 cycles in the eastern part (1/50000 model)

same rotation; magnitude of the residual flow is about ten times larger in the small model. Though this measurement was done in the condition of verified tides in both models, M_2 -amplitude of tidal current is larger in the smaller model. This is considered that the stronger current was compensated by steepness of phase lag gradient and the volume transport agreed with each other. Steeper gradient of the phase lag and tidal residual circulation in the small model result in the stronger shear of flow. Fig. 9 shows time changes of the circulations calculated along that circuit. Circulation in this figure is divided by the area involved in the integral circuit; this is equivalent to the mean value of vorticity in the circuit. A circulation represents shear of flow and its peak and mean value is larger in the smaller model. In the c-region, the tidal residual circulation, which have not been clearly observed in prototype, can be found with the

(b) 1/50000 model

Fig. 5. Distribution of tidal residual circulation

Fig. 6. M_2 -amplitude of tidal current

Fig. 7. M_2 -phase lag of tidal current

Fig. 8. Eulerian constant flow

strong and same rotation in both models. The tidal residual flows having a constant direction over long periods at each station have much effects on mass transport in the coastal region and strongly affect the diffusion experiment in hydraulic models. However, the similarity, that is, the generating mechanism of the flow have not been made clear yet. In this paper, since it is said that the tidal residual flow is generated by the non-linearity of the oscillatory component,³⁾ we have compared the tidal residual component and M_2 component between both models. Fig. 10 shows vectors of the tidal residual flow which forms the circulation with counter-clockwise rotation in both models. Nevertheless, the vectors and the diameter

Fig. 9. Time change of circulation

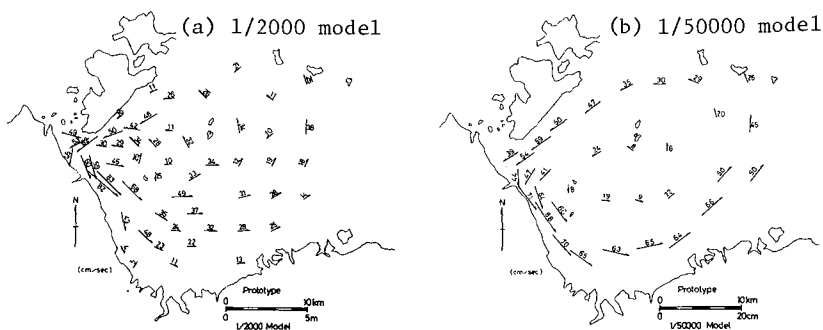

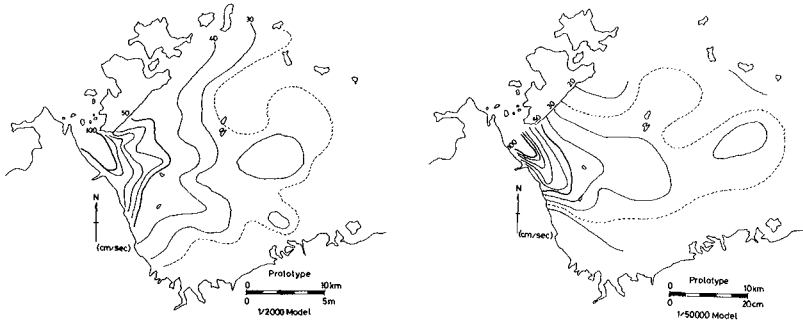

Fig. 10. Eulerian constant flow

of the circulation are larger in the smaller model. The distribution of M_2 -amplitude of major axis is shown in Fig. 11. Fig. 12 shows the distribution of the M_2 phase lag. Studying these figures, equi-amplitude line near the strait is biased more widely in the smaller model and equi-phase-lag lines run parallel to the tidal residual flow and the phase difference is larger in the smaller model. We can recognize that the biased equi-amplitude line and the phase difference substantiate the tidal residual flow.

Diffusion experiment is conducted in the area-d of Fig. 2, where we can treat diffusion phenomenon as one-dimensional mass transport phenomenon. Fig. 13 shows distribution of dye concentration after ten cycles released instantaneously at Mizushima in the larger model. Solution of dye spreads diluting by degrees in the area-d called Bisan-Seto, where concentration is nearly homogeneous transversely and we can treat diffusion phenomenon as one-dimensional mass trans-

Fig. 12. Distribution of M_2 -phase lag of tidal current

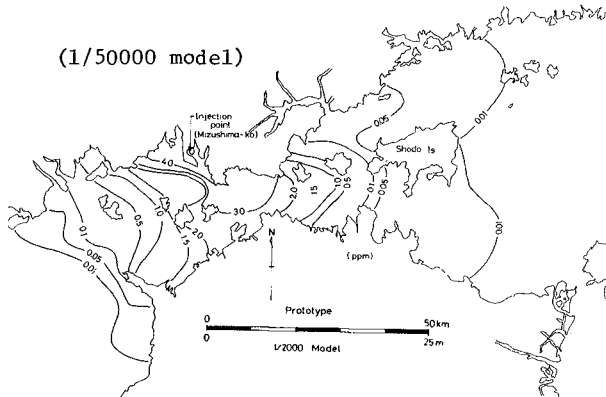

Fig. 13. Distribution of dye concentration after 10 cycles

port phenomenon. Comparative experiment of diffusion was carried out with use of many floats on water surface.

In Fig. 14 is shown time change of longitudinal variance of floats released instantaneously at the Mizushima sound in both models, where ●...● shows the case of floats in the smaller model, ○...○ floats in the larger model and △...△ dye in the larger one. Slope of these lines indicates the magnitude of diffusion and the coefficient of dispersion

are $0.75 \sim 1.3 \times 10^7 \text{ cm}^2/\text{sec}$, $1.3 \times 10^6 \text{ cm}^2/\text{sec}$ and $1.1 \sim 0.5 \times 10^6 \text{ cm}^2/\text{sec}$ in turn. From this figure, difference of the dispersion coefficient between floats and dye is not significant in the larger model. This suggests that dispersive power in this region is not given by vertical shear but by horizontal shear. Coefficient of one-dimensional diffusion in the smaller model is about ten times larger than that in the larger model. In order to study this difference, we obtained the diffusion-coefficient by means of following the motion of ten floats for one tidal cycle in area-b where we had measured Eulerian tidal flow. Tidal loci for one tidal cycle in this region are shown in Fig. 15. This shows that tidal vortex is stronger in the smaller model such as showing in Fig. 9. Table 2 indicates the process for diffusion coefficient with data of the initial variance and the variance after one tidal cycle. The variance σ_λ^2 was given as

$$\sigma_\lambda^2 = (\sigma_x^2 \sigma_y^2 - \sigma_{xy}^2)^{\frac{1}{2}}$$

where σ_y^2 corresponds to the value of latitude direction, σ_x^2 the value of longitude direction and σ_{xy}^2 is covariance. The scale of diffusion

Fig. 14. Comparison of longitudinal variance between two models

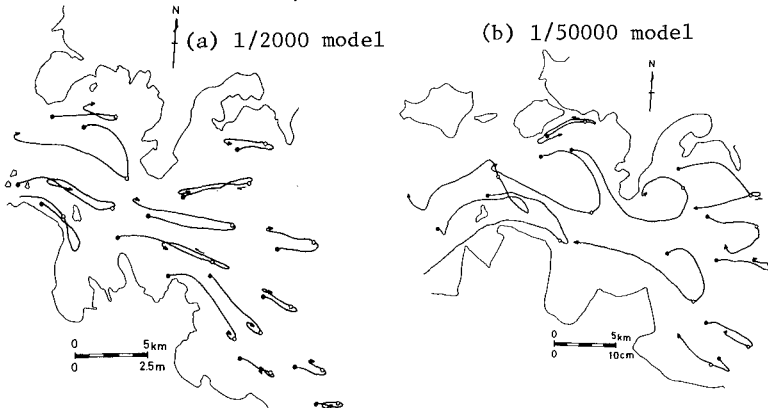

Fig. 15. Comparison of tidal loci between two models

	Initial Variance	Variance after one tidal cycle	Coefficient of Diffusion	Substantial Value of circulation
1/50000 Model	$1.75 \times 10^{10} \text{cm}^2$	$16.09 \times 10^{10} \text{cm}^2$	$32.1 \times 10^2 \text{cm}^2/\text{sec}$	$1.69 \times 10^{-3} \text{sec}^{-1}$
1/2000 Model	$2.36 \times 10^{10} \text{cm}^2$	$4.64 \times 10^{10} \text{cm}^2$	$5.15 \times 10^2 \text{cm}^2/\text{sec}$	$0.43 \times 10^{-3} \text{sec}^{-1}$

Table 2. Comparison of floats spreading speed between two models is the length of a tidal excursion or thereabouts. The last column shows averaged values of absolute circulations over one tidal cycle. This difference in both models corresponds to the diffusion coefficient's K_A that is obtained as follows,

$$K_A = \frac{1}{2} \cdot \frac{\sigma_{\lambda_2}^2 - \sigma_{\lambda_1}^2}{\Delta T}$$

where $\sigma_{\lambda_1}^2$ is the initial variance and $\sigma_{\lambda_2}^2$ is the variance after one tidal cycle; ΔT is the tidal period. This table suggest that horizontal shear of flow contributes to the diffusive effect of relatively large scale.

CONCLUSION

Without exaggerated roughness, both models showed the tendency of producing greater tidal ranges than the corresponding prototype values in the region away from the ocean. Exaggerated roughness around narrow straits has corrected wrong tidal ranges. From the results of comparative experiment with the verified models, we could recognize that the smaller model had following characteristics.

- (1) Oscillatory amplitude of tidal current and phase difference are larger.
- (2) Circulation (vorticity) is larger.
- (3) Constant flow (tidal residual flow) is larger.
- (4) Diffusion coefficient of large scale is larger.

Similarity of friction in hydraulic models has ever been considered only for bottom friction (Higuchi and Sugimoto,⁴ 1968 et al). But in the Seto Inland Sea having very complicated topography, effective friction may be due not only to bottom but to horizontal eddy viscosity which affects the form resistance. The larger the Reynolds number is, generally the smaller this form resistance is and the stronger the shear is. These explain that the separation of tidal flow is stronger in the smaller model and the smaller one has smaller horizontal viscosity due to turbulence, that is, the substantial turbulent Reynolds number affecting the flow pattern is relatively larger in it.

The smaller model is so small as showing Fig. 2 that we could not compare horizontally isotropic diffusion. Therefore we made the experiment of large scale diffusion called dispersion. Experimental result (2) and (4) shows that large scale diffusion is very influenced by horizontal local shear of tidal current velocity.

Though scale effect could not be induced as the numerical value,

it is suggested by those results that similarity of the tidal hydraulic model such as the Seto Inland Sea having complicated topography must be verified by not small scale phenomena hitherto done but large one covering a whole bay.

ACKNOWLEDGEMENTS

The authors wish to express their sincere thanks to Prof. C. Nakajima, Disaster Prevention Research Institute, Kyoto University, for his accommodations and encouragement. They also thank Mr. Y. Kitagawa, Disaster Prevention Research Institute, Kyoto University, and Mr. H. Takeoka, Ehime University, for their assistances in the experiment. Thanks are extended to Mr. Y. Takasugi, Chugoku Institute of Industrial Technology, for his assistances in the data analysis.

CHAPTER 162

A TIDAL SURVEY FOR A MODEL OF AN OFFSHORE AREA

W. J. van de Ree,¹ J. Voogt¹ and J. J. Leendertse²

INTRODUCTION

In support of engineering and environmental investigations for the construction of a storm surge barrier in the southwestern part of the Netherlands (Fig. 1), numerical models are being used. For one of these models, the so-called Randdelta II model, an extensive field survey was made of tides and currents to establish the boundary conditions and to adjust and verify the model. A description of this model and its adjustment procedures are presented elsewhere in these proceedings [1].

The survey was made in the period of August 25 to September 24, 1975. Since not all instruments could be installed and recovered simultaneously, the simultaneous observation period was effectively about 16 days.

A number of permanent water level recording stations are operated by the governments of the Netherlands and Belgium, and the data from these records could easily be obtained. In addition to these permanent stations, gauges were installed in many harbors and other suitable locations on the estuaries, and a total of 32 water level records of on-shore tide gauges was available for analysis. The reference levels of all these on-shore stations were determined by leveling to known benchmarks.

In addition to the on-shore stations, water level recorders were operational on instrument platforms constructed in preceding years in waters up to 10m in depth. These platforms or towers generally also contain instrumentation for wave and wind recording. The locations of these offshore stations are also shown in Fig. 1.

Along the location of the boundary of the model, bottom pressures were measured simultaneously with currents. The bottom pressures were recorded by a relatively simple instrument which punches a slowly-moving paper tape every half hour. The deviation of the mark on the tape from the ordinate on the tape is a measure of the bottom pressure. The accuracy of the readings from the tape is estimated at 2 or 3 cm water level variation.

In the model, the boundaries at the seaward side could best be described by water levels. Since the model covers, in addition to the Eastern and Western Scheldt, a section of the North Sea, the flow conditions in the major part of the model are predominately determined by the boundaries at the seaward sides of the model, and consequently the water levels

¹ Rijkswaterstaat, Delta Service, The Netherlands

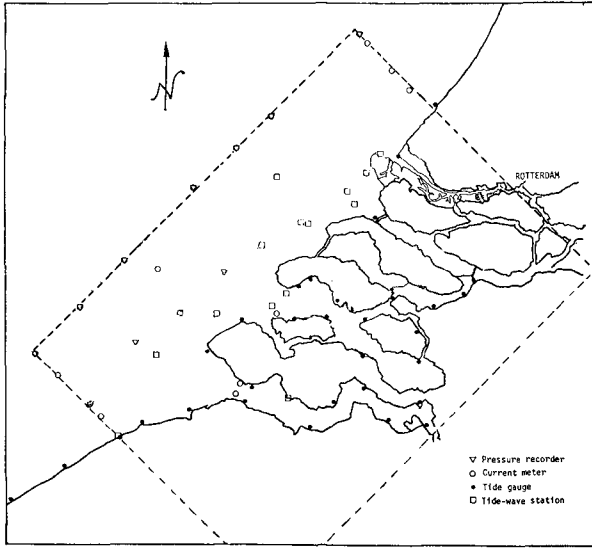

Fig. 1--Layout of models and locations of recording stations

Fig. 2--Instrumentation for current and pressure recording

had to be determined with considerable accuracy and data had to be available at many points on the boundary.

In view of the importance of accurate water level data on the boundary, most stations on the boundary were equipped with two pressure recorders. A typical schematic of the instrumentation layout is shown in Fig. 2. In addition to the stations on the boundary, similar stations were situated inside the model area. Since most stations are located in waters where there is much fishing activity, heavy concrete blocks were used to retain the instruments in place. Even with these precautions, one of the interior stations was moved about a mile! The approaches to two of the largest ports in the world are in the survey area, consequently the location of the stations on the seaward boundaries was limited to areas outside the main fairways, and only a limited number of stations could be installed. Because of all the traffic and the fisheries in the survey area, all stations had to be marked by buoys.

Not all pressure recorders were working satisfactorily during the survey period, but at least one pressure recorder was working satisfactorily at each station.

Current data was recorded by a "Flachsee" current meter at a number of stations in the model area, as indicated in Fig. 1. Because of the large size of these instruments and the method of installation, the recordings were relatively free of noise and were indicative of the average velocity in a vertical water column.

To determine the total tidal flow into the estuaries, current surveys were also made in ranges across the inlets over periods of about 14 hours.

In view of the importance of the pressure data obtained at the boundary of the model area for the studies, much emphasis was given to the analysis of this data, and in the following sections of this paper a description will be given of this analysis.

ESTIMATION OF THE ACCURACY OF THE PRESSURE RECORDERS

The analysis of the bottom pressure recorders presented most of the problems, as the recorded data is pressure data, while water level data is required for the model. Consequently, the records had to be corrected for atmospheric pressure differences, temperature and salinity. In addition, it could be expected that the instruments would settle. To analyze the performance of these pressure recorders, a detailed analysis was made of the records of two recorders at a particular station near the middle of the long open boundary.

In Fig. 3 the water level histories for the two recorders for the period of September 2 through September 5, 1975 are plotted. In this figure the corrections for barometric pressure, temperature and salinity were made, thus the difference between the plotted points is indicative of

Fig. 3--Comparison of observed water levels obtained from two adjacent bottom pressure recorders for the period September 2-5, 1975

Fig. 4--Comparison of observed water levels obtained from two adjacent bottom pressure recorders for the period September 10-13, 1975, in which much wave action was present

the accuracy of the observations, the rate of settling and the influence of swell. The solid and dashed tide lines are smooth lines drawn through the points.

Figure 4 presents the same tide levels, but for a period with very heavy wave action. It will be noted that there are large differences between the two observations.

To gain more insight into the behavior of these two time series and their relative behavior, a cross-spectral analysis was made of the raw data for a 500-hour period. This period covered neap tides and a spring tide, as shown in the pressure record of one of the stations (Fig. 5). The computed spectra for one of the stations (Fig. 6) shows peaks for semi-diurnal tide and the overtides (M_4 , M_6 , M_8 , M_{10}). The coherency between the time series appears to be nearly one only for the diurnal and semi-diurnal tide components, as shown in the graph of the squared coherency in Fig. 7. The M_4 and M_6 tidal frequencies appear to be still strongly correlated, and the M_8 tidal frequency shows some coherency. Components with frequencies higher than 0.4 cycles per hour are essentially uncorrelated.

The amplitude of the frequency response (Fig. 8) appears to be approximately 0.92 in the low frequency range from zero to 0.2 cycles per hour. This value reflects the difference in the lower sensitivity of the second instrument, for which no correction was made as the raw data was processed. For higher frequencies the response function drops rapidly. The phase lag between the two time series is practically zero in the low frequencies (Fig. 9). In the higher frequencies an apparent lag is present.

Since the period of analysis contained a storm period in the latter part of the time series (Fig. 5), the same analysis was made for a period of 372 hours (15.5 days). In this analysis a high coherency was obtained over a larger range of frequencies, as can be seen by comparing Fig. 7 with Fig. 10. Even in the frequency band of the M_{10} tidal component the squared coherency is 0.8, and is thus quite well correlated.

The phase of the frequency response is near zero, as we would expect for two observations made close to each other (Fig. 11). The phase lag in the higher frequencies in the response function for the 500-hour records was apparently generated by swells and aliased into the frequency range of 0.5 to 1.0 cycles per hour (Fig. 9).

Since the response function obtained by cross-spectral analysis is an optimal estimate of the linear relationship between the two time series, the response function can be used for estimating the difference between them. This estimate is made by first deriving the impulse response function from the frequency response function and subsequent convolution of the first series, as described in Ref. 2. In contrast with the description in this reference, we used an impulse function with positive and negative time. The results of the convolution are shown, together

Fig. 11--Phase of the frequency response function between the pressure recorders at Knikpunt III with confidence limits for the recording period without the storm (15.5 days)

with the measured data, in Fig. 12. The differences are small and are plotted in Fig. 13. The standard deviation between the convolved series and the observed series appears to be 3.5 cm.

The difference between these series reflects reading errors, instrument errors and differentials in the rate of settling of the instruments. For the whole series of 500 hours, thus including the storm period, a similar analysis for the difference between the convolved and observed series appeared to be 5.8 cm. From this it was concluded that it would be most advantageous to use only the shorter series of 372 hours (15.5 days) in determining input conditions for the model.

ANALYSIS OF BOTTOM PRESSURE RECORDER DATA

After reading the data from the paper tapes of the instruments, a number of data processing steps were required to achieve water level estimates which could be used for the model study. Most of the processing could be done by computer.

In the first step, the recorded data was corrected for atmospheric pressure, salinity and temperature. Atmospheric pressure data was available from a nearby weather station, and for every half-hourly record the same air pressure correction was made in all records. Salinity and temperatures were measured regularly near the bottom pressure recording stations, and as this data was only very slowly varying, no large errors could be expected to originate from these density differences. The height of the salt water column at the gauge was computed from the readings on tape by:

$$Y_t = \left\{ 10.19(p_o - p_t) + a_o X_t + 35.3(T_t - T_o) \right\} / 1.024$$

where p_o = pressure at time of installation (millibars)

p_t = pressure at recording time t

a_o = instrument constant found by calibration

X_t = reading in 0.1 mm

T_t = sea water temperature at time of recording (Centigrade)

T_o = sea water temperature at time of installation

The constant 10.19 transfers millibars into mm of fresh water and the constant 1.024 represents the average density of sea water during the recording period.

Since the bottom pressure recorders were installed on the sea floor, settling could be expected. To investigate this settling, all data was filtered by taking running averages over a 24.5-hour period. This filter eliminates quite effectively the diurnal and semidiurnal tides without much loss of data at the end of the records. The filtered data for a number of recorders is shown in Fig. 14. By comparing these

Fig. 12--Comparison between the observed time series and the convolved time series of bottom pressure from the other pressure recorder

Fig. 13--Difference between the observed time series and the convolved time series

Fig. 14--Filtered tide data from a number of bottom pressure recorders

filtered records with similarly filtered water level records of adjacent fixed shore stations or instrument platforms, corrections for settling could be made rather easily.

From the filtered data of the fixed stations, which are all tied to the Dutch reference level N.A.P., it is apparent that the mean water levels have a slope along the coast. The mean levels are higher towards the northeast. The slope is approximately 1 cm per 20 km, and is apparently induced by the semidiurnal tidal wave which runs along the coast from southwest to northeast. The mechanism of this phenomenon is described by Van de Kreeke [3].

Not much is known about gradients of the mean water levels perpendicular to the coast. In computing the water levels at the bottom pressure recording stations from the shore stations and fixed offshore stations by use of the momentum equations and observed velocities from this survey and from a previous survey, no slope of the mean water levels could be found. Since the mean levels along the coast were known, the relation between the mean level of the bottom pressure recording station and the reference level could be determined. By this means the complete time histories of water levels at the boundary stations of the model could be determined for a period of about 16 days.

DATA PREPARATION FOR MODEL INPUT

Tide inputs have to be supplied at a number of stations at the open boundary of a two-dimensional model. The modeling system used for the Randdelta model can either make a linear interpolation of the water surface between these stations or interpolate amplitudes and phases of Fourier components between these stations.

The latter method is particularly appropriate here, as the long side of the Randdelta II model is in the direction of tidal wave propagation.

For the simulation period a 150-hour interval was selected. For this period Fourier components of all boundary stations were determined, and 75 of these components were used initially as input of the model. It appeared that the interpolation of amplitudes and phases along the boundary of the model perturbs the water levels by the errors in the observations. This is shown in Fig. 15, where water levels along the open boundary of the model are plotted at hourly intervals. The relatively short waves which are apparent would cause temporal inflow or outflow locally at the long open boundary during the simulation. This is naturally undesirable, and ways had to be found to reduce the errors at the boundary stations.

Again cross-spectral analysis was used. Each boundary station was correlated with three adjacent fixed stations, as shown in Fig. 16. With the impulse response function obtained from each of the relations, a convolution was made of the observed time history of the fixed station. Thus for each boundary station three convolved series were obtained. These three series were weighted according to the inverse

Fig. 15--Water levels along the long open boundary of the model obtained by linear interpolation of amplitudes and phases of the Fourier component of the observed data

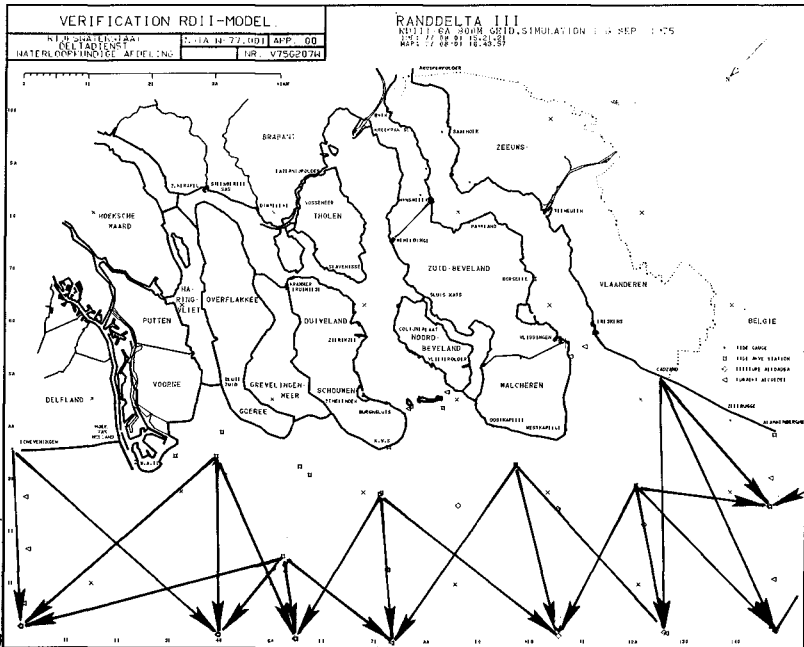

Fig. 16--Pattern of cross-correlation used for prediction of the boundary of the Randdelta II model.

square of the distance. As the accuracy of the fixed stations is relatively high and free of settling, the individual estimates obtained by convolution agreed well with the results of the observed data. Standard deviations were generally within three to five centimeters. Combining the three estimates, the standard deviations were about 3.5 cm.

From the convolved data, the Fourier components were determined again and the boundary was again determined by interpolation of amplitudes and phases. The water levels at the long open boundary, obtained by convolution and by direct observation, are shown at hourly intervals in Fig. 17. The water levels obtained by convolution are indicated by the arrows; it appears that they are essentially free of shorter waves.

The use of these boundary conditions obtained by convolution appeared satisfactory (Fig. 18). The flow fields near the boundary are now essentially unperturbed, as can be seen from the graphical outputs of the simulation for three of the boundary conditions shown in Fig. 17.

GENERAL APPLICATION OF BOUNDARY DETERMINATION TECHNIQUE

The rather extensive method of preparing the boundary conditions of this model with large open boundaries was originally developed to overcome very troublesome errors in the flow field during simulation. It is apparent that the work has very wide application. All fixed stations used in the cross-spectral analysis are permanent recording stations. The response functions appear to have high coherency in the important frequency ranges of the major tide components, thus it can be expected that they are generally applicable. This makes it possible to prepare model boundary conditions for any observed time period without making a new survey with about the same accuracy as is presently being used. The only exception would be storm periods, as these were excluded from our analysis.

ABSTRACT

Three-dimensional modelling of the Irish Sea has led to the determination of regimes of residual elevation and current due to wind, density and sea-surface gradient. These regimes are superimposed, along with tidal residuals from two-dimensional modelling, to yield first estimates of mean sea level distribution and long-term residual circulation.

INTRODUCTION

Earlier papers (Heaps 1974, Heaps and Jones 1977) have formulated a three-dimensional numerical model of the Irish Sea employing a new design in which the horizontal components of current are expanded in terms of a set of eigenfunctions through the depth. Coefficients of the expansion are determined in the horizontal and through time from a two-dimensional finite difference scheme based on the equations of motion and continuity transformed by vertical integration. In this way, the developing three-dimensional current structure is computed, also the changing pattern of sea-surface elevation.

The model has been used to determine the circulation in the Irish Sea produced by various uniform constant wind fields. Similarly, density currents have been computed, given horizontal density distributions obtained from observation. In most of this work a radiation condition has been employed on the open boundaries of the model.

More recently, estimates have been made of the residual circulation arising from nonlinear tidal effects in the Irish Sea. A two-dimensional vertically-integrated numerical model, on the same grid as the three-dimensional model, was used for this purpose. The tidal residuals have also been estimated using a two-dimensional model of finer mesh covering the same area but including the convective accelerations previously omitted from the equations of motion.

A situation has thus materialised where, after some years of work, we now have available, for the Irish Sea, a number of residual flow regimes due respectively to the effects of wind, density gradient and tide. The present paper represents a first attempt to superimpose these, along with a surface gradient flow, to yield the resultant long-term residual flow pattern in the Irish Sea. The results are tentative, even if only because it is assumed that a linear superposition of the various residual fields is permissible: neglected nonlinear interactions between the fields may be significant. Also, model parameters - particularly those defining friction - are not well known. Nevertheless, in spite of uncertainties and doubts, it is instructive at this stage to carry out a preliminary synthesis of residual currents in

Dotted lines mark out the open boundaries. Contours are in fathoms. Flow sections C_1C_2 , C_3C_4 and C_4C_5 are indicated by double lines.

order to find out if the resulting distributions bear any relation to circulation patterns inferred from observations. Model results of this kind can sometimes suggest interesting areas for future measurements. Additionally, mean sea level distribution is a product of the superposition, yielding information on a relatively unexplored topic.

THEORY

The three-dimensional model of the Irish Sea was formulated on the grid network shown in figure 1. The grid has a square mesh of side 7.5 nautical miles and is constructed with reference to a central x -directed line along the parallel of latitude $53^{\circ}20'N$ and a central y -directed line along the meridian of longitude $4^{\circ}40'W$. The x coordinate increases to the east and the y coordinate to the north. Surface elevation ζ is evaluated at the central point of each elemental box, current u (in the x -direction) at the mid-point of each y -directed box side, and current v (in the y -direction) at the mid-point of each x -directed box side. Averaging u and v across an elemental box yields the current components at its centre. The model has open boundaries across the North Channel in the north and across St. George's Channel in the south.

The hydrodynamical equations of the model are

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} \int_0^h u dz + \frac{\partial}{\partial y} \int_0^h v dz = 0, \quad (1)$$

$$\frac{\partial u}{\partial t} - \gamma v = -g \frac{\partial}{\partial x} (\zeta - \zeta') - g(\bar{z} + \zeta) \frac{1}{\rho} \frac{\partial \rho}{\partial x} + \frac{\partial}{\partial \bar{z}} \left(N \frac{\partial u}{\partial \bar{z}} \right), \quad (2)$$

$$\frac{\partial v}{\partial t} + \gamma u = -g \frac{\partial}{\partial y} (\zeta - \zeta') - g(\bar{z} + \zeta) \frac{1}{\rho} \frac{\partial \rho}{\partial y} + \frac{\partial}{\partial \bar{z}} \left(N \frac{\partial v}{\partial \bar{z}} \right), \quad (3)$$

where

$$\frac{\partial \zeta'}{\partial x} = \frac{\partial \bar{\zeta}}{\partial x} - \frac{1}{\rho g} \frac{\partial p_a}{\partial x}, \quad \frac{\partial \zeta'}{\partial y} = \frac{\partial \bar{\zeta}}{\partial y} - \frac{1}{\rho g} \frac{\partial p_a}{\partial y}. \quad (4)$$

Here t denotes time. Coordinates x, y are measured in the horizontal plane of the undisturbed sea surface and \bar{z} is depth below that surface. Also, h denotes the undisturbed depth of water, prescribed realistically over the grid at the mid-points of the box sides. Other symbols are $\bar{\zeta}$ the equilibrium tide, p_a atmospheric pressure on the sea surface, ρ the density of the water - in general a function of x and y , γ the geostrophic coefficient - regarded as a constant, g the acceleration of the Earth's gravity, and N a coefficient of vertical eddy viscosity - assumed to be independent of the depth coordinate \bar{z} and time t , and taken to vary with x and y so that N/h is a constant.

The equations are linear and are solved for ζ, u, v on the grid of figure 1 satisfying

$$-\rho N \left(\frac{\partial u}{\partial \bar{z}} \right) = F_s, \quad -\rho N \left(\frac{\partial v}{\partial \bar{z}} \right) = G_s \quad (5)$$

at the sea surface $\bar{z} = 0$ and

$$-\rho N(\partial u/\partial z) = k\rho u, \quad -\rho N(\partial v/\partial z) = k\rho v \quad (6)$$

at the sea bottom $z = h$, where F_s, G_s are the x, y components of wind stress and k is a constant coefficient of bottom friction. Solutions have been generated numerically through time from an initial state of no motion, prescribing zero normal flow on the land boundaries and a radiation condition on the open boundaries. In the limit as time advances, steady-state solutions have been obtained yielding motion under uniform constant wind stress (with $\partial p/\partial x = \partial p/\partial y = 0$) and also under fixed horizontal density gradients (with $F_s = G_s = 0$). Such solutions are described in this paper. They do not involve the tides but represent residual flows considered as perturbations on the predominant tidal motion - which essentially determines the frictional parameters N and k .

Concerning the method of solution, equations (1), (2), (3) are transformed by vertical integration to yield (with $\partial s/\partial x = \partial s/\partial y = 0$):

$$\frac{\partial s}{\partial t} = - \sum_{r=1}^M \left\{ \frac{\partial}{\partial x} (h a_r \phi_r u_r) + \frac{\partial}{\partial y} (h a_r \phi_r v_r) \right\}, \quad (7)$$

$$\frac{\partial u_r}{\partial t} = -\lambda_r u_r + \gamma v_r - g a_r \frac{\partial s}{\partial x} - \frac{g h b_r}{\rho} \frac{\partial p}{\partial x} + \frac{F_s}{\rho h}, \quad (8)$$

$$\frac{\partial v_r}{\partial t} = -\lambda_r v_r - \gamma u_r - g a_r \frac{\partial s}{\partial y} - \frac{g h b_r}{\rho} \frac{\partial p}{\partial y} + \frac{G_s}{\rho h}, \quad (9)$$

for $r = 1, 2, \dots, M$ where

$$u_r = \frac{1}{h} \int_0^h u \cos(\alpha_r z/h) dz, \quad v_r = \frac{1}{h} \int_0^h v \cos(\alpha_r z/h) dz. \quad (10)$$

Here, M is an integer chosen sufficiently large and

$$\left. \begin{aligned} \lambda_r &= N \alpha_r^2 / h^2, \quad a_r = \sin \alpha_r / \alpha_r, \\ \phi_r &= 2 / (1 + a_r \cos \alpha_r), \\ b_r &= [(1 + s/h) c \cos \alpha_r + \cos \alpha_r - 1] / \alpha_r^2, \end{aligned} \right\} \quad (11)$$

where α_r is the r th positive root, in ascending order, of

$$\alpha \tan \alpha = c, \quad (c = kh/N). \quad (12)$$

Finite difference solutions of the two-dimensional equations (7), (8), (9) determine the spatial fields of s, u_r, v_r ($r = 1, 2, \dots, M$) through time. The initial condition of no motion requires

$$s = u_r = v_r = 0 \quad \text{at} \quad t = 0 \quad (13)$$

Figure 2. Wind-induced residuals W : (a) elevation contours in cm, (b) depth-mean currents, (c) surface currents, (d) bottom currents.

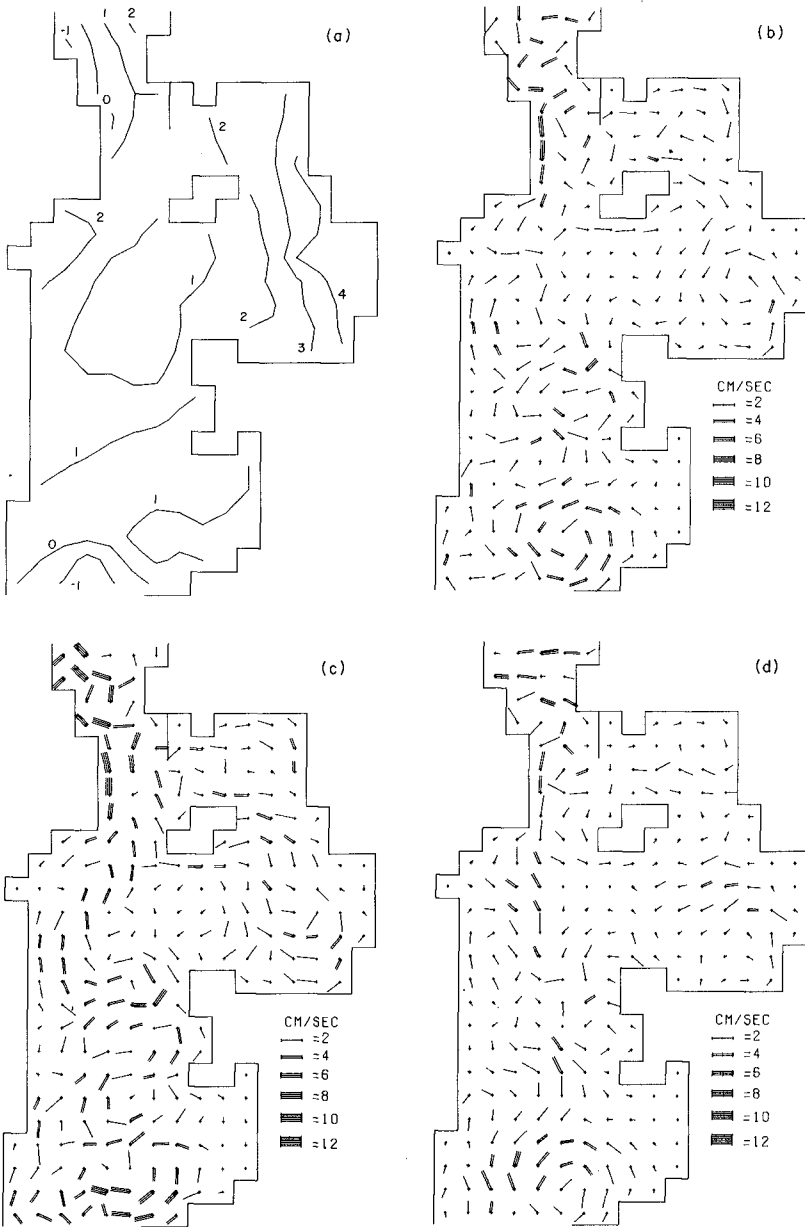

Figure 3. Density-induced residuals D_1 : (a) elevation contours in cm, (b) depth-mean currents, (c) surface currents, (d) bottom currents.

while on the land boundaries with zero normal flow :

$$u_r \cos \psi + v_r \sin \psi = 0 \quad (14)$$

and on the open boundaries with outward radiation like a simple progressive wave :

$$k \phi_r a_r (u_r \cos \psi + v_r \sin \psi) = (gh)^{1/2} \zeta, \\ u_r = v_r = 0, \quad r \geq 2; \quad (15)$$

ψ denotes the inclination of a boundary normal to the x -axis, directed out of the model area.

Having thus solved for u_r and v_r , the components of horizontal current at any depth are found from

$$u = \sum_{r=1}^M \phi_r u_r \cos(\alpha_r z/h), \quad v = \sum_{r=1}^M \phi_r v_r \cos(\alpha_r z/h) \quad (16)$$

yielding the three-dimensional current structure.

More detailed accounts of the theory and its application have been given by Heaps (1974) and Heaps and Jones (1977). As in the latter work, results given in the present paper correspond to the parametric values :

$$N/h = 0.1 \text{ cm/s}, \quad k = 0.2 \text{ cm/s}, \quad c = 2. \quad (17)$$

Also $M = 10$, which means that the expansions of current through the depth according to (16) are in terms of ten eigenfunctions or modes.

WIND-INDUCED RESIDUALS W

On the basis of data given by Hellerman (1967), annual mean wind stress conditions for the Irish Sea are taken as consisting of a uniform westerly stress of 1.0 dyn/cm^2 combined with a uniform southerly stress of 0.6 dyn/cm^2 . Corresponding residual elevations and currents derived from the three-dimensional model are shown in figure 2.

It is apparent from the figure that the winds produce a gradient of sea-surface elevation across the Irish Sea, elevation rising from -2 cm in the south-west to $+7 \text{ cm}$ in the north-east. Surface currents mostly between 3 and 8 cm/s are directed mainly to the east while bottom currents between 0 and about 3 cm/s are mainly west-going. The depth-mean currents show an anticlockwise circulation in Liverpool Bay, and in the north-south channel of the Irish Sea between Ireland and Wales these currents are north-going in the shallow coastal margins and south-going in the deeper central region.

Under the wind influence there is a net northward flow Q through the north-south channel across section C_1C_2 equal to $24.8 \times 10^3 \text{ m}^3/\text{s}$. This divides into a part Q_W passing to the west of the Isle of Man across section C_3C_4 equal to $8.9 \times 10^3 \text{ m}^3/\text{s}$, and a part Q_E passing to the east of the Isle of Man across section C_4C_5 equal to $15.9 \times 10^3 \text{ m}^3/\text{s}$. Figure 1 shows the flow sections C_1C_2 , C_3C_4 and C_4C_5 with

Figure 4. Tidal residuals T_1 : (a) elevation contours in cm, (b) depth-mean currents.

positive flow directions indicated. Table 1 sets out the corresponding flow values Q , Q_W and Q_E .

DENSITY-INDUCED RESIDUALS D_1

The residual elevations and currents of figure 3 are induced by a prescribed pattern of horizontal density gradients representative of the period 6-20 September 1971. The derivation of these results from the three-dimensional model has been fully described by Heaps and Jones (1977).

Manifestly, the elevation residuals build up to values exceeding 4 cm in the north-east from minimum values of around -1 cm near the northern and southern open boundaries. The current patterns are dominated by gyres of various scales, altogether forming a rather complex system of motion. In the Liverpool Bay region it is evident that water enters near the sea bottom moving eastwards and southwards towards the coast, leaving near the sea surface in directions between west and north. The vertically-integrated flow there constitutes a clockwise gyre. Generally, these density currents are smaller than the wind-induced currents of figure 2, particularly near the surface.

Table 1 shows that there is a density-induced flow northwards across C_1C_2 amounting to $17.9 \times 10^3 \text{ m}^3/\text{s}$. The greater part of this ($13.5 \times 10^3 \text{ m}^3/\text{s}$) passes to the west of the Isle of Man, in contrast to the behaviour of the wind-induced northwards flow of regime W (figure 2) most of which passes to the east of the Isle.

Flow Regime	Q	Q_W	Q_E
	$10^3 \text{ m}^3/\text{s}$	$10^3 \text{ m}^3/\text{s}$	$10^3 \text{ m}^3/\text{s}$
Wind (W)	24.8	8.9	15.9
Density (D_1)	17.9	13.5	4.4
Tides (T_1)	43.4	16.8	26.6
$W + D_1 + T_1$	86.1	39.2	46.9
Surface gradient (G)	-39.4	-34.8	-4.6
$G_1 = 1.586G$	-62.5	-55.2	-7.3
$R_1 = W + D_1 + T_1 + G_1$	23.6*	-16.0	39.6

TIDAL RESIDUALS T_1

Employing the equations of motion and continuity in standard vertically-integrated form, including quadratic bottom friction but omitting the convective accelerations and the effects of drying banks, tides were generated on the grid of figure 1 in response to specified open boundary tides consisting of the principal harmonic constituent M_2 . The tidal simulation was carried out along the lines described by Flather and Heaps (1975). Fourier analysis of the results, for the constant term, yielded the elevation and depth-mean current residuals shown in figure 4.

The residual elevations are all less than 1 cm, being zero by design along each open boundary. Although the residual currents are small, mostly less than 1 cm/s, their uniformity conspires to produce a comparatively large northwards flow through the Irish Sea of $43.4 \times 10^3 \text{ m}^3/\text{s}$, over half of which passes to the east of the Isle of Man (table 1).

SURFACE-GRADIENT RESIDUALS G

Setting wind stress and density gradient to zero, the three-dimensional model was used to compute the system of residual elevations and currents in the Irish Sea maintained by an elevation of +1 cm along the northern open boundary with zero elevation along the southern open boundary. These residuals, denoted by G, were found to involve a net flow from north to south through the Irish Sea of $39.4 \times 10^3 \text{ m}^3/\text{s}$, most of this passing to the west of the Isle of Man (table 1).

SUPERPOSITION OF RESIDUAL FIELDS

It is assumed that the total (long-term) residuals in the Irish Sea, constituting a regime R_1 say, may be deduced by summing W, D_1 , T_1 and bG , where b is some as yet unknown multiplying factor. For consistency in the summation, T_1 is considered to have a three-

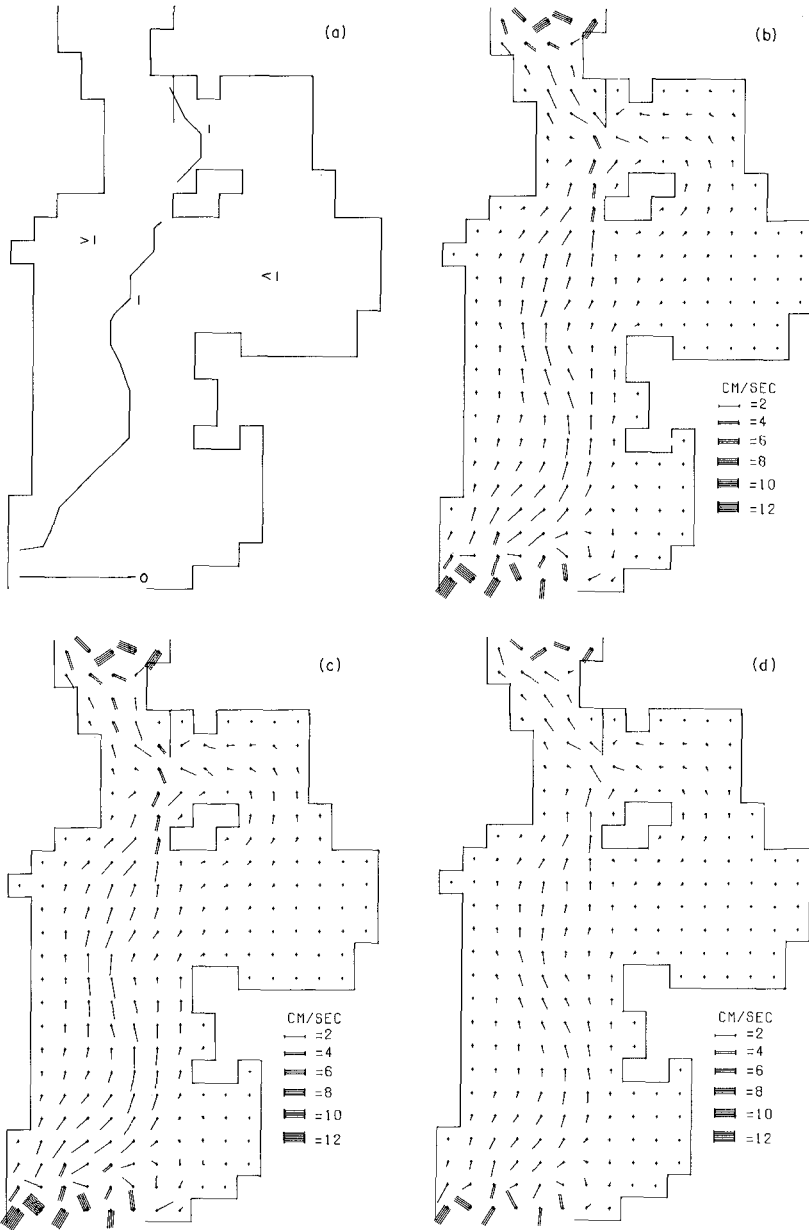

Figure 5. Surface-gradient residuals G_1 : (a) elevation contours in cm, (b) depth-mean currents, (c) surface currents, (d) bottom currents.

Flow regime	Q	Q_W	Q_E
	$10^3 \text{ m}^3/\text{s}$	$10^3 \text{ m}^3/\text{s}$	$10^3 \text{ m}^3/\text{s}$
Wind (W)	24.8	8.9	15.9
Density (D_1)	17.9	13.5	4.4
Tides (T_2)	55.1	50.0	5.1
$W + D_1 + T_2$	97.8	72.4	25.4
Surface gradient (G)	-39.4	-34.8	-4.6
$G_2 = 1.883G$	-74.2	-65.5	-8.7
$R_2 = W + D_1 + T_2 + G_2$	23.6*	6.9	16.7

dimensional current structure, the current at any depth through a vertical being taken equal to the depth-mean current. The effects of barometric pressure are excluded, it being supposed that these influence surface level only - according to the statical law. Thus :

$$R_1 = W + D_1 + T_1 + G_1 \quad (18)$$

where

$$G_1 = bG. \quad (19)$$

The above procedure follows an approach due to Prandle (1978) in estimating residual elevations and flows in the Southern North Sea. Here, b is determined by requiring that R_1 should have a south to north flow across section C_1C_2 equal to $23.6 \times 10^3 \text{ m}^3/\text{s}$, in accordance with the long-term flow values determined by Wilson (1974) from measurements of the distribution of Caesium-137 in the Irish Sea. Thus, referring to table 1,

$$24.8 + 17.9 + 43.4 - 39.4b = 23.6 \quad (20)$$

so that

$$b = 1.586 \quad (21)$$

As subsequently evaluated, residuals G_1 are depicted in figure 5 and the total residuals R_1 in figure 6.

Figure 6 shows surface elevation rising to +11 cm in the north-eastern area of the Irish Sea from a minimum value of around -2 cm in the south. Between the open ends of the Sea there is evidently, at most, a 7 cm increase in elevation from south to north. Adding 2 cm to this in order to allow for a difference in mean barometric pressure of 2 mb between the open ends, a 9 cm increase in elevation from south to north is obtained, falling short of the 15 cm increase deduced from mean sea level studies (K. R. Thompson, private communication). The surface currents in R_1 are dominated by wind influence (compare figure 6 with figure 2). However, the bottom currents are

TABLE 3

Flow regime	Q $10^3 \text{ m}^3/\text{s}$	Q_W $10^3 \text{ m}^3/\text{s}$	Q_E $10^3 \text{ m}^3/\text{s}$
Wind (W)	24.8	8.9	15.9
Density (D_2)	23.6	20.7	2.9
Tides (T_2)	55.1	50.0	5.1
$W + D_2 + T_2$	103.5	79.6	23.9
Surface gradient (G)	-39.4	-34.8	-4.6
$G_3 = 2.028G$	-79.9	-70.6	-9.3
$R_3 = W + D_2 + T_2 + G_3$	23.6*	9.0	14.6

obviously influenced considerably both by the wind-induced and the density-driven residuals. In the Liverpool Bay area, the depth-mean currents indicate a movement of water eastwards and then northwards sensibly parallel to the coast; this pattern is reflected in the surface and the bottom current distributions.

REVISED TOTAL RESIDUALS

In recent work by R. Proctor at I.O.S. Bidston, the tides of the Irish Sea have been computed using a two-dimensional numerical model covering essentially the same area as that shown in figure 1 but having a mesh length smaller by one third. The convective accelerations and the effects of drying banks, previously omitted, have been included. It turns out that the associated tidal residuals, T_2 , are significantly different from the earlier residuals, T_1 . In particular, the residual currents of T_2 exhibit strong eddies not present in the residual currents of T_1 . Eddies of similar type, arising from the convective accelerations, have been computed by Tee (1976) for Minas Channel and Minas Basin at the head of the Bay of Fundy. Using T_2 instead of T_1 in the superposition of residual fields leads to a new system of total residuals, R_2 . Elevations and currents of this system are shown in figure 7 and the corresponding flows Q , Q_W and Q_E are given in table 2. Further, employing an alternative regime of density-induced residuals D_2 in the superposition leads to total residuals R_3 : see figure 8 and table 3. The residuals D_2 are representative of the period 17 September - 6 October 1972 and have been described by Heaps and Jones (1977).

The current distributions of R_2 and R_3 (which are similar) are manifestly complex, with scales of motion scarcely resolvable on the grid network of figure 1. Currents exceed 25 cm/s in places as indicated by the box vectors. There is a distinctive anticlockwise gyre in the Liverpool Bay area reminiscent of some observationally-based results presented by Ramster and Hill (1969). The complexity of the residual circulations is reflected in the associated residual

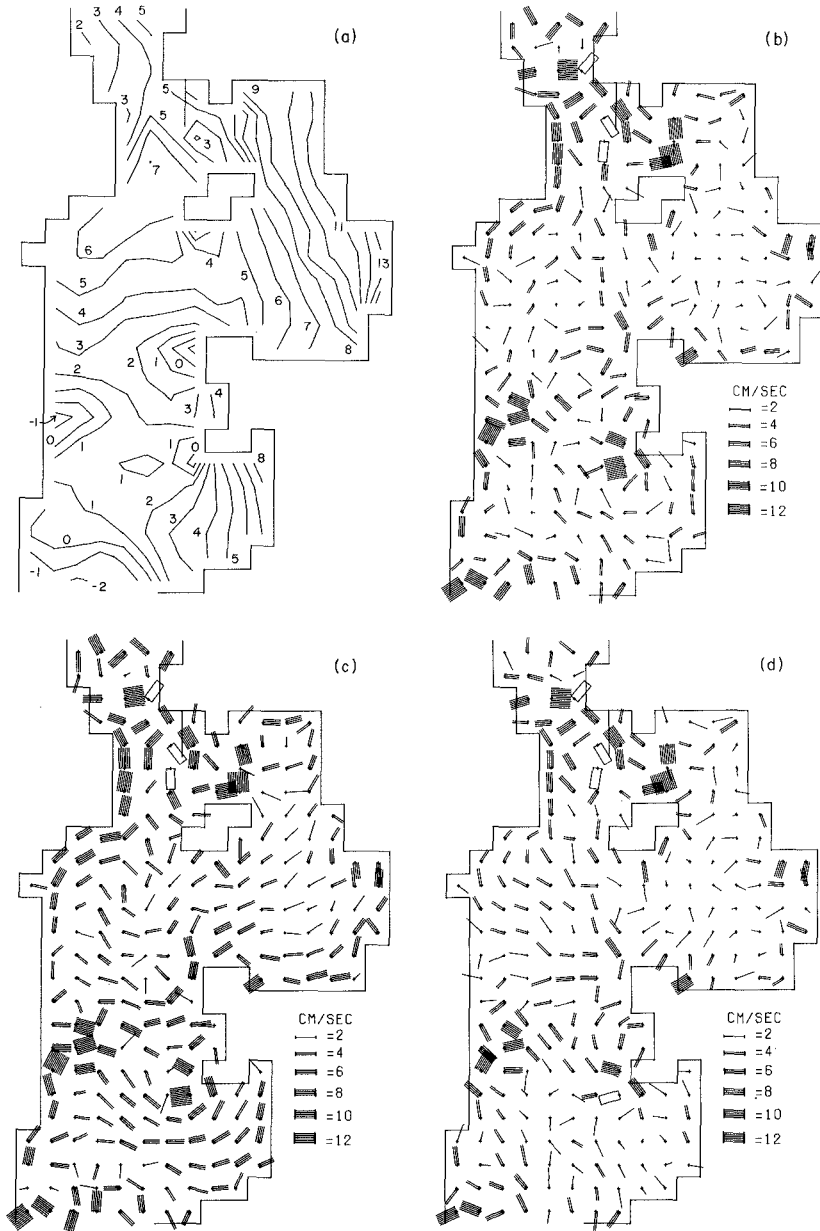

Figure 7. Total residuals R_2 : (a) elevation contours in cm, (b) depth-mean currents, (c) surface currents, (d) bottom currents.

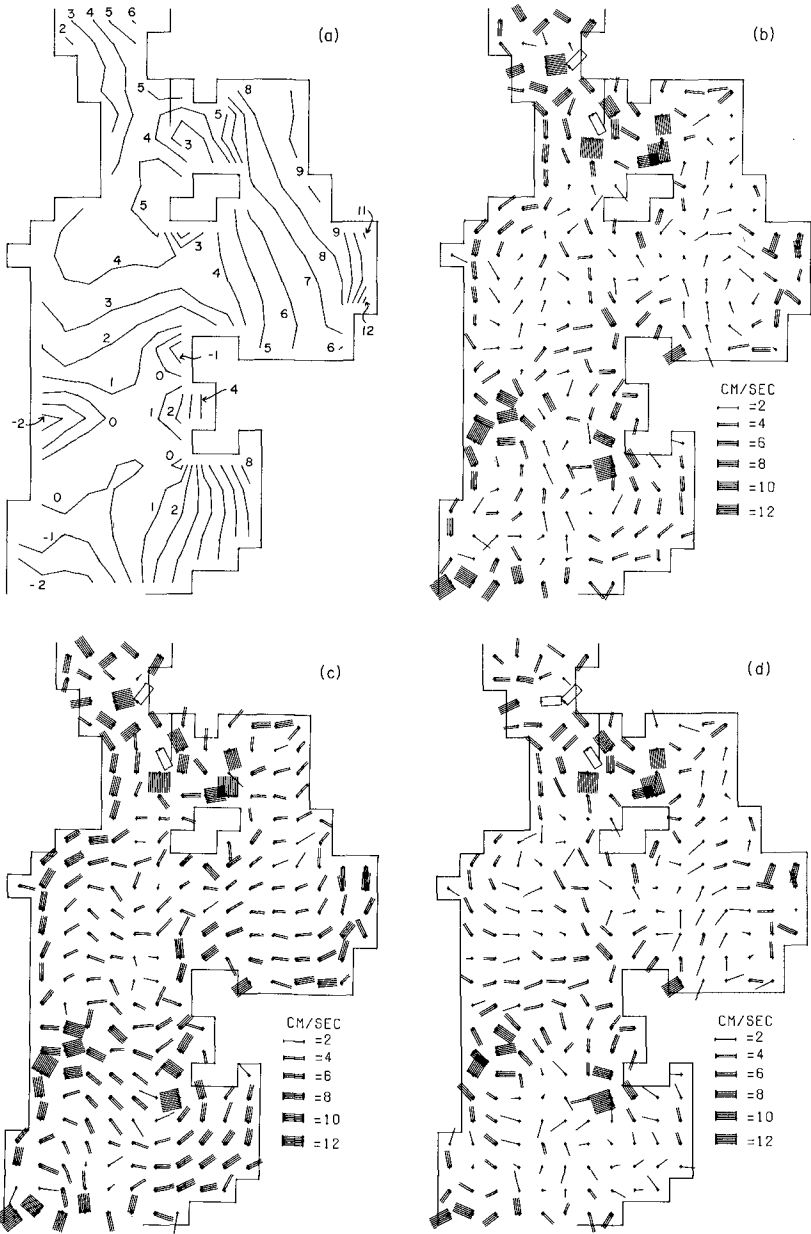

Figure 8. Total residuals R_3 : (a) elevation contours in cm, (b) depth-mean currents, (c) surface currents, (d) bottom currents.

elevations but, overall, these are similar to the residual elevations of R_1 . Tables 2 and 3 demonstrate that the north-going residual flows due to density gradients and tides tend to be balanced by the surface-gradient flows.

Our work on Irish Sea circulation is proceeding and a more comprehensive account of it will be prepared in due course.

ACKNOWLEDGEMENTS

I am indebted to Mr. J. E. Jones for much assistance in this investigation and am grateful to Mr. R. Proctor for permitting me to use some of the results of his work before their publication.

The work described in this paper was funded by a Consortium consisting of the Natural Environment Research Council, the Ministry of Agriculture, Fisheries and Food, and the Departments of Industry and Energy.

CHAPTER 164

THREE-DIMENSIONAL SGS ENERGY MODEL OF EASTERN BERING SEA

S. K. Liu and J. J. Leendertse¹

This paper describes the development, adjustments and verification of a three-dimensional, nonhomogeneous model of Bristol Bay and the St. George Basin. The modeled area (Fig. 1) is situated on the continental shelf area at the southeastern corner of the Bering Sea, which has one of the largest shelf areas of the world's oceans. Because of this, the water mass movement in the modeled area is driven predominantly by wind and tide, whereas waters in the deeper basin to the west are part of the cyclonic Bering Sea slope current system flowing parallel to the continental shelf break. Annual cycles of surface heating and cooling and the duration, strength and phasing of these periods give a distinctive hydrodynamic behavior to the system. During autumn and winter, local negative buoyancy (vertically unstable) exists due to surface cooling and brine rejection during ice formation. In spring, positive buoyancy is added by fresh water runoff, ice melting and insulation. The hydrographic structure in the modeled area is further modified by the seasonal wind, with higher mean speed in autumn and winter.

I. DYNAMIC PROCESSES

In the modeling investigation reported here the physical process involved can essentially be described by a set of partial differential equations associated with the prototype hydrodynamic system. The equations of horizontal motion for an incompressible internally source-free fluid on a rotating earth in Cartesian coordinates with z-axis positive upward are:

$$\frac{\partial u}{\partial t} + \frac{\partial(uu)}{\partial x} + \frac{\partial(uv)}{\partial y} + \frac{\partial(uw)}{\partial z} - fv + \frac{1}{\rho} \frac{\partial p}{\partial x} - \frac{1}{\rho} \left(\frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} \right) = 0 \quad (1)$$

$$\frac{\partial v}{\partial t} + \frac{\partial(vu)}{\partial x} + \frac{\partial(vv)}{\partial y} + \frac{\partial(vw)}{\partial z} + fu + \frac{1}{\rho} \frac{\partial p}{\partial y} - \frac{1}{\rho} \left(\frac{\partial \tau_{yx}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{yz}}{\partial z} \right) = 0 \quad (2)$$

where x, y and z are Cartesian coordinates, positive eastward, northward and upward, respectively; u, v and w denote the respective components of velocity; f represents the Coriolis parameter; ρ is the density of water; τ_{xx} , τ_{xy} , τ_{xz} , etc. are components of stress tensor.

The flow in the modeled area, the vertical acceleration of fluid motion associated with the predominant hydrodynamic process (i.e., tide- and wind-induced circulation) is approximately five orders of magnitude smaller in comparison with the gravitational acceleration. Therefore we can neglect the vertical acceleration and advection, and the equation of motion in the vertical direction becomes the hydrostatic equation

$$\frac{\partial p}{\partial z} + \rho g = 0 \quad (3)$$

The equation of continuity is

¹ The Rand Corporation, Santa Monica, California, U.S.A.

Fig. 1 Location map of Eastern Bering Sea and the approximate boundary of the modeled area

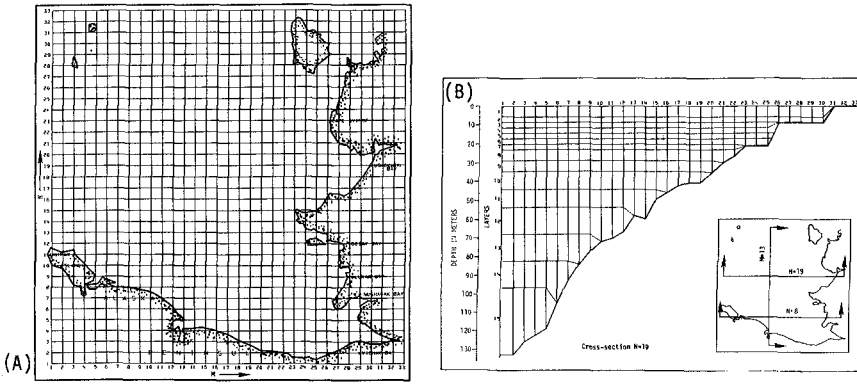

Fig. 2 Horizontal (A) and (B) distribution of grid dimensions of the modeled area

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (4)$$

The equations of salt and heat balance are:

$$\frac{\partial s}{\partial t} + \frac{\partial(us)}{\partial x} + \frac{\partial(vs)}{\partial y} + \frac{\partial(ws)}{\partial z} - \frac{\partial[D_x(\partial s/\partial x)]}{\partial x} - \frac{\partial[D_y(\partial s/\partial y)]}{\partial y} - \frac{\partial[\kappa(\partial s/\partial z)]}{\partial z} = 0 \quad (5)$$

$$\begin{aligned} \frac{\partial T}{\partial t} + \frac{\partial(uT)}{\partial x} + \frac{\partial(vT)}{\partial y} + \frac{\partial(wT)}{\partial z} - \frac{\partial[D_x(\partial T/\partial x)]}{\partial x} \\ - \frac{\partial[D_y(\partial T/\partial y)]}{\partial y} - \frac{\partial[\kappa'(\partial T/\partial z)]}{\partial z} = 0 \end{aligned} \quad (6)$$

where s and T represent salinity and temperature; D_x and D_y are horizontal diffusion coefficients; κ and κ' are vertical exchange coefficients for salt and heat, respectively.

The relationship between density, salinity and temperature can be approximated by an equation of state in the form

$$\rho = \bar{\rho} + \rho'(s, T) \quad (7)$$

Similar equations can be written for subgridscale (SGS) turbulent energy densities and dissolved pollutant constituents:

$$\begin{aligned} \frac{\partial e}{\partial t} + \frac{\partial(ue)}{\partial x} + \frac{\partial(ve)}{\partial y} + \frac{\partial(we)}{\partial z} - \frac{\partial D_e(\partial e/\partial x)}{\partial x} \\ - \frac{\partial[D_y(\partial e/\partial y)]}{\partial y} - \frac{\partial[\kappa(\partial e/\partial z)]}{\partial z} + hD \pm S_e = 0 \end{aligned} \quad (8)$$

$$\begin{aligned} \frac{\partial p}{\partial t} + \frac{\partial(up)}{\partial x} + \frac{\partial(vp)}{\partial y} + \frac{\partial(wp)}{\partial z} - \frac{\partial D_p(\partial p/\partial x)}{\partial x} \\ - \frac{\partial[D_y(\partial p/\partial y)]}{\partial y} - \frac{\partial[\kappa(\partial p/\partial z)]}{\partial z} + hK_p \pm S_p = 0 \end{aligned} \quad (9)$$

where e is the subgridscale turbulent energy per unit mass; p denotes any pollutant concentration of concern; D_e is the dissipation rate for turbulent energy; κ' is the decay rate for the pollutant concentration; and S_e and S_p are the source and sink terms for turbulent energy and pollutant concentration, respectively.

The above set of partial differential equations describes the physical processes only in a limiting sense such that quasi-continuous spatial-temporal representation is required to describe the dynamic features of concern. In the process of finding the numerical solution to the differential equations of the mean flow, certain conceptual descriptions of the fine features of the dynamic behavior are being introduced. The way to describe these fine features becomes the product of an iterative learning process. The modeler's final formulation embodies not only the specific solution method associated with the PDE, but also the investigator's conceptual description of the prototype behavior that he or she learns through data and intermediate modeling results.

Because the prototype data system, the selected model and the modeling investigators are three components in a modeling investigation, an adaptive process takes place. At the beginning, a basic model is selected by the investigators so as to be representative of the basic environmental components of the prototype system according to the available general information about the system at that time. As the modeling effort proceeds, the investigators have an opportunity to look more closely at the involved dynamic processes through the analytic nature of the numerical model. A field sampling program can thus be designed more effectively to resolve the finer details of the system. From these data, new insight leads then to further refinement of the model, and so on.

During the course of our model development, changes in formulation often took place as a consequence of new insight into the dynamic features derived from reviewing the simulation results against updated prototype data. A finite difference model was selected for the study [1,2].

If we use the standard notation for summing, differencing and shifting as defined by

$$\begin{aligned} \bar{F}^x &= \frac{1}{2} [F(i + \frac{1}{2}) \Delta x, j \Delta y, k \Delta z, n \Delta t] + F[(i - \frac{1}{2}) \Delta x, j \Delta y, k \Delta z, n \Delta t] \\ \delta_x F &= \frac{1}{\Delta x} \left\{ F \left[\left(i + \frac{1}{2} \right) \Delta x, j \Delta y, k \Delta z, n \Delta t \right] - F \left[\left(i - \frac{1}{2} \right) \Delta x, j \Delta y, k \Delta z, n \Delta t \right] \right\} \\ F_+ &= F[i \Delta x, j \Delta y, k \Delta z, (n + 1) \Delta t] \\ F_- &= F[i \Delta x, j \Delta y, k \Delta z, (n - 1) \Delta t] \end{aligned}$$

where i, j, k, n denote the discrete representation in the x, y, z, t domain, the finite difference formulation finally adapted for the computation of the modeled area takes the following form [1]:

Equations (1) through (9) for level k with layer-average values, the continuity equation, the mass momentum, and SGS energy balance equations for the interior of the modeled system, and the equation of state are:

$$\bar{\delta}_t \zeta^z = - \sum_k [\delta_x (\bar{h}^x u) + \delta_y (\bar{h}^y v)] \quad \text{at } i, j, n \quad (10)$$

$$\begin{aligned} \bar{\delta}_t (\bar{h}^x u)^t &= - \delta_x (\bar{h}^x \bar{u}^x \bar{u}^x) - \delta_y (\bar{h}^y \bar{u}^x \bar{v}^y) - \bar{h}^x \delta_z (\bar{u}^z \bar{w}^x) + f \bar{h}^x \bar{v}^{xy} - \frac{1}{\rho^x} \bar{h}^x \delta_x p \\ &+ \frac{1}{\rho^x} [h \delta_z E_x \delta_z \bar{u}^{2t} + \delta_x (h A_x \delta_x u)_- + \delta_y \bar{h}^x \bar{A}_y^x \delta_y u_-] \quad \text{at } i + \frac{1}{2}, j, k, n \quad (11) \end{aligned}$$

where E_x is the vertical momentum exchange coefficient and A_x, A_y are horizontal exchange coefficients in x and y direction, respectively.

$$\begin{aligned} \bar{\delta}_t (\bar{h}^y v)^t &= - \delta_x (\bar{h}^x \bar{u}^y \bar{v}^x) - \delta_y (\bar{h}^y \bar{u}^y \bar{v}^y) - \bar{h}^y \delta_z (\bar{v}^z \bar{w}^y) - f \bar{h}^y \bar{u}^{xy} - \frac{1}{\rho^y} \bar{h}^y \delta_y p \\ &+ \frac{1}{\rho^y} \left[h \delta_z E_y \delta_z \bar{v}^{2t} + \delta_x \left(\bar{h}^x \bar{A}_x^y \delta_x v \right)_- + \delta_y (h A_y \delta_y v)_- \right] \quad (12) \\ &\text{at } i, j + \frac{1}{2}, k, n \end{aligned}$$

$$\begin{aligned} \bar{\delta}_t (\bar{h} s)^t &= - \delta_x (\bar{h}^x \bar{u} s^x) - \delta_y (\bar{h}^y \bar{v} s^y) - h \delta_z (w s^z) \\ &+ \delta_x (\bar{h}^x D_x \delta_x s)_- + \delta_y (\bar{h}^y D_y \delta_y s)_- - h \delta_z (\kappa \delta_z s^{2t}) \quad \text{at } i, j, k, n \quad (13) \end{aligned}$$

where D_x and D_y are the horizontal diffusion coefficients and k is the vertical mass exchange coefficient. For temperature we have,

$$\begin{aligned} \overline{\delta_t(\overline{hT})} &= -\delta_x(\overline{h^x u T^x}) - \delta_y(\overline{h^y v T^y}) - h \delta_z(\overline{w T^z}) \\ &+ \delta_x(\overline{h^x D_x} \delta_x T)_- + \delta_y(\overline{h^y D_y} \delta_y T)_- + h \delta_z(\kappa' \delta_z \overline{T^{2t}}) \end{aligned} \quad (14)$$

at i, j, k, n

where k' is the vertical thermodiffusion coefficient. For SGS energy density in the system,

$$\begin{aligned} \overline{\delta_t(\overline{he})} &= -\delta_x(\overline{h^x u e^x}) - \delta_y(\overline{h^y v e^y}) - h \delta_z(\overline{w e^z}) \\ &+ \delta_x(\overline{h^x D_x} \delta_x e)_- + \delta_y(\overline{h^y D_y} \delta_y e)_- + h \delta_z(E_e \delta_z \overline{e^{2t}}) \\ &+ S - Dh \quad \text{at } i, j, k, n \end{aligned} \quad (15)$$

where E_e is the vertical momentum exchange coefficient. For pollutant constituent concentration, we have

$$\begin{aligned} \overline{\delta_t(\overline{hP})} &= -\delta_x(\overline{h^x u P^x}) - \delta_y(\overline{h^y v P^y}) - h \delta_z(\overline{w P^z}) \\ &+ \delta_x(\overline{h^x D_x} \delta_x P)_- + \delta_y(\overline{h^y D_y} \delta_y P)_- + h \delta_z(\kappa \delta_z \overline{P^{2t}}) + S \end{aligned} \quad (16)$$

at i, j, k, n

The equation of state can be approximated by

$$\begin{aligned} \rho &= (5890 + 38T - 0.375T^2 + 3s) / [(1779.5 + 11.25T - 0.0745T^2) \\ &- (3.8 + 0.01T)s + 0.698(5890 + 38T - 0.375T^2 + 3s)] \end{aligned} \quad (17)$$

at $i, j, k, n + 1$

The continuity equation is used to compute the vertical velocity diagnostically:

$$\delta_z w = -\delta_x(\overline{h^x u}) - \delta_y(\overline{h^y v}) \quad \text{at } i, j, k, n+1$$

Similar equations for velocity components u and v can be written for the top and bottom layers, but now the effects of wind and bottom friction must be considered.

$$\begin{aligned} \overline{\delta_t(\overline{h^x u})} &= -\delta_x(\overline{h^x u} \overline{u^x}) - \delta_y(\overline{h^y v} \overline{u^y}) - \overline{h^x} \delta_z(\overline{u^x w^x}) + \overline{h^x} \tau^{xx} - \frac{1}{\overline{\rho^x}} \overline{h^x} \delta_x p \\ &+ \frac{1}{\overline{\rho^x}} \left[\phi \rho_a w_a^2 \sin \psi - (E_x \delta_z \overline{u^{2t}})_{k=3/2} + \delta_x(h A_x \delta_x u)_- \right. \\ &\left. + \delta_y(\overline{h^y A_y} \delta_y u)_- \right] \quad \text{at } i + \frac{1}{2}, j, 1, n \end{aligned} \quad (18)$$

$$\begin{aligned} \overline{\delta_t(\overline{h^y v})} &= -\delta_x(\overline{h^x u} \overline{v^x}) - \delta_y(\overline{h^y v} \overline{v^y}) - \overline{h^y} \delta_z(\overline{v^y w^y}) - \overline{h^y} \tau^{yy} - \frac{1}{\overline{\rho^y}} \overline{h^y} \delta_y p \\ &+ \frac{1}{\overline{\rho^y}} \left[\theta \rho_a w_a^2 \cos \psi - (E_y \delta_z \overline{v^{2t}})_{k=3/2} + \delta_x(\overline{h^x A_x} \delta_x v)_- \right. \\ &\left. + \delta_y(h A_y \delta_y v)_- \right] \quad \text{at } i, j + \frac{1}{2}, 1, n \end{aligned} \quad (19)$$

where ϕ represents the wind-stress coefficient, w_a is wind speed, and ρ_a represents the density of air. At the bottom layer, the momentum equation becomes

$$\begin{aligned} \overline{\delta_i(\overline{h^x u})} &= -\delta_x(\overline{h^x u^x}) - \delta_y(\overline{h^y v^x}) - \overline{h^x} \delta_z(\overline{w^x}) + f\overline{h^x v^{xy}} - \frac{1}{\overline{\rho^x}} \overline{h^x} \delta_x p \\ &+ \frac{1}{\overline{\rho^x}} [(E_x \delta_z \overline{u^{2i}})_{k=\kappa-1/2} - \overline{\rho^x} g u_- (u_-^2 + \overline{v^{xy}})^2]^{1/2} / (\overline{C^x})^2 \\ &+ \delta_x(h A_x \delta_x u)_- + \delta_y(\overline{h^x A_x^y} \delta_y u)_- \quad \text{at } i + \frac{1}{2}, j, K, n \end{aligned} \quad (20)$$

$$\begin{aligned} \overline{\delta_i(\overline{h^y v})} &= -\delta_x(\overline{h^x v^y}) - \delta_y(\overline{h^y v^y}) - \overline{h^y} \delta_z(\overline{w^y}) - f\overline{h^y u^{xy}} - \frac{1}{\overline{\rho^y}} \overline{h^y} \delta_y p \\ &+ \frac{1}{\overline{\rho^y}} [(E_y \delta_z \overline{v^{2i}})_{k=\kappa-1/2} - \overline{\rho^y} g v_- ((\overline{u^{xy}})^2 + v_-^2)]^{1/2} / (\overline{C^y})^2 \\ &+ \delta_x(\overline{h^y A_x^y} \delta_x v)_- + \delta_y(h A_y \delta_y v)_- \quad \text{at } i, j + \frac{1}{2}, K, n \end{aligned} \quad (21)$$

where C denotes the local Chezy's coefficient.

In the modeled area, each vertical motion of water mass has to work against buoyancy forces induced by the density gradient. If the available kinetic energy of the turbulent motion is insufficient to overcome this stabilizing effect, turbulence is inhibited and suppressed. As a consequence, the process of momentum and mass-heat exchange will be lower than the neutral stability condition. The criteria for the onset of this turbulence-suppressing process in the system can be obtained by the local density gradient and turbulent energy level. The exchange coefficient for stratified flow can thus be expressed as

$$E_x = \overline{\rho^{xz}} L \sqrt{e_-^{xz}} \exp \left[m \frac{g}{\overline{\rho^{xz}}} \frac{(\overline{L^z})^2 \delta_z(\overline{\rho^x})}{e_-^{xz}} \right] \quad (22)$$

$$E_y = \overline{\rho^{yz}} L \sqrt{e_-^{yz}} \exp \left[m \frac{g}{\overline{\rho^{yz}}} \frac{(\overline{L^z})^2 \delta_z(\overline{\rho^y})}{e_-^{yz}} \right] \quad (23)$$

$$\kappa = a_4 L \sqrt{e_-^{xz}} \exp \left[r \frac{g}{\overline{\rho^z}} (\overline{L^z})^2 \frac{\delta_z \rho}{e_-^z} \right] \quad (24)$$

$$E_e = a_1 L \sqrt{e_-^z} \exp \left[m \frac{g}{\overline{\rho^z}} (\overline{L^z}) \frac{\delta_z \rho}{e_-^z} \right] \quad (25)$$

where L is a length scale which is taken as a function of the distance from the bottom and surface boundaries as follows:

$$L = k' z (1 - z/d)^{1/2} \quad (26)$$

where k' is the von Karman constant, z represents the vertical distance from the bottom to the point considered, and d is the vertical distance from surface to bottom. In the computation, if the computed L is greater than half of the layer thickness, the latter is used as L. In the horizontal direction, the exchange coefficient is computed as a function of the local vorticity gradient.

$$A = \gamma |(\delta_x \overline{w^y} + \delta_y \overline{w^x})| (\Delta l)^3 \quad (27)$$

where Δl is the grid dimension. From A we obtain the horizontal exchange coefficient

$$D_x = \bar{A}^x \quad D_y = \bar{A}^y \quad (28)$$

In addition, the subgridscale horizontal mixing is estimated by the well-known four-third power law of the grid dimension.

In the interior, the generation of subgridscale energy is derived from

$$S = a_3 \overline{L \sqrt{e}}^2 [(\delta_z \bar{u}^x)^2 + (\delta_z \bar{v}^y)^2] \quad \text{at } i, j, k + 1/2. \quad (29)$$

In the bottom layer, energy which is taken out of the mean flow through the bottom stress immediately enters the subgridscale energy system as a source term.

$$R_x = \frac{1}{\bar{\rho}^x} (\tau^{xz})_{k+1/2} = gu[u^2 + (\bar{v}^{xy})^2]^{1/2} / (\bar{C}^x)^2 \quad \text{at } i + \frac{1}{2}, j, k, n \quad (30)$$

$$R_y = \frac{1}{\bar{\rho}^y} (\tau^{yz})_{k+1/2} = gv[u^2 + (\bar{v}^{xy})^2]^{1/2} / (\bar{C}^y)^2 \quad \text{at } i, j + \frac{1}{2}, k, n$$

$$S = \overline{u_- R_x^x} + \overline{v_- R_y^y} \quad \text{at } i, j, k, n \quad (31)$$

The rate of turbulent energy dissipation is determined from the concept that the dissipation rate depends on the transfer process from larger eddies to smaller eddies according to

$$D = a_2 e^{3/2} / L \quad (32)$$

In the model, the explicit integration scheme is used in the horizontal direction, whereas an implicit scheme is used in the vertical, thus removing the most stringent stability condition associated with the numerical solution method. Some modifications have also been made to handle arbitrary bathymetry in the computational scheme; they are described in [3].

II. MODEL SETUP AND ADJUSTMENT

Because of the nonhomogeneous hydrodynamic behavior, the vertical resolution is essential for good representation of the vertical fine structures in the modeled area. After a series of initial tests, a model of 15 layers was found to be necessary for resolving both the pycnocline and the bathymetric distribution using a vertical grid network with unequal distances. The horizontal and vertical schematization of the modeled area are illustrated in Fig. 2.

The initial conditions for model simulation were selected from a quasi-synoptic hydrographic survey conducted during early summer of 1976 by the National Oceanic and Atmospheric Administration involving 141 sampling stations. For the deeper portion of the bay, the mixed layer thickness was selected uniformly at 22m. CTD data in this area indicate some anomaly from this value, depending on the local wind condition. It is our opinion that this value (i.e., 22m) gives a good representative condition for that period. Any anomaly from this mean value induced by a transient wind field would be accounted for during the simulation.

The horizontal grid dimension of the model is 21.82 km, which is equal

in both directions. The vertical grid dimension (Fig. 2) was selected as such that it gives good resolution near the areas of density nonhomogeneity and at the same time provides accurate bathymetric representation of the system. The top layer is somewhat larger (6m) to accommodate the anticipated tidal range and wind setup near the coastal areas. The step size used for time integration was 3 min.

One of the most difficult and yet important tasks in the numerical simulation of coastal seas is the specification of open-boundary conditions. During the model's setup stage, only two major tidal components, namely, K1 and M2, were used in a series of test runs. The amplitude and phase of these two components were obtained from a set of two tidal charts compiled by NOAA using updated information up to that time. In the model's adjustment process, similar boundary conditions were applied, but now the computed amplitudes and phases at model interior points are compared to the reported values in the cotidal charts. During the course of adjustment, bottom stress coefficients were changed until amplitudes and phases of the main tidal components in the model agreed with the tidal charts.

Computed amplification and phase lag of tidal propagation between the model's boundaries and interior points have been used to adjust the bottom stress coefficients. A Chezy value of 700 (in cgs units) was found to be appropriate. Because of the relatively low tidal dissipation in the bay system, the dynamic field is not very sensitive to the selection of bottom stress coefficients as in many shallow tidal estuaries. On the other hand, the dynamic behavior near the pycnocline is sensitive to the selection of turbulent closure constants relating the vertical density gradient and the transport, generation, and decay of turbulence. After the adjustment process, the same values were used later for the model's verification run. These turbulent closure constants take the following values:

$$\begin{aligned}a_1 &= 1.0 \\a_2 &= .08 \\a_3 &= .08 \\a_4 &= .001\end{aligned}$$

During the initial stages of the study, a series of preliminary test runs was made for the adjustment of the model. During this period, only two tidal constituents were applied at the model's open boundary. As we have mentioned earlier, amplitude and phase of these two tidal components were derived from a set of two tidal charts compiled by NOAA, using updated information during that time.

For each of the simulation runs, the computed field of water level, velocity, temperature, salinity and turbulent energy densities were tabulated and graphed. Computed vertical profiles of salinity and temperature were compared against the observed profiles by which constants in the turbulent closure computations were determined.

III. MODEL VERIFICATION AND PREDICTION

After the model's adjustment phase, a particular period in 1976 was selected for verifying the predictability of the model and the establishment of a set of predictive parameters.

The beginning period from June 16 to June 19, 1976 was selected because during that period vertical pycnic structure was fully developed to represent the spring-summer conditions in the modeled area. In other words, once the model is verified, it can thus be considered useful for predictive purposes for the spring-summer period. Therefore, during the verification run, all the simulation parameters such as turbulent closure constants and bottom stress coefficients were kept the same as those used at the final stages of the model adjustment period.

For the model's verification run, the boundary conditions were obtained indirectly from field measurements. At several points along the boundary of the model, water level data were recorded over long periods of time. Unfortunately, the recording periods were not all simultaneous and did not coincide with the period of current observations in other parts of the modeled area. To make the most effective use of all data in our studies, we used predicted boundaries and simulated time periods for which current data were available for verification. The tide predictions were based upon tidal analysis by our co-workers at NOAA of pressure recordings at the boundary station. From this information, the tide was predicted at the stations which coincide with the field data stations. For the model boundaries between the locations where tide predictions were available, linear interpolation of tidal amplitudes and phases were used for each tidal constituent.

Basic input information used for the verification run were observed average wind condition over the area and the predicted tides at the model's open boundaries. By compiling ship's weather reports, an average SW wind of 15 knots for the verification period was derived. The speed and direction of the wind during that period did not change.

Cumulative effects of surface wind stress outside of the model's area are, of course, unknown unless measured water levels instead of the predicted water levels are used. However, because the model's open boundaries are located approximately halfway between the Kamchatka Peninsula, the USSR and Bristol Bay in the east/west direction, and also located halfway between the Chuktskiy Peninsula, the USSR, and the Alaskan Peninsula in the north/south direction, the model's open boundary is located approximately at the midpoint of the water surface due to wind setup for almost all wind directions. Due to this consideration, the predicted water level at open boundary requires no further wind adjustment for the purpose of our computation.

In this section, observed current at four locations is compared to the computed values, located nearest to those current meter deployments. The current meter locations in the field did not coincide with the grid system. Also, the local depth at the current meter locations is not

necessarily the same as in the model. Consequently, differences in computed and observed values can be expected for these reasons alone.

Figures 3 through 6 present the hourly observed current data and the computed current at locations near the current meter. Also presented in these graphs are the computed water level and the vertical velocity components.

Figure 3 contains four graphs. Graph A gives the water level at grid point (14,14) from dynamic computation. Graph B illustrates the computed east/west current components at four depths at this grid location plotted together with the hourly observed east/west current component at station BC-2 (see insert map), measured at a 20-meter depth. Graph C gives similar comparisons, but for the north/south velocity components. These computed values agree quite well with the reported average values. Some uncertainties still exist. These uncertainties include the true horizontal location of the station. Depth values in the model are schematized according to the published navigation chart, which may not represent the true local depth. Local depth of the mixed layer may also be slightly different from the modeled value. Finally, the predicted water level at the model's open boundary also contains certain random and systematic errors which would affect the computed results. Graph D contains six curves representing the computed vertical velocity components at six selected layers. The vertical velocity of these layers not only reveals tide-induced vertical displacements, but also contains instabilities induced by the vertical stratification. The dynamic behavior of each layer is closely related to the local vertical densimetric Froude number and the Brunt-Väisälä frequency. More detailed discussion on the vertical dynamic behavior will be given later. Figure 4 gives similar comparison graphs for station BC-5. In this figure, the currents are plotted as magnitudes and direction. The computed currents in the lower layers agree quite well with the observed values, whereas surface currents are in general higher than the computed magnitudes--particularly at their maximum range. The predicted current directions are excellent (Graph C). Some of the underestimates in the surface currents at this particular location may be traced to the low turbulent energy content. This is indicated by the dichotomic velocity distribution in the vertical (Graph D). Notice the lack of vertical velocity gradients in the bottom layers as compared to the similar graph in Fig. 3.

The next figure (5) represents the comparison at station BC-14, which is located very close to the Alaskan Peninsula. The computed currents agree well with the observed values, particularly for the east-west component. The vertical motions due to wind and tides increase the turbulence intensity close to the southern boundary and the salinity and temperature distributions are nearly homogeneous. Vertical displacements are very large, resulting in a vertically near-homogeneous structure.

Good agreement is also found at station BC-15 (Fig. 6). This station is shallower than the previous three stations. Vertical displacements of water columns show pronounced instabilities (Graph D), yet the magnitude is only about one-third of that at station BC-14.

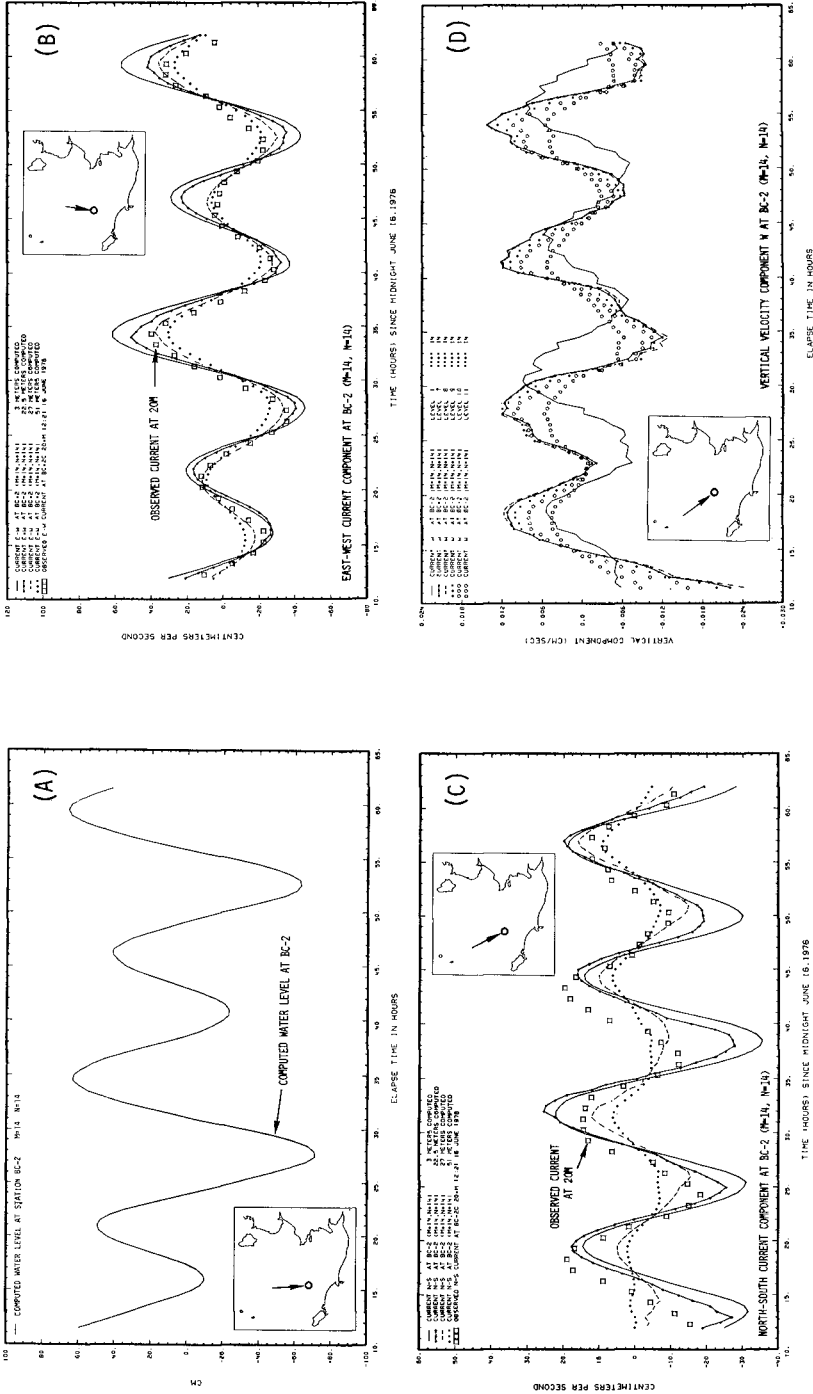

Fig. 3 --Comparison between the computed and the observed current component at a given location (B and C) together with the local water level (A) and vertical velocity component at six selected levels (D) during the period 0000 16 June through 1400 18 June 1976.

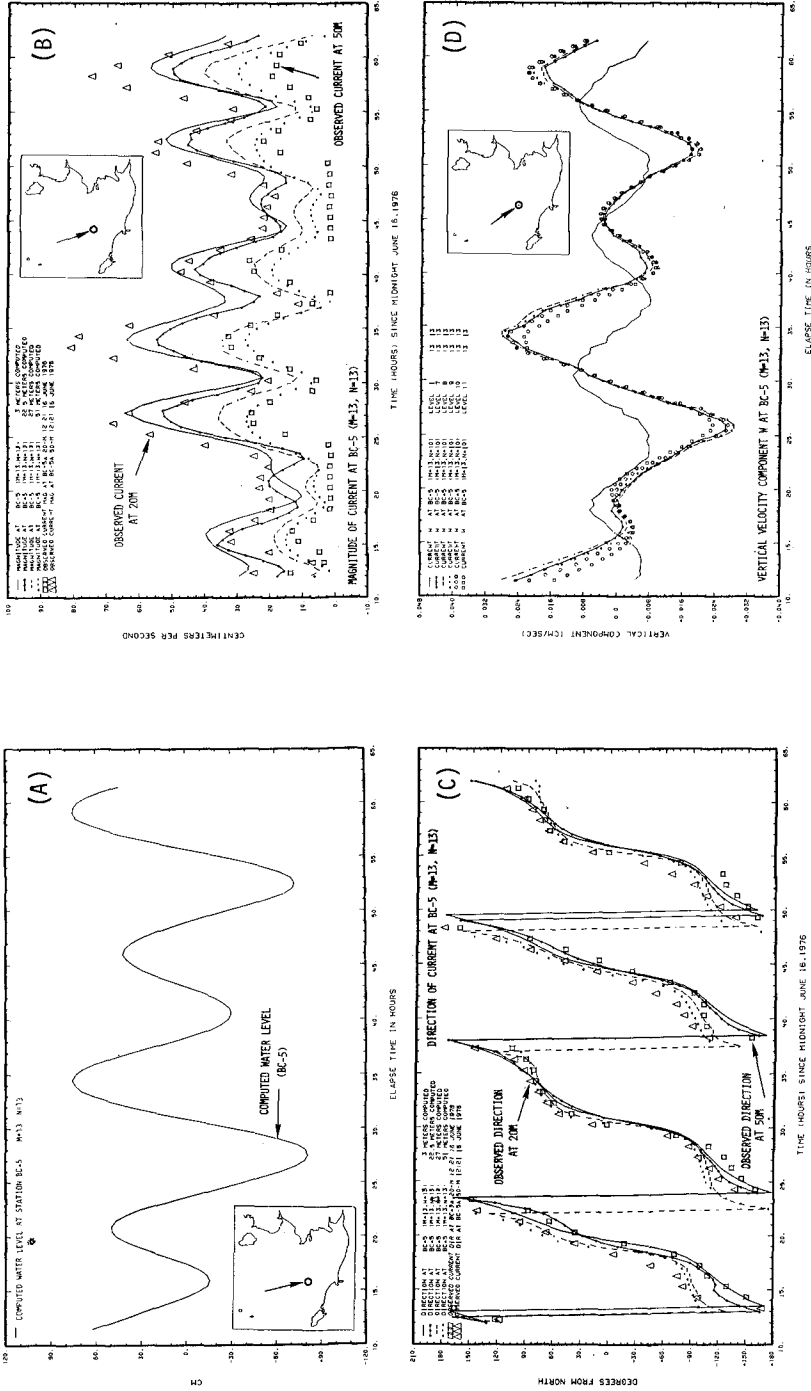

Fig. 4 --Comparison between the computed and the observed current speed and direction (B and C) together with the local water level (A) and vertical velocity component at six selected levels (D) during the period 0000 16 June through 1400 18 June 1976

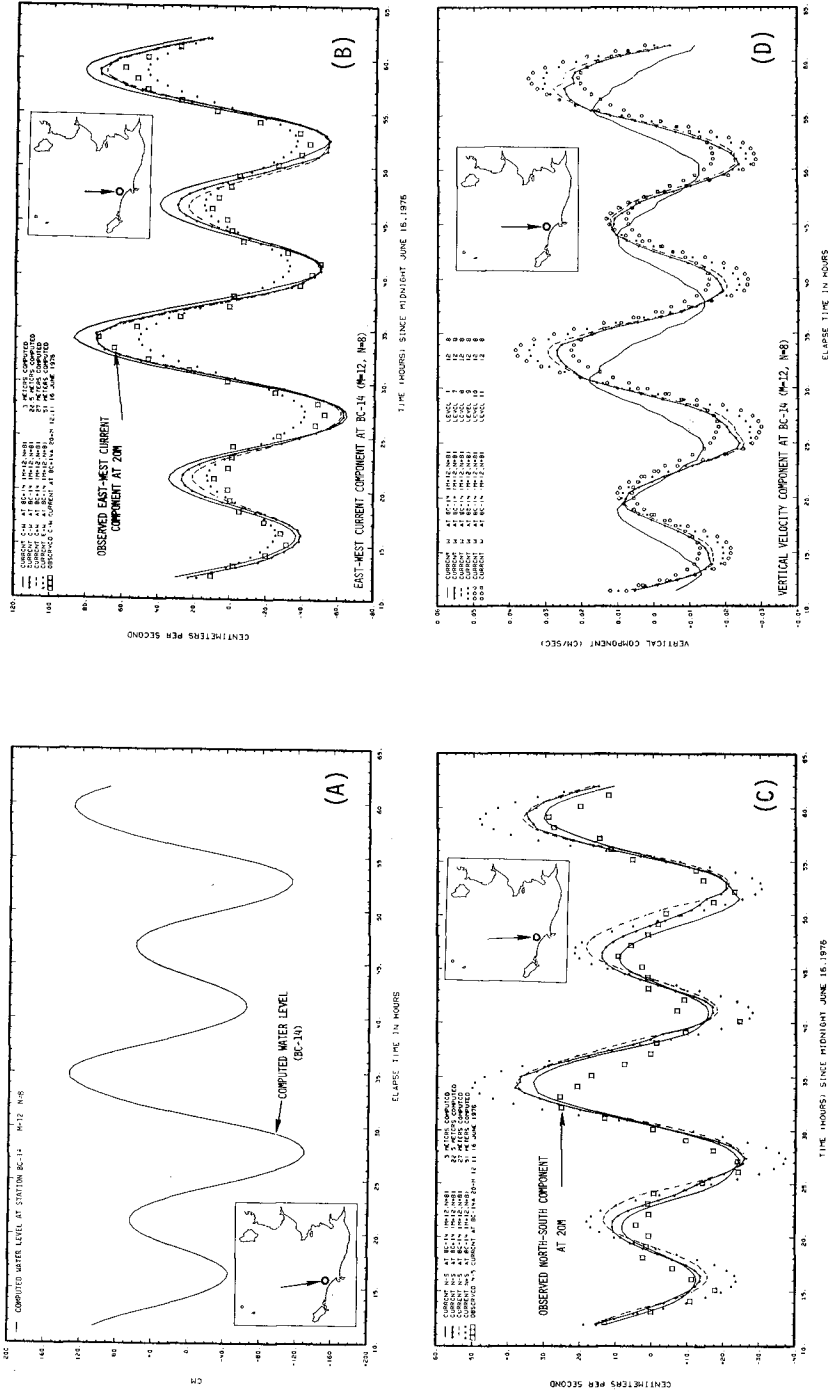

Fig. 5 -- Comparison between the computed and the observed current components at a given location (B and C) together with the local water level (A) and vertical velocity component at six selected levels (D) during the period 0000 hr 16 June through 1400 18 June 1976.

In the spring-summer period, stable stratifications are usually found in the waters with depth greater than 50 meters. This positive density gradient requires additional energy in the vertical turbulent exchange process. As a consequence, not only is upwelling being suppressed, but the bottom layers are also being insulated from the surface wind stress. Unlike the deeper layers where water is nearly neutrally stable, the upper layers tend to oscillate from their equilibrium position. This oscillation can often be characterized by the Brunt-Väisälä frequency which, in the upper layer, can be approximated by

$$N = \left\{ - \frac{g}{\rho_0} \frac{\partial \bar{\rho}}{\partial z} \right\}^{\frac{1}{2}}$$

where N is in radians per second, and ρ_0 is the reference density at the free surface.

From the observed data, the period of oscillation (i.e., $2\pi/N$) varies from a fraction of an hour in the thermocline to several hours in the deeper waters, although it is more difficult to measure in the lower layers. In the simulation the computed vertical velocity component also gives a convenient indication of the vertical displacements by means of frequency-domain analysis. To illustrate this dynamic behavior, we analyzed the vertical velocity component W for selected layers at several locations by the spectral method. For example, in the surface layer at station BC-14, the computed vertical velocity component contains not only tide-generated vertical displacements, but also oscillations induced by the stratification effect (Fig. 7). The shapes of these spectra all possess a similar slope; they fall approximately as f^{-2} at the lower frequencies and then flatten out to around f^{-1} above 0.5 cycles per hour. This characteristic shape agrees with the observed spectra of the first mode internal waves [4].

The computed coherency spectra are shown in Fig. 8. Higher coherencies are found generally in tidal frequencies. Coherency-associated vertical instabilities are between 0.5 and 0.6. This is in general agreement with the observations of Haurwitz, et al. [5].

A sequence of predicted results from the computations is presented in Fig. 9. Figure 9A shows the computed water level, velocity distribution in the surface layer and the rise and fall of the water surface at 1400 p.m., June 18, 1976. Computed velocity distribution in the 8th layer (depth = 27m) is presented in Fig. 9B. Figures 9C and 9D show the instantaneous distribution of salinity and temperature in the surface layer at 1400 p.m. June 18, 1976. At the same point in time, the vertical distribution of salinity, temperature and turbulent energy densities (in ergs per unit mass) through a cross-section are shown in Fig. 10.

The tidal propagation within the modeled area may be illustrated by a set of three-dimensional plots from the results of the hydrodynamic computation. A period of 12 hours of the verification period, from 0200 hour to 1400 hour June 18, 1976, is selected to demonstrate the

Fig. 7

Fig. 8 Computed coherency spectra between the oscillation in the surface layer and layer 7 (A) and between the surface layer and layer 11 (B) near station BC-2

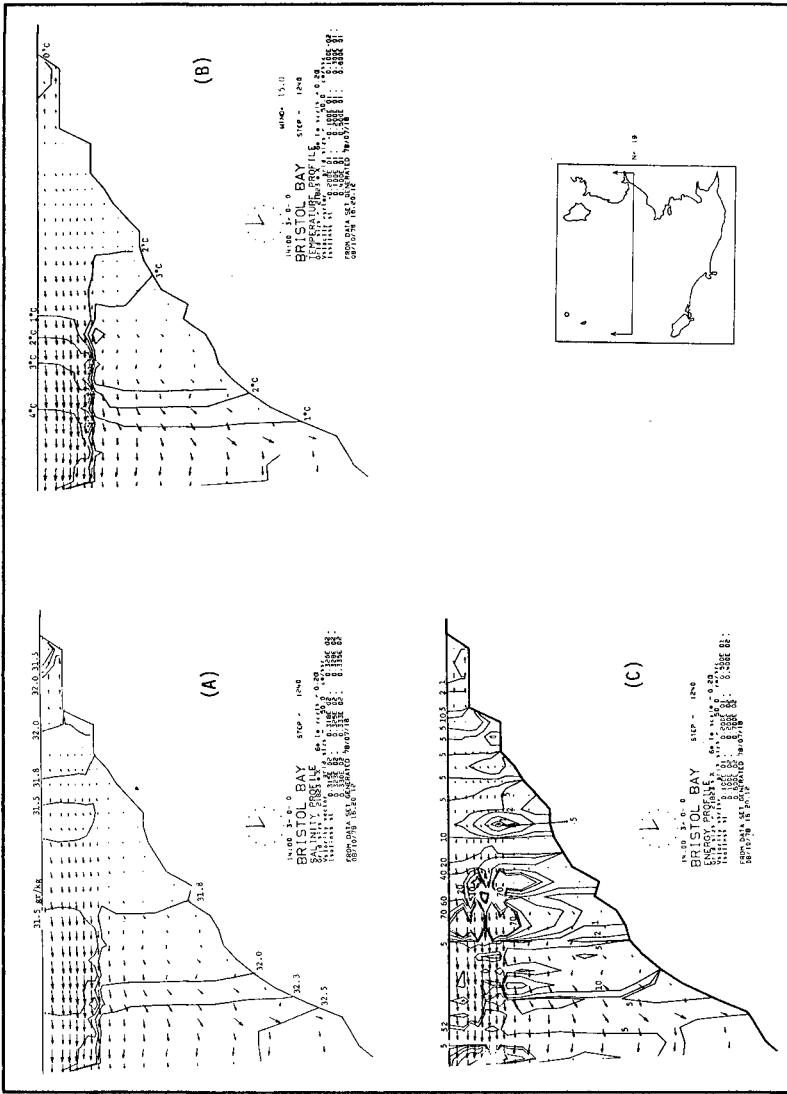

Fig. 10 Computed vertical distribution of salinity (A), temperature (B) and turbulent SGS energy (C) along a profile indicated in inset map at 1400 p.m. June 18, 1976. The vertical plotting scale for the vertical velocity component has been enlarged 727 times.

movement of the water surface in the modeled area. Figure 11 illustrates the rising and falling of the water surfaces in the modeled area at three-hour intervals as they would be seen by a spectator looking from the north toward the Alaska Peninsula. Higher tidal harmonics superimposed on the principal lunar and solar components are also evident. It should be pointed out that the result would be different if the computation were to be carried out assuming a homogeneous density structure. This is due primarily to the different vertical shear structures induced by the vertical density gradient and the modification of the horizontal pressure gradient caused by the variations in the horizontal density distribution.

The computed co-tidal charts for the diurnal and semi-diurnal components are presented in Figs. 12 and 13. These results are derived from 51 hours of computed results by means of 2-D Fourier transformation. They are compared to the observed charts for the K1 and M2 components derived from long-term data compiled by NOAA. Both the phase and the location of amphidromic points agree well with the observed chart. It seems our bottom friction coefficient is still somewhat on the high side.

Acknowledgment

This study was supported by the Bureau of Land Management through interagency agreement with the National Oceanic and Atmospheric Administration, under which a multi-year program responding to needs of petroleum development of the Alaskan continental shelf is managed by the Outer Continental Shelf Environmental Assessment Program (OCSEAP) Office.

CHAPTER 165

The Wind-Driven Circulation in the Northern Arabian Sea

Khawaja Zafar Elahi

and

Jürgen Sündermann
Professor, Hamburg University, FED. REP. GERMANY

ABSTRACT

The circulation pattern in the northern Arabian Sea is presented for the well defined wind fields, which are classified as the South-West Monsoon and the North-East Monsoon. To check the reproduction ability of the model, first tidal waves are computed. The results shows a good agreement with the known values given in literature.

1. INTRODUCTION

The wind-driven circulation represents the major global systems of surface and subsurface currents found in the world ocean. These are caused by the wind, which blows in a steady direction during a reasonable time. It transmits momentum to watermasses through surface frictional stresses.

The Indian Ocean has many variable currents due to monsoon wind systems that blow across it, changing direction as the seasonal changes. Similar effects exist for the northern part of the Arabian Sea.

The well-developed wind fields are classified as:

South - West Monsoon and

North - East Monsoon.

The South - West monsoon lasts from May to September (summer monsoon). Wind direction during this time is from south-west wards over the North Indian Ocean.

The season of the North - East monsoon lasts from November to March and this is also known as the winter monsoon. Over the north Indian Ocean, i.e. the area of the Arabian Sea and Bay of Bengal, the winds blow from the NE-direction. These two wind-periods will be used to reproduce the wind-driven circulation patterns in the modelled area.

2. THE TWO-DIMENSIONAL HYDRODYNAMICAL-NUMERICAL MODEL

The computation of tides and wind driven circulations in the Northern Arabian Sea was based on the quasi-linear, vertically integrated hydrodynamical differential equations:

$$\begin{aligned} \frac{\partial u}{\partial t} - 2\omega \sin \phi v + \frac{r}{H} \sqrt{u^2+v^2} u - A \Delta u + \frac{g}{R \cos \phi} \frac{\partial \xi}{\partial \lambda} &= \frac{\mu}{H} \sqrt{u^2+v^2} u \\ \frac{\partial v}{\partial t} + 2\omega \sin \phi u + \frac{r}{H} \sqrt{u^2+v^2} v - A \Delta v + \frac{g}{R} \frac{\partial \xi}{\partial \phi} &= \frac{\mu}{H} \sqrt{u^2+v^2} v \\ \frac{\partial \xi}{\partial t} + \frac{1}{R \cos \phi} \left(\frac{\partial}{\partial \lambda} (Hu) + \frac{\partial}{\partial \phi} (Hv \cos \phi) \right) &= 0 \end{aligned}$$

The following notations have been used:

u, v	components of vertical averaged velocity in the x-, y-direction, resp.
ξ	water elevation
A_h	horizontal eddy coefficient
g	acceleration due to gravity
h	mean water depth
H	$h + \xi$ actual depth
r	bottom friction coefficient
R	radius of the Earth
t	time
U, V	components of the wind velocity
x, y	space coordinates in E- and N-direction, resp.
λ, ϕ	geographical longitude and latitude
μ	surface friction coefficient
ω	angular velocity of the Earth's rotation

In addition to these equations the following boundary conditions have been considered:

- On the closed boundaries normal and tangential components of velocity are taken to be zero.
- On the open boundaries, which are the supposed joining lines of the modelled part with the main ocean, water-levels as a function of time for 4 main tidal constituents are supposed to be known and are calculated by:

$$\zeta(t) = \sum_{i=1}^4 a_i \cos(\sigma_i t - \kappa_i)$$

where

A_i amplitude

σ_i frequency

κ_i phase of the incoming tide

Moreover, the velocity gradients in the normal direction are zero at an open boundary.

In the case of the circulation model, to avoid the domination of the tidal forces on the flow pattern, waterlevels are supposed to be equal to zero on the open boundaries.

The initial conditions are:

$u = v = 0$; $\zeta = 0$. The solution after a sufficient long time is independent of these conditions.

An explicit finite difference method is used to solve the governing equations, the method is given in detail in reference /1,2/. The sea area is covered with the computational grid shown in fig. 1.

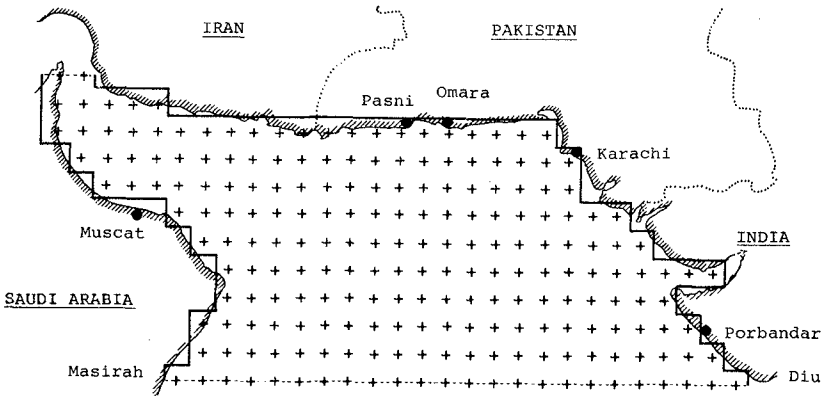

Fig. 1 Computational grid for the Northern Arabian Sea

The computational parameters used in model are as follow:

$\Delta\phi = \Delta\lambda = 0.5$ space step

$\Delta t = 1200$ s resp. 150 s time step

$A_h = 10^6$ cm²/s eddy coefficient

$r = 0.003$ bottom friction coefficient

$\mu = 3.2 \cdot 10^{-6}$ drag coefficient

$W = \sqrt{U^2 + V^2} \cdot \frac{1}{2} = 5$ m/s wind velocity

The larger time step is used for the circulation model, the smaller one for the tidal model.

In deep water areas instead of the real depth the EKMAN depth is used in the wind driven circulation model. As the system of equations is vertically integrated and the maximum depth in the area is 3500 m, wind is not effecting the whole depth, but only the upper layer, known as EKMAN depth. Under the special conditions of the Arabian Sea the value of this parameter is 72 m.

3. RESULTS

For the verification of the model at first the tidal waves in the area have been computed. The numerical results for principal semi-diurnal lunar tide M_2 are presented in fig.2 in the form of co-tide and co-range lines.

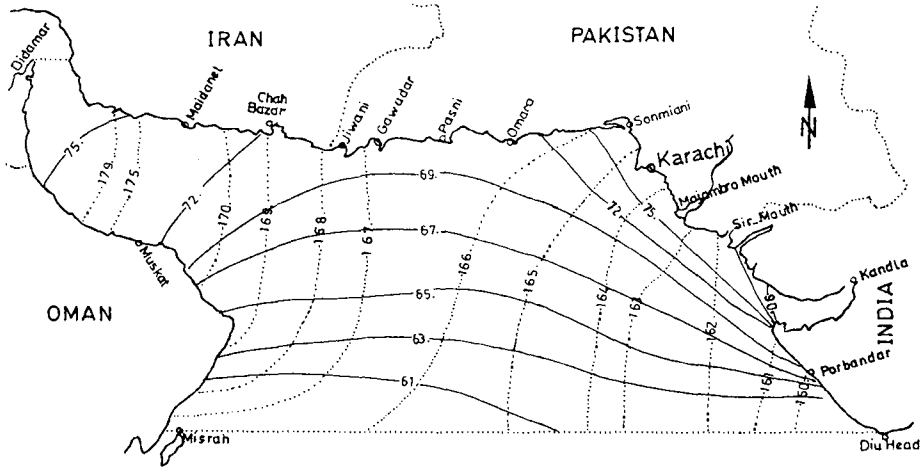

Fig. 2 M_2 -tide in the Northern Arabian Sea
 ——— isolines of amplitude in cm
 isolines of phase in degree related to Greenwich

The harmonic constants for the gauges Porbandar, Karachi, Ormara, Pasni and Muscat are used to compare the computed values. Results on the gauges Porbandar, Karachi and Pasni are in a very good agreement with the observed values, but is a little difference at the gauge Ormara. The observed value for this gauge is known only through the local tide table /3/ and as the results of the other two neighbouring

gauges are in good agreement, one can doubt about the observed value. The difference in values at gauge Muscat is due to cross influence of two open boundaries. The result for four major tidal harmonic constants are presented in table 1 in comparison with the observed values.

TIDAL CONSTITUENT		M_2		S_2		K_1		O_1

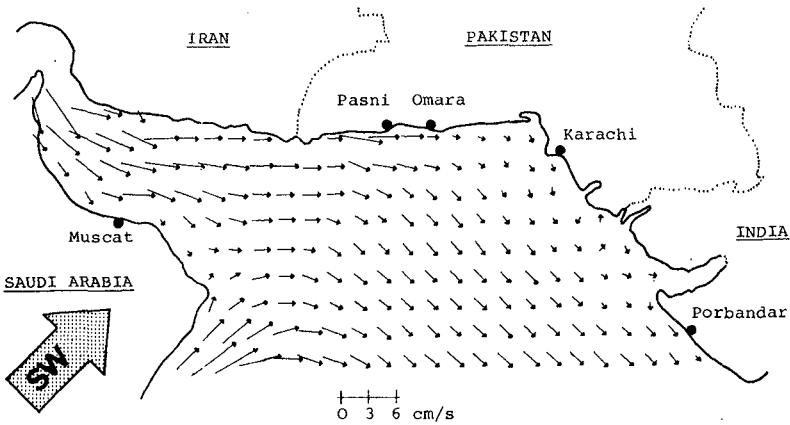

Fig. 3 Steady circulation in the Northern Arabian Sea during South-West Monsoon

The circulation pattern during the south-west monsoon is shown in fig. 3. The circulation field is characterized by a clockwise circulation superimposed by a tangential inflow from the Persian Gulf. The well known westward intensification caused by the latitudinal variation of the CORIOLIS force is seen along the Arabian coast. The circulation pattern is compared with the results of G. Schott, published in 1943 /4/ and presented in fig. 4. The computed results are in very good agreement with this circulation pattern.

Fig. 4 Surface currents in the Indian Ocean in the Northern Summer (after G. Schott, 1943)

Effect of NE-monsoon is also studied and the result regarding the circulation pattern is shown in fig. 5.

CHAPTER 166

SHELF AND COASTAL BOUNDARY LAYER CURRENTS, MISKITO BANK OF NICARAGUA

by

Richard L. Crout and Stephen P. Murray

Coastal Studies Institute, Louisiana State University

Baton Rouge, Louisiana 70803

Abstract

A 2-year study of the currents and salinity (density) fields has been conducted on the broad, shallow Miskito Bank of the eastern coast of Nicaragua.

Observations across the Bank show a southward-flowing low-salinity, seaward-thinning wedge of highly turbid water trapped against the coast within the first 25-40 km offshore. This so-called coastal boundary layer grades seaward into a northward-flowing shelf current of open-sea salinity that is essentially free of suspended sediment. Detailed transects across the coastal boundary layer show the salinity (density) structure to be closely coupled to the high-speed jet of south-flowing water.

Velocity and density measurements from the coastal boundary layer allow quantitative evaluation of each of the terms in the momentum balance equation and of the effect that each has on the circulation dynamics. The Coriolis force, the baroclinic and barotropic pressure gradient forces, and the internal friction force make important contributions to the on-offshore force balance. In the longshore balance, only the baroclinic pressure gradient force was found to be insignificant. A marked difference in this balance of forces was observed in the upper and lower layers of the water column in both the alongshore and on-offshore balances.

Introduction

Studies of continental shelf circulation have been varied in their scope. The middle and outer shelf has been studied primarily by physical oceanographers (Niiler 1975), while the innermost region, essentially the surf zone, has long been under intensive investigation by sedimentologists and engineers.

Much of the research has dealt with the circulation of the mid-shelf region on the United States East Coast, known as the Mid-Atlantic Bight. Stommel and Leetmaa (1972) and Csanady (1976) found that the circulation dynamics in the bight are the result of density differences, wind stress, and longshore surface elevations. On the shelf south of Long Island, observations show that longshore surface slope is balanced by the boundary frictional stresses (Scott and Csanady 1976).

In recent years the zone or prism of water extending out few tens of kilometers from the coast has come to be recognized as a distinct dynamical unit (Csanady 1977). The dominant role of wind stress on the shallow waters, the stratified water column arising from coastal runoff, and the blocking effect of the coast all combine to produce a flow field quite distinct from that on the shelf proper. This zone, commonly referred to as the coastal boundary layer (CBL), is of great practical importance since it is here that sewage and industrial wastes are dispersed offshore and alongshore, erosion of bottom sediment eventually affects beach behavior, and biological productivity reaches a maximum.

The CBL should be fully developed and approximately in a steady state along a shallow coast subject to large, constant, fresh-water runoff and strong persistent winds.

The objectives of this study were (a) to determine the circulation and salinity distributions on a shallow bank subject to a high freshwater input and strong, steady winds, (b) to identify the relationship between flow in the coastal boundary layer and that on the shallow shelf beyond the CBL, and (c) to measure or calculate the forces in the momentum balance of the CBL in order to understand the mechanics controlling its velocity and salinity fields. This experiment was part of a larger project undertaken to understand interrelationships between oceanographic, meteorologic, geologic, and morphologic processes on the Nicaraguan east coast (Owens and Roberts in press; Murray et al. in preparation; Hsu in press; Hsu in press).

Study Area

A suitable area for investigation of these points is found off the Caribbean coast of Nicaragua and Honduras, where the shallow platform of the Miskito Bank extends several hundred kilometers offshore. Figure 1 shows the southern half of this bank and the adjacent ocean area. Near the 100-m contour at the bank edge depths drop precipitously down to several thousand meters. The flat profile of this shallow-water bank is best illustrated by comparing it (Fig. 2) to a profile across the West Florida Shelf (Niiler 1976), considered to be an extremely low sloping continental shelf by North American standards.

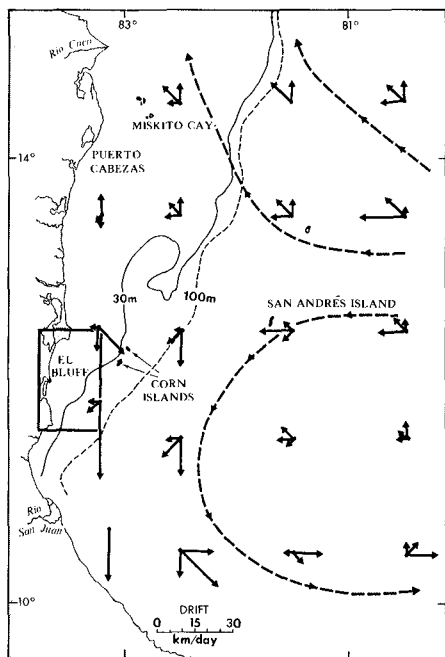

Figure 1. The southern half of the Miskito Bank, off Nicaragua. The outlined area along the coast was the site of a detailed study in 1977. Surface current vectors are plotted by 1° squares.

Figure 2. Comparative bathymetric cross-sections across the Miskito Bank and the West Florida shelf.

Winds across this bank are remarkably persistent in speed and direction, as shown by records from the U.S.-Colombian cooperative weather station on San Andres Island, located near the center of Figure 1. These data (Fig. 3) are a summary of the four times daily observations of surface wind velocity over the 3-year period 1970-72. Most of the year winds are 7-10 m/sec from the ENE, with steadiness factors above 90%. The steadiness factor is the ratio of the absolute value of the vector mean wind speed to the mean wind speed. There, high values, typical of the trade wind belt, indicate that winds are essentially steady and unidirectional over the duration of a month.

This stretch of the Nicaraguan coast is one of the truly rainy areas in the world. Rainfall increases from 3 m/yr in the north to 5 m/yr near the Costa Rican border. Values of 2-2.5 m/yr are considered typical for a tropical rain forest. Murray et al. (in preparation) have calculated that the eventual runoff from the coastal watersheds brings about $1.5 \times 10^{11} \text{ m}^3$ of fresh water each year to the Nicaraguan coast, three times more fresh water per unit length of coast than the Atlantic coast of the U.S.A. receives.

The Caribbean Current, moving westerly across the Caribbean as a well-defined stream of 0.5-1.0 m/sec speed, impacts the Miskito Bank just west of San Andres Island. On Figure 1 we have plotted by 1° squares the three surface current vectors that amount to at least 80% of the observations in the long-term averages for the period July-September available by octant from the

Figure 3. Monthly average wind velocities at San Andres Island (located on Figure 1). The steadiness factor is the ratio of the vectorially averaged wind speed to the average wind speed.

U.S. National Oceanographic Data Center (NODC). A bifurcation in the current on the Bank at about 13°N causes northerly flows north of this line and southerly flows south of it.

Initial Field Observations - August 1976

In August 1976 our research team, consisting of two physical oceanographers, a meteorologist, a geologist, and several technicians, conducted a general study of the currents, waves, boundary layer meteorology, and sedimentary processes across the bank (Murray et al. 1976). Figure 4 shows the cruise track and type of data collected from our research vessel, a 25-m fishing boat chartered out of El Bluff. One of the transects (25 August) of vertical profiles of salinity, temperature, and current velocities from El Bluff northeasterly out to mid-shelf delineated two main flow regimes on the shelf. Figure 5 shows a wedge of low-salinity (30-35 ppt) coastal boundary layer water within 25 km of the coast moving as a distinct unit at high speeds to the south. Salinity gradients along the track drop from 0.23 ppt/km inside to 0.03 ppt/km outside the CBL. Underneath and beyond the CBL there is a transition zone (10 km wide) of low to stagnant currents (0 ± 5 cm/sec), which gradually transform seaward to a distinct core of currents moving with moderate speed to the north. This outer shelf regime is typically well-mixed in the vertical.

A more detailed transect of salinity and current distribution across the coastal boundary layer, made on 26 August, is shown as Figure 6. The very low salinity effluent plume (10-14 ppt) from the Escondido River, which flows into Bluefields Bay behind El Bluff, is evident in the first 5 km offshore. Beyond the plume front salinities increase regularly seaward from 25 to 35 ppt, values considered as typical of the CBL waters. Figure 6 shows the density-salinity structure to be closely coupled to a high-speed jet of southerly flowing water with a maximum speed near the surface about 13 km offshore.

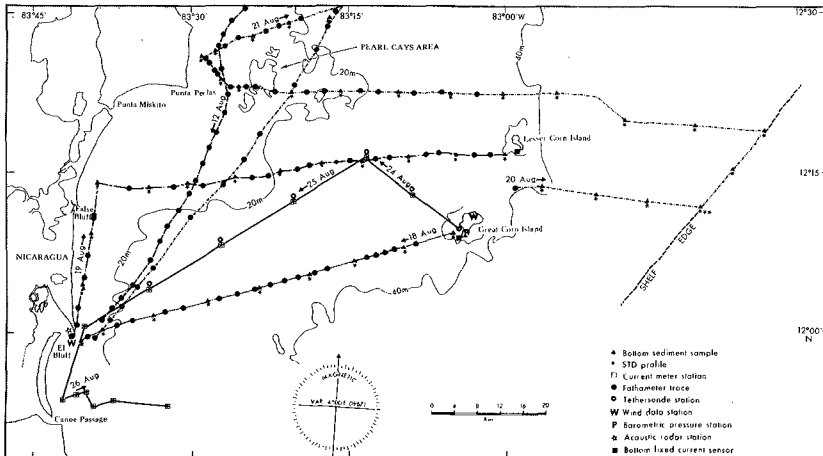

Figure 4. Type, time, and location of data collected during the August 1976 research cruise.

Overall there is good similarity between the salinity and velocity structure of the detailed CBL transect (Fig. 6) and the shelf transect (Fig. 5). A detailed comparison shows some differences, however. The CBL in Figure 5 has a nearshore speed maximum, penetrates no deeper than 10 m, and thins seaward to intercept the surface 30 km offshore. The section in Figure 6 shows that the CBL has a distinct offshore speed maximum, deepens seaward to at least an 18-m thickness, and probably extends as much as 40 km offshore. It is likely that the impact of the immense discharge of the Escondido River (which normally reaches 2,000 m³/sec in August) coming through the El Bluff and Canoe Passages downstream of the shelf transect, that enlarges the CBL and pushes the velocity maximum offshore. Note that the offshore jet is not accompanied by a shoreward rising of the density surfaces, as is usually observed in the Great Lakes (Csanady, 1977).

Coastal Boundary Layer Observations - 1977

Based on the previous year's results, a detailed field study conducted 18-21 September 1977 focused on the coastal boundary layer. Data were collected over the 4-day period along four transects taken perpendicular to the coast. Six stations were occupied along the first three transects and three along the final one, as shown in Figure 7. This detailed study area is outlined in Figure 1. A vertical profile of current observations was taken at each station utilizing a Marine Advisors Q-15 ducted current meter mounted with a pressure transducer for depth setting. Because the Plessey STD used to measure salinity and temperature malfunctioned, water samples were obtained simultaneously with the current readings and were analyzed later on a Guideline Autosal 8400 salinometer. The STD data prior to malfunction indicated that the CBL was relatively isothermal at 28°C (the same as the previous

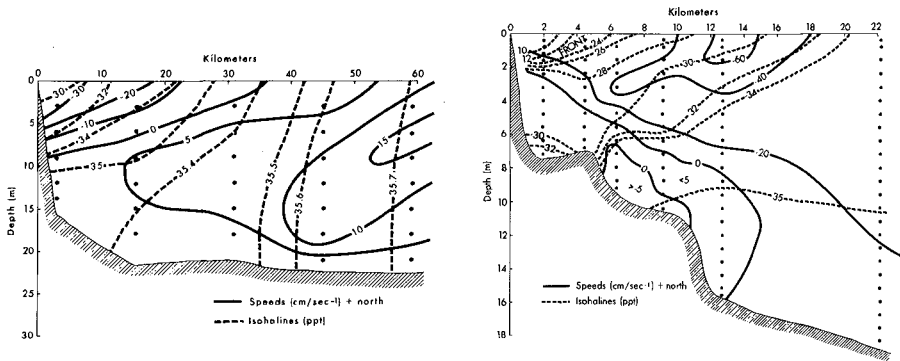

Figure 5. Cross section of Figure 6. Cross section of salinity and north-south current components across the shelf on a line northeast of El Bluff, 25 August 1976.

Cross section of salinity and north-south current components across the coastal boundary layer off Canoe Passage, 26 August 1976.

year), and this figure has been used in subsequent density calculations. Salinity and current observations were also taken in vertical profiles over a 25-hour period at the shelf edge in order to determine the importance of the tidal currents.

Circulation and salinity distribution. The horizontal salinity patterns at the 1.5 m depth level (Fig. 8) from Punta Perlas to Monkey Point provide insights into the spatial variability of the coastal boundary layer. Taking the 35-ppt isohaline as the seaward edge of the CBL, it can be seen that the coastal boundary layer varies from 15 to 25 km in width. A lens of fresher water resulting from discharge of the Rio Escondido is present off El Bluff. A tongue of 34 ppt seawater which intrudes northward into less saline water south of Punta Perlas indicates extreme flow curvature as the water passes the Point.

Salinity variations in the four cross sections are shown in Figure 9. The low-salinity baroclinic layer is wedge shaped in all four cases but does not extend fully to the bottom along line 4 off Monkey Point, where the offshore slope is quite steep. The situation appears much like that observed in estuaries; i.e., the deeper the water, the stronger the onshore intrusion of salt water and vice versa. For example, along the shallowest line (1) the 35.5 isohaline intercepts the bottom 25 km offshore, but along the steepest line (4) the same 35.5 isohaline hits the bottom about 3 km offshore. Thus for the same amount of fresh-water discharge we might expect considerably wider but vertically thinner CBLs off steeply sloping coasts than off shallow sloping coasts.

A comparison of current vectors at the 1.5-m depth in Figure 10 to the salinity patterns in Figure 8 indicates that velocities in the CBL are much higher than those in the outer well-mixed

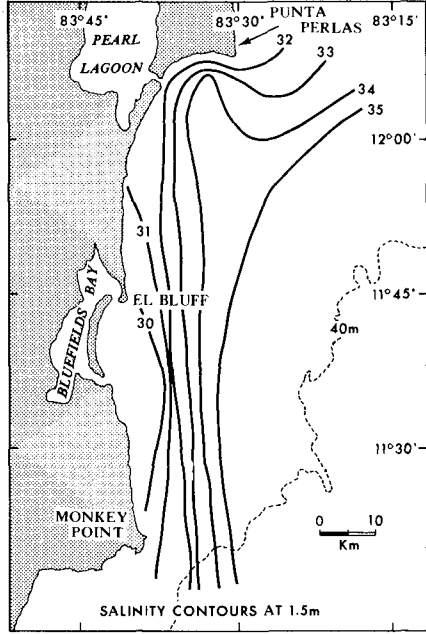

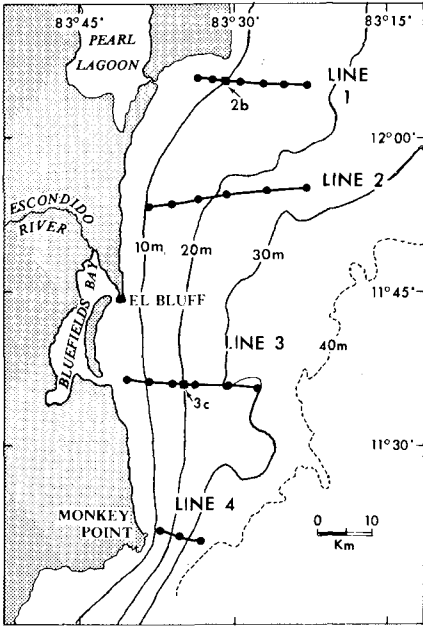

Figure 7. Detailed topography and location of stations for 18-21 September 1977 coastal boundary layer experiment. Computation of momentum balance at stations 3c and 2b are shown in Figures 12 and 13, respectively.

Figure 8. Near-surface salinity distribution, 18-21 September 1977.

region, which are slow and to the northwest. It is also apparent that maximum velocities occur in the core of the CBL and diminish toward each boundary. The flow has a strong tendency to be parallel to the bottom contours (shown in Figure 7), an effect which was studied in detail by Murray, 1975. Note that this topographic control is especially important to the current trajectories along line 2. The slow and variable velocities at the inner portion of line 1 are a result of the shallow depths in the region just south of Punta Perlas, where large mud banks were present. The CBL along this stretch of coast resembles a meandering jet, and we have sketched its probable inner and outer limits on Figure 10.

Figure 11 presents cross-sectional views of the north-south velocity components along the four lines. It is evident that a high-speed jet ($>70 \text{ cm s}^{-1}$) which reaches to the bottom has rounded Punta Perlas (Fig. 11). The seaward extent of the jet is not captured in the data of Line 1 and its outer boundary may lie 20 km

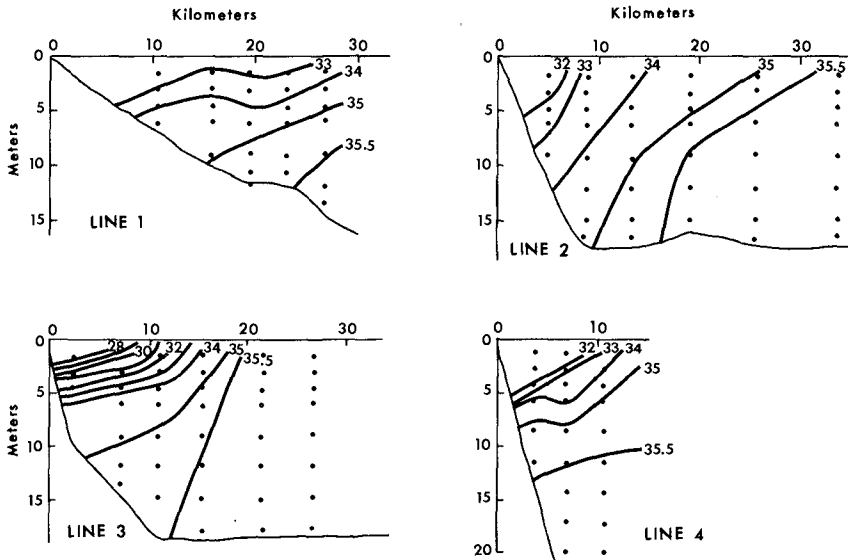

Figure 9. Cross sections of salinity at four time transects, 18-21 September 1977.

farther offshore. Velocities near the coast are negligible. Line 2 shows only weak, southerly flow as the axis of the current jet has turned nearly perpendicular into the coast in a westerly direction. In Line 3 the section is nearly perpendicular to the flow direction and shows a well-defined jet with a major core moving faster than 50 cm s^{-1} . Again the flow extends to the bottom, but is negligible against the coast. The bottom is much deeper in Line 4. As a consequence the flow does not reach below 13 m, but appears to have spread out laterally so that only about half of it is seen in our data. The steepened coast here reduces bottom friction, allowing both (a) higher speeds nearer the coast in the CBL and (b) slow-moving saltier water under the CBL to penetrate closer to the coast. Comparing the 0 cm/s isotachs in Figure 11 and the relative positions of the 35.5 ppt isohalines in Figure 9 shows that the most energetic portion of the coastal boundary layer is indeed confined to the brackish baroclinic layer inside the 35.5 ppt isohaline.

Momentum balance. The momentum equations, neglecting horizontal friction, and with x positive to the east, y positive to the north, and z positive down, can be written

$$\frac{du}{dt} = fv - \frac{1}{\rho} \frac{dp}{dx} - \frac{1}{\rho} \frac{\partial \tau_x}{\partial z} \quad (1a)$$

$$\frac{dv}{dt} = -fu - \frac{1}{\rho} \frac{dp}{dy} - \frac{1}{\rho} \frac{\partial \tau_y}{\partial z} \quad (1b)$$

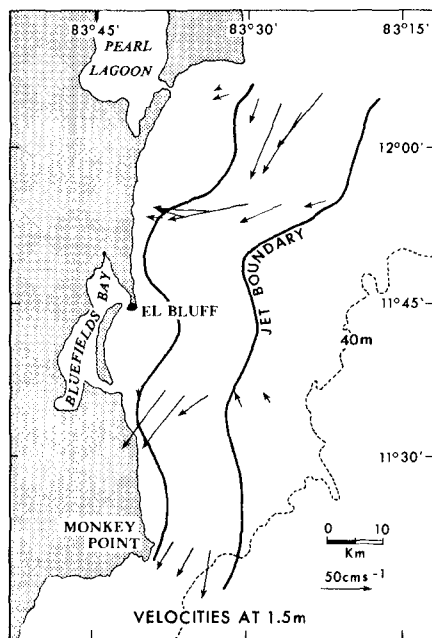

Figure 10. Near-surface velocity field and outline of coastal jet, 18-21 September 1977.

$$\frac{dw}{dt} = g - \frac{1}{\rho} \frac{dp}{dz} - \frac{1}{\rho} \frac{\partial \tau_z}{\partial z} \quad (1c)$$

where u , v , and w are the speeds in the x , y , and z directions, respectively, f is the Coriolis parameter, p is pressure, ρ is density, and τ is the Reynolds or eddy stress.

Due to steady wind and weather conditions over the 4-day observation interval, any temporal accelerations in the study area are most likely a result of tidal oscillations. Maximum accelerations, taken from time series of currents over a 24-hour period, were $2.8 \times 10^{-4} \text{ cm sec}^{-2}$ for $\partial u/\partial t$ and $3.0 \times 10^{-4} \text{ cm s}^{-2}$ for $\partial v/\partial t$. These values are an order of magnitude smaller than other terms in the momentum balance and are used to justify neglecting the temporal accelerations.

For motions on the time and space scales considered, (1c) reduces to the hydrostatic balance and can be used to transform (1a) and (1b) into

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = fv - \frac{g}{\rho} \int_0^z \frac{\partial \rho}{\partial x} dz - g \frac{\partial \eta}{\partial x} - \frac{1}{\rho} \frac{\partial \tau_x}{\partial z} \quad (2a)$$

$$u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -fu - \frac{g}{\rho} \int_0^z \frac{\partial \rho}{\partial y} dz - g \frac{\partial \eta}{\partial y} - \frac{1}{\rho} \frac{\partial \tau_y}{\partial z} \quad (2b)$$

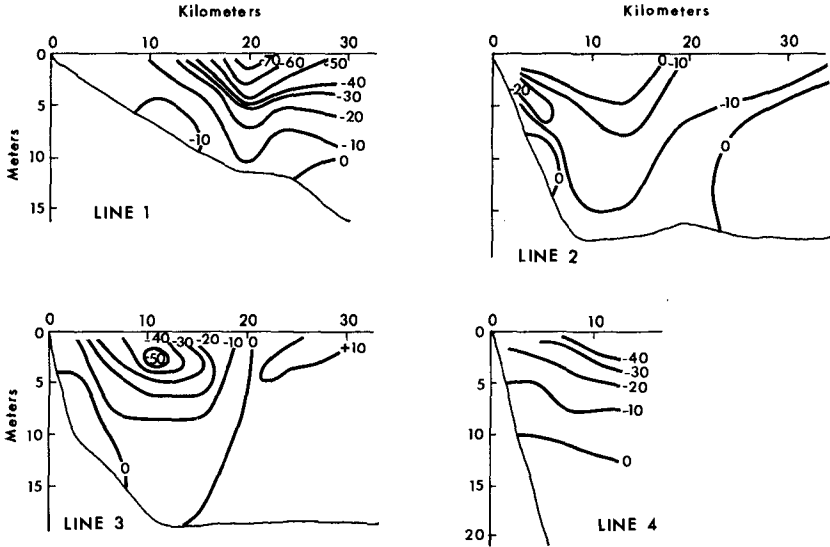

Figure 11. Cross sections of north-south (v) velocity components, 18-21 September 1977. The positive direction of v is north.

where η is the sea surface elevation, positive up, the second and third terms on the right-hand side are the baroclinic pressure gradient force and the barotropic pressure gradient force, respectively. At this junction all of the terms in the momentum equation may be calculated from the data collected during the field study except the barotropic pressure gradient and the internal friction terms. Integrating (2) over depth yields

$$\frac{1}{h} \int_0^h u \frac{\partial u}{\partial x} dz + \frac{1}{h} \int_0^h v \frac{\partial u}{\partial y} dz = f\bar{v} - \frac{g}{\rho h} \int_0^h \int_0^z \frac{\partial \rho}{\partial x} dz \cdot dz - g \frac{\partial \eta}{\partial x} - \frac{1}{\rho h} (\tau_{xb} - \tau_{xs}) \quad (3a)$$

$$\frac{1}{h} \int_0^h u \frac{\partial v}{\partial x} dz + \frac{1}{h} \int_0^h v \frac{\partial v}{\partial y} dz = -f\bar{u} - \frac{g}{\rho h} \int_0^h \int_0^z \frac{\partial \rho}{\partial y} dz \cdot dz - g \frac{\partial \eta}{\partial y} - \frac{1}{\rho h} (\tau_{yb} - \tau_{ys}) \quad (3b)$$

where h is the total water depth and τ_{xb} and τ_{yb} are bottom stresses in the x - and y -directions, respectively and are given by the expression

Figure 12. The vertical distribution of forces in the onshore-offshore (x) momentum equation at station 3c. A positive value of a force acts to the east, or offshore.

$$\tau_{xb} = \rho \kappa u_b |\vec{v}_b|, \quad \tau_{yb} = \rho \kappa v_b |\vec{v}_b| \tag{4}$$

where κ is a coefficient of bottom friction (2.5×10^{-3}), u_b and v_b are speed components 1 m above the bottom, and v_b is the corresponding velocity. Likewise, τ_{xs} and τ_{ys} are wind stress components given by the well-known expression

$$\tau_{xs} = \rho_a C_D u_w |\vec{w}|, \quad \tau_{ys} = \rho_a C_D v_w |\vec{w}| \tag{5}$$

where ρ_a is air density and C_D is the drag coefficient, given as 1.26×10^{-3} for the Miskito Bank study area (Hsu in press a). When these values are substituted into equations (3), they may be solved for the surface slopes, $\partial\eta/\partial x$, $\partial\eta/\partial y$. The values from equation (3) may then be substituted into equation (2) and the internal friction force term computed. Water density is easily computed from salinity and temperature by standard formulas. Thus all terms in the momentum equation (2) are now known either from observations or computations.

Stations 3c and 2b, located on Figure 7, give representative examples of the on-offshore and alongshore force balances in the CBL in Figures 12 and 13, respectively. For purposes of dis-

Figure 13. The vertical distribution of forces in the along-shore (y) momentum equation at station 2b. A positive value of a force acts to the north.

cussion the water column may conveniently be divided into two layers with respect to the force balance.

The baroclinic pressure gradient force is a direct result of the density field initiated by the large freshwater influx into the CBL. This force is directed toward the west or into the coast throughout the water column. In the surface layer this force is less than in the lower portion of the column. The lack of large density gradients parallel to shore results in an insignificant baroclinic pressure gradient force alongshore in the CBL.

The Coriolis force is a function of the current speed and is therefore large in the surface layers, where the speeds are large. As seen in Figure 12, this force is as important as the baroclinic pressure gradient force in the surface layer. The westward force generated by the Coriolis term diminishes below the surface layer as speeds lessen. Figure 13 shows that in the longshore direction this force is quite large and to the north. Again the Coriolis force is insignificant below the surface layer.

The barotropic pressure gradient terms play a large role in the on-offshore and longshore momentum equations, as shown in Figure 12 and 13. The magnitude of this force in the on-offshore direction is larger than any of the other forces; its direction is offshore, or to the east. Alongshore the contribution of the barotropic term is smaller than the on-offshore value, but the southward directed force remains important in the overall balance of forces. The on-offshore force is the result of the sea surface slope initiated by the wind stress, which piles water up against the coast, and the steric elevation of the nearshore water surface

due to the influx of fresh water with a high specific volume.

Figures 12 and 13 also give a representative idea of how the internal friction force behaves in the CBL. In the surface layer the components of the frictional force are directed to the south and east, while this force is in the opposite directions below this layer. As this term is calculated as a residual from the balance of the other terms, it will contain errors that could not be eliminated from the analysis. The largest errors should arise from the effects of the field accelerations, which could not be calculated at most stations due to sampling restrictions. Where these acceleration terms were computed, their contribution to the force balance was small and confined to the surface layer, as can be seen in Figure 12. Therefore, errors in the internal friction force term should have occurred only in the surface layer.

Summary

A 2-year study of the currents and salinity (density) fields has been conducted on the broad, shallow Miskito Bank of the eastern coast of Nicaragua. Tides are quite small on the bank, and the local trade winds are remarkably steady in both speed and direction, thus maximizing the likelihood of a steady-state current field. The adjacent coastal watersheds receive some of the highest rainfall rates in the world and consequently debouch large quantities of fresh water onto the shelf. The large-scale current field deduced from NODC ship drift data on a 1° square resolution show a major current stream (Caribbean Current) crossing the Caribbean from east to west, impacting and riding up onto the Miskito Bank and bifurcating into two arms, one flowing north and the other flowing south along the coast.

Observations across the Bank show a southward-flowing low-salinity, seaward-thinning wedge of highly turbid water trapped against the coast within the first 25-40 km offshore. This coastal boundary layer grades seaward into a northward-flowing shelf current of open sea salinity that is essentially free of suspended sediment. Detailed transects across the coastal boundary layer show the salinity (density) structure to be closely coupled to high-speed jet of south-flowing water.

The forces acting on the CBL in the on-offshore and the along-shore momentum balance were quantitatively evaluated from observations using finite-difference techniques. Each of the forces represented in the momentum balance is important to the circulation dynamics of the Miskito Bank coastal boundary layer, as can be seen in Figure 14, which is a schematic model of the balance of forces. The tremendous amount of rainfall that falls on the drainage basin of eastern Nicaragua creates strong density gradients in the CBL, which result in baroclinic pressure gradient forces that contribute significantly to the on-offshore momentum balance. This freshwater influx combines with setup against the coast caused by the trade winds and initiates a large barotropic pressure gradient force to the east which opposes the baroclinic pressure gradient force. High current speeds parallel to shore are acted on by the Coriolis force in the surface layer and produce another force that acts into the coast. The shallow depths ensure that frictional effects also come into play as forces in the water column. In the surface layer this force acts in concert

SUMMARY - BALANCE OF FORCES

Figure 14. A diagrammatic summary of the balance of forces in the coastal boundary layer, 18-21 September 1977. BC represents baroclinic (density induced) pressure gradient force, BT barotropic or surface slope force, CF Coriolis force, ES eddy stress or internal friction force.

with the barotropic pressure gradient force toward the east but opposes it in the lower layers.

In the alongshore direction frictional forces behave in a similar fashion by acting in opposite directions in the two layers. Very small density gradients parallel to shore are not large enough to produce a significant baroclinic pressure gradient force. Coriolis terms act on velocity components in the surface layer and provides a force that acts toward the north. The remaining force, the barotropic pressure gradient force, is perhaps caused by the piling of water near the coast to the north by the Caribbean Current. The sea surface slope and the resulting barotropic force are directed toward the south.

CHARACTERISTICS OF CIRCULATION
IN BAY WATERS DUE TO WIND ACTION

by Akira Wada* and Yoshihito Miyaike**

ABSTRACT

This report concerns with investigations into the three dimensional mechanism of flow motion in the sea water of Mikawa Bay for the purpose of elucidating the effect of wind, tidal current and topographical features on oceanic environmental fluctuations among factors related to the diffusion process in the bay.

On the assumption that dynamics of the bay water would be affected by the tidal currents and the flow caused by the wind, a numerical simulation analysis of the flow motion phenomenon in the bay water was conducted on the basis of the meteorological and oceanographical observation data collected at the points in the investigated sea region, so as to examine the circulation mechanism of the bay water caused by the above mentioned factors.

As the results of the simulation analysis by the numerical models, large-scale eddies caused by the tidal reciprocating current as well as the constant current as the tidal residual current can be seen in the bay. And also, in the winter time when the distribution of atmospheric pressure is stable, some circulation currents are formed in the bay by the wind-generating current.

Accordingly, it is considered that the formation of these currents has a considerable effect on the diffusion characteristics of substances in the bay.

I. INTRODUCTION

When the ocean is regarded as the environment, one of the research purposes in the nearshore oceanographical process is to determine the kinetic status of the ocean. The reason for it is that physical elementary processes such as flow motion and the density structure in the coastal ocean have their own fluctuations in time and space. Especially, as far as sea water mixing is concerned, it is necessary to grasp these problems in relation to the actual movement of the sea water and elucidate the ocean structure from the viewpoint of time and space scales in the motion. And moreover, it is quite essential to clarify the relation between the random process and the decisive process, so as to make sure how the combination of the above-mentioned two processes would affect the total sea water mixing phenomenon and the water mass formation.

As primary factors that dominate the diffusion phenomena of discharged water in the bay, the flow motion of seawater, dispersion process, topographical conditions, discharge conditions, etc. may be considered. These factors are complicately combined to form the diffusion phenomena of discharged water in the sea region. The reciprocating motion of a tidal current is not so important to a long-term fluctuation process such as water pollution, though it is important to the process of short time scale. Rather, a

** Technical Laboratory, Chubu Electric Power Company, Nagoya City, Aichi Pref., JAPAN.

relatively slow flow motion, such as constant current component, is considered to dominate the diffusion of pollutants. Accordingly, to realize modelling of diffusion, it will be important to know how the constant current component is reproduced.

For this purpose, it is important to make clear the mutual relation between local flow motion in the bay and its whole sea region as well as the extent of contributions of each factor related to the diffusion process to variations in ocean environment. On the basis of these research developments, a reliable diffusion model system can be made in the coastal sea region which enables to make a very reliable prediction of ocean fluctuations in connection with the environmental assessment.

Quite recently the dynamic characteristics of the water in the bay have been elucidated by various analytical solutions and experiments as well as by the field surveys. It has become one of the important research objects in the investigation of the coastal sea region to grasp the dynamic mechanism of the bay water and elucidate the role of many elementary processes which affect the whole ecosystem in the bay.

In this paper, Mikawa Bay was selected as the sea regions for investigation. On the assumption that dynamics of the bay water would be affected by the tidal currents and the flow caused by the wind, a numerical simulation analysis of the flow motion phenomenon in the bay water was conducted on the basis of the meteorological and oceanographical observation data collected at the points in the investigated sea region, so as to examine the circulation mechanism of the bay water caused by the above-mentioned factors.

II. NATURAL ENVIRONMENT OF MIKAWA BAY

Mikawa Bay is, as shown in Fig. 1, the sea region surrounded by two peninsulas, Chita and Atsumi. This bay is connected to Ise Bay at the bay mouth where the Morosaki Channel and the Nakayama Channel meet. The sea bed at this point has terrace-like topography. The western part of Mikawa Bay is sometimes called Chita Bay and the eastern part Atsumi Bay. The water depth of the bay is approximately less than 15 meters and few ups and downs are recognized at the sea bottom. The

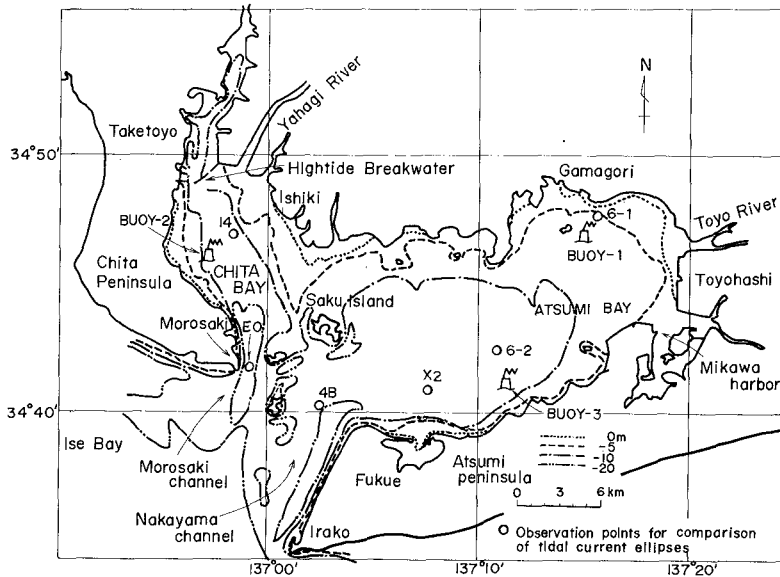

Fig. 1 Topography of Mikawa Bay

tongue shaped plateau with 2 or 3 m under the sea surface, stretching from Ishiki to Saku Island, divides the bay into two small bays, Chita and Atsumi. Both Morosaki and Nakayama Channels form a deep current moving path of 20 or 30 meters in depth, through which the sea water of this bay is exchanged with the water of Ise Bay.

The Yahagi River (average flow rate 24 m³/s) and the Toyo River (average flow rate 15 m³/s) are the main rivers flowing into Chita Bay and Atsumi Bay respectively.

As the topographical features around Mikawa Bay, it has a long stretch of hills less than 100 meters above the sea level in the Chita Peninsula, the Mikawa Plain, ruggy hills 300 meters or 400 meters above the sea level in the southern Mikawa and a long stretch of hills less than 250 meters above the sea level in the Atsumi Peninsula.

The sea water going into and out of Mikawa Bay is divided into two directions by the islands scattered at the bay mouth.

That is to say, one is the direction in which the sea water passes into Chita Bay through the Morosaki Channel and another is the direction in which the sea water passes into Atsumi Bay through the Nakayama Channel. In the center of the Nakayama Channel, the sea water turns in flow to Atsumi Bay 20 minutes earlier than the sea water in the Morosaki Channel. At both high tide and low tide, therefore, very complicated tidal currents are recognized at the mouth of Mikawa Bay. The flow velocity in these channels reaches approximately 1.0 m/s at average tide.

According to the tidal current constants obtained by 15 days-continuous observations at Mikawa Bay, the velocity ratio between the diurnal tide and the semidiurnal tide is 0.15 to 0.84, and the ratio between S₂ and M₂ is about 0.5. From the result of computation concerning energy spectrum for turbulent velocity as shown in Fig. 2, it is easily recognized that the semidiurnal tide is generally more predominant than the diurnal

Fig. 2 Energy spectra for turbulent velocity

Fig. 3 Every two monthly wind blowing frequencies classified by wind directions and the average monthly wind velocities (1951~1960, Irako Meteorological Station)

tide, and especially, the branch component of M_2 tide is predominant.

The data on every two monthly wind blowing frequencies classified by wind directions and the average monthly wind velocities obtained for ten years from 1951 to 1960 at the Irako Meteorological Station in the Atsumi Peninsula are shown in Fig. 3. By observation data mean the average wind velocities measured for ten minutes every three hours. According to the data, spring, fall and winter have a high wind blowing frequency in WNW, NW and NNW directions. Especially in winter the frequency is very high, reaching as much as 90 %. On the other hand, in summer the wind blowing frequency in SW and SE directions is approximately 40 %, and these winds are seldom seen in other seasons. As for the frequencies throughout the year, the wind in NW direction accounts for about 60 %, the wind in S direction about 20 % and the one in other directions 20 %. As far as the wind velocity is concerned, the annual average velocity is 5.5 m/s. And, on the basis of the seasonal classification, the winter has the strongest season wind of 6.6 m/s and the summer has the weakest.

In the winter time, uniformity can be recognized in vertical distributions of water temperatures and salinities in Atsumi and Chita Bays. And there is no density stratification in these regions.

III. MODELLING OF THE SEASONAL WIND

3.1 Selection of the Seasonal Wind

The circulation of the sea water in Mikawa Bay caused by the wind generating current is supposed to be strongly affected by this seasonal wind in winter. The observation data of the wind were obtained at various points along the coast of Mikawa Bay in the winter time. The observation data collected covered three months from December, 1973 to February, 1974. Fifteen observation points were selected as shown in Fig. 4.

The most frequent wind directions and the average wind velocities at each observation point are shown in Fig. 4 along with stream line chart of wind.

Fig. 4 Most frequent wind directions and the average wind velocities

Judging from the case when the distribution of atmospheric pressures of the winter type is stable and the seasonal wind is extremely predominant, it is concluded that the average distribution of seasonal winds at various spots along the coast of Mikawa Bay in the winter time can be expressed by the values of the most frequent wind direction and the average wind velocity to a great extent.

3.2 Stream Line Analysis of the Seasonal Wind

The wind called as the geostrophic wind exists in the higher layer of 1,000 to 2,000 m or more above the sea level.

In this case, the Coriolis' deflecting force and the pressure gradient force are balanced each other.

On the other hand, in the lower layer of several ten meters above the surface of earth, the effect of eddy viscosity caused by air turbulence and friction on the surface of earth are so great that the Coriolis' deflecting force can be ignored. But in the layers between the height of some 10 meters and the height of 1,000 to 2,000 meters, both the frictional force and the deflecting force must be taken into consideration.

The seasonal wind in winter time blows over Mikawa Bay through a wide flat earth like the Nobi plains and the sea region like Ise Bay. If the wind is regarded as being affected by the frictional effect of these surfaces, the effect caused by wind advectives is negligible. And, taking a steady state into consideration, the fundamental equations on the wind can be expressed as follows:

$$-fv = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{\partial}{\partial z} \left(K \frac{\partial u}{\partial z} \right), \quad fu = -\frac{1}{\rho} \frac{\partial p}{\partial y} + \frac{\partial}{\partial z} \left(K \frac{\partial v}{\partial z} \right), \quad \frac{\partial w}{\partial z} = 0 \quad (1)$$

where x, y : coordinates in the horizontal direction, z : coordinate in the vertical direction, u, v, w : wind velocity components in the x, y and z directions, f : parameter of Coriolis, p : pressure, K : coefficient of eddy viscosity, ρ : density.

The effect caused by the frictional force on and near the surface of earth is expressed by the second term of the right side. As for the equation (1), Prandtl obtained the solution as shown in the equation (3), assuming that the coefficient of the eddy viscosity can be expressed by

$$K = L^2 \left[\left(\frac{\partial u}{\partial z} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right]^{1/2}, \quad L = [0.41(Z + Z_0)] / [1 + 0.178 \frac{Z}{u_g}], \quad (2)$$

$$\left. \begin{aligned} u' &= u_g (Z/H_R)^{1/n}, & v' &= u' (1 - Z/H_R) \frac{1}{n} \sqrt{2n + 1}, \\ n &= \log_{10} [H_R / \frac{Z_0}{Dz} + C_0/5.75] \end{aligned} \right\} \quad (3)$$

where Z : altitude from the earth (sea) surface. H_R (m): maximum altitude, in other words, the altitude at which the geostrophic wind is given. u_g : velocity at H_R , corresponding to the geostrophic wind. Z_0 : ground roughness, a constant determined by the status of the surface of earth. Dz : correction coefficient related to the mesh intervals in the z direction to be used for computation. C_0 : parameter which shows the stability

of the atmosphere, generally, following values are used, 5.0 during stable time, 7.0 during neutral time and 8.5 during unstable time. u' (m/s): velocity component in the same direction as the geostrophic wind at H_R . v' (m/s): velocity component in the left hand direction right angled to the leeward direction of the geostrophic wind at H_R .

The equation (3) shows the relations among the frictional force, the pressure gradient force and the geostrophic force. Accordingly, change in wind vector should be approximately expressed by equations concerning the rising and roundabout effects caused by topography and the escape of the wind from the topographical features at the minimum displacement.

In addition, the effect of frictional force on the surface of earth is so large that the geostrophic force can be ignored. And in the layer up to the altitude of some ten meters, the distribution of wind velocities in this layer can be expressed by the exponential law shown in the equation (4).

$$V/V_0 = (H/H_0)^{1/n} \quad (4)$$

where, V_0 : wind velocity at the reference altitude H_0 , V : wind velocity at the altitude H , n : constant obtained by the roughness of the surface of earth.

3.3 Results and Examination of Stream Line Analysis of the Seasonal Wind

Mikawa Bay is approximately some ten kilometers long in both length and width, and in comparison with this scale, the scale of the atmospheric pressure distribution of continental high pressures which are liable to cause seasonal wind in the winter time is extremely large. And also the topography along the coast of the bay is generally flat. Judging from these conditions, it can be regarded that the geostrophic wind is uniform at any point above Mikawa Bay when the winter seasonal wind exists. Since no observation data on the geostrophic wind at the height of H_R were obtained, this computation was made on the assumption of certain geostrophic wind. The atmospheric stability in this computation was set neutral, and the value of C_0 was therefore 7.0.

Judging from these computation results, it is concluded that no local difference is recognized in the velocity and direction of wind blowing over Mikawa Bay at the altitude of 100 meters. In other words, the wind blows at the speed of 5 ~ 6 m/s in the almost same direction.

On the other hand, the observation results show that the wind direction and velocity varies from point to point. This difference is attributable to various conditions such as the effects of topography near the place where the anemometer is installed and the effects of buildings and local winds peculiar to the spot, etc. Moreover, the computation results are based on such large scale model that these local effects cannot be reproduced.

IV. CHARACTERISTICS OF FLOW IN MIKAWA BAY

In Mikawa Bay, automatic sea condition observation buoys belonging to the Aichi Pref. Fisheries Experiment Station were set up at 3 points shown in Fig. 1, and the direction and velocity of flow in the layer 1 m below the water surface was observed every 1 hour.

In order to examine average flow characteristics in Mikawa Bay, seasonal average flow and occurrence frequency classified by directions of flow were obtained by the use of flow observation data obtained by means of these buoys.

Using each buoy, average flows (arithmetic average of data in each season) in winter (December, January and February), spring (April, May and June) and summer (August) were obtained as shown in Fig. 5. In Fig. 5, occurrence frequency in each direction during the observation period and longitudinal direction of M_2 component tide are shown.

Fig. 5 Seasonal average flow and occurrence frequency classified by direction of flow

At Buoy 1 and Buoy 3, development of average flow in the direction which almost agrees with the blowing direction of a predominant winter seasonal wind was recognized in winter. At Buoy 2, on the other hand, development of average flow was recognized in spring and summer, though its direction was almost constant irrespective of seasons. Accordingly, at Buoy 2 and Buoy 3, higher occurrence frequency classified by flow directions is seen in the longitudinal direction of tide as well as in the direction which agrees with the direction of constant flow. At Buoy 1, however, almost uniform occurrence frequency is seen in either direction.

In order to examine the relation between wind blowing direction and flow direction at that time, the occurrence frequency classified by flow directions in each wind direction were obtained using data on the wind observed at the Irako Meteorological Station, as shown in Fig. 6.

Fig. 6 Occurrence frequency classified by flow direction in each wind direction

That is, at Buoy 1, the distribution pattern of occurrence frequency classified by flow directions varies with each wind direction. In this case, regarding the northern wind (W-N-E), the occurrence frequency of flow heading in the direction which almost agrees with the wind blowing direction is high. As to the southern wind (ESE-S-WSW), on the other hand, the flow direction having high occurrence frequency does not agree with the wind blowing direction, considering that the direction of flow is easily affected by surrounding topography.

At Buoy 2 and Buoy 3, the occurrence frequency of flow heading in the direction which agree with the longitudinal direction of M_2 component tide is high irrespective of wind blowing directions. Especially, at Buoy 2, the occurrence frequency of flow heading in the direction which agrees with the direction of seasonal average flow shown in Fig. 5 is conspicuous. With 24 hours of moving average taken into account in the flow observation data, long-period fluctuation characteristics of flow more than one day were obtained. These characteristics are shown in the form of flow vector in Fig. 7.

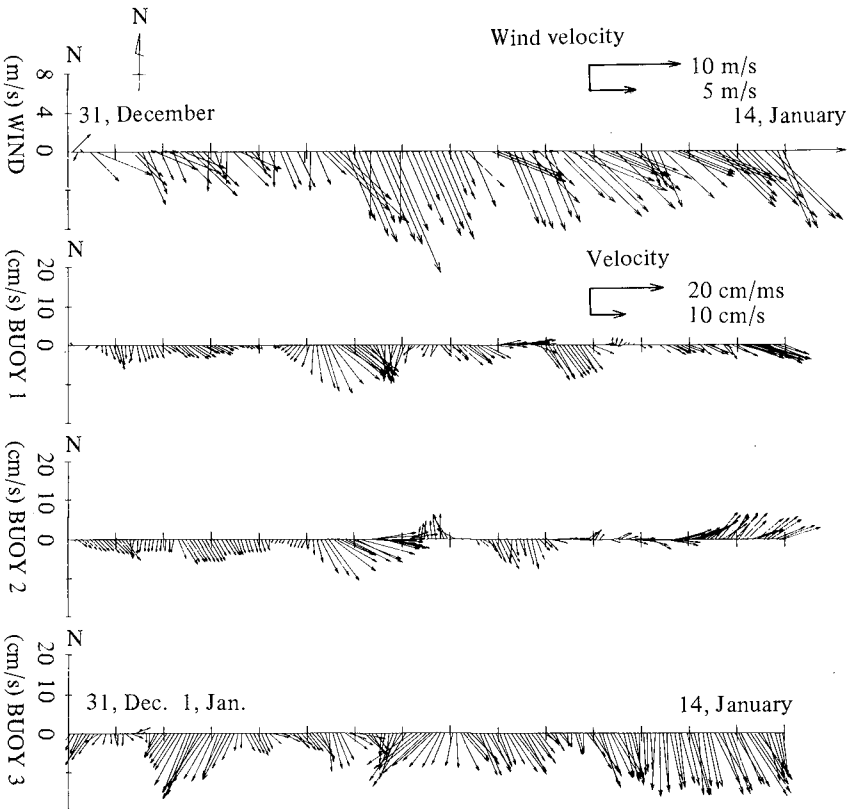

Fig. 7 Vectors of wind and flow in the sea

In order to study the effect of wind on long-period fluctuation of flow, the results of observations made on the wind at the Irako Meteorological station are shown in the form of vector which shows the wind blowing direction.

The flow vector suggests that the long-period fluctuation of flow exists in response to fluctuation of wind direction and wind velocity. The period of these fluctuations varies depending on seasons. In the wintertime, because of the existence of a predominant winter seasonal wind, there is possibility that the period of fluctuation extends over 10 days or more. In spring and summer, as the wind direction and wind velocity rapidly change with the weather which changes at a cycle of 2 or 4 days, the flow changes with a fluctuation cycle of 2 or 4 days. It is, therefore, presumed that the direction of flow vector does not always agree with the wind blowing direction, depending on wind directions, and the flow accompanied by the blowing of wind is sharply affected by surrounding topography.

Thus, considering fluctuation in flow velocity of annual scale in the bay, the existence of long-period phenomena of fluctuation in flow velocity owing to seasonal factors such as seasonal wind and density structure of sea water besides tidal residual flow can be conjectured.

V. ANALYSIS OF WIND GENERATING CURRENT AND TIDAL CURRENT

5.1 Numerical Model

In the sea water of Mikawa Bay in the winter time, there is an approximately uniform distribution of water temperatures and salinities from the sea surface to the bottom, and no density stratification is formed.

Based on this fact, as the first approximate solution, it was assumed that the flow motion of sea water in the bay caused by the wind generating current has a horizontal component. Also an analysis was made on the flow motion of sea water on the basis of the plane two dimensional model.

In order to investigate the mechanism of flow motion in the sea water of the bay caused by the wind-blowing action and the tidal action, a method based on the equations of motion and continuity for the fluid was employed to make analysis on the basis of the three dimensional models.

The fundamental technique for the calculation of dynamic behavior of sea water in the bay is an Eulerian finite-difference approximation to the Navier-Stokes equations.

$$\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial uv}{\partial y} + \frac{\partial uw}{\partial z} = -g \frac{\partial \zeta}{\partial x} + fv + \frac{\partial}{\partial z} (A_w \frac{\partial u}{\partial z}) + A_h \nabla^2 u \quad (5)$$

$$\frac{\partial v}{\partial t} + \frac{\partial uv}{\partial x} + \frac{\partial v^2}{\partial y} + \frac{\partial vw}{\partial z} = -g \frac{\partial \zeta}{\partial y} - fu + \frac{\partial}{\partial z} (A_w \frac{\partial v}{\partial z}) + A_h \nabla^2 v \quad (6)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (7)$$

where u , v and w are the velocity components along the x , y and z directions, ζ is the

elevation of water surface, f is Coriolis' parameter and A_h, A_w are the horizontal eddy viscosity, the vertical one, respectively.

The following equation was applied as the kinetic boundary condition on the water surface.

$$\frac{\partial \xi}{\partial t} + U_s \frac{\partial \xi}{\partial x} + V_s \frac{\partial \xi}{\partial y} - W_s = 0 \quad (8)$$

However, since the free surface doesn't agree with the cell surface, the marker was introduced in order to obtain a better approximate solution to the velocity of flow, and higher precision was confirmed by giving due consideration to the water surface.

The bay was divided into many cells of 1,000 m \times 1,000 m in the horizontal direction and 3.2 m in depth.

For the purpose of computing the flow motion mechanism of the wind generating current in the bay on the basis of the three dimensional model, the vector of wind on the sea obtained by the stream line analysis was applied to the sea surface as the frictional stress. The wind blowing over the sea at the altitude of 100 meters was converted into the wind at the altitude of 15 meters by adopting the exponential law. As the frictional coefficient of wind stress on the sea surface, $k = 3.2 \times 10^{-6}$ was adopted.

As the boundary conditions, the flow velocity is presumed to be zero at the fixed wall. And, in the equations (5) and (6), the frictional stresses at the surface and the bottom are given by the following equation:

$$\left. \begin{aligned} \tau_x &= k_{B1} U_w \sqrt{U_w^2 + V_w^2}, \\ \tau_y &= k_{B1} V_w \sqrt{U_w^2 + V_w^2} \end{aligned} \right\} \quad (9)$$

$$\left. \begin{aligned} \tau_{Bx} &= k_{B2} U \sqrt{U^2 + V^2}, \\ \tau_{By} &= k_{B2} V \sqrt{U^2 + V^2} \end{aligned} \right\} \quad (10)$$

where τ_x, τ_y : the wind frictional stress on the sea surface, τ_{Bx}, τ_{By} : the frictional stress on the sea bed, k_{B1} : frictional coefficient of wind stress on the sea surface, k_{B2} : frictional coefficient of wind stress on the sea bed, U_w, V_w : the wind velocities.

The boundary conditions on the line at the bay mouth between Irako and Toyohama were set as follows:

$$\xi = 0, \quad \partial^2 U / \partial S^2 = \partial^2 V / \partial S^2 = \partial^2 W / \partial S^2 = 0 \quad (11)$$

On the land, breakwaters and islands coasts as well as the sea bed, $u = v = w = 0$. Wind stress at the sea surface is expressed as follows:

$$A_w \frac{\partial u}{\partial z} = \tau_x, \quad A_w \frac{\partial v}{\partial z} = \tau_y. \quad (12)$$

On the other hand, the tidal level is determined on the boundary line between Irako and Morosaki. The tidal level and tidal hour are determined by the tidal constants in Mikawa Bay.

The branch tide M_2 (amplitude 53 cm, lag of the tide 183°) is set on the Irako side, and the branch tide at Morosaki M_2 (amplitude 55 cm, lag of the tide 183°) is set on the Toyohama side. On the boundary line between these two points, the values at both points must be interpolated on the boundary line.

The coefficients of the horizontal eddy viscosity and the vertical eddy viscosity are $10 \text{ m}^2/\text{s}$ and $0.01 \text{ m}^2/\text{s}$, respectively.

5.2 Analytical Results of Wind Generating Current and Tidal Current

In order to examine the circulation currents formed in the bay, the horizontal flow motions at various representative depths are shown in Fig. 8. These figures show that the analytical results obtained on the basis of the three-dimensional models are different from those based on the two dimensional plane models. That is, the formation of horizontal circulation currents can only be seen in the middle layer or the bottom layer and more predominant vertical circulation currents are seen in the wind blowing direction.

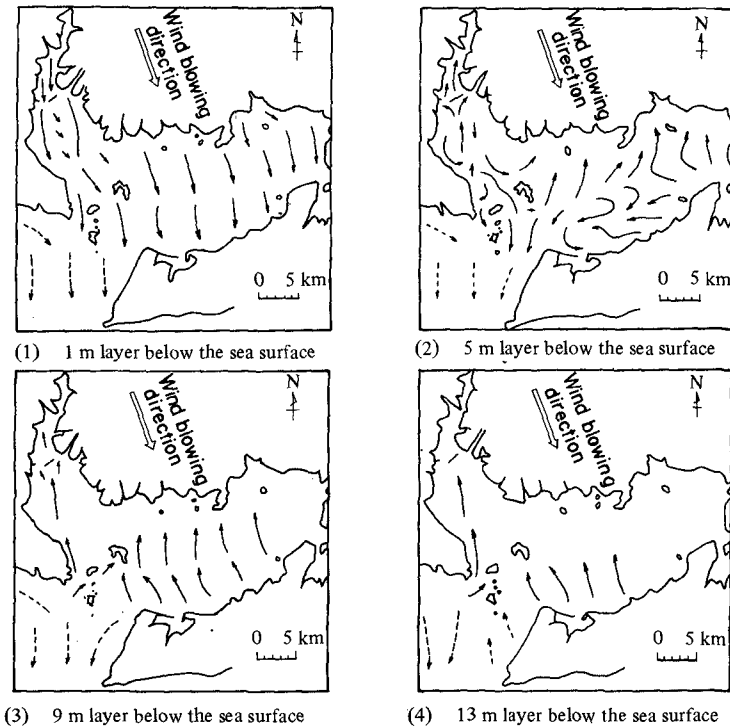

Fig. 8 Horizontal flow motions at various representative depth due to wind action

This type of circulation currents tends to be affected delicately by the topography of sea regions, especially by changes of sea bed configuration.

The existence of large scale vertical circulation currents are recognized in Chita Bay. And these currents flow toward the bay mouth in the surface layer, and run toward the innermost of the bay in the deep layer.

On the other hand, in the whole area of Mikawa Bay, such a large circulation current as to cover the total sea region is not recognized. In the surface layer, however, the flow in the wind blowing direction is predominant. In the middle layer, some small-scale horizontal circulation currents are recognized in the southern sea region and in the innermost of Mikawa Bay. In the deep layer, the vertical circulation current is considered to be formed as a compensation current for the current in the surface layer.

In order to examine if the results of numerical experiments on the tidal current agree with the measured results, comparisons were made between the analytical results and the measured results on the ellipses of the tidal currents. Figure 9 shows the points where the comparisons were made and some ellipses of the tidal currents of the M_2 component. (See Fig. 1)

Judging from these results, it is concluded that the results of the numerical experiments satisfactorily reproduce the tidal currents in Mikawa Bay.

The results obtained based on the three dimensional models are similar with those based on the two dimensional models.

5.3 Results of Computation and Consideration on Tidal Residual Current

From the results of numerical simulation on tidal current, the average value of tidal current in four tide cycles was obtained and with this as tidal residual current, its characteristics were examined. In Fig. 10 (1) through (3), the results of computation on tidal residual current are shown in plane flow vector in a typical water depth.

In this figure, only the steady current observed during a cold weather, season from October to April when no density layer is formed and the outflow of river water is relatively small was extracted, and its current direction and size are shown.

The generation of small-scale circulation currents are seen in the Morosaki Channel, in the neighborhood of the mouth of the storm tide protection breakwater in Chita Bay, and in the coastal region of Atsumi Bay.

The steady current measured in a cold weather season, especially in the sea region where a remarkable plane circulation current is recognized, is showing a current direction which well agrees with the flow pattern based on numerical simulation, thus backing up its existence, as shown in Fig. 10. In the meantime, the vertical circulation current based on tidal residual current is not recognized.

Although the circulation current has a very slow velocity, it is considered that the existence of this current plays a very important role in the long-term dispersion process of substances in the sea region along the coast of the bay.

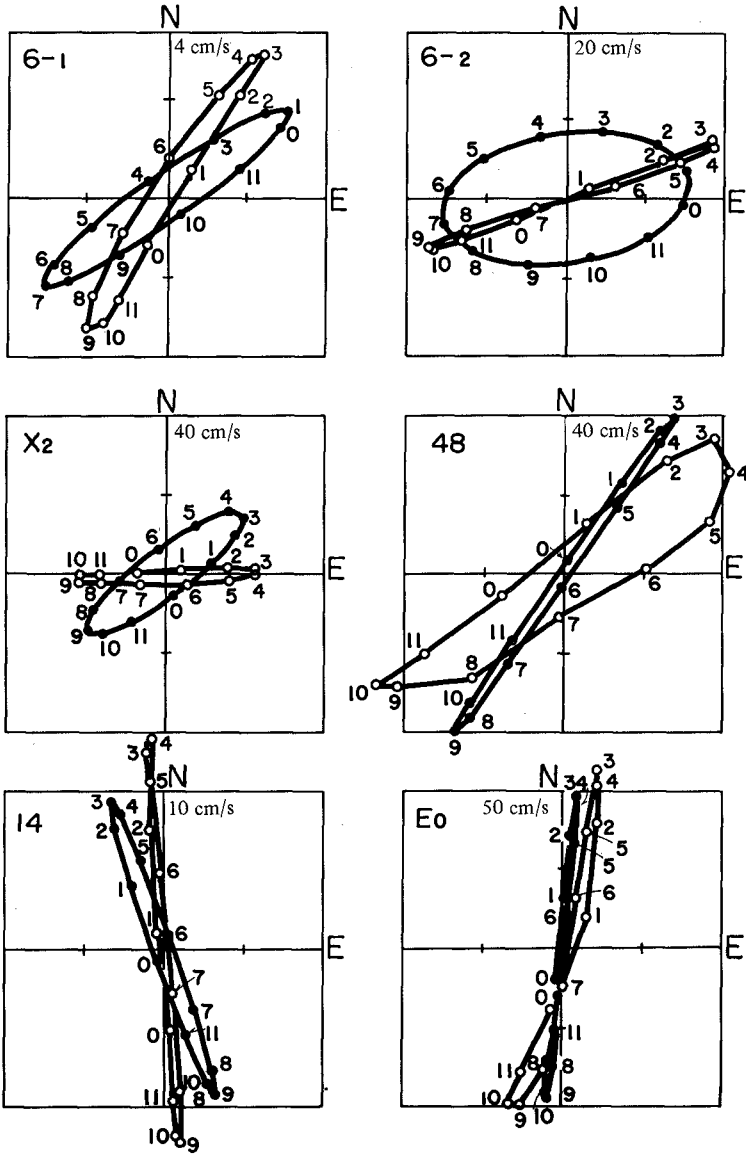

Fig. 9 Comparison between analytical results and results obtained by harmonic analysis of measured values for tidal current ellipses (—●—●— measured results, -○-○- analytical results)

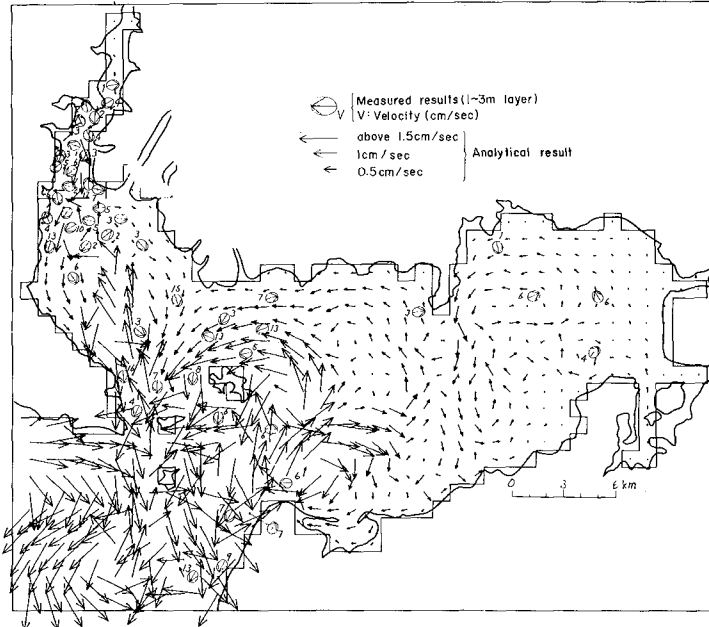

Fig. 10 (1) Tidal residual current (1.6 m layer below the sea surface)

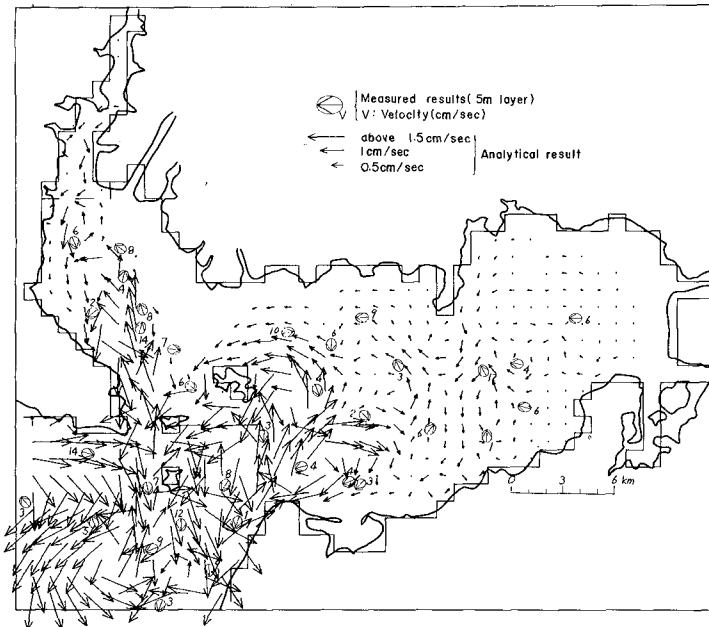

Fig. 10 (2) Tidal residual current (4.8 m layer below the sea surface)

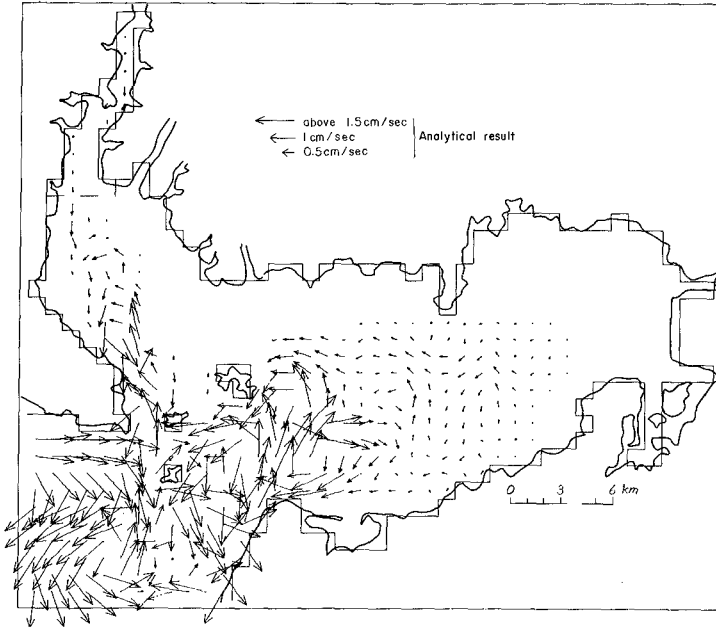

Fig. 10 (3) Tidal residual current (8 m layer below the sea surface)

VI. CONCLUSION

As the results of the simulation analysis conducted on the basis of the numerical models in Atsumi Bay and Chita Bay, large-scale eddies caused by the tidal reciprocating current as well as the constant current as the tidal residual current can be seen in the bays. And also, in the winter time when the distribution of atmospheric pressure is stable, several circulation currents are formed in the bay by the wind-generating current.

Accordingly, it is considered that the formation of these currents has a considerable effect on the diffusion characteristics of substances in the bays.

After comparative examinations between actual measurement and predicted analytical results based on the numerical model developed here, it was confirmed that this analytical method was effective to elucidate the three dimensional motion in real sea region.

ACKNOWLEDGEMENT

Some field data in this paper were offered by the Aichi Pref. Fisheries Experiment Station and the Hydrographical Office of the Maritime Safety Agency.

The authors would like to express their sincere thanks to the members of the Station and the Agency.

CHAPTER 168

BEHAVIORS OF THE SALT WEDGE AND THE SALINITY DISTRIBUTION AT ESTUARIES

by

Isao Yakuwa,^{*} Susumu Takahashi,^{**} and Morimasa Ohtani^{***}

Abstract

The salt wedge has been observed by ultrasonic method at estuaries of the Ishikari, Shiribetsu and Rumoi River in Hokkaido, Japan. According to the records of the longitudinal profile of the salt wedge, behavior of the interface of salt and fresh water is strongly influenced by configurations of the water course and the river bed. Therefore, in this paper, a distance from the front of the salt wedge to the river mouth is divided into two or three sections in accordance with behavior of the interface, and the salinity distribution in the upper layer is estimated in each section.

By solving the differential equation of two dimensional salinity diffusion, the distribution is represented by terms of flow velocity, diffusion coefficients, depth of the upper layer and salinity at the boundary. Where, diffusion coefficients are determined by comparing evaluated longitudinal distribution of surface salinity with observed one.

By estimating the rate of salinity entrainment into the upper layer, the entrainment coefficient E at the interface is evaluated as $E = 0.4 \times 10^{-5} \sim 0.8 \times 10^{-3}$ at three estuaries.

1. Introduction

Authors have observed¹⁾ many salt wedges at estuaries of the Ishikari, Shiribetsu and Rumoi River which flow through the west part of Hokkaido, Japan and pour into the Japan Sea (Fig. 1). Because the Japan Sea has only a small tidal range of about 30cm at its maximum throughout the year, the behavior of the salt wedge at every river mouth is controlled mainly by the river discharge.

While the Ishikari River, a length of about 300 km, is the longest river in Hokkaido, the Shiribetsu and the Rumoi River, lengths of about 130 and 35 km, are examples of middle and short rivers in Japan. Figure 2 shows estuaries of the three rivers. The critical discharges at which salt wedges begin to penetrate into river mouths are obtained as 550, 150 and 5.2 m³/s at estuaries of the Ishikari, Shiribetsu and Rumoi River respectively.

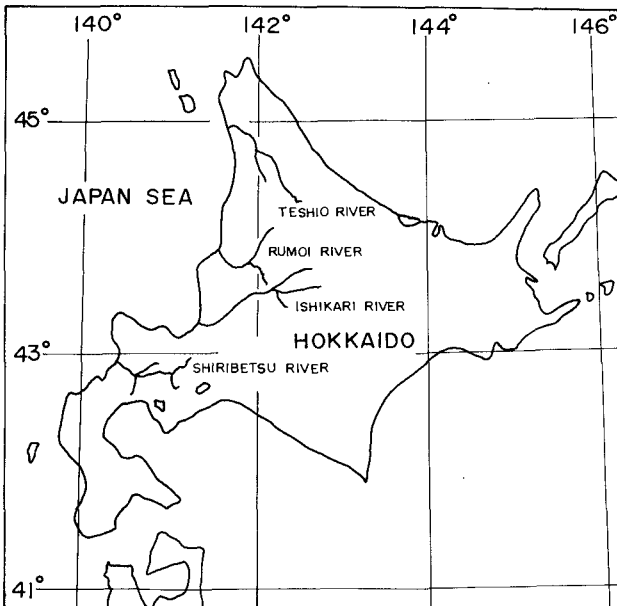

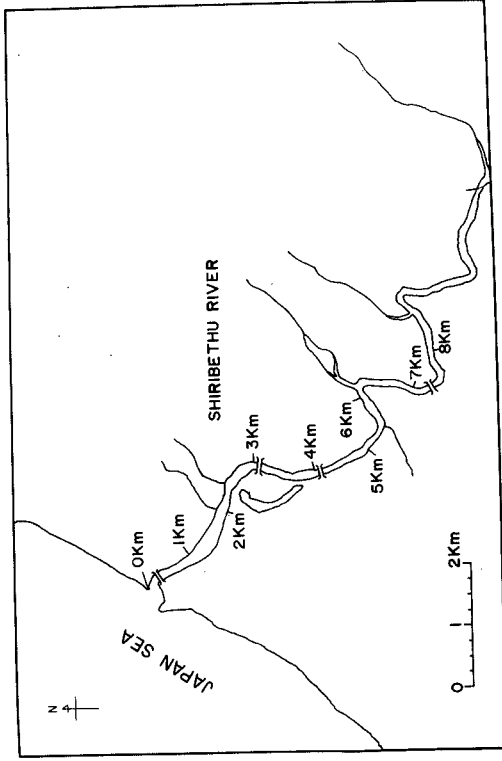

Fig. 1 Hokkaido District

(b) the Shiribetsu River

(c) the Rumoi River

Fig. 2 Estuaries of the three rivers.
(a) the Ishikari River

The ultrasonic method has been used to observe longitudinal profiles of salt wedges. During each sail to record the salt wedge by means of echo-sounding, about 300 cc of the surface water was also sampled an interval of 30 ~ 60 seconds and its chlorinity was measured by chemical analysis to get the longitudinal distribution of surface salinity. At several stations along the salt wedge the boat was anchored and vertical distributions of flow velocity and chlorinity have also been measured.

Generally speaking, the interface of salt and fresh water is stable when the front of the salt wedge is penetrating into the river mouth or the salt wedge is in steady state. When the river discharge increases, however, a mixing of salt and fresh water through the interface grows intense and the front of the salt wedge begins to retrograde downstream.

But, according to records, behaviors of the salt wedge are strongly influenced by configurations of the water course and the river bed. At the location where the water course abruptly curves or there is a big projection on the river bed, a stronger mixing of salt and fresh water was found as compared with all other points, and sometimes a big projection prevented the front of the salt wedge from intrusion. In these cases, the profile of the salt wedge was different from the ideal case of straight water course and flat bed, and the rate at which the salt water entrained into the fresh water layer varied with locations even along one salt wedge in an estuary.

2. Diffusion of salinity in the fresh water layer

Taking x in the downstream direction along the river surface and y in the vertically downward direction, the differential equation of salinity diffusion in the fresh water layer is given by

$$U \frac{\partial S}{\partial x} = D_x \frac{\partial^2 S}{\partial x^2} + D_y \frac{\partial^2 S}{\partial y^2} \dots\dots\dots (1)$$

- where S : Cl concentration of the water
- U : mean velocity of the fresh water layer
- D_x : diffusion coefficient of x direction
- D_y : diffusion coefficient of y direction.

The boundary conditions are expressed by

$$\begin{aligned} \frac{\partial S}{\partial y} &= 0 & \text{at } y &= 0 \\ S &= S_0 & \text{at } y &= h_0 \\ S &= f(y) & \text{at } x &= 0 \end{aligned}$$

where h_0 is the depth of the fresh water layer. The transition layer is excluded from the definition of the fresh water layer in the present case. Under these conditions, the equation (1) can be solved²⁾ as

$$S = S_0 - \sum_{n=0}^{\infty} \left\{ \frac{(-1)^n 4S_0}{(2n+1)\pi} - \frac{2}{h_0} \int_0^{h_0} f(\lambda) \cos \frac{(2n+1)\pi\lambda}{2h_0} d\lambda \right\} \\ \times \cos \frac{(2n+1)\pi y}{2h_0} \cdot \exp \left\{ \frac{U}{2D_x} - \sqrt{\left(\frac{U}{2D_x}\right)^2 + \frac{(2n+1)^2 \pi^2 D_y}{4h_0^2 D_x}} \right\} x \dots \dots (2)$$

And chlorinity of the surface water is given by

$$(S)_{y=0} = S_0 - \sum_{n=0}^{\infty} \left\{ \frac{(-1)^n 4S_0}{(2n+1)\pi} - \frac{2}{h_0} \int_0^{h_0} f(\lambda) \cos \frac{(2n+1)\pi\lambda}{2h_0} d\lambda \right\} \\ \times \exp \left\{ \frac{U}{2D_x} - \sqrt{\left(\frac{U}{2D_x}\right)^2 + \frac{(2n+1)^2 \pi^2 D_y}{4h_0^2 D_x}} \right\} x \dots \dots \dots (3)$$

When the point of the front of the salt wedge is taken as $x = 0$, equations (2) and (3) are simplified by putting $f(y) = 0$.

By the use of observed values for U , h_0 and S_0 in equation (3), the longitudinal distributions of surface salinity can be calculated with various values of D_x and D_y . When one of the calculated distributions agreed fairly well with the observed distribution, these values of D_x and D_y were determined as diffusion coefficients of x and y direction.

Otsubo and Fukushima evaluated³⁾ entrainment coefficient E in stratified flow by solving equations of mass and volume conservation

$$\left. \begin{aligned} \frac{d(A_1 \rho_1 U)}{dx} &= B \rho_2 V \\ \frac{d(A_1 U)}{dx} &= BV \end{aligned} \right\} \dots \dots \dots (4)$$

- where A_1 : sectional area of upper layer
- B : width of upper layer
- ρ_1, ρ_2 : density of upper and lower layer
- U : velocity of upper layer
- V : entrainment velocity ($V = EU$),

and the velocity of lower layer was assumed to be zero. By transforming Eq. (4) into an equation of salinity, they led

$$\frac{S_2 - S_1}{S_{20} - S_{10}} = \exp \left(- \int_0^x \frac{E}{h} dx \right) \dots\dots\dots (5)$$

where h : depth of upper layer
 S_1, S_2 : mean values of salinity concentration in the upper and lower layer at point x
 S_{10}, S_{20} : values of S_1 and S_2 at point $x = 0$.

On the basis of observational results at the mouth of the Ishikari River, they obtained as the mean value of entrainment coefficient $E = 1.7 \times 10^{-5}$.

By assuming that values of $S_2, E, h (= h_0)$ are constant at interval from $x = 0$ to $x = x$, equation (5) leads to

$$S_1 = S_2 - (S_2 - S_{10}) \exp \left(- \frac{E}{h_0} x \right).$$

Therefore, when mean value of salinity concentration in the above equation is calculated by

$$S_1 = \frac{1}{h_0} \int_0^{h_0} S dy$$

with S in equation (2), entrainment coefficient E can be represented as

$$E = \frac{S_0}{S_2 - S_{10}} \sum_{n=0}^{\infty} \left\{ \frac{4}{(2n+1)^2 \pi^2} - \frac{(-1)^n 2}{h_0 S_0 (2n+1) \pi} \int_0^{h_0} f(\lambda) \cos \left(\frac{(2n+1)\pi \lambda}{2h_0} \right) d\lambda \right\} \\ \times \left\{ \sqrt{\left(\frac{h_0 U}{D_x} \right)^2 + \frac{D}{D_x} (2n+1)^2 \pi^2} - \frac{h_0 U}{D_x} \right\} \dots\dots\dots (6)$$

where $S_{10} = \frac{1}{h_0} \int_0^{h_0} f(y) dy$.

When $f(y) = 0$, E is given by

$$E = \frac{S_0}{S_2} \sum_{n=0}^{\infty} \frac{4}{(2n+1)^2 \pi^2} \left\{ \sqrt{\left(\frac{h_0 U}{D_x} \right)^2 + \frac{D_y}{D_x} (2n+1)^2 \pi^2} - \frac{h_0 U}{D_x} \right\}.$$

3. Observational results

Figures 3 and 4 show longitudinal profiles of salt wedge and river bed recorded at mouthes of the Ishikari River on July 27, 1967, Shiribetsu River on July 23, 1977 and Rumoi River on October 26, 1977. Salt wedges had penetrated 8.4, 3.5 and 2.5 km upstream from the mouthes because river discharges (260, 27-29 and 1.7 m³/s respectively) had decreased then below critical discharges.

As shown in Fig. 4(a), there was a big projection on the river bed at a point 3.7 km from the mouth of the Ishikari River and the mixing of salt and fresh water abruptly increased there. At the mouth of the Shiribetsu River (Fig. 4(b)), the interface of salt and fresh water was disturbed and the mixing grew stronger near a projection of the bed about 2.0 km upstream. And at the Rumoi River (Fig. 4(c)), interface was separated into three sections of 0 (river mouth) ~ 1.0 km, 1.6 ~ 2.0 km and 2.1 ~ 2.5 km according to the profile of the river bed.

Figures 5(a), (b) and (c) show the longitudinal distributions of chlorinity of the surface water observed at the Ishikari, Shiribetsu and Rumoi River. According to figures, chlorinity increases rapidly near the points where the mixing is intense. Therefore, the distribution may be calculated from Eq. (3) by dividing a distance from the river mouth to the front of the salt wedge into two or three sections and using for each section constant values of U , h_0 , S_0 and S_2 . A range of sections at each estuary and observed values of U , h_0 , S_0 and S_2 in each section are indicated in Table 1 with boundary condition $f(y)$.

As shown in Fig. 5, the calculated distributions agree fairly well with the observed ones when the values of diffusion coefficients D_x and D_y are taken as given in Table 2.

Value of entrainment coefficient E in each section can be obtained from equation (6) using actual values of U , h_0 , S_0 , S_2 , D_x , D_y and $f(y)$ shown in Table 1 and 2. In Table 2, these values of E are also compared with ones calculated from equation (5) by use of observed values of S_1 , S_2 and h . A good coincidence between values calculated from equations (6) and (5) can be seen, though a distance of each section is very long.

CHAPTER 169

LONGITUDINAL DISPERSION IN SHALLOW WELL-MIXED ESTUARIES

J. Dronkers

Hydraulic Department of Deltaworks,
The Hague, Netherlands

- I. Introduction.
- II. Description of the model.
- III. The effect of mixing in the stagnant area.
- IV. The effect of non-tidal exchanges between the channel and the stagnant area.
- V. The effect of a phase-shift between tide and velocity.
- VI. Generalisation for other geometries.
- VII. Summary and conclusions.

I. Introduction.

In estuaries may be distinguished between several phenomena which are responsible for the dispersion of dissolved constituents. In this paper theoretical expressions are obtained for dispersion processes of a particular type, which appear mainly as a consequence of the tidal motion and the geometry. The results may be applied to estuaries with strong tidal mixing (tidal prism of the same order of magnitude as the average volume of the estuary) and a small fresh water discharge.

The cross-sections in the estuary are divided in two parts: a deep part, representing the channel, in which the longitudinal motion takes place, and a shallow part without longitudinal motion, representing a tidal flat, which is filled and emptied by the tide. The interaction between these two parts generates longitudinal dispersion related with the following three phenomena:

- mixing on the tidal flat caused by an irregular topography and by bottom friction,
- exchange of water between the channel and the tidal flat caused by eddies or density currents,
- the occurrence of a phase-shift between the tidal elevation and the tidal velocity.

An analytical expression for the contribution of these effects to the dispersion coefficient is obtained by considering the resulting transport of constituent through a fixed plane. The application of the model to general geometries is discussed, providing an approximate expression for the dispersion coefficient in natural situations. This expression shows the explicit dependency of the dispersion coefficient on geometrical and tidal parameters.

II. Description of the model

Longitudinal dispersion in estuaries related to the "trapping" of water outside the flow region has been studied by Schijf and Schönfeld [1] and by Okubo [2] for different types of geometry.

Okubo assumed that the exchange process between the channel and the traps is mainly due to some diffusion type process, neglecting the influence of the tidal elevation.

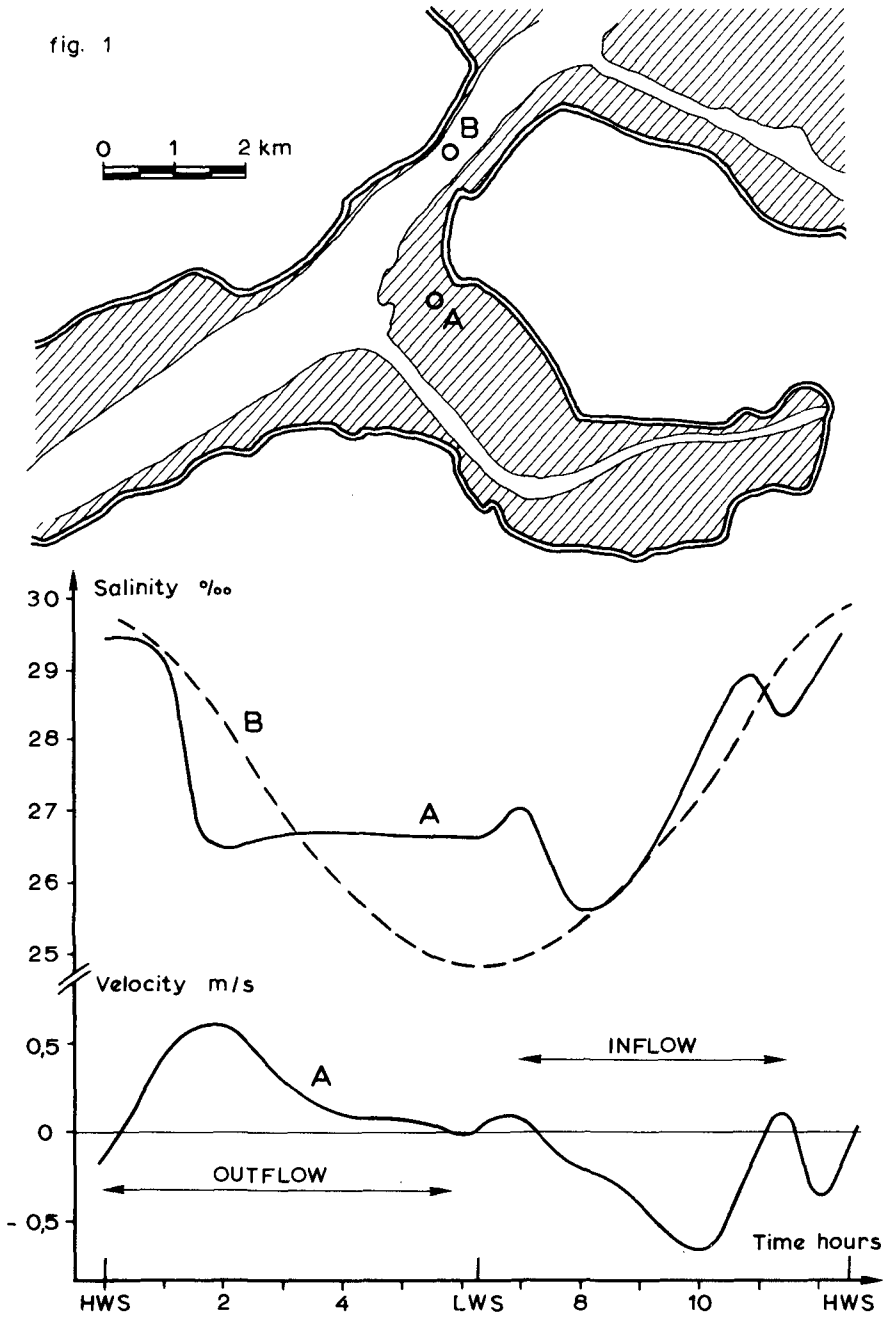

In this paper we consider the trapping of water on tidal flats, as was done by Schijf and Schönfeld. These authors suppose that the longitudinal dispersion arises from the fact that the filling and emptying of the tidal flats does not coincide in general with respectively flood and ebb.

Here it will be shown that often a larger contribution to the longitudinal dispersion is caused by the fact that strong mixing may occur on the tidal flats.

Salinity measurements in the estuary Oosterschelde in Holland provide evidence for mixing on the tidal flats. In fig. 1 a part of this estuary is shown; the shaded regions are tidal flats. Point A lies on the border of a tidal flat, point B lies in the channel.

The salinity of the water flowing onto the tidal flat during the flood period varies as a function of time in a similar way as the salinity in the channel. During the ebb period, when the water flows out of the tidal flat, the salinities on the tidal flat and in the channel behave very differently. The salinity measured in point A is nearly constant, which is precisely a consequence of the mixing which has taken place on the tidal flat.

fig. 1

The following two mechanisms are probably responsible for the mixing of the water on the tidal flat:

- a) The water entering the stagnant area at the end of the flood period has a higher salt concentration, and therefore a higher density than the water entering at the beginning of the flood period. The water with higher density will tend to spread out over the bottom (density currents). At the same time vertical mixing is caused by bottom and surface shear stresses (wind influence). This process ends up with complete mixing in the stagnant area.
- b) Tidal flats in many estuaries have an irregular bottom topography: there are many paths a fluid particle may follow to reach a particular point on a tidal flat. For the same reason fluid particles coming from different parts of the tidal flat can meet during the ebb-period.

A mathematical description of the longitudinal dispersion caused by the presence of tidal flats along a channel is developed in the sections III, IV and V. Successively are introduced the effect of mixing on the tidal flat, the effect of non-tidal exchanges (eddies, density currents) between the channel and the tidal flats, and the effect of a phase-shift between the tide and the tidal velocity.

The description is based on the calculation of the quantity Z , which represents the total amount of constituent which passes through a cross-section of the estuary between two successive periods of low-water slack (LWS).

The quantity Z is related to the LWS dispersion coefficient, D_{LWS} by the general equation

$$Z = T Q_0 c_{LWS} - T D_{LWS} A_{LWS} \frac{d}{dx} c_{LWS} \quad (1)$$

We call T the tidal period, A the channel cross-section, c the concentration and u the velocity; the subscript LWS refers to low-water slack. Further we have

$$Q_0 = \frac{1}{T} \int_{LWS}^{LWS+T} dt \int_A u dA \quad , \quad Z = \int_{LWS}^{LWS+T} dt \int_A u c dA \quad .$$

For the computations we will consider a particular tidal cycle for which $Q_0 = 0$. This simplification has negligible consequences for the results as long as $Q_0 T / A_0 \ll L$,

where A_0 is the average cross-section and L represents the tidal excursion (if u is independent of x):

$$L = \int_{LWS}^{LWS+T} dt \frac{1}{A} \int_A u dA$$

A few other simplifications will also be made:

- the velocity and concentration distribution are homogeneous in each cross-section of the channel,
- the longitudinal gradients of the velocity and the concentration are small. In particular:

$$\left| L^2 \frac{d^2 c}{dx^2} \right| \ll \left| L \frac{dc}{dx} \right|$$

- the fluid particles on the tidal flat have a zero longitudinal velocity component. Therefore, the tidal flat will also be called "stagnant area".

Instead of equation (1) another method to obtain the dispersion coefficient for a trap-channel system has been used by Okubo [2]. This method consists of solving the differential equations governing the system for an instantaneous injection. It is not possible to obtain analytical solutions for these equations in all the cases considered in this paper. The dispersion coefficient defined by Okubo is not identical with D_{LWS} defined here. The main difference is a factor A_{LWS} / A_0 .

III. The effect of mixing in the stagnant area

The influence of mixing in the stagnant area on the longitudinal dispersion in the estuary will first be examined in the following particular situation (see fig. 2): The stagnant area is represented by a narrow branch (width Δx) at the side of the channel, situated at $x = x_0$.

fig. 2 horizontal view

fig. 3 cross-section at $x = x_0$

The resulting amount of constituent ΔZ passing through a fixed plane at $x=0$ due to the mixing in the stagnant area is equal to the difference of the following two quantities:

- the amount of constituent which passes at flood through the plane $x=0$ and which is stored in the stagnant area.
- the amount of constituent flowing out of the stagnant area into the channel at a moment such that it passes the plane at $x=0$ during the ebb.

We suppose that low-water slack coincides with low water (LW) which is chosen as the time origin. Consider now a fluid particle which at time $t=0$ is at $x=0$. We call t_0 the time that this fluid particle reaches $x=x_0$. All the particles which pass by the plane $x=x_0$ in the time interval $t_0 < t < T-t_0$ also pass by the plane $x=0$ in the same tidal cycle. The resulting amount of constituent ΔZ passing the plane $x=0$ is therefore given by

$$\Delta Z = \int_{t_0}^{\frac{1}{2}T} dt \frac{dV'}{dt} c(x_0, t) + \int_{\frac{1}{2}T}^{T-t_0} dt \frac{dV'}{dt} c'(x_0, t) \quad (2)$$

Here $V'(t)$ is the volume of the stagnant area and $c'(x_0, t)$ the concentration in the stagnant area, which for $\frac{1}{2}T < t < T$ is constant and equal to

$$c'(x_0, \frac{1}{2}T) = \left[V'(0)c'(x_0, 0) + \int_0^{\frac{1}{2}T} dt \frac{dV'}{dt} c(x_0, t) \right] / V'(\frac{1}{2}T) \quad (3)$$

In order to obtain explicit expressions for ΔZ we have to specify the shape of the cross-section of the stagnant area. Here the depth with respect to mean level is taken constant and equal to the tidal amplitude h_0 (see fig. 3). Further we assume a sinusoidal tide, so that

$$V'(t) = h_0 b' \Delta x \left(1 - \cos \frac{2\pi t}{T} \right) \quad (4)$$

Neglecting the longitudinal gradient of the velocity, one can write for the path $X(t)$ of a fluid particle which at $t=0$ is at $x=0$:

$$X(t) = \frac{1}{2} L \left(1 - \cos \frac{2\pi t}{T} \right) \quad (5)$$

From this expression one can find t_0 as a function of x_0 . The concentration in the channel can be approximated by

$$c(x, t) = c(X(t), t) + \left[x - X(t) \right] \frac{\partial c}{\partial x} \Big|_{X(t), t} \quad (6)$$

During the flood period the concentration is constant along the path of a fluid particle (diffusion in the channel is neglected), so that

$$c(X(t), t) = c_{LWS}(x=0) \quad (7)$$

As a final approximation, which is discussed in the appendix, we set

$$\left. \frac{\partial c}{\partial x} \right|_{X(t), t} \approx \left. \frac{d}{dx} c_{LWS} \right|_{x=0} \quad (8)$$

Substitution of equations (3-8) in expression (2) yields the result

$$\Delta Z = h_0 b' \Delta x \frac{dc_{LWS}}{dx} x_0 \left(1 - \frac{x_0}{L}\right), \quad 0 \leq x_0 \leq L; \quad (9)$$

$$\Delta Z = 0 \quad \text{elsewhere.} \quad (9)$$

From this expression it appears that mixing in a local stagnant area only produces longitudinal dispersion over a distance which does not exceed the tidal excursion. For this particular transport mechanism the contribution of a second storage area can simply be added to the contribution of the first one. Integration therefore yields the longitudinal dispersion caused by a long stagnant area adjacent to the channel as shown in fig. 4. The result is

$$D_{LWS} = \frac{1}{6} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \quad (10)$$

fig. 4 horizontal view

IV. The effect of non-tidal exchanges between the channel and the stagnant area.

In the preceding section it is assumed that the exchange of water between the channel and the stagnant area is only caused by the tide. In practice also exchanges caused by other mechanisms are present, like (turbulent) eddies and density currents, which take place without a net transfer of water. In this section the influence of these non-tidal exchanges, together with the assumption of complete mixing in the stagnant area will be studied.

We consider again the situation of fig. 2: a narrow trap located at $x = x_0$. The quantity of water which is exchanged per

unit time will be called Q_e . The total quantity of water flowing into the trap per unit time, Q_{in} , now equals:

$$Q_{in} = \frac{dV'}{dt} + Q_e, \quad 0 < t < \frac{1}{2}T; \quad Q_{in} = Q_e, \quad \frac{1}{2}T < t < T, \quad (11)$$

and the total quantity of water leaving per unit time,

$$Q_{out} = Q_e, \quad 0 < t < \frac{1}{2}T; \quad Q_{out} = -\frac{dV'}{dt} + Q_e, \quad \frac{1}{2}T < t < T. \quad (12)$$

The resulting amount of constituent ΔZ passing the plane $x = 0$ in a tidal period is given by a formula very similar to (2):

$$\Delta Z = \int_{t_0}^{T-t_0} dt [Q_{in}(t)c(x_0, t) - Q_{out}(t)c'(x_0, t)] \quad (13)$$

The concentration $c'(t) \equiv c'(x_0, t)$ can now be calculated from the mass-balance equation for the stagnant area:

$$\frac{d}{dt} [V'(t)c'(t)] = Q_{in}(t)c(x_0, t) - Q_{out}(t)c'(t)$$

The solution is

$$V'(t)c'(t) = V'(LWS)c'(LWS) \exp \left[-\int_{LWS}^t dt' \frac{Q_{out}(t')}{V'(t')} \right] + \int_{LWS}^t dt' Q_{in}(t')c(x_0, t') \exp \left[-\int_{t'}^t \frac{Q_{out}(t'')}{V'(t'')} \right] \quad (14)$$

In order to compute the formulas (13) and (14) one has to specify the exchange Q_e . Here the following assumptions are made:

- Q_e is proportional to the water depth in the stagnant area,
- exchange by eddies dominates exchange by density currents.

This assumption is plausible if the tidal velocity in the channel is important, and if the fresh water discharge and the depth of the stagnant area are small (these are all characteristics of the type of estuaries considered in this work). Then Q_e is minimum when the velocity is zero and maximum when the velocity is maximum.

From this follows the parametrisation

$$Q_e = \frac{\pi}{T} f_e V'(t) \left| \sin \frac{2\pi t}{T} \right| \quad (15)$$

The parameter f_e is defined as the fraction of the volume of the stagnant area which is exchanged with the channel during the flood period:

$$f_e = \int_0^{1/2 T} dt \frac{Q_e(t)}{V'(t)} \quad (16)$$

The dispersion coefficient D_{LWS} can now be calculated from the formulas (13) and (14) after substitution of the approximations (4-8). The result is

$$D_{LWS} = 2 \frac{h_0 b'}{A_{LWS}} \frac{L}{T} \Delta x \left\{ \frac{2}{f_e} \xi (1 - e^{-f_e(1-\xi)}) + \frac{1}{f_e^2} \left[-1 + e^{-f_e \xi} + \xi e^{f_e \xi} (e^{-2f_e} - e^{-4f_e}) \right] \right\} \quad (17)$$

for $\xi = x_0/L$ ranging from 0 to 1, and $D_{LWS} = 0$ elsewhere. In order to obtain the dispersion coefficient for a storage area with constant width extending along the channel one should consider the fact that a fluid particle can enter and leave the storage area several times during a tidal period. If it is assumed however that it is improbable that a fluid particle enters the stagnant area more than once, ($f_e \ll 1$), then the effect of several stagnant areas is the sum of the individual effects. The dispersion coefficient for a storage area extending along the channel is therefore obtained by integration of (17), with the result:

$$D_{LWS} = 2 \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \left\{ \frac{1}{f_e} - \frac{3}{f_e^2} + \frac{4}{f_e^3} (1 - e^{-f_e}) - \frac{1}{f_e^4} (1 - e^{-f_e})^2 \right\} \quad (18)$$

Expanding this formula as a power series in f_e one finds

$$D_{LWS} = \frac{1}{6} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \left\{ 1 + f_e - \frac{19}{30} f_e^2 + \frac{7}{30} f_e^3 + \dots \right\} \quad (19)$$

Comparing with formula (10) it appears that the non-tidal exchanges between the channel and the stagnant area may amplify the effect of mixing in a stagnant area on the longitudinal dispersion in an estuary. For small values of f_e the result can be interpreted as a virtual increase of the volume of the storage area with a fraction equal to f_e . For very large values of f_e the fluid particles stored into the stagnant area will remain there only a very short time, so that the longitudinal dispersion decreases. Although equation (18) has been derived for small values of f_e , the result is also valid for large values of f_e . Indeed, the dispersion coefficient is proportional to the average square displacement of fluid particles with respect to the main motion times the number of fluid particles being displaced. The average square displacement of a fluid particle is proportional to the number of times n ($n \gg 1$) that it enters and leaves the stagnant area. On the contrary, the number of fluid particles

displaced is inverse proportional to the average number of times $\langle n \rangle$ that the same fluid particle enters and leaves the stagnant area.

V. Effect of a phase-shift between tide and velocity

Mainly due to bottom friction the tidal motion in an estuary differs from a standing wave. This implies that flood and ebb do not coincide with respectively rising and falling tide. It has been shown by Schijf and Schönfeld that this effect generates dispersion in the presence of tidal flats.

Due to the phase-shift between tide and velocity, the water in the stagnant area is submitted to an effective relative motion with respect to the water in the channel, during a tidal cycle. Therefore, assuming the average discharge Q_0 equal to zero, a fluid particle, which is not stored during the tidal cycle, will not return to its initial position; it will undergo a net displacement δ in the upstream direction. A fluid particle which remains in the stagnant area during some part of the tidal cycle will undergo a net displacement in the downstream direction.

Consider the path $X(t)$ of a fluid particle, which at time $t = LWS + T$ is at $x = 0$ (the time origin is chosen at LW). At $t = 0$ this fluid particle is at $x = -\delta$; it passes by the plane $x = x_0$ at times $t = t_0 < HWS$ and $t = t'_0 > HWS$.

The formulas of the preceding section can now be easily extended to this case; for a single trap at $x = x_0$ one obtains:

$$\Delta Z = \int_{t_0}^{t'_0} dt [Q_{in}(t)c(x_0, t) - Q_{out}(t)c'(x_0, t)] + I$$

for $0 \leq x_0 \leq L$, and

$$\Delta Z = -V'(t_0)c'(x_0, t_0) + V'(LWS)c'(x_0, LWS) + I$$

for $-\delta \leq x_0 < 0$, where

$$I = \int_{-\delta}^0 dx A_{LWS}(x) c_{LWS}(x)$$

(20)

In order to obtain a simpler expression we neglect non-tidal exchanges ($f_e = 0$) and integrate in the variable x_0 . For a stagnant area extending along the channel one then finds

$$Z = \int_{-\delta}^0 dx A_{LWS}(x) c_{LWS}(x) + \int_{LWS}^{1/2T} dt \int_0^{X(t)} dx c(x, t) \frac{\partial A'(x, t)}{\partial t}$$

$$\int_{1/2T}^T dt \int_0^{X(t)} dx c'(x,t) \frac{\partial A'(x,t)}{\partial t} + \int_T^{LWS+T} dt \int_0^{X(t)} dx c(x,t) \frac{\partial A'(x,t)}{\partial t} \quad (21)$$

Here $A'(x,t)$ represents the cross-section of the stagnant area.

The expression (21) is evaluated for the cross-section shown in fig. 3 and assuming a sinusoidal tide.

The net displacement δ can be found from equation (21), by putting $Z=0$ when $c(x,t) = c'(x,t) = \text{constant}$.

The result is

$$\delta = \frac{1}{2} \pi h_0 b' L \sin \varphi / (A_{LWS} - h_0 b' \cos \varphi) \quad (22)$$

with $\varphi = 2\pi LWS/T$ (the time origin is chosen at LW).

In the case of a phase-shift between tide and velocity longitudinal dispersion is generated even when no mixing takes place on the tidal flats. No mixing implies

$$c'(x,t) = c'(x, T-t) \quad (23)$$

Substitution in (21) yields:

$$D_{LWS} = \frac{2}{3} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \sin^2 \varphi \quad (24)$$

When complete mixing on the tidal flats is assumed one may substitute for $c'(x,t)$ the expression (3). The result is

$$D_{LWS} = \frac{1}{6} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \left[1 + \left(1 + \frac{3\pi^2}{16} \right) \sin^2 \varphi \right] \quad (25)$$

In both the formulas (24) and (25) higher order terms in $h_0 b' / A_{LWS}$ have been omitted.

VI. Generalisation for real estuaries.

In the preceding sections a particular cross-section is considered, which may be very different from the type of cross-sections which occur in natural estuaries. In order to present results which can be applied for real estuaries, we will consider here some other types of cross-sections and derive from this more general expressions for the longitudinal dispersion coefficient.

The three particular cross-sections studied in this section are shown in fig. 5a - c.

- a) The depth of the stagnant area is greater than h_0 (fig. 5a). When the depth of the stagnant area becomes large the non-tidal exchanges between the channel and the stagnant area will play a more important role. We consider now the limit that the tidal elevation can be neglected with respect to the depth a' of the stagnant area, as was done by Okubo [2]. The exchange discharge Q_e is assumed to be constant. Computation of equation (13) yields the result

$$D_{LWS} = \frac{\pi^2}{4} \frac{a' b'}{A_{LWS}} \frac{L^2}{T} \frac{1}{f_e} \left(1 + \frac{\pi^2}{f_e^2}\right)^{-1} \left[1 - \frac{1 - e^{-2f_e}}{f_e(1 + \frac{\pi^2}{f_e^2})}\right] \quad (26)$$

With the approximations $f_e \ll 1$ and $a' b' \ll A_{LWS}$ this expression is identical to the one found by Okubo. The results also agree in the limit $f_e \gg 1$; the reason for this has been given previously.

In reality one may expect an important contribution of density currents to the non-tidal exchanges when the stagnant area is deep. The assumption of a constant Q_e should therefore be modified, as well as equation (26). This problem will not be treated here any further.

b) The depth of the stagnant area is smaller than h_0 (fig. 5b).

Instead of a' we write $h_0 \cos \vartheta$, where ϑ is a parameter ranging from 0 to π . The tidal volume per unit length of the stagnant area A'_t is equal to $A'_t = 2\eta h_0 b'$, with $\eta = \cos^2 \frac{1}{2} \vartheta$. In the case of complete mixing equation (13) yields

$$f_e(\eta) = \eta f_e(\eta = 1) \text{ and } D(\eta) = \eta^3 D(\eta = 1) \quad (27)$$

For the interpretation of this result one should consider the fact that the transport of water towards and from the stagnant area only takes place in a limited time interval during which the distance λ travelled by the fluid particles in the channel equals $\lambda = \eta L$. As shown in section III, the mixing in the stagnant area generates an effective transfer of fluid particles over distances smaller than or equal to λ : the distance λ is the maximum mixing length. The result (27) suggests that the dispersion coefficient depends on λ rather than on L .

Considering the effect of the phase-shift φ and no mixing in the stagnant area the result is

$$D_{LWS} = \frac{2}{3} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \sin^2 \varphi \cos^2 \frac{1}{2} \vartheta \left[1 + \cos \vartheta \sin^2 \frac{1}{2} \vartheta \right] \quad (28)$$

In this case the distance over which the mixing takes place at different times is given by the expression $X(t) - X(T-t) = L \sin \varphi \sin \frac{2\pi t}{T}$, which is independent of ϑ . Therefore to a good approximation the dispersion coefficient is equal to the square of $L \sin \varphi$ and to the tidal volume of the stagnant area, except for high tidal flats ($\vartheta > \frac{1}{2} \pi$).

c) The depth of the stagnant area varies linearly (fig. 5c).

The tidal volume of the stagnant area equals $A'_t = h_0 b'$; the dispersion coefficient is obtained from equation (2) by substituting

$$\frac{dA'}{dt} = \frac{1}{2} b' \left(1 - \cos \frac{2\pi t}{T} \right) \frac{dh}{dt}$$

For the case of complete mixing and $\varphi = f_e = 0$ one finds

$$D_{LWS} = \frac{1}{18} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \quad (29)$$

According to the discussion of formula (27) it appears that the dispersion coefficient is not just proportional to the tidal volume of the stagnant area, but that it also depends on the shape of the cross-section. The triangular shape brings about an extra factor $2/3$, with respect to the rectangular shape.

For the case with $\varphi \neq 0$ and no mixing one finds

$$D_{LWS} = \frac{1}{3} \frac{h_0 b'}{A_{LWS}} \frac{L^2}{T} \sin^2 \varphi \quad (30)$$

For this case the dispersion coefficient appears to be proportional to the tidal volume of the stagnant area; the result is independent of the shape of the cross-section.

The preceding considerations lead to the following generalisations:

- longitudinal dispersion caused by mixing on the tidal flats:

$$D_{LWS} = k \frac{A'_t}{A_{LWS}} \frac{\lambda^2}{T} \quad (31)$$

where k is a parameter depending on the shape of the cross-section of the tidal flat: $k = 1/12$ for a rectangular shape, $k = 1/18$ for a triangular shape. The distance $\lambda = L \cos^2 \frac{1}{2} \vartheta$

is the maximum mixing length.

- the increase of longitudinal dispersion caused by non-tidal exchanges between the channel and the tidal flats:

$$\begin{aligned} D(f_e) &= 12 \left\{ \frac{1}{f_e} - \frac{3}{f_e^2} + \frac{4}{f_e^3} (1 - e^{-f_e}) - \frac{1}{f_e^4} (1 - e^{-f_e})^2 \right\} D(f_e = 0) \\ &= \left\{ 1 + f_e - \frac{19}{30} f_e^2 + \frac{7}{30} f_e^3 + \dots \right\} D(f_e = 0) \quad (32) \end{aligned}$$

where f_e is defined in equation (16) as the fraction of the water volume on the tidal flat which is exchanged during the flood period.

- the increase of longitudinal dispersion caused by a phase-shift $\varphi = 2\pi(LWS - LW)/T$ between the tidal elevation and the tidal velocity depends in a rather complicated way on the shape of the cross-section of the tidal flat. When the phase-shift is large ($\sin \varphi \approx 1$) the mixing on the tidal flat only plays a minor role.
- longitudinal dispersion caused by the phase-shift φ , without mixing on the tidal flat, is to a good approximation independent of the shape of the cross-section except when the major part of the tidal flat is above mean level. Otherwise

$$D_{LWS} = \frac{1}{3} \frac{A'_t}{A_{LWS}} \frac{L^2}{T} \sin^2 \varphi \quad (33)$$

In spite of these generalisations it remains difficult to obtain from these formulas accurate estimates for the dispersion coefficients in real estuaries.

Specially the following problems should be mentioned:

- the specification of the part of the estuary cross-section which may be considered as "stagnant area",
- the definition of the maximum mixing length when the velocity distribution is inhomogeneous,
- the determination of the degree of mixing in the stagnant area,
- the estimation of exchange coefficient f_e .

The last two problems are also related to the occurrence of density effects, which therefore contribute implicitly in the formulas (31-33).

In Holland the estuaries Westerschelde, Oosterschelde and Eems belong to the class of shallow well mixed estuaries studied in this paper. In these estuaries the geometrical factor

A'_t / A'_{Lws} ranges between 0.3 and 0.45 and the maximum mixing length λ between 12 and 15 kilometers. Estimating the exchange coefficient f_e between 0.1 and 0.5, one finds values for the dispersion coefficient in the interval 88-273 m²/s. The measured dispersion coefficient is found in the interval 150-450 m²/s. The phase-shift φ is small and therefore contributes little. A small increase of the dispersion coefficient with increasing discharge, which has been observed experimentally, could be related to the influence of density effects on the mixing and exchange processes on the tidal flats.

VII. Summary and conclusions

Experimental evidence is shown for the occurrence of strong mixing on tidal flats. In estuaries with an important tidal motion and large tidal flats the mixing of water on the tidal flats produces longitudinal dispersion, which is enhanced by two other phenomena: the exchange of water between the channel and the stagnant area by other mechanisms than the tide (eddies, density currents) and the occurrence of a phase-shift between the tidal elevation and the tidal velocity due to the damping of the tidal wave in the estuary. Explicit expressions are given for the contribution of these phenomena to the longitudinal dispersion.

It is shown that the dispersion coefficient depends linearly on the tidal volume of the stagnant area and that it is proportional to the square of the maximum mixing length, which is the distance covered by a water particle in the channel during the period that the stagnant area is being flooded by the tide.

From the formulas it is possible to obtain for real estuaries an estimate of the dispersion caused by mixing and exchange processes on the tidal flats. For several estuaries in Holland

with an important tidal motion and large tidal flats, the results are compared to experimental values for the dispersion coefficient. It appears that the tidal flats account for about 50% of the longitudinal dispersion.

APPENDIX.

A. The sensitivity of the results for the approximation

$$\left. \frac{\partial c}{\partial x} \right|_{X(t),t} \approx \left. \frac{dc_{LWS}}{\partial x} \right|_{x=0} \quad (8)$$

In order to evaluate the first order correction term, we consider a small section in the channel of variable length $l(t)$, moving in such a way that no transport takes place through the front or the back. The difference between the concentrations in the front and in the back is constant, and equals Δc . When $l(t)$ is taken small enough, then

$$\Delta c = l(t) \left. \frac{\partial c}{\partial x} \right|_{X(t),t} \quad (34)$$

The function $l(t)$ can be obtained from the continuity equation

$$\frac{d}{dt} [A(t)l(t)] + l(t) \frac{dA'}{dt} = 0$$

which is solved for the model estuary (see fig. 3) and a sinusoidal tide, with the approximation

$$\gamma = h_0(b + b') / A_0 \ll 1$$

The result is

$$l(0) / l(t) = (1 - \gamma \cos \frac{2\pi t}{T}) / (1 - \gamma) \quad (35)$$

From this, and from the equations (8) and (37) follows

$$\left. \frac{\partial c}{\partial x} \right|_{X(t),t} = \left. \frac{dc_{LWS}}{\partial x} \right|_{x=0} \frac{1 - \gamma \cos \frac{2\pi t}{T}}{1 - \gamma} \quad (36)$$

Substitution in equation (21) introduces in the formulas (24) and (25) a factor $1 / (1 - \gamma)$ and some correction terms.

Assuming complete mixing in the stagnant area, the correction to the dispersion coefficient (25) has a relative magnitude of order $\gamma \sin 2\phi$

Assuming no mixing in the stagnant area, the dispersion coefficient (24) contains correction terms with a relative magnitude of order γ^2

INTERFACIAL FRICTION COEFFICIENTS IN
A TWO-LAYERED STRATIFIED FLOW

By

Emmanuel Partheniades¹ and Vassilios Dermassis²

ABSTRACT

The friction factors at the interface in a two-layered stratified flow have been studied experimentally in a closed rectangular duct with freshwater flowing over a quasi-stagnant salt water. The analysis of the flow was based on the application of the one-dimensional mass and energy equations for each layer. It was found that the interfacial friction coefficient, \bar{f}_i , is best correlated with the dimensionless number ReF^2 , where Re and F are some non-densimetric Reynolds and Froude numbers of the flow, and with the relative density difference of the two layers $\Delta\rho/\rho$. Good agreement has been obtained with results of previous laboratory investigations and field data.

INTRODUCTION

The hydrodynamics of arrested saline wedges plays a dominant role in a variety of engineering problems related to estuarine hydraulics and, in general, to the management of stratified or nearly stratified estuaries. Among the most important parameters which appear in the pertinent equations are the shear stresses at the interface and at the bed as well as the related shear stress coefficients. Indeed equations are available which give the length of intrusion, L_i , and the shape of the salinity wedge in terms of the densimetric Froude number, F'_0 , and an average interfacial shear stress coefficient, \bar{f}_i , over the length of intrusion. These equations, developed by Schijf and Schoenfeld (15)*, are based on the energy balance in the upper and lower layer respectively, on negligible rates of salt water entrainment through the interface and on zero average velocity through any cross section of the salinity wedge. They have the following form:

*Numbers in parenthesis indicate references at the end of the paper.

$$\frac{\bar{f}_i}{8} \frac{x}{h_o} = \frac{h_1}{h_o} \left[\frac{1}{5(F'_o)^2} \left(\frac{h_1}{h_o}\right)^4 - \frac{1}{4(F'_o)^2} \left(\frac{h_1}{h_o}\right)^3 - \frac{1}{2} \left(\frac{h_1}{h_o}\right) + 1 \right] + 3(F'_o)^{2/3} \left[\frac{1}{10}(F'_o)^{2/3} - \frac{1}{4} \right] \tag{1}$$

and

$$L_i = \frac{2h_o}{\bar{f}_i} \left[\frac{1}{5(F'_o)^2} - 2 + 3(F'_o)^{2/3} - \frac{6}{5}(F'_o)^{4/3} \right] \tag{2}$$

where, referring to Fig. 1, h_o = the total depth of flow at the end of the salinity intrusion, h_1 = the fresh water depth, x = the distance from the ocean end of the channel and F'_o = the densimetric Froude number, defined by the Eq.:

$$F'_o = \frac{V_o}{\sqrt{g \frac{\Delta\rho}{\rho} h_o}} \tag{3}$$

Fig. 1 Definition sketch of an arrested saline wedge

where V_o = the fresh water velocity upstream of the end of salinity intrusion, ρ = the fresh water density, $\Delta\rho$ = the density difference between the fresh water and salt water and g = the acceleration of gravity. With F'_o normally known the length of salinity intrusion, L_i , can be obtained from Eq. 2 if \bar{f}_i can be estimated. Likewise, knowing \bar{f}_i the shape of the arrested salinity wedge could be determined either from Eq. 1 or from an equation developed elsewhere (12).

The importance of the interfacial shear stress coefficient motivated numerous investigations for the purpose of linking f_i to some readily determinable gross flow and salinity parameters. The basic assumptions, however, and the methodology of approach varied widely among the various investigations, as expected. As a result, the graphical and analytical expressions obtained give, if applied to the same physical system, values of the f_i differing widely, sometimes by orders of magnitude. The flow within the interfacial zone

has often been assumed to be laminar. This is by no means the general case. On the contrary, experimental evidence suggests that the velocity may considerably exceed its critical value for salt water entrainment and mixing (10, 12) with the flow maintaining its stratified appearance with a sharp interface. Thus sufficient exchange of fresh and salt water may take place through the interface for Reynolds stresses to develop, while the rate of entrainment and mixing remains negligible in comparison to the fresh water flow rate.

The objective of this study has been the derivation of generalized relationships between the interfacial friction coefficient, \bar{f}_i , and the pertinent parameters which fully describe the flow and salinity conditions. The to-date results are herein reported*.

PARTIAL REVIEW OF EARLIER INVESTIGATIONS

Keulegan (9, 10) derived the following analytical expression for \bar{f}_i on the assumption of laminar flow conditions in the neighborhood of the interface:

$$\bar{f}_i = \frac{8T_i}{\rho V_0^2} = \frac{A_1}{R_0} \quad (4)$$

where T_i = average interfacial shear stress over the length of salinity intrusion, $R_0 = V_0 h_0 / \nu$, A_1 = a dimensionless constant equal to 152 for $h_{sc} = 0.5 (h_0)$ and h_{sc} = the value of h_s at the ocean entrance given by the equation:

$$h_{sc} = h_0 \left[1 - (F'_0)^{2/3} \right] \quad (5)$$

An experimental expression similar to Eq. 4 was derived by Bata and Knezevich for laminar density underflows (2) but with a value of $A_1 = 180$ and $R_e = 4Vh_0/\nu$. For turbulent underflows the same investigators found $\bar{f} = 0.010$ for smooth bottom and $\bar{f} = 0.020$ for rough bottom. It should be noted though, that \bar{f} is an average friction factor incorporating the frictional effects of bottom, interface and sidewall.

Shi-igai (14) calculated the energy dissipation, ϵ , per unit surface of fluid caused by the internal waves and defining $\tau_i = \epsilon/V_1$, where V_1 = the uniform velocity of the moving fresh water layer, derived the following Eq.:

$$f_i = \frac{2\tau_i}{\rho V_1^2} = 8\pi^2 \left(\frac{a}{\lambda} \right)^2 \frac{1}{R_e (F'_1)^2} \quad (6)$$

where $R_e = V_1 h_1 / \nu$, $F'_1 = V_1 / \sqrt{g \frac{\Delta\rho}{\rho} h_1}$, h_1 = thickness of the

upper layer, a = the amplitude and λ = the length of internal waves. On the basis of limited experimental data at that time the factor $8\pi^2(a/\lambda)^2$ was tentatively estimated to be about 12.

For a laminar density underflow under uniform conditions Ippen and Harleman (6) derived the following equation for the average friction coefficient \bar{f} , which incorporates, like in Bata and Knezevich experiments, the frictional resistance of both the bed and the interface:

$$\bar{f} = \frac{228}{R_e} \tag{7}$$

where $R_e = 4h_2V_2/\nu$, h_2 = the uniform depth of the underflow and V_2 = the average velocity of the latter.

Abraham and Eysink (1) reanalyzed some of the test data of Keulegan and Barr for values of $R_e = VR_1/\nu$ up to 1.5×10^4 . For $F'_0 \approx 0.8$ they found a smooth curve relating f_i to R_e in a log-log plot. The curve becomes flatter as the Reynolds number increases, something which is indicative of turbulent shear stresses within the interfacial zone.

Georgiev studied the case of a uniform underflow in a two-layered system and determined the Reynolds stresses at the interface by direct measurements with hot film. His experimental data satisfy the relationship:

$$f_i = \frac{0.275}{R_e^{0.276}} \tag{8}$$

where $R_e = V_2R_{h_2}/\nu$ ranged from 10^3 to 10^4 and where R_{h_2} = the hydraulic radius of the underflow. It is noteworthy that this last relationship is quite close to Blasius formula:

$$f = \frac{0.316}{R_e^{0.25}} \tag{9}$$

for smooth pipe flow (16). The scattering of Georgiev's points is relatively small; however, the unique dependence of f_i only on Reynolds number in a turbulent two-layered stratified flow and the narrow range of the latter raises doubts as to its universal validity.

More recently Harleman and Stolzenbach (7), using data of other investigators, arrived at the following experimental equation for f_i :

$$\frac{1}{\sqrt{f_i}} = 2 \log Re\sqrt{f_i} - 0.8 \tag{10}$$

where $R_e = 4VR_h/\nu$.

The scattering of the data points, however, which exceeds an order of magnitude, and the fact that f_i is given again as a function of only the Reynolds number for values of the latter as high as 6×10^6 raises, as in the previous case, serious questions.

Lofquist (11) conducted extensive experimental research on a two-layered system in which the lower layer was moving with uniform depth and velocity, while the upper one was quasi-stagnant. His results were given graphically with dependent variable the ratio β of the turbulent shear stresses to the corresponding laminar ones and independent variables the Reynolds number and the densimetric Froude number. For laminar flow at the interface Lofquist's relationship approaches quite closely that of Keulegan (9, 10).

At this point it would be interesting to compare the results obtained by various formulas for the South Pass of the Mississippi River (12). The given data are: $Q = 100,000$ cfs, $b = 1500$ ft, $h = 45$ ft, $V_0 = 1.48$ ft/sec, $\Delta\rho/\rho = 0.02$, $\nu = 1.09 \times 10^{-5}$ ft²/sec, $F'_0 = 0.275$ and a length of salinity intrusion, $L_i = 14$ miles. It is first observed that the critical velocity for the initiation of entrainment is (8, 10):

$$V_{1m} = 7.3 \left(\nu g \frac{\Delta\rho}{\rho} \right)^{1/3} \quad (11)$$

which for the given data gives $V_{1m} = 0.14$ ft/sec. This is much smaller than the fresh water velocity. Therefore, there is entrainment through the interface and the flow around it is turbulent. The following results can then be obtained:

- (a) Schijf and Schoenfeld Eq. 2 gives $\bar{f}_i = 0.00185$.
- (b) Keulegan's Eq. 4 gives $\bar{f}_i = 2.5 \times 10^{-5}$.
- (c) Bata and Knezevich's equation for $R_e = 244.4 \times 10^5$ gives $\bar{f} = 0.74 \times 10^{-5}$.
- (d) Shi-igai's Eq. 6, after properly converting R_e and F' to mean flow conditions over the wedge through Eqs. 1, 2, and 5, gives $f_i = 0.96 \times 10^{-5}$.
- (e) Harleman and Stolzenbach's Eq. 10 gives $\bar{f}_i = 0.0071$.
- (f) If a smooth boundary replaces the interface then for the values of $h_1 = 34.2$ ft, i.e. the mean fresh water depth, and $V_1 = 1.95$ ft/sec, i.e. the mean fresh water velocity, we obtain $\bar{f}_i = 0.0075$ which is quite close to the former.

The above example shows first that the actual value of \bar{f}_i

based on field measurement in real estuaries may exceed the values given by formulas based on the assumption of laminar flow around the interface by two to three orders of magnitude; second, that Shi-igai's theory seems to be valid rather for laminar flow near the interface and finally that Harleman and Stolzenbach's Eq. 12 gives too high values of \bar{f}_i bordering those corresponding to a smooth solid wall.

The results of the most important up to 1974 investigations have been reviewed and summarized by the Hydraulic Laboratory in Delft, Netherlands (3). Fig. 2 represents an attempt to find a relationship between \bar{f}_i and the Reynolds number $Re_1 = V_1 h_1 / \nu$ for the cases where the upper layer is moving and the lower one is quasi-stationary. It is readily seen that Ippen and Harleman's line, valid for laminar underflow and for $Re_1 \leq 1000$, crosses two groups of points by Rid-del; nevertheless, each group could very well correspond to a different line particularly since the flow for $Re_1 > 1000$ is turbulent. Lanzoni's line covers too narrow a range of Re_1 while Averkiev and Kinds data fall in a line almost parallel to that of Ippen and Harleman but exceeding it by a factor of about 5. Zanotti's data are too limited and too scattered and finally the only two field data cannot be meaningfully connected with the laboratory test data. It seems rather doubtful whether \bar{f}_i is indeed a function of the Reynolds number only. This conclusion is further strengthened by Fig. 3, which summarizes results of underflows with the lower layer only moving and where the spread of the experimental points approaches one order of magnitude. Clearly \bar{f}_i must depend on other factors besides Re_e . In fact \bar{f}_i seems to be very weakly correlated to Re_e with an average value of about 0.0208 for the group of points of low Re_e and 0.0144 for the group of points of high Re_e . The corresponding ranges are 0.008 to 0.08 for the first group and 0.008 to 0.0456 for the second. All these values are much higher than the $\bar{f}_i = 0.00185$ for the South Pass of the Mississippi River as estimated earlier. A trend similar to that of Fig. 3 has been observed in cases where both the upper and lower layers are moving in opposite directions.

Fig. 4 shows an attempt to correlate $\bar{f}_i/8$ with the product $Re_e (F')^2$ while using at the same time F' as a parameter. The correlation seems to be rather poor. The average value of \bar{f}_i is around 0.0160, that is quite close to the value of the previous figure. Fig. 5 (13) shows a summary of several test data where $\theta =$ the Keulegan number defined as:

$$\theta = \frac{1}{V} \left(v g \frac{\Delta \rho}{\rho} \right)^{1/3} \quad (12)$$

Fig. 2 Variation of \bar{f}_i with Re for flow in upper layer (3)

Fig. 3 Variation of \bar{f}_i with Re for flow in lower layer (3)

Fig. 4 Variation of \bar{f}_i with $Re(F')^2$ and F' according to Lofquist's experiments^(3, 11)

Fig. 5 Variation of \bar{f}_i with Keulegan's number θ

It is obvious that $\theta^{-3} = Re(F')^2$. It is observed that the results of Iwasaki fall on a straight line with little scattering; however, all other points fall on a distinctly different line whose mean slope with respect to the θ^{-3} axis is considerably smaller than that of the first line.

This limited review leads to two major observations: (a) None of the presented correlations seems to be of universal validity and, (b) in several plots the scattering of data points is too wide for reliable conclusions. Both observations suggest that either the correlation parameter or parameters were not properly selected, or additional flow and salinity parameters should be taken into consideration in a way that each one of them should have the maximum possible

weight on \bar{f}_1 . This is the objective of the experimental work to be presented.

EQUIPMENT AND PROCEDURE

Theoretical Analysis

The experimental studies were conducted in a 15 m long closed rectangular duct whose lower part was occupied by a quasi-stagnant salt water layer over which fresh water was flowing at predetermined rates (4). Application of the energy balance to each layer of a two-layered stratified flow (Fig. 6) gives:

Fig. 6 Definition sketch for stratified two-layered flow in a closed duct

$$\frac{dH}{dx} + \frac{V_1}{g} \frac{dV_1}{dx} - S_{e1} = 0 \tag{13}$$

for the upper layer, where H = the elevation of piezometric line and S_{e1} = the slope of the energy grade line and

$$\left(1 - \frac{\Delta\rho}{\rho}\right) \frac{dH}{dx} + \frac{\Delta\rho}{\rho} \cdot \frac{dh'}{dx} + \frac{V_2}{g} \frac{dV_2}{dx} - S_{e2} = 0 \tag{14}$$

for the lower layer, where h' = the elevation of the interface and S_{e2} = the slope of the energy grade line. Considering that $h' = z_0 + h_2$, $h_1+h_2=h_0$ =depth of the duct=constant and $dz_0/dx = S_0$ = slope of the duct (Fig. 6) it follows that:

$$\left(1 - \frac{\Delta\rho}{\rho}\right) \frac{dH}{dx} + \frac{\Delta\rho}{\rho} S_0 - \frac{\Delta\rho}{\rho} \frac{dh_1}{dx} + \frac{V_2}{g} \frac{dV_2}{dx} - S_{e2} = 0 \tag{15}$$

For negligible rate of entrainment and mixing through the interface the continuity equation gives $h_1V_1 = \text{const.}$ and $h_2V_2 = \text{const.}$ Considering that $V_2 = 0$ for the lower layer, Eqs. 13 and 15 take the forms:

$$\frac{dH}{dx} - \frac{V_1^2}{gh_1} \cdot \frac{dh_1}{dx} - S_{e1} = 0 \tag{16}$$

and

$$\left(1 - \frac{\Delta\rho}{\rho}\right) \frac{dH}{dx} + \frac{\Delta\rho}{\rho} S_0 - \frac{\Delta\rho}{\rho} \frac{dh_1}{dx} - S_{e2} = 0 \tag{17}$$

For uniform boundary roughness S_e is given by:

$$S_e = \frac{\tau_b}{\gamma R_h} \tag{18}$$

where τ_b = the average boundary shear stress. In the present case, however, of a closed duct of finite width, b , and with composite roughness, i.e. with a Darcy-Weisbach friction coefficients f_i at the interface and f_w at the wall, Eq. 18 has to be modified. Considering the force balance of a small element of the duct it can readily be shown that:

$$(2h_1 + b)\tau_w + b\tau_i = bh_1\rho S_{e1} \tag{19}$$

Assuming now $\tau = \frac{f}{8} \rho V^2$ for both τ_w and τ_i it follows that:

$$S_{e1} = \frac{V_1^2}{gh_1} \left(\frac{f_w + f_i}{8} + \frac{h_1}{4b} f_w \right) \tag{20}$$

The same procedure for the lower layer gives:

$$S_{e2} = - \frac{V_1^2 f_i}{8g(h_0 - h_1)} \tag{21}$$

Then from Eqs. 16 and 17 it is finally obtained:

$$\frac{dh}{dx} = \frac{\frac{dh_1}{dx} \left[\frac{V_1^2}{g} + (h_o - h_1) \frac{\Delta\rho}{\rho} \right] + \frac{V_1^2 f_w}{8g} \left(1 + \frac{2h_1}{b} \right) - \frac{\Delta\rho}{\rho} (h_o - h_1) S_o}{(h_o - h_1) \left(1 - \frac{\Delta\rho}{\rho} \right) + h_1} \quad (22)$$

and

$$f_i = \frac{8 \left[\left(\frac{gh_1}{V_1^2} - \frac{\rho}{\Delta\rho} + 1 \right) \frac{dH}{dx} - S_o \right] - f_w \left(1 + \frac{2h_1}{b} \right)}{1 + \frac{V_1^2}{\frac{\Delta\rho}{\rho} g (h_o - h_1)}} \quad (23)$$

Eqs. 22 and 23 will serve as a basis for the analysis of the experimental data.

Basic Research Equipment

The basic research equipment, constructed at the Laboratory of Hydraulics and Hydraulic Structures of the School of Engineering of the University of Thessaloniki, Greece, is outlined in Fig. 7. (4) It consists of a rectangular plexiglass duct 15 m long, 50 cm wide and 20 cm high.

The duct is equipped with six tanks, T_1 to T_6 , necessary for the preparation, storage, supply and regulation of the flows of salt and fresh water. The entire duct-tank system has a length of 20 m. Tank T_1 is the main fresh water supply tank. It is located right below the downstream end of the duct and is 3 m long, 1 m wide and 1.20 m deep. The tank is divided by a 45° sharp crested weir into two chambers A and B of which A serves as a stilling basin and B as an equalization reservoir.

From chamber B of tank T_1 the fresh water is pumped through an axial flow pump to head tank, T_2 , where its kinetic energy is dissipated while the remaining large scale eddies are being reduced to a minimum by passage through two walls of perforated bricks. The tank is 1.5 m long, 0.90 m wide and 0.50 m deep and it is equipped with an adjustable overflow system so that the excess water returns to chamber B of the previous tank. Tank T_3 serves for the storage and supply of salt water, it is supported on a separate frame and it has a length of 2 m, a width of 1 m and a depth of 0.50 m. Tank T_4 is 2 m

long, 0.50 m wide and 0.40 m deep and it is essentially an extension of the main duct also constructed of plexiglass. It was used to control the slope of the piezometric line in the main duct through a gate, to collect the entrained salt water, which settles to the bottom and to discharge it. Provisions were made for the proper supply of fresh water in Tank T₁ so that the water levels in chambers A and B and, therefore, the flow discharge, remained practically constant.

Tank T₅ is just an accessory to Tank T₄, and, Tank T₆ is a sort of a booster tank to provide additional water for experiments with high discharge.

The salt water layer was formed by placing two variable

Fig. 7 Outline of experimental closed duct.

A and B = sills

Fig. 8 Location of sills.

height sills at points A and B of the duct 15 m apart, as shown in Fig. 8. The sill crest elevation was controlled by adding and subtracting 2.2 cm thick plexiglass blocks.

Procedure

Each experiment started by filling the between the sills space with salt water at predetermined salinity. Next, the fresh water was introduced initially at very low rates to avoid any mixing with salt water. Once the entire system was filled the experiments started at the selected flow rates. Upon the beginning of the fresh water flow, shear stresses at the interface developed as a result of which the level of the interface increased downstream and salt water was entrained over the sill to Tank T₄. The measurements were then taken over a time interval of 2 to 4 minutes for which the flow parameters were not changed measurably. The following variables were measured: The mean depth of the upper layer, \bar{h}_1 , the fresh water discharge, the average slope of the interface, the water temperature and the salinity distribution. At every section the interface was defined as the point at which the salinity was about the average of the salinities of the two layers. Since some water entrainment was unavoidable the salinity of recirculating fresh water was checked at regular time intervals and as soon as its density increased by one tenth of the original density difference, $\Delta\rho$, the tanks were emptied and refilled with fresh water.

In order to be able to observe the interfacial zone and its changes, fluorescent dye was added in the salt water.

ANALYSIS OF EXPERIMENTAL DATA

A total of 217 experiments were conducted for their analysis. Eqs. 22 and 23 had to be slightly transformed to the following forms in terms of average values of the variables over the measurement section:

$$\frac{d\bar{H}}{dx} = \frac{\frac{d\bar{h}_1}{dx} \left[\frac{\bar{v}_1^2}{g} + (h_o - \bar{h}_1) \frac{\Delta\rho}{\rho} \right] + \frac{\bar{v}_1^2 f_w}{8g} \left(1 + \frac{2\bar{h}_1}{b} \right) - \frac{\Delta\rho}{\rho} (h_o - \bar{h}_1) S_o}{(h_o - \bar{h}_1) \left(1 - \frac{\Delta\rho}{\rho} \right) + \bar{h}_1} \quad (24)$$

and

$$\bar{f}_1 = \frac{8 \left[\left(\frac{g\bar{h}_1}{\bar{v}_1^2} - \frac{\rho}{\Delta\rho} + 1 \right) \frac{d\bar{H}}{dx} - S_o \right] - f_w \left(1 - \frac{2\bar{h}_1}{b} \right)}{1 + \frac{\bar{v}_1^2}{g \frac{\Delta\rho}{\rho} (h_o - \bar{h}_1)}} \quad (25)$$

where the bar indicates average values over the effective channel length. $d\bar{H}/dx$ was first estimated from Eq. 24 and

its value was subsequently introduced in Eq. 25 for the evaluation of \bar{f}_i .

In each run the density profile was determined through a number of samples. Fig. 9 shows an example of such profiles for $H_0/h_0 = 0.45$ where H_0 and h_0 are defined in Fig. 8. The mean width of the interfacial zone, i.e. the zone where the density changes from ρ to $\rho + \Delta\rho$, was about 2 cm with a maximum deviation of 30%. The density variation within that zone was very nearly linear with the exception of the upper and lower 10% range of $\Delta\rho/\rho$.

The experiments have been grouped in 8 distinct groups on the basis of the following 8 values of the relative density difference, $\Delta\rho/\rho$: 3‰, 10‰, 15‰, 20‰, 25‰, 30‰, 35‰, and 40‰. Each group was then divided into four sub-groups on the basis of the initial fresh water depth, H_0 , i.e. the distance from the top of the sills to the top of the channel. The following values of H_0 were used: 0.156 m, 0.134 m, 0.112 m and 0.09 m.

It was first attempted to correlate \bar{f}_i with the Reynolds number:

$$R_e = \frac{4\bar{V}_1 \bar{R}_{h1}}{v} \quad \text{where} \quad \bar{R}_{h1} = \frac{b\bar{h}_1}{2(b+\bar{h}_1)} \quad (26)$$

and with the relative density difference, $\Delta\rho/\rho$, for various average fresh water depths, \bar{h}_1 . It was found that for each value of $\Delta\rho/\rho$ the log-log plot of \bar{f}_i vs R_e gave reasonably straight lines albeit with rather wide scattering sometimes by a factor of 2. However, the superposition of these curves did not reveal any consistent variation of \bar{f}_i - R_e lines with $\Delta\rho/\rho$ while at the same time the plot of all points for all values of $\Delta\rho/\rho$ indicated a wide spread with no specific trend.

Subsequent attempts to correlate \bar{f}_i with (a) $F'_1 = \bar{V}_1/\sqrt{\Delta\rho/\rho g \bar{R}_{h1}}$ as an independent variable and $\Delta\rho/\rho$ and \bar{h}_1 as

Fig. 9 Density profile in interfacial zone

parameters, (b) R_e as an independent variable and $\Delta\rho/\rho$ and F_1' as parameters (c) F_1' as independent variable and only R_e as a parameter and finally (d) $R_e(F_1')^2$ with F_1' as a parameter did not succeed either in discovering consistent trends of variation. This was indicative that the variables entering into the problems so far were not properly separated for the effect of each one to be clearly displayed.

The first sign of success appeared when \bar{f}_i was plotted against $R_e F^2$, where F = the regular Froude number of the entire layer given by:

$$F = \frac{\bar{V}_1}{\sqrt{gR_{h0}}} \quad (27)$$

and where R_{h0} = the hydraulic radius of the entire cross section of the duct, while $\Delta\rho/\rho$ was treated as an independent parameter. That is the gravity forces, which generate the principal flow and the density parameter, which determines the buoyant forces responsible for the stratification and secondary flow, have now been separated.

Fig. 10 shows the plots of \bar{f}_i vs $R_e F^2$ for the eight values of $\Delta\rho/\rho$. The points give well defined mean lines with quite small scattering in comparison to the previous plots.

The eight average lines have been redrawn together in Fig. 11. It is observed that this family of curves follows a distinct and consistent pattern, with \bar{f}_i increasing with $\Delta\rho/\rho$ for the same $R_e F^2$. In Fig. 12 the line of the previous figure corresponding to $\Delta\rho/\rho = 20\text{‰}$ has been reproduced and the reanalyzed data of Abraham and Eysink (1) obtained for a quite different type of flow have been plotted. Those data fall very closely on the 20‰ curve and on its immediate extrapolation. Finally, the point corresponding to one single set of data from the South Pass of the Mississippi River (10, 12) has been plotted. In spite of the wide gap of the parameter $R_e F^2$ between the laboratory data and the Mississippi estuary data, the latter falls on a smooth extrapolation of the 20‰ line of the present study and is, moreover, consistent with the laboratory data of Abraham and Eysink. This is indicative that the correlation parameters have been properly selected and that an extrapolation of the family of curves of Fig. 11 to field conditions seems now quite possible if and when field data from several stratified estuaries become available. Fig. 12 shows a quantitative extrapolation of the curves to field conditions. This extrapolation, however, should be considered only tentative, since only one field data point was used.

a. $\Delta \rho / \rho = 3\%$

b. $\Delta \rho / \rho = 10\%$

SUMMARY AND CONCLUSIONS

The results of an experimental research on the interfacial friction coefficient in a two-layered stratified flow have been presented. The experiments were conducted in a closed rectangular duct with the salt water forming a quasi-stagnant pool over which fresh water was flowing.

A review of some of the most well-known research results prior to this study revealed a wide discrepancy between results obtained by various experimental and semitheoretical laws and sometimes a very wide scattering of experimental points within the same study. This was attributed to the restricted range of validity of certain assumptions and to the lack of introduction of the proper flow and salinity parameters.

The average interfacial friction coefficient, \bar{f}_i , over the measurement section of the duct was evaluated from the measured quantities on the basis of a one-dimensional flow analysis along the general lines of Schijf and Schoenfeld's approach for open channels. After several attempts it was found that \bar{f}_i can be best correlated with the number, $Re F^2 = 4\bar{V}^3 R_{h1} / \nu g R_{h0}$ and with the relative density difference, $\Delta\rho/\rho$. The results are given as a family of curves with $Re F^2$ as an abscissa and $\Delta\rho/\rho$ as an independent parameter. This correlation is further strengthened by the close agreement of reanalyzed laboratory data of earlier studies and of field data from the Mississippi River. On the basis of the latter, the derived family of curves has been tentatively extrapolated to field values of $Re F^2$, i.e. to values of the order of 10^5 .

ACKNOWLEDGEMENTS

The experimental work presented in this paper has been conducted at the Laboratory of Hydraulics and Hydraulic Structures of the University of Thessaloniki in Greece. This paper has been prepared at the Department of Engineering Sciences of the University of Florida as part of continuing research work by the authors on the dynamics of a two-layered stratified flow currently supported by the National Science Foundation under Grant No. ENG 76-11537. This support is gratefully acknowledged.

CHAPTER 171

STABILITY STUDY OF AN ARTIFICIAL SALT INTRUSION IN ESTUARIES

by

Dr. C. Marche, Eng.
Associate Professor, Civil Engineering Department
Ecole Polytechnique

A B S T R A C T

The stratification and salinity structure of the water mass in the lower portions of tidal estuaries are important factors of the general circulation and local water quality. In natural conditions an equilibrium can be observed in each estuary and depends on the geometry of the estuary, the motion of tides inside the estuary and the freshwater discharge.

Extensive studies of the salinity structure in the estuaries of the La Grande and Grande Baleine rivers have shown that water of high salinity content will be expected along the total length of the estuary, for the discharge expected during the fill up period.

Sand-bars being present in several transverse sections in these estuaries, it is of the greatest importance to verify if the saltwater introduced upstream of these bars by a provisionnal modification in the freshwater discharge would not be definitely present.

This paper presents the relevant parameters, the theoretical formulation and the results obtained for the above mentioned estuaries.

INTRODUCTION

The stratification and salinity structure of the water mass in the lower portions of tidal estuaries are important factors of the general circulation and local water quality. In natural conditions, an equilibrium can be observed in each estuary and depends on the geometry of the estuary, the motion of tides inside the estuary and the freshwater discharge. Any change in the range of variation of these factors affects this equilibrium and specially the salt intrusion length for all the stratified estuaries.

This problem is of the greatest interest in the northern region of Quebec where engineers are called upon to modify the natural flow regime of some estuaries; hydroelectric developments are planned upstream, two such cases in point being La Grande and Grande Baleine Rivers.

In these cases, the discharges will be modified in two phases, in the first phase, the discharge will decrease greatly downstream of the dam, in conjunction with the reservoir fill-up. In the second one, a discharge, often increased by the partial drainage of other basins, and therefore higher than the natural one must be considered as a definite change.

The studies of the salinity structure in the estuaries of La Grande and Grande Baleine rivers have shown that saltwater will be observed along the total length of the estuary for the discharge expected during the fill up period. However, the water mass will remain highly stratified in all parts of these estuaries.

Sand-bars being present in several transverse sections in these estuaries, it is of the greatest importance to verify if the saltwater introduced upstream these sand-bars by a provisionnal modification in the freshwater discharge, would not be definitely present.

The study presented here describes a method to calculate the minimal discharge ensuring the saltwater flushing downstream all bars in an estuary. Some results illustrate an application to the La Grande and Grande Baleine estuaries (Figures 1 and 2).

HYDRAULIC FORMULATION

The one dimensional equations of motion for the steady non-uniform flow of a two layered system given by Schijf and Schönfeld (1), have been used. Neglecting the vertical accelerations in the fluids, and considering only the mean velocities in the layers, the equations, in accordance with the notation of Figure 3, are:

- For the upper layer

$$\frac{dh}{dx} + \frac{dh'}{dx} + \frac{U}{g} \frac{dU}{dx} + S_{1e} - \tan \beta = 0 \quad (1)$$

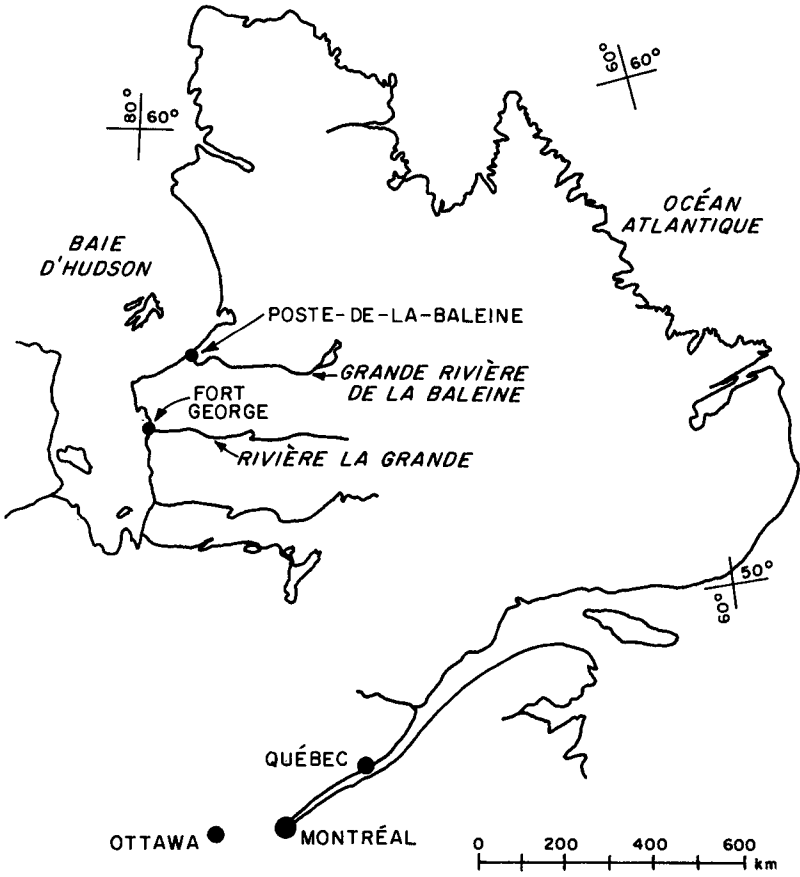

FIG. 1 LOCATION MAP

FIG. 2 THALWEG PROFILES

FIG. 3 DEFINITION SKETCH

and for the lower layer, considered as stationary one:

$$\left(1 - \frac{\Delta\rho}{\rho}\right) \frac{dh}{dx} + \frac{dh'}{dx} + S_{2e} - \tan\beta = 0 \quad (2)$$

The energy gradients S_{1e} and S_{2e} are defined by

$$S_{1e} = \frac{\tau_i}{\rho gh} \quad (3)$$

$$S_{2e} = \frac{\tau_o - \tau_i}{\rho gh'} = - \frac{\tau_i}{\rho gh'} \quad (4)$$

The shear stresses τ_o at the bottom, and τ_i at the interface are respectively

$$\tau_o = 0 \quad (5)$$

$$\tau_i = \rho f_i |U|U/8 \quad (6)$$

and expressions (3) and (4) become

$$S_{1e} = f_i |U|U/8gh \quad (7)$$

$$S_{2e} = -f_i |U|U/8gh' \quad (8)$$

in which f_i is the interfacial friction factor.

The continuity equation for the upper layer is

$$\frac{dh}{dx} = -\frac{h}{U} \frac{dU}{dx} \quad (9)$$

Equations (1) and (2) can be reformulated as

$$R = \frac{U}{g} \frac{dU}{dx} - f_i \frac{U^2}{8gh} \quad (10)$$

$$R = \frac{\Delta\rho}{\rho} \frac{dh}{dx} - f_i \frac{U^2}{8gh'} \quad (11)$$

in which

$$R = \frac{dH}{dx} - \tan\beta \quad (12)$$

can be practically neglected.

Substituting the continuity equation we obtain successively

$$\frac{dU}{dx} = -f_i \frac{U}{8h} \quad (13)$$

$$\frac{dh}{dx} = f_i \frac{U^2}{8g'h'} \quad (14)$$

Equations (9), (13) and (14) are used to find the general solution

$$F(h', x, Q) = 0 \quad (15)$$

and the freshwater discharge insuring the saltwater evacuation is found in a second step by solving

$$F(0, x, Q) = 0 \quad (16)$$

We must note that the function $h'(x, Q)$ obtained in consideration of a stationary lower layer, represents the different equilibrium positions taken by a saltwater intrusion upstream of a sand-bar for various freshwater discharges in the upper layer.

The solution of the simultaneous equations (9), (13) and (14) is obtained in three steps; first, replacing f_i by the average interfacial friction factor \bar{f}_i , the freshwater depth is given by

$$h = \bar{f}_i \frac{x}{8} + h_0 \quad (17)$$

and the saltwater depth by

$$h' = \frac{Q^2}{g'B^2} \frac{1}{\left(\bar{f}_i \frac{x}{8} + h_0\right)^2} \quad (18)$$

The constant h_0 is found at $x = 0$, by using the total water depth over the bar H_0 , and the relation

$$H_0 = h_0 + h'_0 \quad (19)$$

Hence

$$h_0^3 - H_0 h_0^2 + \frac{Q^2}{g'B^2} = 0 \quad (20)$$

In a second step the average interfacial friction factor \bar{f}_i can be computed by writing

$$\frac{dH}{dx} = \frac{dh}{dx} + \frac{dh'}{dx} \quad (21)$$

and finally

$$\frac{(\bar{f}_1 - \beta)}{8} \left(\frac{\bar{f}_1 x}{8} + h_0 \right)^3 = \frac{Q^2 \bar{f}_1}{4g'B^2} \quad (22)$$

In the third step the saltwater depth $h'(x, Q)$ is computed by use of Equation (18), and the relation between the minimum discharge ensuring the saltwater evacuation and the intrusion length is found by solving

$$h'(L_2, Q_2) = 0 \quad (23)$$

in each case.

Assuming the presence of salt upstream of sand-bar no 1 in the Grande Baleine estuary (GBB1), Figure 4 shows the successive interfaces computed for several freshwater discharges.

RESULTS

Based on recent studies of the salinity structure in the above mentioned estuaries (2) and (3), the relations between the salt intrusion length L_1 and the fluvial discharge Q_1 are available in each case (Figures 5 and 6). We have summarized on the same graph the flushing condition (L_2, Q_2) computed by solving equation (23) in each case. Figure 5 applies to the La Grande estuary, summaries the relevant data sets and gives in each case the minimal discharge ensuring the saltwater evacuation.

So, taking into account the 1315 cfs discharge anticipated during the reservoir fill up and the occurrence of spring tides, a salt intrusion length of 107000 ft is anticipated. Salt will be removed by any discharge of 34000 cfs or more. This result being under the normal operation discharge (118000 cfs), saltwater upstream LGB1 will be only a provisionnal modification of the salinity structure of the estuary.

Figure 6 applies to the Grande Baleine estuary. Using the same procedure and a minimal discharge of 1000 cfs, the intrusion length is found to be in the range of about 34000 ft. In this case, a freshwater discharge higher than 38000 cfs is able to remove saltwater downstream GBB2. The freshwater discharge must be higher than 22800 cfs to ensure that saltwater would not be definitely present upstream GBB1.

However, when a large intrusion length is considered as in the case of GBB1 in the prevision example, some of the assumptions (constant width, average interfacial friction factor on each segment) could affect the validity of the solution and it would be preferable to make use of a numerical technique of integration to solve the simultaneous equations (9), (13) and (14).

CHAPTER 172

EFFECT OF HARBOURS ON SALT INTRUSION IN ESTUARIES

A. Roelfzema^{*}) and A.G. van Os^{**}), Delft Hydraulics Laboratory

^{*}) Research Engineer, ^{**}) Head Density Currents and Transport Phenomena Branch

ABSTRACT

A harbour, connected to a tidal river, will affect the salt intrusion in the river. To study the interaction between harbour and river a systematic investigation has been carried out in the tidal salinity flume of the Delft Hydraulics Laboratory (Fig. 1a). The investigation included measurements of the density distribution in harbour and river and measurements of the exchange phenomena in the harbour entrance. The study was executed as part of a long-term basic research program on salt intrusion in tidal rivers, commissioned to the Delft Hydraulics Laboratory by the Rijkswaterstaat (Dutch Government Public Works Department).

1 INTRODUCTION

Generally spoken, the salt distribution in a tidal river is mainly determined by its boundary conditions and by its geometry. This study deals with the effect of a harbour, being one of the geometry parameters of an estuary. A harbour considered in this way has in principle the same effects as a shoreline irregularity. Because of its fundamental character, the investigation has been carried out under strongly schematized circumstances with regard to the geometry of river and harbour. Under these circumstances the following parameters were varied systematically:

- the location X_1 of the harbour along the river, in relation to the salt intrusion length without a harbour, Li_0 (Fig. 1a)
- the surface area A_b of the harbour basin (Fig. 1c)
- the cross-section A_d of the harbour entrance (variation in depth and width) (Fig. 1c)
- the shape (rounded or sharp-edged) and orientation α of the entrance with respect to the river axis (Fig. 1c)
- the presence of an air bubble screen in the entrance, and
- the location of the harbour with respect to the location of its entrance (Fig. 1c).

Studying the interaction between harbour and river, stratification can be an important parameter. Therefore three different degrees of stratification were studied. These degrees were obtained by varying the tidal elevation a_0 of the sea and the fresh water discharge Q_f .

2 SET-UP OF THE MODEL

The perspex tidal salinity flume has a rectangular cross-section, 0.672 m wide and 0.50 m high. Its total length is about 100 m (Fig. 1a). The downstream end of the flume is formed by a schematized seabasin. By means of a control gate any periodic tidal movement of the waterlevel of this basin can be generated. The density of the seawater is kept constant by means of salt water injection. At the upstream end of the flume a constant and a periodically variable discharge of fresh water can be supplied separately. So, the theoretical length of the tidal river, simulated in the flume is not confined to the actual length of the flume. The possibility of varying this theoretical length implies variations in the applied periodic up-

FIG 1a PLAN TIDAL FLUME

FIG 1b

FIG 1c

SET-UP OF THE MODEL, HARBOUR PARAMETERS

stream discharge. A detailed description of the flume is given by Van Rees and Rigter (1969). For this investigation the flume has been extended with a perspex harbour construction (Figs. 1a and 1b).

Figure 1c shows the several variations of the geometry of harbour and harbour entrance. Figure 2 shows the sampling system of flume and harbour (entrance).

3 ANALYSIS OF SALT INTRUSION

Rigter (1973) analysed the salt intrusion in estuaries by means of dimensional analysis. He found:

$$\frac{L_{i \min}}{h_o} \frac{g}{C^2} = f\left(\frac{\hat{q}_{ebb}}{h_o \sqrt{\epsilon g h_o}}, \frac{q_f}{h_o \sqrt{\epsilon g h_o}}\right) \quad (1)$$

where: $L_{i \min}$ - minimum salt intrusion length
 h_o - mean waterdepth
 g - acceleration due to gravity
 C - roughness coefficient according to Chézy
 \hat{q}_{ebb} - maximum ebb discharge at the downstream boundary ($x = 0$) per unit of width
 q_f - fresh water discharge per unit of width
 ϵ - $\frac{\Delta \rho}{\rho}$, relative density difference

This means that different combinations of the parameters \hat{q}_{ebb} , q_f and h_o can give the same salt intrusion length. However, these different combinations will give a different degree of stratification. According to Simmons (1955) the stratification can be characterized by the flood number

$$\alpha = \frac{Q_f T}{P_t} \quad (2)$$

where: Q_f = total fresh water discharge
 T = tidal period
 P_t = flood volume: the volume of seawater entering the river during flood

Because of the mutual dependency of the tidal elevation a_o and the maximum ebb- and flood velocities, expression (2) can be written as

$$\alpha :: \frac{q_f}{\hat{q}_{ebb}} \quad (3)$$

Experimentally the following was found by the Waterways Experiment Station (1955):

$\alpha \leq 0.1$ well-mixed situation
 $0.2 < \alpha < 0.5$ partly mixed situation
 $\alpha \geq 1.0$ stratified situation

So, by varying \hat{q}_{ebb} and q_f it was possible to execute tests with nearly equal minimum salt intrusion length and different degrees of stratification. By doing so, the effect of the stratification on the harbour influences has been studied. Table 1 shows the parameters used in this research.

FIG. 2 SAMPLING SYSTEM

Table 1 Initial river conditions

Expression (1) indicates changes in Li_{min} when \hat{q}_{ebb} is changed. The connection of a harbour to the river will change \hat{q}_{ebb} , the actual value being dependent on the location and surface area of the harbour along the river. This effect can be calculated with a one-dimensional tidal computation. The results are given in Figure 3a as the relative change of the first Fourier component Q_1 ($\sim \hat{q}_{ebb}$) of the amplitude of the tidal discharge at the rivermouth as a function of the location of the standard harbour along the river ($X_1 = 0$ (no harbour), 5, 11, 21, 33, 45 and 60 m). The parameters of the standard harbour are those of the reference test T 406, see table 2. For these reference circumstances figure 3a shows a maximum change in Q_1 of approximately 3%, leading to an increase of salt intrusion length. From field observations Hensen (1953) found the same tendencies. A more theoretical consideration, again only by taking the tidal movements into account, has been given by Schijf and Schönfeld (1953). In their view a harbour affects the salt distribution in the river by the mixing interaction between river and harbour over the tidal period. More recently Okubo (1973) and Hamrick (1975) discussed the role of traps along a tidal river. Their studies, based on one-dimensional analytical expressions, indicate that the interaction between river and trap may play an important role in longitudinal dispersion in estuaries.

From these investigations it can be concluded that a harbour connected to a river will affect the salt intrusion by:

- changing the tidal discharges of the estuary
- generating exchange processes between harbour and river due to tidal storage and density differences

With respect to the effect of the location of the harbour along the river on the salt intrusion, the area of interest has therefore been subdivided into three parts:

- part ①, between sea and minimum salt intrusion length, (Li_{min}).

Due to the combined effect of the increase of tidal discharges and of the exchange phenomena, a harbour connected in this part increases the salt intrusion.

Because of the considerations that the density-induced contribution in the exchange phenomena at a location near the seabasin will be small compared with the contribution at a more upstream location, the tendency of the increase of salt intrusion length will be a positive one.

- part ②, between minimum and maximum salt intrusion length, (Li_{max}).

For the same reasons as mentioned for a harbour connected in part ①, a harbour connected in part ② will increase the salt intrusion. However, changing the harbour location from Li_{min} to Li_{max} , the density induced contribution in the exchange phenomena will diminish due to the

a) RELATIVE CHANGE OF THE AMPLITUDE OF THE TIDAL DISCHARGES NEAR THE SEABASIN

b) RELATIVE INCREASE OF MINIMUM INTRUSION LENGTH

c) RELATIVE INCREASE OF MAXIMUM INTRUSION LENGTH

FIG. 3

decreasing density differences between harbour and river. Therefore the positive tendency of the increase in part ①, will change into a negative one in part ②.

- part ③, upstream of $L_{i\max}$. A harbour connected in this part causes an increase of tidal discharges. The exchange phenomena only consist of the tidal effect and of the flow-induced effect. According to Rigger (1973) the increase of the tidal discharges due to the harbour location tends to zero, and therefore the increase of intrusion length too, will tend to zero.

This qualitative indication of the influence of the location of the harbour on the salt intrusion has been summarized below.

ΔL_i = increase of salt intrusion with respect to L_0
(L_0 = salt intrusion in case of no harbour)

X_i = location of the harbour

4 RESULTS SALT INTRUSION

Test results with respect to variation of the location of the standard harbour along the river are shown in Figure 3b (minimum intrusion length at about LWS) and in Figure 3c (maximum intrusion length at about HWS). They show a considerable increase of the salt intrusion in the river, with respect to the situation without a harbour. The tendencies of the analysis in Chapter 3 can be recognized clearly. The increase of about 60% for the well-mixed situation is striking. Figure 3d shows the tidal mean salt intrusion \bar{L}_i , with the same tendencies as the figure for minimum and maximum intrusion length.

In Figure 4 the longitudinal salt distribution is shown at LWS and HWS in the cases of no harbour ($X_i = 0$) and of a harbour located at $X_i = 11$ m. The effect of exchange currents between harbour and river is obvious. Table 2 gathers the results of the influence of "harbour parameters" on salt intrusion (partly mixed conditions, $X_i = 11$ m).

With respect to the salt intrusion in the river, it can be concluded that the magnitude of its increase depends largely on the location of the harbour along the river (Figs. 3). Compared to this, the influence of the so-called "harbour parameters" at $X_i = 11$ m (Table 2) is of secondary importance:

- reduction of the surface area of the harbour from 6 m^2 up to 3.6 m^2 reduces the maximum salt intrusion length with 0.80 m, while the reduction in the case of no harbour amounts to 2.20 m.
- doubling or reducing by half the width of 0.50 m of the harbour entrance, gives an increase of maximum intrusion length with 0.40 m and a decrease with 1.30 m respectively, these values again to be compared with the reduction of 2.20 m in the case of no harbour.
- variations in shape and orientation of the harbour entrance, show small differences in intrusion length with respect to the influence of the location of the harbour.

These conclusions are supported by the results of $\Delta L_{i\min}$ and $\Delta L_{i\max}$ of test T432, where the total surface area, being 6 m^2 , had been divided

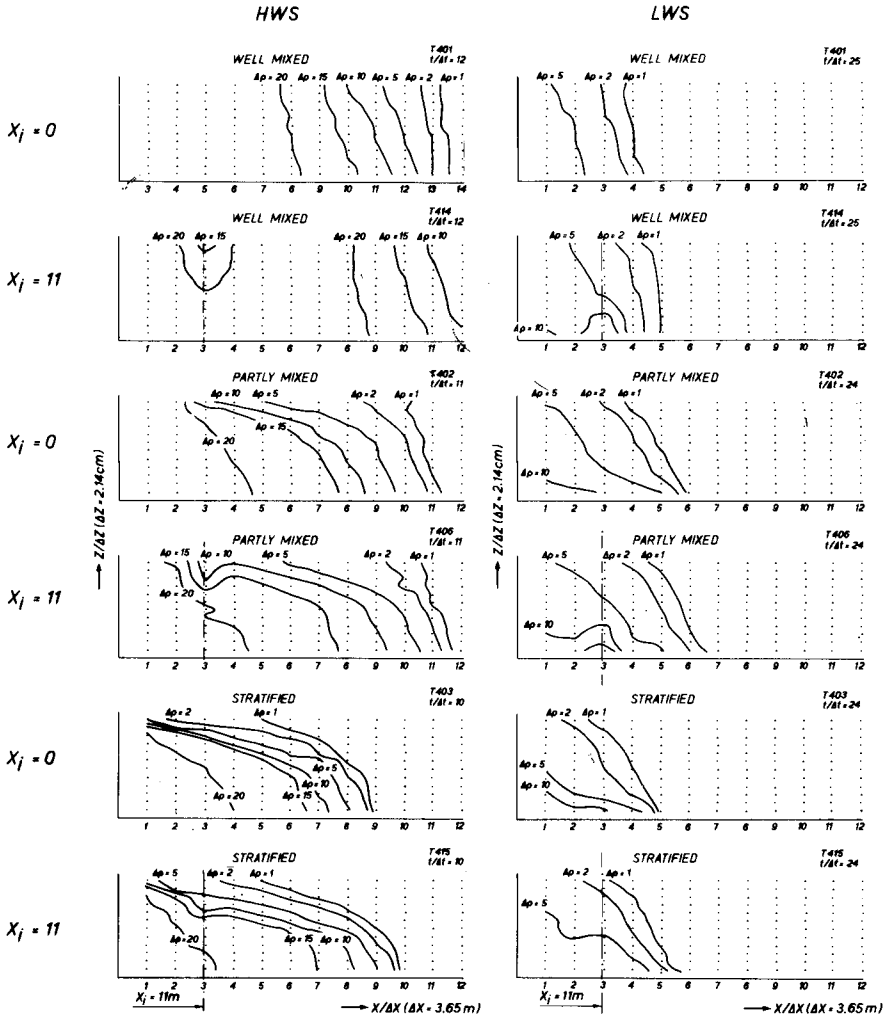

FIG. 4

into 3.6 m² connected to the river at $X_i = 11$ m and into 2.4 m² connected at $X_i = 21$ m (Table 2).

Table 2 Effect of harbour parameters on salt intrusion in the river

5. ANALYSIS EXCHANGE CURRENTS

In tidal circumstances exchange currents between harbour and river are composed of three components: the tidal effect T (the tidal filling and emptying of the harbour), the flow induced current effect C (eddies with vertical axis) and the density difference effect D. The principle of the corresponding flow phenomena of these components is drawn below (Table 3).

Table 3 Principle of the three exchange phenomena

It may be expected that the three components are not completely independent. However to understand the principle of each phenomenon it can be assumed that they are independent, so the velocities of the three components in the harbour entrance are proportional to respectively:

$$v_t :: \frac{dh}{dt} \quad (\text{tidal effect}) \quad (4)$$

$$v_c :: f(u) \quad (\text{current effect}) \quad (5)$$

$$v_d :: (\Delta\rho)^{\frac{1}{2}} \quad (\text{density effect}) \quad (6)$$

where u is the instantaneous velocity in the river at the harbour entrance, and $\Delta\rho$ is the instantaneous density difference between river and harbour water, so $v_d :: |\rho_{\text{river}} - \rho_{\text{harbour}}|^{\frac{1}{2}}$. By measuring horizontal velocities perpendicular to the cross-section in the harbour entrance one obtains a velocity representing the combined effect of the three components, flowing into the harbour or out of the harbour. Integration over the cross-section gives the total exchange discharge Q_e between harbour and river:

$$Q_e = \int \int \int_B^h v_{(x,z)} dh dB \quad (7)$$

So, the instantaneous exchange discharge in the tidal period is given by:

$$Q_e = T + C + D \quad (8)$$

Over a tidal period the total tidal mean exchange discharge is given by:

$$\tilde{Q}_e = \frac{1}{T} \int_0^T |Q_e(t)| dt \quad (9)$$

Literature indicates the important contribution of the density effect D in the total exchange, see for instance Allen and Price (1959), Abraham (1975/1976) and Vollmers (1976).

In homogeneous fresh tidal circumstances the total exchange in the harbour entrance is given by:

$$Q_{e.f} = T + C \quad (10)$$

The tidal effect ($:: \frac{dh}{dt}$) will be equal in homogeneous fresh circumstances and in salt-fresh circumstances. Assuming no interaction between the density effect and the flow-induced effect, expression (8) minus expression (10) results in

$$Q_e - Q_{e.f} = D \quad (11)$$

6 RESULTS EXCHANGE CURRENTS

As an example, test results of Q_e are given in Figure 5a for a harbour location $X_i = 11$ m. This figure gives the results of the mixed-, partly mixed-, stratified- and homogeneous fresh circumstances. Compared to the partly mixed circumstances the only difference with the homogeneous test is that $\rho_{\text{sea}} = \rho_{\text{fresh}} \approx 1000 \text{ kg/m}^3$. Tidal mean exchange discharges Q_e as a function of X_i are shown in Figure 5b.

The results show the strong dependency of the exchange discharges on the harbour location X_i . Besides the important contribution of the density component D is clear; up to 75% (under partly mixed circumstances), depending on the location X_i . The tests showed also that in salt-fresh

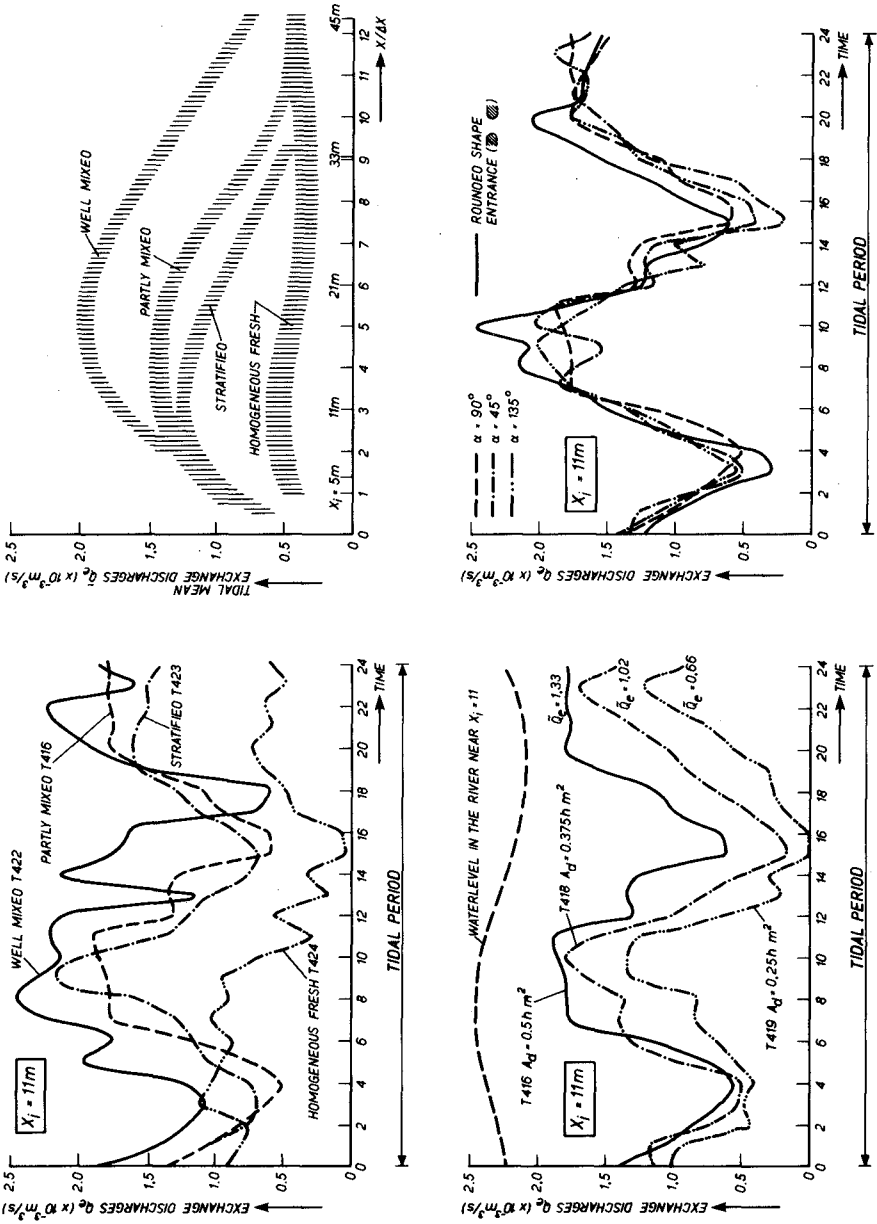

FIG. 5

circumstances maximum exchange discharges occur at HW and LW (density effect dominating). In homogeneous fresh circumstances the maxima appear in another phase of the tidal period, viz. when dh/dt (the tidal effect) and u (the flow-induced effect) have maximum values. Figure 5c shows the direct proportionality of exchange discharges to the width of the harbour entrance. According to Figure 5d orientation and shape (rounded- or sharp-edged) of the harbour entrance do not seem of much importance with respect to exchange discharges in salt-fresh circumstances. These results are similar to those with respect to the influence on the salt intrusion, indicating a direct relation between exchange discharges and increase in salt intrusion.

7 DISCUSSION

In Figure 6 tidal mean values for the exchange discharges $|\tilde{Q}_e|$ are plotted along with the increase of the tidal mean salt intrusion as a function of the harbour location. The results show a similar character. Analysis of tidal propagation and velocities of the various tests showed that dh/dt and the tidal velocity u did not vary much with respect to the harbour location along the area of interest (up to about 50 m from the sea). So, $T (=f(dh/dt))$ and $C (=f(u))$, too must have rather constant values along this area. With this respect, however, the homogeneous fresh test results of Figure 5b show at $X_1 = 11$ m a different behaviour. It is plausible that this behaviour should be attributed to the limitations of the velocity measuring instruments. The low velocities (some centimeters per second), present in the harbour entrance give rise to a relatively high rate of inaccuracy.

According to the above mentioned analysis the considerable variation of Q_e must be attributed mainly to the density component D . The driving force for D is the density difference $\Delta\rho$ between harbour density (hardly fluctuating) and river density (strongly fluctuating), (Figs. 7a, 7b and 7c). So, even in more mixed situations, exchange currents will occur, due to the periodically varying density of the river. Between harbour and river the transport of salt S can then be given by the proportionality:

$$S :: (T + C + D)\Delta\rho \quad (12)$$

A harbour behaves as a source and sink of salt to the estuary. Therefore increase of salt intrusion ΔLi is a function of S , so

$$\Delta Li = f(S) \quad (13)$$

The precise expression (13) will be subject of further research.

8 CONCLUSIONS

From the results of this research the following conclusions can be drawn:

- A harbour connected to a tidal river will increase the salt intrusion in that river as compared to the situation without a harbour (Fig. 3).
- The location of the harbour along the river with respect to the minimum and maximum salt intrusion length without harbour is an important parameter for the influence on the salt intrusion. Maximum influence is found with a harbour located in the vicinity of minimum salt intrusion length in the area between minimum and maximum intrusion length (Fig. 3).
- Increasing the cross-section of the harbour entrance or the surface area of the harbour also has an increasing effect on the salt intru-

FIG. 6 TIDAL MEAN EXCHANGE DISCHARGES AND TIDAL MEAN INTRUSION LENGTHS AS A FUNCTION OF THE HARBOUR LOCATION X_j

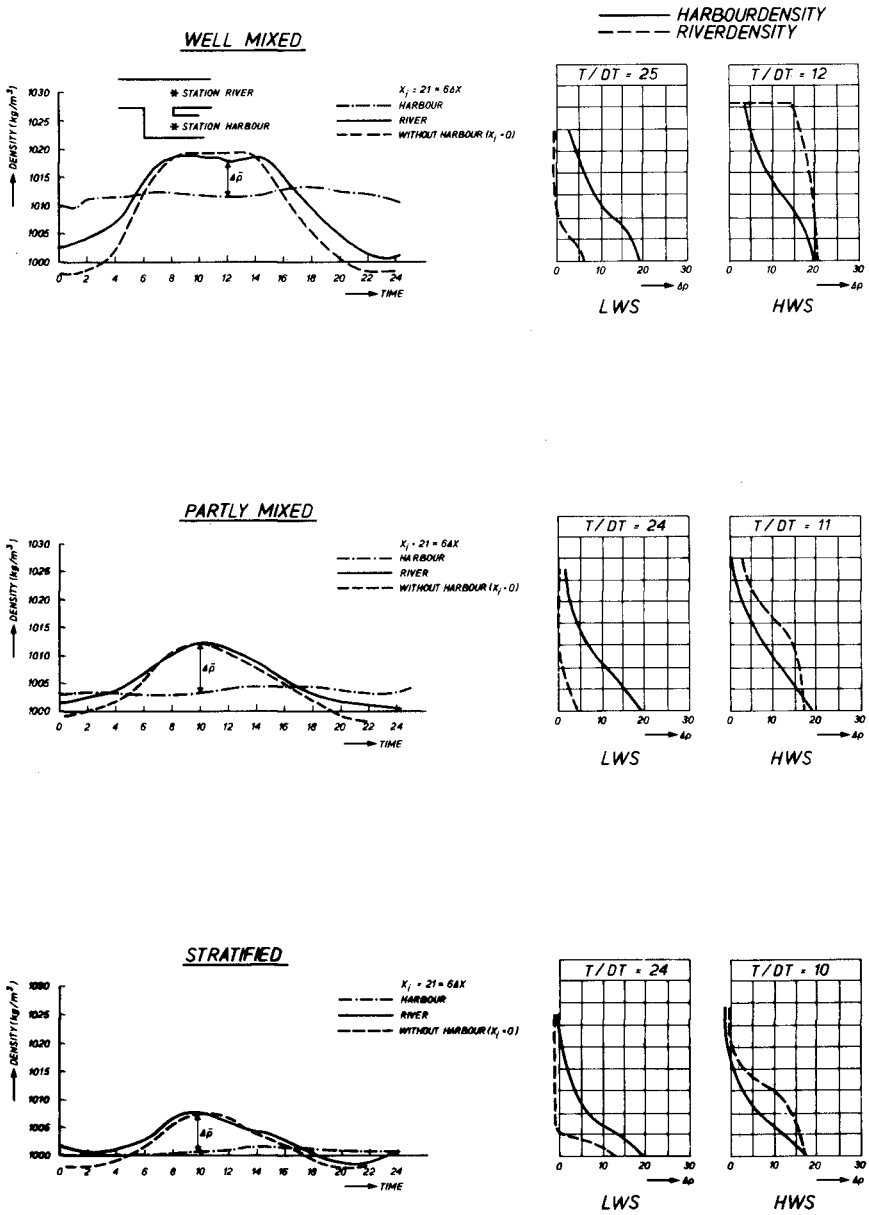

FIG. 7

sion. However, these "geometrical" effects are of minor importance when compared to the effect of the location of the harbour along the river (Table 2).

- The shape and orientation of the entrance with respect to the river hardly have significant effects on the salt intrusion length (Table 2).
- The exchange flows between harbour and river can be subdivided into three components: a tidal effect, a flow-induced effect and an effect due to the density differences between harbour and river (Fig. 7). The density effect is dominating in the situation where the harbour is located within the range where salt intrusion is present ($X_i < L_{i\max}$), (Figs. 5a, 5b and 6b).
- The similarity in the relationship between increase in salt intrusion and harbour location and between exchange flows and harbour location respectively proves that a direct relationship between increase in salt intrusion and exchange flows exists (Fig. 6).
- The results of this study can give a rough estimate of the influence of a planned harbour (re)construction along a tidal river. The detailed physical information resulting from this investigation also can be used for the development of mathematical models, describing salt intrusion affected by harbours or other shoreline irregularities.

CHAPTER 173

TIDAL HYDRAULICS AND SALT BALANCE OF LAKE WORTH, FLORIDA

J. van de Kreeke* and J. D. Wang*

Formulation of the Problem

In the central and southern part of Florida, groundwater levels are maintained via an intricate system of canals. During the rainy season large quantities of freshwater are discharged through the canals into the estuaries surrounding the Florida coast, resulting in a considerable lowering of the salinities. This in turn has an effect on the biota and in particular tends to reduce the species diversity.

A typical example is the Lake Worth lagoon, where salinities in the interior part can be as low as 10 ppt during the wet season and as high as 35 ppt at the end of the dry season. Based on the results of a biological study, it was concluded that maintaining salinities of 30 ppt or higher in the interior of the lagoon would permit the further expansion of the rich species assemblage presently existing in the more saline water near North Lake Worth Inlet, van de Kreeke, et al. [1977]. From the onset it was clear that this would require that large quantities of freshwater be diverted elsewhere. As part of the overall problem to arrive at a rational decision with respect to the amount of freshwater diversion the following specific problems are addressed in this paper:

- identification and quantification of freshwater sources.
- determination of freshwater/saltwater transport mechanisms and the resulting salinity distribution.
- the effect of reducing the freshwater inflow on the flushing time.

For this purpose a series of field measurements was carried out and mathematical models describing the hydrodynamics and salinity distribution were developed.

General Features

The Lake Worth lagoon, Fig. 1, is approximately 100,000 ft long and 1,500 ft wide. Depths vary from 7 ft in the interior to 30 ft near the Port of Palm Beach. The lagoon is connected to the ocean by two inlets, North Lake Worth Inlet with a cross-sectional area of 25,000 ft² and South Lake Worth Inlet with a cross-sectional area of approximately

* Division of Ocean Engineering, Rosenstiel School of Marine and Atmospheric Science, University of Miami

2,500 ft². The lagoon consists of a conveying channel intermittently bordered by shallow storage regions. The highly irregular bottom topography of Lake Worth, a result of dredge and fill operations, is indicated in Fig. 2.

FIGURE 1—LAKE WORTH LAGOON; PLAN VIEW

Tides in the ocean off Lake Worth are semi-diurnal with an average amplitude of 1.4 ft. Starting at North Lake Worth Inlet and going north, tidal amplitudes and phase lags slightly increase, Fig. 3. South of the inlet tidal amplitudes increase, reaching a maximum at about $x = 16,000$ ft. A sharp decrease in tidal amplitude is found between $x = 16,000$ ft and $x = 23,000$ ft. For values of $x > 23,000$ ft the tidal amplitude gradually decreases to a value of 86% of the ocean tide at the southern extreme of the lagoon. Phase lags south of North Lake Worth show a somewhat similar pattern. Over the first 20,000 ft phase lags slightly decrease then show a sharp increase between $x = 20,000$ ft and $x = 23,000$ ft. For values of $x > 23,000$ ft, phase lags gradually increase to a maximum of 2 hours at the southern end of the lagoon. The sharp changes in tidal amplitude and phase at $x \approx 20,000$ ft can be contributed to a strong decrease in cross-sectional area and average depth in this region.

Cross-sectionally averaged tidal velocities are about 1 ft/sec in the northern part of the lagoon and 0.5 ft/sec in the southern part. Typical velocities in North Lake Worth Inlet and South Lake Worth Inlet are respectively 3 ft/sec and 6 ft/sec.

Readily identifiable sources of freshwater are the West Palm Beach Canal and the Boynton Canal of the South Florida Water Management District, see Fig. 1. A typical hydrograph for the West Palm Beach Canal is shown in Fig. 4. The hydrograph shows a seasonal pattern similar to the rainfall i.e. the bulk of the freshwater is discharged during the rainy season, May through September. Discharges of the Boynton Canal show a similar trend but are in general much smaller than those of the West Palm Beach Canal. Also because of its proximity to South Lake Worth Inlet the effect of the Boynton Canal discharges on the lagoon are less profound.

Field Measurements

To obtain insight in the salinity variations, and salt transport mechanisms and to aid in the development, calibration and verification of the mathematical models a series of field measurements were carried out consisting of:

- a time series of weekly salinity measurements at $x = 33,500$ ft covering a period of one year.
- a number of quasi-synoptic salinity profiles along the longitudinal axis of the lagoon during periods of High and Low Water
- simultaneous salinity - velocity measurements at $x = 15,000$ ft, $x = 40,000$ ft and $x = 68,000$ ft covering a full tidal cycle.

The results of the weekly salinity measurements are presented in Fig. 4. The gross features of the salinity variations correspond closely to the variations in freshwater inflow as characterized by the discharge of the West Palm Beach Canal. Lowest and highest salinities are respectively 15 ppt and 35 ppt. Attention is drawn to the relatively low steady state salinity of 34 ppt during the month of April when there was hardly any inflow from the West Palm Beach Canal and the Boynton Canal and offshore salinities were about 36 ppt. It is postulated that this is the result of groundwater seepage as will be discussed in the section Sources of freshwater inflow, flushing time. Fig. 4 also shows that the biologically preferred conditions of 30 ppt or higher in the interior region limit the discharge of the West Palm Beach Canal to between 100 - 200 cfs; at present highest discharges are on the order of 2000 cfs.

An example of the longitudinal salinity distribution is presented in Fig. 5. Minimum salinities are found near the discharge point of the West Palm Beach Canal and gradually increase going towards both inlets. North of the West Palm Beach Canal, tidal time variations in salinity are closely related to the tidal excursion. This is much less the case south of the West Palm Beach Canal, where the tides

FIG. 2 BATHYMETRY OF LAKE WORTH

FIG. 3 TIDAL AMPLITUDES AND PHASE LAGS

entering North Lake Worth Inlet and South Lake Worth Inlet meet resulting in low tidal velocities.

Depending on the freshwater inflow, vertical stratification can be very strong especially in the southern part of the lagoon, Fig. 6. The stratification parameter used in this figure is the ratio of the mean vertical salinity over the surface salinity. Except close to the West Palm Beach Canal and the Boynton Canal lateral variations in salinities were less than 1 ppt.

Examples of measured water levels and discharges at $x = 40,000$ ft are presented in Fig. 7. In the same figure, as an indicator of the prevailing wind stress, the square of the wind velocity component parallel to the longitudinal axis of the lagoon is presented. The results are based on hourly values of wind speed and direction measured at the Palm Beach International Airport.

Data on tides and velocities indicated that on the average, high and low tides precede the times of slack water. A typical value is 30 min, however this can vary strongly depending on freshwater inflow, wind, type of tide and location. Times of maximum and minimum values of salinity correspond approximately to high and low tide.

Sources of Freshwater Inflow, Flushing Time

As mentioned earlier besides the West Palm Beach Canal and the Boynton Canal, groundwater seepage is expected to be an important source of freshwater. A conservative estimate of the magnitude of the groundwater seepage was made using the known steady-state salinity distributions for the first two weeks of September 1974 and September 1975. Except for the discharge of the West Palm Beach Canal, contributions of other sources were the same for both periods.

	<u>Sept. 1974</u>	<u>Sept. 1975</u>
Boynton Canal	0 cfs	0 cfs
Evaporation	63	63
Rainfall	0	0
West Palm Beach Canal	500	180
Groundwater seepage	Same for both periods based on observed groundwater levels	

Assuming the overall flushing time T_f to be the same for both periods, yields for the groundwater seepage a value of 300 cfs. The corresponding flushing time is 5 days. Note that for steady state conditions $T_f = V_r/Q_f$ in which V_r = freshwater content of the lagoon and Q_f = the sum of all freshwater sources and sinks. Values of V_r obtained from the measured salinity distribution in the lagoon were $V_r = 3.01 \times 10^8$ cuf for September 1974 and $V_r = 1.67 \times 10^8$ cuf for September 1975.

FIG. 4 TIDALLY AVERAGED SALINITY AT X = 33,500 FT. AND DISCHARGE OF W. PALM BEACH CANAL

Difference in Waterlevels is Between Data at 23,000Ft. and 56,000Ft.

FIG. 7 WATER LEVELS AND DISCHARGES FOR JULY 9, 1975

Because of the increased density currents one could argue that instead of being the same, the flushing time decreases with increasing freshwater inflow (i.e. flushing time is shorter for September 1974). With this assumption the values for the groundwater seepage would be even larger and therefore the 300 cfs can be considered to be a conservative estimate.

Comparing with the contributions of the Boynton Canal and West Palm Beach Canal it follows that groundwater seepage is a source which needs to be accounted for when computing the salinity distribution in the Lake Worth lagoon.

Salt Transport Mechanisms

Tidally Averaged Transport

Transport mechanisms can be divided in advective and dispersive mechanisms. For Lake Worth the advection of salt is associated with the tidally averaged discharge. The tidally averaged discharge in addition to the freshwater inflow is determined by a tide-induced residual circulation between the two inlets. Unfortunately the discharge measurements carried out in the lagoon were not accurate enough to determine the value of the tide-induced residual circulation. An estimate of 200 cfs to the south was arrived at using an analytical model, van de Kreeke [1976]. A numerical model for the hydromechanics of the lagoon to be discussed in the next section yielded values of 150 cfs and 50 cfs to the south respectively without and with the presence of the baroclinic term in the dynamic equation. The dispersive mode of transport is associated with gravitational circulation, shear flow and trapping. Trapping is attributed to particles residing part of the tidal period in the storage regions (tidal flats) before returning to the conveying channel.

Based on field data an estimate of the advective salt transport and the salt transport by trapping at $x = 30,000$ ft is made for September 18, 1974. The data base was not sufficient to estimate the dispersive transport resulting from gravitational circulation and shear flow. At $x = 30,000$ ft the average cross-sectional area $A_0 = 15,000$ ft² and the tidal variation in cross-sectional area $A_2 = 2,000 \sin(\sigma t + 15^\circ)$. The tidally averaged salinity $\langle s \rangle = 27$ ppt, see Fig. 5 and the corresponding salt concentration $\langle c \rangle = 1.68$ lb/cuf. The tidal variation in salt $c_2 = 0.15 \sin(\sigma t + 15^\circ)$ lb/cuf, the tidal velocity $u_2 = -1 \cos \sigma t$ ft/sec. The phase angle of 15° corresponds with the earlier observed 30 min lag between slack water and high and low tide. Computer simulation for the flow on September 18 yielded a value of the tidally averaged discharge $\langle Q \rangle = 250$ cfs to the north. The corresponding advective salt transport $\langle Q \rangle \langle c \rangle = 420$ lbs/sec to

the north. An estimate of the trapping effect $A_0 \langle u_2 c_2 \rangle = 283$ lbs/sec to the south*. This shows trapping to be an important salt transport mechanism, but at the same time does not exclude the gravitational and shear flow as major contributors to the salt transport. In fact, as suggested by the relatively large vertical and lateral variations in salinity, gravitational circulation is probably the major dispersion mechanism close to the discharge point of the West Palm Beach Canal.

Tidal Time Variations

Tidal time variations in salinity are mainly a result of tidal advection as demonstrated by the oscillation of the salinity distribution over approximately the length of the tidal excursion see also Fig. 5.

Transport by Wind

In addition to the advective salt transport resulting from the tide-induced net circulation and the freshwater inflow, the effect of wind-induced currents should be mentioned. During the summer when freshwater inflow is largest, winds are predominantly from the south-east, resulting in a south - north current. The magnitude of the wind-induced currents cannot easily be computed in the 1-D model to be discussed in the next section. Attempts to determine the wind-induced circulation from long term current measurements failed because of fouling of the current meter by floating debris.

Salinity Model

To model the salinity distribution a real-time finite difference model was selected. The model is based on the one-dimensional advection-dispersion equation. In view of the multitude of transport mechanisms, it is realized that such a simplified model cannot correctly represent the physical processes. The best one can hope for is that after extensive calibration for a large set of freshwater discharges, the model will be of some use in comparing the effect on the salinity distributions of different freshwater diversion schemes.

The discharges in the advection-dispersion equation are derived from a model simulating the hydromechanics of the lagoon. This model uses the one-dimensional long wave equations including the convective

*It is usually assumed that trapping is the major contributor to the value of the covariance of u_2 and c_2 . To the authors knowledge this has never been proven.

term for the interior part of the lagoon. The flow in the inlet is described by an equation of the form

$$\Delta\eta = F_i \frac{L}{h} \frac{u^2}{g}$$

in which $\Delta\eta$ = head differences across the inlet, L = length of inlet, F_i = inlet coefficient, h = average depth, u = cross-sectionally averaged velocity, g = gravity acceleration. The equations constituting the hydromechanics model are solved by means of an explicit finite difference technique. Separate algorithms, based on the inlet equations are used to treat the connections between the lagoon and the ocean, van de Kreeke [1972]. The schematization of the lagoon as used in the computations is presented in Fig. 8.

To calibrate the hydromechanics model, inlet coefficients and friction factors F (= 1/8 of the Darcy Weisbach friction factor) for the interior of the lagoon had to be determined. The tide at Port of Palm Beach appeared to depend mainly on the characteristics of North Lake Worth Inlet and the surface area of the lagoon and to be rather insensitive to the inlet coefficient of South Lake Worth Inlet and the friction values in the interior of the lagoon. A relatively narrow range of values for the inlet coefficient $F_i = .02 - .03$ for North Lake Worth Inlet could therefore be determined by matching measured and computed tides at Port of Palm Beach. These relatively high values are a result of the actual flood and ebb currents not using the full cross-sectional area of the inlet. Based on simultaneous water level and discharge measurements a value of the inlet coefficient $F_i = 0.005$ was found for South Lake Worth Inlet. Friction factors in the lagoon were determined by matching computed and measured water levels in the stations $x = 15,000$ ft, $x = 40,000$ ft and $x = 68,000$ ft. Lastly the friction factor for North Lake Worth Inlet was adjusted to an ultimate value of $F_i = .02$ in order to yield an overall best fit of discharges in the lagoon. The final configuration of the friction factors is presented in Fig. 8. A value often cited in the literature is $F = 2 \times 10^{-3}$, which is considerably lower than the values for the Lake Worth lagoon. This should be attributed to energy losses associated with constrictions and variations in the bottom topography which are of the same order as the average depth, see Fig. 2. A similar trend for the values of the friction factors was found in Chincoteage Bay, Harleman and Lee [1969], with values of F ranging from 0.02 to 0.06. To illustrate the importance of the friction, tidal amplitudes and phases in the lagoon computed for different values of the friction factor are presented in Fig. 3.

An example of computed tides and discharges at $x = 40,000$ ft is presented in Fig. 7 using the values of the friction factors in Fig. 8. The agreement is reasonable with the ebb discharge (S to N) being slightly underestimated. This could be caused by wind which increased

during the ebb period. Although wind forcing was included in the model, an accurate representation of wind driven currents could not be achieved because of the one-dimensional treatment of the lagoon.

The numerical grid used for solving the advection-dispersion equation was the same as that for the hydrodynamic equations. To solve the equation an implicit finite difference scheme was used, van de Kreeke, et al. [1977]. Examples of computed salinity distributions for three values of the dispersion coefficient are presented in Fig. 5. The inflow of the West Palm Beach Canal and the Boynton Canal are respectively 500 cfs and 0 cfs. The distributed inflow (groundwater seepage, evaporation) is 218 cfs. A value of about $1100 \text{ ft}^2/\text{sec}$ seems to best describe the salinity distribution.

Conclusions

- In addition to the discharge of the flood control canals, groundwater seepage is an important source of freshwater for the Lake Worth lagoon.

- The overall flushing time for the Lake Worth lagoon is on the order of one week.

- For steady-state conditions the advective salt transport resulting from the tidally averaged discharge is in the near field balanced by a dispersive mode of transport associated with density currents and is in the far field balanced primarily by trapping. The tidally averaged discharge results from the freshwater inflow and a tide-induced residual circulation between the two inlets. Because of the lack of long term current measurements the effect of wind on the advective transport could not be discerned.

- Calibration of an earlier developed model simulating the hydro-mechanics of the lagoon yielded values of friction factors considerably higher than those cited in the literature. The reason for this is the irregular bathymetry, in particular the constrictions, leading to a three-dimensional flow pattern and increased dissipation. The associated stresses are not properly accounted for in the one-dimensional model which in turn is reflected in the friction coefficient.

- To describe the tidal time variations in the salinity distribution a numerical solution was developed for the advection - dispersion equation. A constant value of the longitudinal dispersion coefficient was assumed. Matching measured and computed salinity distributions for the early part of September 1974 yielded a value of the dispersion coefficient $E = 1100 \text{ ft}^2/\text{sec}$. It is emphasized that this value does not necessarily apply to periods with significantly

different freshwater inflow. Limited knowledge of the dependence of the dispersion coefficient on the freshwater inflow restricts the usefulness of the advection-dispersion model without further calibration.

NUMERICAL TIDAL-SALINITY MODELS OF THE EMS ESTUARY

Karsten Fischer

Lehrstuhl für Strömungsmechanik

Technische Universität Hannover

West Germany

1. Introduction

As a consequence of the increased usage of estuarine resources and capacities, the need of estuary models for research and prediction purposes has led to strong developments in this field and high levels of modelling art today. Depending on the specific problems to be investigated by the engineers, the complexity of the models and the cost of running them can vary drastically, and it is not always a priori clear which effects must be treated carefully, and which simplifications can be made, in order to get a model working accurately as well as economically.

Tidal and salinity models are used to obtain information on the salinity intrusion and the sediment transport in estuaries. They can be used as a starting point for more ecological models [1].

Two major problems are observed when constructing salinity intrusion models: First, the numerical errors of the simpler solution algorithms for the advection equation are too large to be negligible; and second, the use of vertically averaged models is questionable because the driving forces for the salinity intrusion process are varying strongly with the water depth.

However, solving the equations of motion and advection-diffusion by very elaborate algorithms on three-dimensional grids with reasonably fine grid spacings can hardly be done by the fastest computers that are commonly available today. As a consequence, two essential questions arise for numerical tidal and salinity models:

- a) what measure of numerical effort must be applied to obtain what measure of accuracy in the results, and
- b) what simplifications (by neglecting and averaging etc.) can be made within a given range of accuracy to restrict the model to the essential physical interactions?

The first question is very difficult to answer and has never

been investigated, in the author's opinion, in a more general way.

Assuming that the second question can be treated independently of the first, it is studied in this paper by application of various models of the Ems estuary, situated on the North Sea coast between the Netherlands and Germany.

2. Description of Numerical Models

High complexity of the geometry and the physical conditions usually encountered in estuaries was the reason for the development of a family of computer programs for calculating tidal and salinity motions. Information on the members of this program family is given below. The individual programs are based on an explicit finite difference simulation of the relevant partial differential equations, using a staggered grid formulation with mass-conservative and transportive (upstream) finite-difference expressions. The models are similar to those developed by Hansen [2], Leendertse [3], Sündermann [4], and Simons [5]. They can be run as self-standing modules or as subroutines, and they are easily applied for purposes of coupling and nesting of sub-models. The present paper gives an example for the coupling of two submodels. Applications are facilitated by a full dynamic storage assignment. As it is a program family for research purposes, all routines are highly modularized in order to allow for quick exchange and replacement of sub-units. No effort was undertaken to develop a comfortable user-oriented input-output structure (e.g. a problem-oriented language), because it was felt that such a structure is only useful if the model structure is not expected to change in the future; however, such a state of modelling art has, after the author's opinion, not yet been achieved for tidal-salinity estuary models.

2.1 One-dimensional Model

Equation of motion:

$$u_t + uu_x + \frac{r}{h}|u|u - \frac{\lambda}{h}|w|w - Au_{xx} + \frac{1}{\rho}p_x = 0 \quad (1)$$

Here, and in the following, differentiation is indicated by subscripts. t is the time coordinate, u the velocity along x , h the water depth, ρ the density, \bar{p} the average hydrostatic pressure, W the wind speed, r the bottom friction coefficient, λ the wind stress coefficient, and A the horizontal turbulent stress coefficient.

Equation of hydrostatic pressure:

$$p(z) = g \int_z^h \rho(z) dz \quad (2)$$

where z is the vertical coordinate, g the gravitational acceleration.

Equation of continuity:

$$b \zeta_t + (Fu)_x = 0 \quad (3)$$

where ζ is the tidal fluctuation part of h , b the surface width, and F the cross-sectional area.

Transport equation:

$$F \rho_t + (uF\rho)_x = (BF\rho_x)_x \quad (4)$$

where B is the dispersion coefficient.

2.2 Two-dimensional Horizontal Model

Equations of motion:

$$\begin{aligned} u_t + uu_x + vu_y - fv - A(u_{xx} + u_{yy}) + \frac{1}{\rho} \bar{p}_x \\ + \frac{r}{h} |u|u - \frac{\lambda}{h} |x_W| x_W = 0 \end{aligned} \quad (5)$$

$$\begin{aligned} v_t + uv_x + vv_y + fu - A(v_{xx} + v_{yy}) + \frac{1}{\rho} \bar{p}_y \\ + \frac{r}{h} |v|v - \frac{\lambda}{h} |y_W| y_W = 0 \end{aligned} \quad (6)$$

where u and v are the velocity components along the horizontal space coordinates x and y , respectively, x_W and y_W the wind speed components, f the Coriolis acceleration.

Equation of continuity:

$$\zeta_t + (uh)_x + (vh)_y = 0 \quad (7)$$

Transport equation:

$$h\rho_t + (u\rho h)_x + (v\rho h)_y = (Bh\rho_x)_x + (Bh\rho_y)_y \quad (8)$$

2.3 Two - Dimensional Vertical Model

Equation of motion:

$$u_t + uu_x - Au_{xx} - z_A u_{zz} + \frac{1}{\rho} P_x = 0 \quad (9)$$

where z_A is the vertical eddy viscosity coefficient.

Equation of continuity:

$$({}^X_F u)_x + ({}^Z_F w)_z = 0 \quad (10)$$

where w is the vertical velocity, X_F and Z_F the cross-sectional areas of the control volume, taken perpendicular to the x - and z -axes, respectively.

Transport equation:

$$b\rho_t + (ub\rho)_x + b(w\rho)_z = (bB\rho_x)_x + b({}^Z_B \rho_z)_z \quad (11)$$

where Z_B is the vertical eddy diffusivity coefficient.2.4 Three - dimensional Model

Equations of motion:

$$u_t + uu_x + vu_y - fv - A(u_{xx} + u_{yy}) - z_A u_{zz} + \frac{1}{\rho} p_x = 0 \quad (12)$$

$$v_t + uv_x + vv_y + fu - A(v_{xx} + v_{yy}) - z_A v_{zz} + \frac{1}{\rho} p_y = 0 \quad (13)$$

Continuity equation:

$$({}^X_F u)_x + ({}^Y_F v)_y + ({}^Z_F w)_z = 0 \quad (14)$$

Transport equation:

$$\rho_t + (u\rho)_x + (v\rho)_y + (w\rho)_z = (B\rho_x)_x + (B\rho_y)_y + ({}^Z_B \rho_z)_z \quad (15)$$

2.5 Boundary Conditions

In the vertically discretized models 2.3 and 2.4 the transport equations for the top and bottom layers are somewhat more complicated than eqs. (11) or (15) due to the variable layer thicknesses, but these formulae were omitted for

shortness. Wind and bottom stress are imposed as boundary conditions for the top and bottom layers, and the corresponding turbulence coefficients take account of the decay of eddy viscosity near these boundaries. The vertical eddy viscosity and diffusivity terms are treated by implicit finite differences in order to remove some general stability constraints. Surface, bottom, and lateral closed boundaries are simulated by non-slip velocities and vanishing normal density gradients. At open lateral boundaries, water levels, or normal velocities, densities, and normal gradients of the velocity are required; in most cases the normal gradients can be set zero.

3. Model Applications

Various models were applied to the Ems estuary, situated on the North Sea coast between the Netherlands and Germany. Fig. 1 shows the model area and the boundaries.

Fig. 1: The Ems estuary

Parts of the open sea boundaries were replaced by closed boundaries, as indicated in Fig. 1, but this artificial closed boundary was situated in regions of very shallow water and low flow velocities. The estuary was represented by a horizontal two-dimensional grid of 1.5 km spacing, supplemented by a horizontal one-dimensional appendix of 1.0 km spacing; the time step was 90 sec, due to a maximum water depth of about 16 m.

Because of the limited amount of available measured data, several assumptions had to be made. For the tidal motion, a near-normal measured tidal cycle of 12 h 25 m was used as periodic excitation of the boundary water level. A set of mean constant discharge values was taken to supply fresh water at three different locations. A set of salinity records, taken under appropriate discharge conditions, and

averaged over several measurement events, was applied to give the boundary condition at K 1 and used for comparison with calculated data at BW 1 and T 27 (see fig. 1).

3.1 Hydrodynamical Vertically Averaged Model

The first step in the model development was the construction of a vertically averaged model for the tidal hydrodynamics. This model was used to get information about the bottom friction and to verify the topographic data. Later on it was supplemented by the salinity transport module and run for comparisons with the vertically discretized model.

3.2 Baroclinic Vertically Discretized Model

This model and six layers of 2 - 3 m thickness in the horizontal two- and one-dimensional parts. The coupling of the model parts was done under conservation of water and salinity mass. The following parameters were found to give a satisfactory agreement between measured and calculated data:

bottom friction	$r = 0.006$
eddy viscosities	$Z_A = 0.0019 \text{ m}^2/\text{s}$
	$A = 0$
eddy diffusivities	$Z_B = 0.00023 \text{ m}^2/\text{s}$
	$B = 0$

Some of the model results are illustrated in fig. 2.

Here the values for velocity and salinity are vertically averaged data from the results of the three-dimensional model. Large areas of tidal flats can be observed in fig. 2 b; the drying- and wetting-mechanism was incorporated in the upper model layer. The relative stagnation of the salinity in shallow regions is evident in fig. 2 a; this is one of the most important mechanisms for dispersion. The irregularity of the velocities near the open boundary is of computational nature and does not affect the interior of the solution, because it is only effective on the tangential velocities at the boundary.

It can be seen in the figure that the representation of the Dollart area near the river inflow is represented only very schematically in the model, and this is indeed the region where the biggest deviations from the measured data occur.

Though the amount of information contained in a three-dimensional model is very large, only one further detail shall be illustrated because of space restrictions. Fig. 3 shows the time variation of the vertical profiles of

- a) the west-east component of the velocity, and
- b) the salinity at point BW 1.

3 a

3 b

Fig. 3: a) Vertical velocity profiles at point BW 1
 b) Vertical salinity profiles at point BW 1
 Numbers at the curves indicate the sequence in time

The typical deviations of the vertical velocity profiles due to the baroclinic forces cannot be observed in Fig. 3 a, because these deviations are two orders of magnitude smaller than the tidal velocities shown in the figure. However, these deviations are most essential for the salinity intrusion process. The anomalies in the curves during flood tide are caused by the Coriolis force and geometrical effects.

The associated salinity profiles in Fig. 3 b show a certain degree of stratification during the ebb tide which is vanishing during flood tide. This effect is caused by the quicker motion of the upperlayers; during flood tide an unstable stratification can be reached which is followed by a rapid vertical mixing.

A test calculation without baroclinic forces showed no significant short-time changes in the vertical profiles of Fig. 3.

4. Model Calibration and Verification

Test runs with the vertically averaged model showed that a satisfactory representation of the tidal motions could be achieved with a constant bottom friction parameter everywhere, except in the region of the Dollart basin. Due to the fact that only a limited set of measurement data was present for comparison purposes, and that this work was a first study to investigate the model properties, it was decided to restrict the calibration to only global parameters that were constant in space and time. This restriction is of no practical interest because the work necessary for calibration is minimal and a three-dimensional model is usually difficult to be calibrated because of computer requirements.

As a first step, the tidal dynamics were calibrated by adjusting bottom friction and vertical eddy viscosity. The salinity transport module was not used in this phase. As a second step, the salinity transport was calibrated by adjusting the vertical eddy viscosity; then, the bottom friction had to be corrected in order to match the water level data. The second step had to be iterated in order to find an optimum solution for both parameters. For each salinity transport calibration, six tidal cycles were calculated, starting from the previously calculated model state. Finally, the stratification was fitted by tuning the vertical eddy diffusivity; this process could be done separately from the other calibration steps. Test calculations showed that the parameters of horizontal exchange A and B could be set zero.

Fig. 4 shows the results for the water level calculations at three points in the estuary. The deviations of the calculated values from the measured data are mainly caused by the over-schematization of the Dollart basin, and show up in the curves for Oterdum (near the river inflow) and Pogum (upstream in the river). The schematization of the

open-sea boundary by a closed boundary in the shallow parts does not lead to severe errors in the simulation.

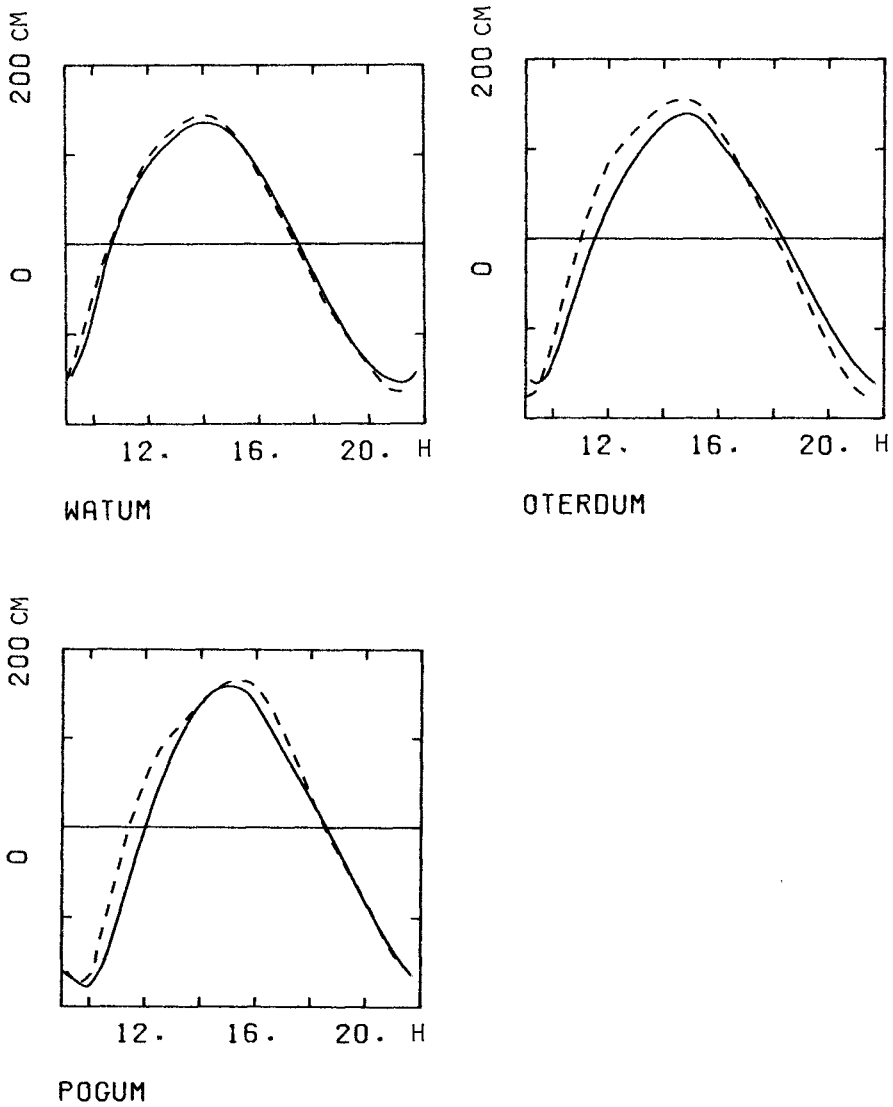

Fig. 4: Calculated (———) and measured (- - - - -) water levels vs. time

Fig. 5: Calculated (smooth lines) and "measured" (polygon-shaped lines) salinity vs. time. Each triple of curves represents salinity at bottom, center, and top of water column.

Fig. 5 shows salinity curves for three points in the estuary. The upper curves (K1) represent the "measured" and prescribed boundary data; for the model a fully mixed condition was taken. The salinity in the model is systematically too high, due to the large amount of numerical diffusion of the upstream differences scheme. However, as the "measured" data are averages taken from several measurement periods under different tidal conditions ⁶, they are associated with considerable intervals of scatter, and a comparison to the calculated prototype tide should not be too close. Tidal phase and range, average salinity, and degree of stratification appear to be acceptable from a practical point of view. The vanishing of the stratification during the flood period is

evident in the figure, and it is at least indicated in the measurement curves.

Salinity at the open boundary K 1 was varied in order to study the effect of this boundary condition in the interior. Taking a constant value of 30 ppt instead of the time variation shown in Fig. 5, the results in the interior of the model were changed only insignificantly. This result indicates that the average value of the boundary salinity is important, but slight variations in time do not affect the results strongly. As a consequence, it is not necessary to define the open model boundary so far outside in the sea that practically no tidal variations of the salinity can be observed; in the present example, the constant salinity condition was fully sufficient. No discrimination between inflow and outflow boundary condition had to be made because of the use of upstream differences.

A final verification of the model is given in Fig. 6.

Fig. 6: Comparison of external salinity values along the estuary axis, obtained from mathematical model (———), hydraulic model (- - - - -), and measurements (······).

Here the extremal values of the salinity variation during the tidal cycle, taken along the estuary axis (dash-dot-line in Fig. 1), are shown for the present model calculation, a hydraulic model investigation performed by the Bundesanstalt für Wasserbau [7], and an average data set evaluated from several measurements. Due to the fact that the various curves have been obtained under different tidal (and possibly discharge) conditions, no perfect agreement can be expected. The largest deviations occur in the area of the Dollart basin, both for the mathematical and the hydraulic model. The figure shows that the approximation of the measurement data by both models is of comparable quality.

Another simulation of the salinity intrusion was tried with the vertically averaged model. It was impossible by fitting bottom friction and one global horizontal diffusion parameter to get acceptable results for the salinity distribution, as is demonstrated in another report [8]. Experiments with time- and space-variable diffusion parameters were not undertaken, but it is assumed that good results can be obtained when the model's number of degrees of freedom is high enough.

5. Conclusions

A satisfactory salinity intrusion simulation of a mixed estuary has been obtained by application of a spatially three-dimensional finite difference model with three adjustable parameters. The results of the mathematical model were of a quality comparable to the results of a hydraulic model. The salinity intrusion was found to be mainly influenced by the combined action of vertical eddy viscosity and bottom friction. The vertical eddy diffusivity parameter could be adjusted separately and had only influence on the vertical stratification. The accuracy of the simulation was limited by the grid coarseness and artificial diffusion effects of the numerical method. An analogous simulation by means of a vertically averaged model with constant horizontal diffusion parameter gave no acceptable results.

Given a certain range of desired accuracy in the results (mainly defined by the accuracy of the available measurement data), the following model restrictions were possible to obtain satisfactory results:

- a) constant vertical eddy viscosity,
- b) constant bottom friction,
- c) constant vertical eddy diffusivity,
- d) constant salinity at the open boundary,
- e) a coarse grid in the horizontal plane,
- f) only six vertical grid points.

These restrictions made a simulation of the vertical and lateral dispersive fluxes possible in the framework of a model consuming computer-time to a still moderate extent.

For practical purposes the following classification of models and their applications can be made. Vertically averaged models are useful for calculating the tidal dynamics, and this problem can be solved under neglect of baroclinic forces. A discretization in the lateral direction is necessary if the lateral depth variations are strong. For the salinity intrusion of a mixed estuary, a vertically discretized model should be used; lateral discretization is necessary when lateral depth variations are strong. For the salinity intrusion of a stratified estuary, the same conditions are met; however, in this case a stratification-dependent vertical eddy viscosity is probably necessary to be applied.

6. Acknowledgments

The present work was done with the help of funds of the Deutsche Forschungsgemeinschaft, Sonderforschungsbereich 79. The author is indebted to D. Steen of the Wasser- und Schifffahrtsamt Emden, for most of the measured data, to P. Ströhmoer of the Bundesanstalt für Gewässerkunde Koblenz, for an internal report on salinity measurements in the Ems estuary, and to the Bundesanstalt für Wasserbau, Hamburg, for the hydraulic model data.

CHAPTER 175

A HYBRID MODEL OF THE ST. LAWRENCE RIVER ESTUARY

by

E.R. Funke* AND N.L. Crookshank**

INTRODUCTION

A hydraulic model of the St. Lawrence River Estuary described by Ploeg (1) had to be partially dismantled because of space requirements in the laboratory. In order to re-establish an upstream boundary for the simulation outside the zone of influence of proposed navigational improvements to the lower estuary, a numerical model of the dis-banded upstream river section was dynamically coupled to the remaining hydraulic model. This combination of a numerical and physical model running simultaneously and interactively is referred to as a hybrid model and operates similar to the one described by Holz (2). The implementation of this hybrid configuration was undertaken in part to re-activate the St. Lawrence model as well as to study the feasibility of this novel approach in preparation for more ambitious model studies.

HYBRID MODEL

The hybrid modelling concept described in this paper is illustrated in Fig. 1. Here, a physical and a numerical model are running simultaneously and interactively by exchanging information at their interface with the numerical model operating in the time domain of the physical model.

The physical or scale model of the river system is controlled at two boundaries by a computer. At each control-interval the downstream boundary is controlled on a known tidal elevation, while the upstream boundary is controlled on a calculated discharge supplied by the numerical model. The simulation is therefore extended upstream from the limit of the physical model to the upstream limit of the numerical model whose downstream boundary is in turn supplied from a measured tidal elevation in the physical model.

The exchange of information at the interface is synchronized by having the numerical model operate in the time domain of the physical model. This implies that the numerical model is the slave of the master physical model, waiting to supply and to receive information.

*Senior Research Officer and **Engineer, Hydraulics Laboratory, National Research Council of Canada, Ottawa, Canada, K1A 0R6.

FIG.1 HYBRID MODEL

ST. LAWRENCE RIVER HYBRID MODEL

The original hydraulic model of the St. Lawrence River Estuary that had to be partially dismantled extended from Father Point in the lower estuary of the St. Lawrence River upstream to Montreal (Fig. 2). The section removed encompasses the stretch of river from Neuville to Montreal. In order to re-establish an independent upstream boundary for the simulation, a numerical model was formulated of this upstream portion of the river and was dynamically coupled to the remaining hydraulic model, Neuville to Father Point. The complete hybrid model therefore reproduces the tidal motion in the St. Lawrence River from Father Point to Montreal, a distance of 550 kilometers, leaving 330 kilometers simulated by the physical model, and 220 kilometers simulated by the numerical model.

At the downstream end of the hybrid model, the river itself is 47 kilometers wide with a depth of up to 300 meters. At Neuville, the coupling point of the two models, the width of the river is approximately 3 kilometers with a depth averaging 15 to 20 meters.

The tide entering the system at Father Point ranges from 1.5 to 4.5 meters in elevation with a maximum discharge of 2,000,000 cu m/sec. Propagating upstream, the tidal range peaks just downstream of Quebec City with ranges varying between 3.5 and 6.0 meters. This region also marks the limit of salt water penetration into the system. After Quebec City, the tide is attenuated rapidly by a narrow channel and increasing bed steepness. At Neuville, the coupling point, the tidal range is approximately 3 to 5 meters with the maximum discharge reaching 28,000 cu m/sec. At Montreal, no diurnal or semi-diurnal tidal components remain, leaving only a fresh water discharge averaging 7,000 cu m/sec.

PHYSICAL MODEL

The physical model, 165 meters in length, has a horizontal scale of 1:2000, and a vertical scale of 1:120. The downstream boundary is 23.5 meters wide and is connected to a bidirectional variable pitch impeller pump with a capacity of 1 cu m/sec. Computer control at this point follows a known vertical tide. The upstream boundary is discharge controlled by means of a fixed inflow into a 4 x 4 meter tidal basin and a variable outflow from this basin over a sharp edged 3 meter horizontal weir operating under computer control. The difference between basin inflow and outflow is the model discharge which is bidirectional and of the order of 0.02 cubic meter per second.

The data acquisition and control software is an advanced version of that described by Funke (3). The diur-

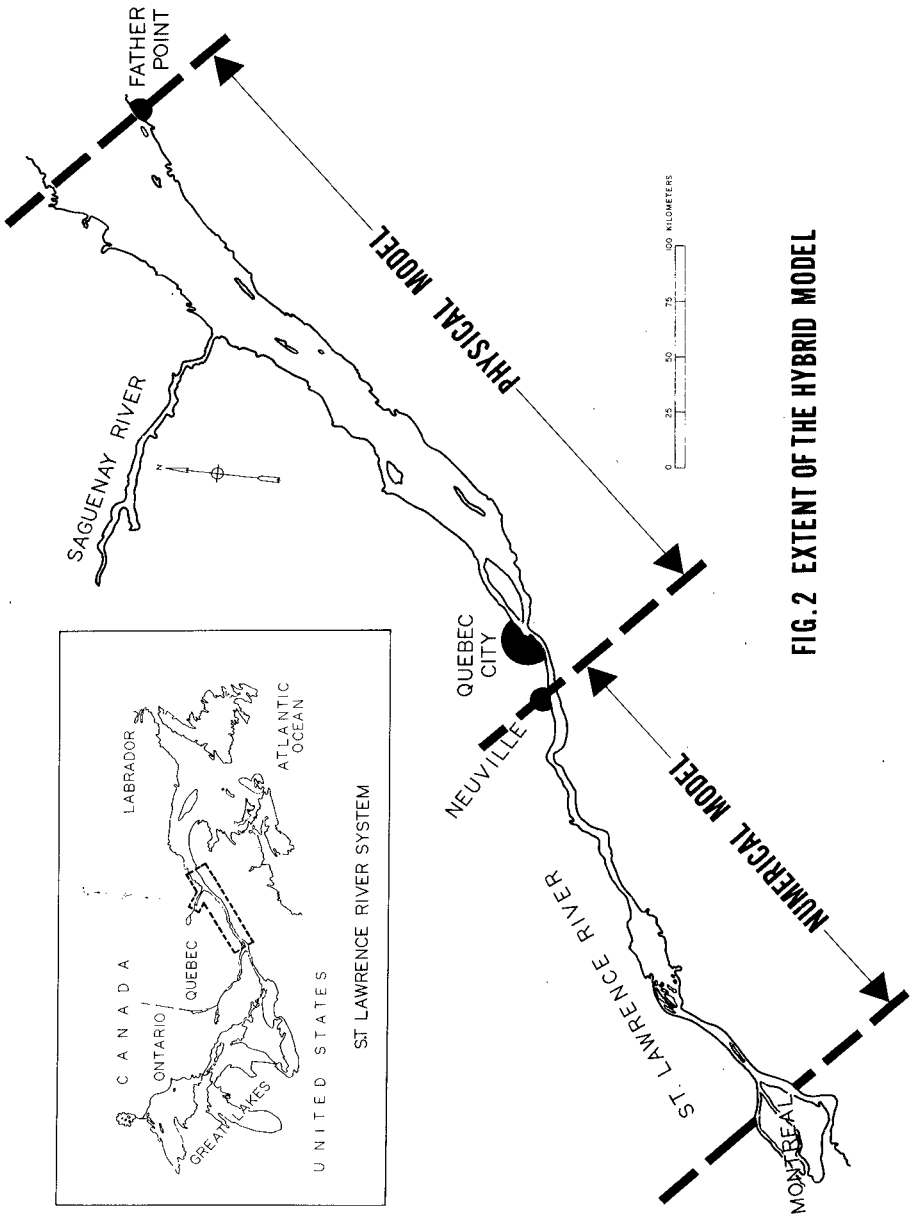

FIG. 2 EXTENT OF THE HYBRID MODEL

nal vertical tide and the pump control curve at the lower boundary are now harmonic recompositions of the Fourier coefficients for the specified tide and the control curve. This feature now makes it possible to generate 14 day tidal cycles including the injection of wind set-ups. The "controller", a computer subprogram dedicated to the generation of control signals to the actuators on the basis of measured differences between desired and actual values, is now implemented by means of a new error trajectory control algorithm which has proved more stable than the previously used three term controller. The sample interval is 1 second and a diurnal tide has a 490 second repetition period.

The on-line computer system and other hardware used for control and data acquisition on the physical model is also described by Funke (3). In addition, a second computer, an EAI Facer 1000 with 64 Kbytes of memory was added. This machine is similar to the control computer but slightly faster (1 second memory cycle time) and is dedicated to the numerical model. It therefore must run in parallel with the data acquisition and control computer. Both computers have access to several common peripherals including a serial data acquisition system. This analog to digital subsystem is a recently developed serial data link which carries the measurement data from distributed converter and transmitter stations along the model over a single wire loop to the computer centre, Ref. 4.

NUMERICAL MODEL

The numerical model, based on a one-dimensional explicit finite-difference solution of the shallow water wave equations, represents 220 kilometers of river by 58 sections of 3.2 and 4.8 kilometers. Inputs to this portion of the simulation are: upstream a constant discharge at Montreal and downstream a variable water elevation at Neuville as provided by a water level gauge on the hydraulic model. The numerical model in turn supplies an instantaneous discharge at Neuville which is returned to the control computer for the discharge control of the upper boundary. Since the hydraulic model dictates the time domain of the hybrid simulation, the solution time of the numerical model has to be synchronized to the hydraulic model. In order to reduce the time delay between the discharge computation and the discharge control, advantage is taken of the nature of the explicit solution which yields computed results after each finite distance step. A shore calculation is therefore performed to obtain the required discharge value at the lower boundary before proceeding upstream with the remainder of the calculations. This calculation is illustrated in Fig. 3.

A = CROSS-SECTIONAL AREA

B = SURFACE BREADTH

R = HYDRAULIC RADIUS

**FIG. 3 CALCULATION OF Q_I
EXPLICIT FINITE-DIFFERENCE SCHEME**

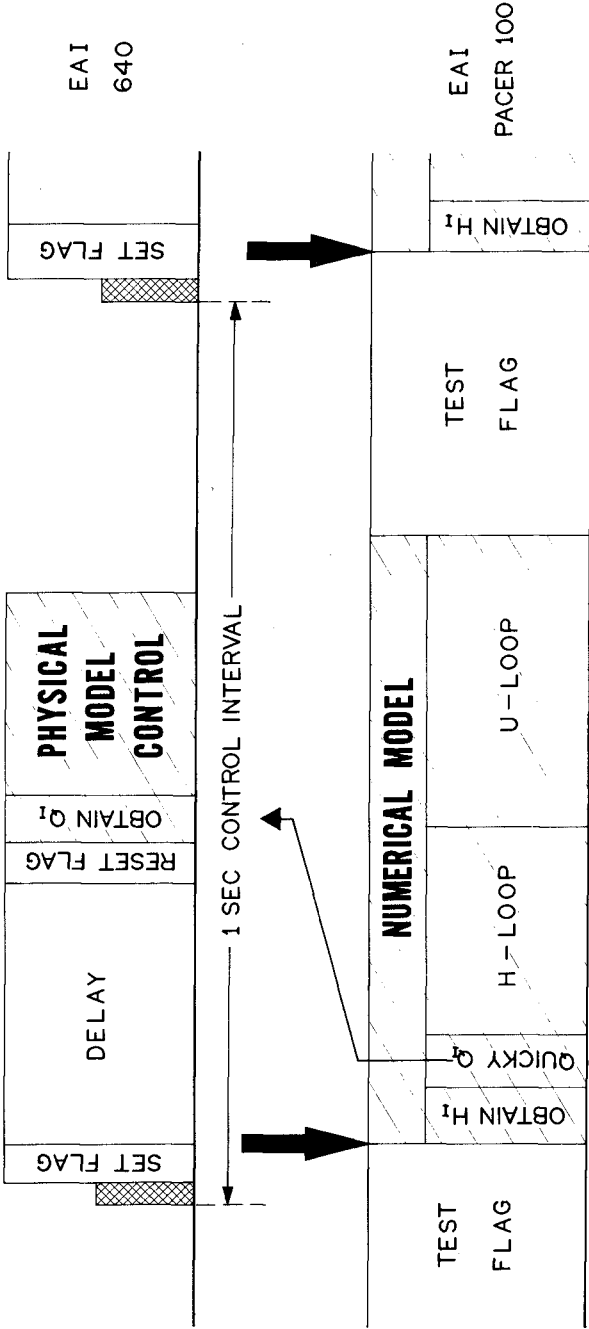

- Step (1): The water elevation immediately upstream from the boundary is calculated using the water elevation supplied from the physical model and previous numerical results. In a purely numerical model this H calculation would be repeated for each section of the river. However, in this case, before proceeding, steps (2) and (3) are executed.
- Step (2): The velocity at the interface is calculated using the just calculated water level and previous numerical results.
- Step (3): The required discharge (Q_I) is calculated, which can now be passed to the physical model.

The numerical model then continues by finishing up with the suspended water level calculations followed by the remainder of the velocity calculations.

DYNAMIC LINK

The computer to computer interface, which is used at this time, is not ideal because of the unavailability of the necessary bidirectional digital data link. Each of the two computers now relies upon the reading of analog signals to complete the data exchange between the models. A "handshake" arrangement is provided between the control computer and its slave, the dedicated numerical model processor. This is illustrated in Fig. 4.

At the start of each control interval, the control computer signals to its slave that the measured water elevation at Neuville is available. The slave is assumed to be in a standby position testing a flag at this time. On recognizing the signal, the slave samples the serial data acquisition system to obtain H_I , the interface water elevation and then computes Q_I , the discharge at the interface required for the physical model. The discharge is returned via the analog link to the control computer which was in a fixed delay state to allow for the data transfer. The control computer then proceeds with the generation of the two physical model control signals while the slave computer finishes the numerical model calculations and returns to its standby state.

H₁ = PHYSICAL MODEL WATER ELEVATION AT UPSTREAM BOUNDARY (HYBRID INTERFACE)
Q₁ = NUMERICAL MODEL DISCHARGE AT DOWNSTREAM BOUNDARY (HYBRID INTERFACE)

FIG.4 DYNAMIC LINK

PHYSICAL MODEL RESPONSE

In Fig. 5, the response of downstream boundary to the control signals is shown. At the downstream end of the model the boundary condition is provided by the known tidal elevation at Father Point, in this particular case the diurnal tide of June 22, 1967. The model was run by repeating this diurnal cycle and updating the control curve for the pump. For the first portion of the figure, without updating, there is considerable error between the actual and the desired tide as indicated by the error curve. However, once updating is initialized, the response of the model soon becomes quite satisfactory.

The upstream response of the physical model to the discharge curve provided by the numerical model for the same diurnal tide is shown in Fig. 6. The difference here is that no updating was necessary to obtain a satisfactory response. This can be explained from the fact that discharge control using weirs is inherently more stable than elevation control using pumps.

ANALYSIS OF RESULTS

A comparison of water elevations against recorded prototype values for two locations in the physical model immediately downstream of the coupling point is shown in Figs. 7 and 8. These stations are located in the area of prime interest during past investigations on the physical model.

Fig. 7 contains a comparison of results for St. Francois located 50 kilometers from the coupling point. The square points represent the actual prototype recorded values while the solid line shows the results from the physical model operated prior to dismantling the upper portion. The dashed line represents results from a numerical model run from Father Point to Montreal and finally the dotted line shows the output obtained from the hybrid model. Fig. 8 contains the results for Lauzon located 25 kilometers downstream of the coupling point.

From these two stations it is evident that the hybrid model results show an improvement on the numerical model while not showing the same degree of accuracy as obtained from the stand alone physical model. How can this be explained? It should be noted that:

- 1) the original physical model was very carefully calibrated and verified;
- 2) the numerical model used for coupling was not calibrated or verified to anywhere near the same degree of accuracy;

FIG.5 DOWNSTREAM PHYSICAL MODEL RESPONSE
TO CALIBRATION TIDE (22 JUNE, 1967)

TOTAL MODEL DISCHARGE = $4.18 \cdot 10^{10}$ CU.FT. (PROTOTYPE) OUTFLOW

TOTAL PROTOTYPE DISCHARGE = $4.29 \cdot 10^{10}$ CU.FT. (PROTOTYPE) OUTFLOW

FIG.6 UPSTREAM PHYSICAL MODEL RESPONSE TO DISCHARGE CURVE FROM NUMERICAL MODEL

FIG. 7

**FIG.8**

- 3) the physical model has been inoperative for several years;
- 4) no attempt was made to calibrate the combined hybrid model.

Taking these points into consideration, the results are acceptable at this stage in the development of the hybrid model. With additional effort put into a new calibration it could be expected to obtain the same degree of accuracy as the previous physical model.

CONCLUSIONS

The following conclusions have been reached:

- 1) hybrid models are both technically and economically practical, providing a new way to extend the boundaries of a physical model to regions uninfluenced by proposed changes in the model. This would in many cases allow a larger scale to be used for the construction of the model, further exploiting the advantages of a physical model in investigating three-dimensionally complex flow patterns.
- 2) for other applications where more extensive numerical modelling would be required, time constraints would require considerably more computing power. This especially would be true if two-dimensional numerical models were necessary. The one-dimensional model used for the St. Lawrence, fully loaded existing facilities.
- 3) improved discharge control machinery would be necessary to operate two-dimensional hybrid interface control.

With these points taken into consideration, the following developments are under way in the laboratory:

- 1) to increase existing computing capacity for hybrid modelling, an HP 1000 computing system with 256 Kbytes of memory as well as a Floating Point Systems AP120B array processor have been purchased.
- 2) to achieve better control between physical and numerical models, development is under way of improved control machinery for multi-directional flow control which may be used to provide multi-point boundary control for two-dimensional models.

CHAPTER 176

FIELD DATA ANALYSIS FOR CHESAPEAKE BAY MODEL VERIFICATION

by

Ronald E. Nece¹ and Norman W. Scheffner²

INTRODUCTION

Chesapeake Bay is located on the eastern coastline of the United States. The bay and its tributaries form a large estuarine system having a surface area of about 11,400 sq km and reaching approximately 320 km northward from its mouth at the Atlantic Ocean to the mouth of the Susquehanna River, its primary inflow. The bay is a major shipping artery, with major ports at Norfolk-Hampton Roads and Baltimore; it also supports an extensive seafood industry, and serves as a tourist and recreation area for the 8 million-plus population in adjoining states. The need for addressing the complexities apparent in present and future management of the water resources of Chesapeake Bay was reflected in Section 312 of the River and Harbor Act of 1965 which directed the Corps of Engineers to undertake a complete investigation of water use and control of the Chesapeake Bay basin. A physical hydraulic model of the bay was specified as a major part of the study.

The maximum width of the bay is approximately 50 km, the mean depth of the bay proper is less than 8.5 m, and the maximum local depth is 53 m. Currents and salinities in the generally shallow, partially mixed estuary are strongly influenced by winds in addition to tides and to time-variable freshwater inflows from the drainage basin of approximately 166,000 sq km. The large size of the actual estuary ruled out the possibility of obtaining synoptic prototype data of sufficiently fine-grained detail against which to verify the recently constructed Chesapeake Bay model. This paper presents the procedures used in an initial treatment of the prototype data.

Consideration is given to two objectives in the treatment of the field data for purposes of model verification. First, the proper quasi-steady tide-freshwater inflow-boundary salinity combination for the bay was sought so that the long-term average salinity distribution could be obtained to provide a basis of comparison for no-wind verification tests

-

 2. Chief, Data Analysis Section, U.S. Army Engineer Waterways Experiment Station, Chesapeake Bay Model Project, Stevensville, Maryland, U.S.A.

on the physical model and which would be compatible with the management tool purposes of the model. The proper combination of inflow hydrographs and tides was necessary in order to obtain representative seasonal salinity distributions. In particular, procedures used to eliminate effects of low-frequency, non-astronomical energy associated with wind fields over the bay are discussed.

The limits of the area modeled are delineated in Figure 1. The distorted fixed-bed model has horizontal and vertical scale ratios of 1:1000 and 1:100, respectively. Tidal boundary conditions are provided at the Atlantic Ocean and at the Chesapeake and Delaware (C & D) Canal, a sea-level connection to Delaware Bay.

FIELD DATA PROGRAM

Prototype tidal height data collection was accomplished primarily by the United States National Ocean Survey (NOS). Tide gages covering the main bay and its tributaries were located at 75 stations indicated in Figure 2. Sampling began in 1970 and continued into 1974, with the majority of the data collected in 1971 and 1972. The time span for which data were obtained at each station is shown in Figure 3. The scale of the figure here precludes station identification and precise times of data collection; significant is the obvious shortage of synoptic tidal height data. The data were reduced by NOS and transferred to magnetic tape; tidal heights were given to the nearest 0.01 - ft and recorded in time increments of 30 minutes. In addition to the raw field data, NOS also provided harmonic analyses of tidal records at a number of stations. A 365-day analysis was performed at 49 stations where adequate records were available, and four 29-day analyses were performed at 16 other stations where the data sampled represented the seasonal variations of the tidal constituents; 37-constituent analyses were performed for the 365-day analyses.

Current velocity and salinity data were obtained through a joint effort of the Chesapeake Bay Institute (CBI, of Johns Hopkins University), the Chesapeake Biological Laboratory (University of Maryland) and the Virginia Institute of Marine Science (VIMS). The current and salinity data were generally taken concurrently. Velocity data were taken at a total of 770 sampling locations distributed over 205 stations; the number of depths at which data were taken varied from one for shallow areas to a maximum of 12 for deep-water stations. Three reports each were issued by VIMS and CBI concerning the data collection procedures; details on sampling in the main bay are given in representative References 1 and 2. Velocity-salinity ranges having more than one station are shown in Figure 4, where the number of stations is shown for each of these ranges. There were 8 main bay ranges, with range CB-00 (9 stations) at the mouth to range CB-07 (5 stations) north of Baltimore. Ranges (composed of one or more stations) or individual stations were established on 34 separate rivers or sub-bays, with the emphasis on the larger rivers entering Chesapeake Bay on its western shore. In order proceeding up the bay, the number of ranges or single stations on these rivers were: James, 8; York, 7; Rappahannock, 10; Potomac, 13; Patuxent, 7. Sampling times on

Figure 1. Model limits and freshwater inflow points.

Figure 2. Prototype tide station locations.

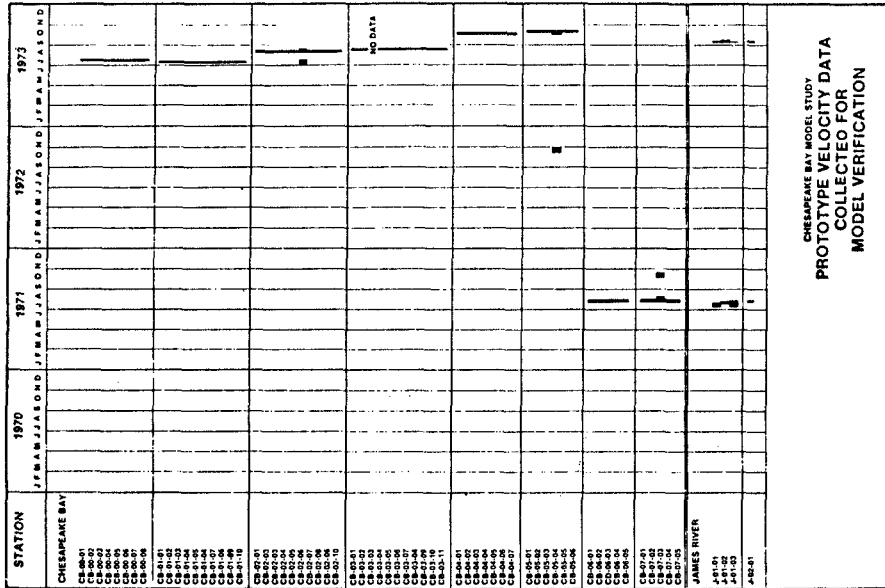

Figure 3. Periods of prototype tide records, and representative velocity sampling periods.

Figure 4. Prototype velocity - salinity ranges.

the main bay ranges are given in Figure 3.

Data were taken in 3-day or, more commonly, 5-day periods of record. Velocity magnitudes and directions were obtained using recording current meters. Velocity data were generally taken continuously at 10-, 20-, or 30-minute intervals. Salinity measurements were obtained with various in situ conductivity-temperature probes and also by laboratory analyses of water samples. All results were transferred to magnetic tapes for analysis. Sampling for salinities was done during 13-hour ('daylight') periods during the deployments at the respective stations. In addition, some slack salinity runs were conducted each month from January 1971 through December 1972 along the main channel of the bay to the upper limit of intrusion of sea-derived salinity (1).

Wind data were provided at 21 different stations located in various parts of the bay; 3 stations, distributed along the main axis of the bay, had daily observations for the complete period 1970-1973.

Relationships between freshwater inflows were based upon analyses performed by the Baltimore District, Corps of Engineers, on records for 70 U.S. Geological Survey stream gages during the water years 1969, 1970, 1971, and 1973. (The 1972 water year covered the effects of run-off from tropical storm Agnes, June 1972). Run-off from 126 drainage areas was consolidated for model purposes into the 21 discrete inflow points, shown on Figure 1. The average flow of the Susquehanna River (approximately $1,100 \text{ m}^3/\text{s}$) accounts for about one-half of the total run-off into the Chesapeake Bay.

TIDES

Various studies of Chesapeake Bay have revealed the existence of significant amounts of tidal energy associated with non-astronomical periods. Early spectral analysis performed at the U.S. Army Engineer Waterways Experiment Station (WES) on the field data taken for the Chesapeake Bay model project indicated a significant amount of tidal energy having a period of approximately 100 hours. Another more recent study of this non-tidal variability in Chesapeake Bay has been reported by Wang and Elliott (3). Their study revealed that non-tidal sea level fluctuations in the bay occurred at three dominant periods: 20, 5, and 2.5 days. The 20-day fluctuations originated from changes of sea level at the Atlantic coast (mouth of the bay) which had been generated by alongshore winds. The 5-day fluctuations were the result of non-local forcing due to the coastal sea level changes and local forcing due to lateral winds (Ekman effect) over the bay. The 2.5-day fluctuations were seiche oscillations forced by longitudinal winds over the bay; these fluctuations did not respond to the sea level changes at the coast.

Wind data studied in connection with the model project indicated that wind fields causing the above fluctuations tend to be fairly uniform over the area of the bay.

Because of the problems associated with this low frequency non-astronomical tide energy, it was decided that one of the approaches to

model verification would be to use only the M_2 tidal component. This method of M_2 verification, which eliminates low frequency wind effects as well as other long term effects, has been tested at WES in several physical models of estuaries and has been found to be satisfactory for initial verification. A number of reasons supporting this approach in the Chesapeake Bay study are listed below.

Tides in the Chesapeake Bay are more regular and semi-diurnal than they are mixed (4). Further, the double amplitude of the M_2 constituent as determined from the NOS harmonic analyses of prototype data for the model was, for almost all tide stations used, equal to more than 0.9 of the mean tide range for each respective station.

Most of the energy in the "semi-diurnal" tidal constituent frequencies is contained in the M_2 frequency. Table 1 lists the amplitudes of the 12 "semi-diurnal" constituents at three stations identified on Figure 2; the values are taken from the NOS 365-day harmonic analyses. Also shown are the mean ranges at the respective stations (4); the ratio of M_2 double amplitude to mean range at Station 68 (Baltimore) is the lowest of any station along the main bay.

Table 1

Amplitudes of "Semi-Diurnal" Tide Constituents at Selected Stations in Chesapeake Bay

Constituent	Angular Vel. Degrees/Hour	Amplitude, Feet		
		Sta. 3	Sta. 34	Sta. 68
M_2	28.9841	1.188	0.552	0.486
N_2	28.4397	0.230	0.119	0.104

Mean Range		2.5	1.1	1.1

A pragmatic reason for using the procedure was that the ocean station providing source tide data was not available during the prototype data collection period; station 1 (Figure 2) was damaged by storms, and produced no data during the 1970-1974 period (Figure 3). Station 3 was then selected for source tide control in the initial verification tests.

As noted tidal data series were collected at non-concurrent times. However, the 365-day harmonic analysis at each of 49 stations provided an M_2 tidal amplitude and epoch which could be used to construct an M_2 tide for verification.

$$h_t = H_o + a \cos \left(\frac{2\pi\omega t}{360} - \frac{2\pi\epsilon}{360} \right) \quad (1)$$

where: h_t = M_2 tide height at any time t
 H_o = mean height above reference datum
 a = M_2 amplitude
 ω = M_2 constituent angular velocity ($^\circ$ /hr)
 ϵ = phase angle in degrees measured from equilibrium tide passing Greenwich at 0 hr GMT(epoch)
 t = time.

This procedure then provided tidal height data and phase relationships (times of arrival) for use in model verification without having to rely on the raw prototype data contaminated by wind effects which could not be reproduced in the model.

CURRENT VELOCITIES

The determination of an M_2 velocity from raw prototype data to be used in verification was not as straight forward as that of tidal heights. The difficulty was in eliminating wind contamination effects and extracting an M_2 velocity constituent from the non-synoptic current measurement series which were of 3-day or (usually) 5-day duration. The major problem was posed by the short length of the data series.

An initial effort was to apply a 144 point symmetric, non-recursive digital filter to the raw velocity data; the band pass filter was designed to retain only that semidiurnal portion of the signal having a period of between 11 and 14 hours. The time increment used corresponded to that of the data for each station. The set of 144 Fourier expansion coefficients so obtained were applied to the raw data series to obtain a filtered velocity as a function of time over the entire 3-day or 5-day sampling interval. A typical comparison of the filtered velocity so derived and the original raw data is shown in the top set of curves on the Figure 5; the data station is the most southerly on the velocity/salinity range at the bay mouth. The filtered velocity magnitudes are seen to be too large. Although this filtering process worked well with the smoother, longer tidal height data, the field velocity data were too choppy and the data series too short for good analysis. Because this procedure was not carried out further, details are not presented here.

A three-constituent harmonic analysis was performed on the

Velocities at CB-00-01, Depth = 3 Ft.

Figure 5. Sample prototype velocity data vs. results obtained by various analysis procedures (see text for details).

filtered, semi-diurnal velocity data to attempt the separation of the M_2 , N_2 and S_2 constituents. This was unsuccessful because the least squares solution to the harmonic analysis becomes unstable when the attempt is made to separate three constituents of nearly the same period from a short data record. Therefore, a one-constituent harmonic analysis (M_2 only) was applied to the filtered velocity data. This technique yields an M_2 amplitude which contains both the N_2 and the S_2 constituents, and retains the large amplitudes of the filtered data. The middle diagram on Figure 5 shows that the calculated velocity amplitudes are considerably larger than the raw data velocity amplitudes.

A single-constituent (M_2) harmonic analysis was then applied directly to the raw velocity data. The results of this least squares cosine curve fit, shown in the bottom diagram of Figure 5, produce a velocity curve which comes closer in amplitude to fitting the raw data than does the filtering processes described above. Since the curve resulting from the one-constituent harmonic analysis comes close to following the raw data, it evidently reflects many other astronomical constituents than just the M_2 . Therefore, a slightly different approach was used to separate the M_2 velocity amplitude from the results of the harmonic analysis. All of the approaches described above gave essentially the same M_2 phase angle value; therefore, the phase angle value resulting from the one-constituent analysis of the raw data was considered to be the valid M_2 constituent phase angle for velocity in the M_2 verification process.

Two factors led to the choice of procedure described below. Tide and current data at nearby stations were not synoptic, and gaps in the records prevented complete dependence on field data only. Consequently, an harmonic analysis using 12 major diurnal and semi-diurnal constituents (including the first six constituents listed in Table 1) was applied to a 2-month record of tidal data obtained at centrally located Station 53 (Figure 2) beginning June 1, 1971. The resulting individual constituent amplitudes and epochs were then used to synthesize a tidal record at Station 53 for approximately 2 1/2 years based on the relationship:

$$h_t = \sum_{n=1}^{12} a_n \cos \left(\frac{2\pi\omega_n t}{360} - \frac{2\pi\epsilon_n}{360} \right) \quad (2)$$

where: h_t = synthesized tidal height at time t
 a_n = nth constituent amplitude
 ω_n = nth constituent angular velocity ($^\circ$ /hr)
 ϵ_n = nth constituent epoch
 t = time

A 5-day one-constituent (M_2) harmonic analysis was then used on the synthesized series of data beginning on June 1, 1971, and leap-frogged every 12 hours. For example, at 0.5-hour intervals, there are 240 data points in 5 days, and harmonic analyses were run using points 1-240, 25-264, 49-288, etc., until the 2 1/2 year period was spanned. This resulted in a least squares cosine curve best fit yielding an M_2 tidal amplitude and phase angle for each 5-day data series beginning at time zero and then at each successive 12-hour time increment.

The common long wave assumption was then made that tidal amplitudes are proportional to the amplitudes of resulting tidal currents. (As a side comment, Hicks (5) has shown that Chesapeake Bay is long enough to contain just more than one complete tidal wave, and that the tide behavior in the lower and part of the middle bay is that of a long wave of translation).

The following relation was then used to relate the long term velocity and tidal height amplitudes to the corresponding velocity and tidal height amplitudes associated with the short 3-5 day period of record.

$$\frac{H}{h} = \frac{V}{v}$$

where: H = long-term M_2 component tidal amplitude.
 h = short-term M_2 tidal amplitude, derived from one constituent harmonic analysis (least squares best fit) of 5-day segment of the 2 1/2 year synthesized tide.
 V = long-term M_2 component velocity amplitude (to be used in verification)
 v = short-term M_2 component velocity amplitude derived from one constituent harmonic analysis of the 3-5 day raw data series.

In the above, H is the M_2 tidal amplitude obtained from the NOS 365-day harmonic analysis; h will not equal H because of the short period (5-day) portion of the synthesized tide from which the former was obtained. In this procedure, both h and v are obtained from comparable, short data series by least squares best fits of cosine curves, yielding phase angles, as well as amplitudes; the phase relationships for M_2 velocities V are thus established.

Results of this procedure are demonstrated in Figure 6. The upper diagram illustrates the variation of the multiplier H/h (by which v must be multiplied to obtain V for a 5-day period beginning on the date and time given in 12-hour increments on the abscissa) with time at Station 53. The curve designated as "Synthesized" was obtained as outlined above; the curve marked as "Prototype Data" was obtained using the actual prototype tidal height series instead of the 2 1/2-year synthesized tidal series at the station. The comparison indicates the general validity of the procedure.

The lower diagram in Figure 6 indicates how the H/h multiplier derived for the synthesized tide at Station 53 compared with the multiplier obtained from analysis of the raw prototype data at Station 34 for comparable times. The diagram provides an indirect indication that different sections of the bay respond in a comparable way to wind fields over the bay. Similar results were obtained for other locations in the bay, with good agreement between the multipliers based on the Station 53 synthesized tide and prototype tide data at the respective stations. Therefore, it was concluded that the H/h multiplier based on the synthesized tide at Station 53 could be used to obtain the M_2 velocity amplitude at the various stations and times corresponding to velocity data collection

Figure 6. Prototype H/h values vs. H/h values derived from synthesized tide, Station 53.

periods at all stations.

SALINITY

Salinity data obtained as part of the prototype velocity-salinity program were too fragmentary to be of use for model verification. The same-slack salinity data taken at 12 stations along the longitudinal axis of the bay during the 2-year period 1971-1972 were of more value, although they were limited to the main bay only and because the only stations occupied were along the bay axis the transverse variations in salinity associated with the combination of Coriolis effects and predominate freshwater inflows from the western shore were not incorporated. A further problem related to the use of these data was that tropical storm Agnes occurred in June, 1972, and the "normal" summer salinity structure in the bay was not reestablished until approximately 100 days after the storm (6). Average salinity values based on the 1971-1972 same slack data were lower than long-term average values.

Salinity values selected for verification purposes were based upon results obtained by CBI over the period 1949-1961 (7). These data, taken on a total of 27 cruises during the stated period, are summarized in graphical presentations of four seasonal average salinity and temperature distributions over the Chesapeake Bay system. Specifically, charts of seasonal isohalines were presented for discrete depths. Figure 7 shows the seasonal average surface salinities for spring and autumn; these two sample plots show the range in seasonal salinities in the bay.

The long-term CBI salinity data (7) were reduced for model study use by the following process. At each prototype-model salinity station, values of the salinity were estimated by visual interpolation between isohalines on the CBI plots containing values for 6 different depths for each of 4 seasons. Salinity values obtained at each depth for each station for the 4 seasons were averaged, and the high and low values were recorded. The average values provide the basis of comparison for long-term model tests and for quasi-steady state tests using constant freshwater inflows and repetitive M_2 source tides. The lower drawing in Figure 8 shows the average salinity profile along the bay axis transect indicated in the upper drawing.

The spring and autumn salinities provided the limits anticipated when the model would be operated with seasonally varying freshwater inflows. The hydrograph employed was a two-year 'average' hydrograph; model tides at both the Atlantic Ocean and the C & D Canal were synthesized 16-constituent tides with repetitive 28-day cycles.

CONCLUSIONS

The methods employed in utilizing prototype data for verification of the Chesapeake Bay Model generally were not new individually, but were employed in the aggregate in order to best adapt the extensive, costly, and highly non-synoptic data over a large geographic area to a physical model incapable of reproducing the complicated physics of the prototype.

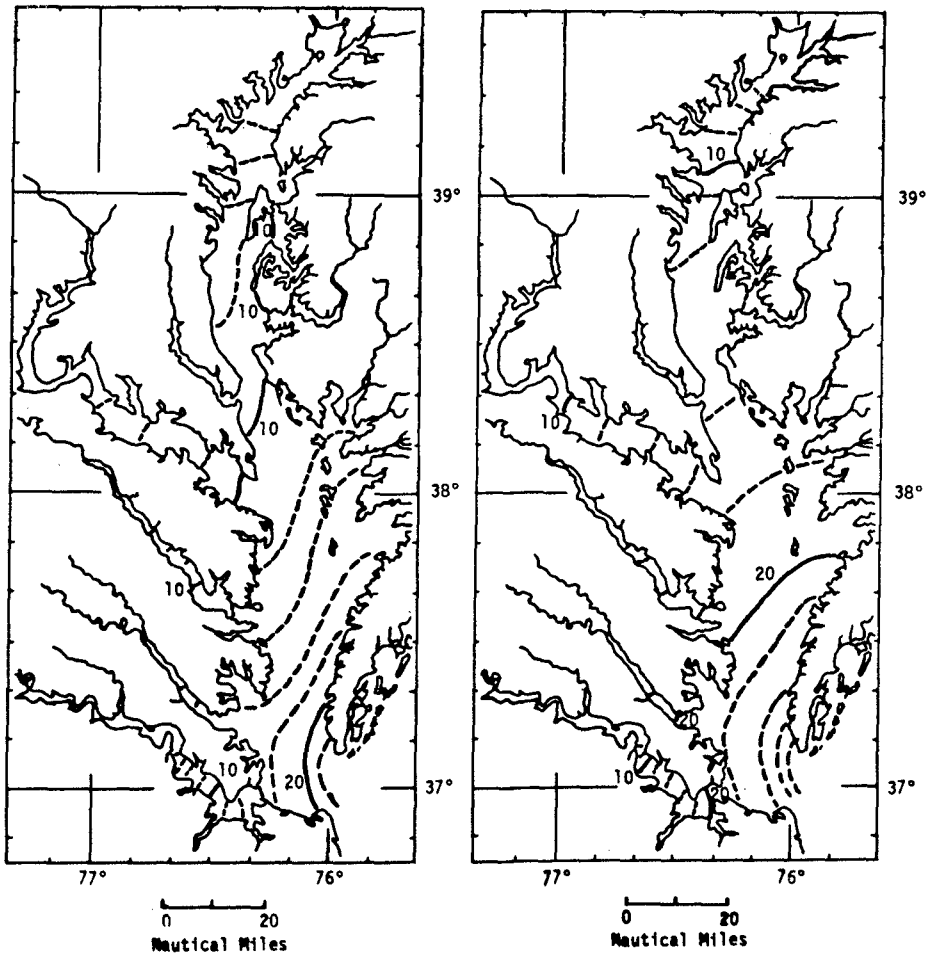

Figure 7. Long-term seasonal average surface salinities in Chesapeake Bay: left, spring; right, autumn.

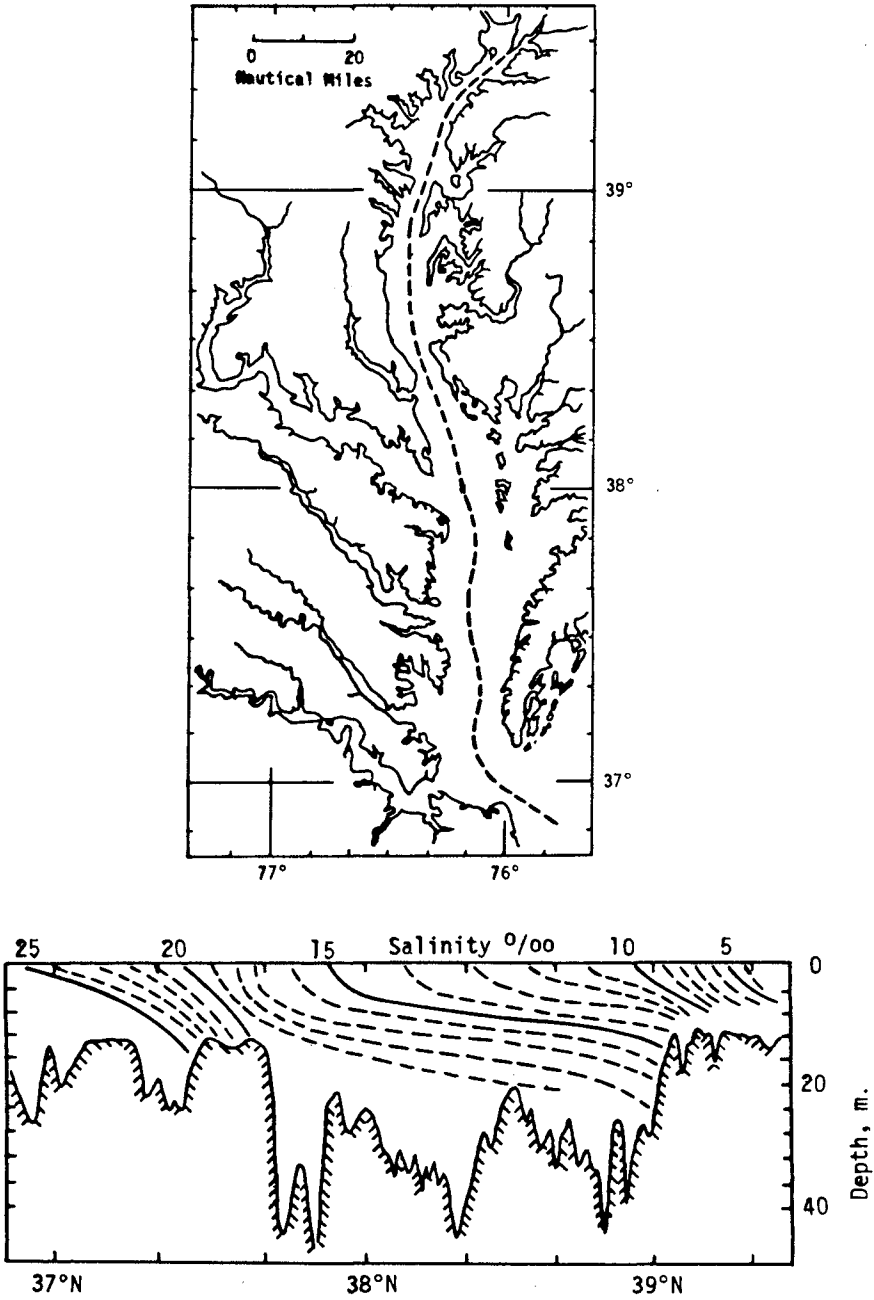

Figure 8. Long-term average salinity profile, Chesapeake Bay (lower) along bay axis (upper drawing).

The feasibility of verifying a physical hydraulic model by using tidal constituents, for example, has been demonstrated previously by Whalin et.al. (8). One of the recommendations (8) was that field experiments on the prototype should be designed to define the principal tidal constituents and their overtides for both the tidal elevation stations and the tidal velocity stations, with one month of record required as a minimum. Such a program is indeed possible for a prototype which is much smaller and simpler than Chesapeake Bay.

The questions to be asked of a model must be considered in the design of a field program mounted to provide prototype data for purposes of model verification. The fact that the salinity data taken specifically for this purpose could not be used points up the necessity for careful planning of field programs when these programs must, of necessity, be wide ranging and extensive. In addition, existing data must always be examined for possible use.

CHAPTER 177

NUMERICAL STUDY OF DISTORTION IN A FROUDE MODEL

T. A. McClimans and S. A. Gjerp

River and Harbour Laboratory
Norwegian Institute of Technology
Trondheim, Norway

ABSTRACT

A numerical model utilizing a fully time-centered implicit (ADI) computational algorithm is used to investigate the effects of distortion of the laboratory model of the Tromsø sound where advective accelerations are important. The numerical model is used to study the individual effects of bottom and side resistance in order to obtain a better understanding of the dynamics and energetics of the tidal flow. Bottom friction is modeled by Chezy's formula. Correspondingly, a lateral viscosity proportional to the local velocity is used to obtain a realistic representation of turbulent lateral momentum exchange. Deviations between the results of the models and field observations are found to be within the natural variability from one tidal cycle to the next, indicating that the laboratory simulation is not seriously affected by distortion.

DISTORTED FROUDE MODELS

It is well known that laboratory simulations of geophysical systems require a geometrical exaggeration of the depth scale in order to produce a sufficiently turbulent flow with a reasonable horizontal dimension. This exaggeration is called model distortion. In an earlier paper (Audunson, et al., 1975) a comparison was made between numerical and laboratory models of dispersion in the Tromsø area. Current velocity patterns in the models compared favorably with field measurements; however, it was indicated that distortion may have caused a discrepancy regarding the simulation of dispersion.

Dispersion is an exceedingly difficult process to model because it depends on a wide spectrum of motions from the general circulation patterns, to the energy containing eddies and farther down the ladder to small scale turbulence. In general, however, the energy containing eddies will determine how much activity is present in the smaller eddies. The limitation of similitude will be the eddy size for which the quasi-two-dimensional turbulence transfers energy to the vertical turbulence. In a distorted model, vertical disper-

sion must be modeled independently of horizontal dispersion. This is perhaps the crucial point for most laboratory models, and it depends on the distortion.

For numerical models the extent of the turbulence spectrum modeled depends on the grid size. Thus to be of comparable resolution, a numerical model has to have a grid size on the order of the depth of the distorted model. The fine scale turbulence, which is not properly simulated in the distorted laboratory model can be calibrated in the numerical model by a variety of coefficients. In the laboratory model it is usually done by means of bottom roughness elements and strips extending into the main flow. Clearly, such calibrations represent an art which goes beyond the theoretical framework of Froude modeling.

Table 1 gives a summary of some dispersion studies in distorted Froude models. In general the models give less dispersion than that observed in nature (the prototype), but the agreement is remarkably good considering that only the tidal currents are simulated. The last entry in the table is the distortion study for Brouwershavense Gat, for which Abraham (1975) claimed good agreement with field measurements. From the table there does not appear to be any correlation between the quality of the simulation and the distortion. This is partly due to the fact that the type of flows vary considerably and roughness elements have been used in some cases. The larger dispersion in nature is probably due to wind effects (except perhaps for San Diego Bay). Sugimoto (1974), in reviewing other Froude model studies of dispersion, shows essentially the same result.

Table 1. Some dispersion tests in distorted Froude models.

<u>SOURCE</u>	<u>BASIN</u>	<u>DISTORTION</u>	<u>ARTIFICIAL ROUGHNESS</u>	<u>($\frac{\text{MODEL DISP.}}{\text{PROTOTYPE DISP.}}$)</u>
Bailey, et.al. (1966)	San Francisco Bay	10	Yes	> 0.5
Simmons & Hermann (1970)	San Diego Bay	5	Yes	0.75
McClimans (1973)	Borgenfjorden	25	No	0.55
Higuchi & Sugimoto (1974)	Seto Inland Sea	12	No	> 0.5
Abraham (1975)	Brouwershavense Gat	3 37½	Yes Yes	Less than 10% difference

Using the one dimensional dispersion equation for a fully developed turbulent channel flow, Fischer & Holly (1971) concluded that distorted Froude models are unlikely to be useful for pollutant dispersion studies. Abraham (1975) showed, however, that distortion is not a serious problem for wide, shallow estuaries for which dispersion is primarily due to horizontal eddies. Fischer (1976) concurs that dispersion studies in distorted laboratory models are feasible when the tidal advective processes of "pumping and chopping" dominate, and are adequately modeled. For wide, shallow estuaries, for which the tidal driving force is in near equilibrium with bottom friction, artificial roughness is necessary to model these processes adequately in a distorted model. Tidal straits, however, exhibit a different balance of forces and the dynamics of these regions warrant a new look at the problem.

ENERGETICS OF TIDAL STRAITS

An understanding of the energetics of the flow is the key to understanding the conditions for which distortion and bottom roughness must or may not be used. Of the energy supplied to the flow by the surface slope, how much dissipation occurs locally and how much downstream?

McClimans (1978) found that the most important resistance force for short tidal narrows is the advective acceleration which forms a jet that mixes with its surroundings downstream. The acceleration term scales to the Froude model law and is independent of distortion. The mixing, however, is affected by distortion if it is not strictly two dimensional.

Local friction was found to dominate when the ratio of the length of the sound to the hydraulic radius is greater than ca. 100. Both vertical and horizontal velocity shears provide friction. This becomes physically apparent through the development of viscous boundary layers, the thicknesses of which are important for diagnostics.

If the flow resistance is a form drag due to an irregular shoreline, the dynamics are essentially two dimensional and distortion has no limitation. This, however, applies only to the dynamics. It is also important to know to what degree the turbulence is two dimensional, for example, the degree to which the energy is transferred from the driving force to the backwaters. This is a measure of dispersion similitude and is a very difficult process to model.

THE TROMSØ SOUND

The currents in the Tromsø sound have been reported by Mosby (1943), Sætre (1972), McClimans (1974, 1977) and Audunson, et.al. (1975). A bathymetric map of the area is given in Fig. 1. The sill region has an average depth of ca. 7 m at low spring tide. The width at the sill is ca. 450 m.

Fig. 1. Bathymetry of the Tromsø sound. Isobaths in meters. (Adapted from sea chart 451.)

Observations of water level and current speed north* are shown in Fig. 2. The two have opposite phases indicating a progressive wave propagating southwards through the sound. Due to the large velocities at the sill and the modest supply of fresh water to the area, the fluid may be considered homogeneous.

A vertical profile of the current speed at the sill (Fig. 3) shows that there is a thin boundary layer at the bottom, typical for accelerating flows. Thus we expect that a large portion of the dissipation of tidal energy occurs in a jet region downstream. The momentum exchange may thus be lateral as well as vertical. Due to the asymmetry of the topography in the sill region it is likely that the type of

* For simplicity we refer to the NE direction as north and the SW direction as south.

Fig. 2. Current speed north (—) and water level (---) in the Tromsø sound at the sill.

Fig. 3. Vertical velocity distribution in the middle of the sound ca. 1 h after high tide. ($\Delta H = 204$ cm)

momentum exchange is different for northern currents than for southern currents.

Audunson, et.al. (1975) compared laboratory and field measurements with a numerical model using bottom resistance alone. In the present work an improved version of the numerical model is used to investigate the individual effects of bottom and side resistance. This is done to obtain a better understanding of the dynamics and energetics of the process and determine which effects, if any, may be ascribed to geometrical distortion of a laboratory model.

THE LABORATORY MODEL

The laboratory model of the Tromsø sound (Næser, et.al., 1974) is a distorted Froude model. The length scale is 1:2000 (model to prototype) and the depth scale is 1:200, giving a distortion of 10. No roughness elements were necessary to calibrate the observed velocities in the sound to given tidal waves, implying that the macro-roughness of the topography is the important wall effect.

The particular challenge with this model was that the region has three open boundaries to the sea. Two of the three, however, are quite narrow. Here the advective accelerations dominate the momentum balance and influence the boundary conditions of the inner region. Jet currents from these narrows drive large circulations to the north and south of the Tromsø sound, and are a major factor in the long term dispersion properties of the area.

THE NUMERICAL MODEL

Basic equations for the dynamic model.

The numerical model is an improved version of a model introduced by Leendertse (1967). The model utilizes the vertically integrated equations of motion and continuity for an incompressible fluid. The horizontal velocity components u and v in the x and y directions, respectively, are integrated vertically from the bottom (at depth $-h(x,y)$) to the free surface (at height $\zeta(x,y,t)$, varying with time (t)), giving

$$U = \frac{1}{h + \zeta} \int_{-h}^{\zeta} u dz \quad (1)$$

$$V = \frac{1}{h + \zeta} \int_{-h}^{\zeta} v dz \quad (2)$$

The long wave approximation is used. The vertical accelerations and velocities are thus neglected, and the pressure is hydrostatic

$$p(z) = \rho g (\zeta - z) + p_0 \quad (3)$$

Here p_0 is the atmospheric pressure, ρ is the density, g is the acceleration of gravity and z is the vertical coordinate, positive upwards. The bottom stress vector is expressed as

$$\tau_v = \rho g C^{-2} \mathbf{v} |\mathbf{v}| \quad (4)$$

where $|\mathbf{v}|$ is the velocity amplitude and C is the so-called Chezy coefficient.

Vertical integration of the horizontal equation of motion over the region $z = -h(x,y)$ to $z = \zeta(x,y,t)$ employing (1) to (4) gives

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} - fV + g \frac{\partial \zeta}{\partial x} + gU \frac{(U^2 + V^2)^{\frac{1}{2}}}{C^2(h + \zeta)} - \nabla \cdot \nu \nabla U = 0 \quad (5)$$

$$\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + fU + g \frac{\partial \zeta}{\partial y} + gV \frac{(U^2 + V^2)^{\frac{1}{2}}}{C^2(h + \zeta)} - \nabla \cdot \nu \nabla V = 0 \quad (6)$$

where f is the Coriolis parameter, ν is the horizontal eddy viscosity, t is time and ∇ is a two-dimensional vector operator. In these equations the effects of the tide generating forces and derivatives introduced by vertical integration are neglected. The wind stress and barometric pressure are also neglected. The only driving force is thus the surface elevation $\zeta(t)$ at the open boundaries.

Using the kinematic boundary condition at the free surface and at the bottom, the vertically integrated equation of continuity is

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} [(h + \zeta)U] + \frac{\partial}{\partial y} [(h + \zeta)V] = 0 \quad (7)$$

Numerical solution of the dynamic equations.

A space staggered scheme is used for the solution of (5) to (7). The spatial grid arrangement for the dependent variables, at any time step, is shown in Fig. 4. The solution technique is multioperational, consisting of an implicit x - sweep for calculation of $(U, \zeta)^{n+\frac{1}{2}}$, an explicit calculation of $(V)^{n+\frac{1}{2}}$, an implicit y - sweep for $(V, \zeta)^{n+1}$ and an explicit step for $(U)^{n+1}$ when integrating from time step n to $n+1$. Details of the solution technique are given by Leendertse (1967) and Hodgins (1977).

Using a fully time-centered scheme, first proposed by Leendertse, his (1967) difference scheme has been improved such that it is consistent with the differential equations, analytically stable (by the Fourier series method) and numerically stable and accurate (Hodgins, 1977). The improved version differs from Leendertse's original version only in the non-linear convective inertia terms, using what

Fig. 4. Space grid for the dependent variables at any time step.

Leendertse described as the "preferred" expressions. The form of these non-linear terms are shown in Table 2.

Table 2. Comparison of the expressions for the non-linear terms in the Leendertse schemes. L-3 is the original Leendertse scheme and L-4 is the improved scheme. The double overbar denotes a symmetrical four-point space average.

DIFFERENTIAL TERM	DIFFERENCE METHOD	DIFFERENCE FORM L-3	DIFFERENCE FORM L-4
$U \frac{\partial U}{\partial x} + v \frac{\partial U}{\partial y}$	Implicit	$U^{n+\frac{1}{2}} \frac{\partial U^n}{\partial x} + \bar{v}^n \frac{\partial U^n}{\partial y}$	$U^{n+\frac{1}{2}} \frac{\partial U^{n+\frac{1}{2}}}{\partial x} + \bar{v}^n \frac{\partial U^n}{\partial y}$
$U \frac{\partial V}{\partial x} + v \frac{\partial V}{\partial y}$	Explicit	$\bar{U}^{n+\frac{1}{2}} \frac{\partial V^n}{\partial x} + v^{n+\frac{1}{2}} \frac{\partial V^n}{\partial y}$	$\bar{U}^{n+\frac{1}{2}} \frac{\partial V^{n+\frac{1}{2}}}{\partial x} + v^n \frac{\partial V^n}{\partial y}$
$U \frac{\partial U}{\partial x} + v \frac{\partial U}{\partial y}$	Explicit	$U^{n+\frac{1}{2}} \frac{\partial U^{n+\frac{1}{2}}}{\partial x} + \bar{v}^{n+1} \frac{\partial U^{n+\frac{1}{2}}}{\partial y}$	$U^{n+\frac{1}{2}} \frac{\partial U^{n+\frac{1}{2}}}{\partial x} + \bar{v}^{n+1} \frac{\partial U^{n+1}}{\partial y}$
$U \frac{\partial V}{\partial x} + v \frac{\partial V}{\partial y}$	Implicit	$\bar{U}^{n+\frac{1}{2}} \frac{\partial V^{n+\frac{1}{2}}}{\partial x} + v^{n+1} \frac{\partial V^{n+\frac{1}{2}}}{\partial y}$	$\bar{U}^{n+\frac{1}{2}} \frac{\partial V^{n+\frac{1}{2}}}{\partial x} + v^{n+1} \frac{\partial V^{n+1}}{\partial y}$

There are several ways of solving the implicit steps. Following Hodgins (1977), $[\zeta_{j-\frac{1}{2}}, U_j, \zeta_{j+\frac{1}{2}}]^{n+\frac{1}{2}}$ are used as the dependent variables of the momentum equation. The resulting tri-banded coefficient matrix then contains $(\partial U / \partial x)^{n+\frac{1}{2}}$. Using $(\partial U / \partial x)^n$ as the initial approximation, all solutions

are iterated to convergence in the ζ field. In all tests with the improved scheme, one adjustment in the approximation of $(\partial U/\partial x)^{n+\frac{1}{2}}$ (i.e. two calculations) is sufficient. An analogous separation of variables in the y - sweep momentum equations is used and the same iteration procedure is performed.

Solving the implicit sweeps in this way removes the restriction of the size of the time step Δt (Courant-Friedrich-Levy condition), but it doubles the time (and cost) of advancing from n to $n+1$ because of the iteration.

The improved scheme causes a further complication in the explicit steps. In the y momentum equation, for example, $(V_j)^{n+\frac{1}{2}}$ is a function of $(V_{j-1}, V_{j+1})^{n+\frac{1}{2}}$, resulting in a set of simultaneous linear equations. The calculation step is therefore not strictly "explicit". The solution of the set of equations can be achieved only with additional boundary conditions. In the present work the solution is iterated by successive approximations of $(V_{j-1}, V_{j+1})^{n+\frac{1}{2}}$. For smooth hydraulic problems, one adjustment is adequate. Further details are given in Hodgins (1977).

Boundary conditions.

At the open boundaries the water level ζ varies sinusoidally as

$$\zeta = A \sin(2\pi(t - \omega)/\tau) + \zeta_0 \quad (8)$$

where A is the tidal amplitude, τ is the tidal period, ζ_0 is the mean sea level and ω is the phase of the tidal wave relative to that in the southern part of the sound.

Along closed U-boundaries in the y -direction, a procedure is followed in which the effect of the side friction can be isolated to the viscous terms. A zero wall velocity is used in the viscous terms, while a slip condition is used in all other terms. A similar condition is used along closed V-boundaries in the x -direction.

To assure that no instabilities in the form of short waves can be introduced at the open boundaries, the equations are linearized over three points along these boundaries.

NUMERICAL TESTS

Numerical tests were made using the NORD-10 minicomputer at the River and Harbour Laboratory. The grid net was 16 x 56 points, giving sufficient details of jet currents and backwaters to discriminate the effects of bottom friction

and side friction. The calculations were performed with a grid length $\Delta x = \Delta y = 167$ m, a time step $\Delta t = 120$ s and a Courant number

$$\frac{\Delta t}{\Delta x} (8gd_{\max})^{\frac{1}{2}} = 43 \quad (9)$$

where d_{\max} is the maximum depth.

The dynamical equations were solved for bottom friction alone (Chezy model), for side friction alone (v -model) and a combination in which half of the flow resistance at the sill was accounted by each term (v -Chezy model). The Chezy friction coefficient was obtained from the earlier model (Audunson, et.al., 1975) with viscous damping. The results of the new scheme, without viscosity, were essentially the same as the earlier one.

A constant horizontal eddy viscosity is an oversimplification of the lateral turbulent momentum exchange and gives a very viscous flow with a weak development of backwaters. This was verified in an early test. The eddy viscosity is a function of the flow properties, the simplest one being a *linear* function of the flow speed. *This* gives a resistance force proportional to the square of the velocity, as in the Chezy friction law. Thus the v -model is based on an eddy viscosity

$$v = v_0 + C_1(U^2 + V^2)^{\frac{1}{2}} \quad (10)$$

in which v_0 is the molecular viscosity of water ($= 10^{-6}$ m²/s) and C_1 is a constant to be calibrated to the flow. For the Tromsø sound tests were run with $C = 29$ m²/s or $C_1 = 60$ m.

RESULTS AND COMPARISONS

Some of the results are compared with field and laboratory measurements in Figs. 5-7. Fig. 5 shows the current patterns, at high and low tide. Fig. 6 shows the lateral distribution of current speed at the sill for low and high tide and Fig. 7 shows the current speed at the sill through $1\frac{1}{2}$ tidal cycles.

The field measurements in Fig. 5 (Mosby, 1943) were averaged over ca. three hours of northern/southern currents, whereas the models give instantaneous pictures. The laboratory tests (Næser, et.al., 1974) showed that the circulation patterns farther to the north develop long after high and low tides.

In Fig. 7, the laboratory results show a high frequency

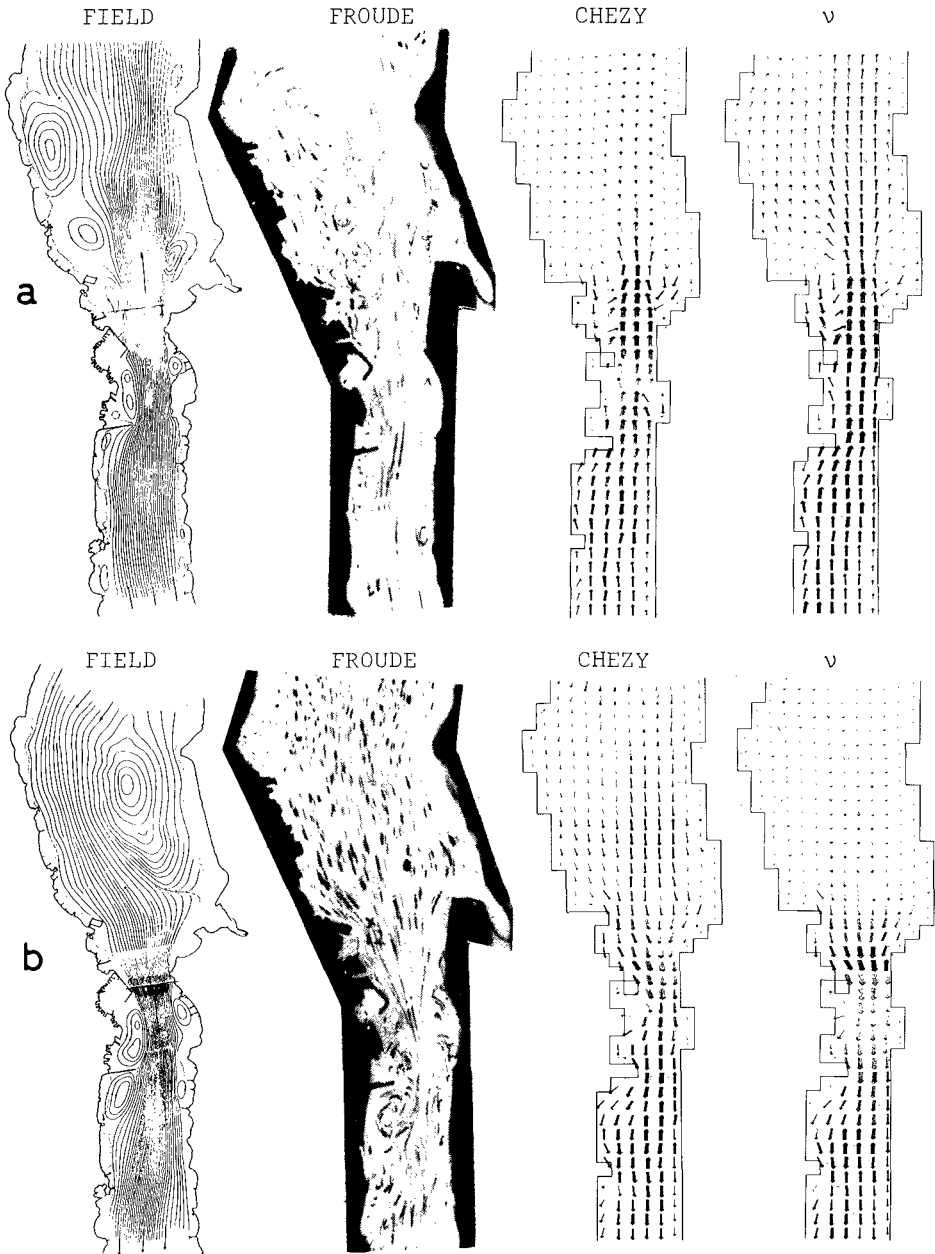

Fig. 5. Comparison of three models with nature at (a) low tide and (b) high tide.

fluctuation. This is the result of the regulation system controlling the tidal levels at the three seaward connections.

Qualitatively, all models give good results for the flow near the sill. It is possible to test the models quantitatively by three means; a) the lateral distribution of current speed at the sill (Fig. 6), b) the time history of current speed at the sill (Fig. 7) and c) the maximum reverse velocity in the backwaters on each side of the sill. The results for the last test are given in Table 3.

Fig. 6. Lateral distribution of current speed $u(y)$ at (a) low tide and (b) high tide.

Results of test a)

The available measurements from the laboratory model are not sufficiently detailed to subject it to this test. Of the numerical models, the v -model gives the best results for northern currents while a combined lateral/vertical friction (v -Chezy) model gives better results for southern currents.

Results of test b)

The laboratory model gives the best results. Of the numerical models, the v -Chezy model is best. (For southern currents, the Chezy model shows a better profile.)

Fig. 7. A comparison of field measurements of current speed in the Tromsø sound with four models.

Table 3. Maximum reverse currents in the backwaters near the sill in the Tromsø sound. Values are given in cm/s in the reverse direction of the flow. The backwaters are identified on the map.

TIDAL PHASE		LOW TIDE = NORTHERN FLOW				HIGH TIDE = SOUTHERN FLOW			
BACKWATER		NW	NE	SW	SE	NW	NE	SW	SE
METHOD	FIELD OBS.	?	22	25	20	-	-	25	25
	FROUDE	40	16	18	8	-	-	17	20
	CHEZY	59	21	7	21	-	-	17	-
	v	41	14	8	0	-	-	18	-
	v-CHEZY	56	14	7	7	-	-	15	-

Results of test c)

Only the laboratory model gives backwaters in the same detail as those observed in the field. This must be a result of poor resolution, since there are so few grid points in the backwaters south of the sill. For northern flow, the Chezy model is about as good as the Froude model, whereas the v -model shows generally less energy in the eddies.

To sum up, the distorted Froude model gives a better simulation than the combined numerical efforts. A combination of side friction and bottom friction gives the best combined quantitative result. The differences between the various models, however, are not large and in many cases they are within the variability of the system.

In the above comparisons it should be noted that the magnitude of the velocities would be more accurately modeled with larger values of C and C_1 . This, however, does not affect the conclusions and has not been further pursued.

DISCUSSION OF TURBULENCE, FRICTION AND DISTORTION

The goal of the present study is to use the improved Leendertse scheme implemented by Hodgins (1977), to test hypotheses on the dynamics and energetics of the Tromsø sound in order to diagnose the possible effects incurred by distortion of the Froude model of the area. Since the Froude model gives a better simulation and shows more detail than the numerical models, we have to consider the hypothetical, limiting case of large distortion.

Infinite distortion will, in effect, eliminate bottom friction from the model, leading to the result of the v -model. The degree to which the v -model simulates lateral dispersion is thus the limit of the error which can be incurred by model distortion. Although the v -model gives good results locally (Fig. 6), it is inadequate for the backwaters, implying that the energetics cannot be explained in terms of side friction alone. Thus we can conclude that unlimited distortion is not dynamically correct and will lead to an error in dispersion similitude. In narrow passages, however, and perhaps also immediately downstream in a jet, lateral momentum and energy exchange must be included in a numerical simulation.

Bottom friction is also an essential factor in the Tromsø sound. This conclusion is not unexpected. The length to depth ratio of the Tromsø sound is greater than 100, which, according to McClimans (1978) means that local friction is a significant factor in the energetics of the flow. In spite of the thin boundary layer at the sill, the entire sill region exerts a significant friction force on the flow. This force is presumably partly bottom drag from the irregular

bottom and partly the effects of drag from the irregular shoreline.

The *local* flow resistance is a combination of the advective acceleration ($U\partial U/\partial x$) and the friction. A comparison of the numerical results shows that, at the sill, the advective acceleration is 4 times as large as the friction (corresponding to the location where the data in Fig. 3 was obtained), while over a length of three grid points the two terms are roughly equal (length to depth ≈ 50). For the entire length of the sill, the role of the advective acceleration is to transport the momentum to regions of weaker surface slopes where the local friction dominates over the advective acceleration. This process is taken into account in the different models in different ways: The Chezy model imparts the force to the bottom while the v -model imparts it to the neighboring regions and eventually to the shores and/or bottom.

The ocean circulation was simulated by Stommel (1948) using bottom friction and by Munk (1950) using side friction. Their models used resistance laws with coefficients that are independent of the flow velocity (i.e. Guldberg-Mohn friction and constant lateral viscosity). Their results also gave the large scale features, which depend mostly on the distribution of wind stress and the rotation of the earth. Thus, when other terms (e.g. accelerations) dominate the dynamics, the particular law of friction matters little. Friction provides an energy sink for the forcing function to avoid an accumulation of energy.

The present results show that lateral friction plays a significant role **for** the lateral velocity shear which is an important factor for dispersion studies. A constant lateral viscosity does not model the flow very well in a tidal strait. A viscosity proportional to the local velocity, corresponding to a Chezy friction law, models the flow quite well, especially near the sill. It appears that this viscosity law (10) is a good expression of the turbulence.

Eddy viscosity is proportional to the turbulent velocity times the integral length scale of the energy containing eddies. If the turbulent velocities are on the order of a tenth of the current velocities, then, from (10), $C_1 = 60$ m leads to a turbulent length scale on the order of 500 m. This is the order of the width at the sill as well as the width of the jet issuing from the sill. This seems reasonable and implies that the turbulent energy is contained in the large-scale horizontal eddies in tidal straits.

The build-up time for large eddies in the Tromsø sound is on the order of half a tidal cycle. The decay time appears to be longer, leaving a significant residual kinetic energy at current reversals. This leads to a time-smoothing of the

dissipation.

All models appear to give a reasonable estimate of the flow, within the variability of the field measurements from one tidal cycle to another. In view of this it seems unlikely that model distortion caused any large inaccuracies in the simulation of the flow. This may be due to the fact that the bottom resistance is in the form of macro-roughness (i.e. bottom topography) which is also exaggerated. It is also possible that the roughness of the model (smooth cement) was appropriate for the thin viscous boundary layers (Fig. 3). The skin friction coefficient is larger for the model Reynolds numbers than for the prototype Reynolds numbers. Distortion remedies this to some extent.

Calibration of the flow in a tidal channel with roughness elements is truly an art, since the energetics depends also on flow direction. Such a calibration of a distorted Froude model, when necessary, has the same effect as calibrating coefficients to the numerical models. The type of modeling used by Svensson (1978), in which the sources and sinks for the turbulent energy are taken into account in a realistic manner is perhaps a better way to obtain the proper energetics and dispersion characteristics of tidal flows in straits.

ACKNOWLEDGEMENTS

CHAPTER 178

IMPROVEMENTS ON TIDAL ESTUARIES AND THE EFFECTS ON TIDAL CURRENT

by
Hermann Harten*

ABSTRACT

With the enlargement of industrialization in the 19th century and the growth of world trade the sea navigation increased considerably. The sea routes had to be improved. This development continued very fast in the last 30 years. The capability of extension in the particular estuary (for example: Elbe, Weser, Jade, Ems) is limited. The improvements include not only the deepening of navigational channels, but also groins, training-walls, fixation of bars, partial or total damming up from by-channels, new localization of main navigational channel lines, new ports etc. The tidal low water is falling and the tidal high water rises, the tidal lift and the tidal volume increase and the flood-as well as the ebbcurrent is floating more powerfully through the tidal estuary. This shows the effect of constructions.

GENERAL

The tides come from the Atlantic Ocean and through the English Channel into the North Sea. The tide from the north is running along the British coast, converges with the tide coming from the Channel and transformed into a rotary tide the so-called amphidrome.

Fig. 1 shows the German Bight with the tidal rivers Elbe, Weser, Ems and the Ocean Bay of the Jade.

* Dipl.-Ing., Bundesanstalt für Wasserbau (BAW)
Hamburg, Fed. Rep. of Germany

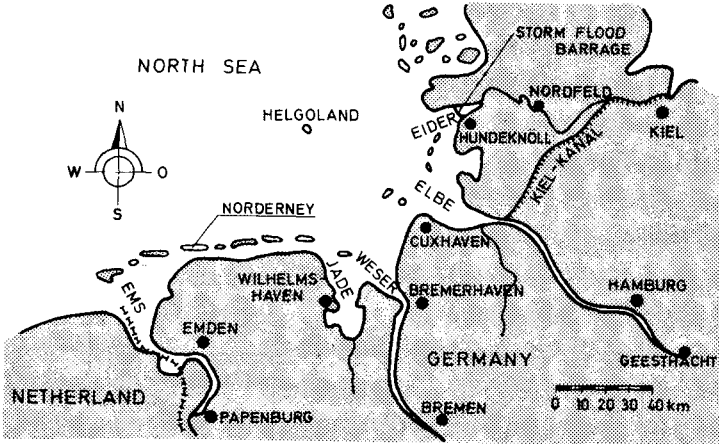

FIG. 1 - MAP OF THE GERMAN BIGHT

FIG. 2 - LINES OF SHIP-DRAUGHTS

These estuaries of the German coast may have been transport ways since prehistoric times. The draught of boats used at that time was unimportant and the natural depth of water was sufficient.

The marshland was small populated, and no dikes protected it against stormtides. The water masses could easily and extensively intrude. About the year 1000 A.D. first dikes were built. By and by due to the increase of population the entire coast had been diked [1], and stormtides ran upwards the river-beds only as the normal tides do.

Until the beginning of the 19th century the largest ships draught had reached 3.5 m only. With the expanding of industry during the 19th century and the growth of world trade the sea navigation increased considerably.

The ships were enlarged for economic reasons, and their development progressed from the sailing boat to the combined sailing-steamship, to the simple steamer, the present day large tankers and containerships. For that reason it was necessary to improve the sea-routes. Nowadays the possible ship-draught amounts to 20 m at the sea route Wilhelmshaven, 14 m to the harbours Bremerhaven and Hamburg, and 10 m to Emden (Fig. 2).

These improvements include not only the deepening of the navigational channels, but also groins, training walls, fixation of sand bars, partial or total damming up of whole estuaries or tributaries, relocations of main navigational channel lines, new ports etc.

Here the deepening of a navigational channel will be considered first theoretically.

The simple formula $v = \frac{Q}{F}$ being completed with the flood or ebb duration, shows an important dependance.

$$v_{im} = \frac{v_{Ti}}{D_i \cdot F_{im}}$$

- v_{im} [m/s] = mean flood or ebb velocity
 V_{Ti} [m³] = tidal volume (flood or ebb tide)
 D_i [s] = flood or ebb duration
 F_{im} [m²] = mean discharge cross section
 (flood or ebb tide)

If a discharge cross section is in natural balance to the discharge, presuming sandy bottom material, it is easy to realize that v_{im} is in relation with the bed material. In case of extending the discharge plane the flow velocity will be diminished, that means, assuming that the tidal volume as well as the flood and ebb duration are unchanged, sedimentation will occur on account of the lower velocity. This phase will last so long as a natural balance condition will be reached again. Therefore the dredging material, achieved by deepening of navigational channels, should be deposited lateral in the same cross section.

Thereby it is possible to give the river-system theoretical a perfect funnel-shape.

The formula of Manning-Strickler is:

$$v = K \cdot R^{2/3} \cdot I^{1/2}$$

Dividing the discharge cross section in many parts (Fig. 3) the formula can be written as follows:

$$v = K \cdot I^{1/2} \cdot \frac{1}{n} \sum_{i=1}^n t_i^{2/3}$$

where v is the velocity and K the friction factor, while I is the slope and t the water depth.

It is easy to understand that with rising water depth t_i in the simple section the velocity v rises, that means, in the deepened channel area there will be a concentration of stream.

While in the areas beside, the dredging goods deposited, by falling depth the velocity decreases. As generally, however, a hydraulic more favourable discharge cross section is re-

FIG. 3 - DISCHARGE CROSS SECTION

FIG. 4 - WATERLEVELS HW AND LW AT THE GAUGE TÖNNING

sulting from the deepening, the tide is also turning more unimpeded in the estuary. The tidal range is causing a tidal lift and tidal volume increase. Model investigations with an idealistic discharge profile give the following result: The increase of tidal lift goes to one quarter in the rise of high water (HW) and to three quarters in the fall of low water (LW). Moreover, time of progress is shortened and the flow velocities rise in the area of the improved main channel. But these effects are different for each estuary. Of course, the result depends on percentage of enlargement related for example to the normal mean water cross section and to other improvements. Except the total damming up, the tide can intrude better to the estuary because of less reflexion and less decrease of energy.

The following gives a description about changing of mean HW and LW levels resulting from improvement and in addition some information about stormtides.

River Eider

The graph (Fig. 4) shows the yearly mean tidal high and low water levels at the gauge Tönning from 1900 up to now. The row of dots marks the mean values over a period of five years. By the total damming up at Nordfeld in the year 1936 the HW rises 18 cm and the LW falls about 44 cm.

After such a drastic change in the flow conditions the river needs a long time (10 or even 30 years) to come back into the natural balance between flow and morphology.

In the year 1973 the storm flood barrage (line Hundeknöll/Vollerwiek) was completed. Result of model tests: The mean tide will not be influenced by the barrage. However, higher tides will be changed by this construction which will be closed during stormtides. Therefore a clear fall of the mean HW is effected.

River Elbe

The mean water level line of the gauge Cuxhaven shows a

small increase only, while the tidal lift in Hamburg-St.Pauli increases - rise of HW, fall of LW - because of the deepening of the Elbe up to Hamburg from 10 m to 13.5 m below chart datum and other improvements (Fig. 5); model values show the same tendency. The draught of inland navigation and the falling LW dictated the construction of the weir Geesthacht.

The stormtides from 1825 and 1962 are looking very similarly at the gauges Cuxhaven and Hamburg-St. Pauli. Also the tide from 1825 is lying in Cuxhaven as well as in Hamburg nearly 50 cm below the HW 1962, though there are very different morphological conditions.

A map of the river Elbe from 1816 (Beautempes-Beaupré) gives a good survey.

In the year 1865 (map by Schuback) the depth in the Hamburg region, especially near Blankenese, was 3.0 m, and in maximum 4.0 m below normal tidal LW.

Obviously the storm tide course depends not much on the deep channel parts of a cross section but more on the large storm flood section lying above.

River Weser

The registered water levels at the gauge Bremerhaven indicate few changes in water level only since any changes can be balanced rapidly in the vast area of the Outer Weser. The gauge Bremen, however, shows a clear decrease of LW level due to the deepening of the Inner and Outer Weser, and the relocation of the navigational channel into the, by nature already favoured, Fedderwarder Arm, from 1921 until 1928 (Fig. 6). Surely other measures also influence this decrease.

Stormtides show an accumulation about the years 1915 and 1975. Upon comparing the two tables of values (Fig. 6) one can recognize that not every stormtide from Bremerhaven appears in Bremen and vice versa.

Tidal Bay Jade

Both water gauges Wilhelmshaven and Norderney are situated in

FIG. 5 - WATERLEVELS HW AND LW AT THE GAUGES CUXHAVEN AND HAMBURG- ST. PAULI

FIG. 6 - WATERLEVELS HW AND LW AT THE GAUGES BREMERHAVEN AND BREMEN

FIG. 7 - WATERLEVELS HW AND LW AT THE GAUGES WILHELMSHAVEN AND NORDERNEY

FIG. 8 - WATERLEVELS HW AND LW AT THE GAUGES EMDEN AND PAPENBURG

areas with adjoining large waterplanes, therefore the gauge Wilhelmshaven does not registrate any effect due to the Jade improvement from 10.0 m to 18.5 m below chart datum. The mean value of the gauge Wilhelmshaven rises a little in HW only. Within the increase of water levels at the gauge Norderney there is the rise of water level due to the settling of land in reach of the German Coast (Fig. 7).

River Ems

The gauge Emden is located in the mouth of the river Ems. More changes are shown at the gauge Papenburg (Fig. 8). Although no larger improvements were made in this region, it is possible that the fall of the water level (LW) results from improvements in the Outer Ems. By and by the river found back to a natural balance and the effect of improvement work reaches the upstream region. Stormtides were concentrated about the years 1910 and 1970.

With the knowledge of historical evolution, field measurements and the result of model tests navigational channels may be optimally improved.

CHAPTER 179

INFLUENCE ON TEMPERATURE INCREASES IN TIDAL RIVERS CAUSED BY WASTE HEAT INJECTIONS WITH RESPECT TO TIDAL CYCLES AND STORM SURGES

by

Horst Schwarze¹⁾ and Wilfried Falldorf²⁾

1) Dr.-Ing., Chief Engineer, Franzius-Institut of the
University of Hannover, Germany

2) Dipl.-Ing. Scientific Assistent, Franzius-Institut
of the University of Hannover, Germany

ABSTRACT

The influence of tidal cycles with neap and spring tides or of storm surge events on the distribution of temperature increases caused by heat injection in an estuary was investigated in a thermal-hydraulic model. The results of the model tests have shown, that under natural tidal conditions as of the Elbe River during tidal cycles as well as storm surge events in the far field region no higher temperature increases occurred than under mean tidal conditions.

INTRODUCTION

Far-field investigations on temperature increases in tidal rivers, caused by waste heat input, are carried out in hydraulic models as well as in mathematical models in general under consideration of mean tides. Natural hydrological conditions of a tidal river, however, are described unsufficiently by this means. The influence of a tidal cycle with neap and spring tides or storm surge events on the spreading of injected waste heat and on the corresponding temperature increases in a tidal river can probably be of importance for the judgement of a waste heat injection. Therefore, thermal hydraulic investigations were carried out in the FRANZIUS-INSTITUT in order to show the dependence of temperature increases with respect to natural tidal conditions.

PARAMETERS OF INFLUENCE

Temperature increases in the far field region of a tidal river in general depend on the spreading and mixing of the injected heated cooling water in the tidal river as well as on the heat exchange between the water surface and the atmosphere. The distribution of the cooling water in the tidal river is influenced

1. by the initial mixing in the near field region with a vertical and a horizontal spreading,
2. by the multiple load of a waterbody with heated cooling water in consequence of the tidal movement and
3. by the removal of waste heat out of the influential reach of the cooling water injection by the freshwater discharge as well as in the brackish water zone of a tidal river by the exchange of fresh water and salt water.

According to the difference between flood- and ebbways of the tides following one another a waterbody will more or less often pass the cooling water outlet moving downstream saw-likely. So it will not reach the outlet again with the flood-stream after several tides. Flood- and ebbways are determined by the portion of the fresh water discharge of the tidal river on the ebb discharge and by the different flood- and ebb tide volumes with respect to the semidiurnal and semimonthly inequality of the tide as well as beyond that by wind set-up effects (storm surges).

In every tide of a natural tidal cycle otherwise as in a sequence of equal mean tides different current and discharge distributions will occur according to different periods of flood- and ebbstream as well as different tidal falls and tidal rises. The phases of slackwater after ebb or flood current are of special influence on the horizontal spreading of the injected heated cooling water.

INVESTIGATIONS IN A THERMAL HYDRAULIC TIDE MODEL

1. Hydraulic tide model

In a thermal hydraulic tide model of the Elbe River in the FRANZIUS-INSTITUT especially the influences of tidal cycles and storm surges, not being considered in most of all thermal hydraulic investigations, on the temperature increases in the far field region of a tidal river were investigated. In this model 60 km of the Elbe River from the sea half-way to Hamburg were simulated in a scale of 1:300 for the lengths and 1:100 for the depths. Fig. 1 shows a part of the model region of about 30 km with the

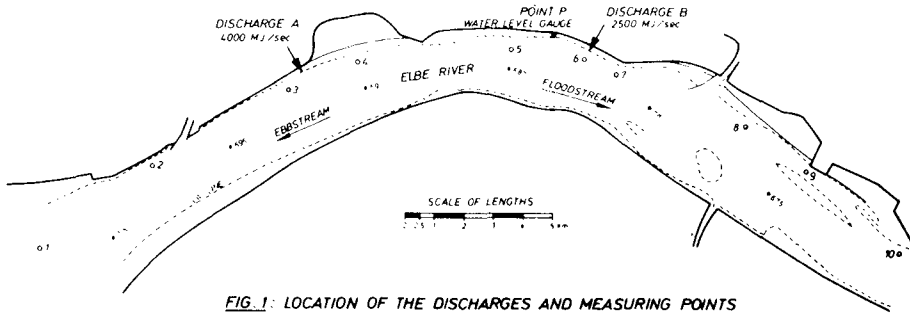

FIG. 1: LOCATION OF THE DISCHARGES AND MEASURING POINTS

outlets A and B for cooling water discharges of $Q_C = 92 \text{ m}^3/\text{s}$ and $Q_C = 60 \text{ m}^3/\text{s}$ respectively both heated up by $\Delta T_C = 10 \text{ K}$ (about 4,000 MJ/sec and about 2,500 MJ/sec). In model the cooling water discharge was constant during the total time of the tests.

The temperature measuring points 1 through 10, plotted in Fig. 1, only show a part of the actually used about 100 measuring points with temperature sensors in three water depths each, in order to be able to give a three-dimensional description of the tide dependent temperature increases in the far field region. All tidal curves shown in the following figures are measured at the tide gauge point P.

The control of the tide model as well as data collection and evaluation was carried out by a computer.

Before starting the model tests with tidal cycles and storm surges more than 20 mean tides had been controlled into the model. This number of tides under mean tide and mean fresh water discharge conditions is necessary so that a waterbody loaded with heated cooling water for the first time at the turn of the ebb current can move downstream so far that it will not reach the outlet with the flood current again.

2. Tests with a tidal cycle

2.1 Hydrological conditions

Fig. 2 shows schematically the difference between spring tides and neap tides in the model region of the Elbe River. The mean spring tidal range amounts to 295 cm and the mean neap tidal range amounts to 235 cm.

A typical tidal cycle of 18 days shown in Fig. 3 was chosen as model tide. In the neap time tides have tidal ranges about 16 % smaller than the mean tidal range of the 18 days period. Spring tidal ranges are about 14 % larger than mean tidal ranges.

FIG. 3: TYPICAL TIDAL CYCLE OF 18 DAYS IN THE ELBE ESTUARY AT POINT P

2.2 Results of the model tests

Selected results of the model tests are plotted in Fig.4 as time dependent temperature increases of a neap tide (tide No 6) and of a spring tide (tide No 22) for the measuring points 2 (downstream of the cooling water outlets), 3 (near outlet A), 5 (near outlet B) and 8 (upstream of the outlets).

FIG.4: TEMPERATURE INCREASE DURING A NEAP TIDE AND A SPRING TIDE

The plots show that differences between the temperature increases only come to about 0.1 K in spite of the different tidal ranges of spring and neap tides. Mean

temperature increases of one tide are nearly equal for spring and neap tides.

The reasons for these results are, that temperature increases in the far field region depending mostly on the waste heat injected during previous tides react on different tidal conditions in the course of a tidal cycle only insignificantly.

3. Tests with storm surges

3.1 Hydrological conditions

For the investigations two in principle different storm surges were simulated in the model. Fig. 5 shows the model storm surges I and II. Both storm surges had the same maximum highest water levels, but different wind set-up behaviour. The wind set-up is defined as the water level difference between the predicted astronomical tide and the storm surge actually obtained in the prototype.

FIG. 5: COMPARISON OF THE TWO DIFFERENT STORM SURGES

In storm surge I the wind set-up rises after the first tide in about 1 1/2 tides from 0 up to 3 m and falls in about 1 tide to 0 again. In storm surge II, however, the wind set-up increases with the start of the first tide in about 3 tides to about 2.8 m and decreases in about 1 1/2 tide to 1 m and remains constantly on 1 m for 1 1/2 tide.

In Fig. 6 and Fig.7 a comparison of the tidal falls and tidal rises of the storm surges with those of mean tidal conditions is shown. The differences partly amount to more than 50 % in storm surge I and up to 40 % in storm surge II.

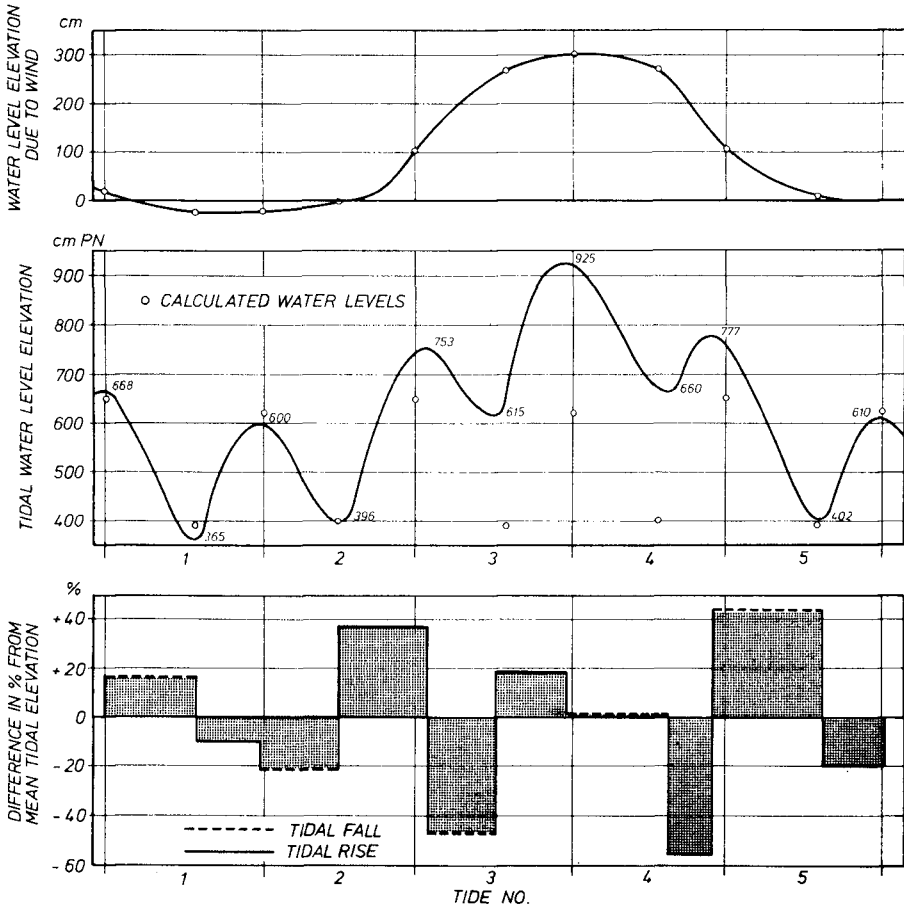

FIG. 6 : TIDAL WATER LEVEL ELEVATION DURING STORM SURGE I

FIG. 7: TIDAL WATER LEVEL ELEVATION DURING STORM SURGE II

3.2 Results of the model tests

In Fig. 8 temperature increases averaged over one tide are plotted for the first, the second and the third tide respectively, i.e. the tides before HHW, along the measuring points No 1 through 10 (vid. Fig. 1) in a longitudinal section of the river region influenced by the injected waste heat.

Fig 8. shows, that mean temperature increases for storm surge I as well as for storm surge II because of the dominant currents in flood stream direction from tide to tide decrease downstream and increase upstream of the cooling water outlets.

It is obvious that the rapid rise of the wind set-up of storm surge I causes more remarkable decreases of the

FIG. 8: AVERAGE TEMPERATURE INCREASE DURING THE STORM SURGES

average temperatures downstream and increases upstream respectively, than the slow rise of the wind set-up lasting over a longer time. The waste heat transported in the region upstream of the cooling water outlets by storm floods produces no higher temperature increases in the tidal river during the fall of the storm surge than obtained during the rise of the storm surge. The maximum temperature increases measured in the tidal river under mean tidal conditions were not exceeded during the investigated storm surge events. This is to trace back first of all to the bigger water volume available for the dilution of the injected cooling water.

CONCLUSION

In a thermal hydraulic tide model of the Elbe Estuary II in the FRANZIUS-INSTITUT the influences of tidal cycles and storm surges on the temperature increases in the far field region were investigated.

With the chosen hydrological boundary conditions, which correspond to natural tidal conditions of the Elbe River, no higher maximum temperature increases than for mean tides were obtained for tidal cycles or storm surges. Therefore for corresponding tidal conditions investigations with mean

tides can be admitted as representative for the judgement of thermal loads of tidal rivers.

Under other tidal conditions as for instance tides with remarkably higher semidiurnal or semimonthly inequalities or essentially more unfavorable ratios of fresh water discharge or cooling water discharge respectively and tidal discharges, i.e. a less number of passages of a waterbody at the outlets or a relatively higher admission of the tidal river with cooling water, investigations only with mean tides are not determining for the judgement of thermal loads of tidal rivers.

Storm surge events do not yield to higher temperature increases than mean tides in the lower regions of a tidal estuary first of all according to the bigger water volume available for mixing. But beyond that it must be noticed that a certain shifting of the admitted region upstream occurs. In that region no higher temperature increases than in the region influenced by waste heat injection under mean tidal conditions were measured.

Further basic investigations on the influence of different tidal conditions on temperature increases in a tidal river are projected.

OUTFLOW DYNAMICS AT A RIVER MOUTH

by

Masakazu Kashiwamura*

and

Shizuo Yoshida**

ABSTRACT

It has been extensively recognized from many past studies, that the interfacial Froude number must be unity at a river mouth, under the condition of a salt wedge existing inside the river. However, there seems no study having paid efforts to clarify how its numerical values distribute horizontally, inside or outside the river mouth. This problem has come to mind very important for the present authors, in order to obtain better understandings on the dynamical structure of the density current.

The river mouth has been thought to be an extremely singular place, from many field observations and laboratory experiments, because it forms a boundary between two quite different phases in flow pattern, inside and outside. For example, abrupt changes in velocity, thickness and mixing occur for the fresh water, at the river mouth. In order to solve its essential behavior, the transient motion of the fresh water, when it passes through the river mouth, was analysed based on some ideal conditions.

As a result, the flow of the fresh water was revealed to be identical in its property with the transonic flow in aerodynamics, where the interfacial Froude number plays a dominant part in place of the Mach number. If a salt wedge lies along the river bed, numerical values of the interfacial Froude number are known to be less than unity inside the river mouth. In such a case, the flow of the fresh water corresponds to the subsonic flow. On the other hand, once the fresh water passes through the river mouth, it changes into that of the supersonic flow, because the interfacial Froude number exceeds unity there. From those view points, horizontal distributions of the interfacial Froude number were investigated by rearranging past field data, and as a result, the wide area was occupied by the fresh water which was equivalent to the supersonic flow, and was stretching far offshore from the river mouth.

Next, the mechanism of mixing between the fresh water and the sea water was examined from both field measurements and laboratory experiments. As a result, different mechanisms were found to prevail inside the river mouth and outside, respectively. The outside mechanism is believed to belong to breaking of the interface due to the Kelvin-Helmholtz instability, but the inside is caused in a

* Professor, ** Instructor, Department of Engineering Science, Hokkaido university, Sapporo, Japan.

different manner that the interference of the interfacial wave to the roughness with a cusped shape which occurs along the interface in a certain condition, gradually breaks the interface, although the intensity of mixing is much less in the latter case.

Besides those two, if the tidal effect is remarkable, there is another type, in which vortices induced by a strong tidal current behind each of bed irregularities, attack the interface and destroy it.

INTRODUCTION

The present authors have continued a series of observational studies on the density current, for past twenty years, mainly in the neighborhood of the mouth of the Ishikari River, which is the second largest river in Japan and is the largest in Hokkaido. The location is shown in Fig. 1 and the enlarged map is shown in Fig. 2.

As the Japan Sea, to which the Ishikari River opens, has small tidal ranges, a typical salt wedge can be detected inside the Ishikari River, for the distance of several kilometers, in usual river discharges. Main studies performed so far, are as follows; the relationships between the river discharge and the length of the salt wedge, the interfacial friction, the transient flow of the fresh water passing through the river mouth, changes in velocity, thickness and density for the fresh water, mixing of the fresh water and the sea water, etc. Phenomena thus obtained in field observations are reproduced in laboratory experiments, and their properties are investigated in detail with changing the condition variously. Those results are finally analysed theoretically. Such a process is a conventional way for the authors.

Studies on dynamics of the outflow of the river water and the mechanism of mixing between the fresh water and the salt water are very important problems in near-shore regions including river mouths, but also for better understandings on the thermal discharge issued from nuclear or thermal power plants.

Several phenomena showing singularities of river mouths, which have been experienced in field observations and mathematical treatments will be presented in the followings. The other important problem on mixing will be described in the last paragraph.

2. REVIEW ON RESULTS OF THE PAST MEASUREMENTS

An example of vertical distributions in velocity, observed longitudinally along the Ishikari River, is shown in Fig. 3¹⁾, in which the river mouth is taken as the origin and the seaward direction is positive. Salinity distributions were observed at the same time but are not presented in the figure. However, it can easily be seen that the sea water flows upstream along the bed, and the fresh water flows down over the sea water and spreads out over the sea surface. It must be carefully observed, that the fresh water gains its maximum value in velocity, around the river mouth. In other words, the fresh water is temporarily accelerated at the river mouth, and decays again with the offshore distance. This fact has frequently been examined at any other observations.

Fig. 4 is another illustration of three kinds of observation made

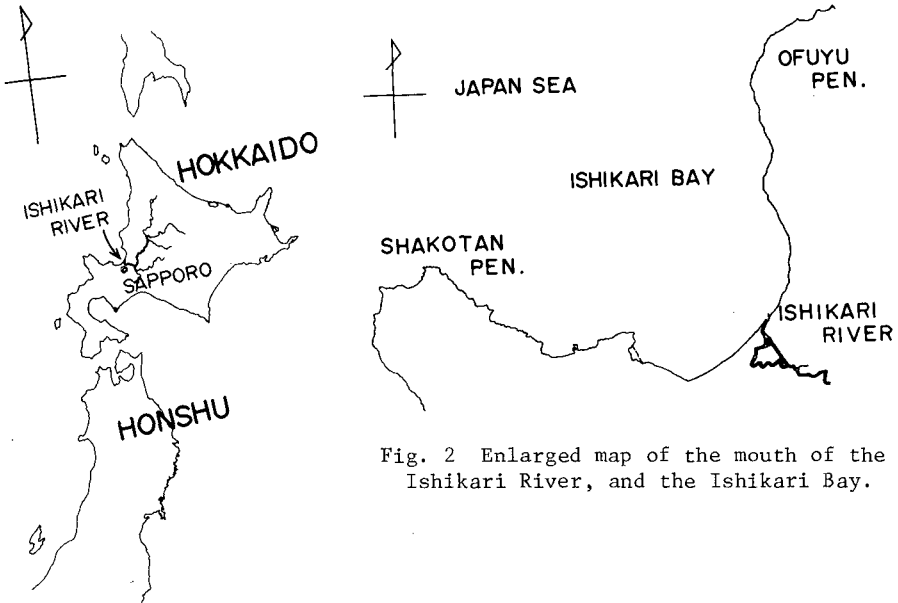

Fig. 2 Enlarged map of the mouth of the Ishikari River, and the Ishikari Bay.

Fig. 1 Location of Hokkaido and the Ishikari River.

Fig. 4 Three kinds of quantity changing through the river mouth.

AUG. 7. 1968.

on the same day.^{1),2)} The left is the longitudinal change in no-net-flow depth, which means a depth where no velocity, upstream or downstream, is found. The depth is usually levelled at a little length below the density interface. The no-net-flow depth becomes suddenly shallower at the river mouth and the internal jump is formed. The central figure shows how the fresh water changes in velocity as mentioned before. The maximum is found at a short distance off the river mouth, where q denotes the velocity, q_0 is its value at the mouth, and b is the breadth of the river mouth. The right shows a longitudinal change in specific weight for the fresh water. Abrupt growth of mixing can be inferred between the fresh water and the salt water, outside the river mouth. From those three examples, the inside and the outside can be understood to be governed by different dynamical conditions.³⁾

Next, the flow patterns of the fresh water are reexamined.³⁾ Fig. 5 shows a plane map of stream lines for the fresh water, which was made from a great number of measurements on the velocity and its direction. The measurements needed many hours, but the result was not disturbed by the tide, because it is negligible in this sea area, as stated before. The growing rate of the spacing between two stream lines is shown against the distance in the lower figure, in which the width of the two stream lines at the distance of 400 m inside the mouth is taken as the standard, l_0 . The distance is measured along the line connecting every point with the highest velocity across any section of the surface flow. It can be understood that the spacing grows exponentially with the distance, viz., $l = l_0 \exp(kx)$.

Such a result is always detectable, under the condition of the salt wedge existing inside the river mouth. In the far offshore region, the same trend may not be considered to remain any more, by the effect of the sea current, wind and waves. Therefore, the exponential growth of the spacing should be considered as a transitional phenomenon, in the near shore region around the river mouth. When the river discharge increases, the numerical value of k also increases, and in an extreme case, k seems to become variable with the distance x . If the discharge decreases, the area where the value of k keeps constant becomes smaller within a limited scale. Then, it may be reasonable that k is, in general, taken as a function of x and Q which is the river discharge.

Fig. 6 shows all kinds of flow pattern, which were found experimentally in the past.^{3),4)} The top figure A is an extreme type which is obtainable in a very small river discharge, and the stream lines stretch radially in all directions from the river mouth. The bottom figure E is the other extreme type which occurs, if the river discharge reaches a great amount beyond a certain value, and the flow is that of a turbulent jet with the stream lines undistinguishable, but the border lines with both sided sea areas stretches initially parabolically with the distance, and finally becomes parallel in the offshore direction. There are several types, B, C and D, which are transitional between those two extremes.

The state of a salt wedge varies with the flow pattern, as shown in Fig. 7. The salt wedge develops extremely upstream in the case of A, and retreats conversely seawards in the case of E. Judging from the observational result of the salt wedge, the flow pattern in Fig. 5 seems to correspond to the case of B or C. The classification of the flow pattern, thus obtained, was made in laboratory experiments, in

Fig. 5 Stream lines of the fresh water issued from the mouth of the Ishikari River.

Fig. 6 Various patterns of the fresh water issued from the outlet of an open channel.

which the transient acceleration of the fresh water was also found without exception in each case.

Fig. 8 (a), (b) and (c) show the acceleration areas in different conditions, with contour lines of identical values of velocity.²⁾ Other groups of lines with arrows are stream lines. The condition of (a) is close to that of A in Fig. 6, and the characteristic of potential flow is stressed at both corners, where the acceleration zones are remarkable, but along the center line, the acceleration is slightly detectable at the small distance off the mouth. The figure (b) seems to correspond to the flow of B or C in Fig. 6. The acceleration becomes remarkably stronger on the center line, and at the same time, at both corners. The figure (c) may belong to the type of C or D in Fig. 6. The acceleration at the corners goes down, while that on the center line grows up.

Such a kind of growth in transient acceleration on the center line is peculiar to the two-layered flow around the outlet or the river mouth. As for the type of E in Fig. 6, the investigation is still insufficient, by the reason of the limited condition in experiments.

It is understandable that the river mouth is a dynamically singular place, and it implies that different equations dominate the inside of the mouth, and the outside, respectively.

3. A THEORETICAL APPROACH WITH ENTRAINMENT TAKEN INTO CONSIDERATION

In order to analyse those interesting problems, the senior author, first, attempted a theoretical approach with the entrainment phenomenon taken into consideration. A simple model of the flow is shown in Fig. 9, where q denotes velocity, h the depth of the fresh water, and ρ the density of the fresh water. Those three are all variable with x . It is assumed that the density ρ_0 of the lower sea water is constant, and the entrained velocity V across the interface, into the fresh water, is proportional to the velocity q of the fresh water, viz. $V = Eq$, where E is the entrainment coefficient. In addition, the spacing l of stream lines is taken into account.

The problems are, thereby, arranged into the following one-dimensional equations.

$$\frac{d(qhl)}{dx} = Vl = Eq l \quad (1)$$

$$\frac{d(\rho qhl)}{dx} = \rho_0 V l = \rho_0 E q l \quad (2)$$

$$\frac{d(\rho q^2 h l)}{dx} = -(\rho_0 - \rho) g h l \frac{dh}{dx} \quad (3)$$

Eqs.(1), (2) and (3) are those of conservation of volume, mass and momentum, respectively. Besides, the empirical equation, that $l = l_0 \exp(kx)$, is employed in the differential form,

$$\frac{dl}{l} = K dx \quad (4)$$

where the coefficient k may, in general, be variable with x , as explained in the preceding paragraph. The following parameters, that $\epsilon = 1 - (\rho/\rho_0)$, $Re = hq/\nu$, $F_1^2 = q^2/\epsilon gh$ and $\psi = F_1^2 Re$, are also introduced,

Fig. 7

Correspondence of the state of the salt wedge to the type of outflow pattern.

Fig. 8

Velocity distribution of the outflow illustrated with contour lines.

Fig. 9

Illustration of the model for the outflow of the fresh water.

where R_e is the Reynolds number, F_i is the interfacial Froude number and ψ is the third root of the inverse of the Keulegan number, respectively.

By rearranging those four equations, the followings are successively derived.

$$\frac{d\epsilon}{\epsilon} = -\frac{E}{h} dx \quad (5) \quad \frac{dq}{q} = \frac{\frac{E}{h}(1+F_i^2) - K}{1-F_i^2} dx \quad (6)$$

$$\frac{dh}{h} = -\frac{(2\frac{E}{h} - K)F_i^2}{1-F_i^2} dx \quad \frac{dF_i^2}{F_i^2} = \frac{3\frac{E}{h}(1+F_i^2) - K(2+F_i^2)}{1-F_i^2} dx \quad (7) \quad (8)$$

$$\frac{dR_e}{R_e} = (\frac{E}{h} - K) dx \quad (9) \quad \frac{d\psi}{\psi} = -\frac{2\frac{E}{h}(2+F_i^2) - 3K}{1-F_i^2} dx \quad (10)$$

It is, at the present, impossible to obtain a solution of each parameter against x , from those, because the characteristics of E and k have still been unsolved. However, there are a few equations which are convenient for calculating numerical values of some parameter from field observational data. For example, Eq. (5) is such one, which is useful for obtaining a distribution of the entrainment coefficient E , along the stream.

Table 1 shows various kinds of parameter varying with the distance x along the center line of the fresh-water flow at the Ishikari River. The right-end column gives the longitudinal change of E , which was obtained by using Eq. (5). If Eqs. (5) and (9) are combined, the value of k ought to be derived from the values of ϵ and R_e , which are obtainable from observations, but the validity of calculated values on k is still uncertain for lack of sufficient field data.

Distance ^m	ϵ	q ^{m³/s}	h ^m	F_i^2	R_i	R_e	ψ	E

ISHIKARI RIVER AUG. 4. 1970.

Table 1

As for other parameters, they are also difficult to determine their numerical values particularly in the neighborhood of the river mouth, because the denominators included in right sides in Eqs. (6), (7), (8) and (10), are all $1 - F_i^2$, which becomes zero or very small at the mouth and then, has a great possibility to produce extended errors on estimating the values of parameters.

But, if we accept the general recognition, that $F_i = 1$ at the river mouth, when the salt wedge exists inside, all the numerators in Eqs. (6), (7), (8) and (10) must be also zero simultaneously. This fact leads to a single result, viz., $\frac{E}{kh} = 1/2$ at the river mouth. It can be concluded that three different parameters E , k and h must be

unified just at the river mouth, in a form of the above equation, although its validity is also uncertain at the present.

However, from many facts, thus described, it is inferable that the river mouth is expected, also in a mathematical sense, a very singular place. Then, it seemed important for the senior author to re-examine the essentials lying within a transient process given by the fresh water, when it passes through the river mouth. This will be described in the following paragraph.

4. SIMILARITY BETWEEN FRESH-WATER FLOW AND TRANSONIC FLOW

Idealizing the fresh-water flow to be inviscid, immiscible with the sea water, and also irrotational, a transient behavior of the fresh water, when it passes through the river mouth, is treated. To neglect mixing has the same meaning with the sea water stagnant, and it results no change in density for the fresh water, viz., ϵ can be put as a constant. The equations describing the motion of the fresh water are given as follows.

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + \epsilon g \frac{\partial h}{\partial x} = 0 \quad (11)$$

$$u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + \epsilon g \frac{\partial h}{\partial y} = 0 \quad (12)$$

$$\frac{\partial}{\partial x} (h u) + \frac{\partial}{\partial y} (h v) = 0 \quad (13)$$

Eqs. (11) and (12) are equations of motion, and Eq. (13) is that of continuity. The axis x is taken in the offshore direction and y is parallel to the sea shore. The symbols u and v are components of velocity in the x and y axes, respectively.

First, transformation of Fig. (13) leads to,

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = -\frac{1}{h} (u \frac{\partial h}{\partial x} + v \frac{\partial h}{\partial y}) \quad (14)$$

Eqs. (11) and (12) can be transformed into

$$\left. \begin{aligned} \frac{1}{\epsilon g h} (u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y}) &= -\frac{1}{h} \frac{\partial h}{\partial x} \\ \frac{1}{\epsilon g h} (u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y}) &= -\frac{1}{h} \frac{\partial h}{\partial y} \end{aligned} \right\} (15)$$

The two right-handed sides in Eq. (15) are substituted into the right side in Eq. (14). Thus, the following is derived immediately.

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = \frac{1}{\epsilon g h} (u^2 \frac{\partial u}{\partial x} + u v \frac{\partial u}{\partial y} + u v \frac{\partial v}{\partial x} + v^2 \frac{\partial v}{\partial y})$$

Since the flow is irrotational, then

$$\frac{\partial u}{\partial y} = \frac{\partial v}{\partial x}, \quad u = \frac{\partial \phi}{\partial x}, \quad v = \frac{\partial \phi}{\partial y}$$

where ϕ is the velocity potential.

The above equation can be arranged into the form,

$$\left(1 - \frac{u^2}{\epsilon gh}\right) \frac{\partial^2 \phi}{\partial x^2} - 2 \frac{uv}{\epsilon gh} \frac{\partial^2 \phi}{\partial x \partial y} + \left(1 - \frac{v^2}{\epsilon gh}\right) \frac{\partial^2 \phi}{\partial y^2} = 0 \quad (16)$$

This expression is surprisingly the same in form with the well-known equation of the two-dimensional air flow, viz.

$$\left(1 - \frac{u^2}{a^2}\right) \frac{\partial^2 \phi}{\partial x^2} - 2 \frac{uv}{a^2} \frac{\partial^2 \phi}{\partial x \partial y} + \left(1 - \frac{v^2}{a^2}\right) \frac{\partial^2 \phi}{\partial y^2} = 0$$

where a is the local sound velocity. If we put $\sqrt{\epsilon gh}$ in place of a , the above becomes Eq. (16).

As is well known, the discriminant D of the above equation is written as,

$$D = \left(\frac{uv}{a^2}\right)^2 - \left(1 - \frac{u^2}{a^2}\right)\left(1 - \frac{v^2}{a^2}\right) = \frac{q^2}{a^2} - 1 = M^2 - 1$$

where $q = \sqrt{u^2 + v^2}$, and M is the local Mach number, that is, $M = q/a$.

Two-dimensional linear partial differential equations, in general, have three quite different types, elliptic for $D < 0$, parabolic for $D = 0$, and hyperbolic for $D > 0$. Therefore, properties of the air flow are classified as follows.

	Equation	Flow Characteristic
$M < 1$	elliptic	subsonic flow
$M = 1$	parabolic	sonic flow
$M > 1$	hyperbolic	supersonic flow

If a body is placed in a comparatively high subsonic flow, three different zones, for $M < 1$, $M = 1$ and $M > 1$, are frequently formed around the body, where the flow is subsonic,

sonic, and supersonic, respectively. The flow thus combined, is called a "transonic flow". All described here are well-known facts in aerodynamics.

As easily understandable from those mentioned so far, attention must be centered on that the fresh-water flow lies under a mathematically and dynamically identical condition with the air flow.

The discriminant of Eq. (16) is as follows.

$$D = \frac{q^2}{\epsilon gh} - 1 = F_1^2 - 1 \quad (17)$$

The interfacial Froude number F_1 plays, undoubtedly, a dominant part on the fresh-water flow, as well as the Mach number M does on the air flow. Corresponding to, that $F_1 < 1$, $F_1 = 1$ and $F_1 > 1$, the mathematical condition varies as, elliptic, parabolic and hyperbolic, respectively.

In a case of the salt wedge existing inside the river, it is already known that $F_1 < 1$ for the inside, $F_1 = 1$ at the river mouth and $F_1 > 1$ for the outside.⁵⁾ This case corresponds to the transonic flow, where the inside is subsonic, the flow at the mouth is sonic, and the outside is supersonic. The reason, why various kinds of flow pattern occur as shown in Fig. 6, seems to depend deeply on the interfacial Froude number F_1 , whose value is determined at the distance far upstream from the mouth or at the front of the salt wedge.

Considering from those evidences described so far, there seems to be a possibility that the entire region including the outside has no

5. ON THE MECHANISM OF MIXING BETWEEN TWO LAYERS

Descriptions in preceding paragraphs are those of hydraulic aspect on the dynamical behavior of the fresh water. In this paragraph, from more physical view points, the mechanism of mixing of the fresh water and the salt water, is examined in detail, by the junior author.

A great number of studies have been made on mixing by many researchers until now, but a decisive explanation on the entire phases in mixing, inside and outside the river mouth, has not been achieved yet. This paragraph is no exception, but some new mechanisms, which seem very important, have been discovered by the author, and then, a new opinion on mixing, inside and outside, will be presented.

As a conclusion, there are three mechanisms. One is that due to breaking of the interface between the fresh water and the salt water, based on the Kelvin-Helmholtz instability. Another is due to the interference of the interfacial gravity wave to the interfacial cusped roughness which arises in a certain condition. The last one is due to vortices generated behind bed irregularities by a strong tidal current.

5-1. Experimental Apparatus and Methods

Fig. 13 shows a general view of the experimental apparatus, which consists of a wide and shallow vessel, $3\text{ m} \times 2\text{ m} \times 0.5\text{ m}$ and a long channel with a rectangular cross-section, $6\text{ m} \times 0.08\text{ m} \times 0.15\text{ m}$. The former corresponds to the sea, and the latter to the river, respectively. The wide vessel is separated, upper and lower, with a vinyl film in order to generate a tide, in the manner that the upper salt water is moved, up and down, by taking in and out another water, from below, under the vinyl film. The surface level can be controlled to follow any tidal change. The controller is illustrated in a block diagram, as shown in Fig. 14.

Experiments were made in two cases, with the bed smooth, and rough with square wooden pieces. The flow, the surface level and the interface level were detected with a light beam illuminated through a very narrow slit, into the direction at a right angle with the channel, and with the aid of a solution of fluorescein sodium as a tracer, as shown

in Fig. 15. This equipment can detect a motion of the tracer at an arbitrarily selected cross-section. Density was measured, through conversion, with an electrode, and a device specially designed to move the electrode, up and down, as shown in Figs. (16) and (17). The level of the electrode can be determined with a potentiometer, which is set in the device.

5-2. The Mechanism of Mixing in a Steady Two-Layered Flow

a) In a case of the outside of the river mouth

If a velocity of the fresh water is small enough, the interface, between the fresh water and the salt water, maintains itself very clearly, even at the distance far from the mouth. In such a case, the horizontal distribution of the fresh-water velocity was already shown in Fig. 8 (a). Once the velocity increases, this figure gradually approaches Fig. 8 (c). As mentioned before, acceleration area appear at both corners of the mouth and on the center line of the flow. In those special areas, the Keulegan number θ^7), which is denoted by $(\epsilon g \nu)^{1/3} / U$, where U is the velocity of the moving layer and ν is a coefficient of kinematic viscosity, is smaller than that of surrounding areas. Unstable interfacial waves appear in those areas, at first, at both corners where the condition that $\theta \leq 0.06-0.07$ is satisfied prior to other places.

Increase of the river discharge brings this condition also into the area on the center line of the flow off the mouth, and unstable waves develop there. Photo 1 shows such unstable interfacial waves, whose growing processes are very smooth with drawing spiral curves. This kind of waves is similar to that Thorpe discovered in an experiment of exchange flow⁸). The generating condition of this wave, which Thorpe determined, was that $\theta \leq 0.06$ and it is very close to that the author discovered. Therefore, it is inferable that the interfacial waves, which were observed by the author on the center line, are based on the mechanism of the Kelvin-Helmholtz instability. Those waves are detectable in laboratory experiments and also in field observations, where an ultrasonic echo-sounder is preferable. When such unstable waves occur at the interface, lumps of clear sea water buoy up intermittently on the surface, which is covered by the muddy fresh water.

b) In a case of the inside of the river mouth

In a steady flow, the upstream velocity within the salt wedge is so weak that no mixing appears, due to vortices which are produced by the interference with bed roughness. Then, the results will be described in a case with a smooth bed, in experiments. Keulegan discovered, in 1949, that the interface was destroyed by breaking of cusps of interfacial gravity waves, in experiments.⁷) The criterion of the limit of such cusped breaking was given by him, with three kinds of channel whose cross-sections were 2 cm \times 4 cm, 4 cm \times 8 cm and 11.3 cm \times 28.5 cm, respectively, as shown in the followings.

$$\theta = 0.178 \quad \text{for } R_e < 450 \quad (18)$$

$$\theta = 0.127 \quad \text{for } R_e > 450 \quad (19)$$

where $R_e = RU/\nu$, R is the hydraulic radius and U is the mean velocity of a moving layer.

Many researchers have accepted that this kind of cusped breaking

is the main cause of mixing in a steady flow. However, the investigation on its detailed mechanism and the theoretical treatments are still unsuccessful, in spite of many efforts paid through a series of studies on the instability of shear flows.

The junior author has discovered a noticeable fact, after a long-termed investigation, that the cusped breaking is induced little by the amplification of wave heights but is produced, in almost all cases, by a superposition of the interfacial gravity waves and a certain kind of waves which have not been detected by anyone yet. Those waves, thus newly found, are cycloidal in shape, as shown in Photo. 2, and differ from any kinds ever known, for example, at a point of their extremely slow motions. They are never believed to be identical to capillary waves at the interface, by comparison of numerical orders of their velocities. They seem to be rather interfacial roughness, than waves.

The breaking of interfacial waves takes place, in fact, in the manner that when any interfacial wave goes over one top of the cycloidal-shaped interfacial roughness, the wave deforms itself due to instability, into a shape of cusp, which grows gradually into a spiral, composed of the fresh water and the sea water, and this mechanism brings mutual entrainment between the two layers.

As shown in Photo. 3, the interfacial cycloidal roughness is caused only by a vortex formed in a spiral-shape, within the salt-water layer between the interface and the no-net-flow layer below. Thus, the spiral vortex plays a leading role over the entire mechanism of this kind of mixing. This vortex is induced by the instability due to the shear flow of the salt water, just below the density interface. Theoretical consideration has already been made, on this mechanism, and published by the junior author.⁹⁾

As mentioned thus far, the cusped breaking was revealed to have a local fine mechanism. Throughout those experiments, the overall condition of the cusped breaking was that $\theta \leq 0.13$, where θ is the Keulegan number. This value is consistent with that proposed by Keulegan, as shown in Eq. 19. It should be stressed that the dimension of the apparatus employed by the author is of the same order with that by Keulegan. Therefore, it is inferable that both the breakings observed by Keulegan and the author, are quite identical. But it must be noticed that the difference of apparatus in scale seems to result a different condition of the cusped breaking. Table 2 shows those different conditions. Limit values of the breaking are shown with θ and R_1 which is the Reynolds number with a representative length taken as a thickness of the moving layer. Although R_1 changes little with a scale of the apparatus, the limit value of θ increases with a growth in scale for the apparatus. There is no any more information yet outside those scales, but it seems certain that the cusped breaking occurs without exception in any scale, if $\theta \leq 0.13$.

It is believed that there must be such a type of mixing inside the actual river mouth, but it is difficult technically to detect it, because the phenomenon is too delicate to catch the entire process, and moreover, the mixing degree is much smaller than that experienced outside, in the type of the Kelvin-Helmholtz instability. Studies in this direction, therefore, should be made with more efforts, in future.

5-3. The Mechanism of Mixing due to Tide

Photo. 2

Photo. 3

Breaking of the interfacial waves by the interference with the roughness formed along the density interface.

Table 2

Cross-section of moving layer	width height 30cm×30cm	width height 8cm×45cm	width height 8cm×15cm
The value of θ , at the limit of cusped breaking	0.215	0.177	0.13
The value of R_1 , at the limit of cusped breaking	1200-1300	1200-1500	1500-3000

It is well known that there can be three types of density current, inside the river mouth, viz., of negligible, of moderate, and of intense mixing. The two-layered flow belongs to the negligible mixing type and the salt wedge develops. This type is, in general, found at a river, which opens its mouth to the sea with a small tidal range. Contrary to this, the intense-mixing type is found in a case with a great tidal range. But, however great it is, the intense-mixing type cannot be reproducible in laboratory experiments, if the channel bed is smooth.

Many opinions agree with each other, about the reason for arising of the intense-mixing type, as that it is the tidal current induced inside the river. But, for the detailed mechanism, opinions are divided, such that, it is the increase of instability of the interface due to shear, breaking of the interface by internal waves, etc.

The junior author has arrived a conclusion that the bed roughness is the most dominant cause for it. In his experiments, even for the strongest tidal current, the interface was always stable, although it oscillated with a large amplitude. The shear flow near the interface, the interfacial wave itself, and the growth of the boundary layer at the bed can never be a destroyer of the interface. The further experiment brought to him a fact that only a single small obstacle at the bed could be a destroyer.

Photo. 4 shows such an example, in which the interface breaks at some distance behind a rectangular wooden piece, 0.6 cm \times 0.6 cm in cross-section, placed on the bed, under the tide of 1 cm in vertical range and of 333 sec. in period. This detailed mechanism is shown very clearly in Photo. 5, in which spiral vortices separate from the piece, next, grow along the border line of the wake behind the piece, and finally attack the interface and destroy it into mixing. But, it is noticeable that if the bed has a single obstacle, the interface, once broken, recovers its form again far downstream, accompanied by the decay of vortices.

Then, the establishment of the intense-mixing type needs a series of successively placed pieces, with suitable spacings. If the spacing is too small, vortices disappear, opposite to expectation, and the interface keeps its identity. According to the experiments, the intense-mixing type develops most effectively, in a condition of the spacing of 10-15 times as long as the height of the piece.

Spiral vortices produced behind the piece are probably caused by the instability of the free boundary layer which is formed downstream from the piece. The experimental results are compared with those obtained through theoretical studies by Lessen¹⁰⁾, and Tatum and Gotoh¹¹⁾, as shown in Fig. 19. The structure of flow at the distance of 2.1 cm behind the rectangular piece is illustrated in Fig. 18, where the uniform velocity U_∞ is 4.0 cm which was measured at a point of onset of unstable waves.

With those values and other data on the wave number κ and the distance x of onset of instability together, the dimensionless wave number $\kappa_* (= \delta \kappa)$ and the Reynolds number $R (= \delta U_o / \nu)$ were obtained as shown in Fig. 19, where $\delta = 0.439 \sqrt{\nu x / U}$ and $U_o = U_\infty / 2$. The calculated values are all within the unstable region, and therefore, the vortices are undoubtedly caused by the instability of the free boundary layer developed behind the rectangular piece.

Photo. 4 The interface breaks at some distance behind a small piece placed on the bed, at the right hand. Vortices induced by a strong tidal current, plays a leading role on the breaking.

Photo. 5 Vortices induced by the tidal current behind a rectangular piece. They are formed through the instability of the free boundary layer behind the piece.

Fig. 18 velocity distribution behind the piece.

Fig. 19 Calculated points are all within the unstable zone. From this, Those vortices are proved to be formed by the instability of the free boundary layer.

CONCLUSION

This paper consists of two main parts, one of which is on the transient behavior of the fresh water, when it passes through a river mouth, and the other is on the mechanism of mixing of two layers inside and outside the river mouth.

In the former, the fresh-water flow is concluded to be dynamically identical with the transonic flow in aerodynamics. In the latter, three types of mixing are described. One is that of the Kelvin-Helmholtz instability, found outside the mouth. Another is a new type due to the interference of the interfacial waves and the roughness at the interface. This type is expected to occur inside the mouth. The last one is that induced by the tidal current.

The former part was made by the senior author and the latter was by the junior author. The authors are deeply indebted to the members of the laboratory, for their helpful collaboration, in field measurements, laboratory experiments and other works for preparing this paper.

CHAPTER 181

THERMAL AND BIOLOGICAL IMPACT OF LNG VAPORIZER DISCHARGE

BY

PETER A. MANGARELLA AND GORDON A. ROBILLIARD*

ABSTRACT

A simplified steady state multilayered (horizontally homogeneous) thermal model is described and applied to assess the effects of the cold water discharge created by a proposed liquid natural gas (LNG) regasification facility. The model, similar to ones developed for predicting average cooling pond performance, accounts for advection and diffusion between layers, atmospheric and solid boundary heat exchange, and heat exchange due to tidal and density currents. For the configuration in which both the intake and discharge were located in a dredged turning and docking basin, recirculation created thermal deficits from -8°C to -17°C . Adverse environmental effects on migrating species (particularly various life stages of shrimp) and the benthic community and costs associated with auxiliary seawater heating suggested that other alternatives (such as a separate intake basin or an offshore diffuser) would be more appropriate.

*Senior Project Engineer and Senior Aquatic Biologist, Environmental Systems Division, Woodward-Clyde Consultants, 3 Embarcadero Center, San Francisco, California U.S.A.

INTRODUCTION

The importation of LNG requires the construction and operation of regasification facilities. In the process of vaporizing the LNG energy is required. In the case considered* the energy source was the water in a nearby bay. The vaporization process utilized a once-through system in which seawater drawn from the bay passed through the vaporizers, was cooled and then discharged back into the bay.

The bay, created by a barrier island, has a relatively uniform depth of around 3.5 m. The principal navigational channel in the bay is dredged to 11 m and is located approximately 1000 m offshore of the site. To accommodate the LNG carriers a turning and docking basin and approach channel dredged to 12.5 m was required. A typical cross section of the turning basin for a nearshore location is shown in Figure 1. The surface area of the turning and docking basin was about 1 square kilometer.

Since the bay is an estuarine system, the salinity varies spatially and temporally in response to freshwater inflow and tidal exchange with the Gulf of Mexico. Maximum salinity (~30 ppt) occurs near the tidal passes. The shallowness of the bay coupled with wind and tidal induced mixing promote vertically well-mixed conditions. However, in the deeper navigational channels Holmes (1977) indicates that strong longitudinal and vertical stratification may occur. The tides are classified as mixed and have a maximum astronomical range of about 0.5 m.

The proposed average production of natural gas was approximately 26 million cubic meters per day requiring a seawater flowrate of $92 \text{ m}^3 \text{ sec}^{-1}$. The temperature drop through the vaporizers (Figure 2) for average plant output varied from about -4.5°C to -5°C . For intake temperatures below 9°C auxiliary heating of the intake water was required to safeguard against ice formation in the vaporizers.

The original design called for discharging the colder water from the vaporizers into the bottom of the turning basin and withdrawing the water from near the surface of the same basin. The horizontal distance between the intake and discharge was about 950 meters.

It was reasoned that the continuous discharge of cold water into the bottom of the turning basin would tend to create a stratified thermal regime analogous to that found in a cooling pond. The discharge would create density currents which will spread out from the discharge point and create a cold layer of water extending over much of the bottom of the turning basin.

*This paper reports the findings of special studies associated with the environmental impact assessment of a proposed LNG regasification facility located on the Gulf Coast.

Figure 1. TYPICAL SECTION OF TURNING BASIN

Figure 2. TEMPERATURE DROP ACROSS THE VAPORIZERS VERSUS INTAKE SEAWATER TEMPERATURE

On the other hand wind and tidal-induced mixing would tend to destratify the basin. Vertical and longitudinal mixing would also be created by interaction of tidal and density influenced flow between the approach channel and the turning and docking basin. It was concluded that, in spite of vertical mixing which might create local vertical well-mixed conditions for short time periods of the order of several days to a week, the monthly average condition would be adequately described by assuming a stably stratified system.

THERMAL MODEL

The conceptual model of a three-layered, stratified system and of the principal flow and heat exchange mechanisms governing the thermal balance in the basin is shown in Figures 3 and 4 using standard notation. The conservation equations for flow and energy applied to each layer form the basis of the model. Other elements of the model are: empirical surface and bottom heat exchange relations, estimates of mass and energy flux associated with tidal and density-induced currents, and the vaporizer temperature differential relationship already discussed.

The relationship for atmospheric heat exchange used the simplified rate equation relating heat flux to temperature differential via a heat exchange coefficient which is a function of wind speed and water temperature (Ryan and Stolzenbach, 1972). The values of the heat exchange coefficient and equilibrium temperature were computed from average monthly meteorological data. The bottom heat exchange was calculated using a similar formulation.

The mass and energy flux associated with density currents in the approach channel was based on a simplified counterflow model (Schijf and Schonfeld, 1953). The model assumed that the cold bottom layer of water in the turning basin would create a density flow out of the basin along the approach channel. Typical values of the calculated density current flowrate were $2.1 \text{ m}^3 \text{ sec}^{-1}$ for July and $1.4 \text{ m}^3 \text{ sec}^{-1}$ for January. The average tidal flowrate (over a half tidal cycle) in the approach channel was estimated at $3.5 \text{ m}^3 \text{ sec}^{-1}$ based on an estimate of the tidal prism.

The surface currents in the bay were quite strong because of the proximity of the site to major tidal passes. Given the strong surface currents it was assumed that the temperature of the surface layer of the turning basin (when located at either of two offshore sites) equalled the ambient surface temperature of the bay.

Diffusive flux between the surface and intermediate layers was calculated using the eddy diffusivity formulation given by Kullenberg (1971). The eddy diffusivity, a function of wind speed, stratification, and the vertical current shear, was of the order of 10^{-1} to $10^{-2} \text{ cm}^2 \text{ sec}^{-1}$ depending on the month and the intake discharge configuration.

Figure 3. CONCEPTUAL MODEL OF FLOW WITHIN THE TURNING BASIN

Figure 4. CONCEPTUAL MODEL OF HEAT EXCHANGE MECHANISMS WITHIN THE TURNING BASIN

The accuracy of the model is limited more by the deficiencies and assumptions used in conceptualizing the model than by the accuracy of the input data. The accuracy of similar cooling pond models (which do not involve many of the exchange processes considered here) has been examined by Ryan (1972). In general, Ryan found that comparisons of field data with model predictions were satisfactory after a suitable calibration. In this case no data were available for calibration and the results must therefore be considered preliminary. In spite of suspected deficiencies in the absolute accuracy of the model, results were of practical value in comparing the relative merits and deficiencies of alternative intake discharge configurations.

MODEL RESULTS

The model was applied to a series of intake-discharge configurations in which both the configuration and offshore location of the basin were varied (Table 1). As discussed earlier, these alternatives were considered after significant recirculation problems were discovered for the initial configuration (C1). Note that an offshore diffuser was also considered (C4).

Typical model predictions for the temperature of the bottom layer of the basin are given in Figures 5 and 6. Recirculation was predicted for all cases in which both the intake and discharge are in the same basin and the intake withdraws from the intermediate layer. During the winter (November through March) auxiliary heating was required for these cases. An estimate of the magnitude of the heating requirements is given in Table 2. Recirculation caused the temperature deficits to be a maximum in the summer as the surface layer warms and diffusive heat exchange between the surface and intermediate layer was limited by the stratification. For other cases the temperature deficit is relatively constant throughout the year.

ENVIRONMENTAL IMPACT OF INTAKE DISCHARGE CONFIGURATIONS

The major environmental impacts associated with the intake and discharge of seawater are (1) entrainment and impingement of organisms as a result of seawater intake, (2) cold shock to migratory organisms due to discharge of cooled seawater, (3) development of a cold water benthic community in the turning basin.

Among the cases analyzed (Table 1) the basin located at the 1-m isobath is less desirable than at the 2-m or 3-m isobaths because it is closer to the nearshore, shallow-water migration routes of shrimp and fish, and entrainment/impingement impacts are expected to be greater. There is relatively little difference between the impacts at the 2-m and 3-m isobaths: However, in cases A2 and B2, withdrawing water from

**Intake withdraws 1/4 of total intake flowrate from surface layer, 3/4 from intermediate layer.

the surface layer would have potentially greater entrainment and impingement impacts because there tend to be more planktonic larval forms in the surface water layers.

Only in cases A1, B1 and C1, where the intake and discharge are both in the turning basin, and the intake withdraws water wholly from the turning basin, is there a potential ecologically significant difference in thermal regimes among turning basin locations. The 1-m location (case C1) is expected to result in a greater maximum cold shock impact than the 2-m or 3-m locations (cases B1 or A1).

Based on the assessment of thermal impact alone, the four intake-discharge configurations can be compared as follows. Discharge offshore (case C4) and intake in a separate basin (cases A3, B3 and C3) are expected to have the least impact; but one does not appear to be distinctly better than the other. Cases A2 and B2 are expected to have an intermediate level of impact. The greatest impacts are expected in cases A1, B1, and C1, primarily due to the accumulation of cold water in the bottom of the basin.

SUMMARY

A simplified steady state thermal model assuming horizontally homogeneous thermal conditions was useful in comparing the relative thermal impact created by several intake discharge configuration for an LNG regasification facility. Recirculation appeared to be a serious problem when both the intake and discharge were in the basin and the intake withdrew from below the surface of the upper mixed layer.

CHAPTER 182

PREVENTION OF FREEZING IN FJORDS

by

SVEINUNG SÆGROV[†]

ABSTRACT

Criteria for the design of outlet arrangements from hydro-electric power stations, necessary to prevent ice formation in fjords in the winter months, are presented. The initial entrainment of seawater to the fresh water discharge has been investigated by means of laboratory models. A numerical model of the fjord dynamics, as well as a simplified analytic model, is used to study the estuarine circulation and entrainment in the fjord. Heat loss to the atmosphere is parametrized using small modifications of well known empirical formulas.

INTRODUCTION

As a result of power development, the fresh water supply to several Norwegian fjords is or will be increased during the winter months. This may lead to more severe ice conditions in cold periods. There are two reasons to avoid this: first, necessary ship traffic in the fjords will be obstructed; and second, there is a possibility of climate changes, due to an ice-covered fjord, that may be disastrous for fruit harvests.

[†] Address: River and Harbour Laboratory
Klaebuveien 153, N 7034 Trondheim, Norway.

By mixing the fresh water from the power station with warmer, more saline water in the fjord, the risk of freezing may be reduced. One way of doing this, is to discharge the fresh water below the pycnocline with a considerable velocity. The principle may be compared with the dilution of a submerged sewage outlet. In our case, however, the fresh water discharge is much greater and will influence the currents in the whole fjord.

The purpose of our investigations is to find the necessary mixing of fresh water with saline water to prevent freezing, and the discharge velocity and depth which will give this mixing.

FJORD DYNAMICS AND INITIAL MIXING

A typical Norwegian fjord shows large variations in the width, and usually one or more narrows are to be passed before the fresh water reaches the sea. Figure 1 shows the most important hydraulic conditions of a typical fjord. The fresh water discharge mixes with the fjord water and forms a brackish layer. If the fjord is deep, and the tidal and wind effects are of minor importance, it can be shown that the velocity and the depth of the brackish layer passing through the entrance of the fjord correspond to a densimetric Froude number for the brackish layer (F_d^1) equal to 1. This is called a hydraulic control. The densimetric Froude number is defined in this way:

$$F_d^1 = \frac{u}{\sqrt{g \cdot \frac{\Delta\rho}{\rho} \cdot h}} \quad (1)$$

where

u is the velocity of the brackish layer, h is the depth, ρ is the density, $\Delta\rho$ is the density difference between the layers and g is the acceleration of gravity.

Figure 1. Some characteristics of fjord dynamics. u_{lm} is the velocity of the brackish water at the mouth, h is the thickness of the brackish water, ρ_1 is the density of the brackish water and ρ_2 is that of the fjord water.

The control condition also determines the depth of the brackish layer inside the fjord mouth. For further discussion of this see BINNEY (1972).

In many cases the fjord is narrow and the effects of the Earth's rotation can be neglected.

The details of the initial mixing process, which occurs at the fresh water outlet, are shown in Figure 2.

Figure 2. Mixing of fresh water and salt fjord water near the outlet. H is the outlet depth, D is the diameter and h is the thickness of the brackish layer in the fjord.

The discharge water enters the recipient with a considerable velocity (2-5 m/s). In the area near the outlet, the velocity leads to an intense mixing with the saline fjord water. The jet rises to the surface, and forms a brackish water current towards the fjord mouth. The influence of wind tends to maintain the turbulence in the upper brackish layer, and leads to entrainment to the brackish layer from below.

A typical density profile of the fjord is also shown in the figure. The brackish layer is rarely fully mixed and has therefore a density gradient.

LABORATORY EXPERIMENTS

The near field mixing is investigated quantitatively in a laboratory model. The experimental setup is shown in Figure 3.

Figure 3. Arrangement for the laboratory experiments.

Fresh water is discharged into the salt water reservoir through tubes of various diameters and at various depths.

The width of the fjord mouth must be correctly scaled in the reservoir to simulate the hydraulic control (STIGEBRANDT 1975).

The brackish water is sucked from the surface by an arrangement which consists of a plate to prevent suction from the lower layer, and 4 pipes placed at an angle to the surface. In this way, the suction has no effects on the reservoir currents.

To maintain stationarity, salt water is supplied to the reservoir by means of a diffuser. This has a considerable outlet area to avoid turbulence. To avoid dynamic effects of the flow, a rough estimate of necessary salt water discharge has

to be made for each test.

During the experiments, horizontal and vertical profiles of salt and velocity are measured at the section shown in Figure 3.

The laboratory experiments are scaled geometrically according to the Froude scaling, that is that the Froude number F_d is the same in model and prototype (reality) (ABRAHAM, 1975). The definition of F_d for this purpose is:

$$F_d = \frac{u_o}{\sqrt{g \cdot \frac{\Delta\rho}{\rho} \cdot D}} \quad (2)$$

where

- u_o = discharge velocity,
- D = outlet diameter,
- $\Delta\rho$ = density difference fjord water-fresh water,
- ρ = density of fresh water,
- g = gravity acceleration

This gives the following scaling ratios, where the index m represents the model scale, p the prototype scale and r the ratio between the two.

Length scale	$L_r = L_m/L_p$
Volume scale	L_r^3
Time scale	$L_r^{0.5}$
Velocity scale	$L_r^{0.5}$
Discharge scale	$L_r^{2.5}$

In our tests we have used $L_r = 1:300$ for scaling ratios.

The experiments are carried out under the assumption that the topography has no prohibitive effect on the initial mixing process.

The results from the laboratory experiments are shown in Figures 4 and 5. Figure 4 shows how the mixing ratio P , defined as the brackish water flux through the measuring section relative to the fresh water discharge, depends on the densimetric Froude number F_d and the relative outlet depth of the jet H/D . Increased F_d or relative depth leads to increased mixing.

Figure 4. Mixing due to outlets below the brackish layer. P is the mixing ratio, F_d is the densimetric Froude number, H the outlet depth and D the outlet diameter.

As shown earlier, the densimetric Froude number depends on discharge velocity, diameter and density difference between

the fresh water and the fjord water.

A larger velocity gives a more intense mixing. In addition, the jet passes a longer distance before it reaches the surface. A smaller diameter, for example by using two outlet openings, leads to a larger contact area between the fresh water jet and the surrounding fjord water. All these effects lead to greater mixing, in accordance with the figure.

When the outlet depth is increased, the jet has a longer ascent through the fjord water. Increased depth also leads to a more vertical path for the jet. Experiments show that this leads to a greater mixing and a more homogeneous brackish layer.

When the outlet is near the surface, one has to take into account the thickness of the brackish water layer. Figure 5 shows some test results for outlets in or near the brackish layer. The figure shows how the mixing ratio P depends on the densimetric Froude number F_d and the thickness of the brackish layer compared to the outlet depth.

The figure clearly shows that for a given F_d , the mixing ratio will decrease if the thickness of the brackish layer increases or the outlet depth becomes smaller. One reason for this effect may be reentrainment of brackish water. This makes the mixing between fresh water and fjord water less efficient.

Figure 5. Mixing of fresh water outlets near the surface. P is the mixing rate, F_d is the densimetric Froude number, h the thickness of the brackish layer and H the outlet depth.

In Figure 6, the laboratory results are combined in a different way. The figure shows how the mixing ratio depends on the energy loss and the relative outlet depth. The energy loss at the outlet is defined as

$$h_f = \frac{u_o^2}{2g} + \frac{\Delta\rho}{\rho} \cdot H \quad (3)$$

The symbols are defined in eq. 2.

Figure 6. Mixing rate in the near field. Dependence of energy loss.

According to the results, there is an optimal outlet depth which is ca. 8 times the outlet diameter.

The laboratory experiments also show that there may arise a considerable stratification in the brackish water layer. The stratification is important because it prevents some of the heat content in the brackish layer from reaching the water surface. A criterion which we have applied is that we can use the entire brackish water as a heat magazin, provided the salinity difference within the brackish layer is less than 2 ppt. This limit is based on experience, and depends on wind homogenizing and convection due to cooling of saline surface water.

There is obviously a connection between the stratification and the mixing ratio. The higher the mixing ratio, the more complete is the mixing between the fresh water and fjord water.

HEAT TRANSPORT

The heat transport through the surface is governed by many meteorological processes. The main contributions in our cases are short and long wave radiation, evaporation, condensation and conduction. For the heat exchange between water and atmosphere, the following empirical equations are used:

Short wave radiation

$$H_s = (0.93 - C^2) H_{sc} \cdot (1-f) \quad (4)$$

C = cloud cover,

H_{sc} = sun radiation (W/m^2),

f = albedo of the surface, depends on latitude and time of day.

Only a fraction of the short wave radiation is absorbed by the water masses, the other part is reflected back to the atmosphere. The contribution from short wave radiation is not significant during the winter season.

Long wave radiation

$$H_l = 0.97 \cdot \sigma (T_a^4 (1 - 0.26 \exp(0.000888 T_a^2)) - T_s^4) \quad (5)$$

σ = Stefan Boltzmann constant = $5.67 \cdot 10^{-8} W/(\text{°K}^4 m^2)$

T_a = air temperature (°K)

T_s = surface temperature. (°K)

The long wave radiation is important for the heat budget. The sea surface radiates almost as a black body, and the outgoing energy from the long wave radiation is proportional to the fourth power of the absolute temperature. This is also a considerable amount of incoming energy due to long wave radiation.

Evaporation, condensation and conduction

$$H_e + H_c = - f(W) [(e_s - e_a) + C_1(T_s - T_a)] \quad (6)$$

e_s = saturation pressure at temp. T_s (mb)

e_a = vapour pressure at 2 m level (mb)

C = 61.3 Pa/°K

$f(W)$ = wind function.

Evaporation, condensation and conduction processes at the surface of the water depend on relative humidity and the temperature difference between air and water surface.

They also depend on the wind. This dependence is given by a wind function $f(W)$, which accounts for the forced convection of heat from the water surface due to shear generated motions in the air.

Wind function

$$f(W) = 0.027 (T_{sv} - T_{av})^{1/3} + 0.031 W \quad (7)$$

W = wind velocity (m/s)

$T_{sv} = T_s / (1 - 0.378 \frac{e_s}{p})$

$T_{av} = T_a / (1 - 0.378 \frac{e_a}{p})$

p = atmospheric pressure (10^2 Pa)

The total amount of heat exchange between water and atmosphere can be written as

$$H_n = H_s + H_l + H_e + H_c \quad (8)$$

Further details are given in RYAN et al. (1975).

MODEL OF THE ESTUARINE CIRCULATION

To account for the effect of mixing and cooling in the fjord, a numerical model of the fjord circulation has been developed.

The model describes the fjord circulation as a two layer system, in accordance with Figure 1. The upper layer of brackish water moves towards the fjord mouth, and a weak compensation current below the brackish water current supplies the brackish water to the mixing regions.

The equations for the brackish layer are developed from a work by STOMMEL and FARMER (1952) and presented in AUDUNSON et.al. (1976).

The equations are:

Conservation of volume

$$\frac{d(u h b)}{dx} = w_e b \quad (9)$$

Conservation of salinity

$$\frac{d(u h b S_1)}{dx} = w_e S_2 b \quad (10)$$

Conservation of momentum

$$\frac{d}{dx} (u^2 h b) - u w_e b = - g h b \frac{d\zeta}{dx} - \frac{1}{2} g h^2 \frac{b}{\rho_1} \frac{d\rho_1}{dx} + \left(\frac{\tau_\zeta}{\rho_1} - \frac{\tau_h}{\rho_1} \right) b \quad (11)$$

where w_e is the entrainment velocity, u the velocity of the brackish layer, h the thickness of the brackish layer, b the width of the fjord, S_1 the salinity of the brackish layer, S_2 the salinity of the fjord water, ζ the surface level, ρ_1 the density of the brackish layer, τ_ζ the friction force at the surface and τ_h the friction force at the boundary layer.

Further, a shear stress between the two layers, proportional to the square of the velocity, is included. (LONG, 1975). The lower layer is assumed to be in hydrostatic equilibrium

The boundary conditions are the volume flux, temperature and salinity of the mixing near the outlet of fresh water. In addition, the air temperature and the wind distribution within the fjord area are important input data. To simulate correct control condition, the width of the narrows is an important boundary condition. The density of the water is assumed to be independent of temperature.

The model contains the equations (4) - (8) for heat exchange with the atmosphere.

The equations are solved by means of the Runge Kutta integration method. From these equations and boundary conditions, the model gives values of temperature, salinity, velocity and thickness of the brackish layer step by step along the fjord.

The necessary initial mixing to keep the water temperature at the mouth of the fjord over the freezing point is estimated from the model by trial and error.

More details of the model are given in Norwegian by AUDUNSON et.al (1976).

SIMPLE SOLUTION FOR NECESSARY MIXING RATE

For small fjords, a simple solution gives the necessary mixing rate with sufficient accuracy.

To keep the fjord free from ice, the heat loss from the surface must be balanced by the heat supply from the initial mixing and heat supply from entrainment to the more turbulent upper layer.

In many cases, the heat supply from wind entrainment is negligible compared to initial entrainment. The heat supply of the fresh water **discharge** is also usually negligible. The equations for heat loss and heat supply can therefore be written as follows:

$$\text{Heat loss: } A \cdot H_n \quad (12)$$

$$\text{Heat supply: } (P-1)q_f \cdot \rho_2 \cdot C_p \cdot (T_b - T_s) \quad (13)$$

H_n = heat transport through the surface

A = surface area

P = mixing ratio

q_f = fresh water discharge

ρ_2 = density of fjord water

C_p = heat capacity

T_D = fjord temperature at the outlet depth

T_S = surface temperature.

The necessary mixing ratio P to prevent freezing in the fjord is thus

$$P = 1 + \frac{A \cdot H_n}{q_f \cdot \rho_2 \cdot C_p \cdot (T_D - T_S)} \quad (14)$$

In this simple analytic calculation, mean values of wind, air temperature, fjord temperature and salinity over the whole fjord basin are used. Comparisons between this calculation and the numerical model show little difference. With the above calculation, the necessary mixing ratio is overestimated by less than 10%.

APPLICATIONS

The above methods have been used to recommend design depths and diameters of the discharge tunnels from several planned power stations. In one case it has been prescribed how to regulate the fresh water discharge and the discharge velocity for various meteorological conditions (MATHISEN and SÆGROV 1977).

Figure 7 is a scheme of how the discharge should be varied to avoid freezing in the Aurland fjord with different air temperatures. The outlet consists of two tunnels, denoted R1 and R2. The one (R1) has a diameter of 3.1 m and the other one has a diameter of 3.6 m.

The depth of both is about 20 m. With two outlet tunnels one obtains a flexible arrangement to take care of variable fresh water discharges.

WIND (m/s)	SEATEMP. (°C)	OUTLET TUNNEL	AIRTEMPERATURE (°C)		
			-1 - -2	-2 - -5	-5 - -10
< 4 m/s	< 10 °C	R1	25 - 31	27 - 33	30 - 37
		R2	31 - 45	33 - 47	37 - 52
		R1 + R2	45 - 75	47 - 75	52 - 75
	> 10 °C	R1	22 - 26	24 - 28	27 - 31
		R2	26 - 37	27 - 41	31 - 46
		R1 + R2	37 - 75	41 - 75	46 - 75

Figure 7. The figure shows a plan to avoid ice formation during light winds with various air temperatures in the Aurland fjord. Due to variations of sea temperature and air temperature, the outlet opening and the fresh water discharge are to be varied according to the scheme. Numbers refer to the necessary discharge in m^3/s .

The scheme applies for a wind force less than 4 m/s. There are alternative schemes for sea temperature at the outlet depth less than $10^\circ C$ and higher than $10^\circ C$, and for various air temperatures.

Example: The sea temperature is less than $10^\circ C$, wind is less than 4 m/s, air temperature $-4^\circ C$ and the fresh water discharge is restricted to $40 m^3/s$. Then, according to Figure 7, the discharge of fresh water through the R2 tunnel will prevent ice formation. The energy cost amounts to a 1.3 m pressure height loss.

The energy cost of the method is estimated to 1-2 m pressure height loss for the conditions included in Figure 7.

The method presented here will be used at two Norwegian power

stations which are now under construction.

DISCUSSION

Several mathematical models are available for computing the dilution of buoyant discharges in stratified recipients. These models are useful for sewerage outlets. The fresh water supply from a hydro power plant, however, is an order of magnitude larger. This makes use of common mathematical models for the initial mixing doubtful. For example, due to the large amount of fresh water discharge, there is a considerable amount of kinetic energy left when the jet reaches the surface. The mathematical models do not take account of the mixing effect of this energy. Further, the width of the fjord mouth will control the stratification and thereby the residence time of the brackish water in the fjord. It is not possible to include this effect in the mathematical models for the initial dilution. To investigate the fresh water discharge from hydro power plants to fjords, laboratory studies are therefore necessary at the present state of the art.

The general laboratory studies which are discussed in this paper do not cover all of the hydraulic conditions one may expect in an arbitrary fjord. The width of the fjord mouth should be correct to ensure a correct stratification. The topography near the outlet may be of great importance. This has to be investigated for each case. The results presented here may be used as a first estimate for the design of an outlet arrangement to keep the fjord ice-free.

To develop the present method, a number of difficulties had to be overcome. The result gives a somewhat rough picture of one method for solving ice problems. The simple analytical calculation for the necessary initial

mixing uses average values of temperatures and wind over the whole fjord. The numerical model uses some simplifications for the circulation patterns of the fjord. The equations for heat exchange with the atmosphere are based on a large amount of data. However, the scatter is considerable. The wind function is based on data measured at rather high temperatures (25-30°C) and is subjected to some uncertainty for low temperatures. The laboratory results also show some scatter. Therefore, a great deal of work remains to be done to improve the method.

In 1981 the first power plant employing this method to prevent freezing will commence. This will give an opportunity to check the results at full scale.

Another device to obtain the necessary initial mixing, is a bubble curtain placed across the mouth of a river or a channel. This has also been studied at the River and Harbour Laboratory. A bubble curtain has been successfully used at the mouth of the Rana river for more than a decade (CARSTENS 1971).

ACKNOWLEDGEMENTS

The work that is presented here is a result of the efforts of a number of scientists at the River and Harbour Laboratory. In particular, research work conducted by T. Audunson, J.P. Mathisen, T. McClimans and A. Stigebrandt should be mentioned. The author wishes to thank T. McClimans and H. Rye for valuable advice and encouragement during this work.

The work has been supported by Konesesjonsavgiftsfondet, (Found of license fees) administered by the Norwegian Water Resources and Electricity Board.

Beach Cusps and Edge Waves, David A. Huntley and A. J. Bowen, 1378
- Bed forms; Discharge (water); Dunes; Flow rates; Sediment deposits; Time dependence; Unsteady flow; Water depth**
Time Lag of Dunes for Unsteady Flow Conditions, Horst Nasner, 1801
- Bed forms; Friction coefficient (hydraulic); Hydrodynamic pressure; Hydrodynamics; Numerical analysis; Ocean bottom; Ripple marks; Tidal effects**
The Influence of Dune and Flow Parameters on the Friction Factor, Jurgen Sundermann, H. Vollmers and W. Puls, 1787
- Bed roughness; Distortion; Friction coefficient (hydraulic); Laboratory tests; Mathematical models; Numerical analysis; Tidal effects; Acceleration**
Numerical Study of Distortion in a Froude Model, T. A. McClimans and S. A. Gjerp, 2887
- Bed roughness; Estuaries; Mixing; Rivers; Saline water-freshwater interfaces; Salinity; Stream flow; Velocity distribution; Vortices; Wave energy**
Outflow Dynamics at a River Mouth, Masakazu Kashiwamura and Shizuo Yoshida, 2925
- Biological properties; Density currents; Discharge (water); Heat exchangers; Liquid natural gas; Model studies; Thermal pollution; Tidal currents; Vaporizers**
Thermal and Biological Impact of LNG Vaporizer Discharge, Peter A. Mangarella and Gordon A. Robilliard, 2945
- Bores (wave); Breaking energy; Energy dissipation; Energy losses; Predictions; Random processes; Shallow water; Wave height**
Energy Loss and Set-Up Due to Breaking of Random Waves, J. A. Battjes and J. P.F.M. Janssen, 569
- Bores (wave); Breaking energy; Hydraulic jump; Water depth; Wave height; Wave propagation; Waves; Wave velocity**
Spilling Breakers, Bores and Hydraulic Jumps, D. H. Peregrine and I. A. Svendsen, 540
- Bores (wave); Field tests; Littoral current; Model tests; Storms; Surf; Water circulation; Water levels; Wave height; Waves; Wind; Bathymetry**
Comparison of Model and Observed Nearshore Circulation, James H. Allender, John D. Ditmars, Wyman Harrison and Robert A. Paddock, 810
- Bottom sediments; Dredges; Dredging; Models; Sediments; Spoil; Spoil banks; Beach nourishment**
Importance of Handling Losses to Beach Fill Design, R. D. Hobson and W. R. James, 1873
- Boundary conditions; Coastal plains; Mixing; Ocean engineering; Ocean waves; Rivers; Runoff; Suspended sediments; Two-dimensional; Wave propagation; Wind loads**
Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Boundary conditions; Forecasting; Morphology; Stability analysis; Tidal currents; Tidal flats; Tides; Two-dimensional; Water depth**
Two-Dimension Stability Analysis of Tidal Basins and Tidal Flats of Larger Extent, Eberhard Renger, 1971
- Boundary conditions; Mathematical models; Sand; Shear stress; Turbulent flow; Velocity distribution; Wave propagation; Wave velocity**
Near-Bottom Velocities in Waves with a Current, W. T. Bakker and Th. van Doorn, 1394
- Boundary conditions; Netherlands; Responses; Storms; Storm surges; Surveys (data collection); Tidal hydraulics; Water levels; Barriers**
A Tidal Survey for a Model of an Offshore Area, W. J. van de Ree, J. Voogt and J. J. Leendertse, 2656

- Boundary layer flow; Continental shelf; Currents (water); Littoral current; Nicaragua; Pressure gradients; Salinity; Suspended sediments**
Shelf and Coastal Boundary Layer Currents, Miskito Bank of Nicaragua, Richard L. Crout and Stephen P. Murray, 2715
- Brazil; Current meters; Harbor facilities; Littoral current; Littoral drift; Water depth; Wave height; Wave period; Wave recorders (water waves); Wave spectrum**
Coastal Study of Espirito Santo Brazil, Paulo Augusto Vivacqua, Hildebrando de Araujo Goes Filho and Octavio de Sampaio Ferraz Jardim Sayao, 2104
- Brazil; Meteorology; Ocean waves; Wave action; Wave energy; Wave height; Wave period; Wave recorders (water waves)**
Wave Climate in Some Zones off the Brazilian Coast, Alberto Homsí, 114
- Breaking energy; Classification; Field tests; Photographic analysis; Predictions; Water depth; Wave height; Wavelength; Waves**
Field Study of Breaking Wave Characteristics, Lee L. Weishar and Robert J. Byrne, 487
- Breaking energy; Coring; Histograms; Sediment deposits; Surf; Tidal effects; Tracers; Wave action; Wave height; Beaches**
Depth of Disturbance of Sand in Surf Zones, Michael K. Gaughan, 1513
- Breaking energy; Deep water; Particle trajectories; Slope; Velocity; Waves; Wave velocity; Beaches**
Estimation of Water Particle Velocity of Breaking Wave, Tetsuo Sakai and Yuichi Iwagaki, 551
- Breaking energy; Energy dissipation; Energy losses; Predictions; Random processes; Shallow water; Wave height; Bores (wave)**
Energy Loss and Set-Up Due to Breaking of Random Waves, J. A. Battjes and J. P.F.M. Janssen, 569
- Breaking energy; Hydraulic jump; Water depth; Wave height; Wave propagation; Waves; Wave velocity; Bores (wave)**
Spilling Breakers, Bores and Hydraulic Jumps, D. H. Peregrine and I. A. Svendsen, 540
- Breaking energy; Ocean waves; Probability density functions; Probability theory; Secondary waves; Surf; Wave height; Wave period; Waves; Wave spectra**
Probability Density Functions of Breaking Waves, Edward B. Thornton and George Schaeffer, 507
- Breakwaters; Coastal engineering; Coastal structures; Floating bodies; Oil spills; Tires; Wave action; Wave attenuation**
Scrap Tyre Breakwaters in Coastal Engineering, Robert Charles McGregor and Neil Sinclair Miller, 2191
- Breakwaters; Coastal plains; Damage; Estuaries; History; Hydraulic models; Armoring (streambed) Models — Can We Learn from the Past? Some Thoughts on the Design of Breakwaters, W. A. Price, 25**
- Breakwaters; Coastal plains; Diffraction; Groins (structures); Jetties; Littoral drift; Numerical analysis; Predictions; Refraction; Sediment transport; Barriers; Beaches**
Prediction of Beach PlanForms with Littoral Controls, Marc Perlin and Robert G. Dean, 1818
- Breakwaters; Coastal structures; Erosion control; Littoral zone; Marine terminals; Piers; Rubble-mound breakwaters; Sands; Shore-line cover; Beach erosion**
Coastal Structures' Effects on Shorelines, Ronald M. Noble, 2069
- Breakwaters; Computer programs; Harbors; Hydraulic models; Numerical analysis; Wave diffraction; Wave height; Wave reflection**
A Numerical Approach for the Determination of the Wave Height Distribution in a Harbour, Soren Kohlhase, Karl-Friedrich Daemrich, U. Berger, E. Tautenhain and O. Burkhardt, 664
- Breakwaters; Damage; Hydraulic models; Rubble-mound breakwaters; Stability; Wave energy; Wave height; Wave spectra; Wave tanks**
Effects of Wave Grouping on Breakwater Stability, R. R. Johnson, E. P.D. Mansard and J. Ploeg, 2228
- Breakwaters; Density; Flumes; Slope stability; Stability; Standardization; Test reproducibility; Tests; Armoring (streambed)**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwiaborn, 2285
- Breakwaters; Diffraction; Ocean waves; Random processes; Wave diffraction; Wave height; Wave reflection; Wave spectra**
Diffraction Diagrams for Directional Random Waves, Yoshimi Goda, Tomotsuka Takayama and Yasumasa Suzuki, 628
- Breakwaters; Diffraction; Sediment transport; Wave diffraction; Wave height; Wave phases; Bathymetry; Bays (topographic features); Beach erosion; Beaches**
Diffraction Calculation of Shoreline PlanForms, Robert G. Dean, 1903
- Breakwaters; Dredging; Hydraulic models; Inlets (waterways); Jetties; North Carolina; Sediment deposits; Simulation; Spoil banks; Beaches**
Coastal Processes at Oregon Inlet, North Carolina, James T. Jarrett, 1257
- Breakwaters; Experimentation; Friction coefficient (hydraulic); Ocean waves; Predictions; Wave dispersion; Wave height; Wave reflection**
Wave Transmission through Trapezoidal Breakwaters, Ole Secher Madsen, Paisal Shusang and Sue Ann Hanson, 2140
- Breakwaters; Field tests; Harbors; Laboratory tests; Models; Prototypes; Wave recorders (water waves); Waves**
A Comparison Between Model and Prototype Waves in Harbours, Sverre Bjordal and Alf Torum, 677
- Breakwaters; India; Performance; Shape; Silting; Underwater structures; Wave attenuation; Barriers**
Performance Characteristics of Submerged Breakwaters, J. Dattatri, H. Raman and N. Jothi Shankar, 2153

- Breakwaters; Japan; Land reclamation; Littoral current; Littoral drift; Movable bed models; Ocean bottom; Sediment transport; Waves**
Estimation Using a Movable Bed Model of Shoreline Change Caused by a Reclamation Projected into the Sea, Shoji Sato and Hiroaki Ozasa, 1839
- Breakwaters; Laboratory tests; Wave diffraction; Wave energy; Wave generation; Wave recorders (water waves); Wave spectra; Wind forces; Wind pressure**
Wind-Generated Wave Diffraction by Breakwater Gap, Hooshang Raissi and R. L. Wigle, 609
- Breakwaters; Maintenance; Site selection; Storm surges; Tidal effects; Tidal waters; Wave height; Wave period; Australia**
Rosslyn Bay Breakwater, Queensland, Australia, D. N. Foster, B. L. McGrath and W. Bremner, 2086
- Breakwaters; Model tests; Reflection; Refraction; Walls; Wave action; Wave diffraction; Wave reflection**
Influence of Breakwater-Reflection on Diffraction, Karl-Friedrich Daemrich and Soren Kohlhasse, 651
- Breakwaters; Ocean waves; Pneumatic systems; Underwater structures; Wave damping; Wave energy; Wave period; Waves**
Combination Effect of Pneumatic Breakwater and Other Type Breakwater on Wave Damping, Yuichi Iwagaki, Toshiyuki Asano and Tsutomu Honda, 2172
- Breakwaters; Permeability; Shallow water; Standing waves; Tests; Wave diffraction; Wave energy; Wave height; Wavelength; Wave tanks**
Wave Height Distribution Around Permeable Breakwaters, Shintaro Hotta, 695
- Breakwaters; Rubble-mound breakwaters; Slope stability; Stability; Wave energy; Wave height; Armoring (streambed)**
Dolos-Armored Breakwaters: Special Consideration, Robert D. Carver and D. Donald Davidson, 2263
- Breakwaters; Slots; Standing waves; Storms; Storm surges; Wave height; Wave period; Wave pressure; Wave reflection**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360
- Buoys; Design criteria; Offshore platforms; Offshore structures; Surveys (data collection); Wave energy; Wave height; Wave recorders (water waves)**
Comparison of Shipborne Wave Recorder and Waverider Buoy Data Used to Generate Design and Operational Planning Criteria, C. G. Graham, G. Verboom and C. J. Shaw, 97
- Buoys; Drifting (aquatic); Floating bodies; Mass transfer; Wave height; Wave period; Waves; Amplitude**
Drift Speed of Buoys in Waves, John H. Nath, 859
- Buoys; Hurricanes; Measurement; Monitoring; Offshore platforms; Radar operation; Wave height; Waves; Wind; Wind speed**
HF Skywave Radar Measurement of Hurricane Winds and Waves, Joseph W. Maresca, Jr. and Christopher T. Carlson, 190
- Calculations; Fourier transformation; Interactions; Nonlinear systems; Sampling; Spectral analysis; Wave spectra**
Higher Order Wave Spectra, Paul C. Liu and Albert W. Green, 360
- Calibration; California; Instrumentation; Performance; Profile measurement; Sand; Sediment transport; Vehicles; Wave action**
Tracked Vehicle for Continuous Nearshore Profiles, Richard J. Seymour, Alan L. Higgins and David P. Bothman, 1542
- California; Dredging; Estuaries; Harbor facilities; Harbors; Littoral current; Littoral drift; Littoral materials; Sediment deposits; Sediments; Shoaling; Accretion (geomorphology)**
Maintenance of Santa Cruz Harbor, California, U.S.A., Orville T. Magoon and Don C. Baer, 1276
- California; Instrumentation; Performance; Profile measurement; Sand; Sediment transport; Vehicles; Wave action; Calibration**
Tracked Vehicle for Continuous Nearshore Profiles, Richard J. Seymour, Alan L. Higgins and David P. Bothman, 1542
- Canada; Dredging; Harbors; Models; Salinity; Sedimentation; Sediment transport; Silting; Suspended sediments; Temperature; Tidal effects; Turbidity**
Tidal Sedimentation in Gros-Cacouna Harbor, Georges Drapeau and Guy Fortin, 1986
- Canada; Field tests; Gravity waves; Hurricanes; Sediments; Sediment transport; Storms; Storm surges; Wave energy; Wave period; Wave velocity**
Infragravity Waves in Storm Conditions, R. A. Holman, David A. Huntley and A. J. Bowen, 268
- Centrifugal pumps; Concrete piles; Dredging; Failure; Intake structures; Jetties; Offshore structures**
Problems of Design and Construction of an Offshore Sea-Water Intake, D. W. Standish-White and J. A. Zwamborn, 2125
- Channel beds; Clays; Entrainment; Experimentation; Finite element method; Sediment concentration; Suspended sediments; Time dependence**
Concentration of Suspended Clay in Periodic Flow, Akira Watanabe, P. Thimakorn and A. Das Gupta, 1918
- Classification; Field tests; Photographic analysis; Predictions; Water depth; Wave height; Wavelength; Waves; Breaking energy**
Field Study of Breaking Wave Characteristics, Lee L. Weishar and Robert J. Byrne, 487
- Clays; Entrainment; Experimentation; Finite element method; Sediment concentration; Suspended sediments; Time dependence; Channel beds**
Concentration of Suspended Clay in Periodic Flow, Akira Watanabe, P. Thimakorn and A. Das Gupta, 1918
- Coastal engineering; Coastal structures; Floating hodies; Oil spills; Tires; Wave action; Wave attenuation; Breakwaters**
Scrap Tyre Breakwaters in Coastal Engineering, Robert Charles McGregor and Neil Sinclair Miller, 2191

- Coastal engineering; Flooding; Frequencies; Probability; Storm surges; West Germany; Wind forces; Wind pressure; Wind velocity**
Frequencies and Probabilities of Extreme Storm Surges (On the Time-Dependent Changes of the Probability of Extreme Storm Floods at the German North Sea Coast), Alfred Fohrboter, 949
- Coastal engineering; Laboratory tests; Movable bed models; Scale effect; Sediments; Sediment transport; Wave height; Wave period; Beaches**
Scale Relations for Equilibrium Beach Profiles, Hideaki Noda, 1531
- Coastal engineering; Mathematical models; Mathematics; Mixing; Physics; Sediments; Structures; Tidal currents; Wave energy; Waves**
Struggle of Physics and Mathematics in Coastal Engineering, H. Lundgren, 13
- Coastal morphology; Delaware; Inlets (waterways); Littoral drift; Marshes; Morphology; Sedimentation; Tidal hydraulics; Barriers; Beach erosion**
Morphology of Coastal Barriers, Delaware, U.S.A., John C. Kraft, Chacko J. John and Evelyn M. Maurmeyer, 1232
- Coastal plains; Confidence level; Ocean waves; Probability distribution functions; Shore protection; Statistical analysis; Wave height; Wave period**
On Long-Term Statistics for Ocean and Coastal Waves, Michel K. Ochi, 59
- Coastal plains; Cost effectiveness; Floods; Hurricanes; Numerical analysis; Predictions; Simulation; Storm surges; Texas; Tidal effects; Tsunamis; Water levels**
Coastal Flood Simulation in Stretched Coordinates, H. Lee Butler, 1030
- Coastal plains; Currents (water); Ripple marks; Sediment transport; Shear stress; Three-dimensional; Wave height; Waves; Wave tanks**
Sediment Transport and Ripples Due to Waves and Currents, Zbigniew Pruszk and Ryszard B. Zeidler, 1638
- Coastal plains; Damage; Estuaries; History; Hydraulic models; Armoring (streambed); Breakwaters**
Models — Can We Learn from the Past? Some Thoughts on the Design of Breakwaters, W. A. Price, 25
- Coastal plains; Damage; Ocean waves; Recreational facilities; Storm surges; West Germany**
Welcoming Address — IV, Hans-Werner Partensky, 10
- Coastal plains; Diffraction; Groins (structures); Jetties; Littoral drift; Numerical analysis; Predictions; Refraction; Sediment transport; Barriers; Beaches; Breakwaters**
Prediction of Beach PlanForms with Littoral Controls, Marc Perlin and Robert G. Dean, 1818
- Coastal plains; Diffusion; Dispersion; Mathematical models; Outfall sewers; Sewage effluents; Statistical analysis; Time series analysis; Waste disposal**
Outfall Diffusion Models for the Coastal Zone, D. C.L. Lam and C. R. Murthy, 2584
- Coastal plains; Dredging; Gravel; Great Britain; Licensing; Littoral drift; Sand; Shore protection; Tidal currents; Wave action; Wave energy; Wave refraction**
The Effect of Offshore Dredging on Coastlines, W. A. Price, J. M. Motyka and L. J. Jaffrey, 1347
- Coastal plains; Dynamic loads; Shore protection; Storm surges; Surf; Water levels; Wave energy; Wave recorders (water waves); Wave runoff**
Wave Set-Up in the Surf Zone, Uwe A. Hansen, 1071
- Coastal plains; Eigenvalues; Mass; Momentum; Offshore structures; Rip currents; Spacing; Surf; Wave action; Waves; Wave velocity**
Rip Current Spacing as an Eigenvalue, Noriyuki Iwata, 828
- Coastal plains; Evaluation; Geological maps; Littoral deposits; Littoral materials; Sedimentation; Sediment transport; Surveys (data collection)**
A New Method for the Representation of Sedimentary Sequences in Coastal Regions, Hansjorg Streif, 1245
- Coastal plains; History; Shore protection; Storm surges; West Germany**
Welcoming Address — I, Karl-Edward Naumann, 1
- Coastal plains; Littoral current; Littoral deposits; Models; Ocean bottom; Sediments; Sediment transport; Surf; Wave dispersion; Wave energy; Beaches**
A Model Study of Alongshore Sediment Transport Rate, J. W. Kamphuis and J. S. Readshaw, 1656
- Coastal plains; Littoral deposits; Littoral drift; Littoral zone; Samples; Sediment concentration; Suspended sediments; Wave height**
Sled System for Profiling Suspended Littoral Drift, J. P. Coakley, J. A. Savile, M. Pedrosa and M. Laroque, 1764
- Coastal plains; Mixing; Ocean engineering; Ocean waves; Rivers; Runoff; Suspended sediments; Two-dimensional; Wave propagation; Wind loads; Boundary conditions**
Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Coastal plains; Probability; Probability distribution functions; Sea level; Statistical analysis; Storm surges; Tides; Beaches**
Extreme Sea Levels from Tide and Surge Probability, D. T. Pugh and J. M. Vassie, 911
- Coastal structures; Currents (water); Jetties; Numerical analysis; Ocean bottom; Scouring; Sediment transport; Time factors**
A Numerical Model for Sediment Transport, J. P. Lepetit and A. Hauguel, 1715
- Coastal structures; Dikes; Erosion control; Japan; Land reclamation; Scouring; Sea walls; Shore protection; Wave energy; Wave reflection; Beach erosion**
Effectiveness of Seadikes with Rough Slope, Osamu Toyoshima, 2528

- Coastal structures; Erosion control; Littoral zone; Marine terminals; Piers; Rubble-mound breakwaters; Sands; Shore-line cover; Beach erosion; Breakwaters**
Coastal Structures' Effects on Shorelines, Ronald M. Noble, 2069
- Coastal structures; Floating bodies; Oil spills; Tires; Wave action; Wave attenuation; Breakwaters; Coastal engineering**
Scrap Tyre Breakwaters in Coastal Engineering, Robert Charles McGregor and Neil Sinclair Miller, 2191
- Color photography; Images; Remote sensing; Shallow water; Water depth; Aerial photography; Bathymetry**
Visible-Region Photographic Remote Sensing of Nearshore Waters, Tsuguo Sunamura and Kiyoshi Horikawa, 1439
- Computation; Cylindrical bodies; Experimentation; Model tests; Numerical analysis; Piles; Transverse waves; Wave energy; Wave height; Wave interference**
Wave Forces on a Row of Cylindrical Piles of Large Diameter, J. C.W. Berkhoff and J. V.D. Weide, 2433
- Computation; Damping; Spectrum analysis; Tidal effects; Tides; Two-dimensional; Wave damping; Waves**
A New Approach for Tidal Computations, C. Le Provost, 1104
- Computer programs; Harbors; Hydraulic models; Numerical analysis; Wave diffraction; Wave height; Wave reflection; Breakwaters**
A Numerical Approach for the Determination of the Wave Height Distribution in a Harbour, Soren Kohlhase, Karl-Friedrich Daemrich, U. Berger, E. Tautenhain and O. Burkhardt, 664
- Concrete piles; Dredging; Failure; Intake structures; Jetties; Offshore structures; Centrifugal pumps**
Problems of Design and Construction of an Offshore Sea Water Intake, D. W. Standish-White and J. A. Zwamborn, 2125
- Confidence level; Ocean waves; Probability distribution functions; Shore protection; Statistical analysis; Wave height; Wave period; Coastal plains**
On Long-Term Statistics for Ocean and Coastal Waves, Michel K. Ochi, 59
- Continental shelf; Currents (water); Littoral current; Nicaragua; Pressure gradients; Salinity; Suspended sediments; Boundary layer flow**
Shelf and Coastal Boundary Layer Currents, Miskito Bank of Nicaragua, Richard L. Crout and Stephen P. Murray, 2715
- Cooling water; Discharge (water); Model studies; Rivers; Storm surges; Temperature effects; Thermal pollution; Tidal effects; Tidal hydraulics**
Influence on Temperature Increases in Tidal Rivers Caused by Waste Heat Injections with Respect to Tidal Cycles and Storm Surges, Horst Schwarze and Wilfried Falldorf, 2915
- Cooling water; Loads (forces); Outfall sewers; Scale effect; Tests; Thermal pollution; Wave energy; Wave height; Wave pressure**
Non-Breaking and Breaking Wave Loads on a Cooling Water Outfall, G. R. Mogridge and W. W. Jamieson, 2461
- Coral reefs and islands; Energy; Probability density functions; Spectral analysis; Surf; Wave action; Wave height; Wave period; Waves**
The Energy Spectra of Surf Waves on a Coral Reef, Theodore T. Lee and Kerry P. Black, 588
- Coring; Histograms; Sediment deposits; Surf; Tidal effects; Tracers; Wave action; Wave height; Beaches; Breaking energy**
Depth of Disturbance of Sand in Surf Zones, Michael K. Gaughan, 1513
- Correlation analysis; Deep water; Frequencies; Intensity; Wave energy; Wave propagation; Waves; Wave spectra; Bathymetry**
Deepwater Direction from an Intensity Array, Alan L. Higgins and Richard J. Seymour, 305
- Correlation techniques; Ocean waves; Offshore structures; Shore protection; Wave height; Wave period; Wave spectra**
The Observed Joint Distribution of Periods and Heights of Sea Waves, Yoshimi Goda, 227
- Cost effectiveness; Floods; Hurricanes; Numerical analysis; Predictions; Simulation; Storm surges; Texas; Tidal effects; Tsunamis; Water levels; Coastal plains**
Coastal Flood Simulation in Stretched Coordinates, H. Lee Butler, 1030
- Costs; Revetments; Rubble-mound breakwaters; Slope stability; Stability; Wave energy; Wave pressure; Armoring (streambed)**
Blanket Theory and Low Cost Revetments, C. T. Brown, 2510
- Cross sections; Estuaries; Inlets (waterways); Tidal currents; Tidal effects; Tidal flats; Two-dimensional; Wave tanks**
Periodic Flows from Tidal Inlets, D. L. Wilkinson, 1336
- Current meters; Harbor facilities; Littoral current; Littoral drift; Water depth; Wave height; Wave period; Wave recorders (water waves); Wave spectrum; Brazil**
Coastal Study of Espirito Santo Brazil, Paulo Augusto Vivacqua, Hildebrando de Araujo Goes Filho and Octavio de Sampaio Ferraz Jardim Sayao, 2104
- Currents (water); Density; Eddies; Eddy currents; Mixing; Tidal currents; Turbulence; Velocity; Water depth; Wind loads; Aerial photography**
Large Scale Turbulence in Tidal Currents, John B. Hinwood, 2598
- Currents (water); Density; Friction coefficient (hydraulic); Model studies; Three-dimensional; Water circulation; Wind loads**
Three Dimensional Modelling of the Irish Sea, Norman Stuart Heaps, 2671
- Currents (water); Design criteria; Energy conversion; Environmental effects; Environmental impact statements; Hurricanes; Site selection; Thermal energy; Waves; Wind**
Some Design Criteria for OTEC Installations for Keahole Point, Hawaii, Frederick C. Munchmeyer and Charles L. Bretschneider, 2633

- Currents (water); Diffusion; Eddies; Environmental factors; Simulation; Tidal hydraulics; Water circulation; Wind loads; Bays (topographic features)**
 Characteristics of Circulation in Bay Waters due to Wind Action, Akira Wada and Ioshihito Miyaike, 2730
- Currents (water); Dolphins (structures); Marine structures; Offshore platforms; Offshore structures; Pile foundations; Underwater foundations; Vibration**
 Tripod Concept for Pile Structures in Fast Current, J. Khanna and J. S. Wood, 2481
- Currents (water); Eddies; Oil spills; Three-dimensional; Viscosity; Water depth; Water pollution; Wind loads**
 3-D Current Model with Depth Varying Eddy Viscosity, Bryan R. Pearce, Cortis Cooper and Susan Nelson, 2602
- Currents (water); Edge effect; Frequencies; Littoral current; Ocean waves; Wave energy; Waves; Wave spectra; Wave velocity**
 Observation of Nearshore Current and Edge Waves, Tamio O. Sasaki and Kiyoshi Horikawa, 791
- Currents (water); Experimentation; Fetch; Wave generation; Wave height; Waves; Wave spectra; Wave tanks; Wave velocity; Wind forces; Wind pressure**
 Experimental Study of Wind Waves Generated on Currents, Hajime Kato and Hiroichi Tsuruya, 742
- Currents (water); Field tests; Sands; Sediment transport; Suspended load; Suspended sediments; Tidal effects; Wave action; Wave energy; Wave period; Waves**
 Effect of Waves on Sand Transport by Currents, Michael W. Owen and Michael F.C. Thorn, 1675
- Currents (water); Heated water; Jet flow; Mixing; Plumes; Surf; Temperature effects; Thermal pollution; Tracers; Turbulent flow**
 Mixing of Heated Water Discharged in the Surf Zone, Kiyoshi Horikawa, Ming-Chung Lin and Tamio O. Sasaki, 2563
- Currents (water); Jetties; Numerical analysis; Ocean bottom; Scouring; Sediment transport; Time factors; Coastal structures**
 A Numerical Model for Sediment Transport, J. P. Lepetit and A. Hauguel, 1715
- Currents (water); Littoral current; Nicaragua; Pressure gradients; Salinity; Suspended sediments; Boundary layer flow; Continental shelf**
 Shelf and Coastal Boundary Layer Currents, Miskito Bank of Nicaragua, Richard L. Crout and Stephen P. Murray, 2715
- Currents (water); Ocean bottom; Surface waves; Water depth; Wave energy; Wave measurement; Acoustic measuring instruments**
 Near-Bottom Current Measured by Acoustic Sensors, K. A. Selanger and T. Carstens, 878
- Currents (water); Ripple marks; Sediment transport; Shear stress; Three-dimensional; Wave height; Waves; Wave tanks; Coastal plains**
 Sediment Transport and Ripples Due to Waves and Currents, Zbigniew Pruszk and Ryszard B. Zeidler, 1638
- Currents (water); Sediment load; Sediments; Sediment transport; Wave action; Wave energy; Waves**
 Sediment Load under Waves and Currents, D. H. Willis, 1626
- Cyclones; Frequencies; Mathematical models; Probability distribution functions; Tropical cyclones; Wave equations; Wave recorders (water waves); Wind forces; Wind pressure; Australia**
 Wind Wave Frequencies in a Tropical Cyclone Region, Rodney J. Sobey, 76
- Cylindrical bodies; Diffraction; Particle trajectories; Spectral energy distribution; Time dependence; Water levels; Wave diffraction; Wave energy**
 Wave Forces Induced by Irregular Waves on a Vertical Circular Cylinder, Hajime Ishida and Yuichi Iwagaki, 2397
- Cylindrical bodies; Displacement; Dynamic characteristics; Dynamic response; Experimentation; Piles; Wave period; Wave propagation**
 Dynamic Behavior of Vertical Cylinder due to Wave Force, Toru Sawaragi and Takayuki Nakamura, 2378
- Cylindrical bodies; Drag; Experimentation; Loads (forces); Predictions; Reynolds number; Water flow; Wave energy; Wave pressure**
 Wave Loads on Horizontal Cylinders, P. Holmes and J. R. Chaplin, 2449
- Cylindrical bodies; Dynamic response; Loading; Mathematical models; Ocean waves; Responses; Water waves; Waves**
 Loading and Response of Cylinders in Waves, G. N. Bullock, P. K. Stansby and J. G. Warren, 2415
- Cylindrical bodies; Experimentation; Model tests; Numerical analysis; Piles; Transverse waves; Wave energy; Wave height; Wave interference; Computation**
 Wave Forces on a Row of Cylindrical Piles of Large Diameter, J. C.W. Berkhoff and J. V.D. Weide, 2433
- Damage; Dikes; Hydrodynamics; Statistical analysis; Wave height; Wave period; Wave runoff; Wave spectra**
 New Dike Design Criteria Based on Wave Spectra, Hans Kaldenhoff and Suhan M. Gokcesu, 2500
- Damage; Earthquake loads; Earthquake resistant structures; Loading; Rubble-mound breakwaters; Seismic design; Settlement (structural); Slope stability; Acceleration**
 Loadings on Rubble-Mound Breakwaters due to Earthquakes, H. Wang, C. Y. Yang, C. Lamison and S. S. Chen, 2244
- Damage; Estuaries; History; Hydraulic models; Armoring (streambed); Breakwaters; Coastal plains**
 Models — Can We Learn from the Past? Some Thoughts on the Design of Breakwaters, W. A. Price, 25
- Damage; Hydraulic models; Rubble-mound breakwaters; Stability; Wave energy; Wave height; Wave spectra; Wave tanks; Breakwaters**
 Effects of Wave Grouping on Breakwater Stability, R. R. Johnson, E. P.D. Mansard and J. Ploeg, 2228

- Damage; Ocean waves; Recreational facilities; Storm surges; West Germany; Coastal plains**
Welcoming Address — IV, Hans-Werner Partensky, 10
- Damping; Spectrum analysis; Tidal effects; Tides; Two-dimensional; Wave damping; Waves; Computation**
A New Approach for Tidal Computations, C. Le Provost, 1104
- Damping; Tidal currents; Tidal energy; Wave damping; Wave dispersion; Wave energy; Wave height; Wave runup; Waves; Wind speed**
Wave Climate Study in the Region of the East Frisian Islands and Coast, Hanz Dieter Niemyer, 134
- Deep water; Frequencies; Intensity; Wave energy; Wave propagation; Waves; Wave spectra; Bathymetry; Correlation analysis**
Deepwater Direction from an Intensity Array, Alan L. Higgins and Richard J. Seymour, 305
- Deep water; Particle trajectories; Slope; Velocity; Waves; Wave velocity; Beaches; Breaking energy**
Estimation of Water Particle Velocity of Breaking Wave, Tetsuo Sakai and Yuichi Iwagaki, 551
- Delaware; Hydraulic models; Inlets (waterways); Jetties; Sedimentation; Sheet piles; Tidal effects; Trends; Beach erosion**
Case Studies of Delaware's Tidal Inlets: Roosevelt and Indian River Inlets, W. A. Dennie, G. A. Lanan and Robert A. Dalrymple, 1282
- Delaware; Inlets (waterways); Littoral drift; Marshes; Morphology; Sedimentation; Tidal hydraulics; Barriers; Beach erosion; Coastal morphology**
Morphology of Coastal Barriers, Delaware, U.S.A., John C. Kraft, Chacko J. John and Evelyn M. Maurmeyer, 1232
- Density; Eddies; Eddy currents; Mixing; Tidal currents; Turbulence; Velocity; Water depth; Wind loads; Aerial photography; Currents (water)**
Large Scale Turbulence in Tidal Currents, John B. Hinwood, 2598
- Density; Estuaries; Flumes; Harbors; Mathematical models; Netherlands; Rivers; Saline water intrusion; Salinity**
Effect of Harbours on Salt Intrusion in Estuaries, A. Roelfzema and A. G. van Os, 2810
- Density; Flumes; Slope stability; Stability; Standardization; Test reproducibility; Tests; Armoring (streambed); Breakwaters**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwamborn, 2285
- Density; Friction coefficient (hydraulic); Model studies; Three-dimensional; Water circulation; Wind loads; Currents (water)**
Three Dimensional Modelling of the Irish Sea, Norman Stuart Heaps, 2671
- Density; Friction coefficient (hydraulic); Open channel flow; Saline water-freshwater interfaces; Salinity; Stratified flow; Two phase flow; Water flow**
Interfacial Friction Coefficients in a Two-Layered Stratified Flow, Emmanuel Partheniades and Vassilios Dermisiss, 2778
- Density currents; Discharge (water); Heat exchangers; Liquid natural gas; Model studies; Thermal pollution; Tidal currents; Vaporizers; Biological properties**
Thermal and Biological Impact of LNG Vaporizer Discharge, Peter A. Mangarella and Gordon A. Robilliard, 2945
- Design criteria; Energy conversion; Environmental effects; Environmental impact statements; Hurricanes; Site selection; Thermal energy; Waves; Wind; Currents (water)**
Some Design Criteria for OTEC Installations for Keahole Point, Hawaii, Frederick C. Munchmeyer and Charles L. Bretschneider, 2633
- Design criteria; Offshore platforms; Offshore structures; Surveys (data collection); Wave energy; Wave height; Wave recorders (water waves); Buoys**
Comparison of Shipborne Wave Recorder and Waverider Buoy Data Used to Generate Design and Operational Planning Criteria, C. G. Graham, G. Verboom and C. J. Shaw, 97

- Return flow; Sands; Scouring; Sea walls; Slopes; Tsunamis; Two-dimensional; Water depth; Wave energy; Waves; Ocean bottom; Ocean waves**
Scouring at the Toe of a Seawall due to Tsunamis, Hitoshi Nishimura, Akira Watanabe and Kiyoshi Horikawa, 2540
- Revetments; Rubble-mound breakwaters; Slope stability; Stability; Wave energy; Wave pressure; Armoring (streambed); Costs**
Blanket Theory and Low Cost Revetments, C. T. Brown, 2510
- Reynolds number; Water flow; Wave energy; Wave pressure; Cylindrical bodies; Drag; Experimentation; Loads (forces); Predictions**
Wave Loads on Horizontal Cylinders, P. Holmes and J. R. Chaplin, 2449
- Rip currents; Sediment transport; Shoaling; Water waves; Wave diffraction; Wave height; Wave period; Wave refraction; Wave velocity**
Rip Currents and Their Causes, Robert A. Dalrymple, 1414
- Rip currents; Shore-line cover; Wave diffraction; Wave refraction; Wind loads; Accretion (geomorphology); Beach nourishment; Erosion; Groins (structures); Mathematical models**
Mathematical Modeling of Shoreline Evolution, Bernard Le Mehaute and Mills Soldate, 1163
- Rip currents; Spacing; Surf; Wave action; Waves; Wave velocity; Coastal plains; Eigenvalues; Mass; Momentum; Offshore structures**
Rip Current Spacing as an Eigenvalue, Noriyuki Iwata, 828
- Rip currents; Surf; Temporal distribution; Variations; Wave spectra; Edge effect; Gravity waves; Littoral current**
Variability of Longshore Currents, R. T. Guza and Edward B. Thornton, 756
- Ripple marks; Sands; Scale effect; Shore protection; Storm surges; Beach erosion; Dunes; Erosion; Movable bed models**
Movable Bed Model Tests on Dune Erosion, P. Vellinga, 2020
- Ripple marks; Sediment transport; Shear stress; Three-dimensional; Wave height; Waves; Wave tanks; Coastal plains; Currents (water)**
Sediment Transport and Ripples Due to Waves and Currents, Zbigniew Pruszk and Ryszard B. Zeidler, 1638
- Ripple marks; Shallow water; Waves; Wind pressure; Field tests; Laboratory tests; Ocean bottom; Oscillation**
On the Geometry of Ripples Due to Waves, M. S. Yalin and E. Karahan, 1776
- Ripple marks; Tidal effects; Bed forms; Friction coefficient (hydraulic); Hydrodynamic pressure; Hydrodynamics; Numerical analysis; Ocean bottom**
The Influence of Dune and Flow Parameters on the Friction Factor, Jurgen Sundermann, H. Vollmers and W. Puls, 1787
- Rivers; Runoff; Suspended sediments; Two-dimensional; Wave propagation; Wind loads; Boundary conditions; Coastal plains; Mixing; Ocean engineering; Ocean waves**
Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Rivers; Saline water-freshwater interfaces; Salinity; Stream flow; Velocity distribution; Vortices; Wave energy; Bed roughness; Estuaries; Mixing**
Outflow Dynamics at a River Mouth, Masakazu Kashiwamura and Shizuo Yoshida, 2925
- Rivers; Saline water intrusion; Salinity; Density; Estuaries; Flumes; Harbors; Mathematical models; Netherlands**
Effect of Harbours on Salt Intrusion in Estuaries, A. Roelfzema and A. G. van Os, 2810
- Rivers; Shallow water; Tidal effects; Turbulence; Estuaries; Flood routing; Hydraulic models; Hydrodynamics; Numerical analysis**
Hydrodynamic Modelling of the Southern North Sea, David Prandle, 1122

- Rivers; Storm surges; Temperature effects; Thermal pollution; Tidal effects; Tidal hydraulics; Cooling water; Discharge (water); Model studies**
Influence on Temperature Increases in Tidal Rivers Caused by Waste Heat Injections with Respect to Tidal Cycles and Storm Surges, Horst Schwarze and Wilfried Falldorf, 2915
- Roughness (hydraulic); Velocity distribution; Vortex generators; Jets; Laminar flow; Ocean bottom; Oscillation**
Oscillatory Laminar Flow Above a Rough Bed, C. B. George and J. F. A. Sleath, 898
- Rubble-mound breakwaters; Sands; Shore-line cover; Beach erosion; Breakwaters; Coastal structures; Erosion control; Littoral zone; Marine terminals; Piers**
Coastal Structures' Effects on Shorelines, Ronald M. Noble, 2069
- Rubble-mound breakwaters; Seismic design; Settlement (structural); Slope stability; Acceleration; Damage; Earthquake loads; Earthquake resistant structures; Loading**
Loadings on Rubble-Mound Breakwaters due to Earthquakes, H. Wang, C. Y. Yang, C. Lamison and S. S. Chen, 2244
- Rubble-mound breakwaters; Slope stability; Stability; Wave energy; Wave height; Armoring (streambed); Breakwaters**
Dolos-Armored Breakwaters: Special Consideration, Robert D. Carver and D. Donald Davidson, 2263
- Rubble-mound breakwaters; Slope stability; Stability; Wave energy; Wave pressure; Armoring (streambed); Costs; Revetments**
Blanket Theory and Low Cost Revetments, C. T. Brown, 2510
- Rubble-mound breakwaters; Stability; Wave energy; Wave height; Wave spectra; Wave tanks; Breakwaters; Damage; Hydraulic models**
Effects of Wave Grouping on Breakwater Stability, R. R. Johnson, E. P. D. Mansard and J. Ploeg, 2228
- Runoff; Suspended sediments; Two-dimensional; Wave propagation; Wind loads; Boundary conditions; Coastal plains; Mixing; Ocean engineering; Ocean waves; Rivers**
Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Saline water; Fjords; Freezing; Heat loss; Hydroelectric powerplants; Ice control; Model studies; Numerical analysis; Outlet works**
Prevention of Freezing in Fjords, Sveinung Saegrov, 2958
- Saline water-freshwater interfaces; Saline water intrusion; Salinity; Sampling; Tidal hydraulics; Verification inspection; Field tests; Model studies**
Field Data Analysis for Chesapeake Bay Model Verification, Ronald E. Nece and Norman W. Scheffner, 2870
- Saline water-freshwater interfaces; Saline water intrusion; Salinity; Stratified flow; Tidal currents; Tidal hydraulics; Water quality; Estuaries**
Stability Study of an Artificial Salt Intrusion in Estuaries, C. Marche, 2798
- Saline water-freshwater interfaces; Salinity; Stratified flow; Two phase flow; Water flow; Density; Friction coefficient (hydraulic); Open channel flow**
Interfacial Friction Coefficients in a Two-Layered Stratified Flow, Emmanuel Partheniades and Vassilios Dermisis, 2778
- Saline water-freshwater interfaces; Salinity; Stream flow; Velocity distribution; Vortices; Wave energy; Bed roughness; Estuaries; Mixing; Rivers**
Outflow Dynamics at a River Mouth, Masakazu Kashiwamura and Shizuo Yoshida, 2925
- Saline water-freshwater interfaces; Salinity; Ultrasonic tests; Diffusion coefficient; Entrainment; Estuaries; Japan**
Behaviors of the Salt Wedge and the Salinity Distribution at Estuaries, Isao Yakuwa, Susumu Takahashi and Morimasa Ohtani, 2746
- Saline water-freshwater interfaces; Shallow water; Standing waves; Tidal flats; Tidal hydraulics; Dispersion; Estuaries; Mixing; Model studies**
Longitudinal Dispersion in Shallow Well-Mixed Estuaries, J. Dronkers, 2761
- Saline water intrusion; Salinity; Density; Estuaries; Flumes; Harbors; Mathematical models; Netherlands; Rivers**
Effect of Harbours on Salt Intrusion in Estuaries, A. Roelfzema and A. G. van Os, 2810
- Saline water intrusion; Salinity; Sampling; Tidal hydraulics; Verification inspection; Field tests; Model studies; Saline water-freshwater interfaces**
Field Data Analysis for Chesapeake Bay Model Verification, Ronald E. Nece and Norman W. Scheffner, 2870
- Saline water intrusion; Salinity; Simulation; Tidal hydraulics; Estuaries; Hydraulic models; Mathematical models; Model studies; Numerical analysis**
Numerical Tidal-Salinity Models of the Ems Estuary, Karsten Fischer, 2840
- Saline water intrusion; Salinity; Stratified flow; Tidal currents; Tidal hydraulics; Water quality; Estuaries; Saline water-freshwater interfaces**
Stability Study of an Artificial Salt Intrusion in Estuaries, C. Marche, 2798
- Salinity; Density; Estuaries; Flumes; Harbors; Mathematical models; Netherlands; Rivers; Saline water intrusion**
Effect of Harbours on Salt Intrusion in Estuaries, A. Roelfzema and A. G. van Os, 2810
- Salinity; Salt balance; Salt water intrusion; Tidal hydraulics; Wind loads; Florida; Friction coefficient (hydraulic); Model studies**
Tidal Hydraulics and Salt Balance of Lake Worth, Florida, J. van de Kreeke and J. D. Wang, 2827
- Salinity; Sampling; Tidal hydraulics; Verification inspection; Field tests; Model studies; Saline water-freshwater interfaces; Saline water intrusion**
Field Data Analysis for Chesapeake Bay Model Verification, Ronald E. Nece and Norman W. Scheffner, 2870
- Salinity; Sedimentation; Sediment transport; Silting; Suspended sediments; Temperature; Tidal effects; Turbidity; Canada; Dredging; Harbors; Models**
Tidal Sedimentation in Gros-Couana Harbor, Georges Drapeau and Guy Fortin, 1986

- Salinity; Simulation; Tidal hydraulics; Estuaries; Hydraulic models; Mathematical models; Model studies; Numerical analysis; Saline water intrusion**
Numerical Tidal-Salinity Models of the Ems Estuary, Karsten Fischer, 2840
- Salinity; Stratified flow; Tidal currents; Tidal hydraulics; Water quality; Estuaries; Saline water-freshwater interfaces; Saline water intrusion**
Stability Study of an Artificial Salt Intrusion in Estuaries, C. Marche, 2798
- Salinity; Stratified flow; Two phase flow; Water flow; Density; Friction coefficient (hydraulic); Open channel flow; Saline water-freshwater interfaces**

- Sediment transport; Wave action; Wave energy; Waves; Currents (water); Sediment load; Sediments**
 Sediment Load under Waves and Currents, D. H. Willis, 1626
- Sediment transport; Wave diffraction; Wave height; Wave phases; Bathymetry; Bays (topographic features); Beach erosion; Beaches; Breakwaters; Diffraction**
 Diffraction Calculation of Shoreline PlanForms, Robert G. Dean, 1903
- Sediment transport; Wave height; Wave period; Beaches; Coastal engineering; Laboratory tests; Movable bed models; Scale effect; Sediments**
 Scale Relations for Equilibrium Beach Profiles, Hideaki Noda, 1531
- Sediment transport; Waves; Breakwaters; Japan; Land reclamation; Littoral current; Littoral drift; Movable bed models; Ocean bottom**
 Estimation Using a Movable Bed Model of Shoreline Change Caused by a Reclamation Projected into the Sea, Shoji Sato and Hiroaki Ozasa, 1839
- Seismic design; Settlement (structural); Slope stability; Acceleration; Damage; Earthquake loads; Earthquake resistant structures; Loading; Rubble-mound breakwaters**
 Loadings on Rubble-Mound Breakwaters due to Earthquakes, H. Wang, C. Y. Yang, C. Lamison and S. S. Chen, 2244
- Sensors; Storms; Surf; Suspended sediments; Wave period; Littoral deposits; Sediment concentration; Sediment transport**
 Storm Induced Periodicities of Suspended Sand Movement, Jay E. Leonard and Benno M. Brennknecher, 1744
- Settlement (structural); Slope stability; Acceleration; Damage; Earthquake loads; Earthquake resistant structures; Loading; Rubble-mound breakwaters; Seismic design**
 Loadings on Rubble-Mound Breakwaters due to Earthquakes, H. Wang, C. Y. Yang, C. Lamison and S. S. Chen, 2244
- Sewage effluents; Statistical analysis; Time series analysis; Waste disposal; Coastal plains; Diffusion; Dispersion; Mathematical models; Outfall sewers**
 Outfall Diffusion Models for the Coastal Zone, D. C.L. Lam and C. R. Murthy, 2584
- Shallow water; Standing waves; Tests; Wave diffraction; Wave energy; Wave height; Wavelength; Wave tanks; Breakwaters; Permeability**
 Wave Height Distribution Around Permeable Breakwaters, Shintaro Hotta, 695
- Shallow water; Standing waves; Tidal flats; Tidal hydraulics; Dispersion; Estuaries; Mixing; Model studies; Saline water-freshwater interfaces**
 Longitudinal Dispersion in Shallow Well-Mixed Estuaries, J. Dronkers, 2761
- Shallow water; Storm surges; Temperature; Water depth; Water levels; Air water interactions; Air-water interfaces; Forecasting**
 Storm Surge Forecasting Methods in Enclosed Seas, P. F. Hamblin, 998
- Shallow water; Suspended sediments; Tidal effects; Wave height; Waves; Wave spectrum; Mud; Mud systems; Sediment concentration; Sediment transport**
 Suspension and Transportation of Fluid Mud by Solitary-Like Waves, John T. Wells, James M. Coleman and W. J. Wiseman, Jr., 1932
- Shallow water; Tidal effects; Turbulence; Estuaries; Flood routing; Hydraulic models; Hydrodynamics; Numerical analysis; Rivers**
 Hydrodynamic Modelling of the Southern North Sea, David Prandle, 1122
- Shallow water; Water depth; Aerial photography; Bathymetry; Color photography; Images; Remote sensing**
 Visible-Region Photographic Remote Sensing of Nearshore Waters, Tsuguo Sunamura and Kiyoshi Horikawa, 1439

- Shallow water; Water depth; Wave action; Wave diffraction; Wavelength; Wave propagation; Wave reflection; Wave refraction; Mathematical models**
 Computations of Short Waves in Shallow Water, M. B. Abbott, H. M. Petersen and Ove Skovgaard, 414
- Shallow water; Water depth; Wave energy; Beach erosion; Littoral current; Littoral deposits; Littoral drift**
 Vocooidal Theory for All Non-Breaking Waves, D. H. Swart and C. C. Loubser, 467
- Shallow water; Wave height; Bores (wave); Breaking energy; Energy dissipation; Energy losses; Predictions; Random processes**
 Energy Loss and Set-Up Due to Breaking of Random Waves, J. A. Battjes and J. P.F.M. Janssen, 569
- Shallow water; Waves; Wind pressure; Field tests; Laboratory tests; Ocean bottom; Oscillation; Ripple marks**
 On the Geometry of Ripples Due to Waves, M. S. Yalin and E. Karahan, 1776
- Shape; Silting; Underwater structures; Wave attenuation; Barriers; Breakwaters; India; Performance**
 Performance Characteristics of Submerged Breakwaters, J. Dattatri, H. Raman and N. Jothi Shankar, 2153
- Shear flow; Water depth; Wave action; Wave height; Wavelength; Wave period; Wave refraction; Refraction (water waves)**
 Wave Refraction Across a Shearing Current, Ivar G. Jonsson and Ove Skovgaard, 722
- Shear stress; Surf; Water depth; Littoral deposits; Littoral drift; Littoral materials; Ocean bottom; Sediments; Sediment transport**
 Distribution of Sand Transport Rate across a Surf Zone, Toru Sawaragi and Ichiro Deguchi, 1596
- Shear stress; Three-dimensional; Wave height; Waves; Wave tanks; Coastal plains; Currents (water); Ripple marks; Sediment transport**
 Sediment Transport and Ripples Due to Waves and Currents, Zbigniew Pruszk and Ryszard B. Zeidler, 1638
- Shear stress; Turbulent flow; Velocity distribution; Wave propagation; Wave velocity; Boundary conditions; Mathematical models; Sand**
 Near-Bottom Velocities in Waves with a Current, W. T. Bakker and Th. van Doorn, 1394
- Sheet piles; Tidal effects; Trends; Beach erosion; Delaware; Hydraulic models; Inlets (waterways); Jetties; Sedimentation**
 Case Studies of Delaware's Tidal Inlets: Roosevelt and Indian River Inlets, W. A. Dennie, G. A. Lanan and Robert A. Dalrymple, 1282
- Shingles (beach); Tracers; Beaches; Littoral drift; Metal detectors; Monitoring; Sediment transport**
 Shingle Tracing by a New Technique, Peter Wright, J. S. Cross and N. B. Webber, 1705
- Shipping; Shore protection; Storms; Tidal currents; West Germany; Dikes; Estuaries; Ports**
 Welcoming Address — II, Helga Elstner, 4
- Shoaling; Accretion (geomorphology); California; Dredging; Estuaries; Harbor facilities; Harbors; Littoral current; Littoral drift; Littoral materials; Sediment deposits; Sediments**
 Maintenance of Santa Cruz Harbor, California, U.S.A., Orville T. Magoon and Don C. Baer, 1276
- Shoaling; Water waves; Wave diffraction; Wave height; Wave period; Wave refraction; Wave velocity; Rip currents; Sediment transport**
 Rip Currents and Their Causes, Robert A. Dalrymple, 1414
- Shore-line cover; Beach erosion; Breakwaters; Coastal structures; Erosion control; Littoral zone; Marine terminals; Piers; Rubble-mound breakwaters; Sands**
 Coastal Structures' Effects on Shorelines, Ronald M. Noble, 2069
- Shore-line cover; Wave diffraction; Wave refraction; Wind loads; Accretion (geomorphology); Beach nourishment; Erosion; Groins (structures); Mathematical models; Rip currents**
 Mathematical Modeling of Shoreline Evolution, Bernard Le Mehaute and Mills Soldate, 1163
- Shore protection; Spoil; Spoil banks; Beach erosion; Beach nourishment; Dredging; Groins (structures); Sea walls**
 Some Facts and Fancies about Beach Erosion, Richard Sylvester, 1888
- Shore protection; Statistical analysis; Wave height; Wave period; Coastal plains; Confidence level; Ocean waves; Probability distribution functions**
 On Long-Term Statistics for Ocean and Coastal Waves, Michel K. Ochi, 59
- Shore protection; Storms; Tidal currents; West Germany; Dikes; Estuaries; Ports; Shipping**
 Welcoming Address — II, Helga Elstner, 4
- Shore protection; Storm surges; Beach erosion; Dunes; Erosion; Movable bed models; Ripple marks; Sands; Scale effect**
 Movable Bed Model Tests on Dune Erosion, P. Vellinga, 2020
- Shore protection; Storm surges; Surf; Water levels; Wave energy; Wave recorders (water waves); Wave runup; Coastal plains; Dynamic loads**
 Wave Set-Up in the Surf Zone, Uwe A. Hansen, 1071
- Shore protection; Storm surges; West Germany; Coastal plains; History**
 Welcoming Address — I, Karl-Edward Naumann, 1
- Shore protection; Tidal currents; Wave action; Wave energy; Wave refraction; Coastal plains; Dredging; Gravel; Great Britain; Licensing; Littoral drift; Sand**
 The Effect of Offshore Dredging on Coastlines, W. A. Price, J. M. Motyka and L. J. Jeffrey, 1347
- Shore protection; Water depth; Bathymetry; Beach erosion; Beach nourishment; Morphology; Sands**
 Morphologic Effects of Westerland Beach Nourishment 1972, Dieter Wenzel, 1859

- Shore protection; Wave energy; Wave reflection; Beach erosion; Coastal structures; Dikes; Erosion control; Japan; Land reclamation; Scouring; Sea walls**
Effectiveness of Seadikes with Rough Slope, Osamu Toyoshima, 2528
- Shore protection; Wave height; Wave period; Wave spectra; Correlation techniques; Ocean waves; Offshore structures**
The Observed Joint Distribution of Periods and Heights of Sea Waves, Yoshimi Goda, 227
- Shores; Stresses; Surf; Water circulation; Wave energy; Wave propagation; Waves; Barriers; Friction coefficient (hydraulic); Littoral current**
Longshore Currents Due to Surf Zone Barrier, P. Bettess, C. A. Fleming, J. C. Heinrich, O. C. Zienkiewicz and D. I. Austin, 776
- Silting; Suspended sediments; Temperature; Tidal effects; Turbidity; Canada; Dredging; Harbors; Models; Salinity; Sedimentation; Sediment transport**
Tidal Sedimentation in Gros-CaCouna Harbor, Georges Drapeau and Guy Fortin, 1986
- Silting; Underwater structures; Wave attenuation; Barriers; Breakwaters; India; Performance; Shape**
Performance Characteristics of Submerged Breakwaters, J. Dattatari, H. Raman and N. Jothi Shankar, 2153
- Silting; Wave energy; Experimentation; Littoral current; Littoral drift; Predictions; Sediments; Sediment transport**
Longshore Sediment Transport Data: A Review, Matthew N. Greer and Ole Secher Madsen, 1563
- Simulation; Spoil banks; Beaches; Breakwaters; Dredging; Hydraulic models; Inlets (waterways); Jetties; North Carolina; Sediment deposits**
Coastal Processes at Oregon Inlet, North Carolina, James T. Jarrett, 1257
- Simulation; Storm surges; Texas; Tidal effects; Tsunamis; Water levels; Coastal plains; Cost effectiveness; Floods; Hurricanes; Numerical analysis; Predictions**
Coastal Flood Simulation in Stretched Coordinates, H. Lee Butler, 1030
- Simulation; Storm surges; Water levels; Wind forces; Forecasting; Mathematical models; Meteorological data; Meteorology; Numerical analysis; Predictions**
Numerical Storm Surge Forecasting, Manfred Engel, 975
- Simulation; Tidal hydraulics; Estuaries; Hydraulic models; Mathematical models; Model studies; Numerical analysis; Saline water intrusion; Salinity**
Numerical Tidal-Salinity Models of the Ems Estuary, Karsten Fischer, 2840
- Simulation; Tidal hydraulics; Water circulation; Wind loads; Bays (topographic features); Currents (water); Diffusion; Eddies; Environmental factors**
Characteristics of Circulation in Bay Waters due to Wind Action, Akira Wada and Ioshihito Miyaake, 2730
- Simulation; Wave damping; Wave energy; Wave period; Wave pressure; Wind loads; Wind pressure; Dynamic response; Oscillation; Responses**
Simulation of Wave/Wind Forced Harbor Oscillation, S. K. Liu, H. S. Hou and Charles C.C. Chang, 2551
- Site selection; Storm surges; Tidal effects; Tidal waters; Wave height; Wave period; Australia; Breakwaters; Maintenance**
Rosslyn Bay Breakwater, Queensland, Australia, D. N. Foster, B. L. McGrath and W. Bremner, 2086
- Site selection; Thermal energy; Waves; Wind; Currents (water); Design criteria; Energy conversion; Environmental effects; Environmental impact statements; Hurricanes**
Some Design Criteria for OTEC Installations for Keahole Point, Hawaii, Frederick C. Munchmeyer and Charles L. Bretschneider, 2633
- Slope; Velocity; Waves; Wave velocity; Beaches; Breaking energy; Deep water; Particle trajectories**
Estimation of Water Particle Velocity of Breaking Wave, Tetsuo Sakai and Yuichi Iwagaki, 551
- Slopes; Tsunamis; Two-dimensional; Water depth; Wave energy; Waves; Ocean bottom; Ocean waves; Return flow; Sands; Scouring; Sea walls**
Scouring at the Toe of a Seawall due to Tsunamis, Hitoshi Nishimura, Akira Watanabe and Kiyoshi Horikawa, 2540
- Slopes; Water depth; Wave height; Wavelength; Wave period; Waves; Wave tanks; Wave velocity; Beaches; Random processes**
Wave Length, Wave Velocity and Shoaling Characteristics of Random Waves, Akira Kimura and Yuichi Iwagaki, 320
- Slope stability; Acceleration; Damage; Earthquake loads; Earthquake resistant structures; Loading; Rubble-mound breakwaters; Seismic design; Settlement (structural)**
Loadings on Rubble-Mound Breakwaters due to Earthquakes, H. Wang, C. Y. Yang, C. Lamison and S. S. Chen, 2244
- Slope stability; Stability; Standardization; Test reproducibility; Tests; Armoring (streambed); Breakwaters; Density; Flumes**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwiarnborn, 2285
- Slope stability; Stability; Wave energy; Wave height; Armoring (streambed); Breakwaters; Rubble-mound breakwaters**
Dolos-Armored Breakwaters: Special Consideration, Robert D. Carver and D. Donald Davidson, 2263
- Slope stability; Stability; Wave energy; Wave pressure; Armoring (streambed); Costs; Revetments; Rubble-mound breakwaters**
Blanket Theory and Low Cost Revetments, C. T. Brown, 2510
- Slots; Standing waves; Storms; Storm surges; Wave height; Wave period; Wave pressure; Wave reflection; Breakwaters**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360

- Soil stabilization; Wind forces; Wind pressure; Airspeed; Beach erosion; Dunes; Erosion control; Fences; Sands; Sediment deposits**
Using Fences to Create and Stabilise Sand Dunes, Brian B. Willetts and Christopher J. Phillips, 2040
- South Carolina; Suspended load; Tidal currents; Tidal effects; Tidal waters; Wind; Discharge (water); Hydrodynamics; Meteorology; Rainfall; Salt marshes; Sediment transport**
Hydrodynamics and Sediment Transport in a Salt Marsh Tidal Channel, Larry G. Ward, 1953
- Spacing; Surf; Wave action; Waves; Wave velocity; Coastal plains; Eigenvalues; Mass; Momentum; Offshore structures; Rip currents**
Rip Current Spacing as an Eigenvalue, Noriyuki Iwata, 828
- Spectral analysis; Surf; Wave action; Wave height; Wave period; Waves; Coral reefs and islands; Energy; Probability density functions**
The Energy Spectra of Surf Waves on a Coral Reef, Theodore T. Lee and Kerry P. Black, 588
- Spectral analysis; Wave spectra; Calculations; Fourier transformation; Interactions; Nonlinear systems; Sampling**
Higher Order Wave Spectra, Paul C. Liu and Albert W. Green, 360
- Spectral energy distribution; Time dependence; Water levels; Wave diffraction; Wave energy; Cylindrical bodies; Diffraction; Particle trajectories**
Wave Forces Induced by Irregular Waves on a Vertical Circular Cylinder, Hajime Ishida and Yuichi Iwagaki, 2397
- Spectrum analysis; Tidal effects; Tides; Two-dimensional; Wave damping; Waves; Computation; Damping**
A New Approach for Tidal Computations, C. Le Provost, 1104
- Spoil; Spoil banks; Beach erosion; Beach nourishment; Dredging; Groins (structures); Sea walls; Shore protection**
Some Facts and Fancies about Beach Erosion, Richard Sylvester, 1888
- Spoil; Spoil banks; Beach nourishment; Bottom sediments; Dredges; Dredging; Models; Sediments**
Importance of Handling Losses to Beach Fill Design, R. D. Hobson and W. R. James, 1873
- Spoil; Spoil banks; Suspended sediments; Diffusion; Dredges; Dredging; Estuaries; Models; Plumes; Sediment concentration**
Factors Governing the Distribution of Dredge-Resuspended Sediments, W. Frank Bohlen, 2001
- Spoil banks; Beach erosion; Beach nourishment; Dredging; Groins (structures); Sea walls; Shore protection; Spoil**
Some Facts and Fancies about Beach Erosion, Richard Sylvester, 1888
- Spoil banks; Beaches; Breakwaters; Dredging; Hydraulic models; Inlets (waterways); Jetties; North Carolina; Sediment deposits; Simulation**
Coastal Processes at Oregon Inlet, North Carolina, James T. Jarrett, 1257
- Spoil banks; Beach nourishment; Bottom sediments; Dredges; Dredging; Models; Sediments; Spoil**
Importance of Handling Losses to Beach Fill Design, R. D. Hobson and W. R. James, 1873
- Spoil banks; Suspended sediments; Diffusion; Dredges; Dredging; Estuaries; Models; Plumes; Sediment concentration; Spoil**
Factors Governing the Distribution of Dredge-Resuspended Sediments, W. Frank Bohlen, 2001
- Stability; Standardization; Test reproducibility; Tests; Armoring (streambed); Breakwaters; Density; Flumes; Slope stability**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwamborn, 2285
- Stability; Wave energy; Wave height; Armoring (streambed); Breakwaters; Rubble-mound breakwaters; Slope stability**
Dolos-Armored Breakwaters: Special Consideration, Robert D. Carver and D. Donald Davidson, 2263
- Stability; Wave energy; Wave height; Wave spectra; Wave tanks; Breakwaters; Damage; Hydraulic models; Rubble-mound breakwaters**
Effects of Wave Grouping on Breakwater Stability, R. R. Johnson, E. P.D. Mansard and J. Ploeg, 2228
- Stability; Wave energy; Wave pressure; Armoring (streambed); Costs; Revetments; Rubble-mound breakwaters; Slope stability**
Blanket Theory and Low Cost Revetments, C. T. Brown, 2510
- Stability analysis; Tidal currents; Tidal flats; Tides; Two-dimensional; Water depth; Boundary conditions; Forecasting; Morphology**
Two-Dimension Stability Analysis of Tidal Basins and Tidal Flats of Larger Extent, Eberhard Renger, 1971
- Standardization; Test reproducibility; Tests; Armoring (streambed); Breakwaters; Density; Flumes; Slope stability; Stability**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwamborn, 2285
- Standardization; Test reproducibility; Tests; Turbulent flow; Wave period; Wave refraction; Armoring (streambed); Open channel flow; Performance**
Performance of Dolos Blocks in an Open Channel Situation, Arthur Brebner, 2305
- Standing waves; Storms; Storm surges; Wave height; Wave period; Wave pressure; Wave reflection; Breakwaters; Slots**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360
- Standing waves; Storm surges; Wave energy; Wave pressure; Barriers; Impact; Marine structures; Mathematical models; Pressure distribution; Scale effect**
A Model Law for Wave Impacts on Coastal Structures, C. Ramkema, 2308
- Standing waves; Tests; Wave diffraction; Wave energy; Wave height; Wavelength; Wave tanks; Breakwaters; Permeability; Shallow water**
Wave Height Distribution Around Permeable Breakwaters, Shintaro Hotta, 695

- Standing waves; Tidal flats; Tidal hydraulics; Dispersion; Estuaries; Mixing; Model studies; Saline water-freshwater interfaces; Shallow water**
Longitudinal Dispersion in Shallow Well-Mixed Estuaries, J. Dronkers, 2761
- Standing waves; Water depth; Waves; Wave tanks; Beaches; Edge effect; Excitation; Interactions**
Excitation of Low Frequency Trapped Waves, Robert King and Ronald Smith, 449
- Statistical analysis; Storm surges; Tides; Beaches; Coastal plains; Probability; Probability distribution functions; Sea level**
Extreme Sea Levels from Tide and Surge Probability, D. T. Pugh and J. M. Vassie, 911
- Statistical analysis; Stress; Surf; Wave spectra; Wave velocity; Wind velocity; Littoral current; Predictions; Regression analysis**
Wind-Generated Longshore Currents, Dag Nummedal and Robert J. Finley, 1428
- Statistical analysis; Tidal waters; Water levels; Frequencies; Great Britain; Ports; Sampling; Sea level**
Analysis of Maximum Sea Level in Southern England, J. Graff and D. L. Blackman, 931
- Statistical analysis; Time series analysis; Waste disposal; Coastal plains; Diffusion; Dispersion; Mathematical models; Outfall sewers; Sewage effluents**
Outfall Diffusion Models for the Coastal Zone, D. C.L. Lam and C. R. Murthy, 2584
- Statistical analysis; Wave height; Wave period; Coastal plains; Confidence level; Ocean waves; Probability distribution functions; Shore protection**
On Long-Term Statistics for Ocean and Coastal Waves, Michel K. Ochi, 59
- Statistical analysis; Wave height; Wave period; Wave runup; Wave spectra; Damage; Dikes; Hydrodynamics**
New Dike Design Criteria Based on Wave Spectra, Hans Kaldenhoff and Suhan M. Gokcesu, 2500
- Statistical analysis; Wave height; Wave recorders (water waves); Forecasting; Hawaii; Meteorological data; Meteorology**
An Evaluation of Extreme Wave Climate at Keahole Point, Hawaii, Charles L. Bretschneider and Richard E. Rocheleau, 152
- Stochastic processes; Wave generation; Wave height; Wavelength; Waves; Wave spectra; Wave tanks; Hydrodynamic pressure; Numerical analysis**
An Inclined-Plate Wave Generator, Fredric Raichlen and Jiin-Jen Lee, 388
- Stochastic processes; Wave generation; Wave spectra; Dynamic pressure; Frequencies; Hydrodynamic pressure; Responses**
Analysis of Hinged Wavemakers for Random Waves, Robert T. Hudspeth, Douglas F. Jones and John H. Nath, 372
- Storms; Storm surges; Surveys (data collection); Tidal hydraulics; Water levels; Barriers; Boundary conditions; Netherlands; Responses**
A Tidal Survey for a Model of an Offshore Area, W. J. van de Ree, J. Voogt and J. J. Leendertse, 2656
- Storms; Storm surges; Tidal waters; Water levels; Waterways (transportation); West Germany; Economic analysis; Environmental factors; Financing**
Welcoming Address — III, Volker Hauff, 7
- Storms; Storm surges; Wave energy; Wave period; Wave velocity; Canada; Field tests; Gravity waves; Hurricanes; Sediments; Sediment transport**
Infragravity Waves in Storm Conditions, R. A. Holman, David A. Huntley and A. J. Bowen, 268
- Storms; Storm surges; Wave height; Wave period; Wave pressure; Wave reflection; Breakwaters; Slots; Standing waves**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360
- Storms; Surf; Suspended sediments; Wave period; Littoral deposits; Sediment concentration; Sediment transport; Sensors**
Storm Induced Periodicities of Suspended Sand Movement, Jay E. Leonard and Benno M. Brenninkmeyer, 1744
- Storms; Surf; Water circulation; Water levels; Wave height; Waves; Wind; Bathymetry; Bores (wave); Field tests; Littoral current; Model tests**
Comparison of Model and Observed Nearshore Circulation, James H. Allender, John D. Ditmars, Wyman Harrison and Robert A. Paddock, 810
- Storms; Tidal currents; Wave action; Wave height; Wave runup; Waves; Wave spectra; Wind velocity; Estuaries; Reefs**
Analysis of Storm Tide Waves, Volker Barthel, 1016
- Storms; Tidal currents; West Germany; Dikes; Estuaries; Ports; Shipping; Shore protection**
Welcoming Address — II, Helga Elstner, 4
- Storms; Water depth; Wave equations; Wave period; Bars (riverine); Beach erosion; Lakes; Nile River Valley; Oceans; Sediment deposits; Sediment load; Sediment transport**
Undulated Bottom Profiles and Onshore-Offshore Transport, Madhav Manohar, 1454
- Storms; Wavelength; Wave propagation; Wind; Wind speed; Hurricanes; Mathematical models; Models; Numerical analysis; Radar operation**
Radar Observations of Hurricane Wave Directions, B. D. King and O. H. Shemdin, 209
- Storm surges; Beach erosion; Dunes; Erosion; Movable bed models; Ripple marks; Sands; Scale effect; Shore protection**
Movable Bed Model Tests on Dune Erosion, P. Vellinga, 2020
- Storm surges; Surf; Water levels; Wave action; Wave dispersion; Wave period; Fourier transformation; Gravity waves**
Anomalous Dispersion of Fourier Components of Surface Gravity Waves in the Near Shore Area, Fritz Busching, 247
- Storm surges; Surf; Water levels; Wave energy; Wave recorders (water waves); Wave runup; Coastal plains; Dynamic loads; Shore protection**
Wave Set-Up in the Surf Zone, Uwe A. Hansen, 1071

- Storm surges; Surveys (data collection); Tidal hydraulics; Water levels; Barriers; Boundary conditions; Netherlands; Responses; Storms**
A Tidal Survey for a Model of an Offshore Area, W. J. van de Ree, J. Voogt and J. J. Leendertse, 2656
- Storm surges; Temperature; Water depth; Water levels; Air water interactions; Air-water interfaces; Forecasting; Shallow water**
Storm Surge Forecasting Methods in Enclosed Seas, P. F. Hamblin, 998
- Storm surges; Temperature effects; Thermal pollution; Tidal effects; Tidal hydraulics; Cooling water; Discharge (water); Model studies; Rivers**
Influence on Temperature Increases in Tidal Rivers Caused by Waste Heat Injections with Respect to Tidal Cycles and Storm Surges, Horst Schwarze and Wilfried Falldorf, 2915
- Storm surges; Texas; Tidal effects; Tsunamis; Water levels; Coastal plains; Cost effectiveness; Floods; Hurricanes; Numerical analysis; Predictions; Simulation**
Coastal Flood Simulation in Stretched Coordinates, H. Lee Butler, 1030
- Storm surges; Tidal currents; Tidal effects; Tidal energy; Tide gages; Wind; Wind velocity; Forecasting; Predictions**
Storm Surge Prediction by Combined Wind and Tide Data, Hermann Christiansen and Winfried Siefert, 965
- Storm surges; Tidal effects; Tidal energy; Tide gages; Dynamics; Estuaries; Forecasting; Predictions**
Storm Surge Prediction in Tidal Rivers: A New Conception, Winfried Siefert, 986
- Storm surges; Tidal effects; Tidal waters; Wave height; Wave period; Australia; Breakwaters; Maintenance; Site selection**
Rosslyn Bay Breakwater, Queensland, Australia, D. N. Foster, B. L. McGrath and W. Bremner, 2086
- Storm surges; Tidal effects; Wave height; Bays (topographic features); Friction coefficient (hydraulic); Inlets (waterways); Mathematical models; Numerical analysis; Sediment transport**
Numerical Model Investigation of Selected Tidal Inlet-Bay System Characteristics, William N. Seelig and Robert M. Sorensen, 1319
- Storm surges; Tidal waters; Water levels; Waterways (transportation); West Germany; Economic analysis; Environmental factors; Financing; Storms**
Welcoming Address — III, Volker Hauff, 7
- Storm surges; Tides; Beaches; Coastal plains; Probability; Probability distribution functions; Sea level; Statistical analysis**
Extreme Sea Levels from Tide and Surge Probability, D. T. Pugh and J. M. Vassie, 911
- Storm surges; Tracers; Wave energy; Beaches; Field tests; Gravel; Littoral current; Littoral deposits; Littoral drift; Sediment transport**
Field Experiment on Beach Gravel Transport, Masataro Hattori and Takasuke Suzuki, 1688
- Storm surges; Water levels; Wind forces; Forecasting; Mathematical models; Meteorological data; Meteorology; Numerical analysis; Predictions; Simulation**
Numerical Storm Surge Forecasting, Manfred Engel, 975
- Storm surges; Wave energy; Wave period; Wave velocity; Canada; Field tests; Gravity waves; Hurricanes; Sediments; Sediment transport; Storms**
Infragravity Waves in Storm Conditions, R. A. Holman, David A. Huntley and A. J. Bowen, 268
- Storm surges; Wave energy; Wave pressure; Barriers; Impact; Marine structures; Mathematical models; Pressure distribution; Scale effect; Standing waves**
A Model Law for Wave Impacts on Coastal Structures, C. Ramkema, 2308
- Storm surges; Wave height; Wave period; Wave pressure; Wave reflection; Breakwaters; Slots; Standing waves; Storms**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360
- Storm surges; West Germany; Coastal plains; Damage; Ocean waves; Recreational facilities**
Welcoming Address — IV, Hans-Werner Partenscky, 10
- Storm surges; West Germany; Coastal plains; History; Shore protection**
Welcoming Address — I, Karl-Edward Naumann, 1
- Storm surges; West Germany; Wind forces; Wind pressure; Wind velocity; Coastal engineering; Flooding; Frequencies; Probability**
Frequencies and Probabilities of Extreme Storm Surges (On the Time-Dependent Changes of the Probability of Extreme Storm Floods at the German North Sea Coast), Alfred Fohrboter, 949
- Stratified flow; Tidal currents; Tidal hydraulics; Water quality; Estuaries; Saline water-freshwater interfaces; Saline water intrusion; Salinity**
Stability Study of an Artificial Salt Intrusion in Estuaries, C. Marche, 2798
- Stratified flow; Two phase flow; Water flow; Density; Friction coefficient (hydraulic); Open channel flow; Saline water-freshwater interfaces; Salinity**
Interfacial Friction Coefficients in a Two-Layered Stratified Flow, Emmanouel Partheniades and Vassilios Dermisiss, 2778
- Stream flow; Stream gages; Tidal currents; Tidal effects; Water levels; Estuaries; Groins (structures); Navigable canals**
Improvements on Tidal Estuaries and the Effects on Tidal Current, Hermann Harten, 2905
- Stream flow; Velocity distribution; Vortices; Wave energy; Bed roughness; Estuaries; Mixing; Rivers; Saline water-freshwater interfaces; Salinity**
Outflow Dynamics at a River Mouth, Masakazu Kashiwamura and Shizuo Yoshida, 2925
- Stream gages; Tidal currents; Tidal effects; Water levels; Estuaries; Groins (structures); Navigable canals; Stream flow**
Improvements on Tidal Estuaries and the Effects on Tidal Current, Hermann Harten, 2905
- Stress; Surf; Wave spectra; Wave velocity; Wind velocity; Littoral current; Predictions; Regression analysis; Statistical analysis**
Wind-Generated Longshore Currents, Dag Nummedal and Robert J. Finley, 1428

- Stresses; Surf; Water circulation; Wave energy; Wave propagation; Waves; Barriers; Friction coefficient (hydraulic); Littoral current; Shores**
 Longshore Currents Due to Surf Zone Barrier, P. Bettess, C. A. Fleming, J. C. Heinrich, O. C. Zienkiewicz and D. I. Austin, 776
- Stress measurement; Tidal currents; Tidal flats; Velocity; Wave action; Wave velocity; Flooding; Flowmeters; Inlets (waterways)**
 Velocity and Stress Measurements in a Tidal Inlet, David A. Huntley and Dag Nummedal, 1320
- Structures; Tidal currents; Wave energy; Waves; Coastal engineering; Mathematical models; Mathematics; Mixing; Physics; Sediments**
 Struggle of Physics and Mathematics in Coastal Engineering, H. Lundgren, 13
- Surf; Surface waves; Turbulence; Vibration; Wave action; Wave energy; Wave equations; Wave height; Wave propagation; Waves**
 Wave Characteristics in the Surf Zone, I. A. Svendsen, P. A. Madsen and J. Buhr Hansen, 520
- Surf; Suspended sediments; Water sampling; Wave height; Wave period; Waves; Wind velocity; Beaches; Littoral current; Measurement**
 Surf Zone Measurements of Suspended Sediment, Timothy W. Kana, 1725
- Surf; Suspended sediments; Wave period; Littoral deposits; Sediment concentration; Sediment transport; Sensors; Storms**
 Storm Induced Periodicities of Suspended Sand Movement, Jay E. Leonard and Benno M. Brenninkmeyer, 1744
- Surf; Temperature effects; Thermal pollution; Tracers; Turbulent flow; Currents (water); Heated water; Jet flow; Mixing; Plumes**
 Mixing of Heated Water Discharged in the Surf Zone, Kiyoshi Horikawa, Ming-Chung Lin and Tamio O. Sasaki, 2563
- Surf; Temporal distribution; Variations; Wave spectra; Edge effect; Gravity waves; Littoral current; Rip currents**
 Variability of Longshore Currents, R. T. Guza and Edward B. Thornton, 756
- Surf; Tidal effects; Tracers; Wave action; Wave height; Beaches; Breaking energy; Coring; Histograms; Sediment deposits**
 Depth of Disturbance of Sand in Surf Zones, Michael K. Gaughan, 1513
- Surf; Turbulence; Wave dispersion; Wave energy; Wave height; Wave reflection; Beaches; Littoral current; Littoral deposits; Littoral drift**
 Morphodynamic Variability of High-Energy Beaches, Lynn Donelson Wright, B. G. Thom and John Chappell, 1180
- Surf; Water circulation; Water levels; Wave height; Waves; Wind; Bathymetry; Bores (wave); Field tests; Littoral current; Model tests; Storms**
 Comparison of Model and Observed Nearshore Circulation, James H. Allender, John D. Ditmars, Wyman Harrison and Robert A. Paddock, 810
- Surf; Water circulation; Wave energy; Wave propagation; Waves; Barriers; Friction coefficient (hydraulic); Littoral current; Shores; Stresses**
 Longshore Currents Due to Surf Zone Barrier, P. Bettess, C. A. Fleming, J. C. Heinrich, O. C. Zienkiewicz and D. I. Austin, 776
- Surf; Water depth; Littoral deposits; Littoral drift; Littoral materials; Ocean bottom; Sediments; Sediment transport; Shear stress**
 Distribution of Sand Transport Rate across a Surf Zone, Toru Sawaragi and Ichiro Deguchi, 1596
- Surf; Water levels; Wave action; Wave dispersion; Wave period; Fourier transformation; Gravity waves; Storm surges**
 Anomalous Dispersion of Fourier Components of Surface Gravity Waves in the Near Shore Area, Fritz Busching, 247
- Surf; Water levels; Wave energy; Wave recorders (water waves); Wave runoff; Coastal plains; Dynamic loads; Shore protection; Storm surges**
 Wave Set-Up in the Surf Zone, Uwe A. Hansen, 1071
- Surf; Wave action; Wave height; Wave period; Waves; Coral reefs and islands; Energy; Probability density functions; Spectral analysis**
 The Energy Spectra of Surf Waves on a Coral Reef, Theodore T. Lee and Kerry P. Black, 588
- Surf; Wave action; Waves; Wave velocity; Coastal plains; Eigenvalues; Mass; Momentum; Offshore structures; Rip currents; Spacing**
 Rip Current Spacing as an Eigenvalue, Noriyuki Iwata, 828
- Surf; Wave dispersion; Wave energy; Beaches; Coastal plains; Littoral current; Littoral deposits; Models; Ocean bottom; Sediments; Sediment transport**
 A Model Study of Alongshore Sediment Transport Rate, J. W. Kamphuis and J. S. Readshaw, 1656
- Surf; Wave height; Wave period; Waves; Wave spectra; Breaking energy; Ocean waves; Probability density functions; Probability theory; Secondary waves**
 Probability Density Functions of Breaking Waves, Edward B. Thornton and George Schaeffer, 507
- Surf; Wave reflection; Waves; Wave spectra; Beaches; Edge effect; Littoral current; Morphology; Resonance**
 Surf Zone Resonance and Coupled Morphology, John Chappell and Lynn Donelson Wright, 1359
- Surf; Wave spectra; Wave velocity; Wind velocity; Littoral current; Predictions; Regression analysis; Statistical analysis; Stress**
 Wind-Generated Longshore Currents, Dag Nummedal and Robert J. Finley, 1428
- Surface waves; Turbulence; Vibration; Wave action; Wave energy; Wave equations; Wave height; Wave propagation; Waves; Surf**
 Wave Characteristics in the Surf Zone, I. A. Svendsen, P. A. Madsen and J. Buhr Hansen, 520

- Surface waves; Velocity field; Water waves; Wave energy; Ocean bottom; Sands; Sediments; Sediment transport**
Sediment Motion Caused by Surface Water Waves, A. G. Davies and R. H. Wilkinson, 1577
- Surface waves; Water depth; Wave energy; Wave measurement; Acoustic measuring instruments; Currents (water); Ocean bottom**
Near-Bottom Current Measured by Acoustic Sensors, K. A. Selanger and T. Carstens, 878
- Surveys (data collection); Coastal plains; Evaluation; Geological maps; Littoral deposits; Littoral materials; Sedimentation; Sediment transport**
A New Method for the Representation of Sedimentary Sequences in Coastal Regions, Hansjorg Streif, 1245
- Surveys (data collection); Tidal effects; Water levels; Wave propagation; Wave velocity; Estuaries; Field data; Flood protection; Mathematical models; Numerical analysis**
Adjustment and Verification of the RANDDELTA II Model, A. Langerak, M. A.M. deRas and J. J. Leendertse, 1049
- Surveys (data collection); Tidal hydraulics; Water levels; Barriers; Boundary conditions; Netherlands; Responses; Storms; Storm surges**
A Tidal Survey for a Model of an Offshore Area, W. J. van de Ree, J. Voogt and J. J. Leendertse, 2656
- Surveys (data collection); Wave energy; Wave height; Wavelength; Imaging; Ocean waves; Radar; Radar photography**
The Use of Imaging Radar in Studying Ocean Waves, M. G. Mattie and D. Lee Harris, 174
- Surveys (data collection); Wave energy; Wave height; Wave recorders (water waves); Buoys; Design criteria; Offshore platforms; Offshore structures**
Comparison of Shipborne Wave Recorder and Waverider Buoy Data Used to Generate Design and Operational Planning Criteria, C. G. Graham, G. Verboom and C. J. Shaw, 97
- Surveys (data collection); Wave height; Wave recorders (water waves); International compacts; Inventories; Questionnaires**
A World Wave Data Centre, Laurence Draper, 51
- Suspended load; Suspended sediments; Tidal effects; Wave action; Wave energy; Wave period; Waves; Currents (water); Field tests; Sands; Sediment transport**
Effect of Waves on Sand Transport by Currents, Michael W. Owen and Michael F.C. Thorn, 1675
- Suspended load; Tidal currents; Tidal effects; Tidal waters; Wind; Discharge (water); Hydrodynamics; Meteorology; Rainfall; Salt marshes; Sediment transport; South Carolina**
Hydrodynamics and Sediment Transport in a Salt Marsh Tidal Channel, Larry G. Ward, 1953
- Suspended sediments; Boundary layer flow; Continental shelf; Currents (water); Littoral current; Nicaragua; Pressure gradients; Salinity**
Shelf and Coastal Boundary Layer Currents, Miskito Bank of Nicaragua, Richard L. Croust and Stephen P. Murray, 2715
- Suspended sediments; Diffusion; Dredges; Dredging; Estuaries; Models; Plumes; Sediment concentration; Spoil; Spoil banks**
Factors Governing the Distribution of Dredge-Resuspended Sediments, W. Frank Bohlen, 2001
- Suspended sediments; Temperature; Tidal effects; Turbidity; Canada; Dredging; Harbors; Models; Salinity; Sedimentation; Sediment transport; Silting**
Tidal Sedimentation in Gros-CaCouna Harbor, Georges Drapeau and Guy Fortin, 1986
- Suspended sediments; Tidal effects; Wave action; Wave energy; Wave period; Waves; Currents (water); Field tests; Sands; Sediment transport; Suspended load**
Effect of Waves on Sand Transport by Currents, Michael W. Owen and Michael F.C. Thorn, 1675
- Suspended sediments; Tidal effects; Wave height; Waves; Wave spectrum; Mud; Mud systems; Sediment concentration; Sediment transport; Shallow water**
Suspension and Transportation of Fluid Mud by Solitary-Like Waves, John T. Wells, James M. Coleman and W. J. Wiseman, Jr., 1932
- Suspended sediments; Time dependence; Channel beds; Clays; Entrainment; Experimentation; Finite element method; Sediment concentration**
Concentration of Suspended Clay in Periodic Flow, Akira Watanabe, P. Thimakorn and A. Das Gupta, 1918
- Suspended sediments; Two-dimensional; Wave propagation; Wind loads; Boundary conditions; Coastal plains; Mixing; Ocean engineering; Ocean waves; Rivers; Runoff**
Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Suspended sediments; Water sampling; Wave height; Wave period; Waves; Wind velocity; Beaches; Littoral current; Measurement; Surf**
Surf Zone Measurements of Suspended Sediment, Timothy W. Kana, 1725
- Suspended sediments; Wave height; Coastal plains; Littoral deposits; Littoral drift; Littoral zone; Samples; Sediment concentration**
Sled System for Profiling Suspended Littoral Drift, J. P. Coakley, J. A. Saville, M. Pedrosa and M. Larocque, 1764
- Suspended sediments; Wave period; Littoral deposits; Sediment concentration; Sediment transport; Sensors; Storms; Surf**
Storm Induced Periodicities of Suspended Sand Movement, Jay E. Leonard and Benno M. Brenninkmeyer, 1744
- Temperature; Tidal effects; Turbidity; Canada; Dredging; Harbors; Models; Salinity; Sedimentation; Sediment transport; Silting; Suspended sediments**
Tidal Sedimentation in Gros-CaCouna Harbor, Georges Drapeau and Guy Fortin, 1986
- Temperature; Water depth; Water levels; Air water interactions; Air-water interfaces; Forecasting; Shallow water; Storm surges**
Storm Surge Forecasting Methods in Enclosed Seas, P. F. Hamblin, 998

- Temperature effects; Thermal pollution; Tidal effects; Tidal hydraulics; Cooling water; Discharge (water); Model studies; Rivers; Storm surges**
Influence on Temperature Increases in Tidal Rivers Caused by Waste Heat Injections with Respect to Tidal Cycles and Storm Surges, Horst Schwarze and Wilfried Falldorf, 2915
- Temperature effects; Thermal pollution; Tracers; Turbulent flow; Currents (water); Heated water; Jet flow; Mixing; Plumes; Surf**
Mixing of Heated Water Discharged in the Surf Zone, Kiyoshi Horikawa, Ming-Chung Lin and Tamio O. Sasaki, 2563
- Temperature effects; Three-dimensional; Tidal effects; Water flow; Water levels; Wind loads; Dynamic response; Model studies**
Three-Dimensional SGS Energy Model of Eastern Bering Sea, S. K. Liu and J. J. Leendertse, 2687
- Temporal distribution; Variations; Wave spectra; Edge effect; Gravity waves; Littoral current; Rip currents; Surf**
Variability of Longshore Currents, R. T. Guza and Edward B. Thornton, 756
- Test reproducibility; Tests; Armoring (streambed); Breakwaters; Density; Plumes; Slope stability; Stability; Standardization**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwamborn, 2285
- Test reproducibility; Tests; Turbulent flow; Wave period; Wave refraction; Armoring (streambed); Open channel flow; Performance; Standardization**
Performance of Dolos Blocks in an Open Channel Situation, Arthur Brebner, 2305
- Tests; Armoring (streambed); Breakwaters; Density; Flumes; Slope stability; Stability; Standardization; Test reproducibility**
Dolos Packing Density and Effect of Relative Block Density, J. A. Zwamborn, 2285
- Tests; Thermal pollution; Wave energy; Wave height; Wave pressure; Cooling water; Loads (forces); Outfall sewers; Scale effect**
Non-Breaking and Breaking Wave Loads on a Cooling Water Outfall, G. R. Mogridge and W. W. Jamieson, 2461
- Tests; Turbulent flow; Wave period; Wave refraction; Armoring (streambed); Open channel flow; Performance; Standardization; Test reproducibility**
Performance of Dolos Blocks in an Open Channel Situation, Arthur Brebner, 2305
- Tests; Wave diffraction; Wave energy; Wave height; Wavelength; Wave tanks; Breakwaters; Permeability; Shallow water; Standing waves**
Wave Height Distribution Around Permeable Breakwaters, Shintaro Hotta, 695
- Texas; Tidal effects; Tsunamis; Water levels; Coastal plains; Cost effectiveness; Floods; Hurricanes; Numerical analysis; Predictions; Simulation; Storm surges**
Coastal Flood Simulation in Stretched Coordinates, H. Lee Butler, 1030
- Thermal energy; Waves; Wind; Currents (water); Design criteria; Energy conversion; Environmental effects; Environmental impact statements; Hurricanes; Site selection**
Some Design Criteria for OTEC Installations for Keahole Point, Hawaii, Frederick C. Munchmeyer and Charles L. Bretschneider, 2633
- Thermal pollution; Tidal currents; Vaporizers; Biological properties; Density currents; Discharge (water); Heat exchangers; Liquid natural gas; Model studies**
Thermal and Biological Impact of LNG Vaporizer Discharge, Peter A. Mangarella and Gordon A. Robilliard, 2945
- Thermal pollution; Tidal effects; Tidal hydraulics; Cooling water; Discharge (water); Model studies; Rivers; Storm surges; Temperature effects**
Influence on Temperature Increases in Tidal Rivers Caused by Waste Heat Injections with Respect to Tidal Cycles and Storm Surges, Horst Schwarze and Wilfried Falldorf, 2915
- Thermal pollution; Tracers; Turbulent flow; Currents (water); Heated water; Jet flow; Mixing; Plumes; Surf; Temperature effects**
Mixing of Heated Water Discharged in the Surf Zone, Kiyoshi Horikawa, Ming-Chung Lin and Tamio O. Sasaki, 2563
- Thermal pollution; Wave energy; Wave height; Wave pressure; Cooling water; Loads (forces); Outfall sewers; Scale effect; Tests**
Non-Breaking and Breaking Wave Loads on a Cooling Water Outfall, G. R. Mogridge and W. W. Jamieson, 2461
- Three-dimensional; Tidal currents; Tide gages; Two-dimensional; Water circulation; Mathematical models; Models; Numerical analysis; Ocean engineering; Oceanography**
Role of 2D and 3D Models in JONSDAP '76, A. M. Davies, 1085
- Three-dimensional; Tidal effects; Water flow; Water levels; Wind loads; Dynamic response; Model studies; Temperature effects**
Three-Dimensional SGS Energy Model of Eastern Bering Sea, S. K. Liu and J. J. Leendertse, 2687
- Three-dimensional; Viscosity; Water depth; Water pollution; Wind loads; Currents (water); Eddies; Oil spills**
3-D Current Model with Depth Varying Eddy Viscosity, Bryan R. Pearce, Cortis Cooper and Susan Nelson, 2602
- Three-dimensional; Water circulation; Wind loads; Currents (water); Density; Friction coefficient (hydraulic); Model studies**
Three Dimensional Modelling of the Irish Sea, Norman Stuart Heaps, 2671
- Three-dimensional; Water depth; Wave energy; Wave height; Wave spectra; Accretion (geomorphology); Beach erosion; Beaches; Dynamic models; Geomorphology**
Wave Power and Beach Stages: A Global Model, Andrew D. Short, 1145
- Three-dimensional; Wave height; Wave propagation; Waves; Wave spectra; Mathematical models; Numerical analysis; Ocean waves; Scale effect**
Natural Wave Trains: Description and Reproduction, H. Lundgren and S. E. Sand, 312

- Three-dimensional; Wave height; Waves; Wave tanks; Coastal plains; Currents (water); Ripple marks; Sediment transport; Shear stress**
Sediment Transport and Ripples Due to Waves and Currents, Zbigniew Pruszk and Ryszard B. Zeidler, 1638
- Tidal currents; Tidal effects; Tidal energy; Tide gages; Wind; Wind velocity; Forecasting; Predictions; Storm surges**
Storm Surge Prediction by Combined Wind and Tide Data, Hermann Christiansen and Winfried Siefert, 965
- Tidal currents; Tidal effects; Tidal flats; Two-dimensional; Wave tanks; Cross sections; Estuaries; Inlets (waterways)**
Periodic Flows from Tidal Inlets, D. L. Wilkinson, 1336
- Tidal currents; Tidal effects; Tidal waters; Wind; Discharge (water); Hydrodynamics; Meteorology; Rainfall; Salt marshes; Sediment transport; South Carolina; Suspended load**
Hydrodynamics and Sediment Transport in a Salt Marsh Tidal Channel, Larry G. Ward, 1953
- Tidal currents; Tidal effects; Water levels; Estuaries; Groins (structures); Navigable canals; Stream flow; Stream gages**
Improvements on Tidal Estuaries and the Effects on Tidal Current, Hermann Harten, 2905
- Tidal currents; Tidal effects; Wave energy; West Germany; Beaches; Dispersion; Environmental factors; Georgia; Inlets (waterways); Morphology; Sediment deposits**
Process-Response Models for Depositional Shorelines: The German and the Georgia Bights, Dag Nummedal and Ian A. Fischer, 1215
- Tidal currents; Tidal energy; Wave damping; Wave dispersion; Wave energy; Wave height; Wave runup; Waves; Wind speed; Damping**
Wave Climate Study in the Region of the East Frisian Islands and Coast, Hanz Dieter Niemyer, 134
- Tidal currents; Tidal flats; Tides; Two-dimensional; Water depth; Boundary conditions; Forecasting; Morphology; Stability analysis**
Two-Dimension Stability Analysis of Tidal Basins and Tidal Flats of Larger Extent, Eberhard Renger, 1971
- Tidal currents; Tidal flats; Velocity; Wave action; Wave velocity; Flooding; Flowmeters; Inlets (waterways); Stress measurement**
Velocity and Stress Measurements in a Tidal Inlet, David A. Huntley and Dag Nummedal, 1320
- Tidal currents; Tidal hydraulics; Water circulation; Diffusion coefficient; Experimentation; Hydraulic models; Japan; Scale effect**
Experimental Study on Scale Effect of Tidal Model, Haruo Higuchi, Hideichi Yasuda and Norio Hayakawa, 2646
- Tidal currents; Tidal hydraulics; Water circulation; Water levels; Waves; Wind loads; Model studies; Monsoons**
The Wind-Driven Circulation in the Northern Arabian Sea, Khawaja Zafar Elahi and Jurgen Sundermann, 2708
- Tidal currents; Tidal hydraulics; Water quality; Estuaries; Saline water-freshwater interfaces; Saline water intrusion; Salinity; Stratified flow**
Stability Study of an Artificial Salt Intrusion in Estuaries, C. Marche, 2798
- Tidal currents; Tide gages; Two-dimensional; Water circulation; Mathematical models; Models; Numerical analysis; Ocean engineering; Oceanography; Three-dimensional**
Role of 2D and 3D Models in JONSDAP '76, A. M. Davies, 1085
- Tidal currents; Turbulence; Velocity; Water depth; Wind loads; Aerial photography; Currents (water); Density; Eddies; Eddy currents; Mixing**
Large Scale Turbulence in Tidal Currents, John B. Hinwood, 2598
- Tidal currents; Vaporizers; Biological properties; Density currents; Discharge (water); Heat exchangers; Liquid natural gas; Model studies; Thermal pollution**
Thermal and Biological Impact of LNG Vaporizer Discharge, Peter A. Mangarella and Gordon A. Robilliard, 2945
- Tidal currents; Wave action; Wave energy; Wave refraction; Coastal plains; Dredging; Gravel; Great Britain; Licensing; Littoral drift; Sand; Shore protection**
The Effect of Offshore Dredging on Coastlines, W. A. Price, J. M. Motyka and L. J. Jaffrey, 1347
- Tidal currents; Wave action; Wave height; Wave runup; Waves; Wave spectra; Wind velocity; Estuaries; Reefs; Storms**
Analysis of Storm Tide Waves, Volker Barthel, 1016
- Tidal currents; Wave energy; Waves; Coastal engineering; Mathematical models; Mathematics; Mixing; Physics; Sediments; Structures**
Struggle of Physics and Mathematics in Coastal Engineering, H. Lundgren, 13
- Tidal currents; West Germany; Dikes; Estuaries; Ports; Shipping; Shore protection; Storms**
Welcoming Address — II, Helga Elstner, 4
- Tidal effects; Acceleration; Bed roughness; Distortion; Friction coefficient (hydraulic); Laboratory tests; Mathematical models; Numerical analysis**
Numerical Study of Distortion in a Froude Model, T. A. McClimans and S. A. Gjerp, 2887
- Tidal effects; Bed forms; Friction coefficient (hydraulic); Hydrodynamic pressure; Hydrodynamics; Numerical analysis; Ocean bottom; Ripple marks**
The Influence of Dune and Flow Parameters on the Friction Factor, Jurgen Sundermann, H. Vollmers and W. Puls, 1787
- Tidal effects; Tidal energy; Tide gages; Dynamics; Estuaries; Forecasting; Predictions; Storm surges**
Storm Surge Prediction in Tidal Rivers: A New Conception, Winfried Siefert, 986
- Tidal effects; Tidal energy; Tide gages; Wind; Wind velocity; Forecasting; Predictions; Storm surges; Tidal currents**
Storm Surge Prediction by Combined Wind and Tide Data, Hermann Christiansen and Winfried Siefert, 965

- Tidal effects; Tidal flats; Two-dimensional; Wave tanks; Cross sections; Estuaries; Inlets (waterways); Tidal currents**
 Periodic Flows from Tidal Inlets, D. L. Wilkinson, 1336
- Tidal effects; Tidal hydraulics; Cooling water; Discharge (water); Model studies; Rivers; Storm surges; Temperature effects; Thermal pollution**
 Influence on Temperature Increases in Tidal Rivers Caused by Waste Heat Injections with Respect to Tidal Cycles and Storm Surges, Horst Schwarze and Wilfried Falldorf, 2915
- Tidal effects; Tidal waters; Wave height; Wave period; Australia; Breakwaters; Maintenance; Site selection; Storm surges**
 Rosslyn Bay Breakwater, Queensland, Australia, D. N. Foster, B. L. McGrath and W. Bremner, 2086
- Tidal effects; Tidal waters; Wind; Discharge (water); Hydrodynamics; Meteorology; Rainfall; Salt marshes; Sediment transport; South Carolina; Suspended load; Tidal currents**
 Hydrodynamics and Sediment Transport in a Salt Marsh Tidal Channel, Larry G. Ward, 1953

Drift Speed of Buoys in Waves, John H. Nath, 859
- Wave period; Waves; Breakwaters; Ocean waves; Pneumatic systems; Underwater structures; Wave damping; Wave energy**
Combination Effect of Pneumatic Breakwater and Other Type Breakwater on Wave Damping, Yuichi Iwagaki, Toshiyuki Asano and Tsutomu Honda, 2172
- Wave period; Waves; Coral reefs and islands; Energy; Probability density functions; Spectral analysis; Surf; Wave action; Wave height**
The Energy Spectra of Surf Waves on a Coral Reef, Theodore T. Lee and Kerry P. Black, 588
- Wave period; Waves; Currents (water); Field tests; Sands; Sediment transport; Suspended load; Suspended sediments; Tidal effects; Wave action; Wave energy**
Effect of Waves on Sand Transport by Currents, Michael W. Owen and Michael F.C. Thorn, 1675
- Wave period; Waves; Wave spectra; Breaking energy; Ocean waves; Probability density functions; Probability theory; Secondary waves; Surf; Wave height**
Probability Density Functions of Breaking Waves, Edward B. Thornton and George Schaeffer, 507
- Wave period; Waves; Wave tanks; Wave velocity; Beaches; Random processes; Slopes; Water depth; Wave height; Wavelength**
Wave Length, Wave Velocity and Shoaling Characteristics of Random Waves, Akira Kimura and Yuichi Iwagaki, 320
- Wave period; Waves; Wind velocity; Beaches; Littoral current; Measurement; Surf; Suspended sediments; Water sampling; Wave height**
Surf Zone Measurements of Suspended Sediment, Timothy W. Kana, 1725
- Wave period; Wave spectra; Correlation techniques; Ocean waves; Offshore structures; Shore protection; Wave height**
The Observed Joint Distribution of Periods and Heights of Sea Waves, Yoshimi Goda, 227
- Wave period; Wave spectrum; Aquifers; Ground water; Groundwater elevation; Littoral current; Oscillations; Piezometers; Wave height**
Beach Ground-Water Oscillations, Andrzej Lewandowski and Ryszard B. Zeidler, 2051
- Wave period; Wave velocity; Canals; Field tests; Gravity waves; Hurricanes; Sediments; Sediment transport; Storms; Storm surges; Wave energy**
Infragravity Waves in Storm Conditions, R. A. Holman, David A. Huntley and A. J. Bowen, 268
- Wave phases; Bathymetry; Bays (topographic features); Beach erosion; Beaches; Breakwaters; Diffraction; Sediment transport; Wave diffraction; Wave height**
Diffraction Calculation of Shoreline PlanForms, Robert G. Dean, 1903
- Wave pressure; Armoring (streambed); Costs; Revetments; Rubble-mound breakwaters; Slope stability; Stability; Wave energy**
Blanket Theory and Low Cost Revetments, C. T. Brown, 2510
- Wave pressure; Barriers; Impact; Marine structures; Mathematical models; Pressure distribution; Scale effect; Standing waves; Storm surges; Wave energy**
A Model Law for Wave Impacts on Coastal Structures, C. Ramkema, 2308
- Wave pressure; Cooling water; Loads (forces); Outfall sewers; Scale effect; Tests; Thermal pollution; Wave energy; Wave height**
Non-Breaking and Breaking Wave Loads on a Cooling Water Outfall, G. R. Mogridge and W. W. Jamieson, 2461
- Wave pressure; Cylindrical bodies; Drag; Experimentation; Loads (forces); Predictions; Reynolds number; Water flow; Wave energy**
Wave Loads on Horizontal Cylinders, P. Holmes and J. R. Chaplin, 2449
- Wave pressure; Wave reflection; Breakwaters; Slots; Standing waves; Storms; Storm surges; Wave height; Wave period**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360
- Wave pressure; Wave spectra; Hydrodynamic pressure; Impact; Impact forces; Measurement; Scale effect; Water waves; Wave energy**
Impact Wave Forces on Vertical and Horizontal Plate, S. R. Massel, M. Oleszkiewicz and W. Trapp, 2340
- Wave pressure; Wave tanks; Groups; Loading; Load transfer; Marine structures; Ocean waves; Wave action**
Load Analysis from Wave Groups, A. I. Kuznetsov and G. D. Khaskhatchikh, 2328
- Wave pressure; Wind loads; Wind pressure; Dynamic response; Oscillation; Responses; Simulation; Wave damping; Wave energy; Wave period**
Simulation of Wave/Wind Forced Harbor Oscillation, S. K. Liu, H. S. Hou and Charles C.C. Chang, 2551
- Wave propagation; Cylindrical bodies; Displacement; Dynamic characteristics; Dynamic response; Experimentation; Piles; Wave period**
Dynamic Behavior of Vertical Cylinder due to Wave Force, Toru Sawaragi and Takayuki Nakamura, 2378
- Wave propagation; Wave reflection; Wave refraction; Mathematical models; Shallow water; Water depth; Wave action; Wave diffraction; Wavelength**
Computations of Short Waves in Shallow Water, M. B. Abbott, H. M. Petersen and Ove Skovgaard, 414
- Wave propagation; Waves; Barriers; Friction coefficient (hydraulic); Littoral current; Shores; Stresses; Surf; Water circulation; Wave energy**
Longshore Currents Due to Surf Zone Barrier, P. Bettess, C. A. Fleming, J. C. Heinrich, O. C. Zienkiewicz and D. I. Austin, 776
- Wave propagation; Waves; Surf; Surface waves; Turbulence; Vibration; Wave action; Wave energy; Wave equations; Wave height**
Wave Characteristics in the Surf Zone, I. A. Svendsen, P. A. Madsen and J. Buhr Hansen, 520

- Wave propagation; Waves; Wave spectra; Bathymetry; Correlation analysis; Deep water; Frequencies; Intensity; Wave energy**
 Deepwater Direction from an Intensity Array, Alan L. Higgins and Richard J. Seymour, 305
- Wave propagation; Waves; Wave spectra; Mathematical models; Numerical analysis; Ocean waves; Scale effect; Three-dimensional; Wave height**
 Natural Wave Trains: Description and Reproduction, H. Lundgren and S. E. Sand, 312
- Wave propagation; Waves; Wave velocity; Bores (wave); Breaking energy; Hydraulic jump; Water depth; Wave height**
 Spilling Breakers, Bores and Hydraulic Jumps, D. H. Peregrine and I. A. Svendsen, 540
- Wave propagation; Wave spectra; Dissipation; Friction coefficient (hydraulic); Ocean bottom; Water depth; Water waves; Wave dispersion; Wave energy**
 Bottom Dissipation in Finite-Depth Water Waves, S. V. Hsiao and O. H. Shemdin, 434
- Wave propagation; Wave velocity; Boundary conditions; Mathematical models; Sand; Shear stress; Turbulent flow; Velocity distribution**
 Near-Bottom Velocities in Waves with a Current, W. T. Bakker and Th. van Doorn, 1394
- Wave propagation; Wave velocity; Estuaries; Field data; Flood protection; Mathematical models; Numerical analysis; Surveys (data collection); Tidal effects; Water levels**
 Adjustment and Verification of the RANDDELTA II Model, A. Langerak, M. A.M. deRas and J. J. Leendertse, 1049
- Wave propagation; Wind; Wind speed; Hurricanes; Mathematical models; Models; Numerical analysis; Radar operation; Storms; Wavelength**
 Radar Observations of Hurricane Wave Directions, B. D. King and O. H. Shemdin, 209
- Wave propagation; Wind loads; Boundary conditions; Coastal plains; Mixing; Ocean engineering; Ocean waves; Rivers; Runoff; Suspended sediments; Two-dimensional**
 Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Wave recorders (water waves); Brazil; Meteorology; Ocean waves; Wave action; Wave energy; Wave height; Wave period**
 Wave Climate in Some Zones off the Brazilian Coast, Alberto Homs, 114
- Wave recorders (water waves); Buoys; Design criteria; Offshore platforms; Offshore structures; Surveys (data collection); Wave energy; Wave height**
 Comparison of Shipborne Wave Recorder and Waverider Buoy Data Used to Generate Design and Operational Planning Criteria, C. G. Graham, G. Verboom and C. J. Shaw, 97
- Wave recorders (water waves); Forecasting; Hawaii; Meteorological data; Meteorology; Statistical analysis; Wave height**
 An Evaluation of Extreme Wave Climate at Keahole Point, Hawaii, Charles L. Bretschneider and Richard E. Rocheleau, 152
- Wave recorders (water waves); International compacts; Inventories; Questionnaires; Surveys (data collection); Wave height**
 A World Wave Data Centre, Laurence Draper, 51
- Wave recorders (water waves); Wave runup; Coastal plains; Dynamic loads; Shore protection; Storm surges; Surf; Water levels; Wave energy**
 Wave Set-Up in the Surf Zone, Uwe A. Hansen, 1071
- Wave recorders (water waves); Waves; Breakwaters; Field tests; Harbors; Laboratory tests; Models; Prototypes**
 A Comparison Between Model and Prototype Waves in Harbours, Sverre Bjordal and Alf Torum, 677
- Wave recorders (water waves); Wave spectra; Wind forces; Wind pressure; Breakwaters; Laboratory tests; Wave diffraction; Wave energy; Wave generation**
 Wind-Generated Wave Diffraction by Breakwater Gap, Hooshang Raissi and R. L. Wigle, 609
- Wave recorders (water waves); Wave spectrum; Brazil; Current meters; Harbor facilities; Littoral current; Littoral drift; Water depth; Wave height; Wave period**
 Coastal Study of Espirito Santo Brazil, Paulo Augusto Vivacqua, Hildebrando de Araujo Goes Filho and Octavio de Sampaio Ferraz Jardim Sayao, 2104
- Wave recorders (water waves); Wind forces; Wind pressure; Australia; Cyclones; Frequencies; Mathematical models; Probability distribution functions; Tropical cyclones; Wave equations**
 Wind Wave Frequencies in a Tropical Cyclone Region, Rodney J. Sobey, 76
- Wave reflection; Beach erosion; Coastal structures; Dikes; Erosion control; Japan; Land reclamation; Scouring; Sea walls; Shore protection; Wave energy**
 Effectiveness of Seadikes with Rough Slope, Osamu Toyoshima, 2528
- Wave reflection; Beaches; Littoral current; Littoral deposits; Littoral drift; Surf; Turbulence; Wave dispersion; Wave energy; Wave height**
 Morphodynamic Variability of High-Energy Beaches, Lynn Donelson Wright, B. G. Thom and John Chappell, 1180
- Wave reflection; Breakwaters; Computer programs; Harbors; Hydraulic models; Numerical analysis; Wave diffraction; Wave height**
 A Numerical Approach for the Determination of the Wave Height Distribution in a Harbour, Soren Kohlhasse, Karl-Friedrich Daemrich, U. Berger, E. Tautenhain and O. Burkhardt, 664
- Wave reflection; Breakwaters; Experimentation; Friction coefficient (hydraulic); Ocean waves; Predictions; Wave dispersion; Wave height**
 Wave Transmission through Trapezoidal Breakwaters, Ole Secher Madsen, Paisal Shusang and Sue Ann Hanson, 2140
- Wave reflection; Breakwaters; Model tests; Reflection; Refraction; Walls; Wave action; Wave diffraction**
 Influence of Breakwater-Reflection on Diffraction, Karl-Friedrich Daemrich and Soren Kohlhasse, 651

- Wave reflection; Breakwaters; Slits; Standing waves; Storms; Storm surges; Wave height; Wave period; Wave pressure**
Wave Pressures on Split-Type Breakwaters, Shoshichiro Nagai and Shohachi Kakuno, 2360
- Wave reflection; Drag; Experimentation; Friction coefficient (hydraulic); Friction studies; Wave action; Wave energy**
Non-Conservative Wave Interaction with Fixed Semi-Immersed Rectangular Structures, Robert B. Steimer and Charles K. Sollitt, 2209
- Wave reflection; Wave refraction; Mathematical models; Shallow water; Water depth; Wave action; Wave diffraction; Wavelength; Wave propagation**
Computations of Short Waves in Shallow Water, M. B. Abbott, H. M. Petersen and Ove Skovgaard, 414
- Wave reflection; Waves; Wave spectra; Beaches; Edge effect; Littoral current; Morphology; Resonance; Surf**
Surf Zone Resonance and Coupled Morphology, John Chappell and Lynn Donelson Wright, 1359
- Wave reflection; Wave spectra; Breakwaters; Diffraction; Ocean waves; Random processes; Wave diffraction; Wave height**
Diffraction Diagrams for Directional Random Waves, Yoshimi Goda, Tomotsuka Takayama and Yasumasa Suzuki, 628
- Wave refraction; Approximation method; Finite element method; Harbors; Integral equations; Oscillations; Tides; Water waves; Wave diffraction**
A Combined FE-BIE Method for Water Waves, A. Hauguel, 715
- Wave refraction; Armoring (streambed); Open channel flow; Performance; Standardization; Test reproducibility; Tests; Turbulent flow; Wave period**
Performance of Dolos Blocks in an Open Channel Situation, Arthur Brebner, 2305
- Wave refraction; Coastal plains; Dredging; Gravel; Great Britain; Licensing; Littoral drift; Sand; Shore protection; Tidal currents; Wave action; Wave energy**
The Effect of Offshore Dredging on Coastlines, W. A. Price, J. M. Motyka and L. J. Jaffrey, 1347
- Wave refraction; Mathematical models; Shallow water; Water depth; Wave action; Wave diffraction; Wavelength; Wave propagation; Wave reflection**
Computations of Short Waves in Shallow Water, M. B. Abbott, H. M. Petersen and Ove Skovgaard, 414
- Wave refraction; Refraction (water waves); Shear flow; Water depth; Wave action; Wave height; Wavelength; Wave period**
Wave Refraction Across a Shearing Current, Ivar G. Jonsson and Ove Skovgaard, 722
- Wave refraction; Wave velocity; Rip currents; Sediment transport; Shoaling; Water waves; Wave diffraction; Wave height; Wave period**
Rip Currents and Their Causes, Robert A. Dalrymple, 1414
- Wave refraction; Wind loads; Accretion (geomorphology); Beach nourishment; Erosion; Groins (structures); Mathematical models; Rip currents; Shore-line cover; Wave diffraction**
Mathematical Modeling of Shoreline Evolution, Bernard Le Mchoute and Mills Soldate, 1163
- Wave runup; Coastal plains; Dynamic loads; Shore protection; Storm surges; Surf; Water levels; Wave energy; Wave recorders (water waves)**
Wave Set-Up in the Surf Zone, Uwe A. Hansen, 1071
- Wave runup; Waves; Wave spectra; Wind velocity; Estuaries; Reefs; Storms; Tidal currents; Wave action; Wave height**
Analysis of Storm Tide Waves, Volker Barthel, 1016
- Wave runup; Waves; Wind speed; Damping; Tidal currents; Tidal energy; Wave damping; Wave dispersion; Wave energy; Wave height**
Wave Climate Study in the Region of the East Frisian Islands and Coast, Hanz Dieter Niemeier, 134
- Wave runup; Wave spectra; Damage; Dikes; Hydrodynamics; Statistical analysis; Wave height; Wave period**
New Dike Design Criteria Based on Wave Spectra, Hans Kaldenhoff and Suhan M. Gokcesu, 2500
- Waves; Amplitude; Buoys; Drifting (aquatic); Floating bodies; Mass transfer; Wave height; Wave period**
Drift Speed of Buoys in Waves, John H. Nath, 859
- Waves; Barriers; Friction coefficient (hydraulic); Littoral current; Shores; Stresses; Surf; Water circulation; Wave energy; Wave propagation**
Longshore Currents Due to Surf Zone Barrier, P. Bettess, C. A. Fleming, J. C. Heinrich, O. C. Zienkiewicz and D. I. Austin, 776
- Waves; Breaking energy; Classification; Field tests; Photographic analysis; Predictions; Water depth; Wave height; Wavelength**
Field Study of Breaking Wave Characteristics, Lee L. Weishar and Robert J. Byrne, 487
- Waves; Breakwaters; Field tests; Harbors; Laboratory tests; Models; Prototypes; Wave recorders (water waves)**
A Comparison Between Model and Prototype Waves in Harbours, Sverre Bjordal and Alf Torum, 677
- Waves; Breakwaters; Japan; Land reclamation; Littoral current; Littoral drift; Movable bed models; Ocean bottom; Sediment transport**
Estimation Using a Movable Bed Model of Shoreline Change Caused by a Reclamation Projected into the Sea, Shoji Sato and Hiroaki Ozasa, 1839
- Waves; Breakwaters; Ocean waves; Pneumatic systems; Underwater structures; Wave damping; Wave energy; Wave period**
Combination Effect of Pneumatic Breakwater and Other Type Breakwater on Wave Damping, Yuichi Iwagaki, Toshiyuki Asano and Tsutomu Honda, 2172

- Waves; Coastal engineering; Mathematical models; Mathematics; Mixing; Physics; Sediments; Structures; Tidal currents; Wave energy**
Struggle of Physics and Mathematics in Coastal Engineering, H. Lundgren, 13
- Waves; Computation; Damping; Spectrum analysis; Tidal effects; Tides; Two-dimensional; Wave damping**
A New Approach for Tidal Computations, C. Le Provost, 1104
- Waves; Coral reefs and islands; Energy; Probability density functions; Spectral analysis; Surf; Wave action; Wave height; Wave period**
The Energy Spectra of Surf Waves on a Coral Reef, Theodore T. Lee and Kerry P. Black, 588
- Waves; Currents (water); Field tests; Sands; Sediment transport; Suspended load; Suspended sediments; Tidal effects; Wave action; Wave energy; Wave period**
Effect of Waves on Sand Transport by Currents, Michael W. Owen and Michael F.C. Thorn, 1675
- Waves; Currents (water); Sediment load; Sediments; Sediment transport; Wave action; Wave energy**
Sediment Load under Waves and Currents, D. H. Willis, 1626
- Waves; Cylindrical bodies; Dynamic response; Loading; Mathematical models; Ocean waves; Responses; Water waves**
Loading and Response of Cylinders in Waves, G. N. Bullock, P. K. Stansby and J. G. Warren, 2415
- Waves; Ocean bottom; Ocean waves; Return flow; Sands; Scouring; Sea walls; Slopes; Tsunamis; Two-dimensional; Water depth; Wave energy**
Scouring at the Toe of a Seawall due to Tsunamis, Hitoshi Nishimura, Akira Watanabe and Kiyoshi Horikawa, 2540
- Waves; Surf; Surface waves; Turbulence; Vibration; Wave action; Wave energy; Wave equations; Wave height; Wave propagation**
Wave Characteristics in the Surf Zone, I. A. Svendsen, P. A. Madsen and J. Buhr Hansen, 520
- Waves; Wave spectra; Bathymetry; Correlation analysis; Deep water; Frequencies; Intensity; Wave energy; Wave propagation**
Deepwater Direction from an Intensity Array, Alan L. Higgins and Richard J. Seymour, 305
- Waves; Wave spectra; Beaches; Edge effect; Littoral current; Morphology; Resonance; Surf; Wave reflection**
Surf Zone Resonance and Coupled Morphology, John Chappell and Lynn Donelson Wright, 1359
- Waves; Wave spectra; Breaking energy; Ocean waves; Probability density functions; Probability theory; Secondary waves; Surf; Wave height; Wave period**
Probability Density Functions of Breaking Waves, Edward B. Thornton and George Schaeffer, 507
- Waves; Wave spectra; Mathematical models; Numerical analysis; Ocean waves; Scale effect; Three-dimensional; Wave height; Wave propagation**
Natural Wave Trains: Description and Reproduction, H. Lundgren and S. E. Sand, 312
- Waves; Wave spectra; Wave tanks; Hydrodynamic pressure; Numerical analysis; Stochastic processes; Wave generation; Wave height; Wavelength**
An Inclined-Plate Wave Generator, Fredric Raichlen and Jjin-Jen Lee, 388
- Waves; Wave spectra; Wave tanks; Wave velocity; Wind forces; Wind pressure; Currents (water); Experimentation; Fetch; Wave generation; Wave height**
Experimental Study of Wind Waves Generated on Currents, Hajime Kato and Hiroichi Tsuruya, 742
- Waves; Wave spectra; Wave velocity; Currents (water); Edge effect; Frequencies; Littoral current; Ocean waves; Wave energy**
Observation of Nearshore Current and Edge Waves, Tamio O. Sasaki and Kiyoshi Horikawa, 791
- Waves; Wave spectra; Wind velocity; Estuaries; Reefs; Storms; Tidal currents; Wave action; Wave height; Wave runoff**
Analysis of Storm Tide Waves, Volker Barthel, 1016
- Waves; Wave spectrum; Mud; Mud systems; Sediment concentration; Sediment transport; Shallow water; Suspended sediments; Tidal effects; Wave height**
Suspension and Transportation of Fluid Mud by Solitary-Like Waves, John T. Wells, James M. Coleman and W. J. Wiseman, Jr., 1932
- Waves; Wave tanks; Beaches; Edge effect; Excitation; Interactions; Standing waves; Water depth**
Excitation of Low Frequency Trapped Waves, Robert King and Ronald Smith, 449
- Waves; Wave tanks; Coastal plains; Currents (water); Ripple marks; Sediment transport; Shear stress; Three-dimensional; Wave height**
Sediment Transport and Ripples Due to Waves and Currents, Zbigniew Pruszek and Ryszard B. Zeidler, 1638
- Waves; Wave tanks; Wave velocity; Beaches; Random processes; Slopes; Water depth; Wave height; Wavelength; Wave period**
Wave Length, Wave Velocity and Shoaling Characteristics of Random Waves, Akira Kimura and Yuichi Iwagaki, 320
- Waves; Wave tanks; Wave velocity; Ocean waves; Offshore structures; Predictions; Random processes; Vibration; Wave equations; Wave generation; Wave height**
Periodic Theory Velocity Prediction in Random Wave, John H. Nath and Koji Kobune, 340
- Waves; Wave velocity; Beaches; Breaking energy; Deep water; Particle trajectories; Slope; Velocity**
Estimation of Water Particle Velocity of Breaking Wave, Tetsuo Sakai and Yuichi Iwagaki, 551
- Waves; Wave velocity; Bores (wave); Breaking energy; Hydraulic jump; Water depth; Wave height; Wave propagation**
Spilling Breakers, Bores and Hydraulic Jumps, D. H. Peregrine and I. A. Svendsen, 540
- Waves; Wave velocity; Coastal plains; Eigenvalues; Mass; Momentum; Offshore structures; Rip currents; Spacing; Surf; Wave action**
Rip Current Spacing as an Eigenvalue, Noriyuki Iwata, 828

- Waves; Wind; Bathymetry; Bores (wave); Field tests; Littoral current; Model tests; Storms; Surf; Water circulation; Water levels; Wave height**
Comparison of Model and Observed Nearshore Circulation, James H. Allender, John D. Ditmars, Wyman Harrison and Robert A. Paddock, 810
- Waves; Wind; Currents (water); Design criteria; Energy conversion; Environmental effects; Environmental impact statements; Hurricanes; Site selection; Thermal energy**
Some Design Criteria for OTEC Installations for Keahole Point, Hawaii, Frederick C. Munchmeyer and Charles L. Bretschneider, 2633
- Waves; Wind; Wind speed; Buoys; Hurricanes; Measurement; Monitoring; Offshore platforms; Radar operation; Wave height**
HF Skywave Radar Measurement of Hurricane Winds and Waves, Joseph W. Maresca, Jr. and Christopher T. Carlson, 190

Adjustment and Verification of the RANDDELTA II Model, A. Langerak, M. A.M. deRas and J. J. Leendertse, 1049
- Wave velocity; Flooding; Flowmeters; Inlets (waterways); Stress measurement; Tidal currents; Tidal flats; Velocity; Wave action**
Velocity and Stress Measurements in a Tidal Inlet, David A. Huntley and Dag Nummedal, 1320
- Wave velocity; Ocean waves; Offshore structures; Predictions; Random processes; Vibration; Wave equations; Wave generation; Wave height; Waves; Wave tanks**
Periodic Theory Velocity Prediction in Random Wave, John H. Nath and Koji Kobune, 340
- Wave velocity; Rip currents; Sediment transport; Shoaling; Water waves; Wave diffraction; Wave height; Wave period; Wave refraction**
Rip Currents and Their Causes, Robert A. Dalrymple, 1414
- Wave velocity; Wind forces; Wind pressure; Currents (water); Experimentation; Fetch; Wave generation; Wave height; Waves; Wave spectra; Wave tanks**
Experimental Study of Wind Waves Generated on Currents, Hajime Kato and Hiroichi Tsuruya, 742
- Wave velocity; Wind velocity; Littoral current; Predictions; Regression analysis; Statistical analysis; Stress; Surf; Wave spectra**
Wind-Generated Longshore Currents, Dag Nummedal and Robert J. Finley, 1428
- Weathering; Estuaries; Littoral deposits; Nicaragua; Rainfall; Sedimentation; Sediments; Sediment transport; Water circulation; Wave energy**
Variations of Wave-Energy Levels and Coastal Sedimentation, Eastern Nicaragua, E. H. Owens and H. H. Roberts, 1195
- West Germany; Beaches; Dispersion; Environmental factors; Georgia; Inlets (waterways); Morphology; Sediment deposits; Tidal currents; Tidal effects; Wave energy**
Process-Response Models for Depositional Shorelines: The German and the Georgia Bights, Dag Nummedal and Ian A. Fischer, 1215
- West Germany; Coastal plains; Damage; Ocean waves; Recreational facilities; Storm surges**
Welcoming Address — IV, Hans-Werner Partenscky, 10
- West Germany; Coastal plains; History; Shore protection; Storm surges**
Welcoming Address — I, Karl-Edward Naumann, 1
- West Germany; Dikes; Estuaries; Ports; Shipping; Shore protection; Storms; Tidal currents**
Welcoming Address — II, Helga Elstner, 4
- West Germany; Economic analysis; Environmental factors; Financing; Storms; Storm surges; Tidal waters; Water levels; Waterways (transportation)**
Welcoming Address — III, Volker Hauff, 7
- West Germany; Wind forces; Wind pressure; Wind velocity; Coastal engineering; Flooding; Frequencies; Probability; Storm surges**
Frequencies and Probabilities of Extreme Storm Surges (On the Time-Dependent Changes of the Probability of Extreme Storm Floods at the German North Sea Coast), Alfred Fohrboter, 949
- Wind; Bathymetry; Bores (wave); Field tests; Littoral current; Model tests; Storms; Surf; Water circulation; Water levels; Wave height; Waves**
Comparison of Model and Observed Nearshore Circulation, James H. Allender, John D. Ditmars, Wyman Harrison and Robert A. Paddock, 810
- Wind; Currents (water); Design criteria; Energy conversion; Environmental effects; Environmental impact statements; Hurricanes; Site selection; Thermal energy; Waves**
Some Design Criteria for OTEC Installations for Keahole Point, Hawaii, Frederick C. Munchmeyer and Charles L. Bretschneider, 2633
- Wind; Discharge (water); Hydrodynamics; Meteorology; Rainfall; Salt marshes; Sediment transport; South Carolina; Suspended load; Tidal currents; Tidal effects; Tidal waters**
Hydrodynamics and Sediment Transport in a Salt Marsh Tidal Channel, Larry G. Ward, 1953
- Wind; Wind speed; Buoys; Hurricanes; Measurement; Monitoring; Offshore platforms; Radar operation; Wave height; Waves**
HF Skywave Radar Measurement of Hurricane Winds and Waves, Joseph W. Maresca, Jr. and Christopher T. Carlson, 190

- Wind; Wind speed; Hurricanes; Mathematical models; Models; Numerical analysis; Radar operation; Storms; Wavelength; Wave propagation**
Radar Observations of Hurricane Wave Directions, B. D. King and O. H. Shemdin, 209
- Wind; Wind velocity; Forecasting; Predictions; Storm surges; Tidal currents; Tidal effects; Tidal energy; Tide gages**
Storm Surge Prediction by Combined Wind and Tide Data, Hermann Christiansen and Winfried Siefert, 965
- Wind forces; Forecasting; Mathematical models; Meteorological data; Meteorology; Numerical analysis; Predictions; Simulation; Storm surges; Water levels**
Numerical Storm Surge Forecasting, Manfred Engel, 975
- Wind forces; Wind pressure; Airspeed; Beach erosion; Dunes; Erosion control; Fences; Sands; Sediment deposits; Soil stabilization**
Using Fences to Create and Stabilise Sand Dunes, Brian B. Willetts and Christopher J. Phillips, 2040
- Wind forces; Wind pressure; Australia; Cyclones; Frequencies; Mathematical models; Probability distribution functions; Tropical cyclones; Wave equations; Wave recorders (water waves)**
Wind-Wave Frequencies in a Tropical Cyclone Region, Rodney J. Sobey, 76
- Wind forces; Wind pressure; Breakwaters; Laboratory tests; Wave diffraction; Wave energy; Wave generation; Wave recorders (water waves); Wave spectra**
Wind-Generated Wave Diffraction by Breakwater Gap, Hooshang Raissi and R. L. Wigle, 609
- Wind forces; Wind pressure; Currents (water); Experimentation; Fetch; Wave generation; Wave height; Waves; Wave spectra; Wave tanks; Wave velocity**
Experimental Study of Wind Waves Generated on Currents, Hajime Kato and Hiroichi Tsuruya, 742
- Wind forces; Wind pressure; Wind velocity; Coastal engineering; Flooding; Frequencies; Probability; Storm surges; West Germany**
Frequencies and Probabilities of Extreme Storm Surges (On the Time-Dependent Changes of the Probability of Extreme Storm Floods at the German North Sea Coast), Alfred Fohrboter, 949
- Wind forces; Wind pressure; Wind velocity; Drifting (aquatic); Water depth; Water surface; Wave tanks**
Wind-Induced Water Surface Set-Up and Drift Currents, Frederick L.W. Tang, Jin Wu, Charles C.C. Chang and Shan-Hwei Ou, 841
- Wind loads; Accretion (geomorphology); Beach nourishment; Erosion; Groins (structures); Mathematical models; Rip currents; Shore-line cover; Wave diffraction; Wave refraction**
Mathematical Modeling of Shoreline Evolution, Bernard Le Mehaute and Mills Soldate, 1163
- Wind loads; Aerial photography; Currents (water); Density; Eddies; Eddy currents; Mixing; Tidal currents; Turbulence; Velocity; Water depth**
Large Scale Turbulence in Tidal Currents, John B. Hinwood, 2598
- Wind loads; Bays (topographic features); Currents (water); Diffusion; Eddies; Environmental factors; Simulation; Tidal hydraulics; Water circulation**
Characteristics of Circulation in Bay Waters due to Wind Action, Akira Wada and Ioshihito Miyaike, 2730
- Wind loads; Boundary conditions; Coastal plains; Mixing; Ocean engineering; Ocean waves; Rivers; Runoff; Suspended sediments; Two-dimensional; Wave propagation**
Mixed Layer Models for Coastal Waters, W. J. Wiseman, Jr., L. J. Rouse, Jr. and O. K. Huh, 2619
- Wind loads; Currents (water); Density; Friction coefficient (hydraulic); Model studies; Three-dimensional; Water circulation**
Three Dimensional Modelling of the Irish Sea, Norman Stuart Heaps, 2671
- Wind loads; Currents (water); Eddies; Oil spills; Three-dimensional; Viscosity; Water depth; Water pollution**
3-D Current Model with Depth Varying Eddy Viscosity, Bryan R. Pearce, Cortis Cooper and Susan Nelson, 2602
- Wind loads; Dynamic response; Model studies; Temperature effects; Three-dimensional; Tidal effects; Water flow; Water levels**
Three-Dimensional SGS Energy Model of Eastern Bering Sea, S. K. Liu and J. J. Leendertse, 2687
- Wind loads; Florida; Friction coefficient (hydraulic); Model studies; Salinity; Salt balance; Salt water intrusion; Tidal hydraulics**
Tidal Hydraulics and Salt Balance of Lake Worth, Florida, J. van de Kreeke and J. D. Wang, 2827
- Wind loads; Model studies; Monsoons; Tidal currents; Tidal hydraulics; Water circulation; Water levels; Waves**
The Wind-Driven Circulation in the Northern Arabian Sea, Khawaja Zafar Elahi and Jurgen Sundermann, 2708
- Wind loads; Wind pressure; Dynamic response; Oscillation; Responses; Simulation; Wave damping; Wave energy; Wave period; Wave pressure**
Simulation of Wave/Wind Forced Harbor Oscillation, S. K. Liu, H. S. Hou and Charles C.C. Chang, 2551
- Wind pressure; Airspeed; Beach erosion; Dunes; Erosion control; Fences; Sands; Sediment deposits; Soil stabilization; Wind forces**
Using Fences to Create and Stabilise Sand Dunes, Brian B. Willetts and Christopher J. Phillips, 2040
- Wind pressure; Australia; Cyclones; Frequencies; Mathematical models; Probability distribution functions; Tropical cyclones; Wave equations; Wave recorders (water waves); Wind forces**
Wind Wave Frequencies in a Tropical Cyclone Region, Rodney J. Sobey, 76
- Wind pressure; Breakwaters; Laboratory tests; Wave diffraction; Wave energy; Wave generation; Wave recorders (water waves); Wave spectra; Wind forces**
Wind-Generated Wave Diffraction by Breakwater Gap, Hooshang Raissi and R. L. Wigle, 609

- Wind pressure; Currents (water); Experimentation; Fetch; Wave generation; Wave height; Waves; Wave spectra; Wave tanks; Wave velocity; Wind forces**
Experimental Study of Wind Waves Generated on Currents, Hajime Kato and Hiroichi Tsuruya, 742
- Wind pressure; Dynamic response; Oscillation; Responses; Simulation; Wave damping; Wave energy; Wave period; Wave pressure; Wind loads**
Simulation of Wave/Wind Forced Harbor Oscillation, S. K. Liu, H. S. Hou and Charles C.C. Chang, 2551
- Wind pressure; Field tests; Laboratory tests; Ocean bottom; Oscillation; Ripple marks; Shallow water; Waves**
On the Geometry of Ripples Due to Waves, M. S. Yalin and E. Karahan, 1776
- Wind pressure; Wind velocity; Coastal engineering; Flooding; Frequencies; Probability; Storm surges; West Germany; Wind forces**
Frequencies and Probabilities of Extreme Storm Surges (On the Time-Dependent Changes of the Probability of Extreme Storm Floods at the German North Sea Coast), Alfred Fohrboter, 949
- Wind pressure; Wind velocity; Drifting (aquatic); Water depth; Water surface; Wave tanks; Wind forces**
Wind-Induced Water Surface Set-Up and Drift Currents, Frederick L.W. Tang, Jin Wu, Charles C.C. Chang and Shan-Hwei Ou, 841
- Wind speed; Buoys; Hurricanes; Measurement; Monitoring; Offshore platforms; Radar operation; Wave height; Waves; Wind**
HF Skywave Radar Measurement of Hurricane Winds and Waves, Joseph W. Maresca, Jr. and Christopher T. Carlson, 190
- Wind speed; Damping; Tidal currents; Tidal energy; Wave damping; Wave dispersion; Wave energy; Wave height; Wave runoff; Waves**
Wave Climate Study in the Region of the East Frisian Islands and Coast, Hanz Dieter Niemeyer, 134
- Wind speed; Hurricanes; Mathematical models; Models; Numerical analysis; Radar operation; Storms; Wavelength; Wave propagation; Wind**
Radar Observations of Hurricane Wave Directions, B. D. King and O. H. Shemdin, 209
- Wind velocity; Beaches; Littoral current; Measurement; Surf; Suspended sediments; Water sampling; Wave height; Wave period; Waves**
Surf Zone Measurements of Suspended Sediment, Timothy W. Kana, 1725
- Wind velocity; Coastal engineering; Flooding; Frequencies; Probability; Storm surges; West Germany; Wind forces; Wind pressure**
Frequencies and Probabilities of Extreme Storm Surges (On the Time-Dependent Changes of the Probability of Extreme Storm Floods at the German North Sea Coast), Alfred Fohrboter, 949
- Wind velocity; Distribution functions; Predictions; Rainfall; Samples; Sampling; Wave energy; Wave height; Wave spectra**
Extremal Prediction of Significant Wave Height, Enrique Copeiro, 285
- Wind velocity; Drifting (aquatic); Water depth; Water surface; Wave tanks; Wind forces; Wind pressure**
Wind-Induced Water Surface Set-Up and Drift Currents, Frederick L.W. Tang, Jin Wu, Charles C.C. Chang and Shan-Hwei Ou, 841
- Wind velocity; Estuaries; Reefs; Storms; Tidal currents; Wave action; Wave height; Wave runoff; Waves; Wave spectra**
Analysis of Storm Tide Waves, Volker Barthel, 1016
- Wind velocity; Forecasting; Predictions; Storm surges; Tidal currents; Tidal effects; Tidal energy; Tide gages; Wind**
Storm Surge Prediction by Combined Wind and Tide Data, Hermann Christiansen and Winfried Siefert, 965
- Wind velocity; Littoral current; Predictions; Regression analysis; Statistical analysis; Stress; Surf; Wave spectra; Wave velocity**
Wind-Generated Longshore Currents, Dag Nummedal and Robert J. Finley, 1428
